HISTORICAL BACKGROUND

Turner syndrome (TS) is defined as a disorder caused by complete or partial absence of the second sex chromosome, with or without cell line mosaicism. This further needs to be associated with one or more characteristic physical features in a phenotypic female, such as short stature or primary ovarian insufficiency. The eponym comes from a study published in 1938 by Henry Turner, who described seven women with short stature, sexual infantilism, neck webbing, a low posterior hairline, and an increased carrying angle or cubitus valgus¹ (Fig. 17.1). Several years earlier (in 1930), the clinical geneticist Otto Ullrich had independently described an 8-year-old girl with short stature, lymphedema of the hands and feet, neck webbing, a high arched palate, low-set external ears, and some other characteristics that are now recognized features of TS.² Ullrich subsequently recognized that his patient and those of Turner

probably had the same condition.³ He further called attention to the work of Bonnevie, who described neck distention and malformations of the ears, face, and limb buds in mice, secondary to dissection of subcutaneous fetal tissues by fluid. Ullrich suggested that fetal lymphatic obstruction may cause neck webbing and other features of TS and proposed the eponym *Bonnevie-Ullrich* to describe this constellation of anomalies. Ullrich's contributions gave rise to the eponym *Ullrich-Turner syndrome* more commonly used in Europe.

Endocrine and pathology studies performed already in the 1940s revealed the presence of primary ovarian failure in TS women, further associated with elevated gonadotropins, reduced estrogen concentrations, and "streak" ovaries, consisting of connective tissue depleted of germ cells. These early studies also described an increased incidence of hypertension and aortic disease in young TS individuals.⁴ The first link between TS and a sex chromosome anomaly was provided in 1954 by Polani and colleagues, who reported on three women with TS and coarctation of the aorta, while also being sex chromatin negative.⁵ Soon thereafter, advances in cytogenetic identification of specific chromosomes revealed that TS was associated with the presence of a single X chromosome (X monosomy).⁶ These observations signified a major shift in our appreciation of the role of the human sex chromosomes in sex determination, as reviewed by Opitz and Pallister.⁷ They also described the significant heterogeneity of patients grouped under the umbrella of gonadal dysgenesis. *Dysgenesis* and *agenesis* represent inaccurate descriptions for TS individuals' ovarian histopathology, because fetal ovarian development appears normal in TS, and the ovarian tissue degeneration occurs mainly around the time of birth. Although eponyms have their disadvantages, the designation *Turner* (or *Ullrich-Turner*) *syndrome* is also more specific than *gonadal dysgenesis*.

GENETICS

Chromosomal Origins

In 1959 TS was linked to monosomy X in a 14-year-old girl by using a karyotype of colchicine-arrested metaphase bone marrow cells.⁸ In a subsequent study of 307 individuals with gonadal dysgenesis and sex chromosome anomalies, the short arm of the X chromosome was identified as the critical region responsible for TS.⁹

Today, 6 decades after the first karyotyping of TS, the molecular mechanisms that lead to monosomy X and TS are still not completely understood. Based on other aneuploidies, especially the trisomies, such as Down syndrome, the most popular hypothesis for the molecular basis of TS is an error in meiosis. A maternal X is present in 70% to 80% of individuals with TS,¹⁰ suggesting a male predisposition to meiotic errors. Fluorescent in situ hybridization (FISH) studies in sperm support a male predisposition to meiotic errors in the sex chromosomes as autosomal disomy occurs in 0.1% and sex chromosome disomy occurs in 0.27%.¹¹ If indeed TS results from an error in meiosis, unlike for trisomy investigations, the stage of meiosis that contributes to monosomy X cannot be determined. For example, in Down syndrome, nonsegregation is known to occur in meiosis II, when two chromosome 21s are homologous.

Besides an error in meiosis, the other possibility explaining monosomy X is a postzygotic nonsegregation in mitosis.

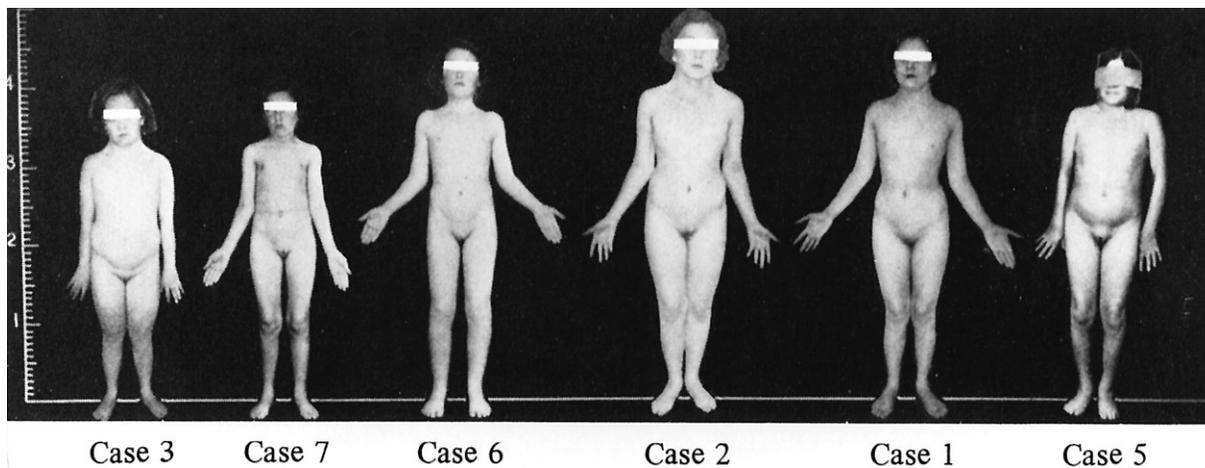

Fig. 17.1 Patients described by Dr. Henry Turner. Note the height marker at the left indicating the short stature, although with large variation in absolute height among these women. Note also lack of obesity among these women evaluated in the 1930s. (From Turner, H. H. (1938). A syndrome of infantilism, congenital webbed neck and cubitus valgus. *Endocrinology*, 23, 566.)

Postzygotic nonsegregation is an attractive hypothesis considering that approximately half of individuals with TS are mosaic. However, there are no empirical data in humans to support this hypothesis. However, there is evidence in the mouse model that the Y chromosome is predisposed to nondisjunction during early cleavage division, and more research in humans should provide further answers.¹²

In addition to nonsegregation in meiosis and mitosis, there are a number of structural anomalies of the X chromosome, including isochromosome X [46,X,i(Xq)] and partial deletion of Xp and Xq. The X isochromosome is the most common isochromosome in humans, and it is likely caused by chromosome breakage and recombination in the proximal Xp, resulting in an isodicentric X i(Xq) chromosome.¹³

Epidemiology

TS is a common finding in newborn females with a birth incidence of 1 in 2500.¹⁴ However, TS is diagnosed more frequently prenatally. Using the Danish Cytogenetic Central Register, Gravholt et al. compared the prenatal prevalence of TS to its postnatal prevalence.¹⁵ A postnatal prevalence of 32/100,000 was found compared with 176/100,000 in diagnoses by amniocentesis and 392/100,000 by chorionic villus sampling (CVS).¹⁵ Wharton and Hook, in their study of the New York state registry, also found a higher prevalence in prenatal diagnoses: 22.2/100,000 and 85/100,000 in postnatal age and prenatally by amniocentesis, respectively.¹⁶

Turner Karyotypes

Most karyotype determinations are made from mitotic peripheral lymphocytes that have been arrested in metaphase or prometaphase. The limitation of the peripheral blood karyotype is that only blood is tested and no other tissues, thus mosaicism cannot be tested reliably. A second tissue, such as skin fibroblasts, or buccal mucosa cells, or bladder epithelial cells, should be evaluated when a peripheral blood karyotype is normal and TS is still suspected.¹⁷ A large Danish study has set the fractions of various peripheral blood karyotypes and found that in 781 individuals with TS: 45% were found to have 45,X; 11% had a karyotype that included an isochromosome, such as 46X,i(Xq) or 45,X/46X,i(Xq); and the remaining 44% were mostly mosaic, such as 45,X/46,XX.¹⁸ Supporting further a high rate of

mosaicism in TS, a review of 532 live born girls and women with TS found that approximately half were mosaic.¹⁹

From a clinical and genetic counseling perspective, it is important to consider why and when a karyotype is obtained, as the timing of karyotype analysis often correlates with the phenotype severity in TS. Many prenatal karyotypes diagnosing TS have been done for advanced maternal age and compared with postnatal diagnoses, these individuals have decreased cardiac anomalies and decreased incidence of phenotypic features, such as neck webbing and low hairline, while characterized by a higher incidence of mosaicism.²⁰ For the purpose of genetic counseling of 45,X/46,XY mosaics, it is important to highlight that in a study of 92 cases of prenatally diagnosed 45,X/46,XY mosaic cases, 95% had normal male genitalia.²¹

A significant finding on a karyotype is the presence of Y chromosome material, which has implications in clinical management. A Y chromosome detected by karyotype is a risk for gonadoblastoma.¹⁷ In a study of 114 females with TS, 14 (12.2%) had Y material found by polymerase chain reaction (PCR), of which seven had detectable Y chromosome material on karyotype.²² Interestingly, of the 10 individuals in this study who underwent ovariectomy, only one (10%) had a gonadoblastoma. In another study of 171 individuals with TS, 14 (8%) were found to have Y chromosome material by Y chromosome repeat markers, and four of the 12 individuals who had a gonadectomy had gonadoblastoma detected.²³ In a more recent study of 130 individuals with TS, three individuals were found to have Y chromosome material by karyotype and six by reverse transcription-PCR.²⁴ Of these nine individuals with Y chromosome material, all underwent gonadectomy and one was found to have a gonadoblastoma. Although the aforementioned studies are heterogeneous in their methods, the risk of gonadoblastoma based on the best evidence available is roughly 10% if Y chromosome material is present. Current recommendation is for gonadectomy to be performed in TS individuals with Y chromosome material found on a standard karyotype analysis (Fig. 17.2).¹⁷

X Chromosome Genes and Turner Syndrome

Genotype-Phenotype Associations

Over 160 million years ago, the X and Y chromosomes were homologous, until the Y chromosome acquired the sex

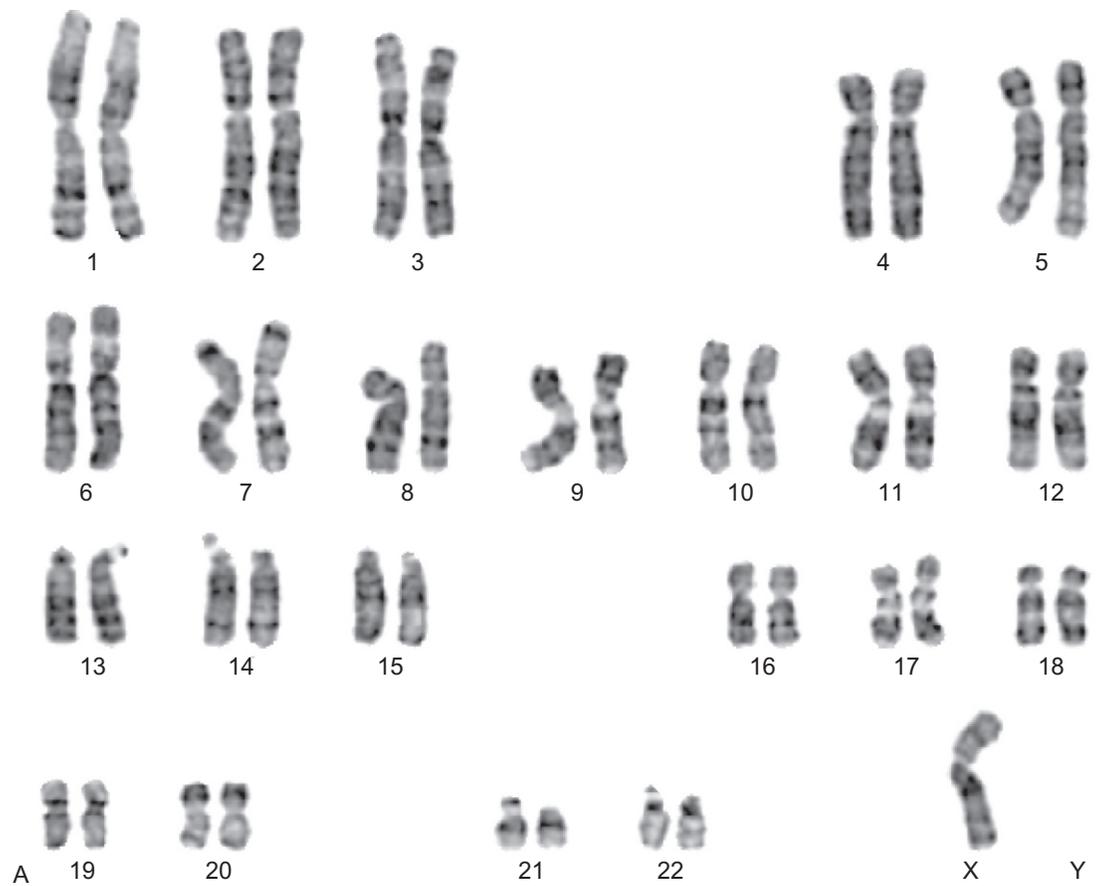

Fig. 17.2 A, Karyotype of an individual with Turner syndrome where there is absence of a second sex chromosome (45,X).

Continued

determining gene *SRY* and slowly lost many of its genes because of isolation from recombination by inversion.²⁵ A dosage compensation system evolved to equalize expression of the X chromosome genes on the 46,XX female and 46,XY male.²⁵ The compensation mechanism is X chromosome inactivation (XCI), which is achieved by the ribonucleic acid (RNA) coding gene *XIST* expressed on the inactive X chromosome; *XIST* then coats the inactive X chromosome making it inactive.²⁶ However, 20% to 30% of X-linked genes escape X inactivation and are expressed on the inactive X chromosome.²⁷ Pseudoautosomal region 1 (PAR1) located at the distal tip of the short arm of the X chromosome (Xp) and the short arm of chromosome Y (Yp) contains 24 genes that escape this X inactivation. The pseudoautosomal region (PAR) is divided into two regions, PAR1 at the terminus of the short arm of X and Y, and PAR2 on the long arm. The PARs pair and recombine during meiosis. There are four genes on PAR2 on both the X and Y chromosomes, and these genes, interestingly, do not escape X inactivation on the X chromosome.^{25,28} There are further 17 X-Y ancestral homologs, of which also 14 escape X inactivation. However, the remaining majority of X-linked genes that escape XCI do not have homologs on the Y chromosome.²⁹ Genes that escape XCI are haploinsufficient in TS and have historically been candidates for genotype-phenotype investigations. However, few X genes have been correlated with the TS phenotype. The short stature homeobox containing gene on the X chromosome (*SHOX*) is the most cited example (Fig. 17.3).

SHOX is located at Xp22 on the pseudoautosomal region of the X chromosome. Both males and females have two copies of *SHOX*. *SHOX*, a transcription factor, has been implicated in short stature and the skeletal anomalies associated with TS.³⁰ In a study of over 1600 prepubertal non-TS children with short stature, deletions or pathogenic variants in *SHOX* were found in approximately 4% of individuals.³¹ *SHOX* heterozygous variants, most commonly a deletion, may cause isolated short stature or other anomalies, such as mesomelia or the Madelung wrist deformity, observed in Leri-Weill dyschondrosteosis. The concept of haploinsufficiency of a gene, such as *SHOX* located in the PAR, is an attractive explanation for part of the TS phenotype. However, there is currently little evidence of any other monogenic variants on the PARs associated with the TS phenotype.

In addition to short stature, infertility and primary ovarian insufficiency are phenotypes for which a genetic etiology has been sought. Mapping partial X chromosome deletions in women, with and without TS, has provided loci associated with primary ovarian insufficiency (POI). Starting with the short arm of the X chromosome (Xp), TS phenotypes including POI have been mapped to Xp11.2-Xp22.1.³² In non-TS women, there is one gene located in this locus that has been associated with POI. Bone morphogenetic protein 15 (*BMP15*), located on Xp11.2, is an oocyte growth factor that stimulates folliculogenesis and granulosa cell (GC) growth, and has been implicated in POI. Di Pasquale et al. presented

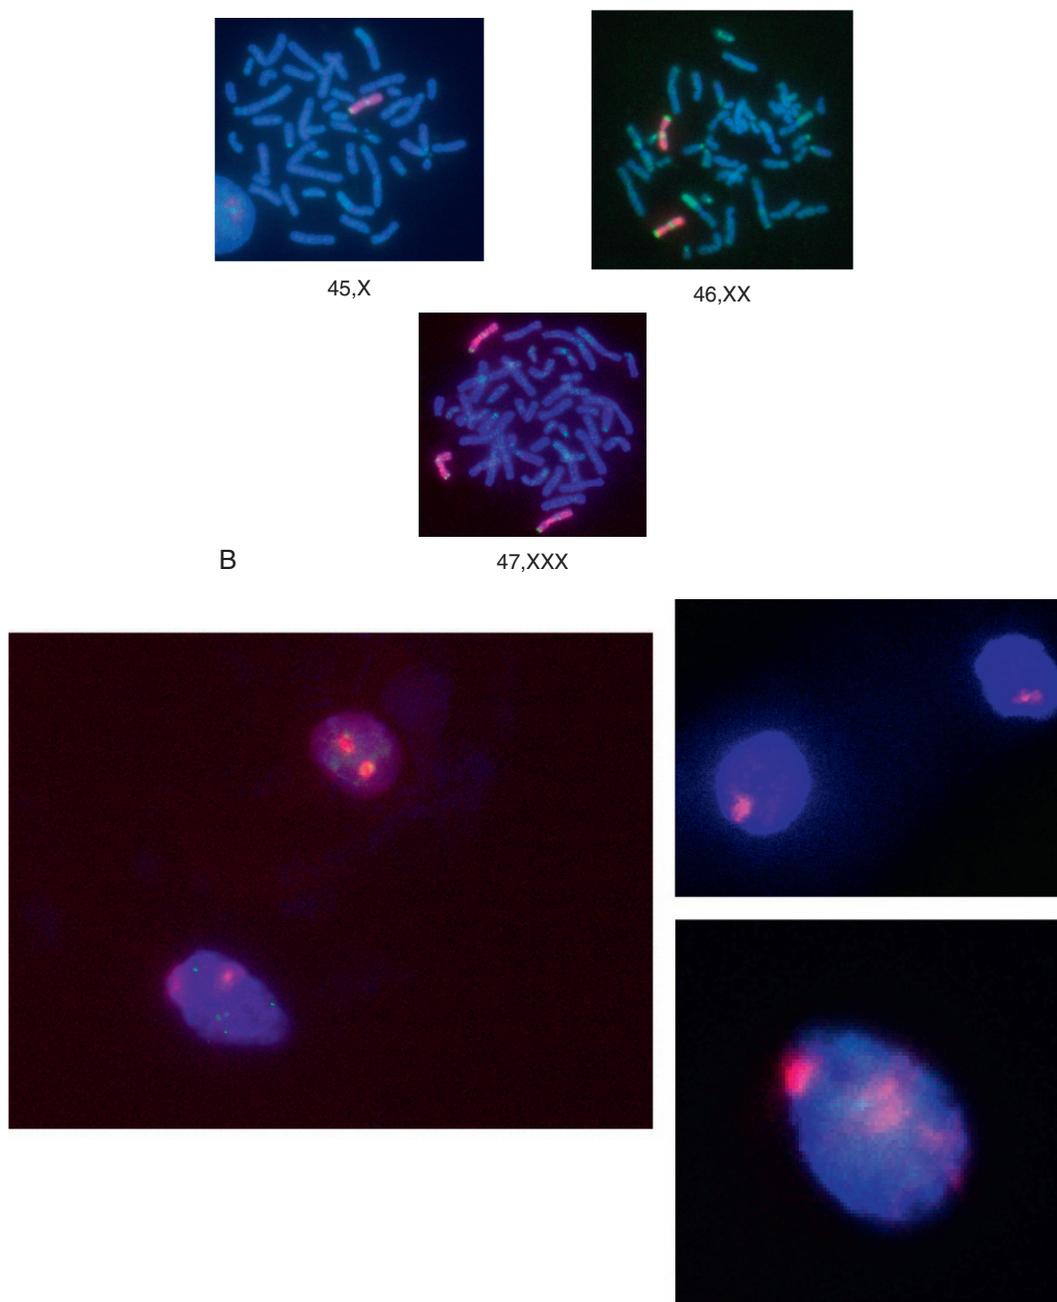

Fig. 17.2, cont'd B, Fluorescence in situ hybridization (FISH) with two-color XY specific probes. Chromosomes are in metaphase and counterstained with DAPI (*blue*). Note that there are three different X chromosome numbers: 45,X; 46,XXX; and 47,XXX. The X chromosomes are colored in red; the small amount of green is the shared regions of the X and Y chromosomes, or the pseudoautosomal regions. (Provided by Dr. Amalia Dutra, NHGRI.)

two sisters with a heterozygous missense variant in *BMP15* (p. Y235C) and functional studies suggested a dominant negative mechanism.³³ In a more recent study of 300 women with POI, six variants were found in *BMP15* with three of the variants leading to marked decrease in protein production.³⁴ Interestingly, there is a report of a small 554kb duplication involving the genes *BMP15* and *SHROOM4* in a woman with TS and spontaneous menarche, adding more evidence to *BMP15*'s association with POI.³⁵

On the long arm of the X chromosome (Xq), a number of X chromosome-autosome translocations in non-TS women have

identified two additional loci or critical regions associated with POI: Xq13-Xq21 (critical region I) and Xq23-Xq27 (critical region II).^{36,37} In these critical regions, a small number of women without TS have shown associations with genetic variants and POI. In an X-autosome translocation [t(X;11)(q24;q13)] found in both a mother and daughter with POI, disruption in the gene progesterone receptor membrane component-1 (*PGRMC1*) was found, based on reduced gene expression levels.³⁸ *PGRMC1* mediates antiapoptotic action of progesterone and several cytochrome P450 reactions in ovarian cells. Mansouri et al. screened 67 females with POI and found one

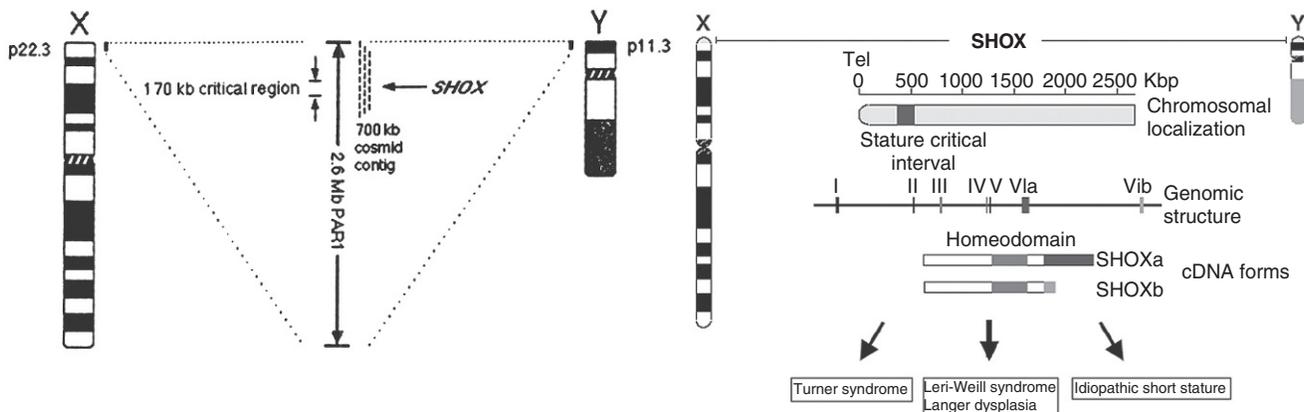

Fig. 17.3 X and Y chromosome ideograms showing the terminal pseudoautosomal regions (PAR) at Xp22.3 and Yp11.3 where the *SHOX* gene has been mapped (A&C), and X chromosome regions historically associated with aspects of phenotype. (From Zinn, A. R. (1997). Growing interest in Turner Syndrome. *Nat Genet*, 16, 3. With permission from Macmillan Publisher Ltd.)

person with a p.H165R variant that was shown to interfere with cytochrome P450 7A1 (*CYP7A1*) binding to *PGRMC1*.³⁸ In a large database of over 43,000 presumed healthy individuals, this particular variant was found in 0.2%.³⁹ Located in Xq21, a report of five daughters with POI to a consanguineous couple identified a homozygous variant in premature ovarian failure protein 1B (*POF1B*).⁴⁰ This variant was also shown to affect nonmuscle myosin binding.⁴⁰ One prior report in a woman with POI demonstrated a translocation involving chromosome 1 and the X chromosome [t(X;1)(q21;p34)] with a breakpoint in the third intron of *POF1B*.⁴¹ *POF1B* is of interest as it escapes X inactivation and is located in POI1. Also located in critical region I, dachshund homolog 2 (*DACH2*) was first identified by fine-mapping the breakpoint of an autosome-X chromosome translocation in a patient with POI.⁴² Two missense variants in *DACH2* have been associated with women with POI. However, there is no functional studies' evidence to support *DACH2*'s role in POI.

Although not in the two critical loci noted earlier, two missense variants in androgen receptor gene (*AR*) on Xq12 have been associated with POI in Indian women with POI,⁴³ but the study did not evaluate these variants with functional studies. The androgen receptor is of potential interest as deficiency of *AR* in the mouse model results in POI.⁴⁴

A gene on the X chromosome worthy of special mention is fragile X mental retardation (*FMR1*) on Xq27.3. A premutation, 50–200 CGG repeats in the 5' untranslated CGG repeat, of *FMR1* on Xq27.3 leads to methylation-coupled silencing of *FMR1* and absence of the fragile X mental retardation protein (*FMRP*), causing the classical Fragile X syndrome.⁴⁵ Fragile X syndrome is a common X-linked cause of cognitive impairment in males when the CGG repeat is greater than 200.⁴⁵ Although haploinsufficiency of *FMR1* is unlikely to cause POI in TS, a premutation is a common cause of POI, explaining 5% of sporadic POI cases and 10% to 15% of familial cases.⁴⁶ The mechanism of POI in *FMR1* premutation is thought to be an increase in messenger RNA (mRNA).⁴⁷

Short stature and POI are the most studied phenotypes in TS, and cognitive impairment will only be discussed briefly. The gene *XIST* has been associated with cognitive impairment in TS. Cognitive impairment is infrequently associated with TS and has mostly been observed in individuals with mosaic (short) ring chromosome [45,X/46,X,r(X)]. Cognitive impairment was first described in nine of 21 individuals with such a ring chromosome.⁴⁸ The initial hypothesis for cognitive impairment was thought to be absence of the *XIST* gene on the ring

chromosome, resulting in the failure of the X-inactivation of the ring chromosome.⁴⁹ However, Leppig noted that in nine individuals with an r(X), eight had *XIST* genes present, questioning the original "absence of *XIST*" hypothesis.⁴⁸

It must be emphasized that genotype-phenotype relationships in TS remain largely unknown. New approaches, such as methylation- and RNA expression studies are beginning to provide new answers. In a lymphocyte methylation and RNA expression study comparing TS women and 46,XX and 46,XY controls, women with TS were found to have genome wide hypomethylation altered expression in genes on both the autosomes and sex chromosomes compared with controls.⁵⁰ Other studies have identified X chromosome microRNA that escapes X-inactivation and may play an important role in disease differences between males and females.⁵¹

X Chromosome Genomic Imprinting

Imprinting studies for TS have shown mixed results. Skuse et al. proposed that individuals with 45,X who inherited a paternal X chromosome had a higher social cognition, meaning a significant difference in verbal and higher-order executive function skills.⁵² This study was based on 80 individuals with TS, of whom 55 had inherited a maternal X. In a smaller study of 39 participants with TS, Bishop et al. found that immediate and delayed recall was in the normal range for girls with TS.⁵³ A study that looked at brain morphology in 40 girls with 45,X (23 girls with a maternal X and 17 with a paternal X) found differences in brain morphology based on X chromosome origin: those who inherited a paternal X had a thicker cortex in the temporal regions, and those who inherited a maternal X had enlargement of gray matter in superior frontal regions.⁵⁴ Lepage et al. also noted that girls with a paternal X had a lower full-scale IQ than those that had inherited a maternal X. In contrast to these studies, a study of 50 girls with TS showed no association between parental X and IQ scores, as determined by the Wechsler Intelligence Scale for Children.⁵⁵ Finally, for the most recognized phenotype of short stature, there is no evidence of X chromosome imprinting based on a small study of 25 individuals with TS.⁵⁶

Diagnostic Tests

There are multiple testing options available for TS diagnosis, both prenatally and postnatally. As noted earlier, the first

diagnosis was made in 1959 by karyotype testing and this method continues to be the standard of care.^{8,17,57} A karyotype can be made from any metaphase or prometaphase cell that is actively dividing, including peripheral blood lymphocytes, amniocytes, and fibroblasts. Chromosomal microarray has the same level of accuracy as a karyotype, but has the advantage of more precise chromosomal breakpoints in the case of partial deletions and translocations.⁵⁸ Although not a first-line test for TS, next generation sequencing can accurately diagnose TS and has the advantage of being able to simultaneously diagnose single gene variant conditions such as Noonan syndrome.⁵⁹ FISH may be used to diagnose TS and has the advantage of being faster than karyotype testing, and can be performed on nondividing cells, such as those derived from buccal swabs.

Indications for Karyotype Testing

There is a distinct biphasic pattern in the diagnosis of Turner syndrome with a substantial proportion being diagnosed around the time of birth, and another large group being diagnosed around 12 years of age (Fig. 17.4). When there is a clinical suspicion of TS, the American College of Medical Genetics recommends a 20-cell karyotype⁵⁷ that should be able to detect mosaicism greater than 11%.⁶⁰ For a prenatal 45,X karyotype diagnosis, TS should be confirmed with a postnatal karyotype¹⁷.

Differential Diagnosis

When TS is suspected prenatally or postnatally, other genetic etiologies should be considered. In the prenatal period, TS may be diagnosed with noninvasive prenatal testing (NIPT) or CVS. Confined placental mosaicism, when the placenta is 45,X and the fetus is euploid, is in the differential diagnosis and should be resolved with amniocentesis. In addition to NIPT and CVS, prenatal ultrasound findings may suggest TS and other syndromes (Fig. 17.5). The following prenatal ultrasound findings may be found in other genetic syndromes: hygroma colli, fetal hydrops, coarctation of the aorta, and increased nuchal translucency.⁶¹ In first trimester ultrasound of 185 singleton pregnancies with cystic hygroma colli, the most frequent chromosomal abnormality was TS ($n = 49$; 26.5%), followed by trisomy 21 ($n = 32$; 17.3%), and trisomy 18 ($n = 27$; 14.6%).⁶² In this same study, 15 euploid fetuses were tested for Noonan syndrome and

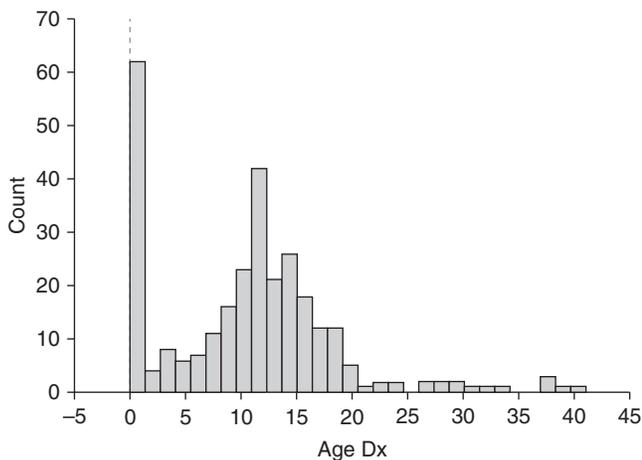

Fig. 17.4 Age of Turner diagnosis. The histogram shows the age of diagnosis for 292 patients evaluated in the National Institutes of Health Turner natural history protocol between 2005 and 2010. The median age of diagnosis was 11 years.

six (40%) were found to have it.⁶² In 65 cases of hydrops fetalis, six (9.2%) were diagnosed with TS, three (4.6%) with trisomy 21, and two cases with Noonan syndrome (3%).⁶³

Postnatally, TS may be suspected in childhood because of short stature, or during the pubertal age because of (primary) amenorrhea. Short stature affects 3% of children and there are numerous genetic etiologies.³¹ Common etiologies on the differential diagnosis include Noonan syndrome and haploinsufficiency for the *SHOX* gene. Although Noonan syndrome has been labeled “male TS” by some in the past,^{64,65}

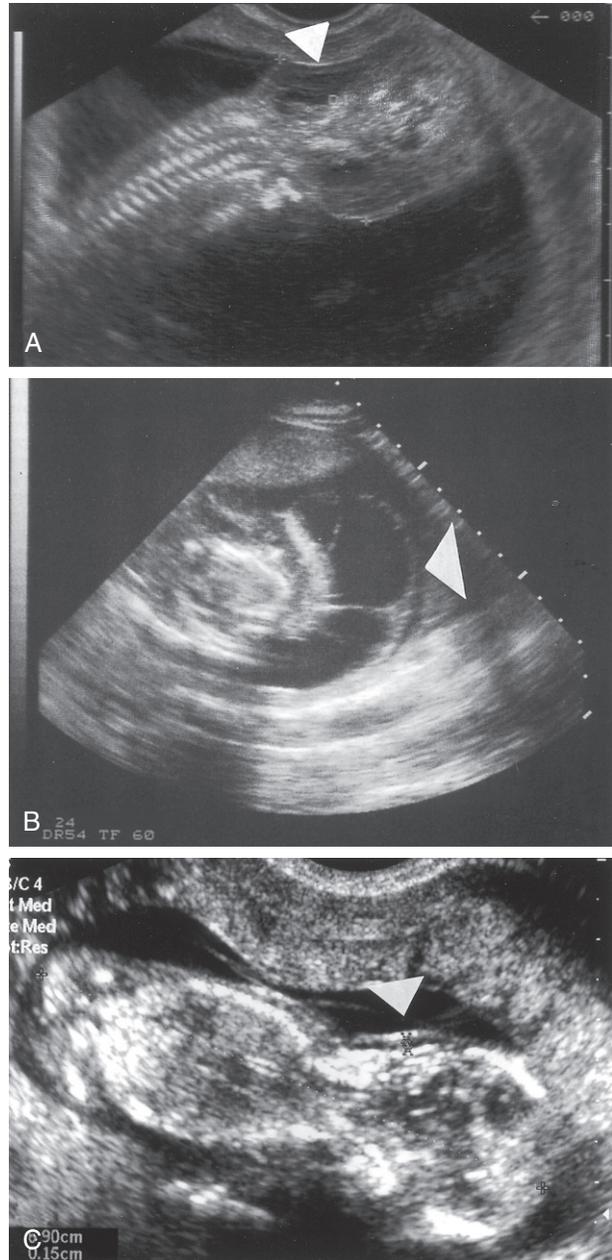

Fig. 17.5 A, A 14-week-old fetus with Turner syndrome and a cystic hygroma (arrow). B, A 13-week-old fetus with a normal karyotype and normal nuchal translucency of 1.5 mm (arrow). C, Same fetus as in view (A) in transverse plane. Large septated cystic hygroma (arrow) can be seen around the fetal neck. (Courtesy Pekka Taipale, MD, PhD, Kuppio University Hospital, Finland.)

the facial, cardiac, and development features are quite different between these two syndromes.⁶⁶

Prenatal Diagnosis

NIPT has changed the timing and accuracy of genetic prenatal screening, especially for aneuploidy syndromes, such as TS. NIPT is based on small fragments of circulating cell-free fetal deoxyribonucleic acid (ccfDNA) that originate from placental cells that are continuously released, and can be detected as early as 5 weeks of gestation.⁶⁷ Approximately 10% to 15% of cell free DNA in the maternal circulation is from the placenta, when measured between 10 and 20 weeks of gestation,⁶⁸ and the half-life of ccfDNA is less than a day.⁶⁹ There are a number of methods using NIPT to screen for TS prenatally, and most techniques count the number of copies of sequenced DNA fragments using next generation sequencing techniques.

In a Cochrane database systematic review,⁷⁰ a pooled analysis of over 7000 high-risk pregnancies involving 45,X, in 12 studies using massive parallel shotgun sequencing, showed a clinical sensitivity of 91.7% (95% confidence interval [CI], 78.3–97.1) and a clinical specificity of 99.6% (95% CI, 98.9–99.8). The Cochrane database study found similar results for roughly 1000 high-risk individuals in four studies, using targeted massive parallel sequencing, which only evaluates select loci of the genome.⁷⁰ Even with high sensitivity and specificity, the positive predictive values for NIPT for TS may be as low as 23% to 26%, which strongly reinforces the need for confirmatory testing.^{70–72} The American College of Obstetricians and Gynecologists recommends that all women with a positive cell free DNA result have a diagnostic procedure before clinical measures, such as pregnancy termination is taken.⁷³

The diagnosis of monosomy X is possible in embryos formed after in vitro fertilization (IVF) and is termed *preimplantation genetic diagnosis (PGD)* or *preimplantation genetic screening*. A biopsy of a blastomere at the cleavage stage or a trophoblast biopsy at the blastocyst stage allows for an aneuploidy assessment, using techniques including FISH, chromosomal microarray, and next generation sequencing. PGD analysis of IVF embryos is motivated by the belief that selection of euploid embryos will improve IVF outcome. However, to date, there is no evidence that PGD improves the live birth rate after IVF.^{74–76} More research is needed in PGD applications to aneuploidy, especially with respect to diagnosing TS.

CLINICAL CHARACTERISTICS AND COMORBIDITIES

Individuals with TS may present with a variety of phenotypic features: some patients have few and others are characterized by a multiplicity of findings. The typical physical characteristics can vary significantly between patients with similar karyotype (Fig. 17.6), and some of the clinical signs may be subtle. Table 17.1 summarizes the clinical features most commonly encountered in girls and women with TS.

Lymphedema

Lymphedema is relatively common in TS and begins in utero. Fig. 17.7 demonstrates the generalized edema that can be observed in many 45,X fetuses. It is the consequence of malformations of the lymphatic vessels, resulting in lymphatic hypoplasia and obstruction.⁷⁷ A cystic hygroma is a fluid-filled sac that often is located in the head/neck area, but may occur in other parts of the body, and results from abnormal communication between the jugular and central lymphatics draining into

the heart. Peripheral lymphatic hypoplasia or aplasia has also been demonstrated. Using lymphangiography hypoplasia, and even aplasia, can also be observed in the peripheral lymphatic vessels of the extremities.^{78,79}

Clinical features resulting from nuchal lymphatic obstruction include webbing of neck, also called *pterygium colli*, and is observed in up to 25% of TS patients. Additional features that appear to result from this tenting and stretching of facial/scalp and neck skin is thought to result in low-set, rotated external ears, ptosis and downslowing of the eyelids, and the development of a low posterior hairline, with upward growing hairs (see Fig. 17.6). The occurrence of thick hair growth, including thick eyelashes and eyebrows, may also be, at least in part, a consequence of the distended cutaneous structures during fetal

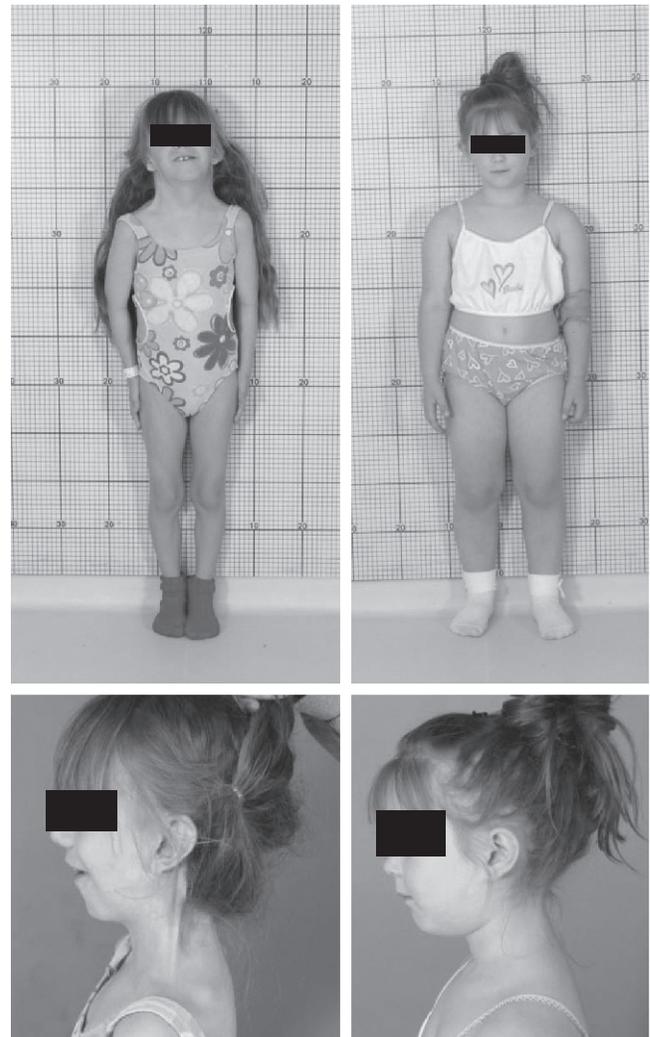

Fig. 17.6 Phenotypic variability in Turner syndrome. Both of these 7-year-old girls with short stature have Turner syndrome with a 45, X karyotype confirmed in analysis of 50 lymphocytes. The girl on the left was diagnosed at birth because of prominent neck webbing and low-set and posteriorly rotated ears. She also has micrognathia and a low posterior hairline. In contrast, the girl on the right was diagnosed at age 7 years because of short stature without “classical” stigmata of Turner syndrome, and she is more typical of the clinical presentation of the majority of girls with Turner syndrome diagnosed in the 21st century. (This image can be viewed in full color online at ExpertConsult.)

TABLE 17.1 Clinical Features in Girls With Turner Syndrome

Physical Diagnosis		Percentage Affected	
Skeletal	Short stature	100	
	Short neck	40	
	↑ Upper:lower body ratio	97	
	Cubitus valgus	47	
	Short metacarpal	37	
	Scoliosis	12.5

	Graves disease	1	
	Type 1 diabetes	0	
	Celiac	5	
	Inflammatory bowel	3	

"Physical Diagnosis" describes findings from physical examinations of more than 200 girls seen by Drs. Barbara Lippe and Paul Saenger between 1985 and 2000. Information on pubertal development is not included because many girls were not old enough to assess. The "screening evaluation" data are from 100 girls aged 7 to 17 years, who underwent standardized imaging and laboratory testing as part of the National Institutes of Health natural history study, performed between 2001 and 2008. The cardiovascular evaluation included magnetic resonance imaging and cardiac echo.

^aUnder the cardiovascular listing, the "Other" category included partial anomalous pulmonary veins, aberrant right subclavian artery, and atrial septal defects. Blood pressure was measured on 24-hour ambulatory monitors. All patients also had renal and hepatic ultrasound studies. Abnormal liver function was defined as greater than 10% elevation of aminotransferase(s). Hashimoto was defined by history of clinical hypothyroidism or elevation of circulating thyroid antibodies.

life. Swelling of the dorsum of the hands and feet at birth indicates the presence of a nonpitting type of peripheral edema. The lymphedema usually improves over the first 1 to 2 years of postnatal life. It may even resolve, but in many patients it persists to some degree.⁷⁹ Some TS individuals demonstrate intermittent worsening of their peripheral edema, and this appears to be associated with puberty or the introduction of growth

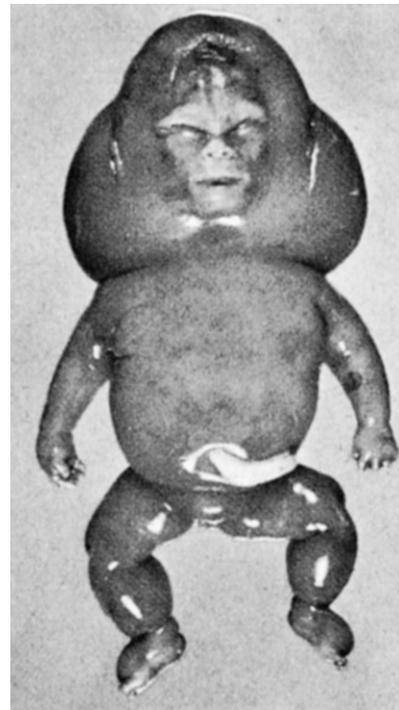

Fig. 17.7 A 45,X abortus demonstrating generalized lymphedema. Note the distended cervical region. With resolution of the edema, the redundant skin may cicatrize, resulting in a webbed neck. The edema of the hands and feet may persist and be present at birth. (From Gellis, S. S., & Feingold, M. (1978). Picture of the month. *Am J Dis Child*, 132, 417. Copyright © 1978, American Medical Association.)

hormone (GH) or sex steroid therapy (both somewhat salt-retaining).

Growth failure, Short Stature, and Skeletal Anomalies

Short stature is the most common physical abnormality seen in TS. Poor statural growth affects essentially every patient to some degree. Their growth failure is disproportionate and they have a relatively large trunk with broad shoulders and pelvis; together with the reduced height this renders them with a "stocky" appearance.⁸⁰ They often have a short neck because of hypoplasia of one or several cervical vertebrae.⁸¹ Long bone growth is preferentially impaired: patients do have relatively large hands and feet relative to their height, but the relatively short lower extremities lead to an increased upper-to-lower segment ratio.⁸² Selected bones can be more affected than others: an increased carrying angle at the elbow joint, also called *cubitus valgus*, is observed in nearly half of TS individuals. This carrying angle is the angle of intersection of the long axis of the upper arm with the long axis of the fully extended and supinated forearm. In adult normal females, this elbow angle is approximately 12 degrees (twice the size as seen in males).⁸³ This angle is between 15 and 30 degrees (Fig. 17.8) in many girls and women with TS because of abnormal development of the head of the trochlear bone.

The finding of a shortened fourth metacarpal, as shown on a bone age radiograph (Fig. 17.9A) is also quite common. On physical examination, it manifests as absence or less prominence of the fourth knuckle when making a fist. Sometimes the

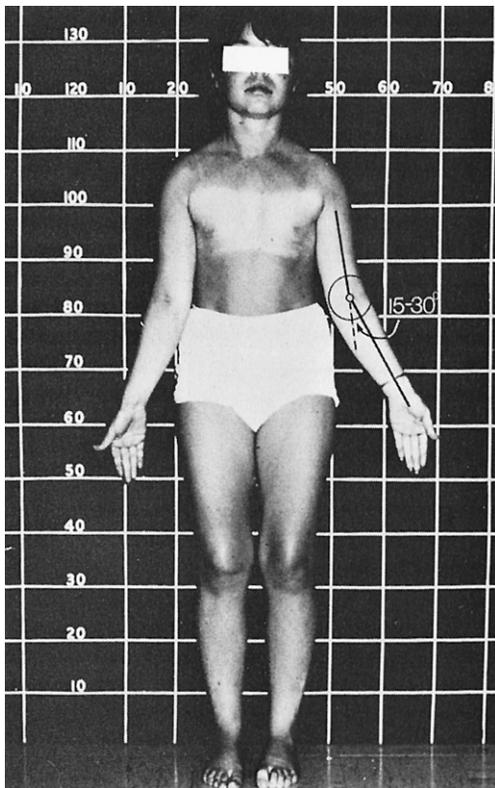

Fig. 17.8 A 16-year-old girl with Turner syndrome and absence of puberty. Note absence of most characteristic stigmata save short stature and an increased carrying angle (cubitus valgus).

fifth knuckle is also affected. Short fourth metatarsals can be found in some patients. The Madelung deformity is less common and is caused by a curvature of the distal radius in addition to a dorsal subluxation of the distal ulna (Fig. 17.10).⁸⁴ This anomaly also occurs as part of Leri-Weill dyschondrosteosis, and in both conditions is an indicator of a deficiency of SHOX. The previously described *cubitus valgus* and short metacarpals are also the result of SHOX deficiency.

At least 10%, and possibly as many as 20% of TS girls between 5 and 20 years of age develop scoliosis, defined as a lateral curve greater than 10 degrees. Kyphosis may develop in up to 40% of patients.⁸⁵ Both findings likely are the result of vertebral development anomalies. Abnormalities of the development of facial bones and skull base result in a micrognathic and retrognathic mandible and/or high arched palate in 60% of patients.

Osteoporosis and fractures are more common in women with TS. Hand and wrist radiographs may reveal mild osteopenia (Fig. 17.9B),⁸⁶ a coarse trabecular bone pattern, and ballooning of the tips of the terminal phalanges.⁸⁷ This osteoporotic appearance is observed during childhood and adolescence, suggesting it may be related to a developmental role of SHOX inherent to TS rather than to primary estrogen deficiency, which may still be a contributory factor. The fact that cortical bone mineralization is selectively reduced in TS, independent of estrogen exposure, is consistent with this.⁸⁸ Fractures of the long bones not associated with significant trauma are more frequently observed among girls with TS.^{89,90} It should be noted, however, that interpretation of studies of bone mineralization in young individuals with TS is difficult because areal instead of volumetric bone mineral density is measured. Nevertheless, prepubertal TS girls have decreased markers of bone formation because of a state of low-bone turnover and decreased bone deposition.

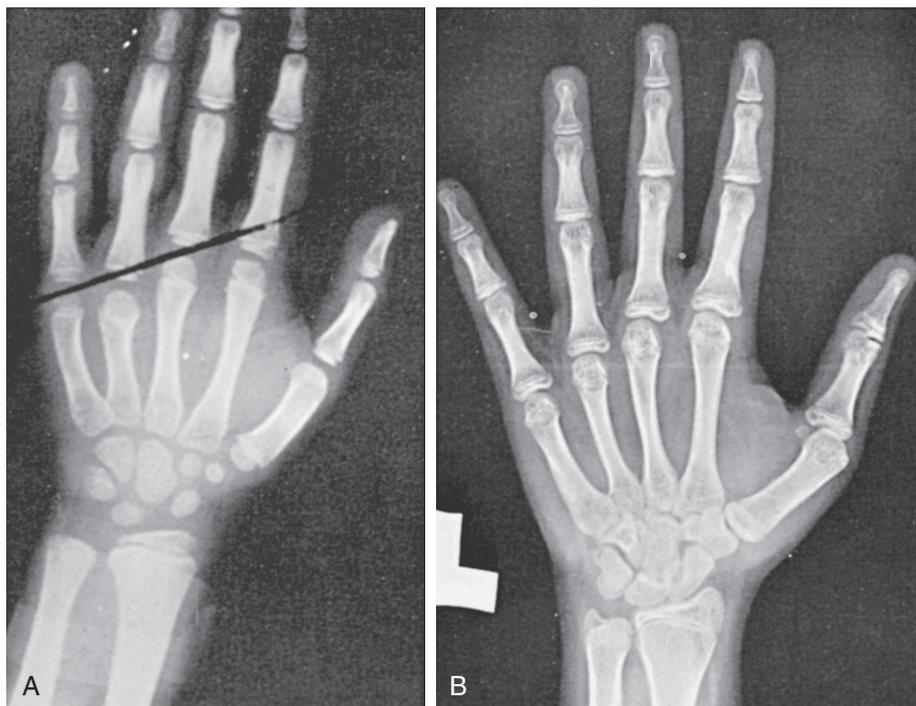

Fig. 17.9 Two characteristic hand radiographs. A, Short fourth metacarpal, the tip falling below a straight line drawn between the third and fifth metacarpals. B, Generalized lacy ("fish net") appearance of the carpals and tufting of the distal phalanges, characteristic of the osteoporotic appearance of the bones of patients with Turner syndrome.

Fig. 17.10 A 19-year-old-patient with Turner syndrome and bilateral bayonet-like Madelon deformities of the wrists.

Poor linear growth in childhood and adolescence leads to adult TS women ending up about 20 cm shorter than their non-Turner female peers. The short stature in TS can be attributed to the deleterious effect of SHOX haploinsufficiency.

One of the first large-scale assessments of the growth failure present in TS was reported by Ranke et al. in 1983.⁹¹ Fig. 17.11 shows cross-sectional height and height velocity data from 150 TS children who did not receive growth-promoting therapy. Davenport and coworkers⁹² further elaborated on the different stages of impaired growth throughout a TS patient's life. Prenatally, there is a mild degree of growth restriction resulting in a length at birth that is about 1 standard deviation (SD) below the mean. During infancy and up to 3 years of age, a further mild growth deceleration can be seen.⁹³ Continued subnormal growth is observed throughout childhood, so that between ages 3 and 13 years, TS girls develop more deflection from both their target percentile and the normal height curves. There is failure to experience a normal pubertal growth spurt, and slow growth may be prolonged for several more years, potentially into the early 20s.

Height at diagnosis,⁹⁴ ultimate height achieved, and mid-parental height are positively correlated.⁹⁵ The adult height deficit is approximately 20 cm and this is irrespective of patients' ethnic background.⁹⁶ TS-specific growth curves have been developed by Lyon and associates,⁹⁷ based on the data from Ranke and colleagues, as well as other European centers. These curves provide mean height and SD values for age and indicate a mean adult height of 143.1 cm (about 56.5 inches). A strong correlation between the initial height on these Turner curves and the adult height was also observed by Lyon and colleagues, independently of bone age at the time of the first height.⁹⁷ This essentially allows for the adult height prediction of any girl with TS based on her height at an earlier age.

Ovarian Insufficiency

Initial reports on the presence of gonadal pathology described TS individuals as having streak ovaries. These small fibrous gonadal structures have few if any oocytes present. It appeared as if the ovaries had failed to develop normally. Subsequent studies revealed that early ovarian development actually occurs in a normal manner, with adequate numbers of oocytes and primordial follicles present in 14- to 16-week-old Turner fetuses.⁹⁸ However, later in development, Turner ovaries become relatively depleted of oocytes and have fewer developing follicles. This suggests a process of accelerated oocyte demise and follicular atresia.^{99,100} Despite this, some TS girls have follicles in various stages of development, even during the second decade of life.¹⁰¹ Fig. 17.12 shows pelvic ultrasound studies comparing the pelvic structures of TS individuals with those of a normal pubertal females. The cause for the high rate of oocyte attrition in most girls with TS is unknown. One possible explanation is that premature oocyte depletion is caused by abnormal meiosis because of the aneuploidal status.¹⁰² Another possible explanation is that normal oocyte generation and survival require diploid expression of certain genes on the X chromosome. The chromosomal location of putative genes important for fertility has yet to be defined. This is because POI/gonadal failure is frequently observed in Xp deletions with an intact Xq complement, but also in some cases of Xq deletion with normal Xp complement.¹⁰³ In addition, it has been reported that terminal Xq deletions can be associated with POI in women who have few, if any features of TS (see earlier section on Genetics, for more detailed description).¹⁰⁴

Because there is a broad range of gonadal dysfunction in TS individuals, it is hard to predict which patient will spontaneously enter puberty, and who will not, or to determine which women could become pregnant. Based on information from ovarian biopsies the strongest predictor for the presence of ovarian follicles is a karyotype with mosaicism for 45,X and 46,XX cell lines. TS arising from 45,X monosomy or structural defects of one X chromosome are much less likely to be associated with the presence of follicles in the ovaries.¹⁰⁵ Additional positive predictors of follicle presence include both normal follicle-stimulating (FSH) and anti-Müllerian hormone (AMH) concentrations—see also Figs. 17.13 and 17.14.^{106,107} Although less robust than the blood karyotype, the occurrence of spontaneous puberty is also a positive predictor.¹⁰⁵ Spontaneous puberty was observed in approximately 15% of girls with 45,X monosomy and in 30% of girls with a second cell line with more than one X chromosome (i.e., 45,X/46,XX; 45,X/47,XXX)—based on the findings of a study that included more than 500 girls with TS.¹⁰⁸ Even when spontaneous puberty occurs, it may not progress normally, and menarche may be delayed or does not happen. Even if menarche occurs, oligomenorrhea and anovulation are common, so that less than 5% of 20-year-old TS women end up having normal menstrual cycles.

Spontaneous pregnancy may occur in 2% to 3% of women with TS.^{108–110} It is more common in women with 45,X/46,XX (or 45,X/47,XXX) cell line mosaicism. However, spontaneous pregnancies occurring in 45,X women, without evidence of mosaicism, are well-documented.^{110–112} In the initial literature on spontaneous pregnancy in TS individuals, increased fetal mortality or malformations were reported.¹¹³ However, this has not been observed in more recent, population-based studies^{110,114}—even for women with X monosomy.^{110,115} If the case where a TS mother has a sex chromosome structural abnormality, such abnormal chromosome may be passed on to her offspring. The risk of

maternal complications with spontaneous or assisted pregnancies is quite high for women with TS.

Gonadoblastoma

A gonadoblastoma is a rare benign gonadal tumor, and is almost always found in a (dysgenetic) gonad with Y chromosome material. This tumor has a distinctive histological appearance, which distinguishes it from other gonadal neoplasms. The gonadoblastoma is composed of large germ cells surrounded by sex cord derivatives that resemble small cells with variable granulosa, lutein, or immature Sertoli-like morphology. Because it strongly resembles the histology of a developing gonad, it was assigned the name "gonadoblastoma." Although the tumor is considered a benign growth, it has both the potential for steroid production (can produce both testosterone and estrogen), as well as for malignant transformation (into a dysgerminoma).¹¹⁶ Gonadoblastomas are found in approximately 40% of females with 46,XY mixed gonadal dysgenesis.¹¹⁷ The frequency among girls with TS and Y chromosomal material is between 10% and 30%, but is likely closer to the lower end of this range.¹¹⁶ These data are based on histologic examination of ovaries that were "prophylactically" removed from girls who carried Y chromosome material. Analyses of Danish health registry data did not find increased morbidity or mortality related to any type of ovarian tumor among women with TS.^{118,119} A large British registry study ascertained gonadoblastoma diagnoses in 8% of women with Y chromosome in their peripheral blood karyotype.¹²⁰

Prophylactic gonadectomy has been standard practice since the time that an excess of gonadal tumors was first observed in girls and women who had both Y chromosome material and intraabdominal gonads.¹²¹ Such a surgical approach was taken because these gonads tended to be nonfunctional, and caused an increased risk for tumor formation. However, spontaneous puberty and even pregnancy may occur in individuals with TS and Y chromosome material.¹²²⁻¹²⁴ Portnoi et al. reported on an 8-year-old TS girl who was found to have a translocation of Y chromosome material onto the X chromosome (see Fig. 17.2). The patient did not undergo gonadectomy, developed spontaneous puberty, and eventually had a well-supervised pregnancy with good outcome.¹²² It should also be noted that our clinical experience in TS associated with gonadoblastoma and/or dysgerminoma is based on patients whose karyotype included visible Y chromosome material; in some cases, there even was clinical evidence of virilization. Because of this, the recommendation for ovariectomy was initially only applicable to individuals with visible Y chromosome material or virilization.^{125,126} With the introduction of newer molecular technologies, several reports indicate detection of Y chromosome sequences in 45,X girls without evidence of Y chromosome material on their karyotype. In some of these patients, gonadoblastoma has been detected after gonadectomy. It has been suggested by some that all patients with 45,X monosomy undergo molecular screening for cryptic Y chromosome material. Because it has been shown that PCR amplification may yield false positive results,¹²⁷ the risk of overtreatment is a real concern. In addition, immature ovaries may contain nests of germinal cells that are benign but resemble a gonadoblastoma.

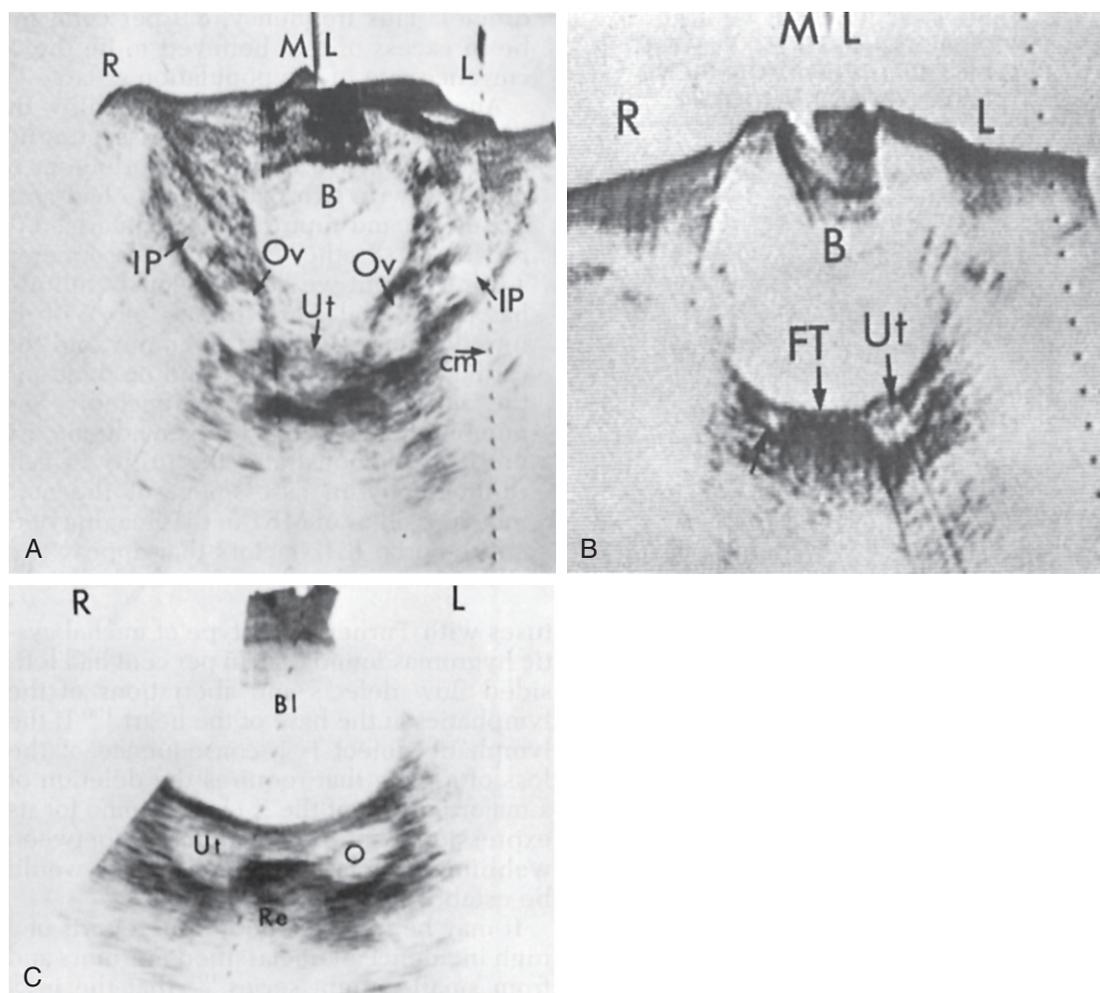

Fig. 17.12 Examples of pelvic ultrasound studies. A, Normal pubertal female demonstrating ovaries of adult size. B, Patient with Turner syndrome. The corpus of the uterus is seen slightly to the left of the midline. The fallopian tube can be followed into the right adnexa and observed to terminate in a small structure (*arrow*) believed to be the fimbriated end of the tube. No ovaries are identified. C, Patient with 45,X/46,XY Turner syndrome previously treated with estrogen. The corpus of the uterus is enlarged to adult size. In the left adnexa, a large gonadal mass (O) is seen. Histologically, this was identified as a gonadoblastoma. The images are transverse, oriented right (R) and left (L) of the midline (ML). The dotted scales are in centimeters. B, BL, bladder; FT, fallopian tube; IP, iliopsoas; O, gonadoblastoma; OV, ovary; Re, rectum; Ut, uterus.

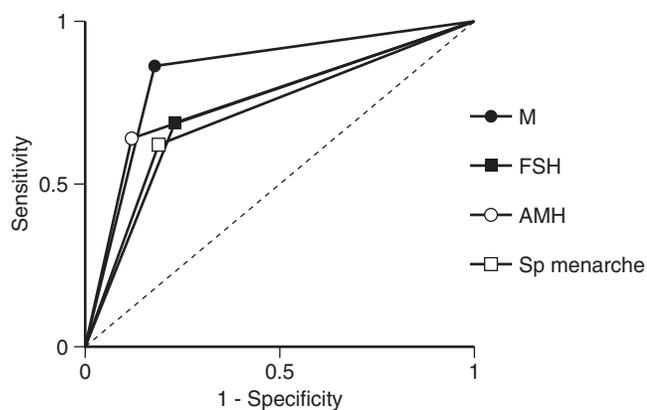

Fig. 17.13 Receiver operating characteristic curves showing the relationship between sensitivity and specificity regarding the four investigated variables with the highest sensitivity. (From Borgström, B., Hreinsson, J., Rasmussen, C., et al. (2009). Fertility preservation in girls with Turner syndrome: prognostic signs of the presence of ovarian follicles. *J Clin Endocrinol Metab*, 94, 74–80. Erratum in *J Clin Endocrinol Metab*, 94, 1478, Figure 2.)

There is currently a paucity of information on the use of imaging or serum markers for surveillance of potential gonadal tumors in TS. In any case where Y chromosomes/sequences are detected and gonadoblastoma is suspected, there needs to be education and counseling of patients or family concerning gender identity, sexual functioning, and reproductive consequences relevant to the decision for gonadectomy. Preservation of follicles or oocytes may be an option for some patients undergoing gonadectomy. Further discussion of gonadoblastoma issues is found under the Patients with Y Chromosome section presented later in the chapter.

Cardiovascular System Anomalies

Congenital Cardiovascular Malformations in Turner Syndrome

Congenital cardiovascular malformations (CVMs) are the most serious, life-threatening consequences of X chromosome monosomy.^{118,120,128} Coarctation of the aorta is one of the first CVMs documented in patients with TS.^{5,129–131} The frequency and spectrum of TS-specific CVMs, based on data combining chromosomal genotyping and imaging, is summarized in

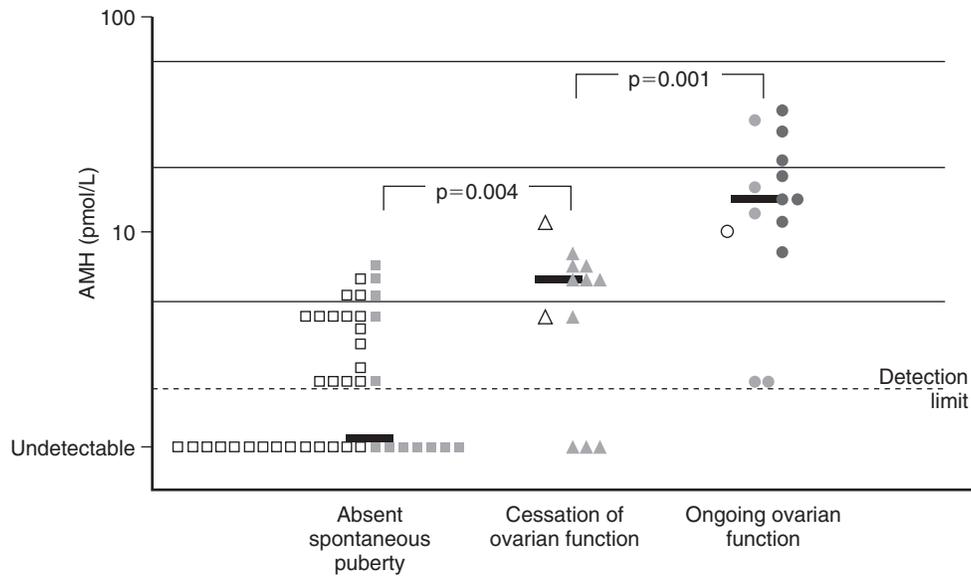

Fig. 17.14 Anti-Müllerian hormone (AMH) levels and ovarian function at time of AMH measurement in patients with Turner syndrome, aged 12 to 25 years. Dotted line represents the detection limit of the assay; squares represent patients with absent puberty; triangles represent patients with cessation of ovarian function; circles represent patients with ongoing ovarian function. Thick black bars, median of AMH; black, patients with 45,X. (From Hagen, C. P., Aksglaede, L., Sorensen, K., et al. (2010). Serum levels of anti-Müllerian hormone as a marker of ovarian function in 926 healthy females from birth to adulthood and in 172 Turner syndrome patients. *J Clin Endocrinol Metab*, 95, 5003–5010. Figure 3. This image can be viewed in full color online at ExpertConsult.)

Table 17.2. Approximately 75% of spontaneously aborted TS fetuses and 30% of living patients have a clinically apparent CVM. Obstructive lesions of the left ventricular outflow tract (LVOT) predominate, ranging in severity from nonstenotic bicuspid aortic valve (BAV) to aortic stenosis, coarctation of the aorta, ascending aortic aneurysm, and mitral valve anomalies (see Table 17.2).¹³² The most severe form of left-sided CVM, with poor prognosis, is hypoplastic left heart syndrome.^{133,134} The association of TS and left-sided CVM is characteristic among malformation syndromes.

There exists a significant association between neck webbing and aortic coarctation in girls with TS.¹³⁵ This is supported by: (1) observations from aborted fetuses,¹³⁶ and (2) additional studies reporting a much higher prevalence of aortic coarctation and BAV in girls with neck webbing.^{137,138} The underlying pathophysiologic mechanism proposes that lymphectasia causes a mechanical defect: engorged fetal lymphatic structures compress the developing ascending aorta, which affects intracardiac blood flow, and ultimately leads to a spectrum LVOT anomalies.¹³⁵ Another potential explanation is derived from observations in 45,X fetuses with severe aortic arch defects and aortic valve abnormality. It invokes generalized hypoplasia of the fourth branchial arch tissues associated with defective

migration of neural crest cells.¹³⁹ LVOT anomaly defects also occur in TS patients without neck webbing, and neck webbing is observed in TS girls with normal cardiovascular structure and function.¹⁴⁰ Taken together, both explanations may play a role here, and haploinsufficiency for certain genes on the X chromosome could lead to both severe fetal lymphedema and aortic heart developmental defects, independent of each other. How manifest the CVM ultimately becomes may be further influenced by genetic variations on the autosomes with/without additional environmental effects.

Nonsyndromic LVOT defects (e.g., aortic coarctation and BAV), in the general population, are not associated with lymphedema or neck webbing. They are also more commonly observed in males than in females by a ratio close to 3:1. This CVM phenotype is observed in individuals with TS who present with either a deletion of just the short arm of the X or Y chromosome.^{129,141} This indicates that loci important for LVOT development are likely present on both Xp and Yp. The putative candidate gene for LVOT development would then have to escape X inactivation in females and be expressed from both the X and Y chromosomes in males. The Yp allele may be more prone to disruption in males, as a consequence of inherent Y chromosome instability.¹⁴² Localization of an LVOT-related

TABLE 17.2 Congenital Cardiovascular Malformations in Turner Syndrome

	Mode	BAV	COA	ASD/VSD	PAPVC	ARSC	ETA	Any

gene on the PAR1 of the X chromosome may explain the greater prevalence of LVOT anomalies in males, because the meiotic recombination rate for PAR1 is sevenfold greater in males than females,¹⁴³ increasing the overall risk for *Yp* gene disruption.

Disease of the Aorta

Complications of CVMs are the leading cause of morbidity, as well as premature and increased mortality in TS.^{119,120,128} The major cardiovascular complications include aortic valve disease and aortic dilation, dissection, or even rupture. Approximately 30% of girls with TS are born with a congenitally abnormal aortic valve. Because careful appropriate screening for the presence of, for example a BAV, is sometimes lacking, congenitally abnormal valves are often not detected until the third decade of life or later.^{141,144} Carolyn Bondy's group studied 74 patients with BAV, at a median age of 30 years (range 7–67 years). Of these women, 55% had normal valve function, 30% had mild aortic regurgitation, and 15% had moderate to severe aortic regurgitation.¹⁴¹ In this BAV cohort, aortic stenosis was present in only 2/74 patients. The prevalence of BAV was equal in pediatric and adult subgroups, but adults were more likely to have functionally abnormal valves. A large National Institutes of Health screening study using advanced imaging technology (magnetic resonance angiography or cardiac MRA) confirmed a BAV prevalence of 34% of girls with TS.¹⁴⁵ In a more recent study using similar imaging techniques, Kim et al. report a prevalence of BAV as high as 39%.¹⁴⁶ It is imperative to screen all girls and women with TS for aortic valve pathology, as the aortic valve may deteriorate over time, leading to heart failure. In addition, aortic valve abnormalities are linked to further aorta pathology, with increased risk for the development of aortic dilation, dissection, and rupture.^{147–154}

In individuals who have an abnormal aortic valve, this is often associated with relative dilation of the ascending part of the aorta, using age and body surface area nomograms.^{141,152} The magnitude of ascending aortic dilation is greatest in patients whose valve is also functionally abnormal,^{141,152} although individuals with normal valve function may also develop dilation.¹⁵⁵ In about 10% of patients who have a normal tricuspid aortic valve (and normal blood pressure), mild-moderate ascending aortic dilation can also be found.^{141,152} There is an increasing body of evidence for the existence of a generalized vasculopathy in individuals with TS. Some of the observations supportive of this include an enlarged diameter of the carotid and brachial arteries,¹⁵⁶ as well as aneurysms of other arteries.^{157,158} The term *aortopathy* has come into wider use and describes the presence of aortic disease of diverse etiologies, including Marfan syndrome and vascular disorders not associated with valvular disease. *Aortopathy* exists in addition to aortic disease associated with BAV.¹⁵⁹

From the analysis of epidemiologic data obtained from the Danish registry we can safely state that the risk for serious aortic complications is 100-fold or greater increased in girls and women with TS, compared with the general female population.¹⁵¹ For example, the median age of aortic dissection was 35 years (in the general female population, this is an event usually observed in the seventh or eighth decade of life), with the few pediatric cases clearly associated with a history of more severe aortic valve disease or coarctation. Aortic valve abnormalities and aortic coarctation, with or without surgical repair, are important predisposing factors for aortic dissection. Hypertension is another risk factor for aortic disease, in the general population, as well as in TS individuals. The presence of aortic dilation is a strong risk factor for aortic dissection in TS, although dissection can occur in women with TS who do

not harbor any of the known aforementioned risk factors. Nevertheless, cardiology follow-up in these patients should always include direct and reliable measurements of ascending aortic diameters at the sinuses of Valsalva, sinotubular junction, and ascending aorta for all patients, together with body surface area and age.¹⁶⁰ Spontaneous and assisted pregnancies are associated with a further increased risk for life-threatening aortic complications in TS, and the French College of Obstetrics and Gynecology,¹⁶¹ as well as the American Society of Reproductive Medicine,¹⁶² have issued stringent guidelines on pre-conception screening and maternal care aimed at reducing these risks. In the past, too often TS women went through a pregnancy without such detailed evaluations.

Other Cardiovascular Health Issues

Aortic valve disease and risk for aortic complications are major concerns in TS, but other CVMs are also observed with a higher frequency. Partial anomalous pulmonary venous connection (PAPVC), or return (PAPVR), is increased in TS;^{163,164} it has a reported prevalence between 1% and 16%.^{137,165–168} The higher prevalence is found after using contrast cardiovascular MRA for screening purposes, and is likely a reflection of the true increased prevalence, because echocardiography is a suboptimal technology to study the anatomy of the pulmonary veins.^{167,168} This diagnosis should especially be pursued in girls with exercise intolerance, unexplained pulmonary issues (reactive airway disease), or evidence of pulmonary hypertension or right heart hypertrophy. The significance of incidentally discovered PAPVC in the screening of asymptomatic patients is unclear. Only 9% to 14% of PAPVC patients reported from two case series had a clinically significant left-to-right shunt necessitating surgical intervention.^{167,168} Aberrant right subclavian artery is another relatively common anomaly (5%–10%; Fig. 17.15)^{167,168} that may compress the esophagus, leading to dysphagia and chest pain.¹⁶⁹ One important clinical note relates to the origin of an aberrant right subclavian artery from the descending aorta: this could mask the presence of aortic coarctation if the right upper extremity alone is chosen to screen for upper versus lower extremity blood pressure difference. Atrial or ventricular septal defects and mitral valve disease are more common than in the general female population, but less frequent than aortic defects and PAPVC (see Table 17.2).

Minor electrocardiographic findings, including right axis deviation, T wave abnormalities, bundle branch block, QTc prolongation, and increased heart rate variability are more common among girls (30%) and adults (>50%) with TS, compared with age-matched female controls.^{170,171} Most of these findings are of uncertain significance. Specifically for QTc prolongation, there does not appear to be a worsening of this finding with increasing age. It is recommended to obtain a screening electrocardiogram (ECG) on all patients with TS, and recommend those with a prolonged age-specific QTc to avoid medications associated with QTc prolongation.¹²⁶ An ECG should also be done after initiation of QTc prolonging drugs, if these cannot be avoided. However, unlike in familial long QT syndrome, there is no evidence that prolonged QTc in TS is associated with sudden cardiac death. In case right axis deviation is detected on ECG, PAPVC, or PAPVR needs to be considered. Impaired autonomic responses are suggested by resting tachycardia, reduced heart rate variability, and the absence of the expected nocturnal dip in blood pressure.^{172,173} Systemic hypertension is more common in girls and women with TS, compared with age-matched female controls: at least 25% of patients.^{174–176} The higher prevalence of hypertension

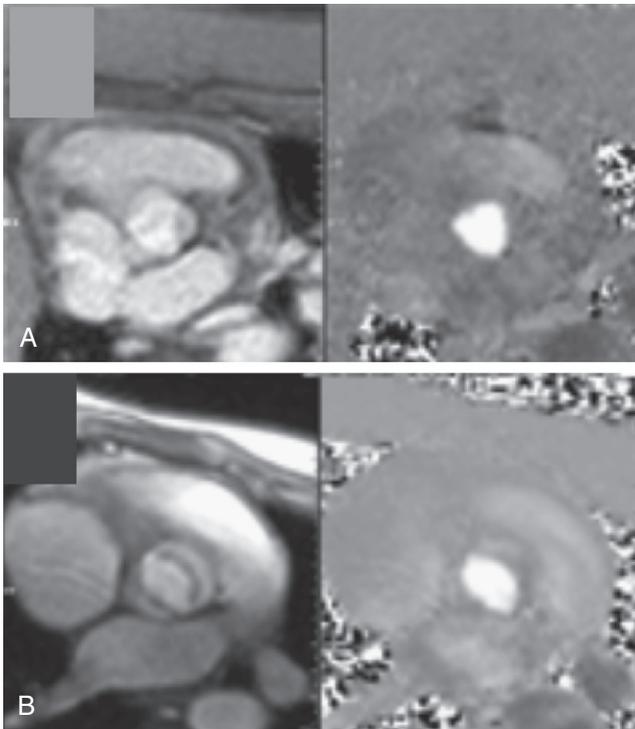

Fig. 17.15 Aortic valve structure shown by cardiac magnetic resonance imaging (MRI). Anatomy is shown on the left and blood flow on the right side of each panel. Cardiac MRI is able to visualize the aortic valve more consistently than transthoracic cardiac echo. This figure shows normal tricuspid (A) and bicuspid (B) aortic valves.

appears independent of renovascular or aortic disease¹⁷⁷ — although secondary hypertension may occur if vascular pathology or renovascular disease coexists (rare). The hypertension appears not adversely impacted by the usual recommended estrogen treatment regimens.^{176,178} In the majority of patients, the cause of the hypertension is unknown, and it probably has a multifactorial etiology. Sympathetic hyperactivity, increased activity of the renin-angiotensin-aldosterone system, and estrogen deficiency may all be contributory. Further studies are needed to determine ideal systemic blood pressures for girls and women with TS given their smaller stature and increased risk for aortic and also atherosclerotic disease. Moreover, further investigation is required to identify beneficial pharmacotherapy for patients with hypertension or BAV and aortic dilation.¹⁷⁹ We currently define hypertension in TS using the guidelines for the general population and use corrected norms for age, sex, and height when evaluating children.¹⁷

Cardiovascular Screening in Turner Syndrome

When a girl with TS is diagnosed with a CVM, either in infancy or in childhood, it is recommended she is followed by the pediatric cardiology team, ideally at a specialized tertiary care center, and preferably by a cardiologist with special expertise in following congenital heart disease. Most girls diagnosed with TS later in childhood or adolescence do not present with clinically obvious cardiovascular disease. Close cardiovascular examination and consultation with pediatric cardiology are required at the time of diagnosis however, with particular attention to blood pressure measurements in all extremities. The mode of imaging and the frequency of follow-up are determined by the clinical situation in each case. Transthoracic

echocardiography has been the standard approach to screen for congenital CVM for decades, but this modality has important limitations related to operator dependency and limited acoustic windows, especially in the context of abnormal chest anatomy and obesity, which are common physical features seen in TS.¹⁸⁰ Cardiovascular magnetic resonance (CMR) imaging provides excellent visualization of cardiovascular anatomy and function, with dimensions of ascending, transverse, and descending aorta, in any desired imaging plane (see Fig. 17.15 and Fig. 17.16). Importantly, CMR may detect significant cardiovascular anomalies, including chronic aortic dissection, aortic coarctation and dilation, aortic valve abnormality, and PAPVR (PAPVR) not always so easily demonstrated by routine echocardiography.^{153,167,168,180–182}

Asymptomatic BAV or aortic dilation and some cases of coarctation pose risks for aortic complications, but may escape detection with standard evaluation and echocardiography. Current recommendations include the more advanced imaging (i.e., CMR) when possible, without excessive risks of sedation or radiation exposure, usually by age 12 years.^{17,126} The detection of asymptomatic BAV and aortic dilation is crucial to assess the individual's risk for aortic complications, as well as the requirement for ongoing cardiac monitoring during adulthood. In addition, since 2017 new guidelines are available that help educate the young patient and her family about the risks of high-impact or high-resistance exercise and the knowledge of coexisting CVMs will enhance counseling in this area.¹⁷

Ongoing Cardiac Care

Pediatric TS patients with known congenital CVMs require continued care by the pediatric cardiology team and should be transferred to adult congenital heart disease specialists when appropriate for age.^{17,142} Patients who have had aortic coarctation repair in childhood need ongoing surveillance for detection of hypertension, development of aortic valve disease, as well as imaging of the aorta to monitor for restenosis, dilatation, or true aneurysm formation.^{183,184} Patients with BAV or aortic dilation need regular and continued monitoring for hypertension, valve function, and potential progression of aortic dilation. The optimal frequency of monitoring is not exactly known because it is uncertain if there is continuous progressive dilation of the aorta, as seen in Marfan syndrome, or whether changes occur by leaps rather than by gradual transition.¹⁸⁵ The latter process could be influenced, for example, by a stressor, such as a motor vehicle accident, participation in high-resistance exercise, or an associated pregnancy. Available evidence describes a small annual rate of dilation near the detection limit of current imaging methods.^{186,187} Further studies are required to identify parameters that may be more useful in predicting imminent aortic decompensation, such as aortic wall thickness, compliance, or circulating markers (e.g., natriuretic peptide).¹⁸⁸ The aforementioned 2017 guidelines provide a cardiac imaging and cardiology evaluation follow-up protocol, which was arrived at by reviewing the current available literature, combined by consensus agreement from experts in the field of TS cardiac disease.¹⁷

Beta-blockers and angiotensin receptor blockade have shown some efficacy in preventing aortic dilation in Marfan syndrome, but neither form of treatment has been carefully investigated in affected TS patients. Children at increased risk for aortic dissection because of BAV and aortic dilation, with or without hypertension, and their families should be counseled about possible presenting symptoms (e.g., chest or back pain). Wearing a medical identification bracelet indicating the presence of aortic disease could be of benefit in case the family

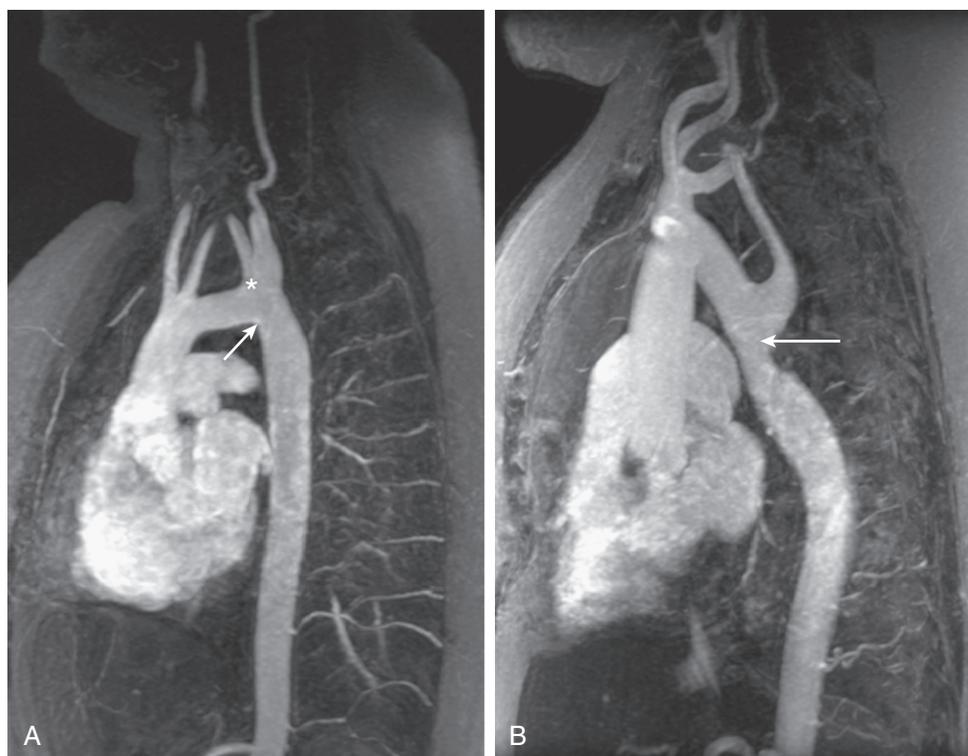

Fig. 17.16 Cardiac magnetic resonance imaging (MRI) aortograms in Turner syndrome. The image on the left (A) shows a squared off, elongated transverse aortic arch (ETA) with a kink in the lesser curvature (*arrow*). This kink has been called *pseudocoarctation* and is associated with risk for type B dissection. This patient also has a dilated origin of the left subclavian artery (*) and an aberrant origin of the right subclavian artery. The image on the right (B) shows a tortuous aortic arch with coarctation just below the take-off of the left subclavian. There is moderate dilation of the ascending aorta and poststenotic dilation of the descending aorta as well. This image was obtained from a 41-year-old woman with long-standing hypertension who had been followed with cardiac echo over the years.

is not able to advocate for their child in distress. Delayed or missed diagnosis is the most important cause of fatality in acute aortic dissection, a major concern if the emergency department staff fails to consider dissection in an atypical patient presenting with clinical features consistent with acute aortic dissection. The most common presenting symptom should be pain, often of abrupt onset. Typically, the pain is increasing in intensity and may be described as sharp. The pain is typically felt in the anterior chest but may be experienced in the back in case of descending aorta dissection.

For the patient with no identified cardiovascular defects after adequate cardiovascular evaluation and imaging, routine pediatric care with continued monitoring of blood pressure is advised. It seems also prudent to reevaluate aortic dimensions at 5- to 10-year intervals (see later). Heart-healthy moderate aerobic exercise is emphasized and should be encouraged. As noted before, eligibility for competitive sports for all with TS should be determined by a cardiologist, after a comprehensive evaluation that includes magnetic resonance imaging (i.e., CMR) of the aorta.

Risk for Premature Atherosclerotic Disease

Epidemiologic analysis of registry data from Denmark described a 3-fold increased risk of coronary and cerebrovascular disease among women with TS.¹¹⁸ It was not determined if the coronary disease and stroke were secondary to atherosclerosis or to underlying congenital CVMs. Adults with nonsyndromic aortic coarctation have an increased risk of hypertension, coronary disease, and stroke—despite apparently successful coarctation repair.¹⁴² Total cholesterol concentrations are often elevated in untreated girls with TS, compared with age-matched

females,¹⁸⁹ with improvements in the metabolic profile with GH treatment.¹⁹⁰ Atherogenic risk factors, including abdominal adiposity and lipid profile, are higher in women monosomic for the maternal X chromosome versus those with retained paternal X chromosome,¹⁹¹ but they are not usually increased into the atherogenic range.¹⁷⁵ Recommendations for preventing atherosclerosis apply equally to girls with TS and the general pediatric population and include promoting a healthy lifestyle, monitoring blood pressure, and preventing obesity. Although many pediatricians initiate lipid screening around 10 years of age, with repeat assessment in the transition years (between ages 17 and 21 years), the recent guidelines recommend a lipid profile to be performed in individuals who have at least one risk factor for cardiovascular disease and starting at 18 years.¹⁷

Renal Anomalies

Some 20% to 30% of girls with TS will have a renal abnormality.^{192,193} Duplication of the pelvocaliceal collecting system, a horseshoe kidney, renal ectopia, and unilateral renal agenesis are the more commonly occurring anomalies. The etiology of the renal anomalies is unknown. There is no apparent correlation between the renal anomalies and other features of TS, such as neck webbing or congenital CVMs.¹³⁸ However, a horseshoe kidney is thought to occur more commonly in patients with a 45,X karyotype.¹⁹⁴ Most TS children with congenital renal anomalies have normal renal function, but some are at increased risks for urinary tract infections. Pyelonephritis can occur if there is evidence of obstructive collecting system lesions, and this may require

surgical repair. It is recommended that all patients undergo ultrasound imaging of the renal system at diagnosis. Additional tests (e.g., voiding cystourethrogram or renal scintigraphy) may be required in patients with (recurrent) urinary tract infections. Renal function should be tested on a regular basis for those individuals with a horseshoe or single kidney. Additional studies are necessary to determine if renal anomalies diagnosed in TS patients are associated with gradual worsening of renal function or the development of proteinuria and hypertension during later life.

Otologic Disorders

Recurrent middle ear infections are one of the most common medical problems in young girls with TS. Anderson et al.¹⁹⁵ first described the presence of middle ear pathology in girls with TS: recurrent otitis media, eardrum perforations frequently requiring surgical intervention, and significant hearing loss occurring in up to one-quarter of affected patients.¹⁹⁶ Many other reports further address the conductive hearing loss that occurs secondary to refractory otitis media in TS, and having a karyotype with loss of the short arm of the X chromosome (Xp) seems to predispose to this.^{197–200} Many girls will require repeated tympanostomy tube placement. Despite this, some patients may develop complications, including the development of cholesteatoma.²⁰¹ The frequent otitis media may be the consequence of abnormalities in the shape and growth of the cranial base, leading to an abnormal relationship of the middle ear to the Eustachian tube. Together with anatomic abnormalities of the palate, a predisposition to fluid collection and secondary infection may be predisposing factors explaining the common occurrence of this problem, rather than a form of immunologic dysfunction, as initially entertained.

Although conductive hearing loss is most common and severe in children and is correlated with middle ear pathology,¹⁹⁷ sensorineural hearing loss is more common in adults with TS. This sensorineural hearing loss is usually bilateral and characterized by a dip in the mid-frequency range (between 500 and 2000 Hz) during audiology testing (Fig. 17.17). Sensorineural hearing loss seems progressive and is likely not a pure congenital abnormality. By middle age, more than 90% of women with TS have a hearing loss of more than 20 dB, and more than 25% will eventually require hearing aids. Significant conductive hearing loss in adults with TS may coexist, either as a consequence of scarring of the tympanic membrane, as a result of the frequent bouts of otitis during childhood, or it

may indicate ongoing middle ear pathology.¹⁹⁷ The aggressive treatment of ear, nose, and throat problems in childhood to avoid injury to the inner ear may reduce the risk of long-term hearing loss.

Autoimmunity

The most common autoimmune disorder encountered in TS is Hashimoto lymphocytic thyroiditis. Elevated antithyroid antibodies (antithyroid peroxidase, antithyroglobulin), with or without overt primary hypothyroidism, have been reported in as many as 50% of Turner patients, and this increases as patients get older.¹¹⁵ Although the prevalence of autoimmune thyroid disease is increased in all TS patients compared with the general female population, having an isochromosome X further increases the likelihood of developing autoimmune thyroiditis.^{200–205} The clinical picture of overt hypothyroidism in TS may be different from the general population because even severely affected individuals may not show any signs or symptoms of the disease.²⁰⁴ Coupled with the higher prevalence, annual screening of all TS patients for hypothyroidism is currently recommended—although it is unlikely that hypothyroidism will develop in early childhood. The prevalence of Graves disease is also slightly increased among TS girls.²⁰⁶ In one longitudinal study, 24% of 84 children with TS, who were followed for about 8 years, developed hypothyroidism, whereas 2.5% developed hyperthyroidism.²⁰⁷ Rarely, thyroid disease has been reported as early as 4 years.²⁰⁸ There is an overall consensus that women with TS are further at an increased risk of a variety of other autoimmune diseases. An association of juvenile rheumatoid arthritis (JRA) and TS was reported by Zulian et al.²⁰⁹ A 6-fold increase in JRA was detected based on a survey of 28 pediatric rheumatology centers (18 girls with TS had JRA among 15,000 JRA patients). Additional information on the occurrence of autoimmune disorders can be derived from a comprehensive evaluation of 204 TS adults in the United States: Hashimoto thyroiditis was noted in 37%, celiac disease in 2.7%, and inflammatory bowel disease in 4% of TS individuals compared with age-matched females with POI not caused by TS, and compared with the general female population.²⁰⁵

Disorders of the Gastrointestinal System

Liver Disease

Mild liver enzyme elevations are common in girls and women with TS. This is almost always not associated with manifest liver disease.²¹⁰ Approximately 20% to 25% of girls,²¹¹ and 40% of TS women²¹² may have increased aminotransferase concentrations, including aspartate-, alanine-, and gammaglutamyltransferases and, less commonly, alkaline phosphatase. The liver enzyme elevations may be associated with estrogen, progestin, or oxandrolone use,^{211,213} but over the long term, estrogen replacement therapy is thought to lead to normalization of the hepatic enzymes.²¹² In a cohort ($n = 100$) of 7- to 17-year-old TS girls, 27% had modest transaminase elevation (see Table 17.1) not correlated with GH or estrogen use. No evidence of fatty infiltration liver ultrasound was found.¹⁹² Aside from rare case reports, there appears no association between autoimmunity and hepatic abnormalities. In one study where liver biopsy was performed in TS adults who had the typical enzyme elevations described earlier, no diagnostic pathologic process has been identified to explain the transaminitis.²¹⁴ The authors suggested the hepatic disorder could be caused by intrinsic vascular changes/vasculopathy affecting normal liver physiology.

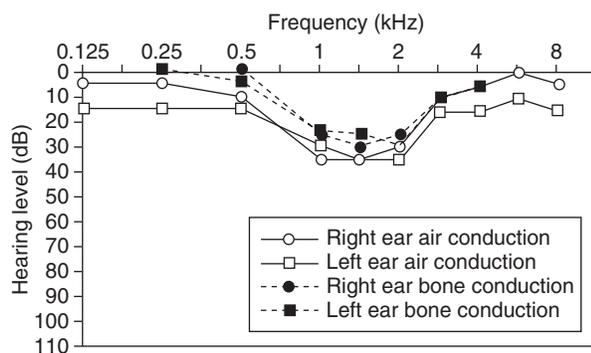

Fig. 17.17 Audiogram showing the typical dip with the peak of 35 dB in the 1.5-kHz frequency region in a 12-year-old girl with Turner syndrome (karyotype 45,X). This girl has no subjective hearing problems. (From Stenberg, A. E., Nylen, O., Windh, M., & Hultcrantz, M. (1998). Otological problems in children with Turner syndrome. *Hear Res*, 124, 85–90.)

Gastrointestinal Bleeding

Gastrointestinal bleeding occurring in patients with TS has been reported on several occasions.^{215,216} The bleeding episodes have been caused by intestinal telangiectasia, hemangiomatosis, or even angiodysplasia in the intestinal tract. Management of these cases may be problematic, but a conservative approach to avoid extensive bowel resection is preferred. Affected patients may require repeated transfusions to maintain a normal hemoglobin concentration. Estrogen replacement in these patients needs to be individualized.^{217,218} There is some anecdotal evidence that estrogen/progesterone supplementation is helpful in individuals affected by recurrent bleeding because of angiodysplasia.

Inflammatory Bowel Disease

Girls and women with TS have an increased risk for inflammatory bowel disease (IBD) and ulcerative colitis.^{219–223} Because growth failure and delayed pubertal development are manifestations of both IBD and TS, a detailed history and review of systems is needed to differentiate between the two, and to avoid attributing delayed sexual maturation to bowel disease without ruling out other causes, such as TS.

The prevalence of celiac disease is also increased in individuals with TS.^{224–226} Growth failure and pubertal delay can also be manifestations of celiac disease and TS as well, and attention needs to be directed to short girls with celiac disease, with or without pubertal delay, to ascertain they do not have TS. TS girls should be screened by measurement of tissue transglutaminase immunoglobulin (Ig)A antibodies beginning at age 2 years, and repeated every 2 years; adults with suggestive symptoms should also be screened.^{17,227,228}

Abnormalities of Carbohydrate Metabolism

Decreased carbohydrate tolerance in TS individuals was first described in 1963,²²⁹ and glucose intolerance has been further reported in many studies. Although insulin deficiency,²³⁰ as well as insulin resistance have both been proposed as causative, the true etiology of this glucose intolerance is still uncertain.²³¹ Data from the Danish health registry indicate an increased incidence of both type 1 and type 2 diabetes mellitus,¹¹⁹ although an increased rate of type 1 diabetes has not been observed in other countries or other reports. Clinical studies have consistently shown hyperglycemia in response to glucose challenge with variable insulin responses. Most patients are not insulin dependent or ketosis prone.²¹⁶ Determining the exact etiology of glucose intolerance in TS is made difficult, as most studies do not include control groups appropriately matching the girls and women with TS. The latter usually have increased adiposity and are exposed to less to normal concentrations of ovarian hormones. In addition, many TS patients are treated with GH or anabolic steroids that alter metabolic responsiveness to carbohydrate loading. TS individuals with a maternally derived X chromosome show excess visceral adiposity compared with individuals with a paternally derived X chromosome.¹⁹¹ This distinction between the different genotypes is usually not taken into account when submitting TS to studies on carbohydrate metabolism.

Some studies do shed some light on the potential pathogenic mechanism underlying the disordered carbohydrate metabolism.²³² One such study evaluated insulin sensitivity via a euglycemic insulin clamp approach in girls with TS (compared with age, but not body mass index [BMI]–matched control girls) and showed that Turner girls had decreased insulin sensitivity.²³³ More recently, the decreased glucose intolerance appears to be caused by insulin deficiency rather than insensitivity based on several reports.^{178,234,235} Still, another study documented insulin resistance that was associated with

obesity.²³⁶ Another study compared nonobese women with TS to age-matched women with 46,XX premature ovarian failure. Both groups discontinued sex hormone replacement therapy for 2 weeks, prior and during testing procedures.²³⁷ Fasting glucose was normal in both groups, but glucose concentrations after both oral and intravenous glucose loads were significantly higher and glucose-stimulated insulin was lower in the Turner subgroup. This points toward impaired insulin secretion rather than insulin resistance as a contributory factor to the diabetes risk in TS patients.

Four hundred Turner patients were further evaluated from 2001 to 2010, and only one presented with type 1 diabetes.²³⁵ Type 2 diabetes mellitus was not found in any children. However, type 2 diabetes was present in 25% of the adults during the same follow-up. Type 2 diabetes was also more than twice as common among women with an isochromosome Xq compared with women with 45,X or with Xp deletion TS karyotypes.²³⁵ A different (cross-sectional) study found that girls with TS have decreased beta-cell function, causing impaired glucose tolerance with normal insulin sensitivity, despite increased adiposity and higher blood pressure.²³⁸ In conclusion, many girls and women with TS do not appear to exhibit a picture of insulin resistance associated with excess adiposity, as is observed in non-TS females.²³⁹

Neurocognition and Psychological Features

Intelligence of TS individuals is in the normal range and girls with TS are similar to their siblings in overall intelligence quotient (IQ). Significant developmental delays have been reported in individuals ascertained because of a severe neurodevelopmental phenotype: these patients had a ring chromosome X, without the unique characteristic features of TS.^{240–244} This high risk of significant developmental delay is caused by failure of inactivation of the ring X as a consequence of loss of the X inactivation center (XIST), which leads to dysomy of certain normally X-inactivated genes.

Many individuals with TS have selective impairments in visual-spatial reasoning and information processing, arithmetic skills, and the coordination of motor and visual-perceptual skills.^{245–247} In some, this is associated with hyperactivity.²³² The discrepancy between verbal and performance IQ has been documented in many studies, and ranges between 10 and 15 points—with verbal IQ higher than performance IQ.^{245–251} In addition, brain size has been correlated with the maternal X chromosome.⁵⁴

The parental origin of the single normal X chromosome has been implicated in certain aspects of the TS neurocognitive presentation. Skuse et al. investigated 80 females with TS, and 25 (the expected proportion) of them had an X chromosome of paternal origin (Xpat). These individuals showed satisfactory social adjustment and had higher verbal IQ and executive functional skills than the larger group of girls with the retained X chromosome of maternal origin (Xmat).⁵² In an extension study, the investigators studied if verbal and nonverbal memory characteristics were at all related to the origin of their X chromosome.²⁵² In this study 45,Xpat Turner females matched controls in verbal memory, but 45,Xmat females did not. However, the results of 45,Xmat patients matched those of controls in visual-spatial memory tests, but the 45,Xpat patients did not do so. These data indicate an imprinted locus for social cognition on the X chromosome that appears silenced for the X of maternal origin. This may result in difficulties with social and nonverbal communication, and even possible increased risk for autism spectrum disorder. Because the parental origin of the X chromosome has not been correlated with cognitive or behavioral phenotype in more recent studies,^{253–256} further work is needed to confirm the aforementioned described findings.

Estrogen deficiency (and replacement therapy) are important factors to consider as playing a role for the cognitive, social, and functional disposition of girls and women with TS. Estrogen replacement therapy (compared with placebo) appears to enhance motor speed, nonverbal processing, and memory in estrogen-treated TS patients.^{257,258}

The risk for psychiatric illness in TS has been studied in 100 adults between 2001 and 2003.²⁵⁹ The incidence of major depression was 5% and that of anxiety disorder was 8%. Women with TS reported a higher rate of lifetime depression compared with rates observed in community-based studies—but similar to those obtained from gynecology clinic patients. Affective symptomatology was prospectively compared with age-matched women who have POI not caused by TS.²⁵⁵ The two groups have similar levels of shyness and social anxiety higher than seen in normal controls. They had similar levels of self-esteem lower than in controls. This indicates that ovarian failure contributes to the neuropsychological profile of girls and women with TS. The first systematic investigation of the personality of girls and women with TS dates from the 1970s.²⁶⁰ From then, and from additional work in this area, it shows that TS individuals have a high stress tolerance, tend to be overcompliant, and demonstrate a higher need of dependence, with often limitations in emotional competence.^{248,252,261} Most women with TS report unambiguous female gender identification.²⁵³ Although delayed sexual debut is common,^{254,255} sexual fantasies are similar to what other women report. Sexual activity among married Turner women also appears similar to that reported by the general female population.^{262–266}

MEDICAL MANAGEMENT

Initial Evaluation

Important elements of the initial evaluation include the following: disclosure of the condition and discussion of etiology, a detailed phenotyping using a variety of methods to identify which features of TS are present and which are not, identification of any coexisting comorbidities and, the development of a management plan to address current concerns, as well as the risk for future disease. Patients come to be diagnosed with TS at a variety of ages, depending largely on the presence of the specific clinical features that provoke evaluation. Because the issues differ somewhat, depending on the age of diagnosis, the initial evaluation will be discussed separately for those diagnosed in infancy, childhood, and adolescence (Boxes 17.1 and 17.2 and Table 17.3).

Patients diagnosed in infancy, typically display physical features that suggest the diagnosis, such as lymphedema of the dorsae of the hands and feet or characteristic cardiac anomalies, as previously described. At this age, the main tasks are to identify any concomitant renal or cardiovascular abnormalities by ultrasound measures. The disclosure and discussion can be somewhat challenging, as the specifics of the future health and development of the child are unclear. Perhaps most difficult are those TS individuals who have been diagnosed via prenatal genetic testing and are yet to be born. It is important to remember that individuals with sex chromosome anomalies diagnosed prenatally may have very modest phenotypes, especially those with mosaicism.

During childhood (ages 1–10 years), the most common feature leading to a diagnosis of TS is short stature. In addition to evaluation for cardiac and renal anomalies, the approach broadens to include investigation of autoimmune conditions, cognitive and behavioral status, and assessment of hearing. After assessment of comorbidities, the management plan generally focuses on short stature and the options for treatment as described later. The issues of fertility status and puberty may

BOX 17.1 Screening at Diagnosis of Turner Syndrome in Children and Adults

ALL PATIENTS

- Cardiovascular evaluation by specialist^a
- Renal ultrasound
- Hearing evaluation by an audiologist
- Evaluation for scoliosis/kyphosis
- Evaluation for knowledge of Turner syndrome; referral to support groups
- Evaluation for growth and pubertal development

AGES 0–4 YEARS

- Evaluation for hip dislocation
- Eye examination by pediatric ophthalmologist (if age \geq 1 year)

AGES 4–10 YEARS

- Thyroid function tests (T₄, TSH) and celiac screen (TTG Ab)
- Educational/psychosocial evaluation
- Orthodontic evaluation (if age \geq 7 years)

AGES \geq 10 YEARS

- Thyroid function tests (T₄, TSH) and celiac screen (TTG Ab)
- Educational and psychosocial evaluations
- Orthodontic evaluation
- Evaluation of ovarian function/estrogen replacement
- LFTs, FBG, lipids, CBC, Cr, BUN
- BMD (if age 18 years)

^aSee Box 17.2.

BMD, Bone mineral density; BUN, blood urea nitrogen; CBC, complete blood count; Cr, creatinine; FBG, fasting blood glucose; LFTs, liver function tests.

BOX 17.2 Cardiovascular Screening and Monitoring Algorithm for Girls and Women With Turner Syndrome

SCREENING (ALL PATIENTS AT TIME OF DIAGNOSIS)

- Evaluation by cardiologist with expertise in congenital heart disease
- Comprehensive examination, including blood pressure in all extremities
- All require clear imaging of heart, aortic valve, aortic arch, and pulmonary veins
- Echocardiography is usually adequate for infants and young girls
- MRI and echo for older girls and adults
- ECG

MONITORING (FOLLOW-UP DEPENDS ON CLINICAL SITUATION)

- Patients with apparently normal cardiovascular system and blood pressure need reevaluation with imaging at timely occasions (e.g., at transition to adult clinic), before attempting pregnancy, or with appearance of hypertension; girls who have only had echocardiography should undergo MRI when old enough to cooperate with the procedure
- For asymptomatic adults, imaging every 5 to 10 years
- For patients with cardiovascular pathology, treatment and monitoring determined by the cardiologist

ECG, Electrocardiogram; MRI, magnetic resonance imaging.

Neurocognitive Deficit	Neuropsychological assessment by professional	PRN clinical suspicion	At start of primary school, e.g., age 5 years	At entry to high school or equivalent, e.g., age 15 years	PRN clinical suspicion

25 OHD, 25-Hydroxyvitamin D; AlkP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate transaminase; CMR, cardiovascular magnetic resonance; DXA, dual energy x-ray absorptiometry; GGT, gammaglutamyl transferase; HgbA1c, hemoglobin A1c; MRI, magnetic resonance imaging; PRN, as needed; T4, thyroxine; TSH, thyroid stimulating hormone.

(Modified from: Gravholt, C.H., Andersen, N.H., Conway, G.S., Dekkers, O.M., Geffner, M.E., Klein, K.O., et al., International Turner Syndrome Consensus Group. (2017). Clinical practice guidelines for the care of girls and women with Turner syndrome: proceedings from the 2016 Cincinnati International Turner Syndrome Meeting. *Eur J Endocrinol*, 177, G1–70.)

seem less important at this age and are not as easy to assess, although measurement of circulating AMH can give prognostic information concerning future ovarian function.^{266,267} Recurrent otitis media is common in this age group and referral to an ear nose and throat specialist is frequently indicated, as are myringotomy tubes.

Childhood is also the time when neurocognitive or behavioral problems, which are more common in girls with TS, may emerge. It is recommended that neuropsychological assessment by a professional be performed in those showing symptoms and at key transitional times during development. These would be when the child first enters school and again when advancing to middle and high school or other higher educational institutions.

Patients diagnosed during adolescence or later frequently come to attention because of pubertal delay or infertility. The initial approach is similar to that for those diagnosed during childhood; however, the focus will be more on the lack of fertility and the need for sex hormone replacement. In some cases, significant short stature will be present and the pros and cons of initiating estrogen therapy at this age versus later (see later) will need to be discussed openly with the patient.

A management plan for patients following diagnosis has been detailed in recent guidelines¹⁷ and is summarized in Table 17.4. As patients progress from early childhood through adolescence, their clinical status and plan should be revisited on a regular basis. Experienced genetic counselors or psychologists, working as part of a multidisciplinary care center, can

be helpful in this regard, as can patient support groups, which exist in several countries.

Cardiovascular Assessment and Monitoring

Congenital heart disease and anomalies of the vascular system are frequent in TS and are major causes of morbidity and mortality.^{268,269} Details of the impact of the CVMs on the quality of life for TS individuals are included in prior paragraphs describing the clinical features of TS. Appropriate medical management first involves defining the structure of the heart and major blood vessels, and ongoing monitoring of the aortic root, as progressive dilation of the aortic root is a precursor to aortic dissection and rupture. The extent and frequency of testing depends on the anomalies present, as well as the age of the patient. A monitoring protocol is also detailed in the most recent guidelines¹⁷ and can be summarized as follows: all patients receive transthoracic echocardiographic examination at diagnosis, along with an electrocardiogram. Those classified as low risk (no structural cardiac anomaly or hypertension and a normal sized aortic root) are monitored every 5 to 10 years, typically by transthoracic echocardiogram. Those in moderate risk categories (those with the beginnings of aortic dilation or structural abnormalities of the heart or great blood vessels) may be evaluated every year or two, and should be monitored by a pediatric cardiologist. Although the evaluation by echocardiogram is easier and less costly, there is evidence that CMR imaging is more sensitive for evaluation of

TABLE 17.4 Guidelines for Adult Health Surveillance

	Action	Suggested Frequency	Comments
Obesity	Weight	Annually	Many comorbidities are weight related, e.g., diabetes, elevated cholesterol, and liver dysfunction. Weight management is the most important health intervention at annual visits. Obesity may be caused by low physical fitness, sedentary lifestyle, and poor food choices.
Cardiovascular	Echocardiogram	3–5 years—yearly if aortic root >3 cm	Management shared with GUCH (Grown-ups with congenital heart defects) clinic preferable. Congenital malformations include bicuspid aortic valve, coarctation of the aorta, and aortic dilation
	MRI aorta	As appropriate	Some units use echocardiography for routine monitoring and reserve MRI for ambiguous findings or as part of prepregnancy assessment. The place of MRI scanning depends on expertise of the echocardiography service
	Blood pressure	Annually	Hypertension affects up to 50% of young adults and contributes to the risk of aortic dissection. Refer to age-specific reference data. Hypertension can be treated to normal guidelines including use of beta-blockers or angiotensin receptor blockers. For aortic root >3.0 cm and BAV, aim for systolic blood pressure <140 mmHg if tricuspid aortic valve or <120 mmHg if bicuspid valve
Bone metabolism	DXA scan	Every 5 years	Estrogen replacement required until ~50 years (or older if there have been many years of estrogen deficiency) to prevent osteoporosis. Bone density of spine reads low in short stature with DXA. Osteoporosis can be treated as in other situations
	Vitamin D and calcium profile	3–5 years	Monitor bone profile in those with low calcium and low vitamin D levels; exclude celiac disease (see later)
Liver	Liver function tests	Annually	Liver enzymes, especially gammaglutamyl transaminase (GGT), are commonly elevated. Slowly progressive, but improves with estrogen and weight loss. Consider viral screen for acute changes (rarely positive)
	Liver ultrasound	As appropriate	Liver ultrasound required for markedly raised (GGT), alkaline phosphatase, or transaminases. Consider special scans measuring fibrosis and steatosis, and biopsy if structural defects identified on US
Diabetes	HbA1c+ fasting plasma glucose	Annually	Consider OGTT if HbA1c is elevated. High risk of developing impaired glucose tolerance (50%) due a combination of insulin deficiency and insulin resistance. Fasting plasma glucose underestimates defect of insulin secretion
Fertility	Adoption and oocyte donation education	As appropriate	Spontaneous pregnancy occurs in 2%–5%. Ovarian failure occurs in 90%. Medical review on advisability of pregnancy with regard to risk of aortic dissection is required
	Uterine ultrasound	As appropriate	Ultrasound of the uterus should take place on arrival in the adult clinic and again during the workup for pregnancy
Psychological	Review psychological issues	As appropriate	Increased risk of social isolation, anxiety, and obsessive behavior. Higher levels of shyness and social anxiety, and reduced self-esteem. Review problems in workplace or in relationships. Problems are responsive to clinical psychology support.
Audiology	Audiogram ENT History	3–5 years	Deafness is common and under reported. Self-reporting unreliable. Otitis media is common in childhood (60%–80%), which can lead to conductive hearing loss. Sensorineural hearing loss common and progressive in adults
Dermatology	Skin inspection	Annually	Assess for keloid and changes in pigmented nevi
Orthodontics	Teeth inspection	Annually	Referral recommended if required
Blood tests	Thyroid function	Annually	Increased risk of autoimmune thyroiditis. In hypothyroidism (24%) or hyperthyroidism (2.5%) include TPO antibodies if previously negative
	Celiac screen	With suggestive symptoms	Increased risk (4%–6%) of celiac disease. Check transglutaminase IgA antibodies (and total IgA) and vitamin B ₁₂

BAV, Bicuspid aortic valve; DXA, dual energy x-ray absorptiometry; ENT, ear, nose, and throat; HbA1c, hemoglobin A1c; Ig, immunoglobulin; MRI, magnetic resonance imaging; OGGT, oral glucose tolerance test; TPO, thyroid peroxidase.

(From Gravholt, C.H., Andersen, N.H., Conway, G.S., Dekkers, O.M., Geffner, M.E., Klein, K.O., et al; International Turner Syndrome Consensus Group. (2017). Clinical practice guidelines for the care of girls and women with Turner syndrome: proceedings from the 2016 Cincinnati International Turner Syndrome Meeting. *Eur J Endocrinol*, 177(3), G1–G70.)

aortic root structure and can detect anomalies, such as PAPVR that might be missed otherwise.^{270,271} Thus current guidelines recommend that patients receive a CMR examination as soon as this can be accomplished without general anesthesia.

Hypertension is relatively common in girls and women with TS and should be aggressively treated in those with aortic root abnormalities. Four-extremity blood pressure measurement at initial diagnosis is recommended because of the increased prevalence of coarctation of the aorta.

Patients with Y Chromosome

As discussed previously, patients with TS who harbor overt or cryptic portions of the Y chromosome are at increased risk for

gonadoblastoma. Although gonadoblastoma is not a threat in itself, concern about malignant transformation to dysgerminoma has led to the recommendation that gonadectomy be performed in patients with Y chromosome mosaicism or marker chromosomes derived from the Y chromosome.²⁷² The gonadectomy was justified because of the increased risk for tumor and the lack of any detriment to removing gonads with no prospect for function. Such recommendations still stand,¹⁷ but the situation is becoming more complicated because newer, PCR-based molecular techniques detect cryptic Y chromosome sequences in 5% to 10% of patients with TS, who are Y chromosome negative by standard tests,²⁷³ but also because the risk for dysgerminoma appears to be relatively low in the population of TS.²⁷⁴ Current guidelines recommend

using standard karyotype and FISH probes for determination of marker chromosome origin to exclude the possibility of Y chromosome material, but do not endorse using the more advanced molecular techniques for all patients with TS. Recent studies now suggest that the rate of gonadoblastoma, in patients with Y chromosome detected by molecular probe testing, may be equivalent to those with cytogenetically detectable Y chromosome.²⁷⁵ Note that any patient with TS who shows signs of masculinization or virilization should have more extensive evaluation, which could include either molecular specific probes and/or testing of additional cell types (e.g., skin fibroblast, buccal epithelium).

The age of gonadectomy varies widely among patients with TS. The risk of malignant transformation within a gonadoblastoma before pubertal age is extremely low and thus there is no urgency to perform such procedures in the very young.²⁵⁹ Observation might be warranted for patients with functioning ovarian tissue, given the low risk for dysgerminoma overall. A better delineation of the risk loci for gonadoblastoma/dysgerminoma hopefully will allow a better assessment of risk in the future.

Growth-Promoting Therapies

Short stature is a nearly universal feature of TS and remains a prominent concern of affected children and adults. Even though patients with TS are not classically GH deficient, it was postulated that administration of human GH to yield modestly supraphysiologic concentrations could overcome the growth deficit associated with TS. Initial studies with relatively small numbers of patients clearly demonstrated the capacity of GH to stimulate skeletal growth over the short term. Subsequent, larger studies proved efficacy beyond doubt, leading to approval by regulatory bodies for the treatment of short stature caused by TS. The goal of treatment, at a minimum, is to prevent functional impairment because of short stature. Ideally though, treatment should be initiated at an age young enough to allow the patient to maintain her stature within the range typical for peers and avoid delay in pubertal induction.

The first studies evaluated the potential use of GH were done in the 1980s.^{276,277} Since that time, there have been dozens of reports describing short- and long-term effects of GH administration. Despite the numerous studies, an optimal therapy remains elusive because the studies varied widely in the doses used, the ages of the patients at initiation, and procedures and timing of feminization therapy, all of which affect growth and adult height. Nevertheless, several conclusions concerning GH therapy can be made.

GH therapy has the potential to normalize the stature of most patients with TS when treatment is initiated in mid to early childhood and at sufficient dosage. Van Pareren et al.²⁷⁸ showed that when patients were treated with escalating doses of GH from around 6 years of age, most reached an adult height within the normal range, even when feminization therapy began at age 12 years. In that trial, GH was administered at 6 to 8 IU/m²/day (up to approx. 67–90 mcg/kg/day) for almost 9 years, resulting in an adult height of 12 to 17 cm above that expected in the absence of treatment. Studies that use more typical doses (50 mcg/kg/day) usually report around 7 to 8 cm of height gain or about 1 cm gain for every year of treatment.²⁷⁹ Factors that result in a favorable response include higher GH dose, longer duration of treatment before feminization, younger age, and greater height at the initiation of therapy.^{280,281} However, it should be noted that the individual responses are quite variable and the reasons for this remain incompletely understood.

Treatment with GH is commonly recommended for those with heights below the normal range for their unaffected peers

and who have a reasonable potential for further growth, for example, bone age 12 years or less. Very young patients who stand within the low-normal range may also be candidates for treatment if they display a growth velocity which would eventually lead to significant short stature, that is, a growth velocity less than the 25th percentile for age. See also Fig. 17.18 for the effect of GH therapy in toddlers with TS. Current guidelines recommend beginning therapy around 4 to 6 years of age when possible.¹⁷ Although the majority of individuals with TS will be short as adults without growth-promoting therapy, occasional patients, especially mosaic variants or those with tall parents, will reach heights in the low-normal range in the absence of any treatment.

A typical starting dose for GH is approximately 50 mcg/kg/day, given as a single daily subcutaneous injection. Higher doses are not routinely recommended, although increased doses might be considered for patients with the most severe short stature, or late diagnosis. Measurements of circulating GH and insulin-like growth factor-I (IGF-1) are not required before treatment, although thyroid function should be normal before initiating therapy. Growth-promoting therapy is typically continued until the bone age is greater than 13.5 to 14 years and the growth velocity less than 2 cm/year, or the patient is satisfied with her height.¹⁷

Administration of exogenous GH reduces insulin sensitivity in girls with TS, as has been observed in all other conditions where GH is used.²⁸² A doubling of the fasting insulin concentration is typical. However, dysglycemia is rare, with a modest increase in blood glucose concentrations reported in one study,²⁷³ but not in others.²⁸² Similarly, there is no adverse effect on lipid metabolism in the majority.²⁸³ Once GH therapy ceases, these metabolic changes seem to resolve.^{282,284}

GH treatment may also yield favorable effects on body composition. Two months of treatment reduces fat mass and increases lean body mass.²⁸³ Although the BMI of adults with TS, treated with GH in their youth, is no different than those who never received GH,²⁸⁵ there is evidence that some of the favorable effects may persist with a reduction in abdominal adiposity and improved glucose tolerance.²⁸⁶

Patients with TS have been shown to have measurable deficits in bone mineral content and structure; however the clinical significance of these findings is controversial.^{287,288} GH typically increases bone mineral content along with increases in bone length. Recent studies have borne this out and show that patients treated with GH during childhood and who receive appropriate estrogen therapy tend to have favorable changes in bone microarchitecture and probably are not at increased risk for fractures.^{289,290}

True adverse effects of GH are uncommon. Scoliosis, which is more prevalent in girls with TS, may be exacerbated by the rapid growth that occurs with GH therapy. Insulin resistance and dysglycemia are also more prevalent and may worsen with therapy. One study reported an increase in type 2 diabetes in GH-treated children,²⁹¹ whereas others have not found this to be the case.²⁹² Benign intracranial hypertension, pancreatitis, and slipped capital femoral epiphysis also seem to appear with greater frequency in GH-treated TS patients.²⁹³ No specific recommendations are made for monitoring other than standard clinical assessments.

Women with TS are at increased risk for cardiovascular events, including dissection of the ascending aorta. Prior GH treatment does not appear to increase cardiac dimensions above that expected with increased growth.²⁹⁴ However, one study has reported an association with increased aortic dilation over time in adults previously treated with GH.²⁹⁵ At present, there is no contraindication for using GH in girls with TS harboring the cardiovascular anomalies typical of TS.

Circulating concentrations of IGF-1 are in part GH dose dependent and increase during therapy. Guidelines suggest that

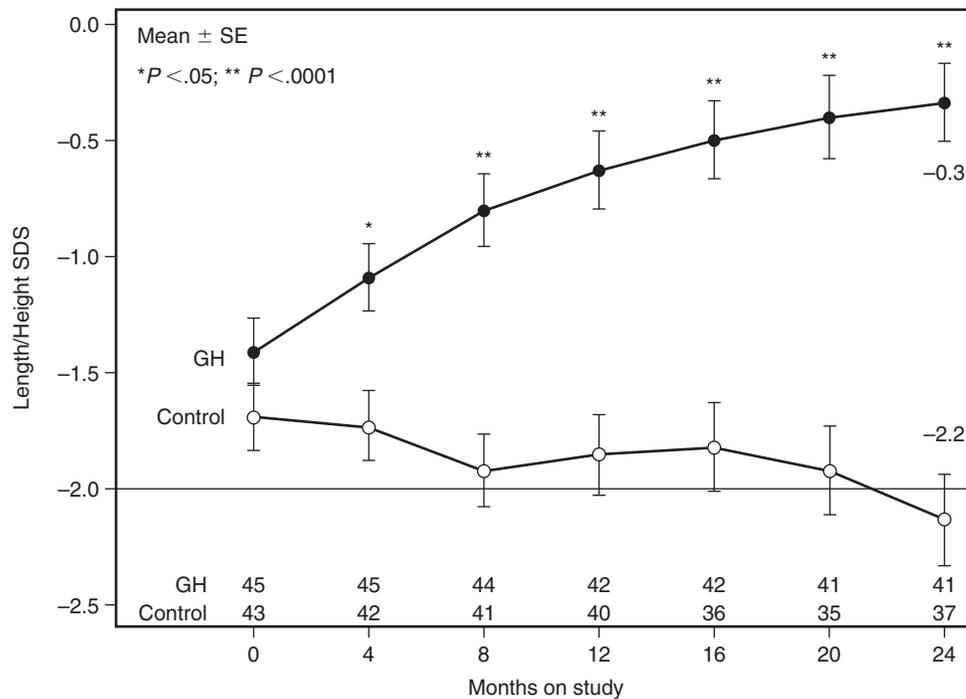

Fig. 17.18 Growth hormone treatment of toddlers with Turner syndrome. Length/height standard deviations (SDs) for the untreated control group (open symbols) and the growth hormone treatment group (filled symbols) during the 2-year study. Between-group difference at end point was 1.6 ± 0.6 SDs ($P < .0001$). Mean age at baseline was 24 ± 12.1 months. (From Davenport, M. L., Crowe, B. J., Travers, S. H., et al. (2000). Growth hormone treatment of early growth failure in toddlers with Turner syndrome: a randomized, controlled, multicenter trial. *JCEM*, 92, 3406–3416, Figure 1.)

circulating IGF-1 concentrations be measured during treatment and if they exceed $+3$ SD for age and sex, that a dose reduction be considered.¹⁷ Although perhaps prudent, there is little evidence to indicate that such a practice will reduce adverse events. In addition, it should be noted that most studies of GH safety in TS have focused on the during-treatment period. Longer follow-up studies are needed to assess the prevalence of late adverse effects.

Oxandrolone, a nonaromatizable, weak androgenic steroid was first used in TS as a sole growth-promoting agent with modest success.²⁹⁶ In fact, early GH studies demonstrated that combining GH with oxandrolone improved short-term height velocity and adult stature. The effect of GH combined with oxandrolone on adult height of girls with TS is shown in Fig. 17.19.²⁹⁷ Subsequent studies confirmed this, indicating that not only is interval growth more rapid, but that an additional inch (2.5 cm) or more can be added to adult height.²⁹⁸ Although mild virilization is a hazard (e.g., clitoromegaly, lowering pitch of the voice), these are uncommon when the drug is used as recommended. Current guidelines recommend using oxandrolone in those age 10 years and older, at a dose beginning at 0.03 mg/kg/day, and not to exceed 0.05 mg/kg/day.¹⁷ Patients for whom combination therapy could be considered would be those with more severe short stature or who were diagnosed relatively late. Oxandrolone can cause insulin resistance, although metabolic changes revert to baseline after withdrawal.^{299,300}

Estrogens also stimulate skeletal growth, but the problem is that the effect on skeletal maturation exceeds the growth stimulation, which shortens the period of growth and generally results in a reduction in stature. However, the maturing effects on the growth plate may be attenuated and a better growth response achieved when very low doses of estrogen are used. This was tested in a single randomized, placebo-controlled trial

where the effect of combining GH therapy with very low-dose estrogen in young patients was examined.³⁰¹ This study showed an enhanced growth response from the combined therapy. However, there have been no confirmatory studies and the GH dose used was lower than what is now standard practice. Thus using low-dose estrogen for growth promotion is not currently recommended for patients with TS.

The effects on growth and stature are clearer when estrogens are administered for the purposes of feminization. For those who begin treatment around age 12 years, one may expect a slight increase in growth velocity and 2 to 3 years of additional meaningful growth. As noted earlier, the duration of GH treatment before feminization is a significant predictor of adult stature in this population. One would expect that bone age at start, dosage, and perhaps form of estrogen would also influence the outcome, but this has not been sufficiently studied.

Short stature is commonly perceived by women with TS as leading to dissatisfaction in life.³⁰² It would seem obvious that an increase in stature would show measurable benefits in quality of life. However, studies thus far have not definitively shown this to be the case.³⁰³ Whether this reflects inadequacies in the quality of life assessment instruments used, the variability in the patients and the ages at which they are studied, or other factors, remains to be determined.

In summary, GH has been used to increase the stature of girls and women with TS for more than 3 decades. The effect on adult stature is clear and the safety profile is reassuring, but the degree to which the treatment confers long-term benefit requires further evaluation.

Puberty, Pubertal Induction, and Feminization

Ovarian failure in TS leads to estrogen and androgen insufficiency,³⁰⁴ whereas spontaneous pubertal development does

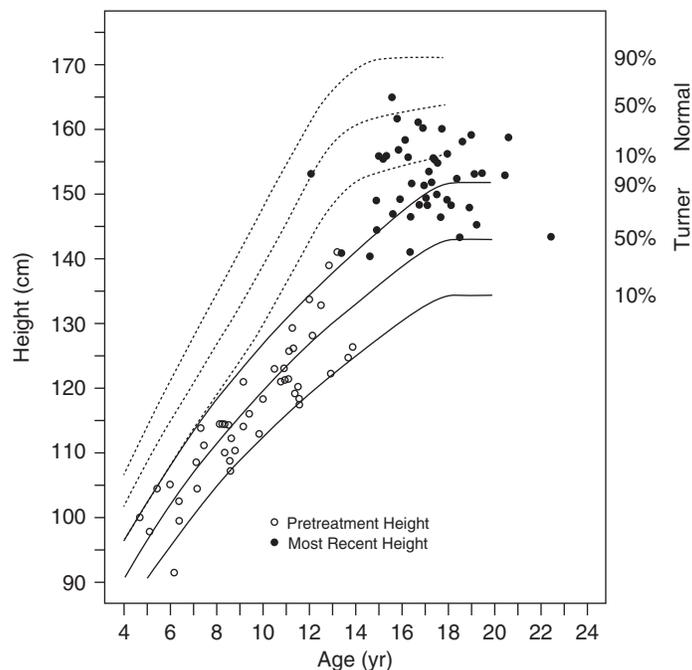

Fig. 17.19 Effect of human growth hormone combined with oxandrolone on adult height of girls with Turner syndrome. Growth centiles (10th–50th–90th, dotted lines) for normal females are from National Center for Health Statistics. Solid lines are Turner Syndrome specific. Open circles are for individuals before treatment, closed circles following treatment. Treatment duration was approximately 6 years on average. (From Rosenfeld, R. G., Attie, K. M., Frane, J. et al. (1998). Growth hormone therapy of Turner syndrome: beneficial effects on adult height. *J Pediatr*, 132(2), 319–324. With permission.)

occur and rarely spontaneous pregnancies.^{305,306} Spontaneous menarche presents in few (6%–9%) 45,X TS,^{307,308} and about one-third continue to have regular menstrual bleedings (2%–3%), but almost invariably with premature ovarian failure ensuing. Interestingly, mosaic TS (45,X/46,XX), with no structural abnormalities of the second X, presents with spontaneous menarche in 20% to 40% of the cases. Despite this, the great majority proceed to early POI. According to recent TS guidelines, female hormone replacement therapy (HRT) should be initiated³⁰⁹ in TS females with primary or secondary amenorrhea, preferably starting between 11 and 12 years of age, and continue until the normal age of natural menopause. Hormone replacement therapy is necessary to induce puberty, to maintain secondary sex characteristics, and to facilitate uterine growth, appropriate peak bone mass, and possibly neurocognitive function and improvement of the metabolic profile via a positive influence on body composition.³¹⁰ However, empirical data on the long-term effects of HRT in women with TS are limited, especially the impact on endocrine conditions, cardiovascular diseases, and mortality. Some have raised concern that HRT in TS may induce the development of deep venous thrombosis and lung emboli, although at present there is no data to support this notion.^{311,312} Additional studies will be necessary to clarify this point.

TS women are most often infertile, this being often the greatest factor influencing their quality of life.³¹³ Very few can become pregnant with their own oocytes. Most females with TS are likely to experience POI and are less likely to become pregnant. Spontaneous pregnancies occur in 4.8% to 7.6% of women with TS^{306,314}; however, one study showed that of the fertile women registered with 45,X/46,XX, several had 45,X in less than 10% of analyzed cells, indicating that some of these women might not have many, if any, signs of TS.³¹⁵ A recent study indicated that the frequency of 45,X/46,XX might be higher than previously anticipated. These individuals also show a phenotype that is distinct from the typical diagnosed

TS woman, and are often also often fertile.³¹⁶ With other words, patients with 45,X/46,XX diagnosed incidentally may be different from women with 45,X/46,XX diagnosed because of a clinical phenotype compatible with TS.

According to the new international TS guidelines,¹⁷ it is recommended to initiate estrogen replacement when the patient is between 11 and 12 years of age, increasing to adult dosage over 2 to 3 years. Low-dose estradiol is recommended, and transdermal administration is preferred because of a perceived more physiologic mode of delivery. There are no studies that firmly show that transdermal administration has fewer side effects compared with oral estradiol administration.³¹⁷ Once breakthrough bleeding occurs, progesterone should be added.

With adequate hormone replacement, it is possible to stimulate uterine growth, which can become susceptible to oocyte donation from a foreign donor. In mosaic TS women, pregnancy after FSH-stimulated oocyte retrieval, freezing of own oocytes until the female becomes older, followed by IVF treatment, is possible—if it is initiated at a young age before ovarian failure.^{318,319} Counseling not to postpone pregnancy is advisable. If pregnancy is accomplished, TS women experience a higher number of complications and miscarriages. A study reported a complication rate of up to 45%.^{306,314} It is also clear that pregnancy after oocyte donation carries a higher risk than the rare spontaneous pregnancy among TS women.³²⁰ Especially pregnancy-associated hypertensive disorder, gestational diabetes, and preeclampsia are frequent. We currently include prompt treatment of hypertension, diabetes, and prophylactic treatment with aspirin to reduce the risk of preeclampsia,³⁰⁹ and view pregnancy among women with TS as a high-risk situation.¹⁷

TRANSITION TO ADULT CARE

A myriad of diseases and conditions occur more frequently among females with TS, partly dependent on karyotype and

partly apparently independent of it. Knowledge of the breadth of the conditions is necessary when caring for adults with TS. The same is true when educating/counseling the young adult with TS to explain the need for continuing adherence to care in the outpatient clinic.

Both type 1 and type 2 diabetes occurs more frequently among women with TS and leads to increases in both morbidity and mortality.^{312,321–324} There is a significantly increased frequency of hypertension present in up to 50% of adults with TS at the age of 50 years.^{325,326} Hypertension often occurs already in childhood or adolescence.^{327,328} Other features of the metabolic syndrome, such as obesity^{310,325,329} and elevated cholesterol,³³⁰ can interact with CVMs and necessitate a multidisciplinary approach to the care of the adult woman with TS.

Liver enzymes are frequently elevated in TS adult life,³³¹ and this seems to be caused by dual influences from obesity and lack of estrogen. The transaminitis can be either completely or partly normalized by appropriate weight loss and substitution with estradiol therapy.^{332,333}

The current clinical care guidelines on TS recommend that diabetes, hypertension, and other features of the metabolic syndrome should be approached according to guidelines, as put forth by the specific relevant societies addressing these metabolic comorbidities.¹⁷

That all autoimmune conditions occur more frequently in TS³³⁴ is important to bear in mind. Especially, hypothyroidism is frequent and by the age of 50 years, it is estimated that about 50% will have acquired hypothyroidism.^{323,325,335} A recent meta-analysis of thyroid diseases among TS individuals showed a prevalence of 39% of all studied populations, including pediatric patients.³³⁶ Likewise, the occurrence of celiac disease is more frequent than among women in general.³³⁷

Osteoporosis and fractures were frequent in older populations of TS patients,^{323,338} but recent data indicate that with appropriate care, the prevalence is likely much lower.³²⁵ It is important to keep in mind that a considerable part of females with TS are diagnosed late,³²⁴ and thus women with TS diagnosed late will often present with osteopenia or frank osteoporosis.³³⁹ Appropriate hormone replacement therapy, even when instituted relatively late in life, can either partly or completely correct a bone mineral deficit³⁴⁰ (Fig. 17.20).

Hearing is a very frequent problem in any given TS cohort, often starting already in childhood. Approximately half of women with TS develop sensorineural hearing loss, which occurs when the inner ear or the neural pathways from the inner ear to the brain are damaged.³⁴¹ A sensorineural hearing deficit occurs often early in adult life and necessitates the use of hearing aids and even cochlear implants in some.³²⁵

Outpatient Care and Treatment

Guidelines for surveillance of adult patients with TS are noted in Table 17.4.

Given the increased risk of a number of diseases and conditions, it is recommended to follow-up all females with TS regularly in the outpatient clinic (see Table 17.4). The time interval (usually every 6–12 month) depends on the burden of comorbidities.

It is further recommended to establish a multidisciplinary setup, including an endocrinologist, a cardiologist with knowledge of congenital heart disease, a gynecologist, a psychologist, an otolaryngologist, a gastroenterologist, an MR radiologist, as

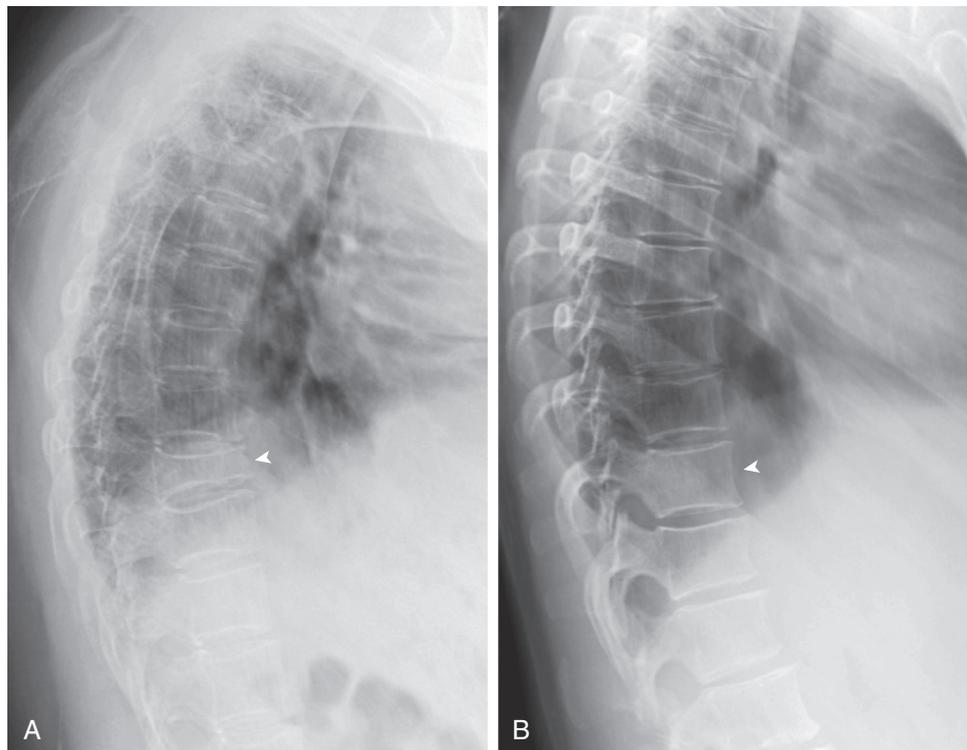

Fig. 17.20 Estrogen treatment prevents osteoporosis. These lateral chest x-rays are from two 30-year-old women with Turner syndrome. Both had a karyotype of 45,X, both received growth hormone treatment for several years during childhood, and both were started on estrogen treatment at age 12 years. One patient stopped taking estrogen at age 18 years (A), and the other adhered to treatment (B). The woman who discontinued estrogen treatment experienced height loss, dorsal kyphosis, and chronic pain caused by collapse and wedging of vertebral bodies. The arrowhead points to T12 in each woman.

TABLE 17.5 Some Common Low-Dose Estrogen Treatment Options for Pubertal Induction in TS and Considerations for Use

Preparation ^a	Doses Available, Frequency, Route	Starting Dose at Puberty	Dose Increase Approximately Every 6 Mo to Adult Dosing	Considerations for Use
Transdermal options (some brands)		3–7 mcg/day	25–100 mcg/day	See text on applying patches
Menostar (Bayer) (matrix)	14 mcg weekly TD	One-half patch weekly	Only used for low dosing, not full replacement	Easiest way to give low dose; once a week dosing
Vivelle-Dot (Novartis) (matrix)	25, 37.5, 50, 75, 100 mcg twice weekly	One-quarter patch weekly, or one patch per month (no patch other 3 weeks)	25–100 mcg twice weekly	Designed for twice-weekly dosing, but can give once per week to increase dose more slowly
Vivelle Mini (matrix)	25, 37.5, 50, 75, 100 mcg twice weekly	Too small to cut consistently	25–100 mcg twice weekly	Smaller size patch, but not smaller dosing
Generic (different brands in different countries)	25, 37.5, 50, 75, 100 mcg twice weekly	One-quarter patch weekly, or one patch per month (no patch other 3 wk)	25–100 mcg twice weekly	Once-weekly dosing can be used.
Estraderm (matrix)	50, 100 mcg twice weekly	Not small enough to initiate puberty	50–100 mcg twice weekly	Cannot use to initiate puberty
E ₂ gel		0.25 mg per pump	One pump daily	Only available in some countries at the low dose
Estragel (Ascend), 0.06%	0.75 mg E ₂ per pump			
Divigel (Vertical), 0.1%	0.25, 0.5, 0.1 mg E ₂ per pump			
Oral options				
17β-E ₂ (e.g., Estrace [Allergen], Cetura [ACE])	0.5, 1, 2, 4 mg/day	One-half pill daily	1–4 mg/day	Cheapest option, brands vary by country
EE		2 mcg/day	10–20 mcg/day	Not available in many countries
Premarin (Pfizer) (a CEE)	0.3, 0.625, 0.9, 1.25 mg/day	One-half pill daily	0.625–1.25 mg/day	Not available in many countries, not recommended based on safety
Depot options				
Depot E ₂ (E ₂ cypionate)	5 mg/mL	0.2 mg/mo	2 mg/mo	Not available in Europe

^aThe reader should be aware that availability and trade names differ among countries. The list is not all inclusive.

(Klein, K.O., Rosenfield, R.L., Santen, R.J., Gawlik, A.M., Bäckeljauw, P.F., et al. (2018) Estrogen replacement in turner syndrome: literature review and practical considerations. *J Clin Endocrinol Metab*, 103, 1790–1803.)

well as certain other medical specialties, dependent on the morbidity profile of the individual patient.

Appropriate female HRT is the mainstay of treatment to address the POI in adult life and has numerous beneficial effects on blood pressure,³²² lipid composition,³³⁰ bone,^{340,342} uterine size,³⁴³ possibly neurocognitive function,^{344–347} sexuality,³⁴⁶ and quality of life.³⁴⁷ One can get HRT in the form of oral tablets, transdermal patches, and as injectable depot formulations. Very few studies have made head-to-head comparisons of different routes of delivery and, presently, there is no firm evidence to suggest that any route is superior to others, although the transdermal route is seen as more physiologic because of its similarity with the physiologic delivery of estradiol from the ovaries.

The adult dose of estradiol replacement is quite individual and some women can be treated with estradiol 2 mg orally, whereas others may need a higher dose of up to estradiol 3 to 4 mg orally. Table 17.5 provides an overview of commonly used low-dose estrogen options for pubertal induction treatment in TS. If fertility is an issue, it is sometimes necessary to treat for periods of time with estradiol doses up to 8 mg to ensure adequate growth of the uterus and increase the yield for achieving a successful pregnancy.

Puberty is the process through which children attain adult secondary sexual characteristics and reproductive capability.¹ In humans, two distinct processes of sexual maturation are recognized: gonadarche and adrenarche. Gonadarche is defined as the growth and maturation of the gonads, resulting in increased sex steroid secretion (most notably testosterone in boys) and spermatogenesis. Gonadarche requires an intact hypothalamic-pituitary-gonadal (HPG) axis, and any disruption of this axis can result in temporary or permanent disorders of reproductive endocrine function. Adrenarche is defined as maturation of the adrenal cortex, leading to increased secretion of adrenal androgens and development of pubic and axillary hair, apocrine body odor, and acne. The physiologic foundations for puberty begin in utero with the development of the neurobiologic structures that comprise the hypothalamic-pituitary component of the HPG axis and with the differentiation and development of the gonads. The entire process, extending from fetal life through achievement of reproductive competence, results from the dynamic and coordinated interactions of an expanding list of genes, proteins, signaling molecules, endocrine and paracrine factors, and epigenetic events.

DEVELOPMENT OF THE REPRODUCTIVE ENDOCRINE SYSTEM

Development of the Gonadotropin-Releasing Hormone Neuronal Network

In postnatal life, the gonadotropin-releasing hormone (GnRH) neurons are located in the hypothalamus. These neurons produce intermittent discharges of GnRH into the hypophysial-portal circulation to stimulate the pituitary gonadotropes to synthesize and secrete the gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

The development of the HPG axis is exceptional in that GnRH neurons develop in metazoan embryos outside the central nervous system (CNS). Immature GnRH neuronal precursors become detectable in the olfactory placode and in the anlage of the nose (vomeronasal organ) from an early embryologic stage (around the sixth week of gestation in human and embryonic days E10.5–E11 in mice) and then begin their complex journey toward the hypothalamus. The embryonic migration of GnRH neurons to the hypothalamus is key for the

development of the neuroendocrine network that allows normal pubertal development.²

The pathway along which the GnRH neurons travel includes scaffolds formed by olfactory, vomeronasal, and terminal nerves 3 and 4. Migratory GnRH neurons are known to have receptors for at least 20 signaling molecules. They receive a plethora of guidance and movement-inducing messages during their journey, which appear to be distinct depending on the stage of their migration.² These signals may act directly on GnRH neurons or indirectly on olfactory axons, as disruption of the olfactory tract “scaffolds” themselves can disrupt GnRH migration. The molecular signals involved include adhesion molecules (e.g., neuronal cell adhesion molecule [N-CAM]), extracellular matrix molecules (e.g., heparin sulphotransferases), cytokines (e.g., leukemia inhibitory factor, hepatocyte growth factor), those controlling cell-to-cell interactions (membrane receptors [e.g., neuropilin-2]), and transcription factors (e.g., Ebf2,) as well as both chemoattractants and chemorepellents (e.g., Reelin). Gradients of chemokines (e.g., CXCL12) may be particularly important for promoting and guiding the movement of GnRH neurons. This combination of factors has a high degree of redundancy, such that loss of any one factor may not fully disrupt GnRH neuronal migration.

The neurons begin their migration in the nasal compartment in or around the vomeronasal organ, pass the cribriform plate and penetrate the CNS in close proximity to the olfactory bulbs, and finally migrate apposed to a subset of vomeronasal nerves that diverge caudally into the basal areas of the forebrain. At the end of their journey, GnRH neurons diverge from guiding axons to disperse into their final positions in the septohypothalamic region, including the diagonal of Broca, the medial septum, and the preoptic areas of the hypothalamus. Eventually, these neurons reach the hypothalamus where they extend projections to the median eminence to form a network, which completes this aspect of GnRH neuronal development.

The whole process of migration involves no more than a few hundred neurons per hemisphere in mice and several thousand in primates or humans. The absolute number of GnRH neurons required for pubertal development is not known, but there appears to be a degree of redundancy in the system. Rodent studies suggest that around 12% of the GnRH neuron population is sufficient for pulsatile gonadotropin secretion and puberty onset, whereas between 12% and 34% are required for estrous cycling and ovulation in adult female mice. In addition, adult *Reeler* mice (which were initially identified based on an ataxia phenotype) have significantly fewer GnRH neurons in the hypothalamus and display a phenotype of delayed pubertal maturation and low fertility.

GnRH neurons extend their neurites to the median eminence under the control of factors that remain mostly unknown. Fibroblast growth factor receptor 1 (FGFR1) signaling is known to be important for this process of axon extension, as evidenced by reduced projections to the median eminence in transgenic mice expressing a dominant negative FGFR1 (dnFGFR1) in GnRH neurons.³

The final stage of GnRH neuronal development comprises functional activity. By the 15th week of human gestation, the GnRH pulse generator is modulating the function of the fetal gonadotropes. The entire HPG axis is functionally active for the first time during fetal development, and after a brief perinatal pause, it continues to function in infancy (during the so-called *minipuberty*), until it enters a relative quiescent state, often referred to as the *juvenile pause* or *prepuberty*.

As discussed subsequently, pathological abnormalities of pubertal development have been identified with each aspect of GnRH neuronal development: (1) defects in the synthesis of GnRH, which result mainly from an abnormal migration

of GnRH neurons from the olfactory placode toward the hypothalamus during the first trimester of fetal life; (2) defect in the maturation and function of the GnRH neuronal network; (3) loss of function of GnRH itself or its receptor also known as a *defect of the bioactivity of GnRH*⁴ (Fig. 18.1).

As a prismatic example, *ANOS1*, previously known as *KAL1*, encodes anosmin-1, an extracellular matrix protein that regulates axonal pathfinding and cellular adhesion. Anosmin-1 promotes branching of olfactory bulb neurons. Subjects with *ANOS1* loss-of-function mutations have arrest of both olfactory bulb neurons and GnRH neurons at the level of the cribriform plate, resulting in abnormal sense of smell and hypogonadotropic hypogonadism (HH). Additional genetic factors involved in GnRH neuronal development and function are described in detail in the “Delayed Puberty, Hypogonadotropic Hypogonadism” section later in this chapter.⁵

Pituitary Development

The pituitary consists of the anterior lobe (or adenohypophysis) and the posterior lobe (or neurohypophysis), as well as the pars intermedia and the infundibulum (or pituitary stalk). The anterior lobe derives from epithelial precursors/oral ectoderm and the posterior lobe derives from neural ectoderm, both under the control of a cascade of transcription factors. The spatial and temporal expression of these factors is critical, and mutations in the genes encoding these factors can lead to HH, as well as combined/multiple pituitary hormone deficiencies (see “Delayed Puberty” section later; reviewed in^{6,7}).

Organogenesis of the pituitary gland begins during the fourth week of gestation with an upward extension of the oral ectoderm (to form Rathke’s pouch) toward the neural ectoderm. Simultaneously, the neural ectoderm of the ventral diencephalon extends downward, allowing for the connection of these two elements and leading to the eventual formation of the composite, two-lobe structure of the adult pituitary.⁷

Initiation of organogenesis and formation of Rathke’s pouch involves signaling molecules, such as *Hex1*, *Otx2*, *Pitx1/2/3*, *Sox2*, *FGF8*, and *Lhx3*. Subsequent cell lineage determination depends on molecules, such as *Prop1*, *POU1F1* (*Pit1*), and *Nr5a1* (*SF1*) among others.⁷ Because of the complex pattern transcription factor control, different molecules are key to the development of different cell lineages at different times. For example, *Lhx3* and *Hex1* affect the development of all lineages as does *Pitx1/2/3*; *Prop1* affects differentiation of gonadotrophs, thyrotrophs, somatotrophs, lactotrophs but perhaps plays a less independent role in development of corticotrophs; *POU1F1* regulates differentiation of thyrotrophs, somatotrophs, and lactotrophs; *Nr5a1* largely affects gonadotrophs. As noted, in the absence of functional redundancy, mutations in the genes for these regulatory factors can lead to pituitary hormone deficiencies, with the hormones affected largely predicted by the cell types whose development is dependent on the particular transcription factor. However, some mutations, such as in *HESX1* or *OTX2*, can lead to combined pituitary hormone deficiencies, as expected, but also to isolated growth hormone (GH) deficiency and to septooptic dysplasia.⁶

The pituitary develops early in gestation and, similar to the GnRH neuronal network, becomes functional in utero. The gonadotrophs are the last anterior pituitary cell types to develop,⁶ but gonadotropin release is detectable by week 14 in response to GnRH secretion. Gonadotropin secretion peaks around 20 to 22 weeks in utero and subsequently increases and decreases in accordance with the dynamic hypothalamic GnRH secretion, described earlier, and with positive and negative feedback loops, described later.

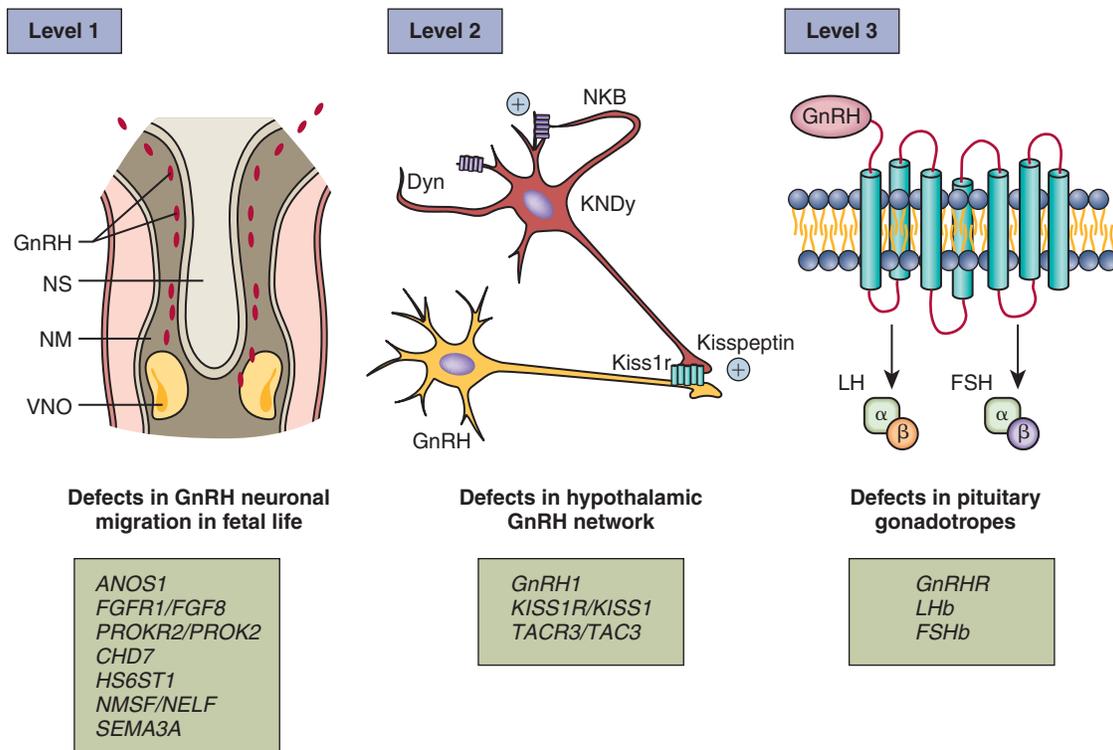

Fig. 18.1 Mutations in single genes at three different levels of the hypothalamic-pituitary-gonadal (HPG) axis can cause hypogonadotropic hypogonadism. Schematic of the three levels along with genes that affect HPG function at each level are shown. See text for details regarding each gene. *ARC*, Arcuate nucleus; *Dyn*, Dynorphin; *ME*, median eminence; *NKB*, neurokinin B; *NM*, nasal mesenchyme; *NS*, nasal septum; *POA*, preoptic area; *VNO*, vomeronasal organ.

Testicular Development

A brief summary of prenatal testicular differentiation and development follows; a more detailed description of testicular differentiation and sex development can be found in [Chapter 6](#). Beginning at approximately 4 to 6 weeks of gestation, the primordial bipotential gonad arises from a condensation of the mesoderm of the urogenital ridge. During this time, the primordial germ cells proliferate and migrate from the hindgut to colonize the developing gonad. In the human male fetus, the testicular compartments, tubular and interstitial components, and specific cell types, Leydig, Sertoli, and germ cells can be visualized by 11 weeks of gestation. During early gestation, placental human chorionic gonadotropin (hCG) governs Leydig cell proliferation and secretion of testosterone and insulin-like factor 3 (INSL3); endogenous LH begins to regulate these activities in midgestation. Because of the role of placental hCG during early gestation, gonadotropin deficiency does not influence male sexual differentiation. However, LH secretion does influence the number of fetal Leydig cells, as demonstrated by a reduced number in anencephalic fetuses and an increased number in 46,XY fetuses who have elevated gonadotropin concentrations secondary to complete androgen insensitivity.⁸ Testosterone production secondary to fetal LH secretion is also critical for phallic growth during the second and third trimesters; males with LH deficiency typically have normally formed but small penises at birth. FSH secretion influences Sertoli cell differentiation and anti-Müllerian hormone (AMH) and inhibin B secretion.⁹

Testicular descent occurs in two phases. The transabdominal phase begins at approximately 12 weeks of gestation and is influenced by the Leydig cell product, INSL3, and its cognate receptor, leucine-rich repeat-containing G-protein-coupled receptor 8 (LGR8). The second androgen-dependent phase,

descent of the testes through the inguinal canal, is usually accomplished by the end of week 35.¹⁰

Following a brief pause in activity after birth, the hypothalamic-pituitary-testicular axis is active during the first few months of life with testosterone concentrations peaking at 1 to 2 months of age.¹¹ By approximately 6 months of age, testosterone concentrations decline to prepubertal levels. During the brief period of increased neonatal HPG activity, sexual hair does not develop and gametogenesis does not occur because of limited androgen receptor (AR) signaling in certain tissues (e.g., Sertoli cells). During infancy and childhood, seminiferous cords are solid and generally filled with immature Sertoli cells. The germ cells are limited to spermatogonia and Leydig cells are rarely visualized.¹² Inhibin B and AMH continue to be secreted during childhood and serve as valuable markers of Sertoli cell function.

PHYSIOLOGY OF PUBERTY

Hypothalamic KNDy and Gonadotropin-Releasing Hormone Neurons

GnRH release is coordinated by inhibitory and excitatory neuronal and glial inputs¹³ (Fig. 18.2). Retrograde tracing studies in mice have demonstrated that GnRH neurons are controlled by a complex neuronal network of inputs from many regions of the brain, including the brain stem, limbic system, hypothalamic nuclei, motor and sensory circuits, and basal ganglia.

Among the various regulators of GnRH neurons, kisspeptins and neurokinin B are the most essential. The distribution of kisspeptin neurons in the hypothalamus varies with species. Kisspeptin neurons have been anatomically mapped in mice to reside within the hypothalamus caudally, in the mediobasal hypothalamus, which includes the arcuate nucleus (ARC)/

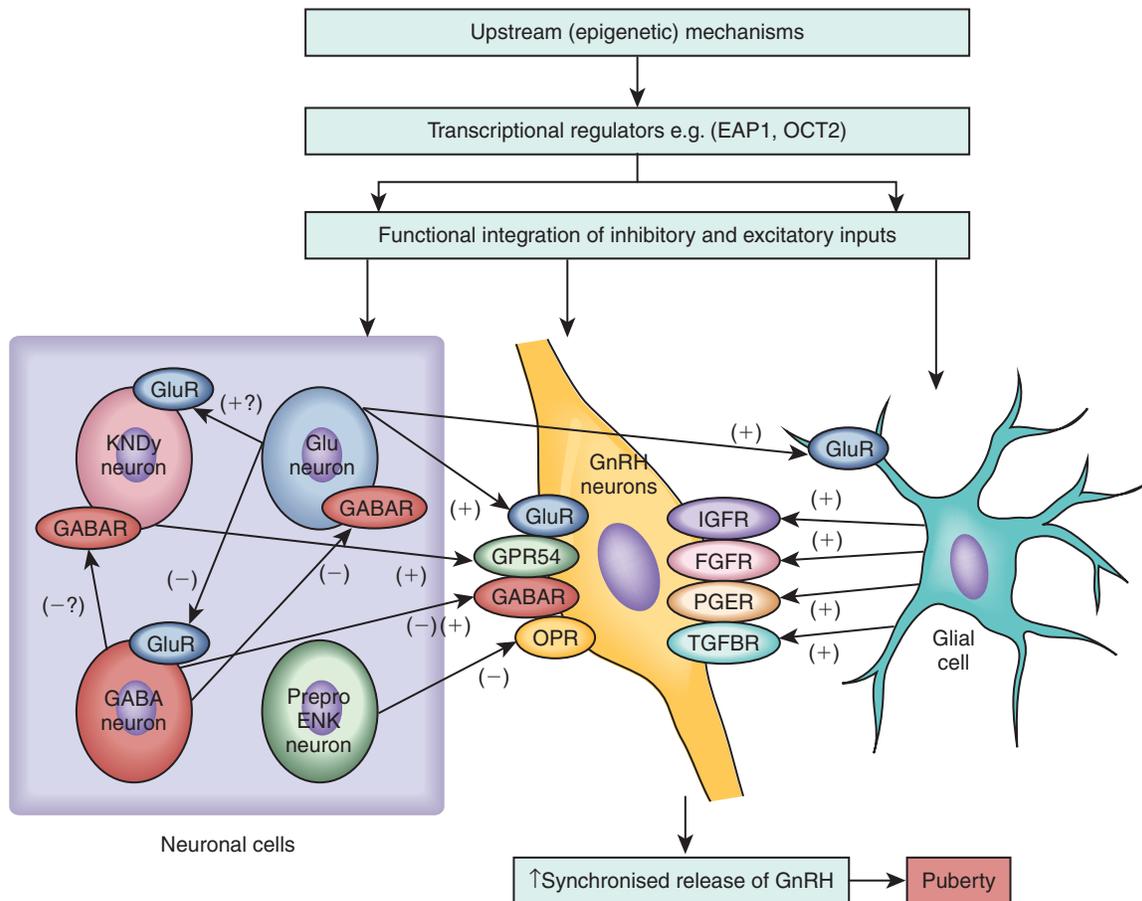

Fig. 18.2 Regulators of gonadotropin-releasing hormone (GnRH) neuronal function. GnRH neurons are regulated by a network including epigenetic and transcriptional factors, as well as transsynaptic and glial modifiers during puberty. (Modified from Ojeda, S.R., Lomniczi, A., Mastronardi, C., Heger, S., Roth, C., Parent, A.S., et al. (2006). Minireview: the neuroendocrine regulation of puberty: is the time ripe for a systems biology approach? *Endocrinology*, 147:1166–1174.¹³)

infundibular region. In mice, a second population is located in the rostral part of the hypothalamus called the *anteroventral periventricular* (AVPV) region. In rats, monkeys, and humans, this regional distribution of kisspeptin neurons is less clear. The two populations of kisspeptin neurons in mice exhibit marked functional differences, with, for example, the AVPV kisspeptin neurons having a role in mediating the positive-feedback effects of estrogen, leading to the GnRH/LH surge that triggers ovulation, and the ARC kisspeptin neurons having a role in mediating negative-feedback effects of sex steroids on tonic activity of the HPG axis. AVPV kisspeptin neurons exhibit clear sexual dimorphism, with female rodents at puberty having a much greater number of kisspeptin neurons in this area.

Kisspeptin, an excitatory neuropeptide, was identified as a vital permissive factor in puberty onset by the discovery of patients with GnRH deficiency with loss-of-function mutations in the kisspeptin receptor, *KISS1R*, previously known as *GPR54*.^{14,15} Subsequently, an activating mutation in *KISS1R* was identified in a girl with central precocious puberty,¹⁶ and an activating mutation in *KISS1*, which encodes kisspeptin itself, has been reported in a child with central precocious puberty.¹⁷ Moreover, mice with knockout of *Kiss1r* are infertile, despite normal distribution of GnRH neurons and normal hypothalamic GnRH levels,¹⁵ and mice with *Kiss1* knockout also have a phenotype consistent with normosmic GnRH deficiency.

Kisspeptins are synthesized by hypothalamic neurons that contact GnRH neurons and their projections. Kisspeptin

neurons are located outside the blood-brain barrier and therefore come directly in contact with peripheral sex hormones. Most GnRH neurons express the kisspeptin receptor and kisspeptin neurons express steroid receptors (estrogen receptor alpha, androgen receptor, and progesterone receptor) and are the main relay for the negative and positive feedback of steroid hormones on the gonadotropic axis.

Kisspeptin signals directly to GnRH neurons to control pulsatile GnRH release. Kisspeptin is upregulated in both primates and mice in the peripubertal period, and its administration to pubertal rodents advances the onset of sexual maturation. Interestingly, kisspeptin also appears to be downregulated in functional amenorrhea, suggesting its role as a mediator of environmental factors, such as emotional well-being and nutritional status. In addition, as noted, kisspeptin has been shown to be an important neuroendocrine regulator of ovulation. In mice, kisspeptin neurons located in the AVPV mediate the positive feedback of estradiol on the GnRH neuronal network and therefore the generation of the LH preovulatory pulse. In contrast, estrogens have an inhibitory effect on Kiss1 neurons in the ARC. Thus kisspeptin signaling appears to have both positive and negative feedback loops in the HPG axis. Whilst kisspeptin has been identified as a pivotal upstream regulator of GnRH neurons, whether kisspeptin is the key factor in triggering the onset of puberty remains unclear.¹⁸

Another excitatory neuropeptide, neurokinin B, has been implicated in the upstream control of GnRH secretion. Identification of this pathway was based on discovery of

loss-of-function mutations in *TAC3*, encoding neurokinin B, and its receptor *TACR3*, in patients with pubertal failure caused by normosmic HH.¹⁹ Kisspeptin neurons located in the ARC synthesize neurokinin B and dynorphin A and have been called *KNDy* (Kisspeptin, Neurokinin B, Dynorphin) neurons. Both *TAC3* and *KISS1* expression in the ARC is downregulated by estrogen. Therefore these neurons are considered as the relay of the negative feedback of steroid hormones on the gonadotropic axis. *KNDy* neurons also express the neurokinin B receptor, NK3R, suggesting that paracrine and autocrine loops control GnRH release. Dynorphin inhibits the release of GnRH, and together these peptides are currently believed to play a fundamental role in regulating the pulsatile GnRH release.

More recently, another RF-amide-related peptide (RFRP1, RFRP3), the mammalian orthologue of the avian peptide *gonadotrophin-inhibiting hormone (GnIH)*, was discovered as another inhibitory regulator of the gonadotropic axis by directly controlling GnRH neurons.²⁰ GnIH plays an essential role in the inhibition of the HPG axis in several species. In addition to neuropeptides, several neurotransmitters participate in the control of the GnRH network. Gamma aminobutyric acid (GABA) and glutamate control GnRH neuronal excitability in the ARC. In female rats, glutamine synthase is downregulated and glutamate dehydrogenase becomes more abundant in the hypothalamus at puberty, both leading to increased availability of glutamate, which acts through its n-methyl-D-aspartate (NMDA) and kainate receptors.²¹ The administration of glutamate agonists to prepubertal primates can stimulate the onset of puberty.

The neural network of GABA is quite complex because some of these neurons will have a direct effect on GnRH neurons, and others will act on interneurons. The inhibitory role of GABAergic neurotransmission in restraining the initiation of puberty has been clearly shown in primates but is more ambiguous in rodents. GABAergic signaling pathways are likely to be important in the stress-induced suppression of LH.

Some recent evidence highlights the importance in mice of micro ribonucleic acid (microRNAs) (particularly the miR-200/429 family and miR-155) in the epigenetic upregulation of GnRH transcription during the murine equivalent of the mini-puberty.²² Moreover, miR-7a2, has been demonstrated to be essential for normal pituitary development and HPG function, with deletion in mice leading to HH and infertility.

Corticotropin-releasing hormone (CRH) signaling has long been known to play an important role in the stress-induced suppression of the GnRH pulse generator in rodents. Intracerebroventricular (ICV) administration of CRH decreases LH pulse frequency in rats, whereas stress-induced suppression of LH pulses by insulin-induced hypoglycemia is blocked by ICV administration of a CRH antagonist. Juxtaposition of CRH immunoreactive fibers to GnRH neurons has been observed in the infundibular region of the hypothalamus in the human.

Finally, the synchronous pulsatile secretion of GnRH is also controlled through neuron-glia signaling pathways. Glial inputs appear to be predominantly facilitatory and they consist of growth factors and small diffusible molecules, including transforming growth factor (TGF) β 1, insulin-like growth factor 1 (IGF-1), and neuregulins, that directly or indirectly stimulate GnRH secretion.²³ Glial cells in the median eminence regulate GnRH secretion by production of growth factors, acting via receptors with tyrosine kinase activity. FGF signaling is required for GnRH neurons to reach their final destination in the hypothalamus, as well as for GnRH neuronal differentiation and survival. In addition, GnRH neuron secretory activity is facilitated by IGF-1 and by members of the epidermal growth factor family, such as neuregulin 1 β . Plastic rearrangements of glia-GnRH neuron adhesiveness, mediated by soluble molecules, such as

N-CAM and synaptic cell adhesion molecule (SynCAM), coordinate the controlled delivery of GnRH to the portal vasculature, a process that is also subject to sex steroid regulation.

Pituitary Gonadotropins

GnRH stimulates the production and secretion of LH and FSH from the gonadotrophs by binding to a cell-surface receptor, which triggers increased intracellular calcium concentration and phosphorylation of protein kinase C. LH is released from readily releasable pools, which lead to a rise in serum LH within minutes after a bolus of GnRH, but also from pools which take longer to mobilize. Whereas episodic stimulation by GnRH increases gonadotropin secretion, continuous infusion of GnRH decreases LH and FSH secretion and downregulates the pituitary receptors for GnRH—a phenomenon that is used in the medical treatment of central precocious puberty. Alterations in the GnRH receptor have other important roles in regulating gonadotroph function as estrogens increase and androgens decrease GnRH receptors.

FSH and LH are glycoproteins composed of two subunits, an α subunit that is common for all the glycoprotein hormones and distinct β subunits that confer receptor specificity. The β subunits are 115 amino acids long with two carbohydrate side chains. hCG produced by the placenta is almost identical in structure to LH except for an additional 32 amino acids and additional carbohydrate groups. Rare cases of mutations in the β subunit of gonadotropin molecules that cause pathological effects have been reported: a single case of an inactivating mutation of *LHB* caused absence of Leydig cells and lack of puberty in a male²⁴ and two cases of inactivating mutations of *FSHB* led to lack of follicular maturation and amenorrhea and, in two males, azoospermia.²⁵ In addition, a woman with a homozygous mutation in a 5' splice-donor site in the noncoding region of *LHB* displayed impaired LH secretion, normal pubertal development, secondary amenorrhea, and infertility.²⁶ What is conceptually important from these observations is that normal pubertal maturation in women, including breast development and menarche, can occur in a state of LH deficiency, whereas normal LH secretion appears obligatory for ovulation. This implies that although LH is essential for the normal maturation of Leydig cells and steroidogenesis in men, its primary role in women is to induce ovulation.

The same gonadotroph cell produces both LH and FSH in the pituitary. Gonadotroph cells that are not stimulated, for example, because of disease affecting GnRH secretion, are small in diameter, while the gonadotroph cells in primary hypogonadism, stimulated by large amounts of GnRH, are large in diameter and demonstrate prominent rough endoplasmic reticulum.

Gonadal Hormone Production

Sex Steroids

The LH stimulation of Leydig cells leads to increased testicular testosterone secretion, and typical Leydig cells become apparent on histology. Testosterone acts as a paracrine factor to induce Sertoli cell maturation. Pubertal maturation of the seminiferous tubules is characterized by cytoskeletal rearrangements, including development of tight junctions, Sertoli cell polarization, Sertoli cell proliferation, migration of spermatogonia toward the basement membrane, and decreased AMH secretion.²⁷

The Leydig cells of the testes synthesize testosterone through a series of enzymatic conversions for which cholesterol is the precursor. When LH binds to Leydig cell membrane receptors, the ligand-receptor complex stimulates membrane-bound

adenyl cyclase to increase cyclic adenosine monophosphate (cAMP), which then stimulates protein kinase A, which in turn causes the stimulation of the conversion of cholesterol to pregnenolone by P450_{sc} (side-chain cleavage enzyme), the first step in the production of testosterone. With substantial exposure to LH, the number of receptors for LH and the postreceptor pathway decrease their responsiveness to LH for at least 24 h. This explains the clinical finding of insensitivity to LH after daily injections of LH or hCG compared with every-other-day injections. When assessing the response of testes to LH, hCG or LH must be administered at 2- to 3-day intervals to avoid such downregulation.

When testosterone is secreted into the circulation, the majority is bound to sex-hormone-binding globulin. The remaining free testosterone (95% of which is bound to albumin with low affinity) is conventionally considered the active moiety. At the target cell, testosterone dissociates from the binding protein, diffuses into the cell, and may be converted by 5 α -reductase type 2 (a surface enzyme located on the genital skin and elsewhere and encoded by a gene on chromosome 2) to dihydrotestosterone or by aromatase (CYP19) to estrogen. Testosterone or dihydrotestosterone binds to the androgen receptor that is encoded by a gene on the X chromosome (Xq11-q12). The testosterone/dihydrotestosterone-receptor complex then attaches to the steroid-responsive region of genomic deoxyribonucleic acid (DNA) to initiate androgen-dependent transcription and translation, ultimately leading to virilization. However, androgens must be converted to estrogens to stimulate bone maturation at the epiphyseal plate.

FSH binds to specific receptors on the cell surface of Sertoli cells and causes a sequence of events that culminates in increased protein kinase A activity in a manner similar to the stimulatory effect of LH on Leydig cells. However, FSH causes an increase in the mass of seminiferous tubules, and in an undefined way supports the development of sperm. The increase in Sertoli cell number contributes to the increase in testicular volume that provides a physical marker of the onset of gonadarche in boys. As puberty progresses, the seminiferous tubules enlarge and develop a lumen. Although much variation in chronologic age and testicular volume has been described, spermathe (initial sperm production) precedes peak pubertal linear growth velocity and occurs at a median testicular volume of 10 to 12 mL, although sometimes as low as 4 mL.²⁸

Activin and Inhibin B

FSH stimulates Sertoli cells to secrete inhibin B, which from midpuberty onward serves as the major negative regulator of pituitary FSH secretion. Before puberty, inhibin B is germ cell independent. After puberty, inhibin B secretion becomes germ cell dependent and provides a marker of germ-cell integrity in adults.²⁹

Inhibin B is a heterodimeric glycoprotein member of the TGF- β family produced in males exclusively by the testis, primarily in the prepubertal testis by the Sertoli cells, and by the ovarian granulosa cells and the placenta in the female. Several studies show that serum inhibin-B levels in children change in concert with the secretion of gonadotropins. During the "minipuberty" serum inhibin-B levels increase to similar or higher levels to those observed in adolescent boys and adult men. This early inhibin-B secretion is sustained until the age of 18 to 24 months; thereafter, serum concentrations decline to lower but readily measurable levels. Early in puberty, between Tanner stages G1 and G2, serum inhibin-B concentrations again increase and reach peak levels at Tanner stage G2, but then the levels plateau. Inhibin suppresses FSH secretion from the pituitary gland and provides another explanation

for different serum concentrations of LH and FSH with only one hypothalamic peptide (GnRH) stimulating them. Activins are homodimers of the β subunit of inhibin and have the opposite effect, stimulating the secretion of FSH from the pituitary gland. Absence of inhibin B because of gonadal failure causes a greater rise in serum FSH than LH in pubertal and adult subjects.

Anti-Mullerian Hormone. AMH belongs to the same TGF- β family as inhibin and is produced from the Sertoli cells of the testes from the time of testicular differentiation to puberty, and in females by the granulosa cells from birth until menopause. In normal males, AMH is high in the fetus and newborn with peak levels around 2 months of age and then decreases by the age of 1 year. Patients with dysgenetic testes have decreased serum AMH, whereas values are elevated in Sertoli cell tumors and females with granulosa-cell tumors. Undetectable AMH and inhibin B are characteristic of congenital anorchia but may also be seen in severe hypogonadotropic hypogonadism in males. In infant girls, a similar pattern in AMH levels during the first months of life has been reported, but the levels in girls are significantly lower. AMH decreases during puberty as a sign of androgen action. Beginning in early puberty, testosterone represses AMH secretion by Sertoli cells, and testosterone and AMH begin to show an inverse relationship. Intratesticular testosterone and signaling through androgen receptors in Sertoli cells are essential for the decline in AMH concentrations, meiosis, and spermatogenesis.¹² Hence, AMH concentrations provide an indication of Sertoli cell function and androgen action in the testes.

Putting It All Together: the Pubertal Reactivation of the Gonadotropic Axis

Hormonal Changes

The gonadotropic axis undergoes complex cycles of activation and inhibition from fetal life to puberty (Fig. 18.3).

Fetal testosterone secretion early in pregnancy is caused by placental hCG stimulation. The fetal hypothalamus contains GnRH-containing neurons by 14 weeks of gestation, and the fetal pituitary gland contains LH and FSH by 20 weeks. The hypothalamopituitary portal system develops by 20 weeks of gestation, allowing hypothalamic GnRH to reach the pituitary gonadotrophs. At midgestation, there is a striking rise of circulating gonadotropin levels in both male and female fetuses, which reaches its peak at 34 to 38 weeks in the male fetus, and then falls to low levels at birth. This change in gonadotropin secretion results from the development of a negative feedback system through sex steroids, as well as from the development of inhibiting influences from the CNS on GnRH neurons.

LH and FSH secretion rise during the first month after birth, probably because the negative feedback effect of placental estrogens is withdrawn. LH is secreted in pulses during this postnatal period, often termed the *minipuberty*. After this postnatal activity, the HPG axis becomes relatively dormant in children between the age of 2 and 8 to 9 years.

The transition from the relative prepubertal quiescence to the adolescent pattern of GnRH secretion is a gradual rather than abrupt process. LH and FSH pulsatility has been detected in normal children as young as 4 years of age.³⁰⁻³³ Throughout childhood, GnRH secretion appears to undergo small but progressive increases until the onset of puberty, when GnRH secretion increases, first at night and eventually throughout the day.^{34,35} Because of the episodic nature of gonadotrophin secretion, a single gonadotrophin determination is not informative regarding the secretory dynamics of these hormones. However, modern

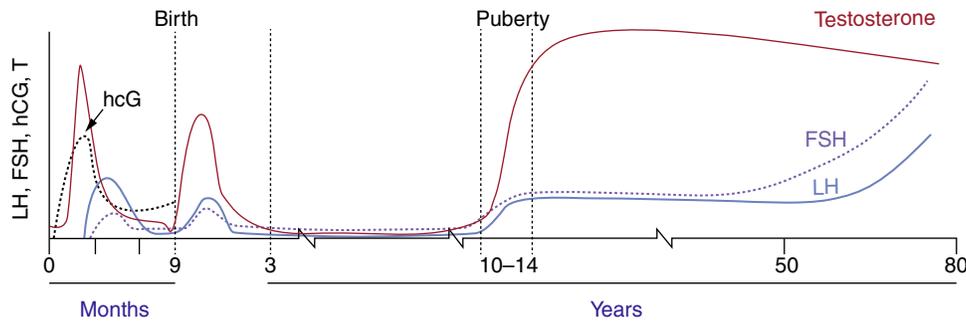

Fig. 18.3 Circulating concentrations of gonadotropins (hCG, FSH, LH) and testosterone during the life span of a male. The function of the reproductive endocrine axis is dynamic throughout life. Here levels are shown for the in utero, neonatal, prepubertal, pubertal, and adult periods. The “minipuberty” shown in the figure between birth and 3 years occurs at approximately 6 to 10 weeks of life. *hCG*, Human chorionic gonadotropin; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone. (Modified from Huhtaniemi, I., Howard, S., Dunkel, L., Anderson, R.A. (2017). The gonadal axis: a life perspective. In: Pfaff, D.W., Joels, M., editors. *Hormones, Brain, and Behavior*. 3rd ed: Oxford, Academic Press.³¹¹)

third-generation assays are sufficiently sensitive to indicate the onset of puberty in single basal unstimulated samples.

The first biological change demonstrating that the HPG axis is being reactivated at puberty is the augmentation of nocturnal LH pulses in children; this reactivation is subclinical and begins before clinical development of Tanner genital stage 2. This period may thus be seen as the hormonal onset of puberty. The differences between daytime and nighttime levels of LH remain until late stages of puberty but disappear by early adulthood. During this reactivation of the axis, there is a gradual development of a dynamic interplay between the central production of GnRH and gonadotropins and gonadal sex-steroid production. A progressive maturation of negative-feedback loops occurs but so too the prepubertal suppressant drive from the CNS gradually abates, and transient intensifying positive feedback results from increasing gonadal sex-steroid production.

During the period of relative quiescence, testosterone and estrogen are also measurable in the circulation using sensitive assays, demonstrating low but definite activity of the prepubertal gonads. However, gonadal contribution to the inhibition of the hypothalamic-pituitary system occurs later, becoming operative only at midpuberty, and eventually becomes dominant over the central inhibitory feedback drive (Fig. 18.4). Both mean LH and FSH levels increase through pubertal development, although LH rises to a greater extent, probably because of differences in feedback mechanisms for these two hormones. These rises are the result of both an increase in basal levels of LH and FSH, and a greater number and amplitude of LH peaks.

In boys during puberty, plasma testosterone levels increase dramatically. The pubertal increase in testis size results primarily from an increased number of proliferating and differentiating germ cells and, to a lesser extent, an increase in Sertoli cells. In early and midpuberty, there is a pronounced diurnal rhythm with a morning peak in measurable testosterone, but this is less pronounced in later puberty and declines gradually with age, probably because of decreased day-night ratios of gonadotropins.

The biological reactivation of the gonadotropic axis occurs earlier in girls than boys, and the dynamic of the reactivation of the gonadotropic axis is not identical in the two sexes. The secretion of testosterone increases shortly after the increase in the plasma concentration of LH and FSH. In girls, estradiol increases together with increasing LH and FSH. Then, a hormonal dialogue between gonads, the hypothalamus, and pituitary contributes to the progressive activation of the gonadotropic axis, until the occurrence of the LH ovulatory pulse in females. The basis for this sexual dimorphism is unclear and may be related to differences in gonadal hormone production and could also be a feature of the sexual dimorphism of the brain.

There are also some data suggesting that although most genes regulate the timing of puberty similarly in boys and girls, there is a small subset that may exert sex-specific effects.³⁶

Physiological Mechanisms. Our understanding of the activation of the gonadotropic axis at the end of the prepuberty remains incomplete but has advanced in some areas (see discussion later). GnRH neuronal activity is under the control of several neurotransmitters and neuropeptides, as described earlier, and the onset of puberty is triggered by a decline in these inhibitory signals and amplification of the excitatory inputs, leading to increased frequency and amplitude of GnRH pulses. The neuroendocrine mechanisms that control the activation of the gonadotropic axis in the fetus, as well as during the “minipuberty” are less well understood. Likewise, the exact nature of the brake that functions during prepuberty remains unknown.

One change at puberty is a shift in the balance of GABA-glutamate signaling in the brain. Another is an increase in dendritic spine density and a simplification of the dendritic architecture of GnRH neurons. A third is an increase in kisspeptin signaling in the hypothalamus, which is caused by an increase of kisspeptin synthesis, as well as an increased responsiveness of GnRH neurons to kisspeptin stimulation. Although mainly described in mice, this paradigm, which is well conserved in evolution, is probably true in monkeys as well in humans.³⁷

The mechanisms responsible for the increased biosynthesis of kisspeptins in the hypothalamus at the end of the juvenile period remain unknown. Data pointing to hypothalamic regulation via a hierarchical network of genes (see Fig. 18.2) have mainly come from a systems biology approach³⁸ and animal models,³⁹ with little data from human subjects to date; however, integration of findings from human genome-wide association studies will likely enrich these models. Candidate transcriptional regulators that have been identified via these approaches include octamer transcription factor 2 (*Oct-2*), thyroid transcription factor-1 (*TTF-1*), and enhanced at puberty 1 (*EAP1*). *TTF-1* is a homeobox gene that enhances GnRH expression. *TTF-1* expression is increased in pubertal rhesus monkeys. *Oct-2* is a transcriptional regulator of the POU-domain family of homeobox-containing genes. *Oct-2* messenger RNA (mRNA) is upregulated in the hypothalamus in juvenile rodents; blockage of *Oct-2* synthesis delays age at first ovulation; and hypothalamic lesions, which induce precocious puberty (e.g., hypothalamic hamartomas), activate *Oct-2* expression. *EAP1* mRNA levels also increase in the hypothalamus of primates and rodents during puberty, *EAP1* transactivates the *GnRH* promoter, and *EAP1* knockdown with small interfering RNA (siRNA) causes delayed puberty (DP) and disrupts estrous cyclicity in rodents.

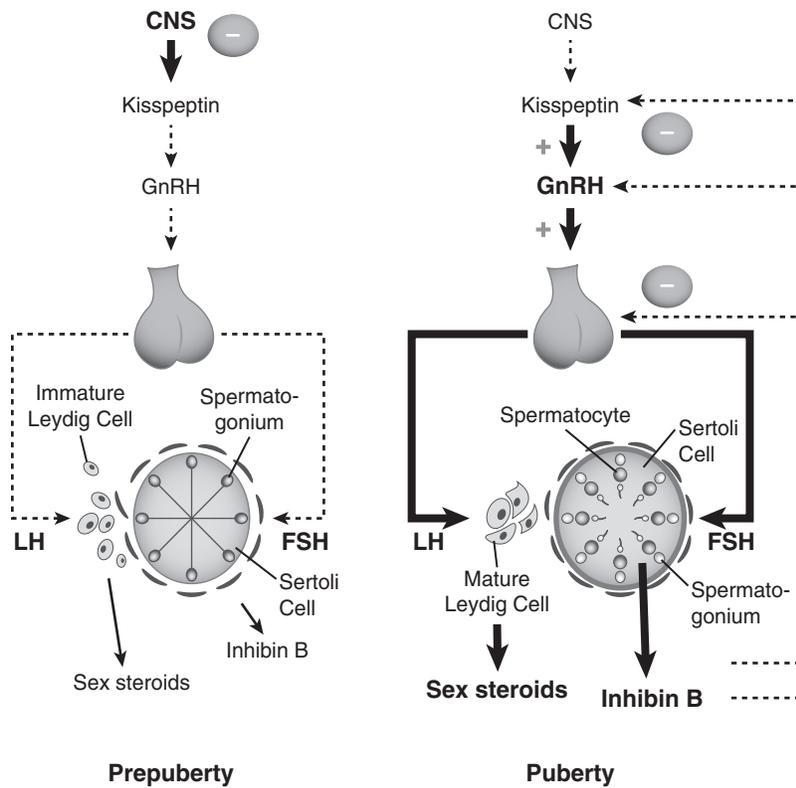

Fig. 18.4 Overview of the hypothalamic-pituitary-gonadal (HPG) axis prepuberty versus postpuberty. Although testicular products, such as inhibins, play a small role in regulation of the HPG axis before puberty, most of the dampening of the HPG axis after infancy and until the onset of puberty (*left panel*) derives from central inhibition. The basis for that inhibition is not fully understood nor is the basis for its diminution, which leads to emergence of central activation (*right panel*), increased gonadotropin-releasing hormone (GnRH) secretion, and the onset of puberty. As pubertal development progresses, inhibin B secreted from Sertoli cells of the mature testes (*right panel*) has a more substantial role in regulating/inhibiting hypothalamic-pituitary activity. The weight of lines (from dotted to thin solid to thick solid) indicates increasing strength of the particular signal. LH, luteinizing hormone; FSH, follicle-stimulating hormone.

Recent data have highlighted the importance of a genetic program that controls the expression of *Kiss1*. The intervention of the polycomb complex proteins, EED and Cbx7, in the transcriptional repression of *Kiss1* has recently been revealed.⁴⁰ The expression of these genes in the prepubertal period progressively decreases with increasing methylation of their promoters. Thus the binding of EED on the *Kiss1* promoter decreases at puberty. The inhibition of the repression of *Kiss1* is also correlated with a decrease in the expression of transcription factors with zinc-finger motifs. In addition, a microRNA switch was proposed to regulate the rise of *GnRH1* synthesis, which occurs during the juvenile period in GnRH neurons. The initiation of puberty from the hypothalamus therefore results from a complex network of transcription factors mainly acting as repressors of *Kiss1* and *GnRH1* transcription.

The concept that puberty results from the disappearance of gonadotropic axis repression is also supported by the description of loss-of-function mutations of *MKRN3* and *DLK1* in familial central precocious puberty (CPP, discussed in detail in "Precocious Puberty" later).⁴¹ Where these factors function in the hierarchical network of genes controlling kisspeptin has yet to be determined.

Somatic Changes

In boys, the first physical finding that marks the onset of puberty is the change from Tanner genital stage G1 to stage G2, including enlargement of the testes (i.e., achievement of volume ≥ 4 mL or testicular length ≥ 25 mm). Originally

Marshall and Tanner reported the mean (standard deviation [SD]) onset of puberty in boys to be 11.64 (1.07) years.^{42,43} These pubertal stages (Fig. 18.5) were based on longitudinal photographic observations of genital development of a relatively small sample of 228 boys living in a children's home. Despite the probably poor representative nature of this sample, studies in Switzerland,⁴⁴ the United States,⁴⁵ and Denmark⁴⁶ have reported roughly similar mean ages of puberty onset.

Although the mean age of onset may be fairly uniform across populations, the range of ages for onset of puberty in normal, healthy adolescents varies widely. Several pathologic states may further influence the timing of puberty either directly or indirectly and may contribute to this splay, but the great majority of the variation in pubertal timing cannot be attributed to clinical disorders. Some 95% of boys experience the onset of genital development between 9.5 and 13.5 years,^{47,48} and these data have led to the traditional definition of sexual precocity in boys as development of secondary sexual characteristics before age 9 years and DP as lack of testicular enlargement by age 14 years.

Development of secondary sexual characteristics results from both gonadarche and adrenarche. Adrenarche refers to the maturation of the zona reticularis of the adrenal gland, resulting in increased production of the adrenal androgens dehydroepiandrosterone (DHEA) and androstenedione, as well as the relatively inactive metabolite DHEA sulfate (DHEA-S). These adrenal androgens, along with testicular androgens, contribute to secondary sexual characteristics, such

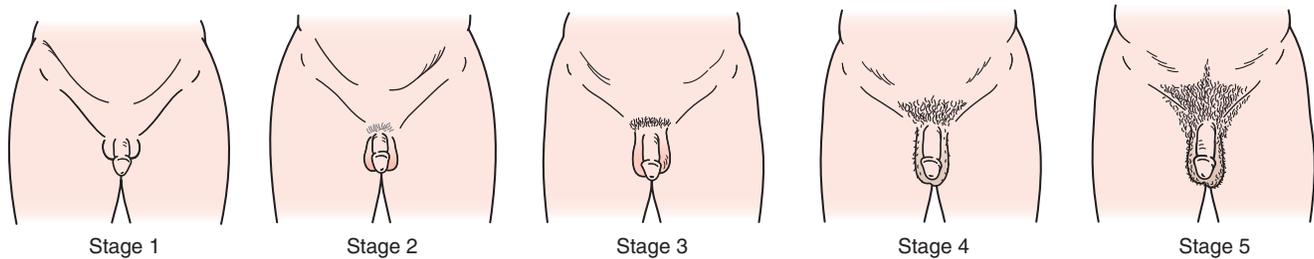

Fig. 18.5 Tanner stages in the male. In boys, genital development is rated from 1 (preadolescent) to 5 (adult); stage 2 marks the onset of pubertal development and is characterized by an enlargement of the scrotum and testis and by a change in the texture and a reddening of the scrotal skin. Pubic hair stages are rated from 1 (preadolescent, no pubic hair) to 5 (adult), and stage 2 marks the onset of pubic hair development. Although pubic hair and genital development are represented as synchronous in the illustration, they do not necessarily track together and should be scored separately. (Modified from Halpern, B., Blackburn, T., Incremona, B., et al. (1996). Preparticipation sports physicals. In: Zachazewski, J.E., Magee, D.J., Quillen, W.S., editors: *Athletic Injuries and Rehabilitation*, Philadelphia, WB Saunders, p. 855.)

as pubic hair (pubarche), axillary hair, apocrine body odor, and acne. Like gonadarche, the onset of adrenarche appears to be a gradual, progressive maturational process that begins in early childhood and is marked by the further increases of production of adrenal androgens around the time of puberty.⁴⁹ Although adrenarche and gonadarche typically overlap, they are separate processes that are independently regulated.^{50,51} The triggers for adrenarche remain unknown; however, alterations in body weight and body mass index (BMI), as well as in utero and neonatal physiology, likely modulate this developmental process, perhaps along with intraadrenal cortisol production.⁵²⁻⁵⁴

REGULATION OF THE TIMING OF PUBERTY

Secular Trends in the Timing of Puberty

The mean age of menarche in mid-nineteenth century Europe is reported to be between 17 and 18 years. Starting from the late nineteenth century to the mid-twentieth century, a gradual decline in age at puberty has been reported, after which this trend appears to have slowed. Much of this change in the timing in puberty has likely been the result of better hygiene and nutrition related to increased socioeconomic stability.

More recent declines in the age at puberty are more convincingly demonstrated among girls than in boys.^{55,56} In the mid-1990s, data from the Third National Health and Nutrition Examination Survey (NHANES III), where genital ratings were performed by visual inspection, reported earlier age at puberty in both boys and girls,⁵⁷⁻⁶⁰ than what previously had been reported from the United States.^{47,59,61} Using the traditional cutoff of 9 years, these data suggest that an increased number of boys would be classified as having precocious puberty. However, because of lack of data on pubertal onset in the previous population-based study (Third National Health Examination Survey [NHES III]),⁴⁷ some controversy remained as how to interpret the NHANES III findings.⁶²

Furthermore, questions have been raised regarding the criteria used for genital staging in NHANES III.⁶³ A subsequent secular trend analysis between NHES III (which lacked data from the early pubertal stages) and NHANES III did not find clear evidence supporting earlier age at puberty, although some indications were present in non-Hispanic white boys.⁵⁹ These data were also reviewed by an expert panel, which concluded that the available data are insufficient in quality and quantity to confirm a change in pubertal timing in US boys.⁵⁶ At the same time in Europe, in comparison with NHANES III studies, some data even reported suggesting older ages at pubertal onset in boys.^{44,64-66}

Secular trends in the timing have been assessed in a few European studies within specific populations. Earlier studies

do not support a substantial enough change in the age at pubertal onset in boys from the mid-1960s to the late 1990s to warrant a change in the age definitions for precocious and DP.^{46,65} However, the most recent data from Copenhagen, comparing the timing of puberty in boys assessed between 2006 and 2008 compared with a group assessed between 1991 and 1993, does report earlier mean age of onset of puberty (11.62 vs. 11.92 years).⁶⁶

In summary, data are conflicting but there is likely an overall suggestion that puberty may be occurring earlier in boys than in the past. However, the change is not as dramatic as in girls, and age cutoffs used to define disorders of puberty have not been uniformly changed.

Genetic Contributions to Variation in Normal Puberty

Although the precise mechanisms that trigger puberty remain unknown, it is well established that the timing of puberty is influenced by both genetic and environmental factors.^{55,67} Evidence for the genetic contribution is provided by correlations in timing within families and between monozygotic twins.^{55,62,68-75} It is important to note that this genetic component does not preclude a significant role for environmental influences; indeed, genetics alone cannot explain secular trends in the timing of puberty. However, the strong genetic component provides an opportunity to identify factors that modulate the timing of normal puberty in the general population.⁷⁶ Approaches used to identify specific genetic factors include candidate-gene studies and genome-wide association (GWA) studies.

Candidate Gene-Based Studies

One approach for identifying the variants that affect complex traits, such as the timing of puberty in the general population, has been candidate gene-based association studies, which seek to demonstrate a higher prevalence of genetic variants in one or more prespecified genes in cases than in controls.

In an association study that tested for associations between common variants in 10 HH-related genes (*GNRH1*, *GNRHR*, *KISS1R/GPR54*, *KISS1*, *LEP*, *LEPR*, *FGFR1*, *KAL1*, *PROK2*, and *PROKR2*) and age at menarche, only nominally significant associations between single nucleotide polymorphisms (SNPs) in several of the genes and age at menarche were identified.⁷⁷

Other work similarly did not identify associations between SNPs in *GNRH1* and *GNRHR* or *LEP* and *LEPR* and alterations in pubertal timing. However, large-scale GWA studies (see later) have demonstrated that variants in some of these genes do in fact influence pubertal timing and have revealed relatively

small effect sizes of these variants, such that earlier candidate-gene studies likely had insufficient power to detect these small effect sizes.

Genome-Wide Association Studies

In large-scale GWA studies, the age of menarche has been the most commonly used marker of the timing of puberty. The first GWA studies on age of menarche involved between 17,000 and 25,000 women, all of European descent. Common variants in *LIN28B* were associated with age at menarche in four independent GWA studies and one metaanalysis.^{78–82} *LIN28B* is a human homologue of *lin-28*, which in *Caenorhabditis elegans* controls the rate of progression from larval stages to adult cuticle formation, indicating conservation of specific micro-RNA regulatory mechanisms involved in developmental timing.⁷⁹ In each case, age at menarche (AAM) was analyzed, but in one study,⁸² additional phenotypes (breast development in girls, voice breaking and pubic hair development in boys, and tempo of height growth in both boys and girls) were found to associate with variants in *LIN28B*, suggesting that *LIN28B* affects timing of puberty more generally, not just timing of menarche, and that control of pubertal timing in boys and girls shares some common elements, although subsequent studies in mice suggest that this pathway may also exert sex-specific effects.⁸³ Effect sizes in the GWA studies were estimated at approximately 1.2 months earlier menarche per effect allele for *LIN28B*.^{80,82} A second menarche locus was identified in two of the four studies at 9q31.2.^{78,80} The biology behind the locus at 9q31.2 remains unknown, but its effect size is similar to the locus in/near *LIN28B*.⁸⁰ The associated SNPs lie in an intergenic region with no obvious candidate genes nearby. The closest gene is *TMEM38B*, a transmembrane protein gene, which lies approximately 400 kb away from the signal at 9q31.2.⁸⁰ Although these studies were groundbreaking, the *LIN28B* and 9q31.2 loci together explain only 0.6% of the variance in age at menarche.⁷⁸

Subsequent GWA studies have used larger and larger sample sizes, resulting in increases in statistical power and identification of many more genetic loci that influence pubertal timing.^{79,84}

The most recent GWA study on age at menarche studied over 350,000 women of European descent and identified 389 independent, genome-wide significant loci that influence pubertal timing.⁸⁵ Collectively, these loci are estimated to account for 7.4% of the overall variation in timing of menarche. There was significant enrichment of expression of genes associated with these loci in the brain, consistent with the hypothesis that pubertal timing is mainly regulated by hypothalamic factors.

A GWA study has also been performed on age at voice-breaking in over 55,000 men and identified 11 genome-significant loci.⁸⁶ Ten of these 11 loci have also been shown to be significantly associated with age at menarche, and the eleventh (*ANOS1* on the X chromosome, which is also associated with X-linked Kallmann syndrome, discussed further later) nearly reached genome-wide significance. Furthermore, analyzing all common variants across the genome, nearly all loci had similar effects on both age at voice breaking and age at menarche. Thus the mechanisms regulating pubertal timing in girls and boys appear to be largely, although not completely,³⁶ overlapping.

GWA studies are designed to assess the contribution of common genetic variants to a particular phenotype. However, it is likely that other forms of inheritance also underlie constitutional delay of growth and puberty (CDGP), including rarer variants (frequency <5% in the general population) with large or even small phenotypic effects; interactions (epistasis) between variants within a single gene or in multiple genes (oligogenicity); structural variation, such as copy number variants;

and epigenetics. Indeed, some of these mechanisms have been identified as causes of hypothalamic amenorrhea.⁸⁷

Other Factors that Modulate the Timing of Puberty

Although these genetic advances are exciting, genetic factors alone cannot explain the reported secular changes in pubertal timing that have occurred since the late twentieth century. Clearly, changes in environmental factors must be involved as well, whether as independent regulators or through gene-environment (G X E) interactions. Variables, such as increased adiposity, insulin resistance, physical inactivity, psychological factors, changed dietary habits, and endocrine-disrupting chemicals have all been implicated as environmental factors that influence pubertal timing.^{55,56,88}

Effect of Body Mass Index on Pubertal Timing

Among white American children aged 6 to 11 years, rates of obesity increased from approximately 5% between 1963 and 1965 to 12% in 1999 to 2000.⁸⁹ The possibility that the increasing rates of obesity contributed to the secular trend toward early puberty onset was originally highlighted in 1997.⁹⁰ However, despite strong evidence in girls in support of a link between increased adiposity and early onset of pubertal markers,⁹¹ data in boys have remained somewhat ambiguous, with increased BMI being associated with earlier puberty in most studies, but with some studies showing obesity being associated with no change in pubertal timing or even with DP.^{88,92–96}

For example, in a study of 463 Danish choir boys, a significant downward trend in age at voice break was found over a 10-year period (from 14 years to 13.7 years).^{89,96} Age at voice break was significantly different between boys in the different prepubertal BMI quartiles, and a trend toward earlier voice break was associated with increasing BMI SDS. Boys in the heaviest quartile at 8 years of age had an increased likelihood of earlier voice break compared with those in the thinnest quartile, suggesting a relationship between prepubertal BMI and the timing of puberty in boys.^{96,97}

In the Copenhagen study discussed earlier, secular trends in pubertal onset over a 15-year period were assessed as were their relationship to BMI in boys.^{66,98} In a total of 1528 boys, onset of puberty, defined as age at attainment of a testicular volume greater than 3 mL, occurred 3 months earlier in 2006 to 2008 than in 1991 to 1993. BMI SD scores increased significantly from 1991 to 1993 to 2006 to 2008 as well. Interestingly, age of pubertal onset was no longer significantly different between study periods after adjustment for BMI indicating that the observed decline in age at onset of puberty was associated at least partly with an increase in BMI.⁶⁶

In a study from Jamaica, the effect body composition on the timing of onset of puberty were assessed in both boys and girls.^{90,99} Elevated fat mass at 8 years of age was associated with advanced puberty in both sexes. These data support the hypothesis that fast growth throughout childhood, especially fat-mass accretion, is associated with advanced pubertal development.^{99,100}

But not all studies agree. For example, in one study from Germany, body weight, height, peak height velocity, and pubertal stages were evaluated in 1421 peripubertal children.¹⁰¹ In contrast to the findings from studies earlier, the researchers found no significant differences in mean pubic hair stage in girls and boys with obesity when compared with either lean or normal-weight children. When analysis was restricted to children at pubic hair stage 2, age at this stage was found not to differ significantly between normal-weight and obese individuals. In boys, testicular volume at a given age was also similar

across all weight groups.¹⁰² In the United States, a cohort of obese boys with DP has also been described.⁹²

In summary, research to date highlights inconsistencies in how obesity affects pubertal timing in boys. Recent data from a study in the United States may shed light on a reason for some of the inconsistency among the studies.¹⁰³ Some 3872 boys were divided based on BMI into three categories (normal weight, overweight, and obese). Based on genital development, puberty among white and African American boys occurred earlier in the overweight compared with normal weight group but later in the obese compared with overweight category. This relationship was not observed among Hispanic youth. These data suggest that the relationship between earlier puberty and body weight may not be linear in boys and may differ by racial/ethnic population group.

Effect of Endocrine-Disrupting Chemicals

Some evidence supports associations between human pubertal timing and exposure to environmental modifiers, although much of the data relate to girls.¹⁰⁴ For example, earlier menarche and pubarche have been associated with exposure to polybrominated biphenyls (PBBs) and dichlorodiphenyl dichloroethene (DDT), whereas delayed breast and pubic hair development, as well as delayed menarche have been associated with lead exposure.^{105,106} In addition, elevated serum levels of a mycotoxin (zearalenone) have been reported in girls with precocious puberty.¹⁰⁷

Some studies among boys have also been reported. Among the strongest studies is a longitudinal assessment of growth and pubertal timing among a cohort of around 500 boys in

Russia.¹⁰⁸ The results from this study have recently been summarized, with data indicating that prepubertal exposures to nondioxin-like polychlorinated biphenyls accelerate puberty, whereas levels of insecticides, dioxin-like compounds, organochlorine pesticides, and lead delay puberty.¹⁰⁹ Other studies indicate that greater exposure to pesticides is associated with cryptorchidism or hypospadias.¹¹⁰

The extent to which these are associations versus cause-and-effect relationships is not fully known, nor are underlying mechanisms. What effects these exposures have in the general population as opposed to isolated examples of associated abnormalities is also not clear. Certainly more research in this area is needed.¹¹¹⁻¹¹³

PRECOCIOUS PUBERTY

Traditionally, the onset of secondary sexual characteristics in a boy before age 9 years has been defined as precocious, whereas lack of testicular enlargement by age 14 years has been classified as DP. In clinical settings, boys present less often with precocious puberty than with DP, which is discussed more extensively later in the chapter. For clinical assessment, in addition to these dichotomous age cutoffs, a recent online tool allows for assessment of the stage of development (pubic hair, testicular volume, genital staging) relative to population norms. The progression of puberty can be monitored by using the puberty plots presented as stage line diagrams (Fig. 18.6).¹¹⁴ These plots provide probability curves for an individual being at a certain developmental stage at certain age. The centile value on the y-axis is a quantitative assessment of pubertal timing for the individual being assessed on the

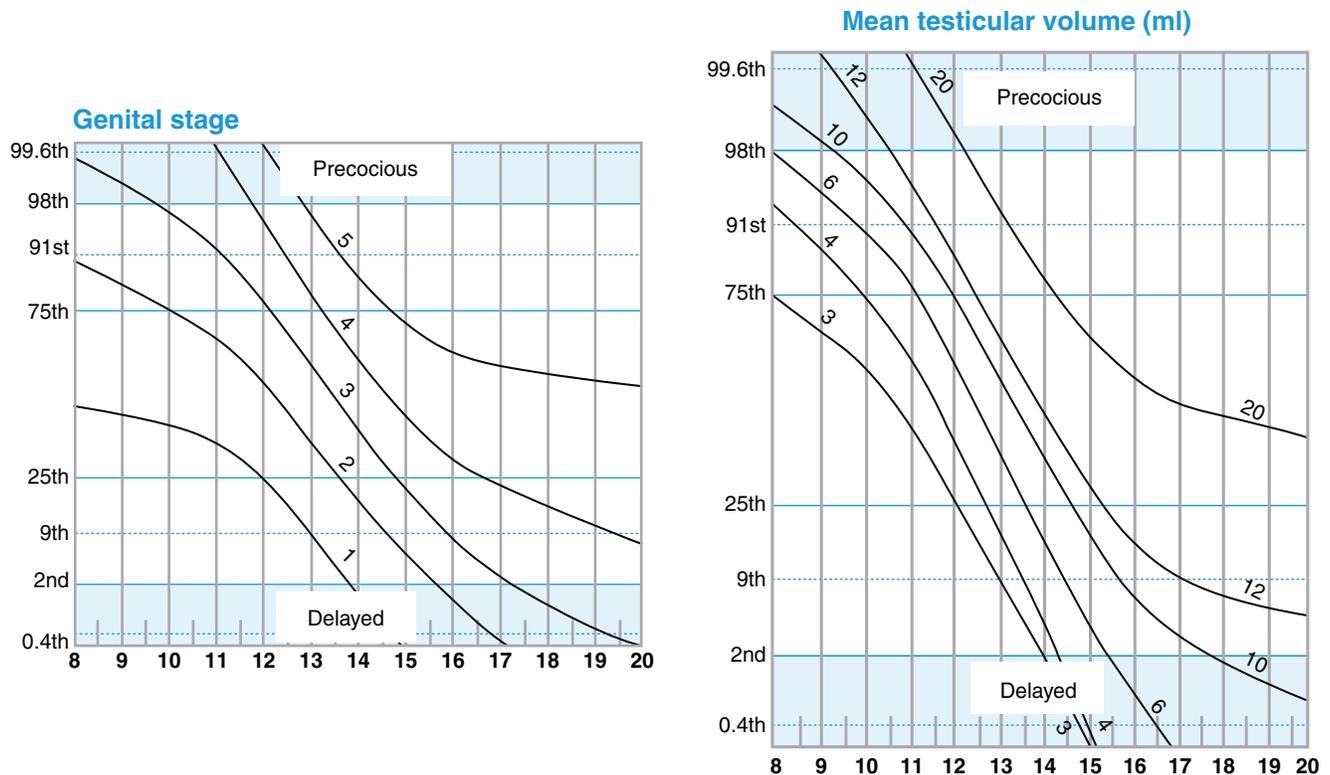

Fig. 18.6 The distribution of Tanner genital (G) stages and testis volume in healthy boys. In these stage line diagrams, lines 1–5 correspond to Tanner stages 1–5 (left panel) or testis volume in mL (right panel). X-axis values are age in years and the y-axis displays gender-appropriate centiles for development. Individuals can have their Tanner stage and testis volume plotted to determine precocity, delay in development, or appropriate progression to determine if development has plateaued or arrested. (From van Buuren, S. (2014). Growth charts of human development. *Stat Methods Med Res*, 23, 346–368.¹¹⁴)

plots. Such diagrams assist in identifying early and delayed development, as well as finding differences in the progression of puberty.

Gonadotropin-Releasing Hormone-Dependent Forms of Precocious Puberty

The most common form of precocious puberty is caused by the early activation of pulsatile GnRH secretion, termed *CPP* or *gonadotropin-dependent precocious puberty*. CPP may result from hypothalamic tumors or CNS lesions (neurogenic CPP) but in most cases remains unexplained (idiopathic CPP) (Table 18.1).^{115,116}

Hypothalamic hamartomas are an example of a cause of neurogenic CPP. The hamartomas are congenital malformations characterized by heterotopic gray matter, neurons, and glial cells, and they are generally located on the floor of the third ventricle or attached to the tuber cinereum. On magnetic resonance imaging (MRI), hamartomas exhibit an isodense fullness. Histologic examination has shown immunoreactivity for GnRH and for astroglial factors, such as TGF- α . Postulated mechanisms include GnRH secretion directly from these neurons, secretion of TGF- α that in turn stimulates GnRH secretion from GnRH neurons, and electrical activation of adjacent neural centers. Most hypothalamic hamartomas are sporadic, but they may occur in association with Pallister-Hall syndrome, which is caused by mutations in the *GLI3* gene. Optic gliomas, which can be associated with neurofibromatosis 1, can also cause neurogenic GnRH-dependent precocious puberty.¹¹⁷ Other etiologies of neurogenic CPP include pineal tumors, suprasellar cysts, head trauma, CNS radiation, and static encephalopathy.¹¹⁸

Loss-of-function mutations of the *MKRN3* gene, located at chromosome 15q11-q13, have been associated with GnRH-dependent precocious puberty. *MKRN3* encodes makorin RING-finger protein 3, which may function as an RNA-binding and/or a ubiquitin ligase. All clinically affected individuals inherited the mutated allele from their fathers, which can be explained because this gene is maternally imprinted and expressed only from the paternal allele. Both boys and girls are affected, although the degree of precocity appears to be greater in girls than boys. About 30% of familial cases and 3% of sporadic cases of CPP are associated with mutations in

MKRN3 (OMIM ID 603856). The mutations in *MKRN3* associated with CPP include frameshift mutations that are likely to cause loss of function; this suggests that *MKRN3* normally acts to delay the onset of puberty and calls attention to the importance of inhibitory factors in the regulation of pubertal timing.⁴¹

There is compelling evidence that mutations disrupting the *DLK1* gene can also cause CPP.¹¹⁹ Deletions and imprinting defects in the region on chromosome 14 around *DLK1* cause Temple syndrome, which is associated with precocious puberty. A smaller deletion that appears to affect *DLK1* alone was identified in four individuals with CPP from the same family, suggesting that disruption of *DLK1* is responsible for the precocious puberty seen in Temple syndrome. The association of *DLK1* with precocious puberty was confirmed by a subsequent report of frameshift mutations in *DLK1* in individuals with precocious puberty from three additional unrelated families.¹²⁰ Like *MKRN3*, *DLK1* is imprinted, and CPP is observed only if the paternal allele is disrupted. *DLK1* encodes a non-canonical ligand for the Notch family of receptors, and its precise function is unknown.

Gonadotropin-Releasing Hormone-Independent Forms of Precocity

Precocious development of secondary sexual characteristics may also be caused by mechanisms that do not involve activation of pulsatile GnRH secretion. These forms of precocity are called *gonadotropin-independent* or *peripheral precocity* and include gonadal and adrenal tumors, inappropriate activation of LH receptor because of gene mutations or signaling by tumors producing hCG, and exposure to exogenous sex steroids (see Table 18.1). Familial male-limited precocious puberty (FMPP, OMIM ID: 176410), formerly known as *testotoxicosis*, is a rare, dominant form of gonadotropin-independent precocity caused by constitutively activating mutations of the LH/hCG receptor (*LHCGR*).¹²¹ This disorder usually presents by age 1 to 4 years with rapid virilization, growth acceleration, skeletal (bone age) advancement, and elevated testosterone levels despite prepubertal levels of LH.^{122,123} McCune-Albright syndrome (MAS, OMIM ID: 174800) is another rare genetic cause of male sexual precocity. It is caused by postzygotic somatic activating mutations in *GNAS1*, the gene that encodes the α subunit of the heterotrimeric G_s protein. G_s transduces the signal from multiple G-protein-coupled receptors, including the LH receptor, and the constitutive activation of G_s signaling leads to autonomous cell proliferation and scattered hyperfunction in endocrine organs, with a wide phenotypic spectrum that depends on which organs carry the mutation.^{124,125} The classical features of MAS include the clinical triad of bone fibrous dysplasia (BFD), café-au-lait skin spots, and precocious development of secondary sexual characteristics. In addition, hyperthyroidism caused by activation of the thyroid-stimulating hormone (TSH) receptor, hypercortisolism caused by constitutive activation of the CRH and/or adrenocorticotropin hormone (ACTH) receptor, kidney phosphate wasting, cholestasis, and hypertrophic heart disease can be present.^{124,126} For reasons that are not clear, MAS leads to sexual precocity more often in girls than in boys. Many boys may have unrecognized testicular pathology, but the predominant finding is Leydig cell hyperplasia, which may not warrant active intervention.¹²⁷

In 1960 Van Wyk and Grumbach first described a syndrome characterized in girls by breast development, uterine bleeding, and multicystic ovaries in the presence of long-standing primary hypothyroidism.¹²⁸ A unique diagnostic feature of the Van Wyk-Grumbach syndrome is the combination of delayed bone age with apparent sexual precocity. Boys with this syndrome have macroorchidism without significant virilization.

TABLE 18.1 Common Etiologies of Sexual Precocity in Boys

Central (GnRH Dependent)	Peripheral (GnRH Independent)
Idiopathic	Congenital adrenal hyperplasia
Central nervous system (CNS) masses	McCune-Albright syndrome
– Hamartomas	Testosterone producing tumors
– Astrocytomas	– Adrenal carcinoma or adenoma
– Adenomas	– Leydig cell tumor
– Gliomas	hCG-producing tumors
– Germinomas	– Choriocarcinoma
CNS infection	– Dysgerminoma
Head trauma	– Hepatoblastoma
Iatrogenic	– Chorioepithelioma
– Low-dose CNS radiation	– Teratoma
– Chemotherapy	– Gonadoblastoma
– Surgical	Exogenous exposure to androgen
Malformations of CNS	Familial male limited precocious puberty
– Arachnoid or suprasellar cysts	Hypothyroidism (Van Wyk-Grumbach syndrome)
– Hydrocephalus	

hCG, Human chorionic gonadotropin.

(Modified from Nathan BM, Palmert MR (2005). Regulation and disorders of pubertal timing. *Endocrinol Metab Clin North Am*, 34:617–641, ix.)

Testicular histology shows enlargement of the seminiferous tubules without an increase in Leydig cell number.^{129,130} If performed, GnRH stimulation shows a prepubertal response with suppressed LH, confirming GnRH-independent precocity. Most cases appear to originate from autoimmune thyroid disease, but there are some case reports where the syndrome is secondary to unrecognized congenital hypothyroidism.¹³¹ The pathophysiology of Van Wyk–Grumbach syndrome involves a complex mechanism, which is mediated at least in part by the direct action of TSH on FSH receptors. Recombinant human TSH (Rec-hTSH) elicits a dose-dependent cAMP response in cells expressing the human FSH receptor *in vitro*; however, the concentration of rec-hTSH required for half-maximal stimulation is several logs greater than that of hFSH.¹²⁹ Early recognition and initiation of thyroid hormone replacement can lead not only to resolution of symptoms and improvement in adult height but also to avoidance of further diagnostic procedures.

GnRH-independent precocity can also be caused by the virilizing forms of congenital adrenal hyperplasia (CAH). These are autosomal recessive disorders of cortisol synthesis that present with premature pubic hair development, axillary hair development, accelerated linear growth, and phallic enlargement in the absence of testicular enlargement. The most common form is 21-hydroxylase deficiency because of loss-of-function mutations in *CYP21A2*. Mutations in 11 β -hydroxylase (*CYP11B1*) and 3 β -hydroxysteroid dehydrogenase type 2 (*HSD3B2*) account for 5% to 10% of cases. Androgen-secreting tumors are another rare cause of GnRH-independent precocity in boys. Leydig cell tumors secrete testosterone. Because these tumors are usually unilateral, testicular volume may be asymmetric. The majority of Leydig cell tumors are benign. Ultrasound may be useful because the tumor may be too small to palpate. Mutations in the *LHCGR* gene have been identified in some testicular adenomas.¹³² Tumors secreting hCG also stimulate testosterone secretion in boys and can resemble familial male limited precocious puberty (testotoxicosis). These tumors are generally hepatic in origin (of note, activating mutations of the LH receptor and hCG-secreting tumors do not cause precocious puberty in girls, as estradiol production requires activation of both the FSH and LH receptors). Adrenal tumors in children may secrete androgens, and virilization is a common presentation.

Whether precocious puberty is gonadotropin dependent or gonadotropin independent not always clear. Both forms can sometimes be present because peripheral forms of sexual precocity, such as CAH or testicular or adrenal tumors, can eventually lead to superimposed central precocious puberty through mechanisms that are unknown. In contrast, in some cases of precocious pubertal development among girls, pubertal manifestations will stop progressing or regress, making treatment unnecessary; such cases are not as commonly seen in boys.^{133,134} The mechanisms responsible for these nonprogressive forms of precocious puberty are not known, but there is evidence that in some cases the HPG axis is intermittently but not fully activated.^{134,135}

Premature Adrenarche

Another form of early development of secondary sexual characteristics occurs when the zona reticularis of the adrenal cortex matures early, causing premature adrenarche. Premature adrenarche, more common among girls, is not associated with progressive pubertal development and is manifested by pubic and axillary hair with modest elevation of DHEA-S. Usually, there is no substantial advancement in bone age; however, even in the subset with more advanced bone ages there appears to be little to no compromise of adult height, although admittedly, most of these data derive from studies among girls.^{136,137} As a result premature adrenarche does not require treatment.

Consequences of Precocious Puberty

In cases of progressive central precocious puberty or peripheral precocity, the concerns include adverse psychosocial outcomes and short adult stature because of early epiphyseal fusion.^{115,138} Several studies have assessed adult height in subjects with a history of precocious puberty, demonstrating that loss in adult height can be substantial.¹³⁹ Height loss is inversely correlated with the age at the onset of puberty.¹³⁹ It is especially important to assess carefully the growth rate and skeletal maturation of individuals with central precocious puberty because of CNS lesions (e.g., tumors, cerebral malformations or injury from trauma or radiation) because these lesions may be associated with concomitant GH deficiency, which can be masked by sex steroid-driven growth that may deceptively appear adequate. In such cases, the combination of undiagnosed and untreated GH deficiency and rapid skeletal maturation driven by sex steroids may result in severely compromised adult height.

Although available data derive mostly from study of girls with pubertal onset at the earlier end of the normal range, it has been suggested that a higher proportion of early-maturing adolescents within the general population engage in exploratory risky behaviors (sexual intercourse and substance use) at an earlier age than adolescents with average or late timing of maturation.^{140,141} However, available data regarding potential adverse psychosocial outcomes specific to patients with precocious puberty are limited, and it is not clear that data obtained from individuals with maturation at the early end of the normal spectrum are fully applicable to precocious puberty.

Epidemiological studies have associated earlier pubertal timing with increased risk for a number of negative adult health outcomes, including obesity; reproductive cancers, such as breast cancer in women and prostate cancer in men; type 2 diabetes; and cardiovascular disease.^{86,142} Most of these studies were conducted in women because recalled age at menarche is a fairly reliable indicator of pubertal timing, and a comparable marker is lacking in men, although recalled age at voice breaking has been used in some studies. Also most of these studies examined pubertal timing more generally rather than precocious puberty specifically, but many of the observed associations extended into the precocious range.

Early association studies were unable to establish causality, that is, whether DP causes the increased risk directly or whether some common upstream factor affects pubertal timing and adult-disease risk independently. More recently, human genetic approaches have been used to address this issue. One approach is to compare the effects of common genetic variants on two traits to determine whether the traits share a common genetic basis; this approach has been used to demonstrate that pubertal timing and BMI have shared genetic determinants.⁸⁶ Another technique called *Mendelian randomization* assesses whether (after adjustment for pleiotropy) the genetic determinants of one trait also influence a second trait, with the logical inference that any such influence is mediated by the first trait influencing the second trait. This technique has been used to suggest that it is pubertal timing itself that influences risk of reproductive cancers, including breast, ovarian, and endometrial cancers in women and prostate cancer in men.⁸⁵ Mendelian randomization also indicates that earlier pubertal timing leads to higher blood pressure in adulthood.¹⁴³ With regard to BMI, pubertal timing has been shown to influence adult BMI,¹⁴⁴ and childhood obesity has been shown to affect pubertal timing¹⁴⁵; thus more than one mechanism underlies the relationship between pubertal timing and BMI.

Pathologic entities leading to sexual precocity warrant treatment, but whether and at what ages one should initiate

treatment for idiopathic central precocious puberty is less clear, particularly if adult height does not appear to be compromised. Currently, robust data regarding the short-term and long-term psychosocial sequelae of CPP and data regarding whether treating CPP with GnRH analogues (GnRHa) alter these outcomes are lacking.¹⁴⁶ Thus one needs to be cautious when using psychosocial outcomes as a rationale for pharmacologic intervention to halt pubertal progression, especially among boys with the onset of puberty close to the normal range.

Evaluation of the Boy With Precocious Development of Secondary Sexual Characteristics

Boys with sexual precocity require careful evaluation because many have underlying disorders.¹¹⁵ Those with premature pubarche (early development of pubic hair or body odor) need to be assessed for peripheral causes of precocity before determining that the premature pubarche stems simply from premature adrenarche. Premature adrenarche may be distinguished from true precocity over time by lack of rapid progression. Conversely, progressive precocity is marked by significant bone age advancement (>2 SD for age), growth acceleration, and rapid progression of secondary sexual characteristics on physical examination.

The evaluation of a boy with sexual precocity is outlined in [Box 18.1](#). Considerations include first verifying that the pubertal development is occurring outside the range of normal development before initiating an evaluation. It is also important to note that not all tests are appropriate in each case and that the diagnostic yields of various tests are not known. Hence it is important to allow history and physical examination to guide the evaluation. The child with both testicles enlarged to 8 mL or more, for example, is most likely to have central precocious puberty, with FSH having led to the expansion of seminiferous tubule volume (whereas cases of testotoxicosis, and hCG-secreting tumors can also present with modest bilateral

testicular enlargement, volumes in these conditions are usually no more than 6 mL). Conversely, the child with bilateral prepubertal-sized testicles is more likely to have peripheral precocity; the child with unilateral testicular enlargement may have a testicular tumor. Testing should be directed accordingly.

Peripheral causes of sexual precocity are characterized by suppressed LH and FSH values in the setting of elevated sex steroid levels. Testosterone levels will be elevated in instances of isosexual precocity (secondary sexual characteristics consistent with male sex), whereas estradiol levels may be elevated in the rare instances of contrasexual precocity (secondary sexual characteristics inconsistent with sex, such as marked breast development as the presenting sign in a boy). Determining the underlying mechanism for progressive peripheral precocity is important because all instances will result from pathologic conditions or exogenous exposures.¹⁴⁷ DHEA-S is often used as a screen for adrenal tumors or adrenal pathology. Determination of the 17-hydroxyprogesterone concentration is used to screen for congenital adrenal hyperplasia because of 21-hydroxylase deficiency. Congenital adrenal hyperplasia and hormone-secreting tumors of the adrenal gland are discussed in detail in [Chapter 14](#). Evaluation of skeletal maturation with a bone age is an important adjunct, as it allows for prediction of adult height.

Historically, the gold standard for the diagnosis of central precocious puberty was GnRH stimulation testing and the demonstration of pubertal gonadotropin responses that derive from the gonadotropes having been primed by endogenous GnRH secretion. However, with the advent of ultrasensitive gonadotropin assays,¹⁴⁸ the recognition that these assays can identify individuals with CPP using unstimulated random samples,¹⁴⁹ and the unavailability of GnRH for testing has led many to forego stimulation testing. GnRH agonists can be used as an alternative to GnRH for stimulation testing, but again the diagnosis can often be made through the combination of clinical features and a baseline LH value in the pubertal range. Although determining the diagnostic cutoff for the basal LH level is difficult because of a lack of normative data and variability among assays, a value of 0.3 IU/L or more, using an ultrasensitive assay with a detection limit near 0.1 IU/L, is commonly cited.¹⁴⁶ If stimulation testing is done, a diagnostic cutoff of 5 IU/L for peak value has been suggested. LH values are more useful than FSH values in the diagnostic evaluation of precocious puberty, but stimulated LH/FSH values can help to identify patients with slowly progressive precocious puberty because these children tend to have FSH-predominant responses.^{134,150} Idiopathic central precocious puberty is a more common cause of precocious puberty among girls than among boys in endocrinology clinics.^{151,152} Hence all boys with CPP should have brain MRI to exclude underlying pathology.¹⁴⁶

In summary, it is important for physicians evaluating patients with suspected precocious puberty to address these questions: Is pubertal development occurring outside the normal range of development? What is the underlying mechanism, and is that mechanism associated with a risk of a serious condition, such as an intracranial lesion? Is the pubertal development likely to progress, and could this impair the child's normal physical and psychosocial development?

Treatment of the Child With Precocious Puberty

Unless there is underlying pathology that requires intervention, whether the precocious pubertal development is likely to impair the boy's normal physical or psychosocial development is often the feature that determines if treatment is needed.

BOX 18.1 Outline of the Evaluation of Sexual Precocity in Boys

COMMON INITIAL SCREENING TESTS

- Careful history, physical examination, and assessment of growth velocity
- Bone age
- LH, FSH
- Testosterone (and in some cases estradiol)
- DHEA-S
- 17-hydroxyprogesterone (to screen for congenital adrenal hyperplasia)
- TSH, T⁴

SECONDARY TESTS TO CONSIDER

- MRI of pituitary and brain (to screen for a central nervous system lesion)
- GnRH agonist stimulation test (can distinguish central precocious puberty from peripheral precocity)
- ACTH stimulation test (to diagnose congenital adrenal hyperplasia)

ACTH, Adrenocorticotropic hormone; DHEA-S, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging; T⁴, thyroxine; TSH, thyroid-stimulating hormone.

(Modified from Nathan, B. M., Palmert, M. R. (2005). Regulation and disorders of pubertal timing. *Endocrinol Metab Clin North Am*, 34, 617–641, ix.)

Central Precocious Puberty

Because nonprogressive forms of precocious puberty do not require intervention, a prerequisite for the consideration of therapy for CPP is the presence of documented, progressive pubertal development over a 3- to 6-month period, although this period of observation may not be necessary if the child is at or beyond Tanner stage 3 genital development.¹⁴⁶ Epiphyseal fusion is an estrogen-dependent process, and early and progressive production of sex steroids can cause rapid advancement of skeletal maturation and result in compromised adult height. Thus preservation of adult stature is one of the main reasons to consider treatment of CPP with GnRH agonists, which downregulate the pituitary-gonadal axis and limit pubertal progression. Although the data derive primarily from studies among girls, it appears that the risk of short stature is most pronounced in those children with earlier onset of symptoms.¹⁵³ An advanced bone age also contributes to poorer height outcomes.¹⁵³ Available data suggest that the greatest height gain (preservation) occurs with treatment of girls with onset of puberty before 6 years of age, with more modest benefit being seen with onset between 6 and 8 years.¹⁴⁶ However, insufficient data exist to draw similar conclusions regarding age of onset and height outcomes among boys^{154,155}; consequently, a consensus conference recommended considering initiation of GnRHa therapy for all boys with onset of CPP before age 9 years who have compromised height potential.¹⁴⁶

The second main reason to consider therapy in CPP is to mitigate potential psychosocial effects of precocious puberty. However, as noted earlier, additional studies are needed to determine the effects of precocious puberty on quality of life and psychosocial functioning and to evaluate whether treatment with GnRHa therapies affects these outcomes. Thus the consensus conference concluded that the use of GnRHa therapies solely to influence psychosocial consequences of precocious puberty needs to be considered carefully, given the absence of convincing data.¹⁴⁶ These cautions are even more pertinent for boys because data regarding males are even more scarce.

Finally, although the associations with pubertal timing and later life health outcomes mentioned earlier are intriguing, there are no data regarding whether treatment of precocious (or delayed) puberty affects the risk of such outcomes. This question represents an important area of further study because the ability to mitigate risks for cancer or cardiovascular disease would be an important consideration when deciding for or against treatment of precocious puberty.

Various formulations (intramuscular, subcutaneous, and intranasal) of short- (daily) and long-acting GnRH agonists are available to treat CPP. The depot formulations are preferred, as they are easier for patients and families to administer regularly over a long treatment period. The initial depot medications were 1-month formulations, which have been shown to be well tolerated and effective.^{156,157} Subsequently, 3-month and 6-month depot formulations were developed,^{146,158,159} and a 1-year implant (histrelin-acetate) has also become available.¹⁶⁰⁻¹⁶² Which GnRHa to use depends on patient and provider preference, local regulatory approvals, and reimbursement systems.¹⁴⁶

GnRH agonists are generally well tolerated. Occasionally, an initial, temporary flare of GnRH activity can occur and result in transient advancement of secondary sexual characteristics. Local reactions (sterile abscesses) can occur in 10% to 15% of patients using injected depot formulations of GnRH analogs. Other considerations include long-term effects of GnRH agonists on bone mineral density (BMD) and reproductive function. These outcomes have largely been studied among girls, and the available data are reassuring.¹⁴⁶ Whether GnRHa

use is associated with increased obesity is less clear, and data among boys with CPP are sparse. However, most studies in girls are reassuring and indicate that this concern is not great enough to argue against use of GnRHa in cases of CPP, especially because risk factors for obesity may be associated with CPP itself and not necessarily the use of GnRHa.¹⁴⁶

Monitoring of GnRH agonist therapy should consist of assessment of Tanner stage and growth velocity every 3 to 6 months, with assessment of skeletal maturation every 6 to 12 months. Progression of pubertal development or of rapid skeletal maturation indicates a lack of efficacy, poor adherence, or a misdiagnosis. Such patients warrant reevaluation, including potential measurement of baseline or stimulated LH levels. Whether it is helpful to routinely measure gonadotropins to monitor suppression during GnRHa treatment is controversial.^{116,146} When to discontinue GnRH agonist therapy must be evaluated for each individual patient. Data among boys are limited, but examination of clinical characteristics at the discontinuation of therapy—such as treatment duration, height, growth velocity, bone age, and chronologic age—has failed to identify clear predictors of adult height that might guide decisions around when to discontinue GnRH agonist therapy. In the absence of this data, it seems reasonable to time discontinuation based on patient and family preference, typically with the intent of having pubertal development resume at an age that allows for development to occur in parallel with the patient's peers.¹⁴⁶

Peripheral Precocity

In the past, treatment of GnRH-independent causes of sexual precocity, such as MAS or familial male-limited precocious puberty, included using inhibitors of steroidogenesis (ketokonazole), weak antiandrogen agents (spironolactone), and first-generation aromatase inhibitors (AIs) (testolactone).¹⁶³⁻¹⁶⁷ Although these therapies were partially effective in slowing growth velocity and reducing virilization,¹⁶⁸⁻¹⁷¹ the risk of hepatotoxicity and adrenal insufficiency with ketoconazole, as well as the requirement of multiple daily dosing, were obstacles to achieving a favorable therapeutic outcome.¹⁷² More recently, short-term combination therapy with a potent antiandrogen agent, bicalutamide, and third-generation AIs, anastrozole and letrozole, appears to be effective in reducing growth rate and virilization and improving predicted adult height.¹⁷³⁻¹⁷⁶ This combination therapy provides a more convenient once-daily dosing regimen, although the therapy is more expensive than previous treatments and can be associated with gynecostasia. Full endorsement of these regimens awaits further controlled clinical trials, including the evaluation of the long-term effects of such therapy on adult height, fertility, metabolic parameters, cognitive functions,¹⁷⁷ and bone health.¹⁷⁸ If superimposed CPP develops in a patient with peripheral precocity, treatment with a GnRH agonist may be warranted.

DELAYED PUBERTY

The etiologies, evaluation, and treatment of DP have previously been reviewed by the authors.¹⁷⁹ DP is defined as the absence of testicular enlargement 2 to 2.5 SDs later than the population mean (traditionally age 14 years in boys). As noted previously, because of the downward trend in pubertal timing in some but not all reports from the United States,^{58,180,181} and other countries,^{66,182} some advocate for younger age cutoffs for the general population or perhaps for particular countries or ethnic groups. However, the secular change in the onset of puberty has not been as notable in late developing boys⁶⁶ and hence the need to readjust age definitions for DP in males may not be necessary. Of note, because pubarche may result from

maturation of the adrenal glands (adrenarche) independent of HPG axis activation, the presence of adrenarchal signs (such as pubic hair) does not exclude a diagnosis of DP.

DP is often quite concerning to patients and families.¹⁸³ It can affect psychosocial well-being, peer relationships, and sports participation, and these issues are common reasons for initiating therapy. However, as with precocious puberty, further studies are needed to assess fully the psychosocial distress experienced by individuals with DP, whether this distress has long-term sequelae, and what impact sex-steroid supplementation has on these outcomes.¹⁷⁹ Patients, families, and practitioners are also often worried that DP may affect adult stature, and many patients present with relative familial short stature, along with DP and lack of a pubertal growth spurt, which accentuates concerns about both current and adult stature. Adult height can indeed be affected by DP, but on average it is only slightly below the genetic target.¹⁸⁴ It remains unclear whether adult bone mass is adversely affected by pubertal delay¹⁸⁵ and whether concerns related to bone health represent a medical reason to initiate therapy. Finally, as with early puberty, older age at onset of puberty has been associated with later life outcomes,^{86,142} but it is not known if treatment of DP affects these associations.

Etiologies of Delayed Puberty

The most common cause of DP in boys is self-limited DP or CDGP, which refers to an extreme of the normal spectrum of pubertal timing. In two large series, approximately between 65% to 80% of boys and 30% to 50% of girls with DP had self-limited DP^{186,187} (Fig. 18.7). However, because the data derive from referral centers, these percentages may underestimate the frequency of self-limited DP encountered by primary care providers.

Although self-limited DP/CDGP represents the single most common cause of DP in boys, it is a diagnosis of exclusion, and potential pathologic causes of delay should be considered. Other causes of DP can be divided into three main categories^{179,186,187} (see Fig. 18.7 and Table 18.2): persistent HH, which represents approximately 10% of cases among boys and is characterized by low LH and FSH levels caused by

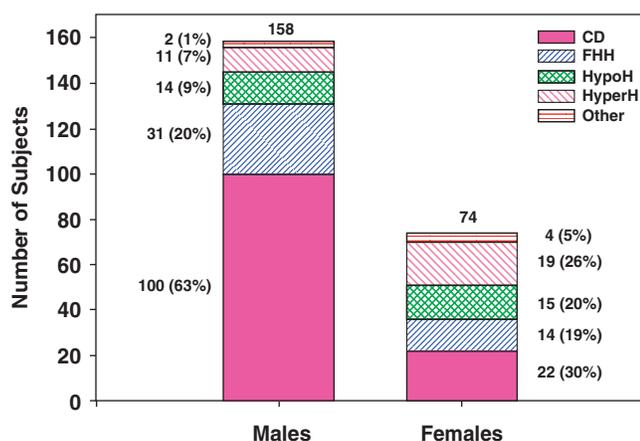

Fig. 18.7 Distribution of diagnostic categories among males and females with delayed puberty. CD, Constitutional delay of growth and puberty; FHH, functional hypogonadotropic hypogonadism; HypoH, persistent hypogonadotropic hypogonadism; HyperH, permanent hypergonadotropic hypogonadism. (From Sedlmeyer, I. L., & Palmert, M. R. [2002]. Delayed puberty: analysis of a large case series from an academic center. *J Clin Endocrinol Metab*, 87, 1613–1620. With permission.)¹⁸⁶

hypothalamic or pituitary disorders; functional HH, which represents approximately 10% to 20% of cases and where pubertal delay is transient and secondary to underlying conditions; and hypergonadotropic hypogonadism caused by primary gonadal insufficiency, which represents approximately 5% to 10% of cases and is characterized by elevated LH and FSH levels because of lack of negative feedback from the gonads.

Persistent Hypogonadotropic Hypogonadism

Genetic defects are a major cause of HH, and the study of genetic disorders that cause GnRH deficiency has significantly increased our understanding of development and function of the HPG axis.^{74,189–196} GnRH deficiency is more common in boys than girls, affecting one in 7500 males but only one in 70,000 females; the reason for this sex difference is unclear.¹⁹⁶ Inheritance patterns include X-linked, autosomal dominant, and autosomal recessive. However, sporadic cases are more common than familial forms. HH has been subclassified into three major categories: (1) HH associated with anosmia, called *Kallmann syndrome (KS)*; (2) isolated HH (IHH) without anosmia; and (3) acquired HH. However, there is likely to be overlap among these categories, as the same mutation may cause heterogeneous phenotypes even within families.

Genes Involved Gonadotropin-Releasing Hormone Neuronal Development

The association of HH with an abnormal sense of smell seen in KS arises from the developmental origins of GnRH neurons in the olfactory placode and migration of GnRH neurons along olfactory pathways. Several genes critical to HPG axis function and olfactory development have been identified through investigation of KS.^{58,60} The classic form of KS is characterized by isolated gonadotropin deficiency, anosmia, and X-linked inheritance. This disorder is caused by mutations in anosmin 1 encoded by the *ANOS1/KALI* gene, resulting in failure of GnRH neurons to migrate to the hypothalamus.^{70,71,197,198} MRI can confirm reduced size or complete absence of the olfactory bulbs. Nonreproductive features may include unilateral renal agenesis and synkinesia (“mirror movements,” with movements on one side of the body causing involuntary movements on the contralateral side). *ANOS1* mutations are also associated with a relatively high incidence of cryptorchidism, microphallus, and decreased inhibin B concentrations.

The list of genes associated with HH is expanding, and nonreproductive phenotypes implicate the causative gene in some cases. To date, numerous mutations have been identified in the *FGFR1* gene, the most common autosomal dominant cause of KS; associated features can include skeletal anomalies, hearing loss, and synkinesia.^{199,200} Mutations in *FGF8*, the ligand for *FGFR1*, have been associated with holoprosencephaly, septooptic dysplasia, and Moebius syndrome.²⁰¹ Nonreproductive clinical features of patients with mutations *PROK2* and *PROK2R*, which encode prokineticin 2 and its G-protein-coupled receptor, respectively, include fibrous dysplasia, obesity, synkinesia, and epilepsy.^{194,200,202,203} One study reported a patient heterozygous for both a *PROK2R* mutation and an *ANOS1* mutation, suggesting a possible digenic mode of inheritance in some cases.^{200,202} Mutations in *CHD7* can be associated with other features of CHARGE (coloboma, heart defects, atresia choanae [also known as choanal atresia], growth retardation, genital abnormalities, and ear abnormalities) syndrome. Both normosmia and anosmia have been reported for all of these genes.

The NMDA receptor synaptonuclear signaling and neuronal migration factor (NSMF, also known as *nasal embryonic LHRH factor, NELF*) is also implicated in KS. NSMF appears to have an

^aSome genes have been identified as causes of both Kallmann syndrome and isolated hypogonadotropic hypogonadism (IHH). *CHARGE*, Coloboma, heart defects, atresia choanae [also known as choanal atresia], growth retardation, genital abnormalities, and ear abnormalities; CNS, central nervous system; *HPG*, hypothalamic-pituitary-gonadal. (Modified from Palmert, M. R., Dunkel, L. (2012). Clinical practice. Delayed puberty. *N Engl J Med*, 366, 443–453.)

important role as a common guidance molecule for olfactory axon projections and subsequently, either directly or indirectly in the migration of GnRH neurons.^{204,205} A heterozygous deletion in *NSMF* was initially reported as a component of digenic KS, along with *FGFR1*,²⁰⁶ but it has since been reported that *NSMF* can lead to HH or KS via apparently monogenic inheritance as well.^{5,207}

Mutations in *HS6ST1*, *SEMA3A*, and *WDR11*, have also been identified in patients with HH.^{207–210} In families carrying mutations in these genes, phenotypic heterogeneity for anosmia occurs, and HH often segregates as a complex trait found in association with mutations in other genes. Thus it remains to be determined whether mutations in these genes alone are sufficient to lead to GnRH deficiency. Mutations in genes encoding proteins, such as *FGF17* and *IL17RD* that modulate the signaling efficiency of FGF8 through FGFR1, have been identified, suggesting the existence of a FGF8 synexpression group that may form an oligogenic basis for HH.²¹¹

Genes Involved in Gonadotropin-Releasing Hormone Neuronal Function

Conditions that affect GnRH neuronal function but not GnRH neuronal development would be expected to cause the normosmic variety of IHH, as would conditions that cause resistance to GnRH. Indeed, mutations in *GNRHR*, which encodes the GnRH receptor, account for 3.5% to 10.4% cases of normosmic HH.^{191,212,213} Interestingly, a case of CDGP has also been associated with a homozygous partial loss-of-function mutation in *GNRHR*,^{204,214} and pedigrees of probands with HH can include individuals with delayed but otherwise normal puberty.

Mutations in *GNRH1* have also been identified in patients with normosmic HH but only in rare case reports.^{192,193,215,216}

Mutations in *KISS1* and *KISS1R*, which encode kisspeptin and its receptor, respectively, are rare causes of IHH. Mutations in the genes encoding neurokinin B and its receptor, *TAC3* and *TACR3*, respectively, have been identified in IHH patients.²¹⁷ As noted previously, these genes are highly expressed in the same neurons that express kisspeptin, emphasizing the role of kisspeptin in the regulation of pubertal timing. The gene for prohormone convertase-1 (*PCSK1*) has been associated with obesity, HH, insulin-deficient diabetes mellitus, and ACTH deficiency, with HH presumably, as a result of defective processing of neuropeptides and prohormones that are components of GnRH secretion.^{193,218} Curiously, patients have been reported to have reversible HH, with achievement of normal reproductive endocrine activity in adulthood, despite carrying loss-of-function mutations in *FGFR1*, *CHD7*, *TAC3*, or *TACR3* genes. The biologic mechanism for this reversible gonadotropin deficiency remains unclear, and it remains possible that some cases of HH may represent severe versions of CDGP, further blurring the distinction between HH and CDGP.^{98,220–222}

Genes That Modulate Gonadotropin-Releasing Hormone Neuronal Function

The adipocyte hormone leptin appears to act as a permissive factor in pubertal maturation, highlighting the importance of adequate nutrition in modulating maturation and function of the HPG axis.⁶⁸ HH accompanied by obesity can result from defects in leptin signaling either because of mutations in the leptin (*LEP*) or the leptin receptor (*LEPR*) genes. Furthermore,

GWA studies have demonstrated that common genetic variants near *LEPR* influence pubertal timing, underscoring the role of leptin in regulating GnRH neuronal activity. The neuronal targets for leptin's action are incompletely explained because leptin receptors are not expressed by GnRH neurons, suggesting that the site of leptin action may be upstream of the GnRH neurons.

Genes Involved in Pituitary Development

Mutations in the GnRH receptor (*GNRHR*) gene are one of the more common causes of normosmic IHH. The phenotype ranges from neonatal presentation with micropHallus and cryptorchidism to adolescent presentation of DP.²²² Mutations in the genes encoding FSH-beta and LH-beta have also been described. Developmental anomalies of pituitary development, such as midline defects or septooptic dysplasia, can be associated with gonadotropin and other pituitary hormone deficiencies. Genes associated with developmental anomalies of the pituitary include *HESX1*, *SOX2*, *PITX2*, *LHX3*, and *PROP1*, as well as some of the genes known to cause HH, such as *FGFR1*, *FGF8*, and *PROKR2*.

Conditions that Affect Both the Hypothalamus and Pituitary Gland

Adrenal hypoplasia congenita is an X-linked disorder caused by mutations in *NROB1/DAX1* and is characterized by primary adrenal insufficiency and a complex pattern of hypogonadism. In this disorder, the fetal adrenal cortex develops normally, but the adult zone of the adrenal cortex fails to develop. Affected males may present with adrenal insufficiency at 6 to 8 weeks of age. If assessed, the minipuberty of infancy may be present,²²³ but patients then exhibit HH in adolescence, and some may present for the first time because of DP. Decreased hypothalamic GnRH secretion or decreased pituitary responsiveness can occur leading to decreased LH, FSH, and testosterone concentrations. Interestingly, patients may also have primary gonadal insufficiency that is masked by the HH. Mutations in this gene may be part of a contiguous gene-deletion syndrome that also causes Duchenne muscular dystrophy and glycerol kinase deficiency.²²⁴ Mutations in *NR5A1/SF-1* may also affect both hypothalamic and pituitary development.

Nongenetic etiologies can also cause HH. Nongenetic factors, such as maternal cocaine abuse, valproate toxicity, and intrauterine vascular disruptive events may cause CNS developmental anomalies and lead to HH. Intracranial tumors can also lead to HH. The most common neoplasm is a craniopharyngioma, which is thought to arise from remnants of Rathke's pouch. Other symptoms can include decreased growth velocity, headache, polyuria/polydipsia, and visual disturbances. Suprasellar or intracellular calcifications may be detected on computed tomography (CT) scans. Other tumors include germ cell tumors, epidermoid and dermoid cysts, prolactinomas, and optic gliomas. Histiocytosis X is characterized by infiltration of lipid-laden histiocytes into skin, bone, or visceral organs. Although diabetes insipidus is the most common endocrine manifestation of histiocytosis X, other anterior pituitary hormone deficiencies may occur.

Hyperprolactinemia can also lead to HH, as prolactin suppresses pulsatile GnRH secretion. Hyperprolactinemia can be caused by a prolactin-secreting tumor, including pituitary microadenomas (adenomas <10 mm) and macroadenomas (>10 mm) and can also be caused by disruption of the pituitary stalk, as hypothalamic dopamine release inhibits prolactin secretion. MRI provides greater anatomic detail than CT scans. Hyperprolactinemia may also be caused by primary hypothyroidism (because thyrotropin-releasing hormone also induces

prolactin secretion) or psychotropic medications with antido-paminergic properties.

Finally, several syndromes are associated with HH. These syndromes include Prader-Willi, Bardet-Biedl, Alström, and Bloom syndromes. Hereditary hemochromatosis leads to iron overload and iron deposition in endocrine organs leading to HH, impaired glucose tolerance, and diabetes mellitus.

Self-limited Delayed Puberty or Constitutional Delay of Growth and Puberty

Self-limited DP or CDGP is a condition in which puberty is late to start but, once started, progresses to full sexual maturity.¹⁸³ Delays may also be seen in other aspects of growth and physical development. Review of growth records often shows that linear growth during the first few years of life decelerates, followed by growth velocity tracking along lower percentiles than expected based on parents' heights during childhood. Skeletal maturation is usually delayed as well. The etiology of self-limited DP is unknown. Suggested causes include increased total energy expenditure²²⁵ and increased insulin sensitivity,²²⁶ but no definitive etiology has been identified.

Self-limited DP does have a strong genetic basis. Fifty percent to 80% of variation of the timing of puberty in humans is caused by genetic factors,⁷⁶ and 50% to 75% of individuals with self-limited DP have a family history of DP.^{227,228} The inheritance patterns observed among pedigrees with self-limited DP are variable but are most often consistent with an autosomal dominant pattern, with or without complete penetrance. Inheritance of self-limited DP is not sex specific and is characterized by family members having either relatively delayed development (e.g., the average age at menarche among mothers of individuals with self-limited DP is 14.3 years compared with a mean of 12.7 among controls³³) or evidence of pubertal timing that would have met clinical criteria for DP.

As discussed earlier, the investigation of etiologies of persistent HH—KS and IHH—has led to the identification of genes that play critical roles in development and regulation of the HPG axis. Some, but not all, studies suggest that mutations in the genes identified to date can also cause self-limited DP, but most cases of self-limited DP are not associated with mutations in IHH/KS genes.^{77,189,229} Loci that are associated with the age of menarche in the general population,^{79–82,231} have also been associated with variation in the timing of puberty in boys,⁸⁶ with some slight sex differences having been noted²³⁰; however, the neuroendocrine pathophysiology and its genetic basis remain unclear in the majority of patients with self-limited DP. The phenotype of self-limited DP represents the tail of a normally distributed trait within the population. Therefore the genetic analyses of families with self-limited DP is complicated by the fact that gene variants that govern the inheritance of this condition can also be found in the general population at a low level, confounding interpretation of data from sequencing studies.

A few studies have specifically examined the contribution of mutations in genes underlying KS/IHH to the phenotype of self-limited DP. In a direct sequencing study that assessed variation in *FGFR1*, *GNRHR*, *TAC3*, and *TACR3* in 146 Finnish subjects, variants in the coding regions of these genes were not identified as likely causes of CDGP in the general population.^{19,229} Similarly, genetic variation in neither *GNRH1* nor *GNRHR* nor other HH-related genes is a common cause of late puberty in the general population.^{77,205,231} Variation in *FGFR1* also does not appear to be a major cause of CDGP,^{77,232} although loss-of-function mutations in *FGFR1* can cause DP in members of HH pedigrees.^{208,213,234–237}

In contrast, another study did identify mutations in *FGFR1*, as well as *HS6ST1* and *Klotho Beta (KLB)*, in some of the kindreds of KS/IHH patients and their relatives with DP phenotype that is not associated with persistent GnRH deficiency.^{208,236,237} In addition, a limited number of variants in KS/IHH genes including *GNRHR*, *TAC3*, *TACR3*, *IL17RD*, *SEMA3* have been discovered by whole exome sequencing in some cases of self-limited DP.²³⁸ However, many of these variants have not been tested in vitro or in vivo for pathogenicity, or investigated for segregation with trait within pedigrees, and thus the finding may be an overestimation of how often KS/IHH genes are found within self-limited DP. Most recently, a comparative study of the frequency of mutations in 24 KS/IHH genes between probands with self-limited DP and those with KS/IHH found a significantly higher proportion of mutations in the KS/IHH group (51% of KS/IHH probands vs. 7% of DP probands, $P = 7.6 \times 10^{-11}$).²³⁹ The same study also reported a higher proportion of oligogenicity in the KS/IHH group, indicating that the genetic architecture of the KS/IHH group was distinct from self-limited DP. In addition, mutations in KS genes, such as *ANOS1* and *NELF*, have not been identified in pedigrees with DP to date.

Thus although the data are at times contradictory, overall, the sum of the available data suggests that although there may be some overlap, either the genetic background of IHH/KS and DP is largely different or it is shared by genes yet to be discovered.²²⁹

Genetic variation in the GnRH receptor gene (*GNRHR*) is another example of partial overlap but mostly distinct pathogenesis. Loss-of-function mutations within the GnRH receptor gene are the most frequent cause of autosomal recessive normosmic IHH, accounting for 16% to 40% of patients.²⁴⁰ On the other hand, variation in self-limited DP is extremely limited. To date, a homozygous partial loss-of-function mutation in *GNRHR* was found in only two brothers, one with self-limited DP and one with normosmic IHH,²⁴¹ and a further heterozygous mutation found in one male with self-limited DP.²²⁹

Genes underlying self-limited DP have recently been reviewed (<https://www.ncbi.nlm.nih.gov/pubmed/?term=31220230>). Whole exome and targeted resequencing methods from a large Finnish cohort have implicated two pathogenic mutations in *immunoglobulin superfamily member 10 (IGSF10)* as the causal factor for self-limited DP in six unrelated families.²⁴² Functional studies indicate that mutations in *IGSF10* appear to cause a dysregulation of GnRH neuronal migration during embryonic development, which presents in adolescence as pure DP, without affecting the prepubertal linear growth rate. Pathogenic *IGSF10* mutations leading to disrupted IGSF10 signaling may result in reduced numbers or mistimed arrival of GnRH neurons at the hypothalamus, suggesting that intact GnRH neurosecretory network is necessary for the correct temporal pacing of puberty. A GnRH neuronal migration defect system might cause an increased “threshold” for the onset of puberty, with an ensuing delay in pubertal timing. *IGSF10* loss-of-function mutations were also discovered in patients with a hypothalamic amenorrhoea. Although loss-of-function mutations in *IGSF10* are also enriched in patients with KS/IHH, these mutations do not alone appear sufficient to cause the phenotype of full GnRH deficiency. These findings represent a new concept of fetal origin of self-limited DP.

Further analysis of individuals from the cohort in which *IGSF10* was identified also provides additional data in support of the partial overlap among KS/IHH and DP genes. A deleterious mutation in the KS/IHH gene *HS6ST1* was found as the causal factor for self-limited DP in one pedigree from the same large cohort of patients with familial DP.²⁴³ The variant was carried by six family members from three generations, all with typical features of self-limited DP. In the same report parallel studies in a murine model corroborated heterozygous *Hs6st1*

deficiency as a cause of delayed pubertal timing without compromised fertility. *Hs6st1*^{+/-} mice were born at normal Mendelian ratios without obvious defects in GnRH neuron or testes development, but they later exhibited delayed pubertal onset. GnRH deficiency was excluded by reproductive competence and by normal spermatogenesis in males. These findings suggest that perturbations in a single allele of a gene regulating the HPG axis are sufficient to cause self-limited DP. Furthermore, data from this example suggest that more deleterious alterations in the same gene, or in combination with additional genes, can cause more severe KS/IHH phenotypes.²⁰⁶

Mutations in genes implicated in body mass and timing of puberty in the general population may also underlie self-limited DP. In a recent study functionally annotated pathogenic, rare variants in *FTO* were found to cause familial self-limited DP in three families.²⁴³ The mutations were also associated with leanness in these subjects.

The neuroendocrine control of puberty is regulated by a hierarchically organized network of transcriptional factors acting upstream of GnRH (Fig. 18.2). These include enhanced at puberty 1 (*EAP1*), which contributes to the initiation of puberty through transactivation of the GnRH promoter. Recently, the first *EAP1* mutations leading to reduced GnRH transcriptional activity resulting in a phenotype of self-limited DP was reported.²⁴⁴

Functional Hypogonadotropic Hypogonadism

Transient causes of HH or functional HH, in which pubertal delay is secondary to effects of underlying conditions, are the cause in 10% to 20% of patients with DP, likely affecting more girls than boys (see Table 18.2).^{186,187} Examples of these conditions include anorexia nervosa, which is a chronic disorder characterized by decreased caloric intake, weight loss, and excessive physical activity. Although anorexia nervosa primarily affects females, approximately 10% of patients are male. Osteopenia and osteoporosis are potential consequences. In addition to low gonadotropin concentrations, cortisol, GH, and reverse T₃ concentrations may be elevated. Chronic disorders, such as sickle cell anemia, thalassemia, cystic fibrosis, inflammatory bowel disease, celiac disease, and chronic renal disease may also be associated with DP. Intensive physical activity and the need to “make weight” in wrestlers may disrupt pubertal development. For wrestlers, these changes generally reverse within months of the end of the wrestling season.

Hypergonadotropic Hypogonadism

Primary gonadal insufficiency leads to loss of negative feedback inhibition and hypergonadotropic hypogonadism. Although they represent only 5% to 10% of the causes of DP, etiologies within this category are broad and include gonadal injury and/or loss, aberrant gonadal differentiation, and disorders affecting steroid hormone synthesis and action. Some disorders, such as Klinefelter syndrome, Noonan syndrome, and Prader-Willi syndrome affect both Leydig and Sertoli cell function.

Chemotherapy, Radiation Therapy, and Cancer Survival

Treatment of childhood cancers can lead to gonadal insufficiency, DP, and infertility. As treatments have improved, quality-of-life concerns have become increasingly relevant because many young cancer patients become long-term cancer survivors. Multiple components of the HPG axis may be affected by chemotherapy and radiation therapy with specific consequences, depending on the drugs and fields of irradiation. The germ cells of the gonads are particularly vulnerable to radiation. Discussions regarding fertility preservation are crucial

for pediatric patients with cancer and their parents; however, detailed discussion of this important subject is beyond the scope of this chapter.

Androgen Insensitivity Syndrome and Gonadal Dysgenesis

Androgen insensitivity syndrome in 46,XY individuals; gonadal dysgenesis in 46,XY individuals or in individuals with mosaicism/chimerism affecting the Y chromosome; and testicular and ovotesticular disorders of sex development in 46,XX individuals can all result in a range of phenotypes. Although many cases present early because of genital ambiguity and/or discordance between genital appearance and a previously established karyotype, some cases may have no obvious external phenotype or a mild phenotype (e.g., isolated hypospadias). In these cases, the condition may not have been recognized as a difference in sex development (DSD), and patients may first present to medical care for evaluation of stalled pubertal development. These conditions, as well as other DSDs, such as those caused by steroidogenic defects that can cause lack of complete endogenous pubertal development, are discussed extensively in [Chapter 6](#).

Syndromes Associated With Delayed or Stalled Puberty

Klinefelter syndrome, which is associated with 47,XXY karyotype, is not a cause of DP per se but can be a cause of a prolonged or stalled pubertal course. The incidence is reported to be one in 667 when ascertained by prenatal cytogenetic analysis, but it is much lower when identified solely by clinical features. Thus incomplete ascertainment of affected individuals likely occurs.²⁴⁶

The typical clinical features of Klinefelter syndrome are small, firm testes; tall stature; small penis; and gynecomastia. Boys with mosaic karyotypes with one normal 46,XY cell line tend to have a milder phenotype. The tall stature may be caused by the extra copy of the short stature homeobox-containing (*SHOX*) gene in the pseudoautosomal region of the X chromosome.²⁴⁷ Both androgen secretion and spermatogenesis are impaired. Inhibin B concentrations are relatively normal during childhood but decline during puberty, consistent with the progressive testicular failure. AMH levels similarly follow the normal male pattern but progressively decline from midadolescence because of Sertoli cell dysfunction.

The decreased testicular volume is secondary to degeneration of the seminiferous tubules. The magnitude of testosterone deficiency and testicular failure varies among affected men, but most men require treatment with testosterone at some point. Treatment goals include development of secondary sexual characteristics, increased muscle mass, optimal bone density, and sexual function.

Apart from decreased number of germ cells, testicular architecture is relatively normal in fetal and prepubertal testes. Loss of germ cells beginning in utero, culminating in fibrosis and hyalinization of the seminiferous tubules, is the proximate cause of the infertility associated with Klinefelter syndrome.²⁴⁸ Fertility preservation is a relevant topic for the older adolescent boys. Some men with Klinefelter's have oligospermia and are able to father children without medical intervention. For others, paternity has been achieved with microdissection and testicular sperm extraction combined with intracytoplasmic sperm injection (microTESE-ICSI), and offspring do not appear to be at increased risk for sex chromosome aneuploidies.²⁴⁹

Nonreproductive features can include an increased incidence of type 2 diabetes, breast cancer, mediastinal tumors, and vascular disease.²⁵⁰ Academic and emotional difficulties are common, and some boys are detected through their learning disabilities. The cognitive phenotype is characterized by deficits in language and executive function. The executive

dysfunction is characterized by poor decision making, problem solving, reasoning, and planning issues. Difficulties with self-control, increased distractibility, and reduced fine- and gross-motor skills are common.²⁵¹

Although much is known,²⁵² there are also several unanswered questions about the management of boys with Klinefelter syndrome. These questions include: does sperm banking/extraction in early adolescence versus young adulthood result in higher success rates? Are behavioral and cognitive deficits improved by administration of testosterone in early childhood or even infancy? Should testosterone be administered in adolescence even if LH values remain in the normal range? These topics are areas of active investigation, and results will influence care of these individuals in the future.

Noonan syndrome is an autosomal dominant disorder characterized by short stature, ptosis, hypertelorism, mild intellectual disability, and congenital heart disease. Cryptorchidism is common in males. Approximately 50% of cases are caused by mutations in the protein-tyrosine phosphatase, nonreceptor type 11 protein (*PTPN11*) gene (also known as *SHP2*). Other genes associated with Noonan syndrome include *KRAS*, *SOS1*, *NRAS*, and *RAF1*. The proteins encoded by these genes are members of the RAS-MAPK signaling pathway. In one longitudinal study, LH, FSH, testosterone, AMH, and inhibin B concentrations were comparable to healthy boys before the onset of puberty. However, some individuals with Noonan syndrome have DP, and adult men with Noonan syndrome have higher LH, FSH, and testosterone concentrations and lower AMH and inhibin B concentrations compared with healthy controls.²⁵³

Prader-Willi syndrome can also be associated with DP. Cryptorchidism is common in boys with Prader-Willi syndrome. Inhibin B concentrations are generally normal in infants and prepubertal boys. As puberty progresses, inhibin B concentrations decline and FSH concentrations increase. Testicular histology is variable and is reported to range from normal to complete absence of spermatogonia (Sertoli cell only syndrome).²⁵⁴ Longitudinal data indicate that the hypogonadism among boys with Prader-Willi syndrome is likely caused by primary testicular dysfunction involving both Sertoli and Leydig cell compartments. Inadequate HPG axis function may also contribute to the hypogonadism.²⁵⁵

Consequences of Delayed Puberty

Sex steroids are essential for the acquisition and maintenance of BMD. Men with IHH have lower BMD, men with Klinefelter syndrome are at increased risk for osteopenia, and some studies have suggested that [this is](#) also true for men with a history of constitutional delay.^{256–258} Mendelian randomization studies have demonstrated that the association between late puberty and BMD is likely causal, that is, that late pubertal timing itself leads to decreased BMD in adulthood.²⁵⁹

Early epidemiological studies demonstrated that earlier pubertal timing is associated with increased risk for cardiovascular disease in adulthood. A larger study has now shown that this relationship is nonlinear in women, such that both early and late pubertal timing demonstrate this increased risk.²⁶⁰ However, data in men suggest that later pubertal timing is protective against cardiovascular outcomes.²⁶¹

Late voice breaking has also been associated with increased risk for psychiatric issues, such as anxiety and depression, as well as atopic conditions, including eczema and asthma.²⁶¹ For all of these associations, one wonders if timely intervention with sex-steroid treatment could lower these risks. One study has demonstrated that earlier age at initiating testosterone treatment was associated with higher BMD in men with IHH²⁵⁷; however, for most of these associations, direct evidence for benefits of sex-steroid treatment on adult disease risk is lacking.

EVALUATION OF THE YOUNG MAN WITH DELAYED PUBERTY

Initial Evaluation

The aim of the initial evaluation is to rule out causes of DP other than CDGP (Table 18.3 and Fig. 18.8). Eventual normal progression of puberty verifies a diagnosis of CDGP, whereas absent or slow development, or cessation of development after onset, is consistent with persistent hypogonadism. Whether caused by a referral bias or by differences in underlying biology,⁵⁵ more boys than girls are seen in endocrinology clinics for DP in general and CDGP in particular.¹⁸⁶

History

The medical history should inquire about chronic diseases, such as inflammatory bowel disease, sickle cell disease, celiac disease, asthma, chronic renal failure, cardiac disease; endocrine disorders, such as hypothyroidism and poorly controlled diabetes mellitus; and chronic therapy with glucocorticoids,²⁶² all of which may delay both linear growth and puberty. Inadequate nutritional intake, when associated with conditions, such as cystic fibrosis, anorexia nervosa, or excessive energy utilization²²⁵ because of vigorous exercise in athletes or ballet dancers, may result in pubertal delay. Successful intervention in such situations can be followed by catch-up growth and pubertal progression.

TABLE 18.3 Investigations for Delayed Puberty

FIRST-LINE INVESTIGATIONS		
Variable	Requirements and Limitations	Interpretation
Growth rate	Two or more height measurements, preferably 6–12 months apart.	In early adolescence in both sexes a growth rate less than 3 cm/year is suggestive of a disease specifically inhibiting growth (e.g., GH deficiency, hypercortisolism, hypothyroidism), but such rates can also be seen in CDGP. Boys with delayed puberty who are overweight tend to have height and predicted adult consistent with the genetic height potential. ^{9,22,62}
Tanner stages	Pubic hair stages and genital stages should be scored separately because they do not necessarily track together	Testicular volume of ≥ 4 mL is a more reliable indicator of the onset of puberty than Tanner stage 2 genital development.
Testis volume	Prader's orchidometer or a ruler	Testicular volume of ≥ 4 mL (≥ 2.5 cm in length) indicates central puberty. Most healthy boys with a testicular volume 4 mL or greater will have a further increase in testicular volume, pubic hair stage, or both, at repeated examination 6 months later. ⁶¹
Bone age	X-ray of left hand and wrist. Greulich and Pyle Atlas. Bone age is also used to predict adult height.	A bone age delay of more than 2 years has arbitrarily been used as a criterion for CDGP but is not always present and is also not specific to that condition. A bone age delay of 4 years has been associated with an average of 8 cm over prediction of adult height, whereas in short stature with no bone age delay, adult height is usually underestimated by the Bayley-Pinneau tables. ³¹²
Biochemistry	Evaluation varies but common tests include complete blood count, erythrocyte sedimentation rate, creatinine, electrolytes, thyrotropin, and free thyroxine.	To rule out chronic disorders evaluation should be directed based on history and physical examination because the yield of untargeted screening is low. Additional investigations may be necessary based on family history, symptoms, and signs, including screening for celiac disease and inflammatory bowel disease.
Serum luteinizing hormone (LH)	Morning sample. Use immunochemiluminometric (ICMA) or immunofluorometric (IFMA) assays with a lower limit of detection at or below 0.1 IU/L.	At low levels, values obtained on ICMA are at least 50% lower than those by IFMA. ²⁷¹ Values < 0.1 IU/L are not specific for hypogonadotropic hypogonadism. Value > 0.6 (IFMA) or 0.2 (ICMA) IU/L is specific but not sensitive for the initiation of central puberty, because in early puberty some adolescents have lower values. ²⁷¹ In delayed puberty, elevated values suggest primary hypogonadism.
Serum follicle-stimulating hormone (FSH)	Morning sample. Use ICMA or IFMA assays with a lower limit of detection at or below 0.1 IU/L if possible.	At low levels, values obtained on ICMA are $\sim 50\%$ lower than those by IFMA. Values < 0.2 (ICMA) or < 1 (IFMA) IU/L suggest hypogonadotropic hypogonadism but are not diagnostic. ^{270,271} In delayed puberty, a value above the upper limit of normal for the assay is a marker of inhibin B deficiency and of primary gonadal insufficiency with high sensitivity and specificity.
Serum insulin-like growth factor 1 (IGF-1)	Blood samples should be processed within 2 h to avoid an artifactual increase in results. Only assays that recognize IGF-1 without any interference from IGF binding proteins provide reliable results.	IGF-1 level is used to screen for GH deficiency. An increase in the levels during follow-up or during or after treatment with sex steroids makes the diagnosis of GH deficiency less likely. The IGF-1 concentration shows the greatest change during childhood and puberty and then changes more slowly with advancing age. Therefore normal values for children and adolescents should include narrow age ranges and Tanner stages. GH provocation tests are needed to diagnose GH deficiency.
Serum testosterone	Morning sample is ideal. Use an assay with a lower limit of detection at or below 10 ng/dL (0.35 nmol/L) if possible. Concentrations show diurnal variation.	An 8 am serum testosterone value of ≥ 20 ng/dL (0.7 nmol/L) often predicts the appearance of pubertal signs within 12 to 15 months. ³¹³
SECOND-LINE INVESTIGATIONS		
Variable	Requirements and Limitations	Interpretation
Gonadotropin-releasing hormone (GnRH) test ^a	Assay requirements are the same as for basal LH and FSH. Test can be performed any time of day. LH and FSH values vary according to assay used and with the stimulating agent (GnRH or GnRH agonist)	A predominant LH over FSH response after GnRH stimulation or peak LH levels of 5 to 8 IU/L (depending on assay) suggests onset of central puberty. There is an overlap between prepubertal and early pubertal post-GnRH values. ²⁷¹ A prepubertal response is seen in some patients with CDGP as well as in hypogonadotropic hypogonadism, but a post-GnRH LH value < 0.8 IU (IFMA) and FSH value < 1.1 IU/L (IFMA) may be more consistent with hypogonadotropic hypogonadism in boys. ²⁷¹

Continued

TABLE 18.3 Investigations for Delayed Puberty—cont'd

Human chorionic gonadotropin (hCG) test ^a	IM or SC injections on several days. There are number of different protocols available. Results vary by the protocol.	Peak testosterone concentrations to both 3-d and 19-d hCG tests have been reported to be significantly lower in patients with hypogonadotropic hypogonadism compared with CDGP. A combination of the GnRH test and hCG test (peak LH cutoff, 2.8 U/L; peak 19-d testosterone cutoff, 275 ng/dL [9.5 nmol/L]) gave a sensitivity and a specificity of 100% in a small study of CDGP and hypogonadotropic hypogonadism. ³¹⁴
Serum inhibin B ^a	Can be measured any time of day. Has diagnostic value only in boys.	Measurement is used in differentiation of hypogonadotropic hypogonadism from CDGP. Boys with higher baseline inhibin B levels had a higher likelihood of CDGP in one study. ²⁷² In prepubertal boys, sensitivity and specificity of 100% was obtained at concentration of >35 pg/mL. With Tanner stage 2 genitalia, sensitivities were 86% and 80%, and specificities 92% and 88%, respectively, for CDGP with an inhibin B value of >65 pg/mL. In boys, unmeasurable inhibin B indicates testicular insufficiency.
Serum prolactin	Measurement is indicated only in some cases. Physiologic states including stress, exercise, and sleep can increase prolactin levels, as can hypothyroidism and some medications.	Elevated levels may indicate either a prolactin-secreting tumor or disruption of the pituitary stalk, in which case additional pituitary-hormone deficiencies may be present. Macroprolactin (physiologically inactive form of prolactin) measurement is recommended as additional test in patients with hyperprolactinemia.
Brain magnetic resonance imaging (MRI)	Indicated in any suspicion of CNS pathology (e.g., headache, changes in vision, changes in behavior).	Imaging is primarily performed to rule out lesions of the hypothalamic-pituitary region. Other findings may include aplasia or hypoplasia of the olfactory bulb and sulcus in patients with Kallmann syndrome, which may help differentiate the Kallmann syndrome from isolated hypogonadotropic hypogonadism in patients with an apparently normal or difficult-to-evaluate sense of smell. In hypogonadotropic hypogonadism there is a moderate agreement between the MRI of the olfactory bulbs and formal smell testing (overall Kappa 0.5), but in the presence of aplastic bulbs and anosmia, there is good agreement (Kappa 0.9).
Olfactory function test	One test, UPSIT, ³¹⁵ uses microencapsulated odorants, which are released by scratching standardized odor-impregnated test booklets.	Used to assess for hyposmia and anosmia as part of evaluation for Kallmann syndrome.
Genetic testing	In more than 60% of patients with Kallmann syndrome or isolated hypogonadotropic hypogonadism no specific gene defect is found.	Genotyping for known monogenic causes is currently a research procedure and not warranted in routine clinical practice. It may be warranted when there is a positive family history or the patient has phenotypic signs suggestive of a specific mutation. If performed, genetic testing should be accompanied by genetic counseling.
GH testing	Various protocols both for testing and priming are available. The choice of GH stimuli to be used is variable.	Response in GH provocation test is greater after the administration of exogenous (aromatizable) androgens or estrogens (priming). Reliable assay performance and appropriate normative data are critical for appropriate use of GH and IGF-1 measurements.
Karyotype		Diagnostic of Klinefelter syndrome

^aThese tests are used to try to differentiate CDGP and IHH. However, validation in larger, independent studies is needed before they can be endorsed for routine clinical use.^{268,269} Clinical follow-up is often needed to confirm the diagnosis; no endogenous puberty by age 18 years is diagnostic of IHH. CDGP, Constitutional delay of growth and puberty; CNS, central nervous system; GH, growth hormone; IM, intramuscular; SC, subcutaneous; UPSIT, University of Pennsylvania smell identification test. (Modified from Palmert, M. R., Dunkel, L. (2012). Clinical practice. Delayed puberty. *N Engl J Med*, 366, 443–453.)

Delayed cognitive development associated with obesity or dysmorphic features may suggest an underlying genetic syndrome. Cryptorchidism or small penis at birth, hyposmia, or anosmia may suggest HH. A history of chemo- or radiotherapy may indicate primary gonadal failure. However, some patients receiving treatment for malignancy may have elevated gonadotropin levels during and shortly after therapy, but subsequently, the gonadotropin levels may decrease as these patients can experience varying degrees of gonadal recovery. As noted previously, although Klinefelter syndrome is a type of hypergonadotropic hypogonadism, males with this condition commonly present with unusually small testes, lack of pubertal progression, or infertility rather than pubertal delay.

A family history—including childhood growth patterns, age at pubertal onset of the parents, and infertility—should be obtained. DP in a parent or sibling, regardless of gender, followed by spontaneous onset of puberty suggests CDGP. However, if pubertal development was induced by sex steroids in family members, IHH is also possible, as reversal of hypogonadism is noted after discontinuation of sex steroids in 10% or more of IHH cases.^{219,220}

Physical Examination

Previous height and weight measurements should be obtained and plotted so that longitudinal growth can be carefully assessed. Height, weight, and body proportions should be determined. Compared with previous data, height and weight can be used to calculate annual growth rates, preferably based on a 12-month interval, as intervals less than 4 to 6 months can be inadequate. DP is often associated with short stature and slow growth for age and for midparental target height, although height and growth rate are usually within the normal prepubertal range. Individuals who are underweight for height have a higher likelihood of an underlying condition delaying HPG axis activation. Conversely, in boys, unlike girls, being obese can be associated with later pubertal development as discussed previously.^{92,263} Upper-to-lower segment ratio can be determined by measuring sitting height or lower segment (from top of pubic symphysis to floor) and compared with normal for age: ratio decreases with age to 1 or lower depending on racial group. Arm span (fingertip to fingertip) should be within 5 cm of the standing height. Longer limbs suggest hypogonadism.

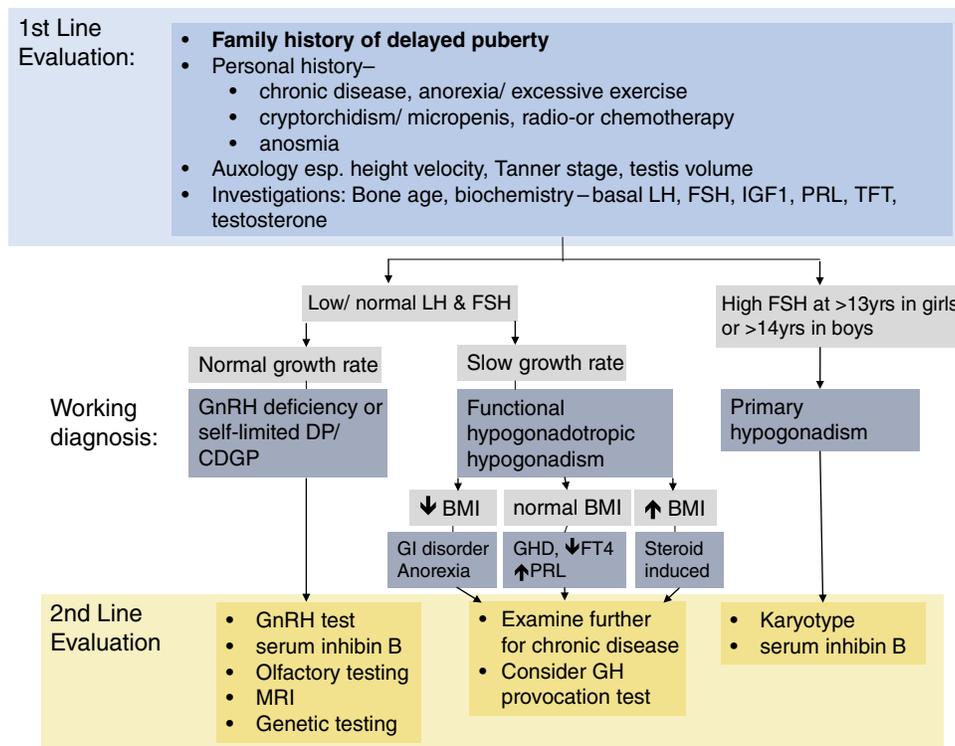

Fig. 18.8 Flowchart for the evaluation of a patient with delayed puberty. *BMI*, body mass index; *CDGP*, constitutional delay of growth and puberty; *DP*, delayed puberty; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *GHD*, growth hormone deficiency; *GI*, gastrointestinal; *GnRH*, gonadotropin-releasing hormone; *IGF-1*, insulin-like growth factor 1; *LH*, luteinizing hormone; *MRI*, magnetic resonance imaging; *PRL*, prolactin; *TFT*, thyroid function tests. (Modified from Palmert, M. R., & Dunkel, L. [2012]. Clinical practice: delayed puberty. *N Engl J Med*, 366, 443–453.)¹⁷⁹

The physical examination should also concentrate on identifying markers of chronic disease, malnutrition, neurologic abnormalities, thyroid and other endocrinopathies, and syndromic features. In boys, in addition to determining height, weight, and skeletal proportions, documentation should include assessment of penile size, using a stretched length if necessary, position of urethral opening, testicular size, and whether both testes are present in a normally developed scrotum. Cryptorchidism, bifid scrotum, micropenis, or perineoscrotal hypospadias may indicate a disorder of sex development because of defects in gonadal development or gonadal steroidogenesis. Small testes, eunuchoid habitus, and gynecomastia suggest Klinefelter syndrome. The presence of an abnormal neurological examination and/or visual field deficits raises concern for a space-occupying lesion of the hypothalamic-pituitary region. Obesity and DP may suggest defects in the prohormone convertase 1 (*PCSK1*), leptin, or leptin receptor genes. When obesity is associated with DP and dysmorphic features, it suggests Prader-Willi, Bardet-Biedl, or other genetic syndromes.

In boys, Tanner stage 2 genitalia mark the onset of pubertal development and are characterized by enlargement of scrotum and testes and by a change in the texture and color of the scrotal skin (see Fig. 18.5). Pubic hair stage and testicular volume should also be measured; a testicular volume of 4 mL or more indicates the initiation of central puberty. As with assessment of precocious puberty, some find use of “puberty plots” that assess stages of development compared with population data useful (see Fig. 18.6). In patients with CDGP, both adrenarche and hormonal activation of the gonads often occur later than average, but in isolated HH adrenarche usually occurs at a normal age.^{186,264}

Testing

The history and physical examination should direct the laboratory and radiologic studies so that a parsimonious, cost-effective evaluation is performed. **Certainly**, not all tests need to be performed in all individuals.^{265,266}

An individual who is experienced in interpreting bone ages should review these x-rays. A delay in bone age is characteristic of CDGP but is not diagnostic, as a delayed bone age may also occur in individuals with chronic illness, HH, or gonadal failure. Adult height prediction is an important part of counseling if short stature is a component of the presentation, and practitioners need to be aware that the Bayley-Pinneau tables overestimate adult height in patients with CDGP if bone age is delayed by more than 2 years (see Table 18.3).

Pubertal onset is characterized by accentuation of diurnal gonadotropin and testosterone secretion before apparent phenotypic changes. Basal LH and FSH levels are low in CDGP and in HH, whereas they are usually elevated in gonadal failure. In general, LH is a better marker of pubertal initiation than FSH, and FSH is a better marker of gonadal failure than LH. Serum IGF-1 concentrations can help in the evaluation of GH deficiency but must be interpreted carefully because levels are often low for chronologic age but within normal range for bone age in patients with DP. Thyroid function tests are often obtained but may not be necessary in the absence of any signs or symptoms of thyroid disease other than DP.

Brain and pituitary MRI may be indicated when there are signs or symptoms to suggest a CNS lesion. Otherwise, although some clinicians obtain brain imaging routinely, a reasonable strategy is to defer this test until age 15 years,

at which point many patients with CDGP will have spontaneously begun puberty and will require no further evaluation. Full neuroendocrine testing is warranted in patients with hypothalamic-pituitary tumors causing HH, as affected individuals may have additional pituitary hormone deficiencies. Assessment of olfactory bulbs on MRI may be helpful in patients with HH and anosmia, although there have been reports of patients with normal reproductive endocrine function despite anosmia and absence of olfactory bulbs.²⁶⁷

Additional Evaluation

Most boys will not have an apparent alternative cause for DP on initial evaluation, suggesting CDGP as the likely diagnosis. However, no current test can reliably distinguish CDGP from IHH, so the diagnosis of CDGP cannot be made with certainty.^{268,269} Observation usually resolves this conundrum; IHH is diagnosed if endogenous puberty has not begun by age 18 years. Several tests have been proposed to distinguish CDGP from IHH (see Table 18.3). If basal gonadotropin levels are inconclusive, some have suggested that stimulation by GnRH or a GnRH agonist may be helpful.^{270,271} Stimulated LH levels in the pubertal range indicate reactivation of the HPG axis and suggest that secondary sexual development is likely to occur within 1 year. However, the GnRH test alone often cannot differentiate CDGP from HH because prepubertal values may be observed both in HH and in individuals with CDGP who have not yet activated the HPG axis. Furthermore, individuals with HH experiencing stalled pubertal development will exhibit pubertal responses to GnRH. Data suggest that baseline inhibin B levels may facilitate discrimination between these conditions.^{272,273} Low inhibin B levels may predict IHH, but some adults with HH have normal inhibin B levels. Interestingly, recent data indicate that testicular volume may be as good as stimulated LH and inhibin B levels at distinguishing CDGP from HH.^{186,187} Thus further experience is needed before these additional biochemical tests can be adopted routinely.

GH secretion in the basal state, as well as after provocative testing, may be decreased in individuals with CDGP compared with pubertal peers. If concerns about growth are sufficient to warrant GH stimulation testing, sex-steroid priming with estrogen or testosterone is necessary for reliable results in patients with DP; estrogen stimulates endogenous GH secretion, and sex-steroid priming facilitates separation of true GH deficiency from physiologic low GH secretion that stems from low circulating sex steroids. Another strategy of assessing for true GH deficiency is to remeasure IGF-1 levels after the initiation of testosterone therapy. If IGF-1 increases appropriately with administration of testosterone, then true GH deficiency is less likely. If a patient has normal growth rate, GH provocation tests are not necessary, whereas low IGF-1 levels together with reduced growth velocity warrant testing.

TREATMENT OF DELAYED PUBERTY

The main options for management of CDGP include expectant observation or therapy with low-dose testosterone (Table 18.4 and recent reviews^{4,179,274,275}). If puberty has started, clinically or biochemically, and stature is not a major concern, reassurance with realistic adult height prediction is frequently all that is needed. If therapy is initiated, it is usually to assuage psychosocial difficulties that may derive from negative interactions with peers, decreased self-esteem, and anxiety about growth rate or body habitus.¹⁷⁹ Therapy is usually not initiated solely for medical reasons, such as accrual of bone mass. However,

conflicting data regarding the effect of pubertal timing on bone mass suggest that additional data are needed to determine definitively whether medical reasons to initiate therapy should be given more consideration.¹⁸⁵

Since the 1980s, there have been numerous studies of treatment of CDGP in boys, mostly involving treatment with short courses of low-dose androgens. There are limited randomized controlled trials, most with small numbers of subjects, but data from these and other studies strongly suggest that treatment leads to increased growth velocity and sexual maturation and positively affects psychosocial well-being without significant side effects, rapid advancement of bone age, or reduction of adult height.^{276–279} For boys who elect to be treated, we initiate supplementation with 50 mg testosterone enanthate or cypionate intramuscular (IM) each month for 3 to 6 months, which can be repeated for another 3 to 6 months with dose escalation (see Table 18.4). Although administration of IM testosterone esters is the mainstay of treatment, IM injections are painful and may require frequent healthcare visits for administration; moreover, serum testosterone levels lack diurnal rhythm and are characterized by nonphysiologic peaks and troughs. Hence there is rationale for alternative approaches, including subcutaneous testosterone injections²⁸⁰; oral androgens, such as testosterone undecanoate²⁸¹; and transdermal testosterone gels.^{282–284} The use of testosterone gels during the initiation of secondary sexual characteristics is somewhat limited by the requirement for low doses that can be delivered reproducibly. Novel therapies, such as synthetic kisspeptin,^{285,286} are also being explored. Although promising, additional data and experience are needed before these alternatives can be recommended for routine management in place of testosterone esters.

If spontaneous puberty has not occurred after 1 year, other diagnoses, such as persistent HH, should be reconsidered, and an MRI of the brain may be indicated. With lack of endogenous puberty, doses of testosterone can be gradually advanced toward adult levels, while still assessing (examination of testicular size, measurement of LH, FSH and testosterone) every 6 months for evidence of spontaneous puberty.

For a subset of patients with CDGP, short stature can be more concerning than DP, and indeed in idiopathic short stature (ISS) there is a component of pubertal delay in many of the subjects.²⁸⁷ Although the US Food and Drug Administration (FDA) has approved the use of GH for the treatment of ISS and height SDS 2.25 (or less) for age, this therapy has at best a modest effect on adult height in adolescents with CDGP, and its routine use in CDGP is not recommended.²⁸⁸ Nor do we use anabolic steroids, such as oxandrolone, for treatment of DP. Its use for treatment of ISS was not endorsed by the Consensus Statement,²⁸⁷ and it is rare that boys after age 14 years are not concerned about the lack of pubertal changes, which cannot be induced by oxandrolone because of its weak androgenic effects.

In boys with CDGP and short stature, another potential therapeutic approach is aromatase inhibition.^{289,290} AIs inhibit conversion of androgens to estrogens. Because estrogen is the predominant hormone needed for epiphyseal closure, AIs could prolong linear growth and potentially increase adult height.²⁹¹ In controlled trials in boys with short stature or DP,^{289,290} or GH deficiency,²⁹² AIs have been shown to delay bone maturation and increase predicted adult height. However, adult heights have not been reported from all studies, and characteristics of patients who respond and those who do not as well as the optimal timing, dose, and duration of AI treatment remain unresolved.²⁹³

A complete profile of the potential side effects associated with the use of AIs has not been established.²⁹⁴ Testosterone levels are elevated during AI therapy, and erythrocytosis has been observed in pubertal boys treated with AIs and in men

TABLE 18.4 Medications Used for the Treatment of Constitutional Delay of Growth and Puberty and Persistent Hypogonadism

Drug and Formulation	Treatment of Boys Recommended Dose		Side Effects and Cautions
	CDGP	HYPOGONADISM	
Testosterone ^a			Erythrocytosis, weight gain, prostate hyperplasia. High doses can cause premature epiphyseal closure. Not for use in boys with bone age < 10 years
Testosterone enanthate, cypionate, and propionate Testosterone enanthate has longer duration of effect than testosterone propionate. Intramuscular injection.	Not initiated until diagnosis of delayed puberty is made (~age 13.5–14 yrs). Initial dose 50–100 mg every 4 weeks for 3 to 6 months. If no signs of endogenous puberty after one course, consider repeat treatment with 25–50 mg increment in dose (not exceeding 100 mg).	Can initiate at age to allow puberty to occur in concert with peers at 50 mg every 4 weeks. Increase with 50-mg increments every 6 to 12 months. After reaching 100–150 mg monthly, decrease interval to every 2 weeks. Adult dose ~100–200 mg every 2 weeks IM or 80 mg SC weekly.	All intramuscular preparations: local side effects (pain, erythema, inflammatory reaction and sterile abscess). Priapism can occur in patients with sickle cell disease.
Testosterone undecanoate Intramuscular injection	No data available	Adult dose is 1000 mg every 10–14 weeks	
Testosterone gel Transdermal preparations, applied topically at bedtime.	No data available	Can be started when ~50% adult dose with intramuscular testosterone has been achieved. Adult dose 50–80 mg daily.	Local irritation. After applying, avoid close skin contact with others, and gel must be completely dry before putting on clothes.
Aromatase Inhibitors			Not yet approved for this indication. After onset of puberty, may increase gonadotropin secretion and circulating T levels. ³¹⁶
Letrozole PO	2.5 mg daily	Not recommended	Decreased level of high-density lipoprotein cholesterol, erythrocytosis, vertebral deformities have been reported. ¹⁷⁸
Anastrozole PO	1 mg daily	Not recommended	Less potent than letrozole
Pulsatile GnRH Subcutaneous pump ^b	Not recommended routinely	Initial: 5–25 ng/kg/pulse every 90–120 min; increase to 25–600 ng/kg/pulse	Requires extensive experience. Most physiologic form of replacement.
hCG plus recombinant FSH Subcutaneous or intramuscular hCG injections Subcutaneous rhFSH injections ^b	Not recommended routinely	hCG: dose 500 to 3000 IU twice weekly, increased to every 2 days. Dose adjusted based on serum T levels rhFSH: dose 75 to 225 IU 2–3 times weekly.	hCG: inflammation locally in the testis, may induce apoptosis of germ cells. In hypogonadotropic hypogonadism with prepubertal onset it is necessary to add FSH to induce testicular growth and spermatogenesis. No data on effects on future fertility.

^aTestosterone undecanoate tablets and anabolic steroids are not recommended for the induction of secondary sexual characteristics.

^bInduction of fertility may be less successful in men who have lower baseline testicular volumes, have received previously testosterone treatment,²⁹⁹ and have not previously received treatment with GnRH,^{296,297} or gonadotropins.²⁹⁶

CDGP, Constitutional delay of growth and puberty; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; IM, intramuscular; PO, orally; rhFSH, recombinant human follicle-stimulating hormone; SC, subcutaneous.

(Modified from Palmert, M. R., Dunkel, L. (2012). Clinical practice. Delayed puberty. *N Engl J Med*, 366, 443–453.)

with aromatase deficiency. Theoretical risks include a decline in adiponectin and subsequent development of nonalcoholic hepatic steatosis. Letrozole has no apparent adverse effects on BMD in adolescents. However, estrogen deficiency and letrozole treatment have been associated with impaired trabecular bone development in boys with ISS, and letrozole treatment during prepuberty or early puberty has also been associated with increased risk of vertebral body deformities.¹⁷⁸ Thus the use of AIs, even in adolescents with compromised predicted adult height, requires further careful study.²⁹⁵

In boys with persistent hypogonadism, the initial sex-steroid therapy is the same as for CDGP except that in cases of known defects therapy can be initiated at younger ages. Testosterone doses are gradually increased to full adult replacement levels over approximately 3 years (see Table 18.4). During the last year of dose escalation, the interval of

testosterone ester administration is decreased from once each month to once every 2 weeks, with a typical regimen for adult replacement being 100 to 200 mg IM every 2 weeks or 80 mg subcutaneously weekly. Transdermal preparations can be initiated during the final stages of dose escalation, if preferred. In HH, exogenous testosterone does not induce testicular growth or spermatogenesis. Thus if male patients with persistent HH wish to father a child or achieve increased testicular volume, induction of testicular growth and fertility can be accomplished through treatment with exogenous gonadotropins;²⁹⁶ in hypothalamic disorders, pulsatile GnRH can be also be used if available,^{296–299} (see Table 18.4). It remains an area of uncertainty whether fertility outcomes would be improved if GnRH and/or gonadotropins were used to induce puberty instead of waiting to administer these agents in adulthood.^{4,274,275,300–302}

In some cases of hypergonadotropic hypogonadism, individuals may still be able to father children using assisted reproductive technologies, such as intracytoplasmic sperm injection (ICSI), although this technology may be associated with a slightly increased risk of birth defects.³⁰³ In cases where ICSI is not desired or not feasible, adoption and in vitro fertilization using donor sperm provide additional options for those wanting to have children. As noted earlier, fertility preservation is an important topic for boys with Klinefelter syndrome and those with malignancies.

GYNECOMASTIA

Gynecomastia deserves discussion, although it is not necessarily associated with alterations in pubertal timing. Physical examination is extremely important in the evaluation of gynecomastia to distinguish among true gynecomastia, pseudogynecomastia, and pathologic gynecomastia. With the patient lying supine with his hands clasped beneath his head, the examiner can slowly compress the breast area between forefinger and thumb beginning from the sides of the breast. In true gynecomastia, the breast tissue is located concentrically under the nipple-areolar complex, feels rubbery or firm, and is often bilateral. During the early phase, ductal and epithelial proliferation occurs. This early proliferation is associated with periductal inflammation and edema, which correspond to the tenderness noted by the patient.²⁵⁴

The differential diagnosis includes lipomastia or pseudogynecomastia that is characterized by breast fullness and the absence of a nipple-areolar complex mound, such that the rib cage can be palpated under the areolae. Lipomas and neurofibromas can occur in the breast. Although extremely rare in adolescents, breast cancer feels firm or hard and is often located outside the nipple-areolar complex. Nipple discharge, skin dimpling, and nipple retraction do not occur in physiologic gynecomastia.

Pubertal or physiologic gynecomastia is a common midpubertal finding noted at Tanner stage 3 to stage 4 for pubic hair.³⁰⁴ Pubertal gynecomastia has been attributed to a relative and transient imbalance in the testosterone to estradiol ratio. With the progression of puberty and rising testosterone concentrations, the gynecomastia typically resolves or at least stabilizes.

Medications, exposures, and rare hormone disorders are associated with pathologic gynecomastia. Medications associated with gynecomastia include spironolactone, cimetidine, ketoconazole, estrogens, antiandrogens, GH, GnRH analogs, and 5 α -reductase inhibitors.³⁰⁵ Exposures to estrogen-containing substances, such as lavender and tea tree oils, and phytoestrogens have been considered to be etiologies. Other drugs associated with gynecomastia include tricyclic antidepressants, chemotherapeutic agents, and cardiovascular medications (e.g., digitalis). Drugs of abuse associated with gynecomastia include marijuana, ethanol, heroin, and amphetamines.

Estrogen excess can cause pathologic gynecomastia. Autosomal dominant mutations in the aromatase (*CYP19A1*) gene result in constitutively increased gene transcription and overexpression of the aromatase enzyme.³⁰⁶ Feminizing tumors can directly secrete estrogen. Peutz-Jeghers syndrome (PJS) is characterized by mucocutaneous pigmentation, multiple gastrointestinal polyps, and a variety of neoplasms. Gynecomastia has been described in prepubertal boys secondary to large cell calcifying Sertoli cell tumors associated with PJS or Carney complex.³⁰⁷ Gynecomastia can occur in other conditions including hyperthyroidism, hypogonadism, Klinefelter syndrome, androgen insensitivity, and ovotesticular disorder.³⁰⁸ Additional associations include obesity and liver disease.

Gynecomastia in a prepubertal boy is pathologic and warrants investigation. In contrast, gynecomastia occurring in a

midpubertal boy who is otherwise healthy most likely represents physiologic gynecomastia for which an extensive laboratory evaluation is unwarranted. Physiologic gynecomastia is typically self-limited. If present, treatment of the underlying disorder or removal of environmental causes is appropriate and may lead to regression of the breast tissue. AIs and estrogen receptor blockers have been used. An open label study concluded that anastrozole reduced breast size.³⁰⁹ However, the single randomized double-blind, placebo-controlled pediatric trial noted that anastrozole was no more effective than placebo to reduce gynecomastia, indicating that its routine use cannot be recommended.³¹⁰ If the gynecomastia is persistent and particularly troubling to the youth, surgical reduction can be pursued.

CONCLUSION

The foundations for the pubertal process are laid during gestation with the differentiation and development of the components of the HPG axis. The tools of molecular biology and molecular genetics have brought research into the factors governing the timing and tempo of puberty to the forefront of reproductive endocrinology. The identification of novel genes associated with pubertal disorders has generated more questions regarding the elusive critical components governing GnRH and gonadotropin secretion. Additional new discoveries about HPG axis regulation will further enhance our understanding of normal variation in pubertal timing and provide further insight into the etiology and treatment of pubertal disorders.

INTRODUCTION

Concurrent with increasing public awareness of individuals whose gender identity is not aligned with their physical sex characteristics, there has been an increasing number of gender nonconforming/transgender youth seeking medical services to enable the development of physical characteristics consistent with their experienced gender. In eligible individuals, current clinical practice guidelines endorse use of agents to block endogenous puberty at Tanner stage 2 development with subsequent use of gender-affirming sex hormones, and are based on longitudinal studies demonstrating that youth first identified as gender dysphoric in childhood and who continue to meet mental health criteria for gender dysphoria (GD)/gender incongruence (GI) at early puberty are likely to be transgender as adults. Limited outcomes data support current practice and long-term studies are necessary to optimize care. This chapter reviews definitions relevant to gender nonconforming/transgender youth, epidemiology, developmental trajectories of gender, evidence supporting a role for biology in gender identity development, mental health comorbidities associated with GD, current treatment models, barriers to care, and priorities for research.

DEFINITIONS AND EPIDEMIOLOGY

According to the *Merriam-Webster's Medical Dictionary*, sex and gender have distinct meanings. Sex refers to "either of two major forms of individuals that occur in many species and that are distinguished respectively as female or male, especially on the basis of their reproductive organs and structures." In contrast, gender refers to the "behavioral, cultural, or psychological traits typically associated with one sex." Gender itself is then subdivided into gender identity and gender role/behavior. Gender identity is a person's internal sense of being male or female, whereas gender role is the expression of masculinity or femininity.¹ There has been increasing recognition that gender identity exists on a spectrum and that some individuals identify as nonbinary.^{2,3} Sexual orientation is one's sexual attraction toward partners of the opposite sex/gender (heterosexual), same sex/gender (homosexual), or both (bisexual). Gender identity does not predict sexual orientation. A person of any gender may have any sexual orientation.

"Gender Dysphoria," listed in the *Diagnostic and Statistical Manual of Mental Disorders (DSM) V* refers to clinically significant distress of at least 6 months, duration, related to the incongruence between one's affirmed or experienced gender and one's "assigned (or natal) gender" (gender incongruence).⁴ This term replaces *gender identity disorder (GID)*, which was included in the earlier DSM IV. Replacing the term "disorder" with "dysphoria" underscores the concept that a transgender identity, in and of itself, is no longer considered pathological, and focuses clinical concern on the distress that an individual with GI may experience. A summary of terms used in this chapter is detailed in [Box 19.1](#).

A 2017 report from the Williams Institute of the University of California Los Angeles School of Law, informed by state level population-based surveys, indicated that 0.6% of US adults (25–64 years) and 0.7% of adolescents and young adults (13–24 years) identify as transgender.⁵ A population-based study of self-reported gender identity in 80,929 Minnesota high school students reported a prevalence of 2.7% gender nonconforming or transgender.⁶ Transgender prevalence estimates ranging from 0.5% to 1.3% of birth-assigned males and 0.4% to 1.2% of birth-assigned females have been reported in a recent international review, representing an estimate of 25 million transgender people worldwide.⁷ In recent years, there has been a striking inversion in the sex ratio of adolescents seeking services for GD, with a predominance of birth-assigned females.⁸

BIOLOGICAL DETERMINANTS OF GENDER IDENTITY

Studies from several biomedical disciplines—genetics, endocrinology, and neurology—support the concept that there are biological underpinnings to gender identity development. Results of these studies support the concept that gender identity is not simply a psychosocial construct but likely reflects a complex interplay of biological, environmental, and cultural factors.⁹

With respect to genetics and gender identity, a recent study reports heritability estimates for gender identity in the range of 30% to 60%.¹⁰ A study supporting a role for genetic factors in gender identity outcome in transgender individuals

BOX 19.1 Definitions of Terms Used in This Chapter

Biological sex, biological male or female: These terms refer to physical aspects of maleness and femaleness. As these may not be in line with each other (e.g., a person with XY chromosomes may have female-appearing genitalia), the terms biological sex and biological male or female are imprecise and should be avoided.

Cisgender: This means not transgender. An alternative way to describe individuals who are not transgender is “nontransgender people.”

Gender-affirming (hormone) treatment: See “gender reassignment”

Gender dysphoria: This is the distress and unease experienced if gender identity and designated gender are not completely congruent. In 2013 the American Psychiatric Association released the fifth edition of the DSM-5, which replaced “gender identity disorder” with “gender dysphoria” and changed the criteria for diagnosis.

Gender expression: This refers to external manifestations of gender, expressed through one’s name, pronouns, clothing, haircut, behavior, voice, or body characteristics. Typically, transgender people seek to make their gender expression align with their gender identity, rather than their designated gender.

Gender identity/experienced gender: This refers to one’s internal, deeply held sense of gender. For transgender people, their gender identity does not match their sex designated at birth. Most people have a gender identity of man or woman (or boy or girl). For some people, their gender identity does not fit neatly into one of those two choices. Unlike gender expression (see later), gender identity is not visible to others.

Gender identity disorder: This is the term used for GD/gender incongruence in previous versions of DSM (see “gender dysphoria”). The ICD-10 still uses the term for diagnosing child diagnoses, but the upcoming ICD-11 has proposed using “gender incongruence of childhood.”

Gender incongruence: This is an umbrella term used when the gender identity and/or gender expression differs from what is typically associated with the designated gender. Gender incongruence is also the proposed name of the gender identity–related diagnoses in ICD-11. Not all individuals with gender incongruence have gender dysphoria or seek treatment.

Gender variance: See “gender incongruence”

Gender reassignment: This refers to the treatment procedure for those who want to adapt their bodies to the experienced gender by means

of hormones and/or surgery. This is also called *gender-confirming* or *gender-affirming treatment*.

Gender-reassignment surgery (gender-confirming/gender-affirming surgery): These terms refer only to the surgical part of gender confirming/gender-affirming treatment.

Gender role: This refers to behaviors, attitudes, and personality traits that a society (in a given culture and historical period) designates as masculine or feminine and/or that society associates with or considers typical of the social role of men or women.

Sex designated at birth: This refers to sex assigned at birth, usually based on genital anatomy.

Sex: This refers to attributes that characterize biological maleness or femaleness. The best known attributes include the sex-determining genes, the sex chromosomes, the H-Y antigen, the gonads, sex hormones, internal and external genitalia, and secondary sex characteristics.

Sexual orientation: This term describes an individual’s enduring physical and emotional attraction to another person. Gender identity and sexual orientation are not the same. Irrespective of their gender identity, transgender people may be attracted to women (gynephilic), attracted to men (androphilic), bisexual, asexual, or queer.

Transgender: This is an umbrella term for people whose gender identity and/or gender expression differs from what is typically associated with their sex designated at birth. Not all transgender individuals seek treatment.

Transgender male (also: trans man, female-to-male, transgender male): This refers to individuals assigned female at birth but who identify and live as men.

Transgender woman (also: trans woman, male-to-female, transgender female): This refers to individuals assigned male at birth but who identify and live as women.

Transition: This refers to the process during which transgender persons change their physical, social, and/or legal characteristics consistent with the affirmed gender identity. Prepubertal children may choose to transition socially.

Transsexual: This is an older term that originated in the medical and psychologic communities to refer to individuals who have permanently transitioned through medical interventions or desired to do so.

(From Hembree, W.C. et al. (2017). Endocrine treatment of gender-dysphoric/gender-incongruent persons: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrine Metab*, 102 (11), 1–35; by permission of the Endocrine Society.)

demonstrated a 39.1% concordance for GID (based on DSM-IV criteria) in 23 pairs of monozygotic twins, with no concordance for GID in 21 same-sex dizygotic female and male twin pairs or in seven opposite sex twin pairs.¹¹ Although a number of investigators have sought to identify polymorphisms in specific candidate genes that may be more prevalent in transgender versus nontransgender controls, such studies have been inconsistent and lacking strong statistical significance.^{12–15}

With respect to hormonal influences on gender identity, it should be noted that most transgender individuals do not have a disorder/difference of sex development (DSD) or any obvious abnormality in sex steroid production or response. However, studies in individuals with a variety of DSDs have informed our understanding of the role that hormones (prenatal and early postnatal androgens, in particular) may play in gender identity development. For example, in studies of 46 XX individuals reared female, with virilizing congenital adrenal hyperplasia (CAH) caused by mutations in the *CYP21A2* gene, there is a greater degree of a transgender identity outcome (female-to-male) than what would be expected in the general population.^{16–18} In a meta-analysis of 250 adults with this condition, raised female, although nearly 95% accepted a female gender identity, 5.2% reported either a male gender identity or

GD.¹⁶ By comparison, the prevalence of a transgender identity in adults in recent population estimates in the United States is 0.5% to 0.7%.⁵ A separate study of adult 46 XX individuals with classical 21-hydroxylase deficiency demonstrated a relationship between severity of disease and gender identity outcome. Of 42 patients with the salt-wasting form, three (7.1%) either had GD or a male gender identity; no GD was seen in less severely affected individuals.¹⁷ A study in 46 XX youth with 21-hydroxylase deficiency (salt-wasting or simple virilizing) found that 12.8% demonstrated cross-gender identification.¹⁸ In a recent cross-sectional study from Europe, of 221 individuals with 46 XX CAH, 28 were noted to have experienced a “gender change”; in 25, this was reported to have occurred prepubertally; in one postpubertally; and in two the timing of “gender change” was unknown.¹⁹ The 25 individuals in this study described as having a prepubertal “gender change,” were, in fact, individuals who underwent feminizing genital surgery in the newborn period (before one’s gender identity is known); furthermore, the one individual reported in this study to have a gender change postpubertally was, in fact, a 46 XX individual with a male gender identity who had undergone masculinizing genital surgery (personal communication with Dr. Baudewijntje P.C. Kreukels, VU University Medical Center, Amsterdam). The

report of this cross-sectional European study did not indicate the number of 46 XX CAH individuals reared female that actually developed either gender dysphoria or a male gender identity (personal communication with B.P.C. Kreukels). It is noteworthy that in 46 XX individuals with virilizing CAH from 21-hydroxylase deficiency, prenatal androgens are more likely to affect gender expression/behavior and sexual orientation than gender identity.^{20,21} A role for prenatal/early postnatal androgens in gender identity development is also supported by studies in a variety of other hormonal and nonhormonal DSDs.²²

With respect to brain and gender identity, numerous studies in transgender adults, carried out before treatment with gender-affirming sex hormones, indicate that some sexually dimorphic brain structures are more closely aligned with gender identity than with physical sex characteristics.^{23,24} A gray matter study in gender dysphoric youth has shown a similar trend.²⁵ In addition, functional studies (e.g., analysis of hypothalamic blood flow in response to smelling odorous compounds and brain-imaging studies carried out during mental rotation tasks) demonstrate that patterns typically observed to be sexually dimorphic were more closely aligned with gender identity than with physical sex characteristics, even before treatment with gender-affirming sex hormones, in both transgender adolescents and adults.^{26–28}

EMERGENCE AND DEVELOPMENTAL TRAJECTORIES OF GENDER

To identify when a child is exhibiting gender nonconforming behavior, it is necessary to understand what gender behaviors are typical at various developmental stages and how these behaviors may change over time.²⁹ It is also important to appreciate how some expressions of gender vary in different environments.^{30,31} Recent reports of higher estimated prevalence rates of GD among youth in Australasia, Western Europe, and North America^{32–36} may reflect a greater willingness of people to seek treatment, as a result increased access to multidisciplinary gender clinics, as well as societal changes in attitudes about gender diversity.

Infancy

Although sex differentiation begins during early fetal development, gender differences from birth throughout infancy are limited to gross movement and emotional expressivity. For example, boys produce fewer tongue movements and weaker suckling than girls during early life;^{37,38} however, infant boys spend more time awake and produce greater movement of their trunk and limbs.³⁹ Finally, infant girls smile more than boys and are less likely to exhibit angry facial expressions.^{39,40} Additional differences in behavior between boys and girls either do not yet exist, or are unable to be detected with current technology at this very young time.

Early Childhood

An important milestone that starts to occur between 18 months and the second year of life is the emergence of gender identity.^{29,41} This occurs around the time language skills develop so that young children increasingly use gender labels (e.g., girl, boy, woman, man) as their speech evolves.⁴² Boys begin to exhibit preferences for gender-typed toys, such as trucks by 2 years of age,^{43,44} and by the third year of life children prefer same-sex peers and this preference intensifies over time.^{45,46} Interestingly, young children who understand and use gender labels are more likely to prefer gender-typed toys,⁴⁷ in support of the self-socialization theory of gender development that posits children socialize themselves into gender categories.²⁹

Children referred for treatment of GD prefer cross-sex toys, activities,⁴⁸ and playmates⁴⁹ more than their gender conforming peers and siblings. These differences in early childhood are not surprising, as the majority of transgender teens and adults recall that the onset of their GD occurred before puberty.^{50,51} Unknown at this time, is whether children with GD use gender labels differently during early childhood or experience the emergence of gender identity differently from gender conforming peers, during the first 2 years of life. Also unknown at this time is whether or not preferences for same- or cross-sex toys, activities, and playmates are stable throughout childhood for either gender conforming or nonconforming children.

Adolescence

Fewer studies of gender development have been conducted in adolescents compared with younger children. The theory of gender intensification suggests that adolescents experience increased pressure to conform to societal expectations of masculinity and femininity, and this pressure acts to further strengthen their gender identity.⁵² Although some studies support this theory, others do not.⁵³ Some adolescents who experienced GD as younger children no longer do so as adolescents (desisters), whereas others continue to experience GD, as they mature (persisters).⁵⁴ Thus for some people, gender identity evolves during adolescence in ways not predicted from earlier childhood. As noted earlier, the stability of gender from early childhood through later life has not been well studied. However, some investigators have attempted to identify factors that predict GD “persisters” versus “desisters,” as detailed in the section on “Natural History of Gender Dysphoria,” later. One of the recommended areas of future research in youth with GD is to identify additional predictors of GD persistence.^{55,56}

MENTAL HEALTH COMORBIDITIES ASSOCIATED WITH GENDER DYSPHORIA

Gender nonconforming people have historically presented with psychological symptoms, such as anxiety, depression, and suicidality and self-harm at rates much higher than the general population.^{34,57} Until recently, most studies of psychiatric comorbidities associated with GD were conducted in transgender adults who had limited family and peer support, as well as poor access to gender-affirming treatment and counseling.⁵⁸ As research on mental health of gender nonconforming youth broadens to include those who are both supported during their social transition and who receive multidisciplinary care,³ comorbidities are fewer. Nonetheless, behavioral and emotional problems for gender nonconforming youth in the community who are, and are not, referred for treatment are increased.⁵⁹ As these youth continue to be followed, evidence will build to address long-term safety and efficacy of multidisciplinary treatment on their health and wellbeing.

Internalizing Disorders and Gender Dysphoria

Data from nationally representative samples of students,⁶⁰ and also clinic-based studies of youth seeking medical treatment for GD^{34,51,61,62} reveal marked increases in depression among transgender youth compared with their cisgender counterparts. Clinically significant anxiety is also common.⁵⁸ In contrast, children with GD who socially transition with the support of their family exhibit levels of depression that are no different, and anxiety levels that are only mildly elevated, from age-matched population norms.⁶³ Additional evidence that support of others is important to maintain good mental health for gender nonconforming youth are associations between poor peer relations (i.e., gets teased, not liked by others) and

emotional problems.⁶⁴ Thus internalizing disorders, such as depression and anxiety are not necessarily a comorbidity of GD per se. Rather, psychological distress is likely caused by social ostracism and maltreatment by others.

Suicidality and Nonlethal Self-Harm

Transgender youth are more likely to think about suicide, attempt suicide, and inflict nonlethal self-harm (i.e., cutting, burning, or hitting) than cisgender youth.^{58,62} Self-harm in youth with GD is most common among assigned females and those impacted by psychologic symptoms, such as anxiety and depression.⁶⁵ A report from Ontario, Canada, found that transgender adolescents and young adults were more likely to have greater self-esteem and life satisfaction, as well as decreased depression, suicidal ideation, and suicide attempts if their parents were supportive of their gender identity, in comparison to those individuals whose parents were “somewhat to not at all supportive.”⁶⁶ Further investigations of the impact of social support and of gender-affirming multidisciplinary care warrant greater resources and effort, as studies of transgender youth continue to expand in pediatric medicine.

Eating Disorders

In the largest survey study of transgender youth to date, a higher rate of eating disorders was observed compared with cisgender women.⁶⁷ Furthermore, assigned females are at particular risk.⁶⁸ A smaller study reported high rates of overweight and obesity among transgender youth.⁵¹ For these youth, having too little or too much body fat may be a way to hide undesired physical characteristics. Thus it is recommended to screen for eating disorders in gender nonconforming children and adolescents.⁶⁸

Traits of Autism Spectrum Disorder

There is growing evidence from parent and teacher ratings, as well as review of medical records, that traits of autism spectrum disorder (ASD) and GD cooccur in some youth and adults.^{36,69–72} Although ASD is more prevalent in boys than in girls, in gender conforming individuals,⁷³ the association between ASD and GD is similar for both natal males and females.^{70,72} Although there are no clinical guidelines for the delivery of care to children and adolescents with cooccurring GD and ASD traits, initial consensus guidelines for assessment and care are available.⁷⁴

NATURAL HISTORY OF GENDER DYSPHORIA

Information about the natural history of GD is limited. This is in part because medical treatment has been inaccessible to many because of expense and/or stigmatization surrounding this condition. In addition, much of what is known about GD focuses on adults. Thus basic understanding about the natural history of GD in youth is only now being elucidated. Here we review what is currently understood about remission versus persistence of GD in children and adolescents, and also the impact of family support and medical treatment on mental health status of young people whose gender identity is incongruent with their natal sex.

Desistence Versus Persistence

Historically, the majority of children who presented for treatment of GD experienced remission (desisters) by late childhood or early adolescence.⁵⁴ Studies of desisters, and also those who continue to experience GD into later adolescence

and adulthood (persisters), are beginning to reveal factors that distinguish between these groups. Specifically, natal females, those with more intense GD in childhood and adolescence, and those who experience greater dissatisfaction with their primary and secondary sex characteristics are more likely to be persisters. Persisters are also more likely to be sexually attracted to members of their natal sex.⁵³ In addition, when asked if they are a boy or a girl, children whose GD persists are more likely to report that they believe themselves to be the sex opposite their natal sex, whereas desisters are more likely to report that they wished they were the other sex.⁵⁴ The possibility of remission of GD in later childhood or early adolescence, coupled with the ability to use the onset of puberty, as a diagnostic tool for persistence of GD, motivate recommendations for delaying pubertal suppression (see “Medical Treatment,” later) until after transyouth enter the first stages of puberty (Tanner stages 2–3).^{3,75}

Impact of Family Support and Treatment

Among prepubertal children with GD who have the support of their families and who have socially transitioned, depression is no different from population averages and anxiety is only mildly elevated.⁶³ Later in development, puberty suppression is associated with improved psychosocial functioning in adolescents whose GD persists.⁷⁶ Among older adolescents and young adults with GD who received puberty suppression, cross-sex hormone treatment, and in some cases gender reassignment surgery—psychological function was comparable with the general population.⁶⁴ In all of these studies, mental health support was part of multidisciplinary care delivered by experienced healthcare teams. Thus many of the mental health comorbidities of GD discussed earlier are ameliorated when family support is coupled with access to multidisciplinary care for children and adolescents of various developmental stages.

ROLE OF MENTAL HEALTH IN MULTIDISCIPLINARY CARE

The Standards of Care of the World Professional Association for Transgender Health (WPATH) (WPATH, 7th Version) and the Endocrine Society Clinical Practice Guideline for Gender-Dysphoric/Gender-Incongruent Persons^{2,3} promote several approaches for the psychological support of youth with GD and their families. It is recommended that youth receive mental healthcare before, during, and after their social and medical transition. Roles for mental healthcare providers include¹: the ability to assess GD/GI in children and adolescents and appropriately use the DSM and International Classification of Diseases for diagnosing these conditions²; provide counseling and supportive psychotherapy to youth and their families³; diagnose and treat other psychiatric conditions apart from GD⁴; refer for pubertal suppression, cross-sex hormone therapy; and gender reassignment surgery when appropriate, including assessment of comprehension of the risks and benefits of these treatments⁵; refer patients and families to peer support; and⁶ educate and advocate on behalf of patients and their families.

Both the WPATH and the Endocrine Society outline competency requirements for mental health professionals who provide services to children and adolescents with GD. These include¹ training in child/adolescent gender development (including gender nonconforming identities and roles) and child/adolescent psychopathology, with a minimum of a Master’s degree in clinical psychology from an accredited program and relevant licensing,² and supervised training and competency in psychotherapy or counseling, including treatment of GD, as well as continued education in these areas.^{2,3}

Social Transition

Some children benefit from a social (nonmedical) transition to help determine if their GD will remit or persist. Reversible changes that allow a child to live according to the gender they identify with at home and school (such as hair length, clothing, and name change) are associated with improved mental health among this group.⁶³ Children who undergo social transition are less likely to experience remission of their GD,⁵³ and it is unclear if this is because only those with stronger GD initiate social transition, or if social transition itself impacts the evolution of GD in youth. Because current understanding of the effects of childhood social transition on GD is limited, mental health professionals may work with families to determine if this option is best for their child. For example, social transition may be considered exploratory (as opposed to finite) and may be first attempted while families vacation or in the privacy of the home.²

MEDICAL TREATMENT

Current Treatment Models

GD that either emerges or worsens with the onset of physical puberty is highly predictive of a transgender identity during adulthood.⁷⁷ This observation is central to the rationale for medical intervention in eligible transgender adolescents. Medical care of transgender youth has been primarily informed by Clinical Practice Guidelines from the Endocrine Society³ and cosponsoring organizations and by Standards of Care from WPATH.² These documents endorse the use of gonadotropin-releasing hormone (GnRH) agonists at Tanner Stage 2 of pubertal development (testicular volume ≥ 4 mL for assigned males at birth or initial stages of breast budding for assigned females at birth) in adolescents who meet the criteria for GD (optimally determined by a qualified mental health gender specialist) that has either emerged or worsened with the onset of puberty. Additional criteria for initiation of pubertal suppression with GnRH agonists include the following: the adolescent has requested treatment and has provided informed assent and the parents or legal guardians have provided informed consent, and any coexisting medical or psychosocial concerns that could interfere with treatment have been addressed.³ GnRH agonists should not be used in prepubertal gender dysphoric children to block the initiation of puberty.³

Considered fully reversible, GnRH agonists, by pausing puberty, provide additional time for gender identity exploration, without the pressure of continued pubertal progression, and prevent irreversible development of secondary sex characteristics associated with the puberty that is not aligned with the person's affirmed gender identity.³ Such undesired physical changes include breast development, female body habitus, and potentially short stature in assigned females at birth, and Adam's apple, lowered voice, male bone configuration, and potentially tall stature in assigned males at birth.²² A protocol for baseline and follow-up monitoring of physical examination, and laboratory testing during pubertal suppression with GnRH agonists is outlined in Box 19.2. GnRH agonists, while the preferred option for pubertal suppression, are costly and often inaccessible. Alternatives for pubertal suppression include depot and oral progestins.³

Adolescents who have undergone pubertal suppression at early puberty and continue to meet the criteria for GD may request phenotypic transition with sex steroids. Age-specific recommendations for initiation of gender-affirming sex steroids in gender dysphoric adolescents are not delineated in the WPATH Standards of Care seventh version.² The most recent version of the Endocrine Society Clinical Practice

BOX 19.2 Baseline and Follow-Up Protocol During Suppression of Puberty

Every 3–6 mo
Anthropometry: height, weight, sitting height, blood pressure, Tanner stages
Every 6–12 mo
Laboratory: LH, FSH, E2/T, 25OH vitamin D
Every 1–2 y
Bone density using DEXA
Bone age on x-ray of the left hand (if clinically indicated)

DEXA, Dual-energy x-ray absorptiometry; E2, estradiol; FSH, follicle-stimulating hormone; LH, luteinizing hormone; T, testosterone. (From Hembree, W.C. et al. (2017). Endocrine treatment of gender-dysphoric/gender-incongruent persons: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrine Metab*, 102 (11), 1–35; by permission of the Endocrine Society.)

Guidelines recommends initiating treatment “using a gradually increasing dose schedule after a multidisciplinary team of medical and mental health professionals has confirmed the presence of GD/GI, and sufficient mental health capacity to give informed consent, which most individuals have by age 16 years.”³ In addition, the most recent version of the Endocrine Society Clinical Practice Guidelines acknowledges that there may be compelling reasons to initiate sex hormone treatment before 16 years of age in some gender dysphoric adolescents. In gender dysphoric adolescents whose puberty is blocked at Tanner stage 2, delaying gender-affirming sex hormone treatment until 16 years of age could be detrimental to bone health; furthermore, keeping someone suspended in a prepubertal state until the age of 16 years could have detrimental mental health effects.³ A protocol for induction of puberty in gender dysphoric adolescents, and recommendations for baseline and follow-up physical examination and laboratory monitoring during pubertal induction are provided in Boxes 19.3 and 19.4, respectively.

During pubertal induction with gradually increasing doses of estrogen or testosterone, initial sex steroid levels will not be sufficient to suppress endogenous sex steroid secretion. In transgender females, even when adult levels of estrogen are reached, it is recommended that GnRH agonist treatment (or another antiandrogen) be continued until gonadectomy.³ Given that some transgender adults may not choose to have gonadectomy, long-term studies are needed to assess potential risks of prolonged GnRH agonist treatment. GnRH agonist treatment can typically be stopped in transgender males, once adult levels of testosterone have been achieved.³

It is not uncommon for some transgender adolescents to initially present for care when they have either virtually completed puberty or are already postpubertal. In such cases, transgender females are treated with estrogen, as well as an agent that blocks testosterone secretion and/or action, using protocols typical for transgender adults. With respect to estrogen treatment, 17 β -estradiol (transdermal, oral, or parental) is preferred to conjugated (e.g., premarin) or synthetic estrogens (e.g., ethinyl estradiol) because conjugated and synthetic estrogen levels cannot be monitored in the serum and ethinyl estradiol is associated with increased risk for venous thromboembolic disease and death from cardiovascular causes in studies of adults.³ Postpubertal transgender male adolescents can be treated with testosterone alone, following protocols typical for transgender adults. Although testosterone typically induces amenorrhea within a few months, a progestin or other agent may be used if uterine bleeding persists.⁷⁸

BOX 19.3 Protocol Induction of Puberty

Induction of female puberty with oral 17 β -estradiol, increasing the dose every 6 mo:

- 5 mcg/kg/day
- 10 mcg/kg/day
- 15 mcg/kg/day
- 20 mcg/kg/day
- Adult dose = 2–6 mg/day

In postpubertal transgender female adolescents, the dose of 17 β -estradiol can be increased more rapidly:

- 1 mg/day for 6 mo
- 2 mg/day

Induction of female puberty with transdermal 17 β -estradiol, increasing the dose every 6 mo (new patch is placed every 3.5 day):

- 6.25–12.5 mcg/24 hour (cut 25-mcg patch into quarters, then halves)
- 25 mcg/24 hour
- 37.5 mcg/24 hour
- Adult dose 50–200 mcg/24 hour

Adjust maintenance dose to mimic physiological estradiol levels.

Induction of male puberty with testosterone esters increasing the dose every 6 mo (IM or SC):

- 25 mg/m²/2 wk (or alternatively, half this dose weekly, or double the dose every 4 wk)
- 50 mg/m²/2 wk
- 75 mg/m²/2 wk
- 100 mg/m²/2 wk
- Adult dose = 100–200 mg every 2 wk

In postpubertal transgender male adolescents the dose of testosterone esters can be increased more rapidly:

- 75 mg/2 wk for 6 mo
- 125 mg/2 wk

Adjust maintenance dose to mimic physiologic testosterone levels.

IM, Intramuscularly; SC, subcutaneously.

(From Hembree, W.C. et al. (2017). Endocrine treatment of gender-dysphoric/gender-incongruent persons: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrine Metab*, 102 (11), 1–35; by permission of the Endocrine Society.)

BOX 19.4 Baseline and Follow-up Protocol During Induction of Puberty

Every 3–6 mo

- Anthropometry: height, weight, sitting height, blood pressure, Tanner stages

Every 6–12 mo

- In transgender males: hemoglobin/hematocrit, lipids, testosterone, 25OH vitamin D
- In transgender females: prolactin, estradiol, 25OH vitamin D

Every 1–2 y

- BMD using DEXA
- Bone age on x-ray of the left hand (if clinically indicated)

BMD should be monitored into adulthood (until the age of 25–30 y or until peak bone mass has been reached).

BMD, Bone mineral density; DEXA, dual-energy X-ray absorptiometry.

(From Hembree, W.C. et al. (2017). Endocrine treatment of gender-dysphoric/gender-incongruent persons: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrine Metab*, 102 (11), 1–35; by permission of the Endocrine Society.)

With respect to surgery, some transgender adolescents seek such procedures to bring their bodies into closer alignment with their gender identity. It is recommended that gender-affirming genital surgery involving gonadectomy and/or hysterectomy not take place until the individual has reached at least 18 years of age, or the age of legal majority in their country.³ For transgender males seeking breast reduction surgery, the Endocrine Society Guidelines acknowledge that some adolescents may consider this procedure before 18 years of age, but note there is insufficient evidence to recommend a specific age requirement.³ These guidelines suggest that clinicians should consider the physical and mental health status of the individual patient, when determining the timing of this procedure.

Outcomes and Potential Adverse Effects

Limited outcomes data are available based on current treatment models. As noted earlier, one published study has thus far evaluated mental health in transgender adolescents/young adults before and after GnRH agonist treatment, following gender-affirming sex steroid treatment, and 1 year after “gender reassignment surgery.”⁶⁴ At the completion of the observation period, GD was resolved, general psychological functioning had improved, and a sense of “wellbeing” was observed to be equal or greater to that found in age-matched controls. In addition, none of the 55 study participants regretted treatment.⁶⁴

Potential adverse effects of pubertal suppression with GnRH agonists in transgender youth, as recently reviewed, include impaired bone mineral density (BMD) and compromised fertility. In addition, there are unclear effects on brain development, body mass index (BMI), and body composition.⁷⁹

With respect to skeletal health, a 6-year longitudinal study (that spanned the period of pubertal suppression, gender-affirming sex hormone treatment, and gonadectomy), observed a significant decrease in lumbar spine areal BMD z-scores (relative to natal sex) in transgender females, with a similar decrease, following pubertal suppression in transgender males.⁸⁰ Potential study limitations, as acknowledged by the authors, included a relatively small number of study participants, relatively low doses of sex hormones, and lack of information regarding other factors that can influence BMD, including vitamin D status, dietary calcium intake, and weight-bearing exercise.⁸⁰ During pubertal suppression with GnRH agonists in early pubertal transgender adolescents, it is recommended to monitor vitamin D status and supplement if necessary, and to encourage adequate dietary calcium intake and weight-bearing exercise.²² In a separate study, bone turnover markers and bone mineral apparent density (BMAD) z-scores decreased, following GnRH agonist treatment in younger transgender adolescents, whereas an increase in BMAD was observed after 2 years of gender-affirming sex hormone treatment, in both younger and older transgender adolescents.⁸¹ A 22-year follow-up study of a gender dysphoric adolescent, treated initially with GnRH agonist and subsequently with gender-affirming sex hormones, found that BMD was in the normal range for both sexes when evaluated at 35 years of age.⁸²

A discussion about implications for fertility must precede any treatment of gender dysphoric adolescents with either GnRH agonists or gender-affirming sex hormones. Transgender adolescents may wish to preserve fertility, which will likely be compromised if puberty is suppressed at an early stage, and the individual subsequently transitions with gender-affirming sex hormones. In vitro maturation of human germ cells has not yet been achieved, although some families elect to freeze a section of prepubertal gonadal tissue for potential future use.⁸³ Cryopreservation of mature sperm or eggs is an option for late pubertal/ fully pubertal adolescents. However, recent reports indicate that even when provided with counseling regarding

potential impact of sex hormone treatment on fertility and options for fertility preservation, only a small percentage of such adolescents opted to pursue fertility preservation.^{84,85} Questionnaires to assess fertility and fertility preservation attitudes in transgender youth and their parents have been recently developed.^{86,87}

With respect to brain function, few studies have thus far evaluated potential adverse effects of GnRH agonists in transgender adolescents. When comparing small groups of GnRH agonist-treated versus untreated transgender adolescents (both male-to female and female-to male), there was no significant compromise of executive functioning, a developmental milestone typically achieved during puberty.⁸⁸ A 28-month longitudinal study in one transgender adolescent, undergoing treatment with GnRH agonist, showed lack of expected variation in white matter fractional anisotropy, a measure of brain maturation thought to normally occur during puberty, as well as a 9-point drop in operational memory testing after 22 months of pubertal suppression.⁸⁹ Given this relative lack of data, further longitudinal studies are needed to assess the impact of GnRH agonist treatment on brain development and function in transgender adolescents.

Studies assessing the impact of GnRH agonist treatment on BMI and body composition have also been carried out. Although variable results have been observed with respect to BMI,^{80,90} an increase in fat percentage and a decrease in lean body mass percentage, after 1 year of treatment with GnRH agonist, have been reported in both transgender male and female adolescents.⁹⁰ In a separate study, significant weight gain was reported in one of 27 transgender adolescents treated with GnRH agonist, although this individual's BMI was noted to be greater than the 85th percentile before treatment.⁹¹

A small number of short-term studies have thus far evaluated potential adverse effects of gender-affirming sex hormones in transgender adolescents. No change in blood pressure, BMI standard deviation score, lean body mass percentage, or fat percentage were observed in a study from the Netherlands of 28 transgender females treated for 1 to 3 years, primarily with gradually increasing doses of 17 β -estradiol.⁹² In addition, no abnormalities were observed with liver enzymes or creatinine, and there was no change in hematocrit or hemoglobin A1c. Hyperprolactinemia was observed in one individual who had received high-dose ethinyl estradiol treatment to limit statural growth.⁹²

Two studies from the United States have assessed potential adverse effects of gender-affirming sex hormones in transgender adolescents and young adults. Following treatment with 17 β -estradiol in 44 transgender females, no abnormalities were seen in blood pressure, BMI, hemoglobin/hematocrit, lipids, renal and liver function studies, or in prolactin.⁹³ Following treatment with testosterone in 72 transgender males, there was an increase in BMI and in hemoglobin/hematocrit (supraphysiologic hematocrit levels were seen in 4% of the individuals) and a decrease in high-density lipoprotein cholesterol levels; no abnormalities were seen in blood pressure, renal and liver function studies, or in hemoglobin A1c.⁹³ A separate prospective study, after 21 to 31 months of treatment with gender-affirming hormones in 25 transfeminine and 34 transmasculine individuals, showed no clinically significant adverse effects in a variety of metabolic parameters.⁹⁴

CHALLENGES TO DELIVERY OF CARE

Multidisciplinary care for transgender youth represents a relatively new focus of clinical service and research. Although there have been significant advances, beginning with pioneering work from the Netherlands, there are only limited safety and efficacy studies, with virtually no published data on the use of GnRH agonists to suppress puberty in gender dysphoric

youth younger than 12 years of age, or cross-sex hormones in transgender adolescents younger than 16 years of age. Randomized controlled trials are often considered the gold standard; however, this approach to study hormonal interventions in gender dysphoric youth has not been considered feasible or ethical.^{95,96} Although an increasing number of clinical programs have emerged around the world in recent years, there are many geographic areas where no such services exist, requiring patients and their families to travel long distances. In addition, there are significant limitations to access for medical treatments, given that all hormonal interventions for gender dysphoric youth are considered "off-label" in the United States, are expensive (GnRH agonists, in particular), and are often denied by insurance companies. Furthermore, lack of formalized training of providers and prejudice and misunderstanding on the part of family, community, and both medical and mental health providers limit access to optimal care.⁹⁷

There are additional challenges to providing optimal care for transgender youth. Whereas almost all published research has been conducted in the context of a binary gender model, there are increasing numbers of youth seeking care that identify as gender nonbinary.⁹⁸ Another limitation to the delivery of evidence-based care is that most studies of children, adolescents, and young adults with GD include only those with early-onset GD. A phenomenon known as *rapid-onset gender dysphoria* (ROGD), in which GD is first expressed by older youth during or after the completion of puberty, is poorly understood at this time.⁹⁹ Methodological concerns have been raised regarding the ROGD report (calling into question the existence of ROGD, itself), including the fact that only parents (recruited from websites) and none of the gender dysphoric youth participated in the study, and that parents were not recruited from websites supportive of transgender youth.¹⁰⁰ More research is needed to better understand those youth who have been described to have ROGD to optimally provide safe and effective care for these individuals.

CONCLUSIONS

Significant advances in our understanding of transgender/gender nonconforming youth have been achieved, although significant gaps in knowledge remain. Compelling studies have emerged supporting the concept that gender identity is not simply a psychosocial construct, but reflects a complex interplay of biological, environmental, and cultural factors. The removal of the term "gender identity disorder," replacing it with "gender dysphoria" in the DSM-V, underscores that a transgender identity, in and of itself, is no longer considered pathological, and that clinical concern should focus on GD that may be present, along with concomitant mental health challenges. The first long-term study, based on current models of care, indicates that mental health comorbidities in gender dysphoric youth either significantly diminish or resolve, when such individuals are provided with gender-affirming care, optimally delivered in a multidisciplinary clinical setting.⁶⁴ Further prospective, long-term outcome studies are needed to optimize care for transgender/gender nonconforming youth.

CONCLUDING REMARKS	801

Disorders of calcium, magnesium, and phosphate metabolism and of bone formation, accrual, and maintenance during the first 2 decades of life result from suboptimal ingestion, absorption, or retention of constituent nutrients, abnormal vitamin D metabolism or bioactivity, disorders of parathyroid hormone (PTH) synthesis, secretion, or action, and intrinsic aberrations in cartilage and bone cells. The origins of these illnesses may be intrinsic because of pathological variations in the genes controlling these processes or to acquired insults (Table 20.1). Serum concentrations of calcium vary by age.¹ Although serum total and ionized calcium (Ca^{2+}) concentrations generally are intrinsically related, dissociation between these analytes may be observed in patients with hyperproteinemia or hypoproteinemia and at extremes of plasma pH—either alkalosis or acidosis.² Hypocalcemia is present when the serum concentrations of Ca^{2+} are below, and hypercalcemia is identified by serum values of Ca^{2+} above the normal range for age, respectively.¹ For an integrated overview of calcium, mineral, and skeletal homeostasis, the reader is referred to Chapter 9.

HYPOCALCEMIA

In children older than 1 year of age, depending on the analytic laboratory hypocalcemia is defined by a decrease in Ca^{2+} values below the lower limits of normal for age of 4.64 to 4.80 mg/dL = 1.16 to 1.20 mmol/L; the lower normal range for age of the total calcium concentration is 8.5 to 8.9 mg/dL = 2.20 to 2.3 mmol/L.^{1,2} If the serum concentration of albumin declines by 1 g/dL, the total calcium value will fall by 0.8 mg/dL (0.2 mmol/L), whereas the level of Ca^{2+} does not vary. Symptoms of hypocalcemia reflect heightened neuromuscular irritability, such as paresthesias, tetany, carpopedal spasm, laryngospasm, muscular cramps and/or myotonic spasms, and focal or generalized convulsions; physical signs of hypocalcemia include presence of a Chvostek sign (tapping on facial nerve elicits twitching of facial muscles ipsilaterally) and/or a Trousseau sign (carpopedal spasm after maintaining an inflated blood pressure cuff slightly above systolic pressure for 3 minutes).³ During hypocalcemia the electrocardiographic QT interval is prolonged.

Hypocalcemia in the Neonate and Infant

In utero, fetal concentrations of total and ionized calcium are higher than they are postnatally; total calcium levels exceed maternal values by approximately 2.0 mg/dL = 0.5 mmol/L, because placental calcium transport is stimulated by parathyroid hormone-related protein (PTHrP); in term umbilical cord blood, mean total calcium values are 10 to 11 mg/dL and Ca^{2+} levels approximate 6.4 mg/dL = 1.6 mmol/L, respectively.^{4,5} In the fetus, serum concentrations of phosphate, PTHrP, and calcitonin are higher than in the pregnant woman, while fetal levels of 1,25-dihydroxyvitamin D₃ (calcitriol) and PTH are low and those of 25-hydroxyvitamin D₃ (calcidiol) approximate maternal values.⁵ In the neonate, total calcium and Ca^{2+} concentrations decline in the first 24 hours after birth to values approximating 8 to 9 mg/dL (2.0–2.75 mmol/L) and 4.4 to 5.4 mg/dL (1.1–1.35 mmol/L), respectively; calcium levels then plateau and subsequently increase to the midnormal range by the third day of life. Neonatal concentrations of PTHrP and calcitonin decline after delivery, whereas values of PTH and calcitriol increase over the first 2 postnatal days. Subsequently, in healthy infants, Ca^{2+} concentrations vary by postnatal age: 1 month—5.2 to 6.1 mg/dL = 1.28 to 1.52 mmol/L; 3 months—5.2 to 6.0 mg/dL = 1.30 to 1.49 mmol/L; 12 months—5.0 to 5.6 mg/dL = 1.24 to 1.39 mmol/L.²

Clinical manifestations of hypocalcemia occurring in the neonate (defined as values of total calcium <7.5–8.0 mg/dL and/or Ca^{2+} <4.4 mg/dL [1.1 mmol/L] in newborns with birth weights >1500 g and <7.0 mg/dL and/or Ca^{2+} <3.6 mg/dL [0.9 mmol/L] in newborns with birth weights <1500 g) are principally those of neuromuscular hyperexcitability:

See Tables 20.13 and 20.14 for genes associated with osteochondrodysplasias.

irritability, hyperacusis, jitteriness, tremulousness, facial spasms, tetany, laryngospasm, and focal or generalized seizures.^{2,4} Nonspecific symptoms, such as apnea, tachycardia, cyanosis, emesis, and feeding problems may also occur. Causes of neonatal hypocalcemia may be considered in relation to the age of onset (before or after 72 hours of life = early/late) (Tables 20.2A, 20.2B).

Early Neonatal Hypocalcemia

In the absence of hypoproteinemia, hypocalcemia occurring within the first 72 hours after birth is considered “early

neonatal hypocalcemia.” It occurs most commonly in prematurely delivered or small-for-gestational-age, low birth weight (LBW), or asphyxiated neonates, or in those born to women with gestational or permanent forms of diabetes mellitus (rarely unsuspected maternal hyperparathyroidism) and is the consequence of subnormal PTH secretion in response to declining serum calcium values and delayed renal tubular phosphaturic response to PTH characteristic of the neonate, unusually prolonged secretion of calcitonin, and/or hypomagnesemia.² Total calcium and Ca^{2+} concentrations decline more rapidly from high intrauterine values to lower nadir levels in

TABLE 20.2A Causes of Hypocalcemia

I Neonatal

A Maternal disorders

- 1 Diabetes mellitus
- 2 Toxemia of pregnancy
- 3 Vitamin D deficiency
- 4 High intake of alkali or magnesium sulfate
- 5 Use of anticonvulsant medications
- 6 Hyperparathyroidism

B Neonatal disorders

- 1 Low birth weight: prematurity, intrauterine growth restriction
- 2 Peripartum asphyxia, sepsis, critical illness
- 3 Hyperbilirubinemia, phototherapy, exchange transfusion
- 4 Hypomagnesemia, hypermagnesemia
- 5 Acute/chronic renal failure
- 6 Nutrients/medications—high phosphate intake, fatty acids, phytates, bicarbonate infusion, citrated blood, anticonvulsants, aminoglycosides
- 7 Hypoparathyroidism
- 8 Vitamin D deficiency or resistance
- 9 Osteopetrosis type II

II Hypoparathyroidism

A Congenital

- 1 Transient neonatal
- 2 Congenital hypoparathyroidism - see also Table 20.2B
 - a Familial isolated hypoparathyroidism
 - (1) Autosomal recessive hypoparathyroidism (*GCMB*, *PTH*)
 - (2) Autosomal dominant hypoparathyroidism (*CASR*, *GNA11*, *PTH*)
 - (3) X-linked hypoparathyroidism (*SOX3*)
 - b DiGeorge syndrome (*TBX1*)
 - c Sanjad-Sakati syndrome (short stature, developmental delay, dysmorphism—HRD)
 - Kenny-Caffey syndrome 1 (short stature, osteosclerosis, immunodeficiency) (*TBCE*)
 - d Kenny-Caffey syndrome 2 (developmental delay, dysmorphism) (*FAM111A*)
 - e Barakat syndrome (sensorineural deafness, renal dysplasia—HDR) (*GATA3*) Lymphedema-hypoparathyroidism-nephropathy, nerve deafness
 - f Mitochondrial deletions Kearns-Sayre: ophthalmoplegia, pigmented retina, cardiomyopathy; MELAS: mitochondrial encephalopathy, lactic acidosis, stroke-like episodes, MTPD: mitochondrial trifunctional protein deficiency (*HADHB*)
- 3 Insensitivity to parathyroid hormone
 - a Blomstrand chondrodysplasia (*PTH1R1*)
 - b Pseudohypoparathyroidism - type Ia (*GNAS*)
 - Pseudohypoparathyroidism - type IB (*GNASAS1*) IB (*STX16*)
 - 1b (*GNAS*)
 - Pseudohypoparathyroidism - type Ic (*GNAS*)
 - Pseudohypoparathyroidism - type II (?)
 - Pseudopseudohypoparathyroidism (*GNAS*)
 - c Acrolyostosis with hormone resistance (*PRKAR1A*, *PDE4D*)
 - d Hypomagnesemia (see Tables 20.7A, 20.7B)

B Acquired

- 1 Autoimmune polyglandular syndrome - type I (*AIRE*)
- 2 Activating antibodies to the calcium sensing receptor
- 3 Postsurgical, radiation destruction
- 4 Infiltrative (excessive iron [hemochromatosis, thalassemia] or copper [Wilson disease] deposition; granulomatous inflammation, neoplastic invasion; amyloidosis, sarcoidosis)
- 5 Maternal hyperparathyroidism
- 6 Hypomagnesemia/hypermagnesemia

III Vitamin D Deficiency (See Disorders of Mineralization)

IV Other Causes of Hypocalcemia

A Calcium deficiency

- 1 Nutritional deprivation
- 2 Hypercalciuria

B Disorders of magnesium homeostasis - see Tables 20.7A, 20.7B

- 1 Congenital hypomagnesemia
- 2 Acquired
 - a Acute renal failure
 - b Chronic inflammatory bowel disease, intestinal resection
 - c Diuretics

C Hyperphosphatemia

- 1 Renal failure
- 2 Phosphate administration (intravenous, oral, rectal)
- 3 Tumor cell lysis
- 4 Muscle injuries (crush, rhabdomyolysis)

D Miscellaneous

- 1 Hypoproteinemia
- 2 Hyperventilation
- 3 Drugs - furosemide, bisphosphonates calcitonin, anticonvulsants, ketoconazole, antineoplastic agents (plicamycin, asparaginase, cisplatin, cytosine arabinoside, doxorubicin), citrated blood products
- 4 Hungry bone syndrome
- 5 Acute and critical illness - sepsis, acute pancreatitis, toxic shock a
 - a Organic acidemia - propionic, methylmalonic, isovaleric

TABLE 20.2B Genetic Variants Associated With Hypocalcemia/Hypoparathyroidism

Gene Protein Chromosome OMIM	Disorder OMIM	Clinical/Biochemical Manifestations	Gene Function/Transmission
Autosomal dominant hypoparathyroidism <i>CASR</i> Calcium sensing receptor 3q13.3-q21.1 601199	Autosomal dominant hypocalcemia type 1, (isolated hypoparathyroidism) 601198	Hypocalcemia-mediated increased neuromuscular irritability: paresthesias, tetany, seizures; may also result in hypokalemia & secondary hyperaldosteronism	Encodes calcium sensing receptor expressed on plasma membrane of parathyroid gland & renal tubules; gain-of-function variants increase sensitivity & response of CaSR to low serum concentrations of calcium, AD (may be associated with Barter syndrome type 5 caused by coimpairment of renal tubular reabsorption of sodium chloride, AD 601198)
<i>GNA11</i> Guanine nucleotide-binding protein, alpha-11 19p13.3 139313	Autosomal dominant hypocalcemia type 2 (isolated hypoparathyroidism) 615361	Hypocalcemia-mediated increased neuromuscular irritability: paresthesias, tetany, seizures	Encodes G-protein alpha subunit (G α 11) that initiates intracellular signal transduction after binding of Ca ²⁺ to CaSR, AD
Familial isolated hypoparathyroidism <i>PTH</i> Parathyroid hormone 11p15.3 168450	Familial isolated hypoparathyroidism 146200	Hypocalcemia-mediated increased neuromuscular irritability: paresthesias, tetany, seizures	Encodes parathyroid hormone, AD/AR
<i>GCM2</i> Glial cells missing, drosophila, homolog of, 2 6p24.2 603716	Familial isolated hypoparathyroidism 146200	Hypocalcemia-mediated increased neuromuscular irritability: paresthesias, tetany, seizures	Encodes transcription factor essential for differentiation of the parathyroid glands, AD/AR
<i>FHL1</i> Four-and-a-half Lim domains 1 300163 Xq26.3	Isolated hypoparathyroidism 146200	Hypocalcemic seizures	Encodes gene essential for differentiation of the parathyroid glands, X-linked
Complex hypoparathyroidism <i>TBX1</i> T-box 1 22q11.21 602054	DiGeorge syndrome (DGS) type 1 (deletion chromosome 22q11 syndrome) 188400	Hypoparathyroidism, thymic hypoplasia, congenital heart anomalies, cleft palate, impaired renal function, dysmorphic facial features	T-box transcription factor embryonically expressed in the tissues adversely impacted in DGS; AD
<i>NEBL</i> Nebulette 10p12.31 605491	DiGeorge syndrome type (complex) 2, 601362	Thymic aplasia, congenital heart anomalies, cleft palate, impaired renal function, dysmorphic facial features	Protein expressed in cardiac & striated muscle, associated with actin, myofibrils, & cellular adhesion complexes, AD
<i>CHD7</i> Chromodomain helicase DNA-binding protein 7 8q12.2 608092	CHARGE syndrome 214800	CHARGE = Coloboma, Heart anomaly, Choanal atresia, Retardation, Genital, & Ear anomalies	Regulator of neural crest gene expression & ribosomal RNA formation, AD
<i>GATA3</i> GATA-binding protein 3 10p15 131320	HDR (Barakat syndrome) 146255	Hypoparathyroidism, sensorineural deafness, renal dysplasia	Transcription factor/ enhancer element required for development of parathyroid glands, auditory system, kidneys & for expression of genes encoding T-cell receptor subunits, AD
<i>TBCE</i> Tubulin-specific chaperone E 1q42.3 604934	HRD (Sanjad-Sakati syndrome—SSS), 244460; Kenny-Caffey syndrome type 1 (KCS1) 241410	HRD: Hypoparathyroidism, retardation, dysmorphism; KCS1: aforementioned + osteosclerosis & recurrent infections	Chaperone protein necessary for correct folding of tubulin subunits & stability of cellular cytoskeleton, AR
<i>FAM111A</i> Family with sequence similarity 111, Member A 11q12.1 615292	Kenny-Caffey syndrome type 2 (KCS2), 127000; Gracile bone dysplasia (GBD), 602381	KCS2: Hypoparathyroidism, retardation, dysmorphism; GBD: Hypocalcemia, thin but dense & fragile bones, may be lethal perinatally	Functional effect(s) in man unknown, (host range restriction factor in viruses), AD

TABLE 20.2B Genetic Variants Associated With Hypocalcemia/Hypoparathyroidism—cont'd

Gene Protein Chromosome OMIM	Disorder OMIM	Clinical/Biochemical Manifestations	Gene Function/Transmission
Mitochondriopathic hypoparathyroidism Deletion mitochondrial chromosome	Kearns-Sayre syndrome (KSS) 530000	Hypoparathyroidism, ophthalmoplegia, retinitis pigmentosa, sensorineural deafness, cerebellar ataxia, abnormal cardiac conductivity, myopathy, growth retardation, renal tubular dysfunction, hypoadrenocorticism, hypogonadism, diabetes mellitus	Mitochondrial genes encoding energy-generating electron transport proteins, Maternal, AD
Deletion mitochondrial chromosome	Mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes (MELAS) 540000	Hypoparathyroidism, myopathy, ophthalmoplegia, neuropathy, cardiomyopathy, impaired cognition	Mitochondrial genes encoding energy-generating electron transport proteins, Maternal, AD
<i>HADHB</i> Hydroxylacyl-CoA dehydrogenase/3-Ketoacyl-CoA thiolase/Enoyl-CoA hydratase, beta subunit 2p23.3 143450	Mitochondrial trifunctional protein deficiency syndrome, 609015	Because of inability to metabolize an energy source, clinical presentation may vary from acute & lethal in the perinatal period to hepatic Reye-like syndrome in older infants to skeletal myopathy in adolescents	Nuclear gene encoding beta subunit of mitochondrial trifunctional protein catalyzing beta oxidation of long chain fatty acids, AR
Autoimmune hypoparathyroidism <i>AIRE</i> Autoimmune regulator 21q21.3 607358	Autoimmune polyendocrinopathy syndrome, type I 240300	Hypoparathyroidism, hypoadrenocorticism, mucocutaneous candidiasis, alopecia, pernicious anemia, hypogonadism	Expressed in thymus, essential for recognition of self-antigens, AD/dominant negative/AR
Pseudohypoparathyroidism <i>GNAS</i> GNAS complex locus 20q13.32 139320	Pseudohypoparathyroidism type 1A, 103580	Hypocalcemia, hyperphosphatemia, subnormal renal tubular cyclic AMP response to exogenous PTH, Albright hereditary osteodystrophy phenotype (AHO)	Inactivating mutations or deletions of maternal <i>GNAS</i> or biallelic paternal expression of <i>GNAS</i> (isochromosomes) lead to proximal renal tubular & skeletal resistance to PTH, AD
<i>GNAS</i> GNAS complex locus 20q13.32 139320	Pseudohypoparathyroidism type 1B, 603233	Hypocalcemia, hyperphosphatemia, subnormal renal tubular cyclic AMP response to exogenous PTH, normal erythrocyte cyclic AMP activity, normal phenotype	Maternally transmitted epigenetic methylation defect of maternal <i>GNAS</i> leads to its silencing & proximal renal tubular resistance to PTH, AD
<i>GNASAS1</i> GNAS complex locus, antisense transcript 1 20q13.32 610540	Pseudohypoparathyroidism type 1B 603233	Hypocalcemia, hyperphosphatemia, absent renal tubular cAMP response to exogenous PTH, normal phenotype	Maternally transmitted deletion leads to paternal expression of <i>GNASAS1</i> resulting in silencing of maternal <i>GNAS</i> because of an epigenetic methylation defect of & proximal renal tubular resistance to PTH, AD
<i>STX16</i> Syntaxin 16 20q13.32 603666	Pseudohypoparathyroidism type 1B 603233	Hypocalcemia, hyperphosphatemia, absent renal cyclic AMP response to exogenous PTH, normal phenotype	Maternally transmitted epigenetic methylation defect of maternal <i>GNAS</i> leads to its silencing & proximal renal tubular resistance to PTH, AD
<i>GNAS</i> GNAS complex locus 20q13.32 139320	Pseudohypoparathyroidism type 1C	Hypocalcemia, hyperphosphatemia, absent renal cyclic AMP response to exogenous PTH, AHO phenotype, normal erythrocyte cyclic AMP activity	Inactivating mutations or deletions in exon 13 of maternal <i>GNAS</i> lead to proximal renal tubular & skeletal resistance to PTH, AD
?	Pseudohypoparathyroidism type 2, 203330	Hypocalcemia, hyperphosphatemia, partial resistance to PTH, normal phenotype	Despite normal increase in urinary cyclic AMP after PTH administration, patients are resistant to phosphaturic effect of PTH
<i>GNAS</i> GNAS complex locus 20q13.32 139320	Pseudopseudohypoparathyroidism, 612463	Phenotype of AHO but normocalcemia	Skeletal resistance to PTH because of loss-of-function variants of paternal <i>GNAS</i>

TABLE 20.2B Genetic Variants Associated With Hypocalcemia/Hypoparathyroidism—cont'd

Gene Protein Chromosome OMIM	Disorder OMIM	Clinical/Biochemical Manifestations	Gene Function/Transmission
<i>PRKAR1A</i> Protein kinase, cAMP dependent, regulatory, type 1 alpha 17q24.2 188830	Acrodysostosis 1 101800	Skeletal dysplasia: short stature, brachydactyly, facial dysostosis, nasal hypoplasia; with/without hormone resistance	Encodes a regulatory subunit of cyclic AMP-dependent protein kinase A requisite for intracellular signal transduction
<i>PDE4D</i> Phosphodiesterase 4D, cAMP-specific 5q11.2-q21.1 600129	Acrodysostosis 2 614613	<i>Vide supra</i> , developmentally challenged	Encodes enzyme that degrades cyclic AMP, thereby inhibiting intracellular signal transduction

AD, Autosomal dominant; AR, autosomal recessive; cAMP, cyclic adenosine monophosphate; PTH, parathyroid hormone; RNA, ribonucleic acid. (From Mannstadt M, Bilezikian JP, Thakker RV, et al. Hypoparathyroidism. *Nat Rev Dis Primers*. 2017;3:17055; Thiele S, Mantovani G, Barlier A, et al. From pseudohypoparathyroidism to inactivating PTH/PTHrP signalling disorder (IPPSD), a novel classification proposed by the EuroPHP network. *Eur J Endocrinol*. 2016;175:P1–P17; Vahe C, Benomar K, Espiard S, et al. Diseases associated with the calcium-sensing receptor. *Orphanet J Rare Dis*. 2017;12:19.)

preterm than in term neonates. In LBW neonates, hypocalcemia may be further attributed to the rapid accretion of skeletal calcium in the presence of relative resistance to the calcium absorptive and reabsorptive effects of calcitriol on the intestinal tract and bone, respectively. Offspring of severely vitamin D-deficient mothers may become hypocalcemic shortly after birth. Hypocalcemia develops in approximately one-third of asphyxiated newborns who are products of complicated and compromised deliveries, including those associated with maternal diabetes mellitus, toxemia of pregnancy, vitamin D deficiency, use of anticonvulsant drugs, and (unsuspected) maternal hyperparathyroidism.² In these infants, increased phosphate load caused by cellular injury, reduced calcium intake, and hypercalcitonemia are important pathogenetic factors in the development of hypocalcemia. Neonates born prematurely and those with intrauterine growth restriction, asphyxia, infections, respiratory distress syndrome, or other critical illness are often hypocalcemic.

Some 50% of infants of mothers with diabetes mellitus develop early neonatal hypocalcemia; the incidence may be reduced by strict maternal glycemic control.² Its causes are multifactorial and include reduced placental transfer of calcium because of substantial maternal urinary excretion of calcium and magnesium, decreased neonatal secretion of PTH, hypercalcitonemia, hypomagnesemia (occurring in 40% of offspring of diabetic women), and limited intake and impaired absorption of ingested calcium. Maternal hypercalcemia caused by unsuspected hyperparathyroidism leads to increased transfer of calcium to the fetus and still further increase in in-utero serum calcium concentrations that suppress fetal PTH synthesis and release and stimulate calcitonin secretion—aberrations in homeostatic mechanisms that persist postpartum and may result in hypocalcemic tetany/seizures in her offspring. Suppression of PTH secretion may persist for several months and be undetected until symptomatic hypocalcemia develops after weaning of the infant from breast milk to higher phosphate containing cow milk formula. Maternal ingestion of large quantities of calcium carbonate in antacids has also led to neonatal hypocalcemia.

Hypocalcemia may occur in neonates with hyperbilirubinemia undergoing exchange transfusion and in those exposed to phototherapy. Neonates with acute rotavirus infection and severe diarrhea may present with hypocalcemic seizures. Aminoglycoside antibiotics (e.g., gentamycin) increase urinary excretion of calcium and magnesium, thereby facilitating the

development of neonatal hypocalcemia. Compounds that complex with and sequester calcium, such as citrate (present in transfused blood), phosphates (that alter the calcium x phosphate product), and fatty acids (given as caloric supplements) lower Ca²⁺ levels. Bicarbonate administered to correct acidosis increases calcium binding to albumin and thus lowers Ca²⁺ values. Hypomagnesemia impairs release of PTH from the parathyroid glands. Hypocalcemia may also occur in hyperventilated infants with severe respiratory alkalosis, as well as in those with other causes of metabolic alkalosis. Phytates in soy milk bind calcium and phosphate and interfere with their absorption. Neonates and infants with malignant osteopetrosis type II and impaired osteoclastogenesis⁶ may present with either early or late neonatal hypocalcemia.^{6–8}

Late Neonatal Hypocalcemia

Late transient hypocalcemia (first developing when the neonate is >72 hours of postnatal age) may be caused by increased intake of phosphate, hypomagnesemia, hypoparathyroidism, or vitamin D deficiency (see Tables 20.2A, 20.2B). Neonatal hypocalcemia may develop after 3 days of age in offspring born in the late winter-early spring of the year to multiparous women with inadequate intake of vitamin D or exposure to sunlight. High phosphate content of evaporated milk or modified cow milk formulas may lead to formation of poorly soluble calcium salts limiting the intestinal absorption of calcium while raising serum phosphate values. Premature introduction of fiber-containing cereals into the infant's diet also decreases calcium absorption. Affected infants may have an associated defect in renal phosphate excretion or coexisting vitamin D deficiency. Hyperphosphatemia and hypocalcemia may initially suggest hypoparathyroidism, but serum PTH concentrations are usually normal or modestly elevated in infants with excessive phosphate loading in response to reciprocal reduction in serum calcium; markedly elevated or persistently high PTH values raise the question of whether pseudohypoparathyroidism (PHP, rarely acrodysostosis—a skeletal dysplasia with hormone resistance related to inactivating variants of *PRKAR1A* or *PDE4D*, vide infra) may be present. Newborns and infants with chronic renal insufficiency because of renal hypoplasia or obstructive nephropathies often are hypocalcemic and hyperphosphatemic with elevated serum PTH levels as well, but they are also azotemic. Hypomagnesemia leads to impaired secretion of PTH and decreased

peripheral responsiveness to PTH and may be transient or related to congenital abnormalities of intestinal absorption or renal tubular reabsorption of magnesium.² Hypermagnesemia may occasionally be associated with neonatal hypocalcemia.

Hypocalcemia and hypophosphatemia caused by fetal/neonatal deficiency of vitamin D occurs in offspring of mothers with substantial deficiency of vitamin D (either for cultural or socioeconomic reasons), impaired hepatic 25-hydroxylation of cholecalciferol or renal 25-hydroxyvitamin D-1 α hydroxylase activity or loss-of-function mutations of the vitamin D receptor (VDR). Hypovitaminosis D may develop in an older breastfed infant of a vegetarian mother who shields herself from sunlight and ingests a diet low in vitamin D. Marginal deficiency of vitamin D in neonates and infants is much more common than has been recognized heretofore.^{9,10} "Late-late" neonatal hypocalcemia occurs in premature infants with low bone mass at 3 to 4 months of age in whom the intake of calcium, phosphate, and vitamin D has been marginal; it is perhaps caused by avid deposition of available calcium into bone.² Hypocalcemia caused by vitamin D deficiency may develop rather acutely and in the absence of clinical or radiographic signs of rickets in the older infant and young child ingesting an elimination diet low in vitamin D because of severe allergies and/or maintained indoors with limited exposure to sunlight.

Hypocalcemia initially manifesting after 72 hours of age often heralds the presence of significant compromise of calcium homeostatic mechanisms, such as those associated with hypoparathyroidism because of malformation of the parathyroid glands (e.g., the DiGeorge syndrome or variant of a gene critical for embryogenesis of these structures) or functional error in PTH secretion (e.g., an abnormality in the activity of the calcium sensing receptor [CaSR]).

Hypoparathyroidism

Hypoparathyroidism presenting in infancy is often transient and related to delayed developmental maturation of parathyroid gland function; it may resolve within the first several weeks of life (see Tables 20.2A, 20.2B and Fig. 20.1). When persistent, hypoparathyroidism may be caused by an error in the embryogenesis of the parathyroid glands or in the synthesis or secretion of PTH or to peripheral unresponsiveness to PTH (functional hypoparathyroidism, i.e., PHP, occurs in patients who are resistant to PTH [vide infra]). Familial isolated congenital hypoparathyroidism may be transmitted as an autosomal dominant, autosomal recessive, or X-linked recessive trait caused by loss-of-function mutations in genes required for differentiation of the parathyroid glands leading to congenital aplasia or hypoplasia of these structures occurring as a unitary disorder. Thus, familial isolated hypoparathyroidism (OMIM 146200) has been related to inactivating mutations in *PTH*, glial cells missing (*GCM2*), and four-and-a-half Lim domains 1 (*FHL1*) and autosomal dominant hypocalcemia with suppressed secretion of PTH because of gain-of-function variants of *CASR* and guanine nucleotide binding protein alpha 11 (*GNA11*).^{3,11} Inactivating mutations in the exons encoding the signal peptide of *PTH* interfere with the processing of preproPTH to the bioactive 84 aa functional PTH molecule resulting in hypoparathyroidism that may be transmitted as an autosomal dominant or recessive characteristic.¹² Depending on the specificity of the immunoassay for PTH, serum levels of PTH may be low, normal, or even high in these patients. *GCM2* is a gene with five exons that encodes a 506 aa deoxyribonucleic acid (DNA)-binding transcription factor whose expression is restricted to the parathyroid glands. Intra-genic deletions or homozygous missense inactivating mutations in exons 2, 3, and 5 of *GCM2* result in hypoparathyroidism in humans.¹²⁻¹⁵ Mutations in *GCM2* exons 2 and 3 (encoding

DNA binding and transactivation domain 1) lead to impaired protein synthesis and stability and autosomal recessive transmission of congenital hypoparathyroidism whereas those in exon 5 (encoding transactivation domain 2) lead to mutations with a dominant negative effect and autosomal dominant transmission of this disorder.¹⁵ (Expression of *GCM2* takes place soon after specification of parathyroid cells and is dependent on normal transcriptional function of *GATA3*, the gene mutated in patients with the Barakat syndrome of hypoparathyroidism-deafness-renal dysplasia [HDR] [vide infra].¹⁶ Activating mutations of *GCM2* are associated with hyperparathyroidism [vide infra].) X-linked hypoparathyroidism is associated with agenesis of the parathyroid glands; the disorder is caused by loss-of-function variants of *FHL1* (encoding Four-and-a-half Lim domains 1, OMIM 300163), a gene whose product is essential for differentiation of the parathyroid glands.¹¹ *FHL1* is a 280-amino-acid (aa) protein with a LIM domain (double zinc finger motif) that is also expressed in testes, cardiac, and skeletal muscle.

Hypocalcemia associated with impaired secretion of PTH caused by monoallelic activating mutations in *CASR* have been identified in neonates, infants, children, and adults.^{17,18} Hypercalciuric hypocalcemia is an autosomal dominantly transmitted form of hypoparathyroidism that is caused by gain-of-function mutations in *CASR* (autosomal dominant hypocalcemia type 1) or *GNA11* (autosomal dominant hypocalcemia type 2) that result in enhanced "sensitivity" of the CaSR to the PTH-suppressive effects of Ca²⁺ in the chief cells of the parathyroid glands and in renal cells in the thick ascending limb of the loop of Henle (TALH). The CaSR monitors plasma concentrations of Ca²⁺, whereas *GNA11* is the alpha subunit—guanine nucleotide binding protein of the trisubunit guanosine protein binding receptor (GPCR) transmitting the signal of the CaSR to intracellular signal transduction pathways. A lowered "set-point" of the CaSR or enhancement of the postreceptor signal transduction system itself enables PTH secretion to be suppressed and renal tubular reabsorption of calcium to be depressed (thus increasing urine calcium excretion) by extremely low concentrations of Ca²⁺ resulting in marked hypercalciuria. Activating mutations (e.g., p.Lys47Asn, p.Leu616Val, p.Phe788Leu) may be scattered throughout *CASR* but occur predominantly in the second peptide loop of its extracellular domain.¹⁸ Some activating monoallelic variants (e.g., p.Cys141Trp, p.Leu125Pro, p.Ala843Glu) of *CASR* may also inhibit function of the renal outer medullary potassium channel (encoded by *KCNJ1*, OMIM 600359), leading to a Bartter-like syndrome with hypokalemic metabolic alkalosis, hyperreninemia, hyperaldosteronism, and hypomagnesemia, as well as hypercalciuric hypocalcemia (designated Bartter syndrome type 5, OMIM 601198). These paired metabolic defects are partially responsive to treatment with hydrochlorothiazide and low doses of calcitriol. However, children with hypercalciuric hypocalcemia caused by gain-of-function mutations in *CASR* are very sensitive to even low doses of calcitriol that can lead to even more marked hypercalciuria and to nephrocalcinosis. Thus management of these patients has been difficult. Administration of recombinant human PTH¹⁻³⁴ to a 14-month-old hypocalcemic male infant with a de novo nonsense mutation in *CASR* (p.Leu727Gln) for 17 months partially restored calcium homeostasis with increased but still subnormal serum levels of calcium, while urinary excretion of calcium decreased into the normal range.¹⁷ During treatment, the child was clinically asymptomatic, did not develop nephrocalcinosis, and tolerated the drug well. However, administration of PTH to such a patient may increase urine calcium excretion and the risk of nephrocalcinosis. Use of calcilytic agents (type II calcimimetics), such as cinacalcet that antagonize the effects of calcium upon the CaSR in the parathyroid glands and renal tubules may prove therapeutically useful in these patients. Neonates with

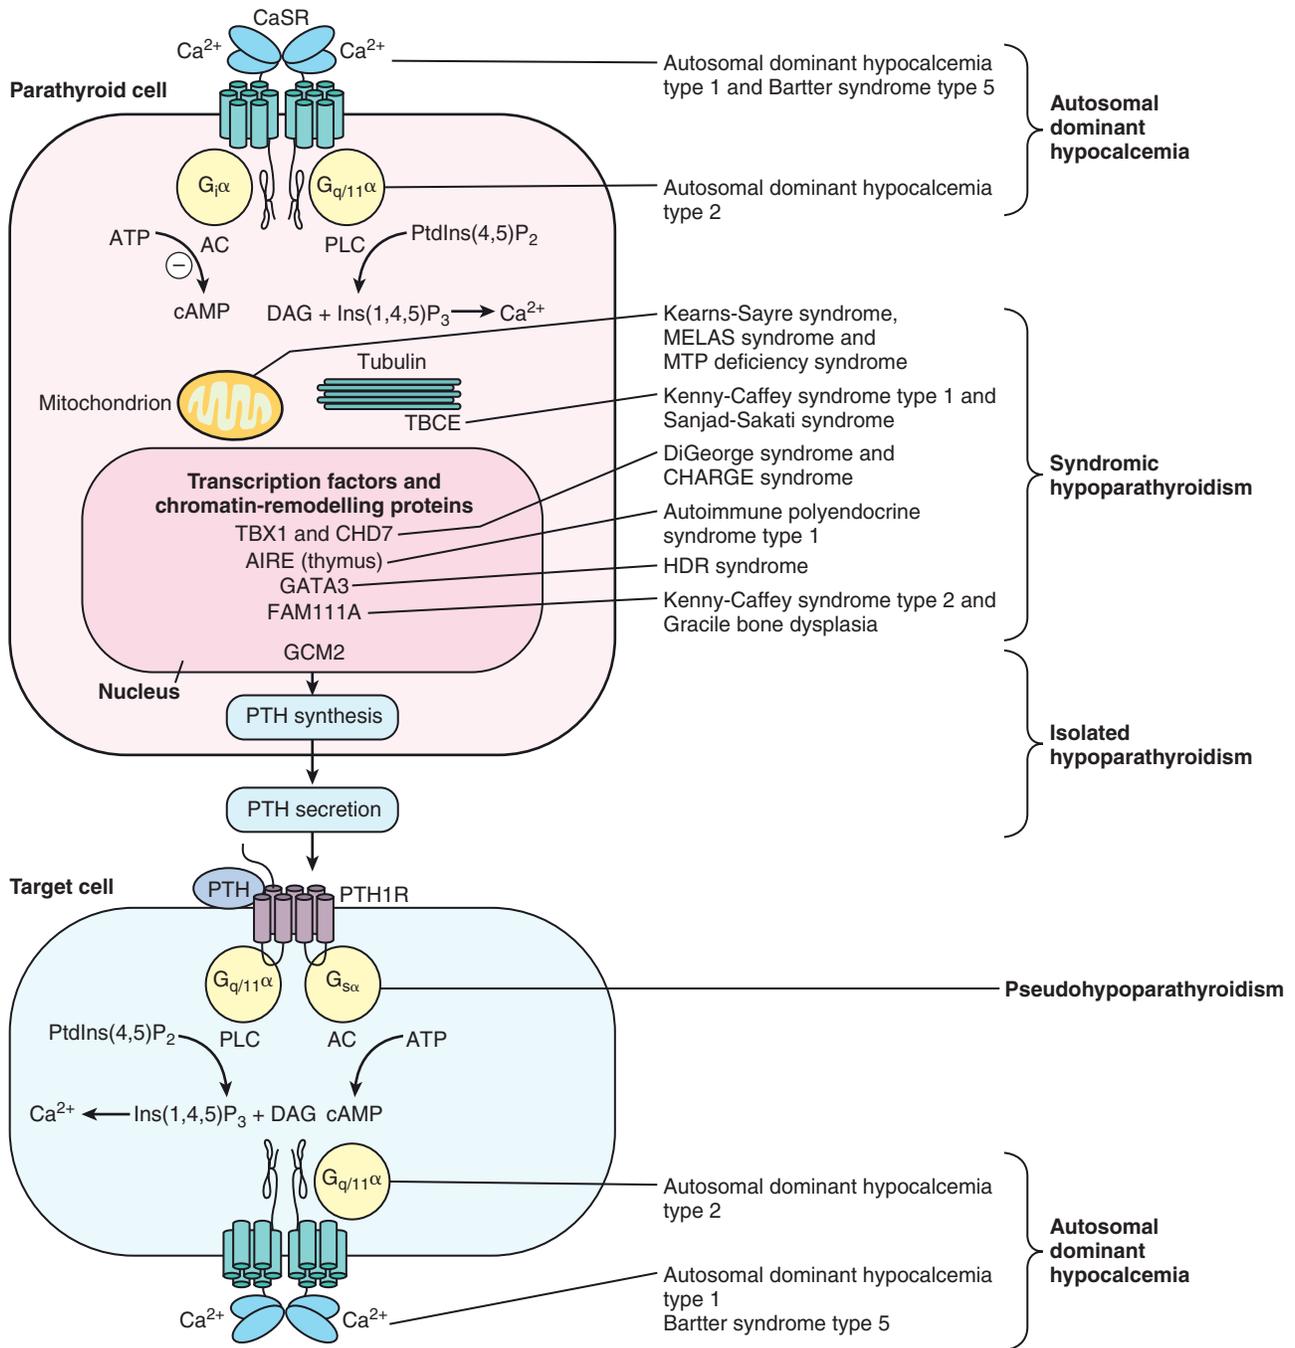

Fig. 20.1 Regulation of parathyroid hormone (PTH) secretion and genetic disorders resulting in hypoparathyroidism. In the parathyroid gland the calcium sensing receptor (CaSR) monitors the circulating Ca^{2+} concentration and mediates the secretion of PTH that acts through the PTH receptor on the plasma membrane of the target bone or renal cell. Genetic errors in this pathway lead to hypoparathyroidism. AC, Adenylyl cyclase; AIRE, autoimmune regulator; ATP, adenosine triphosphate; Ca^{2+} , ionized calcium, CaSR, calcium sensing receptor, cAMP, cyclic adenosine monophosphate; CHD, chromodomain; DAG, diacylglycerol; FAM111A, family with sequence similarity 111A; GATA3, GATA binding protein 3; GCM2, glial cell missing transcription factor 2; Ins(1,4,5)P₃, inositol trisphosphate; PLC, phospholipase C; PtdIns, phosphatidylinositol; PTH, parathyroid hormone; PTH1R, PTHrP receptor; TBCE, tubulin-specific chaperone E; TBX1, T-box transcription factor 1. (From Mannstadt M, Bilezikian JP, Thakker RV, et al. Hypoparathyroidism. *Nat Rev Dis Primers*. 2017;3:17055, with permission.)

variants of *GNA11* may not have the same degree of hypercalciuria as do those with mutant *CASR*.

The most commonly encountered forms of hypoparathyroidism are those associated with constellations of congenital abnormalities (see Tables 20.2A, 20.2B and see Fig. 20.1). The most frequent complex form of hypoparathyroidism is that associated with the DiGeorge syndrome type 1 (OMIM 188400), a disorder that occurs with a frequency of 1:4000 births and is present in approximately 70% of children with

isolated hypoparathyroidism.^{19,20} In many infants with the DiGeorge syndrome, hypoparathyroidism partially remits over time only to reappear in periods of stress, such as infections or trauma. The DiGeorge syndrome is a neurocristopathy—the result of disturbed migration of cervical neural crest cells and consequent maldevelopment of tissues of neural crest origin derived from the third and fourth pharyngeal pouches and first to fifth branchial arches. DiGeorge syndrome type 1 is associated with microdeletions of chromosome region 22q11.2

(del22q11.2—the DiGeorge critical region), a segment on which more than 35 genes are sited and thus is a contiguous gene syndrome (a disorder caused by deletion of several adjacent genes that when individually mutated may result in a distinctive clinical feature but when collectively lost leads to a group of apparently unrelated clinical findings). The chromosome 22q11.2 microdeletion is contained within regions of low copy number repeats, and it is this characteristic that results in unequal segmental exchange between the paired 22nd chromosomes during meiosis.²⁰ Subjects with the DiGeorge syndrome usually have the triad of: (1) hypocalcemia because of hypoplasia of the parathyroid glands often manifest in the neonatal period but which may not be detected until an older age, (2) defective T lymphocyte function and impaired cell-mediated immunity because of partial or complete absence of thymic differentiation leading to increased frequency of viral and fungal infections and propensity of autoimmune disorders, and (3) conotruncal defects of the heart or aortic arch (Tetralogy of Fallot, ventricular septal defect, interrupted or right aortic arch, truncus arteriosus, vascular ring).²⁰ To a substantial extent, DiGeorge syndrome type 1 is related to loss or deleterious variants of T-box 1 (*TBX1*, OMIM 602054) within the 22q11.2 chromosomal segment. Experimental disruption of *Tbx1* impairs development of the pharyngeal arch arterial vasculature, whereas introduction of null mutations in *Tbx1* results in anomalies of the cardiac outflow track and hypoplasia of the thymus and parathyroid glands. The transcription factor encoded by *TBX1* is part of a network of gene products (including those encoded by *ISL1*, *SHH*, *FOXA2*, *FOXC2*) that controls development of the parathyroid glands and thymus by regulating expression of *GATA3*, *GCM2*, and *PAX9*.²⁰ Mutations of *TBX1* specifically account for five major manifestations of the DiGeorge syndrome: parathyroid hypoplasia and hypocalcemia, thymic aplasia, cardiac anomalies, unusual facial features (low set ears, micrognathia, slanted eyes, short palpebral fissures and philtrum, small mouth), and cleft palate with velopharyngeal insufficiency. *TBX1* haploinsufficiency can also cause isolated hypoparathyroidism. Also within this two megabase microdeletion at chromosome 22q11.2 is *HIRA* (histone cell cycle regulation, OMIM 600237), a transcription regulatory factor that is expressed in developing heart and upper body neural crest elements and is necessary for normal cardiac development. Another critical gene sited at chromosome 22q11.2 is *UFD1L* (ubiquitin fusion degradation 1-like, OMIM 601754), whose product is important for the posttranslational processing of proteins and/or their degradation by interaction with the ubiquitin fusion protein. Experimentally, the DiGeorge syndrome has been linked to genes encoding endothelin-1, vascular endothelial growth factor, and fibroblast growth factor-8 (*Fgf8*, a target gene for *TBX1*). In the mouse hypomorphic for *Fgf8*, there are cardiovascular, craniofacial, parathyroid, and thymic defects—an experimental phenocopy of the human del22q11.2 syndrome.²¹ (Maternal diabetes mellitus, alcoholism, or ingestion of retinoic acid may occasionally be associated with the DiGeorge syndrome in the offspring.)

Prenatally, the presence of the DiGeorge syndrome may be considered when fetal ultrasonography reveals an interrupted aortic arch or truncus arteriosus and may be confirmed by appropriate studies (microarray, fluorescent in situ hybridization [FISH]) on samples of chorionic villi or amniotic fluid. Other clinical features of the DiGeorge syndrome include: growth retardation, renal dysplasia, gastrointestinal malformations (esophageal atresia, anal atresia), cervical spine instability, impaired vision, and ocular malformations, malformation of the cerebral cortex (perisylvian polymicrogyria), and developmental delay.²⁰ DiGeorge syndrome type 1 (OMIM 188400) may occur sporadically or be transmitted as an autosomal dominant trait. DiGeorge syndrome type 2/Velocardiofacial syndrome complex 2 (OMIM 601362) has been

associated with interstitial deletion of chromosome 10p13 but attributed, in part, to loss of *NEBL* (Nebulette, OMIM 605491), sited at chromosome 10p12.31. *NEBL* encodes a protein expressed in cardiac and striated muscle that associates with actin, myofibrils, and cellular adhesion complexes; DiGeorge syndrome type 2 is transmitted as an autosomal dominant characteristic.³ The DiGeorge syndrome has also been associated with microdeletions of chromosomes 18q21.33 and 4q21.2-q25—indicative of the cascade of genes likely involved in the generation of this phenotype. In addition to DiGeorge syndrome type 1, deletion of chromosome 22q11.2 has been associated with the velocardiofacial and other syndromes. Collectively, these syndromes display similar facial features (ocular hypertelorism, lateral displacement of inner canthi, short palpebral fissures, swollen eyelids, dysmorphic “segmented” nose, small mouth, low set ears with abnormally folded pinnae, short philtrum, micrognathia, malar hypoplasia, velopharyngeal insufficiency with/without cleft palate), olfactory dysfunction, short stature, nonverbal learning disabilities, and various psychological maladies.^{19,22} Takao velocardiofacial syndrome (included in OMIM 188440) consists primarily of the typical cardiac defects described earlier that may also be associated with hypocalcemia; Shprintzen velocardiofacial syndrome (OMIM 192430) is characterized by craniofacial and palatal defects and cardiac anomalies; Cayler cardiofacial syndrome (OMIM 125520) is associated with partial unilateral facial paresis because of hypoplasia of the depressor angulioris muscle and anomalies of the heart and aorta. These syndromes have been grouped as the CATCH-22 syndromes of cardiac defects, abnormal face, thymic hypoplasia, cleft palate, hypocalcemia.

Hypocalcemia has been observed in some subjects with microduplication of chromosome 22q11.2, a copy number variant; clinical characteristics of individuals with this genetic anomaly vary from those who are entirely normal to patients with multiple congenital anomalies, severe developmental delay, autism, and schizophrenia.^{23,24} The duplication chromosome 22q11.2 syndrome appears to be transmitted as an autosomal dominant characteristic whose expression is modified by other factors. The pathophysiology of hypocalcemia in affected subjects is uncertain. In one family in which the proband had the DiGeorge syndrome associated with del22q11.2, the normal father had the same anomaly on one of his 22nd chromosomes and dup22q11.2 on his other 22nd chromosome; paternal quantitative expression of the genes located on chromosome 22q11.2 was normal indicating that the adverse effects of the 22q11.2 deletion were compensated by the 22q11.2 duplication.²⁵

There are several other syndromes with multisystem involvement and hypoparathyroidism. Hypoplasia of the parathyroid glands and consequent hypoparathyroidism may be observed in patients with the CHARGE syndrome (coloboma, heart anomaly, choanal atresia, retardation, genital and ear anomalies, OMIM 214800) as a result of deletion of chromosome 8q12 or specifically to a heterozygous inactivating variant of *CHD7* (chromodomain helicase DNA-binding protein 7, OMIM 608092).²⁶ *CHD7* encodes a transcription regulating factor essential for differentiation of the neural crest that may coassociate with *TBX1*. *CHD7* is an adenosine triphosphate (ATP)-dependent chromatin remodeler that regulates movement of nucleosomes. The incidence of the CHARGE syndrome is approximately 1/10,000 births. The CHARGE and DiGeorge syndromes share several anomalies including hypoparathyroidism, cardiac and renal anomalies, cleft palate, ear abnormalities, and developmental delay. Indeed, hypoparathyroidism is more common (72%) in neonates with CHARGE than in those with the DiGeorge syndrome (26%).

The Barakat or HDR syndrome of hypoparathyroidism, sensorineural deafness, and renal disease (dysplasia, steroid-resistant

nephrosis with progressive renal failure—OMIM 146255) has been attributed to monoallelic deleterious variants of *GATA3* encoding GATA-binding protein-3 (OMIM 131320), a zinc-finger transcription factor/enhancer element that is required for development of the parathyroid glands, auditory system, and kidneys and for expression of genes encoding the four T-cell receptor subunits.¹² Heterozygous inactivating mutations of *GATA3* primarily involving loss of its carboxyl terminal DNA-binding segment are transmitted as an autosomal dominant disorder. Insertions, missense, and nonsense mutations in *GATA3* have also been identified in patients and families with HDR.²⁷ *GATA3* is a zinc-finger transcription factor that regulates expression of *GCM2* and thus is critical for the embryonic development of the parathyroid glands, as well as for the kidneys, otic vesicles, and thymus. The parathyroid glands of these children are hypoplastic or absent. Hypocalcemia may be present in the newborn period or unrecognized until later childhood. Malformations of the uterus and vagina (didelphic uterus, septate vagina) may be present in females with this disorder.

The Sanjad-Sakati syndrome of congenital hypoparathyroidism, mental retardation, and facial dysmorphism (depressed nasal bridge, long philtrum, thin upper lip, long filtrum) (HRD, OMIM 241410) is caused by biallelic loss-of-function mutations (often a 12 base pair deletion in the third coding exon) in *TBCE* (tubulin-specific chaperone E, OMIM 604934).²⁸ *TBCE* is a chaperone protein that is essential for formation/folding and stability of microtubules—cytosolic structures composed of heterodimeric α - and β -tubulin subunits that form the cytoskeleton, mitotic apparatus, cilia, and other cellular components; this chaperonin assists in the correct folding of α - and β -tubulin subunits and the formation of α - β -tubulin heterodimers. The α - and β -tubulin subunits and *TBCE* are necessary for normal embryogenesis of the parathyroid glands. Mutations in *TBCE* result in lowered microtubule formation and consequently in decrease in subcellular components, such as the cytoskeleton, Golgi apparatus, and endosomal compartments required for normal intracellular movement of proteins, as well as formation of the mitotic apparatus and cilia. The majority of infants with HRD sustain intrauterine growth retardation and manifest hypocalcemic seizures with low serum concentrations of PTH and normal phosphaturic responses to exogenous PTH in the first several weeks and months after birth. Children with HRD are short, developmentally delayed, and seizure prone; they have medullary stenosis of the long bones and other skeletal anomalies; they are microcephalic with faces characterized by deeply recessed eyes or microphthalmia, depressed nasal bridge, beaked nose, long philtrum, thin upper vermilion border, micrognathia, and large floppy earlobes. The cardiovascular system of these patients is intact, but as infants, they are susceptible to life-threatening pneumococcal infections.²⁹ Additional features in HRD subjects as assessed by neuroimaging include adenohipophyseal hypoplasia and attenuation of the pituitary stalk, infundibulum, and corpus callosum.

When a patient with the Sanjad-Sakati syndrome—HRD triad also manifests cortical thickness and medullary stenosis of the long bones, osteosclerosis of the skull, and susceptibility to recurrent infections and has biallelic variants of *TBCE*, the complex is termed the *Kenny-Caffey syndrome type 1* (KCS1, OMIM 244460). Neonates with KCS1 are often severely hypocalcemic early in the postnatal period. As children they are short, with microcephaly and craniofacial anomalies because of absence of diploic space in the skull, osteosclerosis, and thickening of the cortices of the long bones with narrowing of the medullary compartment, normal or mildly delayed development, and increased susceptibility to recurrent bacterial infections. Interestingly, the identical mutation in *TBCE*—a homozygous 12-bp deletion in exon 2—may result in either the HRD or KCS1 phenotype in a specific family.³⁰ The clinical,

laboratory, and radiographic findings in patients with Kenny-Caffey syndrome 2 (KCS2, OMIM 127000) are similar to those in subjects with KCS1, except that patients with KCS2 have normal intelligence. KCS2 is the result of monoallelic loss-of-function mutations in *FAM111A* (family with sequence similarity 111, Member A, OMIM 615292). Allelic to KCS2 is gracile bone dysplasia (OMIM 602361), in which the bones are thin, slender, and brittle, the diaphyses are dense, the basal cranial sutures close prematurely, there is microphthalmia, and hypocalcemia because hypoparathyroidism is common. Hypomagnesemia is often present as well. Heterozygous variants in *FAM111A* have been identified in these patients. *FAM111A* encodes a factor whose expression is lowest in stage G0 of the cell cycle but whose primary function is unknown; it has been suggested that *FAM111A* may interact with *TBCE* to regulate gene expression or function.³¹

Mitochondria are cytoplasmic organelles that are primarily donated to the embryo within the cytoplasm of the fertilized ovum and are therefore of maternal origin. Mitochondria are the primary intracellular site of respiration and energy utilization. The mitochondrial genome consists of a single circular chromosome with 37 embedded genes. Thirteen mitochondrial genes encode proteins required for electron transport and energy generation; 22 mitochondrial genes encode transfer ribonucleic acids (RNAs) required for protein synthesis. In addition, there are mitochondrial proteins whose genes reside in the cell's nucleus but that are expressed within mitochondria. Thus mitochondrial dysfunction leading to hypoparathyroidism may be caused by deletion and/or duplication of mitochondrial DNA encoding genes intrinsic to the mitochondrion itself or to variants of nuclear DNA encoding a protein expressed within the mitochondrion.³ Clinical manifestations of mitochondrial DNA mutations almost always involve muscle dysfunction, as well as other tissues depending upon the postconceptual age and cellular site(s) in which the mitochondrial DNA variation occurs. The Kearns-Sayre syndrome (OMIM 530000) is associated with agenesis or dysgenesis of the parathyroid glands leading to hypoparathyroidism. Primary manifestations of this syndrome include progressive external ophthalmoplegia, pigmentary retinopathy, sensorineural deafness, cerebellar ataxia, abnormal cardiac conductivity, myopathy, growth retardation, and renal tubular dysfunction, as well as hypoadrenocorticism, hypogonadism, and diabetes mellitus.³² Both deletions and duplications of mitochondrial DNA may be found in patients with this syndrome. The syndrome of mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS, OMIM 540000) is also associated with hypoparathyroidism, as well as myopathy, ophthalmoplegia, neuropathy, cardiomyopathy, impaired cognition, and diabetes mellitus. Biallelic mutations in *HADHB* (Hydroxylacyl-CoA dehydrogenase/3-Ketoacyl-CoA thiolase/Enoyl-CoA hydratase, beta subunit, beta subunit, OMIM 143450) encoding mitochondrial trifunctional protein impair intramitochondrial beta oxidation of fatty acids resulting in the inability to use an energy source. Depending upon the extent of the enzymatic deficiency, clinical presentations may vary from acute and lethal in the perinatal period to a hepatic Reye-like syndrome in older infants to a skeletal myopathy in adolescents. Occasionally, hypoparathyroidism may occur in these patients.³³

PHP is a conglomerate of clinical disorders most often characterized by end-organ insensitivity to the biological effects of PTH (and PTHrP) resulting in hypocalcemia despite substantial secretion of endogenous PTH. The PTH receptor (*PTH1R*, OMIM 168468) is a heptahelical transmembrane G-protein-coupled structure that after binding to extracellular PTH or PTHrP initiates intracellular signal transduction by changing its configuration, thereby enabling the linked submembrane stimulatory guanine nucleotide-binding protein (Gs-protein)

to exchange guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the alpha subunit (*GNAS*, OMIM 139320) of the heterotrimer of alpha, beta, and gamma subunits that together comprise the G_s-protein.³⁴ After substitution of GTP for GDP on the α subunit, G_{s α} dissociates from its linked $\beta\gamma$ subunits. G_{s α} then stimulates intracellular adenylyl cyclase (*ADCY3*, OMIM 600291) enzymatic activity, thereby converting ATP to cyclic adenosine monophosphate (AMP) and releasing it from the intracellular surface of the plasma membrane of the PTH-responsive cell. Cyclic AMP in turn binds to the regulatory alpha subunit of protein kinase A or PKA (*PRKAR1A*, OMIM 188830), thereby initiating intracellular signaling.³⁴ The catalytic subunits of PKA then phosphorylate a number of intracellular proteins including the cyclic AMP-responsive binding protein (*CREB1*, OMIM 123810) that in turn initiate transcription of cyclic AMP target genes. CREB1 is inactivated by one of several phosphodiesterases encoded by *PDE4D* (OMIM 600129) and *PDE3A* (OMIM 123805). After G_{s α} has propagated signal transmission through activation of adenylyl cyclase, the intrinsic GTPase activity of G_{s α} hydrolyzes the attached GTP to GDP, thereby halting further signal transduction.

Neonates with biallelic loss-of-function mutations in *PTH1R* are functionally hypoparathyroid despite elevated serum concentrations of PTH and thus represent a form of "PHP."^{35,36} Because of subresponsiveness to PTHrP in utero, fetal bone formation is abnormal resulting in Blomstrand chondrodysplasia—an osteochondrodystrophy characterized by short extremities and advanced skeletal and dental maturation—abnormalities detectable in utero by fetal ultrasonography. Histologically, the proliferative zone of the cartilage growth plate is narrowed with relatively few resting and proliferating chondrocytes, whereas the hypertrophic zone is composed of irregular columns of chondrocytes. Transmitted as an autosomal recessive trait, its clinical characteristics include polyhydramnios, hydrops fetalis, short-limbed dwarfism, facial anomalies, aberrant tooth development, aplasia of the nipples and breasts, hypoplastic lungs, preductal aortic coarctation, and neonatal hypocalcemia and hyperphosphatemia despite elevated serum concentrations of PTH. Although Blomstrand osteochondrodysplasia (OMIM 215045) is usually lethal, skeletal malformations may be more (type I) or less severe (type II). Mutations in *PTH1R* that result in complete absence of normal protein (e.g., Arg104Ter) are designated type I while mutations that permit some *PTH1R* synthesis (Pro132Leu) result in type II Blomstrand osteochondrodysplasia.³⁷ Eiken chondrodysplasia (OMIM 600002) is also caused by biallelic loss-of-function mutations in *PTH1R* but is clinically and radiographically distinct from Blomstrand osteochondrodysplasia as affected subjects have mild growth retardation, markedly delayed epiphyseal ossification, multiple epiphyseal dysplasia, and persistent islands of cartilage in the pelvis.³⁸ Variants of *PTH1R* that occur in patients with the Eiken syndrome are located in the carboxyl terminal portion of the gene/protein (e.g., pArg485Ter). Heterozygous inactivating mutations of *PTH1R* may result in an autosomal dominant nonsyndromic failure of tooth eruption (OMIM 125350).³⁹

Classically, PHP is the term applied to the clinical state that is associated with abnormalities of the signaling pathway that transmits the message conveyed by interaction of PTH/PTHrP with *PTH1R*. Neonates and infants with PHP are often hypocalcemic and hyperphosphatemic with elevated serum levels of PTH, whereas older patients with PHP exhibit the characteristic phenotype and skeletal malformations of Albright hereditary osteodystrophy ([AHO]; growth retardation; brachydactyly of the third, fourth, and fifth metacarpal bones; round face; impaired dentinogenesis; and subcutaneous ossifications) with or without biochemical abnormalities.^{40,41} The AHO phenotype

of growth retardation and brachydactyly is the result of accelerated closure of cartilaginous growth plates in long bones—the consequence of G_{s α} haploinsufficiency in chondrocytes and early phase osteoblasts that accelerates osteoblast maturation. Palpable heterotopic subcutaneous ossifications, at times associated with a bluish discoloration of the overlying skin, develop in 70% of patients with AHO associated with PHP1a and pseudopseudohypoparathyroidism (PPHP); their number and size may increase over time and become acutely or chronically painful. Other unusual consequences of PHP1a include spinal stenosis, carpal tunnel syndrome, sensorineural and conductive hearing loss, olfactory impairment, sleep apnea, and asthma. Consistent with resistance to endogenous PTH, administration of exogenous PTH does not reduce the number of sodium-phosphate cotransporters (NaPi2a, NaPi2c) and thus does not increase renal excretion of phosphate or cyclic AMP.

GNAS is an imprinted gene; although *GNAS* is expressed from both maternal and paternal *GNAS* genes in many tissues, *GNAS* is expressed only from the maternal gene in the proximal renal tubule, thyroid, gonads, and adenohypophysis (vide infra).⁴² Thus in the proximal renal tubule *GNAS* expression is "imprinted"; that is, there is differential gene expression depending on the parent of origin of the allele. *GNAS* is composed of 13 exons; it has multiple transcripts that arise through splicing of four unique first exons onto shared exons 2 to 13 (Fig. 20.2).⁴² Transcripts of *GNAS* include: (1) the G_{s α} transcript—a protein that stimulates adenylyl cyclase and generates cyclic AMP—G_{s α} is expressed by both maternal and paternal alleles in most tissues (including skin, white adipose tissue, chondrocytes, bone); however, only the maternal allele of *GNAS* is expressed in the proximal renal tubule, thyroid, gonads, and anterior pituitary (because of silencing of paternal *GNAS* caused by an epigenetic imprint)⁴¹; (2) XL α s yields a G_{s α} isoform that is specifically expressed in neuroendocrine and nerve tissues and is identical to G_{s α} except that it has a very long amino terminal sequence of amino acids; it is expressed only by the paternal allele; (3) the neuroendocrine secretory protein-55 (NESP55) transcript is a chromogranin-like protein that is expressed in neuroendocrine tissues but only by the maternal *GNAS* allele; and (4) the alternative first exon A/B (exon 1A) transcript is expressed ubiquitously but only at low levels and by the paternal *GNAS* allele and is not translated. The promoters of XL α s, NESP55, and exon 1A transcripts lie within the 5' differentially methylated region (DMR) of *GNAS*. Methylation of the promoter usually silences expression of that *GNAS* transcript.

Loss-of-function mutations in *GNAS* or epigenetic (methylation) aberrations that result in failure of expression of a parental G_{s α} transcript of *GNAS* lead to PHP types IA, IB, and IC and PPHP. PHP type 1A (PHP1a, OMIM 103580) is associated with resistance to protein hormones that signal through GPCRs and is the consequence of loss-of-function mutations in the maternal allele that encodes *GNAS*. Inactivating variants of maternal *GNAS* (functionally resulting in biallelic inactivity of *GNAS* and near total loss of G_{s α} activity in the proximal renal tubule) lead to resistance to the biological effects of PTH in the proximal renal tubule and decreased reabsorption of filtered calcium resulting in hypocalcemia, exaggerated proximal renal tubular reabsorption of filtered phosphate leading to hyperphosphatemia, and elevated serum concentrations of PTH. In response to exogenous PTH, neither the urinary excretion of cyclic AMP nor that of phosphate increases. Erythrocyte G_{s α} activity is subnormal in patients with PHP1a.³⁴ (Resistance to thyroid-stimulating hormone [TSH] also occurs in patients with PHP1a. Thus PHP1a may be suspected in a neonate with hypocalcemia in whom hyperthyrotropinemia has been detected in the neonatal screening study for congenital hypothyroidism.⁴³) More than 200 heterozygous loss-of-function mutations in maternal

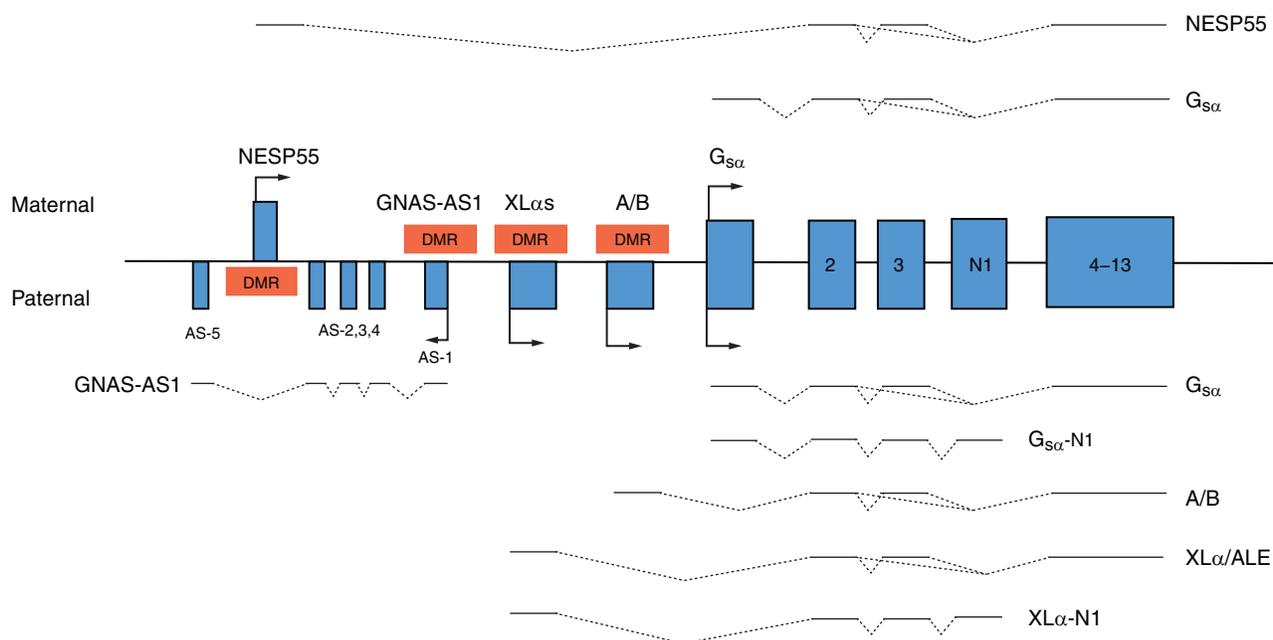

Fig. 20.2 Schematic view of the *GNAS* gene complex. Three major transcripts that encode proteins are derived from *GNAS* (neuroendocrine secretory protein-55 [NESP55], XL α s, and G $_{S\alpha}$) by linking of their first exon to the common exons 2–13. The transcript GNAS-AS1 is transcribed in the reverse/antisense direction. Through epigenetic imprinting regulated by the differentially methylated regions (DMR), the transcripts of XL α s and GNAS-AS1 are expressed only by the paternal allele, whereas NESP55 is expressed only by the maternal *GNAS* gene. G $_{S\alpha}$ is expressed from both parental *GNAS* alleles except in the proximal renal tubule, thyroid, gonads and adenohypophysis where only the maternal G $_{S\alpha}$ allele is expressed. The maternal *GNAS* transcripts are shown above the horizontal line, while the paternal transcripts are represented below the line. Bold lines represent exons; dashed lines indicate introns. (From Pignola RJ, Ramaswamy G, Fong JT, et al. Progressive osseous heteroplasia: diagnosis, treatment, and prognosis. *Appl Clin Genet*. 2015;8:37–48, with permission.)

GNAS have been described. A four base pair deletion in exon 7 (codons 188–189) in *GNAS* that leads to a frameshift and premature stop codon has been found in a number of families with PHP1a and appears to be a “mutational hotspot” as it impairs DNA polymerization and replication. Other mutations alter intracellular movement of *GNAS* protein (p.Leu99Pro, p.Ser250Arg), increase the rate of release of GDP (p.Arg258Trp, p.Ala366Ser), or impair coupling of G-protein to PTH1R (p.Arg385His). Inasmuch as *GNAS* is expressed by both maternal and paternal alleles in the distal renal tubule where filtered calcium is also reabsorbed, nephrocalcinosis does not usually develop in patients with PHP1a.³

Although patients with PHP type IB (PHP1b, OMIM 603233) generally have a normal phenotype (except for mild brachydactyly or obesity), they are hypocalcemic, hyperphosphatemic, and resistant to the biological effects of exogenous PTH and to TSH. PHP type IB occurs only in the offspring of obligate female carriers in whom loss of maternal *GNAS* expression in the kidney results in selective proximal renal tubular resistance to PTH; inasmuch as skeletal expression of both maternal and paternal *GNAS* is intact, bone formation is normal. PHP type IB is the result of defects in methylation of cytosine nucleotides within maternal *GNAS* resulting in its inactivation/conversion to a paternal *GNAS* epigenotype and the same functional consequences as those observed in patients with PHP type IA inasmuch as maternal *GNAS* is “silenced” in imprinted tissues, particularly the kidney. In some instances, this maternal epigenetic error has been transmitted by a maternal carrier to her offspring. In some patients, PHP type IB is caused by deletions within a DMR of *GNAS* or to loss of a 5' cis-acting imprinting control center that is essential for methylation of the *GNAS* DMR that regulates expression of maternal *GNAS* in the proximal renal tubule.^{40,44} PHP type IB may also be caused by microdeletions of maternal *GNAS* exons AS3–4 or

loss of methylation in maternal exons A/B of the differentially methylated region resulting in silencing of maternal *GNAS* or to variants of *GNAS*-AS1 or *STX16*.^{3,34} *GNAS*-AS1 (*GNAS* complex locus, antisense transcript 1, OMIM 610540) is embedded within the *GNAS* coding region, whereas *STX16* (Syntaxin16, OMIM 603666) is positioned immediately centromeric (5') to *GNAS* on the long (q) arm of chromosome 20; mutations (loss of exons 3–6) of maternal *STX16* are associated with loss of methylation of *GNAS* exons A/B. Nevertheless, the genetic basis for most patients with sporadic PHP1b remains unknown; some of these patients appear to have global epigenetic methylation defects. Paternal uniparental isodisomy of the long arm of chromosome 20 (site of *GNAS*) may be the cause of PHP1b in some patients. These patients have two normal paternal 20th chromosomes but no functional *GNAS* in specific tissues (i.e., proximal renal tubules). Imprinting defects involving *GNAS* have also been identified in patients with AHO IB and microdeletions of chromosome 2q37. Inasmuch as bone is responsive to PTH in patients with AHO IA/IB, an occasional subject may develop osteitis fibrosa cystica over time. Nevertheless, because PTH also has anabolic effects on endocortical bone, bone mineralization in some patients with PHP1a/1b may be increased.

Patients with PHP type IC have the AHO phenotype and are hypocalcemic and hyperphosphatemic, but erythrocyte Gas activity is normal.³⁴ PHP type I is related to variants of the maternal *GNAS* allele in exon 13 (see Fig. 20.2) near its carboxyl terminal, often leaving intact the adenylate cyclase activity region. Patients with PHP type II (OMIM 203330) have hypocalcemia, hyperphosphatemia, and elevated serum levels of PTH but a normal phenotype. In response to exogenous PTH, patients with PHP type II increase the urinary excretion of cyclic AMP but do not increase urine phosphate excretion, indicating a defect in intracellular signaling distal to generation

of adenylyl cyclase. Erythrocyte $G_{s\alpha}$ activity is normal in patients with PHP type II. The pathogenesis of PHP type II has not as yet been identified, but in some subjects it has been suggested that it may be related to vitamin D deficiency and PTH resistance secondary thereto; others may be ingesting anti-convulsant medications that accelerate degradation of vitamin D and its bioactive metabolites. Subjects with PPHP (OMIM 612463) caused by inactivating mutations of paternal *GNAS* have the AHO phenotype because of haploinsufficiency of *GNAS* expression in bone but are not obese and are intellectually intact; their kidneys, where maternal *GNAS* is expressed, are normally responsive to endogenous and exogenous PTH, and hence these patients are normocalcemic and normophosphatemic.³ Heterozygous mutations in *GNAS* on either parental allele have been associated with intrauterine growth retardation, with severity greatest when the variant is in the paternal allele, suggesting that a paternally derived *GNAS* transcript is required for normal fetal growth. The postnatal growth retardation of PHP and PPHP is possibly the extended consequence of cartilage growth plate resistance to PTH in utero and postnatally.³⁴ Patients with PHP type IA are resistant to many hormones that signal through *GNAS* including: TSH that may present as congenital hypothyroidism with hyperthyrotropinemia, growth hormone releasing hormone (GHRH) associated with growth hormone (GH) deficiency, luteinizing (LH) and follicle-stimulating (FSH) hormones presenting as delayed puberty, and melanocortin (MSH) associated with obesity of early onset.

Acrodysostosis is a chondrodysplasia with many features of PHP1a (short stature, obesity, brachydactyly, abnormal face with nasal and maxillary hypoplasia, hypertelorism, markedly advanced skeletal maturation) that is caused by gain-of-function variants of *PRKARIA* (OMIM 188830) or *PDE4D* (OMIM 600129) encoding components of the signal transduction systems activated by $G_{s\alpha}$ (vide supra).^{45,46} *PRKARIA* encodes the cyclic AMP-dependent regulatory alpha subunit of PKA, the protein kinase that is downstream of $G_{s\alpha}$ and cyclic AMP and whose activation leads to the cascade of intracellular signal transduction that regulates cell division, differentiation, metabolism, function, and apoptosis. Paradoxically, prolonged activation of the regulatory alpha subunit of PKA results in decline in the functional activity of the catalytic subunit of PKA. In a patient with acrodysostosis type 1 (OMIM 101800), a de novo germline gain-of-function mutation (pArg368Stop) in *PRKARIA* is present that leads to functional resistance to PTH and TSH.^{45,47} The mutant *PRKARIA* is a shortened protein whose binding avidity to the catalytic subunit of PKA is increased, because it lacks one of two cyclic AMP binding domains; hence it can only be slowly released from the catalytic subunit of PKA by cyclic AMP, thereby maintaining the catalytic subunit of PKA in the inactive state. In some patients with acrodysostosis type 1, resistance to PTH, GHRH, TSH, and the gonadotropins is present. *PDE4D* encodes phosphodiesterase 4D, an enzyme that hydrolyzes and inactivates cyclic AMP; hormone resistance is not present in patients with acrodysostosis type 2 (OMIM 614613) related to variants of *PDE4D*, although these patients are developmentally challenged.⁴⁵ In patients with inactivating mutations in *PDE4D*, the rate of degradation of cyclic AMP is increased.

(An alternative nomenclature for PHP has been presented by the EuroPHP network and termed the *inactivating PTH/PTHrP signaling disorder* [iPPSD] classification.³⁴ In this schema, the clinical disorders are linked to the genetic mutation in a component of the signal transduction pathways transmitting the messages of PTH and PTHrP that initiate cellular responses. For example, iPPSD1 is associated with biallelic inactivating mutations of *PTHRI* leading to the usually fatal Blomstrand chondrodysplasia [OMIM 215045] of short limbs, sclerotic

bones, advanced bone maturation, and facial dysmorphism associated with polyhydramnios and hydrops fetalis; Eiken syndrome [OMIM 600002] is an osteodysplasia with markedly delayed epiphyseal maturation that is also associated with biallelic mutations in *PTHRI*; Murk-Jansen chondrodysplasia [OMIM 156400] is the result of monoallelic activating mutations of *PTHRI* and is characterized by small stature, short and bowed limbs, clinodactyly, abnormal face, hypercalcemia, and hypophosphatemia despite normal to low serum concentrations of PTH. Inactivating mutations of *GNAS* leading to PHP1a are designated iPPSD2. Methylation defects involving *GNAS* giving rise to PHP1b are designated iPPSD3. Heterozygous mutations in *PRKARIA* [OMIM 188830] leading to deficient PKA activity result in acrodysostosis type 1 [OMIM 101800] characterized by growth retardation, variable facial dysmorphism, brachydactyly, and advanced skeletal maturation often associated with end-organ resistance to PTH and other G-protein-associated hormones are designated iPPSD4. Monoallelic variants of *PDE4D* [OMIM 600129] resulting in abnormalities of cyclic AMP-specific phosphodiesterase hydrolytic activity leading to acrodysostosis type 2 [OMIM 614613] whose phenotype resembles that of type 1 in association with developmental delay is termed iPPSD5. Brachydactyly with hypertension [OMIM 112410] has been related to variants of *PDE3A* [OMIM 123805, chr. 12p12.2] and assigned to iPPSD6. The designation iPPSD7 is used for disorders of unknown genetic pathogenesis.)

Progressive osseous heteroplasia (POH, OMIM 166350) is one of a group of disorders associated with intra- or subdermal ossification/calcification, in addition to the AHO phenotype of PHP, that is related to inactivating variants of paternal *GNAS* (vide infra).⁴² POH is a disorder caused by loss-of-function mutations involving the paternal *GNAS* allele that is characterized clinically by dermal ossifications that begin in infancy and progress to diffuse heterotopic bone formation in skeletal muscle and deep fascia.^{40,42,48} POH is to be distinguished from other syndromes associated with ectopic calcification and ossification, including fibrodysplasia ossificans progressiva (OMIM 135100; *ACVR1*—OMIM 135100) and hyperphosphatemic tumoral calcinosis (OMIM 211900; *GALNT3*—OMIM 211900). Although not as yet clinically described, an inactivating mutation in *LRP6* (encoding lipoprotein receptor-related protein 6—OMIM 603507) might also be associated with resistance to the biological effect of PTH. In addition to its primary role in receptor-mediated endocytosis of lipoproteins, *LRP6* is essential for the movement of $G_{s\alpha}$ to the plasma membrane and for its coupling to *PTH1R*.⁴⁹

Evaluation and Management

Evaluation of the neonate with hypocalcemia begins with review of the maternal preconceptional history, the conduct of gestation, and the peripartum, postnatal, and family histories followed by a comprehensive physical examination (Fig. 20.3). Historical data include those related to maternal parity and complications of pregnancy, such as maternal diabetes mellitus, toxemia of pregnancy or ingestion of agents that may cause maternal hypercalcemia (excessive alkali), intrauterine growth restriction, abnormalities of delivery, neonatal sepsis, or other early postpartum illnesses. The family history is examined for members with abnormalities of mineral metabolism, such as renal calculi, rickets, or hypocalcemia (e.g., seizure disorders). The social history provides information about the socioeconomic status of the mother and her cultural milieu that may have impacted maternal diet and exposure to sunlight during gestation. Physical examination of the neonate (abnormal face, cardiac murmur consistent with congenital heart disease) may suggest a complex form of hypocalcemia. Determination of a

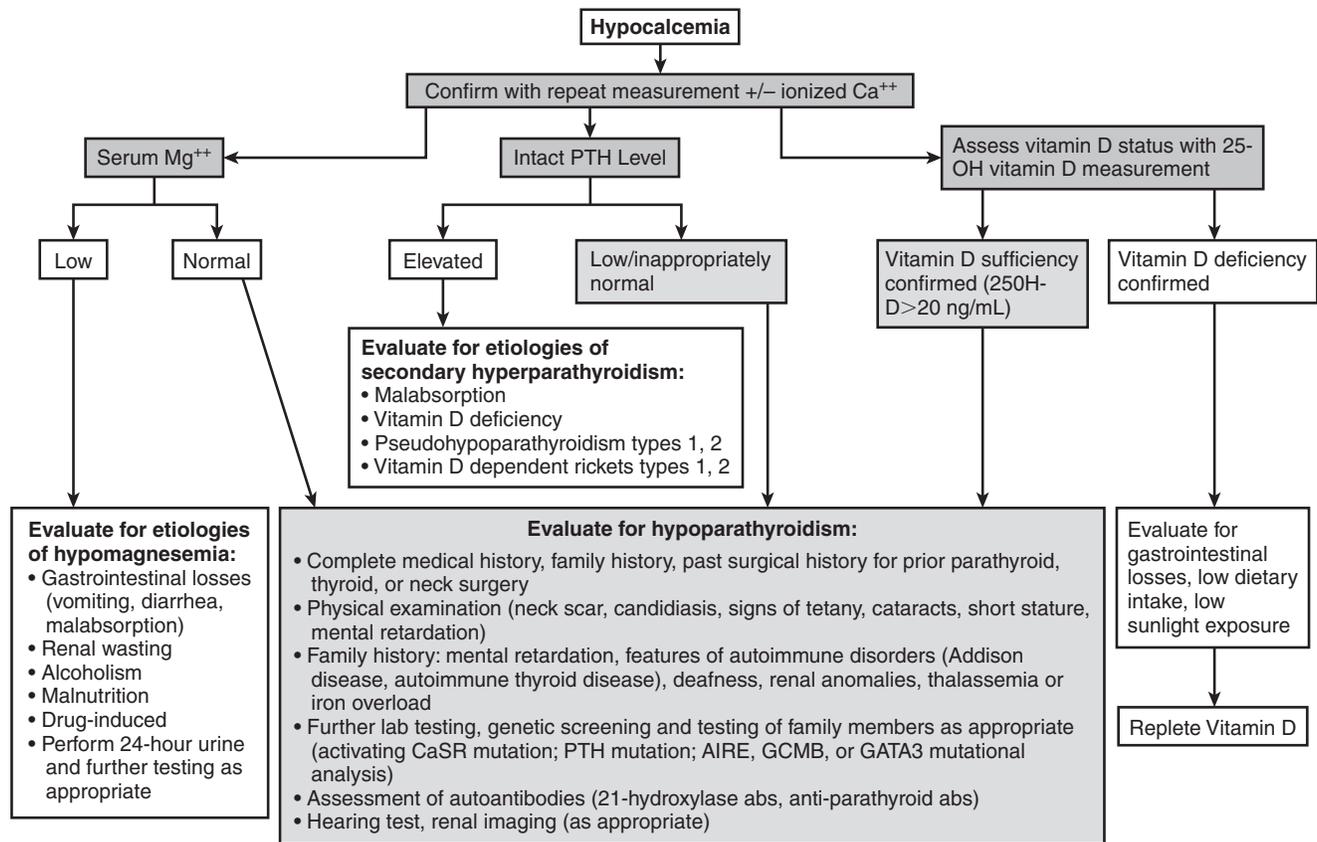

Fig. 20.3 Evaluation of hypocalcemia. (From Bilezikian JP, Khan A, Potts JT Jr, et al. Hypoparathyroidism in the adult: epidemiology, diagnosis, pathophysiology, target-organ involvement, treatment, and challenges for future research. *J Bone Mineral Res.* 2011;26:2317–2337, with permission.)

complete blood count, serum concentrations of total calcium, Ca^{2+} , magnesium, phosphate, creatinine, intact PTH, calcidiol, and calcitriol, and urinary calcium and creatinine concentrations in a spot urine should precede initial therapy of the hypocalcemic newborn whenever possible. Decreased serum concentrations of PTH are common in neonates with early-onset hypocalcemia, but persistently low PTH levels suggest impaired PTH secretion, at times because of inactivating variants of *PTH* or to gain-of-function mutations of *CASR* or *GNA11*. High PTH concentrations are present in patients with vitamin D deficiency or insensitivity, PTH resistance caused by loss-of-function mutations in *PTH1R*, *GNAS* (PHP), or *PRKARIA* (acrodysostosis type 1) or impaired renal function. Low levels of calcidiol signify decreased maternal (and hence fetal) vitamin D stores or rarely a defect in *CYP27B1* encoding vitamin D-25 hydroxylase, whereas calcitriol concentrations are inappropriately low in subjects with severely compromised renal function, hypoparathyroidism, or those with deficiency of 25OHD-1 α -hydroxylase. Elevated calcitriol values suggest vitamin D resistance perhaps caused by an abnormality in VDR, a disorder that may be associated with alopecia. Skeletal radiographs may disclose osteopenia, whereas chest x-ray may not identify a thymic shadow (but is an unreliable sign in a severely ill or stressed neonate). Serum levels of calcium, Ca^{2+} , phosphate, and intact PTH should be measured in the mothers of neonates with unexplained hypocalcemia as some may have unsuspected hyperparathyroidism.

In neonates with hypocalcemia not otherwise explained, evaluation for possible DiGeorge syndrome should be undertaken—particularly when physical examination reveals an

abnormal face, and a congenital anomaly of the outflow tract of the heart is present. The white blood and T (CD4) lymphocyte counts are low and the thymic shadow often absent in these subjects. The diagnosis of the DiGeorge syndrome is confirmed by the presence of a microdeletion of chromosome 22q11.2 as demonstrated by single nucleotide polymorphism based chromosomal microarray or FISH. Single nucleotide polymorphism microarray enables detection of both copy number variation (deletions or duplications) and copy-neutral structural variants, such as regions of homozygosity and uniparental disomy. Occasionally, sequence analysis of *TBX1* may be needed to establish this diagnosis, if the other studies are normal. Because DiGeorge syndrome may be heritable, genetic evaluation of the parents and siblings of an affected infant is indicated. It should be noted that the majority of neonates and infants with DiGeorge syndrome are recognized primarily because of cardiac anomalies and that subjects without these lesions may not be identified until mid or late childhood or adolescence.⁵⁰ Neonates with PHP1a may present with elevated serum levels of TSH in the neonatal metabolic screening survey but often do not have the characteristic skeletal phenotype (brachymetacarpals) of AHO; if no cause of congenital hypothyroidism is identified, the diagnosis of PHP1a should be suspected and measurement of serum calcium levels and, if appropriate, genotyping and methylation studies of *GNAS* are indicated.⁴⁰

Early neonatal hypocalcemia is often asymptomatic, but nevertheless treatment is indicated when the total serum calcium concentration is below 8 mg/dL (2 mmol/L) (Ca^{2+} <4.4 mg/dL [1.1 mmol/L]) in term infants or prematurely born

neonates with birth weights over 1500 g, or in a very LBW newborn with a total calcium value less than 7 mg/dL (1.75 mmol/L) ($\text{Ca}^{2+} < 4.0 \text{ mg/dL}$ [1.0 mmol/L]).⁴ Asymptomatic neonates are most easily managed by increasing the oral intake of calcium and establishing an overall ratio of calcium:phosphate intake of 4:1 (including that in feedings with a low-phosphate formula, such as Similac PM 60/40—calcium:phosphate ratio 1.6:1) with calcium gluconate or calcium carbonate administered in divided doses every 4 to 6 hours (Table 20.3). Eucalcemia is almost always restored in these subjects within 3 weeks after birth and often earlier. In the hypocalcemic infant with tetany or frank seizures, 10% calcium gluconate (elemental calcium 9.3 mg/mL) at a dose of 1 to 3 mg/kg and rate of less than 1 mL/min and a total dose not to exceed 20 mg of elemental calcium/kg may be administered by intravenous infusion over 15 minutes; often seizures will cease after 1 to 3 mL of 10% calcium gluconate have been administered.⁴ Cardiac rate and rhythm must be carefully

monitored to prevent bradycardia and asystole. Further intravenous bolus doses of calcium (~10 mg/kg at 6-hour intervals) should be used sparingly as they result in wide excursions in serum calcium values. After initial treatment of neonatal hypocalcemia, 500 mg of calcium gluconate/kg/24 hours may be administered by continuous intravenous infusion, taking care to prevent extravasation or infiltration as extracellular calcium will precipitate in soft tissues.⁵¹ These infants may receive supplemental oral calcium if necessary (vide supra). Depending on the cause of the hypocalcemia, supplemental vitamin D or calcitriol may also be needed. In a neonate with hypocalcemia caused by hypoparathyroidism, administration of synthetic PTH¹⁻³⁴ (teriparatide) or recombinant human PTH¹⁻⁸⁴ may occasionally be required to restore eucalcemia.⁵² Serum and urine calcium and creatinine levels should be determined frequently and treatment modified to maintain eucalcemia and the urine calcium/creatinine ratio under 0.2 in an effort to avoid iatrogenic hypercalcemia, hypercalciuria, nephrocalcinosis, and

TABLE 20.3 Preparations of Calcitriol, Calcium, Magnesium, and Phosphate

Content	Elemental Mineral	
Vitamin D		
Vitamin D		
Calciferol	8000 IU/mL	
	50,000 IU/capsule	
Calcidiol	20 or 50 mcg/tablet	
Calcitriol		
Rocaltrol	1 mcg/mL (oral solution)	
	0.25 mcg or 0.5 mcg/capsule	
Dihydroxycholesterol		
Hytachero	0.2 mg/5 mL	
	0.125, 0.2, 0.4 mg/tablet	
Calcium		
Calcium acetate		
Phoslyra	667 mg/5 mL	667 mg/capsule
Calcium gluconate (iv)	93 mg/10 mL	93 mg/g
	500, 650 mg/tablet	
Calcium gluconate (solution)	64 mg/g	115 mg/5 mL
Calcium carbonate	400 mg/g	500, 600, 750, 1250 mg/tablet
Titralac	420 mg tablet	168 mg/tablet
	780 mg tablet	300 mg/tablet
Os-Cal	650 mg tablet	260 mg/tablet (Vitamin D)
	1250 mg tablet	500 mg/tablet (Vitamin D)
Tums	500 mg tablet	200 mg/tablet
	750 mg tablet	300 mg/tablet
	1000 mg tablet	400 mg/tablet
	1250 mg tablet	280 mg/tablet
Caltrate	1500 mg tablet	600 mg/tablet (Vitamin D)
Calcium carbonate (suspension)	1250 mg/5 mL	500 mg/5 mL
Calcium chloride	100 mg/mL	
Calcium citrate	210 mg/g	200 mg/tablet
Citracal	950 mg tablet	200 mg/tablet
Calcium lactate	130 mg/g	84 mg/tablet
Magnesium		
Magnesium sulfate	49 mg/mL (50% intramuscular solution)	
	0.32, 0.64, 4 mEq/mL (intravenous solution)	
Magnesium oxide	603 mg/g	241 mg/tablet
Magnesium gluconate	54 mg/g	27 mg/tablet
Magnesium chloride	120 mg/g	64 mg/tablet
Phosphorus		
Sodium phosphate (Phospha-Soda)		127 mg/mL
Sodium/potassium phosphate (Phos-NaK)		250 mg/packet (powder)
Potassium phosphate (Neutraphos-K)		250 mg/packet (powder)
Potassium phosphate (K-Phos Original)		114 mg/tablet
Sodium/potassium phosphate (K-Phos #2)		250 mg/coated tablet
Sodium/potassium phosphate (K-Phos Neutral)		250 mg/tablet

(From Alon US. Hypophosphatemic vitamin D-resistant rickets. In: Favus MJ (ed). *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism*, 6th ed. Washington, DC: American Society for Bone and Mineral Research; 2006:342–345; Shoback D. Hypoparathyroidism. *N Engl J Med*. 2008;359:391–403.)

renal insufficiency. In neonates that require parenteral alimentation, 50 mg of elemental calcium/kg/24 hours should be incorporated into the infused solution; elemental phosphate must also be administered as permitted and indicated but separately from calcium.

After restoration of eucalcemia in the infant with DiGeorge syndrome, other components of this disorder must be addressed. Cardiac anomalies often require surgical correction as do palatal clefts. In affected infants who are immunocompromised and experience recurrent infections because of thymic aplasia, appropriate antiinfectious therapy is mandatory. Transplantation of fetal or cultured postnatal thymic tissue, bone marrow, or peripheral blood mononuclear cells has restored immune function in infants with this disorder. Supplemental calcitriol (20–60 ng/kg/d) and calcium are necessary for restoration and maintenance of eucalcemia in infants with hypoparathyroidism. Poor growth caused by feeding difficulties and learning disabilities caused by developmental delay must be managed on an individual basis and illustrate the need for a multidisciplinary approach to the care of these patients.⁵⁰ Hypocalcemia caused by hypomagnesemia is managed acutely by the intravenous infusion or intramuscular injection of 50% magnesium sulfate at a dose of 0.1 to 0.2 mL/kg while monitoring cardiac status.

Hypocalcemia in the Child and Adolescent

Etiology

Causes of hypocalcemia in the child and adolescent include many that also result in neonatal hypocalcemia and are listed in Tables 20.2A, 20.2B and Fig. 20.1. Hypocalcemia is defined by the norms of the analytical laboratory; total serum calcium and phosphate concentrations vary by age.^{1,2} (A general guideline for age-related total calcium concentrations is: 1–5 years: 9.4–10.8; 6–12 years: 9.4–10.2; >20 years: 8.8–10.2 mg/dL.) Total calcium levels are low in the hypoalbuminemic patient—a correction for hypoalbuminemia may be calculated by adding 0.8 mg/dL to the recorded total calcium concentration for every decrease in albumin concentration of 1 g/dL. Thus it is appropriate to measure both total and Ca^{2+} values when evaluating the hypocalcemic child. It is particularly important to monitor Ca^{2+} values in the hypocalcemic critically ill child.⁵³ In the very ill child/adolescent, a low total calcium value may at times be related to hypoproteinemia or to altered acid-base balance and variable binding of calcium to serum proteins, but it may also be caused by impaired secretion of PTH related to hypomagnesemia or to decreased synthesis of vitamin D and consequent subnormal intestinal absorption of calcium. Mechanistically, hypocalcemia develops as a consequence of either too little inflow of calcium from the gastrointestinal tract, bone, or kidney into the extracellular and vascular spaces or excessive loss of calcium from these spaces into urine, stool, or bone. Thus hypocalcemia may be caused by decreased intake or absorption or excessive loss of calcium, decreased production of bioactive PTH because of congenital abnormalities of parathyroid gland development or PTH synthesis or of the CaSR, destruction of parathyroid glands by autoantibodies, metal overload (copper, iron), surgical or radiation insults, granulomatous infiltration, or to impaired cellular responsiveness to PTH. Restricted exposure to sunlight or reduced intake, absorption, metabolism, or activity of vitamin D leads to hypocalcemia. Hypomagnesemia impairs the secretion (but not the synthesis of PTH) and blunts tissue responsiveness to PTH. Hypocalcemia occurs after exposure to a number of drugs and medications. Thus hypocalcemic tetany may develop after the administration of phosphate containing enemas by rectum or laxatives by mouth.⁵⁴ At times, the hypocalcemic child or adolescent may be asymptomatic and identified by chemical

screening for an unrelated problem or may present with intermittent muscular cramping either at rest or during exercise (when the increase in systemic pH caused by hyperventilation lowers still further the concentration of Ca^{2+}); paresthesias of fingers, toes, or circumoral regions; tetany (carpopedal spasm, laryngospasm, bronchospasm); or seizures (grand mal, focal, petit mal, adynamic or syncopal). Prolonged and severe hypocalcemia may lead to congestive heart failure.⁵⁵ Physical examination often reveals a positive Chvostek (twitching of the cheek upon tapping of the ipsilateral seventh cranial nerve) and/or Trousseau sign (carpopedal spasm) and hyperreflexia. However, a positive Chvostek sign is commonly present in normal adolescents.

Hypoparathyroidism may occur as a solitary disorder, as part of a multidimensional autoimmune polyendocrinopathy, or as one manifestation of a group of complex congenital anomalies (as described in the section on neonatal hypocalcemia).^{3,55} Hypoparathyroidism may be the consequence of total thyroidectomy performed to excise a malignant thyroid lesion because of inadvertent removal of the four parathyroid glands or insults to their arterial blood supply.⁵⁶ There are sporadic and familial forms of hypoparathyroidism; when familial, hypoparathyroidism may be transmitted as an autosomal dominant, autosomal recessive, or X-linked recessive trait (see Tables 20.2A, 20.2B and see Fig. 20.1). Abnormalities in the development of the parathyroid glands, transcription of *PTH*, and in processing of the translated product have been associated with inherited forms of hypoparathyroidism. Familial isolated/autosomal dominant dysmaturational hypoparathyroidism may be caused by a monoallelic T \Rightarrow C transition in codon 18 (p.Cys18Arg) of the 25 aa signal peptide of preproPTH that impairs efficient transport of protein from the ribosome and interaction of preproPTH with the signal recognition particle, movement of the precursor peptide into and exit from the rough endoplasmic reticulum, its cleavage by a signal peptidase, and its incorporation into a secretory granule. Familial isolated/autosomal recessive dysmaturational hypoparathyroidism has also been associated with a homozygous G \Rightarrow C transversion in nucleotide 1 of intron 2 of *PTH* within the signal sequence that prevented normal cleavage of preproPTH and decreased secretion of PTH. Occasionally, isolated hypoparathyroidism may be found in patients with deletion of chromosome 22q11.2 without other signs or symptoms of the DiGeorge or related syndromes.

Autosomal dominant hypocalcemia type 1 (OMIM 601198) is caused by heterozygous gain-of-function mutations in the extracellular, transmembrane, and intracellular domains of *CASR* that transcribe a CaSR that is not intrinsically constitutively active but is exceptionally sensitive to and easily activated by very low serum Ca^{2+} concentrations may be identified in infancy or in older subjects (Fig. 20.4). In this disorder, even at hypocalcemic levels, Ca^{2+} binds avidly to the CaSR and activates phospholipase C- β 1 increasing cytosolic levels of inositol phosphate and Ca^{2+} and stimulating the mitogen-activated protein kinase (MAPK) signal transduction pathway in parathyroid chief cells, thus suppressing PTH synthesis and secretion, and in the kidney, there decreasing renal tubular reabsorption of calcium and magnesium, leading to urinary wasting of these cations (hypercalciuric hypocalcemia) and decreased urinary concentrating ability. In these subjects, serum levels of phosphate are increased and magnesium values decreased; PTH concentrations are low or inappropriately normal. Autosomal dominant hypocalcemia type 2 is caused by heterozygous variants of *GNA11* (OMIM 139313) that encodes a G-protein alpha subunit ($\text{G}\alpha$ 11) that initiates intracellular signal transduction after binding of Ca^{2+} to the CaSR. Its clinical and biochemical manifestations are similar to those caused by variants of *CASR* with seizures, laryngospasm, hypocalcemia, hyperphosphatemia, and relatively low serum levels of PTH. Because

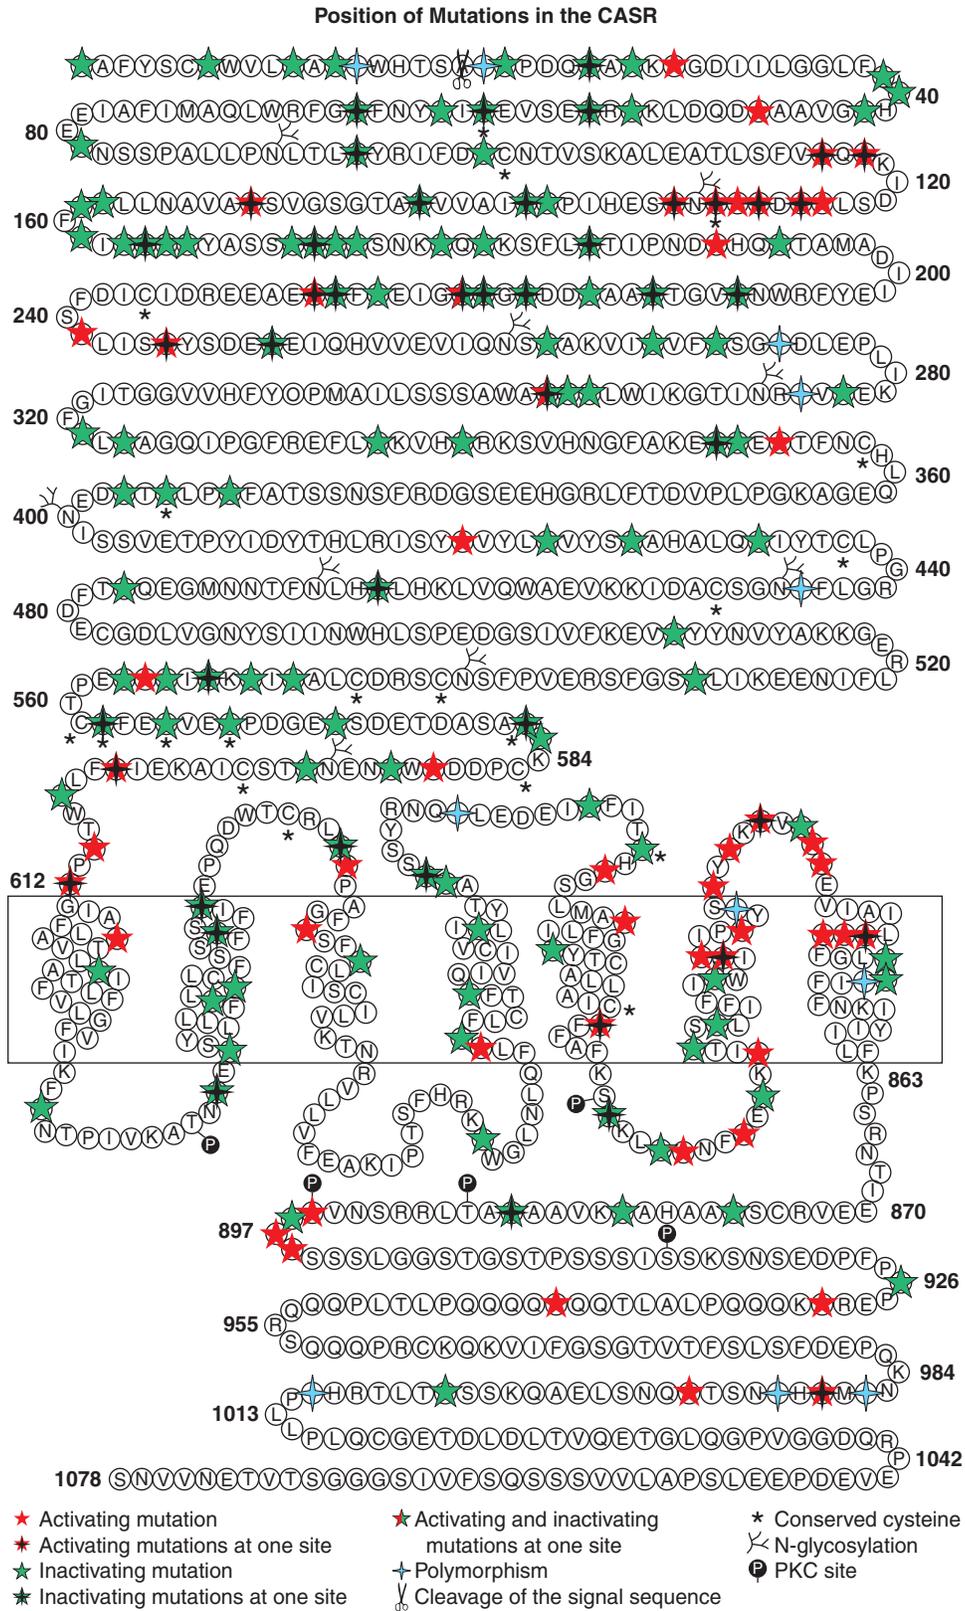

Fig. 20.4 Schematic view of the calcium sensing receptor (CaSR) depicting inactivating (hereditary/familial hypocalciuric hypercalcemia) and activating (autosomal dominant hypoparathyroidism) mutations. Note that mutations at adjacent codons may result in either a gain- or loss-of-function of the mutant CASR product (e.g., codons 565, 567, 568). (Downloaded from Google on April 27, 2013.)

patients with autosomal dominant hypocalcemia frequently have symptomatic hypocalcemia, such as tetany and seizures, and are very sensitive to vitamin D, the dose of calcitriol must be limited to that which raises serum calcium values to asymptomatic values even if not within the normal range as larger doses lead to hypercalciuria (sometimes even when serum calcium levels remain subnormal), nephrocalcinosis, and functional renal insufficiency. Administration of recombinant human (rh)PTH¹⁻³⁴ (teriparatide) restores calcium homeostasis in this disorder but does not necessarily prevent nephrocalcinosis.^{17,57,58} However, recombinant human PTH¹⁻³⁴ is not routinely administered to children because experimentally, there is an increased incidence of osteosarcoma in young rats receiving very large amounts of this agent, although primates appear to be less susceptible to PTH-induced bone tumor formation than do rodents. Development of stimulatory autoantibodies to the CaSR results in an acquired variant of spontaneous hypoparathyroidism that may be isolated or part of a complex autoimmune endocrinopathy.⁵⁹ Indeed, in perhaps as many as one-third of patients with acquired isolated idiopathic hypoparathyroidism, antibodies directed against epitopes in the extracellular domain of the CaSR may be present. This form of acquired hypoparathyroidism may be reversible, as these antibodies do not destroy the parathyroid glands. In patients with other forms of autoimmune hypoparathyroidism, the antibodies are cytotoxic and accompanied by lymphocytic infiltration, atrophy, and fatty replacement of parathyroid tissue.

In mid-childhood and adolescence, acquired hypoparathyroidism may be a delayed or late manifestation of a genetic variant (e.g., the DiGeorge syndrome), but it may also be the result of destruction of the parathyroid glands by autoimmune disease or surgical removal or operative trauma to the vascular supply of these structures. Unusual causes of acquired hypoparathyroidism in this age group include infiltration by iron (hemosiderosis, excessive blood transfusions) or copper (Wilson hepatolenticular degeneration), granulomatous diseases, or radiation (mantle radiation for Hodgkin/non-Hodgkin lymphoma or radioiodine therapy of hyperthyroidism).⁶⁰

Autoimmune hypoparathyroidism may occur as an isolated disorder or as part of the complex of autoimmune polyendocrinopathy syndrome type I (APS1).⁶¹ Development of an autoimmune endocrinopathy is initiated by failure of recognition of a peptide specific for a target organ by a subgroup of regulatory T cells that ordinarily recognize that peptide. When immunological tolerance for that peptide is lost, clones of CD4 regulatory T cells for the peptide expand; type 1 helper T cells secrete inflammatory cytokines, such as interferon- γ (IFN- γ), whereas type 2 helper T cells stimulate B cell function and lead to autoantibody-mediated inflammation. Loss of immune tolerance may be the consequence of the postinfectious inflammatory state caused by activation of the innate immune system or caused by a gene mutation that depresses immune tolerance and permits expansion of a CD4+ regulatory T cell clone after exposure to quantitatively small amounts of antigen. Genetic variations within the major histocompatibility complex (human leukocyte antigen [HLA]-DQ, HLA-DR) that determine peptide (antigen) presentation to CD4+ regulatory T cells join with genetic abnormalities in immune regulation to induce autoimmune disease. In 30% of patients with isolated idiopathic hypoparathyroidism the disorder is caused by antibodies to the extracellular domain of the CaSR and thus functionally inhibitory but potentially reversible; in approximately 33% of patients serum antibodies to other components of the parathyroid chief cell may be present.⁵⁹ There are several types of autoimmune polyendocrinopathy syndromes but only in type I is hypoparathyroidism a major component.

APS1 (OMIM 240300) is an autosomal recessive disorder with the classic triad of autoimmune polyendocrinopathy,

mucocutaneous candidiasis, and ectodermal dystrophy (APECED).⁶¹ It is characterized by childhood-onset of multiple autoimmune systemic disorders and endocrinopathies including hypoparathyroidism, primary adrenal insufficiency, and chronic mucocutaneous candidiasis, and less often pernicious anemia, hepatitis, primary ovarian and testicular failure, keratitis, retinitis, alopecia, and reversible metaphyseal dysplasia. Autoimmune polyendocrine syndrome 1 is caused by loss-of-function variants of autoimmune regulator (*AIRE*, OMIM 607358).⁶¹ In a Finnish cohort of 91 patients with APS1/APECED, the cardinal manifestations were mucocutaneous candidiasis involving the nails and mouth occurring in 100% of patients—often in the first 2 years of life, hypoparathyroidism, and hypoadrenocorticism both of which illnesses developed in 80% to 90% of affected subjects.⁶² Hypoparathyroidism occurred most often between 2 and 10 years and hypoadrenocorticism developed between 5 and 15 years of age. Almost all females with APECED developed hypoparathyroidism whereas 80% of affected males did so. Hypomagnesemia, often severe and recalcitrant to therapy, was common in patients with hypoparathyroidism caused by APECED. The most frequent presenting manifestations of APECED were mucocutaneous candidiasis—60%, hypoparathyroidism—32%, and hypoadrenocorticism—5%; the disease first became apparent between 2 months and 18 years of age. However, 10% of patients presented with another manifestation of APECED. In addition to hypoparathyroidism and hypoadrenocorticism, other endocrinopathies encountered in APECED included autoimmune oophoritis leading to ovarian failure (70%), orchitis resulting in testicular failure (30%), diabetes mellitus (30%), thyroiditis (30%), and hypophysitis (4%). Besides mucocutaneous candidiasis, dermatological manifestations and complications of APECED in the Finnish cohort included alopecia (40%), vitiligo (30%), and rashes with fever (15%). Keratoconjunctivitis developed in 20% of affected subjects, pernicious anemia in 30%, hepatitis in 20%, and chronic diarrhea in 20%. In a Norwegian population of 36 patients with APECED, 13 had clinical evidence of disease at or before 5 years of age and an additional 15 subjects presented at or before 15 years of age.⁶³ In a Russian population of 46 patients, mucocutaneous candidiasis was present in 70%, hypoparathyroidism in 83%, and adrenal insufficiency in 54%.⁶⁴ Other common problems were alopecia (27%), thyroid dysfunction (20%), and malabsorption syndromes (18%). Unusual findings in this cohort were retinitis pigmentosa and metaphyseal dysplasia—both occurring in 7% of patients. Later manifestations of APECED include esophageal and oral squamous cell carcinoma, asplenia, and interstitial nephritis. The diagnosis of APECED usually requires the presence of two of three of its major diseases (mucocutaneous candidiasis, hypoparathyroidism, hypoadrenocorticism), but occasionally chronic candidiasis, hypoparathyroidism or primary adrenal insufficiency alone may be the only manifestation of an inactivating mutation in *AIRE*.⁶⁴

APS1 is the result of homozygous or compound heterozygous loss-of-function mutations in *AIRE*, a 14 exon gene encoding a 545 aa protein with two zinc-finger motifs that is expressed in nuclei of thymic medullary epithelial cells and in lymph nodes, spleen, and monocytes.⁶¹ *AIRE* also serves as an E3 ubiquitin ligase, an essential component of the ubiquitin-proteasomal system for protein modification and destruction involved in cellular division and differentiation, protein transport, and intracellular signaling. Structurally, *AIRE* contains two plant homeodomains—a sequence of amino acids composed of an octet of cysteines and histidines that coordinate two zinc ions; the first plant homeodomain is essential for the E3 ubiquitin ligase activity of the protein and the second plant homeodomain is required for its transcription-regulating action. *AIRE* also contains a SAND domain, a

structure that permits it to bind DNA. AIRE enables thymic cells (T lymphocytes) to distinguish between normal self-antigens and proteins that are foreign to the host. AIRE does so by inducing the expression of normal self-antigens in the thymus and then eliminating the clonal subsets of T lymphocytes that recognize them thereby establishing self-tolerance. To develop an immune system that is capable of distinguishing between “self” and “foreign” antigens, thymic stromal medullary epithelial cells locally transcribe the majority of protein encoding genes expressed in various peripheral tissues to permit their recognition by developing T cells before the release of these T cells from the thymus and thus prevent an autoimmune response when these proteins are encountered by T cells in the periphery. The autoimmune regulatory gene *AIRE* enables the thymic transcription and expression of these genes by interacting with nuclear transporters (e.g., exportin), chromatin binding proteins (e.g., histones), transcription factors and postinitiation transcription processes (e.g., CREB; complex of DNA-dependent protein kinase-polymerase-topoisomerase), and pre-messenger (m)RNA splicing and processing factors.⁶⁵ *AIRE* does not function as a specific transcription factor. Inasmuch as nuclear *AIRE* binds to the unmethylated tails of histone-3 in chromatin, it has been proposed that *AIRE* activates quiescent genes by attracting to their site the transcription apparatus that enables initiation of transcription, elongation, and pre-mRNA processing. In the Finnish and Russian populations with APS1, the most common loss-of-function mutation in *AIRE* was a homozygous truncating mutation at codon 257 (p.Arg257Ter). Pathogenic mutations in *AIRE* detected in patients with APECED include missense, nonsense (p.Arg139Ter), insertions, and deletions (e.g., 13 base pair deletion—964del13, NT 1094, exon 8) that alter the subcellular distribution of *AIRE* and/or decrease its transcriptional activation capacity and/or its E3 ubiquitin ligase activity.⁶⁴ *AIRE* also stimulates development of thymic FoxP3+ regulatory T cells (Treg) that are able to inhibit autoreactive T cells.⁶¹

Thymic levels of *AIRE* are lower in normal postpubertal estrogenized females than those in normal postpubertal masculinized males, possibly accounting in part for the increased susceptibility of females to the later development of autoimmune disorders.⁶⁶ Despite thymic expression of three copies of *AIRE*, subjects with trisomy 21 (Down syndrome) have decreased thymic tissue levels of *AIRE*, thereby perhaps predisposing this patient population to the development of autoimmune diseases.⁶⁷ When *AIRE* is inactivated by biallelic loss-of-function mutations (e.g., p.Arg257X, p.Cys322del13), self-recognition of T cells is lost; normal self-proteins are not distinguishable from foreign proteins, and thus a destructive (auto) immune response to self-antigens is initiated. (Some variants of *AIRE* are transmitted as autosomal dominant or dominant negative disorders.⁶¹) Patients with mutations of *AIRE* and autoimmune polyendocrinopathy type 1 develop organ-related antibodies to cytoplasmic proteins (e.g., to parathyroid-specific NALRP5 [NACHT-domain, leucine-rich repeat, pyrin domain-containing protein 5, OMIM 609658] that are often demonstrable in patients with hypoparathyroidism). The presence of autoimmune polyendocrinopathy syndrome type 1 is established by the clinical findings, associated endocrinopathies, and measurable autoantibodies to other endocrine tissues (e.g., glutamic acid decarboxylase 65 [type 1 diabetes mellitus], 21-hydroxylase [adrenocortical failure]), and nonendocrine tissues (e.g., retina) and confirmed by genotyping of *AIRE*.⁶⁸ Patients with endocrinopathies attributed to autoimmune polyendocrinopathy type 1 are treated appropriately for the hormone deficiency(ies) present, as well as for the other manifestations of this illness. Patients with hypoparathyroidism require supplemental vitamin D (calcitriol), calcium, and magnesium; recombinant PTH¹⁻³⁴ and PTH¹⁻⁸⁴ have been used in adults for treatment of hypoparathyroidism (although not US Food and Drug

Administration [FDA] approved for use in children because of concern about their oncogenic potential). All asymptomatic first-degree relatives of the patient with autoimmune polyendocrinopathy type 1 should be surveyed for the presence of a pre-symptomatic stage of this illness.

Autoimmune polyendocrine syndrome type II is a polygenic autoimmune disorder manifested by adrenalitis, thyroiditis, and type 1 diabetes mellitus (and in some patients pernicious anemia, hypergonadotropic hypogonadism, hepatitis, celiac disease, myasthenia gravis, alopecia, and vitiligo) and is related to variants in major histocompatibility complexes, for example, DR3-DQ2, DR4-DQ8, DRB1*04, DQB1*02, and others.^{61,69} Hypoparathyroidism does not occur in patients with this disorder. The syndrome of Immunodeficiency, Polyendocrinopathy, and Enteropathy-X-linked (IPEX - OMIM 34790) is associated with the early (neonatal and early childhood) onset of autoimmune enteropathy, insulin-dependent diabetes mellitus, autoimmune thyroid disease, eczema, glomerulonephritis, thrombocytopenia, and hemolytic anemia that occurs only in males because it is the result of loss-of-function mutations in *FOXP3* (OMIM 300292). *FOXP3* is a transcription factor that is essential for normal development of naturally occurring T regulatory cells that maintain self-tolerance.^{61,70} IPEX is a disorder with variable clinical manifestations associated with resistance to the action of PTH whose clinical phenotypes and genetic variabilities have been discussed earlier.

Deficiency of vitamin D intake, aberrant metabolism of cholecalciferol, or decreased biological responsiveness of the VDR may result in hypocalcemia.⁷¹ In the subject with skeletal demineralization caused by marked vitamin D deficiency, serum calcium concentrations may fall precipitously after administration of even small amounts of vitamin D as renewed mineralization of bone matrix caused by accelerated osteoblastic activity consumes calcium and phosphate (the “hungry bone” syndrome). After parathyroidectomy for primary hyperparathyroidism, calcium concentrations often decline rapidly by the same mechanism. Drugs that inhibit PTH secretion (excessive magnesium), osteoclast resorption of bone (bisphosphonates), or renal resorption of calcium (furosemide) may lead to hypocalcemia. Intravenous infusion or rectal administration of phosphate (in enemas), acute cellular destruction by tumor cell lysis or rhabdomyolysis, and acute and chronic renal failure increase serum phosphate levels and lead to reciprocal decline in calcium values. Serum calcium concentrations decline in patients receiving multiple transfusions of citrated blood or during plasmapheresis. In subjects with acute pancreatitis, calcium complexed with free fatty acids generated by pancreatic lipase is deposited in necrotic tissue.⁷² Acute severe illness of diverse pathogenesis is often associated with hypocalcemia; this has been attributed to hypoalbuminemia, hyperphosphatemia, alkalosis, functional hypoparathyroidism, hypercalcitonemia, hypomagnesemia, vitamin D deficiency, decreased calcitriol synthesis, alkalosis and increased serum concentrations of free fatty acids (the latter increase binding of Ca²⁺ to albumin), increased cytokine activity, and administered medications (e.g., aminoglycosides, citrated blood, calcium chelators, fluoride).⁵³

Evaluation

Fig. 20.3 outlines the evaluation of the child/adolescent with hypocalcemia. Hypocalcemia may be asymptomatic until detected by a multiassay chemical profile obtained for another purpose. A prolonged QT interval noted by electrocardiography obtained for evaluation of a functional heart murmur or arrhythmia suggests the presence of hypocalcemia. Roentgenograms obtained for evaluation of abdominal pain or following a head injury may reveal nephrocalcinosis, renal calculi, or calcification of the basal ganglia of the brain, respectively; such

findings merit measurement of the serum calcium concentration. The major symptoms and physical signs of hypocalcemia depend on its rapidity of onset and depth.⁷³ The more quickly is the onset of hypocalcemia and the lower the calcium value achieved, the more substantial are the symptoms. Symptoms may include paresthesias (numbness and tingling of the hands, feet, perioral region), muscular hyperexcitability, including cramping, carpedal spasm (flexion of the elbow and wrist, adduction of the thumb, flexion of the metacarpal/metatarsal-phalangeal joints, and extension of the interphalangeal joints), tetany—particularly during vigorous exercise—occasionally generalized seizures, bronchospasm, and at times neuropsychiatric symptoms. (Laryngospasm is a life-threatening complication of hypocalcemia.) Review of the past medical and family histories may reveal symptoms consistent with or illnesses associated with hypocalcemia (recurrent infections, congenital cardiac anomalies, surgical procedures in the neck, cervical radiation, infiltrative diseases), or may identify related members with hypoparathyroidism, dysmorphic physical characteristics, autoimmune endocrinopathies, or hypomagnesemia.

Physical examination may disclose characteristic abnormalities in children with PHP type IA in whom the phenotype of AHO is present (short stature, round face, subcutaneous hard nodules, brachymetacarpals), the DiGeorge syndrome (atypical face, recurrent infections, cardiac murmur), or familial APS1 (chronic mucocutaneous candidiasis and other ectodermal abnormalities, such as vitiligo, alopecia, keratoconjunctivitis), whereas rachitic deformities in the hypocalcemic child imply the presence of a form of hypovitaminosis D. Most commonly, however, the physical examination reveals no striking abnormality in the hypocalcemic child other than those of increased neuromuscular irritability, such as hyperreflexia, positive Chvostek sign (twitching of the circumoral muscles when tapping lightly over the seventh cranial nerve) or Trousseau sign (carpal pedal spasm when maintaining the blood pressure cuff 20 mm Hg above the systolic blood pressure for 3 minutes) and occasionally cataracts, papilledema, or abnormal dentition. (Tetany also occurs in subjects with hypo- and hypernatremia, hypo- and hyperkalemia, and hypomagnesemia, and a positive Chvostek sign may be found in many normal adolescents.)

Laboratory evaluation of hypocalcemia includes measurements of serum concentrations of total calcium, Ca^{2+} , phosphate, magnesium, PTH, and 25-hydroxyvitamin D, and determination of the urine calcium excretion. In most hypocalcemic patients, urine calcium excretion is low; however, if the urine calcium excretion is inappropriately normal or high, disorders, such as autosomal dominant hypocalcemia type 1 (gain-of-function mutation in *CASR* or *GNA11*) may be considered; these genes may then be analyzed or antibodies to CaSR determined as clinically indicated. Antibodies to the CaSR have been detected in approximately 50% to 80% of patients with autoimmune polyendocrinopathy type 1. The child/adolescent with hypocalcemia, hypocalciuria, hyperphosphatemia, and low or undetectable serum PTH concentration (and normal or only slightly low serum magnesium level) likely has hypoparathyroidism because of a primary defect in PTH synthesis or secretion related to congenital malformation or acquired destruction of the parathyroid glands. Patients with hypoparathyroidism often have low serum concentrations of calcitriol, normal levels of calcidiol, decreased excretion of urinary nephrogenous cyclic AMP, and increased renal tubular reabsorption of phosphate.⁷⁴ The DiGeorge syndrome may be identified by microarray or FISH analysis of chromosome 22q11.2 using probes directed to the deleted segment; occasionally *TBX1* genotyping may be helpful. Analysis of *CASR*, *GNA11*, *PTH*, *GCM2*, *FHL1*, and other genes associated with isolated or syndromic hypoparathyroidism (*TCBE*, *GATA3*) may be indicated in the appropriate clinical context. The diagnosis

of APS1 is based on clinical and laboratory findings and genotyping of *AIRE*. The presence of two of three of its major manifestations (candidiasis and/or ectodermal dystrophy, hypoparathyroidism, hypoadrenocorticism) are accepted criteria for its clinical diagnosis, but isolated hypoparathyroidism, adrenal insufficiency, or chronic mucocandidiasis may occasionally be its only manifestation.⁶⁴ Antibodies to the CaSR or other cellular components of the parathyroid glands, the adrenal glands (side-chain cleavage, 21-hydroxylase, 17 α -hydroxylase enzymes), neurotransmitters (aromatic L-amino acid decarboxylase, tryptophan hydroxylase), and IFNs- α and - ω may be determined; antibodies to IFN- ω are commonly present in patients with APS1/APECED.^{63,75} Genotyping of *AIRE* and identification of the mutation(s) confirm the diagnosis of APECED. There is wide variability in the clinical expression of APECED both between families and among siblings because the phenotype is not directly related to the genotype. In patients with isolated, idiopathic hypoparathyroidism, a search for antibodies to the CaSR and/or to parathyroid tissue is warranted. In hypomagnesemic subjects, magnesium and PTH levels are quite low, and PTH secretion increases rapidly after intravenous administration of magnesium. Primary hypomagnesemia should be considered when hypocalcemia and hypercalciuria coincide and serum PTH and magnesium values are low; urinary magnesium excretion should then be quantitated and *CLDN16* (OMIM 603959) genotyped. Because hypomagnesemia may also be caused by a selective small intestinal defect in magnesium absorption, mutations in the transient receptor potential, cation channel, subfamily M, member 6 (*TRPM6*, OMIM 607009) should be examined as warranted. Primary hypomagnesemia must be differentiated from that caused by the Gittleman and Bartter syndromes (vide infra).

An elevated serum concentration of PTH in a hypocalcemic subject suggests that the patient is either secreting an abnormal PTH molecule or is resistant to PTH or there is a compensatory (secondary) PTH secretory response to hypocalcemia (see Fig. 20.3). Physicochemical characterization of the PTH molecule and analysis of *PTH* (OMIM 168450) enable one to define the abnormality in PTH synthesis, posttranslational processing, secretion, or activity leading to the functionally hypoparathyroid state. Analysis of *GNAS* (OMIM 139320) and its pattern of imprinting permits identification of the specific genetic defect in the majority of patients with clinical PHP type IA and PPHP. Skeletal and renal responsiveness to PTH may be assessed if warranted by measurement of changes in serum calcium, Ca^{2+} , phosphate, cyclic AMP, and calcitriol concentrations and urinary nephrogenous cyclic AMP and phosphate excretion following administration of biosynthetic PTH¹⁻³⁴ (Elsworth-Howard test). In the normal subject and in the patient with primary hypoparathyroidism, urinary cyclic AMP excretion increases 10- to 20-fold and that of phosphate severalfold; in the patient with PHP types IA and IB there is less than a threefold increase in the excretion of cyclic AMP after administration of PTH¹⁻³⁴. The diagnosis of PHP type IB may be established by examining the imprinting patterns of *GNAS* (i.e., the methylation status of the differentially methylated regions of *GNAS*) and analysis of *STX16* (OMIM 603666) and the 5' sequences of *GNAS* as indicated. Acrodystostosis 1 and 2 (OMIM 101800;614613) are skeletal dysplasias with hormone resistance that should also be considered when evaluating a hypocalcemic infant with inappropriately elevated serum levels of PTH. This chondrodystrophy is attributable to inactivating variants of *PRKARIA* (OMIM 188830) or *PDE4D* (OMIM 600129). *PRKARIA* encodes a component of PKA—the major mediator of postreceptor intracellular signal transduction; *PDE4D* encodes a cyclic AMP-specific phosphodiesterase, loss of which alters cyclic AMP function. In the child with vitamin D deficiency, serum levels of calcidiol are low. In patients with decreased renal 25OHD₃-1 α -hydroxylase activity, serum concentrations of calcidiol are normal whereas those of calcitriol are inappropriately

low. Increased concentrations of calcitriol suggest the presence of a defect in the nuclear VDR. The patient with renal failure is recognized by an increased serum creatinine value. Other findings in hypocalcemic subjects include prolongation of the QT interval by electrocardiography and calcification of the basal ganglia by cranial computerized tomography.

Management

The primary goal in the care of the hypocalcemic child and adolescent is to increase serum calcium concentrations to levels at which the patient is asymptomatic and as close to the lower range of normal as possible without inducing hypercalcemia; the secondary goal is to identify the cause of hypocalcemia as quickly as possible to provide disease-specific management.^{55,71,74} The overall aims of management of hypocalcemia in general and hypoparathyroidism specifically are to: (1) ameliorate the signs and symptoms of hypocalcemia, (2) to prevent hypercalcemia by (3) maintaining the serum concentration of calcium at or slightly below the lower range of normal in order (4) to maintain the calcium \times phosphate product below 55 mg/dL and thus (5) to prevent hypercalciuria and (6) calcium/phosphate precipitation and extraskeletal calcifications.^{3,76}

Asymptomatic hypocalcemia (total calcium >7.5 mg/dL = 1.88 mmol/L) may not require immediate intervention. With lower serum calcium levels or when hypocalcemia is symptomatic (tetany, seizures, laryngospasm, bronchospasm), acute management may require the intravenous administration of 10% calcium gluconate (93 mg of elemental calcium/10 mL vial) at a slow rate (not >2 mL [1.86 mg of elemental calcium]/kg over 10 minutes) while closely monitoring pulse rate (and the electrocardiographic QT interval). Acutely, intravenous administration of calcium is intended to ameliorate the more serious consequences of hypocalcemia, such as seizures, bronchospasm, or laryngospasm, not to restore and maintain the eucalcemic state. Intravenously, calcium should not be administered with phosphate or bicarbonate, because these salts may coprecipitate. Extravascular extravasation of calcium is to be avoided because it may precipitate and cause local tissue injury. After the acute symptoms have resolved, calcium gluconate (10 mL = 93 mg of elemental calcium in 100 mL 5% dextrose/0.25 normal saline) may be infused intravenously at a rate sufficient to maintain calcium levels in the asymptomatic low-normal range while the cause of the hypocalcemia is identified and more specific therapy for persistent hypocalcemia prescribed. In the child with marked hyperphosphatemia as a cause of hypocalcemia, in addition to parenteral calcium administration infusion of normal saline sufficient to maintain urine output at or above 2 mL/kg per hour is necessary.⁵⁴ Frequent measurement of serum calcium and phosphate concentrations permits rapid adjustment of fluid and electrolyte therapy. The evaluation should proceed as rapidly as possible and oral therapy begun reasonably quickly.

After stabilization, patients with hypoparathyroidism or PHP may be treated with calcitriol (20–60 ng/kg/d in 2 equally divided doses) and supplemental calcium (calcium gluconate, calcium citrate, calcium carbonate), 30 to 75 mg elemental calcium/kg/d in 4 divided doses daily often with meals—(see Table 20.3) to restore and maintain eucalcemia.⁷³ The serum calcium concentration should be maintained within the low-normal range. Each patient must be carefully monitored to avoid hypercalcemia, hypercalciuria (calcium excretion greater than 4 mg/kg/24 h), nephrocalcinosis, and nephrolithiasis. Basal and periodic measurements of serum concentrations of calcium, phosphate, magnesium, and creatinine and urinary calcium and creatinine excretion (every 3 months) are advisable. Twice yearly, renal sonograms are also suggested to identify the development of nephrocalcinosis in its earliest stage. Children with autosomal dominant hypocalcemia caused by

gain-of-function mutations in *CASR* (OMIM 601199) or *GNA11* (OMIM 139320) are extremely sensitive to vitamin D and its metabolites. Even small doses of calcitriol may lead to hypercalciuria with minimal increase in serum calcium levels; in that instance, addition of hydrochlorothiazide (0.5–2.0 mg/kg/d) may increase renal tubular reabsorption of calcium and lower the calcitriol requirement. Administration of recombinant human PTH^{1–34} has been beneficial in individual subjects with hypoparathyroidism.^{17,57,58} In adults and children with hypoparathyroidism caused by a variety of causes, the use of rhPTH^{1–34} (0.4–0.5 mcg/kg every 12 hours subcutaneously) together with calcium carbonate and vitamin D (1200 mg/day of elemental calcium and 800 IU/day of cholecalciferol in 4 equally divided doses) has proven effective and safe for as long as 3 years.⁵⁸ rhPTH^{1–34} led to acceleration of bone turnover as reflected by increases in serum alkaline phosphatase and osteocalcin and urinary excretion of pyridinoline and deoxypyridinoline, while accrual of bone mineral mass, linear growth, and weight gain were not adversely impacted in treated children. In six children with primary hypoparathyroidism, subcutaneous administration of rhPTH^{1–34} (12.5 mcg twice daily) was well tolerated and allowed withdrawal or lowering of the doses of supplemental calcium and calcitriol.⁷⁷ Continuous infusion of rhPTH^{1–34} has also proven effective in maintaining reasonable serum calcium concentrations in adults with postsurgical hypoparathyroidism with fewer fluctuations in calcium levels and lower urine calcium values when compared with twice daily subcutaneous injections of rhPTH^{1–34}.⁷⁸ However, at present rhPTH^{1–34} is not indicated for routine treatment of children with hypoparathyroidism because of concerns about its link to osteosarcoma. In adults, rhPTH^{1–34} has also been used in the treatment of hypoparathyroidism with substantial decline in supplemental calcium and calcitriol doses and stabilization of serum and urine calcium values over 6 years.³ In addition, bone turnover markers reflected increase in skeletal formation documented by measurement of bone mineral density (BMD) of the lumbar spine. The relationship of rhPTH^{1–34} to bone tumor formation, if any, is unknown at present.

When undertaking total thyroidectomy for treatment of a thyroid malignancy, consider the possible effects of this procedure upon function of the parathyroid glands. Before surgery, serum concentrations of calcium, magnesium, phosphate, and PTH should be recorded. During the operation, efforts to identify and preserve the parathyroid glands and their blood supply should be undertaken.⁵⁶ Physical examination seeking signs of hypocalcemia (Chvostek) and serial measurements of calcium, magnesium, and PTH should begin immediately after completion of surgery and continue as clinically indicated.

Because PHP type IA is associated with resistance to a number of peptide hormones that act through GPCR, periodic assessment of pituitary-thyroid and pituitary-ovarian function and GH secretion is necessary and hormone replacement therapy begun as indicated.⁴⁰ In general, the short stature of PHP type IA reflects the AHO phenotype and not GH deficiency. However, PHP-associated hyposomatotropism may be responsive to exogenous recombinant human GH. Transient hypoparathyroidism of infancy may be the initial manifestation of later onset hypoparathyroidism; thus assess calcium homeostasis in such subjects throughout childhood. Patients with apparently isolated hypoparathyroidism of unknown etiology should be reevaluated periodically to identify the development of autoimmune disorders in the patient or family. Assessment of thymic function is important in those subjects with findings suggestive of the DiGeorge syndrome. The management of patients with vitamin D deficiency or resistance is discussed in subsequent sections.

When hypomagnesemia is symptomatic, administration of magnesium sulfate parenterally may be necessary (50%

solution, 0.1–0.2 mL/kg intramuscularly, repeated after 12–24 hours if needed). The patient with primary hypomagnesemia may require daily parenteral (intramuscular, intravenous) doses of magnesium sulfate to prevent tetany, seizures, and other neurological symptoms (slurred speech, choreoathetoid movements, weakness), and to enable normal growth and development. Calcitriol alone raises serum calcium levels in hypomagnesemic subjects but is ineffective in the prevention of tetany. Continuous overnight nasogastric infusion of magnesium may help alleviate the gastrointestinal side effects of multiple large doses of oral magnesium. More mild and transient forms of hypomagnesemia may be treated with oral magnesium gluconate or tribasic magnesium citrate (see Table 20.3).

HYPERCALCEMIA

Hypercalcemia is present when the serum concentration of ionized calcium is above the normal range for age.¹ The total serum calcium concentration reflects both the serum protein level and serum pH; generally, both total and ionized calcium concentrations should be routinely measured when hypercalcemia is suspected. Hypercalcemia may be considered mild when the total serum calcium concentration is above the upper limit of the normal range and below 12 mg/dL (3.0 mmol/L), moderate with total calcium values of 12 to 14 mg/dL (3.00–3.50 mmol/L), or severe when the total serum calcium value exceeds 14 mg/dL (3.50 mmol/L). Pathophysiologically, hypercalcemia may be the result of excessive intestinal absorption of ingested calcium (e.g., vitamin D excess), increased reabsorption of skeletal calcium caused by enhanced PTH action or a lytic bone lesion, or increased renal tubular reabsorption of calcium caused by a medication, such as a thiazide diuretic. Thus hypercalcemia may be caused by aberrations that are PTH-dependent or -independent.

Hypercalcemia in the Neonate and Infant

Hypercalcemia in neonates and very young infants is defined as total blood calcium concentration above 10.8 to 11.3 mg/dL (2.70–2.83 mmol/L) and Ca^{2+} greater than 5.92 to 6.40 mg/dL (1.48–1.60 mmol/L) (depending on the analytical laboratory). However, substantial symptoms and signs of hypercalcemia (e.g., lethargy, anorexia, emesis, constipation, polyuria, dehydration, gastroesophageal reflux and emesis, constipation, and lethargy and hypotonia or irritability and seizures) may not occur until the total serum calcium level exceeds 12.5 to 13 mg/dL (3.12–4.25 mmol/L).^{1,79} Hypercalcemic infants frequently are polyuric because of renal resistance to antidiuretic hormone and may become dehydrated if fluid intake is restricted. Because of the vasoconstrictive effect of calcium, the hypercalcemic infant may be hypertensive. Hypercalcemia also shortens the S-T segment and can lead to heart block and ultimately asystole. In older infants and young children with chronic hypercalcemia, poor growth and “failure to thrive” are often presenting manifestations. Hypercalcemia also leads to hypercalciuria, nephrocalcinosis, and nephrolithiasis. Hypercalcemia may also be present in patients with phenotypic abnormalities, for example, the Williams-Beuren syndrome (WBS).

Etiology

Causes of hypercalcemia in neonates and infants are listed in Tables 20.4A, 20.4B. Neonatal/infantile hypercalcemia may be iatrogenic in origin—for example, administration of excessive calcium or vitamin D—at times to the mother who secretes cholecalciferol in her breast milk; administration of thiazide diuretics that increase renal tubular absorption of calcium; or purposeful restriction of phosphate. Hypercalcemia, hypophosphatemia, hyperphosphatasemia, and radiographic evidence

of rickets may develop in very premature infants receiving intravenous alimentation deficient in phosphate or in those fed only human breast milk, the phosphate content of which is low. Hypophosphatemia leads to increased synthesis of calcitriol by: (1) stimulating renal tubular 25OHD-1 α hydroxylase activity directly, and (2) inhibiting synthesis of FGF23, thereby removing an agent that depresses activity of 25OHD-1 α hydroxylase; the two pathways additively increase 25OHD-1 α hydroxylase activity, calcitriol synthesis, and intestinal calcium absorption.⁷⁹ The problem may be circumvented by increasing the amount of parenteral phosphate administered to the extent possible or by the use of breast milk fortified with phosphate. (Adequate extrauterine mineralization of the preterm skeleton requires intakes of both calcium and phosphate of approximately 200 mg/kg/d each.) Extracorporeal membrane oxygenation may also be associated with hypercalcemia in neonates, perhaps related to increased secretion of PTH by the neonate.^{1,80}

Hypervitaminosis D may be caused by prolonged feeding of an improperly prepared formula or commercial dairy milk containing excessive vitamin D, iatrogenic prescription of vitamin D, calcidiol, or calcitriol, or increased endogenous production of calcitriol from inflammatory sites.⁸¹ In infants with severe birth trauma, perinatal asphyxia or hypothermia, subcutaneous fat necrosis may develop within the first 6 weeks after birth as manifested by indurated, extremely firm, tender, violaceous nodules on the cheeks, trunk, shoulders, buttocks, arms, and legs.⁸² Hypercalcemia may be present when the lesions first appear or develop as the nodules resolve several weeks later. Histologically, the skin lesions are composed of adipocytes, an inflammatory lymphohistiocytic infiltrate, and multinucleated giant cells in a bed of calcium crystals. The hypercalcemia of subcutaneous fat necrosis has been attributed to reabsorption of precipitated calcium, extrarenal synthesis of calcitriol by local macrophages and resultant hyperabsorption of ingested calcium, and increased osteoclastic activity because of enhanced prostaglandin secretion. The 25OHD-1 α -hydroxylase activity of these inflammatory macrophages is not under the control of PTH, calcium, or phosphate, but is suppressible by glucocorticoids. Excessive production of prostaglandin E and interleukins (IL)-1 and -6 further contributes to hypercalcemia in this disorder by increasing the rate of bone turnover. Hypercalcemia attributable to subcutaneous fat necrosis is managed by the ingestion of a formula low in calcium, avoidance of vitamin D, and administration of fluids, calcitonin, or bisphosphonate (pamidronate), as needed.^{60,82} Administration of loop diuretics (e.g., furosemide) and glucocorticoids should be avoided if possible. Hypercalcemia caused by subcutaneous fat necrosis has also been observed in older children with major trauma or disseminated varicella.⁸¹ Congenital deficiency of lactase and other disaccharidases have also been associated with infantile hypercalcemia, likely because of increased intestinal absorption of calcium promoted by disaccharides.

Neonatal severe hyperparathyroidism (NSHPT) is a potentially lethal form of familial (hereditary) hypocalciuric hypercalcemia (HHC). It is most commonly caused by homozygous or compound heterozygous inactivating mutations of *CASR* that greatly increase the serum concentration of Ca^{2+} needed to suppress PTH synthesis and secretion. However, in several infants with NSHPT, there have been heterozygous inactivating mutations of *CASR* (e.g., pArg185Gln, pArg227Leu) suggesting that the products of these mutations exert a dominant-negative effect on the normal *CaSR*, perhaps by interfering with migration of wild-type receptor to the cell surface or inactivation of wild-type receptor by linking to the mutated *CaSR* once embedded in the cell membrane, or by sequestration of G-proteins.⁸³ In addition, the fetus bearing a heterozygous mutation in *CASR* that has been inherited from an affected father but residing in the womb of a normal mother may be relatively “hypocalcemic” in utero,

TABLE 20.4A Causes of Hypercalcemia**I Neonate/Infant**

- A Maternal disorders
 - 1 Excessive vitamin D ingestion, hypoparathyroidism, pseudohypoparathyroidism
- B Neonate/infant
 - 1 Iatrogenic—excessive intake of calcium, vitamin D, vitamin A
 - 2 Phosphate depletion
 - 3 Subcutaneous fat necrosis
 - 4 Williams-Beuren syndrome (del7q11.23/BAZ1B)
 - 5 Neonatal severe hyperparathyroidism (CASR)
 - 6 Metaphyseal chondrodysplasia, Murk-Jansen type (PTH1R)
 - 7 Idiopathic infantile hypercalcemia type 1 (CYP24A1)
 - 8 Idiopathic infantile hypercalcemia type 2 (SLC34A1)
 - 9 Persistent parathyroid hormone–related protein
 - 10 Lactase/disaccharidase deficiency (LCT)
 - 11 Infantile hypophosphatasia (TNSALP)
 - 12 Mucopolidosis type II (GNPTAB)
 - 13 Blue diaper syndrome
 - 14 Antenatal Bartter syndromes types 1 & 2 (SLC12A1, KCNJ1)
 - 15 Distal renal tubular acidosis
 - 16 IMAGE syndrome (CDKN1C)
 - 17 Postbone marrow transplantation for osteopetrosis
 - 18 Endocrinopathies: Primary adrenal insufficiency, severe congenital hypothyroidism, hyperthyroidism

II Hyperparathyroidism

- A Sporadic
 - 1 Parathyroid hyperplasia, adenoma, carcinoma
- B Familial
 - 1 Hypocalcemic hypercalciuria type 1/neonatal severe hyperparathyroidism (CASR)
 - 2 Hypocalcemic hypercalciuria type 2 (GNA11)
 - 3 Hypocalcemic hypercalciuria type 3 (APS21)
 - 4 Multiple endocrine neoplasia, type I (MEN1)
 - 5 Multiple endocrine neoplasia, type IIA (RET)
 - 6 Multiple endocrine neoplasia, type IIB (RET)
 - 7 Multiple endocrine neoplasia, type IV (CDKN1B)
 - 8 McCune-Albright syndrome (GNAS)
 - 9 Familial isolated hyperparathyroidism 1 (CDC73)
 - 10 Familial isolated hyperparathyroidism 2 (jaw tumor syndrome) (CDC73)
 - 11 Familial isolated hyperparathyroidism 3
 - 12 Jansen metaphyseal dysplasia (PTH1R)
- C Secondary/tertiary
 - 1 Postrenal transplantation
 - 2 Chronic hyperphosphatemia
- D Hypercalcemia of malignancy
 - 1 Ectopic production of PTHrP
 - 2 Metastatic dissolution of bone

III Familial Hypocalciuric Hypercalcemia

- A Familial hypocalciuric hypercalcemia I (CASR)
 - 1 Loss-of-function mutations in CASR
 - a Monoallelic—Familial benign hypercalcemia
 - b Biallelic—Neonatal severe hyperparathyroidism
 - 2 Hypocalcemic hypercalciuria type 2 (GNA11)
 - 3 Hypocalcemic hypercalciuria type 3 (APS21)
- B Familial hypocalciuric hypercalcemia II—Linked to chromosome 19p13.3
- C Familial hypocalciuric hypercalcemia III—Oklahoma variant—Linked to chromosome 19q13
- D CaSR blocking autoantibodies

IV Excessive Calcium and/or Vitamin D

- A Milk-alkali syndrome
- B Exogenous ingestion of calcium or vitamin D or topical application of vitamin D (calcitriol or analog)
- C Ectopic production of calcitriol associated with granulomatous diseases: sarcoidosis, cat scratch fever; tuberculosis, histoplasmosis, coccidioidomycosis, leprosy; human immunodeficiency virus; cytomegalovirus; chronic inflammatory bowel disease
- D Neoplasia
 - 1 Primary bone tumors
 - 2 Metastatic tumors with osteolysis
 - 3 Lymphoma, dysgerminoma
 - 4 Tumors secreting PTHrP, growth factors, cytokines, prostaglandins, osteoclast activating factors
- E Williams-Beuren syndrome (del7q11.23)

V Immobilization**VI Other Causes**

- A Drugs—thiazides, lithium, vitamin A & analogs, calcium, alkali, antiestrogens, aminophylline
- B Total parenteral nutrition
- C Endocrinopathies: hyperthyroidism, hypoadrenocorticism, pheochromocytoma
- D Vasoactive intestinal polypeptide-secreting tumor
- E Acute or chronic renal failure/administration of aluminum
- F Hypophosphatasia
- G Juvenile rheumatoid arthritis - cytokine mediated

CaSR, Calcium sensing receptor; PTHrP, parathyroid hormone–related protein.

leading to hyperplasia of the fetal parathyroid glands that persists after birth giving rise to NSHPT. Occasionally, NSHPT may be transmitted as an autosomal recessive disorder by clinically and biochemically normal parents.^{84,85} In subjects with homozygous mutations near the amino terminal of CASR (e.g., p.Leu13Pro), hypercalcemia may not be manifested until midchildhood or even adulthood.⁸⁶ Thus the clinical spectrum of NSHPT ranges from mild (constipation, polyuria) with calcium concentrations ranging from 11 to 13 mg/dL (2.75–3.25 mmol/L) to severe and life-threatening (dysrhythmia, respiratory distress caused by hypotonia, demineralization and fractures of the ribs) when calcium levels exceed 15 mg/dL (3.75 mmol/L).^{79,87} Thus NSHPT may present within the first few days of life to several months of age depending on the degree of hypercalcemia. Search of the family history may identify members with mild hypercalcemia caused by

autosomal dominant HHC. Physical examination often reveals hypotonia, feeding difficulties, and respiratory distress. The serum calcium concentration is frequently markedly elevated (average 14 mg/dL, range 11 to >20 mg/dL; 3.5 mmol/L, 2.75 to 5 mmol/L) as is the PTH value (average 540 pg/mL, range 55 to >1000 pg/mL).⁸⁸ Other findings include: hypophosphatemia, hypermagnesemia, hyperphosphatasemia, and elevated calcitriol values, low renal tubular reabsorption of phosphate and relative hypocalciuria. Radiographically, there is evidence of hyperparathyroid bone disease—osteopenia, metaphyseal widening and irregularity, subperiosteal resorption, varus angulation of the hips, and fractures.

Lowering of the elevated serum calcium concentration present in NSHPT is only modestly affected by induction of diuresis by infusion of sodium chloride and by administration of furosemide; calcitonin and a bisphosphonate

TABLE 20.4B Genetic Variants Associated With Hypocalcemia/Hyperparathyroidism

Gene Protein Chromosome OMIM	Disorder OMIM	Clinical/Biochemical Manifestations	Gene Function/Transmission
CASR Calcium sensing receptor 3q13.3-21.1 601199	Familial hypocalciuric hypercalcemia (FHH) type I, 145980; Neonatal severe hyperparathyroidism (NSHPT) 239200, Adult-onset primary hyperparathyroidism (AOPH)	Hypercalcemia, NSHPT—life-threatening AOPH—nephrolithiasis, low bone mineralization	Calcium receptor regulating synthesis, secretion of PTH, inactivating variant FHH1—AD NSHPT—AD/AR AOPH—AD/AR
GNA11 Guanine nucleotide-binding protein, alpha-11 19p13.3 139313	Familial hypocalciuric hypercalcemia type II, 145981	Hypercalcemia	Encodes G-protein transmitting signal of CaSR to intracellular signal transduction pathways, inactivating variant, AD
AP2S1 Adaptor related protein complex 2, sigma1 subunit 19q13.31 602242	Familial hypocalciuric hypercalcemia type III, 600740	Hypercalcemia, low bone mineralization, impaired cognition	Adaptor-related protein complex 2 interacts with β -arrestin (<i>ARRB1</i> , chr. 11q13.4, OMIM 107940) to form complex facilitating retrograde movement (endocytosis) of the CaSR from the cell surface & its return to the cytoplasm, inactivating variant AD
CYP24A1 Cytochrome P450, family 24, subfamily A, polypeptide 1 20q13.2 143880	Infantile hypercalcemia 1 143880	Hypercalcemia, vomiting, anorexia, inanition, nephrocalcinosis with inappropriate normal/high levels of calcitriol	Encodes 1,25-dihydroxyvitamin D-24-hydroxylase that inactivates calcitriol, AR
SLC34A1 Solute carrier family 34 (Type II sodium phosphate cotransporter), member 1, 5q35 182309	Infantile hypercalcemia 2 616963	Hypercalcemia, vomiting, anorexia, inanition, nephrocalcinosis	Encodes a proximal renal tubular sodium phosphate cotransporter, AR
TRPV6 Transient receptor potential, cation channel, subfamily V, member 6 7q34 606680	Transient neonatal hyperparathyroidism 618188	Skeletal demineralization in utero & postnatally, eucalcemia or hypocalcemia	Encodes a calcium selective channel active in the placental trophoblast, renal tubule, and intestinal tract, AR
Deletion 7q11.23 syndrome 194050	Williams-Beuren syndrome: Infantile hypercalcemia	Hypercalcemia, supravalvular aortic stenosis, peripheral pulmonary arterial stenoses, characteristic face, developmentally challenged, friendly personality, verbal & musical skills	Deletion of 28 (\pm) contiguous genes including <i>ELN</i>
MEN1 Men1 gene 11q13.1 613733	Multiple endocrine neoplasia, type 1 131100	Tumors of the parathyroid, pancreatic islets, intestinal endocrine cells, adenohypophysis	Tumor suppressor, nuclear scaffold protein interacting with several transcription factors, inactivating variant AD
RET Rearranged during transfection protooncogene 10q11.21 164761	Multiple endocrine neoplasia, type 2A 171400; type 2B 162300	Medullary carcinoma of thyroid (2A,2B), pheochromocytoma (2A, 2B), parathyroid adenoma (2A), marfanoid habitus/ganglioneuromas (2B)	Transmembrane receptor tyrosine kinase, activating variant, AD
CDKN1B Cyclin-dependent kinase inhibitor 1B 12p13.1 600778	Multiple endocrine neoplasia, type 4 610755	Parathyroid adenoma, gastric carcinoid, pituitary adenoma	Blocks cell cycle at G0/G1 phase, regulates cell motility, apoptosis, inactivating variant AD
CDC73 Cell division cycle protein 73, S cervisiae, homolog of 1q31.2 607391	Familial isolated hyperparathyroidism—type 1 (145000) & type 2 (145001—associated with the hyperparathyroidism—jaw tumor syndrome)	Parathyroid adenoma/carcinoma, ossifying fibromas of mandible & maxilla, Wilms tumor	Parafibromin—protein intrinsic to the cell division cycle; tumor suppressor, inactivating variant, AD

TABLE 20.4B Genetic Variants Associated With Hypocalcemia/Hyperparathyroidism—cont'd

Gene Protein Chromosome OMIM	Disorder OMIM	Clinical/Biochemical Manifestations	Gene Function/Transmission
<i>GCM2</i> Glial cells missing, drosophila, homolog of, 2 6p24.2 603716	Familial isolated hyperparathyroidism- type 4 617343	Familial isolated hyperparathyroidism with multiple parathyroid adenomas, carcinoma	Encodes transcription factor essential for differentiation of the parathyroid glands, activating variant AD
<i>PTH1R</i> Parathyroid hormone receptor 1 3p21.31 168468	Metaphyseal chondrodysplasia, Murk- Jansen type 156400	Marked growth retardation, genu varum, small mandible, hypercalcemia, hypophosphatemia	G-protein coupled receptor for PTH & PTHrP, activating variant, AD

AD, Autosomal dominant; AR, autosomal recessive; PTH, parathyroid hormone; PTHrP, parathyroid hormone related protein.

(e.g., pamidronate/zolendronate) may be required to suppress resorption of bone calcium and reduce serum calcium levels. These agents do not reduce the elevated level of PTH, however, and do not address the marked skeletal demineralization of hyperparathyroidism. The allosteric calcimimetic cinacalcet hydrochloride that acts directly on the CaSR has also been effective in lowering serum calcium concentrations in infants with NSHPT.⁸⁹ (However, cinacalcet is not approved for use in subjects less than 18 years of age.) Subtotal parathyroidectomy may be a requisite lifesaving measure at times. Children with NSHPT who remain hypercalcemic are anorectic, fail to thrive, and at risk for developmental delay.

Secondary hyperparathyroidism in the neonate may be the result of maternal hypocalcemia caused by hypoparathyroidism, PHP, renal tubular acidosis, or vitamin D deficiency.⁷⁹ Maternal hypocalcemia reduces placental transport and net delivery of calcium to the fetus resulting in relative fetal hypocalcemia, leading to hyperplasia of the fetal parathyroid glands and secondary hyperparathyroidism proportional to the maternal calcium deficit. Although only 25% of infants of hypocalcemic mothers are hypercalcemic, most have skeletal changes that reflect PTH excess that vary from severe demineralization with fractures to osteopenia detectable only by bone mineral densitometry. Secondary hyperparathyroidism usually resolves within a few weeks after birth as the infant ingests adequate calcium and phosphate. Normal transplacental maternal-fetal calcium transport is dependent upon three placental trophoblast processes: (1) apical Ca²⁺ entry through Ca²⁺ channels via an electrochemical gradient, (2) intracellular binding of Ca²⁺ to calbindin D9k, and (3) extrusion of Ca²⁺ through the basolateral membrane of the trophoblast. Transient neonatal hyperparathyroidism (OMIM 618188) may also occur in newborns with biallelic inactivating variants of *TRPV6* (OMIM 606680) encoding a permeable calcium selective channel active in the placental trophoblast, renal tubule, and intestinal tract. In this disorder, decreased transplacental transport of calcium from the mother to the fetus leads to in utero fetal hypocalcemia and secondary hyperparathyroidism manifested by skeletal abnormalities, including thin, short bones, some with fractures that resolve within 2 years after birth. Mucopolysaccharidosis type II (OMIM 252500) has also been associated with neonatal secondary hyperparathyroidism; this Hurler-like disorder is characterized by facial abnormalities (asymmetry, flat nasal bridge), hepatosplenomegaly, skeletal deformities (dysostosis multiplex), and developmental delay and is caused

by inactivating mutations in a gene (*GNPTAB*, OMIM 607040) encoding N-acetylglucosamine-1-phosphotransferase, α/β subunits, a lysosomal phosphotransferase required for synthesis of mannose 6-phosphate.⁹⁰ In this disease, maternal calcium concentrations are normal, but placental histology is abnormal suggesting impaired placental transport of calcium and fetal hypocalcemia, leading to compensatory increase in PTH generation by the fetus. In turn, skeletal evidence of PTH excess (osteopenia, fractures) develops; secondary hyperparathyroidism and its adverse effects remit within the first several weeks to months after birth. Transient neonatal distal renal tubular acidosis has also been associated with hypercalcemia because of secondary hyperparathyroidism. Occasionally, neonates with primary congenital hypothyroidism are transiently hypercalcemic.

Murk-Jansen metaphyseal chondrodysplasia (OMIM 156400) is an autosomal dominant chondrodystrophy associated with marked hypercalcemia as a consequence of heterozygous mutations that lead to constitutive, ligand-independent activation of *PTH1R* expressed in the kidney, bone, and growth plate chondrocytes.⁷⁹ Enhanced functional PTH1R leads to accelerated chondrocyte proliferation, decreased rate of chondrocyte maturation, delayed bone formation, and increased bone resorption. Phenotypically, the patient with Murk-Jansen chondrodysplasia manifests short-limbed dwarfism; deformities of the long bones, digits, spine, and pelvis; choanal atresia; highly arched palate; micrognathia; widely open cranial sutures (in infancy); sclerosis of the basal cranial bones; disorganization of the metaphyses (delayed chondrocyte differentiation, irregularly calcified cartilage protruding into the diaphysis); and excessive loss of cortical bone but normal trabecular bone. Although birth length and physical appearance may be normal in affected neonates, there is radiographic evidence of the chondrodysplasia. Affected neonates are often eucalcemic, but later (infancy and childhood) develop hypercalcemia, hypophosphatemia, increased serum concentrations of calcitriol and elevated urinary excretion of nephrogenous cyclic AMP and calcium but low or undetectable serum levels of PTH and PTHrP. (Adults with this disorder are often eucalcemic, as well as very short [adult height 100 cm]; skeletal maturation is delayed; metaphyses of the long bones are long and histologically disorganized; and cranial bones are sclerotic.) Constitutively activating mutations of *PTH1R* in these subjects include most commonly p.His223Arg at the junction of the first intracellular loop and second transmembrane domain and p.Thr410Pro in

the sixth transmembrane domain—sites that are specifically important in conferring ligand-independent activity upon PTH1R.⁸¹ SLK family kinase 3 (*SIK3*, OMIM 614776) is active in the PTH1R intracellular signal transduction pathway; a biallelic inactivating variant of *SIK3* results in a hypercalcemic spondyloepimetaphyseal chondrodysplasia similar to but distinct from that of Murk-Jansen.⁹¹ Excessive secretion of PTHrP and resultant hypercalcemia have also been recorded in infants with neonatal iron storage disease and embryonal renal tumors (Wilms, mesoblastic nephroma).

WBS (OMIM 194050) is a hemizygous contiguous gene deletion syndrome (involving approximately 26–28 genes on chromosome 7q11.23) that is transmitted as an autosomal dominant disorder and whose prevalence is 1/7500 to 1:15,000 live births.^{92,93} The WBS is characterized by intrauterine and postnatal growth retardation, hypercalcemia in infancy in 15% of patients that usually resolves by 2 years of age but may occasionally persist into adulthood, consistent hypercalciuria, supravalvular aortic stenosis in 30% of subjects, narrowing and stenoses of the thoracic aorta and coronary, pulmonary, renal, mesenteric, and celiac arteries, hypertension, microcephaly, “elfin” face (broad forehead, epicanthal folds, stellate iris pattern, esotropia, short nose with full nasal tip, arched upper and prominent lower lips, long philtrum, full cheeks with flattened malar eminences, dental malocclusion), hoarse voice, hyperacusis in childhood associated with nerve deafness, radioulnar synostosis, renal hypoplasia or unilateral agenesis, developmental delay (poor visual-motor integration, attention deficit disorder, mean IQ 58, range 20–106), and short stature. Although most patients with WBS are developmentally challenged, they have unique and proficient verbal skills with a large vocabulary and enhanced auditory memory particularly for names, adept social language skills, and exceptional musical aptitude including the ability to memorize and sing many musical compositions and play many instruments.⁸¹ Children with WBS prefer to be in the company of adults rather than with their peers and are not shy or fearful of strangers.⁹²

Hypercalcemia in subjects with the WBS may be pathogenetically related to partial loss of function of the Williams syndrome transcription factor (WSTF) encoded by *BAZ1B* (Bromodomain adjacent to zinc-finger domain, 1B, OMIM 605681). The WSTF is a nuclear protein that is part of a multimeric, ATP-dependent, chromatin remodeling complex termed WINAC (WSTF including nucleoside assembly complex).⁹⁴ Independently of ligand-binding, the VDR interacts with WINAC. Under usual circumstances, binding of calcitriol to the VDR-WINAC complex (1) represses expression of renal tubular *CYP27B1*, the gene encoding 25-hydroxyvitamin D-1 α -hydroxylase, and (2) enhances transcription of *CYP24A1*, the gene encoding 25-hydroxyvitamin D-24-hydroxylase. Hence haploinsufficiency of WSTF may lead to increased and relatively unregulated synthesis of calcitriol while slowing its rate of degradation; in response to the increase in calcitriol generation, the intestinal absorption of calcium increases and hypercalcemia ensues. Other endocrinopathies associated with WBS include glucose intolerance and hypothyroidism.

WBS is the consequence of deletion of chromosome 7q11.23 caused by unequal meiotic recombination (unequal crossover of genes between chromosome 7 homologs during meiosis); this genetic error occurs with equal frequency in the gametes of both parents and results in the loss of 26 to 28 genes.⁸² Hemizygosities of *ELN* (OMIM 130160) encoding elastin is the attributed cause of the cardiovascular malformations and hypertension observed in WBS, inasmuch as partial loss of *ELN* leads to compensatory increase in the number of rings of smooth muscle and elastic lamellae resulting in arterial thickening and increased risk of obstruction. Functional hemizygosities for general transcription factor II-I (*GTF2I*, OMIM 601679), *GTF2IRD1* (OMIM 604238),

HIP1 (OMIM 601767), and *YWHAQ* (OMIM 605356) may underlie the neurocognitive deficits and strengths that characterize WBS and their distinctive personalities.^{92,95} Haploinsufficiency of LIM domain kinase 1 (*LIMK1*, OMIM 601329) may also be linked to the neurocognitive defects in patients with WBS.⁹⁶ Hemizygous loss of *STX1A* (OMIM 186590) may be pathogenetically related to development of glucose intolerance in WBS subjects.⁹⁷ The WBS phenotype has also been associated with interstitial deletion of chromosome 6q22.2-q23, as well as defects in chromosomes 4, 11, and 22—implying that the syndrome is genetically heterogeneous. The diagnosis of the WBS syndrome is suspected on the basis of the characteristic clinical phenotype (with/without hypercalcemia) and confirmed by demonstration of the microdeletion at chromosome 7q11.23 by microarray or FISH, although a normal chromosome analysis does not entirely eliminate this diagnosis. Specific genotyping may also prove diagnostically useful on occasion. Hypercalcemia is managed by ingestion of a low calcium, vitamin D-free formula; occasionally short-term glucocorticoid therapy may be necessary to restore eucalcemia.

A contiguous gene deletion syndrome characterized by developmental delay and seizures involving a segment of chromosome 7q11.23 distal to the deletion associated with the WBS has been described (OMIM 613729). Duplication of chromosome 7q11.23 results in a syndrome associated with heart defects, diaphragmatic hernia, cryptorchidism, and neurocognitive and behavioral aberrations.⁹⁸ Additional findings in patients with dup7q11.23 include short stature and minor dysmorphic facial features (prominent forehead, long nasal tip, short philtrum, thin lips, retrognathia, folded ear helices). Neurocognitively, there is severe speech delay and often autistic behavior but intact visuocognitive skills—characteristics that are opposite to those present in patients with the WBS.

Although phenotypically normal, infants with hypercalcemia of infancy types 1 and 2 manifest anorexia, impaired growth, developmental delay, febrile episodes, polyuria, and vomiting, leading to dehydration, hypercalciuria, and nephrocalcinosis associated with hypercalcemia in the presence of decreased serum concentrations of PTH.^{97,99} Infantile hypercalcemia type 1 (OMIM 143880) is characterized by elevated or inappropriately normal levels (relative to serum calcium concentrations) of calcitriol most often caused by biallelic inactivating variants of *CYP24A1* (OMIM 126065) encoding 24-hydroxylase, the enzyme that converts 25-hydroxyvitamin D to 24,25 dihydroxyvitamin D and 1,25-dihydroxyvitamin D to 1,24,25-trihydroxyvitamin D, thereby increasing their solubility and subsequent excretion in bile and urine.^{97,100,101} Delaying the degradation of 1,25-dihydroxyvitamin D prolongs its effective biological life. In many patients with infantile hypercalcemia type I, hypercalcemia resolves within the first several years of life but it may persist to older ages.² Inactivating mutations in *CYP24A1* have also been found in adults with hypercalcemia, hypercalciuria, and nephrolithiasis.^{102–104} *CYP24A1* mutations may either decrease the binding of the enzyme to its substrate or interfere with the interaction of heme and enzyme protein; either type of mutation decreases its function.¹⁰⁵ Avoidance of vitamin D, low dietary calcium intake, increased fluids, and occasionally glucocorticoids to reduce intestinal absorption of calcium are therapeutic modalities for this disorder. Infantile hypercalcemia type 2 (OMIM 616963) is the result of biallelic variations in *SLC34A1* encoding solute carrier family 34 (Type II sodium phosphate cotransporter), member 1 (OMIM 182309), a proximal renal tubular sodium phosphate cotransporter, and is manifested by vomiting, anorexia, inanition, hypercalcemia, hypophosphatemia, hypercalciuria, and nephrocalcinosis.^{99,106,107} In this disorder, decreased renal tubular transport of phosphate results in hyperphosphaturia and hypophosphatemia, leading to decreased

synthesis of FGF-23 and consequently to increase in functional activity of 25OHD-1 α hydroxylase (*CYP27B1*) and the ensuing synthesis of calcitriol and hyperabsorption of intestinal calcium. Restricted intake of calcium and vitamin D have also been used in the management of patients with infantile hypercalcemia type 2, but phosphate supplementation may also be considered.¹⁰⁷ As adults, patients with variants of either *CYP24A1* or *SLC34A1* are of normal height and weight and in reasonably good health, although in some subjects, nephrocalcinosis persists. Some affected patients, however, develop progressive renal failure as adults.

Antenatal/neonatal Bartter syndromes type 1 (OMIM 601678) and type 2 (OMIM 241200) are clinically and biochemically similar and are caused by biallelic loss-of-function mutations in genes controlling a transepithelial sodium-potassium-chloride transporter (*SLC12A1*, OMIM 600839) and an inwardly rectifying apical potassium channel (*KCNJ1*, OMIM 600359), respectively, expressed in the renal tubular TALH. Affected fetuses develop polyhydramnios, leading to premature delivery with postnatal salt-wasting and secondary hyperaldosteronism; increase renal and systemic production of prostaglandin E2 inhibits sodium and chloride reabsorption in the TALH and enhances juxtaglomerular renin release resulting in hypokalemic metabolic acidosis, hyperparathyroidism, hypercalcemia, hypercalciuria, nephrocalcinosis, hypomagnesemia, osteopenia, and often death in type 1 antenatal Bartter syndrome.^{108,109} Type 2 neonatal Bartter syndrome caused by variants of *KCNJ1* is manifested by hypokalemia (occasionally transient hyperkalemia), reduced intravascular volume, and increased levels of angiotensin leading to renal and systemic production of prostaglandin E2 that also impair renal tubular reabsorption of sodium and chloride in the TALH. Hypochloremic, hypokalemic alkalosis, hyperprostaglandin E, hypercalcemia, hypercalciuria, and nephrocalcinosis suggest neonatal Bartter syndrome. Replacement of fluid and electrolytes and administration of potassium-sparing diuretics (thiazides) and cyclooxygenase inhibitors (indomethacin) may be effective in ameliorating the biochemical and clinical manifestations of the disease.

Neonatal or infantile hypercalcemia may occur in patients with one of several inborn errors of metabolism.¹ Both congenital lactase deficiency (OMIM 223000) caused by mutations in *LCT* (OMIM 603202) and sucrase-isomaltase deficiency (OMIM 222900) caused by variants of *SI* (OMIM 609845) have been associated with infantile hypercalcemia, likely caused by increased intestinal absorption of calcium promoted by disaccharides. Hypercalcemia may also be encountered in infants with primary oxalosis (OMIM 259900) that may be the result of variants in one of three genes (*AGXT*, OMIM 604285; *GRHPR*, OMIM 604296; *DHDPSL*, OMIM 613597). The "blue diaper syndrome" (OMIM 211000) is the result of inability of the gastrointestinal tract to absorb tryptophan that intestinal bacteria metabolize to an indole that is absorbed and excreted in the urine resulting in indicanuria that is then oxidized to the pigment "indigo blue" thus staining the diaper of the affected neonate and infant. Hypercalcemia, hypercalciuria, and nephrocalcinosis are common but not invariable; the pathogenesis of hypercalcemia in these patients is unknown. This disorder has been associated with a homozygous loss-of-function mutation in *PCSK1* encoding a prohormone convertase/calcium-dependent serine endoproteinase (proprotein convertase, subtilisin/kexin-type 1, OMIM 162150) that converts a multicomponent protein to specific bioactive protein products.¹¹⁰ Variants of *PCSK1* have also been related to defects in insulin synthesis, as well as several endocrinopathies (hypogonadotropism, central hypoadrenocorticism, and central diabetes insipidus).¹¹¹ Hypercalcemia may also occur in patients with the IMAGe syndrome of

intrauterine growth retardation, metaphyseal dysplasia, adrenal hypoplasia congenita, and genital anomalies (OMIM 614732) caused by heterozygous variants of *CDKN1C* encoding cyclin-dependent kinase inhibitor 1C (OMIM 600586), a regulator of early cell division.

Hypophosphatasia (HPP) is a congenital disorder of bone mineralization resulting in rickets of variable severity that is caused by a decreased osteoblast synthesis of tissue nonspecific alkaline phosphatase (TNSALP)—the consequence of monoallelic or biallelic inactivating mutations in *ALPL* (OMIM 171760) (vide infra).¹¹² Decreased production of alkaline phosphatase leads to a deficit in phosphate ions impairing synthesis of hydroxyapatite resulting in rickets, whereas continued intestinal absorption of calcium can lead to hypercalcemia. The infantile form of hypophosphatasia (OMIM 241500) is caused by biallelic loss-of-function variants of *ALPL*. It becomes clinically apparent after the first month of life but usually before 6 months of age and is often fatal. Initial symptoms are failure to thrive associated with impaired feeding, weakness, and delayed achievement of motor milestones; rachitic deformations of the thorax and limbs are visible. Radiographically, it is characterized by demineralization of the calvarium and peripheral skeleton, rickets, spurs of cartilage and bone extending from the sides of the knee and elbow joints, and premature craniosynostosis, leading to increased intracranial pressure. Also present are vitamin B₆-dependent seizures, hypercalcemia, and hypercalciuria.^{112,113} Defective osteoblast synthesis of TNSALP is the result of loss-of-function missense, nonsense, and donor splice site mutations of *ALPL*. The lethal homozygous or compound heterozygous mutations of *ALPL* are located within or near the enzyme domain and/or the homodimer and tetramer interfaces. Inappropriately low serum bone alkaline phosphatase activity differentiates this illness from other rachitic or osteopenic states (osteogenesis imperfecta congenita [OIC] or achondrogenesis type 1A) in which alkaline phosphatase activity is usually normal or elevated. Increased urine phosphoethanolamine and serum inorganic pyrophosphate (an inhibitor of hydroxyapatite crystallization that also impairs skeletal mineralization) and pyridoxal-5'-phosphate values are consistent with the diagnosis of hypophosphatasia, whereas analysis of *ALPL* identifies the gene mutation(s) itself. The diagnosis of hypophosphatasia can be suspected on prenatal ultrasonography and confirmed by *ALPL* genotyping. The hypercalcemia of infantile hypophosphatasia is managed by hydration, diuretics that act upon the TALH (e.g., furosemide), and administration of bisphosphonates (pamidronate), calcitonin, or glucocorticoids as necessary. Dietary calcium intake should be restricted and vitamin D and its metabolites avoided. Bone marrow transplantation and "stem cell boosts" of transfused donor osteoblasts have also been used to treat affected patients. Administration of a bone-targeted form of TNSALP has been used successfully to treat life-threatening hypophosphatasia and is currently FDA approved for this purpose.^{114,115}

Hypercalcemia and hypercalciuria of unknown pathogenesis occur occasionally in subjects with the IMAGe syndrome (OMIM 614732) caused by gain-of-function variants of *CDKN1C* (OMIM 600856, chr. 11p15.4) encoding a paternally imprinted (maternally transmitted) cyclin-dependent kinase inhibitor critical for normal regulation of the cell's mitotic processes. Craniosynostosis, cleft palate, and scoliosis may also develop in these patients.

Evaluation and Management

After historical review (the family history is explored for members with mineral disorders and maternal status considered in depth, and the infant's intake of calcium, phosphate, and

vitamin D is estimated) and physical examination (nonspecific manifestations of hypercalcemia include—hypertension, subnormal growth, hypotonia, weakness, lethargy, stupor, occasionally seizures; specific findings associated with hypercalcemia include—facial and cardiovascular signs of WBS, subcutaneous nodules consistent with fat necrosis, skeletal deformities suggestive of metaphyseal chondrodysplasia or infantile hypophosphatasia) have been completed, evaluation of the hypercalcemic neonate and infant continues with measurements of total serum calcium and Ca^{2+} , phosphate, alkaline phosphatase, PTH, calcidiol, and calcitriol and determination of urine calcium and creatinine levels (Fig. 20.5). Hypocalciuria in the presence of hypercalcemia suggests the presence of NSHPT. Occasionally, one may encounter a neonate in whom the total calcium concentration is elevated because of hyperproteinemia but the Ca^{2+} value is normal, a state termed *pseudohypercalcemia*.⁷⁹ In infants

with suspected WBS, microarray or FISH analysis searching for deletion of chromosome 7q11.23 should be undertaken. In those in whom the diagnosis of NSHPT is being considered, determination of parental serum and urine calcium and creatinine values is often helpful unless the disorder has been transmitted as an autosomal recessive disease.⁹⁰ Genotyping of *CASR* should be undertaken when NSHPT is suspected.

Treatment of hypercalcemia in neonates and infants must be directed to prevention of progression, identification of cause, and assessment of severity. Use of a formula low in calcium and avoidance of vitamin D (excessive intake or sunlight) are helpful in the majority of neonates with modest hypercalcemia. Infants with significantly elevated serum calcium levels, particularly if long-standing, are often dehydrated. Immediate treatment consists of infusion of 0.9% sodium chloride with 30 mEq/L of potassium chloride (10–20 mL/kg over 1 hour);

Hypercalcemic disorders in children. *J Bone Mineral Res.* 2017;32:2157–2170, with permission.)

after dehydration has been corrected and adequate urine flow established and if substantial hypercalcemia persists an intravenous bolus injection of furosemide (1–2 mg/kg) may be administered. Currently, bisphosphonates, analogs of pyrophosphate that adhere to the surface of hydroxyapatite crystals and are incorporated by osteoclasts thereby inhibiting osteoclast-mediated dissolution of bone mineral and matrix, are the agents of choice for the treatment of substantial hypercalcemia in infants. Pamidronate (0.5–2.0 mg/kg in 30 mL normal saline intravenously over 4 hours) has been successfully used in infants with hypercalcemia caused by vitamin D intoxication, subcutaneous fat necrosis, NSHPT, and other causes.^{1,79,116} The effects of bisphosphonate last for several weeks to months and when administered in excess can lead to hypocalcemia, hypophosphatemia, and hypomagnesemia. Other agents that may be considered in the treatment of a hypercalcemic infant include salmon calcitonin (2–4 units/kg subcutaneously every 6–12 hours) to inhibit calcium mobilization from bone. Although the type II calcimimetic—cinacalcet—has been demonstrated to improve function of many inactive mutant forms of the CASR and to be of clinical benefit in adults with familial hypocalciuric hypocalcemia, this agent is not approved for use in children in the United States, a therapeutic trial of this agent may be considered in a patient with NSHPT with appropriate safeguards and permissions. In the newborn with life-threatening NSHPT, total parathyroidectomy may be urgently required.¹¹⁶ Postoperatively, the patients may become hypocalcemic as calcium is avidly deposited in bone (hungry bone syndrome) and require large amounts of supplemental calcium until stabilized.

Infants with hypercalcemia caused by WBS (that often remits by 2 years of age) or with some forms of osteopetrosis may be managed by use of a low-calcium formula (e.g., Calcilo XD—2.9 mg of calcium per 100 calories; free of vitamin D) and withholding of supplemental vitamin D. Infants with “idiopathic” hypercalcemia of infancy caused by inactivating mutations of *CYP24A1* should receive the low-calcium formula and supplemental vitamin D should be withheld. Some children with hypercalcemia caused by inactivating mutations of *CYP24A1* respond to ketoconazole, which inhibits conversion of calcidiol to calcitriol or rifampin, which also inactivates metabolites of vitamin D. Patients with mutations in *SLC34A1* may respond to administration of supplemental phosphate. Mineral homeostasis must be monitored closely in infants receiving a low-calcium formula and from whom vitamin D is being withheld to prevent deficiencies of both nutrients and development of secondary hyperparathyroidism.

Hypercalcemia in the Child and Adolescent

Hypercalcemia is present in the child/adolescent when the serum calcium concentration exceeds plus two standard deviations above the normal mean; for subjects 4 to 18 years of age these values are: total calcium 10.7 mg/dL (2.70 mmol/L); Ca^{2+} 5.52 mg/dL (1.38 mmol/L).¹ Hypercalcemia is most often asymptomatic in the older child and adolescent and identified unexpectedly by routine serum chemical analysis for an unrelated problem. Clinical manifestations of hypercalcemia in the child/adolescent include: anorexia, nausea, vomiting, constipation, abdominal or flank pain, polydipsia, polyuria, renal colic, altered alertness, lethargy, hypotonia, irritability, or seizures.^{1,117,118} Unrecognized, chronic hypercalcemia may impair growth, lead to nephrocalcinosis and nephrolithiasis preceding renal failure, pancreatitis, impaired cognition, or symptoms of mental illness. Long bone fracture through a fibrous cystic “brown tumor” (osteitis fibrosa cystica) may be a presenting complaint. Physical findings are nonspecific and may include hypertension, weakness, hyporeflexia, dull affect, aberrant mentation, or flank tenderness.

Etiology and Pathogenesis

Causes of hypercalcemia in children and adolescents are listed in Tables 20.4A, 20.4B. In the presence of a normal serum protein concentration, hypercalcemia occurs when the “set point” for serum Ca^{2+} is increased because of a loss-of-function mutation in *CASR* or the set point is reversibly increased by lithium, or when the rate of entry of calcium into the extracellular and circulatory compartments from bone, intestinal tract, or kidney exceeds its rate of loss.¹¹⁹ The resorption rate of bone mineral may be increased by excessive secretion of PTH or PTHrP, constitutive activation of PTH1R, excessive intake of vitamin D or metabolites, increased production of osteoclast-activating inflammatory cytokines or localized osteolytic processes, such as metastatic neoplasms, and dissociation of the rates of bone formation and resorption—for example, immobilization. The absorption rate of intestinal calcium may be increased by excessive intake of calcium, by hypervitaminosis D of exogenous or endogenous origin, or by increased secretion of PTH or PTHrP. Augmented renal tubular reabsorption of filtered calcium may occur with administration of calcium-sparing diuretics, such as thiazides, an effect that may “unmask” hypercalcemia in a previously eucalcemic patient with hyperparathyroidism. Thus hypercalcemia may be considered to be PTH mediated or PTH independent.¹⁰³ In the presence of hyperalbuminemia, the total serum calcium concentration but not the Ca^{2+} concentration is increased (pseudohypercalcemia). Venous stasis (e.g., by tourniquet during blood sampling) results in spuriously altered local pH and Ca^{2+} values.

Hyperparathyroidism is most often caused by a single parathyroid adenoma but may also be caused by hyperplasia of all four parathyroid glands as in patients with HHC caused by loss-of-function variants of *CASR*, *GNA11*, or *AP2S1*. Respectively, these genes encode the plasma membrane heptahelical CaSR, its guanosine triphosphate–coupled signal transduction factor (Gq/11 α), and an adaptor-related protein complex that facilitates endocytosis of the CaSR.^{117,120,121} Familial HHC type 1 (HHC1, OMIM 145980) is an autosomal dominant disorder with complete penetrance at all ages characterized by PTH-dependent, usually asymptomatic (total and ionized) hypercalcemia with hypocalciuria (and, therefore absence of nephrocalcinosis or calcium-containing renal calculi), hypermagnesemia, hypomagnesuria, and hypophosphatemia that is caused by heterozygous loss-of-function mutations in *CASR* (OMIM 601199).^{121–124} Consequently, higher serum concentrations of Ca^{2+} are required to activate the CaSR and inhibit synthesis and secretion of PTH. Serum concentrations of PTH may be normal or slightly elevated, but inappropriately high for the Ca^{2+} level; calcidiol and calcitriol values are normal. In children, HHC1 is most commonly suspected initially by the presence of unexpected hypercalcemia (11–13 mg/dL) in a chemistry profile or through family screening of a parent or other relative with hypercalcemia. Although patients with HHC1 are hypercalcemic, they are paradoxically hypocalciuric because inactivation of the CaSR results in enhanced distal renal tubular reabsorption of filtered calcium. PTH levels are normal or slightly elevated. When mutations in *CASR* are biallelic or when a neonate with a monoallelic variant of *CASR* is born to a normocalcemic woman, hypercalcemia may become extreme and even life-threatening (NSHPT). Older subjects with HHC1 may complain of fatigue, weakness, or polyuria; there is a slightly increased incidence of relapsing pancreatitis, cholelithiasis, chondrocalcinosis, and premature vascular calcification in subjects with HHC1, but bone mass and fracture rate are normal. Because of decrease in the number or functional competence of parathyroid chief cell membrane CaSRs, the set point for Ca^{2+} suppression of PTH secretion is reset upward.¹²⁵ The parathyroid glands are slightly hyperplastic.

In renal tubular cells, decrease in the number and activity of CaSRs results in increased renal tubular reabsorption of filtered calcium and relative hypocalciuria (ratio of calcium clearance/creatinine clearance <0.01 in 80% of patients with HHC1); because the renal tubular reabsorption of magnesium is also increased, hypermagnesemia and hypomagnesuria are present; urinary concentrating ability and other measures of renal function are normal; in hypercalcemia of other pathogenesis, urinary calcium excretion is increased and renal concentrating function depressed. Usually, HHC1 requires no therapy, but must be differentiated from mild primary hyperparathyroidism in which hypomagnesemia and hypercalciuria are present. Subtotal parathyroidectomy in HHC1 does not lower calcium levels as the residual parathyroid glands hypertrophy; total parathyroidectomy is unnecessary except in a rare infant with NSHPT. More than 100 nonsense, missense, insertion, and deletion mutations in *CASR* associated with HHC1 or NSHPT have been identified, mostly in the receptor's extracellular Ca^{2+} binding domain; these mutations either decrease receptor affinity for Ca^{2+} or alter intracellular processing of the CaSR (glycosylation, dimerization—e.g., p.Arg66His, p.Asn583Stop) in the endoplasmic reticulum preventing its translocation to the surface of the cell membrane^{122,125,126} (Fig. 20.6). Many of the mutations are located in the extracellular domain of CaSR between codons 39 to 300, a region rich in aspartate and glutamate residues in which Ca^{2+} may nestle. Glycosylation is necessary for both dimerization and trafficking of the CaSR. Missense mutations involving arginine at codon 66 (p.Arg66His/Cys) result in a product that is able to be only partially glycosylated; it can form homodimers in the endoplasmic reticulum but cannot enter the Golgi apparatus and be transported to the cell's plasma membrane.¹²⁶ Experimentally, approximately 50% of the products of inactivating mutations of *CASR* can be “escorted” to the plasma membrane and functionally stabilized by the allosteric calcimimetic cinacalcet proffering a potential therapeutic agent for the management of patients with symptomatic hypercalcemia because of loss-of-function *CASR* mutations, especially those with NSHPT, if it proves safe to do so in children. Mutations in *CASR* tend to be unique to the affected family. In approximately one-third of families with HHC1, no mutations in the coding region of *CASR* have been identified; thus they may have a mutation in a noncoding region of *CASR* or a variant of *GNA11* or *AP2S1*. Although the phenotypes are similar, these are two other genetic causes of hypocalcemic hypercalciuria designated types 2 and 3. Hereditary hypocalcemic hypercalciuria type 2 (OMIM 145981) is caused by loss-of-function variants of *GNA11* (OMIM 139313), encoding a CaSR G-protein transmitting signal ($G\alpha_{11}$) to intracellular signal transduction pathways. Hereditary HHC type 3 (OMIM 600740) is the consequence of inactivating mutations in *AP2S1* (OMIM 602242) encoding a protein complex that interacts with β -arrestin (*ARRB1*, OMIM 107940, chr. 11q13.4) forming a structure enabling movement of the CaSR from the cell membrane and its return to the cytoplasm; as adults, patients with HHC3 may have hypophosphatemic osteomalacia. Autoantibodies against the amino terminal extracellular domain of the CaSR that reversibly inhibit receptor activity have been identified in patients with acquired HHC; this disorder may be responsive to glucocorticoid therapy.¹²⁷ In some patients with primary or uremic secondary hyperparathyroidism, there is reduced expression of *CASR* and an increased set point for suppression of PTH secretion.

Primary hyperparathyroidism is an unusual childhood disorder with an incidence of 2 to 5/100,000 as compared with that in adults of approximately 100/100,000.^{117,128,129} In adults with hyperparathyroidism, females outnumber males 3:1; in children the female/male ratio is closer to one. In older

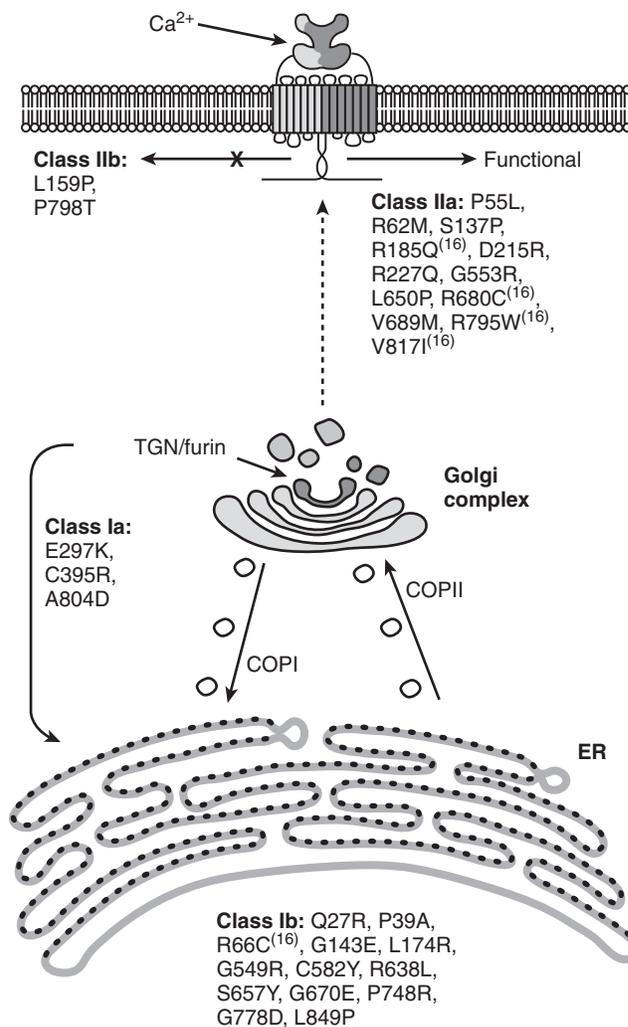

Fig. 20.6 Movement of the calcium sensing receptor (CaSR) through the endoplasmic reticulum (ER) and Golgi complex to the cell membrane before insertion. Inactivating mutations of CaSR may arrest movement of CaSR at various sites along this pathway, including immediately below the cell membrane. The mutations are designated classes Ia, Ib, and IIa, depending on the site of arrested movement as depicted. Class IIa mutants are able to be inserted into the cell membrane but remain subactive. (From White E, McKenna J, Cavanaugh A, Breitwieser GE. Pharmacochaperone-mediated rescue of calcium sensing receptor loss-of-function mutants. *Mol Endocrinol*. 2009;23:1115–1123, with permission.)

children and adolescents, primary hyperparathyroidism is most often a sporadic disease and usually the result of a single parathyroid adenoma. Hyperparathyroidism may occur as an autosomal dominant disorder in patients with familial isolated primary hyperparathyroidism involving variants of *CDC73* (OMIM 607391) and *GCM2* (OMIM 603716) (vide infra). Familial hyperparathyroidism also occurs in patients with variants of the genes responsible for the syndromes of multiple endocrine neoplasia (MEN) type 1 (*MEN1*, OMIM 613733), MEN types 2/3 (*RET*, OMIM 164761), and MEN type 4 (*CDKN1B*, OMIM 600778).^{1,79,116,130}

MEN types 1 and 4 are clinically similar in that both entities are associated with neoplastic lesions of the parathyroid glands, adenohypophysis (somatotropinoma, prolactinoma), and endocrine secreting cells of the intestinal (gastrinoma, insulinoma) or genitourinary tracts. MEN1 is the consequence of

heterozygous loss-of-function mutations in *MEN1* encoding a nuclear scaffold protein that interacts with multiple transcription factors and is a tumor suppressive agent. *MEN2A* is associated with loss-of-function variants of *RET* encoding a transmembrane receptor tyrosine kinase that is associated with parathyroid adenoma, medullary carcinoma of the thyroid, and pheochromocytoma; *RET* variants associated with *MEN2A* involve cysteine residues in its extracellular domain. *MEN2B* is associated with medullary carcinoma of the thyroid (MCT) that is highly aggressive, pheochromocytoma, thickening of corneal nerves, mucosal ganglioneuromas on the tongue, lips, and eyelids, and a marfanoid habitus; genetically, *MEN2B* is related to the *RET* variant p.Met918Thr in exon 16, the site of the receptor's tyrosine kinase domain. *MEN4* is associated with adenomas of the parathyroid gland, adenohypophysis, and gastrointestinal tract that is the consequence of monoallelic inactivating variants of *CDKN1B*, a cyclin-dependent kinase inhibitor that blocks the cell cycle at the G0/G1 phase. (Cyclins are cell proteins that regulate progression of the cell cycle of growth, division, and duplication by activating selected cell cycle-related kinases [phosphorylases].) Familial isolated hyperparathyroidism type 1 (OMIM 145000) and familial isolated hyperparathyroidism type 2 associated with fibrous tumors of the maxilla and mandible (OMIM 145001) are caused by loss-of-function mutations in *CDC73* (OMIM 607391) encoding a tumor suppressor. Familial isolated hyperparathyroidism type 3 (610071) has been mapped to chromosome 2p14-p13.3. *GCM2* (OMIM 603716) encodes a transcription factor essential for differentiation of the parathyroid glands. Gain-of-function variants of *GCM2* result in familial isolated hyperparathyroidism type 4 (OMIM 239200) with development of multiple parathyroid adenomas and occasionally carcinomas. *NSHPT* (OMIM 239200) is the consequence of inactivating mutations of *CASR* (OMIM 601199).

Children and adolescents with hypercalcemia caused by hyperparathyroidism may be asymptomatic or may display personality and behavioral changes—particularly depression, headache, malaise, proximal muscle weakness, anorexia, abdominal cramping, nausea and vomiting, constipation, polydipsia and polyuria or have symptoms reflecting the consequences of this disorder, such as flank pain and hematuria caused by renal calculi (hypercalciuria), abdominal pain (pancreatitis), or pathological fractures (through areas of osteopenia or lesions of osteitis fibrosa cystica).^{88,116} Rarely is it possible to palpate a cervical mass in these patients, although the physical examination may reveal slight weakness of proximal musculature. Hypercalcemia, hypophosphatemia, and elevated serum concentrations of intact PTH are present in the majority of children with hyperparathyroidism. In subjects with primary hyperparathyroidism, hypercalcemia is the result of increased secretion of PTH caused by loss of the normal relationship between the set point of serum Ca^{2+} and PTH synthesis and release and to Ca^{2+} -independent (constitutive) PTH secretion related to the mass of parathyroid tissue.^{117,128} Ultrasonography, magnetic resonance imaging, computed tomography (CT), and radionuclide scans (^{99m}technetium-labeled sestamibi-single photon emission CT scan) have been used to localize the abnormal parathyroid gland(s) before surgical excision. (Sestamibi is methoxyisobutylisonitrile, a lipophilic cation.) Occasionally, the parathyroid tumor may be located ectopically in the thymus, thyroid gland, or mediastinum. Further studies may reveal superiosteal bone resorption, nephrocalcinosis, or nephrolithiasis.

Pathologically, hyperparathyroidism in children is most often because of a chief cell adenoma involving one parathyroid gland, but adenomas in several parathyroid glands and diffuse hyperplasia (particularly in patients with MEN type 1), and rarely carcinoma of the chief cells may also occur. The majority

of parathyroid adenomas are monoclonal in origin; that is, a single mutant cell develops into a tumor. In adolescents, parathyroid tumors may occasionally develop after external radiation of the neck for treatment of lymphoma. In some parathyroid tumors, increased expression of cyclin D1 (encoded by *CCND1*, OMIM 168461, chr. 11q13.3) has been demonstrated. Overexpression of *CCND1* in parathyroid chief cells is at times the result of a somatic chromosome mutation—inversion (rotation) of regions 11p15 and 11q13 in which the promoter region of *PTH* is repositioned to serve as a promoter for *CCND1*, thereby increasing the rate of chief cell division whenever the (hypocalcemic) stimulus for PTH generation is received and leading ultimately to (benign) tumor formation. However, in many parathyroid adenomas, there is increased activity of cyclin D1 without this chromosomal rearrangement. In patients with parathyroid adenomas and carcinomas, overexpression of the retinoblastoma and p53 tumor-suppressor genes, whose products normally inhibit the cell cycle at the G1/S step, has also been demonstrated as have somatic mutations in *CDC73*.¹³¹ In approximately 35% of sporadic parathyroid adenomas, a somatic loss-of-function mutation of the tumor suppressor factor menin—the germline mutation in patients with MEN type 1—can be identified together with loss of heterozygosity on chromosome 11.¹³¹ Germline loss-of-function mutations in *MEN1* and *CASR* and gain-of-function variants in *GCM2* have also been detected in patients with isolated primary hyperparathyroidism in association with multi-glandular involvement; in this instance, patients with *CASR* mutations may not have the typical biochemical findings of HHC1 (see Table 20.4B). Chronic renal insufficiency leads to secondary hyperparathyroidism because of hyperplasia of the parathyroid glands and also to monoclonal parathyroid tumors (tertiary hyperparathyroidism) associated with somatic chromosomal deletions in some instances.

Familial isolated hyperparathyroidism type 1 (OMIM 145000) and type 2 (OMIM 145001—hyperparathyroidism associated with familial benign and malignant parathyroid tumors or multiple ossifying fibromas of the maxilla and mandible, respectively) are both caused by germline mutations in *CDC73* (OMIM 607393, chr. 1q31.2) encoding parafibromin, a protein intrinsic to the cell division cycle. Hyperparathyroidism occurs in 80% of subjects with a mutation in *CDC73* at a mean age of 32 years but may also appear in children before 10 years of age. In these patients, the parathyroid lesion may be an atypical, potentially premalignant cystic adenoma (65%), hyperplasia (20%), or even carcinoma (15%); the parathyroid tumor may be an isolated finding or it may be associated with maxillary and/or mandibular bone tumors composed of ossified fibrous tissue; renal (Wilms tumor, papillary renal cell carcinoma, hamartoma, polycystic kidney), pancreatic (carcinoma), and uterine (tumor) lesions may also develop in these patients. Lesions within the parathyroid glands may develop asynchronously. *CDC73* is a 17 exon gene that encodes parafibromin, a 531 aa nuclear protein that is a component of a complex of accessory factors that modulates the activity of RNA polymerase II and of a histone methyltransferase and hence regulates gene expression and cell proliferation—functioning as both a transcriptional activator and repressor.^{132,133} For a parathyroid tumor to develop, a “second hit” must occur that results in loss of heterozygosity: that is, the germline inactivating mutation of *CDC73* on one allele must be matched by a mutation in or deletion of *CDC73* in the remaining normal allele. When a germline mutation in *CDC73* has been detected, screening of family members for this mutation and longitudinal evaluation of affected subjects is recommended as asymptomatic individuals with atypical adenoma or carcinoma of the parathyroid glands may be so identified. Somatic mutations in *CDC73* have also been identified

in atypical parathyroid adenomas and many parathyroid carcinomas but are unusual in the typical sporadic parathyroid adenoma. Familial isolated hyperparathyroidism type 3 (OMIM 610071) has been linked to chromosome 2p14-13.3 but a specific gene variant in this site has not been identified. Hyperparathyroidism type 4 (OMIM 617343) is the result of variants of *GCM2* (OMIM 603716) whose product is essential for differentiation of the parathyroid glands.¹

The syndromes of MEN are familial autosomal dominant diseases of high penetrance associated with the development of tumors in two or more endocrine glands within a single individual.¹³⁰ There are four defined MEN syndromes—1, 2A, 2B, and 4 (Table 20.5). MEN1 is characterized by development of tumors of the parathyroid glands (adenoma), pituitary (prolactinoma, somatotropinoma), and enteropancreatic unit (gastrinoma, insulinoma, pancreatic polypeptide-oma, carcinoid). In addition, neoplasms of the adrenal cortex, neuroendocrine tumors of the bronchopulmonary tree and thymus, lipomas, angiofibromas, collagenomas, and meningiomas develop in affected subjects. The postmortem incidence of MEN1 is 0.25%; in hyperparathyroid subjects 1% to 18%; and in patients with gastrinoma 16% to 38%. Hyperparathyroidism (because of a solitary parathyroid adenoma or tumors within several parathyroid glands or hyperplasia of all four parathyroid glands) is the most common manifestation of MEN1 occurring in more than 90% to 95% of affected patients; it is the most frequent endocrinopathy in children with MEN1, at times developing before 10 years of age. Unlike other forms of hyperparathyroidism, equal numbers of males and females are affected in MEN1. Pituitary tumors secreting prolactin and/or GH often (30%–40% of MEN1 subjects) develop as do

gastrin- (Zollinger-Ellison syndrome), insulin, and glucagon-secreting tumors of the pancreatic islets and gastrointestinal system (30%–70% of patients); these neoplasms also occur in children and adolescents with MEN1. Hypercortisolemia in patients with MEN1 may be caused by excessive secretion of adrenocorticotropin by a pituitary adenoma or ectopically by a neoplasm or to a primary adrenal tumor. Thyroid neoplasms occur in 25% of patients with MEN1. Nonendocrine tumors, such as lipomas (34%), intestinal and bronchial carcinoids, and other intestinal neoplasms are reasonably common in subjects with MEN1. Indeed, the dermatological manifestations of MEN1, including angiofibroma (85%), collagenomas (70%) are extremely sensitive and specific indicators of this disease. Patients with MEN1 may also develop a schwannoma or a pheochromocytoma, the latter a tumor most often present in patients with MEN types 2A and 2B. Although most of the tumors that develop in MEN1 are benign but functionally hyperactive, those of pancreatic, intestinal, and foregut origin may be malignant.

Germline mutations in *MEN1*, a 10 exon gene that encodes a 610 aa cytoplasmic and nuclear protein termed *menin*, have been demonstrated in the majority of patients with familial and sporadic forms of MEN1. Menin regulates cell growth, division, and demise in two sites and through multiple pathways. In the cytoplasm, menin binds AKT1 (protein kinase B—OMIM 164730, chr. 14q32.33) preventing its translocation to the cell membrane where it is ordinarily activated by phosphorylation enabling AKT1 to exert proliferative and antiapoptotic effects; by binding of menin to AKT1, both the cytosolic level of AKT1 and its kinase activity are depressed, thereby suppressing its effects on cell division and survival.¹³⁴ Menin enters the

(From Thakker RV, Newey PJ, Walls GV, et al. Clinical Practice Guidelines for Multiple Endocrine Neoplasia type 1 (MEN1). *J Clin Endocrinol Metab*.

2012;97:2990–3011; Marx SJ, Simonds WF. Hereditary hormone excess: genes, molecular pathways, and syndromes. *Endocr Rev*. 2005;26:615–661.)

nucleus with the guidance of two nuclear localization signals in its carboxyl terminus (aa 479–498, 589–608) where it is involved directly in the regulation of transcription, replication, and survival. By binding directly to JunD, menin blocks JunD-mediated inhibition of transcription of activating protein-1 (and consequently cell division); many of the mutations in *MEN1* in patients with MEN1 cluster in exon 4 and interrupt the binding of these two proteins (between menin aa 139–142 and 323–428). By interacting with small mothers against decapentaplegic (SMAD)3 (OMIM 603109, chr. 15q22.3), menin inhibits signaling by transforming growth factor (TGF) β and impairs TGF β -mediated inhibitory control of cell replication. Interaction of menin with the SMAD 1/5 complex inhibits signaling by bone morphogenetic protein (BMP) 2; menin also inhibits the transcription regulating protein—nuclear factor κ B (NF- κ B). Further, menin interacts directly with a histone methyltransferase complex and with genes that regulate DNA repair and cell replication and apoptosis, such as tumor suppressor *TP53* (p53), *CDKN1A*, *CDKN1B*, *GADD45A*, *POLR2A*, *BBC3*, *TP5313*, and *FAS*.¹³⁵ Variants of *CDKN1A* (OMIM 116899), *CDKN2B* (600431), and *CDKN2C* (OMIM 603369), proteins that regulate the cell division cycle, have been associated with nonsyndromic primary hyperparathyroidism.¹

In subjects with heterozygous germline loss-of-function mutations in *MEN1*, unregulated cell growth and tumor formation occur when a second insult leads to loss of *MEN1* on the normal allele within susceptible tissues. As with *CDC73* (vide supra), the “two hit” hypothesis of tumorigenesis in *MEN1* denotes that the patient inherits germline susceptibility to neoplasia superimposed on which is a second insult, leading to loss of heterozygosity for chromosome segment 11q13 and biallelic loss of *MEN1*; the second hit may be deletion of a segment of chromosome 11 that includes 11q13 or a mutation (missense, frameshift) within the wild-type *MEN1* allele itself, an observation that also extends to MEN type 1 tumors with somatic mutations in *MEN1*.¹²¹ Several hundred germline mutations in *MEN1* have been identified in patients with MEN1; 25% have been nonsense mutations, 15% missense mutations, 45% frameshift insertions or deletions, with more than 80% leading to the synthesis of an inactive product because of loss of the nuclear localization signal or the ability to bind to JunD or other downstream factor. Especially susceptible germline mutational “hot-spots” in *MEN1* are the nucleotide 5168 G \Rightarrow A transition that results in a novel splice site in intron 4, codons 83 to 84, 118 to 119, 209 to 211, 418, and 516 where collectively mutations have been identified in 37% of patients with MEN1. On either side of many of these sites are segments of repeat DNA sequences of single nucleic acids or of dinucleotides to octanucleotides; this configuration may lead to increased susceptibility to “replication-slippage” because of misalignment of the nucleotide repeat segments during DNA replication permitting deletion or insertion of nucleotides at inappropriate sites. Mutations within the exonic/intronic splice site coding region of *MEN1* have been detected in approximately 70% of patients with familial MEN1; likely in the remaining 30% of subjects, there is either deletion of one *MEN1* allele or a mutation in one of its noncoding regions.¹³⁶ New mutations of *MEN1* occur sporadically in 10% of patients with MEN1. Familial autosomal dominant, isolated primary hyperparathyroidism has been variably associated with germline mutations (e.g., Val184Glu, Glu255Lys, Gln260Pro) in *MEN1* as well. Somatic mutations in *MEN1* have also been identified in patients with sporadic, isolated tumors of the parathyroid glands, pancreatic islet cells, anterior pituitary, and adrenal cortex. Clinically apparent disease because of mutations in *MEN1* increases with advancing age: at 10 years of age 7% of children with a mutation in *MEN1* have a detectable endocrinopathy (primarily hyperparathyroidism); 52% of

affected 20-year-old subjects manifest one or more tumors; penetrance increases to 87% by 30 years, to 98% by 40 years, and to 100% by 60 years.¹³⁰

There are several forms of MEN type 2—subtypes 2A, 2B, and familial medullary thyroid carcinoma (2C). MCT is the most common neoplasm encountered in MEN 2A occurring in 90% of patients (OMIM 171400) (see Table 20.5) (Thakker et al 2012¹³⁰; Arnold & Marx 2008¹³⁶). It evolves from antecedent parafollicular or C cell hyperplasia within the thyroid gland. These subjects also develop adrenal medullary pheochromocytomas (50%), parathyroid hyperplasia or adenoma (20%–30%), localized cutaneous lichen amyloidosis (suprascapular pruritic deposits of subepidermal keratin), and partial or complete megacolon. Calcitonin, the secretory product of thyroid C cells, is also produced in very large amounts by MCT; its measurement aids in the diagnosis of MCT and in monitoring the response of this tumor to therapy. In addition to MCT and pheochromocytoma, patients with MEN 2B (OMIM 162300) have a Marfanoid habitus, mucosal ganglioneuromas of the lips and tongue, gastrointestinal ganglioneuromas, medullated corneal nerve fibers, and megacolon, but they do not develop parathyroid disease.^{130,136} Familial isolated MCT is a variant of these disorders. Germline heterozygous gain-of-function mutations in the *RET* protooncogene underlie the pathogenesis of the type 2 hereditary MENs. *RET* is a 20-exon gene encoding an 860 aa glycosylated cell membrane tyrosine kinase receptor with extracellular, transmembrane, and intracellular domains that is expressed in tissue of neural crest origin (sympathetic ganglia, adrenal medulla, thyroid parafollicular cells) (Fig. 20.7). The natural ligand of this receptor is glial cell line–derived neurotrophic factor (*GDNF*, OMIM 600837). Constitutively activating mutations of one of six cysteine residues in the extracellular domain of *RET*—codons 609, 611, 618, 620, 630, and particularly codon 634 (Cys \Rightarrow Arg)—are present in patients with MEN 2A. Loss of

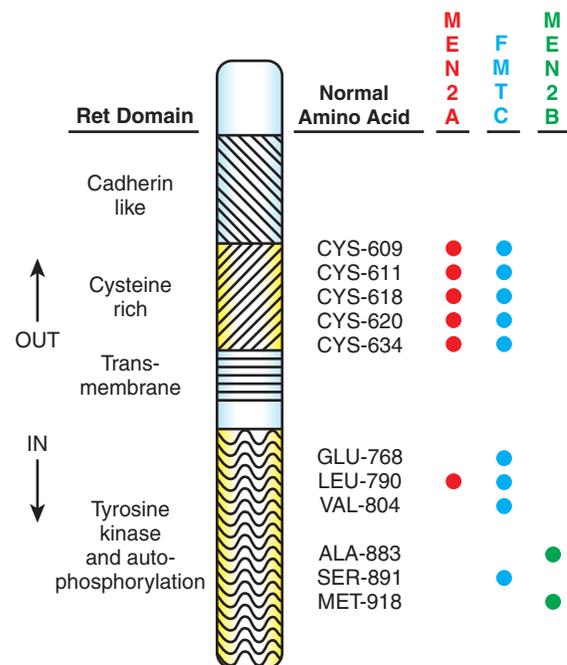

Fig. 20.7 Schematic depiction of the domains of the *RET* protooncogene with sites of activating mutations in *RET* associated with multiple endocrine neoplasia types 2A and 2B and familial medullary carcinoma of the thyroid. (From Marx SJ, Simonds WF. Hereditary hormone excess: genes, molecular pathways, and syndromes. *Endocr Rev.* 2005;26:615–661, with permission.)

but one cysteine residue facilitates receptor homodimerization without ligand binding, thereby activating the RET intracellular tyrosine kinase domain resulting in autophosphorylation of critical tyrosine residues (particularly at codons 1015 and 1062), and subsequent signal transduction. An activating mutation has been identified at codon 918 (Met \Rightarrow Thr) in more than 95% of patients with MEN 2B; this site lies within the tyrosine kinase domain and this mutation permits signal transduction and neural cell transformation and differentiation in the absence of both ligand binding and receptor homodimerization. The p.Met918Thr MEN IIB-associated *RET* mutation often arises de novo from sporadic mutations that occur in the germline of an older father, because this mutation confers a "selective advantage" upon the mutated spermatocyte.¹³⁷ Other missense mutations of *RET* associated with MEN 2B have been identified at codons p.Val804, p.Ala883, and p.Ser904. Missense mutations at *RET* codons 609, 611, 618, 620, and 634 within the extracellular domain and at codons 768, 790, 804, and 891 within the intracellular tyrosine kinase domain have been found in patients with familial MCT. In children, hyperparathyroidism may be an unusual manifestation of the McCune-Albright syndrome (OMIM 174800) because of a postzygotic activating mutation in *GNAS*. Hyperparathyroidism and nephrogenic diabetes insipidus have been noted in subjects with antenatal Bartter syndrome (OMIM 601678) associated with biallelic variants of *SLC12A1* (OMIM 600839), the gene encoding a sodium-potassium-chloride transporter protein.¹⁰⁹

Ingestion of excessive amounts of vitamin D or calcitriol for therapeutic reasons (treatment of rickets, hypoparathyroidism, or other causes of hypocalcemia), megavitamin intake, manufacturing errors in the preparation of vitamin supplements, or inappropriate fortification of milk are significant causes of vitamin D-mediated hypercalcemia.^{103,138} Topical application of creams containing vitamin D or an analogue (e.g., 22-oxacalcitriol) for treatment of psoriasis might also lead to hypercalcemia—particularly if the urinary excretion of calcium is compromised. Patients with granulomatous diseases (noninfectious: sarcoidosis, berylliosis, eosinophilic granuloma, subcutaneous fat necrosis, inflammatory bowel disease; infectious: tuberculosis, histoplasmosis, coccidioidomycosis, candidiasis, cat-scratch disease) and neoplastic disorders (B-cell lymphoma, Hodgkin disease, dysgerminoma) develop hypercalcemia because of associated monocytic (macrophage and other cells) expression of *CYP27B1* and resulting production of calcitriol.¹³⁹ Unlike renal tubular cells in which 25-hydroxyvitamin D-1 α hydroxylase activity is within mitochondria and the transcription of *CYP27B1* is closely regulated by PTH, calcitriol, calcium, and phosphate, in monocytes, this enzyme is microsomal in location and its gene is constitutively expressed and calcitriol synthesis quantitatively determined by the amount of substrate. The monocytic expression of *CYP27B1* is very sensitive to stimulation by IFN- γ and its postreceptor signal transducer nitric oxide, as well as by leukotriene C₄; it is readily suppressible by glucocorticoids, ketoconazole, and chloroquine. In patients with inactivating mutations of *CYP24A1*, calcitriol is unable to be further hydroxylated and excreted.

Patients with acquired immunodeficiency disease may become hypercalcemic by infection with granuloma-forming organisms or by osteoclast-activating cytokines elaborated during the course of this disorder. Elevated serum calcium concentrations have also been recorded in children with congenital hypothyroidism, primary oxalosis, congenital lactase deficiency, trisomy 21, and juvenile idiopathic (rheumatoid) arthritis.¹⁴⁰ In some hypercalcemic children, excessive prostaglandin production may be of pathogenetic significance. Hypercalcemia develops frequently in young subjects with the infantile form of hypophosphatasia, likely a consequence

of the dissociation of the rates of low bone formation and normal bone resorption. By the same pathogenetic mechanism, acute immobilization of the rapidly growing child with a femoral fracture or a spinal cord injury results in decreased bone mineral accretion and uncoupling of the interaction of osteoblasts and osteoclasts with an increased rate of bone resorption, leading to hypercalciuria, hypercalcemia, and "acute disuse osteoporosis."¹⁴¹ Acute disuse osteoporosis and hypercalcemia can even occur in the immobilized hypoparathyroid or vitamin D-depleted individual. Children and adolescents ingesting a ketogenic diet in an effort to manage refractory epilepsy may develop hypercalciuria and hypercalcemia and experience decline in bone mineralization because of dissociation between the rates of bone accrual and bone mineral reabsorption. Hypercalcemia may occur in children receiving excessive amounts of milk and alkali for treatment of gastritis. It may follow successful bone marrow transplantation in infants with osteopetrosis as functional osteoclasts rapidly reabsorb excess bone mineral.

Oncogenic or malignancy-associated hypercalcemia may be the consequence of synthesis and secretion of osteoclast activating agents, such as PTHrP, (rarely PTH), calcitriol, or cytokines (ILs, tumor necrosis factor [TNF], TGF β), or it may be caused by direct invasion and destruction of bone by the neoplasm.^{79,116} Although hypercalcemia occurs in less than 1% of children with cancer, it may develop in patients with acute lymphatic and monocytic leukemias, Hodgkin and non-Hodgkin lymphoma, rhabdomyosarcoma, hepatoblastoma, neuroblastoma, and Ewing sarcoma.¹⁴² When the rate of bone resorption exceeds the renal tubular capacity for excretion of calcium, hypercalcemia ensues. Increased intake of calcium and absorbable alkali (milk or calcium containing antacids, such as calcium carbonate) for peptic ulcer disease or as dietary supplements lead to absorptive hypercalcemia, hypercalciuria, and nephrocalcinosis. Parenteral nutrition with excessive calcium or aluminum or too little phosphate can also result in hypercalcemia. Hypophosphatemia of various etiologies leads to hypercalcemia as the body attempts to maintain the calcium \times phosphate product over 30. Drugs causing hypercalcemia include: thiazide diuretics increase renal tubular resorption of calcium and decrease plasma volume; vitamin D and analogs increase intestinal absorption of calcium; vitamin A and its retinoic acid analogs stimulate bone resorption; lithium increases the set point for PTH secretion—thereby increasing serum calcium concentrations while lowering urinary calcium excretion and thus mimicking HHC1. In the thyrotoxic subject, hypercalcemia is the result of thyroid hormone-mediated stimulation of osteoclast function and subsequent increase in the rate of bone resorption.¹¹⁶ Pheochromocytomas and some islet cell tumors may be associated with hypercalcemia, in some instances because of cosecretion of PTHrP. Hypercalcemia in the patient with hypoadrenocorticism is the consequence of continued mobilization of bone calcium, decreased renal glomerular filtration of this cation and its increased renal tubular reabsorption and is reversed by restoration of the eucorticoid state.

During recovery from acute renal failure, serum calcium levels may increase because of mobilization of calcium from ectopic sites, such as muscle in which it had been deposited during the hyperphosphatemic phase of the illness from which it is released by rhabdomyolysis.¹¹⁶ Hypercalcemia can develop in patients with chronic renal failure caused by a combination of factors including: immobilization, aluminum toxicity, excessive ingestion of calcium-containing antacids or vitamin D or its analogs, and secondary hyperparathyroidism. After renal transplantation, hypercalcemia is often the result of secondary hyperparathyroidism caused by hypertrophy and hyperplasia of parathyroid chief cells that occurred in response to the PTH stimulatory effects of hyperphosphatemia,

hypocalcemia, and decreased synthesis of and response to calcitriol during the period of chronic renal insufficiency. In patients with compromised renal function, mild hypocalcemia and calcitriol deficiency develop when the glomerular filtration rate falls below 80 to 60 mL/min/1.73 m², whereas phosphate retention occurs after the glomerular filtration rate has fallen to 60 to 30 mL/min/1.73 m².¹⁴³ The secretion of PTH rises secondarily in these patients in an effort to increase the synthesis of calcitriol, increase renal tubular reabsorption of calcium, raise calcium levels, decrease renal tubular reabsorption of phosphate, and lower phosphate values. Prolonged, uncontrolled secondary hyperparathyroidism can lead to relatively autonomous parathyroid hyperfunction ("tertiary hyperparathyroidism") and hypercalcemia, primarily in patients with chronic renal failure. Hyperplasia of chief cells is followed by defects in function of the CaSR and loss of effective downregulation of PTH secretion refractory to increased serum concentrations of Ca²⁺. There is an expanded number of monoclonal chief cells in which the expression of CaSR and the number of vitamin D nuclear receptors have declined. Secondary and tertiary hyperparathyroidism have occurred in patients with prolonged nutritional vitamin D deficiency rickets and in subjects with X-linked hypophosphatemic rickets receiving large amounts of phosphate.¹⁴⁴ Secondary hyperparathyroidism (in which by definition serum calcium concentrations are normal) also develops in patients with inadequate dietary calcium, impaired intestinal absorption of calcium (lactose intolerance, ingestion of phytates, malabsorption syndromes caused by pancreatic insufficiency or celiac disease), or excessive calcium loss in the urine or soft tissues. Enhanced but transient secretion of PTH may accompany the administration of GH to adolescents with chronic renal failure, likely the result of superimposing upon a high basal rate of PTH secretion further increase in the rate of bone remodeling related to somatotropin and sex hormones. In acutely ill adults, administration of GH has been associated with hypercalcemia as well.¹⁴¹

Isolated hypercalciuria in the eucalcemic child may be idiopathic or caused by renal medullary or tubular dysfunction or increased intestinal absorption of calcium, including mutations in genes encoding the vitamin D and CaSRs and soluble adenylyl cyclase, demineralizing disorders, such as juvenile idiopathic arthritis, hyperalimentation, metabolic acidosis, excessive protein ingestion, and diabetes mellitus; hypercalciuria with/without hypercalcemia may be observed in patients with familial forms of hypomagnesemia, several types of Bartter syndrome, and distal renal tubular acidosis.

Evaluation

Evaluation of the child with hypercalcemia requires systematic examination of each of its possible causes (see Fig. 20.5). Careful review of the personal and family histories and thorough physical examination precede measurement of serum levels of total and ionized calcium, phosphate, creatinine, intact PTH, and 25-hydroxyvitamin D and of urinary calcium and creatinine excretion; renal ultrasonography is used to detect nephrocalcinosis or renal calculi if hypercalciuria is present. If the serum concentration of PTH is not suppressed in a patient with hypercalcemia, the presence of hyperparathyroidism is to be further considered. If repetitive determinations are consistent with hyperparathyroidism, then its pathogenesis is to be identified. Imaging studies of the neck to be undertaken may include ultrasonography (a parathyroid adenoma is hypoechoic), technetium-99m sestamibi scanning with single-photon-emission CT, dynamic (4D) CT imaging (useful to detect multiple and ectopic parathyroid adenomas), and magnetic resonance imaging (thus avoiding radiation exposure).¹²⁹

When hypercalcemia is mild (total calcium concentration <12 mg/dL), there may be few, if any, symptoms; thus children/adolescents with mild hypercalcemia are often identified unexpectedly by a screening panel of blood chemistries obtained for another purpose. Hypercalcemia may also be detected during studies for renal calculi, abnormal bone mass, pathological fractures, or during screening of families for associated problems. An elevated serum (total or ionized) calcium concentration in a single specimen may also reflect assay variability and must be verified by repeated determinations in a reliable laboratory. Pseudohypercalcemia is the presence of persistently elevated total calcium concentrations whereas the Ca²⁺ is normal and is found in subjects with hyperalbuminemia and other dysproteinemic states. Symptoms attributable to hypercalcemia are independent of its cause and are related to the degree of hypercalcemia and include: intestinal— anorexia, nausea, vomiting, abdominal pain (peptic ulceration, acute pancreatitis), and constipation; urinary—polydipsia, nocturia, and polyuria (calcium acts as an osmotic diuretic whereas hypercalcemia impairs the concentrating function of the distal renal tubule); skeletal—bone pain; nervous system—headache, muscular weakness, impaired ability to concentrate, increased requirement for sleep, altered consciousness (ranging from lethargy and confusion to irritability, delirium, stupor, and coma); on occasion, depression may be the major presenting concern in an adolescent with hypercalcemia.^{116,119} In the toddler and young child, hypercalcemia is manifested by anorexia, constipation, poor weight gain, and impaired linear growth ("failure to thrive"). In a series of 52 children and adolescents with hypercalcemia caused by primary hyperparathyroidism, 80% were symptomatic; the most common symptoms were fatigue/lethargy (35%), depression (14%), headache (35%), nausea (29%), vomiting (23%), and polydipsia (21%).¹⁴⁵ Bone involvement (low bone mass, fractures) was present in 30%. All of the children (*n* = 17) with nephrolithiasis in this series were symptomatic. In another series of 44 children and adolescents (26 girls) with primary hyperparathyroidism, mean age at diagnosis was 13 years (range 6–18 years), overall 37 were symptomatic (anorexia, weight loss, malaise, depression) and there were 18 patients with nephrolithiasis.⁸⁸ At surgery, 29 patients had a parathyroid adenoma and 11 had hyperplastic parathyroid glands—two of whom had MEN. Several features of hyperparathyroidism in children and adolescents differ from those in adults, including heavier and larger adenomas and higher serum and urinary calcium levels but comparable serum levels of iPTH, phosphate, and alkaline phosphatase.

Evaluation of the hypercalcemic child begins with the historical review during which the family/patient is queried not only about symptoms related to hypercalcemia and its consequences (renal calculi) but also about possibly excessive intake of vitamin D, vitamin A and related compounds (such as retinoic acid for treatment of acne), calcium (perhaps to "prevent" osteoporosis), and alkali, or drugs that affect calcium metabolism (thiazide diuretics may "unmask" hyperparathyroidism by increasing renal tubular resorption of calcium thereby raising borderline calcium concentrations into the hypercalcemic range). The family history is explored for members with known disorders of calcium metabolism (HHC1, hyperparathyroidism, renal calculi) or familial neoplasms (galactorrhea as a sign of a prolactinoma, severe peptic ulcer disease as an indicator of a gastrinoma). Except in extreme instances when hypertension (if normally hydrated) or bradycardia, dehydration, decreased muscular strength, or altered consciousness may be present or in the Marfanoid subject with MEN IIB, physical examination of the hypercalcemic child and adolescent is usually normal. Rarely, is a paratracheal (parathyroid) mass palpable in the hyperparathyroid patient. (Subjects with hypercalcemia caused

by subcutaneous fat necrosis have firm to hard, irregular, movable masses scattered about the trunk and extremities. Those with WBS have a typical face whereas those with Jansen metaphyseal chondrodysplasia have characteristic skeletal deformities.)

After confirming the presence of total and ionized hypercalcemia, the urinary excretion of calcium is next measured (Table 20.6). If the PTH concentration is normal or elevated and the calcium excretion is low, it is most probable that the patient has HHC1; this diagnosis can be substantiated by the finding of asymptomatic HHC in one of the parents and further defined by identification of the inactivating mutation in *CASR*. If the patient is hypercalciuric, other causes of hypercalcemia should be sought. With highly sensitive and specific immunoassays for intact PTH¹⁻⁸⁴ in comparison with serum calcium values, separation of patients with hyperparathyroidism from those with other causes of hypercalcemia in whom PTH values are low or subnormal is usually possible. In the absence of secondary hyperparathyroidism (chronic renal insufficiency, malabsorption syndromes, ingestion of thiazide diuretics or lithium), consistently elevated PTH concentrations in the hypercalcemic, hypophosphatemic, hypercalciuric child or adolescent are consistent with primary hyperparathyroidism. Although the diagnosis of primary hyperparathyroidism is usually quite apparent in children and adolescents, there is an occasional patient in whom serum calcium and/or PTH values may not be elevated in a single specimen and in whom repeated measurements of serum and urine calcium and PTH values are necessary before this diagnosis can be established. In 52 children/adolescents with hyperparathyroidism, serum calcium values were normal in 10% and PTH levels in 15%; however, in all subjects, the PTH concentration was inappropriately increased relative to the calcium level.¹⁴⁵ Hypercalcemia, hypophosphatemia, and elevated PTH concentrations were recorded in all 44 children and adolescents (6–18 years of age at diagnosis) with primary hyperparathyroidism in a second series.⁸⁸ Osteitis fibrosa cystica, brown tumors (localized nonneoplastic areas of bone resorption composed of osteoclast-like multinuclear giant cells, fibroblast-like spindle shaped cells, and hemorrhagic infiltrates), and subperiosteal and endosteal bone resorption can be detected radiographically in most children with hyperparathyroidism, whereas cortical (distal radial) BMD is likely to be decreased in these subjects. Nonspecific findings in the hypercalcemic subject of diverse etiology include shortening of the QT interval by electrocardiography because the rate of cardiac repolarization is accelerated by increased calcium levels, bradycardia, and first-degree atrioventricular block, and nephrocalcinosis and renal calculi detected by ultrasonography. Serum concentrations of PTHrP should be measured when clinical and laboratory findings are consistent

with primary hyperparathyroidism, but PTH values are low and humoral hypercalcemia of malignancy is suspected. When PTH concentrations are low in the hypercalcemic patient, metabolites of vitamin D (calcidiol, calcitriol) should be measured and other causes of hypercalcemia sought.

Preoperatively, a parathyroid adenoma may be localized by high resolution ultrasonography, dynamic (4D) single photon-emission computed tomography (SPECT), radionuclide scanning with ^{99m}Tc-sestamibi coupled with SPECT, or magnetic resonance imaging.¹²⁹ The ^{99m}Tc-sestamibi radionuclide is taken up by both the thyroid and parathyroid glands but quickly “washed out” from the thyroid gland; thus two scans obtained 2 hours apart permit differentiation of parathyroid from thyroid tissue. ^{99m}Tc-sestamibi scans may be obtained by conventional two-dimensional or CT techniques, the latter offering a three-dimensional image; lateral views may better locate the enlarged parathyroid gland. Fusion of ^{99m}Tc-sestamibi SPECT and CT methodology has been successful in localizing ectopic parathyroid adenomas. Combining ^{99m}Tc-sestamibi scanning and ultrasonography affords a sensitivity approaching 90% in children with parathyroid adenomas. Rarely is it necessary to undertake selective venous catheterization with sampling of local PTH levels and/or arteriography to identify the site of a parathyroid adenoma. Evaluation for associated endocrine tumors is necessary, if the family history suggests the possibility of MEN 1 or MEN IIA or if there are clinical findings (galactorrhea, excessive growth, hypertension) that suggest the presence of a prolactinoma, somatotropinoma, or pheochromocytoma. Patients at risk for MEN may be screened by determining basal and stimulated serum concentrations of prolactin, GH/insulin-like growth factor 1 (IGF-1), gastrin, glucagon, pancreatic polypeptide, calcitonin, catecholamines, and other substances as warranted. Genetic screening of MEN candidate genes may also be worthwhile. Indeed, it is reasonable to consider screening children with hyperparathyroidism preoperatively for an associated pheochromocytoma or tumors of the maxilla and mandible and for mutations in *RET*, *MEN1*, and *CDC73*.

In the patient with hypercalcemia caused by ingestion of excessive amounts of vitamin D, serum concentrations of calcidiol are markedly elevated; in those receiving exogenous calcitriol or in hypercalcemic patients with granulomatous, chronic inflammatory and lymphomatous diseases serum levels of calcitriol are increased. Other disorders associated with hypercalcemia (see Table 20.4A) should be eliminated by appropriate historical findings and laboratory and genetic studies.

Management

Appropriate management of the patient with hypercalcemia depends on the severity and the cause of the high calcium

levels. It is important to distinguish the patient with pseudohypercalcemia (because of hyperproteinemia) from one with a pathological cause of hypercalcemia so that effective medical and surgical therapy may be initiated promptly. It is equally important to recognize the child/adolescent with HHC1 so that aggressive therapy is avoided. When the calcium concentration is under 12 mg/dL in the asymptomatic subject, treatment may be delayed until the cause of the hypercalcemia is understood; in the interim, it is reasonable to recommend that the patient increase fluid intake, avoid calcium and vitamin D supplements, and discontinue drugs associated with hypercalcemia if relevant. The child with HHC1 often has serum total calcium concentrations between 11 and 13 mg/dL but no clinical symptoms and requires no therapy under usual circumstances. In the absence of HHC1, if the total serum calcium concentration exceeds 12 mg/dL or if the child is symptomatic (anorexia, nausea, altered sensorium, polydipsia, polyuria, dehydration, muscular weakness, bradycardic with a prolonged QT interval), efforts to lower the serum calcium level are usually necessary because of the adverse effects of hypercalcemia on cardiac, central nervous, renal, and gastrointestinal function. In these children and adolescents, diagnostic studies as outlined earlier and treatment to lower the serum calcium concentration should begin simultaneously. The tools of therapy of hypercalcemia are usually used sequentially.

The therapy of severe hypercalcemia involves: (1) hydration—with 0.9% saline (twice maintenance volume over 24–48 hours)—thus restoring intravascular volume, diluting and decreasing serum Ca^{2+} levels, increasing glomerular filtration of Ca^{2+} , decreasing reabsorption of Ca^{2+} in the proximal and distal renal tubules, and promoting calciuresis; hydration alone usually lowers the total serum calcium concentration 1 to 3 mg/dL; (2) calciuresis—achieved by intravenous infusion of the loop diuretic furosemide (1–2 mg/kg slowly) initiated after restoration of extracellular fluid volume with saline further lowers calcium levels by inhibiting resorption of calcium (and sodium) by the TALH—loop diuretics should be restricted to patients who develop fluid overload while receiving saline as these agents may lead to dehydration and decline in the glomerular filtration rate; bumetanide is a similar but more potent loop diuretic whose use may be considered in the hypercalcemic patient; (thiazide diuretics are to be avoided as they increase renal tubular reabsorption of calcium and increase serum calcium concentrations and are clearly contraindicated in the management of hypercalcemia); (3) inhibition of bone resorption—if hypercalcemia does not respond to the earlier measures, a bisphosphonate that inhibits osteoclast function may be used: pamidronate (0.5–2 mg/kg up to 90 mg infused intravenously over 4–6 hours) and zoledronic acid (0.025–0.05 mg/kg up to 4 mg infused intravenously over 30–60 minutes) have proven useful in the acute management of hypercalcemia in children and adolescents.¹⁴⁶ The full hypocalcemic effects of bisphosphonates are established over several days after administration and last for days to weeks; after bisphosphonate infusion, acute systemic effects (fever, myalgia) are often observed and may be managed symptomatically. Salmon calcitonin lowers serum calcium concentrations rapidly but transiently by inhibiting osteoclast function and inducing calciuresis; it is administered subcutaneously (2–4 U/kg every 6–12 hours). Calcitonin and a bisphosphonate may be paired to lower serum calcium levels more rapidly.

In adults with hypercalcemia of malignancy, denosumab, a monoclonal antibody to the receptor activator of nuclear factor κB (RANK)-ligand that impedes osteoclast formation, function, and survival, has been used successfully and is an option in children with hypercalcemia, but experience with this agent in children is limited.^{147,148} The effect of denosumab on bone turnover is rapidly reversible; thus hypercalcemia may recur

after discontinuation of this agent. Although glucocorticoids do not lower calcium levels in patients with hyperparathyroidism or solid tumor malignancies, they are effective in the management of hypercalcemia because of excess vitamin D ingestion or calcitriol production by activated monocytes or hematological malignancies. Rarely, it may be necessary to dialyze (peritoneal or hemodialysis with low- or zero-calcium dialysate) the severely hypercalcemic patient resistant to conventional therapy. During acute treatment of hypercalcemia, Ca^{2+} concentrations may be assessed indirectly by monitoring the (shortened) QT interval by electrocardiography, but serial measurements of total calcium and Ca^{2+} levels are necessary to monitor the efficacy of therapy and to prevent hypocalcemia.

Although in older adults (>50 years) with asymptomatic primary hyperparathyroidism (without bone disease or renal stones), no immediate intervention may be advised at times, in younger adults, children, and adolescents with hyperparathyroidism, surgical intervention by an experienced and expert surgeon is recommended when the diagnosis is established.¹¹⁷ Whereas hyperparathyroidism in youth is most often (>60%) because of an adenoma, hyperplasia of the parathyroid glands is also common (~30%).^{88,145} Before surgical intervention in a child/adolescent with hyperparathyroidism, a parathyroid adenoma should be localized using one (or more) imaging techniques, such as echography with Doppler analysis, magnetic resonance imaging, high resolution and four-dimensional CT or ^{99m}technetium-sestamibi combined with CT (Fig. 20.8). Construction of a three-dimensional virtual model of the neck by pairing iodine contrast with thin-slice CT imaging with color contrast enables clear definition of the cervical vasculature and its normal and abnormal structures.¹⁴⁹ In adults and older adolescents, minimally invasive focused procedures to remove an anatomically identified parathyroid adenoma(s) may be employed using ^{99m}technetium-sestamibi administered 2 hours before surgery, with dissection directed by insertion of a hand held gamma probe, until the adenoma is located and removed. Video assistance is an alternative method for localization of a parathyroid adenoma. A complementary technique for assessing the completeness of the removal of the adenoma intraoperatively is to measure peripheral levels of PTH by rapid immunoassay before and 10 minutes after removal of the adenoma; a 50% decline in PTH levels indicates complete excision; if the PTH concentration does not decline following removal of suspected abnormal parathyroid tissue further exploration is undertaken and additional tissue removed as guided by the serum PTH level. Serum concentrations of PTH achieve normal values 15 to 30 minutes after removal of a single functioning parathyroid adenoma.¹¹⁷ These procedures are cost-effective because they decrease operative time and patient morbidity; many patients return home within hours after leaving the operating suite. These techniques have been applied to the surgical management of the child and infant with a parathyroid adenoma or hyperplasia of multiple parathyroid glands. If there is parathyroid hyperplasia, total parathyroidectomy is performed and autotransplantation of small fragments of one gland to a forearm pocket undertaken. Following removal of a parathyroid adenoma, many patients develop transient hypocalcemia that may be managed by the administration of supplemental oral calcium. When there is severe osteitis fibrosa cystica and marked demineralization, substantial hypocalcemia may occur as a result of the hungry bone syndrome and require more intense management. Other complications of surgery include (transient or permanent) vocal cord dysfunction and the need for further operations because of development of a second adenoma. If permanent hypoparathyroidism develops postoperatively, it is treated by the administration of calcitriol and supplemental calcium as needed. When hyperparathyroidism is caused by hyperplasia

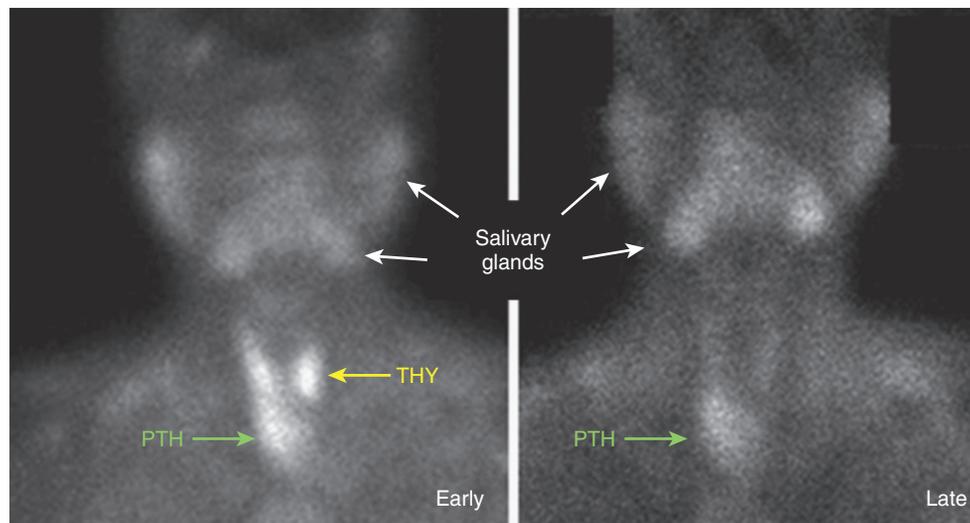

Fig. 20.8 Visualization of a parathyroid adenoma with technetium-99m sestamibi scanning. (From Steenkamp D, Lee SL. Hypercalcemic crisis in a young woman. *Endocrine Today*. 2011:October, with permission from SLACK Incorporated.)

of all parathyroid glands, near total parathyroidectomy is to be considered with implantation of minced parathyroid tissue into a forearm muscular pocket.

Patients with hypercalcemia caused by HHC are usually asymptomatic or only mildly symptomatic (fatigue, weakness) and usually do not require treatment. Neonates with severe neonatal hyperparathyroidism may necessitate urgent total parathyroidectomy if hypercalcemia cannot be controlled by other means (hydration, calciuresis with furosemide, administration of a bisphosphonate or perhaps denosumab). Calcimimetic agents (phenylalkylamines; e.g., cinacalcet) bind to and activate the CaSR on the membrane of the parathyroid chief cell, thereby increasing cytosolic levels of Ca^{2+} and depressing secretion of PTH in adults with mild primary hyperparathyroidism.¹¹⁷ When indicated in a symptomatic older subject with HHC, administration of a calcimimetic agent (cinacalcet) may be considered, although these drugs are approved for administration only to subjects older than 18 years of age.¹²⁴ The use of these agents in children and adolescents with this disorder offers a potential treatment pathway for subjects with diffuse parathyroid hyperplasia. Indeed, this agent has been used successfully in the management of infants with NSHPT.¹⁵⁰ However, in 2013 the FDA suspended the use of cinacalcet in children and adolescents pending further evaluation of its safety in this population. The secondary hyperparathyroidism of chronic renal disease is best managed by lowering serum phosphate concentrations to the extent possible by limiting intake and by administration of oral phosphate binding agents and by maintaining serum Ca^{2+} levels within the low-normal range by the administration of calcitriol or analogue. Parathyroidectomy may be necessary for effective management of refractory secondary and tertiary hyperparathyroidism as manifested by severe renal osteodystrophy, hypercalcemia, and systemic symptoms, such as pruritus and bone pain.¹⁴⁴

Hypercalcemia caused by hypervitaminosis D or excessive production of calcitriol by granulomatous and chronic inflammatory tissues may be treated with glucocorticoids to suppress activity of 25OHD₃-1 α -hydroxylase. Ketoconazole (3–9 mg/kg/d in 3 divided doses) is an antifungal agent that also inhibits renal 25OHD₃-1 α -hydroxylase activity and promptly lowers calcitriol and calcium values in children and adults with such disorders. Side effects of therapy with ketoconazole include nausea, vomiting, abdominal pain, depressed secretion of gonadal steroids, and impaired adrenal

production of cortisol. Therefore careful monitoring of patients receiving ketoconazole is essential. Glucocorticoids ameliorate the hypercalcemia related to excessive IL-1 β production in adolescents with juvenile rheumatoid/idiopathic arthritis. An attempt should be made to prevent hypercalcemia in the immobilized child or adolescent by provision of a low-calcium diet, avoidance of vitamin D, copious fluid intake, and early mobilization. Serum and urine calcium levels should be monitored frequently, and fluids increased still further if hypercalciuria occurs. Once present, hypercalcemia is best treated by mobilization; saline diuresis and/or bisphosphonate administration may be necessary until eucalcemia is restored. Restriction of dietary calcium and limitation of exposure to sunlight may be appropriate in the long-term management of some patients with hypercalcemia not amenable to more specific treatment. Antiprostaglandin agents may be useful in the child with hypercalcemia associated with excessive production of these compounds. Specific treatment of diseases accompanied by hypercalcemia (thyrotoxicosis, hypoadrenocorticism) restores the eucalcemic state.

DISORDERS OF MAGNESIUM METABOLISM

Magnesium (Mg) is a cation essential for control of neuromuscular function and is a required element for enzymatic reactions involving ATP, as well as maintenance of the structures of DNA and RNA. Magnesium regulates the secretion but not the synthesis of PTH and the generation of calcitriol. In serum, magnesium is both complexed to proteins and ionized or free. Approximately 50% of body magnesium stores are deposited within bone adsorbed to the surface of hydroxyapatite. The CaSR recognizes and responds to Mg^{2+} as well as to Ca^{2+} . Serum concentrations of magnesium are maintained within narrowly defined limits (1.6–2.4 mg/dL = 0.66–0.99 mmol/L) by coordinated intestinal absorption and renal tubular reabsorption of this cation. In the proximal renal tubule and thick ascending loop of Henle magnesium reabsorption is primarily passive through paracellular tight junction channels termed claudins. In the intestinal tract and renal distal convoluted tubule, magnesium is actively absorbed/reabsorbed transcellularly through a channel composed of a heterooligomer of TRPM6 (OMIM 607009) linked to TRPM7 (OMIM 605692), a magnesium-permeable cation channel. The paired TRPM6/TRPM7 heterooligomer is expressed on the surface of cells

lining the intestinal tract and the renal distal convoluted tubule enabling transcellular absorption/reabsorption of Mg^{2+} . In the kidney, 10% to 20% of filtered magnesium is reabsorbed in the proximal renal tubule and 65% to 70% is reabsorbed in the TALH by a passive paracellular process; 10% to 20% of filtered magnesium is reabsorbed in the distal convoluted tubule by an active transcellular system.^{151,152}

Hypomagnesemia

Hypomagnesemia (serum total magnesium concentration <1.5 mg/dL = 0.62 mmol/L) may be clinically silent or it may be manifested by fatigue, weakness, paresthesias, heightened neuromuscular irritability (carpal pedal spasm, spasticity, tremors, tetany, seizures) and when prolonged and profound by muscle wasting, weakness, apathy, and an altered state of consciousness; Chvostek and Trousseau signs may be elicited; prolonged PR and QT intervals may be present on an electrocardiogram.¹⁵³ Hypomagnesemia may lead to hypocalcemia by inhibiting the release of PTH and by interfering with its peripheral action. Hypomagnesemia may be the consequence of decreased ingestion or administration, impaired intestinal absorption, or increased loss of magnesium in the stool or urine that may be acquired or congenital (Tables 20.7A, 20.7B). Infants born to mothers deficient in this cation, those with preeclampsia or gestational or type 1 diabetes mellitus and in neonates with LBW—prematurity or intrauterine growth restriction are prone to develop hypomagnesemia.¹⁵⁴ Prolonged nasogastric suctioning, malabsorptive disorders caused by extensive intestinal resection (“short gut” syndrome), intestinal fistulas, or other diseases associated with chronic diarrhea and steatorrhea also lead to infantile hypomagnesemia. Diuretics (furosemide, thiazide) that depress magnesium absorption in the renal loop of Henle, inhibitors of the proton pump (omeprazole), calcineurin inhibitors (cyclosporin A, tacrolimus), platinum derivatives (cisplatin, carboplatin), antibiotics (aminoglycosides, rapamycin), or adrenergic agents that shift magnesium into cells may result in hypomagnesemia as may nephrotoxic agents (e.g., mercury, gentamycin); hypermagnesuria leads to hypomagnesemia.¹⁵³ In infants, children, and adolescents, hypomagnesemia may be primary and caused by a specific defect in the intestinal absorption of Mg^{2+} or in the renal tubular resorption of filtered Mg^{2+} (vide infra) or secondary and caused by gastrointestinal losses (chronic vomiting or diarrhea or malabsorptive states caused by inflammatory bowel disease, bowel resection or fistulas, or pancreatitis); to associated renal tubulopathies (Gitelman and Bartter

syndromes); exposure to alcohol, diuretics, and chemotherapeutic agents; and specific endocrinopathies (e.g., diabetes mellitus, primary hyperparathyroidism, hyperaldosteronism).⁶⁰

Hypomagnesemia may be associated with hypocalcemia and hypercalciuria as in some patients with activating variants of CASR resulting in autosomal dominant hypoparathyroidism (OMIM 601198). Hypomagnesemia occurs in patients with renal tubular disorders, such as Gitelman and Bartter syndromes (vide infra) and as a result of genetic errors in pathways that adversely affect the intestinal absorption or renal tubular reabsorption of magnesium (see Table 20.7B).^{151–153,155} Hypomagnesemia type 1 with secondary hypocalcemia is the consequence of biallelic inactivating mutations of *TRPM6* encoding the ion channel that forms a heterooligomer with TRPM7, a Mg^{2+} - and Ca^{2+} -permeable ion transport channel present in the intestinal tract and renal tubule. Neonates and infants with pathological variants of *TRPM6* have increased neuromuscular irritability (tremors, spasms, and seizures) within the first several months after birth.¹⁵⁶ Pathophysiologically, this disorder is caused by a selective small intestinal defect in transcellular absorption of Mg^{2+} (e.g., the variant p.Ser141Leu impairs linkage of TRPM6 and TRPM7 thus preventing intestinal absorption of Mg^{2+}). Affected newborns present with hypomagnesemic/hypocalcemic tetany and/or seizures leading to myocardial, renal, and arterial calcinosis. Renal excretion of magnesium is normal in subjects with this disease. Hypocalcemia is attributable to decreased secretion of and peripheral insensitivity to PTH. Oral ingestion of large quantities of magnesium is effective therapy for this illness. Monoallelic inactivating mutations in *FXYD2* (OMIM 601814) encoding a gamma subunit of renal Na^+/K^+ -ATPase result in autosomal dominant hypomagnesemia type 2 with hypocalciuria. *FXYD2* encodes a gamma subunit of a Na^+/K^+ -ATPase expressed in the renal distal convoluted tubule. Monoallelic loss-of-function mutations of *FXYD2* result in misrouting of its protein product to the basolateral membrane of the nephron’s epithelial cells, leading to increased urinary loss of magnesium but paradoxically to increased renal tubular reabsorption of Ca^{2+} in the loop of Henle resulting in hypocalciuria.¹⁵⁷ Inactivation of the regulatory transcription factors of *FXYD2* encoded by *HNF1B* (OMIM 189907) and pterin-4- α -carbinolamine dehydratase 1 (*PCBD1*, OMIM 126090) also result in hypomagnesemia. *HNF1B* encodes hepatocyte nuclear factor 1 homeobox B, a transcription factor necessary for normal embryogenesis of the kidney and pancreas.¹⁵⁸ Inactivating mutations in *HNF1B* lead to malformations of the kidney (cysts, renal malformations), hypomagnesemia, and maturity-onset diabetes of the

TABLE 20.7A Disorders of Magnesium Homeostasis

I Hypomagnesemia

- A Congenital
 - 1 Neonates of mothers with diabetes mellitus, eclampsia, magnesium deficiency
 - 2 Intrauterine growth restriction, prematurity
 - 3 Gene mutations—see Table 20.7B
- B Acquired
 - 1 Drugs—loop and thiazide diuretics, antibiotics (amphotericin, gentamycin), sympathomimetic agents, proton-pump inhibitors (omeprazole), digitalis, antineoplastic agents (cisplatin), cyclosporin
 - 2 Nasogastric suction
 - 3 Intestinal malabsorption (celiac disease, intestinal resection)
 - 4 Secretory diarrhea (inflammatory bowel disease)
 - 5 Acute pancreatitis
 - 6 Hypermagnesuria because of diabetes mellitus or alcoholism or following renal tubular necrosis or renal transplantation
 - 7 In association with hypokalemia

II Hypermagnesemia

- A Acquired
 - 1 Renal insufficiency
 - 2 Excessive intake of magnesium salts or laxatives/antacids that contain magnesium
 - 3 Diabetic ketoacidosis, adrenocortical insufficiency, hyperparathyroidism, lithium intoxication

TABLE 20.7B Gene Mutations Associated With Hypomagnesemia

Gene Protein Chromosome OMIM	Disorder OMIM	Gene Function/Transmission
<i>TRPM6</i> Transient receptor potential, cation channel, subfamily M, member 6 9q21.3 607009	Hypomagnesemia 1, intestinal 602014	TRPM6 forms heterooligomer with TRPM7 (chr. 15q21.2, OMIM 605692), a magnesium-permeable cation channel, AR
<i>FXYD2</i> FXD domain-containing ion transport regulator 2 11q23.3 601814	Hypomagnesemia 2, renal 154020	Gamma subunit of renal Na ⁺ -K ⁺ -ATPase, hypermagnesuria & hypocalciuria because of enhanced renal tubular reabsorption of calcium, FXD2 transactivated by HNF1B/PCBD1, AD
<i>CLDN16</i> Claudin 16 3q28 603959	Hypomagnesemia 3, renal 248250	Paracellular magnesium transport channel, hypermagnesuria, hypercalciuria, nephrocalcinosis, amelogenesis imperfecta, AR
<i>EGF</i> Epidermal growth factor 4q25 131530	Hypomagnesemia 4, renal 611718	Activator of TRPM6, Hypermagnesuria, Normocalciuria (variants of EGFR also result in hypomagnesemia)
<i>CLDN19</i> Claudin 19 1p34.2 610036	Hypomagnesemia 5, renal 248190	Paracellular magnesium transport channel, hypermagnesuria, hypercalciuria, nephrocalcinosis, macular colobomata, AR
<i>CNNM2</i> Cyclin M2 10q24.32 607803	Hypomagnesemia 6, renal 613882	Regulator of TRPM7 & its formation of a heterooligomer with TRPM6, AD
<i>HNF1B</i> HNF1 homeobox B 17q12 189907	Hypomagnesemia, congenital tubulointerstitial kidney disease, maturity-onset diabetes of the young, type 5	Transcription factor regulating expression of FXD2 & renal distal tubular reabsorption of magnesium, AD
<i>PCBD1</i> Pterin-4-alpha-carbinolamine dehydratase 1 10q22.1 126090	Hypomagnesemia, maturity-onset diabetes of the young, type 5	Nuclear dimerization cofactor for HNF1B to enhance expression of FXD2-mediated renal distal tubular reabsorption of magnesium, AR
<i>KCNA1</i> Potassium channel, voltage-gated, shaker- related subfamily, member 1 12p13.32 178260	Hypomagnesemia	Voltage-gated potassium channel colocalizes with TRPM6, inactivating variant results in hypermagnesuria by exerting dominant- negative effect on wild-type KCNA1, AD
<i>CLCNKB</i> Chloride channel, kidney, B 1p36.13 602023	Bartter syndrome (type 3) 241200 Bartter syndrome (type 4b), digenic, 613090	Renal tubule chloride channel, AR
<i>SLC12A3</i> Solute carrier family 12 (sodium/chloride transporter), member 3 16q13 600968	Gitelman syndrome—hypokalemic metabolic acidosis, hypocalciuria, hypomagnesemia, 263800	Renal distal convoluted tubular sodium/ chloride cotransporter, AR

AD, Autosomal dominant; AR, autosomal recessive; ATPase; adenosine triphosphatase.

young.¹⁵⁹ *PCBD1* encodes a protein that binds to HNF1B and increases its transcriptional capacity.

Loss-of-function mutations in the genes encoding the claudin-16 and -19 paracellular tight junction transport channels (*CLDN16*, OMIM 603959; *CLDN19*, OMIM 610036) result in renal hypomagnesemia type 3 and type 5, respectively. These diseases often present in infancy and are associated with tetany, hypermagnesuria, hypercalciuria, mild hypocalcemia, nephrocalcinosis, impaired renal function, and secondary hyperparathyroidism. Claudin-16 (also termed *paracellin 1*) is a 305 aa protein with four transmembrane domains and intracellular amino and carboxyl terminals that is expressed within the intercellular tight junctions of renal epithelial cells in the TALH and distal convoluted tubule where it facilitates

paracellular transport and reabsorption of Mg²⁺ and Ca²⁺ from the renal tubule. The first extracellular loop of claudin-16 bridges the intercellular space and is the site of paracellular conductance of ions; a number of missense mutations in *CLDN16* have been identified—particularly at position leucine 151 (p.Leu151Phe, Trp, Pro). Most of the variants of *CLDN16* impair its normal movement to the renal epithelial cell's lateral surface; in other mutations (p.Ala62Val, p.His71Asp), products localize to the tight junctions but are functionally defective.¹⁶⁰ Oral administration of 20 times the normal daily requirement of magnesium has been successful therapy in these subjects. *CLDN19* encodes claudin-19, a 224 aa protein expressed in the interstices between cells of the renal TALH and distal convoluted tubules, biallelic inactivating variants of which give rise

to hypomagnesemia type 5. *CLDN19* is necessary for paracellular transport of both calcium and magnesium.¹⁶¹ *CLDN19* is also expressed in the eye; in addition to ocular anomalies (colobomata, nystagmus, severe myopia), mutations in *CLDN19* result in hypomagnesemia, hypercalciuria, nephrocalcinosis, and renal failure. Biallelic inactivating mutations in *EGF* (OMIM 131530), the gene encoding epidermal growth factor, result in renal hypomagnesemia type 4, a disorder associated with seizures and developmental delay but in which serum and urine levels of calcium are normal.¹⁶² Epidermal growth factor (EGF) is a necessary cofactor for normal renal distal convoluted tubular resorption of Mg^{2+} by TRPM6. An inactivating variant of the EGF receptor (*EGFR*, OMIM 131550) has also been associated with hypomagnesemia, as well as neonatal inflammatory skin and bowel disease (OMIM 616069).¹⁵³ Monoallelic inactivating mutations of *CNNM2* encoding cyclin M2 (OMIM 607803), a protein that is critical for formation of the TRPM6-TRPM7 heterooligomer, result in hypomagnesemia type 6.¹⁶³ Despite hypomagnesemia, urine excretion of magnesium is inappropriately normal; serum and urine calcium values are normal in these subjects. *CNNM2* encodes a protein localized to the basolateral membrane of the cells comprising the renal thick ascending loop of Henle and the distal convoluted tubule where its expression is increased by magnesium deficiency. One function of *CNNM2* may be to “sense” ambient Mg^{2+} concentrations. Hypomagnesemia associated with myokymia (quivering of muscles) has been related to a heterozygous loss-of-function mutation (p.Asn255Asp) in *KCNA1* (OMIM 178260) encoding a renal potassium channel that colocalizes with TRPM6 in the renal distal convoluted tubule and is also critical for Mg^{2+} transport.^{157,164,165}

Hypomagnesemia is encountered in patients with hypokalemic metabolic acidosis in association with the Sesame syndrome (seizures, sensorineural deafness, ataxia, mental retardation, and electrolyte imbalance) caused by inactivation mutations in *KCNJ10* (OMIM 602208—encoding a potassium channel), and antenatal Bartter syndrome type 2 (polyhydramnios, prematurity, poor postnatal growth, salt wasting, and hypercalciuria caused by inactivating mutations in a gene encoding a second potassium channel—*KCNJ1* (OMIM 600359). Bartter syndrome type 1 (OMIM 601678) is an autosomal recessive disorder manifested by salt wasting because of impaired sodium and potassium reabsorption in the renal ascending loop of Henle, hypokalemic metabolic alkalosis, hypercalciuria, and at times hypermagnesuria because of variants of *SLC12A1* (OMIM 600839). (Inactivating biallelic variants in *CLCNKB* [OMIM 602023] encoding a chloride channel [OMIM 602023] are present in patients with the classic form of this illness—Bartter syndrome type 3 [OMIM 607364].) Bartter syndrome type 4a is associated with variants of *BSND* (OMIM 606412) encoding barttin, a beta subunit for the chloride transport channels encoded by *CLCNKA* (OMIM 602024) and *CLCNKB* (OMIM 602023). In children and adolescents, the autosomal recessive Gitelman syndrome (OMIM 263800) of systemic alkalosis, hypokalemia, hypomagnesemia, and hypercalciuria is the result of variants of genes that compose the thiazide-sensitive sodium-chloride symporter in the distal renal convoluted tubule—often *SLC12A3* (OMIM 600968). Hypomagnesemia has also been associated with mitochondrial disorders including infantile histiocytoid cardiomyopathy (OMIM 50000), the Kearns-Sayre syndrome (OMIM 530000), and the syndrome of hyperuricemia—pulmonary hypertension—renal failure—alkalosis (OMIM 613845).¹⁵³

The presence of hypomagnesemia is identified by measurement of serum magnesium concentrations, whereas its pathophysiological etiology is determined by concurrent assay of calcium, phosphate, sodium, potassium, chloride, bicarbonate, creatinine, PTH, and vitamin D levels and assessment of its urinary loss and intestinal absorption.¹⁵⁴ In the concomitant presence of

hypomagnesemia and hypercalciuria, variants of *CLDN16*, *CLDN19*, *CLCNKB*, and *CASR* may be considered.¹⁵³ In hypomagnesemic patients without hypercalciuria, variants of *TRPM6*, *CNNM2*, *EGF/EGFR*, *KCNA1*, and *FAM111A* may be sought.

Hypomagnesemic, hypocalcemic seizures are only transiently responsive and sometimes resistant to parenteral administration of elemental calcium alone. Intravenous or intramuscular administration of a 50% solution of magnesium sulfate ($MgSO_4 \cdot 7H_2O$ —0.05–0.1 mL/kg or 2.5–5.0 mg/kg elemental magnesium with cardiac monitoring) may be necessary to control convulsions in the hypomagnesemic neonate.^{60,154} In older subjects, symptomatic hypomagnesemia is managed by the cautious intravenous administration of 20% magnesium sulfate (800 mmol/L) (30 mL in 500 mL of normal saline or 5% dextrose) with close clinical and electrocardiographic monitoring and frequent measurements of serum concentrations of Ca^{2+} and magnesium (Di Maio et al 2018⁷³). Oral magnesium supplements may also be helpful (50% $MgSO_4 \cdot 7H_2O$ —0.2 mL/kg/d). In adult patients with chronic hypomagnesemia, oral preparations of magnesium chloride or glycerophosphate (120 mg thrice daily) may be considered as tolerated; excessively large doses of magnesium may lead to diarrhea and should be avoided.

Hypermagnesemia

Hypermagnesemia (magnesium >2.6 mg/dL = >1.05 mmol/L) is recorded in the neonatal period after magnesium sulfate has been administered to the pregnant women with hypertension, preeclampsia, or toxemia of pregnancy. Most neonates with hypermagnesemia are asymptomatic; however, when serum magnesium concentrations are exceptionally high, hypotonia and depression of the central nervous system may be present and when extensive, metabolic bone disease may develop.¹⁵⁴ Thus prolonged (9–10 weeks) administration of intravenous magnesium sulfate to women who have entered labor prematurely has been associated not only with hypermagnesemia but also with marked hypocalcemia and significant osteopenia in the offspring.¹⁶⁶ Hypermagnesemia may also result from its parenteral administration or oral ingestion of magnesium-containing antacids or enemas. Hypermagnesemia may also develop in patients with renal insufficiency receiving magnesium-containing antacids. Serum magnesium concentrations are modestly increased in patients with familial HHC because of loss-of-function mutations in *CASR*. In large amounts, magnesium sulfate suppresses secretion of PTH and decreases renal tubular reabsorption of calcium, factors contributing to hypocalcemia. Clinical manifestations of severe hypermagnesemia (magnesium >4.8 mg/dL = >2 mmol/L) are similar to those of hypercalcemia and include altered mentation, nausea, vomiting, fatigue, and weakness; pulse rate and blood pressure may be low; hyporeflexia may be present. Both hypo- and hypermagnesemia impair the secretion of PTH leading to hypocalcemia. Variants of claudin-10 (*CLDN10*, OMIM 617579) lead to enhanced paracellular transport of calcium and magnesium and hypermagnesemia identified in subjects with the HELIX syndrome (hypohidrosis, electrolyte imbalance, lacrimal gland dysfunction, ichthyosis, xerostomia—OMIM 617671).¹⁶⁷ The hypermagnesemic neonate and child are most appropriately managed by withdrawal of exogenous magnesium, saline diuresis, or administration of furosemide if necessary; if the patient is also hypocalcemic and osteopenic administration of calcium and calcitriol is indicated.

DISORDERS OF BONE

Congenital and acquired abnormalities of formation of osteoid, the organic portion of bone matrix composed of fibers of collagen type 1, and/or of orderly deposition of hydroxyapatite

crystals into bone matrix result in compromise of bone strength, resulting in skeletal malformations and deformations and increased fracture risk.

Disorders of Bone Formation and Mineralization in the Neonate and Infant

Low Bone Mass

In the fetus, the formation of the organic portion of bone and its ensuing mineralization proceed sequentially, processes controlled by GH; PTH; PTHrP; vitamins A, D, and C; and various cytokines.¹⁶⁸ Approximately 80% of total bone calcium in the full-term neonate is accrued in the last trimester of pregnancy as the in utero rate of calcium deposition increases more than twofold between 28 and 36 weeks' gestation (calcium accrual in the third trimester approximates 100–130 mg/kg/d). In prematurely delivered neonates, gestational age, birth weight, and rate of postnatal weight gain are important determinants of the postpartum rate of bone mass accrual.¹⁶⁹ Thus prematurely delivered, very LBW (VLBW <1500 g), and extremely LBW (ELBW <1000 g) neonates are particularly vulnerable to the development of metabolic bone disease associated with decreased bone mass (defined as postnatal bone mineral content [BMC] that is less than the BMC of the intrauterine fetus at the same postconceptual age with or without roentgenographic evidence of skeletal hypomineralization). After delivery, extremely preterm neonates are unable to maintain the rapid in utero rates of skeletal growth that require synthesis of organic bone matrix and calcium and phosphate deposition into osteoid from the amount of nutrients that can be provided by oral ingestion and gastrointestinal absorption or by parenteral nutrition.^{168,170,171} Postpartum hypocalcemia and decrease in spontaneous movement against the force exerted by the muscular wall of the uterus also depress the rate of bone mineralization, whereas an increased rate of bone resorption further impairs accrual of skeletal mass in premature infants.^{172,173} Malrotation of the intestinal tract or catastrophic necrotizing enterocolitis, leading to intestinal infarction requiring extensive small bowel resection, substantially increases the risk of malabsorption and consequent low bone mass. Parenteral alimentation of VLBW or ELBW neonates restricts administration of fluid, protein, calcium, and phosphate; excessive aluminum in parenteral fluids also adversely affects bone formation. Increased maternal parity, male gender, severe systemic disease (bronchopulmonary dysplasia), immobility, and pharmacological agents (glucocorticoids, methylxanthines, such as theophylline, diuretics, such as furosemide) also adversely impact bone formation in these neonates.^{173,174} Theophylline and furosemide increase urinary excretion of calcium. Prenatal factors that contribute to low bone mass in VLBW and LBW neonates are: intrauterine growth restriction—possibly by reducing in utero placental transport of calcium and decreasing the rate of bone formation; prenatal exposure to large amounts of magnesium sulfate administered repeatedly to the mother in preterm labor leads to hypocalcemia and osteopenia by suppressing PTH secretion through its interaction with the CaSR and by competing with calcium for deposition at bone surfaces, respectively.¹⁶⁶ In this vulnerable neonatal population, decreased calcification of bone matrix results in low BMC and susceptibility to fracture, whereas depressed calcification of the cartilage growth plate can lead to rickets and its characteristics deformities.

Approximately 30% (16%–40%) of preterm infants with birth weights under 1500 g develop metabolic bone disease within 6 to 16 weeks after birth.^{168,175} Metabolic bone disease of prematurity is associated with decreased BMC; thinning of bone cortices; decreased trabecular bone mass; metaphyseal

flaring, fraying, and cupping; and increased frequency of fracture.^{168,176–178} Biochemically, hypophosphatemia caused by phosphate deficiency and hyperalkaline phosphatasia, evidence of the osteoblast's effort to increase bone mineral deposition, are frequently recorded. Some neonates with metabolic bone disease are calcium deficient as evidenced by increase in serum levels of PTH (secondary hyperparathyroidism); in such enterally alimented neonates, administration of calcitriol may increase intestinal absorption of calcium, thereby raising its serum levels and lowering those of PTH.

In preterm neonates, serum levels of total and bone specific alkaline phosphatase, carboxyl terminal propeptide of collagen type I (PICP), and osteocalcin (markers of osteoblast activity and bone formation) are elevated relative to full-term neonates and older infants and continue to rise over the first 10 weeks of life.¹⁷⁹ It has been recommended that in the VLBW infant, if serum alkaline phosphatase values exceed 500 IU/L and serum phosphate levels fall below 5.6 mg/dL (1.8 mmol/L), the renal tubular reabsorption of phosphate should be determined; values greater than 95% indicate that the infant's phosphate stores are low and initiation of phosphate supplementation is indicated.¹⁷⁷ Urinary hydroxyproline and pyridinoline/deoxypyridoline values (markers of osteoclast activity and bone resorption) are also increased in premature babies, although serum concentration of carboxyl telopeptide of collagen type I (ICTP), another marker of bone resorption, decline during the first 10 weeks after premature delivery. Thus intrauterine and postnatal rates of bone turnover in preterm newborns are rapid and persistently elevated through 40 weeks post-conceptual age, a conclusion confirmed by bone histomorphometry.¹⁸⁰ By photon absorptiometry and quantitative ultrasonography (QUS), bone mass of preterm infants appears to decline during the first several weeks after birth.¹⁸¹ Serum levels of alkaline phosphatase and osteocalcin and urinary excretion of pyridinoline and calcium are high and may remain elevated in LBW infants with low bone mass of prematurity relative to values in LBW infants without bone disease for the first year of life, even though radiographic improvement in skeletal mineralization is usually evident by 6 months of age.¹⁷⁷

Because standard roentgenograms may not detect low bone mineralization before deficits of 20% to 30% or greater have occurred in the second month of life, estimation of BMC by dual energy x-ray absorptiometry (DXA) has become the preferred method to assess bone mineralization in infants because of its accuracy, reproducibility, rapidity of performance, and low radiation exposure (2–3 mrems).¹⁷² Mean whole body BMC in the first 2 days of life ranges from 21.7 g in newborns with birth weights of 1001 to 1500 g to 78.8 g in neonates with birth weights of 3501 to 4000 g, whereas whole body BMD varies from 0.146 mg/cm² (1001–1500 g) to 0.234 gm/cm² (3501–4000 g). BMC and BMD increase through the first year of life and beyond as measured by DXA. At this age, bone mass is best correlated with body weight. QUS may also be used to assess bone integrity and strength in preterm and other LBW infants; QUS may be performed at the crib side, there is no exposure to radiation, and it may be repeated as frequently as necessary.¹⁸² QUS measures the speed of sound (SOS) through a bone (humerus, tibia, radius, patella, os calcis, metacarpal, phalanx), a measurement that is correlated with the strength of the bone; mineral content is but one of several skeletal components (elasticity, cortical thickness, microstructure) that collectively contribute to bone strength. QUS also permits calculation of bone transmission time, a measurement that determines the difference in the velocity of sound as it travels through bone and surrounding soft tissue. There is considerable overlap of SOS values at various ages and somatic sizes; however, bone transmission times may discriminate to a greater extent between these parameters. Humeral and tibial

QUS measurements are lower in preterm than term infants and correlate positively with gestational age, birth weight, postnatal length, and weight.¹⁸³ In neonates with intrauterine growth restriction, tibial SOS levels are variable.¹⁸² The relationships between BMD determined by DXA and bone strength estimated by QUS in preterm and term newborns are weak but significant.¹⁷⁰

With prolonged deprivation of calcium, phosphate, and vitamin D, not only does the LBW infant lag in accumulation of bone mass, but clinical and radiographic evidence of rickets (a disorder of bone mineralization, vide infra) also develops—usually between the 6th and 12th postnatal weeks—and fractures may occur in as many as 24% of VLBW infants.¹⁸¹ The LBW neonate at risk for low bone mass and/or rickets is best managed preventively by maintaining serum calcium concentrations between 8 and 11 mg/dL and serum phosphate values between 5.8 and 9 mg/dL and by providing by daily enteral administration of as much of the needed amounts of calcium (140–160 mg/100 kcal), phosphate (95–108 mg/100 kcal of formula), and vitamin D (400–1000 U), as well as protein (for collagen synthesis) and energy (carbohydrates, lipids) as possible. When parenteral administration of nutrients is necessary in the LBW or VLBW neonate, an attempt should be made to administer the maximum amounts of calcium and phosphate safely attainable. The solubility of calcium and phosphate depends not only on their quantities, but also on the forms selected for infusion, that is, calcium chloride, -gluconate, -glycerophosphate, monobasic phosphate, or dibasic phosphate. Using monobasic phosphate and glycerophosphate, it is possible to infuse as much as 86 mg of calcium/kg/dL and 46 mg/kg/dL of phosphate. However, these preparations increase the risk of metabolic acidosis and hypercalciuria.¹⁷² Infusion of parenteral nutrition solutions containing 60 to 80 mg/kg/d of calcium and 40 to 50 mg/kg/d of phosphate permits only 60% to 70% of the estimated in utero bone mineral accretion rates.¹⁷² Therefore enteral feeding should begin as soon as possible in the VLBW and LBW infant using human breast milk fortified with calcium glycerophosphate (calcium 80–120 mg/kg/d, phosphate 45–60 mg/kg/d).^{171,172,184,185} Prepared formulas for feeding of LBW neonates providing 200 mg/kg/d of calcium and 100 mg/kg/d of phosphate can result in up to 90 mg/kg/d of retained calcium and 40 mg/kg/d of retained phosphate.¹⁷¹ The type of prepared formula (sources of protein, fat and carbohydrates) and its lipid and mineral additives determine the rate of intestinal calcium absorption and retention; therefore the choice of formula must be carefully considered before it is selected. Nevertheless, parenteral nutrition, fortified human milk, and available preterm formulas are unable to provide the amounts of calcium and particularly phosphate that would normally accrue to the fetus in utero. Vitamin D 400 to 1000 IU/day should also be provided to the preterm infant either enterally or parenterally. Monitoring of serum levels of calcium, phosphate, creatinine, and alkaline phosphatase and urinary excretion of calcium, phosphate, and creatinine is essential to prevent hypercalcemia and hypercalciuria and nephrocalcinosis. It is also important to avoid hypocalcemia because of the avidity of bone matrix for calcium once remineralization has commenced (hungry bone syndrome). Passive physical activity (daily range of motion with extension/flexion of all joints of each extremity in the supine infant for 4 weeks, beginning after the neonate has been stabilized between 2 and 6 weeks of postnatal age) with or without gentle massage of the prone infant from head-to-toe increases serum levels of markers of bone formation, as well as bone mineralization by DXA and QUS changes consistent with augmented bone strength.^{176,180,181} Although in the prematurely born infant, bone mass may remain low through infancy and early childhood, size-adjusted (height,

lean body mass, fat mass) bone mineralization eventually normalizes in most adult subjects except perhaps at the femoral neck.^{178,186}

Congenital lethal osteogenesis imperfecta (clinical type 2—vide infra) (OMIM 166210) is a prenatal/perinatal disorder characterized by the presence of “beaded” ribs and long bone deformities and fractures demonstrable in utero and apparent at birth, platyspondyly, and subnormal mineralization of the calvarium.^{187,188} This most severe form of osteogenesis imperfecta is usually the result of heterozygous spontaneously occurring loss-of-function mutations in the genes encoding collagen- α 1(I) (*COL1A1*, OMIM 120150) or collagen- α 2(I) (*COL1A2*, 120160). The mutations may be partial gene deletions resulting in decreased synthesis of the triple helix of type I collagen or missense mutations that lead to amino acid substitutions (e.g., arginine, aspartic acid, cysteine) for the glycine residues that are essential for the normal three-dimensional conformation of collagen- α 1(I)/collagen- α 2(I) and synthesis of the triple helix and structural integrity of type I collagen in extracellular matrix of bone upon which hydroxyapatite is deposited. Lethal osteogenesis imperfecta clinical type 2 may rarely be transmitted as an autosomal dominant trait by a parent who is mosaic for a heterozygous mutation in either collagen- α 1(I) or - α 2(I).^{188–190}

Lethal forms of osteogenesis imperfecta transmitted as autosomal recessive disorders are also attributable to inactivating mutations in *CRTAP* (OMIM 605497), *PPIB* (OMIM259440), or *LEPRE1* (OMIM 610339), three factors necessary for hydroxylation of proline-986 in *COL1A1* and proline-707 in *COL1A2*, essential modifications of these proteins.^{191–193} In addition, variants of *CREB3L1*—encoding cyclic AMP response element-binding protein 3-like 1 (OMIM 616215) may lead to a lethal, prenatal/perinatal form of osteogenesis imperfecta. At the often preterm birth, clinical manifestations of lethal osteogenesis imperfecta include intrauterine growth restriction, long bone deformities and fractures, and a malleable calvarial cortex with large fontanelles; death often occurs in early infancy because of respiratory insufficiency. Radiologically, congenital osteogenesis imperfecta is manifested by short, broad, and “crumpled” long bones, angulation of the tibia, and beading of the ribs. The diagnosis of this illness is most often made in utero; it must be differentiated from achondrogenesis type I, thanatophoric dysplasia, and perinatal hypophosphatasia. and confirmed by quantitation of subnormal amounts of collagen synthesized by fibroblasts in vitro and identification of the gene mutation. The lethal mutations of *COL1A1* are clustered at sites at which the collagen monomer binds integrins, matrix metalloproteinases, fibronectin, and cartilage oligomeric matrix protein; other mutations impair posttranslational processing of collagen α 1(I) and thereby interfere with association of collagen chains or propagation of the triple helix configuration.¹⁹⁴ Mutations in *COL1A2* encoding collagen α 2(I) coincide with binding sites for proteoglycans. Indeed, the lethal mutations in *COL1A1* leading to the clinically most severe forms of osteogenesis imperfecta are more functionally incapacitating to the protein than is complete absence of one *COL1A1* allele; haploinsufficiency of *COL1A1* leads to the less clinically severe osteogenesis imperfecta type I.¹⁹⁵ Although administration of the bisphosphonate pamidronate has been helpful in infants with severe manifestations of osteogenesis imperfecta types III and IV, it has been ineffective in the lethal form of osteogenesis imperfecta (vide infra).¹⁹⁶

Extremely low bone mass is present in infants and children with lysinuric protein intolerance (OMIM 222700), an autosomal recessive disorder of renal tubular and intestinal transport of the dibasic amino acids—lysine, arginine, ornithine—that is caused by loss-of-function variants in *SLC7A7* (OMIM 603593) encoding a cationic amino acid transporter subunit.¹⁹⁷ Clinical

manifestations include vomiting, diarrhea, respiratory distress, failure to thrive, developmental delay, hepatomegaly, and cirrhosis. Affected patients have impaired urea synthesis because of decreased hepatic uptake of ornithine but are episodically hyperammonemic with increased urinary excretion of the dibasic amino acids; there is extremely low bone mass because of marked protein deprivation and perhaps because of increase in cytokine-induced bone resorption. Administration of citrulline has been reported to increase growth and bone mass in some of these patients. Variants of *SLC7A7* include deletion of multiple exons, duplications, missense, nonsense, and splice-site mutations dispersed throughout the gene; patients with the largest deletions had the most severe phenotypes.¹⁹⁸ Subnormal bone mineralization may also be observed in infants with infantile hypophosphatasia (OMIM 241500) and in those with muscular disorders restricting movement, such as the Prader-Willi syndrome (OMIM 176270), glycogen storage disease type II (Pompe disease—OMIM 232300), and forms of arthropodiosis.

Increased Bone Mass

Increased bone mass may be generalized or localized; osteosclerosis refers to thickening of trabecular bone and hyperostosis to increase in cortical bone mass.⁸ The infantile “malignant” form of osteopetrosis (OMIM 259700) is one of several autosomal recessive disorders caused by abnormal osteoclast differentiation or function resulting in defective reabsorption of the mineral phase of bone (vide infra). Infantile osteopetrosis is clinically manifested in affected infants by failure to thrive, delayed development, nasal obstruction, loss of sight, hearing and other cranial nerve functions, and intense bone overgrowth, leading to pancytopenia, hepatosplenomegaly at sites of extramedullary hematopoiesis, and increased susceptibility to infection (e.g., mandibular osteomyelitis) and to fractures because of decreased bone strength despite high bone mass. Death often occurs within the first several years of life because of sepsis, anemia, or hemorrhage. Additional physical findings in newborns and infants with the most severe form of osteopetrosis include impaired linear growth, macrocephaly, frontal bossing, nystagmus, delayed eruption of primary teeth, and ecchymoses. The radiographic hallmark of infantile osteopetrosis is relatively uniform increase in bone density of the skull, vertebrae, and axial skeleton with thickened cortical and trabecular bone, “Ehrlemeyer flask” deformities at the distal ends of the long bones in older children, and alternating bands of sclerotic and lucent bone in the iliac wings and metaphyses.⁸ Biomarkers for osteopetrosis are increased serum levels of acid phosphatase and the brain isoform of creatine kinase. Lethal infantile osteopetrosis may be caused by homozygous or compound heterozygous loss-of-function mutations in genes whose transcripts are essential for normal osteoblast function: T cell immune regulator 1 (*TCIRG1*, OMIM 604592) encodes a subunit of the vacuolar proton pump within the osteoclast ruffled border through which hydrogen ions are transported from the cytosol into the subosteoclast resorption lacuna; chloride channel 7 (*CLCN7*, OMIM 602727) encodes a chloride channel within the osteoclast’s ruffled border required for transport of this cation into and hence acidification of the resorption lacuna; osteopetrosis-associated transmembrane protein 1 (*OSTM1*, OMIM 607649) encodes the beta subunit of *CLCN7* necessary for its normal posttranslational processing (vide infra). In selected subjects, bone marrow transplantation providing osteoclast precursor cells has been effective in arresting progression of this disorder, albeit often with substantial residual deficits. Transient but substantial hypercalcemia may occur after this procedure. Osteopetrosis caused by deficiency of carbonic anhydrase II (*CA2*, OMIM 611492) encoding carbonic

anhydrase II may also present in infancy with failure to thrive or fracture with insignificant trauma.

Disproportionate short stature is the cardinal manifestation of pycnodysostosis (OMIM 265800) and is manifested during infancy or early childhood by a relatively large head circumference with open fontanelles and cranial sutures, dysmorphic facial features (frontooccipital prominence, proptosis, bluish sclerae, hypoplastic maxilla, micrognathia, highly arched palate, malocclusion, beaked nose), stubby and clubbed fingers with hypoplastic nails, narrow thorax, pectus excavatum, lumbar lordosis, kyphoscoliosis, and increased fracture risk.⁸ Radiographically, there is marked osteosclerosis that increases with age, open fontanelles and cranial sutures, thin clavicles with hypoplastic lateral ends, erosion and hypoplasia of the distal phalanges and ribs, and dense vertebrae yet normal transverse processes. Histologically, there is decreased osteoblastic and osteoclastic activity. Pycnodysostosis is caused by homozygous or compound heterozygous loss-of-function mutations (stop, missense, nonsense) in *CTSK* (OMIM 601105)—the gene encoding cathepsin K, a lysosomal cysteine protease expressed in osteoclasts whose loss impairs degradation of collagen and the resorption of osteoid, the organic component of bone matrix, but not its mineral component. The Raine syndrome (OMIM 259775) of prenatal generalized osteosclerosis with periosteal bone formation, facial dysmorphism (hypoplastic nose, low set ears, exophthalmos, cleft palate), and hypoplastic thorax often resulting in perinatal death is the consequence of biallelic inactivating variants of *FAM20C* (OMIM 611061) encoding a phosphorylase that acts upon small integrin-binding ligand N-linked secreted glycoproteins (*SIBLING*) that bind calcium and regulate mineralization of osteoid, the loss of which enhances this process.¹⁹⁹

Disorders of Bone Mineralization and Formation in the Child and Adolescent

Bone formation may be impaired because of lack of minerals (calcium and/or phosphate) or because of deficient production of bone matrix. Bone mineralization may be excessive because of increase in the rate of mineral deposition or decrease in the rate of resorption of the mineral phase of bone. Ectopic calcification of extraskeletal tissues may occur when local calcium and phosphate levels are high, whereas extraskeletal ossification may ensue when the regulation of skeletal bone formation is deranged.

Rickets

Rickets in children is a disorder of the cartilaginous growth plate and the failure to deposit sufficient bone mineral (hydroxyapatite) to achieve necessary bone strength enabling upright weight-bearing and ambulation because of deficiency of calcium, phosphate, vitamin D, or one of many cofactors that ensure appropriate assimilation and utilization of these materials. Thus rickets is a childhood disorder of decreased mineralization of cartilage and primary bone spongiosa of the growth plates at the ends of the long bones and of bone matrix collagen type I below the growth plate that leads to impaired skeletal strength and linear growth and bony deformations (craniotabes, metaphyseal flaring, genu valgum, genu varum), and increased fracture risk.²⁰⁰ Rickets may be caused by lack of calcium and/or phosphate because of limited intake or decreased intestinal absorption of these nutrients; the latter may be related to intrinsic abnormalities of intestinal function (malabsorption syndromes, short bowel length) or to inadequate vitamin D intake or its decreased absorption or subnormal functional efficiency; impaired endogenous cutaneous synthesis of vitamin D may be caused by climatic conditions

resulting in decreased exposure to sunlight, the dermal application of potent ultraviolet light wave-blocking pharmaceutical agents, or the wearing of extensive clothing that substantially limits the skin surface area exposed to sunlight; vitamin D deficiency may also be the consequence of failure to process cholecalciferol to its biologically active metabolite, 1,25-dihydroxyvitamin D (calcitriol), accelerated conversion of 1,25-dihydroxyvitamin D to water soluble 1,24,25-trihydroxyvitamin D and its urinary loss, or to impaired functional activity of calcitriol because of an abnormality of its nuclear VDR; decreased activity of alkaline phosphatase also leads to impaired bone formation^{112,201,202} (Tables 20.8A, 20.8B). In the adult, deficiencies of vitamin D, calcium, or phosphate result in osteomalacia, the failure to mineralize the cortex and trabeculae of bone.

During endochondral bone formation in growing children, cartilage matrix is elaborated and subsequently mineralized. When endochondral matrix is not fully mineralized, cartilage accumulates, there is thickening of the growth plate and disorganization of the chondrocytes; the ends of the long bones (particularly those that are weight-bearing) are distorted resulting in rachitic deformities.²⁰⁰ During the processes of modeling

and remodeling of trabecular bone and the periosteal and endosteal surfaces of cortical bone, osteoid is formed by osteoblasts; failure to mineralize bone matrix in these regions results in osteomalacia. During intervals of calcium and/or phosphate deprivation, the actively growing, weight-bearing child with open cartilaginous growth plates develops rickets and osteomalacia, whereas under similar circumstances adults develop only osteomalacia during remodeling as unmineralized bone matrix accumulates. Thus rickets is the expression of defective endochondral mineralization at the growth plate and osteomalacia is the failure of mineralization of bone cortex and trabeculae.

Clinically, rickets is manifested by skeletal abnormalities, such as delayed closure of the fontanelles, craniotabes (reversible compression of the skull's outer table), frontal bossing (expansion of cranial bones), and occasional craniosynostosis in infants; bowing of the forearms in the preambulatory infant and genu varum and/or valgum in the weight-bearing infant and child; delayed tooth eruption with poor enamel formation and propensity to caries; pectus carinatum, prominence of the costochondral junctions, flaring of the lower rib cage, scoliosis

TABLE 20.8A Disorders of Bone Mineralization: Rickets

I Vitamin D Deficiency

- A Decreased intake, endogenous synthesis, retention, or sequestration
 - 1 Maternal vitamin D deficiency—breastfeeding
 - 2 Reduced skin synthesis—sunlight deprivation, sunscreen use, increased skin pigmentation
 - 3 Malabsorption—celiac disease, hepatobiliary dysfunction, short gut syndrome, cystic fibrosis, inflammatory bowel disease, gastric bypass surgery
 - 4 Drugs—anticonvulsants, glucocorticoids, cholestyramine, antiretroviral agents
 - 5 Nephrotic syndrome
 - 6 Obesity
- B Metabolic errors
 - 1 Deficiency of 25-hydroxylase
 - a Loss-of-function mutation of *CYP2R1*
 - b Hepatic dysfunction
 - 2 Deficiency of 25OH-vitamin D₃-1-hydroxylase
 - a Loss-of-function mutation of *CYP27B1*
 - b Decreased renal mass—hypoplasia, chronic renal insufficiency
 - 3 Impaired response to vitamin D
 - a Loss-of-function mutation of *VDR*
 - b Excessive heterogeneous nuclear ribonucleoprotein C1/C2 (*HNRNPC*)

II Calcium Deficiency—Primary

- A Nutritional deprivation
- B Hypercalciuria—hyperprostaglandin E2 syndromes

III Phosphate Deficiency/Hypophosphatemia

- A Transcellular shifts
 - 1 Glucose or insulin infusion
 - 2 Refeeding
 - 3 Respiratory alkalosis; hyperventilation
 - 4 Salicylate poisoning
 - 5 Catecholamines
- B Decreased intestinal absorption
 - 1 Nutritional deprivation
 - a Low birth weight infant
 - 2 Decreased intestinal absorption
 - a Vitamin D deficiency—nutritional, synthetic error, insensitivity
 - b Aluminum, magnesium, or calcium-containing antacids
 - c Malabsorption because of chronic diarrhea, steatorrhea

C Hyperphosphaturia

- 1 X-linked dominant familial hypophosphatemic rickets (*PHEX*)^a
- 2 X-linked recessive hypophosphatemic rickets (*CLCN5*)
- 3 Autosomal dominant hypophosphatemic rickets (*FGF23*)^a
- 4 Autosomal dominant hypophosphatemia with urolithiasis 1 (*SLC34A1*)^b
- 5 Autosomal dominant hypophosphatemia with urolithiasis 2 (*SLC9A3R1*)
- 6 Autosomal recessive hypophosphatemic rickets 1 (*DMP1*)^a
- 7 Autosomal recessive hypophosphatemic rickets 2 (*ENPP1*)^a
- 8 Autosomal recessive hypophosphatemic rickets with hypercalciuria (*SLC34A3*)
- 9 Hypophosphatemic rickets with hyperparathyroidism (*KL*)
- 10 Hypophosphatemic rickets with Fanconi renal tubular syndrome (*SLC34A1*)^c
- 11 Oncogenic hypophosphatemic rickets/osteomalacia (*FGF23*, *sFRP4*, *MEPE*, *FGF7*)
- 12 FGF23 excess of uncertain pathogenesis (McCune-Albright syndrome [*GNAS*]^a, Jansen type metaphyseal chondrodysplasia [*PTH1R*]^a, Osteoglophonic dysplasia [*FGFR1*]^a, Linear nevus sebaceous syndrome^a, Iron polymaltese^a)
- 13 Renal tubular acidosis/Fanconi syndrome
 - a Heritable—cystinosis, tyrosinemia, hereditary fructose intolerance, galactosemia, idiopathic
 - b Acquired—nephrotic syndrome, vitamin D deficiency, renal vein thrombosis, renal tubular insult because of cadmium, lead, bismuth, outdated tetracycline, 6-mercaptopurine, valproic acid, ifosfamide

D Other causes

- 1 Hyperparathyroidism
- 2 Medications—diuretics (thiazides, acetazolamide, loop diuretics); antiretroviral agents (tenovir, adefovir); antineoplastic drugs (ifosfamide, cisplatin); aminoglycosides, imatinib

IV Hypophosphatasia (*ALPL*)

- A Perinatal, infantile, childhood, adult forms
- B Odontohypophosphatasia
- C Pseudohypophosphatasia

V Inhibitors of Mineralization

- A Aluminum—parenteral
- B Bisphosphonates
- C Fluoride

^aAssociated with increased expression of FGF23.

^bMonoallelic.

^cBiallelic.

TABLE 20.8B Genetic Disorders of Bone Mineralization: Rickets

Gene Chromosome OMIM	Pathophysiology	Mutation—Clinical Manifestations
Disorders of vitamin D metabolism		
<i>CYP2R1</i> —Cytochrome P450, subfamily IIR, polypeptide 1 11p15.2 608713	Hepatic 25-hydroxylase—enzyme that converts vitamin D3 to 25OH ³ (calcidiol)	Biallelic loss-of-function mutation leads to vitamin D hydroxylation-deficient rickets type 1B (also termed <i>vitamin D-dependent rickets type 1B</i>), AR
<i>CYP27B1</i> —Cytochrome P450, subfamily XXVII, polypeptide 1 12q13.1-q13.3 609506	25OH ³ -1 α hydroxylase—enzyme that converts 25OH ³ to 1,25(OH) ² D ³ (calcitriol)	Biallelic inactivating mutations result in vitamin D-dependent rickets type 1A, AR
<i>VDR</i> —Vitamin D receptor 12q12-q14 601769	Vitamin D receptor—transcription factor that transduces the effects of calcitriol on gene activation or repression	Biallelic loss-of-function mutations lead to insensitivity to calcitriol & vitamin D-dependent rickets type 2A, AR
<i>HNRNPC</i> —Heterogeneous nuclear ribonucleoprotein C 14q11.2 164020	Encodes a ribonucleoprotein that regulates gene transcription by reciprocally & transiently occupying the VDRE in the upstream promoter region of vitamin D-responsive target genes	Overexpression in vitamin D-responsive tissues leads to prolonged occupancy of the VDRE that interferes with interaction of the VDR/RXR with the VDRE resulting in vitamin D-dependent rickets type 2B
<i>CYP3A4</i> —Cytochrome P450, subfamily IIIA, polypeptide 4 7q22.1 124010	Encodes a hepatic CYP450 enzyme that oxidatively metabolizes & inactivates calcidiol & calcitriol	Gain-of-function monoallelic variant resulting in rapid catabolism of calcitriol requiring high doses of calcitriol for treatment of rickets (vitamin D-dependent rickets type 3) (AD)
Disorders of phosphate metabolism		
<i>SLC34A1</i> —Solute carrier family 34 (sodium phosphate cotransporter), member 1 5q35 182309	Encodes NPT2a—sodium/phosphate cotransporter expressed on the apical membrane of the proximal renal tubule; under the inhibitory control of PTH	Loss-of-function mutation results in hypophosphatemic rickets with nephrolithiasis, type 1, AD; Fanconi syndrome type 2, AR
<i>SLC34A2</i> —Solute carrier family 34 (sodium phosphate cotransporter), member 2 2p15.31-p15.2 604217	Encodes NPT2b—sodium/phosphate cotransporter expressed in the small intestine, lung, and testes	Loss-of-function mutations associated with pulmonary alveolar microlithiasis & testicular microlithiasis, AR
<i>SLC34A3</i> —Solute carrier family 34 (sodium phosphate cotransporter), member 3 9q34 609826	Encodes NPT2c—sodium/phosphate cotransporter expressed on the apical membrane of the proximal renal tubule	Loss-of-function mutation results in hereditary hypophosphatemic rickets with hypercalciuria, AR
<i>SLC9A3R1</i> —Solute carrier family 9, member 3, regulator 1 17q25.1 604990	Encodes NHERF1—a renal tubular sodium/hydrogen exchange regulatory factor that binds NPT2a anchoring it to the luminal membrane of the proximal renal tubule; phosphorylation by PTH leads to its dissociation from & endocytosis of NPT2a	Loss-of-function mutations result in hypophosphatemic rickets with nephrolithiasis, type 2, AD
<i>CLCN5</i> —Chloride channel 5 Xp11.23-p11.22 300008	Encodes a proximal renal tubular exchanger of chloride & hydrogen ions	Loss-of-function mutations result in X-linked recessive hypophosphatemic rickets, hypercalciuria, nephrocalcinosis, XLR
<i>PHEX</i> —Phosphate-regulating endopeptidase homolog, X-linked Xp22.2-p22.1 300550	Ectoenzyme expressed on the cell membrane of osteoblasts; its physiological substrate may be MEPE & pASARM, its phosphorylated degradation product that coats hydroxyapatite & hinders mineral deposition	Loss-of-function mutation leads to X-linked hypophosphatemic rickets; associated with increased expression of FGF23; X-linked dominant
<i>DMP1</i> —Dentin matrix acidic phosphoprotein 1 4q22.1 600980	Noncollagenous, serine-rich, bone matrix protein; a small integrin-binding ligand, N-linked glycoprotein (SIBLING) expressed in osteocytes	Loss-of-function mutations lead to increased osteocyte synthesis of FGF23, hyperphosphaturia, & autosomal recessive hypophosphatemic rickets, AR
<i>ENPP1</i> —Ectonucleotide pyrophosphatase/phosphodiesterase 1 6q23.2 173335	Ectoenzyme expressed by chondrocytes, bone, & plasma cells that hydrolyzes ATP to pyrophosphate, an inhibitor of bone mineralization	Loss-of-function mutations result in autosomal recessive hypophosphatemic rickets with increased expression of FGF23, AR
<i>ANKH</i> - ANK, mouse, homolog of 5p15.2-141 605145	Transmembrane-spanning cell-surface protein that regulates pyrophosphate secretion	Inactivating mutations result in mild hypophosphatemia & joint ankylosis, developmental delay, deafness, & dentinogenesis imperfecta; AR
<i>FGF23</i> —Fibroblast growth factor 23 12p13.2 605380	Product of osteoblast & osteocyte that depresses renal tubular reabsorption of phosphate & inhibits synthesis of calcitriol	Gain-of-function mutation that decreases the rate of degradation of FGF23 resulting in autosomal dominant hypophosphatemic rickets, AD; excessive ectopic synthesis by neoplasms leads to hypophosphatemic rickets; loss-of-function mutation leading to decreased FGF23 synthesis results in autosomal recessive hyperphosphatemic familial tumoral calcinosis, AR

TABLE 20.8B Genetic Disorders of Bone Mineralization: Rickets—cont'd

Gene Chromosome OMIM	Pathophysiology	Mutation—Clinical Manifestations
<i>GALNT3</i> —UDP-N-Acetyl-alpha-D-Galactosamine: polypeptide N-acetylglucosaminyl transferase 3 2q24.3 601756	Encodes an enzyme that is essential for O-glycosylation of Thr178 of FGF23 during posttranslational processing; failure of this step leads to degradation of FGF23 before its secretion	Loss-of-function mutation leads to autosomal recessive hyperphosphatemic familial tumoral calcinosis, AR
<i>KL</i> — α -Klotho 13q13.1 604824	Coreceptor with FGFR1(IIIc) for FGF23 that converts FGFR1(IIIc) into the specific FGF23 receptor enabling signal transduction	Loss-of-function mutation leads to autosomal recessive hyperphosphatemic familial tumoral calcinosis, AR; Translocation to (9;13)(q21.13;q13.1) results in excessive Klotho formation leading to hypophosphatemic rickets & hyperparathyroidism
Hypophosphatasia <i>ALPL</i> —Alkaline phosphatase, liver 1p36.12 171760	Tissue nonspecific alkaline phosphatase—ectoenzyme expressed on the cell membrane of osteoblasts, removes organically bound phosphate; major substrates are pyrophosphate, phosphoethanolamine, pyridoxal-5'-phosphate	Loss-of-function mutations lead to hypophosphatasia & rickets of variable severity & onset: perinatal, infancy, transitional, childhood, adult, odontohypophosphatasia, pseudohypophosphatasia; AR, AD

AD, Autosomal dominant; AR, autosomal recessive; ATP, adenosine triphosphate; MEPE, matrix extracellular phosphoglycoprotein; ρ ASARM, phosphorylated acidic serine aspartate-rich MEPE-associated motif.

and kyphosis; flaring of the metaphyses of the long bones, and tibial or femoral torsion (Fig. 20.9).²⁰³ Radiographically, rickets is characterized initially by epiphyseal widening and loss of the defined zone of provisional calcification followed by cupping, splaying, and fraying of the metaphyses of long bones (particularly the distal ulna, distal femur, and proximal tibia), demineralization, deformation of the long bones, and fractures. “Looser zones” are radiolucent lines with dense borders that are pseudofractures located in the femoral neck and shaft. The Thacher radiographic scoring system for assessment of the severity of rickets provides a reasonably objective and useful method for determining the extent of rickets and its response to treatment.²⁰⁴ Histologically, as a consequence of impaired calcification within the cartilage growth plate, the pattern of chondrocyte differentiation and maturation is disrupted and disorganized, while osteoid seams are widened.²⁰⁵ In subjects deprived of phosphate, it is the trabeculae that are primarily undermineralized.

Impaired mineralization of osteoid may be caused by dietary deficiencies or depressed intestinal absorption of calcium, phosphate, or vitamin D, inadequate amounts of these nutrients in fluids used in total parenteral nutrition, metabolic errors in the metabolism or action of vitamin D, defects in renal tubular conservation of phosphate or calcium, or abnormalities of alkaline phosphatase generation and function (see Tables 20.8A, 20.8B). Broadly, rickets may be considered to be calciopenic (usually related to nutritional deprivation of vitamin D or rarely to a defect in its metabolism to the active metabolite—calcitriol—or in its cellular action or to decreased intake of calcium or its excessive loss in urine) or phosphopenic (related to renal phosphate wasting because of primary renal tubular defects in phosphate reabsorption or to generation of excessive amounts of phosphatonins—compounds that inhibit renal tubular reabsorption of phosphate). Thus nutritional rickets may be caused by decreased intake of vitamin D (or inadequate exposure to sunlight) or calcium or to marginal intakes of both nutrients.²⁰⁶ Dietary deficiency of phosphate is unusual given its wide availability, but this nutrient may

be deficient in parenteral fluids. Bone mineralization may also be directly impaired by abnormalities of alkaline phosphatase generation or by agents, such as aluminum or fluoride.²⁰⁵

Calciopenic Rickets. Although dietary calcium deficiency is a rare cause of rickets, there is a substantial incidence of vitamin D deficiency and rickets in children—ranging from 2.9 per 100,000 Canadian children to 7.5, 24, and 95 per 100,000 children in the United Kingdom, United States, and Africa, respectively.²⁰⁷ Vitamin D insufficiency/deficiency may arise from decreased nutritional intake in the presence of suboptimal exposure to sunlight, intestinal malabsorptive syndromes (celiac disease, “short-guts,” cystic fibrosis, inflammatory bowel disease, food allergies), impaired renal synthesis of calcitriol caused by chronic renal disease or to variants of *CYP27B1* (OMIM 609506), or medication or drug exposure (phenytoin, carbamazepine, phenobarbital, glucocorticoids—the latter by increasing activity of renal vitamin D-24-hydroxylase). In the neonate, vitamin D status is related to gestational age and intra-uterine growth and the maternal intake of this nutrient and whether maternal dress permits adequate exposure to sunlight and endogenous synthesis of cholecalciferol. Although obesity is associated with lowered serum concentrations of calcidiol caused by its solubility in adipose tissue and hence sequestration in lipids, obesity does not impair the processes of formation or mineralization of bone.^{207,208} The more darkly pigmented is a child’s skin and the higher the altitude at which she or he lives, the greater is the risk of vitamin D deficiency in the absence of supplementation. In addition, the amount of ultraviolet light that reaches the earth’s surface is influenced by the latitude at which the child dwells, season of the year, time of the day, the amount of time spent outdoors and the clothing worn when outside, cloud cover, and intensity of air pollution. Nutritional rickets caused by deficiency of vitamin D or decreased intake of calcium results in defects of chondrocyte differentiation and function and impaired deposition of calcium into cartilaginous matrix and bone osteoid.²⁰⁹ In serum, more than 90% of cholecalciferol and its metabolites

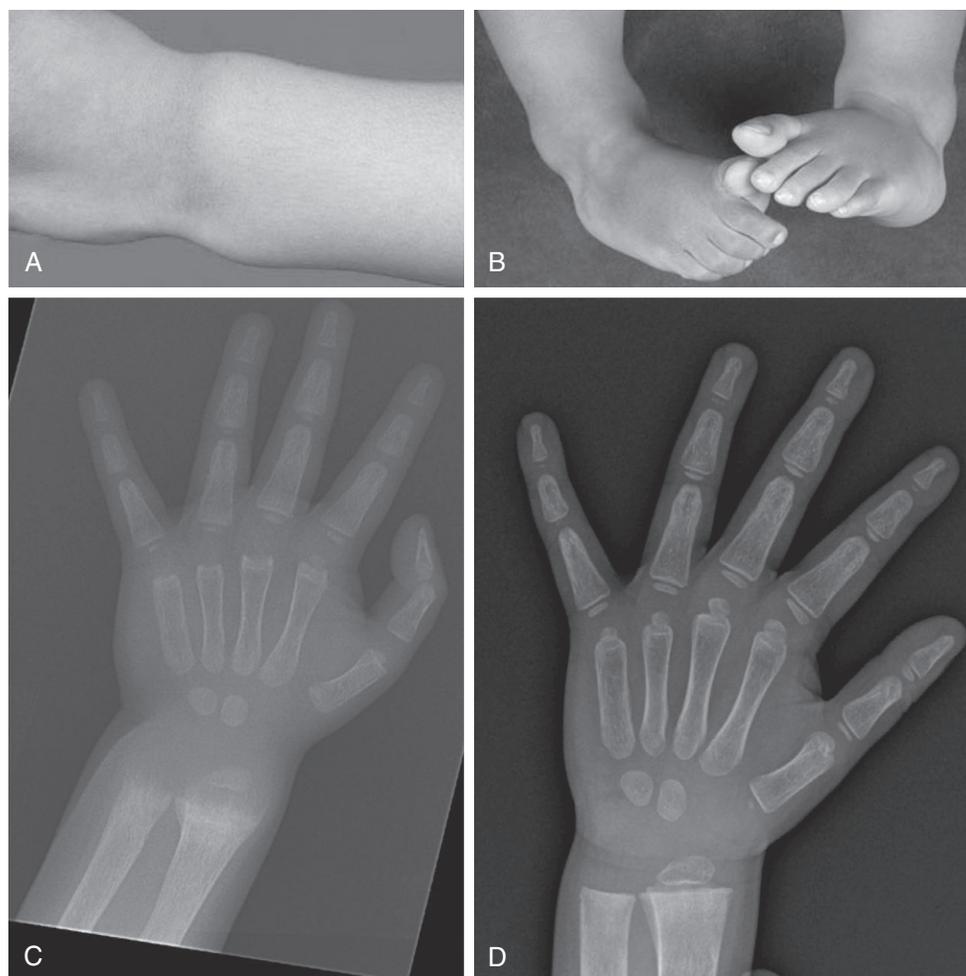

Fig. 20.9 Clinical and radiographic manifestations of vitamin D-deficient rickets in a two year old child. Note flaring of the distal metaphyses of the left wrist (A) and both ankles (B), roentgenographic demonstration of widening of the metaphyses of the radius and ulna © with increased mineralization after treatment with cholecalciferol for three months (D). (From Girgis CM, Clifton-Bligh RJ, Hamrick MW, et al. The roles of vitamin D in skeletal muscle: form, function, and metabolism. *Endocr Rev.* 2013;34:33–83. Images are courtesy of Associate Professor Craig Munns, Childrens' Hospital Westmead, Sydney, Australia.)

(calcidiol, calcitriol) are bound by serum proteins, primarily by vitamin D binding protein (DBP) encoded by *GC* (group-specific component, OMIM 139200). Congenital absence of DBP caused by biallelic deletion of the long arm of chromosome 4 is associated with extremely low but measurable plasma concentrations of total calcidiol and calcitriol without evidence of rickets or osteomalacia—presumably caused by levels of free calcitriol that are adequate for osteoblast-mediated bone formation.²¹⁰ As a consequence of vitamin D deficiency secondary hyperparathyroidism develops resulting in impaired renal tubular reabsorption of filtered phosphate and hypophosphatemia. Although the proximate defect in the vitamin D-deficient subject is calciopenia, impaired growth and development of the cartilaginous growth plate is caused by hypophosphatemia that inhibits expression of *CASP9* (OMIM 602234) encoding caspase 9 that, in turn, impairs phosphate-regulated apoptosis of hypertrophic chondrocytes enabling their continued proliferation.

Thus calciopenic rickets is most often caused by deficiency of vitamin D, which depresses intestinal absorption of dietary calcium and renal reabsorption of filtered calcium. As determined by the measurement of serum concentrations of calcidiol (25OHD), vitamin D deficiency is present when values are below 12 to 15 ng/mL.^{211,212} Calcidiol concentrations between 15 and 19.5 ng/mL indicate vitamin D “insufficiency,” whereas those 20 ng/mL or more are adequate or sufficient. (However, it is critical to assess the validity and variability of

a specific 25OHD/calcidiol assay when interpreting the data provided by that assay as there may be significant quantitative differences between individual reagent sets.²¹³ In addition, because significant concentrations of C-3 epimers of calcidiol are often present in infants that increase the apparent concentration of this analyte, it is important that measurements of serum calcidiol values in children less than 1 year of age be done with an assay that accurately quantifies calcidiol in the presence of C-3 epimers.)

Neonates born to severely vitamin D-deficient mothers may display signs of rickets at birth, including fractures and hypocalcemic seizures; softening of the outer table of the skull in infants and very young children permits its reversible indentation (craniotabes). Clinical manifestations of rickets in preambulatory infants include bowing of the forearms, craniotabes, frontal bossing, and delayed closure of the cranial fontanelles. In children with rickets, anterior bowing of the femora, lateral or medial deviation of the knees leading to genu varum or valgum (bowed legs or “knock knees,” respectively) or a “wind-swept” deformity involving opposite leg deformities, flaring (widening) of the metaphyses of the long bones with markedly enlarged wrists, prominence of the costochondral junctions (rachitic rosary), and indentation of the lower anterior thoracic wall (Harrison’s groove) are noted. Short stature and suboptimal weight are also present frequently. Tooth eruption may be delayed and tooth enamel hypoplastic—predisposing to dental caries. Muscular weakness manifested by hypotonia and delay

in walking may be observed. Hypocalcemic tetany and seizures may occur in a severely vitamin D–deficient infant without gross clinical or radiographic signs of rickets. When vitamin D deficiency is extreme and prolonged in an adolescent hypocalcemic seizures and fractures may occur.²¹⁴

Deficiency of vitamin D is often observed in darkly skinned children and adolescents with limited exposure to sunlight, particularly during and at the end of the winter months, and/or in those ingesting vegetarian diets, or who are being treated with anticonvulsant or antiretroviral drugs.²¹² Because vitamin D has many extraskeletal sites of action because of the multicellular expression of *VDR*, it has been suggested that vitamin D deficiency may play a role in the development of autoimmune, infectious, and systemic disorders (e.g., increased susceptibility to infection—particularly pneumonia—because of both the weakness of the thoracic wall and of the lack of the stimulatory effect of vitamin D on the immune system; asthma and its response to treatment; atopic dermatitis, type 1 diabetes mellitus, inflammatory bowel disease, and cardiovascular disorders).²⁰⁷ Radiographically, decreased bone mineralization with cortical thinning and thin stress fracture lines, as well as cupping, widening, and irregularity (fraying) of the distal metaphyses of the long bones are observed in the rachitic subject.^{9,202} Areas of osteitis fibrosa cystica associated with secondary hyperparathyroidism may sometimes develop.

After introduction of cod liver oil as a dietary supplement in 1918 (and the later fortification of infant formulas and milk and other foods with irradiated ergosterol) and the discovery in 1919 that exposure to sunlight prevented development of rickets, nutritional deficiency of vitamin D became relatively unusual in North America only to reemerge several decades later. Because the fetus is supplied with vitamin D by the transplacental transfer of maternal calcidiol, deficiency of vitamin D occurs predominantly in neonates who are born to mothers with low stores of vitamin D (women of color or those who are vegetarian or poorly nourished, or who have limited exposure to sunlight). Rickets develops in infants and young children who ingest a diet low in vitamin D (little or no milk, meat, eggs, or fish) without supplemental vitamin D who have limited exposure to sunlight because they are confined indoors because of illness, the climate, or parental choice or because they wear clothing that protects the entire body from sunlight. Vitamin D deficiency is more common in breastfed infants because human breast milk contains little vitamin D; black infants are at greater risk than white infants in part because of their increased skin pigmentation resulting in decreased endogenous cutaneous synthesis of cholecalciferol (because melanin absorbs ultraviolet light).²⁰⁵ Normal human breast milk contains only 25 IU/L of vitamin D, therefore it is recommended that all breastfed infants receive supplemental vitamin D 400 IU/day.²¹⁵ Inasmuch as most commercial infant

formulas contain 400 IU/L of vitamin D, it is also recommended that formula-fed infants who consume less than 1 L of formula daily also receive a supplement of 400 IU/day of vitamin D. Infants more than 1 year of age, children, and adolescents should ingest or receive supplemental vitamin D 600 IU daily.

Although definitions of hypovitaminosis D vary between individual studies, subtle forms of vitamin D deficiency or “insufficiency” are likely prevalent throughout the North American population, particularly in the winter months when there is little sunlight exposure and the ultraviolet light requisite for endogenous synthesis of vitamin D is limited.^{9,212,216} Although clinically apparent vitamin D deficiency is unusual in US youth, vitamin D insufficiency may be relatively frequent.^{216,217} In addition to skin pigmentation and northern latitude, low serum calcidiol values have been attributed to meager consumption of milk and multivitamins, large intake of phosphate-containing soft drinks, and increase in fat mass into which vitamin D is deposited and perhaps not readily bioavailable. Using a reliable assay for 25-hydroxyvitamin D, such as those employing liquid chromatography-tandem mass spectrometry, calcidiol concentrations below 12 to 15 ng/mL in children clearly indicate vitamin D deficiency whereas values between 12 to 20 ng/mL are consistent with vitamin D insufficiency.^{207,212} Serum levels of calcidiol that exceed 100 ng/mL are indicative of vitamin D excess. Dietary deficiency of calcium may accentuate the adverse effects of borderline vitamin D stores.²⁰⁶

Vitamin D deficiency may also be the consequence of intestinal malabsorptive disorders, such as celiac or inflammatory bowel diseases, biliary obstruction, gastric and intestinal resection, or pancreatic exocrine insufficiency (e.g., cystic fibrosis), or ingestion of calcium binding agents, such as cholestyramine, or by increased hydroxylation of vitamin D to water-soluble forms that increase its urinary loss by anticonvulsant drugs, such as phenytoin.⁹ Therapeutic doses of glucocorticoids are also associated with lowered serum levels of calcidiol.²¹⁸ In the majority of infants and children with rickets caused by vitamin D deficiency, serum concentrations of total calcium are borderline-normal or low, phosphate levels are low, and alkaline phosphatase activity and PTH concentrations increased (Table 20.9). Secondary hyperparathyroidism develops as the intestinal absorption of calcium is reduced and its serum levels reduced; PTH increases urinary phosphate loss and lowers serum phosphate concentrations, while enhancing the rates of bone resorption and turnover. PTH also increases synthesis of calcitriol, which may increase the rate of calcidiol catabolism and further deplete the body’s store of vitamin D.²⁰⁵ Typically, in patients with vitamin D deficiency serum concentrations of calcidiol are low, whereas calcitriol values may be normal, high, or low depending on whether vitamin D deficiency is modest, moderate, or severe. Serum concentrations of

(From Mannstadt M, Bilezikian JP, Thakker RV, et al. Hypoparathyroidism. *Nat Rev Dis Primers*. 2017;3:17055; Minisola S, Peacock M, Fukumoto S, et al. Tumour-induced osteomalacia. *Nat Rev*. 2017;3:17044.)

osteocalcin are low; serum levels of PICP (a marker of bone formation) and ICTP, and urinary excretion of amino terminal telopeptide of collagen type I (NTx)—both markers of bone resorption—are substantially increased in subjects with vitamin D deficiency rickets indicating increased collagen turnover in this disorder.²¹⁹ With treatment, these values increase transiently and then fall to age-appropriate norms before radiographic healing of the rachitic lesions is complete.

Prevention of vitamin D deficiency is its most effective management. Because the amount of vitamin D in human breast milk is approximately 5 to 80 IU/L and vitamin D supplementation of the breastfeeding mother may be inadequate to ensure normal calcidiol levels in her infant (unless she is receiving approximately 4000 IU per day of vitamin D₃), it is important that all breastfed infants receive a supplement of vitamin D₃ daily (400 IU/day); by extension, this recommendation is also appropriate for infants who are not receiving adequate amounts of vitamin D₃ in their prepared formulas or diet or have suboptimal exposure to sunlight. In the active, lightly dressed white child with skin that normally tans with exposure to sunlight and who plays outdoors 30 minutes thrice weekly or 10 to 15 minutes daily between 1000 to 1500 hours during spring, summer, and fall, endogenous vitamin D synthesis is usually sufficient to achieve satisfactory serum levels of calcidiol.^{205,212} A yellow- or brown-skinned child requires 30 to 45 minutes of outdoor play whereas a black-skinned child requires 60 to 150 minutes of sunlight exposure to achieve serum calcidiol concentrations comparable to those of the white-skinned child. The latitude in which the child lives, season of the year, time of day, local environmental pollutants, amount of clothing, and use of sunscreen affect the time required for sunlight exposure to evoke adequate vitamin D synthesis in the individual child. Between November and February, little or no vitamin D can be synthesized above 35 degrees latitude (Atlanta, GA, USA), but vitamin D insufficiency is also prevalent in lower latitudes.⁹

In obese adolescents, serum concentrations of calcidiol are inversely and PTH values are directly related to fat mass.^{220,221} In a study of 236 adolescent candidates for bariatric surgery, more than 50% were vitamin D deficient as defined by low serum concentrations of calcidiol.²²² Although 43% of these subjects were Caucasian and 15% African American, 82% of the vitamin D-deficient patients were African American compared with 37% of the Caucasian adolescents. Thus obesity is a potential risk factor for subnormal serum concentrations of 25-hydroxyvitamin D; however, bone mineralization by DXA is normal in obese children and adults.^{209,220,223,224} Nevertheless, the normal bone mineralization of obese children and adolescents may not be sufficient to meet the skeletal strength requirements that their higher body mass may need. Therefore obesity is not only nonprotective against fractures in this population but may also increase fracture risk because of the high mechanical load carried by the obese child/adolescent. After diet- and exercise-induced weight loss, abnormalities in serum levels of calcidiol and PTH are reversed, indicating that the aberrations seen in obese children are the consequence and not the cause of obesity.²²¹ It is of interest that the adipocyte and osteoblast are derived from a common mesenchymal stem cell under the direction of different stimuli.²²³ Osteoblastogenesis results when the stem cell progresses along the WNT-Frizzled- β -catenin signal transduction pathway, whereas adipogenesis occurs after stimulation of the stem cell by peroxisome proliferator-activated receptor gamma (PPAR- γ). Whether this dichotomy in cell differentiation plays a role in modulating the effects of obesity on bone mineralization in children is unknown at present. The site of fat deposition may also influence bone mineralization; in adults, abdominal and bone marrow fat may exert adverse effects upon this process.

Evaluation of the child with nutritional rickets includes historical review of dietary intake and sunlight exposure and illnesses encountered, physical examination (documenting deformities of the chest and extremities), roentgenograms of the skeleton (widening of the epiphyses, lucent areas of unmineralized osteoid extending into the metaphyses), and laboratory assessment: complete blood count (hemoglobin, hematocrit), comprehensive chemical measurements (including total calcium, magnesium, phosphorus, bone alkaline phosphatase, creatinine, calcidiol, PTH); spot urinary determination of calcium, creatinine. Nutritional rickets is effectively treated in most subjects by oral doses of vitamin D (cholecalciferol or ergocalciferol): neonates—2000 IU/day for 6 weeks; infants below 1 year of age—2000/day for 6 weeks; children over 1 year of age—2000 IU/day for 8 weeks with the subsequent maintenance dose of 600 to 1000 IU/day.^{212,225} At the beginning of treatment, elemental calcium (30–75 mg/kg/d in 3 divided doses per day) must also be administered to the vitamin D-deficient child receiving vitamin D to avoid the hypocalcemia that accompanies rapid remineralization of bone matrix (the hungry bone syndrome). An alternative therapeutic regimen for treatment of vitamin D-deficient rickets has been the administration of a single oral (or intramuscular) dose of 150,000 to 600,000 units of vitamin D₃ depending on patient age and other individual circumstances.^{9,205} During treatment periodic determinations of total and/or bone-specific alkaline phosphatase values are an effective tool for monitoring the efficacy of treatment as levels decline progressively as the rachitic lesions heal. To avoid hypocalcemia or hypercalcemia, hypercalciuria, and nephrocalcinosis, serial determinations of serum values of calcium, phosphate, and creatinine and urinary excretion of calcium and creatinine should be determined. Sequential radiographs document reversal of rachitic changes (see Fig. 20.9). After completion of therapy and radiographic evidence of healing of the rickets, the vitamin D dose may be lowered to 400 to 600 IU/day; calcidiol values should then be measured prospectively to be certain that the child continues to receive adequate amounts of vitamin D.²⁰⁷

Rickets resulting primarily from low dietary intake of calcium has occurred in infants who ingest low-calcium containing formulas and in children from developing countries receiving a diet with 200 mg (or less) of elemental calcium per day despite normal intake of phosphate and adequate endogenous stores of vitamin D as determined by serum calcidiol levels.²⁰⁵ Calcium deficiency rickets also occurs in the United States if infants are weaned to low-calcium containing foods after completion of breastfeeding. Calcium deficiency rickets may also develop as a consequence of impaired intestinal absorption of dietary calcium because of intrinsic factors or that it has been bound by ingestion of high fiber and phytate containing cereals.²⁰⁶ Calcium deficiency is best addressed by its prevention, ensuring adequate intake of this element according to established guidelines for growing infants, children, and adolescents (recommended calcium intakes: 400–600 mg/day in infants; 700 mg/day in children below 4 years of age; 1000–1300 mg/day in older children and adolescents). When present, calcium deficiency rickets may be effectively treated by ensuring an intake of 1000 to 1500 mg of elemental calcium daily for 6 months with provision of normal amounts of vitamin D by sunlight exposure or supplementation. Codeficiencies of calcium and vitamin D may occur in some children.

Dietary phosphate deficiency is unusual because this anion is present in large amounts in most foods. Hypophosphatemia may be caused by decreased intestinal absorption of phosphate (e.g., starvation, premature infants drinking human breast milk without supplemental phosphate, older infants ingesting a formula very low in phosphate content, subjects ingesting large amounts of aluminum-containing antacids as aluminum

and phosphate coprecipitate in the intestinal tract, patients with the short bowel syndrome, or vitamin D deficiency), administration of parenteral nutrition with fluids low in phosphate, intravenous infusion of iron, increased renal excretion of phosphate in patients with depressed renal tubular reabsorption of this anion, and movement of phosphate from the extracellular fluid space to the intracellular compartment (vide infra).²²⁶ In very premature infants receiving long-term parenteral nutrition, development of metabolic bone disease is frequent and related not only to deficiencies of calcium, phosphate, and vitamin D but also to excess aluminum in the infusates. Infants receiving large amounts of aluminum containing antacids over prolonged periods for treatment of gastroesophageal reflux may also have low bone mass. Aluminum lowers the rate of bone formation by several mechanisms: administered orally aluminum binds intestinal phosphate, thereby impeding its absorption leading to phosphate depletion; administered intravenously during total parenteral nutrition or during hemodialysis, aluminum inhibits osteoblastic function and prevents mineralization of osteoid; it also impairs the secretion of PTH and decreases 25OHD-1 α hydroxylase activity.²²⁷ Patients requiring total parenteral nutrition should receive as much calcium and phosphate as can be administered safely, as well as supplemental vitamin D. Periodic measurements of serum levels of calcium, phosphate, alkaline phosphatase, PTH, and calcidiol, and serial skeletal radiographs and estimations of skeletal mineralization are recommended in patients receiving total parenteral nutrition; if metabolic bone disease develops in spite of these efforts, serum aluminum levels should be measured and if elevated (>100 mcg/L) a search for the source of the aluminum should be initiated and that product eliminated from the infusate if possible. Cadmium, fluoride, and saccharated ferric oxide are also able to impede normal bone mineralization.²²⁷

Metabolic and functional defects of vitamin D lead to rarer forms of rickets (see Tables 20.8A, 20.8B).^{212,228} Biallelic loss-of-function mutations in *CYP2R1* (OMIM 608713), the hepatic 25-hydroxylase enzyme that converts cholecalciferol (vitamin D₃) to 25-hydroxycholecalciferol (calcidiol), result in vitamin D hydroxylation-deficient rickets type 1B (also termed *vitamin D-dependent rickets type 1B*—OMIM 600081). Rickets caused by a defect in 25-hydroxylation has been described in two brothers of Nigerian origin in whom a homozygous loss-of-function mutation (p.Leu99Pro) in *CYP2R1* eliminated the hydroxylase activity of this 501 aa protein.²²⁹ The deleterious homozygous mutation (p.Gly42_LeudelinsArg) in *CYP2R1* has also been identified.²³⁰ 25-Hydroxylase deficiency transmitted as a dominant disorder not because of an identified mutation in the coding exons or intronic regions of *CYP2R1* has been reported also.²³¹ Vitamin D 25-hydroxylation-deficient rickets type 1B is manifested by clinical and radiological signs of rickets in association with hypocalcemia, hypophosphatemia, hyperalkaline phosphatasia, high PTH, and high calcitriol, and very low calcidiol values; heterozygous carriers of a deleterious mutation in *CYP2R1* have reduced levels of calcidiol but do not develop rickets.²³² Affected subjects respond to administration of calcidiol (as well as calcitriol) with improvement in clinical symptoms, normalization of biochemical abnormalities, and increase in vertebral bone mineralization.²³⁰

Vitamin D hydroxylation-deficient rickets, type 1A ([OMIM 264700]—vitamin D-dependent rickets type 1A [VDDR1A] or pseudovitamin D-deficiency rickets type 1A [PDDR1A]) is caused by homozygous or compound heterozygous inactivating mutations of *CYP27B1* (OMIM 609506) encoding the enzyme in the renal proximal tubule that catalyzes 1 α -hydroxylation of carbon-1 of calcidiol converting it to 1,25-dihydroxyvitamin D₃ (calcitriol), the biologically active metabolite of vitamin D.²³³ Although apparently normal at

birth, bone deformities (bowing of the forearms), growth retardation, muscle weakness or spasms, delayed motor milestones (walking), and/or hypocalcemic seizures develop between 6 and 30 months of age in patients with VDDR1A; physical signs of rickets (metaphyseal prominence, rachitic rosary, craniotabes), and hypoplasia of dental enamel is often present; biochemically, hypocalcemia, hypophosphatemia, hyperphosphatemia, markedly elevated serum levels of PTH, normal serum concentrations of calcidiol and inappropriately low calcitriol levels are recorded; radiographs reveal rachitic deformities of the long bones.^{232,234} The diagnosis of VDDR1A is established by the presence of normal serum concentrations of calcidiol whereas calcitriol values are extremely low and do not increase after administration of vitamin D or calcidiol and is confirmed by identification of the mutation in *CYP27B1*. Treatment goals are restoration of eucalcemia without hypercalciuria resulting in increased muscular strength and healing of the rachitic lesions permitting normal growth. The clinical, biochemical, and radiographic manifestations of VDDR1A resolve completely and reasonably rapidly following treatment with physiological amounts of calcitriol (10–20 ng/kg/d). Lifelong therapy is necessary, but effective and compliant treatment leads to normalization of all biochemical parameters, normal linear growth and adult height, and normal bone mineralization. The dose of calcitriol often needs to be increased during pregnancy; however, gestation is uncomplicated and the offspring of affected mothers are normal.²³⁴ VDDR1A is an autosomal recessive disease found with high frequency in a Quebec French-Canadian population but occurs in all races and in diverse geographic regions. *CYP27B1* encodes a 508 aa mitochondrial cytochrome P450 hydroxylase with conserved sites that binds ferredoxin and heme and uses electrons from reduced nicotinamide adenine dinucleotide phosphate and oxygen to convert calcidiol to calcitriol.²²⁸ Many loss-of-function missense, nonsense, splicing, and duplication or deletion/frameshift mutations in *CYP27B1* lead to inactive or truncated protein products that are unable to bind either substrate (calcidiol) or heme, the latter defect preventing electron transfer and inhibiting catalysis. The most common mutation in *CYP27B1* in the Quebec French-Canadian population at risk for VDDR1A is deletion of guanine at nucleotide 958 (exon 2, codon 88) (c.958delG) that changes the reading frame resulting in premature termination of translation and an inactive product (the Charlevoix mutation). A second common mutation in this population is duplication of a 7-base pair sequence in exon 8; however, this mutation is also found in patients of Asian and Hispanic ethnicity.

Biallelic loss-of-function mutations in *VDR* (OMIM 601769) encoding the VDR result in resistance to the physiological effects of calcitriol and vitamin D-resistant rickets type 2A (OMIM 277440).^{228,233} Clinical and biochemical manifestations of resistance to calcitriol include severe infantile-onset bony deformities characteristic of rickets (bowing of the limbs, widening of the distal ends of the long bones, frontal bossing, beading of the costochondral junctions of the rib cage), growth retardation, varying severity of alopecia, hypocalcemia, hypophosphatemia, hyperalkaline phosphatasia, and extraordinarily high serum concentrations of calcitriol (300–1000 pg/mL) and PTH; serum levels of 25-hydroxyvitamin D are normal whereas those of 24,25-dihydroxyvitamin D are often low (see Table 20.9).²³⁵ The high calcitriol values reflect the combined stimulatory effects of hypocalcemia, hypophosphatemia, and secondary hyperparathyroidism on the activity of 25-hydroxyvitamin D₃-1 α -hydroxylase together with decrease in its rate of catabolism because of depressed activity of calcitriol-dependent 1,25 α -dihydroxyvitamin D₃ 24-hydroxylase. Radiographs demonstrate signs of rickets, including metaphyseal cupping and fraying and tibial and

femoral bowing. Genotyping reveals homozygous or compound heterozygous mutations in *VDR* (Fig. 20.10). Intravenous infusions of calcium (0.4–1.4 g/m²/d) have been helpful in restoring normal growth and healing of the rickets but mandate careful monitoring, often in hospital, to avoid cardiac arrhythmias, hypercalciuria, nephrocalcinosis, and related complications. Oral administration of high doses of calcitriol (1–6 mcg/day in 2 divided doses) together with elemental calcium (1–3 g/day) have been used in the treatment of these patients who also require close follow-up and periodic measurements of serum and urinary calcium values.²¹² During treatment, serum values of calcium, phosphate, alkaline phosphatase, creatinine, and PTH, urinary calcium and creatinine excretion, skeletal radiographs, and renal ultrasounds for development of nephrocalcinosis are monitored serially. In patients refractory to oral therapy, continuous intravenous or intracaval administration of large amounts of calcium (0.4–1.4 g of elemental calcium/m²/d) normalizes calcium, phosphate, alkaline phosphatase, and PTH values, heals rickets, and increases growth rate in selected children. If this mode of therapy is used, careful monitoring for catheter sepsis and cardiac arrhythmia, as well as hypercalcemia, hypercalciuria, and nephrocalcinosis is mandatory. After healing of the rickets by parenteral calcium, maintenance therapy with large doses of oral calcium (3.5–9 g of elemental calcium/m²/day) is appropriate. In younger infants with vitamin D-resistant rickets before development of florid rickets, high doses of oral calcium

may ameliorate the rachitic process. These clinical observations suggest that the major defect in patients with vitamin D-resistant rickets is lack of calcium. With treatment, growth may normalize in patients with vitamin D resistance, but alopecia if present is unlikely to resolve.²³⁶ An alternative therapeutic management of vitamin D resistance has been the administration of cinacalcet, a calcimimetic that activates the CaSR in the parathyroid gland thereby lowering the secretion of PTH; short-term (2 months) administration of cinacalcet to a 3-year-old child with vitamin D resistance enabled relatively long-term resolution of the clinical, biochemical, and radiographic manifestations of this disease with maintenance therapy of thrice weekly infusions of calcium.²³⁷ Interestingly, although binding of calcitriol to the VDR is essential for expression of its function in most tissues and hair is dependent on the VDR for normal function of skin keratinocytes and outer root-sheath cells and physiological cycling of the hair follicle, the hair follicle cycle does not require calcitriol; thus maintenance of the normal pattern of hair follicle cycling between phases of rest and growth is likely a ligand-independent function of the VDR achieved by interacting with β -catenin.²³⁸

Although striking in infancy and early childhood, clinical manifestations of vitamin D resistance may vary, and patients with milder defects in *VDR* may not be identified until adolescence or adulthood. In addition, spontaneous remission of the rachitic process may occur, most often between 7 and 15 years of age or when the patient enters puberty.²³⁶ Indeed, after

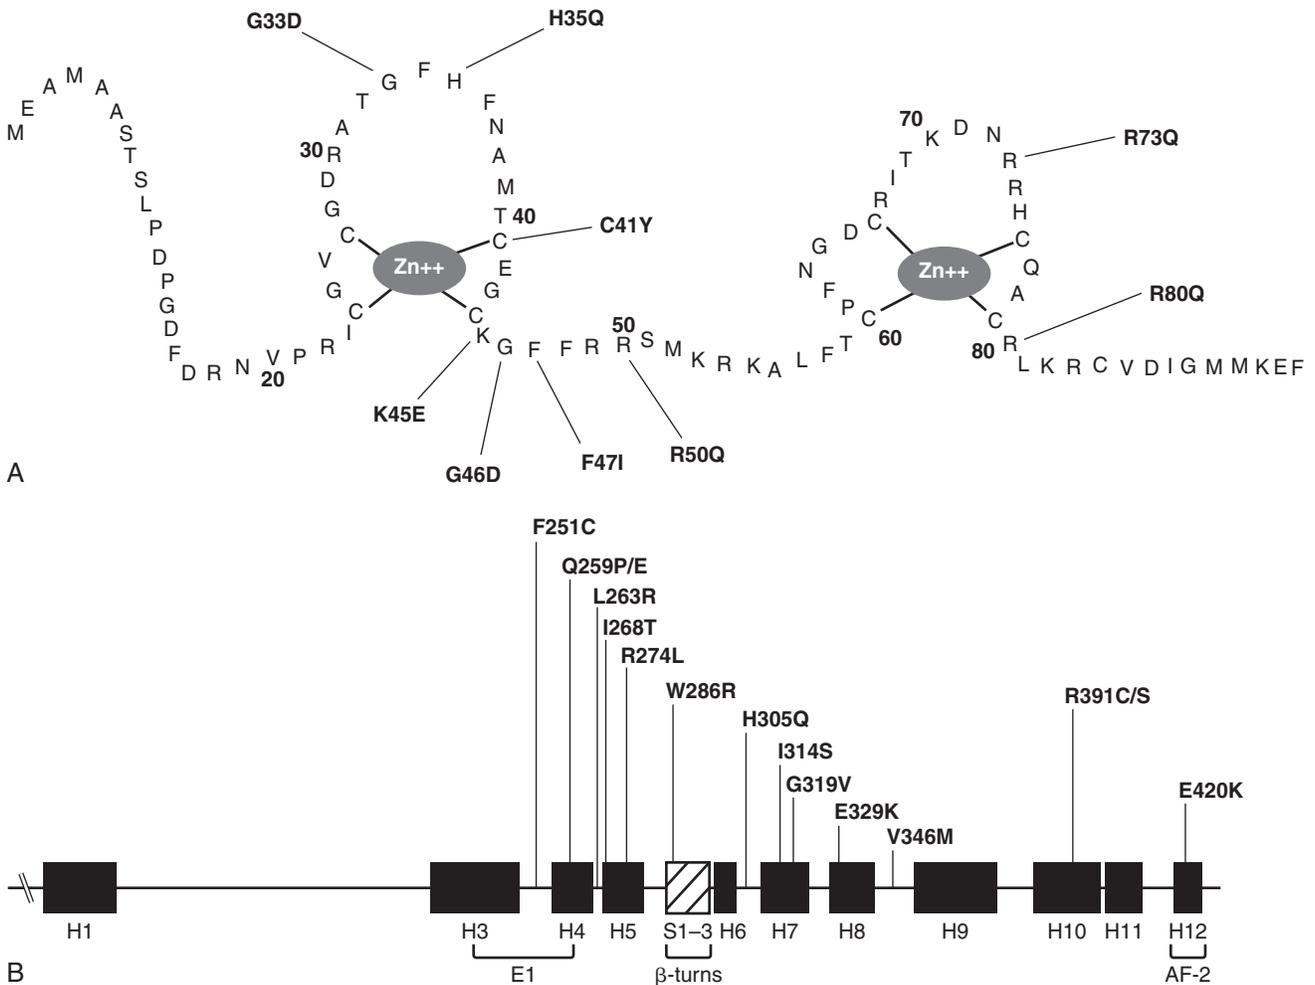

Fig. 20.10 Mutations in the vitamin D receptor (VDR) in patients with end-organ insensitivity to vitamin D. (From Malloy PJ, Feldman D. Genetic disorders and defects in vitamin D actions. *Endocrinol Metab Clin North Am.* 2010;39:333–346.)

puberty in many patients with vitamin D-resistant rickets, serum levels of calcium, phosphate, and alkaline phosphatase normalize and calcium supplementation is no longer needed.²³⁹ Apparently, the skeletal requirement for calcium declines after completion of bone growth, and vitamin D-independent mechanisms of intestinal calcium absorption develop. In a study of 17 patients with vitamin D-resistant rickets between 1.5 and 37 years of age, biochemical parameters improved, the need for supplemental calcium declined, and BMD by DXA normalized in the latter half of the second decade of life, whereas serum calcitriol values remained elevated.²³⁹ Examination of intestinal calcium absorption revealed that the fractional absorption of calcium, while ingesting a low calcium diet, was substantially lower than control subjects in young patients; in patients 18 to 26 years of age, the fractional absorption of calcium was significantly higher than control values; in adult patients, the fractional absorption of calcium was similar to control data. Nevertheless, the growth impairing effects of severe childhood rickets persisted into adulthood in the majority of patients. The VDR is composed of DNA-, ligand-, and retinoic X receptor (RXR)-binding domains and a transactivation domain to which many comodulators of VDR function are recruited. The VDR and RXR bind as a heterodimeric transcription activating complex. Loss-of-function mutations have been found in each VDR domain: thus the mutated VDR may be unable to bind calcitriol because of decreased receptor number or affinity for ligand, incapable of forming heterodimers with RXR or of translocating to the targeted gene in the nucleus, unable to bind to the vitamin D response element (VDRE) or to initiate gene transcription once bound to the VDRE. More than 30 distinct heterozygous mutations in VDR have been identified scattered through the entire VDR protein but with a large number of variants in the ligand binding domain.²²⁸ In general, patients with vitamin D-resistant rickets without alopecia may be more responsive to treatment.

Vitamin D-dependent rickets, type 2B (VDRR2B, OMIM 600785) is a rare, second form of vitamin D-resistant rickets with a phenotype similar to that of patients with a mutated VDR but whose vitamin D nuclear receptor is intact. Overexpression of *HNRNPC* (OMIM 164020), encoding a nuclear ribonucleoprotein C that binds to the VDR/RXR-vitamin D response element (5') upstream of the vitamin D targeted gene and impairs target gene transcription, has been observed in a patient with VDRR2B.²⁴⁰ The mechanism by which overexpression of an otherwise normal ribonucleoprotein occurs and the relationship of this observation to the pathogenesis of VDRR2B are unknown. A variant of *CYP3A4* (OMIM 124010) encoding a hepatic CYP450 enzyme that rapidly oxidatively metabolizes and thereby inactivates calcidiol and calcitriol also results in decreased functional activity of these metabolites of vitamin D, leading to rickets in affected patients who require high doses of calcitriol for therapeutic management. (This disorder has been designated *vitamin D-dependent rickets type 3*.)

Phosphopenic Rickets. Serum concentrations of phosphate decline with age through childhood and adolescence; thus between 0 and 5 days serum phosphate levels range between 4.8 and 8.2 mg/dL; 1 and 3 years—3.8 to 6.5 mg/dL; 4 and 11 years—3.7 to 5.6 mg/dL; 12 and 15 years—2.9 to 5.4 mg/dL; 16 and 19 years—2.7 to 4.7 mg/dL.²³² Acute hypophosphatemia is associated with irritability, confusion, paresthesias, muscle weakness, and ileus; chronic hypophosphatemia leads to rickets in the growing child. Hypophosphatemia in childhood may be caused by hereditary or acquired disorders (see Tables 20.8A, 20.8B and see Fig. 20.12).²²⁶ Hypophosphatemia may be the consequence of the movement of extracellular phosphate into cells (during treatment of diabetic ketoacidosis

with insulin as the intracellular phosphorylation of carbohydrates increases, acute respiratory alkalosis caused by hyperventilation, sepsis), impaired intestinal absorption of phosphate (vitamin D deficiency, chronic ingestion of magnesium or aluminum containing antacids, chronic diarrhea and/or steatorrhea), or increased renal phosphate wasting (secondary to increased secretion of PTH or primary caused by intrinsic abnormalities in the mechanisms that control renal tubular reabsorption of this anion). Hypophosphatemia is observed in nutritionally deprived subjects, such as the LBW neonate or older patient who is dependent on parenteral alimentation, those with severe anorexia, or those who are addicted to alcohol. Hypophosphatemia and metabolic bone disease may occur in infants and children receiving an amino acid based elemental formula with decreased bioavailable phosphate. Hypophosphatemia occurs in many critically ill patients, especially those with sepsis. Rapid remineralization of osteopenic bone is accompanied by hypophosphatemia and hypocalcemia (hungry bone syndrome). Most frequently, chronic hypophosphatemia is the result of hyperphosphaturia—either because of a primary or secondary defect in the regulation of renal tubular phosphate reabsorption in the proximal (where 60%–70% of the filtered load of phosphate is reabsorbed) or distal (where 10%–15% of filtered phosphate is reabsorbed) renal tubule.^{226,241} Thus increased secretion of PTH resulting either from primary hyperparathyroidism or secondary to vitamin D deficiency or other cause can lead to hyperphosphaturia and hypophosphatemia. The Fanconi syndromes are characterized by multiple functional renal tubular defects including abnormalities of phosphate reabsorption. Renal tubular defects that specifically impede the processes through which phosphate is reabsorbed by the renal tubules include abnormalities of transcellular transport of phosphate and excessive production of phosphaturic substances other than PTH, such as FGF23 and other phosphatonins and their cofactors.

In developed countries where severe vitamin D deficiency rickets is not a common problem, X-linked dominant hypophosphatemic rickets (XLHR, OMIM 307800) caused by inactivating variants of phosphate-regulating Endopeptidase homologue (*PHEX*, X-linked—OMIM 300550) is the most frequent form of rickets encountered (1:20,000 births). X-linked dominant hypophosphatemic rickets affects hemizygous males and heterozygous females similarly because of random inactivation of the X chromosome, albeit with substantial inter- and intrafamilial variability in clinical expression. X-linked dominant hypophosphatemic rickets is usually manifested within the first year of life, initially with bowing of the ulna and radius. Physical findings in children with XLHR include short stature, genu varum or valgum that develops when the infant begins to walk, flaring of the metaphyses, rachitic rosary, frontal bossing; increased frequency of dental decay and/or periradicular abscesses in teeth free of caries; bone, muscle, and joint stiffness, aching and occasionally pain. Craniotabes, tetany, and muscular weakness are not found in patients with XLHR as they are in those with vitamin D deficiency. Although they are no longer growing, adults with XLHR have osteomalacia, bone pain, increased fracture rate, and frequent dental abscesses, nephrocalcinosis, and hearing impairment; they may also develop stenosis of the spinal canal and progressive ankylosis of the vertebrae; osteotomies, decompressive laminectomies, and replacement of hip and knee joints are frequently necessary in this population.²⁴² Enesopathy—calcification of tendons, ligaments, and joint capsules—is common in adults with XLHR but may also occur in children with this disorder. The clinical expression of XLHR may vary widely between affected families and between affected children in the same family.²⁴³

Hypophosphatemia, hyperphosphaturia, normocalcemia, hyperalkaline phosphatasia, normal or just slightly elevated

concentrations of PTH, normal calcidiol values, and inappropriately low levels of calcitriol for the degree of hypophosphatemia are present in these patients within the first several months after birth.²³² Because phosphate induces differentiation, maturation, and apoptosis of hypertrophic chondrocytes in the cartilage growth plate of long bones, hypophosphatemia is associated with disorganized overgrowth of chondrocytes. Thus radiographically, distal femoral and proximal tibial metaphyseal flaring is a prominent finding as is bowing of the femora and tibiae in association with knee pain. Children with XLHR who have knee pain but normal radiographs may have bony abnormalities identifiable by magnetic resonance imaging. The axial skeleton may have a dense appearance.

PHEX encodes a zinc metallopeptidase that regulates serum concentrations and urinary excretion of phosphate.²⁴³ *PHEX* is a 22 exon gene that encodes a 749 aa integral membrane protein with a very long extracellular (702 aa) and short transmembrane (27 aa) and intracellular (20 aa) domains. The extracellular domain has 10 conserved cysteine residues and a pentapeptide motif (His-Glu-Phe-Thr-His) characteristic of zinc metallopeptidases that may either convert propeptides to active forms or degrade and inactivate their substrates. *PHEX* is expressed on the surface of osteoblasts and osteocytes, as well as by teeth, muscle, lung, liver, testis, and ovary; *PHEX* transcription by osteoblasts is downregulated by calcitriol. In most patients with XLHR, inactivating mutations of *PHEX* have been found primarily in the extracellular domain and include frameshift deletions (16%), duplications, insertions (8%), deletional-insertional, splice site (15%), nonsense (27%), and missense (34%) mutations, many in exons 15 and 17; a mutation has also been identified in the 5'-untranslated region (A \Rightarrow G transversion 429 bp upstream of the ATG initiation site) (Fig. 20.11).²⁴⁴ Because *PHEX* is a glycosylated protein, failure of glycosylation leads to its sequestration within the endoplasmic reticulum thus impeding its movement (trafficking) to the cell membrane; other mutations interfere with the catalytic function of the protein or its three-dimensional conformation. Mutations in *PHEX* arise spontaneously in more than 20% of patients with XLHR. There is no correlation between the location or type of mutation in *PHEX* and the clinical manifestations or severity of the disease.^{243,244}

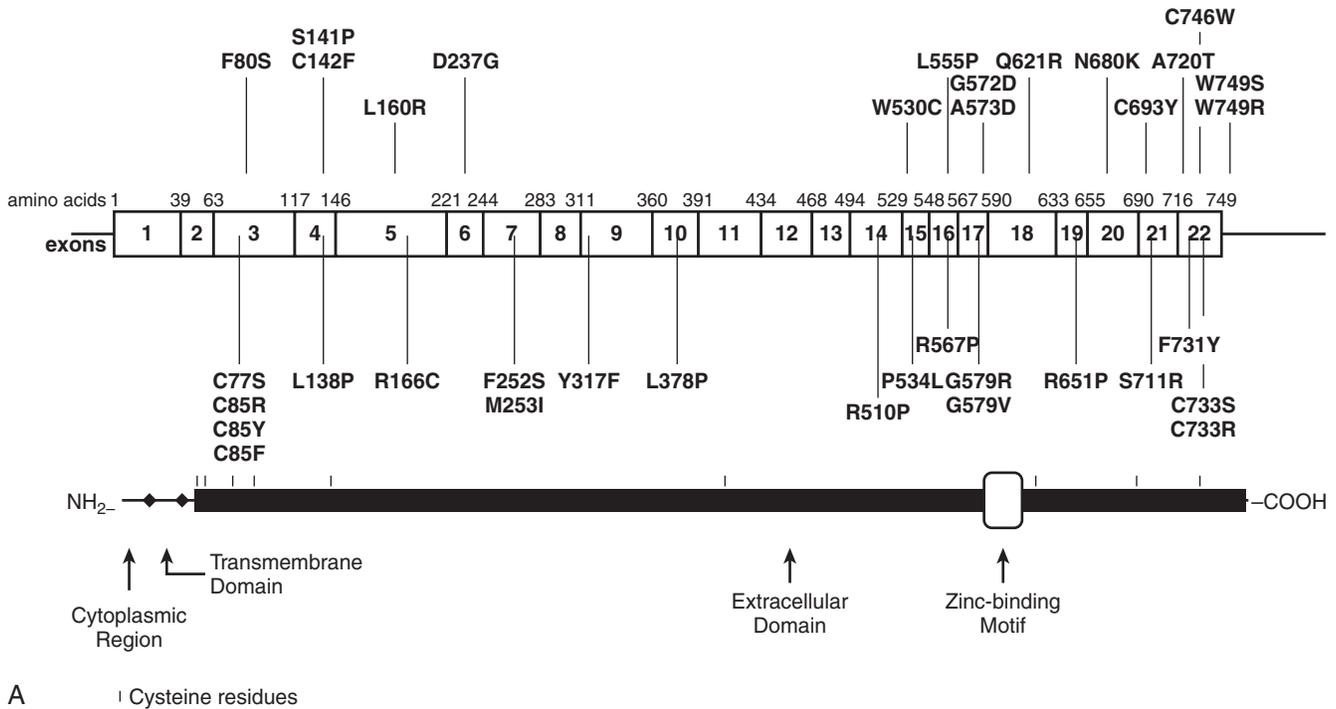

PHEX is a neutral endopeptidase among whose principle substrates are the bone-derived SIBLING family of proteins that include matrix extracellular phosphoglycoprotein (MEPE, OMIM 605912), dentin matrix acidic phosphoprotein 1 (DMP1, OMIM 600980), osteopontin/secreted phosphoprotein 1 (OMIM 166490), integrin-binding sialoprotein (OMIM 147563), and dentin sialophosphoprotein (OMIM 125485), all of whose genes are clustered on the long arm of chromosome 4. SIBLING proteins are secreted into extracellular matrix during mineralization, bind to calcium and regulate biomineralization.^{245,246} MEPE is a 525 aa noncollagenous protein secreted by osteoblasts that is present in extracellular bone matrix, teeth, and brain. As well as affecting biomineralization, MEPE inhibits renal tubular uptake of phosphate and depresses synthesis of calcitriol and is thus a phosphatonin, agents with these dual properties. MEPE and other SIBLING proteins contain an acidic serine aspartate-rich MEPE-associated motif (ASARM = minihibin) within their carboxyl terminal regions that is released by cathepsin B and its serine residue may then be phosphorylated; phosphorylated (p)ASARM binds avidly to hydroxyapatite. *PHEX* binds to MEPE and prevents its proteolytic digestion by cathepsin B, thereby inhibiting release and phosphorylation of ASARM. In the absence of normal *PHEX*-MEPE binding, ASARM is released from MEPE by cathepsin B; in patients with XLHR, serum ASARM levels are increased. Serine-phosphorylated pASARM coats the surface of hydroxyapatite by interacting with its calcium atoms and thus impairs

further deposition of calcium and phosphate and thereby inhibits mineralization. pASARM is also a substrate for the enzymatic activity of *PHEX*, which proteolytically cleaves the peptide between serine-glutamate and serine-aspartate residues; by doing so, *PHEX* destroys pASARM and prevents pASARM-mediated inhibition of bone mineralization. Although nonphosphorylated ASARM also binds (weakly) to hydroxyapatite and inhibits mineralization and can be enzymatically cleaved by *PHEX*, the role of nonphosphorylated ASARM in the mineralization process is as yet incompletely understood. Interestingly, ASARM peptides also impair renal tubular reabsorption of phosphate as pASARM increases expression of *FGF23* (OMIM 605380) in bone cells.²⁴⁵⁻²⁴⁷ Inasmuch as ASARM motifs are present in all SIBLING proteins, pASARM is also derived from osteopontin providing another source of a peptide that is able to bind to and inhibit mineralization of hydroxyapatite; osteopontin-derived pASARM is also a *PHEX* substrate.^{245,248} Accordingly, in XLHR, the primary pathophysiological abnormalities appear to be the failure of mutated, bioinactive *PHEX* to: (1) bind to MEPE, thereby inhibiting cathepsin B-mediated proteolytic cleavage of MEPE and release of ASARM; (2) destroy the pASARM derived from MEPE, thereby permitting pASARM to coat hydroxyapatite and inhibit mineralization; (3) degrade ASARM peptides thus enabling them to depress renal tubular reabsorption of phosphate; and (4) suppress expression of *FGF23* (vide infra).²⁴⁹

Although serum levels of total and ionized calcium are normal in patients with XLHR, hypophosphatemia is marked because of its urinary wastage because of substantially decreased renal tubular reabsorption of filtered phosphate and limited intestinal absorption of this anion. Serum concentrations of PTH and calcidiol are normal, but calcitriol values are inappropriately low for the degree of hypophosphatemia; serum alkaline phosphatase activity is increased as are serum levels of *FGF23* (Fig. 20.12).²⁵⁰ Many of these biochemical abnormalities are present in the affected patient within the first several months after birth. Because the serum ionized calcium concentration is normal, secondary hyperparathyroidism does not occur unless the patient with XLHR receives excessive amounts of supplemental phosphate. Normally, phosphate induces differentiation and death of hypertrophic chondrocytes in the cartilage growth plate by activating the mitochondrial apoptotic pathway that is caspase 9 dependent.^{233,251} Hypophosphatemia leads to delayed loss and increased numbers of hypertrophic chondrocytes and expansion of the growth plate characteristic of rickets. Bone histomorphometry in XLHR reveals unmineralized osteoid accumulating along the trabeculae within cancellous bone (i.e., osteomalacia) and hypomineralized periosteocytic lesions characteristic of this disorder.

FGF23 (OMIM 605380) is a potent phosphaturic agent produced by osteoblasts and osteocytes whose serum concentrations are elevated in patients with XLHR and related inversely to those of phosphate. Pathophysiologically, *FGF23* is responsible for the increased urinary excretion of phosphate characteristic of this disease. Patients with either congenital or acquired disorders that are associated with increased *FGF23* synthesis usually have hypophosphatemia together with normal or low levels of calcitriol, the latter leading to secondary hyperparathyroidism.²⁵² Inasmuch as expression of *FGF23* is downregulated by *PHEX*, inactivating variants of *PHEX* lead to increased production of *FGF23*.^{232,245} In addition, *FGF23* suppresses 1 α -hydroxylation of calcidiol and thus decreases endogenous synthesis of calcitriol impeding intestinal absorption of dietary calcium. *FGF23* inhibits phosphate reabsorption by the renal tubule and when present in excess leads to hyperphosphaturia and consequent hypophosphatemia.²⁵³ *FGF23* is synthesized as a 251 aa protein; after removal of the 24 aa signal sequence, mature *FGF23* circulates as both 227 and 154 aa

PHEX Missense Mutations

PHEX Frameshift Mutations

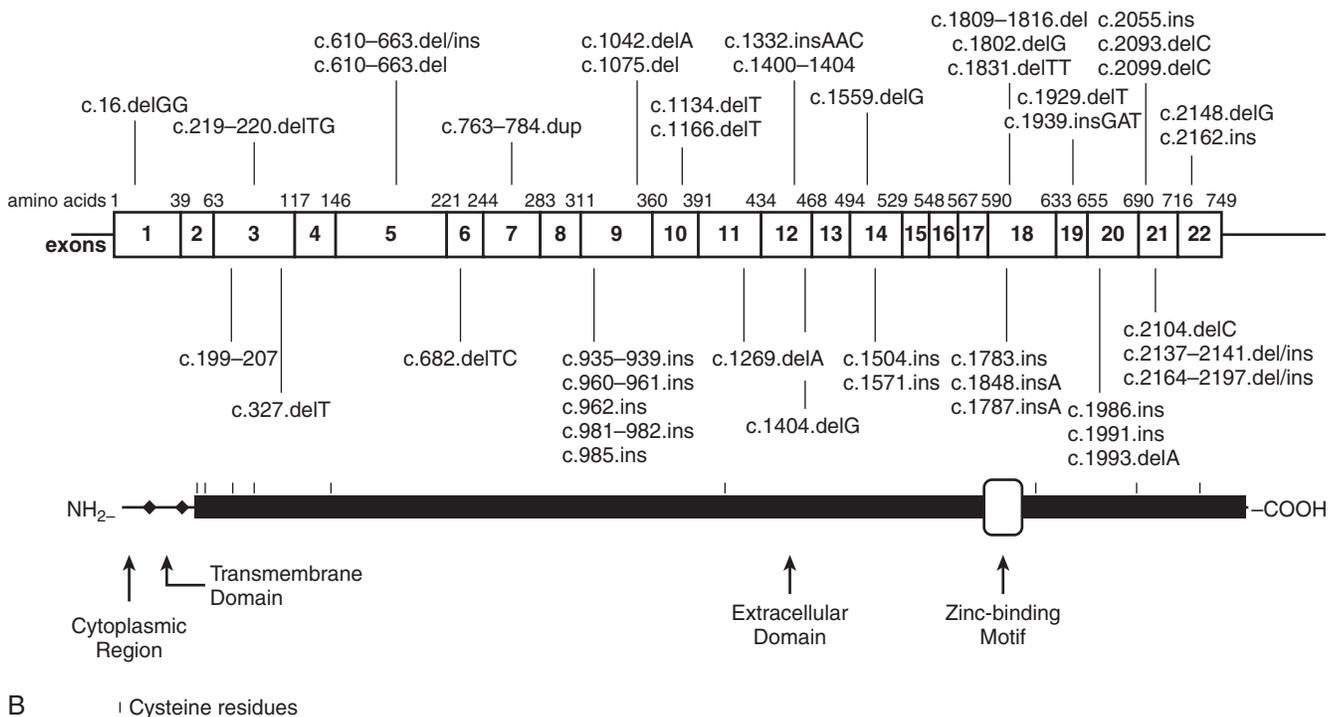

Fig. 20.11 Missense (A) and frameshift (B) mutations in PHEX resulting in X-linked recessive hypophosphatemic rickets. (From PHEXdb, McGill University, Montreal, Quebec, www.phexdb.mcgill.ca/Missense.html and www.phexdb.mcgill.ca/Frameshift.html.)

glycosylated peptides. Acting through fibroblast growth factor receptor 1 (FGFR1) and its coreceptor (α -klotho), FGF23 inhibits sodium-dependent phosphate uptake by renal proximal tubular cells and depresses 25OHD-1 α hydroxylase activity and thus synthesis of calcitriol; thus FGF23 is also a phosphatonin, a family of phosphaturic agents, as is MEPE and serum

frizzled related protein-4 (sFRP4).^{241,254} FGF23 inhibits phosphate reabsorption by downregulating expression of *SLC34A1* and *SLC34A3* that, respectively, encode type II (a and c) sodium-phosphate cotransporters (NPT2a, NPT2c) in the apical membranes of the proximal renal tubule by facilitating their internalization and removal from the renal tubule brush border

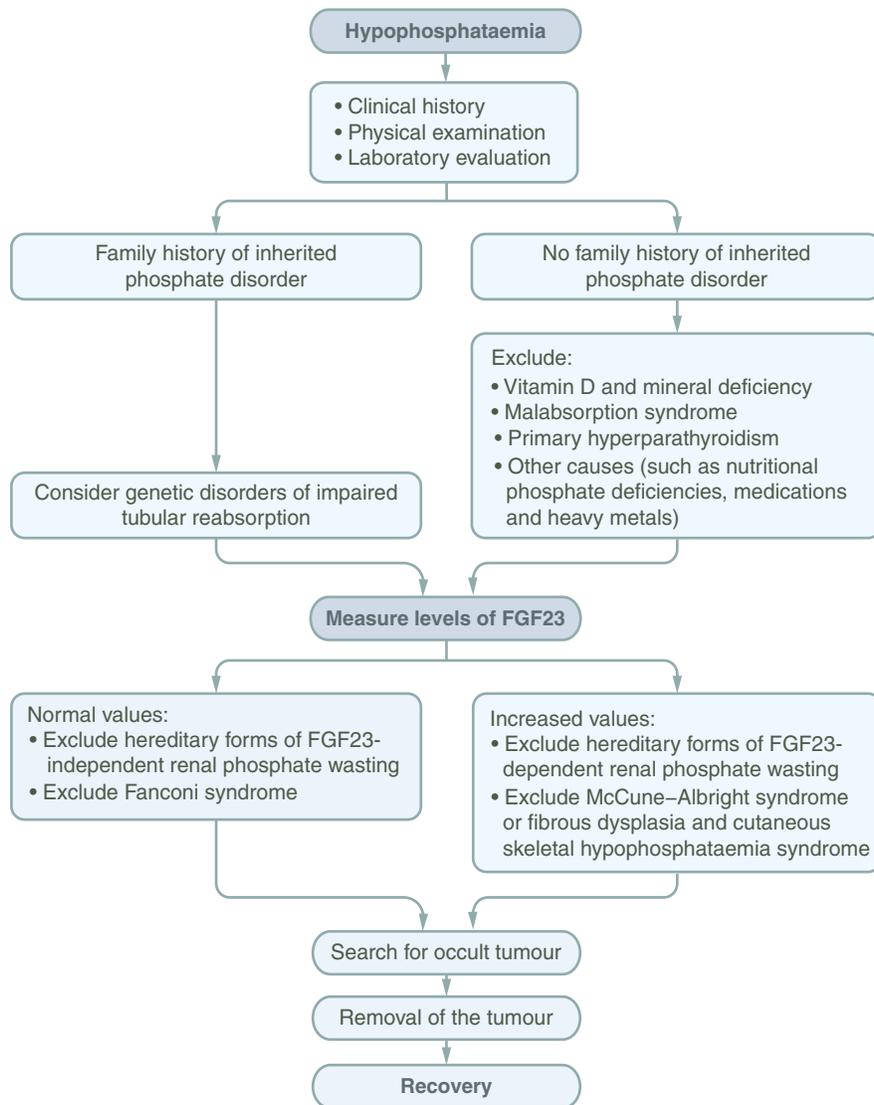

Fig. 20.12 Evaluation of the hypophosphatemic child. (From Minisola, S., Peacock, M., Fukumoto, S., et al. (2017). Tumour-induced osteomalacia. *Nat Rev*, 3, 17044. With permission.)

thereby depressing reabsorption of filtered phosphate.²⁴¹ FGF23 also downregulates expression of *CYP27B1* encoding 25-hydroxyvitamin D-1 α hydroxylase and thus decreases synthesis of calcitriol and induces *CYP24A1* which accelerates inactivation of vitamin D metabolites. *FGF23* is expressed and FGF23 is secreted primarily by osteoblasts and osteocytes; it is coexpressed with *PHEX* in these cells, and *PHEX* inhibits expression of *FGF23*.^{245,246} Although FGF23 is inactivated by cleavage between amino acids Arg179 and Ser180, it is not a biological substrate for *PHEX*.²⁵⁵ Rather, FGF23 is cleaved by subtilisin-like proprotein and furin-like convertases. Inasmuch as *PHEX* decreases expression of *FGF23*, in the absence of *PHEX*, the expression of *FGF23* is increased.²⁴⁵

The diagnosis of XLHR is established when the typical family history (if the patient is not the initial mutant), clinical findings (deformities of the lower extremities, flaring of the metaphyses), roentgenographic (rachitic changes) and laboratory data (hypophosphatemia, hyperphosphaturia, inappropriately low serum level of calcitriol, elevated FGF23 values, normal serum concentrations of PTH, calcium, creatinine, and 25OHD) are present and when other causes of hypophosphatemia and hyperphosphaturia have been excluded (see

Tables 20.8A, 20.8B, 20.9 and see Fig. 20.12). The renal excretion of phosphate may be assessed by measuring the tubular reabsorption of phosphate (TRP) ($1 - \frac{\text{urine phosphate} \times \text{serum creatinine}}{\text{serum phosphate} \times \text{urine creatinine}}$); lower limit of normal ranges between 75% and 85%.²³² In the presence of hypophosphatemia, the TRP is normally greater than 95%. Normally, serum FGF23 values are highest in young infants and decline during childhood and adolescence to adult values (approximately 30 pg/mL using an immunoassay that detects intact FGF23). Concentrations of FGF23 increase with phosphate loading and decline in response to phosphate deprivation.²⁵⁶ However, increased serum concentrations of FGF23 are present in patients with many forms of hypophosphatemic rickets including XLHR, autosomal dominant and recessive hypophosphatemic rickets, the disorders of McCune-Albright, Raine syndrome, opismodysplasia, osteoglyphonic dysplasia, and Jansen type metaphyseal chondrodysplasia, the linear nevus sebaceous syndrome, and tumor-induced rickets/osteomalacia (vide infra).^{232,257} Inasmuch as variants of other genes also result in hypophosphatemic rickets (vide infra), analysis of *PHEX* is occasionally required to confirm the diagnosis of XLHR. Rarely, somatic and germline mosaicism for a mutation

in *PHEX* may mimic autosomal dominant transmission of hypophosphatemic rickets.²⁵⁸

The goals of therapy in XLHR are to correct or minimize rickets/osteomalacia as assessed by resolution of skeletal deformities and radiographic abnormalities and normalization of alkaline phosphatase levels. Restoration of serum phosphate levels is not a treatment goal because doing so increases the risk of secondary hyperparathyroidism and nephrocalcinosis. Traditionally, patients with XLHR have been treated with calcitriol (20–40 ng/kg/d) administered in 2 daily doses with the larger dose given at night when PTH secretion tends to increase and a phosphate preparation (in doses ranging from 40–60 mg/kg/d beginning at a lower dose to avoid diarrhea administered in 4 to 6 divided daily doses depending on age, size, compliance, and response to therapy).²⁴³ Infants and young children may tolerate a phospho-soda solution more readily than other preparation; when able, most older children prefer a chewable phosphate tablet; acidic potassium phosphate products are preferred as they acidify the urine and increase the solubility of calcium phosphate. Calcitriol is available as an oral solution (1 mcg/mL) and as 0.25 and 0.5 mcg capsules. If hypercalcemia or hypercalciuria develops (urine calcium excretion more than 4 mg/kg/d), the dose of calcitriol should be lowered; if the rachitic process exacerbates, addition of an agent that increases renal tubular resorption of calcium (e.g., amiloride) may be added cautiously to the therapeutic program. However, compliance with the intense treatment process is problematic and complications (nephrocalcinosis) frequent. Repeated clinical and laboratory evaluations are necessary to avoid hypercalcemia, hypercalciuria, and nephrocalcinosis, and secondary hyperparathyroidism as high doses of phosphate may lead to counterproductive secondary (and sometimes tertiary) hyperparathyroidism. At least quarterly, clinical evaluation and measurement of serum and urine calcium levels, phosphate, alkaline phosphatase, creatinine, and intact PTH concentrations should be undertaken. Renal sonography before treatment and at 12-month intervals during therapy to identify an early stage of nephrocalcinosis and yearly skeletal radiographs to assess the degree of healing of the rickets are recommended. Development of nephrocalcinosis (and compromise of renal function in some patients) is directly related to the amount of phosphate the patient received as this agent increases counterproductively synthesis of FGF23; hyperoxaluria is also implicated in the pathogenesis of nephrocalcinosis. In a few children with XLHR, short-term administration of cinacalcet, a calcimimetic agent that suppresses secretion of PTH, has been useful in ameliorating the secondary hyperparathyroidism that may occur during treatment of these children. Comanagement of a patient with XLHR with an experienced orthopedist is important, as the orthopedist may prescribe braces or in patients with extreme and progressive deformities perform corrective surgery, such as femoral and tibial hemiepiphysectomies. Defects in the mineralization of dentin lead to dental abscesses and early tooth loss; thus these patients must practice dental hygiene and be monitored by an experienced dentist.

In 2018 the management of XLHR was altered remarkably when it was reported that neutralization of FGF23 with a recombinant human immunoglobulin (Ig)G1 monoclonal antibody to FGF23 (burosumab—administered subcutaneously every 2 to 4 weeks) was therapeutically effective in children with this disorder in whom conventional therapy had been withdrawn.^{259,260} Clinical (decrease in pain, increase in physical activity, increase in growth), radiographic (decline in Thacher rickets severity score), and biochemical improvement (increase in serum levels of phosphate [because of increase in its renal tubular reabsorption] and calcitriol and decline in alkaline phosphatase values) were recorded during administration of burosumab. Whether burosumab will become first-line

therapy for children with XLHR or will be used after a trial of calcitriol/phosphate is yet uncertain. Another agent that might prove useful in the treatment of patients with XLHR is the poly-arginine peptide hexa-D-arginine; in an experimental murine model of XLHR, hexa-D-arginine enhanced degradation of FGF23 into inactive fragments and suppressed FGF23 production thereby improving the primary bone disorder.²⁶¹ Also experimentally, inhibition of CYP24A1, the enzyme responsible for inactivation of calcidiol and calcitriol, substantially improved the skeletal defects in a mouse model of XLHR without altering serum levels of calcium or phosphate.²⁶²

Before the introduction of burosumab, the natural history of patients with XLHR has been that although their birth length was normal, growth rate slowed during the first several years of life leading to progressive shortening of height. Many children with XLHR were significantly short by 5 years of age, although some patients (particularly girls) with minimal involvement grew normally. Treatment of the older child with XLHR with calcitriol and phosphate improved growth rate, in part because of correction of the deformities of the lower extremities. During puberty, gain in height was normal in boys (+28.2 cm) and girls (+24.2 cm) with XLHR; thus the compromised adult stature in XLHR is related to impaired early childhood and preadolescent growth. In a series of 19 closely monitored children with XLHR, initiation of treatment with calcitriol and phosphate at a mean chronological age of 4.2 months (range 7 weeks to 6 months, $n = 8$) resulted in greater adult stature (-0.2 vs. -1.2 SDs) than when treatment began at a mean age of 2.1 years (range 1.3–8.0 years, $n = 11$) with no difference in complication rate (secondary hyperparathyroidism, nephrocalcinosis, craniosynostosis) between the two groups.²⁶³ Despite close adherence to treatment, many children with XLHR have heretofore remained stunted in height primarily because of short lower limbs and retain mild to moderate radiographic signs of rickets and mildly elevated serum alkaline phosphatase activities, although the extent of lower limb deformities is partially ameliorated by good compliance.²⁶⁴ Human GH increases glomerular filtration rate, renal tubular resorption and serum concentrations of phosphate, and the rate of accrual of bone mineral; it accelerates height velocity and the rate of increase in limb length of children with XLHR and may modestly increase adult stature.²⁶⁵ Many untreated adults with XLHR are hypophosphatemic; serum alkaline phosphatase activity is increased and osteomalacia is present on bone biopsy; these patients experience frequent dental abscesses, degenerative hip disease because of deformities of the lower limbs, nephrocalcinosis, and hearing impairment.²⁴² Occasionally, a female with XLHR may be clinically well despite isolated hypophosphatemia. Roentgenographic manifestations of XLHR in adults include degenerative changes in large joints, thickening of the spinous processes and fusion of the vertebrae, and stenosis of the spinal canal. Bone mineralization determined by single and dual photon absorptiometry tends to be normal in adults with XLHR (despite the histomorphological abnormalities), suggesting that most of these subjects are not at increased risk for osteoporotic fractures. However, in approximately 25% of adults with XLHR, there is clinical evidence of osteomalacia, such as progressive lower limb deformities, bone pain, fractures, enesopathies, and pseudofractures. Treatment of selected adult XLHR patients with calcitriol and phosphate may be beneficial. Many adults require osteotomies, replacement of hip and knee joints, and decompressive laminectomies for spinal stenosis.²⁴² Burosumab, the monoclonal antibody to FGF23, may also prove useful in the long-term management of adults with XLHR, although its role in the treatment of adults with this disorder is as yet uncertain.^{243,266}

X-linked recessive hypophosphatemic rickets (OMIM 300554) is associated with hypercalciuria, nephrocalcinosis

and renal failure; it is the consequence of loss-of-function mutations in *CLCN5* (OMIM 300008) encoding a voltage-gated hydrogen/chloride transmembrane exchange transporter expressed in the renal tubule and is independent of FGF23; p. Ser244Leu is a common variant of *CLCN5* associated with this disorder. Inactivating variants of *CLCN5* have also been identified in patients with Dent disease 1 (OMIM 30000—with amino aciduria, proteinuria, glycosuria, hypercalciuria, and nephrocalcinosis) and other renal tubulopathies.

Congenital disorders associated with hypophosphatemic rickets and increased FGF23 production may be related to variants of one of several autosomal or X-linked genes. Children with autosomal dominant hypophosphatemic rickets (ADHR, OMIM 193100) because of activating variants of *FGF23* itself have clinical, biochemical, and radiological evidence of rickets similar to those in patients with XLHR, although in some subjects the extent of disease expression may be minimal or even decline with age; patients with ADHR also manifest muscle weakness as a consequence of hypophosphatemia.^{249,252} Normally, FGF23 is inactivated by cleavage between aa Arg179 and Ser180 by subtilisin-like proteases, but gain-of-function variants of *FGF23* (p.Arg176Gln, p.Arg179Trp) prevent proteolytic cleavage of the intact protein and hence prolong its biological activity leading to persistent hyperphosphaturia and hypophosphatemia with normal or slightly low serum calcium concentrations and low or normal serum levels of calcitriol.^{241,250,257} Because iron deficiency enhances expression of *FGF23*, it is a stimulus to the development of clinical manifestations of ADHR.²³² Treatment involves administration of calcitriol and phosphate with close serial monitoring both for safety and because hyperphosphaturia may occasionally resolve spontaneously. Excessive ectopic synthesis of FGF23 by neoplasms also leads to hypophosphatemic rickets (vide infra).

Hypophosphatemic rickets with hyperparathyroidism (OMIM 612089) is a disorder characterized by onset of hypophosphatemia and diffuse parathyroid hyperplasia in infancy.²⁶⁷ Pathogenetically, it may be the result of excessive production of α -klotho (*KL*, OMIM 604824), the coreceptor with FGFR1(IIIc) for FGF23 that converts FGFR1(IIIc) into the specific FGF23 receptor that stimulates the FGF23 intracellular signaling pathway and its bioactivity. α -Klotho excess appears to enhance the production and bioactivity of FGF23 resulting in hyperphosphaturia and hypophosphatemia and also to mediate parathyroid gland hyperplasia and enhanced synthesis of PTH.²⁵³ In one patient with this disorder, excessive production of α -klotho has been attributed to a spontaneously occurring balanced translocation between the long arms of chromosomes 9 and 13 (–t[9;13][q21.13;q13.1]) possibly involving a promoter region that permitted excessive expression of *KL* and synthesis of α -klotho.²⁶⁷

Mutations in two genes result in autosomal recessive hypophosphatemic rickets (ARHR) that is clinically, biochemically, pathogenetically, and histomorphometrically similar to XLHR but is distinguished by its mode of transmission and development of osteosclerosis at the base of the skull and in calvarial bones. ARHR 1 (OMIM 241520) is caused by loss-of-function biallelic mutations in dentin matrix acidic phosphoprotein-1 (*DMP1*, OMIM 600980), a noncollagenous, serine-rich, bone matrix calcium-binding SIBLING protein synthesized by osteocytes, that also impairs expression of *FGF23*.²³² Without DMP1, osteocytes fail to mature and hydroxyapatite nucleation is hindered; a secondary increase in FGF23 synthesis by osteocytes leads to hyperphosphaturia, hypophosphatemia, and defective bone mineralization.²⁴⁵ In subjects with either ARHR1 or XLHR, bone biopsy reveals a distinct area of nonmineralized osteoid around each osteocyte. Paradoxically, some older patients with ARHR1 develop excessive bone mineralization of the basal and calvarial cranial bones not dissimilar to

that observed in patients with osteopetrosis.²⁴⁹ Type 2 ARHR (OMIM 613312) is the result of biallelic inactivating mutations in ectonucleotide pyrophosphatase/phosphodiesterase 1 (*ENPP1*, OMIM 173335), an enzyme that hydrolyzes extracellular ATP to cyclic AMP, releasing phosphate to form pyrophosphate, an inhibitor of bone matrix mineralization.^{250,257} (ENPP1 and TNSALP together regulate circulating levels of pyrophosphate. Thus the bone disease caused by deficiency of ENPP1 resembles that of hypophosphatasia [vide infra].) Inactivating variants of *ENPP1* result in secondary hypersecretion of FGF23 by an unclear mechanism that leads to hyperphosphaturia and hypophosphatemia, rickets, and ectopic calcifications.²⁵⁷ (Loss-of-function variants of *ENPP1* also result in autosomal recessive generalized arterial calcification of infancy [OMIM 208000].) ENPP1 increases renal expression of *KL* and is required for synthesis of α -klotho in the setting of a high phosphate load, an observation of possible pathophysiologic relevance in patients with ARHR2.²⁶⁸ Increased FGF23 secretion and hypophosphatemic rickets have also been recorded in subjects with osteoglophonic dysplasia (OMIM 166250—craniosynostosis, rhizomelic shortening of the limbs, noncalcifying bone lesions) associated with monoallelic activating mutations in *FGFR1* (OMIM 136350); Jansen type metaphyseal chondrodysplasia (OMIM 156400) caused by constitutively activating mutations in *PTH1R* (OMIM 168468); fibrous dysplasia/McCune Albright syndrome (OMIM 174800) in association with mutations of *GNAS* (OMIM 139320); the Schimmelpenning-Feuerstein-Mims/linear nevus sebaceous syndrome (OMIM 163200) related to postzygotic somatic gain-of-function variants of *NRAS* (OMIM 164790), *HRAS* (OMIM 190020), or *KRAS* (OMIM 190070); and opismodysplasia (a spondylo[epi]metaphyseal dysplasia with delayed ossification, micromelia, platyspondyly, vertebral hypoplasia severe short stature—OMIM 258480) caused by biallelic inactivating variants of *INPPL1* (OMIM 600829) encoding an inositol-1,4,5-trisphosphatase that hydrolyzes inositol-1,4,5-trisphosphate to inositol-4,5-bisphosphate, an important transducer of intracellular signaling.^{232,249,257,269,270} Family with sequence similarity 20, member C (*FAM20C*, OMIM 611061) encodes a phosphorylase whose substrates are the SIBLING family of proteins including DMP1. Loss-of-function mutations in *FAM20C* result in elevated levels of FGF23, leading to hypophosphatemic rickets or the often fatal disorder termed *Raine syndrome* that is associated with congenital sclerotic osteomalacia with cerebral calcifications (OMIM 259775). Raine syndrome is characterized by congenitally increased calcification of all bones (particularly those of the skull resulting in proptosis and midfacial hypoplasia) in association with periosteal formation of bone—a feature not found in patients with osteopetrosis or other sclerosing bone disorders and cerebral calcifications. Many patients with Raine syndrome die in infancy. *FAM20C* encodes a kinase (dentin matrix protein 4) that normally directly phosphorylates DMP1 that then suppresses transcription of *FGF23*; *FAM20C* also phosphorylates the Ser180 residue of FGF23, thereby inhibiting its glycosylation and promoting cleavage and inactivation of FGF23; hence, loss of *FAM20C* results in decreased suppression and inactivation of FGF23 resulting in its prolonged functional activity.^{232,271}

Tumor-induced osteomalacia/rickets is an acquired disorder because of excessive synthesis of one of several phosphatonins by a tumor of mesodermal origin. Many of the mesenchymal neoplasms synthesize and secrete FGF23, resulting in marked hypophosphatemia and impaired bone formation (tumor-induced osteomalacia).^{249,252,272} Other tumors express a form of *FGFR1*, the receptor for FGF23.²⁵² These neoplasms have also synthesized frizzled related protein-4, MEPE, and FGF 7, all of which can increase urinary phosphate excretion and suppress renal synthesis of calcitriol, albeit perhaps not to the same

extent as FGF23.^{254,273} The identification of an FGF23-secreting mesenchymal tumor is dependent on the sensitivity of the FGF23 assay used. Although unusual in children, an 11-year-old girl had significant bone pain and functional limitation associated with biopsy-proven hypophosphatemic osteomalacia/rickets and markedly elevated serum levels of FGF23.²⁷⁴ Following removal of a benign fibrous tumor from a small exostosis on a distal ulnar metaphysis, serum FGF23 concentrations normalized within 7 hours postoperatively and phosphate levels were normal 2 weeks later. Clinical symptoms abated and radiographic and histomorphometric abnormalities resolved within 1 year after surgery. In an 11-year-old boy with severe bone pain, weakness progressing to confinement to a wheelchair, hyperphosphaturia and hypophosphatemia, elevated levels of FGF23 (1874 RU/mL) declined to normal values (43 RU/mL) within 48 hours after removal of an FGF23-containing hemangiopericytoma from his left iliac wing.²⁷² This lesion had not been identified by routine roentgenograms, CT or magnetic resonance imaging, or technetium bone scan; the tumor was demonstrated only by gradient recall echo magnetic resonance imaging (Fig. 20.13). Within 2 weeks after surgery, the lad was walking without assistance, and several weeks thereafter he resumed normal activity.

Although increased production of FGF23 is the most common pathogenetic mechanism of hypophosphatemia, it may also result from disorders that are not associated with increased FGF23 synthesis (see Table 20.8B). ADHR with nephrocalcinosis/nephrolithiasis/osteoporosis type 1 (OMIM 612286) is caused by monoallelic inactivating mutations in *SLC34A1* (OMIM 182309) encoding the sodium-phosphate cotransporter NPT2a (also designated *NaPi-IIa*). Haploinsufficiency of NPT2a in the brush border apical membrane of the proximal renal tubule whose expression is under the inhibitory control of PTH and FGF23 impedes phosphate reabsorption. This disorder is characterized by diminished phosphate reabsorption, hyperphosphaturia, hypophosphatemia, increased synthesis of calcitriol with augmented absorption of intestinal calcium, hypercalcemia with suppression of PTH secretion, hypercalciuria, formation of renal calculi, and osteopenia.²³² Autosomal recessive Fanconi syndrome with hypophosphatemic rickets (OMIM 613388) (also designated Fanconi renal tubular syndrome 2) is caused by biallelic inactivating mutations in *SLC34A1* as is infantile hypercalcemia type 2 (OMIM

616963).^{275,276} Autosomal dominant hypophosphatemia with urolithiasis type 2 (OMIM 612287) is attributable to heterozygous loss-of-function mutations in *SLC9A3R1* (OMIM 604990) that encodes NHERF1—a renal tubular sodium/hydrogen exchange regulatory factor; one of its functions is to bind NPT2a and anchor it to the luminal membrane of the proximal renal tubule; another is to modulate PTH1R signaling in response to PTH. Loss of NHERF1 function leads to its dissociation from NPT2a and subsequent endocytosis of NPT2a resulting in diminished renal tubular reabsorption of phosphate, hyperphosphaturia, and hypophosphatemia.^{250,277} Patients with mutations in *SLC9A3R1* are also osteopenic; serum levels of PTH and FGF23 are normal in these subjects. The pathogenesis and clinical and laboratory characteristics of patients with hypophosphatemic rickets with nephrocalcinosis/nephrolithiasis/osteoporosis type 2 are similar to the type 1 form of this disorder.²³² Hypophosphatemia leads to increased synthesis of calcitriol, intestinal calcium absorption, mild hypercalcemia, hypercalciuria, and nephrolithiasis.²⁷⁸ Patients with mutations in *SLC9A3R1* are also osteopenic. Biallelic loss-of-function mutations in *SLC34A3* (OMIM 609826) encoding NPT2c, the renal tubular phosphate transporter, result in hypophosphatemic rickets with hypercalciuria (OMIM 241530) independently of FGF23.²⁷⁵ This 599 aa protein with eight transmembrane domains is located in the brush border of juxtamedullary proximal renal tubular cells. Loss of activity of NPT2c leads to hyperphosphaturia, hypophosphatemia, increased synthesis of calcitriol with augmented absorption of intestinal calcium, hypercalciuria, formation of renal calculi, and calcium-deficient rickets. Hypophosphatemia leads to increased synthesis of calcitriol and consequently enhanced absorption of ingested calcium, hypercalciuria, and nephrocalcinosis.²³² Heterozygous carriers of inactivating mutations in *SLC34A3* also have moderately increased serum concentrations of calcitriol, hyperphosphaturia, and hypercalciuria but do not have identified metabolic bone disease. Patients with variants of *SLC34A1*, *SLC9A3R1*, or *SLC34A3* may be treated successfully with oral phosphate alone in conjunction with hydration and avoidance of a high-sodium diet, while administration of calcitriol is contraindicated.

Deleterious variants of chloride channel 5 (*CLCN5*, OMIM 300008) result in Dent disease 1 (OMIM 300009) as a result of progressive renal proximal tubule malfunction leading to renal

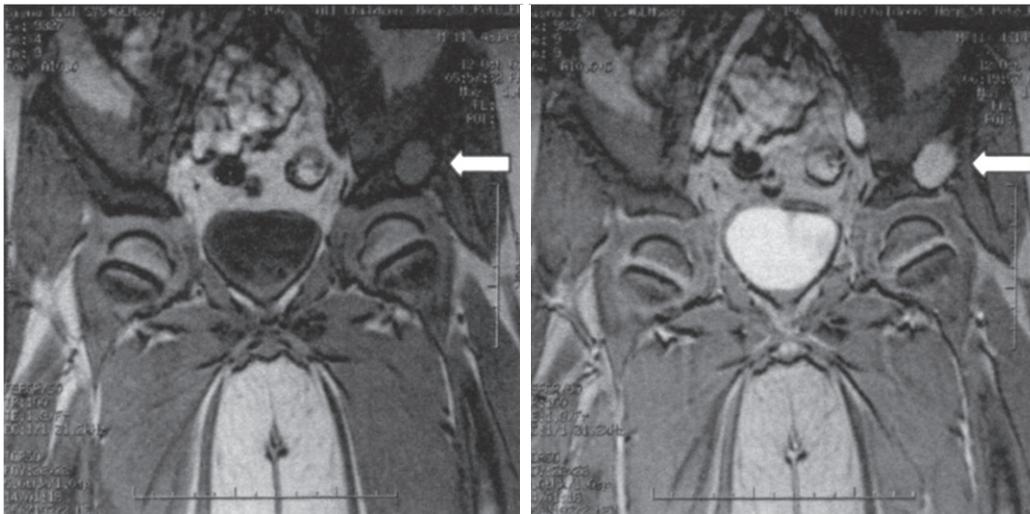

Fig. 20.13 Demonstration by gradient recall echo magnetic resonance imaging of an FGF23-producing hemangiopericytoma in the left iliac wing of an 11-year-old boy with tumor-induced rickets. (From Shulman DI, Hahn G, Benator R, et al. Tumor-induced rickets: usefulness of MR gradient echo recall imaging for tumor localization. *J Pediatr*. 2004;144:381–385.)

failure associated with amino aciduria, proteinuria, hyperphosphaturia, hypophosphatemia, hypercalciuria, glycosuria, and uricosuria and variable associations with metabolic bone disease (hypophosphatemic rickets—OMIM 300554) and nephrocalcinosis (OMIM 310468).²³² Mutations in different domains of this 12 exon, 746 aa transmembrane chloride channel result in varying clinical and biochemical manifestations; the p.Ser244Leu mutation in *CLCN5* has been associated with X-linked recessive hypophosphatemic rickets. The clinical features of Dent disease 2 (OMIM 300555) are similar to those of Dent disease 1, but this disorder is the result of inactivating variants of *OCRL1* (OMIM 300535) encoding a phosphatidylinositol 4,5-bisphosphate-5-phosphatase that affects endocytosis and possibly disrupts the cellular movement of the product of *CLCN5*. The hypophosphatemia of Dent disease patients often can be corrected by oral phosphate supplements. Increased urinary phosphate excretion because of acquired and heritable disorders of the proximal renal tubule is characteristic of the metabolic bone disease that accompanies various forms of the Fanconi syndrome of renal tubular acidosis, glycosuria, and amino aciduria (heritable: cystinosis, tyrosinemia, galactosemia, oculo-cerebral-renal syndrome, fructose intolerance, Wilson disease; acquired: renal transplantation, nephrotic syndrome, renal vein thrombosis, mercury, lead and copper poisoning, outdated tetracycline).²⁷⁹ In addition to hypophosphatemia, acidosis contributes to the pathogenesis of bone disease in Fanconi syndrome by increasing the solubility of the mineral phase of bone and increasing urinary loss of calcium and by impairing conversion of calcidiol to calcitriol. In patients with autosomal recessive Fanconi-Bickel syndrome (OMIM 227810), mutations in *SLC2A2* (OMIM 138160) lead to decreased synthesis of a glucose transporter (*GLUT2*) resulting in impaired utilization of glucose and galactose and consequent accumulation of glycogen in the liver and kidney together with a proximal renal tubular nephropathy. In transgenic mice, deletion of *Slc2a2* results in decreased expression of *Npt2c* in proximal renal tubules.²⁸⁰ Patients with a specific heterozygous missense mutation in *HNF4A* (OMIM 600281) (p.Arg76Trp, c.226C⇒T) also develop the Fanconi-Bickel phenotype as do mice in which *HNF4A* has been eliminated.^{281,282}

Hyperphosphatemia may be caused by intrinsic gene variants or by exogenous causes, such as excessive parenteral administration of phosphate or by the administration of phosphate-containing enemas, acutely increased rate of cellular destruction (crush injuries, rhabdomyolysis, during chemotherapy for malignancy), decreased rate of renal phosphate excretion (renal failure), impaired secretion or action of PTH, and during administration of some bisphosphonates.²⁴¹ Impaired synthesis of FGF23 and/or α -klotho decreases renal tubular excretion of phosphate and impairs renal production of calcitriol leading to hyperphosphatemia, marginal hypocalcemia, and secondary hyperparathyroidism. As a result, there is ectopic calcification of soft tissues—particularly in the periarticular region, a disorder termed *familial hyperphosphatemic tumoral calcinosis* (FHTC). Familial hyperphosphatemic tumoral calcinosis (OMIM 211900) is an autosomal recessive disorder characterized by progressive deposition of calcium phosphate in soft tissues and in periarticular regions of the long bones, manifested clinically by periarticular masses of ectopically deposited calcium and at times by complaints of bone pain.²⁸³ Other sites of ectopic calcification include the brain and blood vessels; radiographically, there is cortical hyperostosis and periosteal reaction involving the long bones. Thus FHTC is the mirror image of ADHR. This disorder is caused by decreased synthesis of FGF23, its rapid degradation, or peripheral resistance to its function related to biallelic inactivating variants of *FGF23*, *GALNT3*, and *KL*, respectively (OMIM 605380, 601756, 604824).^{249,284,285} Thus there may be

decreased synthesis of FGF23 because of loss-of-function mutations in *FGF23* itself, the rapid degradation of FGF23 because it has not been glycosylated because of an inactivating mutation in *GALNT3* encoding UDP-N-acetyl-alpha-D-galactosamine: polypeptide N-acetylgalactosaminyl transferase 3, or tissue non-responsiveness to FGF23 because of an inactivating mutation in *KL*, encoding its coreceptor α -klotho. *GALNT3* is an enzyme that protectively glycosylates FGF23; its loss enables rapid loss of FGF23. In the epithelial cells of the proximal renal tubule, FGF23 interacts with α -klotho-FGFR1 (IIIc)-heparan sulfate to increase renal phosphate excretion by decreasing expression of phosphate transporters. Management of FHTC is limited to ingestion of a low-phosphate diet, administration of intestinal phosphate binding agents (aluminum hydroxide), and increasing urinary phosphate excretion by use of a diuretic, such as acetazolamide; topical application of sodium thiosulfate has been reported to decrease ectopic calcifications on the skin surface perhaps by chelating and thus solubilizing the calcium in these deposits.²⁵² Surgical excision of tumoral masses that impair function, administration of intestinal phosphate binders, agents that increase renal phosphate excretion (acetazolamide), and diets low in calcium and phosphate have been the major therapeutic strategies used in the treatment of these patients.²⁴¹

Disorders of Alkaline Phosphatase Activity. In its most severe forms, hypophosphatasia (OMIM 241500) is an autosomal recessive disorder due to loss-of-function mutations in *ALPL* (OMIM 171760), the gene encoding tissue nonspecific (bone/liver/kidney) alkaline phosphatase (TNSALP); less damaging forms of this disease are transmitted as autosomal dominant traits (OMIM 241510, 146300).^{112,113} TNSALP is a phosphohydrolase expressed on the surface of bone cells that hydrolyzes phosphorylated compounds, such as pyrophosphate, pyridoxyl-5-phosphate, and phosphoethanolamine. Without TNSALP, the phosphate group of inorganic pyrophosphate cannot be removed; inasmuch as pyrophosphate binds to and hinders conversion of amorphous calcium/phosphate to hydroxyapatite, its persistent presence inhibits enlargement of the hydroxyapatite crystal and hence mineralization of collagenous bone matrix. Alkaline phosphatases are zinc and magnesium-dependent alkaline optimum orthophosphoric monoester phosphohydrolases. Bone, liver, and kidney alkaline phosphatase isoforms differ not by their amino acid structure but by their patterns of posttranslational glycosylation.¹¹³ Homotetrameric bone TNSALP is anchored through its carboxyl terminal to the exterior cell membrane of hypertrophic chondrocytes and osteoblasts (i.e., it is an ectophosphatase) by a phosphatidylinositol-glycan moiety. Pathophysiologically, decreased TNSALP activity leads to accumulation of its endogenous substrates—inorganic pyrophosphate, pyridoxal 5'-phosphate, and phosphoethanolamine. Because pyrophosphate is an inhibitor of osteoid mineralization, failure of degradation leads to its accumulation and then to inadequate formation of hydroxyapatite resulting in rickets or osteomalacia, as well as hypercalcemia, hypercalciuria, suppression of PTH synthesis and secretion, increased renal reabsorption of phosphate, and hyperphosphatemia. (The pathophysiology of bone disease caused by TNSALP deficiency resembles that caused by lack of ENPP1 in which disorder pyrophosphate also accumulates but by a distinctively different mechanism [vide supra].) Failure to metabolize pyridoxal 5'-phosphate to pyridoxine leads to pyridoxine-dependent seizures. The clinical severity of hypophosphatasia varies from early lethality to isolated premature shedding of deciduous teeth and is dependent upon the extent of functional TNSALP deficiency as determined by the site(s) of variations in *ALPL*. The younger the age of onset, the more severe is the disease likely to be. The incidence

of severe forms of hypophosphatasia ranges from 1/2500 newborns in Canadian Mennonite families to 1/300,000 in European populations.¹¹³ Currently, there are seven recognized forms or types of hypophosphatasia—six classical forms (numbered 1–6) and one transitional type (here designated type 1A):

1. The perinatal form of hypophosphatasia is identifiable in the fetus in utero and presents clinically at birth with deformities and fractures of the ribs, vertebrae, and limbs; impaired mineralization of the long bones (metaphyseal fraying) and skull (despite which apparent fusion of the sutures of membranous cranial bones may occur resulting in functional craniosynostosis without radiological evidence thereof); and pyridoxine-dependent seizures. Malformations of the skull are associated with intracranial hemorrhage, whereas fractures of the ribs and deformities of the chest wall result in postnatal respiratory insufficiency and apnea. Radiological findings include absent or extremely poor bone mineralization with rachitic deformities, irregular radiolucent extensions into metaphyses, apparently “missing” vertebrae, and protruding midshaft fibular and ulnar bone spurs. The perinatal form of hypophosphatasia has been almost invariably fatal, although the efficacy of enzyme replacement (vide infra) in these patients has not yet been determined;
 - 1A. In the benign prenatal or transitional form of hypophosphatasia, the fetus and neonate manifest skeletal deformities but not radiographic signs of rickets; shortly after birth, there is spontaneous and substantial improvement; findings that distinguish this less severe type of hypophosphatasia are fetal crowding, normal fetal bone mineralization, and appropriate chest volume; this form of hypophosphatasia may be associated with either monoallelic or biallelic mutations in *ALPL*,^{286,287}
2. The infantile form (OMIM 241500) becomes clinically apparent in the first 6 months of life and is characterized by anorexia, impaired linear growth and weight gain, deformities of the long bones and rib cage, widely “open” fontanelles and sutures (calvarial hypomineralization) with functional craniosynostosis with increased intracranial pressure (manifested by prominence of the anterior fontanelle, proptosis, and papilledema), muscular weakness, developmental delay, pyridoxine-dependent seizures, hypotonia, constipation, hypercalcemia, hypercalciuria, nephrocalcinosis, early shedding of deciduous teeth, and radiographic evidence of rickets with marked skeletal hypomineralization; the neonatal and infantile forms of hypophosphatasia are transmitted as autosomal recessive disorders; until the development of enzyme replacement therapy, the majority of patients with perinatal hypophosphatasia and 50% of those with infantile hypophosphatasia died of respiratory failure before their first birthday (vide infra);
3. Patients with the childhood form of hypophosphatasia (OMIM 241510) are clinically heterogeneous; they are well as neonates, but at and after 6 months of age, abnormalities of varying severity may become apparent including: isolated premature shedding of deciduous teeth, craniotabes, prominence of the costochondral junctions, flaring of the metaphyses, and genu valgus and/or varum. Radiologically, there may be signs of rickets with metaphyseal flaring, intrusion of areas of radiolucency into the metaphyses, deformation of the limbs, osteopenia, and craniosynostosis. These patients may improve spontaneously during puberty and or may evolve into the adult form of this disease. These patients have responded well to enzyme replacement therapy (vide infra);
4. The adult form of hypophosphatasia (OMIM 146300) may be subclinical and identified only during study of a

family with an offspring with a more significant form of hypophosphatasia; the parent may have a history of premature loss of deciduous teeth, osteomalacia with increased susceptibility to recurrent fractures predominantly of the metatarsal bones, pseudofractures of the proximal femur, chondrocalcinosis, or pseudogout because of articular deposition of calcium pyrophosphate dihydrate crystals; subtrochanteric femoral pseudofractures may be demonstrated radiographically;

5. Odontohypophosphatasia (included in OMIM 146300) is manifested only by premature shedding of primary teeth before 5 years of age because of decreased mineralization of cementum without radiological skeletal abnormalities; periodontitis may develop; the childhood and adult forms of hypophosphatasia and odontohypophosphatasia are usually (but not invariably) transmitted as monoallelic, autosomal dominant disorders;
6. Pseudohypophosphatasia is phenotypically and biochemically similar to classic type 2 infantile hypophosphatasia but serum alkaline phosphatase activity *in vitro* is normal, indicating that in this disorder enzyme activity toward artificial substrates in high pH solutions is preserved but alkaline phosphatase activity toward endogenous substrates at pH 7.4 is abnormal.¹¹²

In addition to the site(s) of mutation of *ALPL*, the clinical severity of hypophosphatasia is related inversely to the age at which skeletal disease is evident and to individual biological (possibly epigenetic) factors that affect the expression of the disease with wide individual variability even in family members with the identical *ALPL* mutation(s). In the lethal perinatal form of hypophosphatasia, missense, nonsense, and donor splice site mutations and frameshift deletions in *ALPL* cluster in crucial segments of the protein within (p.Ala94Thr, p.Arg167Trp) or near (p.Gly103Arg, p.Gly317Asp) its catalytically active, enzymatically functional site or at the dimeric interface (p.Ala23Val, p.Arg374Cys) or they may impair movement of TNSALP to its active transmembrane site.^{112,113} Mutations may interrupt binding of TNSALP to the phosphorylated ligand or destabilize attachment of necessary cofactors, such as zinc or magnesium. *ALPL* mutations associated with the childhood form of hypophosphatasia (p.Arg119His, p.Asp361Val) tend to cluster on the three-dimensional surface of the enzyme molecule at sites that relate to its tethering to the cell surface or its formation of tetramers; such variants may retain substantial residual bioactivity. In some patients with moderately severe hypophosphatasia, heterozygotic mutations in *ALPL* (p.Gly46Val, p.Arg167Trp, p.Asn461Ile) exert a dominant-negative effect on the intact TNSALP dimer; these mutations have been clustered at the enzyme active site or at the domain (s) involved with dimerization, tetramerization, or membrane anchoring. Odontohypophosphatasia has been associated with heterozygotic mutations in *ALPL* (p.Pro91Leu, p.Ala99Thr).

After identification of clinical and radiological findings of rickets, the diagnosis of hypophosphatasia is suggested by the presence in the patient of paradoxically low values of circulating alkaline phosphatase (related to age standards) and confirmed by identifying the individual genetic variant of *ALPL* responsible for the disease. In other forms of rickets, alkaline phosphatase values are substantially increased (see Table 20.9). In addition, there are increased serum concentrations of pyrophosphate (controls <200 μmol/g of creatinine) and pyridoxal-5'-phosphate (~5000 nM) and elevated urinary excretion of phosphoethanolamine (controls <15 years of age 83–222 μmol/g of creatinine). Serum concentrations of calcium and phosphate are often elevated in patients with the perinatal and infantile forms of the disease, because intestinal absorption of calcium and renal tubular reabsorption of

phosphate are normal while the bone formation rate is depressed; calcium values are usually normal in the childhood and adult forms of hypophosphatasia.^{112,113} Serum levels of PTH are normal or low; there is no evidence of secondary hyperparathyroidism. Although serum alkaline phosphatase activity in vitro is normal in patients with pseudohypophosphatasia, it is functionally inadequate in vivo—perhaps because the TNSALP protein is sequestered within the cell because of a defect in its transport to the cell surface or because the protein is active with artificial substrate but not with natural substrates at physiological pH. Other disorders associated with hypophosphatasemia include the milk-alkali syndrome, hypothyroidism, hypercortisolemia, vitamin D toxicity, vitamin C deficiency, starvation, magnesium, zinc, or copper deficiency, celiac disease, profound anemia, and massive transfusion.^{112,113} The prenatal diagnosis of hypophosphatasia may be considered in a fetus in whom ultrasonography has demonstrated short ribs and long bones, cupping of the metaphyses, osseous spurs, patchy ossification, and demineralization of the skull and thoracic spine and corroborated by analysis of fetal DNA present in maternal circulation.²⁸⁸ To be included in the differential diagnosis of a fetal sonogram with these findings are achondrogenesis and osteogenesis imperfecta type II.

Treatment of hypophosphatasia depends on the severity of the disease. Supportive measures are appropriate, but administration of bisphosphonate agents are usually contraindicated. Administration of even small doses of vitamin D or its metabolites should be avoided as these patients easily develop hypercalcemia. Hypercalcemia in infants with hypophosphatasia responds to bisphosphonates and transiently to calcitonin. Seizures may be responsive to pyridoxine administration. Milder adult forms of hypophosphatasia may be responsive to teriparatide (rhPTH¹⁻³⁴).²⁸⁹ Recombinant, mineral-targeted human TNSALP (alfotase alfa) has been used successfully to treat the perinatal, infantile, and childhood forms of hypophosphatasia.^{112,290} Alfotase alpha is a biosynthetic human recombinant protein consisting of two identical amino acid chains linked by two disulfide bridges containing the catalytic ectodomain of TNSALP fused to the human IgG1 Fc domain and a terminal deca-aspartate motif that targets bone. It has proven extraordinarily effective in the treatment of patients with the perinatal and infantile forms of hypophosphatasia for up to 7 years.¹¹⁴ Administration of this compound to 11 such patients was followed by radiographic healing of rickets after 24 weeks of treatment; in addition, motor development and pulmonary function improved. There were no serious adverse effects recorded in this study. This agent has proven effective in and has been approved for the treatment of children, adolescents, and adults with hypophosphatasia, as well as infants.^{290,291} A scoring system has been developed for assessment of the changes over time in the skeletal abnormalities of patients with hypophosphatasia treated with alfotase alpha.²⁹²

Hyperphosphatasia may be a normal physiological variant or a biochemical sign of disease. Serum bone-specific alkaline phosphatase activity normally increases during puberty and in response to skeletal injuries and reflects increased osteoblastic activity. Transient increase in serum alkaline phosphatase activity may also be observed in children with viral infections (including human immunodeficiency virus), after liver or kidney transplantation, or during treatment of leukemia/lymphoma.²⁹³ Hyperphosphatasemia is also present in patients with juvenile Paget disease/hyperostosis corticalis deformans juvenilis (OMIM 239000), familial expansile osteolysis (OMIM 174810), and osteosclerotic hyperostosis corticalis generalisata/van Buchem disease (OMIM 239100). Benign transient hyperphosphatasemia of infancy and early childhood is encountered in clinically well infants and children less than 5 years of age (median age 16 months); serum activities of both

bone and liver alkaline phosphatase isoforms are increased (despite absence of liver or bone disease); it is a self-limited process with alkaline phosphatase values returning to normal within several months.^{293,294} Transient hyperphosphatasemia (alkaline phosphatase values >1000 U/L) has been reported to occur in approximately 2% to 3% of children less than 2 years of age.²⁹⁵ It has been suggested that benign and transient hyperphosphatasemia are the consequence of excessive sialylation of alkaline phosphatase that delays its degradation and extends its half-life, but the reason for the excessive sialic acid content of the molecule is uncertain.²⁹³ Rarely, hyperphosphatasemia may be familial and transmitted as a benign autosomal dominant trait. Occasionally, an adolescent with persistent, nonfamilial, benign hyperphosphatasemia may be encountered. Hyperphosphatasia associated with mental retardation is a disorder characterized by developmental delay, seizures, hypotonia, and hyperphosphatasemia of diverse genetic pathogenesis (OMIM 239300). The type 1 (of 6) form of this disorder is caused by biallelic loss-of-function mutations in phosphatidylinositol glycan anchor biosynthesis class V protein (PIGV, OMIM 610274), a glycolipid that attaches proteins including alkaline phosphatase to the surface of a cell.²⁹⁶

Chronic Kidney Disease-Mineral and Bone Disorder

Chronic kidney disease-mineral and bone disorder (CKD-MBD) is the term used to characterize the aberrations in calcium and phosphate metabolism, PTH and vitamin D synthesis and secretion, skeletal homeostasis, and ectopic vascular, extravascular, and cardiac calcifications that are encountered in patients with impaired renal function.²⁹⁷⁻³⁰⁰ CKD-MBD replaces the designation of renal osteodystrophy that pertains solely to the pathological changes present in the bones of patients with chronic renal failure. The major skeletal consequences of chronic renal disease are related to bone resistance to the actions of PTH, subnormal synthesis of calcidiol and calcitriol, and the adverse effects of elevated levels of FGF23, sclerostin, and Dickkopf-related protein 1 (DKK1) on bone formation.^{284,299} The bone disease of chronic renal failure leads to decreased growth, bone mineralization and strength, and increased risk of fracture. It may be characterized as hyperdynamic—associated with high turnover of bone and osteitis fibrosa related to secondary hyperparathyroidism, hypodynamic or low turnover, or adynamic—characterized histologically by little fibrosis, subnormal cellularity, bone turnover rate, and bone volume, but paradoxically normal bone mineralization and PTH values related to aggressive therapy with calcium antireabsorptive agents (e.g., bisphosphonates or antibodies to RANKL, or proanabolic agents [e.g., rhPTH¹⁻³⁴, antibodies to sclerostin]), or most commonly a mixture of the high and low turnover forms, termed *mixed renal osteodystrophy*.^{284,299,300}

As renal function declines, the production of both FGF23 and PTH increases. The secretion of FGF23 increases relatively early in patients with CKD when phosphate retention first occurs—even when the glomerular filtration rate exceeds 80 mL/min/1.73 m².³⁰¹ Thus in patients with CKD-MBD serum concentrations of FGF23 rise before renal function declines and before serum levels of phosphate rise, urinary phosphate excretion increases—initially maintaining normal serum phosphate values. Increasing production of FGF23 as renal failure progresses contributes to declining renal tubular synthesis of calcitriol and lower intestinal calcium absorption. As the glomerular filtration rate progressively declines, urinary phosphate excretion is impaired, leading to its intracellular and extracellular accumulation, hyperphosphatemia (when the glomerular filtration rate falls <20 mL/min/1.73 m²), and modest hypocalcemia.²⁹⁸ The secretion of PTH increases when

the glomerular filtration rate declines to values less than 70 mL/min/1.73 m². Increasing serum concentrations of phosphate resulting in hyperphosphatemia (when the glomerular filtration rate falls <20 mL/min/1.73 m²), falling levels of calcium (because of both decreased intestinal absorption of this cation attributable to deficiency of both calcidiol and calcitriol, and the need to maintain a constant calcium x phosphate product), and rising levels of FGF23 that exert a direct stimulatory effect on *PTH* expression lead to secondary increase in *PTH* generation and when uncontrolled to tertiary hyperparathyroidism. Other factors that contribute to the development of parathyroid chief cell hyperplasia and secondary hyperparathyroidism in CKD-MBD include downregulation of the expression of *CASR* in uremic parathyroid glands (resulting in increase of the set point concentration at which calcium depresses *PTH* expression) and skeletal insensitivity to *PTH*. Phosphate may also slow the rate of degradation of *PTH* mRNA within the parathyroid gland and exert a direct enhancing effect on the growth of parathyroid glands as well. Because calcitriol inhibits parathyroid gland growth and function, decrease in its synthesis also results in increased proliferation of parathyroid chief cells and synthesis of *PTH*. In the presence of elevated *PTH* secretion and various cytokines (IL-1, -6, -11, TNF, macrophage-colony stimulating factor [M-CSF]), osteoclastogenesis and the rates of bone resorption and formation are increased. Acidosis contributes to the dissolution of the mineral phase of bone directly and by impairing osteoprotegerin-mediated inhibition of osteoclast generation. Vascular and soft tissue calcification also occur in subjects with chronic renal failure.²⁹⁹

Chronic renal disease and its associated metabolic bone disease in children may be clinically silent except for failure of linear growth; as the disease progresses, deformities of the extremities, slipped epiphyses, fractures, bone and joint pain, muscular weakness, and lassitude develop. In patients in whom the rate of bone formation is diminished and the volume of unmineralized bone (i.e., osteomalacia) increased, the process has been caused by accumulation of aluminum at the mineralization front; with discontinuation of aluminum-containing phosphate binders development of osteomalacia in renal failure is now unusual.¹⁴³ In the absence of osteomalacia, adynamic bone disease in chronic renal failure is the result of decreased *PTH* generation because of improved control of serum phosphate levels, increased calcium stores, higher levels of *PTH*⁷⁻⁸⁴ and other carboxyl terminal fragments of *PTH* that inhibit bone resorption, and other factors that affect the tissue response to *PTH*. The cardiovascular complications (hypertension, ectopic vascular calcifications, uremic vasculopathy, cardiomyopathy) that develop in children with CKD-MBD begin before the need for and progress during dialysis and are the primary cause of death in children and adolescents with CKD.²⁹⁷ Hyperphosphatemia, secondary hyperparathyroidism, and elevated levels of FGF23 adversely affect the cardiovascular system. Children with autosomal dominant polycystic kidney disease may be hypophosphatemic with decreased renal tubular reabsorption of filtered phosphate perhaps related to resistance to the biological activity of FGF23.³⁰²

Biochemically, CKD-MBD is marked primarily by hyperphosphatemia, low-normal serum calcium levels, and increased serum *PTH* and FGF23 concentrations and TNSALP activity. Serum concentrations of the bone turnover markers—bone alkaline phosphatase, tartrate-resistant acid phosphatase (TRAP) 5b, and carboxyl-terminal FGF23 are increased, whereas sclerostin levels are reduced in children with CKD.³⁰³ Radiographic signs of rickets, low bone mass, and pseudofractures are often present in children with renal osteodystrophy. After clinical assessment, the evaluation of bone disease in children with chronic renal disease includes examination of skeletal roentgenograms and quantitation of

BMC and BMD by DXA and/or peripheral quantitative computed tomography (pQCT) and may require biopsy of the iliac crest followed by histomorphometric analyses of the tissue. Therapeutically, the goals in treating a child with chronic renal failure are to minimize the adverse systemic effects of CKD-MBD; to maintain (near) normal serum calcium, phosphate, and alkaline phosphatase values; and to prevent the development or progression of secondary hyperparathyroidism. Treatment of renal bone disease must be individualized; it includes appropriate intake of dietary calcium, supplemental vitamin D or calcidiol and calcitriol, decreased intake of dietary phosphate and administration of agents that bind intestinal phosphate and prevent its intestinal absorption, phosphaturic drugs, and at times subtotal parathyroidectomy.²⁹⁹ Calcitriol decreases the rate of bone formation in patients with chronic renal insufficiency by inhibiting osteoblast differentiation/function, decreasing *PTH* synthesis, altering degradation of *PTH* within the parathyroid glands, and decreasing expression of *PTH1R*. Calcium-containing oral phosphate binders may also be useful. Dialysis fluids must be prepared with aluminum-free water. When indicated, suppression of *PTH* secretion may be further achieved with the use of calcitriol analogues, such as paricalcitol or of a synthetic ligand of the CaSR—cinacalcet hydrochloride.^{143,298} Experimentally, although immunoneutralization of FGF23 in a rat model of CKD-MBD led to decrease in *PTH* secretion, increased calcitriol and calcium concentrations, and improved bone formation, there was increase in aortic calcification and mortality rate in the anti-FGF23-treated animals.³⁰⁴ Thus suppression of FGF23 secretion in patients with CKD might have paradoxically unwanted consequences. Even after successful renal transplantation, secondary hyperparathyroidism may persist for months or years—its extent and intensity reflecting the severity and duration of chronic renal failure before renal transplantation, development of nodular or monoclonal hyperplasia of the parathyroid glands, and the 20-year life span of the parathyroid chief cell. Five years after renal transplantation during childhood, serum concentrations of PICP, osteocalcin, and ICTP remain significantly increased indicating accelerated bone turnover rate, whereas areal and volumetric BMDs at the distal third of the nondominant radius are normal for height but subnormal for age.³⁰⁵ Hypercalcemia and persistent secondary or tertiary hyperparathyroidism requiring parathyroidectomy may become apparent in children after renal transplantation. The osteopenic effects of glucocorticoids and immune suppressive agents, such as cyclosporin, are observed in postrenal transplantation patients as well.

Disorders of Bone Mineralization

Bone mineralization may be depressed or exaggerated by dysfunction of either osteoblasts or osteoclasts. Abnormalities of osteoblast function result in either impaired (e.g., osteoporosis, osteogenesis imperfecta) or exaggerated bone mineralization (e.g., osteosclerosis, osteopetrosis). Thus in patients with the osteosclerotic disorder, hyperostosis corticalis generalisata/van Buchem disease type 1 (OMIM 239100), decreased expression of *SOST* encoding sclerostin (OMIM 605740, chr. 17q21.31), an inhibitor of WNT signaling by its interaction with the WNT coreceptors low-density lipoprotein receptor-related proteins (LRP) 5 and 6, is associated with enhanced osteoblast function and increased bone mineralization. Although derived from a common hematopoietic stem cell, there are a number of osteoclast subtypes with unique physiological profiles that reflect: the site at which they act (intramembranous or endochondral bone, cartilage); the remodeling process in which they participate (targeted—to sites of bone

replacement, stochastic—hormonally [PTH, calcitonin, calcitriol]-mediated for maintenance of eucalcemia); the type of bone (cortical, trabecular) upon which they act; and the time of day (diurnal variation) at which the osteoclast is most active.³⁰⁶ Decreased osteoclast formation or function results in increased bone mass and various forms of osteopetrosis, whereas augmented osteoclast activity leads to decreased bone mass because of osteolysis. In a number of bone disorders, skeletal areas of both increased and decreased bone mineralization may be present. Juvenile Paget disease/hyperostosis corticalis deformans juvenilis (OMIM 239000) is a hyperphosphatase-mic disorder that often begins in early childhood and is characterized clinically by expanded and bowed extremities, nontraumatic fractures of the long bones, kyphosis, macrocephaly, and muscular weakness; this disorder may progress to wheelchair dependence.³⁰⁷ Serum levels of alkaline phosphatase are markedly increased, a coupled response to increased osteoclastic action. Radiographic skeletal abnormalities include cortical thickening, both osteosclerosis and osteopenia, coarse trabeculations, and progressive skeletal deformities. The disorder is caused by biallelic loss-of-function mutations of *TNFRSF11B* (OMIM 602643) encoding osteoprotegerin, a member of the TNF receptor superfamily that functions as a decoy acceptor for and consequently is an inhibitor of RANK (*TNFRSF11*, OMIM 602642), the stromal cell-osteoblast-derived osteoclastogenic factor. Normally, osteoprotegerin inhibits osteoclastogenesis; hence, inactivating mutations of *TNFRSF11B* are associated with enhanced osteoclastogenesis and osteoclastic activity. The severity of juvenile Paget disease depends on the site of mutation in *TNFRSF11B*—those that result in deletion of the entire gene or those in the ligand binding domain that involve loss of cysteine residues result in marked clinical disease.³⁰⁸ Treatment with recombinant osteoprotegerin has resulted in clinical and radiological improvement as has administration of bisphosphonates, but the latter agents are associated with risk of substantial hypocalcemia.³⁰⁹ Familial expansile osteolysis (OMIM 174810) and early-onset familial Paget disease of bone (OMIM 602080) are autosomal dominant, monoallelic disorders that are pathophysiologically similar to juvenile Paget disease although clinically and etiologically distinct. These two disorders are caused by monoallelic gain-of-function mutations of the gene (*TNFRSF11A*, OMIM 603499) encoding RANK that result in an increase in NF- κ B signaling as a consequence of which there is augmented osteoclastogenesis.³¹⁰ In adolescents with familial expansile osteolysis, focal areas of increased bone turnover in the appendicular skeleton appear in the second decade of life followed by medullary expansion, pathological fractures, and skeletal deformities; deafness and premature loss of dentition may occur in these subjects. Patients with either familial expansile osteolysis or early-onset Paget disease of bone demonstrate focal areas of osteolytic and hyperostotic bone, premature loss of teeth, and deafness. Increased activity of mutant RANK is thought to be caused by heterozygous insertional duplications of 18 or 27 base pairs within the signal peptide region of exon 1 of *TNFRSF11A*.³¹¹ However, because the mutant forms of RANK are trapped in the endoplasmic reticulum and unable to interact with RANKL directly, the mechanism(s) through which these heterozygous mutations increase NF- κ B-mediated osteoclastogenesis are uncertain.^{310,312} It has been hypothesized that mutant RANK may be able to interact with residual intact RANK and either slow its rate of degradation or prolong its interaction with RANKL.³¹⁰ Conversely, loss-of-function mutations of *TNFRSF11A* are associated with autosomal recessive, osteoclast-poor osteopetrosis type 7 and hypogammaglobulinemia (vide infra).^{310,313} Inactivating mutations in *TNFRSF11* encoding RANKL are associated with osteoclast-poor osteopetrosis type 2 (vide infra).

Low Bone Mass

Low bone mass or osteoporosis is often associated with increased fracture risk, although in some disorders with high bone mass fracture rate is increased because abnormal bone microarchitecture leads to decreased bone strength (e.g., osteopetrosis, pyknodysostosis—vide infra).³¹⁴ Some 50% of boys and 40% of girls will sustain a traumatic fracture during childhood or adolescence (peak incidence between 11 and 12 years in girls and 13 and 14 years in boys), most often at the distal radius because of transient decline in cortical strength at this site.^{314,315} It is important to distinguish a high-impact traumatic fracture from one that is the result of increased bone fragility, such as compression vertebral fractures, low-impact fractures, and “spontaneous” femoral fractures caused by a primary or secondary disorder of bone mineralization (Tables 20.10A, 20.10B, 20.10C). In adults, osteopenia and osteoporosis (“porous bone”) are terms that designate states of reduced bone mass and matrix, abnormal bone microarchitecture, and decreased bone strength that increase the risk for fracture; osteomalacia refers to decrease in the mineral phase of bone.^{316,317} Osteoporosis in adults (primarily postmenopausal women) is defined by the World Health Organization (WHO) as an areal BMD at a specific bone site that is -2.5 or more SDs below the mean peak young adult value for gender (T score ≤ -2.5). Postmenopausal osteoporosis is usually the consequence of an increase in the rate of bone resorption relative to that of bone formation because of estrogen deficiency. In adults, osteopenia is present when the areal BMD lies between -1.1 and -2.4 SD below the mean peak young adult value for gender (T score -1.1 to -2.4), and a normal areal BMD is one that is not more than one SD below or above the mean peak young adult value (T score -1.0 to $+1.0$). When the areal BMD is more than $+2$ SD above the mean for age and gender (T score $> +2$), bone mass is considered high. Because in premenopausal women, areal BMD alone is not a good assessor of fracture risk, the International Society for Clinical Densitometry (ISCD) recommends that the term *osteoporosis* be restricted to those patients with both low areal BMD (as defined by a BMD Z score of < -2.0 , i.e., one that is below -2 SDs for age and gender-matched control subjects) and a history of low-impact (fragility) fractures.³¹⁸ Women with areal BMDs that are below -2 SDs but have no history of fracture are designated as having an areal BMD that is “below expected range for age;” the use of the term osteopenia is eschewed in this population. The International Osteoporosis Foundation (IOF) has defined osteoporosis in young adults as a vertebral or hip areal BMD T score that is below -2.5 and is associated with a disorder that adversely affects bone mineralization.³¹⁶ Both groups agree that in young adults, the presence of osteoporosis is not defined by low BMD alone. Many of the diseases that lead to osteoporosis in young adults begin during childhood and adolescence. The WHO and IOF-designated criteria for low or high bone mass do not apply to children and adolescents in whom variability in chronological and bone ages, height, weight, and stage of sexual maturation, as well as gender and ethnicity affect bone mineralization. (The term osteopenia is not used when discussing bone mineralization in infants, children, and adolescents.)

In children and adolescents, osteoporosis or low bone mass is considered present when the child/adolescent has sustained: (1) one or more low-traumatic vertebral fractures in the absence of local disease or high-impact injury or (2) two or more low impact fractures of the long bones (fall from standing height or less) if less than 10 years of age or three or more low-impact fractures before 19 years of age together with whole body minus (–) head and posterior-anterior lumbar spine BMC/BMD as assessed by DXA that are minus (–) 2 SD

TABLE 20.10A Disorders of Bone Mineralization: Low Bone Mass**I Primary/Genetic**

- A Osteogenesis imperfecta (Types I–XIII—see Table 20.10B)
- B Osteoporosis-pseudoglioma syndrome (*LRP5*)
- C Idiopathic juvenile osteoporosis (*LRP5*)
- D Marfan syndrome (*FBN1*)
- E Ehlers-Danlos syndrome (*COL1A1*)
- F Homocystinuria (*CBS*)
- G Fibrous dysplasia (*GNAS*)
- H Glycogen storage disease type I (*G6PC*)
- I Galactosemia (*GALT*)
- J Menkes kinky hair syndrome (*ATP7A*)
- K Hypophosphatasia (*ALPL*)
- L Rickets (genetic forms—see Table 20.8B)

II Secondary

- A Suboptimal nutrition
 - 1 Socioeconomic
 - 2 Cultural
 - 3 Excessive exercise (athletic amenorrhea)
 - 4 Anorexia nervosa
 - 5 Vitamin D deficiency
 - 6 Malabsorption—cystic fibrosis, celiac disease, biliary atresia, “short gut” syndrome, postgastric bypass surgery
 - 7 Idiopathic hypercalciuria
- B Endocrinopathies/metabolic diseases
 - 1 Constitutional delay in growth and sexual development
 - 2 Hypogonadism
 - a Hypergonadotropic—gonadal dysgenesis (Turner, Klinefelter syndromes), aromatase deficiency, estrogen receptor deficiency
 - b Hypogonadotropic—Kallmann syndrome, excessive physical activity, hyperprolactinemia
 - 3 Diabetes mellitus
 - 4 Hyperglucocorticoidism
 - 5 Hyperthyroidism, excessive exogenous thyroxine
 - 6 Hyperparathyroidism
 - 7 Panhypopituitarism
 - 8 Inborn errors of metabolism—homocystinuria, lysinuric protein intolerance, propionic aciduria, methylmalonic aciduria, glycogen storage disease, galactosemia
- C Disuse/immobilization
 - 1 Fracture
 - 2 Cerebral palsy
 - 3 Duchenne muscular dystrophy
 - 4 Quadriplegia/paraplegia
 - 5 Spina bifida
 - 6 Weightlessness
- D Inflammatory diseases
 - 1 Juvenile arthritis
 - 2 Systemic lupus erythematosus
 - 3 Dermatomyositis
 - 4 Inflammatory bowel disease
- E Drugs
 - 1 Glucocorticoids, immune suppressants, anticonvulsant drugs, antiretroviral therapy, warfarin, lithium, methotrexate, cyclosporine
 - 2 Alcohol, tobacco
 - 3 Aromatase inhibitors, medroxyprogesterone
 - 4 Protein pump inhibitors
- F Chronic illness
 - 1 Hemoglobinopathies—thalassemia, sickle cell disease
 - 2 Hemophilia
 - 3 Cranial radiation
 - 4 Renal failure, postrenal transplantation, nephrotic syndrome
 - 5 Malignancy—leukemia, lymphoma, cytotoxic chemotherapy
 - 6 Human immunodeficiency virus infection—highly active antiretroviral therapy
 - 7 Severe burns

TABLE 20.10B Clinical/Phenotypic Classification of Osteogenesis Imperfecta (OI)

Type	Clinical & Skeletal Manifestations	Transmission	Genetic Variants ¹
1	Mild—near normal stature; wormian skull bones, vertebrae are biconcave & flattened, femoral bowing on occasion, increased joint mobility, blue sclerae, brittle teeth (dentinogenesis imperfecta), deafness	Autosomal dominant	<i>COL1A1</i> , <i>COL1A2</i>
2	Lethal perinatally, multiple fractures, wormian skull bones, flattened vertebral bodies throughout spine, bowed long bones, flat iliac wings & acetabulae	Autosomal dominant or recessive	<i>COL1A1</i> , <i>COL1A2</i> , <i>CRTAP</i> , <i>LEPRE1</i> , <i>PPIB</i> , <i>CREB3L1</i>
3	Progressive deformities & fractures of long bones, short stature, soft skull bones, vertebral compression fractures, scoliosis, blue sclerae, deafness	Autosomal dominant or recessive	<i>COL1A1</i> , <i>COL1A2</i> , <i>CRTAP</i> , <i>LEPRE1</i> , <i>PPIB</i> , <i>FKBP10</i> , <i>SERPINH1</i> , <i>SERPINF1</i> , <i>BMP</i> , <i>BMP1</i> , <i>WNT1</i> , <i>SP7</i> , <i>TENT5A</i> , <i>MBTPS2</i>
4	Variable propensity to fracture and deformation of long bones, short stature, light blue sclerae, possible dentinogenesis imperfecta deafness	Autosomal dominant or recessive	<i>COL1A1</i> , <i>COL1A2</i> , <i>CRTAP</i> , <i>PPIB</i> , <i>WNT1</i> , <i>TMEM38B</i> , <i>SP7</i>
5	Similar to OI type IV with exuberant callus formation at sites of healing fractures & calcification of interosseous membranes	Autosomal dominant	<i>IFITM5</i>

Please see Table 20.10C for more details concerning specific gene variants associated with osteogenesis imperfecta.

Prepared from: Bonafe L, Cormier-Daire V, Hall C, et al. Nosology and classification of genetic skeletal disorders: 2015 revision. *Am J Med Genet.* 2015;167A:2869–2892; Vierucci F, Saggese G, Cimaz R. Osteoporosis in childhood. *Curr Opin Rheumatol.* 2017;29(5):539–546.

(e.g., Z score -2) below mean for ethnicity, gender, chronological age, and height/height age; when interpreting a DXA study, one should also consider the stage of sexual maturity relative to the chronological age of the subject.^{317,319–323} (Whole-body DXA data that include the head is not considered an optimal measure of BMC/BMD because the skull does not respond directly to environmental factors, such as weight-bearing exercise.) Thus osteoporosis in children and adolescents is suggested by the clinical presentation (bone pain, growth arrest, immobility) because of non/low-traumatic long bone and/or vertebral compression fractures identified by roentgenograms of the long bones and/or findings on lateral radiographs of the thoracolumbar spine.³²² It is essential to differentiate

TABLE 20.10C Gene Variants/Mutations Causally Related to Osteogenesis Imperfecta

Number OMIM Disease—Gene Chromosome/OMIM	Severity/Type	Clinical Features	Growth Impairment	Blue Sclera	Inheritance	Functional Defect
I - 166200 - <i>COL1A1</i> - Collagen type I, alpha-1 17q21.33 1120150 or <i>COL1A2</i> - Collagen type I, alpha-2 7q22.3 120160	Mild - 1	Few (often vertebral) fractures, little deformity, hearing loss in 50%; rarely dentinogenesis imperfecta	Minimal	Present - intense	AD	Nonsense & frameshift mutations result in haploinsufficiency & decreased production of collagen type I
II - 166210 - <i>COL1A1</i> or <i>COL1A2</i>	Perinatal lethal - 2 congenital (see also Types VII, VIII, IX, X)	Many rib & long bone fractures in utero & at birth, severe long bone deformities, "beaded" ribs, unmineralized calvarium	Severe	Present	AD, parental mosaicism	Glycine substitutions in <i>COL1A1</i> or <i>COL1A2</i> result in structurally abnormal collagen type I
III - 259420 - <i>COL1A1</i> or <i>COL1A2</i>	Severe, progressive & deforming - 3	Moderate to severe bowing, multiple long bone & vertebral fractures, dentinogenesis imperfecta, hearing loss	Severe	Present but lighten with age	AD	Glycine substitutions in <i>COL1A1</i> or <i>COL1A2</i> result in structurally abnormal collagen type I
IV - 166220 - <i>COL1A2</i> or <i>COL1A1</i>	Moderately deforming - 4	Mild to moderate bowing, fractures, dentinogenesis imperfecta	Moderate, variable	Grayish or absent	AD	Glycine substitutions in <i>COL1A1</i> or <i>COL1A2</i> result in structurally abnormal collagen type I
V - 610967 - <i>IFITM5</i> - Interferon-induced transmembrane protein-5 11p15.5 614757	Moderately deforming - 5	Mild to moderate bone fragility, ossification of interosseous membranes of forearm, hyperplastic callus formation at fracture sites; "mesh-like" bone lamellation pattern	Mild to moderate	Absent	AD	Osteoblast specific membrane protein essential for osteoblast differentiation; functional consequence of the constant mutation (c.-14C>T) in <i>IFITM5</i> is uncertain
VI - 613982 - <i>SERPINF1</i> - Serpin peptidase inhibitor, clade F, member 1 17p13.3 172860	Moderately to severely deforming - 3	Onset of fractures of long bones & vertebrae in infancy, increased alkaline phosphatase activity & osteoid, "fish-scale" pattern of lamellation	Moderate to severe	Grayish	AR	Loss-of-function mutations in pigment epithelium-derived factor (PEDF)—regulator of bone mineralization & osteoclast differentiation
VII - 610682 ^a <i>CRTAP</i> - Cartilage associated protein 3p22.3 605497	Moderately deforming to severely deforming or lethal - 2, 3, 4	Fractures may be present at birth, rhizomelia, limb deformities	Moderate	Absent or faint	AR	Inactivating mutations (duplication) of <i>CRTAP</i> impair 3-hydroxylation of prolyl-986 of procollagen $\alpha 1(I)$
VIII - 610915 ^a <i>P3HI (LEPRE1)</i> - Leucine- and proline-enriched proteoglycan 1 (Prolyl hydroxylase 1) 1p34 610339	Severely deforming to lethal - 2, 3	Markedly decreased bone mineralization, scoliosis, platyspondyly, prominent metaphyses, long phalanges	Severe	Absent	AR	Inactivating mutations of <i>LEPRE</i> encoding prolyl-3-hydroxylase 1 (leprecan) impair 3-hydroxylation of prolyl-986 of procollagen $\alpha 1(I)$
IX - 259440 - ^a <i>PP1B</i> - Cyclophilin B - 15q22.31 123841	Lethal to severely deforming, see - 2, 3, 4	Shortened, bowed, & fractured long bones in midgestation	Severe	Gray	AR	Inactivating mutations of <i>PP1B</i> encoding peptidyl-prolyl isomerase B impair 3-hydroxylation of prolyl-986 of procollagen $\alpha 1(I)$
X - 613848 - <i>SERPINH1</i> - Serpin peptidase inhibitor, clade H, member 1 11q13.5 600943	Severe - 3	Short bowed femora in utero, multiple fractures in first month of life, dentinogenesis imperfecta	Severe	Present	AR	Loss-of-function mutations in CBP2 (HSP47)—chaperone, essential for maintenance of integrity of the triple helical structure of collagen type 1 & its resistance to proteolytic degradation
XI - 610968 <i>FKBP10</i> - FK506-binding protein 10 17q21.2 607063	Severe & progressive deformities - 3	Limbs are short & bowed, joint contractures; dentinogenesis imperfecta; fish-scale pattern of bone lamellation (see Type VI)	Moderate	Gray	AR	Loss-of-function mutations in a chaperone protein—FKBP65—essential for posttranslational processing of procollagen type I; also mutated in Bruck syndrome type 1

TABLE 20.10C Gene Variants/Mutations Causally Related to Osteogenesis Imperfecta—cont'd

Number OMIM Disease—Gene Chromosome/OMIM	Severity/Type	Clinical Features	Growth Impairment	Blue Sclera	Inheritance	Functional Defect
XII - 613849 - <i>SP7</i> - Transcription factor specificity factor (Sp)7 12q13.13 606633	Moderate to severe - 4	Multiple fractures in early infancy; short, bowed long bones, highly arched palate	Severe	Absent	AR	Inactivating mutations in Osterix, a transcription factor essential for osteoblast differentiation & bone mineralization
XIII - 614856 - <i>BMP1</i> - Bone morphogenetic protein 1 8p21.3 112264	Moderate to severe - 3	Generalized deformities of all bones, multiple fractures despite increased bone mineral density	Severe	Faint blue	AR	Inactivating mutations of procollagen type I C-terminal propeptide endoproteinase impair collagen formation
XIV - 615066 - <i>TMEM38B</i> - Transmembrane protein 38B 9q31.1 611236	Moderate - 3	Variable severity; fractures occur in utero or during early childhood; moderate bowing of the lower limbs	Moderate	Absent	AR	Inactivating mutations of a component of an intracellular monovalent cation channel necessary for Ca ²⁺ release from storage sites
XV - 615220 - <i>WNT1</i> - Wingless integration site family, member 1 12q13.12 164820	Progressively deforming - 3	Multiple fractures & bone deformities in childhood; cerebellar hypoplasia, profound developmental delay	Present	Present	AR	Mutated WNT1 fails to activate LRP5-beta catenin signaling resulting in impaired formation & function of osteoblasts
XVI - 616229 - <i>CREB3L1</i> - Cyclic AMP response element-binding protein 3-like 1 11p11.2 616215	Lethal prenatally - 2	Fractures present in utero -		Present	AR	Loss of transcriptional activation of <i>COL1A1</i>
XVII - 616597 - <i>SPARC</i> - Secreted protein, acidic cysteine-rich 5q33.1 182120	Moderate severity - 4	Limb & vertebral fractures in early childhood, joint laxity, muscular weakness	Present	Not stated	AR	Encodes osteonectin—phosphoprotein secreted by osteoblasts that enables calcification of bone collagen
XVIII - 617592 - <i>TENT5A</i> - Terminal nucleotidyltransferase 5A 6q14.1 611357	Moderately severe - 3	Congenital bowing, multiple fractures by age 1 year, vertebral collapse, progressive scoliosis, dentinogenesis imperfecta	Present	Present	AR	Nucleotidyltransferase catalyzes transfer of nucleoside monophosphate to hydroxyl group of acceptor molecule; expressed in osteoblast
XIX - 301014 - <i>MBTPS2</i> - Membrane-bound transcription factor protease site 2 Xp22.12 300294 Undesignated	Severe - 3	Fractures occur prenatally & postnatally, bowing of long bones, pectus carinatum	Moderate	Present	XLR	Zinc metalloproteinase; regulates proteolysis of transcription & other factors required for secretion & cross-linking of collagen type 1
<i>PLOD2</i> - Procollagen-lysine, 2-oxoglutarate 5-dioxygenase 2 3q24 601865	Severe - 3; osseous fragility with congenital joint contractures	Fractures in infancy, pterygia, scoliosis	Severe	Absent	AR	Encodes a procollagen lysyl hydroxylase necessary for formation of collagen type 1 telopeptide; Bruck syndrome 2
300131 - <i>PLS3</i> - Plastin 3 Xq23 300131	Mild - 1	Osteopenia - incidental finding	Minimal	Absent	XLR	Actin & calcium binding protein required for integrity of osteocyte cytoskeleton
176790 - <i>P4HB</i> - Procollagen-proline, 2-oxoglutarate-4-dioxygenase, beta subunit 17q25.3	Severe - 3	Cole-Carpenter syndrome 1 - Bone fragility, craniosynostosis, hydrocephalus, ocular proptosis	Modest	Present	AD	Beta subunit of prolyl 4-hydroxylase - catalyzes synthesis of 4-hydroxyproline in preprocollagen

Relationship between genotype and skeletal phenotype in children and adolescents with osteogenesis imperfecta. *J Bone Miner Res*. 2010;25:1367–1374.)

vertebral compression fractures from variants of normal vertebral morphology using appropriate semi-quantitative methods. In children and adolescents, bone mass may be quantitated by DXA determination of areal BMD of the “whole body minus head” and of body regions (lumbar spine, hip, distal one-third radius). (DXA analyses of hip bone mass are variable in children and adolescents and not usually used for interpretation of BMC or BMD data.) A portable DXA unit that measures areal BMD in the ultradistal, middistal, and one-third distal regions of the nondominant forearm may also be used to determine areal BMD; it provides data comparable to a fixed DXA instrument. Despite its limitations (provision of areal rather than volumetric BMD data and failure to distinguish between trabecular and cortical bone), DXA is the most widely used bone densitometric method in children at this time. Other methods used for determination of bone mineralization include QCT, pQCT of the tibia and radius, high-resolution pQCT (HRpQCT), and QUS. Estimation of bone mass by QCT provides quantitative three-dimensional information about cortical and trabecular bone volume and mass. Relative to bone strength determined by calculation of the stress-strain index of a long bone with data garnered by pQCT, DXA whole body areal BMC (minus the head) for height also affords a reliable measurement for determining cortical bone strength and hence fracture risk. The report of the BMD/content should include not only the methodology used but also the specific instrument used, the software version used for data analysis, and the ethnic mix of the reference population. Interestingly, in otherwise healthy prepubertal and pubertal boys who sustain a high-impact traumatic fracture, regional BMDs tend to be within the lower half of the normal range; additionally, bone microstructure tends to be aberrant, and bone strength decreased—perhaps reflecting an intrinsic bone defect.³¹⁵

In general, impaired bone strength may develop as a consequence of congenital or acquired disorders that adversely affect bone formation or mineralization.^{322,324} These disorders may be related to suboptimal nutritional intake or nutrient absorption (anorexia nervosa, cystic fibrosis, celiac disease), chronic inflammatory disease (bowel, joint), immobilization (paresis, muscular dystrophy, cerebral palsy), hematological abnormalities (leukemia and its chemotherapy, sickle cell anemia, thalassemia), medications (glucocorticoids, immunosuppressant drugs, anticonvulsant agents), or endocrinopathies (growth,

thyroid, or sex hormone deficiencies or excessive secretion of glucocorticoids). In patients with endogenous or therapeutic excess of cortisol and related glucocorticoids, bone mass and mineralization are decreased whereas fracture risk is increased because of the suppressive effects of these agents on bone formation and acceleration of bone resorption with consequent increase in skeletal fragility.^{325–327} GH deficiency is associated with decreased bone turnover rate and subnormal mineralization of the skeleton, as well as increase in fracture risk with improvement during treatment with recombinant human GH.

Although heritable factors account for 60% to 80% of optimal bone mineralization, modifiable factors that contribute to the development of osteopenia and osteoporosis in adulthood (weight-bearing exercise, nutrition, body mass, hormonal milieu) have their genesis in utero, infancy, childhood, and adolescence.^{328,329} In children as in adults, bone mass, composition, microarchitecture, and size determine bone strength. Because many youths consume excessive amounts of carbonated beverages and diluted fruit juices thus limiting their intake of milk, children and adolescents ingest only 55% to 70% of the recommended daily calcium allowance (1300 mg/day), although late pubertal males tend to consume more than do pubertal females. In adolescent and adult females, excessive intake of cola drinks with high phosphoric acid levels lower body calcium content by sequestering dietary calcium in the intestinal tract and increasing dissolution of bone mineral to neutralize acid with the possible consequent development of mild secondary hyperparathyroidism. Sedentary, non-weight-bearing activities encouraged by television, video, and computer games also impair bone mineralization.³³⁰ In a study of 300 male and female adolescents and young adults (13–21 years of age) using both DXA assessment of body composition and QCT measurement of the axial and appendicular skeletons, a positive correlation between lean mass and all bone measurements has been reported in both genders.³³¹ In children and adolescents, fat mass, waist circumference, and insulin resistance are negatively related to DXA-BMC of the lumbar spine and total body BMD.³³² These observations suggest that bone mass and strength are determined by dynamic muscular forces—not solely by static load. The odds ratios for fractures of the foot, ankle, leg, and knee increase as body mass index rises particularly in 6- to 11-year-old children.³³³

Nutritional deprivation depresses the rate of bone accrual; extreme weight loss, such as in patients with anorexia nervosa has many adverse effects upon bone mass, including decreased areal BMD as assessed by DXA, and low distal radial total and trabecular volumetric BMD, decreased cortical bone thickness and area, and higher cortical porosity as determined by HRpQCT leading to reduced bone strength and increased fracture risk.³²² Anorexia nervosa is a psychiatric disorder in which chronic undernutrition is self-induced because of an underlying emotional disturbance.³³⁴ It occurs more often in females than males and often begins in adolescence (peak age of onset of anorexia nervosa is between 13 and 18 years of age) and may persist well into adulthood. There is a substantially increased fracture risk in these patients that is caused by failure to accrue sufficient bone mass as thickness and area of bone cortex, trabecular number and thickness, turnover rate, and bone strength are reduced relative to normal subjects. Pathophysiologically, low bone mass and decreased bone strength are the consequences not only of a paucity of the protein and mineral components of bone and chronic acidemia, but also of the hormonal adaptation to starvation. Thus resistance to the biological effects of GH manifested by decreased synthesis of IGF-1 and resistance to the appetite-stimulating effects of the GH secretagogue ghrelin, stress-related increase in glucocorticoid production resulting in hypercortisolemia, and depressed synthesis of estrogens and androgens (both testosterone and dehydroepiandrosterone) caused by hypogonadotropism synergize to impede osteogenesis and bone strength, thereby increasing fracture risk. Patients with anorexia nervosa are also hypoleptinemic because of scarcity of adipose tissue. Leptin is an adipokine that decreases appetite, enhances gonadotropin secretion, and may affect bone mass as it directly increases chondrogenesis and osteoblastogenesis and inhibits osteoclastogenesis.³³⁵ Administration of estrogen/progestin to females with anorexia nervosa does not increase bone mass or prevent its loss; bisphosphonates, IGF-1, and dehydroepiandrosterone may maintain or increase BMD in such patients but their use should be limited. Even in adolescents with anorexia nervosa whose disorder is managed successfully, increased fracture risk persists well into adulthood. The “athletic triad” of suboptimal body fat mass, amenorrhea in women, and decreased bone mass attributed to low sex hormone production is encountered in the highly trained female athlete and the elite long-distance male runner. There is a population of well children, adolescents, and young adults with “constitutional thinness” that is characterized by long-standing suboptimal weight for height but normal growth, sexual maturation, and fertility in whom the fracture risk is not increased despite the areal BMD being low.

Although the longer and more intense is weekly sporting activity in children and adolescents, the greater is the vertebral areal BMD independently of calcium intake, excessively prolonged engagement in high-impact activities, such as basketball, gymnastics, and cheerleading the greater is the likelihood of sustaining a fracture in females.^{225,336} In pre- and peripubertal children, simple school physical education programs using jumping, hopping, and skipping exercises 2 to 3 times weekly significantly increases areal BMD at the femoral trochanter in as little as 8 months relative to children engaged in a standard physical education curriculum. Suboptimal nutrition and sedentary activities during childhood and adolescence, as well as consumption of colas and alcohol and smoking of cigarettes, prevent optimal bone mineralization and increase the likelihood of later development of osteoporosis and its complications. Because the risk of developing an osteoporotic fracture as an adult declines by 40% for every 5% increase in peak bone mineral mass, the foundation for the prevention of osteoporosis in the adult must be constructed in the child and adolescent by maintaining

adequate calcium intake, vitamin D stores (serum concentrations of calcidiol >20 ng/mL), and complementary weight-bearing activity during these formative years. Other nutrients, for example, magnesium, protein, vitamins C and K, and copper must also be consumed for optimal bone matrix synthesis.²¹²

Acute immobilization of the healthy, active child and adolescent and the consequent reduction in weight-bearing and decrease in the mechanical load on bones results in a lowered rate of bone formation; in the presence of continued bone resorption, hypercalciuria and later hypercalcemia and lowered bone mass develop.³³⁷ In the chronically immobilized child or adolescent (cerebral palsy, spastic quadriplegia, muscular dystrophy), fracture rate (primarily of the femur) is high during simple maneuvers, such as turning, dressing, or feeding. In this group of subjects, not only lack of weight-bearing but also the severity of the primary illness, body size and pubertal status, state of general nutrition, vitamin D and calcium intake, coexisting inflammatory states, and medications (e.g., anticonvulsants, glucocorticoids), as well as indoor confinement adversely impact bone mass and fracture risk.²²⁵ Distal femoral and lumbar vertebral areal BMDs increase at slower than normal rates in the child with spastic cerebral palsy, resulting in diminution of areal BMD Z scores as an older subject.³³⁸ The intravenous administration of pamidronate and zoledronic acid and subcutaneous injections of recombinant human GH have increased areal BMD in small selected groups of children with quadriplegic and spastic cerebral palsy.³³⁹ Areal BMD increased substantially in 26 immobile patients with quadriplegic cerebral palsy (3–17 years of age) during administration of the bisphosphonate alendronate (1 mg/kg/week orally), calcium (600 mg/day), and vitamin D (400 IU/day) over 1 year of treatment.³⁴⁰ Assisted standing with weight-bearing by itself may also increase BMD in children with severe cerebral palsy.

The importance of normal gonadal sex steroid secretion during age-appropriate sexual maturation is emphasized by the observation that in adult males with delayed sexual development, radial, vertebral, and femoral areal BMDs are lower than in males with normal timing of pubertal maturation.³¹⁶ Histomorphometrically, in adult sex-steroid-deprived bone, there is decrease in cortical width, trabecular number, osteoid, and mineralization activity; reduced bone mass and abnormal microarchitecture result in decreased skeletal strength and increased risk of fracture.³⁴¹ As a consequence of estrogen (and androgen) deficiency, there is increase in the production but decline in the life span of osteoblasts and osteocytes, while osteoclastogenesis is stimulated and the life span of osteoclasts prolonged; these events reflect the sum of the activities of multiple proosteoclastogenic cytokines whose synthesis is regulated by estrogen, including M-CSF, IL-1 and -6, TNF α , RANKL, and osteoprotegerin. Although osteopenia responsive to estrogen has been recorded in adult males with aromatase deficiency, mature women with complete androgen insensitivity are also osteopenic despite normal to increased estrogen production, clearly indicating that androgens are also important for normal bone mineralization.³⁴¹

The increased risk of fractures in prepubertal and adolescent girls and adult women with Turner syndrome (gonadal dysgenesis) has been attributed to both intrinsic abnormalities of bone itself as manifested by the characteristic malformations present in this disorder, including Madelung deformity of the wrist, mesomelia, scoliosis, cubitus valgus, and shortened metacarpal and metatarsal bones—the consequence of haploinsufficiency of Short stature Homeobox-containing gene (*SHOX*, OMIM 312865) and of decreased bone mineralization as a result of chronic estrogen deprivation.³⁴² In patients with Turner syndrome, there is selective deficiency of cortical bone, whereas trabecular bone density

may be normal as may areal and volumetric BMDs when adjusted for height. Inasmuch as FSH stimulates osteoclastogenesis both directly and by enhancing TNF α -mediated increased expression of RANKL and subsequent osteoclast differentiation, the elevated levels of this gonadotropin present in the female with ovarian failure may contribute to the suboptimal bone mineralization of patients with Turner syndrome.³⁴² In addition, disorders that may exert an adverse impact on bone mineralization (e.g., inflammatory bowel disease, celiac disease, hypothyroidism) are more common in patients with Turner syndrome. The frequency of wrist fractures is increased during childhood as is the general risk for fractures in adults with Turner syndrome. In subjects with gonadal dysgenesis, estrogen replacement therapy during early adolescence increases bone calcium deposition and areal BMD and cortical and trabecular bone mass, whereas delayed estrogen replacement is associated with persistent decrease in cortical bone mass albeit normalization of trabecular bone mass.³⁴³ Recombinant human GH administered during childhood increases growth rate, adult stature, and bone size in many patients with Turner syndrome, and perhaps increases bone strength and reduces fracture risk.³⁴⁴ In girls with Turner syndrome, appropriate intake of calcium and vitamin D and weight-bearing exercises are also necessary. Bisphosphonates are not recommended for treatment of Turner syndrome adolescents because these agents act primarily on trabecular bone, the primary target of estrogen. In children with central precocious puberty, administration of a gonadotropin-suppressing agent may decrease the rate of bone mineral accrual, a process that is apparently reversible after completion of therapy.³⁴⁵ Appropriate intake of calcium and vitamin D and weight-bearing exercises should be prescribed for subjects receiving a gonadotropin-suppressing agent.

Pubertal subjects with primary (e.g., Klinefelter syndrome, galactosemia, postradiation or chemotherapy) or secondary hypogonadism (anorexia nervosa, excessive physical training, hypogonadotropism) also have decreased bone mineralization. By decreasing estrogen production, even short-term (6 months) use of the intramuscular contraceptive depot medroxyprogesterone acetate (MPA) results in significant loss in bone mass in adolescent females and young women (18–21 years of age) when BMD would ordinarily be increasing; however, bone mass increases over time after this agent is discontinued.³⁴⁶ The adverse impact of depot MPA on BMD may be prevented by concomitant administration of estrogen.

The low bone mass of glucocorticoid excess is the result of inhibition of osteoblastogenesis and increase in the rate of apoptosis of the osteoblast and osteocyte—leading to decrease in the rate of bone matrix formation and microfracture repair; they enhance osteoclastogenesis and increase osteolysis—the result of increase in expression of RANKL in association with decrease in the rate of apoptosis of the osteoclast—permitting prolonged and excessive bone resorption.^{322,327,347,348} Because glucocorticoids decrease osteocyte-mediated bone formation, during each remodeling cycle the amount of bone replaced is far less than the amount removed and skeletal microarchitecture degraded resulting in declining bone mass and strength over time. Indirectly, glucocorticoids impair bone accretion by suppressing secretion of IGF-1 and by decreasing intestinal calcium absorption.^{327,348} By decreasing muscle strength, glucocorticoids lower the forces exerted on bone further impairing its formation. Children receiving glucocorticoids for treatment of asthma or rheumatic disorders should also receive 2000 IU of vitamin D daily.³²⁴

At the molecular level, glucocorticoids suppress expression and synthesis of *RUNX2* (OMIM 600211, chr. 6p21.1) and *BMP2* (OMIM 112261, chr. 20p12.3), factors essential for prenatal and postnatal osteoblast differentiation, respectively, and

increase osteoblast expression of *TNFSF11* encoding RANKL and decrease expression of *TNFRSF11B* encoding osteoprotegerin—the decoy receptor for RANKL, changes that favor osteoclastogenesis.^{347,349} Glucocorticoids impair WNT/ β -catenin signaling and consequently inhibit synthesis of collagen type I, as well as increase its rate of degradation; they impair IGF-1 formation and function. They also direct the mesenchymal osteoblast precursor into the pathway of adipocyte differentiation. To a limited extent, glucocorticoids inhibit normal vitamin D metabolism and thereby vitamin D-dependent intestinal absorption of calcium. They increase renal loss of calcium by a direct effect on the renal tubule, leading to secondary hyperparathyroidism.^{347,349} Glucocorticoids also reduce production of sex hormones in the adolescent and adult. The muscle weakness of chronic glucocorticoid exposure reduces the impact of mechanical forces on bone formation. Glucocorticoid-mediated inhibition of linear growth and widening of bones contributes to impairment of bone mineralization in children.²³² Glucocorticoids adversely affect trabecular bone formation initially and later impair cortical bone accumulation.³⁵⁰ The disease (e.g., asthma, nephrotic syndrome, acute lymphoblastic leukemia, chronic inflammatory disorders, such as juvenile arthritis) for which pharmacological doses of glucocorticoids have been prescribed contributes to decreased bone mass by impairing mobility and by elaboration of osteoclastogenic cytokines. Although glucocorticoid-reduced bone mass accumulation is greater with frequent intermittent bursts of oral glucocorticoids than with inhaled glucocorticoids in boys with asthma, in high doses over prolonged periods, inhaled glucocorticoids can also lead to decreased bone mass.^{351–353} In young adults with asthma, there is an inverse relationship between vertebral and femoral areal BMDs and cumulative dose of inhaled glucocorticoid with increasing fracture risk as the dose and duration of glucocorticoid administration increases; a cumulative dose of 5000 mg of hydrocortisone leads to a 1-SD decline in vertebral BMD.³⁵⁴ In adult women with 21-hydroxylase deficient congenital adrenal hyperplasia treated with glucocorticoids, bone mineralization is modestly reduced, in part related to the extent of suppression of adrenal androgen production. It is suggested that when children begin to receive either oral or inhaled glucocorticoids that they also be instructed to ingest age-appropriate amounts of calcium and vitamin D and to engage in weight-bearing exercises. In children experiencing adverse effects of glucocorticoids on growth and bone mineralization, it is important to lower their steroid dose to the greatest extent possible and to withdraw them if at all feasible. Although often recommended for adults being treated with glucocorticoids, routine administration of a bisphosphonate to children receiving these agents is not recommended unless there is steady decline in bone mass or the patient has had a low impact or fragility fracture attributable to low bone mass.^{348,350} Nevertheless, early use of a bisphosphonate (e.g., alendronate) might prevent bone loss in glucocorticoid-treated patients with childhood-onset rheumatic disease.

GH exerts direct and indirect actions upon bone formation.³⁵⁵ In growth plate cartilage, GH stimulates local synthesis of IGF-1 that in turn enhances proliferation of resting chondrocytes and endochondral ossification; in bone, GH enhances osteoblast differentiation, proliferation, and function resulting in increased osteoblast synthesis of IGF-1, IGFBP-3, osteocalcin, bone-specific alkaline phosphatase, and procollagen type I; GH stimulates osteoblast synthesis of osteoprotegerin, thereby impairing osteoclastogenesis but it also stimulates osteoclastogenesis and bone resorption indirectly acting through IGF-1-mediated synthesis of RANKL.^{355–357} GH primarily stimulates formation of cortical bone. IGF-1 regulates differentiation of chondrocytes and maintains their rate of

proliferation.³⁵⁷ Osteoblast and osteocyte-synthesized IGF-1 affects osteoblast maturation and the rates of matrix mineralization and bone turnover and mediates the response of bone to a mechanical load and to PTH.³⁵⁷ PTH, thyroid hormone, and estrogen stimulate and glucocorticoids inhibit osteoblast secretion of IGF-1.³⁵⁵ Administration of GH to GH-deficient children and adults increases the rates of both bone formation and destruction, the latter predominating initially; over long periods of treatment (12–18 months) GH increases areal BMD in these patients; to achieve peak bone mass, however, GH therapy must be continued into adulthood. Nevertheless, in many untreated adults with GH deficiency, volumetric BMD is often normal despite low areal BMD values reflecting the smaller size of their bones. In part, low bone mass in the GH-deficient child may also be attributed to the small bone size of the short child compared with age peers when examined as areal BMD by DXA. Measurement of bone mass by either size-corrected areal BMD or volumetric methods (e.g., pQCT) suggests that volumetric BMD is normal or slightly low in the majority of GH-deficient subjects; nevertheless fracture risk is increased in adults with GH deficiency of childhood onset.³⁵⁵ In patients with hypopituitarism of adult onset associated with multiple pituitary hormone deficiencies, fracture risk is increased, but this may be attributable to loss of gonadotropin stimulated sex hormone secretion and to the decreased mechanostat effects of reduced muscle mass on bone accretion in these fully grown subjects. GH primarily enhances cortical bone growth; thus in a state of excessive GH secretion (e.g., acromegaly), increased membrane bone growth results in the characteristic facial features and related bony overgrowth of those affected; however, GH excess may also decrease vertebral areal BMD and increase vertebral fracture risk in these patients.³⁵⁵

Triiodothyronine, the biologically active thyroid hormone, downregulates proliferation of chondrocytes and increases their rate of differentiation to prehypertrophic and hypertrophic chondrocytes.³⁵⁸ Triiodothyronine stimulates osteoblast differentiation and synthesis of osteocalcin, osteopontin, type I collagen, alkaline phosphatase, and IGF-1; it also enhances osteoclastogenesis and, thus the rate of bone resorption, but likely does so indirectly by increasing osteoblast synthesis of RANKL. In children with hyperthyroidism, the rate of cartilage maturation is accelerated, fusion of cranial sutures is enhanced, and osteoclastogenic effects are prominent. Thus in thyrotoxic patients, there is increase in the rate of bone turnover and decrease in the length of the bone remodeling cycle (primarily because of shortening of the bone formation phase) resulting in a net loss of mineralized bone.³⁵⁸ As in adults with thyrotoxicosis, whole body, vertebral, and femoral BMDs are low in children and adolescents with hyperthyroidism, but they substantially increase within the first 12 to 24 months after restoration of the euthyroid state. In hypothyroid children, endochondral maturation is delayed and calcification abnormal; administration of physiological replacement doses of thyroxine to children with acquired or congenital hypothyroidism advances cartilage maturation and endochondral bone formation; treatment does not adversely affect bone mineralization during childhood, although adults with congenital hypothyroidism may have a 10% reduction in radial bone mass.

Hyperglycemia is associated with accumulation of highly glycated proteins (protein bound glucose/fructose) that impair differentiation of mesenchymal stem cells to chondrocytes and osteoblasts with consequent decreased synthesis of osteocalcin and other products of the osteoblast; osteoclastogenesis is also impaired.^{359,360} In patients with type 1 diabetes mellitus, areal BMD is decreased, bone size is reduced, and fracture risk is increased, reflecting the adverse effects of chronic hyperglycemia and insulin deficiency upon bone formation. In adolescents with type 1 diabetes mellitus, whole body, axial, and

appendicular bone mass assessed by DXA is decreased relative to control subjects and inversely related to Hb A1c values. Using pQCT in young, prepubertal subjects with type 1 diabetes mellitus, cortical bone cross-sectional area and BMD were found to be decreased implying an increased risk for fracture.³⁶¹ Although patients with type 2 diabetes mellitus tend to have increased areal BMD (related to decline in the rate of bone turnover perhaps related to hyperinsulinemia), their fracture risk is nevertheless increased.

Bone mass is decreased in the majority of children with acute lymphoblastic leukemia and 26% of these patients sustain a fracture often of a vertebra before or within the first four years of treatment.³²² Pathogenetic factors involved in the development of low bone mass in these subjects include: adverse effects of the disease itself directly on bone—mediated by cytokine-induced increase in osteoclastogenesis and activity and suppression of bone remodeling, radiation injury of bone; inhibitory effects of glucocorticoid, chemotherapeutic, antibiotic, and immunosuppressive agents on bone formation; diminished physical activity; decreased caloric, protein, and vitamin D intake; sex hormone deficiency caused by delayed or arrested adolescent development; and GH deficiency in children who have received cranial radiation.³⁶² After initial treatment of the neoplasm and achievement of a remission, administration of a bisphosphonate, such as zoledronic acid, may substantially increase bone mineralization in these children and adolescents.³⁶³ In solid organ transplant recipients, cyclosporine A induces bone loss by increasing osteoblast expression of RANKL and decreasing production of osteoprotegerin, thereby augmenting osteoclastogenesis. Methotrexate and intrathecal chemotherapy exert significant inhibitory effects on bone mineralization in children with malignancies. These patients should receive appropriate calcium and vitamin D supplements and weight-bearing exercises to the extent possible.³⁶² Those who develop GH deficiency following cranial radiation may be treated with recombinant hGH if they remain GH deficient after the primary illness has been in prolonged remission. Decreased bone mineralization is common in the postbone marrow or solid organ transplant subject; its diverse pathogenesis includes the primary disease itself and the chronic illness that may accompany it, the use of high-dose glucocorticoids and antirejection medications, as well as altered intestinal, renal, hepatic, and gonadal function.^{322,364} In addition to provision of adequate nutrition, calcium, and vitamin D, in adults the effects of transplantation on bone accrual may be partially ameliorated by administration of bisphosphonates.

In severely burned patients and children with hemophilia, sickle cell disease, central diabetes insipidus, Marfan syndrome, homocystinuria, lysinuric protein intolerance, and propionic and methylmalonic aciduria, areal BMD is also decreased. Children with cystic fibrosis may have low vertebral and femoral neck areal BMD as a consequence of suboptimal nutrition, vitamin D deficiency, chronic inflammation, concomitant diabetes mellitus, pubertal delay, and drug therapy. However, approximately one-third of optimally managed cystic fibrosis patients with good clinical control may nevertheless have a subnormal BMD, although this is not necessarily translated into increased fracture risk.³⁶⁵ Low bone mass and vertebral collapse may be early manifestations of chronic inflammatory bowel disease.³²⁴ Vitamin D deficiency and secondary hyperparathyroidism, as well as the chronic inflammatory state and therapeutic agents, such as glucocorticoids, likely contribute to decreased bone formation and increased bone resorption in this illness. That whole body areal BMC in children, adolescents, and young adults with chronic inflammatory bowel disease may be normal relative to lean body mass (although reduced relative to ethnic, age, and height norms) does not necessarily imply that bone strength in these patients is normal as evidenced by the

increased fracture risk of adults with this disorder. Low bone mass is common in children and adults with celiac disease.³⁶⁶ Pathogenetic factors associated with low bone mass in children with celiac disease include malabsorption of vitamin D, calcium, protein, and other nutrients, synthesis of osteoclast activating and proinflammatory cytokines, such as IFN- γ and IL-15, -18, and -21, and secondary hyperparathyroidism. In children and adolescents infected with the human immunodeficiency virus, whole body areal BMD may be decreased as a consequence of the infective agent itself, the chronic inflammatory state it induces, suboptimal nutrition including subtle vitamin D deficiency, and the administration of highly active antiretroviral therapy that may have direct effects upon osteoblast and osteoclast generation and function.³⁶⁷ Despite clinical well being and normal linear growth, the rate of accrual of bone mass is decreased in these subjects while the rate of bone resorption is increased. Bone mass is reduced in children with a variety of connective tissue diseases (juvenile idiopathic arthritis, systemic lupus erythematosus, juvenile dermatomyositis) caused by the chronic inflammatory state and production of proosteoclastic cytokines and to therapy with glucocorticoids.³²⁴

Idiopathic juvenile osteoporosis (OMIM 259750) is a disease of unknown pathogenesis manifested by bone pain and bone fractures with minimal trauma that occurs in the late prepubertal-early pubertal girl or boy (8–12 years of age) and spontaneously abates over time with variable residual manifestations.^{368,369} In affected subjects, roentgenograms obtained for evaluation of joint, muscle, and/or back pain, difficulty walking, foreshortening of the trunk, and/or the presence of kyphosis reveal biconcave vertebrae and/or vertebral compression fractures, radiolucent areas in long bones, and metaphyseal fractures. Analyses by DXA and QCT demonstrate decreased bone mineralization. Chemical studies are normal. Dynamic histomorphometric studies reveal low rates of bone formation and turnover with reduction in cancellous bone volume and trabecular thickness primarily because of decreased osteoblast activity on the endosteal but not the periosteal bone surface; there is no evidence of increased bone resorption. Idiopathic juvenile osteoporosis is quite likely to be genetically heterogeneous in origin. Mutation analyses of *COL1A1* and *COL1A2* have been normal in these subjects. In 15% of patients with juvenile osteoporosis, a familial heterozygous loss-of-function mutation in the gene encoding LDL receptor-related protein 5 (*LRP5*, OMIM 603506) has been detected.³⁷⁰ Biallelic loss-of-function mutations of *LRP5* result in the osteoporosis-pseudoglioma syndrome, whereas heterozygous gain-of-function variants lead to forms of osteopetrosis and osteosclerosis (vide infra). One of the most difficult diagnostic challenges is the clinical distinction between idiopathic juvenile osteoporosis and osteogenesis imperfecta type I (vide infra). The latter disease is characterized clinically by a positive family history, onset in early infancy, lifelong persistence, diaphyseal fractures, wormian bones, lax ligaments and decreased muscular strength, blue sclerae, abnormal dentition, hearing loss, and a high rate of bone turnover.³⁶⁹ In addition, there are some children with low bone mass and recurrent fractures whose clinical picture is not as severe as those with idiopathic juvenile osteoporosis, suggesting that there is a wide spectrum of clinical findings in children and adolescents with marginal bone mineralization. In children with classical idiopathic juvenile osteoporosis, symptomatic treatment is offered; in some patients, calcitriol or supplemental sodium fluoride has been of benefit. Although the disorder ameliorates and even disappears at puberty, treatment of the prepubertal patient with sex steroids does not seem to accelerate the healing process. Administration of the bisphosphonate pamidronate has been helpful in reducing

bone pain and increasing vertebral BMD in small numbers of children with idiopathic juvenile osteoporosis.^{368,369}

LRP5 (vide supra) is a cell membrane protein expressed by osteoblasts that serves as coreceptor for signal transduction through the WNT-Frizzled- β -Catenin pathway leading to differentiation and function of osteoblasts. WNT signaling enhances differentiation of pluripotential mesenchymal precursor cells into the pathway of chondrogenesis and osteogenesis and impedes its differentiation into adipocytes.³⁷¹ By stimulating *RUNX2*, β -catenin further directs the osteochondroprogenitor cell into the osteoblastic track, and in the mature osteoblast, β -catenin enhances expression of osteoprotegerin and thus depresses osteoclastogenesis.³⁷² Sclerostin (encoded by *SOST*, OMIM 605740) binds to the extracellular domain of LRP5 and thereby inhibits WNT signaling.³⁷³ Intrinsic abnormalities of *LRP5* expression have been associated clinically with disorders of both impaired and excessive bone mineralization. The osteoporosis-pseudoglioma syndrome (OMIM 259770) is characterized clinically by congenital or early infantile onset of severe visual impairment because of microphthalmia and hyperplasia of the vitreous (pseudoglioma that may be erroneously identified as retinoblastoma), leading to retinal detachment, glaucoma, and blindness, marked osseous fragility with craniotables and fractures during late infancy, childhood or adolescence, and variable cognitive impairment, ligamentous laxity, and hypotonia.³⁷⁴ The disorder is transmitted as an autosomal recessive trait and is caused by biallelic (homozygous or compound heterozygous) inactivating (missense [p.Val336Met, p.Arg494Gln], nonsense [p.Arg428Ter, p.Arg1002Ter], frameshift, splice-site) mutations in *LRP5*—primarily located in the extracellular domain of LRP5.^{375,376} Missense mutations likely prevent normal binding of LRP5 to the product of the mesoderm development gene (*MESDC2*, OMIM 607783, chr. 15q25.1), a chaperone protein that directs LRP5 to the cell membrane. Although often asymptomatic, heterozygous carriers may be osteopenic; however, vision is not impaired. Intravenous administration of pamidronate over several years can increase bone mass in children with this disorder.³⁷⁶ Loss-of-function mutations in *LRP5* have also been associated with familial exudative vitreoretinopathy (OMIM 133780), a developmental disorder of retinal vasculature that may be transmitted as either an autosomal dominant (p.Leu145Phe) or autosomal recessive (p.Arg570Gly, p.Arg752Gly) trait; these patients also have reduced bone mass. LRP5 transduces not only the WNT signal but also that of *NDP* (OMIM 300658) encoding Norrin whose signal modulates ocular vitreoretinal formation. Gain-of-function mutations in *LRP5* are associated with increased bone mass (vide infra).

Osteogenesis Imperfecta

Osteogenesis imperfecta or “brittle bone disease” is a disorder of increased bone fragility usually associated with low bone mass that varies in clinical severity from lethality in utero or perinatally to mildly increased susceptibility to fractures in later life and that may be transmitted as either autosomal dominant or autosomal recessive traits.^{190,193,377} The original Silence classification of four types of osteogenesis imperfecta based upon underlying pathogenesis, clinical characteristics, and disease course has been modified by establishment of five clinical forms of this disease (designated clinical types 1–5) (see Table 20.10B) whose clinical and radiological manifestations may be attributed to variants of several of the 19 mutated gene currently associated with osteogenesis imperfecta (designated gene types I–XIX) (see Table 20.10C). Thus osteogenesis imperfecta is a primary form of osteoporosis that is caused by heritable errors of bone formation and mineralization of variable severity ranging from mild to lethal that is caused by genetic

variants critical for osteoblast differentiation (osteoblastogenesis) and function, collagen synthesis and processing, and formation of hydroxyapatite. Types (forms) of osteogenesis imperfecta may be classified according to the phenotype, that is, the extent of bone fragility and resulting clinical severity (see Table 20.10B) or by the site of the genetic error(s) in osteoblastogenesis or collagen formation and its modifications (see Table 20.10C).^{190,193,377–380} (The currently designated 19 genetic types [i.e., variant genes] of osteogenesis imperfecta are numbered in the order of their initial clinical description. In addition, there are several genes whose variants are associated with increased osseous fragility that may later be designated as other genetic forms of osteogenesis imperfecta [see Table 20.10C].) The hallmark of each of the five clinical types of osteogenesis imperfecta is increased bone fragility, but severity varies with clinical type 1 being least severe as those so designated having straight limbs and heights within the low normal range and clinical type 2 being lethal in the perinatal period because of respiratory insufficiency as a consequence of multiple rib fractures that reduce chest volume.³⁷⁷ Osteogenesis imperfecta clinical type 3 is associated with substantial deformities of the limbs, but affected patients live through infancy and childhood albeit with marked growth restriction and limited mobility. The severity of osteogenesis imperfecta clinical type 4 is intermediate between clinical types 1 and 3; adult stature is substantially restricted with heights between –3.6 and –4.6 SDs below the mean for gender. The phenotype of patients with osteogenesis imperfecta clinical type 5 (OMIM 610967) is similar to that of clinical type 4 but unique in that this form is associated with exuberant callus formation at sites of healing fractures and calcifications of interosseous membranes that occur only in patients with mutations in IFN-induced transmembrane protein-5 or bone-restricted IFITM5-like protein (*IFITM5*, OMIM 614757) (vide infra). The following classification of osteogenesis imperfecta is based on the functional site of the genetic error in osteoblastogenesis, osteoblast activity, or collagen synthesis, processing, and/or secretion.

Errors in Osteoblast Differentiation, Maturation, Function. Loss-of-function variants of *WNT1* (Wingless-type mouse mammary tumor virus [MMTV] integration site, member 1, OMIM 164820) and *LRP5* (OMIM 603506) have adverse impacts upon differentiation of osteoblasts and consequently inactivating mutations in these genes impair bone formation leading to osteogenesis imperfecta (*WNT1*—gene type XV, clinical types 3 and 4) and the osteoporosis-pseudoglioma syndrome (OMIM 259770) because of variants of *LRP5*. *WNT1* is a key ligand for the canonical WNT signaling pathway of osteoblast differentiation from mesenchymal stem cells. *WNT1* stimulates osteoblastogenesis by binding to the LRP5-Frizzled receptor complex that then activates an intracellular signal transduction pathway that inhibits proteasomal degradation of cytoplasmic β -catenin (*CTNNB1*, OMIM 116806). Accumulated β -catenin translocates to the nucleus of the mesenchymal stem cell where it inhibits differentiation into chondrocytes or adipocytes and stimulates osteoblastogenesis, resulting in increased bone formation and diminished bone resorption.³⁷² *WNT1* indirectly stimulates osteoclastogenesis as well. Inactivating mutations in *WNT1* may be monoallelic or biallelic; the clinical severity of deleterious *WNT1* mutations may vary and may include extraskelatal malformations, such as hypoplasia of a cerebellar hemisphere.

Osteogenesis imperfecta gene type XII (OMIM 613849) is a moderately severe form of this illness (clinical type 4) characterized by multiple fractures in early infancy with short, bowed long bones and highly arched palate but normal teeth, hearing, and sclerae.³⁸¹ It is transmitted as an autosomal recessive

disorder and is caused by inactivating mutations in transcription factor specificity factor 7 or osterix (*SP7*, OMIM 606633). Osterix is a 431 aa essential WNT1-dependent zinc-finger transcription factor requisite for maturation of preosteoblasts into osteoblasts and for functional expression of *COL1A1*; it stimulates both endochondral and intramembranous bone development; its expression is regulated by *RUNX2* (OMIM 600211).³⁸² Although its relevant function in the osteoblast is unknown, biallelic inactivating mutations in *TENTA5* (OMIM 611357) encoding a nucleotidyltransferase termed *FAM46A* that catalyzes transfer of nucleoside triphosphate to a hydroxyl group of an acceptor molecule is associated with osteogenesis imperfecta gene type XVIII.³⁸³ After nuclear transcription and initiation of translation of *COL1A1* and *COL1A2*, their nascent peptide products leave the nucleus and enter the endoplasmic reticulum where they undergo further modifications requiring chaperones for movement through this system. Thus biallelic loss-of-function mutations in serpin peptidase inhibitor, clade F, member 1 (*SERPINF1*, OMIM 172860) encoding the collagen chaperone heat shock protein 47 result in severe osteogenesis imperfecta (gene type VI, clinical type 3).³⁸⁴ Variants of *IFITM5* encoding IFN-induced transmembrane protein-5 (OMIM 614757), a protein synthesized by osteoblasts whose primary function may be to stabilize *SERPINF1*, are associated with a distinct form of osteogenesis imperfecta characterized by ossification of interosseous membranes of the forearm, hyperplastic callus formation at fracture sites, dense metaphyseal bands, and a “mesh-like” bone lamellation pattern (gene type V, clinical type 5).³⁷⁹ Deletion of or mutations in *PLS3* (OMIM 300131) sited on chromosome Xq23, encoding plastin 3—an actin and calcium binding protein essential for the integrity and remodeling of the actin filaments that form the cytoskeleton of the osteocyte, result in an X-linked form of osteogenesis imperfecta of modest severity (clinical type 1).³⁸⁵ Males with monoallelic deleterious variants of *PLS3* have decreased bone mineralization and experience vertebral compression and long bone fractures in early childhood, but do not exhibit blue sclerae, dentinogenesis imperfecta, or joint hyperflexibility. Low BMD may be present in heterozygous female carriers of *PL3* variants in whom clinical manifestations may vary from childhood-onset bone fragility fractures as in males to postmenopausal osteoporosis. Plastin 3 may also regulate osteoclastogenesis and the process of mechanosensing.

Errors in Synthesis and Processing of Collagen Type 1.

Collagen type 1 is a trimer composed of two cross-linked molecules of collagen type 1A1 (*COL1A1*, Collagen type I, alpha-1, OMIM 120150) and one molecule of collagen type 1A2 (*COL1A2*, Collagen type I, alpha-2, OMIM 120160) that intertwine to form collagen type I in bone, skin, ligaments, tendons, sclerae, and teeth.¹⁹¹ The fibers of both collagen type 1A1 and 1A2 are composed of triple repeats of glycine and two additional amino acids—often proline, hydroxyproline, or lysine. Mutations in *COL1A1* (gene type I) or *COL1A2* (gene type II) that lead to a stop codon result in a truncated procollagen product that is rapidly degraded; thus only normal collagen type I is produced but in reduced amounts. Patients with mutations in *COL1A1* or *COL1A2* that change (e.g., substitution of cysteine for glycine at critical positions) its three-dimensional configuration result in the formation of abnormal collagen 1 α 1 fibers and thus more severe bone disease. Usually, variants of *COL1A1* compromise collagen synthesis more severely than do variants of *COL1A2*. Thus osteogenesis imperfecta gene type I (OMIM 166200) is an autosomal dominant disorder (new mutation in 33% of patients) resulting primarily from “functional null alleles”—the result of splicing defects or point mutations leading to insertion errors or truncation of collagen type

1A1 (*COL1A1* - p.Gly178Cys, p.Arg963Ter), mutations that result in decreased transport of procollagen- α 1(I) into the cytoplasm or its release into matrix—thereby modestly decreasing production of intact procollagen type I. Its clinical manifestations are relatively benign: intensely blue sclerae are present at birth and persist throughout adulthood, modestly low bone mass, infrequent fractures with little deformity, low normal adult stature, hearing loss in 50%, mitral valve prolapse in 18%, and rarely dentinogenesis imperfecta (osteogenesis imperfecta gene type IB). (Paradoxically, patients with mild osteogenesis imperfecta gene type I caused by mutations at selected procollagen type I carboxyl terminal propeptide cleavage sites [*COL1A1*—p.Asp1219Asn; *COL1A2*—p.Ala1119Thr] may have normal or increased lumbar spine BMD by both DXA and QCT examinations despite increased bone fragility).³⁸⁶ Lethal mutations in *COL1A1* are those that alter an amino acid with a branched or charged side chain and those within the binding sites of the collagen monomer for integrins, matrix metalloproteins, fibronectin, and cartilage oligomeric matrix protein and those that result in binding to and degradation of intact procollagen subunits.¹⁹¹ Lethal mutations in *COL1A2* are those that interfere with its binding to proteoglycans. Mutations (p.Arg134Cys) in *COL1A1* may also be found in patients with classical Ehlers-Danlos syndrome (OMIM 130000) of hyperextensible skin and laxity of ligaments of the spine and large and small joints. Children with clinical features of both osteogenesis imperfecta (osseous fragility) and Ehlers-Danlos syndrome have been described.³⁸⁷ In these patients, the mutations have been concentrated within the first 90 aa of the helical region of collagen 1 α 1 and prevent normal posttranslational removal of the procollagen aminopropeptide; although the mutant protein can be incorporated into collagen, the structural integrity of the product is impaired as its fibrils are thin and weak.³⁸⁸ Osteogenesis imperfecta gene types I-IV describe forms of variable severity of this disease associated with loss-of-function mutations in *COL1A1* or *COL1A2* (see Table 20.10B).

Mutations of *COL1A1* and *COL1A2* are usually heterozygous (monoallelic) and transmitted as autosomal dominant diseases; the mutant collagen type 1 subunit may exert a dominant-negative effect as it interacts with the intact subunit (gene types I-IV; clinical types 1-4). After synthesis, COL1 α 1 and Col1 α 2 undergo posttranslational modifications, including hydroxylation of selected lysine and proline residues, cross-linking of collagen strands, release from the osteoblast into surrounding matrix, removal of amino and carboxyl-terminal propeptides, and assembly into collagen fibers. Among the most important posttranslational modifications of type I procollagen is hydroxylation of proline and lysine residues by prolyl and lysyl hydroxylases. Hydroxylation of proline residues at carbon 4 affords thermal stability, whereas hydroxylation of lysyl residues permits binding of carbohydrates—galactose or glucosyl-galactose—and the formation of crosslinks within or between procollagen chains.¹⁹³ Hydroxylations of proline at carbon 3 in position 986 of *COL1A1* and at position 707 of *COL1A2* are especially critical for stability of the three-dimensional configuration of type I procollagen and its subsequent maturation to collagen type I.¹⁹³ After synthesis, COL1 α 1 and COL1 α 2 are further modified by hydroxylation on selected proline and lysine residues. Failure to form 3-hydroxyproline at aa 986 of collagen 1 α 1 and aa 707 of collagen 1 α 2 may be caused by loss-of-function variants of one of the three genes involved in this process—prolyl 3-hydroxylase 1 (*P3H1*, OMIM 610339)—also termed *leprecan*, cartilage associated protein (*CRTAP*, OMIM 605497), and cyclophilin B (*CypB*, Peptidyl-prolyl isomerase B, *PPIB*, OMIM 123841). In the absence of any one of these factors, the helical domain of collagen 1 α 1 is modified by other enzymes leading to

alterations in its strength.³⁷⁹ Biallelic loss-of-function variants in any one of these three genes leads to severe to lethal forms of osteogenesis imperfecta (clinical types 2, 3, 4; osteogenesis imperfecta gene types VII, VIII, IX; see Tables 20.10B, 20.10C). Osteogenesis imperfecta gene type VIII (OMIM 610915) caused by mutant *P3H1* occurs primarily in African-American and Middle Eastern subjects.³⁸⁹⁻³⁹¹ Prolyl 3-hydroxylase 1 specifically hydroxylates carbon 3 of the proline residue at codon 986 in collagen 1A1 and at codon 707 in collagen 1A2. The phenotype of osteogenesis imperfecta gene type VIII overlaps with those of clinical types 2 and 3; in addition to osseous fragility, it is associated with substantial growth retraction, white sclerae, and bulbous metaphyses. *CRTAP* and *CypB* stabilize the collagen prolyl 3-hydroxylation complex and also chaperone the movement of collagen from the endoplasmic reticulum.^{193,392} Loss-of-function mutations in *PPIB* have been designated osteogenesis imperfecta type gene type IX, an often lethal disorder in which osseous fragility is evident in utero (see Table 20.10B).³⁹³⁻³⁹⁵ *CRTAP* is expressed in the proliferative zone of developing cartilage and at the chondroosseous junction. *Crtap* “knock-out” mice develop an osteochondrodysplasia (kyphoscoliosis, rhizomelic shortening of the proximal segment of the limbs) and severe osteopenia, the latter caused by reduced production and alteration in the quality of osteoid and consequent decreased rate of mineral deposition.³⁹⁶ Mice deficient in *Crtap* are unable to 3-hydroxylate the proline residue near the carboxyl terminus of bone collagen 1A1, leading to increased hydroxylation of lysine residues and resultant abnormal structure of the collagen fibril—changes that result in defective mineralization of bone collagen type I. Nonhydroxylated proline at codon 986 in bone collagen 1A1 was demonstrated in 3/11 patients with a recessively transmitted lethal or severe osteogenesis imperfecta characterized by multiple fractures of the long bones resulting in rhizomelic shortening of the limbs with externally rotated and abducted legs, poorly mineralized calvaria and ribs, proptotic eyes, and white or light blue sclerae.³⁹⁷ This proved caused by homozygous or compound heterozygous loss-of-function mutations in *CRTAP* (frameshift [c.879delT], 16-bp duplication in exon 1, nonsense [p.Gly276Ter], missense [p.Met1Ile], splice donor site of exon 1 at the first intronic nucleotide [IVS1+1G \Rightarrow C]) that interfered with effective hydroxylation of the proline residue at codon 986 of bone procollagen 1A1. This disorder has been designated osteogenesis imperfecta gene type VII (OMIM 610682). In other patients with osteogenesis imperfecta gene type VII, a homozygous mutation in *CRTAP* has been identified in which alteration of one nucleotide (c.472-1021C \Rightarrow G) generates a cryptic splice donor site that leads to inclusion of 73 bp of intron 1 into the genome of *CRTAP* thus extending exon 2.³⁹⁶ This mutation results in more rapid degradation of *CRTAP* and consequently leads to decreased 3-hydroxylation of proline 986 in bone collagen 1A1. Osteogenesis imperfecta gene type VII has been identified in a Native American population in northern Quebec. Clinically, it is an autosomal recessive disorder in which fractures are present at birth; often the frequency of fractures declines with advancing age—particularly after adolescence; the sclerae are slightly bluish; there is progressive skeletal deformation leading to rhizomelic shortening of the limbs and restricted ambulation.³⁹⁸

Loss-of-function variants in *PLOD1* (OMIM 153454) impair hydroxylation of lysine in the helical regions of collagen type I and have been associated with Ehlers-Danlos syndrome, kyphoscoliosis type 1 (OMIM 225400). Inactivation of *PLOD2* (OMIM 601865) results in the association of osteogenesis imperfecta, congenital joint contractures and pterygia (Bruck syndrome 2, OMIM 609222). (Bruck syndrome 1 [OMIM 259450] has been attributed to inactive variants of *FKBP10* [OMIM 607063], a chaperone protein required for movement

of collagen type I propeptides through the osteoblast.) Deleterious biallelic mutations (p.Phe249Leu; c.34G>C) in *BMP1* (OMIM 112264) prevent removal of the carboxyl terminal propeptides of collagen 1 α 1 and collagen 1 α 2 and hence formation of the collagen type I fibril thus resulting in a moderately severe form of osteogenesis imperfecta (gene type XIII; clinical type 3). Gene type XIII osteogenesis imperfecta is associated with multiple fractures annually, either borderline low or elevated bone mass by DXA, substantial growth retardation, faintly blue sclerae, and normal teeth.^{399,400} *BMP1* is a multifunctional protein; one of its most important activities is as procollagen type I C-terminal propeptide endoproteinase. Inactivation of *BMP1* impairs proteolytic removal of the carboxyl terminal propeptide from procollagen type I and the normal assembly of mature collagen type I fibrils. Interestingly, this form of osteogenesis imperfecta may be associated with either borderline low or even increased lumbar spine areal BMD by DXA despite which treatment with bisphosphonates has been clinically and radiographically useful.³⁹⁹ In this regard, it should be noted that patients with mild osteogenesis imperfecta gene type I/clinical type 1 caused by mutations in the procollagen type I carboxyl terminal propeptide cleavage sites, also have normal or increased lumbar spine BMD by both DXA and pQCT examinations.³⁸⁶ Heterozygous mutations in *IFITM5* (OMIM 614757) result in osteogenesis imperfecta of moderate severity (gene type V; clinical type 5) characterized by formation of painful hyperplastic callus at fracture sites, calcification of the membrane between adjacent radius and ulna bones, and a dense metaphyseal band below the growth plates of the long bones.

Osteogenesis imperfecta gene type II/clinical type 2 is a disorder that is lethal in the perinatal period or in early infancy. It is usually the result of de novo heterozygous mutations in *COL1A1* or *COL1A2* with substitution of an alternative amino acid for glycine in the triple helical domains of the procollagen α 1(I)/ α 2(I) chains (*COL1A1*—p.Gly94Cys, p.Gly391Arg, p.Gly1003Ser; *COL1A2*—p.Gly547Asp, p.Gly865Ser, p.Gly976Asp); these mutations lead to the synthesis of abnormal procollagen chains that bind to and thereby inactivate intact procollagen peptides in a dominant-negative manner severely curtailing the synthesis of intact collagen type I. Osteogenesis imperfecta clinical type 2 is manifested by in utero fractures, long bone deformities, very little calvarial mineralization, and death because of respiratory insufficiency. Lethal phenotypes of osteogenesis imperfecta are also associated with homozygous loss-of-function mutations in *LEPRE*, *CRTAP*, *PPIB*, and *CREB3L1*, the latter encoding cAMP response element-binding protein 3-like 1 (OMIM 616215) (see Table 20.10C).¹⁹⁴ Osteogenesis imperfecta gene type III (OMIM 259420) is an autosomal dominant trait resulting from point or frameshift mutations in *COL1A1* (p.Gly154Arg, p.Gly844Ser) or *COL1A2* (p.Gly526Cys). Osteogenesis imperfecta clinical type 3 is characterized by recurrent fractures leading to progressive bone deformities that are often apparent at birth, kyphoscoliosis, extreme short stature, blue sclerae that lighten with age, abnormal dentition (in 80% of children <10 years of age), and hearing loss; it may be caused by variants of many genes (see Table 20.10B). Osteogenesis imperfecta clinical type 4 (gene type IV, OMIM 166220) is an autosomal dominant disease most often associated with point mutations or small deletions in *COL1A2* (Gly586Val, Gly646Cys, Gly1012Arg) and occasionally in *COL1A1* (p.Gly175Cys, p.Gly832Ser). It is of variable severity with prolonged survival, mild to moderate bone deformities, short stature, normal sclerae, dentinogenesis imperfecta, and hearing loss. Osteogenesis imperfecta clinical type 4 may also be caused by variations in *CRTAP*, *PPIB*, *WNT1*, *TMEM38B*, or *SP7*. Osteogenesis imperfecta clinical type 5 (gene type V, OMIM 610967) is manifested not only by osseous fragility but also by dislocation of the radial head, exuberant callus formation at

sites of healing fractures and calcification of interosseous membranes between adjacent radius/ulna and tibia/fibula and is presently associated only with variants of *IFITM5* encoding IFN-induced transmembrane protein-5 (OMIM 614757, chr. 11p15.5).^{401–403} Other clinical characteristics of gene type V osteogenesis imperfecta are autosomal dominant transmission, moderate to severe bone fragility (lumbar spine areal BMD Z scores range between -7.7 and -0.7), severe to mild growth retardation (adult height Z scores vary from -8.7 to -0.1), dislocation of the radial head, white sclerae, and normal dental development. Histologically, there is irregular arrangement of lamellae. The most frequent mutation in *IFITM5* by whole exome sequencing is a heterozygous c. $-14C>T$ transition within its 5' untranslated region.^{401–404} This mutation is 14 bp upstream of the reference initiation codon and creates a new initiation signal that adds five aa (Met-Ala-Leu-Glu-Pro) to the amino terminus of IFITM5 increasing its length from 132 to 137 aa. The *IFITM5* variant p. Ser40Leu has also been identified in patients with osteogenesis imperfecta gene type V, albeit without its classical features of interosseous calcification and excessive callus formation.⁴⁰⁵ IFITM5 is a protein that is abundantly expressed within osteoblast membranes during embryonic and postnatal development of the skeleton; it has amino and carboxyl extracellular termini, two transmembrane domains, and an intracellular helical domain. IFITM5 encodes an osteoblast differentiation factor that is involved in protein trafficking and folding; experimentally, loss of *Ifitm5* results in decreased bone formation, particularly in utero and in decreased expression of *SERPINF1* (OMIM 172860).^{405,406} Decreased expression of *SERPINF1* results in autosomal recessive osteogenesis imperfecta gene type VI (OMIM 610968) (clinical type 3) and diminished synthesis of its product pigment epithelium-derived factor (PEDF).⁴⁰⁵ PEDF is a chaperone protein, whose concentration may be measured in serum, that regulates osteoblast differentiation and bone mineralization; it is synthesized by chondrocytes, osteoblasts, and osteoclasts; PEDF interferes with function of vascular endothelial growth factor (VEGF), a protein that enhances migration of osteoblasts and osteoclasts into cartilage; PEDF may regulate bone mineralization by increasing synthesis of osteoprotegerin, thereby impeding osteoclastogenesis. Osteogenesis imperfecta gene type VI (OMIM 610968) is phenotypically similar to gene type IV and is characterized clinically by severe bone fragility that first manifests after 6 months of age and microscopically by excess unmineralized osteoid, and a "fish-scale" pattern of lamellation of bone matrix consistent with a defect in bone mineralization.^{193,407–409} Loss-of-function mutations in *SERPINF1* may interfere with bone formation while increasing osteoclast generation and bone dissolution. Serum concentrations of PEDF are undetectable in patients with osteogenesis imperfecta gene type VI providing a diagnostic tool for this illness.⁴¹⁰ Interestingly, patients with osteogenesis imperfecta gene type VI do not respond to treatment with bisphosphonates as well as do patients with other forms of this heterogeneous disease.

Osteogenesis imperfecta gene type XI (clinical type 3) is the result of inactivating mutations in *FKBP10* (FK506-binding protein 10, OMIM 607063) encoding an endoplasmic reticular protein (FKBP65) that is also a chaperone for procollagen type I—one that is essential for hydroxylation of lysine residues in its telopeptide, a modification necessary for cross-linking, as well as its transcellular movement and secretion.⁴¹¹ In the absence of functional FKBP65, procollagen type I accumulates in the endoplasmic reticulum of the osteoblast. This disorder is transmitted as an autosomal recessive trait that begins in infancy; affected patients have repeated long bone fractures and progress to wheel chair dependency in early childhood; they may or may not develop joint contractures but do not

display dentinogenesis imperfecta.^{412–414} Mutations in *FKBP10* have also been recorded in patients with Bruck syndrome 1 (OMIM 259450—pterygia, congenital contractures, fractures in infancy resulting in limb deformities, growth retardation, scoliosis) suggesting that osteogenesis imperfecta gene type XI and Bruck syndrome 1 are likely allelic disorders whose clinical manifestations depend on the mutation site and other modifying factors.⁴¹²

Collagen Secretion and Stress of the Endoplasmic Reticulum. Osteogenesis imperfecta gene type X is an autosomal recessive disorder caused by biallelic inactivating mutations in *SERPINH1* (OMIM 600943) encoding a multifunctional 418 aa peptide designated collagen type 1 binding protein (CBP) 2 that is also termed heat shock protein (HSP) 47. Gene type X osteogenesis imperfecta (clinical type 3) is a severe disorder with fractures occurring throughout the skeleton that begins in utero.^{193,414a} CBP2/HSP47 is essential for cartilage organization, the formation of endochondral bone, and the fabrication and maintenance of the integrity of the triple helical structure of procollagen type I, its transcellular movement and secretion, and its resistance to proteolytic degradation.^{414a,415,416} Biallelic variants of *CREB3L1* (OMIM 616215), a component of the endoplasmic reticular stress response in osteoblasts, have been identified in fetal siblings with severe osteogenesis imperfecta (gene type XVI, clinical type 2).⁴¹⁷ Mutations in membrane-bound transcription factor protease site 2 (*MBTPS2*, OMIM 300294) (encoding a zinc metalloproteinase that regulates intramembrane proteolysis of several transcription factors that regulate secretion of type 1 collagen and is also involved in the stress response of the endoplasmic reticulum) are transmitted as an X-linked trait and result in osteogenesis imperfecta of moderate severity (gene type XIX, clinical type 3).⁴¹⁸ Biallelic variants of transmembrane protein 38B (*TMEM38B*, OMIM 611236) encoding an intracellular potassium channel that alters intracellular Ca^{2+} levels that adversely affect the release of procollagen type I from osteoblasts (and thus increases accumulation of procollagen type I in the osteoblast's endoplasmic reticulum, thereby impairing its further function and leading to endoplasmic reticular stress) has been designated osteogenesis imperfecta gene type XIV.⁴¹⁹ *TMEM38B* encodes the 291 aa trimeric intracellular cation channel type B (TRICB), one component of TRIC, a monovalent cation channel that is critical for the release of Ca^{2+} from intracellular storage sites, such as the sarcolemma and endoplasmic reticulum and thus maintenance of cytosolic Ca^{2+} concentrations, a process necessary for normal cell differentiation, division, and function (including that of the osteoblast). Gene type XIV osteogenesis imperfecta is an autosomal recessive disorder of variable severity (clinical types 3, 4) with fractures occurring in utero or during early childhood but with normal dentition, hearing, and sclerae that has been identified in Middle Eastern families.^{420,421}

Although undesigned as causes of osteogenesis imperfecta, a number of gene variants result in osseous fragility other than those so defined (see Table 20.10C), including those that result in Cole-Carpenter syndromes 1 (OMIM 112240) and 2 (OMIM 616294) characterized clinically by pre- and postnatal fractures of long bones, frontal and coronal craniosynostosis, proptosis, hydrocephalus, and macrocranium. Cole-Carpenter syndrome 1 is the result of inactivating variants of procollagen-proline, 2-oxoglutarate-4-dioxygenase, beta subunit (*P4HB*, OMIM 176790) resulting in decreased hydroxylation of proline residues in preprocollagen type 1. Cole-Carpenter syndrome 2 is the consequence of inactivating variants of *SEC24D* (SEC24-related gene family, member D, OMIM 607186) encoding a component of osteoblastic vesicles that transports/exports protein from the endoplasmic

reticulum within the osteoblast facilitating movement of procollagen type 1 molecules.

Evaluation of Children and Adolescents With Low Bone Mass

Identification of the pathogenesis of decreased bone mineralization in childhood is initiated with careful review of the patient's general medical history, as well as that related to the skeletal system beginning prenatally together with those of immediate family members through several generations, followed by documentation of physical findings (stature, skeletal deformities, scleral color, and dental status), biochemical status (measurement of serum calcium, magnesium, phosphate, creatinine, alkaline phosphatase, calcidiol, calcitriol, and other clinically relevant studies), pertinent roentgenograms, assessment of skeletal mineralization, and ultimately examination of the integrity of genes related to formation and maintenance of the skeleton. Various forms of rickets should be excluded as should disorders known to be associated with suboptimal bone mineralization, such as anorexia nervosa, asthma treated with glucocorticoids, rheumatic joint and bone diseases, chronic inflammatory disorders (e.g., inflammatory bowel disease), and neoplastic disorders and their treatment. Decreased bone mineralization may also occur in patients with disorders of mobility (e.g., cerebral palsy, muscular dystrophy, spinal muscular atrophy) and those with endocrinopathies (GH deficiency, excessive exposure to or overproduction of glucocorticoids, sex hormone deficiencies, type 1 diabetes mellitus), hematological diseases (thalassemia, sickle cell anemia, leukemia), systemic abnormalities (cystic fibrosis), and chronic renal failure before and/or after kidney transplantation.^{321,322,422}

Osteoporosis caused by osteogenesis imperfecta is most often made clinically apparent by the occurrence of nontraumatic fractures occurring in utero, postnatally, during childhood, or in adolescence and confirmed by radiological evaluation of the skeleton and determinations of BMC and concentration.^{323,324,422,423}

Thus evaluation of the child/adolescent with a history of low-impact fractures (defined as two or more long bone fractures sustained by a fall from a distance that is less than the standing height of the patient before chronological age 10 years, or three or more before age 19 years, or a vertebral fracture without local disease or substantial trauma) begins with historical review and physical examination directed to the identification of factors that might adversely affect bone formation, mineralization, and strength.^{314,317} Fractures of the tibia and femoral diaphyses occur often in children with osteogenesis imperfecta.³⁷⁷ In addition to genetic and hormonal influences, the most important elements necessary for the accrual and maintenance of normal bone mass that need to be evaluated are those that relate to diet (sufficient intake of calcium and protein; absence of anorexia nervosa), sustained normal vitamin D stores either by exposure to sunlight or ingestion of supplements, normal mobility with consistent weight-bearing exercise, and the presence of chronic diseases, particularly those that may be treated with glucocorticoids (e.g., asthma, chronic inflammatory states) that might impair bone development. Examination of the patient's growth pattern to determine whether statural growth has been normal and normal weight for stature and gender has been attained and maintained and to assess by physical examination stages of primary and secondary sexual maturation are essential. Determination of skeletal maturation (bone age) is useful to determine if the child is growing in accord with her/his genetic potential. If pertinent, systemic illnesses, such as chronic renal disease, celiac disease, inflammatory bowel disease, and endocrinopathies should be eliminated. Assessment of areal bone mineralization and bone

mineral apparent density is most often accomplished by DXA in children with referral to specific reference data for chronological age, gender, and ethnicity/ancestry, while also taking into consideration such factors as height, pubertal stage, and skeletal maturation.^{317,320,321,424} In a series of 304 children and adolescents undergoing DXA bone mineralization studies, 36% were doing so because of a history of fractures, 27% because of hypogonadism, and 22% because of gastrointestinal (celiac, inflammatory bowel) disease.⁴²⁵ Low body mass index and low vitamin D stores were the most significant predictors of subnormal BMD (<-2 SDs for age and gender). Depending on the individual patient, measurements of serum calcium, phosphate, alkaline phosphatase, creatinine, PTH, calcidiol (25OHD), and reproductive hormones, as well as disease-specific analytes (e.g., for inflammatory bowel or celiac diseases) may be indicated. Bone turnover markers are of marginal diagnostic utility in children, although useful as indices of therapeutic response.^{426,427}

Clinical manifestations of osteogenesis imperfecta vary from mild to moderate, severe, or lethal.^{193,377} Radiographic findings in subjects with osteogenesis imperfecta include, in addition to diffusely low bone mass, thin cortices, metaphyseal flaring, fractures and bone deformities resulting therefrom, wormian skull bones (frequent but not pathognomonic of osteogenesis imperfecta), platybasia that may compress overlying hindbrain, vertebral compression, and a triradiate pelvis.¹⁹¹ In children with osteogenesis imperfecta, bone densitometry, usually but not invariably, reveals decreased mineralization, the extent of which correlates to a degree with clinical manifestations. The diagnosis of osteogenesis imperfecta is established by clinical criteria and confirmed by genotyping of *COL1A1* and/or *COL1A2* or other pertinent gene(s), although failure to detect a genetic mutation does not necessarily rule out this disorder but suggests that more extensive genetic inquiry is warranted (whole exome or whole genome sequencing). Undetectable serum levels of PEDF are indicative of osteogenesis imperfecta caused by inactivation of *SERPINF1*.⁴¹⁰ Occasionally, biopsy of the iliac crest and histological examination of the bone may be necessary for subclassification of the disorder. Osteogenesis imperfecta clinical type 2 can be identified prenatally by fetal ultrasonography; other types might be determined prenatally by analysis of collagen synthesized by cells cultured from chorionic villus biopsies and by genetic analyses. Included in the differential diagnosis of recurrent fractures in children are child abuse, various forms of rickets including hypophosphatasia, the McCune-Albright syndrome of fibrous dysplasia (OMIM 174800), juvenile Paget disease, and juvenile osteoporosis.

Other clinical findings of note in patients with osteogenesis imperfecta include: progressive hearing impairment—present in 40% to 60% of subjects, joint hypermobility in perhaps 60% to 70% of patients that may lead to joint dislocation and/or tendon rupture, and craniocervical junction insults. Cranial-cervical deformities occur in approximately 30% of patients with osteogenesis imperfecta and may be categorized as: basilar invagination, basilar impression, and platybasia—the most common of these complications. The presence of dentinogenesis imperfecta, substantial short stature, and very low lumbar axial BMD are strongly associated with skull-based anomalies. Symptoms/signs of cranial involvement are headaches on movement, coughing or sneezing; trigeminal neuralgia; weakness of arms/legs; and difficulties with balance. Screening of subjects with osteogenesis imperfecta for these complications is essential. It is emphasized that in the absence of a vertebral fracture, the diagnosis of osteoporosis is not established by DXA data alone but requires the corresponding and relevant clinical history of associated disease and documented increased fracture risk. Serial areal BMD measurements at 6- to 12-month intervals

are useful in determining the trend in bone mineralization in children with diseases that place them at risk for development of osteoporosis.⁴²²

Management of Children and Adolescents With Low Bone Mass/Osteogenesis Imperfecta. Keys to the prevention of children and adolescents from developing low bone mass is the provision of a diet adequate in calcium and vitamin D, encouragement of weight-bearing activities and exercise, and the avoidance of exposure to agents that may impede normal accrual of bone mineral. After assessment and when necessary and appropriate, interventions may include treatment of an accompanying underlying systemic disease or endocrinopathy that may be of pathogenetic significance in the development of low bone mass, such as elimination, such as elimination or reduction in glucocorticoid dose in an asthmatic child. Therapeutic agents used in the treatment of patients with low bone mass increase skeletal mass either by inhibiting bone resorption (antiresorptive or antiremodeling drugs) or by stimulating bone formation (anabolic agents).⁴²⁸⁻⁴³⁰ In adults, the most widely used antiresorptive medications are sex hormones, selective estrogen receptor modulators, denosumab (a monoclonal antibody that binds to and inhibits RANKL-mediated osteoclastogenesis—thus mimicking the effect of osteoprotegerin), and bisphosphonates. Selective estrogen receptor modulators (SERMs), such as triphenylethylene, benzothioephene, or naphthalene-related compounds (e.g., raloxifene) bind with high affinity to estrogen receptor α in specific tissues where they alter the three-dimensional configuration of the receptor and recruit tissue-selective cohorts of various cofactors, thus either reducing (breast, brain) or inducing (bone) receptor function in targeted sites.⁴³¹ SERMs decrease osteoclast formation primarily at trabecular bone sites, but their efficacy in increasing BMD is less than that of estrogens themselves.⁴³² Although nasal salmon calcitonin inhibits osteoclast function directly and has modest bone restorative effects, it is seldom used for the treatment of osteoporosis in adults or children.⁴³³ Bone anabolic medications include teriparatide (PTH¹⁻³⁴), abaloparatide (PTH¹⁻³⁴), and romosozumab (a humanized monoclonal antibody against sclerostin, an inhibitor of LRP5/6-WNT- β -catenin-mediated osteoblast differentiation). Although approved for treatment of osteoporosis in adults, denosumab and romosozumab await further development and evaluation in children with osteoporosis of varied pathogenesis.⁴³⁴ Despite having been proven useful in the treatment of adults with osteoporosis, both teriparatide (PTH¹⁻³⁴) and abaloparatide (PTH¹⁻³⁴) have the potential risk of inducing osteosarcoma and are not used in children.

Infants/children/adolescents with osteogenesis imperfecta require care by a team of experienced endocrinologists, orthopedic surgeons, and physiatrists and their corresponding healthcare associates. Rehabilitative services and physical therapy to improve muscle strength and mobility with the restraints of bone fragility are encouraged as is protected exercise—such as walking and swimming. Patients with primary osteogenesis imperfecta (and secondary forms of osteoporosis) with documented vertebral and/or long bone fractures have been treated most often with bisphosphonates. Bisphosphonates are compounds related to pyrophosphates in which the linking oxygen molecular bridge between two phosphate moieties is replaced by a carbon link to which two side chains are attached; one side chain is often a hydroxyl group or chloride atom that together with phosphate residues binds tightly to hydroxyapatite and coats bone surface; the second side chain may be “simple” and contain chloride or sulfur atoms or more complex and heavier with nitrogen atoms and ring structures composed of carbon and oxygen (Fig. 20.14).⁴³⁵ When one side chain attached to the central carbon atom is a hydroxyl group

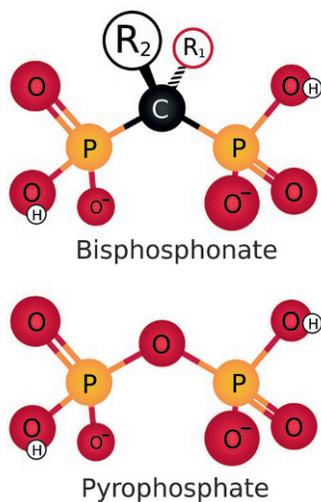

Fig. 20.14 Bisphosphonates are analogues of pyrophosphate in which carbon has been substituted for the oxygen bridge between two phosphate groups; two side chains (R1, R2) are attached to the carbon atom: R1 may be a hydroxyl group or chloride atom that together with phosphate residues binds tightly to hydroxyapatite and coats bone surface; R2 may contain chloride or sulfur atoms or it may be composed of ring structures containing carbon, oxygen, and nitrogen. (Courtesy Wikimedia Commons User Adenosine.)

(OH⁻), binding of the bisphosphonate to hydroxyapatite is increased and the solubility of the mineral phase of bone is reduced, thus decreasing resorption of hydroxyapatite. The second side chain determines the potency and longevity of the bisphosphonate. Bisphosphonates that contain nitrogen as a constituent in one of the side chains are substantially more potent than are the “simple” bisphosphonates.⁴³⁶ In zoledronic acid, a bisphosphonate commonly used in childhood because of its safety profile and prolonged duration of action, the second side chain is CH₂-imidazole.

Bisphosphonates chelate (bind) the calcium ions of hydroxyapatite and thus are targeted to bone; within the resorption lacuna beneath an osteoclast, bisphosphonates dissociate from hydroxyapatite as the pH is lowered by osteoclast secretion of H⁺ and are then endocytosed into the interior of the osteoclast. After bisphosphonates are ingested by osteoclasts, they inhibit the cell’s energy producing capacity, leading to their death and hence decrease in bone resorption and remodeling without impairment of osteoblast-mediated synthesis of new bone with consequent increase in bone mass and strength.⁴²³ Within the osteoclast, bisphosphonates impede osteoclast function by hastening their death by two mechanisms: (1) “simple” bisphosphonates, such as medronate, etidronate, and clodronate are metabolized into analogues of ATP that interfere with release of phosphate and hence with energy generation; additionally, simple bisphosphonates prevent movement of ATP into the osteoclast’s mitochondria as a consequence of which mitochondria disintegrate and osteoclast apoptosis is initiated—thereby further interfering with bone resorption. (2) Large, nitrogen containing bisphosphonates (pamidronate, zoledronic acid) act by impairing cholesterol synthesis by inhibiting farnesyl pyrophosphate synthase activity in osteoclasts. This enzyme is essential for synthesis of cholesterol through the mevalonate pathway; its inhibition prevents prenylation of proteins, a posttranslational modification that enables prenylated proteins to interact with proteins and to bind to cell membranes.³⁹³ Inhibition of this pathway in osteoclasts impairs formation of the ruffled border and actin rings, movement

of osteoclast products into the resorption lacuna, and resorption of degraded bone products—all metabolic functions of osteoclasts essential for bone resorption. The biological activity of a bisphosphonate on osteoclast function is observed immediately after its administration as serum calcium concentrations decline rapidly; indeed, this rapid effect has been used in the treatment of hypercalcemic patients. The effects of bisphosphonates on bone last long after the agent has been discontinued (the “residence time”) enabling some compounds to be given as infrequently as once yearly or half-yearly (e.g., zoledronic acid).³⁸⁰ Because the bisphosphonates remain in bone for extremely long intervals, their long-term effects are cumulative. Histomorphometric analysis has revealed that bisphosphonate-mediated inhibition of osteoclast stimulated bone resorption increase bone mineralization by decreasing the number of resorption cavities and thus the remodeling space, preserving cancellous (trabecular) bone architecture, and decreasing porosity of cortical bone.

Bisphosphonates have been useful in improving mineralization in children with osteogenesis imperfecta and related syndromes, as well as in those with glucocorticoid-induced osteoporosis and those in whom mobility is limited, such as muscular dystrophies and cerebral palsy.⁴³⁵ In many infants and children, intravenous pamidronate (0.5–1 mg/kg/dose on three consecutive days up to 2–15 mg/kg/y administered once every 3 to 6 months for an annual dose of 9 mg/kg/y) has been used. Intravenous infusion of zoledronic acid (first dose 0.025 mg/kg over 30 minutes; 0.05 mg/kg dose at +6, 12, 18, 24 months; continuing dose if required 0.0125 mg/kg every 6 months) has proven effective in increasing BMD, reducing fracture incidence, and improving mobility and wellbeing in patients with osteogenesis imperfecta.^{314,423,429,435,437} Histomorphometric analysis of an iliac bone biopsy after administration of bisphosphonate to children with osteogenesis imperfecta demonstrates increase in thickness of cortical bone and in trabecular number but not trabecular thickness. Discontinuation of bisphosphonate administration may lead to increase in fracture risk between weaker new bone and stronger treated bone. Therefore if there has been no adverse response and positive clinical benefit (absence of new fractures, decreased bone pain, enhanced mobility) and increase in BMD/BMC by serial DXA measurements, treatment with bisphosphonate at half-dose may be continued until adult height is achieved at which point bisphosphonate administration is discontinued and thorough reevaluation undertaken; this plan may be modified depending on the individual’s response to the therapeutic drug.^{324,423} Protocols for the treatment of children/adolescents with secondary forms of osteoporosis have also been presented.^{322,423} Bisphosphonates have also been used in the treatment of children with hypercalcemia recalcitrant to other management (e.g., hydration, diuretics).⁴²³ An expected side effects of bisphosphonate administration is hypocalcemia—anticipated by the provision of supplemental calcium and vitamin D before and for several days after therapeutic administration of the bisphosphonate. To avoid medication-related systemic effects, such as fever, malaise, and myalgia, administration of an analgesic and antipyretic agent for 48 to 72 hours after administration of the bisphosphonate is often used. Serious side effects of bisphosphonates are unusual but include iritis, atypical femoral fracture caused by decreased bone remodeling, and osteonecrosis of the jaw, the latter complication being unusual in children.³⁸⁰ Limited data indicate that oral bisphosphonates (alendronate, olpadronate) administered daily also increase areal BMD in children with osteogenesis imperfecta and connective tissue disease but with lower efficacy than intravenous administration. However, currently although bisphosphonates are not approved for use in children by the FDA, they are widely used.⁴³⁷

Side effects of bisphosphonates have been both acute (fever, myalgia, abdominal pain, vomiting, hypocalcemia) and chronic (inflammatory disorders of the eye, osteonecrosis of the jaw in the elderly, and induced “osteopetrosis”) but have not generally occurred in the pediatric population.⁴³⁷ Experimentally and in adults receiving long-term therapy, bisphosphonates can suppress bone turnover and contribute to hypermineralization, the latter leading paradoxically to reduced mechanical strength and increased fracture risk.⁴³⁸ Therefore when considering a child for treatment with bisphosphonates one must carefully evaluate the primary diagnosis and whether the patient’s low bone mass and fracture frequency merit therapy in view of the potential, albeit rare, side effects of bisphosphonates. Treatment with bisphosphonates several years before conception does not appear to have an adverse effect on fetal outcome, but treatment during pregnancy is contraindicated because of possible toxicity.⁴³⁹

Although not appropriate for use in children and adolescents because of concern about its potential to induce osteosarcoma, PTH¹⁻³⁴ (teriparatide) is a widely used bone anabolic agent in adults. When administered continuously, PTH¹⁻³⁴ increases osteoclast-mediated dissolution of bone, but when administered intermittently it exerts anabolic effects on osteoblast function and bone formation. This property is used clinically through the use of teriparatide (PTH¹⁻³⁴) and abaloparatide (PTHrP¹⁻³⁴) in the treatment of postmenopausal women with osteoporosis. When administered intermittently in small amounts, both agents preferentially accelerate the rates of bone remodeling and of bone formation relative to that of bone resorption by direct effects upon osteoblast differentiation, maturation, and longevity.⁴³⁰ PTH¹⁻³⁴ also acts upon the osteocyte to decrease the production of sclerostin, an inhibitor of bone synthesis that acts by repressing LRP5/6-WNT- and BMP-mediated bone formation.⁴⁴⁰ The quantity of bone formed in each remodeling unit is increased with consequent augmentation of trabecular thickness and interconnectivity and periosteal new bone formation and cortical thickness resulting in increased bone size, mass, and strength. Side effects of PTH¹⁻³⁴ administration include transient hypercalcemia, hypercalciuria, and development of antibodies to the peptide. Although osteosarcoma has been observed in mice receiving very high doses of these agents, no malignant disorders have been recorded in adults receiving either agent. The pediatric use of PTH¹⁻³⁴ has been primarily limited to children with hypocalcemia because of a gain-of-function mutation in *CASR* and consequent hypercalciuric hypocalcemia—one form of familial isolated hypoparathyroidism.⁵⁸

The basic management of patients with osteogenesis imperfecta is directed to prevention of fractures to the extent possible and to the treatment of fractures that do occur by sound orthopedic procedures and by orthopedists familiar with this disorder.³⁷⁷ Expert orthopedic management is essential for the child with osteogenesis imperfecta, as the use of intramedullary rods for correction of long bone deformities and for their linear growth and the proper correction of scoliosis require substantial experience.⁴⁴¹ Dental and rehabilitative services and physical therapy to improve dentition, muscle strength, and mobility within the constraints of bone fragility are to be encouraged as are protected ambulation and exercises, such as swimming.^{191,377} The intermittent administration of bisphosphonates to infants, children, and adolescents with moderately severe forms of osteogenesis imperfecta (clinical type I, III, IV) has been of substantial benefit.⁴³⁵ Patients with these types of osteogenesis imperfecta have responded symptomatically (decreased musculoskeletal pain, increased mobility) to the intermittent intravenous administration of a bisphosphonate—for example, pamidronate, zoledronic acid; bone mass has increased, fracture risk has declined, and

vertebral dimensions may be normalized although the prevalence of scoliosis has not declined.^{377,435,441}

It has been recommended that bisphosphonates be used in infants with osteogenesis imperfecta with congenital and recurrent fractures, deformities of the long bones, and decreased bone mass. Infants as young as 2 months of age have safely tolerated 4-hour intravenous infusions of pamidronate (0.5 mg/kg/d for 3 consecutive days every 6–8 weeks) realizing clinical improvement, such as apparent decline in bone pain, increase in lumbar vertebral BMD of 86% to 227%, and decrease in fracture rate after 1 year of therapy.¹⁹¹ Bisphosphonate administration is also recommended for children with osteogenesis imperfecta and recurrent fractures of the extremities or vertebral collapse that is symptomatic in concert with demonstrated decreased bone mineralization.⁴²⁹ In children (3–16 years of age), pamidronate administered as a 4-hour infusion (1.5–3.0 mg/kg/d) for 3 consecutive days every 4 months, resulted in increases in lumbar spine BMD of 42% per year, metacarpal cortical width of 27% per year, and vertebral size, as well as decline in fracture rate, and symptomatic improvement. During 2 to 4 years of intravenous pamidronate administration, increase in vertebral (trabecular) bone mass and size are accompanied by decline in the extent of vertebral compression and fewer compressed vertebrae than in untreated patients.⁴⁴² In the iliac crest, bisphosphonates increase cortical bone thickness and trabecular number but not trabecular thickness; in metacarpals bisphosphonates enhance cortical thickness. Administration of bisphosphonates is also accompanied by transient hypocalcemia (managed symptomatically), increased levels of PTH and calcitriol, and decreased values of bone turnover markers. Near maximal benefits of bisphosphonates on lumbar vertebral areal BMD by DXA and on mean cortical width, cancellous bone volume, and trabecular bone formation rate by histomorphometric analysis of iliac crest bone biopsies are achieved within the first 2 to 4 years of treatment with little further change with more prolonged therapy. The use of monoclonal antibodies to sclerostin (romosumab) or RANKL (denosumab) may also prove useful in the treatment of children with osteogenesis imperfecta.^{443–445} Transplantation of mesenchymal stem cells, human fetal mesenchymal stem cells or chorionic stem cells, or bone marrow stromal cells have been undertaken in patients with osteogenesis imperfecta but remains experimental therapy as do specific gene replacement and mutation silencing strategies.^{446,447}

Fibrous Dysplasia

Fibrous dysplasia is a usually nonmalignant fibro-osseous disorder that involves long bones, ribs, and skull in which normal bone and bone marrow are replaced by fibrous tissue; it may be monostotic, polyostotic, or panostotic.^{448–450} This disorder may be monostotic or polyostotic and presents as the cause of a pathological fracture with minor injury. Although fibrous dysplasia may be an isolated abnormality, it occurs in patients with the McCune-Albright syndrome (OMIM 174800) in association with very large, irregularly edged café-au-lait pigmentations and various endocrinopathies, including isosexual precocious puberty, hypersomatotropism, thyrotoxicosis, and hyperadrenocorticism, as well as dysfunction in many other tissues (heart, liver, pancreas). Bone and skin lesions are often on the same side of the body.⁴⁴⁹ Fibrous dysplasia is caused by mosaicism for postzygotic, early embryonic, somatic gain-of-function missense mutations (p.Arg201Cys/His/Ser/Gly; p.Gln227Leu) in *GNAS* (OMIM 139320), the gene encoding the α subunit of the Gs-protein that render a G_{s α} constitutively active by prolonging its biological life.⁴⁵¹ The extent and severity of disease is determined by the point in fetal development at which the mutation occurs and its tissue distribution. The

mutations result in loss of intrinsic guanosine triphosphatase activity within the $G_{\alpha s}$ subunit; thus the stimulatory effect of $G_{\alpha s}$ on adenylyl cyclase is extended thereby increasing generation of cyclic AMP. Among the targeted signaling pathways of cyclic AMP is that involving WNT/ β -catenin in osteoblast progenitor cells.⁴⁴⁹ In response to excess cyclic AMP, clones of mutated mesenchymal preosteoblasts proliferate but their differentiation to mature osteoblasts is incomplete and their secreted fibrocellular matrix is abnormal; continued expansion of osteoprogenitor cells in bone marrow leads to local fibrosis. As the osteogenic cells increase in number, they steadily erode contiguous bone. These lesions can also synthesize FGF23 and thus lead to hyperphosphaturia, hypophosphatemia, and excess unmineralized osteoid and a rickets-like clinical state. Fibrodysplastic lesions are initially silent whereas osteoclasts at the periphery of the lesions actively compress and thin bone cortices, ultimately resulting in bone pain and pathological fractures of the long bones, particularly the proximal femoral metaphyses. Children between 6 and 10 years of age have the highest fracture rate (0.4 fractures per year). Within the skull base and facial bones, expansion of fibrous dysplastic lesions leads to disfigurement and compression of cranial nerves. Radiographically, the fibrodysplastic lesion is viewed as a “cyst-like” medullary structure with a “ground-glass” consistency without a trabecular pattern.⁴⁴⁹ Histologically, fibrous dysplasia is characterized by abundant immature bone marrow stromal cells, incompletely differentiated osteoblasts, irregularly formed bone trabeculae that may resemble Chinese characters, many undermineralized osteoid seams characteristic of osteomalacia, and islands of cartilage. The clinical manifestations of fibrous dysplasia depend on the sites and extent of bone involvement and associated endocrinopathies. Diagnosis of fibrous dysplasia is based on clinical characteristics, imaging of the bone lesions (“ground glass” appearance), and confirmation of the genetic mutation in *GNAS*. In addition to managing the multiple endocrinopathies and organ defects, attention must be paid to the osseous lesions. Fractures are repaired by standard techniques, including intramedullary nailing when indicated; occasionally it may be feasible to evacuate a fibrodysplastic lesion surgically and to fill the cavity with bone grafts. In patients with polyostotic fibrous dysplasia without or associated with the McCune-Albright syndrome, administration of the oral bisphosphonate alendronate did not alter the radiographic appearance of the skeletal lesions, ameliorate bone pain, or improve function.⁴⁵² However, in patients with either isolated polyostotic fibrous dysplasia or that associated with the McCune-Albright syndrome, treatment with parenteral pamidronate or zoledronic acid has ameliorated bone pain and decreased serum levels of alkaline phosphatase reflecting decline in bone turnover rate but has not repaired the skeletal lesions.^{453,454} In a 9-year-old boy with a rapidly growing femoral mass because of fibrous dysplasia (and a somatic mutation in *GNAS1*), treatment with denosumab led to rapid decline in the rate of tumor growth and in lowering of the levels of bone turnover markers.⁴⁵⁵ However, the child developed hypocalcemia and secondary hyperparathyroidism requiring supplemental calcium, phosphate, and calcitriol. Cessation of denosumab was marked by rebound increase in values of bone turnover markers and hypercalcemia.

High Bone Mass

Abnormally increased bone mass is the consequence of disruption of the normal equilibrium between the coupled processes of bone formation and resorption. Osteosclerosis is the designation applied to a heritable or acquired disorder characterized by or associated with increase in bone mass and BMD. Specifically, increase in cortical bone width is termed *hyperostosis*;

thickening of trabecular bone is termed *osteosclerosis*.⁸ Osteopetrosis or “marble bone disease” is a group of diseases associated with increased calcified bone but paradoxically complicated by osseous fragility, leading to fractures with minor or no trauma that is primarily caused either by decreased osteoclastogenesis or impaired osteoclast function or rarely by an increase in the rate of bone formation because of excessive osteoblast activity. Failure of osteoclast-mediated bone resorption leads to osteopetrosis that may be associated with a large number of poorly functioning osteoclasts (“osteoclast-rich” osteopetrosis) or with a normal number or paucity of osteoclasts (“osteoclast-poor” osteopetrosis).^{306,456,457}

The 2019 designated genetic causes of osteopetrosis and related forms of osteosclerosis are listed in Tables 20.11A, 20.11B and schematically illustrated in Fig. 20.15. These clinical disorders are transmitted as either autosomal recessive or dominant or X-linked disorders; osteopetrosis caused by mutations of *CLCN7* and *PLEKHM1* may be transmitted either as biallelic or a monoallelic abnormalities.⁴⁵⁶ Osteopetroses that are caused by errors in osteoclast differentiation and associated with “osteoclast poor” osteopetrosis are related to mutations in *TNFRSF11A*, *TNFSF11*, and *IKBKG*. Those associated with “osteoclast-rich” osteopetroses are caused by variants of *TCIRG1*, *CLCN7*, *OSTM1*, *SNX10*, *PLEKHM1*, and *CAII*. Microscopically, the bones of patients with autosomal recessive osteopetrosis types 1, 3, 4, 5, 6, and 8 have abundant but functionally impaired osteoclasts (osteoclast rich); in autosomal recessive osteopetrosis types 2 and 7 and the X-linked form, there are few osteoclasts caused by a paucity of RANKL or RANK (“osteoclast poor”). Autosomal dominant type 1 osteopetrosis is not related to an error in osteoclast differentiation or function and defective bone resorption but rather is associated with increased osteoblastogenesis resulting in enhanced formation and mineralization of bone. This form of osteopetrosis is caused by a gain-of-function variant (p.Gly171Val) of *LRP5* (OMIM 603506) that leads to increased bone mass by impairing the binding of *LRP5* to sclerostin (*SOST*, OMIM 605740) and to *DKK1* (*Dickkopf*, *xenopus*, *homolog of*, OMIM 605189), cofactors that physiologically bind to and inhibit linking of *LRP5* to its ligand. Thus in the presence of mutated *LRP5* the WNT1/Frizzled receptor/*LRP5* coreceptor/ β -catenin signaling pathway within the mesenchymal stem cell is programmed toward osteoblastogenesis. This activating variant of *LRP5* expressed by the osteoblast is associated with increased bone formation (autosomal dominant osteopetrosis type I)—primarily of the cranium; this disorder may be asymptomatic or associated with cranial nerve insults resulting in trigeminal neuralgia, facial nerve paresis, or auditory nerve dysfunction, albeit without the more severe deleterious consequences of the osteoclastic forms of osteopetrosis.

The recessive forms of osteopetrosis (see Table 20.11A) are often clinically more severe than those transmitted in a dominant manner. Manifestations of increased bone mineralization may be present in utero (fractures) or develop in the first several months of life (fractures, trapping of cranial nerves in narrowing foramina with consequent compression atrophy of these nerves and loss-of-function—particularly sight and hearing; compression of the growing brain may lead to developmental delay). Autosomal recessive osteopetrosis type 1 is caused by variants of T cell immune regulator 1 (*TCIRG1*, OMIM 604592) and is associated with increased osteoblastogenesis, leading to enhanced formation and mineralization of bone. Variants in *CLCN7* result in a wide range of clinical manifestations from benign carrier status to rather severe manifestations of osteopetrosis. Inactivating biallelic mutations of either *OSTM1* or *CLCN7* are often associated with a lysosomal storage disease, neurodegeneration, and impaired cognition. Because of loss of bone marrow, hematopoiesis is compromised in

TABLE 20.11A Gene Variants/Mutations Pathogenetically Related to Osteopetrosis

Type OMIM Inheritance: Autosomal recessive (AR) Autosomal dominant (AD)	Gene Protein OMIM Chromosome	Functional Defect	Clinical Abnormality
AR1 259700	<i>TCIRG1</i> T cell immune regulator 1 604592 11q13.2	Encodes the V-H+ATPase $\alpha 3$ subunit, the pump responsible for movement of H^+ from osteoclast cytoplasm to the subosteocytic lacuna where H^+ dissolves the mineral phase of bone; also expressed in gastric mucosa where it is required for intestinal absorption of Ca^{2+}	Osteoclast rich Severe "malignant" osteopetrosis with early lethality; paradoxical rachitic-like osseous phenotype
AR2 259710	<i>TNFSF11</i> Tumor necrosis factor ligand superfamily, Member 11 602642 13q14.11	Osteoblast factor (also designated receptor activated nuclear factor- κB -ligand [RANKL]) that stimulates osteoclastogenesis	Osteoclast poor Severe osteopetrosis
AR3 259730	<i>CAII</i> Carbonic anhydrase II 611492 8q22	Enzyme that catalyzes H^+ production by osteoclastic synthesis & ionization of carbonic acid (H_2CO_3); excess HCO_3^- removed through Cl^-/HCO_3^- ion exchanger	Osteoclast rich Osteopetrosis of intermediate severity; associated with renal tubular acidosis, cerebral calcifications, cognitive defects
AR4 611490 AD2 166600	<i>CLCN7</i> Chloride channel 7 602727 16p13	Chloride channel expressed in osteoclasts that facilitates acidification of subosteocytic lacuna & dissolution of mineral phase of bone	Osteoclast rich AR4—Biallelic variants result in severe osteopetrosis, decreased cognition associated with neurodegeneration because of a lysosomal storage disease; AD2—Monoallelic variants lead to sclerosis of the base of the skull, pelvis, and vertebral endplates resulting in a "sandwich" x-ray appearance of the spine; not associated with increase in rate of fracture but entrap & impair cranial nerve function (hearing, sight)
AR5 259720	<i>OSTM1</i> Osteopetrosis-associated transmembrane protein 1 607649 6q21	Chaperone-like factor that associates with <i>CLCN7</i> during its maturational & translocational processes	Osteoclast rich Associated with severe osteopetrosis, neurodegeneration caused by a lysosomal storage disease
AR6 611497 AD3 618017	<i>PLEKHM1</i> Pleckstrin homology domain containing protein, Family M, Member 1 611466 17q21.31	Factor necessary for vesicular trafficking of proteins in the osteoclast	Osteoclast rich Osteopetrosis of moderate severity; osteoclasts do not form ruffled borders
AR7 612301	<i>TNFRSF11A</i> Tumor necrosis factor receptor superfamily, Member 11A 603499 18q21.33	Transmembrane receptor for RANKL—expressed by osteoclast precursor cell	Osteoclast poor Also designated receptor activated nuclear factor- κB (RANK); severe, associated with hypogammaglobulinemia
AR8 615085	<i>SNX10</i> Sorting nexin 10 614780 7p15.2	Regulator of vacuole formation & vesicle associated protein movement in osteoclasts & stomach	Osteoclast poor (\pm) Severe osteopetrosis, anemia & leukopenia because of obliteration of medullary cavity of bone; paradoxical rachitic-like osseous phenotype
AR osteopetrosis	<i>FERMT3</i> Fermitin family, member 3 607901 11q13.1	Integrin signaling, platelet aggregation	Osteoclast rich. Encodes kindlin-3 protein; mutations associated with osteopetrosis, infections, hemorrhage
AD1	<i>LRP5</i> Low-density lipoprotein receptor-related protein 5 603506 11q13.2	Coreceptor for WNT1 with Frizzled that is essential for osteoblastogenesis	Gain-of-function variants of this WNT1-Frizzled receptor associated protein result in sclerosis of the cranial vault but not with increased frequency of fractures

TABLE 20.11B Gene Mutations Causally Related to Increased Bone Mass/Osteosclerosis

Disorder OMIM	Gene Gene Protein OMIM Chromosome	Function	Functional Defect
Pycknodysostosis 265800	<i>CTSK</i> Cathepsin K 601105 1q21.2	Cysteine proteinase	Failure of enzymatic dissolution of organic matrix of bone during bone remodeling, AR
Van Buchem disease 1 239100	<i>SOST</i> Sclerostin 605740 17q21.31	Factor that binds to extracellular domain of LRP5 and LRP6 inhibiting their binding to WNT1 & its signal transduction	Hyperostosis corticalis generalisata—increased bone mineralization d/t enhanced osteoblastogenesis involving cortex of cranium & long bones resulting in cranial nerve entrapment & loss-of-function, AR
Sclerosteosis 1 269500	<i>SOST</i> Sclerostin 605740 17q21.31		Generalized skeletal osteosclerosis & hyperostosis— increased bone mineralization with enhanced osteoblastogenesis associated with gigantism, syndactyly, increased intracranial pressure, early demise, AR
Van Buchem disease 2 - 607636	<i>LRP5</i> Low-density lipoprotein receptor-related protein 5 603506 11q13.2	Factor that binds to the WNT1-β-catenin complex & enhances osteoblastogenesis	Hyperostosis corticalis generalisata, AD
Sclerosteosis 2 614305	<i>LRP4</i> 604270 11p11.2	Factor that binds to sclerostin & facilitates its inhibitory effect on osteoblastogenesis	Generalized skeletal osteosclerosis & hyperostosis, AR/AD
Raine syndrome 259775	<i>FAM20C</i> Family with sequence similarity 20, member C 611061 7p22.3	Phosphorylase of SIBLING proteins that impede biomineralization	Prenatal generalized osteosclerosis with periosteal bone formation often resulting in perinatal death, AR

AD, Autosomal dominant; AR, autosomal recessive, *SIBLING*, small integrin-binding ligand N-linked secreted glycoproteins.

most subjects with osteopetrosis. Impaired development of osteoclasts results in osteoclast-poor osteopetrosis and is attributable to mutations in genes encoding RANKL (*TNFRSF11*) and RANK (*TNFSF11A*). *IKBKG* is an X-linked gene that encodes a subunit of the inhibitor of kappa B (IκB) kinase complex that is also essential for activation of NF-κB and osteoclastogenesis. Despite being present in normal number or in abundance in patients with osteoclast-rich

osteopetrosis, osteoclast activity may be reduced because of decreased synthesis of acid (because of loss-of-function mutations in *CAII*, the gene encoding carbonic anhydrase), decreased number or activity of ion channels that transport Cl⁻ and H⁺ into the subosteocytic lacunae (channel proteins encoded by *CLCN7* and *TCIRG1* or its cofactor *OSTM1*, respectively), or subnormal generation of proteinases that degrade bone matrix, such as cathepsin K (because of

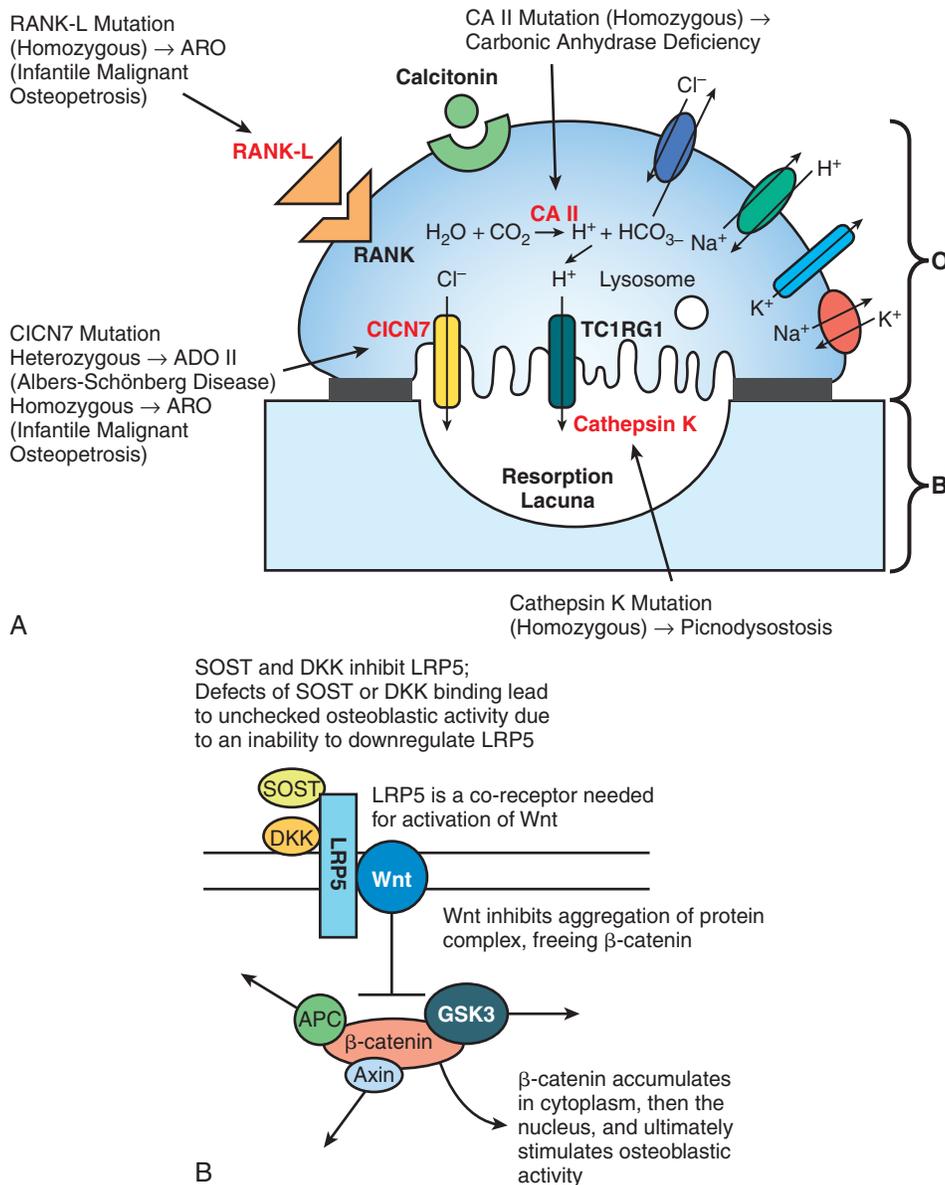

Fig. 20.15 Biochemical defects in osteoclasts (A) and osteoblasts (B) associated with osteopetrosis (see text for details). (Adapted with permission, from de Vernejoul MC. Sclerosing bone disorders. *Best Pract Res Clin Rheumatol* 2008;22(1):71–83.)

inactivating mutations in *CTSK*). Rarely, excessive deposition of bone mineral because of increased osteoblast function may be a consequence of enhancement of the WNT/ β -catenin signal transduction pathway because of gain-of-function mutations in *LRP5* as discussed or to decreased inhibition of this process because of inactivating variants of *SOST* (encoding sclerostin).⁴⁵⁸ Interestingly, in patients with mutations in *LRP5* and autosomal dominant osteopetrosis type I (see Table 20.11A), there is also a paucity of osteoclasts.³⁰⁶ Inactivation of *SOST* (OMIM 605740) leads to sclerosteosis type 1 (OMIM 269500), characterized by bony overgrowth and entrapment of cranial nerves in association with syndactyly attributable to sclerostin-unregulated activity of the LRP5-Frizzled receptor- β -catenin osteoblast stimulating pathway.⁴⁵⁸ Inactivating variants of *LRP4* (OMIM 604270) encoding a protein that binds to sclerostin are also associated with high bone mass (sclerosteosis type 2, OMIM 614305)—the possible consequence of impaired LRP4 assisted sclerostin activity within bone or of the extraskeletal sequestration of sclerostin by mutated LRP4.⁴⁵⁹

Histopathologically, bone in the majority of forms of osteopetrosis is characterized by the presence of quiescent osteoclasts—either increased, normal, or few in number—and retained “islands” of calcified cartilage formed during endochondral ossification (primary spongiosa) because of failure of reabsorption of immature bone.⁸ Although densely packed with minerals, osteopetrotic bone is quite fragile because the abnormality in bone remodeling resulting from decreased osteoclastic bone resorption leads to incorporation of weak calcified growth plate cartilage into bone and to delay in repair of microfractures. Radiographically, osteopetrosis is characterized by diffuse increase in bone mass involving both cortical and trabecular bone, diaphyseal/metaphyseal widening with an “Ehrlenmeyer flask” appearance, alternating bands of sclerotic and lucent bone at the ends of the long bones (“bone-within-bone”), iliac crest, and vertebrae (“rugger jersey” or “sandwich” vertebrae), sclerotic changes at the base of the skull, narrow medullary cavities, and pathological fractures.^{8,457} Cranial CT often reveals narrowing of the bony canals through which pass cranial nerves II, III, IV, VII, and VIII. Although classically, three

clinical forms of osteopetrosis of variable severity were identified—infantile malignant (autosomal recessive), intermediate (autosomal recessive), and adult (autosomal dominant)—as information about the genetic mutations responsible for the disease have been delineated this classification has been replaced by one that identifies its mode of transmission (autosomal dominant or recessive or X-linked recessive) and in accord with the responsible mutated gene (see Tables 20.11A, 20.11B). Thus the infantile/malignant form of osteopetrosis (OMIM 259700) may be caused by biallelic mutations in *TCIRG1*, *CLCN7*, or *OSTM1*—genes encoding osteoclast membrane hydrogen and chloride transport channel proteins or a comodulator through which the osteoclast secretes acid into the subosteoclastic lacuna to dissolve hydroxyapatite, the mineral phase of bone. A severe form of osteopetrosis associated with hypogammaglobulinemia is attributable to deleterious variations in *TNFRSF11A* encoding RANKL. Forms of osteopetrosis of intermediate severity are the result of mutations in *TNFSF11*, *CAII*, *PLEKHM1*—genes encoding RANK, carbonic anhydrase, and a protein that is involved with intraosteoclastic trafficking of lysosomes, respectively. X-linked osteopetrosis is a disorder of moderate severity related to variants of *IKBKG*, a serine/threonine kinase that enhances function of NF- κ B, thereby stimulating osteoblastogenesis (also designated NF- κ B essential modulator [NEMO]; this is an osteoclast-poor (\pm) form of moderately severe osteopetrosis in association with ectodermal dysplasia and immunodeficiency. Activating mutations in *LRP5* and heterozygous inactivating variations in *CLCN7* are associated with osteopetrosis of mild to intermediate severity that are transmitted as autosomal dominant disorders.

The infantile/malignant form of osteopetrosis is an autosomal recessive (AR type 4) disorder with attenuated growth particularly of the limbs, delayed development, increased fracture rate, and failure of tooth eruption because of variants of *CLCN7* (see Table 20.11A). Bony overgrowth leads to macrocephaly, occasionally hydrocephalus, maldevelopment of the paranasal sinuses, and to symptomatic nasal “stiffness.” Narrowing of cranial foramina compromises cranial nerve function (II, III, VII, VIII) with consequent blindness, deafness, or cranial nerve paralysis. Decrease in bone marrow volume results in depressed intramedullary hematopoiesis, anemia, and leukopenia partially compensated by extramedullary hematopoiesis and ensuing hepatosplenomegaly with consequent increased susceptibility to infection and hemorrhage. Retention of teeth within the sclerotic jaw leads to recurrent and persistent mandibular and maxillary osteomyelitis. Physical examination reveals short stature, macrocephaly, frontal bossing, small facial features, and hypertelorism; vision may be compromised by exophthalmos and retinal atrophy. Osteopetrotic neonates and infants are often hypocalcemic (because of inability to reabsorb calcium deposited in bone) with secondary hyperparathyroidism and elevated calcitriol values; levels of serum acid phosphatase and the brain isoenzyme of creatine kinase are also increased.^{7,8} Death usually occurs often within the first decade of life because of sepsis, anemia, or hemorrhage. Autosomal recessive osteopetrosis may be caused not only by biallelic mutations in the osteoclast’s chloride channel—*CLCN7*, but also in the $\alpha 3$ subunit of the osteoclast’s vacuolar proton pump—*TCIRG1*, the osteopetrosis-associated transmembrane protein-1 (*OSTM1*), or a protein that guides *TCIRG1* to the osteoclast’s ruffled membrane (*SNX10*) (vide infra). Biallelic mutations in *TNFRSF11A* encoding RANK give rise to a severe form of osteopetrosis often in association with hypogammaglobulinemia.⁴⁶⁰

The intermediate clinical forms of osteopetrosis are also transmitted as autosomal recessive traits associated with short stature, macrocephaly, variable compromise of cranial nerve function, recurrent fractures, abnormal dental development

predisposing to osteomyelitis of the mandible or maxilla, and anemia. Pathogenetically, they represent the variable penetrance of one of the genetic mutations that may be associated with the infantile form of osteopetrosis, predominantly of *CLCN7*, but also of *CAII*, *TNFSF11*, and *PLEKHM1*. There are three designated clinical and radiographic forms of monoallelic, autosomal dominant osteopetrosis: type 1 (OMIM 607634) is characterized by an enlarged and dense cranial vault and diffuse vertebral sclerosis and is related to activating mutations of *LRP5*; it is not associated with an increase in fracture rate as bone strength is actually increased—hence it has also been termed *high bone mass disease*. Autosomal dominant osteopetrosis type 2 (OMIM 166600) is typified by thickening of the vertebral endplates resembling “bone-within-bone” and resulting in a “rugger jersey spine” and sclerotic bands of bone in the pelvis and base of the skull. It is a variant of Albers-Schonberg disease that results from heterozygous loss-of-function mutations in *CLCN7*.⁸ Affected subjects manifest cranial nerve compromise (16%), mandibular and nonmandibular osteomyelitis (19%), osteoarthritis of the hip (27%), and fractures (78%). Clinical evidence of the disease tends to worsen over time. However, the expression of the trait is variable. Thus one-third of carriers of an inactivating mutation in *CLCN7* have no radiographic or clinical manifestations, although they do have significantly higher BMD than do subjects with the wild-type gene.⁴⁶¹ In one-quarter of clinically apparent patients with a heterozygous loss-of-function mutation in *CLCN7*, the expression of illness (fractures, osteomyelitis, compromised vision) is identifiable at birth or early in infancy or childhood. Patients with radiologic/clinical manifestations of this disorder have elevated serum concentrations of TRAP and the BB isoform of creatine kinase elaborated by osteoclasts; these values are normal in unaffected carriers.⁸ Autosomal dominant osteopetrosis type 3 is the result of monoallelic variants in *PLEKHM1* (OMIM 611466) encoding a factor necessary for trafficking of intraosteoclast organelles. X-linked osteopetrosis has been related to inactivating variants of *IKBKG* (OMIM 300248) encoding a serine/threonine kinase that enhances function of NF- κ B, thereby stimulating osteoclastogenesis; its loss is associated with moderate osteopetrosis, ectodermal dysplasia, and immunodeficiency.⁴⁵⁷

Most often genetic variants that impede resorption of bone in osteopetrotic subjects are related to abnormalities in osteoclastogenesis or osteoclast function—particularly the efficiency of acidification of the resorption lacuna beneath the osteoclast’s ruffled border enabling mineral dissolution or enzymatic degradation of organic bone matrix. *TNFSF11* encodes RANKL, a 317 aa transmembrane protein expressed on the surface of stromal cells and osteoblasts that interacts as a trimer with its receptor—RANK (encoded by *TNFRSF11A*), a plasma membrane protein expressed by osteoclast precursor cells to form a heterohexameric complex that stimulates NF- κ B and thereby induces osteoclastogenesis.⁴⁶² Inactivating mutations in *TNFSF11* and *TNFRSF11A* result in impaired osteoclast formation and thus osteoclast-poor osteopetrosis. Loss-of-function variations in the structure of RANKL associated with osteopetrosis include a missense mutation (p.Met199Lys) and 2-bp (828delCG) and 5-bp (intron 7 – 532 + 4_532 + 8) deletions of *TNFSF11*.⁴⁶³ Patients with osteopetrosis caused by inactivating mutations in *TNFSF11* do not respond to hematopoietic stem cell transplantation because the abnormality in osteoclastogenesis is extrinsic to the osteoclast cell line; because recombinant RANKL protein can transform the monocytes of affected patients into functioning osteoclasts in vitro, a potentially alternative therapeutic avenue might be possible.⁴⁶³ Biallelic missense (p.Gly53Arg, p.Arg 170Cys), nonsense (p.Trp244Stop, p.Gly280Stop), and insertion loss-of-function mutations in

the extracellular domain of RANK also impair binding to RANKL and consequent stimulation of NF- κ B and osteoclastogenesis.^{310,460} Many patients with inactivating mutations in *TNFRSF11A* also develop impaired B lymphocyte function and hypogammaglobulinemia.³¹³ Monocytes from these subjects are functionally unresponsive to recombinant RANKL and to M-CSF *in vitro*; hematopoietic stem cell transplantation is curative in osteopetrotic subjects with deleterious mutations in *TNFRSF11A*.⁴⁶⁰ Inactivating mutations in *IKBKKG*, encoding the inhibitor of the kinase of kappa light polypeptide gene enhancer in B cells (gamma subunit), alternatively termed *NEMO*, also impair NF- κ B generation and osteoclastogenesis resulting in the syndrome of osteopetrosis, lymphedema, anhidrotic ectodermal dysplasia, and immunodeficiency (OL-EDA-ID—OMIM 300301).⁴⁶⁴ *IKBKKG* is a 419 aa component of the I κ B kinase complex that activates NF- κ B. *IKBKKG* is located on the long arm of the X chromosome, and thus its loss is transmitted as an X-linked trait.

CAII (one of several zinc metalloenzymes) is a protein that is expressed in osteoclasts, erythrocytes, brain, and kidney; it regulates the formation of carbonic acid from water and carbon dioxide ($\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$) that then dissociates to form proton/hydrogen (H^+) and bicarbonate (HCO_3^-) ions. Loss-of-function homozygous or compound heterozygous (p.Lys17Glu, p.Tyr40Ter, p.His107Tyr, p.Asn252Asp) mutations in *CAII* lead to autosomal recessive osteopetrosis (type 3) that presents in childhood with failure to thrive, short stature, visual impairment, and developmental delay in association with mild proximal and severe distal renal tubular acidosis, cerebral calcifications within the cortex and basal ganglia, and osteopetrosis with increased fracture risk.⁸ Osteopetrosis is of modest severity and usually nonprogressive; it may even improve at puberty. Bicarbonate may be used to normalize acid-base balance. After generation by CAII, H^+ is extruded from the osteoclast into the subosteoclastic resorption lacuna through transporters and proton pumps. *TCIRG1* (OMIM 604592) encodes an 822 aa, 116 kDa protein that is a subunit of the osteoclast's vacuolar proton pump (H^+ -ATPase). (By alternative splicing, this gene also encodes a 614 aa protein—TIRC7—that is essential for activation of T lymphocytes.) Biallelic inactivating (missense, nonsense, deletion, insertion, splice site) mutations in *TCIRG1* whose loss impairs transport of H^+ and thus decreases bone mineral resorption have been found in 50% of subjects with the neonatal/infantile form of lethal osteopetrosis (AR type 1) (OMIM 259700).^{460,465} *TCIRG1* may be guided to the osteoclast's ruffled membrane above the subosteoclastic lacuna by the product of *SNX10*; biallelic mutations (p.Arg51Gln; c.212+1G>T) in *SNX10* also result in infantile malignant osteopetrosis (autosomal recessive type 8) associated also with stenosis of the foramen magnum, herniation of the cerebellar tonsils, and mandibular osteomyelitis.^{466,467} Osteoclasts in this disorder are distinguished by the increased number of cytoplasmic vesicles they contain, their large size, and their inability to form ruffled borders attributable to defects in the trafficking patterns of endosomes and lysosomes needed to form these structures. Loss-of-function mutations in *CLCN7*, a chloride channel expressed in the ruffled membrane of the activated osteoclast and its lysosomes, also impair acidification of the subosteoclastic resorption space and hence mineral dissolution.⁴⁶⁸ Heterozygotic inactivating mutations (p.Arg767Trp; 2-bp deletion—1423AG) of *CLCN7* lead to an autosomal dominant form of osteopetrosis (type 2), whereas biallelic loss-of-function mutations (p.Ile261Phe, p.Arg762Gln, p.Leu766Pro) are found in infants with the lethal, autosomal recessive, and intermediate forms of this disease (type 4).^{469,470} Mutations in *CLCN7* account for 15% of subjects with severe and 40% of patients with intermediate autosomal recessive osteopetrosis and 75% of adults with autosomal

dominant osteopetrosis type 2. *CLCN7* is coexpressed with and complexed to Osteopetrosis-associated TransMembrane protein 1 (*OSTM1*, OMIM 607649) in endosomes and lysosomes and in the ruffled membrane of activated osteoclasts.⁴⁷¹ By decreasing posttranslational stability of *CLCN7*, homozygous loss-of-function (nonsense, deletion) mutations in *OSTM1* have been pathogenetically related to autosomal recessive lethal osteopetrosis (type 5); variants of *OSTM1* are associated with a severe neurodegenerative process characterized by cerebral atrophy and loss of myelination.^{472,473} In addition, a secreted sequence of *OSTM1* binds to the cell membrane of precursors of osteoclasts, thereby inhibiting fusion and hence formation of multinucleated osteoclasts.⁴⁷⁴ The product of *PLEKHM1* is a protein that is essential for lysosomal movement and distribution within the osteoclast, linking lysosomes to microtubules, fusion with the osteoclast plasma membrane and secretion from the osteoclast and for formation of their supralacunar ruffled borders; biallelic inactivating mutations of *PLEKHM1* result in osteopetrosis of intermediate or substantial severity (autosomal recessive type 6).^{475,476}

If not identified prenatally, clinical findings in infants with osteopetrosis may include failure to thrive, ocular prominence and abnormal extraocular movements, loss of visual and auditory function, facial nerve paresis/paralysis, and signs of increased intracranial pressure. In older children with the intermediate form of osteopetrosis, a nontraumatic fracture may be a presenting complaint of osteopetrosis; genu valgum may be present, as well as abnormalities of cranial nerve function, impacted primary teeth, and hepatosplenomegaly. Other manifestations of this disease include anemia, hypocalcemia, delayed eruption of primary dentition, dental caries, infections of the mandible, hepatosplenomegaly, and growth retardation. Radiographic findings in patients with osteopetrosis may be present *in utero* or early infancy and include: widened calvarium, uniformly increased density of long bones, widening of cortical and medullary bone resulting in narrowing of the marrow cavity, metaphyseal bands of dense bone that alternate with lucent bone areas resulting in a "bone-in-bone" appearance, "club-shaped" metaphyseal modeling (Ehrlemeyer flask deformity), increased rib width, notch in anterior portion of uniformly dense vertebrae or vertebrae with dense superior and inferior margins (rigger-jersey or sandwich vertebrae), new or healed fractures.^{456,457} Symptoms and signs in patients with autosomal dominant osteopetrosis include: fractures associated with minimal trauma, dental abscesses, and osteomyelitis of the mandible. Thus in most patients, the diagnosis of osteogenesis imperfecta is suspected and established on the basis of clinical and radiographic findings. Foremost among diagnostic laboratory investigations in a patient with osteopetrosis is analysis of the genes known to be associated with this disease (see Table 20.11A) or as is rapidly becoming more common—whole genome sequencing. The Osteopetrosis Working Group also recommends in the evaluation and observation of children with suspected/diagnosed osteopetrosis: determination of a complete blood count and measurement of serum concentrations of calcium, phosphate, creatinine, calcidiol, PTH, BB isozyme of creatine kinase, lactate dehydrogenase; urine calcium/creatinine; renal ultrasonography; and magnetic resonance imaging of the cranial nerve foramina/canals.⁴⁵⁷

A multidisciplinary team skilled in the management of patients with osteopetrosis is essential for the optimal care of infants and children with this disorder. Symptomatic therapy of these patients includes avoidance of fracture-inducing activities, transfusion of needed blood components, and administration of supplemental calcium and vitamin D/calcitriol to manage hypocalcemia and rickets ("osteopetrorickets").^{8,477} Osteopetrorickets most often develops in patients with variants of *TCIRG1* because of decreased gastric acidity and consequent

decline in intestinal calcium absorption. Administration of IFN- γ (an indirect stimulus of osteoclastogenesis) may be of limited benefit in patients with autosomal recessive forms of osteopetrosis awaiting stem cell therapy. Administration of high doses of calcitriol to patients with osteopetrosis is not recommended.⁴⁵⁷ When performed in early infancy, hematopoietic stem cell transfusions from HLA-identical donors with replacement of defective osteoclasts by normal osteoclast progenitor cells, although hazardous, have been of value in patients with osteoclast-rich forms of osteopetrosis, although unlikely to reverse already sustained consequences of the disease.^{8,456,457,478,479} Hematopoietic stem cell transplants allow the engraftment of donor-derived osteoclast precursors that differentiate into mature functional osteoclasts permitting bone remodeling and hematopoiesis. Hematopoietic stem cell transfusions are not generally recommended in patients with osteopetrosis who also have primary neurodegeneration (*CLCN7*, *OSTM1*) or in osteoclast poor forms of osteopetrosis related to inactivating mutations in *TNFSF11*, *TNFRSF11A*, and *IKBKG*. The possibility of in utero hematopoietic stem cell transplantation may also be considered. Hypercalcemia often complicates the posttransplantation period as osteoclast function resumes, particularly in patients with inactivating mutations in *TNFRSF11A*.⁴⁶⁰ Hypercalcemia has been managed with dietary restriction, calcitonin, and bisphosphonate administration and/or by use of an inhibitor of RANKL–denosumab, a monoclonal antibody raised against this protein.⁴⁸⁰ Replacement of the defective gene by genome editing or other advancing genetic techniques with restoration of normal gene function may be of benefit to patients with osteopetrosis in the future. In addition to general clinical care by the child's primary care physician, the endocrinologist, hematologist, ophthalmologist, orthopedist, neurologist, and geneticist have fundamental roles to play in the management and coordination of care of patients with osteopetrosis.⁴⁵⁷ With improved treatment, there has been increased life span and improved developmental progress. Osteopetrosis caused by deficiency of CAII is not corrected by restoration of normal systemic acid-base balance, but bone marrow transplantation may be useful.⁸

In addition to the OMIM designated forms of osteoclast-rich osteopetrosis previously discussed, inactivating mutations in *FERMT3* (OMIM 607901) also result in a severe, infantile form of osteopetrosis associated with increased susceptibility to hemorrhage and infection.⁴⁷⁹ Variants of *MITF* encoding microphthalmia-associated growth factor (OMIM 15684), *LRKK1* encoding leucine-rich repeat kinase 1 (OMIM 610986), and *USB1* encoding U6 small nuclear RNA biogenesis phosphodiesterase 1 (OMIM 613276) have also been associated with osteopetrosis/osteosclerosis-like clinical syndromes.⁴⁷⁹ In a rare patient, genetic variants of *SLC29A3* encoding solute carrier family 29 member 3 (OMIM 612373) and *CSF* encoding macrophage colony-stimulating factor (OMIM 120420) have been associated with osteoclast poor forms of osteopetrosis.⁴⁷⁹ Related to the long-acting inhibitory effects of bisphosphonate on bone modeling and remodeling, administration of high doses of intravenous pamidronate (2800 mg) over a 3-year period resulted in an acquired "osteopetrosis-like" disorder in a 12-year-old boy with unexplained hyperalkaline phosphatasemia—an abnormality that persisted for several years after this agent was discontinued.⁴⁸¹ The metaphyses of this lad were extremely dense and club-shaped, the base of the skull sclerotic, and the vertebral endplates thickened. Histologically, iliac crest biopsy revealed bars of calcified cartilage and quiescent osteoclasts. Despite the severity of the radiographic and microscopic findings, the patient was clinically well with normal growth and without evidence of bone marrow suppression or extramedullary hematopoiesis, although the risk for future fractures may have been increased.

In addition to osteopetrosis, there are other clinical forms and genetic variants that cause increased bone mineralization in children (see Table 20.11B). Pycnodysostosis (OMIM 265800) is clinically manifested by disproportionate short stature during infancy and childhood with macrocranium and open cranial sutures, high forehead, small facial features, proptosis, bluish sclerae, beaked and pointed nose, micrognathia, highly arched palate, retained primary teeth, short fingers with hypoplastic nails, narrow thorax, pectus excavatum, and kyphoscoliosis with lumbar lordosis.^{8,482} Radiologically, there is increased bone density that becomes progressively worse with age despite which susceptibility to fractures is increased, open fontanelles, impaction of permanent and supernumerary teeth, clavicles that are slim and hypoplastic bilaterally, partial or total absence of the ribs and hyoid bone, and acroosteolysis of the distal phalanges—a pathognomic characteristic of pycnodysostosis.^{482–484} Laboratory data and bone histology are usually normal, although there may be biochemical evidence of decreased osteoblastic and osteoclastic activity. The microscopic observation that an abundance of osteoclasts with ruffled borders surrounded by enlarged clear zones suggested that dissolution of bone mineral was normal but that degradation of matrix was abnormal in these patients. Indeed, there are large amounts of decalcified matrix both within the subosteoclastic lacunae and the osteoclasts.³⁰⁶ Pycnodysostosis is caused by biallelic loss-of-function mutations in *CTSK* encoding cathepsin K, the osteoclast's lysosomal cysteine protease that degrades organic matrix after the mineral phase of bone has been reabsorbed. Among the variations in *CTSK* identified in patients with pycnodysostosis have been: unipaternal isodisomy for chromosome 1 with paternal *CTSK* harboring an inactivating p.Ala277Val mutation, p.Leu9Pro substitution in the signal peptide of the precursor form of the enzyme protein preventing completion of its posttranslational processing, and p.Ter330Trp substitution permitting the addition of 19 aa to the carboxyl terminus of this enzymatic protein.

In contrast with diseases that increase bone mass by decreasing bone resorption are those disorders that primarily increase bone formation. An example of the latter is the familial, relatively benign form of autosomal dominant high bone mass (OMIM 601884) that is associated with a heterozygous gain-of-function mutation (p.Gly171Val) in *LRP5* already discussed. Dickkopf and sclerostin are proteins that bind to the extracellular domain of *LRP5* and internalize the receptor complex thereby blocking WNT signaling.³⁷³ Although generally benign, activating mutations of *LRP5* may also be associated with neurological complications, such as hearing loss, headaches, and pain in the extremities. In some families, heterozygous activating mutations (p.Ala242Thr) of *LRP5* and exuberant bone formation have been associated with autosomal dominant generalized endosteal osteosclerosis (van Buchem disease, type 2, OMIM 607636). Variants of *SOST* (encoding sclerostin) are associated with van Buchem disease type 1 (OMIM 239100) that has been attributed to a 52-kb deletion three prime (3') of *SOST* with resultant loss of a regulatory element of the gene; this disorder is characterized by markedly thickened cranium—resulting in loss of cranial nerve function, mandible, and long bones, and autosomal recessive sclerosteosis type 1 (OMIM 269500), a generalized, progressive disorder of skeletal overgrowth in association with syndactyly; involvement of the skull results in entrapment and functional impairment of cranial nerves, as well as increased intracranial pressure. Sclerosteosis type 2 (OMIM 614305) is associated with biallelic inactivating variants of *LRP4* (OMIM 604270) encoding low-density lipoprotein-related coreceptor 4 that prevent its interaction with sclerostin thereby disinhibiting sclerostin.⁴⁸⁵ Sclerosteosis type 1 is first manifested in childhood and is characterized by very thick peripheral and cranial

bones with calvarial overgrowth, leading to facial disfigurement, entrapment of cranial nerves II, VII, and VIII, increased intracranial pressure, and brainstem compression.^{8,373,458} Affected patients also have variable asymmetric cutaneous or bony syndactyly of the index and middle fingers and excessive somatic growth; they are extraordinarily resistant to fractures. Serum levels of alkaline phosphatase and procollagen type 1 N-terminal propeptide (P1NP) are elevated in these subjects while concentrations of sclerostin are low or unmeasurable.⁴⁵⁸ Sclerosteosis type 1 is caused by biallelic loss-of-function mutations in *SOST* encoding sclerostin, a 213 aa peptide secreted primarily by osteocytes embedded within bone. Physiologically, sclerostin inhibits WNT-mediated bone formation by binding to and internalizing LRP5, the coreceptor for WNT. When sclerostin activity is decreased, increased bone formation ensues. Sclerostin also increases osteoclastogenesis by increasing osteocytic synthesis of RANKL.⁴⁵⁸ In heterozygous carriers of inactivating mutations in *SOST*, bone mass is increased but not to pathological levels. Hyperostosis corticalis generalisata/van Buchem disease type 1 is an autosomal recessive disorder characterized by thickening and enlargement of the bones of the skull, mandible, ribs, and diaphyses of the long bones that result in increased bone density and encroachment upon cranial nerve passageways resulting in abnormalities of vision, hearing, and facial movement.^{8,458} However, patients with van Buchem disease type 1 do not have syndactyly or tall stature thus distinguishing it from sclerosteosis type 1. This disorder is also caused by biallelic loss of expression of *SOST* but as a result of 52-kb deletion of a regulatory element that is 35 kb downstream (3') of *SOST* rather than by a mutation within the exonic/intronic structure of *SOST* itself.⁴⁸⁶ Thus this disease is allelic to sclerosteosis; it differs clinically in that gigantism and hand abnormalities are present in patients with sclerosteosis type 1 but not in those with van Buchem disease type 1. The clinical manifestations of sclerosteosis type 2 are similar to those of type 1 but are pathogenetically related to biallelic loss-of-function mutations in *LRP4*.⁴⁸⁷ The inhibitory effect upon bone formation of the interaction of sclerostin and LRP5/LRP6 is facilitated by binding of sclerostin to LRP4. Thus inactivating mutations (p.Arg1170Trp, p.Trp1186Ser) in *LRP4* impede the interaction of sclerostin with LRP5/6 and thus the inhibitory effect of sclerostin upon osteoblastogenesis. Treatment of these disorders is primarily symptomatic.

Progressive diaphyseal dysplasia (Camurati-Englemann disease; OMIM 131300) is an autosomal dominant, cranial-peripheral hyperostotic disorder with variable expression that presents in children with problems, such as limping, waddling gait, and/or leg pain, fatigue, and nonprogressive muscular weakness. Radiographically, there is symmetrical cortical thickening (hyperostosis) because of increased periosteal and endosteal bone formation in the diaphyses of the long bones, axial skeletons, and skull, genu valgum, and scoliosis.^{488,489} Pathogenetically, this disorder is caused by missense activating mutations within the "latency associated peptide" domain of the precursor propeptide of *TGFβ1* (OMIM 190180). Normally, after posttranslational processing, two latency associated peptides are noncovalently linked to two mature TGFβ1 peptides to form a "latency complex." Gain-of-function mutations within the latency associated peptide domain of *TGFβ1* (particularly at codon 218—p.Arg218His, p.Arg218Cys—a mutational hotspot) impair this association resulting in premature activation of TGF-β1 and consequent stimulation of intramembranous bone formation and repression of bone resorption. TGF-β1 also inhibits myogenesis and adipogenesis. Because of the inhibitory effects of glucocorticoids on bone formation and their stimulatory effects on bone resorption, these agents have been useful in alleviating many of the clinical symptoms and radiological abnormalities in patients with progressive

diaphyseal dysplasia as have inhibitors of angiotensin receptor II (e.g., losartan).⁴⁸⁹ Other hereditary sclerosing bone dysplasias include osteopoikilosis (OMIM 166700)—nodules of bone overgrowth within pelvic and long bones, cranium, and/or ribs because of heterozygous inactivating mutations in *LEMD3* (OMIM 607844) encoding a nuclear membrane protein that modulates signal transduction by BMPs and TGFβ; osteopoikilosis is associated with hyperdense deformations of cortical bone—melorheostosis; and osteopathia striata (OMIM 300373) is an X-linked disorder caused by loss-of-function mutations in *AMER1* (OMIM 300647) encoding a protein that promotes the proteasomal degradation of β-catenin—its loss thus promotes transfer of β-catenin to the nucleus and extends the biological activity of the WNT/LRP5,6/β-catenin signal transduction system that promotes osteoblast maturation and function leading to endosteal hyperostosis.⁴⁸⁸ The hereditary and nonhereditary (e.g., intramedullary osteosclerosis) sclerosing bone dysplasias must be differentiated from acquired sclerosing diseases, such as sickle cell anemia and myelofibrosis.⁴⁸⁸

Heterotopic Bone Formation/Ectopic Calcification

Disorders of heterotopic ossification are those in which bone develops outside of the skeleton and within soft tissues (Table 20.12).⁴⁸ Dysregulation of the processes of differentiation and maturation enable precursor cells to develop as osteoblasts that then produce normal endochondral or membrane bone but in abnormal, extraskeletal sites. Sporadic heterotopic bone formation occurs in sites of severe wounds and burns, after spinal cord injuries, and in areas of pressure ulcers. Fibrodysplasia ossificans progressiva (OMIM 135100) is a disabling disorder of ectopic bone formation that may develop spontaneously or at sites of injury and lead to ankylosis of all major joints that severely limits mobility.⁴⁸ It is characterized by progressive ectopic ossification of skeletal muscle and connective tissue (fascia, tendons, ligaments) leading to immobility and fusion of the mandible, neck, spine, hips, and other joints and the development of a "second skeleton" that encases and imprisons the body. The disorder may be present at birth and is often manifest by 5 years of age. Fibrodysplasia ossificans progressiva is also associated with congenital abnormalities of the great toes (hallux valgus, malformed first metatarsal bones, monophalangism), characteristic facial features (long narrow face, small mandible, low set ears), deafness, scalp baldness, and mild developmental delay.⁴⁹⁰ Microscopically, there is normal but ectopic endochondral osteogenesis that occurs after a preceding inflammatory phase that develops either in the absence of trauma or following minor injury, such as an immunization; the pathological process proceeds through the phases of monocytic infiltration, muscle fiber degeneration, fibrous proliferation, angiogenesis, chondrogenesis, and osteogenesis.⁴⁸ Although usually sporadic because affected subjects rarely reproduce, fibrodysplasia ossificans progressiva can be transmitted as an autosomal dominant trait. This disease is primarily caused by a highly specific variant (c.617G>A transition leading to p.Arg206His) of *ACVR1* (encoding activin A Receptor, type-1, OMIM 102576); another described *ACVR1* mutation in patients with classical fibrodysplasia ossificans progressiva is c.744G>C transversion leading to p.Arg258-Ser.⁴⁸ Activins are members of the TGFβ superfamily that includes the BMPs together with the inhibitors and Mullerian duct inhibiting factor. *ACVR1* encodes a type I BMP receptor (activin receptor type Ia) that is expressed in chondrocytes and osteoblasts.⁴⁸ The p.Arg206His mutation in *ACVR1* resides at the junction of the receptor's cytoplasmic glycine-serine activation and tyrosine kinase domains and results in a constitutively active BMP type I receptor. Overactivation of the

TABLE 20.12 Genetic Causes of Heterotopic Bone Formation and Ectopic Calcification

Disease Type OMIM	Gene Chromosome OMIM	Clinical Manifestations	Pathophysiology
HETEROTOPIC BONE FORMATION			
Fibrodysplasia ossificans progressiva 135100	<i>ACVR1</i> : Activin A receptor, type I 2q24.1 102576	Progressive ossification of skeletal muscles, fascia, tendons, and ligaments	Specific monoallelic activating mutation (Arg206His) in the cytoplasmic domain of a type 1 BMP receptor increases extraskelatal chondrogenesis and osteogenesis
Progressive osseous heteroplasia 166350	<i>GNAS</i> : GNAS complex locus 20q13.32 139320	Ossification of dermis beginning in infancy followed by membranous bone formation within deep muscle and fascia in childhood	Monoallelic inactivating mutations in the paternally encoded G _{sα} subunit of G-protein enable subcutaneous bone formation; related to pseudopseudohypoparathyroidism
ECTOPIC CALCIFICATION			
Tumoral calcinosis, hyperphosphatemic, familial 211900	<i>GALNT3</i> : UDP-N-acetyl-alpha-D-galactosamine: polypeptide N-acetylgalactosaminyl-transferase 3 2q24.3 601756	Progressive deposition of calcium phosphate crystals in periarticular region, soft tissue, and bone	Biallelic mutations in a cofactor required for synthesis of bioactive FGF23 and renal tubular excretion of phosphate
Tumoral calcinosis, hyperphosphatemic, familial 211900	<i>FGF23</i> : Fibroblast growth factor 23 12p13.32 605380	Progressive deposition of calcium phosphate crystals in periarticular region, soft tissue, and bone	Biallelic inactivating mutations in a factor that inhibits renal tubular resorption of phosphate
Tumoral calcinosis, hyperphosphatemic, familial 211900	<i>KL</i> : Klotho 13q13.1 604824	Progressive deposition of calcium phosphate crystals in periarticular region, soft tissue, and bone	Biallelic inactivating mutation in a cofactor enabling FGF23 to inhibit renal tubular resorption of phosphate
Tumoral calcinosis, normophosphatemic, familial 610455	<i>SAMD9</i> : Sterile alpha motif domain-containing protein 9 7q21.2 610456	Postinflammatory periarticular and peripheral calcified masses	Biallelic inactivating mutations in a protein that regulates cell division, motility, longevity, and inflammation

BMP, Bone morphogenetic protein; *GNAS*, guanosine diphosphate on the alpha subunit.

intracellular signal transduction pathways occurs when BMPs bind to the mutated *ACVR1* receptor. In addition, the p.Arg206His variant appears to change the signaling specificity of the *ACVR1* receptor to activin A, leading to phosphorylation of SMAD 1/5/8 rather than SMAD 2/3, triggering the formation of heterotopic endochondral bone.^{491,492} BMPs alone are able to stimulate complete endochondral osteogenesis in ectopic sites.

Patients with clinical variants of fibrodysplasia ossificans progressiva and *ACVR1* mutations other than p.Arg206His and p.Arg258Ser have been described; they have been classified as those with fibrodysplasia ossificans progressiva plus abnormalities of the brain, eye, and/or bone marrow, or those with fibrodysplasia ossificans progressiva variants—either without abnormalities of the great toes or less severe heterotopic osteogenesis; patients with mutations in codon 328 have varied in severity from classical to late-onset disease; patients with the p.Arg201Ile mutation in *ACVR1* have adult onset of extra-skeletal ossification and normal toes.^{48,493} Management of these patients is primarily symptomatic and palliative to the extent possible, although immunosuppression may diminish the intensity of the extraskelatal ossification.^{48,494}

Glucocorticoids have been used in the treatment of patients with fibrodysplasia ossificans progressiva, but efficacy is poor and side effects substantial. Inhibitors of mast cells and leukotrienes have also been used in an effort to suppress inflammation as have bisphosphonates; however, there are no conclusive clinical trials to support the use of these agents.⁴⁹⁵ Inasmuch as trauma can induce new bone formation in these patients, prevention of injury is the first principle of management. Even an intramuscular injection can provoke local painful ossification.

Avoidance of surgery is paramount as this insult can stimulate not only new bone growth locally but also at a distance. Although presently, there is no therapy for fibrodysplasia ossificans progressiva, treatments directed toward interrupting the primary pathophysiological pathway(s) of this disease, such as monoclonal antibody-mediated neutralization of the activin A receptor or interruption of the SMAD 1/5/8 signal transduction pathway (the mammalian target of rapamycin [mTOR]) may prove beneficial.⁴⁹⁵

POH (OMIM 166350) is characterized by multiple foci (trunk, extremities, or digits) of adipose tissue-associated dermal intramembranous bone formation (osteoma cutis) beginning in infancy in the absence of any local injury or inflammatory insult.^{42,48} Lesions may be asymptomatic or painful. Over time, heterotopic ossification borrows into skeletal muscle and deep connective tissue and may be incorporated into skeletal bone. POH is transmitted as an autosomal dominant trait and occurs in both boys and girls; it is caused by inactivating mutations of the *GNAS* allele usually inherited from the father.⁴⁹⁶ Paternal transmission of mutated *GNAS* is associated with significant intrauterine growth restriction and more severe clinical manifestations of POH than when the *GNAS* mutation is transmitted by the mother. Identical mutations in *GNAS* may be clinically manifested as either POH, PHP, PPHP, or primary osteoma cutis in different members of the same family (e.g., 1-bp del, 725C), all of which disorders are associated with subcutaneous (dermal) ossification. However, patients with POH do not have physical features of AHO nor are they hormone resistant. Thus diagnostic criteria for POH are: superficial osseous lesions, absence of features of AHO (PPHP), and normal responsiveness to PTH.⁴² Only

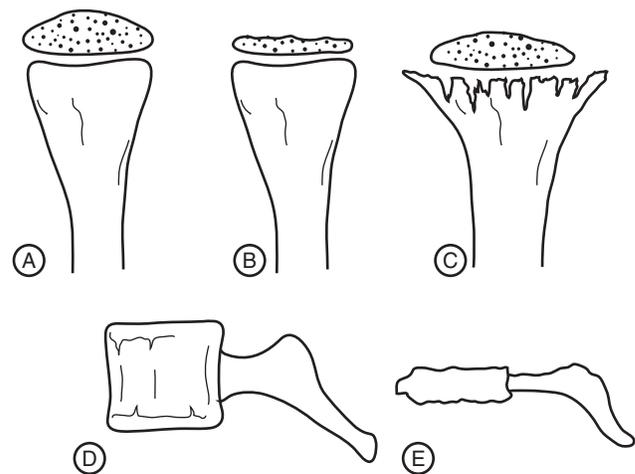

symptomatic treatment of patients with POH is currently available.

Familial tumoral calcinosis is characterized by deposition of basic calcium phosphate into periarticular spaces around the shoulder, elbow, wrist, hip, and knee joints and at times within bone itself that occurs spontaneously or after minimal but repetitive trauma to soft tissues.⁴⁹⁷ Variants of several genes (vide infra) lead to familial tumoral calcinosis with normophosphatemia or hyperphosphatemia—all with similar clinical manifestations. Familial tumoral calcinosis presents in childhood with recurrent bone pain, large, firm, nontender, subcutaneous masses; extensive periarticular masses that may compromise joint mobility; and vascular deposits of calcium phosphate. In some patients the ectopic calcifications may be confined to the eyelids; it is characterized radiographically by cortical hyperostosis, periosteal reaction, and mineral deposits around large joints, particularly hips and shoulders.⁴⁹⁸ Microscopically, there is a histiocytic response with formation of calcified bursa-like structures.⁴⁹⁹ Laboratory studies reveal either normophosphatemia or marked hyperphosphatemia and relative hypophosphaturia, the latter caused by increased renal tubular reabsorption of phosphate and inappropriately normal or elevated serum calcitriol levels, because despite hyperphosphatemia, PTH secretion is not increased and synthesis of calcitriol and intestinal calcium absorption persist. There are one normophosphatemic (OMIM 610455) and three hyperphosphatemic designated types (OMIM 211900, 617993, 617994) of familial tumoral calcinosis and also secondary forms of this disease. The disorder is caused by functional loss of FGF23 action and consequently unhindered renal tubular reabsorption of phosphate. The pathophysiology of this disorder is thus the mirror image of that associated with X-linked and autosomal dominant forms of hypophosphatemic rickets and tumor-induced osteomalacia in which there is excess FGF23 production and exaggerated activity, leading to hyperphosphaturia and consequent hypophosphatemia, rickets, and osteomalacia. Hyperphosphatemic familial tumoral calcinosis is genetically heterogeneous: type 1 (OMIM 211900) is related to inactivating variants of *GALNT3* (OMIM 601756), type 2 (OMIM 617993) to errors in *FGF23* (OMIM 605380), and type 3 (OMIM 617994) to mutations in *KL* (OMIM 604824). Most commonly present in patients with hyperphosphatemic familial tumor calcinosis are biallelic loss-of-function microdeletions, splice site, and missense or nonsense mutations in *GALNT3* (p.Arg162Stop, p.Thr272Lys, p.Cys574Gly, p.Gln592Stop).⁵⁰⁰ The product of *GALNT3* is a glycosyl transferase that initiates O-glycosylation in which N-acetylgalactosamine is the first sugar in the side chain, a step that is essential for secretion of intact, stable, and functional FGF23. Failure to O-glycosylate FGF23 at Thr178 in the Golgi apparatus permits its rapid intracellular cleavage between Arg179 and Ser180 to biologically inactive amino and carboxyl terminal fragments. Homozygous inactivating mutations in *FGF23* (p.Ser71Gly; p.Met96Thr, p.Ser129Phe) have been identified in patients with type familial tumoral calcinosis; in the absence of FGF23, renal tubular resorption of filtered phosphate is unopposed.⁵⁰¹ Serum concentrations of intact FGF23 are low or nondetectable while carboxyl terminal FGF23 levels are elevated in patients with familial tumoral calcinosis because of mutations in either *GALNT3* or *FGF23*. Therapy with an oral phosphate binder and the carbonic anhydrase inhibitor acetazolamide has resulted in hyperphosphaturia and reabsorption of ectopic calcifications without change in serum phosphate or calcium concentrations. The hyperostosis hyperphosphatemia syndrome (OMIM 610233) is a clinical variant of familial tumoral calcinosis and is also caused by mutations in *FGF23* or *GALNT3*; symptoms and signs may precede development of the more typical phenotype of familial tumoral calcinosis.⁵⁰⁰ Hyperphosphatemic familial tumoral calcinosis type 3 has been attributed to a homozygous loss-of-function mutation in *KL* (p.His193Arg)

encoding α -klotho, a cofactor necessary for the interaction of FGF23 with its receptor in the renal tubule.⁵⁰² Normophosphatemic familial tumoral calcinosis is a form of dystrophic calcification as inflammatory lesions precede ectopic calcification; it is associated with inactivating mutations (p.Arg344Stop, p.Lys1495Glu) in *SAMD9* (encoding Sterile alpha motif domain-containing protein 9, OMIM 610456), a 1589 aa protein that regulates cell division, motility, and longevity.⁵⁰³ *SAMD9* is generated in response to TNF α and IFN- γ and regulates expression of *EGR1* (OMIM 128990) encoding a transcription factor that controls expression of *TGFB1* and is involved with cell migration, proliferation, mobility, and survival.⁵⁰⁴ Scleroderma, chronic renal disease with secondary hyperparathyroidism, primary hyperparathyroidism, hypervitaminosis D, after cell lysis induced by cancer chemotherapy, subcutaneous fat necrosis, dermatomyositis, and atherosclerosis may be secondary causes of massive subcutaneous calcifications with comparable clinical findings. Treatment must be individualized and may include phosphate depletion by dietary deprivation, binding of intestinal phosphate, and induction of phosphaturia (acetazolamide), as well as surgical removal of particularly compromising masses.

OSTEOCHONDRODYSPLASIAS

The osteochondrodysplasias are pathogenetically heterogeneous malformations of cartilage and bone that are grouped according to genetic variations (e.g., *FGFR3* chondrodysplasia group; Type 2 collagen—*COL2A1*—group) or clinical characteristics, such as those involving long bone growth (epiphyseal, metaphyseal and/or diaphyseal dysplasias), long bones and vertebrae (spondyloepiphyseal and/or spondyloepimetaphyseal dysplasias), skull (cleidocranial dysplasia), hands and feet (the ectrodactylies), and other skeletal components (Fig. 20.16).⁵⁰⁵ Thus multiple genetic variations (e.g., *FGF23*, *COL1A1*) may adversely influence bone development/

Involvement	Disease Category
A+D	Normal
B+D	Epiphyseal dysplasia
C+D	Metaphyseal dysplasia
B+E	Spondyloepiphyseal dysplasia
C+E	Spondylometaphyseal dysplasia
B+C+E	Spondyloepimetaphyseal dysplasia

Fig. 20.16 Anatomic characterization of osteochondrodysplasias. (From Alanay Y, Rimoin DL. Chondrodysplasias. In: Rosen CJ (Ed.). *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism* (7th ed.). Washington, DC: American Society of Bone and Mineral Metabolism; 2008:428–429.)

formation or mineralization; mutations in one gene may give rise to several different clinically defined disorders together with disorders characterized by clinical and radiographic findings that may be attributable to variations in many different genes (e.g., the acromesomelic dysplasias). Abnormal skeletal phenotypes have been classified into 42 groups based on pathogenetic variations of 436 genes and/or clinical and radiographic manifestations of the disorders.^{329,505} Groups 1 to 8 are disorders attributed to variations in a single gene (e.g., group 1 *FGFR3*; group 2 *COL2A1*; group 3 *COL11A1*; group 4 *DTDST*; group 5 *PLC*; group 6 *AGC1*; group 7 *FLNA/FLNB*; group 8 *TRPV4*). Groups 9 through 42 rely on clinical, radiographic, and genetic findings for classification; within each group variations in different genes may give rise to the same or similar osseous abnormality(ies) (e.g., group 10—multiple epiphyseal dysplasias *COMP*, *COL9A2*, *MATN3*, *COL9A1*, *SMARCAL1*; group 13—Spondyloepi-(meta)-physeal dysplasias *MATN3*, *RAB33B*, *SEDL*, *DYM*; group 17—mesomelic/rhizo-mesomelic dysplasias *SHOX*, *GPC6*, *RDR2*, *FZD2*, *WNT5A*). Group 23 encompasses variants of osteopetrosis, group 25 variants of osteogenesis imperfecta,

group 27 the lysosomal disorders, and group 30 the overgrowth syndromes. Disorders of skeletal development and function are of interest not only because of the diagnostic and therapeutic clinical challenges they present, but also because they have identified many basic physiological factors that normally regulate cartilage and bone development and function. The application of genome-wide association studies to the classification of skeletal disorders has added significant insight into the plethora of genes and intracellular signaling pathways that influence skeletal differentiation, morphology, and function.³²⁹

Table 20.13 describes some of the more commonly encountered genetic variations associated with osteochondrodystrophies. Achondroplasia (OMIM 100800), the most common of the human chondrodystrophies (1/15,000–1/40,000 live births) and its related osteochondrodystrophies (hypochondroplasia, thanatophoric dysplasia—types I and II, syndrome of severe achondroplasia-developmental delay-acanthosis nigricans [SADDAN] syndrome), are caused by gain-of-function mutations in *FGFR3* (OMIM 134934), the gene encoding fibroblast growth receptor 3. *FGFR3* is a transmembrane protein

TABLE 20.13 Genetic Variants Associated With Osteochondrodystrophies (Selected)

Gene Chromosome OMIM	Pathophysiology	Clinical Disorder (OMIM)
<i>TRIP11</i> : Thyroid hormone interactor 11 14q31-q32 604505	Coactivator of the nuclear triiodothyronine receptor; interacts with microtubules and Golgi apparatus	Achondrogenesis, type IA (200600), AR
COLLAGENOPATHIES		
<i>COL2A1</i> : Collagen, type II, alpha 1 12q13.11 120140	Subunit of collagen type II, the major collagen of cartilage comprised of three 3-alpha 1(II) chains	Achondrogenesis, type II/ Hypochondrogenesis (200610), AD Spondyloepiphyseal dysplasia congenita (183900), AD Spondyloepimetaphyseal dysplasia (184250), AD
<i>COL9A1</i> : Collagen, type IX, alpha 1 6q13 120210	Encodes a collagen that is a component of hyaline cartilage	Multiple epiphyseal dysplasia, type 6 (614135), AD Stickler syndrome type 4 (614134), AR
<i>COL10A1</i> : Collagen, type X, alpha 1 6p22.1 120110	Component of cartilage expressed at late stages of endochondral bone formation	Metaphyseal chondrodysplasia, Schmid type (156500), AD
<i>COL11A1</i> : Collagen, type XI, alpha 1 1p21.1 120280	Subunit of collagen type XI composed of two alpha 1 subunits and a modified <i>COL2A1</i> subunit; important for fibrillogenesis	Stickler syndrome type 2 (604841), AD Marshall syndrome (154780), AD
<i>FLNB</i> : Filamin B 3p14.3 603381	Cytoplasmic actin-binding protein enabling formation of and communication with the cytoskeleton; influences vertebral segmentation, endochondral ossification, joint formation	Atelosteogenesis I (108720), AD Atelosteogenesis III (108721), AD
FIBROBLAST GROWTH FACTOR RECEPTORS		
<i>FGFR1</i> : Fibroblast growth factor receptor 1 8p11.22 136350	Transmembrane tyrosine kinase receptor for FGFs	Pfeiffer syndrome (101600), AD
<i>FGFR2</i> : Fibroblast growth factor receptor 2 10q26.13 176943	Transmembrane tyrosine kinase receptor for FGFs	Apert syndrome (101200), AD Crouzon syndrome (123500), AD Jackson-Weiss syndrome (123150), AD Antley-Bixler syndrome with normal steroidogenesis (207410), AD
<i>FGFR3</i> : Fibroblast growth factor receptor 3 4p16.3 134934	Transmembrane tyrosine kinase receptor for FGFs	Achondroplasia (100800), AD Hypochondroplasia (146100), AD Thanatophoric dysplasia types I (187600) and II (187601), AD
SULFATION DISORDERS		
<i>SLC26A2</i> - Solute carrier family 26 (sulfate transporter) 5q32 606718	Also termed <i>DTDST</i> ; encodes sulfate transporter essential for normal collagen synthesis	Achondrogenesis, type IB (600972), AR Atelosteogenesis II (256050), AR Diastrophic dysplasia (222600), AR Multiple epiphyseal dysplasia, type 4 (226900), AR

TABLE 20.13 Genetic Variants Associated With Osteochondrodysostrophies (Selected)—cont'd

Gene Chromosome OMIM	Pathophysiology	Clinical Disorder (OMIM)
<i>HSPG2</i> : Heparan sulfate proteoglycan of basement membrane 1p36.12 142461	Also termed <i>perlecan</i> , a heparan sulfate proteoglycan; coreceptor for FGFR2; stabilizes basement membranes and regulates their permeability	Schwartz-Jampel type 1 myotonic chondrodysplasia (255800), AR
<i>PAPSS2</i> : 3-Prime-phosphoadenosine 5-prime-phosphosulfate synthase 2 10q23.2-23.3 603005	Enzyme that synthesizes the sulfate donor (3'-phosphoadenosine 5'-phosphosulfate) from ATP and sulfate; cofactor for adrenocortical sulfotransferase	Spondyloepimetaphyseal dysplasia (Brachyolmia type 4) (612847), AR
<i>ARSE</i> : Aryl sulfatase E Xp22.33 300180	Enzyme that removes a sulfate group from its protein	Chondrodysplasia punctata type 1 (302950), X-linked recessive
<i>PTPN11</i> : Protein tyrosine phosphatase, nonreceptor, type 11 12q24.1 176876	Encodes SHP2: a nonreceptor protein tyrosine phosphatase that acts upstream of RAS	Monoallelic loss-of-function mutations lead to metachondromatosis (156250), AD Noonan syndrome with multiple lentigenes: monoallelic gain-of-function mutations (163950), AD
OTHERS		
<i>COMP</i> : Cartilage oligomeric matrix protein 19p13.1 600310	Chondrocyte protein that binds calcium and collagen types I, II, and IX	Pseudoachondroplasia (177170), AD Multiple epiphyseal dysplasia (132400), AD
<i>TRPV4</i> : Transient receptor potential cation channel, subfamily V, member 4 12q24.11 605427	Cation channel that mediates calcium influx	Metatropic dysplasia (156530), AD Spondyloepimetaphyseal dysplasia: Maroteaux (184095), AD
<i>SHOX</i> : Short stature homeobox Xp22.33 312865	Homeobox gene transcription factor located on the pseudoautosomal region of Yp	Leri-Weill dyschondrosteosis (127300), X-linked dominant Langer dysplasia (249700), biallelic/X and Y
<i>SOX9</i> : SRY-box 9 17q24.3 608160	Transcription factor essential for chondrogenesis and testicular differentiation	Campomelic dysplasia (114290), Monoallelic because of haploinsufficiency
<i>RUNX2</i> : Runt-related transcription factor 2 6p21 600211	Osteoblast specific transcription factor	Cleidocranial dysostosis (119600), AD
<i>PTH1R</i> : PTH receptor 1 Xp22.33 168468	GPCR recognizing PTH and PTHrP with equal affinity	Inactivating mutations lead to hypocalcemia and Blomstrand osteochondrodysplasia (215045), AR Eiken syndrome (600002), AR; activating mutations result in hypercalcemia and Murk-Jansen metaphyseal chondrodysplasia (156400), AD
<i>PRKAR1A</i> : Protein kinase, cAMP-dependent regulatory, type 1, alpha 17q24.2 188830	Component of PKA response to cyclic AMP that leads to cascade of intracellular signal transduction signals in response to G α s that regulate cell division, differentiation, metabolism, apoptosis	Gain-of-function mutation leads to acrodysostosis (101800) and peripheral resistance to the biological effects of PTHrP, PTH, and TSH (de novo)
<i>POR</i> : Cytochrome P450 oxidoreductase 7q11.2 124015	Flavoprotein cofactor that donates electrons to microsomal 17 α -hydroxylase, 21-hydroxylase, and aromatase	Inactivating mutations lead to congenital adrenal hyperplasia usually with genital ambiguity in both 46XX and 46XY subjects (613571), AR; at times in association with skeletal abnormalities (Antley-Bixler syndrome: craniosynostosis, midface hypoplasia, choanal stenosis, femoral bowing, radioulnar synostosis, 201750, AR)
<i>RMRP</i> : Mitochondrial RNA-processing endoribonuclease, RNA component of 9p13.3 157660	Untranslated RNA subunit of the mitochondrial RNA-processing endoribonuclease: RNase MRP	Dependent on the severity of the biallelic loss-of-function mutation(s) the spectrum of anauxetic dysplasia (607095), cartilage hair hypoplasia (250250) emerges
<i>INPPL1</i> : Inositol polyphosphate phosphatase like-1 11q13.4 600829	Enzyme that hydrolyzes inositol-1,4,5-trisphosphate to inositol-4,5-bisphosphate: transducer of intracellular signaling	Inactivating mutations result in opsismodysplasia (258480); associated with increased skeletal synthesis of FGF23, AR

AD, Autosomal dominant; AR, autosomal recessive, ATP, adenosine triphosphate; cyclic AMP, cyclic adenosine monophosphate; GPCR, G-protein-coupled receptor; PKA, protein kinase A; PTH, parathyroid hormone; PTHrP, parathyroid hormone related protein; RNA, ribonucleic acid; TSH, thyroid stimulating hormone.

(Modified from Bonafe L, Cormier-Daire V, Hall C, et al. Nosology and classification of genetic skeletal disorders: 2015 revision. *Am J Med Genet.* 2015;167A:2869–2892.)

with three immunoglobulin domains in the extracellular region of the receptor and two tyrosine kinase domains in its intracellular portion; the p.Gly380Arg variant within the transmembrane domain of *FGFR3* is present in 98% of achondroplastic patients. The p.Gly380Arg variant of *FGFR3* alters the conformation of the gene product enabling ligand-independent autophosphorylation of tyrosine residues 647 and 648 within its cytoplasmic domain that is then able to propagate signals through MAPK and signal transducer and activator of transcription (STAT) pathways resulting in inhibition of chondrocyte mitosis, matrix synthesis, and terminal (hypertrophic) differentiation.⁵⁰⁶ Experimentally, in mice expressing the gain-of-function mutation in *Fgfr3* associated with achondroplasia, there is enhanced bone development but decreased bone mass and increased osteoclastic activity.⁵⁰⁷ Thus *FGFR3* normally functions as a negative regulator of cartilage and bone formation. As a single gene disorder, it is possible to identify a mutation in *FGFR3* in an affected fetus by analysis of fetal cell-free DNA in maternal plasma, if the mother is unaffected. Achondroplasia is also associated with the p.Gly375Cys variant in *FGFR3*. These disorders are transmitted as autosomal dominant traits but with a high rate of spontaneous mutations (primarily of the paternal *FGFR3* allele). Clinically, achondroplasia is manifested by shortening of the proximal limbs and trunk, macrocranium, frontal bossing, and depressed nasal bridge, and complicated by increased risk for cervical cord compression and spinal stenosis.⁵⁰⁸ The birth to normal parents of a second child with achondroplasia may reflect paternal germinal mosaicism for the p/Gly380Arg mutation in *FGFR3*.⁵⁰⁹ Hypochondroplasia is related to the p.Asn540Lys (60% of patients) variant present within the proximal tyrosine kinase segment of the intracellular domain of *FGFR3*; it is a clinically less severe disorder with usually modest short limbed (rhizomelic) short stature that presents in midchildhood. Hypochondroplasia has also been associated with mutations within the distal (p.Lys650Gln) tyrosine kinase domain, as well in the immunoglobulin domains of the extracellular region (p.Ser84Leu, p.Arg200Cys) and transmembrane domain (p.Val381Glu) of *FGFR3*. Thanatophoric dysplasia type I (OMIM 187600) is related to mutations (p.Arg248Cys, p.Gly370Cys) in the extracellular ligand-binding region next to the transmembrane domain of *FGFR3* and to substitutions at the normally terminal codon 807—p.Ter807Gly/Cys/Arg—all of which lead to addition of 141 aa to the carboxyl terminus of the *FGFR3* protein. Thanatophoric dysplasia type I is manifested by severe bony malformations that include short curved femurs, malformation of the skull, and short ribs, the latter leading to respiratory insufficiency and early death; it is the consequence of the p.Arg248Cys variant in the extracellular domain of *FGFR3*. Thanatophoric dysplasia type II (OMIM 187601) is associated with a mutation (p.Lys650Glu) in the distal tyrosine kinase domain of the intracellular segment of *FGFR3* and is characterized by a cloverleaf skull and short straight femurs. The clinical phenotype of the SADDAN syndrome (OMIM 616482) is also associated with the p.Lys650Met variant of *FGFR3* whose clinical manifestations are intermediate in severity between those of thanatophoric dysplasia and achondroplasia. It is associated with significant rhizomelic short stature, acanthosis nigricans, and mild developmental challenges; acanthosis nigricans may also develop in patients with classical achondroplasia and in those with mutations in *FGFR2*.⁵¹⁰ It is noteworthy that different mutations at p.Lys650 result in three distinct phenotypes—hypochondroplasia, thanatophoric dysplasia type II, and SADDAN syndrome. *FGFR3* activating mutations have also been encountered in patients with Muenke coronal craniosynostosis (OMIM 602849; p.Pro250Arg) and Crouzon syndrome (OMIM 123500)—evidence of the genetic heterogeneity of these clinical syndromes. A loss-of-function mutation (p.Arg621His within

the distal tyrosine kinase domain) in *FGFR3* has been identified in a family whose members display the phenotype of tall stature, camptodactyly, and hearing loss.⁵¹¹ Activating mutations in *FGFR1* and *FGFR2* have been associated with chondrodysplasias complicated by premature craniosynostosis (Pfeiffer, Apert, Crouzon, Jackson-White, Antley-Bixler, and Beare-Stevenson cutis gyrata syndromes). Interestingly, mutations in *FGFR1* have also been associated with hypogonadotropic hypogonadism (OMIM 147950) and anosmia, as *FGFR1* is an essential factor for neuronal migration and angiogenesis.⁵¹² Mutations in *FGFR4* have not been associated with osteochondrodysplasias to date.

Pseudoachondroplasia (OMIM 177170) is an osteochondrodystrophy that does not become manifest until after the first year of life as the fetus and infant with this disorder appear normal.⁵¹³ Growth retardation becomes apparent in the second year of life; stature becomes progressively compromised during childhood in association with genu varum or valgus, brachydactyly, and joint laxity and severe bone and joint pain that impairs movement. Radiographs reveal inhibition of long bone growth; metaphyseal irregularities; and small, undercrossed epiphyses. Pseudoachondroplasia is the consequence of monoallelic inactivating variants in cartilage oligomeric matrix protein (*COMP*, OMIM 600310). *COMP* is a secreted glycoprotein produced by chondrocytes that has four domains—one of which is a calcium binding domain; variations in the base sequences of this domain lead to pseudoachondroplasia because of disrupted protein folding and ensuing chondrocyte malfunction while also exerting a dominant negative effect on the intact product of the normal *COMP* allele and the retention of *COMP* protein in the endoplasmic reticulum of the chondrocyte. Normally secreted *COMP* contributes to collagen strength by cross-linking several different matrix collagens (types I, II, IX, XII, XIV) and its loss impairs this property. Mutant *COMP* retained within the endoplasmic reticulum of the chondrocyte leads to intracellular inflammation and then to chondrocyte death. Experimentally in mice, the inflammatory response to retained, mutated *COMP* can be ameliorated by administration of antiinflammatory agents, such as acetylsalicylic acid with restoration of the animals' growth.⁵¹³ Whether these experimental observations can be duplicated in children with pseudoachondroplasia is as yet unknown.

In addition to the four genetic types (I–IV) of osteogenesis imperfecta attributable to variants of *COL1A1* and *COL1A2*, defects in the formation of several other types of collagen caused by mutations in *COL2A1*, *COL9A1*, *COL9A2*, *COL10A1*, *COL11A1*, and *COL11A2* result in a large number of skeletal malformations depending on the site and developmental timing of the synthetic error (see Table 20.13). Mutations in several different collagen-encoding genes (*COL2A1*, *COL9A1*, *COL9A2*, and *COL11A1*) result in variants of Stickler syndrome (OMIM 609508, 604841, 614134, 614284) characterized by abnormalities of the skeleton (epiphyseal dysplasia), face (micrognathia, cleft palate), vision (myopia, retinal detachment), and impaired hearing that may be transmitted as autosomal dominant or recessive traits. The ectrodactylies or split hand/foot malformations are characterized by absence of the second and third metacarpals/metatarsals and corresponding fingers/toes with residual first and fused fourth and fifth digits (resulting in a “claw-like” appearance of the distal limb) that may be caused by structural abnormalities (rearrangement, deletion, duplication) of chromosome 7q21.3 in which segment reside several genes that influence embryogenesis of the digits, as well as to abnormalities of other chromosomes (Xq26, 2q31, 10q24).

Atelosteogenesis type I (OMIM 108720) is a lethal skeletal disorder characterized by absent, short, or distally tapered femora and humeri, short bowed tibiae and ulnae, absent fibulae, vertebral hypoplasia, and subnormal metacarpal ossification;

this disorder has several variants; it is the result of monoallelic loss-of-function mutations in *FLNB* (OMIM 603381) encoding a cytoplasmic protein that binds actin, thereby enabling actin to form the cytoskeleton, and also facilitates intracellular communication between the cell membrane and its cytoskeleton. Abnormalities of sulfate transport, collagen matrix protein sulfation, and sulfatase activity result in several chondrodysplasias. *SLC26A2* (OMIM 606718) encodes a sulfate transporter that is mutated in patients with diastrophic dysplasia (DTD, OMIM 222600) and achondrogenesis type IB (OMIM 600972). Spondyloepimetaphyseal dysplasia/brachyolmia type 4 is caused by biallelic loss-of-function mutations (p.Thr48Arg, p.Ser438Ter) in the *PAPSS2* (OMIM 603005) encoding 3'-phosphoadenosine-5'-phosphosulfate synthase 2, an enzyme with dual activities; it catalyzes both the synthesis of adenosine 5'-phosphosulfate and its phosphorylation to 3'-phosphoadenosine 5'-phosphosulfate, the universal sulfate donor necessary for sulfation of cartilage and bone matrix proteins. Clinical manifestations of this disorder include short limbs, kyphoscoliosis, brachydactyly, and enlarged knee joints. Inactivating mutations in *ARSE* (encoding arylsulfatase E, OMIM 300180) lead to X-linked recessive brachytelephalangic chondrodysplasia punctata type 1.⁵¹⁴ This disorder is marked clinically by compromised stature attributable to rhizomelic shortening of the limbs in association with stippling of the epiphyses, craniofacial defects, atrophic and pigmented ichthyosiform skin lesions, alopecia, cataracts, and developmental delay.

Loss-of-function mutations (insertions, missense, nonsense) in *SOX9* (OMIM 608160), a transcription factor that is expressed in both developing chondrocytes where it is coexpressed with *COL2A1* and in the genital ridges during gonadal differentiation, cause both campomelic dysplasia (OMIM 114290) and male-to-female sex reversal in 75% of affected 46XY subjects. Inasmuch as *SOX9* is essential for normal expression and function of *COL2A1* during chondrogenesis, its absence leads to impaired formation of cartilage matrix and malformation of bones embryologically derived from endochondral bone. In the developing bipotential gonad of the 46XY fetus, the expression of *SOX9* is governed by *SRY* (OMIM 480000); *SOX9* expression is also essential for normal differentiation and development of Sertoli cells and other components of the testis. Clinically, campomelic dysplasia is characterized by prenatal onset of bowing of tubular bones, hypoplastic scapulae, 11 ribs, cleft palate, and micrognathia leading often to neonatal death, as well as failure of masculinization of the 46XY conceptus.

The X- and Y-linked pseudoautosomal gene *SHOX* (OMIM 312865) encodes two nuclear proteins—SHOXa with 292 aa and SHOXb with 225 aa. *SHOX* is a transcription factor expressed in late proliferative, prehypertrophic, and hypertrophic chondrocytes one of whose target genes is *NPPB* encoding natriuretic peptide precursor B (OMIM 600295) that is also expressed in late proliferative, prehypertrophic, and hypertrophic chondrocytes.⁵¹⁵ Absence of one *SHOX* functional gene is the proximate cause of the short stature of girls with Turner syndrome and some children with "idiopathic" short stature. Heterozygous microdeletions and intragenic inactivating mutations (p.Leu132Val, p.Ala170Pro, p.Arg195Stop) of *SHOX* resulting in haploinsufficiency are present in patients with Leri-Weill dyschondrosteosis (OMIM 127300) typified by mesomelic limb shortening and growth retardation, Madelung deformity of the wrist, bowing of the radius, and ulnar dislocation. The Leri-Weill phenotype has been recorded in patients with intact *SHOX* but with microdeletions of downstream segments of the X chromosome pseudoautosomal region, implying the presence of modifying genes in this region. Biallelic loss (X and Y chromosomes) of *SHOX* leads to Langer mesomelic dysplasia (OMIM 249700) typified by severe hypoplasia of the ulna and fibula and a thickened, curved radius and tibia.

Both gain- and loss-of-function variants of *PTH1R* (OMIM 168468) lead to abnormalities of bone formation and growth. Blomstrand chondrodysplasia (OMIM 215045) is an autosomal recessive disorder lethal in utero that may be identified in the fetus with short, extremely dense long bones and markedly advanced skeletal maturation, as well as somatic anomalies, such as aortic coarctation and facial anomalies. Pathologically, epiphyseal cartilage is reduced, and there are irregular columns and erratic distribution of chondrocytes within matrix. The abnormality is the result of inactivating mutations (deletions, missense mutations—p.Pro132Leu, p.Arg383Gln) of the gene encoding the PTH/PTHrP receptor. The Eiken syndrome (OMIM 600002) of epiphyseal dysplasia with markedly delayed ossification of the primary ossification centers of tubular bones, epiphyses, and pelvic symphysis is also caused by a biallelic loss-of-function mutations (p.Glu35Lys, p.Arg485Stop) in *PTH1R*.³⁸ Patients with Murk-Jansen metaphyseal chondrodysplasia (OMIM 156400) have short bowed limbs, clinodactyly, micrognathia, and deformities of the spine and pelvis, but survive to adulthood where the average adult height is 125 cm and child-bearing is possible. Characteristically, these patients have hypercalcemia, hypophosphatemia, and low or undetectable serum levels of both PTH or PTHrP, the consequences of unregulated activity of the PTH receptor caused by monoallelic activating mutations (p.His223Arg, p.Thr410Pro) of *PTH1R*. These two disorders reflect the altered functional effects of PTHrP/PTH acting through *PTH1R* in developing cartilage where these ligands normally slow chondrocyte differentiation and decrease the rate of chondrocyte apoptosis thus prolonging chondrocyte proliferation and enhancing long bone growth.

Anauxetic dysplasia (OMIM 607095) is a spondylometaphyseal dysplasia transmitted as an autosomal recessive disorder characterized by intrauterine growth retardation (birth length <40 cm), severely compromised adult height (<85 cm), hypodontia, and mild mental retardation. All bones are malformed; there are few chondrocytes in the cartilage growth plates. It is caused by loss-of-function mutations (insertions) in *RMRP* (OMIM 157660), a gene that encodes the untranslated RNA subunit of a mitochondrial RNA-processing endoribonuclease.⁵¹⁶ This enzyme is involved in: (1) the assembly of ribosomes—the structural units in which protein synthesis take place, (2) the generation of RNA primers for replication of mitochondrial DNA, and (3) the regulation of the cyclin-dependent cell cycle. The mutations that result in anauxetic dysplasia impair ribosome assembly and protein synthesis. Inactivating mutations (duplications, insertions) in *RMRP* that modestly impair both ribosome assembly and regulation of the cell cycle are present in patients with cartilage hair hypoplasia (OMIM 250250) and metaphyseal dysplasia without hypotrichosis (OMIM 250460). Thus cartilage hair hypoplasia and anauxetic dysplasia represent different manifestations and severity of inactivation of *RMRP*.

Errors in the biosynthesis of cholesterol have been associated with a number of disorders that adversely affect bone development, as well as many other systems (Table 20.14; Fig. 20.17).⁵¹⁷ Cholesterol is a constituent of the cell's plasma membrane, as well as the membranes of intracellular organelles; it covalently binds to the amino terminal and is essential for the function of Indian hedgehog, Sonic hedgehog, and Desert hedgehog, inductive factors necessary for normal development of cartilage and bone, brain, and testes, respectively. It is a precursor of steroids and bile acids. It is likely that lack of cholesterol exerts its teratological effects by impairing membrane function and/or the intracellular signaling response(s) to normal stimuli. In addition, accumulation of precursors of cholesterol may be toxic to the developing fetus. In patients with the Smith-Lemli-Opitz syndrome (OMIM 270400), inactivating mutations of the microsomal enzyme Δ^7 -dehydrocholesterol reductase (*DHCR7*; OMIM 602858) impair the final step in the synthetic pathway of cholesterol from 7-dehydrocholesterol and lead to intrauterine and postnatal growth retardation, short limbs,

TABLE 20.14 Osteochondrodysostrophies Attributable to Genetic Variants of Proteins Essential for Cholesterol Synthesis

Gene Chromosome OMIM	Pathophysiology	Clinical Disorder (OMIM)
<i>DHCR7</i> : 7-Dehydrocholesterol reductase 11q12-q13 602858	3 β -Hydroxysteroid Δ^7 reductase converts 7-dehydrocholesterol to cholesterol	Smith-Lemli-Opitz syndrome (270400), AR
<i>DHCR24</i> : 24-Dehydrocholesterol reductase 1p32.3 606418	3 β -Hydroxysteroid Δ^{24} reductase converts desmosterol to cholesterol	Desmosterolosis (602398), AR
<i>SC5DL</i> : Sterol C5-desaturase-like 11q23.3 602286	Microsomal enzyme (3 β -hydroxysteroid- Δ 5-desaturase) that converts lathosterol to 7-dehydrocholesterol, precursor of cholesterol and cholecalciferol (vitamin D)	Lathosterolosis (607330), AR
<i>EBP</i> : Emopamil-binding protein Xp11.23 300205	Dual function protein: binding protein; 3 β -Hydroxysteroid Δ^7 , Δ^8 isomerase converts cholest-8(9)-en-3 β -ol to lathosterol	Chondrodysplasia punctata type 2 (302960), X-linked dominant
<i>NSDHL</i> : NAD(P)H steroid dehydrogenase-like protein Xq28 300275	3 β -Hydroxysteroid C4 demethylase complex converts 4,4-dimethylcholest-8(9)-en-3 β -ol to cholest 8(9)-en-3 β -ol; other members of complex are <i>SC4MOL</i> (607545) and <i>HSD17B7</i> (606756)	CHILD (congenital hemidysplasia, ichthyosiform erythroderma, limbs defects) syndrome (308050), X-linked dominant
<i>LBR</i> : Lamin B receptor 1q42.12 600024	Dual function protein: promotes heterochromatin binding to inner nuclear membrane; 3 β -hydroxysteroid Δ^{14} reductase important for synthesis of cholesterol	HEM (hydrops-ectopic calcification-"moth-eaten" or Greenberg) dysplasia (215140), AR
<i>POR</i> : Cytochrome P450 oxidoreductase 1q11.2 124015	Flavoprotein electron donor to all P450 enzymes including P450c17, P450c21, P450arom	Antley-Bixler syndrome (ABS) with genital anomalies and disordered steroidogenesis, (201750), AR (ABS with exclusively skeletal anomalies [207410] because of mutation in <i>FGFR2</i> , AD)

AD, Autosomal dominant; AR, autosomal recessive.

(Modified from Forbes FD, Herman GE. Malformation syndromes caused by disorders of cholesterol synthesis. *J Lipid Res.* 2011;52:6–34.)

syndactyly and polydactyly, characteristic facial features (blepharoptosis, anteverted nares, broad alveolar ridges, cleft palate), congenital malformations of the heart and central nervous system, microcephaly, incomplete virilization of male external genitalia, hypoplastic thumbs, developmental delay, autism, and compromised adrenocortical function, a malformation syndrome with an incidence of 1/15000 to 1/40000 births.⁵¹⁸ Serum concentrations of cholesterol are depressed whereas those of 7- and 8-dehydrocholesterol are elevated. The serum 7-dehydrocholesterol and 8-dehydrocholesterol concentrations are negatively related to the clinical severity and intellectual attainment of subjects with the Smith-Lemli-Opitz phenotype.⁵¹⁹

Desmosterolosis (OMIM 602398) is an autosomal recessive disorder with diverse clinical manifestations that include impaired growth, osteosclerosis, shortened limbs, macro- or microcephaly, cleft palate, micrognathia, thick alveolar ridges, developmental delay, and spasticity. Cranial magnetic resonance imaging reveals little white matter and a thinned to almost complete agenesis of the corpus callosum. Desmosterolosis is caused by biallelic inactivating mutations of the gene (*DHCR24*, OMIM 606418) encoding 3 β -hydroxysteroid- Δ^{24} reductase, an enzyme that converts desmosterol to cholesterol.^{517,520,521} Lathosterolosis (OMIM 607330) is characterized by microcephaly, bitemporal narrowing of the skull, cataracts, anteverted nostrils, and other physical anomalies recorded in patients with the Smith-Lemli-Opitz syndrome.⁵¹⁷ It is the result of loss-of-function mutations in the gene (*SC5DL*, OMIM 602286) encoding 3 β -hydroxysteroid- Δ 5-desaturase, an enzyme that converts lathosterol to 7-dehydrocholesterol. Chondrodysplasia punctata 2 (OMIM 302960) is an X-linked dominant disorder (Conradi-Hunermann-Happle syndrome) that is often lethal in the affected male. It is characterized clinically in the affected female by short stature with asymmetric short proximal limbs (rhizomelic dwarfism), frontal bossing, scaly and erythematous skin lesions that resemble ichthyosis in children and atrophic pigmentary lesions in adults, coarse hair with alopecia, and cataracts; reflecting

functional X-chromosomal mosaicism, in females the phenotype may vary from stillborn to mildly affected.⁵¹⁷ Radiographic examination reveals generalized osteosclerosis, irregular punctate calcification (stippling) of epiphyses of the long bones and vertebrae in children. This disorder is caused by loss-of-function mutations in emopamil-binding protein (*EBP*, OMIM 300205), the gene encoding 3 β -hydroxysteroid- Δ^8 , Δ^7 isomerase, an enzyme that converts cholesta-8(9)-en-3 β -ol to lathosterol; in the serum of subjects with chondrodysplasia punctata 2 plasma concentrations of 8-dehydrocholesterol cholest-8(9)-en-3 β -ol are elevated. This protein also binds many unrelated molecules; its genetic designation derives from its ability to bind emopamil (i.e., EBP)—a calcium ion antagonist. X-linked recessive and autosomal recessive forms of the Conradi-Hunermann-Happle syndrome have also been reported, suggesting genetic heterogeneity for this phenotype. The CHILD syndrome of congenital hemidysplasia with ichthyosiform erythroderma or nevus and limb defects is remarkable for its unilateral distribution of anomalies that are confined to one-half of the body.⁵¹⁷ It is an X-linked disorder caused by loss-of-function mutations in NADPH steroid dehydrogenase-like (*NSDHL*, OMIM 300275) encoding a sterol dehydrogenase or decarboxylase that is part of the 3 β -hydroxysteroid C-4 sterol demethylase complex that also includes the products of *SC4MOL* and *HSD17B7*. This complex converts 4,4-dimethylcholesta-8-en-3 β .ol to cholesta-8(9)-en-3 β -ol.

The often lethal Greenberg dysplasia (OMIM 215140) of hydrops-ectopic calcification-moth-eaten (HEM) skeletal dysplasia is transmitted as an autosomal recessive trait associated with short-limbed dwarfism, polydactyly, and irregularly decreased calcification of the long bones together with calcification of the larynx and trachea. It is caused by a loss-of-function mutation in the gene (*LBR*, OMIM 600024) encoding the lamin B receptor, a nuclear envelope inner membrane protein that not only binds lamin B but also has 3 β -hydroxysteroid- Δ^{14} reductase activity, an enzyme that converts 4,4-dimethylcholesta-8(9)-dien-3 β -ol

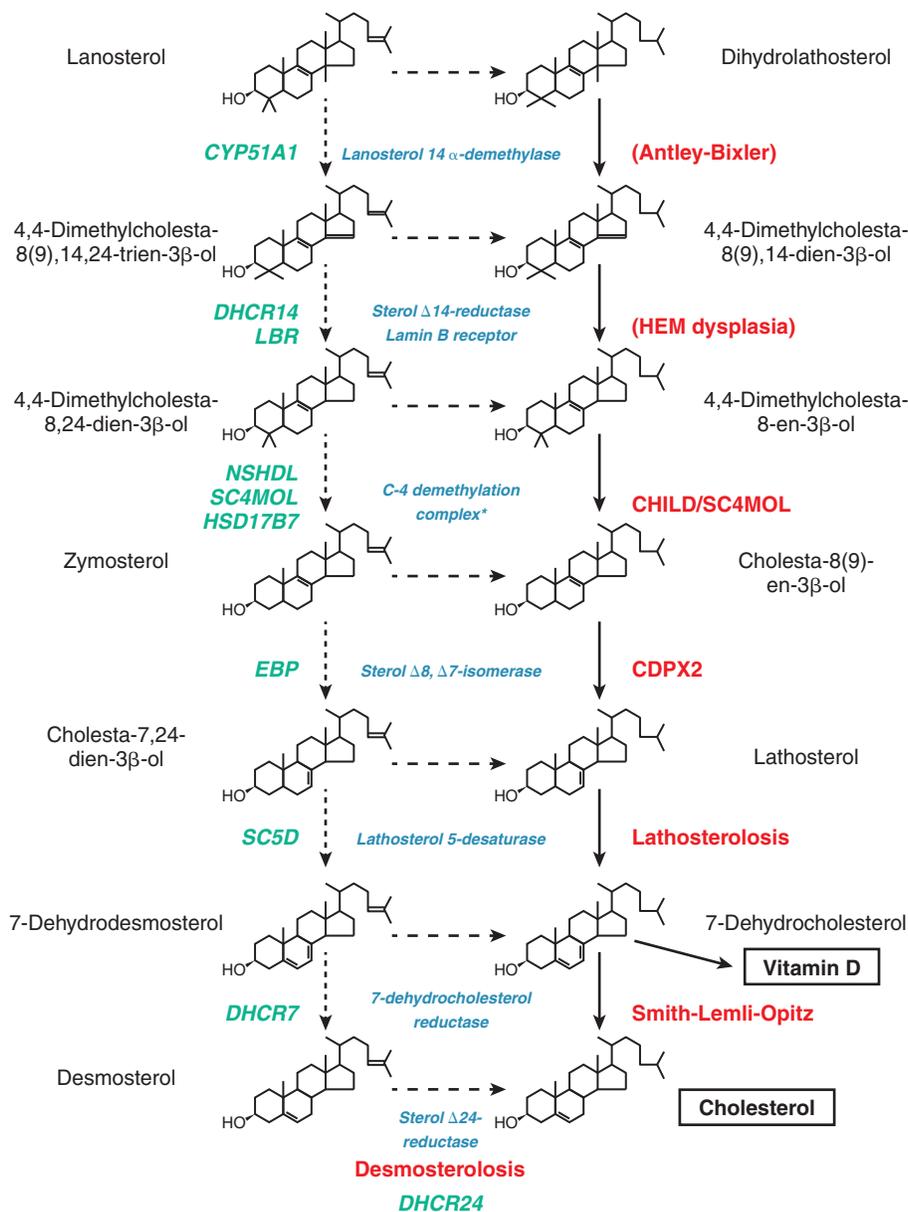

Fig. 20.17 Biosynthesis of cholesterol depicting the sites of enzyme activity lost by inactivating mutations that lead to skeletal, genital, and systemic malformations. The conversion of lanosterol to cholesterol may proceed through two pathways as depicted (see text for details). (From Forbes FD, Herman GE. Malformation syndromes caused by disorders of cholesterol synthesis. *J Lipid Res.* 2011;52:6–34, with permission.)

to 4,4-dimethylcholesta-8-en-3 β -ol, a necessary step for normal cholesterol biosynthesis. 3 β -Hydroxysteroid- Δ ¹⁴ reductase activity is also encoded by *DHCR14*, an endoplasmic reticular enzyme that too catalyzes reduction of unsaturated C14-C15 intermediate sterols.⁵¹⁷ The HEM skeletal dysplasia is considered to be a laminopathy rather than an inborn error in cholesterol biosynthesis. The Antley-Bixler syndrome (OMIM 207410) of craniosynostosis, humeroradial synostosis, femoral bowing, midface hypoplasia, choanal stenosis/atresia, and joint contractures has been associated with heterozygous mutations in *FGFR2* (OMIM 176943). When these skeletal anomalies coexist with genital malformations and defects in steroidogenesis (OMIM 201750), biallelic loss-of-function mutations have been identified in *POR* (OMIM 124015), encoding P450 oxidoreductase, a donor of electrons for the P450 enzymes required for synthesis of adrenocortical and gonadal steroids. Thus when *POR* activity is decreased, function of the enzyme encoded by *CYP51A1* (OMIM 601637) that converts

dihydrolathosterol to 4,4-dimethylcholesta-8(9)14-dien-3 β -ol is depressed.

CONCLUDING REMARKS

Deciphering of the complex mechanisms that underlie the pathophysiology of illnesses that adversely affect the regulation of calcium, phosphate, and magnesium metabolism, chondrocyte differentiation and growth, and bone formation, mineralization, and strength has been further informed by the insights that advances in genetics, epigenetics, and proteomics have brought to these clinical problems. It may be anticipated that further clarification of the very most basic mechanisms that underlie these disorders will enable translation of these findings into the care of many of the disorders that affect our young patients.

ACKNOWLEDGMENT

In memory of Frank B. Diamond, Jr, MD.

DGS	DiGeorge syndrome	PTHrP	PTH-related protein
DMR	Differentially methylated region	PTHrP1	PTH/PTHrP receptor 1
FGF	Fibroblast growth factor	QCT	Quantitative computed tomography
FGFR	FGR receptor	QUS	Quantitative ultrasound
FISH	Fluorescent in situ hybridization	RANK	Receptor activator of nuclear factor κB
GDNF	Glial-derived neurotrophic factor	RANKL	RANK-ligand
GH	Growth hormone	SDS	Standard deviation score
GPCR	G-protein coupled receptor	SERM	Selective estrogen receptor modulator
GDP	Guanosine diphosphate	sFRP4	Serum frizzled related protein-4
G _{sα}	α Subunit of stimulatory G-protein (G _{sα})	SIBLING	Short integrin-binding ligand-interacting glycoprotein
GTP	Guanosine triphosphate	SOS	Speed of sound
H ⁺	Hydrogen ion	TALH	Thick ascending loop of Henle
HDR	Hypoparathyroidism, deafness, renal disease syndrome	TGFβ	Transforming growth factor β
HHC	Hereditary hypocalciuric hypercalcemia	TNF	Tumor necrosis factor
HRD	Hypoparathyroidism, retardation, dysmorphism syndrome	TNSALP	Tissue nonspecific alkaline phosphatase
HSP	Heat shock protein (CBP)	TRAP	Tartrate-resistant acid phosphatase
ICTP	Carboxyl telopeptide of collagen type I	VDDR1A	Vitamin D-dependent rickets type 1A
IFITM5	Interferon-induced transmembrane protein-5 or bone-restricted Itifm5-like protein	VDR	Vitamin D receptor
IGF	Insulin-like growth factor	VDRE	Vitamin D response element
IL	Interleukin	VEGF	Vascular endothelial growth factor
IOF	International Osteoporosis Society	VLBW	Very low birth weight
ISCD	International Society for Clinical Densitometry	WBS	Williams-Beuren syndrome
KCS	Kenny-Caffey syndrome	WINAC	WSTF including nucleotide assembly complex
LBW	Low birth weight	WHO	World Health Organization
MAPK	Mitogen-activated protein kinase	WSTF	Williams syndrome transcription factor
M-CSF	Macrophage-colony stimulating factor	XLHR	X-linked dominant hypophosphatemic rickets
MCT	Medullary carcinoma of thyroid	1,25(OH) ₂ D ₃	1,25-Dihydroxyvitamin D ₃ (calcitriol)
MEN	Multiple endocrine neoplasia	25OHD ₃	25-Hydroxyvitamin D ₃ (calcidiol)
MEPE	Matrix extracellular phosphoglycoprotein		

A, Adenine; C, cytidine; G, guanine; T, thymine.

INTRODUCTION

Diabetes mellitus (DM) is a syndrome of disturbed energy metabolism involving carbohydrate, protein, and fat brought about by absolute or relative deficiency of insulin secretion, in

814

the context of sensitivity or resistance to insulin actions at various tissue sites. Thus both the extent of impairment in insulin secretion and tissue sensitivity to its actions define the severity of the clinical manifestations, most commonly monitored by the extent

of inappropriate fasting and postprandial hyperglycemia. It is the degree of hyperglycemia that leads to the classical symptoms and signs of polyuria, polydipsia, and weight loss. Metabolic disturbances in protein and fat metabolism exist but, in contrast to glucose, are monitored intermittently, not routinely on a daily basis. In time, these metabolic disturbances, if uncontrolled, lead to various micro- and macrovascular complications, such as retinopathy, nephropathy, neuropathy, and large vessel obstruction of peripheral arteries and the heart, which lead to shortening of life span and lower quality of life. The severity and time of appearance of these complications are inversely related to the degree of metabolic control as judged by various parameters, chiefly the degree of hyperglycemia and glucose variability throughout the day. The closer that metabolic control approaches normal, the less likely to occur are the complications.

DM occurs when the normal constant of the product of insulin secretion times insulin sensitivity, a parabolic function termed the *disposition index* (Fig. 21.1), is inadequate to prevent hyperglycemia and its clinical consequences of polyuria, polydipsia, and weight loss. At high degrees of insulin sensitivity, small declines in the ability to secrete insulin cause only mild, clinically imperceptible defects in glucose metabolism. However, irrespective of insulin sensitivity, a minimum amount

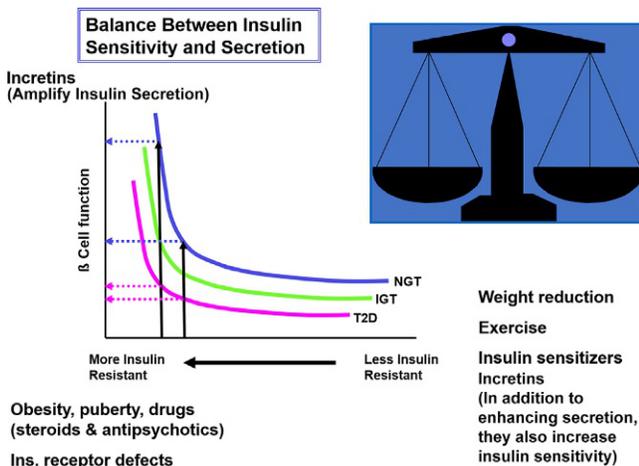

Fig. 21.1 The hyperbolic relationship of insulin resistance and beta-cell function. On the y-axis is beta-cell function as reflected in the first-phase insulin response during intravenous (IV) glucose infusion; on the x-axis is insulin sensitivity and its mirror image resistance. In a subject with normal glucose tolerance (NGT) and beta-cell reserve, an increase in insulin resistance results in increased insulin release and normal glucose tolerance. In an individual for whom the capacity to increase insulin release is compromised, increasing insulin resistance with partial or no beta-cell compensation results in progression from normal glucose tolerance, to impaired glucose tolerance (IGT), and finally to diabetes (T2D). Differences between these categories are small at high insulin sensitivity, which may be maintained by weight reduction, exercise, and certain drugs. At a critical degree of insulin resistance, because of obesity or other listed factors, only a further small increment in resistance requires a large increase in insulin output. Those that can increase insulin secretion to this extent retain normal glucose tolerance; those who cannot achieve this degree of insulin secretion (e.g., because of a mild defect in genes regulating insulin synthesis, insulin secretion, insulin action, or an ongoing immune destruction of beta cells) now unmask varying degrees of carbohydrate intolerance. The product of insulin sensitivity (the reciprocal of insulin resistance) and acute insulin response (a measurement beta-cell function) has been called the “*disposition index*.” This index remains constant in an individual with normal beta-cell compensation in response to changes in insulin resistance. Incretins are hormone such as GLP-1, which augment insulin secretion and also increase insulin sensitivity. (From Ize-Ludlow, D., & Sperling, M.A. (2005). The classification of diabetes mellitus: a conceptual framework. *Pediatr Clin North Am*, 52, 1533–1552.)

of insulin is necessary for normal metabolism. Thus near absolute deficiency of insulin must result in severe metabolic disturbance as occurs in type 1 diabetes mellitus (T1DM).¹ In contrast, with decreasing sensitivity to its action, higher amounts of insulin secretion are required for a normal disposition index. At a critical point in the disposition index curve (see Fig. 21.1), a further small decrement in insulin sensitivity requires a large increase in insulin secretion; those who can mount these higher rates of insulin secretion retain normal glucose metabolism, whereas those who cannot increase their insulin secretion because of genetic or acquired defects now manifest clinical diabetes, as typically occurs in type 2 diabetes mellitus (T2DM).²

By simultaneously considering insulin secretion and insulin action in any given individual, it becomes possible to account for the natural history of diabetes in that person (e.g., remission in a patient with T1DM or ketoacidosis in a person with T2DM). Thus DM may be the result of absolute insulin deficiency, or of absolute insulin resistance, or a combination of milder defects in both insulin secretion and insulin action.² Collectively, the syndromes of DM are the most common endocrine/metabolic disorders of childhood and adolescence. The application of molecular biological tools continues to provide remarkable insights into the etiology, pathophysiology, and genetics of the various forms of DM that result from deficient secretion of insulin or its action at the cellular level.

Morbidity and mortality stem from the metabolic derangements and from the long-term complications.³ The acute clinical manifestations are fully understood in the context of knowledge of the secretion and action of insulin.⁴ Genetic and other etiological considerations implicate autoimmune mechanisms in the evolution of the most common form of childhood diabetes, known as *type 1a diabetes*.^{5,6} Genetic defects in insulin secretion are increasingly recognized and understood as defining the causes of monogenic forms of diabetes, such as maturity-onset diabetes of youth (MODY) and neonatal DM and contributing to the spectrum of T2DM.⁷

Strong evidence that the long-term complications are related to the degree and duration of metabolic disturbances³ form the basis of standard and innovative therapeutic approaches for the spectrum of DM syndromes that include newer pharmacological formulations of insulin, delivery by traditional and more physiological means, and evolving methods to continuously monitor blood glucose to maintain it within desired limits by linking these features to algorithm-driven insulin delivery pumps for an “artificial pancreas.”

CLASSIFICATION

DM is not a single entity, but a heterogeneous group of disorders in which there are distinct genetic patterns, as well as other etiological and pathophysiological mechanisms that lead to impairment of glucose tolerance.^{2,8} Box 21.1 outlines an etiological classification of DM in children, based on the “Report of the Expert Committee on the Classification and Diagnosis of Diabetes Mellitus,” published by the American Diabetes Association (ADA) in January of 2018.⁸

Our classification is modified to reflect more accurately the major categories in childhood, including the emergence of T2DM, cystic fibrosis–related diabetes, and drug-induced diabetes—largely from the antirejection drugs cyclosporine, sirolimus, and tacrolimus (formerly FK-506). Table 21.1 presents a summary of the classification originally proposed in 1979 but incorporates the newer criteria for blood glucose values used to diagnose diabetes, impaired glucose tolerance, and gestational diabetes. Current classification of T1DM includes staging: stage 1 is the presence of two or more islet cell antibodies (ICAs), but without any discernible disturbance in glucose metabolism; stage 2 includes positive antibodies plus impaired fasting glucose or impaired glucose tolerance; stage 3 is the presence of glycemic criteria for

BOX 21.1 Etiological Classification of Diabetes Mellitus

- I. TYPE 1 DIABETES (BETA-CELL DESTRUCTION ULTIMATELY LEADING TO COMPLETE INSULIN DEFICIENCY)
 - A. Immune mediated
 - B. Idiopathic
- II. TYPE 2 DIABETES (VARIABLE COMBINATIONS OF INSULIN RESISTANCE AND INSULIN DEFICIENCY)
 - A. Typical
 - B. Atypical
- III. GENETIC DEFECTS OF BETA-CELL FUNCTION
 - A. MODY syndromes
 1. MODY 1 chromosome 20, HNF4A
 2. MODY 2 chromosome 7, glucokinase
 3. MODY 3 chromosome 12, HNF1A
 4. MODY 4 chromosome 13, IPF-1
 5. MODY 5 chromosome 17, HNF-1 β
 6. MODY 6 chromosome 2q32, neuro-D1/beta-2
 7. MODY7-14, see [Table 21.14](#)
 - B. Mitochondrial DNA mutations (includes one form of Wolfram syndrome, Pearson syndrome, Kearns-Sayre, diabetes mellitus, deafness)
 - C. Wolfram syndrome—DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, deafness): WFS1-Wolframin—chromosome 4p
 1. Wolfram locus 2—chromosome 4q22-24
 2. Wolfram mitochondrial
 - D. Thiamine responsive megaloblastic anemia and diabetes
- IV. DRUG OR CHEMICAL INDUCED
 - A. Antirejection—cyclosporine, sirolimus
 - B. Glucocorticoids (with impaired insulin secretion; e.g., cystic fibrosis)
 - C. L-Asparaginase
 - D. β -Adrenergic blockers
 - E. Vacor (rodenticide)
 - F. Phenytoin (dilantin)
 - G. Alfa-interferon
 - H. Diazoxide
 - I. Nicotinic acid
 - J. Others
- V. DISEASES OF EXOCRINE PANCREAS
 - A. Cystic fibrosis–related diabetes
 - B. Trauma—pancreatectomy
 - C. Pancreatitis—ionizing radiation
 - D. Others
- VI. INFECTIONS
 - A. Congenital rubella
 - B. Cytomegalovirus
 - C. Hemolytic-uremic syndrome
- VII. VARIANTS OF TYPE 2 DIABETES
 - A. Genetic defects of insulin action
 1. Rabson-Mendenhall syndrome
 2. Leprechaunism
 3. Lipoatrophic diabetes syndromes
 4. Type A insulin resistance—acanthosis
 - B. Acquired defects of insulin action
 1. Endocrine tumors—rare in childhood
 - C. Pheochromocytoma
 - D. Cushing
 - E. Others
 1. Antiinsulin receptor antibodies
- VIII. GENETIC SYNDROMES WITH DIABETES AND INSULIN RESISTANCE/INSULIN DEFICIENCY
 - A. Prader-Willi syndrome, chromosome 15
 - B. Down syndrome, chromosome 21
 - C. Turner syndrome
 - D. Klinefelter syndrome
 - E. Others
 1. Bardet-Biedl
 2. Alstrom
 3. Werner
- IX. GESTATIONAL DIABETES
- X. NEONATAL DIABETES
 - A. Transient—chromosome 6q24, *KCNJ11*, *ABCC8*, *INS*, *HNF1 β* , others
 - B. Permanent—agenesis of pancreas—glucokinase deficiency, homozygous, *KCNJ11*, *ABCC8*, others (see [Ch. 10](#))

ABCC8, ATP binding cassette subfamily C member 8; *DNA*, deoxyribonucleic acid; *HNF*, hepatocyte nuclear factor; *IPF*, insulin promoter factor; *KCNJ11*, potassium channel family J number 11; *MODY*, maturity-onset diabetes of the young.

TABLE 21.1 Summary of Classification of Diabetes Mellitus in Children and Adolescents

Category	Criteria
DIABETES MELLITUS	
Type 1	Typical symptoms: glucosuria, ketonuria; random plasma glucose >200 mg/dL; ≥ 2 Abs with normal glucose tolerance is now considered start of T1DM; with abnormal glucose tolerance is Stage 2; with clinical symptoms it is Stage 3
Type 2	Fasting plasma glucose >126 mg/dL with 2-hour intervening value >200 mg/dL on OGTT more than once and in the absence of precipitating factors
Other types	Type 1 or 2 criteria with genetic syndromes, including maturity-onset diabetes of the young (MODY), neonatal diabetes (NDM), drug therapy; pancreatic disease or other known causes or associations
Impaired fasting glucose	Glucose >100 mg/dL but <126 mg/dL
Impaired glucose tolerance	Fasting plasma glucose <126 mg/dL with 2-hour >140 mg/dL but <200 mg/dL on OGTT
Gestational diabetes	Two or more abnormal fasting plasma glucose levels >105 mg/dL, 1-hour >180 mg/dL, 2-hour >155 mg/dL, 3-hour > 140 mg/dL on OGTT
STATISTICAL RISK CLASSES	
Previous abnormality of glucose tolerance	Normal OGTT with previously abnormal OGTT, spontaneous hyperglycemia, or gestational diabetes
Potential abnormality of glucose tolerance	Genetic propensity (e.g., identical twin with diabetes mellitus); 2 islet cell antibodies is considered prediabetes

T1DM, Type 1 diabetes mellitus; OGTT, oral glucose tolerance tests.

diabetes together with the clinical manifestations. Among the insulin-dependent forms, severe lack of insulin secretion results most commonly from presumed autoimmune destruction of islets in genetically predisposed hosts. As noted earlier, evidence of autoimmunity may precede by months to years the clinical deterioration to abnormal glucose tolerance. This form is synonymous with **type 1a diabetes**, formerly called *juvenile-onset diabetes*.^{5,6,9,10} Severe insulin-dependent DM, clinically indistinguishable from the autoimmune form, may, however, not have any evidence of autoimmunity and can result from mitochondrial or other gene defects that interfere with **normal insulin secretion** or rarely from pancreatic agenesis.^{11–14}

The more severe forms of the MODY **syndromes**, subsequently detailed, may also require insulin.^{13,14} Clinically **similar forms of diabetes** may occur secondary to cystic fibrosis^{15,16} from toxic drugs, such as the immunosuppressive agents cyclosporine, sirolimus, and tacrolimus,^{17,18} the rodenticide Vacor,¹⁹ or streptozotocin as used for certain pancreatic islet cell tumors²⁰; with the hemolytic uremic syndrome²¹; or after pancreatectomy, such as for recurrent pancreatitis or persistent hyperinsulinemic hypoglycemia in infancy.²² Childhood insulin-dependent diabetes is generally type 1a DM.

Type 1 Diabetes Mellitus

This condition is characterized by severe insulinopenia and dependence on exogenous insulin to prevent ketosis and to preserve life. Thus it was termed *insulin-dependent DM* (IDDM). The natural history of this disease indicates that there are preketotic noninsulin-dependent phases before and after the initial diagnosis. Although the onset is predominantly in childhood, the disease may occur at any age.² Therefore such names as “juvenile diabetes,” “ketosis-prone diabetes,” and “brittle diabetes” were abandoned in favor of the term type 1 diabetes (T1D).

Type 1a diabetes is generally distinct by virtue of its association with certain histocompatibility locus antigens (HLAs) and other genetic markers the majority of which determine the response to self (or exogenous) antigens, for example, cytotoxic T-lymphocyte antigen 4 (*CTLA4*), autoimmune regulator gene (*AIRE*), variable number of tandem repeats in the insulin gene (*VNTR*), interleukin 2 receptor (*IL2R*) protein tyrosine phosphatase, and protein tyrosine phosphatase non-receptor type 22 (*PTPN22*); by the presence of circulating antibodies to cytoplasmic and cell-surface components of islet cells; of antibodies to insulin in the absence of previous exposure to exogenous injection of insulin, of antibodies to glutamic acid decarboxylase (GAD, the enzyme that converts glutamic acid to γ -aminobutyric acid found abundantly in the innervation of pancreatic islets), of antibodies to IA-2 (an islet cell-associated phosphatase) and antibodies to the zinc transporter molecule (ZnT8); by lymphocytic infiltration of islets early in the disease; and by coexistence with other autoimmune diseases.^{5,6} Occasionally, markers of autoimmunity are not found and yet there is profound insulinopenia and dependence on insulin without evidence of a mitochondrial or other genetic defect. In these cases, T1D is considered idiopathic (type 1b). With the exceptions noted, diabetes in children is usually insulin dependent and fits the type 1a category.²

Type 2 Diabetes

Persons with this subclass of diabetes (formerly known as *adult-onset diabetes*, *maturity-onset diabetes* [MOD], or *stable diabetes*)

may not be permanently insulin dependent and only occasionally develop ketosis. Some may, however, need insulin to correct symptomatic hyperglycemia—and ketosis may develop in some during severe infections or other stress. Therefore this was previously called *noninsulin-dependent DM* (NIDDM).² This form of diabetes is becoming increasingly prevalent in overweight adolescents, especially those from vulnerable groups, such as Africans, Latinos, Native Indians, and other susceptible ethnic groups.^{23,24}

T2DM is not a single entity.² T2DM may be a primary disorder, with inadequate insulin secretion caused by mutations in one of several genes encoding enzymes or transcription factors important to islet cell development and insulin secretion. Several of these defects are now part of the spectrum of the syndromes commonly associated with MODY, which has a dominant mode of inheritance.^{13,14,25} However, some patients with MODY defects may require insulin from the outset or as they grow older and become insulin resistant, exceeding their ability to compensate by increasing insulin secretion (see Fig. 21.1). A defect in the gene regulating glucose transport into the pancreatic beta cell, the GLUT2 transporter, may be responsible for another form of type 2 diabetes (T2D).⁷

Defects in glycogen synthase have also been implicated.^{26,27} A primary defect in insulin receptors—often associated with acanthosis nigricans,²⁸ postreceptor defects (including Rad [Ras associated with diabetes]),²⁹ and milder mitochondrial gene defects¹¹—also may result in T2D. Secondary causes of T2DM include excessive counterregulatory hormones, especially pharmacological doses of glucocorticoids, antibodies to the insulin receptor, and obesity with impaired insulin secretion.^{30–41}

In T2DM, the serum concentration of insulin compared with lean normal persons may be increased, normal, or moderately depressed depending on whether the defect is one of insulin action or secretion.^{28–41} The onset of T2DM commonly occurs in children generally around the time of puberty or shortly thereafter, but it is recognized that it may occur at any age and is becoming increasingly frequent in childhood and adolescence.^{23,24} In some instances, what appears to be T2DM may actually represent slowly evolving T1DM.³⁹ In T2D, there is no association with specific HLA antigens, autoimmunity, or various ICAs.⁴¹ However, several genetic abnormalities regulating insulin secretion or action are increasingly implicated in T2DM, so that the genetic architecture of T2DM is complex and remains incompletely understood.³¹

TYPE 1 DIABETES MELLITUS

Epidemiology

The prevalence of DM is highly correlated with increasing age. Available data indicate a range of one case per 1430 children at 5 years of age to one case in 360 children at 16 years.^{42–49}

Data on incidence in relation to racial or ethnic backgrounds indicate a range of more than 50 new cases annually per 100,000 population in Finland and Sardinia to about one per 100,000 in China and parts of South America^{43–46,50} (Fig. 21.2). In all examined areas, there appears to be an increasing incidence of T1DM of about 2% to 3% per year. However, the incidence of T1DM in Finland was reported to have peaked and slightly declined⁴² with similar data from Norway indicating the increase in incidence may be waning.⁴⁹

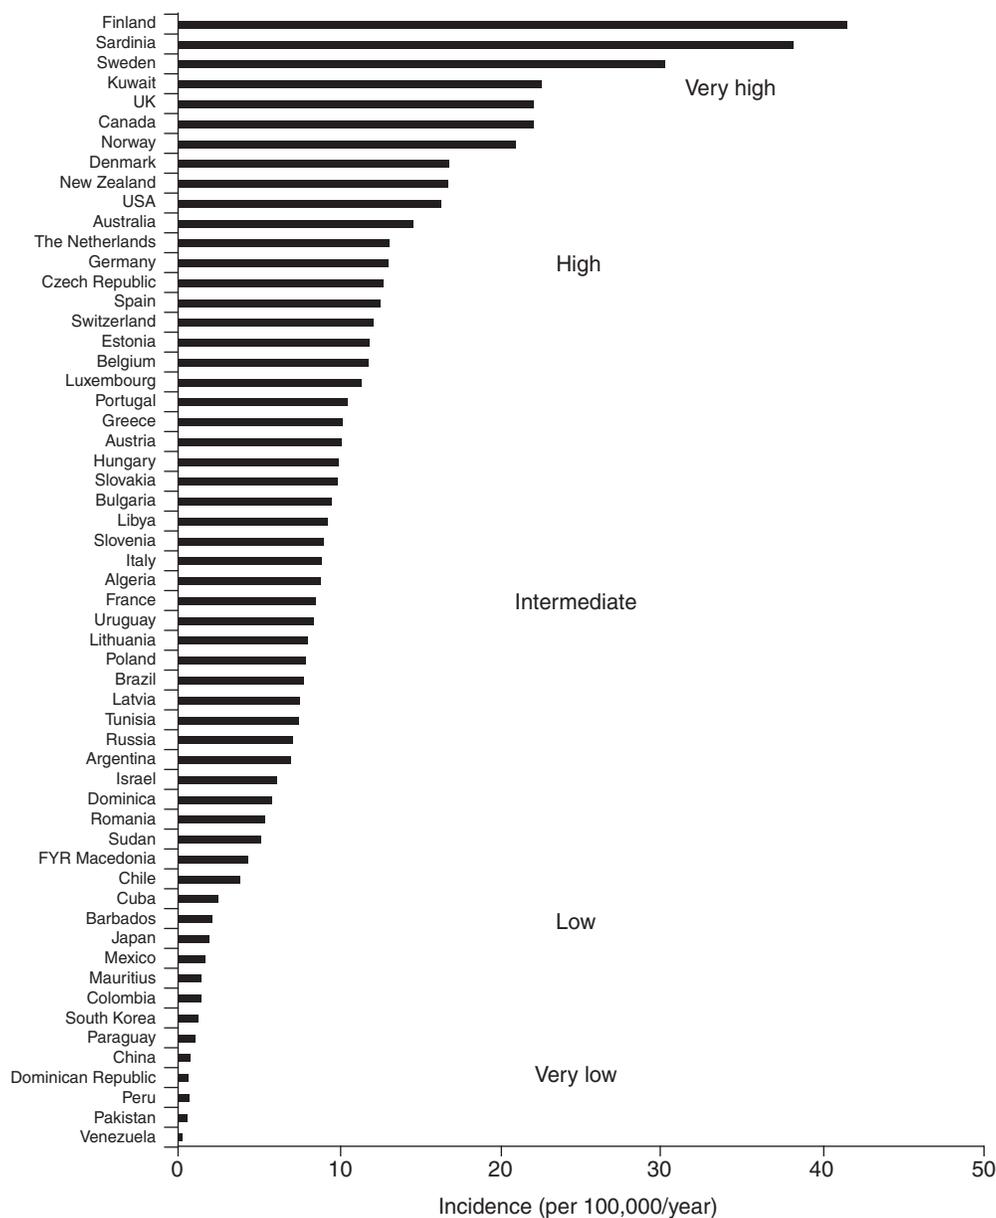

Fig. 21.2 Age-standardized incidence (per 100,000/year) of type 1 diabetes in children younger than 14 years of age in 100 populations. Data for boys and girls have been pooled. Countries are arranged in descending order according to the incidence. (Puerto Rico and the Virgin Islands are presented separately from other populations in the United States.) (From Diamond Project Group (2006). Incidence of trends of childhood type 1 diabetes worldwide 1990-1999. *Diabet Med*, 23, 857-866.)

In the United States, the occurrence of type 1 in Africans had previously been reported to be only between one-third and two-thirds of that in Caucasians.⁵⁰ More recent data suggest that the incidence of DM in African Americans is increasing.^{47,50,51} However, whether some of this reported increase in incidence among African Americans is exclusively type 1 or includes cases of type 2 presenting in ketoacidosis and thus misclassified remained unclear.⁵⁰ The most recently available information indicates an annual incidence in the United States of 20 to 25 cases per 100,000 of the childhood population⁴⁷ with a significant increase of T1DM in all groups, including African-American (see IDF Diabetes Atlas 9th Edition 2019 www.diabetesatlas.org).

Males and females appear to be almost equally affected. There is no apparent correlation with socioeconomic status. Peaks of presentation occur in two age groups: at 5 to 7 years of age and at the time of puberty. The first peak corresponds to the time of increased exposure to infectious agents coincident with the beginning of school. The latter corresponds to the pubertal growth spurt induced by increased sex steroids, as well as pubertal growth hormone secretion that antagonizes insulin action. The incidence of T1D is increasing worldwide, most prominently in certain populations (e.g., Finland) and in certain age groups (especially those aged <5 years).^{45,46} As mentioned, there appears to be a plateau in incidence reported from Finland and Norway.^{42,49} In younger patients, onset

appears to be more abrupt and the extent of immune markers is less apparent than in older children.⁵² Type 1b diabetes with abrupt onset, less evidence of autoimmunity, and indicators of viral infection (including evidence of pancreatitis) have been described in Japan.^{53,54}

Seasonal and long-term cyclical variations have been noted in the incidence of T1D. Newly recognized cases appear to occur with greater frequency in the autumn and winter in the northern and southern hemispheres.⁵⁵ Seasonal variations are most apparent in the adolescent years.⁵⁵ There is no consistent pattern linking long-term cyclicity with the incidence of viral infections; however, there was a definite increased incidence of diabetes in children with congenital rubella.^{56,57} These changing patterns in incidence and associations with viral infections suggest a potential role for viruses or other microbial agents or their products as direct or indirect triggering mechanisms for inducing T1DM in a susceptible host.⁵⁶⁻⁶¹ Detection of a low-grade enteroviral infection in the islets of Langerhans of patients with new-onset diabetes⁶² and the hyperexpression of HLA class 1 antigens on islet cells as a defining feature of T1D lend further credence to the possibility of viral infections as a potential trigger for autoimmunity leading to DM in the genetically predisposed host.⁶³

Etiology, Pathogenesis, and Genetics

The cause of the initial clinical findings in this predominant form of diabetes in childhood is the sharply diminished secretion of insulin.⁶⁴ Although basal insulin concentrations in plasma may be normal in newly diagnosed patients, insulin secretion in response to a variety of potent secretagogues is blunted and usually disappears over a period of months to years. In certain individuals considered at high risk for the development of T1D, such as the nonaffected identical twin of a diabetic, a progressive decline in insulin-secreting capacity has been noted for months to years preceding the clinical appearance of symptomatic diabetes that usually manifests when insulin-secreting reserve is 20% or less than normal for that individual (Fig. 21.3).^{5,6,64} The idealized schema of steady

decline in insulin secretion shown in Fig. 21.3 should not be construed as factual; periods of recovery and steeper declines may occur but eventually lead to significant reduction in insulin secretory capacity.

The mechanisms that lead to failure of the function of pancreatic beta cells point to autoimmune destruction of pancreatic islets in predisposed individuals. T1D has long been known to have an increased prevalence among persons with such disorders as Addison disease and Hashimoto thyroiditis, in whom autoimmune mechanisms are known to be pathogenic.⁶⁴ These conditions, as well as T1DM, are known to be associated with an increased frequency of genes involved in the regulation of immunity, including the autoimmune regulator gene *AIRE*, *PTPN22*, *CTLA4*, and the *INS* gene itself, as well as certain HLAs—in particular, DR3 and DR4.^{64,65} Located on chromosome 6, the HLA system is the major histocompatibility complex—consisting of a cluster of genes that code transplantation antigens and play a central role in immune responses.⁶⁴⁻⁷⁶

Increased susceptibility to a number of diseases has been related to one or more of the identified HLA antigens. The inheritance of HLA DR3 or DR4 confers a twofold to threefold increased risk for developing T1D. When both DR3 and DR4 are inherited, the relative risk for developing diabetes is increased 7- to 10-fold. Application of newer molecular genetic techniques has revealed further heterogeneity in the HLA D region among individuals with and without diabetes despite possessing the DR3 or DR4 markers, suggesting the participation of other susceptibility loci within these markers.⁶⁴⁻⁷⁶

Extensive genome-wide scans of markers associated with T1DM have uncovered more than 40 loci considered to confer susceptibility (Table 21.2). Some of these loci are confirmed and replicated by at least three different datasets. Others are suggestive but as yet not definitively linked. The strongest markers are those on chromosomes 6 and 11 (IDDM1 and IDDM2), respectively, linked to the HLA DQ β chain and the insulin gene itself.

In IDDM1, the homozygous absence of aspartic acid at position 57 of the HLA DQ *b* chain (non-Asp/non-Asp) confers an

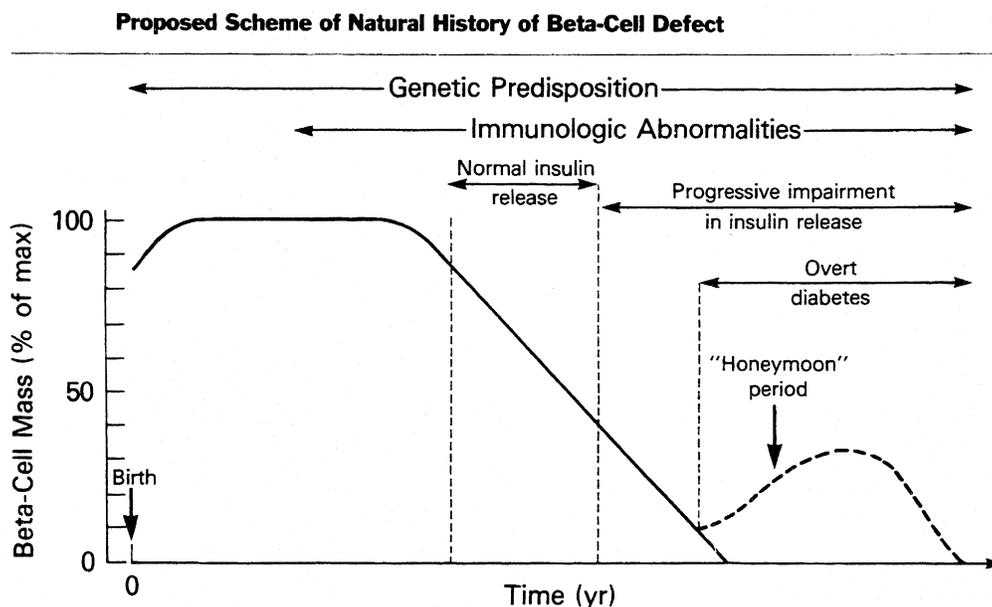

Fig. 21.3 Proposed scheme of natural history of the evolution of insulin-dependent diabetes mellitus with progressive beta-cell failure. (From Sperling, M.A. (Ed.) (1988). *Physician's guide to insulin-dependent (type 1) diabetes mellitus: diagnosis and treatment*. Alexandria, VA: American Diabetes Association.)

(From Morel, P. A., Dorman, J. S., Todd, J. A., et al. (1988). Aspartic acid at position 57 of the HLA-DQ beta chain protects against type 1 diabetes: a family study. *Proc Natl Acad Sci USA*, 85, 8111.)

approximately 100-fold relative risk for developing T1D. Those who are heterozygous with a single aspartic acid at position 57 (non-Asp/Asp) are no more susceptible than individuals who contain aspartic acid on both DQ *b* chains (i.e., homozygous Asp/Asp; Table 21.3). Some studies suggest that T1DM is proportional to the gene frequency of non-Asp alleles in that population.⁷⁵ In addition, arginine at position 52 of the DQ *a* chain confers marked susceptibility to type 1.⁶⁹ Position 57 of the DQ *b* and position 52 of the DQ *a* chains are at critical locations of

the HLA molecule that permit or prevent antigen presentation to T-cell receptors and activate the autoimmune cascade (Fig. 21.4).^{66–69} The importance of these and additional amino acid substitutions in HLA DQ and DR in facilitating antigen presentation and contributing to risk for development of diabetes has been confirmed.⁷⁷

IDDM2 is a polymorphic marker near the transcription start site of the insulin gene, giving rise to VNTR at the promoter end of the insulin gene on chromosome 11. Each tandem repeat element consists of an approximately 14-bp deoxyribonucleic acid (DNA) segment with a consensus nucleotide sequence. The number of repeats ranges from about 25 to about 200, and the three classes of alleles are based on overall size. Class I insulin VNTR consists of 26 to 63 repeats and confers susceptibility, whereas class III consists of 140 to 200 or more repeats and is protective of diabetes. Together, the gene markers on chromosomes 6 and 11 (i.e., IDDM1 and IDDM2) account for 50% to 60% of the heritability of T1D. However, combinations of certain DQ alleles in association with certain DR alleles may confer susceptibility or protection to the development of T1D (see Table 21.3).

In addition, other as yet undefined genetic factors play a role because the same high-risk genotypes are about sixfold more likely to develop diabetes in an individual with a positive family history than in one without a family history without T1D (Table 21.4). Investigation of four genome-wide linkage scans in close to 1500 families with more than one affected member having T1DM identified several susceptibility loci. Of these, about 40% can still be attributed to allelic variation of HLA loci, and the influence of the VNTR in the insulin gene was confirmed.^{65,70}

In addition, the *CTLA4* gene on chromosome 2 and *PTPN22* gene on chromosome 1p13 were found to contribute significantly to predisposition to T1DM. However, the genome scan identified other potential loci conferring susceptibility on chromosomes 2q31–q33, 10p14–q11, and 16q220q24 and a locus on the long arm of chromosome 6 (6q21) distinct from the HLA region on 6p21. The precise genes in these regions that may predispose to T1DM have not been identified as yet, although some have been excluded⁶⁴ and newer candidate genes—such as *CBLB* interacting with *CTLA4*,⁷² the decay-accelerating factor gene (*daf*, a complement inhibitor),⁷³ and the interleukin 2a receptor *IL2R*—are under scrutiny.⁶⁹ Reviews of the genetics of T1DM have received considerable attention⁷⁸ and a genetic risk score predicts progression of islet cell autoimmunity and clinical diabetes in those at risk.⁷⁹ These considerations provide a rational framework for the long-recognized association of type 1 diabetes with genetic factors on the basis of the increased incidence in some families, of the concordance rates in monozygotic twins, and of ethnic and racial differences in prevalence.^{65,69,76} From multiple family pedigrees and HLA typing data, it has been estimated that if a sibling shares both HLA D haplotypes with an index case, the risk for that individual is 12% to 20%; for a sibling sharing only one haplotype, the risk for IDDM is 5% to 7%; and with no haplotypes in common, the risk is only 1% to 2%.⁷⁶ HLA typing is not recommended for routine practice, but for purposes of genetic counseling it can be safely assumed that in whites, the overall recurrence risks to siblings is approximately 6% if the proband is younger than 10 years of age and 3% if older at the time of diagnosis. The risk to offspring is 2% to 5%, with the higher risk in the offspring of a diabetic father.^{69,76}

Factors other than pure inheritance must also be involved in evoking clinical diabetes. For example, DR3 or DR4 is found in approximately 50% of the general population and non-Asp/non-Asp is found in approximately 20% of white nondiabetics in the United States. However, the risk for T1D in these subjects is only 1/10th that in an HLA-identical sibling of an index case with T1D possessing these markers.⁷⁶ Even siblings sharing

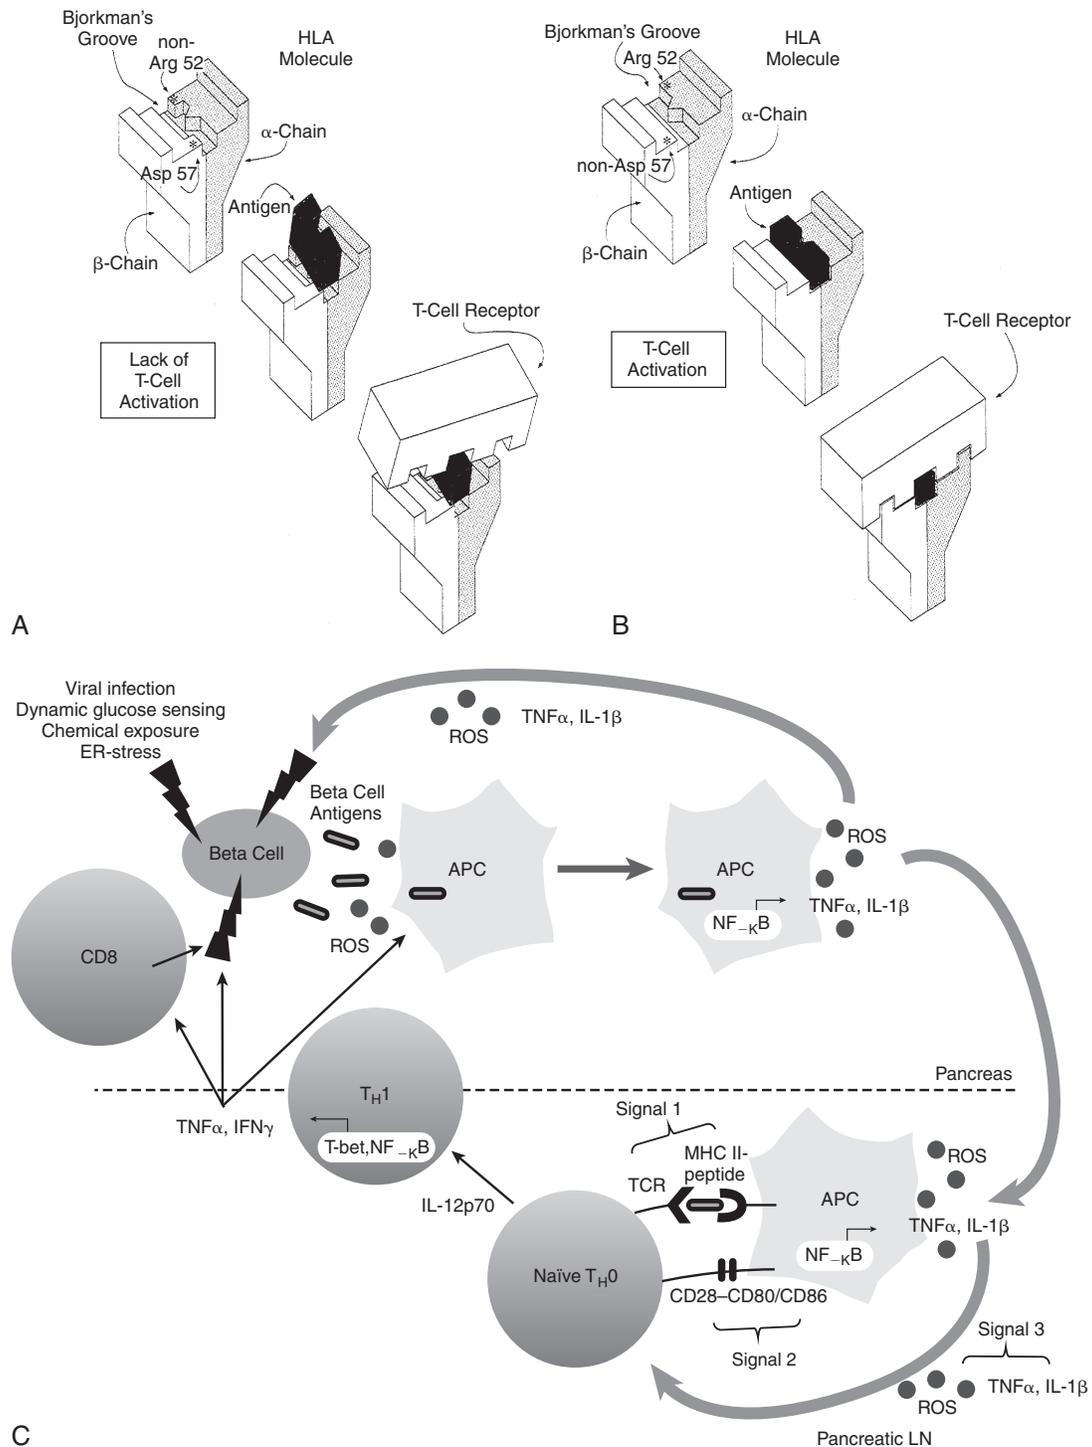

Fig. 21.4 Representation of the interaction between antigen presentation in the context of specific human leukocyte antigen (*HLA*)-DQ subtypes and the T-cell receptor. A, Presence of aspartic acid at position 57 of the DQ *b* chain and an amino acid other than arginine at position 52 of the α chain prevents antigen lodging in the Bjorkman groove. Therefore antigen presentation to the T-cell receptor is impaired—and in the absence of this “fit,” T-cell activation is prevented. B, Lack of aspartic acid at position 57 of the DQ *b* chain and arginine at position 52 of the DQ α chain permits antigen to fit and be recognized by the T-cell receptor that is now activated. C, Role of redox in the immunopathology of type 1 diabetes. An initial genetic or environmental insult to the beta cell triggers the release of beta-cell antigens, as well as the production of reactive oxygen species (ROS). Beta-cell antigens are phagocytosed, and ROS are able to stimulate redox-dependent transcription factors, such as nuclear factor (NF)- κ B, which leads to antigen presenting cell (APC) activation and cytokine secretion. ROS and proinflammatory cytokines secreted by APCs act as the third signal within the T-cell–APC immunological synapse, which occurs in the pancreatic lymph node. ROS play a critical role in the progression of naïve TH0 cells to cytokine-secreting TH1 cells. Release of interferon (IFN) γ by TH1 cells then works directly on the beta cells, as well as activating more APCs and CD8 cells, all of which can impart deleterious effects on the islets. only one haplotype have a 6- to 10-fold greater risk of developing type 1 compared with the normal population (see Table 21.4).

Importantly, approximately 10% to 15% of patients with type 1 do not have HLA DR3 or DR4 (see Table 21.3).⁶⁴ Most compelling is the fact that the concordance rate among identical twins of whom one has insulin-dependent diabetes is only about 50%, suggesting the participation of environmental triggering factors or other genetic factor, such as the postnatal selection of certain autoreactive T-cell clones that bear receptors recognizing “self.” This postnatal process occurs within the thymus and implies that identical twins are not identical with respect to the T-cell receptor repertoire they possess. Identical twins discordant for diabetes have also been shown to possess differential methylation in immune effector cell types suggesting a role for epigenetics in the risk for developing diabetes.⁸⁰ Triggering factors might include viral infections.^{58–61} In animals, a number of viruses can cause a diabetic syndrome, the appearance and severity of which depend on the genetic strain and immune competence of the species of animal tested. In humans, epidemics of mumps, rubella, and coxsackie virus infections have been associated with subsequent increases in the incidence of T1D. The acute onset of DM, presumably induced by coxsackievirus B4, has been described.⁶¹ The viruses may act by directly destroying beta cells, by persisting in pancreatic beta cells as slow viral infections, or by triggering a widespread immune response to several endocrine tissues.⁶¹ Low-grade enteroviral infection in the pancreas of newly diagnosed patients with T1D and hyperexpression of HLA class 1 antigen in islet cells as a defining feature of T1DM adds to the evidence for a potential role of viral triggering of the autoimmune processes.^{62,63} A superantigen response may be involved in triggering T cells, bypassing the classic presentation by antigen-presenting cells (APCs) of the processed antigen in the context of restricted HLA molecules to T-cell receptors.⁸¹ Some viruses and certain endotoxins or exotoxins are capable of inducing a superantigen response. In addition, the virus may induce initial beta-cell damage—which results in the presentation of previously masked or altered antigenic determinants. It is also possible that the virus shares some antigenic determinants with those present on or in beta cells, including GAD, such that antibodies formed in response to the virus may interact with these shared determinants of beta cells, resulting in their destruction, an example of molecular mimicry.^{82–89}

Nitrosamines and early exposure to cow’s milk have been suggested as factors that may trigger diabetes in those genetically at risk, thus explaining the reported lower incidence of diabetes among exclusively breastfed infants. This was the basis for a primary prevention study: the trial to reduce insulin-dependent diabetes in those genetically at risk (TRIGR).^{82–89}

However, in those who were genetically at risk, the TRIGR study failed to show a significant reduction in development of diabetes via delay or exclusion of cow’s milk.⁹⁰

Antecedent stress and exposure to certain chemical toxins have also been implicated in the development of T1D. Although the rodenticide Vacor has been a cause of diabetes in individuals deliberately or inadvertently poisoned by this agent, some of these patients had ICAs, suggesting that such antibodies are secondary to islet damage or that evolving type 1 disease preceded the drug ingestion. Nitrosamines in cured meat have also been implicated in T1D, as have other environmental toxins.^{82,91}

Evidence supports an autoimmune basis for the development of T1D, but why the beta cell is the specific target remains a mystery.^{5,44} Is the pancreatic beta cell the sole target of immune destruction (homicide) or a contributor to its own demise (suicide)?^{5,44} Histological examination of pancreas from patients with type 1 who die of incidental causes has revealed lymphocytic infiltration around the islets of Langerhans. Later, the islets become progressively hyalinized and scarred, a process suggesting an ongoing inflammatory response that is possibly autoimmune.⁹² However, these changes are often patchy in distribution, so that areas that appear to contain normal beta cells are interspersed with areas of beta-cell destruction, similar to the patchy distribution of depigmentation found in vitiligo.^{64,93} Some 80% to 90% of newly diagnosed patients with T1D have ICA directed at cell-surface or cytoplasmic determinants in their islet cells. The prevalence of these antibodies decreases with the duration of established disease. In contrast, after pancreatic transplantation, ICA may reappear in patients whose sera had become negative for ICA before transplantation. Together, these findings suggest that ICA disappears as the antigens intrinsic to pancreatic islets are destroyed and reappear when fresh antigen (transplanted islets) is presented.

Studies in identical twins and in family pedigrees demonstrate that the existence of ICA may precede by months to years the appearance of symptomatic T1D.⁵ In vitro, ICA may impair insulin secretion in response to secretagogues and can be shown to be cytotoxic to islet cells—especially in the presence of complement or T cells from patients with T1D. About 80% of patients may have antibodies to GAD, and 30% to 40% of newly diagnosed patients have spontaneous antiinsulin antibodies at initial diagnosis. These antibodies may be detected months to years before clinical diabetes becomes apparent.^{1,5,66,85} A more recently described antibody, the zinc transporter, ZnT8, appears to be a major marker for progressive impairment of beta-cell function.⁵ There is also evidence of abnormal T-cell function with an alteration in the ratio of suppressor (regulatory) to killer T cells at the onset of the disease.^{5,6,10} Thus the ability of Treg to modify the activity of T effector cells in causing beta-cell destruction is an area of investigation. These findings suggest that T1D (akin to other autoimmune diseases, such as Hashimoto thyroiditis) is a disease of “autoaggression” in which autoantibodies in cooperation with complement, T cells, cytokines, FAS, and FAS ligand, and other factors, induce apoptosis or destruction of the insulin-producing islet cells.^{6–8,10}

Thus the inheritance of certain genes (such as those associated with the HLA system on chromosome 6 or other immunoregulatory or immunomodulatory genes) appears to confer a predisposition for autoimmune disease—including diabetes—when triggered by an appropriate stimulus, such as a virus.^{5,6,10} Evidence of superantigen-triggered T-cell receptor activation was discussed earlier.⁸¹

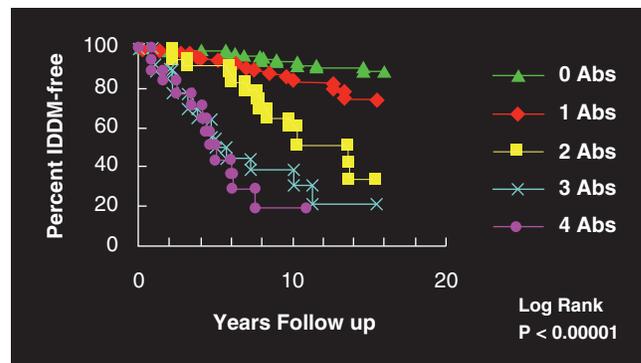

Although it is understood that some insulin-dependent diabetic patients have none of the frequently associated

HLA antigens, the evidence for an immune basis of islet cell destruction is sufficiently compelling to have fostered several studies of different immunosuppressive agents in the treatment of newly diagnosed diabetics. None of these immunosuppressive or immunomodulatory trials has had long-term positive outcome, and some agents (e.g., cyclosporine) have proven toxic to beta cells. Although newer approaches are being attempted, all must be considered as experimental and **not be** viewed as established or recommended therapy.^{85,92-100} The Diabetes Prevention Trial for T1DM [DPT1] was a multicenter randomized but nonblinded study using daily subcutaneous insulin and an annual admission for intravenous [IV] insulin infusion in first-degree relatives with proven risk factors for developing T1DM. Whereas prediction was highly accurate in identifying those most likely to develop T1DM within 5 years of entering the study, insulin injections had **no** protective effect to prevent the appearance of T1DM.⁹²⁻⁹⁹ Figs. 21.3 and 21.4 summarize current concepts of the cause of T1D as an autoimmune disease, the tendency for which is inherited and in which autoimmune destruction of beta cells is triggered by an as yet unidentified agent (possibly a virus). The slope of decline in insulin varies, and there may be periods of partial recovery such that the course of decline in insulin secretion is bumpy rather than smooth. The point at which clinical features appear corresponds to approximately 80% destruction of insulin secretory reserve. This process may take months to years in adolescent and older patients, and weeks in the very young patient in whom acute destruction by nonautoimmune mechanisms may play a significant role. Higher titers of spontaneous antiinsulin antibodies and ICA are characteristic of more active islet cell destruction, typically in the younger **patient**, and may prove useful in predicting evolving diabetes.⁹²⁻⁹⁹

Prediction and Prevention

Although no presently available single marker or test can accurately predict T1DM, evidence suggests that a combination of **immune** and genetic markers for T1D may provide predictability.^{85,92-100} Some authorities suggest that T1D is a predictable disease, but other authorities have raised objections because predictability is not as robust in their studies. Definitive preventive therapy is not available, thereby raising ethical dilemmas, and it is emphasized that the majority of new cases occur sporadically, in the absence of a positive family history in a first-degree relative.

Most predictive studies have been performed in first-degree relatives of patients with new-onset T1D.⁸⁴ Nevertheless, there is increasing evidence that the presence of high titers of islet cell, GAD, IA2, ZnT8, and insulin autoantibodies combined with a consistently diminished first-phase response of insulin to a pulse of IV glucose (corresponding to the ≤ 5 th percentile for age in insulin response) can be used to reliably predict the onset of type 1 disease.⁹²⁻¹⁰⁰

Pietropaolo M. et al. *Diabetologia* 45: 66-76, 2002
Fig. 21.5 Cumulative risk of developing clinical type 1 diabetes (T1DM) in relatives of probands with established T1DM using Ab markers alone (IAA, GAD65, IA-2, ICA). (From Pietropaolo, M. et al. (2002). Progression to insulin-requiring diabetes in seronegative prediabetic subjects: the role of two HLA-DQ high-risk haplotypes. *Diabetologia*, 45, 66-76.)

Fig. 21.5 demonstrates that in a set of first-degree relatives, conversion to T1D was highly dependent on the number of antibodies detected in their sera. Of those with three antibodies, about half developed clinical diabetes within 5 years of follow-up. First-phase insulin response and genetic (HLA) markers may be used to augment the predictability. For example, Table 21.5 demonstrates that the relative risk of developing clinical diabetes within 4 years of detecting ICA is almost 230 among those who possess all four heterodimers in HLA DQ β that predispose to diabetes (i.e., Asp57 2/2 and Arg52 1/1).

As technological improvements continue, it is likely that population-wide screening for antibody markers (alone or combined with specific genetic markers) will be available to identify those at risk for developing T1D. Such population-wide screening would be ethically justified if prevention could be proven effective. Presently, the data are sufficiently persuasive to have fostered national trials in Europe and the United States to predict and possibly prevent the clinical onset of T1D through immune intervention strategies. The European Nicotinamide Diabetes Intervention Trial (ENDIT) was a multicenter trial that screened approximately 22,000 first-degree relatives of patients with T1D to identify 500 considered to be at high risk for developing this disease.⁹⁶⁻⁹⁹ These at-risk individuals were treated with nicotinamide or a placebo in a double-blind fashion. The results of ENDIT showed no positive protection against development of diabetes. The US DPT1 was based on promising pilot data that suggested preservation of insulin secretion and prevention of progression to DM in at-risk individuals treated with insulin.⁹⁵ Daily subcutaneous insulin, coupled with an intensive course of IV insulin every 9 months, prevented diabetes for at least 3 years in five subjects considered to be at risk because of genetic markers, islet cell and insulin

TABLE 21.5 Influence of Diabetic Heterodimers (ASP57neg Arg52pos) and Islet Cell Antibody Status on Relative Risk for Developing Diabetes After 4 Years

	ICA Negative				ICA Positive

Developed IDDM after 4 years	12	16	37	12	12	18	29	15
Relative risk	1.0	2.9	8.6	25.4	9.0	26.5	78.0	229.3

ICA, Islet cell antibody; IDDM, insulin-dependent diabetes mellitus. (Modified from Friday, R.P., Trucco, M., & Pietropaolo, M. (1999). Genetics of type 1 diabetes mellitus. *Diabetes Nutr Metab*, 12, 3.)

autoantibodies, and diminished first-phase insulin response. Among seven similar at-risk subjects who chose not to be treated, six developed insulin-dependent diabetes within 3 years. DPT1 aimed to investigate these promising pilot results in a larger carefully matched cohort and was concluded in 2001; there was no difference in the rates of developing diabetes among the placebo and insulin-treated groups. However, the ENDIT and DPT1 studies proved that large-scale multicenter studies could be successfully undertaken and that the prediction of progression to clinical diabetes was remarkably accurate. Thus in those at highest risk (such as first-degree relatives of patients with T1DM) prediction is feasible and the discovery of successful means of arresting or reversing progression to clinical diabetes is the subject of intense research.

Another study (TRIGR) involved 3000 families in whom half avoided cow's milk for the first 9 months of life to test the hypothesis that the ingestion of breast milk and avoidance of cow's milk formula (with its bovine serum albumin [BSA]) may protect participants from the appearance of diabetes.⁸⁸ As noted earlier, no benefit accrued to those who avoided cow's milk.⁹⁰ Several other studies are examining the utility of antibodies to the IL2R, CD3 antibodies, immune suppressors, such as mycophenolate mofetil, and immune modulators in preventing diabetes, including oral insulin. These studies are conducted by consortia of participating institutions (see www.trialnet.org).

In animal models, oral insulin or oral GAD had been successfully used to prevent diabetes.¹⁰¹ It was postulated that ingestion of T-lymphocyte-dependent antigens may establish immunological tolerance. Such oral strategies have been proposed and oral insulin was tested in humans but again with no definitive benefit.¹⁰¹ The subjects of primary prevention trials and secondary intervention trials to preserve residual insulin secretion at initial diagnosis are of major interest to investigators and clinicians alike. Progress is likely, but at present, all of these strategies must be viewed as experimental and not currently in the domain of daily clinical practice.^{76,100,102,103}

Of immediate relevance are the reports of a decline in the incidence of new-onset T1DM in children vaccinated against rotavirus.^{104,105} If these findings are confirmed, they would add credence to the role of viruses in initiating islet cell damage that may lead to the autoimmune cascade resulting in T1DM and the potential benefits of immunization against these, and yet to be defined other viral agents.

Insulin Biosynthesis

Insulin is synthesized on the ribosomes of pancreatic islet beta cells and released into the circulation as a molecule composed of two separate straight polypeptide chains linked by disulfide bridges between and within these chains.^{106–112} The two chains are not synthesized separately but are derived from a larger precursor, proinsulin, a single coiled chain in which the NH₂ terminus of the A chain is linked to the COOH terminus of the B chain by a connecting peptide, known as *C-peptide* (Fig. 21.6). An even larger precursor (preproinsulin, containing an additional peptide chain on the NH₂ terminus of the A chain) is first synthesized, but this additional piece (important to the initiation of synthesis) is rapidly excised. Further processing of proinsulin within the beta cell cleaves the C-peptide, consisting of 31 amino acids, from the insulin molecule at the sites indicated in Fig. 21.6.

Defects in these cleavage sites are inherited in an autosomal-dominant manner and result in insulin molecules with less-than-normal biological activity that can give rise to two types of familial hyperproinsulinemia. One defect results in B-C proinsulin, cleaved at site 1 but not at site 2 (see Fig. 21.6). This

intermediate has 50% of the biological activity of insulin, which is sufficient to prevent any abnormality in carbohydrate metabolism. The defect at site 1 yields A-C proinsulin, cleaved at site 2 but not at site 1, which has inadequate biological activity to prevent carbohydrate intolerance. A structural mutation in the proinsulin molecule, between the C-peptide and insulin, has been confirmed.^{101,106–110} In addition, a defective enzymatic conversion of a normal proinsulin molecule to insulin results in hyperproinsulinemia and mild carbohydrate intolerance.¹¹⁰

The proconvertases responsible for correct conversion of proinsulin to insulin are also involved in the processing of other hormones. Thus impaired prohormone processing may lead to severe obesity and secondary hypocortisolism owing to defective processing of proopiomelanocortin (POMC), to hypogonadotropic hypogonadism, and to diabetes insipidus.^{111–113} Native proinsulin has less than 5%, whereas C-peptide has none, of the biological activity of insulin. During synthesis, the role of C-peptide appears to be the provision of the spatial arrangement necessary in the formation of the disulfide bonds. Other defects have been described in insulin biosynthesis involving substitution of amino acids in the B chain that lead to impaired glucose tolerance in the presence of hyperinsulinemia.^{106–112,114}

The insulin gene has been cloned and localized to chromosome 11, and genetic defects in insulin synthesis may be associated with diabetes—especially the syndromes MODY 1, 3, 4, 5, and 10, the latter being insulin itself.^{7,13,14} By some estimates, MODY syndromes may constitute 2% to 5% of all lean persons developing clinical diabetes between the ages of 10 and 30 years. The MODY syndromes are briefly discussed later and in detail in Chapter 10. The association of VNTRs in the insulin gene with genetic predisposition for autoimmune T1DM was described earlier.

Under normal circumstances, only small quantities of proinsulin are released into the circulation—amounting to less than 15% of total insulin as measured by radioimmunoassay (RIA). Even smaller quantities of proinsulin intermediates are also released. However, during insulin secretion induced by all stimuli, one molecule of C-peptide is released with each molecule of insulin. Thus the plasma of normal individuals contains small amounts of proinsulin, proinsulin intermediates, and almost equimolar amounts of insulin and C-peptide. The plasma metabolic half-life of C-peptide is, however, longer than that of insulin. Therefore the molar ratio of C-peptide to insulin in peripheral plasma is always greater than 1 and the peak of C-peptide secretion or the nadir after suppression of release appears to occur later than that of insulin. Although standard RIA of insulin will also measure proinsulin, C-peptide will not be measured because it is immunologically distinct (see Fig. 21.6).

Separation of proinsulin from insulin can be achieved by chromatography to separate the larger proinsulin before assay. This is done with the use of an enzyme that degrades insulin but not proinsulin, or with the use of a C-peptide assay that will also measure proinsulin but not insulin. Because C-peptide is immunologically distinct, RIAs for this substance can be used to assess beta-cell secretory reserve even in the presence of insulin antibodies formed in response to injections of human or formerly used bovine-porcine insulin.

Endogenous insulin secretion is accompanied by C-peptide release, whereas exogenous insulin administration suppresses endogenous insulin (and therefore C-peptide) secretion in all circumstances except insulinoma. Results of standard RIA with double-antibody precipitation are high in both circumstances. These attributes are important in distinguishing abuse of individuals by injection of exogenous insulin (high insulin, low C-peptide) from insulinomas or dysregulated insulin

Human Proinsulin

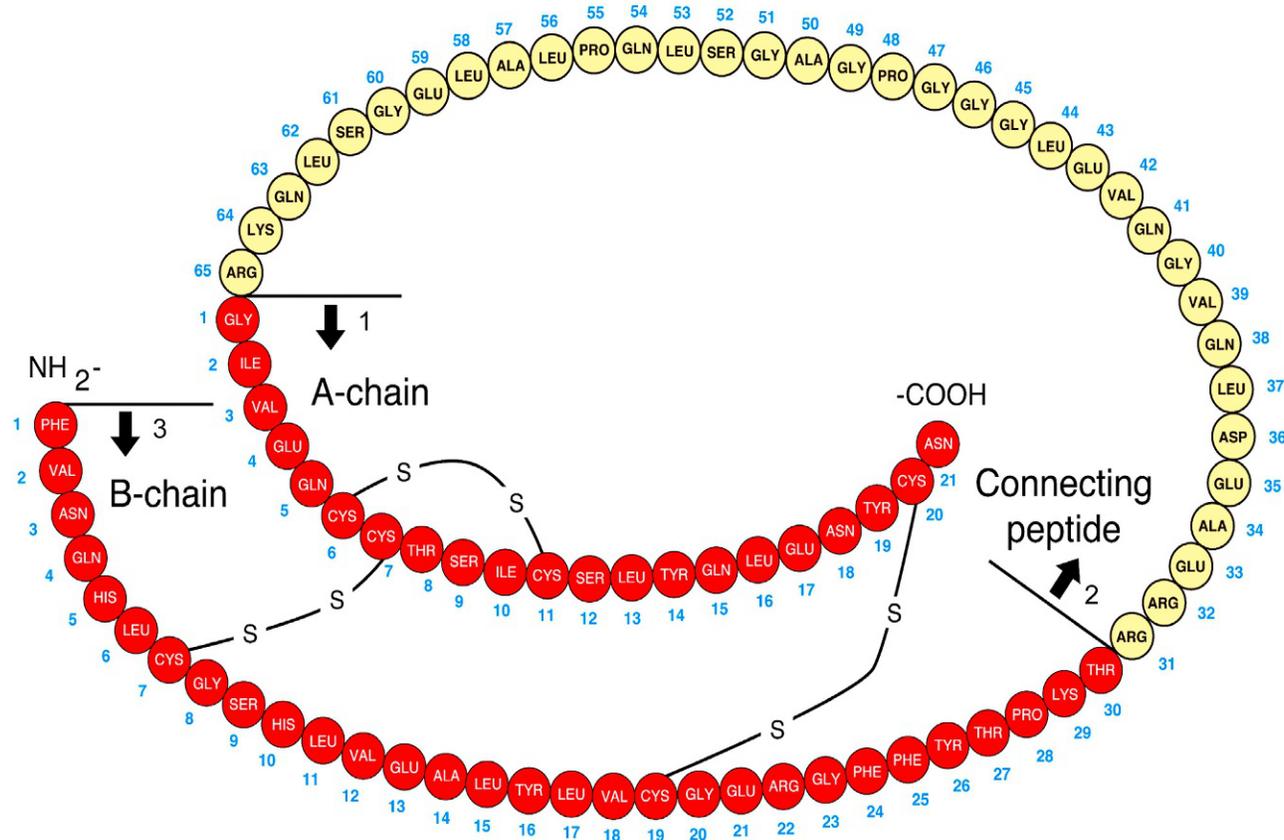

Fig. 21.6 Structure of proinsulin. Arrows 1 and 2 indicate the two sites of normal cleavage that yield insulin and C-peptide when the amino acid residues indicated in the *open circles* are removed. These cleavage points are known mutation sites, are inherited in an autosomal-dominant manner, and can yield two types of familial hyperproinsulinemia. During insulin secretion, equimolar amounts of insulin and C-peptide are released. Arrow 3 indicates the start site of the B-chain at the Amino Terminus of the pro-hormone.

secretion (high insulin, high C-peptide) in cases of hypoglycemia. Measurements of C-peptide kinetics or of urinary excretion of C-peptide can be used as an index of endogenous insulin secretion.³⁰

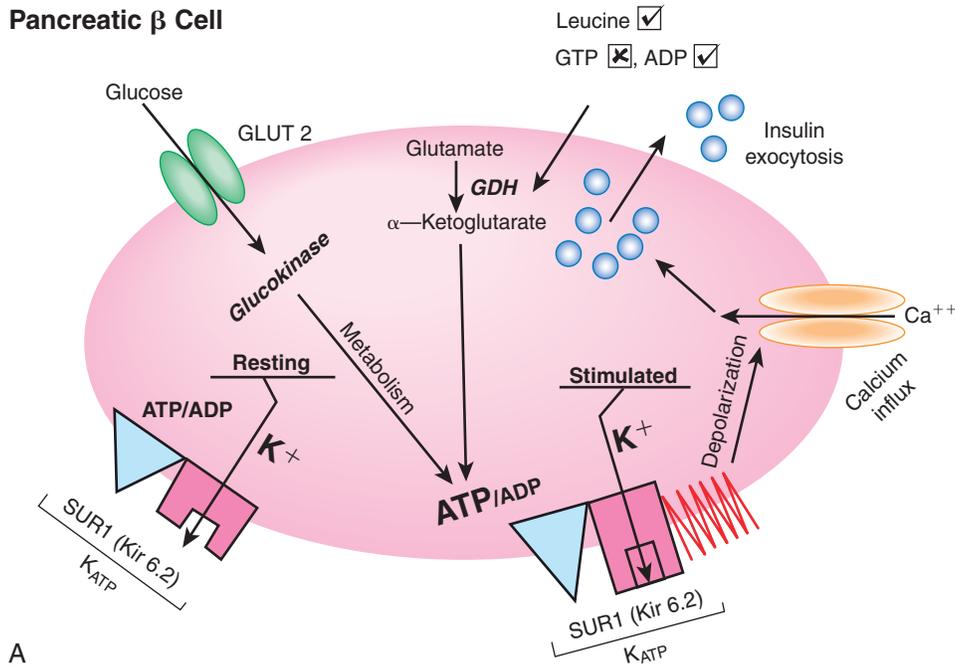

Insulin Secretion

Insulin secretion is governed by the interaction of nutrients, hormones, and the autonomic nervous system. Glucose, as well as certain other sugars metabolized by islets, stimulates insulin release. Basal and peak insulin levels are closely related to the glucose concentration, and prolonged fasting will further reduce glucose and insulin levels—which, however, remain in the measurable range at 2 to 5 mU/mL. There is evidence that a product or products of glucose metabolism may be involved in maintaining insulin secretion and that sugars *not* metabolized by islet cells do not promote insulin release.^{115–117}

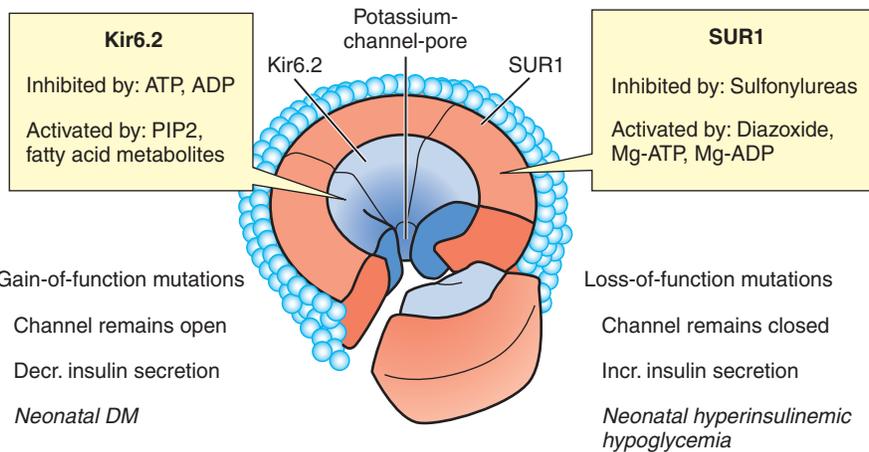

The initial steps of glucose-stimulated insulin release are depicted in Fig. 21.7 and discussed in detail in Chapters 7 and 10 in connection with mutations in the sulfonylurea receptor (SUR)-Kir6 (inward-rectifying potassium channel) complex of the adenosine triphosphate-regulated potassium channel K_{ATP}, along with the subsequent steps that may cause activation of glucose or amino acid-stimulated insulin secretion.¹¹⁸ This schema involves glucose transport into the beta cell through the GLUT2 glucose transporter and

phosphorylation of glucose by means of glucokinase. Defects in the former are associated with T2D, whereas heterozygous inactivating mutations in the latter are associated with MODY2. Homozygous mutations in glucokinase result in permanent neonatal DM (as described in detail in Chapter 10). Heterozygous inactivating mutations in glucokinase are generally associated with normal insulin release at higher glucose concentrations, and therefore with a milder type of diabetes that rarely requires treatment and is not associated with microvascular or other diabetes complications.^{13,119} After IV glucose infusion in normal persons, insulin secretion is biphasic—with an initial spike followed by a sustained plateau. It is proposed that the initial spike represents preformed insulin, whereas the sustained plateau represents newly synthesized insulin.

Cyclic adenosine monophosphate (cAMP) is involved in stimulating insulin release. Therefore agents that inhibit phosphodiesterase and reduce cAMP destruction (such as theophylline) augment insulin release. Translocation of calcium ions into the cytoplasm from the exterior, as well as from the intracellular organelles (see Fig. 21.7), plays a key role in the contractile forces that propel insulin to the cell surface.¹¹⁸ There, the membrane of the insulin vesicle fuses with the cell membrane—allowing extrusion of insulin granules into the surrounding vascular space, a process known as emiocytosis. Other ions, including potassium and magnesium, are involved in the insulin secretion.^{118,120–122} The sulfonylurea receptor is

A

B

Fig. 21.7 A, Model of insulin secretion by pancreatic beta cell. Glucose transported into the beta cell by the insulin-independent glucose transporter (*GLUT 2*) undergoes phosphorylation by glucokinase and is metabolized. This results in an increase in the adenosine triphosphate (*ATP*)/adenosine diphosphate (*ADP*) ratio with subsequent closure of the K_{ATP} channel and initiation of a cascade of events that is characterized by decreased flux of potassium across the membrane, membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by allosterically activating glutamate dehydrogenase (*GDH*) and by increasing the oxidation of glutamate; this increases the *ATP/ADP* ratio and closure of the K_{ATP} channel. The check mark sign (\checkmark) indicates stimulation of insulin secretion; the cross sign (\times) indicates inhibition of insulin secretion. Diazoxide inhibits insulin secretion by interacting with the sulfonylurea receptor; somatostatin and calcium channel blockers interfere with calcium signaling. B, Regulation of insulin secretion. The Kir6.2–SUR1 complex and its regulation and genetic variability. The panel shows the detailed subunit structure of the K_{ATP} channel, which is composed of four small subunits, Kir6.2, that surround a central pore and four larger regulatory subunits constituting SUR1. In the normal resting state, the potassium channel is open, modulated by the ratio of *ATP* to *ADP*. PIP2 denotes phosphatidylinositol-4,5-bisphosphate, Kir6.2 denotes the inward rectifying potassium channel 6.2, SUR1 denotes the sulfonylurea receptor 1, *ADP* is adenosine diphosphate, and *ATP* is adenosine triphosphate. As noted, in gain-of-function mutations, the channel remains open leading to decreased insulin secretion so that neonatal diabetes may result. With loss-of-function mutations, the channel remains closed, leading to persistent insulin secretion and hence is a cause of neonatal hyperinsulinemic hypoglycemia. (Modified from Sperling, M.A. (2006). *ATP-sensitive potassium channels—neonatal diabetes mellitus and beyond*. *N Engl J Med*, 355, 507–510.)

closely linked to potassium channels in the beta cell.^{118,120–122} Amino acids also stimulate insulin release, although the potency of individual amino acids varies.¹²³ A group of amino acids is more potent than any single one, and the insulin-secretory response is potentiated in the presence of glucose.¹²³ Free fatty acids and ketone bodies may also stimulate insulin release.¹²³ Insulin responses to oral glucose administration are always greater than responses to IV administration of glucose that result in the same blood glucose profile, a finding that led to the concept that gut factors (incretins) modulate and increment insulin secretion.¹²⁴ Although a variety of gut hormones participate in promoting insulin release,¹²⁴ gastrointestinal polypeptide (gip) pancreatic glucagon and the glucagon-like peptides (GLP) play a major role in stimulating insulin release.¹²⁴ These properties have found application as agents, collectively named *incretins*, in augmenting insulin secretion in persons with T2DM and in some persons with T1DM.¹²⁵

Somatotropin release-inhibiting factor (somatostatin), produced in the delta cells of islets, inhibits insulin and glucagon release and reduces splanchnic blood flow. These properties have found application to reduce insulin secretion in neonates with hyperinsulinemic hypoglycemia of infancy (see Chapter 7). Together, these factors may finely regulate nutrient intake and its disposition and form an enteroinsular axis for metabolic homeostasis.¹²⁴ In addition to these gut hormones, several other hormones modulate insulin secretion. Growth hormone is involved in insulin synthesis and storage. Persons with congenital growth hormone deficiency have subnormal basal and stimulated insulin responses, whereas in acromegaly, basal and stimulated insulin levels are increased. Human chorionic somatomammotropin (also known as *human placental lactogen*), structurally related to growth hormone, likewise affects insulin release. The stimulatory effect of each hormone on insulin secretion is antagonized by the antiinsulin effect at the peripheral level, however. Similarly, glucocorticoids and estrogens evoke greater insulin secretion while inducing peripheral insulin resistance—in part by decreasing insulin receptors on target cells.

Insulin secretion is constantly modulated by the autonomic nervous system.^{117,126} The parasympathetic arm, through the vagus, directly stimulates insulin release. Modulation of insulin secretion by the sympathetic arm depends on whether α - or β -adrenergic receptors are activated. Activation of β_2 receptors by agents, such as isoproterenol, stimulates insulin secretion by a process that involves cAMP generation. Blockade of β -adrenergic receptors by propranolol blunts basal and stimulated insulin release. Conversely, activation of α -adrenergic receptors blunts insulin secretion, and blockade of these receptors by agents, such as phentolamine, augments basal and glucose-stimulated insulin release. Epinephrine and norepinephrine stimulate predominantly α -adrenergic receptors in islets, resulting in impaired insulin secretion—as observed during stress or in patients with pheochromocytoma.¹¹⁷

In summary, in normal humans, insulin secretion is constantly modulated by the quantity, quality, and frequency of nutrient intake; by the hormonal milieu; and by autonomic impulses. The ingestion of nutrients, principally carbohydrate and protein, produces intestinal hormonal signals that prime and initiate insulin release. The entry of glucose into the beta cell, the phosphorylation of glucose, and the generation of adenosine triphosphate (ATP) by this or other nutrients result in insulin release. This sequence involves cAMP, β -adrenergic receptors, and ions—principally calcium and potassium. Glucose metabolism within the beta cell provides energy for further synthesis and release of insulin.¹¹⁸

Insulin Action

Insulin action on target cells in tissues such as liver, adipocytes, and muscle, begins by binding to specific insulin receptors located on the cell membrane. Binding to these receptors is saturable, occurs with a high energy of association (affinity), and is pH and temperature dependent.^{127–131} The insulin receptor is a heterodimeric glycoprotein consisting of two α and two β subunits linked by disulfide bonds (Fig. 21.8). The α subunit, with a molecular mass of approximately 125,000 kDa, acts as the binding site—whereas the β subunit, with a molecular mass of approximately 90,000 kDa, possesses tyrosine kinase activity for endogenous and exogenous substrates (see Figs. 21.8 and 21.9).^{132,133}

This ability to phosphorylate proteins may underlie some of the manifold actions of insulin. Among the classes of proteins phosphorylated are insulin receptor substrates 1 through 3 (considered an important insulin-signaling effector molecule) and pp 185, another substrate of the insulin receptor (see Fig. 21.9). Other insulin mediators may be involved in insulin action. This action may also be mediated in part by hydrolysis of glycan phosphoinositides in the cell plasma membrane. The insulin receptor gene has been cloned and localized to chromosome 19, whereas the structurally related insulin-like growth factor-1 (IGF-1) receptor has been localized to chromosome 15.^{127–131}

Under normal conditions, only a small proportion of the total available cell receptors need be occupied to achieve maximal biological response. Thus ordinarily there are spare receptors. Insulin receptors display two phenomena: downregulation, in which high ambient insulin concentrations reduce the number of available receptors, and negative cooperativity, in which the occupancy of a receptor reduces the affinity of adjoining receptor sites. Scatchard analysis of insulin-binding data in *in vitro* systems reveals curvilinear plots compatible with negative cooperativity or with two classes of receptors: high-affinity/low-capacity and low-affinity/high-capacity. Total receptor number and the affinities of both classes of receptor sites can be calculated with use of these Scatchard plots.

After binding to the cell surface, the receptor-insulin complex is internalized within the cell and processed by lysosomal enzymes, with release of free insulin and potential recycling of the receptor back to the cell membrane. Binding of insulin to the cell-surface receptor, perhaps with the participation of internalization that permits insulin action at the level of the nucleus, leads to the complex biochemical processes characteristic of insulin action in a given tissue. With postreceptor events assumed to be normal, however, the biological response to insulin in a tissue is a function of the number of receptor/insulin complexes formed—which in turn is directly related to the circulating insulin concentration and to the receptor concentration. Thus a reduction in receptor number could be compensated for by an increase in insulin concentration as long as the critical number of receptors necessary to produce maximal biological response remains. Conversely, reduced insulin concentration could be compensated for by an increase in receptor number, provided the minimum amount of insulin necessary to produce a maximal biological response is present.

Insulin receptors and their signaling proteins (see Figs. 21.8 and 21.9) are widely distributed in various tissues. Using targeted deletions of individual components or various combinations of components of the insulin receptor pathway has provided remarkable insight into the contribution of liver, muscle, fat, the beta cell, and brain to overall glucose homeostasis.^{127–131} Key concepts that have emerged are that the insulin receptor signal cascade on beta cells is critically important in maintaining normal insulin secretion. Thus mutations

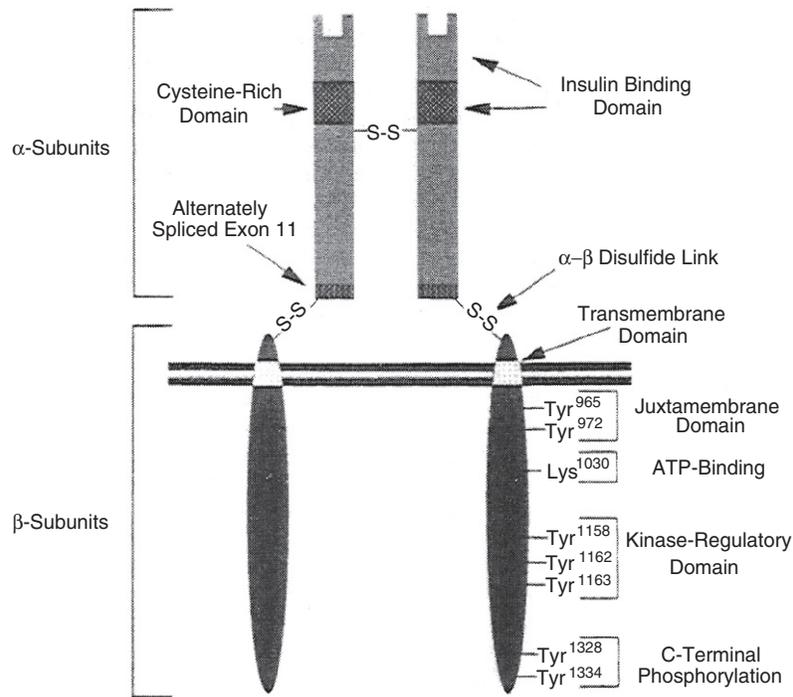

Fig. 21.8 Structure of the insulin receptor. *ATP*, adenosine triphosphate. (From Cheatham, B., Kahn, C.R (1995). Insulin action and the insulin signaling network. *Endocr Rev*, 16, 117.)

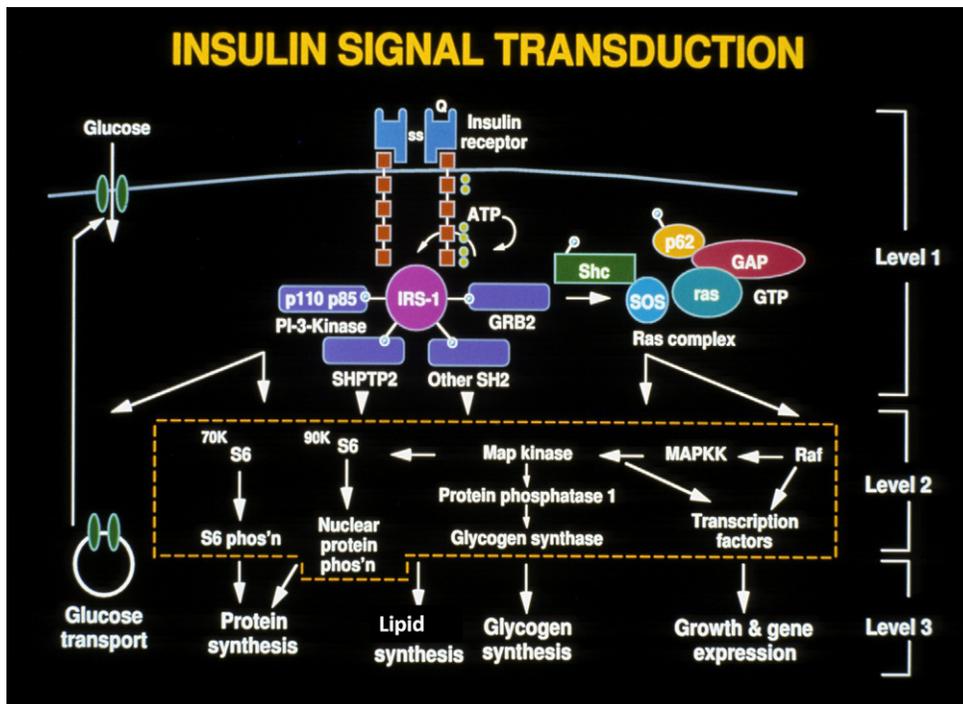

Fig. 21.9 Binding of insulin to the extracellular alpha subunit of the insulin receptor (*IR*) initiates a phosphorylation cascade first by tyrosine kinase on the intracellular beta subunit of *IR*, followed by several other phosphorylation cascades shown in level 1. These phosphorylation processes have immediate function on translocating the glucose transporter (GLUT 4) from the cytoplasm to the cell membrane thereby facilitating glucose transport across the cell membrane in cells, such as muscle, or activate other kinases, such as S6 and MAP kinases (level 2) involved in protein synthesis, lipid synthesis, and glycogen synthesis, as well as activating transcription factors involved in growth and gene expression (Level 3). *ATP*, Adenosine triphosphate; *GAP*, Ras p21 protein activator; *GRB2*, growth factor receptor bound 2; *GTP*, guanosine triphosphate; *IRS-1*, insulin receptor substrate 1; *MAP kinase*, mitogen-activated protein kinase; *MAPKK*, mitogen-activated protein kinase kinase; *p110* and *p85*, subunits of PI3 kinase (phosphoinositide 3 kinase); *p62*, nucleoporin 62; *Raf*, family of serine/threonine-specific protein kinases participating in the MAPK cascade; *S6*, ribosomal protein S6; *SH2*, Src homology region 2; *Shc*, src homology containing; *SHPTP2*, adaptor protein linking Janus kinase 2 and insulin receptor substrates; *SOS*, son of sevenless.

causing insulin resistance at the beta cell eventually lead to relative hypoinsulinemia that can interact with the insulin resistance in peripheral tissues to produce the hallmark of T2D (i.e., peripheral insulin resistance plus relative insulinopenia).

In addition, studies with targeted deletion of the insulin receptor in the brain—the so-called NIRKO mouse (neuron-specific insulin receptor knockout)—demonstrate that these animals developed obesity, increased body fat, insulin resistance with modest hyperinsulinemia, and elevated levels of triglycerides. Reproductive function in both males and females is impaired as a result of abnormal regulation of luteinizing hormone secretion, and serum leptin levels are elevated.¹³¹ Thus insulin signaling in the brain joins the emerging list of factors important in regulating energy homeostasis and reproduction.¹³¹

Primary defects in insulin receptor number or affinity may produce the same profound derangements in intermediary metabolism as deficient insulin secretion, and similar disturbances may result despite normal insulin concentration and normal receptor characteristics if postreceptor steps are defective.¹³⁴ Insulin signaling for the regulation of metabolism has been the subject of considerable research and is extensively reviewed.^{130,134} Examples of each type of defect in the individual components of this integrated system that comprises insulin biosynthesis, secretion, and action exist and can account for the metabolic abnormalities that characterize DM. An approach based on the principles of insulin biosynthesis secretion and action also permits a rational classification of DM.

Pathophysiology

Normal insulin secretion in response to feeding is exquisitely modulated by the interplay of neural, hormonal, and substrate-related mechanisms to permit controlled disposition of ingested foodstuff as energy for immediate or future use in metabolism and growth. Mobilization of energy during the fasted state depends on low plasma levels of insulin. Thus in normal metabolism, there are regular swings between the postprandial high-insulin anabolic state and the fasted low-insulin catabolic state that affect three major tissues: liver, muscle, and adipose tissue (Table 21.6).

Insulin is the key anabolic hormone that promotes the synthesis and storage of carbohydrates, lipids, and proteins while simultaneously restraining their degradation. The uptake of glucose, fatty acids, and amino acids is stimulated—as is the activity or expression of enzymes that promote glycogen, fat, and protein synthesis. Conversely, the activity or expression of enzymes that break down these metabolites is restrained.

All of these anabolic actions of insulin are reversed during the low-insulin state of starvation. T1DM, as it evolves, becomes a permanent low-insulin catabolic (starvation) state in which feeding cannot reverse but rather exaggerates these catabolic processes.

It is important to emphasize that liver is more sensitive than muscle or fat to a given concentration of insulin. That is, endogenous glucose production from the liver by means of glycogenolysis and gluconeogenesis can be restrained at insulin concentrations that do not fully augment glucose utilization by peripheral tissues. Consequently, with progressive failure of insulin secretion, the initial manifestation is postprandial hyperglycemia. Fasting hyperglycemia is a late manifestation that reflects severe insulin deficiency and indicates excessive endogenous glucose production.¹³⁵

Although insulin deficiency is the primary defect, several secondary changes that involve the stress hormones (i.e., epinephrine, cortisol, growth hormone, and glucagon) accelerate and exaggerate the rate and magnitude of metabolic decompensation.

Increased plasma concentrations of these counterregulatory hormones magnify metabolic derangements by further impairing insulin secretion (e.g., epinephrine), by antagonizing its action (e.g., epinephrine, cortisol, and growth hormone), and by promoting glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (e.g., glucagon, epinephrine, growth hormone, and cortisol) while decreasing glucose utilization and glucose clearance (e.g., epinephrine, growth hormone, and cortisol).¹³⁶ With progressive insulin deficiency, especially with concurrently elevated stress hormones, excessive glucose production, and impairment of its utilization result in hyperglycemia with glucosuria when the renal threshold of approximately 180 mg/dL (10 mmol/L) is exceeded.

The resultant osmotic diuresis produces polyuria, urinary losses of electrolytes, dehydration, and compensatory polydipsia. These evolving manifestations, especially dehydration, represent physiological stress—resulting in hypersecretion of epinephrine, glucagon, cortisol, and growth hormone that amplifies and perpetuates metabolic derangements and accelerates metabolic decompensation. The acute stress of trauma or infection may likewise accelerate metabolic decompensation to ketoacidosis in evolving or established diabetes.¹³⁶

Hyperosmolality, commonly encountered as a result of progressive hyperglycemia, contributes to the symptomatology—especially to cerebral obtundation in diabetic ketoacidosis (DKA). Serum osmolality can be estimated with the following formula.

TABLE 21.6 Influence of Feeding (High Insulin) or Fasting (Low Insulin) on Some Metabolic Processes in Liver, Muscle, and Adipose Tissue

	High Plasma Insulin (Postprandial State)	Low Plasma Insulin (Fasted State)
Liver	Glucose uptake Glycogen synthesis Absence of gluconeogenesis Lipogenesis Absence of ketogenesis	Glucose production Glycogenolysis Gluconeogenesis Absence of lipogenesis Ketogenesis
Muscle	Glucose uptake Glucose oxidation Glycogen synthesis Protein synthesis	Absence of glucose uptake Fatty acid and ketone oxidation Glycogenolysis Proteolysis and amino acid release
Adipose tissue	Glucose uptake Lipid synthesis Triglyceride uptake	Absence of glucose uptake Lipolysis and fatty acid release Absence of triglyceride uptake

Insulin is considered the major factor governing these metabolic processes. Diabetes mellitus may be viewed as a permanent low-insulin state that if untreated results in exaggerated fasting.

$$\text{Serum osmolality (mOsm/kg)} = (\text{serum Na [mEq/L]} + \text{K [mEq/L]}) \times 2 + \text{Glucose mmol/L}$$

(Note that 1 mmol/L of glucose is equivalent to 18 mg/dL.)

Consideration of serum osmolality has important implications in the treatment of DKA. The combination of insulin deficiency and elevated plasma values of the counterregulatory hormones is also responsible for accelerated lipolysis and impaired lipid synthesis, with resulting increased plasma concentrations of total lipids, cholesterol, triglycerides, and free fatty acids. The hormonal interplay of insulin deficiency and glucagon excess shunts the free fatty acids into ketone body formation. The rate of formation of these ketone bodies, principally β -hydroxybutyrate and acetoacetate, exceeds the capacity for peripheral utilization and for their renal excretion. Accumulation of these ketoacids results in metabolic acidosis and in compensatory rapid deep breathing in an attempt to excrete excess carbon dioxide (Kussmaul respiration).

Acetone, formed by nonenzymatic conversion of acetoacetate, is responsible for the characteristic fruity odor of the breath. Ketones are excreted in the urine in association with cations and thus further increase losses of water and electrolytes (Fig. 21.10 and Table 21.7). With progressive dehydration, acidosis, hyperosmolality, and diminished cerebral oxygen use, consciousness becomes impaired—with the patient ultimately becoming comatose. Thus insulin deficiency produces a profound catabolic state—an exaggerated starvation in which all

of the initial clinical features can be explained on the basis of known alterations in intermediary metabolism mediated by insulin deficiency in combination with counterregulatory hormone excess. Because the counterregulatory hormonal changes are usually secondary, the severity and duration of the symptoms reflect the extent of primary insulinopenia. Greater details of these considerations are provided in the discussion of diabetic ketoacidosis, which follows later.^{135,136}

Clinical Manifestations of Diabetes Mellitus

The classic presentation of diabetes in children is a history of polyuria, polydipsia, polyphagia, and weight loss. Polyuria may be heralded by the recurrence of bedwetting in a previously toilet trained child and polydipsia by a child constantly requesting fluids to drink. Unexplained weight loss should raise suspicion of the existence of diabetes that should be confirmed or excluded by measurement of blood glucose concentration, first in the postprandial and later in the fasting state. The urine should also be checked for the presence of glucosuria. The duration of these symptoms varies; it often is less than 1 month, but careful history may reveal weeks of thirst, enuresis, fatigue, and weight loss. Most children who are diagnosed with T1DM have been seen by a physician within a week or so of diagnosis, but diabetes was not considered, and a glucose measurement in blood or urine was not performed.^{137,138}

An insidious onset with lethargy, weakness, and weight loss is also quite common. The loss of weight despite increased

Pathophysiology of Diabetic Ketoacidosis

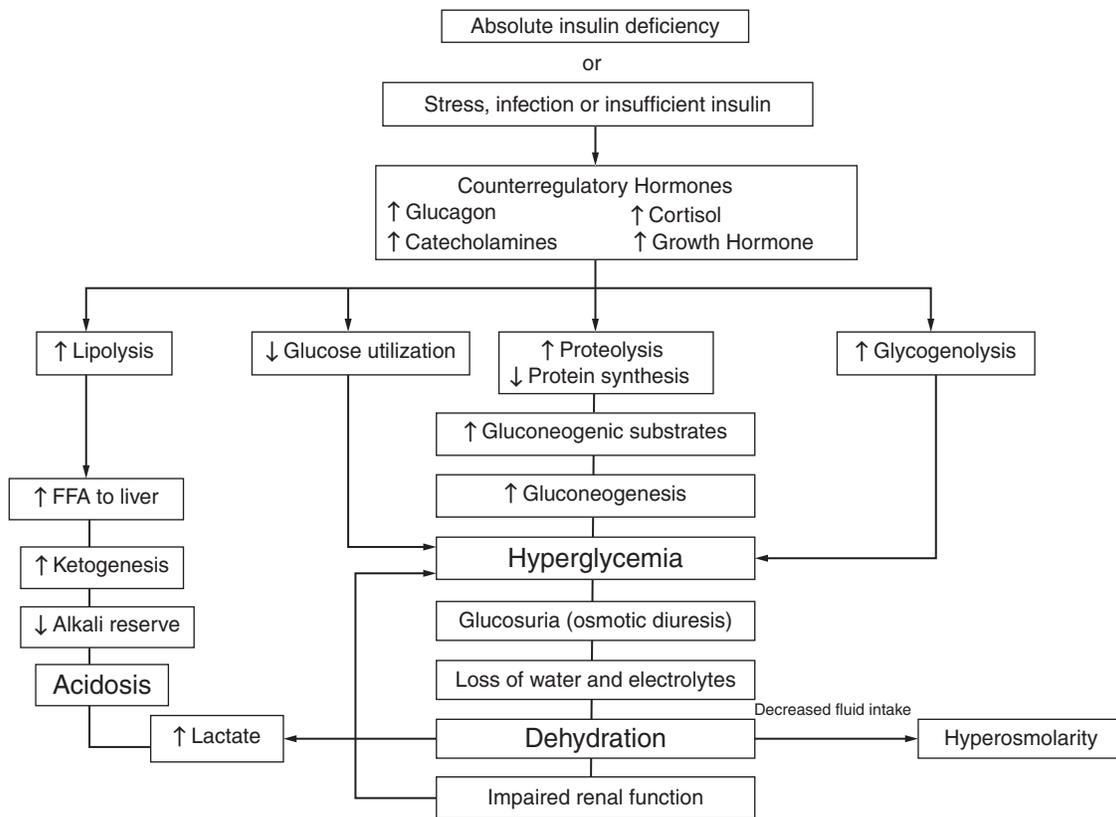

Fig. 21.10 The pathophysiology of diabetic ketoacidosis is illustrated as a function of absolute insulin deficiency or insufficient insulin in the presence of major stress, such as an infection, which leads to increases in the four major counterregulatory hormones. Together, these changes increase glucose production via glycogenolysis and gluconeogenesis, which together result in hyperglycemia, osmotic diuresis, and dehydration. Simultaneously increased lipolysis leads to ketone body production and acidosis in combination with increased lactic acid from dehydration. See text for greater detail.

TABLE 21.7 Fluid and Electrolyte Maintenance Requirements and Estimated Losses in Diabetic Ketoacidosis

Approximate Daily Maintenance Requirements		Average (range) Losses per Kg ^c
Water	Holliday-Segar method First 10 kg: 100 mL/kg/d Second 10 kg: 50 mL/kg/d Each additional 1 kg: 20 mL/kg/d alternatively Surface area method 1500 mL/m ² /d ^a	70 mL (30–100)
Sodium	2–4 mmol ^b	6 mmol (5–13)
Potassium	2–3 mmol	5 mmol (3–6)
Chloride	2–3 mmol	4 mmol (3–9)
Phosphate	1–2 mmol	0.5–2.5 mmol

Using the Holliday-Segar method, for example, for a 10-year-old child weighing 30 kg, maintenance fluid requirement is: 1000 + 500 + 200 = 1700 mL/day

^aThis method should not be used for children <10 kg.

^bMaintenance electrolyte requirements are expressed per 100 mL of maintenance fluid.

^cLosses are expressed per unit of body weight because the losses remain relatively constant in relation to total body weight.

dietary intake is readily explicable by the following example. The average healthy 10-year-old child has a daily intake of 2000 or more calories, of which approximately 50% are derived from carbohydrates. With the development of diabetes, daily losses of water and glucose may be as much as 5 L and 250 g, respectively. This represents 1000 calories lost in the urine, or 50% of average daily caloric intake. Therefore despite the child's compensatory increased intake of food and water, the calories cannot be used, excessive caloric losses continue, and increasing catabolism and weight loss ensue.

Pyogenic skin infections and candidal vaginitis in girls or candidal balanitis in uncircumcised boys are occasionally present at the time of diagnosis of diabetes. They are rarely the sole clinical manifestations of diabetes in children, and a careful history will invariably reveal the coexistence of excessive urination or recurrence of enuresis in a previously toilet-trained child, excessive thirst, and perhaps weight loss. Ketoacidosis is responsible for the initial presentation of many (about 25%–40%) diabetic children. Ketoacidosis is likely to be present more often in children younger than 5 years of age because the diagnosis may not be suspected and a history of polyuria and polydipsia may be difficult to elicit.^{137–145} The early manifestations may be relatively mild and consist of vomiting, polyuria, and dehydration.

In more prolonged and severe cases, Kussmaul respiration is present—and there is an odor of acetone on the breath. Kussmaul respiration may be confused with bronchiolitis or asthma and if erroneously treated with steroids or adrenergic agents, worsen diabetes. Abdominal pain or rigidity may be present and may mimic appendicitis or pancreatitis. Cerebral obtundation and (ultimately) coma ensue and are related to the degree of hyperosmolarity. Laboratory findings include glucosuria, ketonuria, hyperglycemia, ketonemia, and metabolic acidosis. Leukocytosis is common, and nonspecific serum amylase levels may be elevated. The serum lipase level is usually not elevated. In those with abdominal pain, it should not be assumed that these findings are evidence of a surgical emergency before a period of appropriate fluid, electrolyte, and insulin therapy to correct dehydration and acidosis. The abdominal manifestations frequently disappear after several hours of such treatment.

Diagnosis

The diagnosis of DM must be considered in children who have the following manifestations: those who have a history suggestive of diabetes, especially symptoms of polyuria with polydipsia, and failure to gain weight or a weight loss despite a healthy appetite; those who have confirmed glucosuria; and those who have clinical manifestations of metabolic acidosis with or without stupor or coma. In all instances, the diagnosis of DM is dependent on the demonstration of hyperglycemia in association with glucosuria with or without ketonuria. When classic symptoms of polyuria and polydipsia are associated with hyperglycemia and glucosuria that meet the criteria for diagnosing DM as defined by the ADA or World Health Organization (WHO), a glucose tolerance test is contraindicated.

Renal glucosuria may be an isolated congenital disorder or a manifestation of the Fanconi syndrome and other renal tubular disorders owing to severe heavy metal intoxication, ingestion of certain drugs (e.g., outdated tetracycline), or inborn errors of metabolism (e.g., cystinosis). When vomiting, diarrhea, and inadequate intake of food are complicating factors in any of these conditions, starvation ketosis may ensue and simulate DKA. The absence of hyperglycemia eliminates the possibility of diabetes. It is also important to recognize that not all urinary sugar is glucose, and infrequently galactosemia, pentosuria, and the fructosuria will require consideration as diagnostic possibilities.

The discovery of glucosuria, with or without a mild degree of hyperglycemia, during a hospital admission for trauma or infection (or even during the associated emotional upheaval) may herald the existence of diabetes. In most of these instances, the glucosuria remits during recovery.² Because this circumstance may indicate a limited capacity for insulin secretion, which is unmasked by elevated plasma concentrations of stress hormones, these patients should be rechecked at a later date for the possibility of hyperglycemia, clinical features of DM, and family history of diabetes.

A family history of DM in two preceding generations should suggest the possibility of a MODY syndrome; absence of the common antibodies to beta cells, such as IA2, GAD65, ZnT8, or ICA, strengthens the possibility of a diagnosis of MODY.^{7,13,14} Under these circumstances, a glucose tolerance test may be useful to establish a diagnosis. Glucose tolerance testing should be performed several weeks after recovery from the acute illness, with a glucose loading dose adjusted for weight. Evidence indicates that the test is most likely to be abnormal in those with HLA DR3 and DR4, in whom ICA or insulin autoantibodies are detected, or who have MODY.^{7,13,14} Transient hyperglycemia is common in patients with asthma treated with epinephrine and steroids. Further testing in such patients is not indicated. Screening procedures, such as postprandial determinations of blood glucose or oral glucose tolerance tests, have yielded low detection rates in children—even among those considered at risk, such as siblings of diabetic children. Accordingly, such screening procedures are not recommended in children.

DIABETIC KETOACIDOSIS PATHOPHYSIOLOGY AND TREATMENT

Diabetic Ketoacidosis

DKA is the entity of severe metabolic decompensation caused by the combined effects of deficiency of circulating insulin, together with increased levels of the counterregulatory hormones: catecholamines, glucagon, cortisol, and growth hormone, as well as proinflammatory cytokines^{139,146} (see Fig. 21.10). Typical

symptoms and signs are polyuria, enuresis, vomiting, dehydration, increased thirst, Kussmaul respiration, the odor of acetone on the breath, together with characteristic biochemical features, which include hyperglycemia, hyperketonemia, metabolic acidosis, and electrolyte abnormalities.^{147–149}

Severe insulin deficiency occurs as DKA evolves in previously undiagnosed T1DM, or when treated patients deliberately or inadvertently do not take insulin, especially the long-acting component of a multiple daily injection (MDI) regimen, or markedly reduce the doses of insulin, for example, during an illness, such as gastroenteritis. Patients who use an insulin pump can rapidly develop DKA when insulin delivery is interrupted for any reason¹⁵⁰ because pumps deliver only short-acting insulin and there is no long-acting component on board as there is with MDI. Relative insulin deficiency occurs when the concentrations of counterregulatory hormones increase in response to stress (e.g., sepsis, trauma, or febrile illness) and lead to metabolic decompensation despite administration of the usual dose of insulin. Although less common than in T1DM, the SEARCH for Diabetes in Youth Study in the United States reported that nearly 6% of youth with T2DM presented with DKA.¹⁵¹

The combination of absolute or relative insulin deficiency and high counterregulatory hormone concentrations causes an accelerated catabolic state with increased glucose production by the liver and kidney (via glycogenolysis and gluconeogenesis) together with impaired peripheral glucose utilization, which result in hyperglycemia and hyperosmolality (see Fig. 21.10). The combination of low insulin and high counterregulatory hormones also increases lipolysis and ketogenesis that result in hyperketonemia and metabolic acidosis from the accumulating ketoacids predominantly β -hydroxybutyrate. Hyperglycemia exceeding the usual renal threshold, approximately 10 mmol/L (180 mg/dL), causes osmotic diuresis, dehydration, and loss of electrolytes in urine, which often is aggravated by vomiting associated with severe ketosis. These changes stimulate further stress hormone production, which induces more severe insulin resistance and worsening hyperglycemia and hyperketonemia. Lactic acidosis from hypoperfusion or sepsis may contribute to the acidosis. Unless this cycle is interrupted by fluid and electrolyte therapy and administration of exogenous insulin, fatal dehydration and metabolic acidosis will ensue.

DKA is a life-threatening medical emergency that requires prompt recognition and treatment. It must be differentiated from acidosis and coma from other causes, such as hypoglycemia, uremia, gastroenteritis with metabolic acidosis, lactic acidosis, salicylate intoxication, encephalitis, and other intracranial lesions.

The biochemical criteria for the diagnosis of DKA are¹⁵²: hyperglycemia (blood glucose >11 mmol/L [200 mg/dL]), venous pH under 7.3 or serum bicarbonate less than 15 mmol/L, ketonemia or ketonuria (typically $\geq 2+$ positive, “moderate or large”), or blood beta-hydroxybutyrate (BOHB) concentration of 3 mmol/L or higher is indicative of DKA.¹⁵³ Partially treated children and children who have consumed little or no carbohydrate (anorexia or religious fasting, a low-carbohydrate high-fat diet) may have only modestly elevated blood glucose concentrations, referred to as *euglycemic ketoacidosis*.^{154,155} Recently, euglycemic ketoacidosis has been described in patients using sodium glucose transport protein 2 (SGLT2)-inhibitors (not currently approved for use in children).^{156–158} The severity of DKA is defined by the degree of acidosis: mild, venous pH 7.2 to 7.3 or serum bicarbonate 10 to 15 mmol/L; moderate, pH 7.1 to 7.2 or serum bicarbonate 5 to less than 10 mmol/L; severe, pH under 7.1 or serum bicarbonate less than 5 mmol/L.¹⁵⁹

The frequency of DKA at the time of diagnosis varies widely worldwide and inversely correlates with the regional incidence of T1DM, ranging from approximately 15% to 70% in Europe and North America. At the time of diagnosis, approximately 30% to 50% of all children have DKA even in developed countries.^{160–169} Programs that heighten awareness have decreased rates of DKA.¹⁷⁰ DKA is the leading cause of complications, death, and excessive healthcare use and costs in patients with T1DM.¹⁷¹

DKA is more common in younger children (especially <2 years of age, including infants with neonatal diabetes), often the consequence of diagnostic error and delayed treatment.^{172–175} DKA at diagnosis is also more common in ethnic minorities and in children who do not have ready access to medical care for social or economic reasons.^{164,172,176–178} In children with established T1DM the risk of DKA is 1% to 10% per patient per year.^{150,179–183} Risk is increased in children who omit insulin¹⁸⁴; children with poor metabolic control or previous episodes of DKA; intercurrent illness, especially gastroenteritis with persistent vomiting and inability to maintain hydration; children with psychiatric disorders, including those with eating disorders; children living in stressful or dysfunctional family circumstances; and peripubertal and adolescent girls. DKA is a well-recognized hazard associated with use of recreational drugs and binge alcohol consumption in adolescents and young adults.¹⁸⁵ Insulin omission or failure to follow sick day or pump failure management guidelines accounts for almost all episodes of recurrent DKA.

DKA must be distinguished from hyperglycemic hyperosmolar state (HHS), formerly referred to as *hyperosmolar nonketotic coma*, a syndrome characterized by extremely elevated serum glucose concentrations and hyperosmolality without significant ketosis.¹⁴⁵ The criteria for HHS include plasma glucose concentration over 33.3 mmol/L (600 mg/dL), venous pH greater than 7.25 (arterial pH >7.30), serum bicarbonate over 15 mmol/L, small ketonuria, absent to small ketonemia, effective serum osmolality greater than 320 mOsm/kg, obtundation, combativeness, or seizures (occur in approximately 50%).^{145,186}

Although much less common in children and adolescents than DKA, the incidence of HHS is increasing^{187–189}; a recent study found HHS at presentation in 2% of youth with T2DM (often associated with morbid obesity).¹⁹⁰ Unlike the usual symptoms of DKA (hyperventilation, vomiting and abdominal pain), which typically bring children to medical attention, the gradually increasing polyuria and polydipsia of HHS may go unrecognized, eventually resulting in profound dehydration and severe electrolyte losses at the time of presentation; fluid losses in HHS have been estimated to be twice those of DKA. Furthermore, obesity and hyperosmolality make the clinical assessment of dehydration especially challenging because hypertonicity preserves intravascular volume; thus despite severe volume depletion and electrolyte losses signs of dehydration may be less evident. Reports have described a high incidence of pre-existing neurological damage. Profound hyperglycemia may develop over a period of several days; initially, the obligatory osmotic polyuria and dehydration may be partially compensated for by increased fluid intake. However, with progression, thirst becomes impaired, possibly the result of altered function of the hypothalamic thirst center caused by hyperosmolality. In some instances, this is the consequence of a preexisting defect in the hypothalamic osmoregulatory mechanism.

The characteristic features of HHS and DKA may overlap. Some patients with HHS, especially those with severe dehydration and prerenal azotemia, have mild or moderate acidosis because of hypoperfusion and lactic acidosis. Conversely, children with T1DM may have severe hyperglycemia, especially if

BOX 21.2 Aims of Therapy in Diabetic Ketoacidosis

1. Expand intravascular volume
2. Correct derangements in fluid, electrolyte, and acid-base status
3. Correct intermediary metabolism with insulin
4. Identify and treat any precipitating event, such as infection

high-carbohydrate-containing beverages have been consumed to quench thirst.¹⁹¹

The low production of ketones is mainly attributed to hyperosmolarity, which in vitro blunts the lipolytic effect of epinephrine, and to the concomitant antilipolytic effect of residual insulin. Blunting of lipolysis by the therapeutic use of β -adrenergic blockers may also contribute to the syndrome. A key difference between DKA and HHS is the degree of insulinopenia, which is nearly absolute in DKA, whereas in HHS there is sufficient residual insulin activity to limit lipolysis in adipose tissue but inadequate insulin to suppress gluconeogenesis and permit normal peripheral glucose utilization at a time of increased glucose production induced by the increased concentrations of stress or counterregulatory hormones. Depression of consciousness correlates with the degree of hyperosmolarity in both HHS and DKA, and hemoconcentration predisposes to cerebral arterial and venous thromboses^{145,188} (Box 21.2).

Management of Diabetic Ketoacidosis

Treatment of DKA consists of three basic elements: meticulous monitoring of vital signs and biochemical responses; replacement of fluids and electrolytes, with the volume and content based on an estimate of the degree of dehydration and daily maintenance requirements; and provision of IV insulin (see Table 21.7). Treatment should be instituted as soon as the clinical diagnosis is confirmed. Acute management should follow the general guidelines for Pediatric Advanced Life Support (PALS),^{192,193} with particular attention to the following: immediately measure blood glucose and blood BOHB concentrations with bedside meters¹⁵³ or measure urine ketones with test strips (that measure only acetoacetic acid) if bedside blood ketone measurements are not available. Perform a clinical evaluation to identify a possible infection. Weigh the patient and, if body surface area is used for fluid therapy calculations, measure height or length to determine surface area. The current weight should be used for fluid calculations.

Clinical estimation of the degree of dehydration is imprecise^{194–196}; useful signs include prolonged capillary refill time (normal capillary refill is ≤ 1.5 –2 seconds), abnormal skin turgor (“tenting” or inelastic skin), dry mucus membranes, sunken eyes, absent tears, weak pulses, and cool extremities. More signs of dehydration tend to be associated with more severe dehydration¹⁹⁷; weak or impalpable peripheral pulses, hypotension, and oliguria suggest 10% or greater dehydration.

Assess level of consciousness using Glasgow Coma Scale (GCS)—Table 21.8.¹⁹⁸ In the unconscious or severely obtunded patient without normal airway protective reflexes, secure the airway and empty the stomach by continuous nasogastric suction to prevent pulmonary aspiration. Intubation should be avoided if possible; an increase of pCO₂ during or following intubation above the level that the patient had been maintaining may cause cerebrospinal fluid (CSF) pH to decrease and contribute to worsening of cerebral edema.¹⁹⁹

Give oxygen to patients with circulatory impairment or shock. A cardiac monitor should be used for continuous electrocardiographic monitoring to assess T waves for evidence of hyper- or hypokalemia.^{200,201}

A second peripheral IV catheter should be placed for repetitive blood sampling. Unless absolutely necessary, avoid inserting a central venous catheter because of the high risk of thrombosis, especially in the very young child.

Give antibiotics to febrile patients after obtaining appropriate cultures of body fluids.

Bladder catheterization usually is not necessary, but if the child is unconscious or unable to void on demand (e.g., infants and very ill young children) the bladder should be catheterized.

Obtain a blood sample for laboratory measurement of:

- Serum or plasma glucose
- Serum BOHB
- Electrolytes (including serum bicarbonate)
- Blood urea nitrogen, creatinine
- Serum osmolality
- Venous pH, pCO₂
- Hemoglobin, hematocrit. An increased white blood cell count in response to stress is characteristic of DKA and is not indicative of infection²⁰²
- Albumin, calcium, phosphate, magnesium concentrations (if possible)
- Urine ketones (if serum BOHB has not been measured)
- Obtain appropriate specimens for culture (blood, urine, throat) if there is evidence of infection (e.g., fever)
- If laboratory measurement of serum potassium is delayed, perform an electrocardiogram (ECG) for baseline evaluation of potassium status^{200,201}
- Although not essential for management of DKA per se, hemoglobin (Hb)A1c may be useful in specific patients as it provides information about the duration of hyperglycemia

Where Should the Child With Diabetic Ketoacidosis be Managed?

Successful management of DKA and HHS requires meticulous monitoring and recording of the patient’s clinical and biochemical response to treatment so that timely adjustments in treatment can be made when indicated by the patient’s clinical or laboratory data. After initial resuscitation, the child should receive care in a unit that has written guidelines and experienced nursing staff trained in management of DKA in children and adolescents. Children with severe DKA and those at increased risk for cerebral injury (e.g., <5 years of age, severe acidosis, low pCO₂, high blood urea nitrogen) should be treated in an intensive care unit (ICU).^{152,203}

Clinical and Biochemical Monitoring

- Hourly (more frequently as indicated) vital signs including heart rate, respiratory rate, blood pressure
- Hourly (more frequently as indicated) neurological observations (GCS; see Table 21.8) for warning signs and symptoms of cerebral injury (see later in section on cerebral edema)
- Amount of administered insulin
- Hourly (or more frequently as indicated) fluid input and output
- Laboratory tests: serum glucose, electrolytes, blood urea nitrogen, calcium, magnesium, phosphate, hematocrit, and blood gases should be repeated 2 to 4 hourly, or more frequently, as clinically indicated, in more severe cases
- Blood BOHB concentrations, if available, every 2 to 4 hours^{204–208}
- Point-of-care BOHB measurements correlate well with a reference method up to 3 mmol/L, but are not accurate above 5 mmol/L^{206,209}

TABLE 21.8 Glasgow Coma Scale

Best Eye Response	Best Verbal Response	Best Verbal Response (Nonverbal Children)	Best Motor Response
1. No eye opening	1. No verbal response	1. No response	1. No motor response
2. Eyes open to pain	2. No words, only incomprehensible sounds; moaning	2. Inconsolable, irritable, restless, cries	2. Extension to pain (decerebrate posture)
3. Eyes open to verbal command	3. Words, but incoherent ^a	3. Inconsistently consolable and moans; makes vocal sounds	3. Flexion to pain (decorticate posture)
4. Eyes open spontaneously	4. Confused, disoriented conversation ^b	4. Consolable when crying and interacts inappropriately	4. Withdrawal from pain
	5. Oriented, normal conversation	5. Smiles, oriented to sound, follows objects and interacts	5. Localizes pain
			6. Obeys commands

The Glasgow Coma Scale (GCS) consists of three parameters and is scored between 3 and 15; 3 being the worst and 15 the best.⁵⁵ One of the components of the GCS is the best verbal response, which cannot be assessed in nonverbal young children. A modification of the GCS was created for children too young to talk.

^aInappropriate words, random, or exclamatory articulated speech, but no sustained conversational exchange.

^bAttention can be held; patient responds to questions coherently, but there is some disorientation and confusion.

- Useful calculations:
 - Anion gap = $\text{Na} - (\text{Cl} + \text{HCO}_3)$; normal is 12 ± 2 mmol/L. In DKA the anion gap is typically 20 to 30 mmol/L; an anion gap greater than 35 mmol/L suggests concomitant lactic acidosis
 - “Corrected sodium” = measured Na + $2([\text{plasma glucose} - 5.6]/5.6)$ mmol/L or measured Na + $2([\text{plasma glucose} - 100]/100)$ mg/dL
 - Effective osmolality (mOsm/kg) = $2 \times (\text{plasma Na}) + \text{plasma glucose mmol/L}$ ²¹⁰

Fluids and Electrolyte Therapy

Fluid and electrolyte replacement therapy is a cornerstone of DKA management. The aims are to restore circulating volume, replace sodium and the extracellular and intracellular water deficits, improve glomerular filtration, and enhance clearance of glucose and ketones from the blood. Patients with DKA have a deficit in extracellular fluid (ECF) volume usually in the range of 5% to 10% of body weight.^{211,212} Shock with hemodynamic compromise is rare in pediatric DKA. In moderate DKA assume 5% to 7% and in severe DKA 7% to 10% dehydration. It is useful to calculate the corrected sodium concentration (earlier formula) to help assess the magnitude of the deficit of sodium and water.¹⁴⁸ The corrected sodium represents the expected serum sodium concentration in the absence of hyperglycemia. As the plasma glucose concentration decreases (in response to fluid and insulin), the measured serum sodium concentration should increase and the corrected sodium concentration should slowly decrease or remain in the normal range. A rapid and ongoing rise in serum sodium concentration may indicate loss of free water in the urine from diabetes insipidus, an agonal complication of cerebral edema.

There has been considerable controversy concerning the rate of fluid or sodium administration and a possible role of rapid administration of hypotonic fluid in the development of cerebral edema.^{213–215} A recent randomized clinical trial compared acute and long-term neurological outcomes in 1389 episodes in 1255 children with DKA treated with slower versus more rapid fluid administration using either 0.45% saline or 0.9% saline.²¹⁶ Neither the rate nor the sodium chloride content of IV fluids significantly influenced neurologic outcomes, suggesting that a range of fluid infusion rates and fluid sodium content may be safely used to treat DKA in children. Therefore an assumed fluid deficit between 5% and 10% of body weight should be replaced over 24 to 48 hours, together with maintenance fluids, using fluids with a sodium content between 0.45% and 0.9% saline. Most importantly, clinicians should not restrict fluid administration if clinical signs suggest the need for circulatory volume expansion.

Resuscitation Fluids. Immediately begin volume expansion with 0.9% saline 10 mL/kg infused over 30 to 60 minutes to restore the peripheral circulation. If tissue perfusion is poor, the initial fluid bolus is given more rapidly (e.g., over 15–30 minutes) and a second fluid bolus may be needed to ensure adequate tissue perfusion.

Deficit Replacement Fluids. Subsequent fluid management can be with 0.45% to 0.9% saline or a balanced salt solution (Ringer’s lactate, Hartmann’s solution or Plasmalyte).^{217–222} In addition to providing the usual daily maintenance fluid requirement, replace the estimated fluid deficit at an even rate over 24 to 48 hours^{152,219,223} (Table 21.9 provides an illustrative example). When plasma glucose concentrations fall during treatment, vascular volume will decrease; therefore it is essential to provide sufficient fluid and salt to maintain adequate tissue perfusion. Except for severely ill individuals, oral intake typically begins within 24 hours.²²³ Although rehydration is generally planned to occur over longer periods, in a study of 635 episodes of DKA the mean time to correction of DKA and complete restoration of the circulation was 11.6 ± 6.2 hours. Any remaining deficits are replenished by oral intake once DKA has resolved and patients are transitioned to subcutaneous insulin.²²³ Satisfactory outcomes have also been reported using an alternative simplified method: after initial fluid administration of 20 mL/kg of normal saline, 0.675% saline (3/4 normal saline, 115.5 mmol sodium) is infused at 2 to 2.5 times the usual maintenance rate of fluid administration regardless of the degree of dehydration, and decreased to 1 to 1.5 times the maintenance rate after 24 hours, or earlier if acidosis resolved.²²¹

Clinical assessment of hydration status and calculated effective osmolality are useful guides to fluid and electrolyte therapy. The aim is gradually to reduce serum effective osmolality to normal.^{223–225} There should be a concomitant increase in serum sodium concentration by 0.5 mmol/L for each 1 mmol/L decrease in glucose concentration. The sodium content of the fluid should be increased if measured serum sodium concentration is low and does not rise appropriately as the plasma glucose concentration falls.^{218,220,225,226}

The use of large amounts of chloride-rich fluids (combined with preferential renal excretion of ketones over chloride) may be associated with the rapid development of hyperchloremia^{227–229} (defined as a ratio of chloride:sodium $[\text{Cl}^-:\text{Na}^+] > 0.79$)²³⁰ and hyperchloremic metabolic acidosis.^{228,231–233} Hyperchloremic acidosis is more common in patients who receive large amounts of 0.9% sodium chloride than in those who receive fluid containing 0.45% sodium chloride.^{216,234} The acidifying effect of chloride can mask recognition of resolution of ketoacidosis when total base deficit is used to monitor biochemical improvement.²²⁹ When hyperchloremia develops,

TABLE 21.9 Fluid and Electrolyte Therapy for Diabetic Ketoacidosis: Recommendations for Replacement of Fluid and Electrolytes

Replacement Fluids	Approximate Accumulated Losses With 10% Dehydration	Approximate Requirements for Maintenance (36 Hours)	Approximate Totals for Replacement and Maintenance (36 Hours)		
Water (mL)	3000	2250	5250		
Sodium (mmol)	300	70	370		
Potassium (mmol)	180	65	245		
Chloride (mmol)	180	65	245		
Phosphate (mmol)	75	35	110

Approximate Duration	Fluid (Composition)	Sodium mmol	Potassium mmol	Chloride mmol	Phosphate mmol
Hour 1	600 mL 0.9% NaCl (isotonic saline)	92	—	92	—
Hours 2–6 (200 mL/h for 5 hours)	1000 mL 0.9% NaCl plus 40 mmol KCl/L	154	40	194	—
Hour 7–12 (200 mL/h for 6 hours)	1200 mL 0.45% NaCl with 20 mmol/L potassium chloride and 20 mmol/L potassium phosphate	92	48	101	24
Subtotal initial 12 hours	2800 mL	338	88	387	24
Next 24 hours 100 mL/h	2400 mL 5% glucose in 0.45% NaCl with 20 mmol/L potassium chloride and 20 mmol/L potassium phosphate	185	96	233	48
Total over 36 hours	5200 mL	523	184	620	72

a persisting base deficit or low bicarbonate concentration can be erroneously interpreted as being caused by ongoing ketosis.²³⁵ Measurement of bedside BOHB levels will prevent any confusion and demonstrate that ketoacidosis has resolved. Hyperchloremic acidosis resolves spontaneously. Although the anion gap is useful to track resolution of ketosis, it has two limitations in this setting: it is unable to differentiate a mixed metabolic acidosis (hyperchloremic and ketotic), and the degree of hyperchloremic acidosis is not quantifiable. Normally, the difference between the serum sodium and chloride concentrations is 30 to 35 mmol/L. To partition the chloride component of the base deficit, the following formula has been proposed to enable clinicians to track resolution of ketoacidosis at the bedside: chloride-induced base deficit = (plasma sodium – plasma chloride – 32).²²⁹ The chloride load can be reduced by not giving potassium as potassium chloride (use potassium acetate instead) and by using fluids, such as Ringer's lactate or Plasmalyte, in which a portion of the chloride is replaced, respectively, by lactate or acetate.²³⁶ Table 21.9 illustrates fluid and electrolyte therapy for a 30-kg child with severe DKA estimated to be 10% dehydrated.

Insulin Therapy

Rehydration alone causes a marked decrease in blood glucose concentration^{237,238}; however, insulin therapy is essential to suppress glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis; promote normal cellular glucose utilization; and to normalize blood glucose concentrations.²³⁹ Start continuous insulin infusion, 0.05 to 0.1 U/kg/h^{240,241} administered by IV infusion controlled by an infusion pump, at least 1 hour after starting fluid replacement therapy; that is, after the patient has received initial volume expansion.²¹⁵ An IV bolus should not be used at the start of therapy; it is unnecessary,^{242,243} may increase the risk of cerebral edema,^{215,225,244} can precipitate shock by rapidly decreasing osmotic pressure, and can exacerbate hypokalemia. The dose of insulin should usually remain at 0.05 to 0.1 U/kg/h at least until resolution of DKA (pH >7.30, serum bicarbonate >15 mmol/L, BOHB <1 mmol/L, or closure of the anion gap), which invariably takes longer than normalization of blood glucose concentrations.²³⁵ If the insulin effect is adequate serum BOHB should decrease by

approximately 0.5 mmol/L per hour.²⁰⁸ If the patient shows marked sensitivity to insulin (e.g., some young children with DKA, patients with HHS, and some older children with established diabetes), the insulin dose may be decreased provided that metabolic acidosis continues to resolve. For example, if a young child is receiving 0.05 U/kg/h, it may be necessary to reduce the insulin dose to 0.03 U/kg/h to prevent hypoglycemia despite the addition of IV glucose. For mild and moderate DKA (pH >7.1–7.2), 0.05 U/kg/h (0.03 U/kg/h for age <5 years with mild DKA) is usually sufficient to resolve the acidosis.

To prevent hypoglycemia, 5% glucose should be added to the IV fluid when the plasma glucose falls to approximately 14 to 17 mmol/L (250–300 mg/dL) or sooner if the rate of fall is precipitous. It may be necessary to use 10% or even 12.5% dextrose to prevent hypoglycemia while continuing to infuse insulin to correct the metabolic acidosis.

In circumstances where continuous IV administration is not possible and in patients with uncomplicated DKA, hourly or 2-hourly subcutaneous (SC) rapid-acting insulin analog is safe and as effective as IV regular insulin infusion. Initial dose SC: 0.3 U/kg, followed 1 hour later by SC insulin lispro or aspart at 0.1 U/kg every hour, or 0.15 to 0.20 U/kg every 2 to 3 hours.^{245–247} If blood glucose falls to under 14 mmol/L (250 mg/dL) before DKA has resolved, reduce SC insulin lispro or aspart to 0.05 U/kg/h to keep blood glucose around 11 mmol/L (200 mg/dL) until resolution of DKA. SC administration of short-acting insulin (regular) every 4 hours is also a safe and effective alternative to IV insulin infusion in children with pH 7.0 or over. A suggested starting dose is 0.8 to 1 U/kg/24 h; the calculated 24-hour dose is divided by 6 to provide an insulin dose injected every 4 hours. Doses are increased or decreased by 10% to 20% based on the blood glucose level before the next insulin injection (e.g., if a child weighs 45 kg: $45 \times 0.8 = 36$ units; the starting dose is 6 units).²⁴⁸

Potassium Replacement

Children with DKA have total body potassium deficits on the order of 3 to 6 mmol/kg.^{211,212,249,250} Intracellular potassium is depleted from transcellular shifts caused by hypertonicity (increased plasma osmolality causes solvent drag in which water and potassium are drawn out of cells), acidosis, and

glycogenolysis and proteolysis secondary to insulin deficiency also cause potassium efflux from cells.¹⁴⁸ Vomiting and osmotic diuresis are major causes of potassium loss from the body, and secondary hyperaldosteronism in response to volume depletion promotes urinary potassium excretion. Despite total body potassium depletion, serum potassium levels may be normal, increased, or decreased at presentation.²⁵¹ Renal dysfunction reduces potassium excretion and contributes to hyperkalemia²⁵¹; whereas, insulin administration and correction of acidosis drives potassium back into the cells and rapidly decreases serum potassium levels.²⁵² An abrupt decrease in serum potassium concentration can predispose to a cardiac arrhythmia. Therefore potassium replacement is required regardless of the serum potassium concentration, except when there is renal failure.²⁵³ If the patient has hypokalemia, start potassium replacement (20 mmol/L should be used) at the time of initial volume expansion and before starting insulin therapy. Otherwise, start replacing potassium after initial volume expansion and concurrent with starting insulin therapy. If the patient has hyperkalemia, defer potassium replacement therapy until urine output has been documented. If immediate serum potassium measurements are unavailable, an ECG may help to determine whether the child has hyper- or hypokalemia.^{200,201} Prolongation of the PR interval, T wave flattening and inversion, ST depression, prominent U waves, and apparent long QT interval (because of fusion of the T and U waves) indicate hypokalemia. Tall, peaked, symmetrical, T waves and shortening of the QT interval are signs of hyperkalemia. The initial potassium concentration in the infusion should be 40 mmol/L, and subsequent potassium replacement therapy should be based on serum potassium measurements. Potassium phosphate may be used together with potassium chloride or acetate; for example, 20 mmol/L potassium chloride and 20 mmol/L potassium phosphate or 20 mmol/L potassium phosphate and 20 mmol/L potassium acetate. Administration of potassium exclusively as potassium chloride contributes to the risk of hyperchloremic metabolic acidosis, whereas administration entirely as potassium phosphate can result in hypocalcemia. The maximum recommended rate of IV potassium administration is usually 0.5 mmol/kg/h. If hypokalemia persists despite a maximum rate of potassium replacement, then the rate of insulin infusion can be reduced. Profound hypokalemia (<2.5 mmol/L) in untreated DKA is rare and necessitates vigorous potassium replacement, while delaying the start of insulin therapy until serum potassium levels are above 2.5 mmol/L to reduce the risk of cardiopulmonary and neuromuscular compromise.²⁵⁴

Phosphate

Osmotic diuresis causes phosphaturia and depletion of intracellular phosphate.¹⁴⁸ Plasma phosphate levels fall after starting treatment, exacerbated by insulin, which promotes entry of phosphate into cells.²⁵⁵ Phosphate depletion has been associated with a variety of metabolic disturbances.²⁵⁶ Phosphate is essential for the formation of 2,3-diphosphoglycerate (2,3-DPG), which governs the oxygen dissociation curve.²⁵⁷ Deficiency of 2,3-DPG shifts the oxygen dissociation curve to the left (i.e., more oxygen is retained by hemoglobin and less is available to tissues, a situation that predisposes to lactic acidosis). Acidosis per se shifts the hemoglobin-oxygen dissociation curve toward the right (Bohr effect) and thus partially "compensates" for 2,3-DPG deficiency. Because acidosis is corrected by the provision of insulin, the effects of 2,3-DPG deficiency may no longer be compensated for and release of oxygen to tissues may again be impaired. Exogenous phosphate contributes to the formation of new 2,3-DPG, permitting the oxygen dissociation curve to shift to the right, which facilitates release of

oxygen to tissues. Despite the earlier pathophysiological considerations, prospective studies have not shown clinical benefit from routine phosphate replacement.²⁵⁸

Clinically significant hypophosphatemia may occur if IV therapy without food consumption is prolonged beyond 24 hours. Severe hypophosphatemia with cellular phosphate depletion is uncommon but can have severe consequences depending on the severity and chronicity of the phosphate depletion. Symptoms usually do not occur until plasma phosphate is less than 1 mg/dL (0.32 mmol/L). Although severe hypophosphatemia can occur during treatment of DKA, symptoms are uncommon because it usually is acute, typically without antecedent chronic phosphate deficiency. Many organ systems can be affected.²⁵⁶ Manifestations include: metabolic encephalopathy, impaired myocardial contractility, respiratory failure because of weakness of the diaphragm, muscle dysfunction with proximal myopathy, dysphagia and ileus, and rare hematological effects include hemolysis, decreased phagocytosis and granulocyte chemotaxis, defective clot retraction, and thrombocytopenia. Acute hypophosphatemia in a patient with preexisting severe phosphate depletion can lead to rhabdomyolysis.^{256,259} Severe hypophosphatemia associated with any of the earlier symptoms should be treated. Potassium phosphate salts may be safely used as an alternative to or combined with potassium chloride or acetate, provided that careful monitoring of serum calcium is performed to avoid hypocalcemia.^{260,261}

Acidosis

Even severe acidosis is reversible by fluid and electrolyte therapy and insulin replacement; insulin arrests ketoacid production and allows ketoacids to be metabolized, which generates bicarbonate. Treatment of hypovolemia improves tissue perfusion and renal function, thereby increasing the excretion of organic acids. Controlled trials have not shown a clinical benefit from bicarbonate administration.²⁶² Concern regarding the therapeutic administration of bicarbonate centers on four considerations: shifting the hemoglobin-oxygen dissociation curve to the left may diminish the release of oxygen to tissues and predispose to lactic acidosis; bicarbonate administration accelerates the entry of potassium into cells and may cause hypokalemia²⁶³; provision of bicarbonate according to the calculated base deficit overcorrects and may result in alkalosis; and bicarbonate may lead to paradoxical worsening of cerebral acidosis (and cause cerebral depression) during the time when the plasma pH is being restored to normal because HCO_3^- combines with H^+ ; H_2CO_3 then dissociates to CO_2 and H_2O . Whereas HCO_3^- slowly crosses the blood-brain barrier, CO_2 diffuses freely, thereby potentially exacerbating cerebral acidosis.²⁶⁴

Severe acidosis decreases respiratory minute volume, may cause hypotension by peripheral vasodilation, impairs myocardial function, and may cause insulin resistance. For these reasons, bicarbonate administration may be beneficial in the rare patient with life-threatening hyperkalemia or unusually severe acidosis (vpH <6.9) and compromised cardiac contractility.²⁶⁵ If bicarbonate is considered necessary, cautiously give 1 to 2 mmol/kg over 60 minutes. Bicarbonate must not be given by bolus infusion because it may precipitate cardiac arrhythmias.

Transition to Subcutaneous Insulin Injections

The transition to SC insulin and introduction of oral fluids should occur when substantial clinical improvement has occurred and DKA has resolved. Absence of ketonuria should not be used as an endpoint for determining resolution of DKA and clinicians must appreciate that persistent ketonuria

for 1 or more days may not reliably reflect the clinical improvement and should not be interpreted as evidence of a poor therapeutic response. Measurement of urine ketones with test strips (based on chemical reaction with nitroprusside), which measure acetoacetate and acetone (produced by nonenzymatic decarboxylation of acetoacetate) but not BOHB. The usual ratio of BOHB to acetoacetate is approximately 3:1 or 4:1 during fasting, but is commonly greater than or equal to 8:1 in DKA. With correction of acidosis, BOHB is oxidized to acetoacetate and persistent ketonuria typically occurs for several hours after serum BOHB levels have returned to normal.²⁰⁸

When ketoacidosis has resolved, oral intake is tolerated, and the change to SC insulin is planned, a dose of basal (long- or intermediate-acting) insulin should be administered in addition to rapid- or short-acting insulin. There may be benefits to earlier administration of a dose of long-acting insulin while the patient is still receiving IV insulin infusion. For example, in one study, 0.3 U/kg of SC insulin glargine was given in the first 6 hours of management and led to faster resolution of DKA.²⁶⁶ Another retrospective uncontrolled study showed that coadministration of insulin glargine (approximately 0.4 U/kg) early in the course of DKA treatment was well tolerated, did not increase the risk of hypoglycemia, but was associated with more frequent hypokalemia.²⁶⁷ To prevent rebound hyperglycemia, the first SC injection should be given 15 to 30 minutes (with rapid-acting insulin) or 1 to 2 hours (with regular insulin) before stopping the insulin infusion to allow sufficient time for the insulin to be absorbed. The blood glucose level should be monitored before and 2 hours after each meal, and the insulin dose adjusted to maintain blood glucose concentration in the range of 80 to 180 mg/dL. The specific insulin regimen, dose, and type of SC insulin should be according to local preferences and circumstances (see section Insulin Therapy).

The essential steps in managing DKA are summarized in Boxes 21.3 and 21.4.

Cerebral Edema

Although most patients appear to recover uneventfully from an episode of DKA, clinically overt cerebral edema manifesting as an abrupt decline in neurological status occurs in 0.5% to 1% of all episodes of DKA and is the major cause of morbidity and mortality, accounting for 60% to 90% of all DKA deaths.^{268,269}

In a retrospective analysis involving almost 7000 episodes of DKA, the following risk factors were identified: low partial pressure of arterial carbon dioxide ($p\text{CO}_2$) and high serum urea nitrogen concentrations at presentation, and treatment with bicarbonate.²⁶⁸ In 5% of children, radiographically apparent cerebral edema was apparent before initiation of therapy,²⁶⁸ and in another study one in five episodes of cerebral edema was evident at initial presentation before any fluid or insulin therapy could have contributed to water accumulation in the brain.²⁷⁰ These biochemical risk factors may simply reflect the initial severity of biochemical derangements. Thus avoidance of DKA (especially in young children) by early recognition of the signs and symptoms of DM is currently the only way to prevent cerebral edema, and patients with the clinical and biochemical features described earlier require even more careful monitoring.

Despite treatment with hyperosmolar agents (see later), approximately 20% to 25% of patients die and 15% to 35% of survivors have permanent neurological disabilities.^{268–270}

BOX 21.4 Complications of Therapy

- Cerebral edema
- Hypokalemia
- Hyperchloremic acidosis
- Hypoglycemia
- Inadequate rehydration

BOX 21.3 A Synopsis of the Principles of Management of Diabetic Ketoacidosis

1. Confirm diagnosis

Obtain:

- Blood glucose
- Blood beta-hydroxybutyrate (BOHB)
- Serum electrolytes
- Blood gas analysis: venous pH, $p\text{CO}_2$, HCO_3^-

Consider:

- Urine microscopy/culture
- Chest radiograph
- Blood culture
- Throat culture
- Electrocardiogram

Indications for admission to an intensive care unit:

- $\text{pH} \leq 7.00$
- Age ≤ 2 years
- Unconscious
- Blood glucose ≥ 1000 mg/dL

2. Begin intravenous fluids.

- 10–20 mL/kg of 0.9% (normal) saline (NaCl) over 30–60 minutes

3. Reassess the patient: what precipitated this episode?

- Delayed diagnosis
- Infection
- Noncompliance
- Trauma

4. Follow protocol guidelines in Table 21.9. Begin insulin 0.05–0.1

U/kg/h with hour 2 of IV therapy as outlined in Table 21.9

5. Measure glucose every 2 hours; electrolytes and acid-base status every 2 to 4 hours for the first 24 hours

6. Continue treatment with IV insulin as long as acidosis persists.

When plasma glucose approaches 300 mg/dL (17 mM) add 5% glucose to IV fluid and consider reducing insulin to 0.05 U/kg/h

7. If acidosis is not improving despite fluids and insulin infusion of 0.1 U/kg/h, consider:

- Severe sepsis causing lactic acidosis and/or insulin degradation
- Error in preparing intravenous insulin or insulin dose

8. In children age < 10 years (and especially age < 5 years), anticipate possible clinical cerebral edema after 4 to 6 hours of treatment (see Table 21.10 for symptoms and signs)

9. If cerebral edema is clinically apparent:

- Reduce rate of IV fluid administration; adjust rate to ensure maintenance of normal blood pressure
- Give mannitol 0.5 to 1 g/kg IV over 10 to 15 minutes (3% hypertonic saline 2.5–5 mL/kg is an acceptable alternative)
- Repeat in 30 minutes if inadequate response
- Elevate the head of the bed to 30 degrees and keep head in midline position

Although most patients do not exhibit any obvious neurological decline during treatment of DKA, subtle alterations of neurological function are often detectable after recovery, including deficits in memory, attention, and intelligence quotient.^{271–274} Changes in cerebral morphology have also been demonstrated by magnetic resonance imaging (MRI).^{272,275,276}

The cause of cerebral edema is controversial. An earlier theory posited that rapid fluid administration, which abruptly reduces serum osmolality, results in osmotic brain swelling (cytotoxic edema), and many treatment protocols advocate slow rehydration with isotonic fluids.^{152,226,277} It has been observed, however, that the degree of cerebral edema that develops during DKA correlates with the degree of dehydration and hyperventilation at presentation, but not with initial osmolality or osmotic changes during treatment.²⁷⁸ More recent investigations have not shown associations between the rate of fluid administration and brain injury^{268,270} and a large multicenter prospective randomized controlled trial showed that neither the salt content of the hydrating fluid (0.45% vs. 0.9% saline) nor its rate of administration influenced the development of cerebral edema or affected neurocognitive outcomes.²¹⁶ Studies of children and rodent models have found similarities between DKA-related brain injury and ischemia-reperfusion injury: low cerebral blood flow and brain cell swelling, low levels of high-energy phosphates in the brain and elevated lactate levels during untreated episodes of DKA, and cerebral hyperemia and vasogenic edema during treatment of DKA.^{278–280} MRI studies have shown a decrease in the apparent diffusion coefficient after recovery, indicating more pericellular and not intracellular water during treatment.²⁸¹ In addition, symptomatic and even fatal brain injury has been reported to occur before initiation of treatment for DKA.²⁸² The severity of cerebral hypoperfusion per se is unlikely to be sufficient to cause brain injury; therefore other factors probably contribute. DKA is also known to be associated with marked increases in systemic inflammatory cytokines and chemokines that may contribute to brain injury by activating cerebrovascular endothelia and increase leukocyte adhesion^{283–287}; and increased levels of metalloproteinase may promote blood-brain barrier dysfunction.²⁸⁷ A current alternative hypothesis posits that cerebral hypoperfusion (from dehydration and hyperventilation) and the effects of reperfusion together with neuroinflammation and cerebrovascular endothelial dysfunction are primarily involved in causing DKA-related brain injury.^{268,281,283,288,289} A prolonged duration and more severe biochemical derangements before therapy may predispose to cerebral ischemia. Younger children would be more prone because of the higher metabolic rate and oxygen requirement of a child's brain relative to an adult's brain. In addition, there may be a longer time for idiogenic osmoles to accumulate in the brain. An unexplained conundrum is that many children have evidence of raised intracranial pressure on imaging studies (e.g., computed tomography or MRI) consistent with subclinical cerebral edema frequently associated with mild mental status abnormalities, but only a minority develop clinically overt cerebral edema.^{290,291}

Clinically significant cerebral edema usually becomes apparent within the first 12 hours after therapy has started and when there has been improvement in blood glucose level, acid-base status, and state of hydration, but can be present at initial presentation or, rarely, 24 to 48 hours after the start of treatment.^{268,292,293} A previously alert patient may become drowsy, complain of severe headache, develop abnormal neurological findings, progress to coma, and have respiratory arrest with herniation of the brainstem. A constellation of bedside

TABLE 21.10 A Method of Clinical Diagnosis of Cerebral Edema Based on Bedside Evaluation of Neurologic State²⁹⁴

Diagnostic Criteria	Major Criteria	Minor Criteria
<ul style="list-style-type: none"> Abnormal motor or verbal response to pain Decorticate or decerebrate posture Cranial nerve palsy (especially III, IV, VI) Abnormal neurogenic respiratory pattern (grunting, tachypnea, Cheyne-Stokes respiration, apnea) 	<ul style="list-style-type: none"> Altered mentation/fluctuating level of consciousness Sustained heart rate deceleration (more than 20 bpm) not attributable to improved intravascular volume or sleep) Age-inappropriate incontinence^a 	<ul style="list-style-type: none"> Vomiting Headache Lethargy or being not easily aroused from sleep Diastolic blood pressure >90 mmHg Age <5 years

Signs that occur before treatment should not be considered in the diagnosis of cerebral edema. One diagnostic criterion, two major criteria, one major and two minor criteria have a 92% sensitivity and specificity of 96% (false positive rate 4%).

^aRapidly increasing serum sodium concentration suggests loss of free water in the urine from diabetes insipidus (consider that it may have been caused by interruption of blood flow to the pituitary gland because of cerebral herniation).

clinical observations may facilitate the recognition of developing cerebral edema (Table 21.10).²⁹⁴ Although useful, it should be noted that the criteria proposed by Muir and colleagues have not been independently corroborated.

Survival and neurological outcome are markedly improved with prompt recognition and intervention with mannitol or hypertonic saline, respiratory support by means of endotracheal intubation, and hyperventilation. Greater awareness, early recognition, and prompt treatment account for the reported decline in mortality²⁹⁵ (see Table 21.10 and Box 21.5).

BOX 21.5 Other Uncommon or Rare Causes of Morbidity and Mortality Associated With Diabetic Ketoacidosis

- Hypocalcemia, hypomagnesemia
- Severe hypophosphatemia
- Hypochloremic alkalosis
- Central nervous system complications: dural sinus thrombosis, basilar artery thrombosis, intracranial hemorrhage, cerebral infarction
- Venous thrombosis
- Pulmonary embolism
- Sepsis
- Rhinocerebral or pulmonary mucormycosis
- Aspiration pneumonia
- Pulmonary edema
- Adult respiratory distress syndrome (ARDS)
- Pneumothorax, pneumomediastinum, and subcutaneous emphysema
- Rhabdomyolysis
- Ischemic bowel necrosis
- Acute kidney injury including renal failure
- Acute pancreatitis

Treatment of Hyperosmolar Hyperglycemic Syndrome

The goal of initial fluid therapy is to expand the intra- and extravascular volume and restore normal renal perfusion. During therapy decreasing serum osmolality (from increased glucosuria and insulin-mediated glucose uptake) causes movement of water out of the intravascular space resulting in decreased intravascular volume; pronounced osmotic diuresis may continue for many hours in patients with extremely increased plasma glucose concentrations. Early in the course of treatment of HHS, urinary fluid losses may be considerable and, because intravascular volume may decrease rapidly, the rate of fluid replacement should be more rapid than is recommended for DKA to prevent vascular collapse. The initial bolus should be 20 mL/kg or more of isotonic saline (0.9% NaCl) and a fluid deficit of approximately 12% to 15% of body weight should be assumed. Additional fluid boluses should be given rapidly, if necessary, to restore adequate tissue perfusion. Thereafter, 0.45% to 0.75% NaCl should be administered to replace the deficit over 24 to 48 hours aiming for a gradual decline in corrected serum sodium concentration and serum osmolality. Because isotonic fluids are more effective in maintaining circulatory volume, isotonic saline should be restarted if perfusion and hemodynamic status appear inadequate as serum osmolality declines. Serum sodium concentrations should be measured frequently and the sodium concentration in IV fluids adjusted to promote a gradual decline in corrected serum sodium concentration. Mortality has been associated with failure of the corrected serum sodium concentration to decline with treatment, which may be an indication for hemodialysis.¹⁸⁷

Although there are no data to indicate an optimal rate of decline in serum sodium concentration, 0.5 mmol/L per hour has been recommended for hypernatremic dehydration.²⁹⁶ With adequate rehydration alone (i.e., before commencing insulin therapy), serum glucose concentrations should decrease by 4.1 to 5.5 mmol/L (75–100 mg/dL) per hour.^{297,298} A more rapid rate of decline in serum glucose concentration is typical during the first several hours of treatment when an expanded vascular volume leads to improved renal perfusion. If there is a continued rapid fall in serum glucose (>5 mmol/L, 90 mg/dL per hour) after the first few hours, consider adding 2.5% or 5% glucose to the rehydration fluid. Failure of the expected decrease of plasma glucose concentration should prompt reassessment and evaluation of renal function. Unlike treatment of DKA, replacement of urinary losses is recommended.²⁴⁰ The typical urine sodium concentration during an osmotic diuresis approximates 0.45% saline; however, when there is concern about the adequacy of circulatory volume, urinary losses may be replaced with a fluid containing a higher sodium concentration.

Insulin Therapy

Whereas tissue hypoperfusion in HHS commonly causes lactic acidosis, ketosis usually is minimal and early insulin administration is unnecessary. Fluid administration alone causes a marked decline in serum glucose concentration as a result of dilution, improved renal perfusion leading to increased glucosuria, and increased tissue glucose uptake with improved circulation. The osmotic effect of glucose within the vascular space contributes to the maintenance of blood volume; therefore a rapid fall in serum glucose concentration and osmolality after insulin administration may lead to circulatory compromise and venous thrombosis unless fluid replacement is adequate. Patients with HHS also have extreme potassium deficits; a rapid insulin-induced shift of potassium to the intracellular space can

trigger an arrhythmia. Insulin administration should be initiated when or if serum glucose concentration is no longer declining at a rate of at least 3 mmol/L (~50 mg/dL) per hour with fluid administration alone. In patients with more severe ketosis and acidosis, however, insulin administration should be initiated earlier. Continuous administration of insulin at a rate of 0.025 to 0.05 U/kg/h can be used initially, with the dosage titrated to achieve a decrease in serum glucose concentration of 3 to 4 mmol/L (~50–75 mg/dL) per hour. Insulin boluses are not recommended.

Electrolytes. Deficits of potassium, phosphate, and magnesium are also greater in HHS than in DKA. Potassium replacement (40 mmol/L) should begin as soon as serum potassium concentration is within the normal range and adequate renal function has been confirmed. Higher rates of potassium administration may be necessary after starting an insulin infusion. Serum potassium concentrations should be monitored every 2 to 3 hours along with electrocardiographic monitoring. Hourly potassium measurements may be necessary if the patient has hypokalemia. Bicarbonate therapy is contraindicated; it increases the risk of hypokalemia and may adversely affect tissue oxygen delivery. Severe hypophosphatemia may lead to rhabdomyolysis, hemolytic uremia, muscle weakness, and paralysis. Although administration of phosphate is associated with a risk of hypocalcemia, an IV solution that contains a 50:50 mixture of potassium phosphate and another potassium salt (potassium chloride or potassium acetate) generally permits adequate phosphate replacement while avoiding clinically significant hypocalcemia. Serum phosphate concentrations should be measured every 3 to 4 hours. Patients with HHS frequently have large magnesium deficits, but there are no data to determine whether replacement of magnesium is beneficial. Replacement of magnesium should be considered in the occasional patient who experiences severe hypomagnesemia and hypocalcemia during therapy. The recommended dose is 25 to 50 mg/kg per dose for 3 to 4 doses given every 4 to 6 hours with a maximum infusion rate of 150 mg/min and 2 g/h.

Complications. Venous thrombosis associated with use of central venous catheters is a common complication in HHS.²⁹⁹ Prophylactic use of low-dose heparin has been suggested in adults, but there are no data to indicate benefit from this practice. Heparin treatment should be reserved for children who require central venous catheters for physiological monitoring or venous access and are immobile for more than 24 to 48 hours.¹⁴⁵ Rhabdomyolysis (myalgia, weakness, and dark urine) may occur in children with HHS resulting in acute kidney failure, severe hyperkalemia, hypocalcemia, and muscle swelling causing compartment syndrome.³⁰⁰ Monitoring creatine kinase concentrations every 2 to 3 hours is recommended for early detection. For unknown reasons, several children with HHS have had clinical manifestations consistent with malignant hyperthermia, a condition associated with a high mortality rate.^{301–303} Patients with a fever associated and a rise in creatine kinase concentrations may be treated with dantrolene, which reduces release of calcium from the sarcoplasmic reticulum and stabilizes calcium metabolism within muscle cells. Nonetheless, of the three reported patients with HHS treated with dantrolene only one survived.^{301,303} Altered mental status is common when serum osmolality exceeds 330 mOsm/kg; however, cerebral edema is rare. Among 96 cases of HHS reported in the literature in 2010, including 32 deaths, there was only one instance of cerebral edema.¹⁸⁷ A decline in mental status after hyperosmolality has improved with treatment is unusual and should be promptly investigated.

BOX 21.6 Principles of Management of Hyperosmolar Hyperglycemic State

- Rapidly infuse isotonic saline (0.9% NaCl) ≥ 20 mL/kg
- Assume a fluid deficit of 12% to 15% of body weight
- If necessary, additional fluid boluses should be given rapidly, to restore peripheral perfusion
- Thereafter, use 0.45% to 0.75% NaCl and aim to replace fluid deficit over 24 to 48 hours
- Start insulin infusion when plasma glucose is no longer declining ≥ 50 mg/dL per hour with fluid alone
- In patients with mixed HHS and DKA, initiate insulin earlier
- IV insulin at 0.025 to 0.05 U/kg/h; titrate dosage to achieve a decrease in plasma glucose of around 50–75 mg/dL/h
- Begin potassium replacement (40 mmol/L) as soon as serum potassium concentration is within normal range and adequate renal function has been established

DKA, Diabetic ketoacidosis; *HHS*, hyperglycemic hyperosmolar state.

Mixed Hyperosmolar Hyperglycemic Syndrome and Diabetic Ketoacidosis

Treatment must take into consideration potential complications of both DKA and HHS. Mental status must be closely monitored and frequent reassessment of circulatory status and fluid balance is absolutely necessary to guide therapy. To maintain an adequate circulatory volume, the rate of fluid and electrolyte administration usually exceeds that required for the typical case of DKA. Insulin is essential to resolve ketosis and arrest hepatic gluconeogenesis; however, insulin infusion should be deferred until after the patient has received an initial fluid bolus and the circulation has been stabilized. Serum potassium and phosphate concentrations should be carefully monitored as described earlier for HHS (Box 21.6).

TREATMENT OF TYPE 1 DIABETES MELLITUS

General Principles

Optimal management of the child with T1DM (and T2DM) requires an integrated approach, taking into account the overall level of functioning of the child and family, the nutritional and lifestyle patterns specific to that child, and attention to the overall developmental stages of childhood and adolescence. There is no one appropriate insulin regimen or meal plan. The overriding principle should be that the diabetes care plan should fit wherever possible into the surrounding home and school environments, and that the primary childhood tasks of education, socialization, growth, and maturity continue unhindered by the extra responsibilities that diabetes care entails.

This daunting task of assisting families in managing diabetes is best accomplished by a multidisciplinary team, consisting of physicians, nurse educators and practitioners, dietitians, and mental health professionals, all trained and experienced in the nuances of diabetes care in children. Children with diabetes should be seen by the team at frequent intervals (usually every 3 months in established patients) for assessment of glycemic control, growth, and development; evaluation for related disorders and complications; education; troubleshooting; problem-solving; and screening for adjustment problems that may affect diabetes or the overall health of the child.

Goals of Therapy

The Diabetes Control and Complications Trial (DCCT) established that intensive glycemic management leading to near-normal glucose and A1c levels significantly reduced the risk of developing long-term complications and the benefits of this reduced risk outweighed the threefold increase in the risk of severe hypoglycemia.³⁰⁴ Slowing the development of early retinopathy was observed in the DCCT subgroup of intensively treated adolescents, as well as in adults in the study.³⁰⁵ In the Epidemiology of Diabetes Interventions and Complications (EDIC) Study, the observational follow-up to the DCCT, a continued increase in risk of complications was seen in the former conventional treatment group years after the end of the randomized controlled trial despite improved metabolic control in the former conventional treatment group, indicating that near normal glucose and A1c levels should be achieved and maintained in patients with T1DM as early in the course of the disease as possible.³⁰⁶ As a result of this evidence, current recommendations mandate that youth with T1DM should aim to achieve plasma glucose and HbA1c levels as close to normal as possible, as early in the course of the disease as possible, and with as few severe hypoglycemic events as possible.

With respect to specific targets, the ADA treatment guidelines indicate that HbA1c targets should be less than 7.5%¹ and the International Society of Pediatric and Adolescent Diabetes (ISPAD) lowered this to under 7%,³⁰⁷ although both sets of guidelines emphasize individualizing targets for patients and families to also minimize hypoglycemia and enhance quality of life. Previously, higher HbA1c levels were suggested for very young children because of the potential risk of recurrent hypoglycemia on the developing brain. There are many problems with this approach, including increasing evidence that chronic hyperglycemia is also detrimental to the developing brain³⁰⁸ and that lower HbA1c can be achieved without increased risk of severe hypoglycemia in children younger than 6 years of age.³⁰⁹

Types of Insulin

Currently available insulins are classified based on their duration of action as rapid, short, intermediate, and long-acting, and each is available in a concentration of 100 U/mL (U-100). A higher concentration (U-500) of human regular insulin is available for the patient who has severe insulin resistance. Appropriate dilutions can be prepared for younger patients requiring low doses. The development of recombinant DNA technology to synthesize human insulin and human insulin analogs has changed the face of insulin treatment.

The aim of insulin replacement therapy is to simulate the normal pattern of insulin secretion as closely as possible (Fig. 21.11). This aim can best be achieved through the use of basal-bolus therapy using MDI or continuous subcutaneous insulin infusion (CSII) pump therapy. Until recently, options for insulin formulations were limited. Today, there are more than 10 varieties of biosynthetic human and analog insulins, including human regular insulin, human neutral protamine Hagedorn (NPH) insulin, long-acting insulin analogs, rapid-acting insulin analogs, and several kinds of premixed insulins (see Table 21.11).

Human Regular Insulin

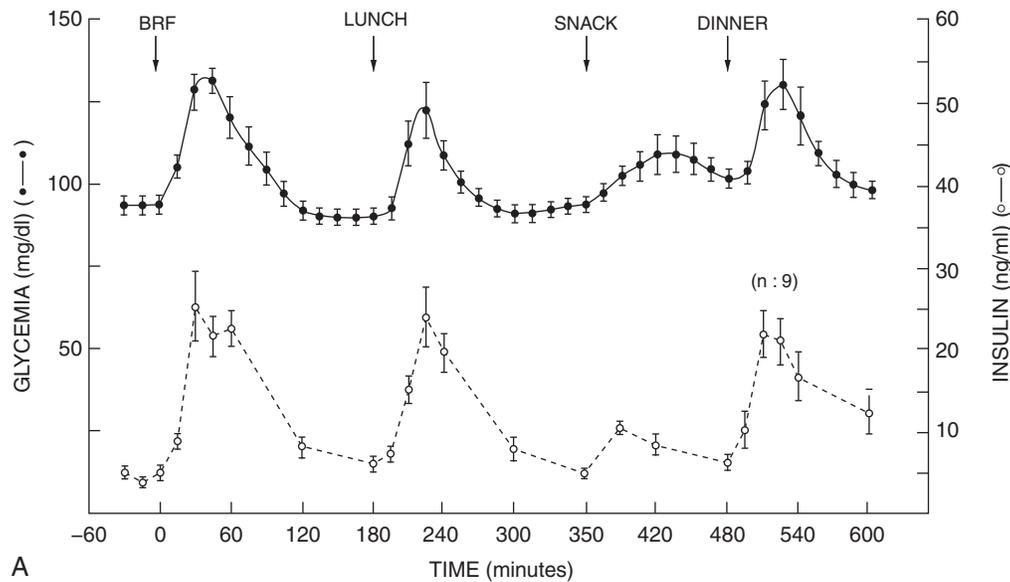

Human regular insulin was a mainstay of insulin management of youth with T1D until the early 2000s when the advent of rapid-acting insulin analogs virtually eliminated its use in children and adolescents, except for IV administration. The delayed absorption and prolonged duration of action of the large

premeal bolus doses of regular insulin that are required by adolescents with T1D to overcome the insulin resistance of puberty contributed to problems with hyper- and hypoglycemia in this age group.³⁰⁵ Regular insulin remains the insulin of choice for IV infusion in the treatment of DKA. A special U-500 (500 units/mL) formulation of regular insulin is available for use in patients with severe insulin resistance who require very large daily doses of insulin.

Rapid-Acting Analogs

Lispro (Eli Lilly), aspart (Novo Nordisk), and glulisine (Sanofi) insulins are produced by amino acid substitutions in the C-terminal region of the B chain that reduce the affinity of insulin molecules to self-aggregate into hexamers. These modifications allow more rapid absorption of the analog into the bloodstream after subcutaneous injection. A new fast-acting

insulin, Fiasp (Fast insulin aspart, Novo Nordisk) has recently been approved for use in children. Compared with regular insulin, the faster absorption of rapid-acting analogs results in higher and sharper peaks and shorter duration of action, pharmacokinetic and pharmacodynamic effects that reduce the risk of late postprandial hypoglycemia and temper early postmeal hyperglycemia.^{310,311} Puberty does not appear to alter the pharmacokinetics of premeal boluses of rapid analogs, but the insulin resistance of puberty reduces the ability of these insulins to stimulate glucose metabolism.³¹² Rapid-acting insulin may be safely mixed with intermediate-acting insulins, but mixing with long-acting insulin is not recommended, as such mixing markedly attenuates the peak action of the rapid-acting analog.^{313,314} All three rapid-acting analogs may be used in an insulin pump, and studies have shown them to be safe and effective.^{315,316} Lispro and aspart insulin may be diluted to concentrations less than U-100, such as U-50 or U-25, using diluents obtained from

A Pharmacokinetic profiles of human insulin and insulin analogs

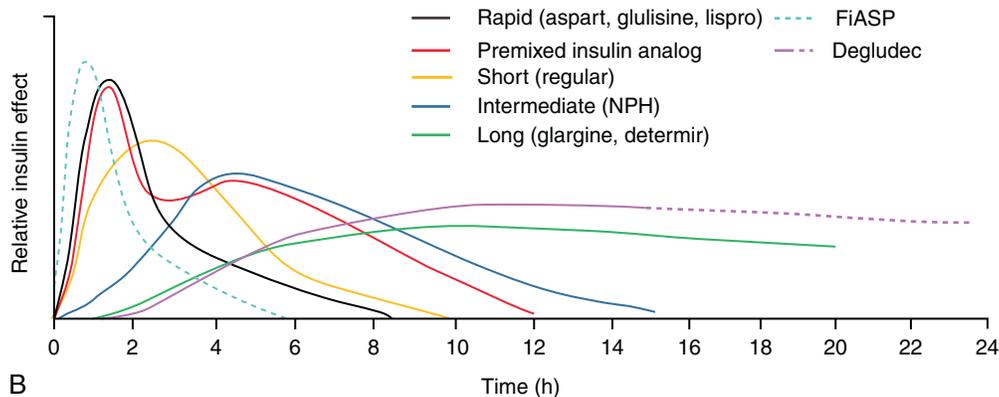

Fig. 21.11 A, Representation of the normal relationships among food intake, blood glucose, and serum insulin concentration. Note that glucose concentration is maintained between 80 and 140 mg/dL. Note also the precise release of insulin that has passed through the portal circulation synchronous with and proportional to the food-induced glycemic excursions. Compare and contrast these patterns with the time pattern of insulin action after subcutaneous injection of aspart/glulisine/lispro, regular, NPH, and glargine/detemir insulins. B, pharmacokinetic profiles of human insulin and its analogs. The pharmacokinetic profiles of several currently used insulin preparations are schematically presented. The fast insulin aspart (FiASP) and long-acting analog (Degludec) have been manually inserted consistent with currently available data. These figures are illustrative of and correspond with the time frames in Table 21.11. (B, Modified from Brunton, S.A. (2013). Integrating advances in insulin into clinical practice. *J Fam Pract.* 62(9 Suppl Insulin), S2-S18).

TABLE 21.11 Types of Insulin Preparations and Suggested Action Profiles for Subcutaneous Administration

Insulin Type	Onset of Action (h)	Peak of Action (h)	Duration of Action (h)
Ultrarapid acting analog (faster aspart) ^{a,c}	0.1–0.2	1–3	3–5
Rapid-acting analogs (aspart, glulisine, and lispro)	0.15–0.35	1–3	3–5
Regular/soluble (short acting)	0.5–1	2–4	5–8
NPH	2–4	4–12	12–24 ^a
Basal long-acting analogs			
Glargine ^b	2–4	8–12	22–24 ^a
Detemir	12	4–7	20–24 ^a
Glargine U300	2–6	Minimal peak	30–36
Degludec ^c	0.5–1.5	Minimal peak	>42

NPH, Neutral protamine Hagedorn insulin. All insulins used must be produced under “Good Manufacturing Practice/Good Laboratory Practice” conditions.

^aThe duration of action may be shorter.

^bBiosimilar glargine approved in some countries.

^cNot yet approved worldwide or not for pediatric indication.

(From Danne, T., et al. (2018). ISPAD Clinical Consensus Guidelines 2018: Insulin treatment in children and adolescents with diabetes. *Pediatr Diabetes*, 19(Suppl. 27), 115–135.)

the manufacturer. Diluted insulin is used in very young children and others who are sensitive to insulin and could benefit from the more accurate dosing. Rapid-acting insulin analogs can be given IV, but they have not been shown to be superior to regular insulin.³¹⁷ A newer insulin analog is Fiasp, which has a slightly faster onset of action and peak and shorter duration of action.^{318,319}

Intermediate-Acting Insulin

NPH is now the only available intermediate-acting insulin. Although the delay in peak action of NPH given before breakfast provides a means to cover lunchtime glucose excursions, NPH is less than satisfactory for overnight basal insulin replacement.³²⁰ As with regular insulin, the advent of long-acting insulin analogs has largely replaced NPH in basal-bolus MDI treatment in pediatrics. However, NPH is still an effective, intermediate duration insulin, particularly useful in special circumstances, such as poor adherence and in those who may be less economically affluent.

Long-Acting Insulin Analogs

Glargine (Lantus manufactured by Sanofi) and detemir (Levemir manufactured by Novo Nordisk) were the first two commercially available long-acting insulin analogs developed to meet the body’s basal insulin requirements for regulating hepatic glucose production. Insulin glargine is an analog of human insulin with C-terminal elongation of the beta chain by two arginine residues and replacement of asparagine in position A21 by glycine. This analog is soluble in the acidic solution in which it is packaged but relatively insoluble in the physiological pH of the extracellular fluid. Consequently, microprecipitates of glargine insulin are formed following subcutaneous injection, which markedly delays its absorption into the systemic circulation. The action of insulin detemir is prolonged by the addition of a fatty acid side chain that promotes reversible binding with albumin in the interstitial fluid and in the circulation.

Pharmacokinetic and pharmacodynamic studies have demonstrated that these long-acting insulin analogs have flat and

prolonged time-action profiles. However, compared with glargine, detemir has been shown to have a more consistent pharmacokinetic profile in children and a more consistent pharmacodynamic profile in adults with T1DM.^{321,322} Basal insulin replacement with insulin detemir is more frequently likely to require two daily injections than treatment with insulin glargine.

Insulin degludec is a new, ultralong-acting insulin that is a product of coupling of Des-B30 threonine insulin to fatty acid side chains. After injection, degludec self-associates, forming long chains of insulin that dissociate very slowly. Plasma insulin levels rise reaching peak concentrations 10 to 12 hours after an injection and the half-life is between 17 to 21 hours, roughly double the duration of action of insulin glargine. Degludec has been shown to be safe and effective in children and adolescents with T1DM.³²³

Premixed Insulin

Various premixed insulin formulations, combining either rapid-acting insulin analogs or regular insulin with NPH or intermediate-acting insulin analogs, are currently available. The percentage of rapid acting/regular to intermediate acting varies with the formulation. The practical advantage of premixed insulins to cover both short- and intermediate-term insulin needs in a single shot is also their greatest limitation. There is less flexibility when using premixed insulin for adjusting the individual insulin components, and this can be particularly problematic in young children or those with variable food intake. Use of premixed insulin has been generally limited to patients and families who have difficulties managing more complicated treatment regimens or in resource limited settings.³²⁴

Syringes Versus Pens

Insulin syringes come in a variety of sizes that are particularly useful in young children. In addition to the traditional 100-unit (1-mL) syringe marked in 2-unit increments, 50-unit (0.5-mL) and 30-unit (0.3-mL) syringes are available that are marked in single-unit increments, and 30-unit syringes with 1/2-unit markings can also be ordered. These syringes are available with needle lengths from 8 to 13 mm. Insulin pens are also available, both as disposable pens and reusable pens with disposable cartridges. Half-unit dosing is available and may be useful in smaller children.

Initiating Insulin Therapy

Most newly diagnosed patients who present with symptoms of diabetes or are in DKA require upward of 1 U/kg/day at the start of insulin treatment. For asymptomatic patients who are “incidentally” diagnosed with diabetes, for example, during a routine sports physical examination or a well-child examination, starting doses may only need to be around 0.5 U/kg/day or less. The goal of initial insulin therapy in children with T1D should be to achieve near normoglycemia over the first few weeks of treatment to give the child the opportunity to enter the “honeymoon,” or partial remission phase. The honeymoon period results from a combination of improved function of residual beta cells and reversal of the insulin resistance that accompanies uncontrolled diabetes. Prompt achievement of optimal control rather than the methods used to achieve good control appears to be the most important factor in obtaining these outcomes.³²⁵ The ability to achieve target A1c levels with little or no severe hypoglycemia is greatly enhanced in T1D patients with residual beta-cell function.³²⁶

Some centers admit all newly diagnosed patients to the hospital for initial diabetes education and insulin dose titration, but others have effective outpatient treatment protocols. During the 2 to 3 weeks following discharge, insulin doses are titrated toward target premeal glucose values of 70 to 130 mg/dL during

daily telephone contact; patients are seen in follow-up clinic visits, approximately 2, 6, 13, 26, 39, and 52 weeks following diagnosis.

INSULIN REGIMENS

Plasma insulin levels in nondiabetic individuals are characterized by relatively low basal levels on which are superimposed meal-stimulated spikes in insulin concentrations. Current intensive treatment regimens attempt to simulate this pattern of plasma insulin fluctuations by using a basal-bolus approach to insulin replacement. Because exogenous insulins are injected or infused subcutaneously rather than directly into the portal vein, their rates of absorption may vary. Also the dose that is injected is determined empirically, so it lacks the precision of endogenously secreted insulin. Thus no insulin replacement regimen will precisely duplicate the pattern of normal insulin secretion; there will be periods of increased plasma insulin concentrations that may produce hypoglycemia and periods of low insulin levels that lead to hyperglycemia. Therefore the goal of current insulin regimens is to minimize the frequency and severity of excursions into the hyper- and hypoglycemic range.

The DCCT and its follow-up, the EDIC studies, established basal-bolus therapy using either MDI or CSII as the gold standard of treatment of T1D. However, insulin only works if the youngster receives it, and other factors must be addressed when determining the best insulin regimen for an individual patient. These factors include the availability of an adult parent/guardian to supervise insulin administration, the ability to count carbohydrates and monitor glucose levels with a glucose meter or a continuous glucose monitor (CGM), and the willingness to wear a pump or take four or more injections of insulin daily.

Multiple Daily Injection Regimens

MDI regimens attempt to replicate normal insulin secretion through the use of a long-acting insulin analog to replace basal insulin needs along with bolus injections of rapid-acting insulin analog to cover food intake and to correct elevations in blood glucose levels. Either once or twice daily basal insulin coverage may be used. Typically, basal insulin accounts for approximately 40% to 50% of the insulin total daily dose (TDD). However, children younger than 5 years of age often require basal insulin doses that are 30% to 40% of TDD, and there is considerable variability between patients. Once-daily glargine or detemir may be given either in the morning or in the evening. Patients treated with detemir may be more likely to need twice-daily injections than those treated with glargine. Some pediatric practitioners mix long- and rapid-acting insulin to reduce the number of injections, but studies indicate that such mixing markedly blunts and delays the absorption and action of the rapid-acting insulin component of the mixture.^{313,314}

Any one of the rapid-acting insulin analogs may be used to cover bolus insulin needs. Ideally, the rapid-acting insulin bolus is given 10 to 15 minutes before eating, but this is a difficult goal to achieve in many youths with T1D. For the most precise dosing of bolus insulin, it is necessary to use an insulin-to-carbohydrate ratio (ICR) and insulin sensitivity or correction factor, as well as the rate and direction of change in sensor glucose levels in patients using continuous glucose monitoring devices. The ICR is defined as the grams of carbohydrate that 1 unit of insulin will cover. This ratio may be determined using the 500 rule, namely, dividing 500 by the TDD will give a starting point for the carbohydrate ratio. For example, in a teenager with a TDD of 50 units, 1 unit of insulin will cover 10 grams of carbohydrate ($500/50 = 10$). It should also be noted that the ICR frequently differs by time of day because

more insulin is often needed per gram of carbohydrate before breakfast and less may be given to cover bedtime snacks. These are intended as guides to then individualize insulin dosing based on glucose results. Accuracy in determining the carbohydrate content of meals is of utmost importance but often a problem in adolescents. Teens tend to underestimate the number of carbohydrates in their meal, and refresher meetings with a dietitian can reinforce the importance of maintaining mastery of this skill. Also carbohydrates are not the sole source of nutrients that require insulin for optimum metabolism; formulas exist for adjusting insulin requirements for protein and fat content.³²⁷ In addition to meal coverage, a correction dose of rapid-acting insulin should be given at meal times to “fix” an elevated blood glucose level. Correction doses may also be given at other points in the day for the same reason. Traditional “sliding scale” insulin doses based on blood glucose levels have given way to more sophisticated dosing algorithms based on an insulin sensitivity factor (ISF); namely, how much will blood glucose be lowered by 1 unit of insulin. The ISF may be determined using the 1800 rule: divide 1800 by the TDD. The correction dose can then be calculated according to the following equation:

$$\frac{(\text{Actual blood glucose (BG)} - \text{Target BG})}{\text{ISF}} = \text{Number of units of insulin}$$

No matter how they are initially calculated, ICRs and ISFs are subsequently adjusted based on glucose monitoring results.

Particular advantages of basal-bolus MDI regimens are that they try to mirror the physiological model of insulin secretion, increase flexibility in the timing and size of meals, and provide more opportunities to “course correct” throughout the day in response to abnormal glucose excursions. A particular disadvantage of these regimens is that they require a large number of daily injections. Indeed, because of the flat time-action profile of the long-acting basal insulin analogs, basal-bolus MDI treatment puts a premium on compliance with premeal bolus dosing. Without bolus doses of rapid-acting insulin, long-acting basal insulin alone cannot prevent marked postprandial hyperglycemia. However, strict adherence to premeal bolus dosing is difficult for teenagers with T1D, even when it is made as easy as possible to accomplish with an insulin pump. These are some of the reasons why mean A1c levels in pediatric patients, especially adolescents, with T1DM, remain well above the target levels recommended by the ADA and ISPAD (Box 21.7).³²⁸

Insulin Pump Therapy

CSII delivered by pumps of varying degrees of sophistication have become a standard means of treatment for children with diabetes. Some of the practical benefits of CSII compared with MDI are listed in Box 21.8. A specific risk of pump therapy is that prolonged accidental or purposeful interruption of insulin delivery over several hours can lead to the development of ketones and DKA because the patients are only receiving rapid-acting insulin.³²⁹ This risk can be reduced or eliminated by regular blood glucose testing and to facilitate blood glucose testing, a variety of devices have been developed. Linking these devices with pumps and algorithms led to the emergence of autoregulated insulin delivery systems, which are constantly improving and becoming incorporated into daily practice as detailed later.

A recent ISPAD guidelines chapter focuses on diabetes technology.³³⁰

Ideal candidates for pump therapy include motivated families who are committed to monitoring blood glucose at least 4 times per day and have a working understanding of basic diabetes management, especially carbohydrate counting and using ICR and ISF to calculate insulin doses.

BOX 21.7 Glycemia and Blood Glucose Target Recommendations

Target HbA1c	HbA1c <53 mmol/mol (<7.0%)		
Necessary elements for successful glycemic management	<ul style="list-style-type: none"> This target must be individualized with the goal of achieving a value as close to normal as possible while avoiding severe hypoglycemia, frequent mild to moderate hypoglycemia, and excessive stress/burden for the child with diabetes and their family Factors that must be considered when setting an individualized target include, but are not limited to: <ul style="list-style-type: none"> Access to technology, including pumps and CGM Ability to articulate symptoms of hypoglycemia and hyperglycemia History of severe hypoglycemia/hypoglycemic unawareness History of compliance with therapy Whether child is a high or low glyculator Whether child has continued endogenous insulin production (e.g., in the new onset or “honeymoon” period of diabetes) HbA1c measurements at least quarterly Glucose monitoring using CGM or self-monitored BG measurements up to 6 to 10 times per day Regular review of glucose values with therapy adjustments as necessary 		
Glycemic targets	NICE goal A1c	ISPAD goal A1c	ADA goal A1c
	≤ 48 mmol/mol (< 6.5%)	< 53 mmol/mol (<7%)	< 53 mmol/mol (7%)
Premeal	4.0–7.0 mmol/L (70–126 mg/dL)	4.0–7.0 mmol/L (70–130 mg/dL)	5.0–7.2 mmol/L (90–130 mg/dL)
Postmeal	5.0–9.0 mmol/L (90–162 mg/dL)	5.0–10.0 mmol/L (90–180 mg/dL)	
Prebed	4.0–7.0 mmol/L (70–126 mg/dL)	4.4–7.8 mmol/L (80–140 mg/dL)	5.0–8.3 mmol/L (90–150 mg/dL)

BOX 21.8 Practical Benefits of Continuous Subcutaneous Insulin Infusion

- Basal infusion rates adjustable up to every 30 minutes
- Programmable temporary basal rates
- Preprogrammable alternate basal rate profiles
- One site insertion every 2 to 3 days (versus many injections each day)
- Dose calculator
- Pump history functions and ability to upload data to data management systems
- Customizable square wave and dual wave boluses
- Ability to program temporary basal rates for sick days and during and after exercise
- Ability to deliver very small (0.025–0.05 units) doses of insulin

Most currently available insulin pumps are “smart” pumps into which both ICRs and ISFs are programmed to create a bolus calculator. Some pumps have the ability to receive and integrate blood glucose values into their bolus calculator through a wireless link with a specific blood glucose meter. Bolus doses can be administered over a few minutes or as square-wave and dual-wave boluses over a longer period of time. Ideally, bolus doses should be delivered 10 to 15 minutes before the meal to minimize postmeal excursions.³³¹ In young children and picky eaters, a small priming bolus of insulin can be given before the meal to cover glucose levels above the target

and the amount of carbohydrate that will be eaten reliably, followed by additional bolus doses depending on how many carbohydrates are actually consumed.

Basal insulin needs are covered by the rapid-acting insulin, which is delivered through a preprogrammed “basal pattern.” This pattern can be made up of multiple different rates, which allow for a waxing/waning pattern of basal insulin delivery. In addition, most pumps allow for multiple 24-hour basal patterns to be preprogrammed and stored in the memory. For example, some adolescents have a basal pattern for school days and one for weekends to account for their tendency to wake up much later on weekends and holidays. Finally, temporary changes can be made to the basal insulin pattern, which can be an effective tool for dealing with exercise or sick day management.

CSII-Based Treatment Regimens

Because of their increasingly important role in managing T1DM in childhood, a detailed description and discussion of pump therapy follows this section; [Box 21.8](#)¹² summarizes several key elements of pump therapy. Practical suggestions for starting sensor therapy are shown in [Box 21.9](#). Linking CSII therapy with implantable sensors constitutes an important step in establishing a “closed loop system” as detailed below.

The use of insulin pumps (CSII) has increased dramatically in children and adolescents with T1D since the 1990s. The T1D Exchange study group has reported that 33% of children younger than 6 years of age, 47% of children aged 6 to 12 years, 50% of adolescents aged 13 to 17 years, and 52% of patients aged 18 to 25 years used an insulin pump in the cohort of 20,555

BOX 21.9 Practical Suggestions for Starting Sensor Therapy**INITIAL TRAINING FOR INSERTION AND ADHERENCE**

- Sufficient time spent at initiation of sensor therapy
- Ensure adequate insertion technique
- Discuss the use of supplementary adhesive products:
 - Wipes: skin tac IV prep, skin prep
 - Dressings and barriers: tegaderm, IV-3000, hypafix (A US-trained Certified Diabetes Educator (CDE) should verify current brand names in the entire list)
 - External wraps: Coban, PreWrap
- Discuss the use of adhesive removers:
 - unisolve or detachol
 - ointments (baby oil)

CALIBRATION (IF REQUIRED)

- Discuss frequency of and ideal times for calibrations
 - Consider preemptive calibration schedule: encourage calibration three times a day (e.g., before breakfast, dinner and bedtime)
 - Discuss calibrating when glucose is relatively stable (no arrows present, no rapid change on sensor glucose graph)

ALERTS AND ALARMS

- Consider leaving alerts off at the start sensor therapy
- Personalize alerts and use wide thresholds at first (i.e., 70–250 mg/dL [3.9–13.9 mmol/L])
- Adjust over time:
 - with recurrent hypoglycemia, set low alert first
 - with suboptimal control, set high alert first
- Judiciously introduce rate of change or predictive alerts
 - suggest only those that will trigger active intervention by the user

REAL-TIME DATA

- Discuss nonadjunctive use of sensor data
- Discuss recommendations on insulin dose/behavioral adjustments based on sensor glucose values and trends
- Discuss data transfer to the “cloud”

RETROSPECTIVE REVIEW

- Encourage regular downloading and review of data
- Encourage insulin dose/behavioral modifications based on retrospective data reviews

participants (11,641 age <18 years) from the United States.³³² This is matched by the 44.4% of 16,570 children and adolescents from the international SWEET registry,³³³ and with many other countries in the European Union and Israel reporting similar insulin pump use in children and adolescents. Several tertiary pediatric centers report the use of insulin pumps as the predominant treatment modality in their pediatric population.³³⁴ CSII has several practical benefits over MDI, including programmable basal insulin rates with multiple basal rate profiles and the possibility of temporary basal rates, adjustable “dual-wave” boluses, same injection site over 2 to 3 days (versus MDI), dose calculators, and the possibility of data upload, all of which facilitate the day-to-day management of the disease.

The use of insulin pumps is associated with improved metabolic control, lower glycated hemoglobin, or less hypoglycemia in many,^{335,336} but not all,^{337–339} clinical trials. Large cohort studies, including several thousand pediatric patients, have described a significant correlation between better metabolic control and the use of insulin pumps.^{332,333} In addition, the quality of life assessed by the PedsQL-T1DM questionnaire is significantly associated with the use of insulin pumps,³³⁹ and preliminary data suggest better cognition, mood, and behavior.^{340,341}

Selection criteria for insulin pump therapy³⁴² in the pediatric patient population broadened as experience and data on its use accumulated.³³⁶ Commonly, poor glycemic control, frequent hypoglycemia, increased glucose variability regardless of HbA1c, compromised quality of life, and increased risk of chronic complications are listed. Self-blood glucose monitoring (SBGM) is still an important prerequisite, as is parental support. Young age, frequent SBGM, and lower HbA1c at pump initiation are associated with better long-term metabolic control.³⁴³ In many instances, particularly in economically developed countries, SBGM has been replaced by continuous glucose monitoring as detailed below. Conversely, female gender, age older than 10 years in girls, and poor metabolic control at pump initiation are associated with higher risk for attrition from insulin pump therapy.³⁴⁴ Interestingly, children with inadequate metabolic control on MDI may experience the highest decrease in their HbA1c when switched to an insulin pump.³⁴⁵ In preschool children, initiating the insulin pump therapy at the disease onset may help patients to maintain lower HbA1c for up to 8 years.³⁴⁶

Insulin pump therapy initialization is a structured multistep process involving the whole (extended) patient’s family and a diabetes team ideally including a pediatric endocrinologist, a pediatric diabetes nurse educator, a specialized dietitian, a child

psychologist, and a social worker. In addition, adequate training of day-care personnel, a nanny, or school personnel is of crucial importance.³⁴⁷

Basal Insulin Rates

A continuous sequence of small boluses approximately every 10 minutes of a short-acting insulin analog provides basal insulin required for suppressing liver gluconeogenesis and ketogenesis and maintaining basal normoglycemia. Age-specific daily patterns of basal rates differ considerably in dose and distribution.^{348,349} Because insulin resistance increases with age, so does the insulin dose. Although preschool children often need highest basal rates between 10 PM and 2 AM, this pattern changes as puberty approaches when the highest insulin requirement usually starts after 4 AM and lasts until wakeup.

When switching a patient from MDI to CSII, the total basal rate dose usually is calculated based on the previous dose of the long-acting insulin analog and is usually reduced by 10% to 20% if HbA1c was under 8%. Alternatively, the total daily insulin dose is reduced by 20% to 30% and then half is administered as the basal rate. Some clinicians calculate the basal rate dose arbitrarily as approximately 0.4 units of insulin per kilogram body weight, especially when the dose of the long-acting insulin analog or the total daily insulin dose when treated with injections was evidently not appropriate and achieved poor metabolic control.

Programming multiple basal rates in the pediatric population seems prudent, as this was associated with better metabolic control.³⁵⁰ Several initial approaches are used³⁵¹ with likely similar success, as basal rates should be subsequently verified and personalized. In infants and toddlers, a flat initial basal rate may be appropriate and tailored to individual need in the first week of insulin pump use. As modern insulin pumps can deliver as little as 0.025 units of insulin per hour, diluting insulin is rarely needed. Intermittent programming of 0 units of insulin per hour for shorter periods of up to 2 hours is sometimes used for neonates. A higher basal insulin rate will be needed around midnight with a lower rate applied in the afternoon. For older children and adolescents, the day may be divided into five parts: from midnight to 4 AM, covering the period with least basal insulin requirement, from 4 to 7 AM covering the dawn phenomenon period, from 7 AM to 1 PM covering the morning, from 1 to 8 PM covering the afternoon, and from 8 PM to midnight covering the evening.³⁵¹ Sometimes, an

additional time frame for the dusk phenomenon may be needed from 5 to 8 PM.³⁵² Several basal rate patterns may be needed for different situations: a standard pattern for regular weekdays, a weekend or leisure pattern with lower basal insulin rates during the morning (e.g., less stress from school or work or more activity), and a “sick days” basal rate pattern with 30% more insulin throughout the 24 hours.³⁵³

Verifying Basal Insulin Rate Settings

The ideal basal rate will keep the blood glucose levels within the desired range during fasting. The need for basal insulin changes with time and depends on insulin sensitivity that varies with age, lifestyle, growth, and several other fluctuating influences. Basal insulin rates can be best verified when food intake is omitted. The nighttime basal insulin rates may be verified first, as the overnight glucose concentration profile is usually of greatest concern. On an uneventful day after an early dinner (at 5–6 PM) that was meticulously covered by an appropriate bolus, SBGM is performed every 2 to 3 hours from 10 PM until wakeup. If the blood glucose changes for more than ± 40 mg/dL (2 mM), the basal rate approximately 1 hour before the blood glucose change is adjusted for $\pm 10\%$ to 20%. Similarly, a morning basal SBGM profile is performed after an uneventful night, skipping the breakfast and morning snack with SBGM every 2 to 3 hours until lunch. Finally, an afternoon basal SBGM profile is performed after an uneventful morning, skipping lunch, with SBGM every 2 to 3 hours until dinner. Basal insulin rates are adjusted as described for the night basal profile. If the blood glucose level falls below or above the usual range between 70 to 180 mg/dL, the condition is treated, the basal profile testing is discontinued, the basal rate is adjusted accordingly, and the basal rate SBGM profile retested in a couple of days. In preschool children basal rates can be verified in shorter time intervals, as only one meal per day can be omitted. Some verify basal profiles without omitting meals but rather after eating standardized small meals covered by appropriate boluses. CGM can be of obvious assistance and can reduce the frequency of SBGM. Frequent phone contacts with the diabetes team are prudent in the first weeks after insulin pump initialization to individually fine-tune basal insulin rates.³⁵³

Temporary Basal Rates and Basal Insulin Suspend

With little insulin in the body between boluses, reducing or stopping the basal insulin rate is an efficient way to prevent hypoglycemia during physical activity or sport.³⁵⁴ Smart pumps can show the amount of remaining insulin in the body after a bolus (so-called active insulin), which can be of considerable help in preventing exercise-associated hypoglycemia, as “active insulin” can be covered with additional carbohydrates.

Bolus Insulin Dosages

Careful and more frequent dosing of insulin for covering food and correcting high blood glucose levels is associated with better metabolic control when using insulin pumps.³⁵⁵ Modern insulin pumps can assist calculations of bolus insulin reducing errors³⁵⁶ and incorporating physiological variability of insulin sensitivity during the course of the day.

Bolus Insulin for Food Coverage

Principles of calculating boluses for food are same as for MDI, with the additional possibility of more precise dosing down to 0.025 units of insulin in some insulin pumps. Solid practical knowledge of carbohydrate counting is paramount. The arbitrary formula of 500 divided by the total daily insulin dose

for older children and adolescents (300 or 200 for preschool children or toddlers, respectively) can help in determining the initial ICR. The ICR can be higher (one unit of insulin covers fewer carbohydrates) in the morning, sometimes by 30% to 100% compared with midday, and slightly higher again in the evening. Bolus calculators are incorporated into modern pumps and do all required calculations based on preset ICRs, the current blood glucose, the planned amount of carbohydrate ingestion, and the glucose target range, typically between 70 and 120 mg/dL (3.9 and 6.5 mM).

Advanced food-bolus determination incorporates protein counting (15 g of carbohydrates for each additional 100 g of protein after the first 100 g)³²⁷ and the use of prolonged or “dual-wave” bolus administration, which is associated with better postprandial glucose control after ingestion of food with low glycemic index.³⁵⁷

Preferably, the bolus is administered 15 to 20 minutes before the meal as the postprandial peak of blood glucose precedes the peak of rapid-acting insulin analog action.^{358,359} As eating habits in smaller children may be unpredictable, a “split-bolus” approach may be used for optimal postprandial control with only 10% to 20% of the calculated bolus administered 15 to 20 minutes before the meal for covering “certainly” ingested food, and the rest administered after the meal according to the amount actually consumed.

ICRs should be verified on a regular basis with hourly postprandial SBGM or CGM, aiming at a blood glucose under 180 mg/dL (10 mM).

Missed prandial boluses, particularly during the school hours, are the most common cause of suboptimal metabolic control.³⁶⁰ Parental and school-personnel supervision and support is valuable.

Bolus Insulin for Correction of Hyperglycemia

ISF can be estimated by dividing 1800 by the TTD in older children and adolescents (2000 or 2200 in preschool children and toddlers, respectively). Again, bolus calculators incorporated into smart insulin pumps calculate correction boluses based on the preset ISF, current blood glucose level, preset blood glucose target range, and the amount of active insulin from previously administered correction boluses. The amount of active insulin calculated by the insulin pump bolus calculator depends on the setting of the insulin action time, commonly set to 3 hours for boluses used in pediatric population. A shorter insulin action time setting allows for more aggressive correction bolusing.

Also ISFs are regularly verified with SBGM 2 to 4 hours post-correction or with CGM. It is advisable to avoid correction boluses less than 2 hours apart as insulin accumulation (stacking) may occur and provoke hypoglycemia.³⁶¹

Specific Considerations and Acute Complications of Insulin Pump Therapy

Regular physical activity is strongly advised but challenging in youngsters with T1D, particularly in relation to hypoglycemia during and after it.^{362,363} The biggest advantage of CSII may be related to its possibility of reducing physical activity-related hypoglycemia.^{364,365} Basal insulin rate can be stopped or diminished by setting a temporary basal rate immediately prior and during the physical activity, depending on its intensity and duration. The presence of active insulin from previous boluses can be verified and an appropriate carbohydrate snack added before the physical activity, in addition to basal insulin rate modification, effectively preventing hypoglycemia. Finally, strenuous or prolonged exercise often results in delayed hypoglycemia, which can be prevented by a diminished temporary basal insulin rate programmed for several hours post physical

activity. Hypoglycemia can therefore be prevented without an excessive use of additional carbohydrates and thus a negative energy balance can be maintained, which is of particular importance for body weight management.

Reduction of hypoglycemia with sensible use of insulin pump therapy was demonstrated in several studies^{366,367} and has many important practical implications that must be discussed during the training of the family. The possibilities of insulin stacking after too frequent correction bolusing; inappropriate counting of carbohydrates; and insulin modifications related to an acute illness (e.g., vomiting), eating disorder, or physical activity are the most important issues that should be taken into consideration.

DKA was traditionally considered as a risk associated with CSII; however, studies report less DKA with the use of modern insulin pump.^{137,367} As only rapid-acting insulin analogs are used in insulin pumps, significant ketonemia may develop 4 to 6 hours after discontinuation of CSII.³⁶⁸ Partial or complete disconnection of the infusion set and plugging or kinking of the subcutaneous catheter are the most common causes. A DKA rescue plan must be included in the structured education provided to patients and caregivers. Blood or urine ketones must be checked if two consecutive blood glucose levels or the fasting blood glucose levels are over 275 mg/dL (>15 mM), and the possibility of infusion set problems considered. Infusion set must be replaced and an appropriate correction bolus administered, alternatively with an insulin pen injector, if the functioning of the infusion set is not certain. If ketonemia is greater than 1.5 mM, an increased temporary basal rate of 150% to 200% may be needed until blood ketones are normalized. Additional fluid intake is advisable. If ketonemia is associated with an acute illness or remains unexplained, contact with the on-call diabetes team is warranted.

Maintaining normoglycemia during acute severe illness has been demonstrated in adults,³⁶⁹ along with diminishing the danger of hypoglycemia. Despite the lacking published evidence for children, teams in pediatric ICU and neonatal ICU need appropriate training for maintaining stable glycemic control with CSII during acute severe illness.³⁷⁰ Anesthesiologists often suggest a switch to IV insulin during prolonged surgery, which with frequent blood glucose level determination provides a well-established and safe treatment modality. CSII should be restarted just before the termination of IV insulin administration. Discontinuing CSII during intermittent hospitalizations on various pediatric or surgery wards is usually associated with poor metabolic control and should be discouraged. A pediatric endocrinology team should be involved in the appropriate care of hospitalized children with diabetes.

Insulin Pump Therapy in Kindergarten and School

Most schools in developed societies accept chronically ill children and provide necessary care either enforced through law and regulations or voluntarily. A structured plan for school personnel and diabetes-related education similar to the one for caregivers facilitate cooperation among parents, the diabetes team, and the school. A cooperative spirit aimed at the best interests of the child with T1D usually yields optimum long-term results. The diabetes team serves as facilitator and coordinator in the collaboration between parents and the school personnel. Ideally, basic training for school personnel includes but is not limited to SBGM and appropriate recording; management of hypoglycemia including discontinuation of insulin delivery; rescue carbohydrates and administration of glucagon; management of hyperglycemia, including correction boluses and ketones checking, carbohydrate counting and determining boluses; and management of physical activity.^{347,371,372}

Despite significant improvements in metabolic control with the routine use of CSII in pediatric populations, most young people with type 1 diabetes still do not reach target metabolic control,³²⁸ with hypoglycemia and DKA remaining as problems.³⁷³ More emphasis on psychosocial support and successful parenting³⁷⁴ are needed in view of challenging modern environments to which children and adolescents are often exposed.

Blood Glucose Monitoring

The safety and success of any insulin regimen depend on frequent monitoring of blood glucose levels. Intensive diabetes control would have been impossible without the development of accurate and easy-to-use home glucose meters. Current models use glucose-oxidase-based electrochemical methods. The meters are fast and require very small volumes of blood (0.1 mL). The smaller blood volume requirement has allowed alternate site testing (e.g., forearm), which may minimize discomfort and improve adherence to self-monitoring regimens.

Frequent blood glucose monitoring, with a minimum of four tests per day, premeals, and at bedtime, is a minimal goal. The most recent ADA Position Statement¹ and ISPAD Guidelines³⁰⁷ recommend 6 to 10 fingerstick glucose checks daily or use of CGM to safely achieve tight glucose control.

Continuous Glucose Monitoring

It has been known for several years that more frequent SMBG correlates with improved HbA1c levels and reduced frequency of acute complications.^{375,376} Indeed, the introduction of real-time CGM systems has revolutionized management of insulin in the treatment of diabetes. Currently available CGM devices are based on sensors inserted transcutaneously and measure interstitial fluid glucose concentrations using glucose-oxidase-based electrochemical methods. Sensor glucose concentrations can be reported in real time, approximately every 5 minutes, with rate of change indicators and 1- to 24-hour retrospective profiles. This wealth of information allows for adjustments in insulin doses based on a retrospective analysis, as well as immediate, "at the moment" adjustments and predicted adjustments in the rate of insulin delivery or its temporary suspension based on the rate of change. Web-based data managing systems are available to assist patients and healthcare providers (HCPs) in evaluating sensor data alone, or in combination with insulin pump or connected pen data.³⁷⁷

In healthy children aged 2 to 8 years, CGM sensor glucose levels remain mainly within 4 to 7.8 mmol/L (72–140 mg/dL), with 9% under 4 mmol/L (<72 mg/dL), 3% <under 3.5 mmol/L (<63 mg/dL), and 1% over 9.0 mmol/L (>162 mg/dL). Importantly, 0% of sensor glucose values are greater than 11.1 mmol/L (>200 mg/dL) in healthy children. The glycemic pattern is very stable, with mean glucose SD 1.0 ± 0.2 mmol/L and coefficient of variation (CV) of 18.87%. Sensor glucose levels are slightly higher in the evening and lower in the morning.³⁷⁸ These physiological data help to guide glycemic targets in children with T1D.

CGM devices currently include blinded/retrospective CGM, real-time CGM, and intermittently scanned CGM (isCGM). The most common use of retrospective CGM is by HCPs over a short period of time for obtaining information on glucose patterns to assist with diagnosis (e.g., cystic fibrosis related diabetes), with therapy adjustments, and with diabetes education.

Real-time CGMs display (near) current interstitial glucose concentration, provide real-time alarms for predetermined thresholds and predictions of low and high glucose

concentration, as well as rate of change alarms for rapid glycemic variations. Several CGM sensors can transmit signals to the “cloud,” and enable caregivers and/or HCPs to remote-monitor CGM tracings with alerts on their own devices, including smartphones, tablets, or smart watches.³⁷⁹

Current isCGM systems do not constantly display real-time interstitial glucose concentrations, trend arrows, graph, or alarms; glucose levels appear only when the user holds a reader, or a cell phone, close to the sensor. All continuous glucose readings are stored and provided on demand. Most CGMs for blinded and real-time use still require calibration using finger-stick blood glucose; however, novel CGMs and isCGMs are factory calibrated and can completely eliminate the need for calibration via SMBG.³⁸⁰ Sensors are inserted transcutaneously by persons with diabetes or their parents/caregivers, and have a lifetime from 6 to 14 days. A new type of long-term implantable subcutaneous real-time sensors is approved for 3 or 6 months use as an alternative for transcutaneous CGM.³⁸¹

CGM use is constantly increasing in persons with diabetes, including the pediatric population. CGM was used by 4.8% of all young patients and in 2.3% of all pediatric patients in the German-Austrian registry Diabetes Patient Documentation (DPV) in 2012.³⁸² The Type 1 Diabetes Exchange (T1DEx) registry in the United States reported CGM use in 6% of children younger than 13 years, 4% of adolescents, and 6% of young adults.³⁸³ Both registries reported exponential growth of CGM use in 2017, with 18.4% (DPV) and 21.7% (T1DEx) use in the pediatric population.³⁸⁴ Higher use in younger children may reflect parental involvement, parental fear of hypoglycemia, reduced burden of SMBG, better reimbursement schemes for this age group, and improving technology.

Clinical Evidence for Continuous Glucose Monitor

The evidence for CGM efficacy in the pediatric population evolved gradually.^{385–387} The Juvenile Diabetes Research Foundation (JDRF) trial from 2008 provided evidence for the adult population; however, no overall benefit of CGM use was demonstrated in the adolescent and school-age groups, likely because of poor sensor use adherence.³⁸⁸ However, a post hoc analysis of these data limited to those with sensor use of more than 6 days/week also demonstrated significant benefit in the school and adolescent age groups.³⁸⁹ Studies conducted after 2010 demonstrated a more consistent improvement in HbA1c levels and reduced glucose variability in adults and in the pediatric population, particularly with near-continuous CGM use of 6 to 7 days/week.^{390–395} Evidence for benefit among younger and particularly preschool children was initially ambiguous: feasibility was demonstrated in children younger than age 10 years^{396,397}; however, an improvement in glycemic control was not demonstrated in a randomized controlled trial (RCT).³⁹⁸ Particularly in toddlers younger than age 4 years, a reduction in HbA1c after 6 months of use remained elusive, despite a high degree of parental satisfaction and a more sustained use of the devices.³⁹⁹ More recent studies provided additional evidence^{400,401} with clear benefit also in the preschool population when the analysis was strictly focused on periods when CGM was used.⁴⁰² Support for the use of CGM devices in kindergartens and schools is of paramount importance,⁴⁰³ as recently emphasized in international guidelines and position statements.^{404,405}

Fewer studies have focused on the impact of CGM on hypoglycemia. The evidence is rather strong in the adult population, both from retrospective analyses⁴⁰⁶ and RCTs.^{407,408} Initially, a reduction in mild hypoglycemia,⁴⁰⁹ and time spent in hypoglycemia with MDI³⁹⁴ and insulin pump therapy³⁹⁵ was demonstrated, along with a reduction in glucose variability.^{410,411} One RCT in children demonstrated a reduction of severe hypoglycemia⁴¹²; however, most former trials were

either not sufficiently powered for detecting a difference in severe hypoglycemia or focused only on reducing HbA1c.⁴¹³

From the beginning of real-time CGM use, individuals treated with MDI were successfully included.^{394,414–416} However, only recently has stand-alone use of CGM,^{417,418} and particularly isCGM,⁴¹⁹ been used nonadjunctively to SMBG,⁴²⁰ an approach gaining intense attention. Increasing evidence for clinical benefit of isCGM in the pediatric population with T1D,^{421,422} as well as during exercise and sport⁴²³ and used nonadjunctively,³⁸⁰ has brought additional confidence for the successful use of all CGM modalities in this most challenging childhood population.

A growing number of sensors can now reach the proposed mark of mean absolute relative difference of less than 10% (MARD <10%), sufficient to permit self-adjustment of insulin dosage without confirmatory SMBG.⁴²⁴ Real-life data from the T1DEx registry provided evidence of the safety and effectiveness of nonadjunctive sensor use as only 26% of participants verified the sensor glucose by performing SMBG.⁴²⁵ The nonadjunctive use of CGM seems to be most reliable when the person is not hypoglycemic and glucose is not changing rapidly. Serious concerns were raised about the nonadjunctive CGM use⁴²⁶; however, there is clear evidence that similar concerns also apply for many blood glucose meters that the US Food and Drug Administration (FDA) approved for SMBG.⁴²⁷ Practical guidelines for nonadjunctive CGM use address several current concerns.^{428,429}

A long-term implantable sensor was recently approved for up to 6 months of wear in the European Union, and for up to 3 months' wear in the United States. An initial RCT demonstrated efficacy and safety in an adult population with T1D,⁴³⁰ with a subsequent RCT reporting a MARD under 10% in all glucose ranges,⁴³¹ indicating the potential of its nonadjunctive use. The obvious advantages of a long-term implantable sensor may currently still be offset by the implantation and removal procedure, albeit performed in an outpatient diabetology setting. No pediatric data are currently available.

Finally, the reimbursement for CGM largely influences its use.⁴³² Recently, CGM and particularly isCGM received broad approval for reimbursement from private and large public insurance systems. Only with such a broad support for the use of CGM can current guidelines on CGM use,⁴³³ particularly related to time in range (TIR), be implemented. CGM metrics with accepted clinical targets for TIR, time below range (TBR), and time above range (TAR) may become the most common parameters for glucose management.

Practical Deliberations for Continuous Glucose Monitor

Thorough initial education along with setting of realistic expectations is mandatory for a successful CGM use.^{434–436} Direct education and educational materials should also be provided to teachers at kindergartens and schools,⁴³⁷ with written individualized healthcare plans agreed upon between parents, school nurses, professional caregivers, teachers, and the child, when suitable.^{403–405} Remote-monitoring can add to success of diabetes management in kindergartens and schools.⁴³⁸

Alarms and alerts may induce fatigue and an increased psychological burden,⁴³⁹ resulting in higher attrition from CGM. Sensible individualized alarm setting is paramount; these, and other aspects of CGM are extensively discussed in the publication titled: *Role of Continuous Glucose Monitoring in Diabetes Treatment*.⁴⁴⁰

Inadequate sensor adhesiveness and skin irritation, particularly in young children where body surface is limited, might be underreported, and represent important barriers to long-term CGM use.⁴⁴¹ Supplementary adhesive products (e.g., liquid adhesives, adhesive wipes, transparent dressings, special tapes)

and external wraps are recommended to help secure the sensor to the skin.⁴⁴² Skin issues might become more prevalent with longtime use of sensors. Regular site rotation to prevent skin irritation and trauma because of frequent application and removal of sensor adhesives is recommended. Adhesive removers also help to prevent skin trauma.

Sensor-Augmented Pump Therapy

Sensor-augmented pump (SAP) therapy comprises a CGM linked to an insulin pump through an algorithm. After the initial RCT in the adult population where SAP did not show an advantage over insulin pump therapy alone, and even increased hypoglycemia, likely because of inadequate sensor wear and use,⁴⁴³ SAP was demonstrated superior to MDI with SMBG in a 1-year RCT, including a pediatric population 7 to 18 years of age, resulting in a significant decrease in HbA1c and neutral effect on hypoglycemia.⁴⁴⁴ School-children used sensors more frequently compared with adolescents; more sensor use was associated with lower HbA1c, decreased hyperglycemic exposure, and decreased glycemic variability independently from HbA1c.^{391,410,444} Similarly, in the 6-month continuation phase, participants in the initial SAP intervention arm retained the improvement in HbA1c at 18 months, with those who crossed over to SAP from the initial MDI group also achieving significantly decreased HbA1c.^{392,444}

The second level of SAP therapy came with an automated low sensor glucose threshold insulin suspend (LGS) modality,⁴⁴⁵ which demonstrated less time spent in hypoglycemia compared with SAP without LGS.⁴⁴⁶ An RCT conducted in the home setting demonstrated that the use of LGS modality reduced the area under the curve (AUC) for a glucose of under 3.9 mmol/L (<70 mg/dL) for nocturnal hypoglycemia by more than one-third, with significantly lower percentage of sensor readings in hypoglycemic ranges, without any elevation of HbA1c.⁴⁴⁷ In another RCT focused on young individuals with proven impaired hypoglycemia awareness, a reduction in combined severe (seizures/coma) and moderate hypoglycemia was associated with the use of LGS compared with pump with SMGB.⁴⁴⁸ Additional evidence from pediatric observational trials corroborates the results from RCTs,⁴⁴⁹ along with an analysis of uploaded data from 935 SAP users providing 49,867 user-days with LGS used for 82%.⁴⁵⁰ A moderate delayed rise in glucose 2 hours after resumption of insulin was described in all studies; however, no significant difference in BOHB was observed, even after LGS was activated during the night at or above normoglycemia.⁴⁵¹

The third level of SAP therapy came with a predictive low sensor glucose insulin suspend (PLGS) modality, further decreasing the risk of hypoglycemia with suspending insulin delivery before predicted hypoglycemia. Home use of an investigational PLGS in adolescents and adults reduced hypoglycemia exposure by 81% and time spent less than 60 mg/dL (<3.3 mmol/L) by 70%,⁴⁵² with comparable results in a pediatric cohort⁴⁵³ and in cohorts with different risk factors for hypoglycemia,⁴⁵⁴ without a significant elevation in BOHB levels.⁴⁵³

Currently, the commercially available PLGS modality interrupts insulin delivery when the sensor glucose is predicted to reach 20 mg/dL (1.1 mmol/L) above the preset low glucose limit within 30 minutes, and automatically resumes basal insulin delivery at normoglycemia. In an initial in-clinic assessment hypoglycemia was avoided in 60% of the 69 experiments.⁴⁵⁵ An RCT with 100 children and adolescents demonstrated a decrease in the number of hypoglycemic events by 40% when the PLGS was used at home, with a modest concomitant rise in the time spent in the mild hyperglycemic range.⁴⁵⁶ A 6-month multicenter RCT demonstrated reduced time spent with sensor glucose less than 63 mg/dL (<3.5 mmol/L), without a

difference in HbA1c level at the end of the study.⁴⁵⁷ Data from real-life assessment support results from RCTs, emphasizing the importance of proper education and training.⁴⁵⁸

More recently, an RCT tested the second commercially available PLGS system in 102 adults, adolescents, and children, and demonstrated a 31% relative overall reduction in sensor time less than 70 mg/dL (<3.9 mmol/L), without a difference in mean glucose concentration, but with a significant increase in AUC greater than 180 mg/dL and time over 250 mg/dL.⁴⁵⁹ However, BOHB levels were assessed on 1954 mornings, half of which occurred after a PLGS activation overnight, and the frequency of BOHB over 0.6 mmol/L was not different.³³⁰ Consensus recommendations on the use of SAP with PLGS do not recommend additional blood BOHB testing.^{460,461}

Practical Deliberations for Sensor-Augmented Pump

Success with SAP, as with CGM, anchors on understanding of the system functionality and realistic expectations. Suggested topics at SAP initialization may include required frequency of sensor use, and possible alarm fatigue.⁴⁶² Alarms for PLGS may be set to off, particularly during the night, possibly with the low threshold alarm on. Should a hypoglycemic event occur despite the insulin suspension with PLGS, rescue carbohydrate intake should be judicious to prevent rebound hyperglycemia. Regular analysis of downloads assists decisions related to all SAP settings, and particularly to those related to PLGS settings.⁴⁶²

AUTOMATED INSULIN DELIVERY—CLOSED-LOOP (ARTIFICIAL PANCREAS)

Devices consisting of pumps, sensors, and algorithms have been recently developed as commercially available products for patients with T1D. These devices are still undergoing refinements with the aim of producing a complete closed-loop system for delivering insulin, a so-called *artificial pancreas*. Automated insulin delivery systems are based usually on CGM, an insulin pump and a computed algorithm that controls the amount and the pace of the insulin delivered to the patients.

The first step toward automated control of insulin delivery was the low-glucose-suspend feature. This feature is an add-on algorithm for patients who are using a sensor-augmented pump approach that allows the basal rate of the patient's pump to be suspended for up to 2 hours if the patient fails to respond to the sensor's low-glucose alarm (see Continuous Glucose Monitoring section earlier). These systems have been tested in adults and children with T1D and have been found to significantly decrease the extent and duration of nocturnal hypoglycemia in patients with T1DM.

The "low glucose suspend" feature was followed by the development of the commercial PLGS, which has the ability to suspend the pump's basal level even before the patient's glucose levels reach the predetermined hypoglycemic range. In this PLGS system, the basal insulin delivery is suspended when the algorithm predicts, based on the sensor glucose trends showing that the patient's blood glucose levels will soon reach the hypoglycemic zone, even though the blood glucose level at that time is still within the normal range (see Continuous Glucose Monitoring section earlier).

Several groups of investigators, as well as pump and sensor manufacturers, are currently developing closed-loop systems also known as *artificial pancreas*. These systems use controller algorithms that automatically regulate insulin infusion rates delivered by the pump, based on the sensor glucose readings every few (generally every 5) minutes yielding 288 readings per 24 hours. The main three basic algorithmic approaches in practice today are the proportional integrative derivative

(PID)⁴⁶³ model predictive control (MPC),⁴⁶⁴ and fuzzy logic.^{465,466} Initially, proof of concept studies with a small number of patients in clinical research centers were conducted^{467,468} and demonstrated their safety and effectiveness. In 2011 the first multicenter, multinational, prospective, randomized crossover-controlled study, involving 54 children and adolescents, using automated insulin delivery in a resort area outside of a hospital's protected environment, was successfully conducted and reported.⁴⁶⁹ That study was followed by a series of studies using closed-loop systems in diabetes camps,^{470–473} as well as out patient environments,^{474–477} and were proven to be safe and effective and within the capabilities of the subjects. These results eventually led to the first European regulatory approval—the CE-Mark—for the algorithm of the automated insulin delivery in 2015. The automated insulin delivery “system” composed of pump, sensor, and meter (Minimed Medtronic 670G), was approved for those aged 14 years and older in the FDA in 2016. By 2018 the system received FDA clearance for age 7 years and older, as well as approval by the European CE-Mark. This automated insulin infusion system is user friendly, and capable of changing the insulin infusion rate according to the blood glucose levels. However, attempts to develop a fully closed-loop system failed to show desired results, mainly because of significant postprandial glycaemic excursions compared with results with premeal boluses.⁴⁷⁸ Therefore the automated insulin delivery systems available today are actually each a “hybrid” system, where basal insulin delivery is controlled by the algorithm, but the patient needs to manually announce meals together with assessment of the carbohydrate content and individual insulin sensitivity to deliver a premeal insulin bolus. Advanced hybrid closed-loop algorithms, currently in clinical studies, are able to inject boluses to correct high glucose levels in between meals or inject a postmeal bolus if patients forget to inject a premeal bolus. Several thousand patients with T1D are already successfully using a commercially available “hybrid” system (670G Medtronic) in the United States, and it is anticipated to become available commercially also in Europe and other parts of the world during 2019. The automated insulin delivery systems available commercially today are based on delivery of insulin only, and therefore are able to increase basal insulin delivery, as well as to inject boluses, if required, and to decrease or even suspend insulin delivery, when needed. However, there are also continuous efforts by several groups in the world to develop a dual-hormone system that will automatically inject insulin and glucagon with the aim to achieve as near as normal metabolic control^{479–483} without hypoglycemia, and better than a system based on insulin only achieves. Yet, there are still several efficacy and safety concerns that have been raised regarding continuous or repeated glucagon injections, so that clinical studies to overcome these concerns of dual-hormone closed-loop systems are ongoing.

Studies of out patients in “free living” conditions demonstrated improved TIR of sensor glucose levels between 70 and 180 mg/dL (3.9–10 mmol/L) associated with reduction in time spent in the hypoglycemia range via use of automated insulin delivery compared with the use of pump alone or with SAP therapy.^{484–502} Automated insulin delivery systems were also shown to reduce nocturnal hypoglycemia following physical activity in the afternoon,⁵⁰³ as well as increased treatment satisfaction.^{504–508}

With the increasing number of patients using closed-loop systems and their growing accessibility, it is important to prepare both patients and HCPs for the new and still evolving technology and to adjust expectations with reality. The ability of the current systems to mitigate hypoglycemia is not absolutely perfect; patients are still required to be alert and respond to the systems' hypoglycemia alarms by ingestion of carbohydrate. Patients should be prepared to face and respond appropriately

to some technical difficulties and alarms that might occur, to be taught when to stop automated insulin delivery and revert to their previous pump settings, to be alert to situations when the system might automatically revert the patients from auto mode to manual pump mode, and what to do when and if sensor glucose levels remain elevated over time.

Future closed-loop systems might include incorporation of additional data derived from other sensors, such as heart rate monitoring, degrees of physical activity, body temperature, sleep pattern, mood, geographic location, and automated carbohydrate counting to be integrated with new artificial intelligence (AI) and algorithms that will replace the hybrid closed-loop systems with a fully automated one, an “artificial endocrine pancreas.”

THE EMERGING DIGITAL WORLD OF DIABETES

Diabetes is a chronic disease that affects all aspects of the patient's daily routine. Patients with diabetes are required to make many decisions each day regarding their activity, diet, and insulin regimen. Patients' interactions with HCPs usually occur once every few months in most diabetes centers in the world. In between these clinical visits, patients are required to manage their diabetes on their own, or with the help of parents, other relatives, or other caregivers in their surroundings.⁵⁰⁹ Moreover, the worldwide increase in the number of patients with diabetes, both type 2 and type 1,⁵¹⁰ the inadequate number of HCPs who specialize in diabetes,^{511,512} and the limited time available for each patient's visit⁵¹³ create the need for new ways to cope with the care of diabetes. Over recent years, digital technology has made huge progress, and the number of people who have access to digital technology via Internet and smartphones has increased dramatically.⁵¹⁴ Therefore attempts emerged to use digital solutions to help patients cope with their diabetes in-between clinical visits, and to help the HCPs with the increasing amount of data during the clinical visit. With the increased use of electronic health records, CSII, CGM, isCGM, and recently the information derived from connected pens (insulin pens that transmit to the cloud information on the dose and the timing of insulin administration), the HCPs are dealing with “big data” derived from different sources, which requires integration, analysis, and eventually a personalized tailored recommendation to each of their patients. Tools based on AI have been developed to help physicians during and in-between patients' visits. Automated diagnosis of diabetic retinopathy (DR) based on fundus photography using AI and deep learning algorithms^{515,516} have been developed and clinically tested. Recently, a study was conducted aiming to evaluate physicians' adjustments of insulin pump settings based on CSII downloads, CGM, and SMBG glucose data gathered over 3 weeks of patients with T1D.⁵¹⁷ In that study, 26 physicians from 16 centers in Europe, Israel, and South America were asked to adjust insulin dosing of 15 patients with T1D. The study showed that the rate of full agreement between physicians on: (1) the trend in insulin adjustments of the basal insulin infusion rate, (2) the insulin: carbohydrate ratio (CR), and (3) the correction factor (CF) were $41 \pm 9\%$, $45 \pm 11\%$, and $45.5\% \pm 13\%$; for complete disagreement they were $12 \pm 7\%$, $9.5 \pm 7\%$, and $10 \pm 8\%$, respectively. Significantly similar results were found between the physicians and an automated decision support algorithm developed for HCPs.⁵¹⁸ Other AI algorithms are being tested with the aim to provide personalized prevention and intervention programs to help HCPs to choose the optimal personalized treatment using deep and machine learning algorithms based on large datasets.^{519–521} The use of AI allows real-time processing of big data coming in from different sources, such as health record datasets, personal genetic information, geographic areas, downloads from devices, and sensors, and turn this information into an

actionable personalized plan for use by the HCPs or by the patients themselves.^{522,523} It appears that patients will soon be able to use such AI tools on a daily basis to adjust their therapeutic regimens to achieve better glucose control without the need to wait for their scheduled meetings with their HCPs.

The Open-Source Movement

With the notion of many patients with T1D that the technology is advancing faster than the regulatory bodies in the world can evaluate and approve, an initiative has emerged from several individuals and groups to form an open-source consortium.⁵²⁴ Tools that use open-source need not be FDA approved and are not for sale; these tools are free to be used by anyone as an open-source system that permits people with diabetes to build their own artificial pancreas for themselves, their spouses, or their children. Some of the open-source algorithms use industry proprietary products, such as pumps and CGMs, with the aim to accelerate the pace by which these tools become available for patients' use to improve their own diabetes management. Another interesting initiative is the nonprofit open source Tidepool project.⁵²⁵ This organization developed a hub for diabetes data that collects data from pumps, CGMs, blood glucose monitors, and other mobile devices and integrates them and allows patients with diabetes to visualize and use it. The Tidepool platform encourages patients to donate their data with the aim to create a huge data source to be available to patients and researchers for developing better algorithms for patients' use.

Technology Challenges

Hundreds of Internet smartphone apps and algorithms for data capturing, as well as glucose management, social support, diet advice, teaching tools, and other different advisors, have been developed and are available for use.^{526,527} However, most tools available today are not FDA approved and their safety and effectiveness were not tested in well-designed prospective RCTs. Real-life studies that test their benefits compared with standard of care are scarce. Privacy issues related to the question of who owns the data derived from the different sensors and devices and the potential of hacking, which might compromise the privacy of the patients and safety of the device' users, is continuously discussed.⁵²⁸ The influx of data derived from different devices and sensors like CSII and CGM raised the need to define new digital biomarkers beyond the traditional HbA1c values, such as time spent in range, hypoglycemia, and hyperglycemia and glucose variability.^{529,530} With more and more sensors and connected devices and the use of AI, which will provide new tools for both patients and HCPs, the interaction and relationships between patients and HCPs during clinic visit and in-between visits will ultimately change. These changes might also change the economic basis that is currently used to manage diabetes in different places in the world.

Digital tools have the potential to empower patients and to provide them with the tools that will be available for their use 24/7; this is so necessary to cope with a chronic disease like T1D from which there is not a single day of respite.

This succinct overview of the computerized digital revolution related to diabetes, particularly in children, is meant to alert the reader to this fast-evolving field with its promise and perils. Promise, because the application of these technologies is at the core of advances in the management of diabetes. This is demonstrated by the development of closed-loop systems for insulin delivery coupled with glucose sensing, the so-called *artificial pancreas*, as well as AI systems to mine, interpret, and apply the huge data emanating from these technologies. Perils, because much of the technology is still under development, lacking stringent safety features, which are so

crucial for the self-treatment of the patients and their families. Above all, our comments as presented here intend to educate the reader, but they should not be viewed as an endorsement or critique of any specific system or product.

LIVING WITH DIABETES

Medical Nutrition Therapy

Proper nutritional management is critical to the short- and long-term health of children with diabetes. In general, terms, such as diet, should be avoided in favor of meal plan or healthy food choices—both for the negative connotation associated with the former and for the simple fact that nutritional requirements for normal growth and development are the same in diabetic and nondiabetic children. Moreover, reasonably accurate estimations of the carbohydrate content of meals are important to optimal glycemic control with current basal-bolus treatment regimens. Indeed, the popularity of basal-bolus therapies and the use of carbohydrate counting to adjust the dose of rapid-acting insulin taken with each meal have fundamentally changed the treatment paradigm.

The traditional approach of adjusting the patient's lifestyle around fixed insulin doses and fixed amounts of carbohydrate intake with each meal has been replaced by a more flexible approach that attempts to adjust the insulin regimen to the patient's lifestyle. The day-to-day variations in appetite in children and adolescents make the latter approach more likely to be successful. It is important to note that in some patients and some families, the traditional approach of trying to consume consistent carbohydrate servings per meal/snack may be more successful because it fits their personalities and lifestyle better.

The currently favored model of nutritional therapy is carbohydrate counting, based on the conceptual model of matching carbohydrate "doses" to insulin doses.^{531,532} Because the total carbohydrate content of foods (rather than the type of carbohydrate) has the greatest impact on blood glucose, the amount of carbohydrates ingested per meal or snack needs to be estimated as accurately as possible. Although the protein and fat contents of meals do affect the pattern of postmeal glucose excursions,^{533,534} they are not usually counted to simplify the procedure. Accounting for fat and protein is often included in more advanced education and for use of insulin pump bolus adjustments (dual or square wave boluses).³²⁷ Food labeling requirements have simplified the process because most foods are clearly labeled with the number of carbohydrate grams per serving and the serving size. Foods less easily quantified may be weighed or estimated, and eating out may be a particular problem. Although the prohibition of "sweets" has been done away with, we still recommend that patients avoid sugar-containing beverages.

In the flexible approach to nutrition counseling, there is no set intake. Rather, the child and parents decide the meal content. The carbohydrates are counted and an insulin dose is calculated based on a ratio of the number of insulin units per grams of carbohydrate determined by the empirical trial-and-error method. Actual insulin-carbohydrate ratios vary from child to child and in the same child according to the time of day. Breakfast often requires relatively more insulin than lunch or dinner. Carbohydrate counting can also be used in the traditional approach to dietary treatment to provide consistent carbohydrate servings per meal/snack. Indeed, a simple approach that stresses consistency in the timing and size of meals may be effective at the time of diagnosis of diabetes—when parents and patients are too overwhelmed to be able to learn more advanced nutritional concepts.⁵³⁵

The ADA's recommendations regarding general nutritional principles in diabetes also take into consideration the long-term goal of preventing the macrovascular and microvascular

complications of diabetes.⁵³⁵ Consequently, heart-healthy diets low in cholesterol and saturated fats are encouraged. Long-term goals of nutritional management of diabetes include maintenance of nutrient intake balance of about 50% carbohydrate, 20% protein, and 30% fat (of which no more than 10% should be saturated). Most important, growth and weight gain should be monitored—and regular follow-up with a dietitian trained in diabetes management should be encouraged to individualize a meal plan for each child based on his or her needs and food preferences. We face an epidemic of childhood obesity in developed countries, and one of the adverse consequences of intensive insulin treatment is that 30% to 35% of pediatric patients with T1D in the United States are overweight or obese.⁵³⁶ Thus any tendency for body mass index (BMI) Z scores to increase excessively needs to be dealt with promptly.⁵³⁷

Exercise

Establishment and maintenance of an active lifestyle should be a goal for all children, but especially children with diabetes, to enhance cardiovascular health. Exercise and increased physical fitness are associated with improved insulin sensitivity and glucose utilization, the clinical correlates of which are lower insulin requirements, lower blood pressures, and better lipid profiles. Improvements in physical fitness are also frequently associated with greater self-esteem and increased motivation to participate in diabetes care. Recent guidelines and consensus statements have reviewed this topic in detail.^{538,539}

Despite its benefits, acute bouts of exercise in children with T1DM actually make regulation of blood glucose levels more difficult. Hypoglycemia is a common complication during exercise,⁵⁴⁰ and excessive snacking to prevent hypoglycemia can result in hyperglycemia and negate some of the metabolic and cardiovascular benefits of exercise. These difficulties are compounded by the irregular pattern of physical activity that characterizes most youth who are not participating in organized sports or regimented training programs and by conventional methods of diabetes management that feature fixed basal insulin replacement doses. The Diabetes Research in Children Network demonstrated that the risk of nocturnal hypoglycemia nearly doubled in youth with T1D following antecedent afternoon exercise versus sedentary days.⁵⁴¹

The effects of exercise must be carefully considered in the context of the entire diabetes care plan. Children participating in school sports or other programs should be counseled to monitor blood glucose before, during, and after exercise to optimize glycemic management. In addition, patients and parents should be aware that late hypoglycemic effects of afternoon exercise are often observed 7 to 11 hours after the bout of exercise in the afternoon,⁵⁴² a phenomenon that appears to be caused by an increase in nonoxidative glucose disposal during sleep, which may serve to support repletion of muscle glycogen stores.⁵⁴²

In patients on pump therapy, simply suspending the basal infusion rate can markedly reduce the risk of hypoglycemia during exercise⁵⁴⁰—and similar benefits may accrue from reducing the overnight basal rates after very active days. Furthermore, real-time CGM can be extremely valuable to provide alerts of impending hypoglycemia. Integrated systems with CGM and pumps that include predicted low glucose suspend reduce hypoglycemia in pediatric studies.^{457,543}

Studies that have examined methods of managing glycemia during exercise illustrate that there is an almost infinite number of combinations of conditions that need to be considered. Because of this complexity, trial and error remains the principal method of managing glucose levels during and after exercise in children and adolescents with T1DM,⁵⁴⁴ although guiding principles exist in numerous guidelines and reviews.^{538,539}

Residual β -Cell Function (the Honeymoon Period)

After the initiation of insulin treatment in newly diagnosed patients, secretory function of residual beta cells improves and the insulin resistance and glucotoxicity of decompensated diabetes are reversed—heralding the onset of the partial remission (honeymoon period) of T1DM.⁵⁴⁵ Most patients require a progressive reduction in their daily dose to avoid excess hypoglycemia. A minority of children (<5% of patients) can even maintain normoglycemia for a time without any administered insulin. Although opinion varies, we do not discontinue insulin treatment unless a daily dose of 0.1 U/kg still causes hypoglycemia.

The duration of the honeymoon phase in children with T1DM is variable, but the lowest HbA1c levels and TDD are usually observed between 3 and 6 months postdiagnosis and both often rise between 9 and 15 months.⁵⁴⁶ With current MDI and CSII treatment methods, the large majority of youth with T1D retain substantial residual insulin secretion, as measured by C-peptide responses to mixed meal tolerance tests, during the first year of their disease, and this can be extended for several years thereafter with maintenance of optimal glycemic control.⁵⁴⁷ In comparison to patients who are C-peptide negative, patients with residual beta-cell function have lower HbA1c levels and total daily insulin doses—as well as a reduced risk of hypoglycemia.⁵⁴⁸ These clinical and metabolic benefits serve as a strong rationale for current research involving immune interventions directed at preserving beta-cell function in newly diagnosed patients.⁵⁴⁹ On the other hand, earlier and more aggressive application of sensor-augmented pump therapy around the time of diagnosis does not appear to confer any advantages over standard MDI and CSII with respect to HbA1c levels or C-peptide responsiveness in youth with T1DM.⁵⁴⁶

Hypoglycemia

Historically, the dark side of intensive treatment regimens that are effective in lowering HbA1c levels is that they also increase the risk of hypoglycemia. In the DCCT, intensive therapy was associated with an approximate threefold increased risk for severe hypoglycemia versus conventional treatment and, irrespective of treatment group, the rate of severe hypoglycemia was about 50% higher for adolescents than for adults.⁵⁴⁸ Hypoglycemia has become the most significant barrier to the pursuit and maintenance of tight glycemic control among people with T1DM, and effectively managing the risk for hypoglycemia is especially important in the treatment of children and adolescents with this disease. However, more recent data from multiple registries worldwide indicate a flattening of the DCCT report, which had demonstrated a curvilinear inverse relationship of A1c with severe hypoglycemia.⁵⁵⁰ Contemporary data indicate that A1c goals can be met without an increase in severe hypoglycemia.⁵⁵¹

The ADA and the ISPAD harmonized their definitions with that of the International Hypoglycemia Study Group^{552–554} as: (1) clinical hypoglycemia alert (a glucose value ≤ 70 mg/dL [3.9 mmol/L]) that requires attention to prevent hypoglycemia; (2) clinically important or serious hypoglycemia (a glucose value < 54 mg/dL [3.0 mmol/L]) indicates serious, clinically important hypoglycemia; and (3) severe hypoglycemia defined as an event associated with severe cognitive impairment (including coma and convulsions) requiring external assistance by another person. In nondiabetic adults, less than 70 mg/dL is the plasma glucose level at which counterregulatory hormone responses engage and at which awareness of symptoms normally occurs. It should be noted, however, that such responses may be triggered at higher glucose levels in healthy 8 to 16 year

olds and in children and adolescents with T1DM who have poor glycemic control.⁵⁵⁵

The two main mechanisms that cause symptoms and signs of hypoglycemia are an outpouring of catecholamines (which results in pallor, sweating, apprehension, trembling, and tachycardia) and the effects of cerebral glucopenia, which include hunger, drowsiness, mental confusion, seizures, and coma. Mood and personality changes may be more subtle cerebral glucopenic effects that provide an early clue that plasma glucose has fallen to a dangerous level. Symptomatic episodes in which patients are able to treat themselves without the assistance of others are considered minor or mild hypoglycemia, whereas episodes in which there is sufficient cognitive impairment that treatment requires the assistance of another person are considered major or severe hypoglycemic events. Hypoglycemic events that cause seizures or coma are usually classified as a subset of severe hypoglycemia. In severe hypoglycemia, ingestion of carbohydrates may be precluded because of loss of consciousness, seizures, or coma—and treatment may require administration of a glucagon injection or IV glucose infusion.

In nondiabetic children, the initial response to falling plasma glucose levels is a prompt suppression of insulin secretion. If plasma glucose continues to fall and threshold values for release of antiinsulin counterregulatory hormones are reached, there are abrupt increases in circulating concentrations of glucagon and epinephrine. Plasma growth hormone and cortisol levels also increase, but these hormones are less important in acutely counteracting the effects of insulin. Defective counterregulation occurs in patients with T1DM because exogenously supplied insulin levels do not decrease in response to low blood glucose levels and the ability to secrete glucagon in response to hypoglycemia is lost early in the course of the disease.^{545,556} Consequently, patients with T1DM depend on sympathetic nervous system responses—especially increases in plasma epinephrine levels—to prevent hypoglycemia.

The episodes of mild hypoglycemia that frequently accompany intensive treatment blunt catecholamine responses and symptom awareness to subsequent hypoglycemic challenges. This phenomenon has been called *hypoglycemia-associated autonomic failure (HAAF)*.^{557,558} Studies have shown that such defects in counterregulatory hormone responses are common in both young children and adolescents with T1DM who are well controlled.⁵⁵⁹ Catecholamine responses to hypoglycemia are also impaired during sleep, which is an important reason why most of the severe hypoglycemia events occur during the night.⁵⁶⁰ As noted earlier, bouts of exercise in the afternoon sharply increase the risk of hypoglycemia on the following night.⁵⁴⁴

The use of basal-bolus therapy with insulin analogs and insulin pumps has reduced the frequency of severe hypoglycemia but by no means has eliminated this problem. HbA1c levels can be reduced in patients who use CGM with or without integration in a sensor-augmented pump system without increasing the risk of hypoglycemia, but reducing severe hypoglycemia remains a clinical priority. In the T1D Exchange Clinic Registry that includes more than 10,000 children with T1D, 1 in 20 patients reported having at least one seizure or coma event related to hypoglycemia in the prior 12 months.⁵³⁶ It is also noteworthy that the risk of severe hypoglycemia in patients with HbA1c levels over 9.5% in this cohort was similar to that in patients with HbA1c levels under 8%. These data indicate that poor control, per se, is not an effective strategy for reducing the risk of hypoglycemia.⁵³⁶

It is important that the patient and family recognize early symptoms and signs of hypoglycemia and known precipitating factors. Mild episodes should be immediately treated with 10–15g (or ~0.3 g/kg) of carbohydrate (e.g., glucose tablets,

juice, or glucose gel). Parents and school nurses also need to be instructed on how to perform injections of glucagon (0.5–1.0 mg) when the patient has lost consciousness and is unable to swallow exogenous carbohydrate. If exercise has been the precipitating factor, the patient should be instructed about preventive measures. Development of orally active glucagon preparations is ongoing and shows promise as an efficient, effective, and self-administered method for avoiding hypoglycemia without the need for cumbersome preparation of the current injectable forms.

Sick Day Management

Children with intercurrent illnesses, such as infections or vomiting, should be closely monitored for elevations in blood glucose levels and ketonuria. On sick days, blood glucose levels should be checked every 2 hours—and the urine should be checked for ketones with every void. Supplemental doses of rapid-acting insulin (0.1–0.3 U/kg) should be given every 2 to 4 hours for elevations in glucose or ketones. Even in the absence of marked hyperglycemia, the presence of ketones indicates insulin deficiency and therefore the need for supplemental insulin.

Adequate fluid intake is essential to prevent dehydration and hasten the excretion of ketones. Fluids, such as flat soda, clear soups, popsicles, and gelatin water are recommended to provide some electrolyte and carbohydrate replacement. In the child tolerating oral rehydration, a fluid “dose” of 1 ounce (30 mL) per year of age per hour serves as a rough guideline, the sugar content of which depends on the serum glucose. For blood glucose values greater than 200 mg/dL, sugar-free fluids should be given. For those levels between 140 and 200 mg/dL, a mixture of sugar-free and sugar-containing fluids should be given. For blood sugar under 140 mg/dL, only sugar-containing fluids should be given.

If emesis precludes normal oral intake, the intermediate or long-acting insulin should be discontinued and small frequent doses of short- or rapid-acting insulin should be given. In pump-treated patients, if emesis precludes normal oral intake, basal insulin should be continued, but higher or lower temporary basal rates may also be used, to avoid hypoglycemia or ketosis depending on changes in glucose and ketone levels. Once the ketones have cleared and the child is tolerating an oral diet, the family may resume the normal routine. If vomiting is persistent and ketones remain moderate or large after several supplemental insulin doses, arrangements should be made for potential hydration and evaluation in a hospital emergency department.

Special attention should be paid to persistent hyperglycemia in patients using pump therapy, as absence of long-acting basal insulin can result in development of ketones and DKA if the rapid acting insulin is not delivered. Because only rapid-acting insulin is administered, an interruption of insulin delivery will result in increases in blood and urine ketone levels in 4 to 6 hours.³²⁹ These interruptions are most commonly caused by problems with the infusion set, such as kinking or occlusion of the subcutaneous catheter. Thus assessment of hyperglycemia and any symptoms of nausea and vomiting must include an evaluation of the integrity of the infusion set and infusion site.

Associated Autoimmune Diseases

Patients with T1DM are at increased risk for other autoimmune diseases. These are detailed in Chapter 22, in the discussion of multiple endocrine deficiency syndromes. Chronic lymphocytic thyroiditis is frequently associated with T1DM in children, and as many as one in five may have thyroid antibodies in their

serum. Only a small proportion of these patients develop clinical hypothyroidism, however. The interval between the diagnosis of diabetes and that of thyroid disease averages about 5 years. Physicians should anticipate the possibility of hypothyroidism in patients with T1DM by periodic examination of the thyroid gland and measurement of serum thyroid-stimulating hormone (TSH) concentration.

When diabetes and thyroid disease coexist, the possibility of adrenal insufficiency should be considered. This may be heralded by decreased insulin requirements, increased pigmentation of the skin and buccal mucosa, salt craving, weakness, and postural hypotension. Rarely, frank Addisonian crisis is the first evidence of adrenal failure. This syndrome generally occurs in the second decade of life or later.

Celiac disease affects from 2% to 8% of children with T1DM,⁵⁶¹ and most of them are not aware of any gastrointestinal symptoms. Early diagnosis requires screening of tissue transglutaminase antibodies, which have high degrees of reproducibility, specificity, and sensitivity if total circulating IgA concentrations are not abnormally low. Antibody-positive children should be referred to a pediatric gastroenterologist for confirmation by small bowel biopsy, as well as for counseling and disease management. When typical signs and symptoms of malabsorption are present or the patient has frequent hypoglycemia or unexplained behavioral mood swings, dietary intervention is indicated. When symptoms are minimal or absent, the decision to introduce gluten-free diets with their additional restrictive and inconvenient burdens on the patient and family are less clear-cut.⁵⁶² To guide their decision, the parents and older children need to be made aware of the risk of bowel malignancies in untreated celiac disease in later life and of other long-term complications of this disease.

Associated Psychosocial Problems

Diabetes in a child affects the lifestyle and interpersonal relationships of the entire family. Guidelines for psychosocial management and support of families with childhood diabetes have been published. Feelings of anxiety and guilt are common in parents. Similar feelings, coupled with denial and rejection, are equally common in children—particularly during the rebellious teenage years. These issues are not unique to T1DM but are observed in families with children who have other chronic disorders difficult to treat. These stresses are often exaggerated in single-parent low-income families and impair their ability to effectively carry out needed self-management tasks, resulting in poor metabolic control.⁵⁶³ Language and cultural barriers are additional obstacles in immigrant families.⁵⁶⁴

Psychosocial difficulties and conflict between patients and parents may result in nonadherence to instructions regarding healthy food choices, insulin therapy, and frequency of blood glucose monitoring. In this era of basal-bolus insulin therapy, missing premeal bolus doses is the most common cause of elevated HbA1c levels, especially in adolescents. Consequently, one of the major advantages of CSII over MDI in pediatric patients is that the bolus history function of current insulin pumps provides a record of the number of daily bolus doses that were actually administered.⁵⁶⁵ Deliberate overdosage with insulin resulting in hypoglycemia or omission of insulin to limit weight gain (also referred to as *diabulimia*) may be pleas for psychological help. Occasionally, they may be manifestations of suicidal intent. Frequent admissions to the hospital for ketoacidosis or hypoglycemia should arouse suspicion of underlying emotional and family conflict. Feelings of being different or of being alone are also common.

The clinician managing a child or adolescent with diabetes should be aware of his or her pivotal role as counselor and

advisor and should anticipate the common emotional problems of the patient. When emotional problems are clearly responsible for poor compliance with the medical regimen, referral for psychological help is indicated. In pediatric centers, psychologists form part of the management team for children with diabetes. Although clinical depression is one of the most common comorbidities in youth with T1DM, problems in this area may not be evident during routine clinic visits, especially in preteens who may present as somewhat withdrawn rather than rebellious.⁵⁶⁶ As a result, treatment guidelines suggest that screening questionnaires for depressive symptoms should be administered to youth with T1DM on a regular basis.⁵⁶⁷ However, it has been difficult to implement this recommendation in most clinical practices.

Outpatient Care

The importance of frequent follow-up by the diabetes health-care team cannot be overemphasized. Children and adolescents with T1DM should be routinely cared for at a diabetes center that uses a multidisciplinary team knowledgeable about and experienced in the management of young patients. This team should ideally consist of pediatric diabetologists, diabetes nurse specialists, nutritionists, and social workers or psychologists.

The ADA and the ISPAD have published guidelines for care of the child and adolescent with diabetes.^{1,568} Regular follow-up visits with the physician or diabetes nurse specialist/practitioner every 2 to 3 months are recommended for most patients. The main purpose of these visits is to ensure that the patient is achieving primary treatment goals. Outpatient visits provide an opportunity to review glucose monitoring (and CGM profiles), to adjust the treatment regimen, and to assess child and family adjustment. At each visit, glucose records should be reviewed and appropriate dosage or schedule changes should be instituted. The nutritionist and psychologist or social worker also gives follow-up advice and support.

A detailed interim history should include questions relating to general health, energy, fatigue, polyuria or nocturia, intercurrent illnesses, hypoglycemic episodes, and the presence of symptoms, such as abdominal pain, bloating, or diarrhea. It is important to remember the comorbidities of other autoimmune disorders that occur with an increased frequency in children with T1DM: thyroiditis, adrenal insufficiency, and celiac disease. The child should be weighed and measured at each visit, and blood pressure documented. Physical examination of the child should focus on the general organ systems and on examination of the skin and insulin injection/pump insertion sites for signs of lipohypertrophy or pigmentary changes, palpation of the thyroid, and determination of the stage of sexual development stage.

Lipohypertrophy was commonly observed in the past but is now a rare complication of insulin therapy.⁵⁶⁹ A deceleration in growth, delay in sexual development, or finding of goiter may herald hypothyroidism. The astute clinician should also consider that frequent unexplained hypoglycemia or reduction in insulin requirements in the absence of exercise or activity might be subtle indicators of hypothyroidism or adrenal insufficiency. Similarly, although a history of having frequent foul-smelling greasy stools is a more obvious indicator of celiac disease, the majority of cases are asymptomatic.

Measurement of glycosylated hemoglobin (HbA1c) provides the gold standard by which to judge the adequacy of the insulin regimen and use of point-of-service methods that can be performed in the office in a few minutes offers the opportunity to make immediate changes in the insulin regimen while the patient is being seen. Results of point-of-care measurements compare favorably with laboratory methods.⁵⁷⁰

Even more important, the results of this test delivered during face-to-face encounters with the clinician serve as the quarterly “report cards” for the child and the parents. Teenagers may not be able to identify with the concept of working hard on their diabetes to be healthier many years in the future, but most are able to understand good grades. Thus the HbA1c level provides a tangible outcome with which they can identify. The goal of treatment is to achieve HbA1c levels as close to normal as possible. Based on DCCT results and ADA recommendations,¹ our general goal of therapy is to try to keep all patients under 7.5%, although ISPAD has recently lowered the goal to 7.0%.³⁰⁷ HbA1c levels are determined at least every 3 months.

Routine screening for associated autoimmune diseases with T4, TSH, and tissue transglutaminase IgA every 1 to 2 years is recommended. Monitoring of the diabetic child for potential complications and cardiovascular risk factors is another important function of the clinic visit. The normal urinary albumin to creatinine ratio is less than 30 mg albumin to grams creatinine, microalbuminuria is 30 to 300 mg/g, and macroalbuminuria is greater than 300 mg/g. Elevated spot samples should be confirmed at least a second positive. Preferably this would be either a first morning void or a timed overnight collection to rule out benign orthostatic proteinuria. If the confirmatory test also demonstrates microalbuminuria, treatment with angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy or referral to pediatric nephrologist is indicated. All diabetic children with hypertension, regardless of albumin excretion status, should be considered candidates for these medications, as well. Current recommendations for nondiabetic children are that blood pressures above the 90th percentile for age warrant lifestyle intervention and those about the 95th merit the use of pharmacological agents with further details available in ADA and ISPAD guidelines.^{1,571}

Other screening studies for complications of diabetes include measurement of serum lipid concentrations. The current standards of care for adults with diabetes indicate that low-density lipoprotein (LDL) concentrations should be maintained below 100 mg/dL, whereas pharmacological therapy for dyslipidemia in children with diabetes is not recommended unless dietary interventions fail to lower LDL concentrations below 130 mg/dL. The ADA recommends that annual dilated retinal examinations be obtained in patients who are over 10 years or age and have had T1DM for 3 or more years. On the other hand, the yield from such examinations is very low in children and adolescents who have normal blood pressure, HbA1c levels that meet current targets, and who are without microalbuminuria.⁵⁷² A detailed discussion of complications, their diagnosis, prognosis and treatments in children with diabetes is found below.

Management During Surgery

Management objectives during surgery are the prevention of hypoglycemia, excessive loss of fluids, and ketosis during anesthesia. The regimens described here are generally applicable, but vigilance and individual adjustments for each patient are necessary to achieve these goals. Evidence-based, controlled studies of perioperative care have not been carried out in children, but detailed expert reviews of management have been published in the anesthesia and pediatric diabetes literature⁵⁷³ and recent ISPAD Guidelines.^{574,575}

The most reliable and straightforward approach to achieving management objectives during major elective or emergency surgery is to use IV infusions of glucose and insulin during the perioperative period. For surgical emergencies that can be briefly delayed, such as acute appendicitis, rehydration and metabolic balance should be restored before the operation. Elective major operations should be performed first thing in the morning, and the glucose and insulin infusions should be started 2 hours or

more before proceeding to the operating room. For elective surgeries, an infusion of 5% glucose in 0.45% or 0.9% saline solution is begun on the morning of surgery—and 1 unit of regular insulin is infused intravenously for each 4 to 6 g of administered glucose. One unit of regular insulin for every 2 to 4 g of exogenous glucose may be required in surgical emergencies because of elevated circulating concentrations of stress hormones or in insulin-resistant obese diabetic patients.

The rate at which IV fluids are administered should be sufficient to provide maintenance fluid requirements plus estimated losses during surgery and other fluid deficits. The blood glucose concentration should be monitored at periodic intervals before, during, and after surgery. Concentrations of 120 to 150 mg/dL should be the goal. This can be achieved by varying the rate of infusion of the glucose and electrolyte mixture or the rate of insulin administration. The IV insulin and glucose infusions can be continued until the patient is awake and capable of taking regular meals, at which time their usual injection or insulin pump regimen can be reinstated. Use of continuous glucose monitoring devices during surgery in children and adolescents has not been adequately studied.

In patients who receive long-acting insulin in the morning and are undergoing surgery of short duration, a standard and effective approach is as follows: on the morning of surgery, half of the usual morning dose of long-acting insulin is administered subcutaneously, the usual dose of rapid-acting insulin is omitted unless needed to correct hyperglycemia, and a maintenance IV infusion of the electrolyte and glucose solution is initiated if needed. Similarly, in patients on insulin pump therapy who are undergoing short procedures, the CSII can be continued at the usual or slightly reduced overnight basal rate. Insulin pump-treated patients can also be maintained on CSII for major procedures, as long as the integrity of the infusion and infusion site is ensured.

The nighttime dose of glargine or detemir insulin may provide sufficient basal insulin coverage for surgery in patients who receive these long-acting insulins before dinner or bedtime. A reduction in the glargine or detemir dose by 20% to 30% on the night before surgery should be considered in patients who have had a tendency to low prebreakfast plasma glucose levels. With all three regimens, a correction dose of rapid-acting insulin can be given subcutaneously immediately after the procedure if needed for hyperglycemia—and repeated as needed to balance initial oral intake (e.g., carbohydrate-containing clear liquids). When the IV infusion is discontinued and the patient is ready to resume regular meals, the usual treatment regimen is reinstated.

Nonautoimmune Type 1 Diabetes

Not all forms of apparently classic T1DM have associated markers of autoimmunity.⁵⁷⁶ In one report, among children presenting with newly diagnosed DM, fewer of those younger than 5 years of age at diagnosis had positive titers of islet cell and GAD antibodies—and fewer had a honeymoon phase within 6 months—compared with a group with onset at a mean age of 10 years.⁵² Similarly, Japanese investigators have reported that some patients with idiopathic T1DM have a nonautoimmune fulminant disorder with abrupt onset characterized by absence of circulating antibodies, evidence of insulinitis in pancreatic biopsies, and high concentrations of pancreatic enzymes—suggesting an acute inflammatory process in the pancreas.^{53,54}

MODY syndromes may also be initially considered to be T1DM.^{13,14} However, a strong family history of vertically transmitted DM in two to three generations, absence of autoimmune markers, and relatively milder features of diabetes should alert the physician to the possibility of a monogenic form of diabetes, such as MODY.

COMPLICATIONS OF DIABETES

The complications of DM can be acute or chronic. Acute complications are primarily those related to morbidity associated with DKA, such as cerebral edema, stroke, pancreatitis, deep vein thrombosis, rhabdomyolysis, pneumomediastinum, pulmonary edema, and mucormycosis. These complications have been described in the section on DKA. Chronic or long-term complications are either metabolic or vascular.

Chronic Metabolic Complications

Mauriac Syndrome

Mauriac syndrome is a metabolic complication of poor glycemic control unique to children. Mauriac syndrome is characterized by growth failure, short stature, delayed puberty, and marked hepatomegaly from massive deposition of glycogen.⁵⁷⁷ This syndrome is seen in children who have been under very poor control (HbA1c usually >10%) for several years. The etiology of the growth retardation is not entirely clear, but the effect of chronic insulinization, which is central to this syndrome, on the growth hormone-IGF-1 (GH-IGF1) axis has been implicated in the pathogenesis of the growth failure.⁵⁷⁸ A recent report of a loss of function mutation in the catalytic subunit of liver glycogen phosphorylase kinase in a patient with Mauriac syndrome implicates this enzyme in the pathogenesis of the hepatomegaly.⁵⁷⁹ Glycogen phosphorylase kinase activates glycogen phosphorylase, the enzyme that catalyzes the first step in breakdown of glycogen. It is posited that in this subject, hyperglycemia because of poor glycemic control combined with the loss of function mutation, inhibited glycogen phosphorylase thereby blocking glycogenolysis and resulting in the massive hepatomegaly that is characteristic of Mauriac disease. Although the more severe forms of this syndrome are rare in the developed countries, the presence of hepatomegaly or subtle degrees of growth failure, especially the blunting of the pubertal growth spurt, is not an uncommon observation in clinical practice in the United States.⁵⁸⁰

Limited Joint Mobility

Limited joint mobility (LJM) is an early clinically evident complication of T1D in children and adolescents.⁵⁸¹ LJM is caused by periarticular connective tissue thickening and stiffness and can manifest as single joint involvement, multiple joint involvement with hand deformity, and even limitation of movement of the spine. The pathology is thickening of the dermis and epidermis with accumulation of collagen and loss of skin appendages.⁵⁸² LJM is associated with poor glycemic control, substantial growth impairment, and increase risk of microvascular disease. The marked decrease in the frequency of LJM and statural deficit in children and youth with diabetes in the 20 years between the late 1970s and 1990s can be attributed to improved metabolic control of children and adolescents.⁵⁸¹ The prevalence of LJM in a population may serve as a measure of quality of diabetes control.

Chronic Vascular Complications

The long-term vascular complications of diabetes include microvascular and macrovascular disease. Microvascular diseases include nephropathy, retinopathy, and neuropathy. Macrovascular disease manifestations include cardiac disease, peripheral vascular disease, and stroke.

Risk Factors for Complications

Until the early 1990s, the dogma was that chronic complications of T1D complications were unrelated to metabolic

control and were inherent to the disease and hence could not be delayed or prevented. A paradigm shift in our understanding of the risk factors for chronic complications ensued from the findings of the DCCT. The DCCT was a multicenter, randomized controlled clinical trial involving 1441 patients with T1D conducted in North America from 1983 to 1993.⁵⁸³ Study participants included 195 pubertal adolescents (aged 13–17 years). Patients were randomized to either intensive or conventional treatment; intensive via pump or MDI of insulin and conventional via two injections of combinations of regular insulin plus NPH or a similar long-acting product. The DCCT provided unequivocal evidence that intensive diabetes treatment and improved glycemic control confer a significant risk reduction for microvascular complications compared with conventional treatment. In the adolescent cohort, the intensive treatment (mean HbA1c 8.1%) compared with conventional treatment (mean HbA1c 9.8%) for a median duration of 7.4 years, reduced the risk and progression of DR by 53%, clinical neuropathy by 60%, and microalbuminuria by 54%. A follow-up study, which continued to track the participants of the DCCT, namely the EDIC study, demonstrated that this positive effect continued after the end of the intervention: that is, that there was a memory effect of improved glycemic control.⁵⁸⁴ The findings of the DCCT and EDIC studies revolutionized our understanding of the risk factors for microvascular complications and made achievement of better glycemic control the cornerstone of current diabetes regimens. Long-term vascular complications are a function of the degree and duration of poor metabolic control. Hence it is not surprising that clinically evident chronic vascular complications are less common in childhood and adolescence compared with the adult. However, studies have shown that early functional and structural abnormalities may be present even within the first few years after the onset of the disease. Thus the importance of understanding and recognizing the pathophysiology and risk factors in childhood and adolescence is to enable the adoption of management strategies and regimens during this period that could prevent or delay the appearance of overt complications later in adult life.

Other Risk Factors for the Development of Complications

Longer duration of diabetes, older age, and puberty are risk factors for complications. A lower prevalence of microvascular complications has been reported for adolescent boys compared with girls.^{585,586} Longitudinal studies have also reported that younger age of T1D onset, particularly before puberty, is associated with a longer time free of complications, such as nephropathy and retinopathy.⁵⁸⁷ Smoking is associated with an increased risk of developing persistent albuminuria, excessive cardiovascular morbidity, and mortality.⁵⁸⁸ High blood pressure and alterations in the circadian blood pressure rhythm have been associated with the risk of developing nephropathy and retinopathy in youth with T1D.⁵⁸⁹ Dyslipidemia was associated with microalbuminuria and retinopathy development in the DCCT/EDIC and other studies.⁵⁹⁰ Higher BMI is a risk factor for microalbuminuria, retinopathy, neuropathy, and cardiovascular disease (Table 21.12).⁵⁹¹ Studies have revealed that there is clustering of complications. For example, complications that co-occur more frequently than expected are retinopathy and diabetic kidney disease, retinopathy and arterial stiffness, and arterial stiffness and cardiovascular autonomic neuropathy.⁵⁹²

Diabetic Nephropathy

Diabetic nephropathy (DN) is one of the most frequent and serious chronic complications of DM. Overt DN is the most

TABLE 21.12 Screening Recommendations and Risk Factors for Vascular Complications in Children and Adolescents With Type 1 Diabetes Mellitus

	Initiation of Screening	Screening Methods	Risk Factors
Nephropathy	11 years with 2–5 years of diabetes	Urinary albumin/creatinine ratio	Hyperglycemia High BP Lipid abnormalities Smoking
Retinopathy	11 years with 2–5 years of diabetes	Fundal photography or mydriatic ophthalmoscopy	Hyperglycemia High BP Lipid abnormalities Higher BMI
Neuropathy	11 years with 2–5 years of diabetes	History Physical examination Clinical tests	Hyperglycemia Higher BMI Age Diabetes duration Genetics
Macrovascular disease	11 years with 2–5 years of diabetes	Lipid profile every 2 years, BP annually	Hyperglycemia High BP Lipid abnormalities Higher BMI Smoking

BMI, Body mass index; *BP*, blood pressure.
(Modified from Donaghue, K.C., et al. (2018). ISPAD Clinical Practice Consensus Guidelines 2018: microvascular and macrovascular complications in children and adolescents. *Pediatr Diabetes*, 19 (Suppl 27), 262–274.)

common cause of excess mortality associated with DM. Overt DN is exceptionally rare before puberty and is uncommon even in teens with long-standing diabetes. However, the processes that lead to overt DN are initiated early in the course of the diabetes. Studies have yielded histological evidence for early stages of DN within 2 to 5 years after diagnosis of T1D.⁵⁹³

DN was originally described as a glomerulopathy associated with diffuse or nodular glomerulosclerosis (Kimmelsteil-Wilson lesion).⁵⁹⁴ However, less than one-third of patients with T1D and microalbuminuria have the typical glomerulopathy described by Kimmelsteil and Wilson. The pathophysiological changes in DN include hyperplasia or hypertrophy of various cell types of the glomerulus and tubules, thickening of glomerular and tubular basement membranes, and expansion of tubulointerstitial and mesangial compartments.⁵⁹⁵ Recent studies have focused on the role of podocytes in the development of DN. Podocytes are unique, highly specialized, terminally differentiated visceral epithelial cells in the renal glomerulus that wrap around the capillaries of the glomerulus.⁵⁹⁶ Podocytes play a key role in maintaining glomerular selectivity of permeability. The development of proteinuria is associated with morphological changes in podocytes causing their dysfunction and subsequent apoptosis, ultimately leading to depletion of these cells within the glomerulus, including foot process effacement. Foot process effacement and decreased podocyte number and/or density per glomerulus have been reported in both T1D and T2D.⁵⁹⁷ Although most of the studies have focused on glomerular changes in the diabetic kidney, more recently, important changes in other sites of the renal tissue have been reported, including the tubules, interstitium, medulla, and papilla.⁵⁹⁸

The identity, evolution, and the temporal sequence of events and processes that play a role in the initiation and progression of DN is incompletely understood. Hyperglycemia is necessary for the initiation of renal structural injury, as subjects without diabetes do not develop the same type of nephropathy. Early in the course of T1D, hyperglycemia disturbs the homeostasis of blood flow and vascular permeability in the glomerulus. In vitro studies have demonstrated that hyperglycemia induces mesangial cell matrix production and mesangial cell apoptosis. Increased concentration of mitochondrial reactive oxygen species is implicated in the pathogenesis of DN. Hyperglycemia-induced overproduction of mitochondrial superoxide is posited to activate pathways of vascular tissue damage, leading to cellular redox imbalance and oxidative stress.⁵⁹⁹ Another process believed to play a significant role in DN is accumulation of advanced glycation end products (AGEs). Many of the proteins with a long life, such as collagen, are extensively glycosylated in patients with diabetes. Furthermore, various AGE receptors, such as RAGE, have been described in the kidney and implicated in mediating some of the deleterious effects of AGEs by inducing the expression of transforming growth factor (TGF)- β and other cytokines that are proposed to mediate the transdifferentiation of epithelial cells to form myofibroblasts, a key step in the development of tubulointerstitial fibrosis.⁵⁹⁹ Activation of intracellular signaling molecules, such as protein kinase C (PKC), has also been shown to result in glomerular basement membrane (GBM) hyperplasia and signal transduction for growth factors.⁶⁰⁰ Increased activity of the GH-IGF1 axis and increased prorenin activity have been suggested as contributing to the development of DN.^{601,602} Low-grade inflammation could play a significant role in the pathogenesis of DN via activation of cytokines, such as TGF- β . Downregulation of the renal expression of nephrin (a transmembrane protein localized to the slit membrane between adjacent podocytes of the glomerulus and expressed by podocytes) is impaired in T1D and been implicated in the malfunctioning of the renal filtration barrier in DN and development of albuminuria.⁶⁰³

The natural history of DN in T1D is traditionally described in the following stages.

Stage 1 (hyperfiltration stage) is the initial phase associated with an increase in glomerular filtration rate (GFR) and increased capillary glomerular pressure. The exact pathophysiology of this stage remains unclear.⁶⁰⁴ Studies have demonstrated a correlation between elevated GFR and later development of proteinuria.⁶⁰⁵ Stage 2 (silent stage) is characterized by absence of overt evidence of renal dysfunction with maintenance of GFR and lack of albuminuria. However, renal morphological studies demonstrate significant structural changes, including basement membrane thickening and mesangial expansion in these nonalbuminuric subjects.⁶⁰⁶ In Stage 3 (microalbuminuric stage) the urinary albumin excretion rate is increased to the microalbuminuric range of 20 to 200 mcg/min or 30 to 300 mg/24 hours. Persistent microalbuminuria is defined when microalbuminuria is confirmed on at least two occasions 3 to 6 months apart. Microalbuminuria is considered as the earliest marker of the development of DN. Microalbuminuria at the higher end of the normal range at the age of 10 to 16 years is associated with an increased risk of progression to microalbuminuria and future cardiovascular disease risk, independently of HbA1c.⁶⁰⁷ However, recent studies showed that microalbuminuria may be temporary and does not necessarily reflect permanent renal impairment.⁶⁰⁸ The reversal of microalbuminuria is more likely when it is of short duration; glycemic control is appropriate; and systolic blood pressure, serum cholesterol, and triglyceride levels are in the normal range.⁶⁰⁹ Conversely, early lesions in both glomerular

and tubular structures may occasionally be present in nonalbuminuric subjects.⁶¹⁰ Stage 4 (macroalbuminuria stage) is defined by the development of urinary albumin excretion rate greater than 300 mg/24 hours (200 mcg/min). This stage is strongly predictive of subsequent progress to renal failure, if left untreated. Stage 5 (renal impairment) characterized by uremia and end-stage renal disease can occur in up to 40% of T1D patients. These patients require either dialysis or renal transplantation.

Screening for Microalbuminuria

The earliest clinical marker of DN is microalbuminuria, and current guidelines recommend that annual screening for microalbuminuria should start from age 11 years with 2 to 5 years diabetes duration.⁵⁹¹ Microalbuminuria is defined as:

- Albumin/creatinine ratio (ACR) 2.5 to 25 mg/mmol or 30 to 300 mg/g (spot urine) in males and 3.5 to 25 mg/mmol or 42 to 300 mg/g in females (because of lower creatinine excretion)
- or
- Albumin excretion rate (AER) between 20 and 200 mcg/min or between 30 and 300 mg/24 h in 24 hours or timed urine collections.

Microalbuminuria is confirmed by finding two or all of three samples abnormal over a 3 to 6 month period. Assessing ACR in a spot urinary sample is the easiest method to carry out in an office setting and it generally provides accurate information. First-voided urine in the morning is preferable because of the diurnal variation in albumin excretion and postural effects. A random sample can be used but is associated with an increased risk of false positive results, and therefore abnormal results should be confirmed with first morning urine collections. Confounding factors that could result in false positive (increased ACR/AER) tests include strenuous exercise, infections, nondiabetic kidney disease (i.e., IgA or other types of nephritis), marked hyperglycemia, fever, and menstrual bleeding. Timed overnight or 24-hour collections are more burdensome and generally do not enhance accuracy or prediction of DN.^{609,610}

Effective antihypertensive therapy in patients with nephropathy prolongs the time to end-stage renal disease. Hypertension in children is defined as blood pressure equal to or above the 95th percentile for age, sex, and height, whereas in adolescents (age ≥ 13 years), it is defined as systolic blood pressure ≥ 130 and/or diastolic blood pressure ≥ 80 . Elevated blood pressure (previously known as *prehypertension*) is defined as blood pressure over the 90th percentile for age, sex, and height, or from the age of 13 years, as blood pressure between 120 to 129/80 mmHg. Similar to overt hypertension, elevated blood pressure is associated with adult hypertension and potentially amenable to treatment. Children and adolescents found to have elevated blood pressure or hypertension should have elevated blood pressure confirmed on 3 separate days. Confirmation of hypertension may be assisted by 24-hour ambulatory blood pressure measurements. In children and adolescents with elevated blood pressure, initial treatment includes lifestyle interventions encompassing dietary modifications and moderate to vigorous physical activity at least 3 to 5 days per week (30–60 minutes per session). If target BP is not reached within 3 to 6 months of initiating lifestyle intervention, pharmacological treatment should be considered (Table 21.13). Pharmacological treatment of hypertension in children and adolescents should be initiated with an angiotensin-converting enzyme (ACE) inhibitor, angiotensin II receptor blocker (ARB), long-acting calcium channel blocker, or a thiazide diuretic.⁶¹¹ ACE inhibitors are recommended for use in children and

TABLE 21.13 Recommended Threshold Values for Intervention and Primary Prevention of Microvascular and Cardiovascular Disease in Children and Adolescents With Type 1 Diabetes

Threshold Value	Intervention
BP >90th percentile for age, gender and height	Lifestyle intervention: exercise, less screen time and diet
BP >90th percentile despite lifestyle intervention	ACE inhibitor or other BP lowering agent If microalbuminuria is present: ACE inhibitor or ARB
BP >95th percentile for age, gender and height	Lifestyle intervention and ACE inhibitor or other BP lowering agent If microalbuminuria is present: ACE inhibitor or ARB
LDL cholesterol >2.6 mmol/L (100 mg/dL)	Dietary and lifestyle intervention
LDL cholesterol >3.4 mmol/L (130 mg/dL) and one or more CVD risk factors	Statins

ACE, Angiotensin-converting enzyme; ARB, angiotensin II receptor blocker; BP, blood pressure; CVD, cardiovascular disease; LDL, low-density lipoprotein.

(Modified from Donaghue, K.C., et al. (2018). ISPAD Clinical Practice Consensus Guidelines 2018: microvascular and macrovascular complications in children and adolescents. *Pediatr. Diabetes*, 19 (Suppl 27), 262–274.

adolescents with hypertension and albuminuria, but an ARB can be used if the ACE inhibitor is not tolerated because of side effects. The goal of treatment is blood pressure consistently under the 90th percentile for age, sex, and height. In adults, ACE inhibitors and ARBs reduce progression from microalbuminuria to macroalbuminuria and increase the regression rate to normoalbuminuria. However, a metaanalysis revealed that the beneficial effects were more modest in those with the lowest levels of microalbuminuria.⁶¹² In addition, there are still concerns regarding the use of ACE inhibitors in protecting long-term renal function in young people without hypertension. Young people with albuminuria would potentially be taking ACE inhibitors for decades. Side effects include cough, hyperkalemia, headache, and impotence. A key safety issue related to the use of ACE inhibitors, as well as to ARBs, is the potential risk of congenital malformation when used during pregnancy. These risks should be discussed with the family before starting treatment and appropriate birth control measures recommended.

Diabetic Retinopathy

Worldwide and in the United States, DR is a leading cause of new cases of blindness.⁶¹³ The significance of DR cannot be overstated in the pediatric age group. Untreated, this complication has disastrous consequences as it typically leads to blindness. In the landmark study of DR carried out in Wisconsin starting in 1980 to 1982, after 15 years of diabetes, 98% had background retinopathy and after 35 years' duration 62% had proliferative retinopathy.⁶¹⁴ The DCCT study demonstrated the value of tight glycemic control in reducing the risk of blindness.⁵⁸³ Subsequent changes in diabetes management have been associated with a reduction in proliferative retinopathy resulting in decreased rates of DR. More recent data from a cohort in midadolescence (median age 16.4 years) with median diabetes duration of 8.6 years revealed that DR had declined from 53% (in 1990–1994) to 23% (in 2000–2004) and to 12% (in 2005–2009).⁶¹⁵ In a younger group aged 11

to 17 years (median age 14.5 years, duration 2–5 years), the prevalence of mild background retinopathy declined from 16% in 1990 to 1994 to 7% in 2003 to 2006.⁶¹⁴ Furthermore, those with shorter duration had considerably less retinopathy, and retinopathy was present in only 6% of the youngest group (aged 11–13 years).

The retina is comprised of neural, glial, and vascular components. Whereas all three components are adversely affected in DM, from a clinical point of view, it is the changes in retinal vasculature that are most obviously affected by diabetes. In diabetes, presumably because of changes in retinal metabolism, there is a demand for increased retinal blood flow. It is posited that increased retinal blood flow is the earliest finding in DR and damage from chronic vasodilation of the retinal vessels leads to the formation of the characteristic retinal lesions seen in DR.⁶¹⁶ Other mechanisms have been postulated to explain retinovascular damage, including oxidative stress, increased glucose metabolism by the polyol pathway, advanced glycosylation end products that may give rise to basement membrane thickening, and activation of protein kinase C.⁶¹⁷

DR is classified into the following types⁵⁹¹: nonproliferative retinopathy is characterized by microaneurysms, retinal hemorrhages both pre- and intraretinal, cotton wool spots related to ischemia and microinfarction, hard exudates because of protein and lipid leakage, intraretinal microvascular abnormalities (IRMAs), and venular dilatation and tortuosity. Mild and moderate stages of nonproliferative retinopathy are not vision-threatening and do not invariably progress to more severe stages of retinopathy. Severe nonproliferative retinopathy (previously known as *preproliferative*) is characterized by vascular obstruction, increase in number of retinal hemorrhages and microaneurysms, IRMAs, marked venous abnormalities, and ischemia and infarctions of the retinal nerve fibers causing cotton wool spots. Proliferative diabetic retinopathy (PDR) is characterized by neovascularization in the retina and/or vitreous posterior surface. The vessels can rupture or bleed into the vitreoretinal space, which is vision-threatening. Diabetic macular edema/maculopathy is characterized by decreased vascular competence and microaneurysm formation, which produce exudation and swelling in the central retina.

Assessment of Retinopathy

Presently, the most sensitive detection methods for retinopathy screening are a clinical biomicroscopic fundus slit examination through dilated pupils by an ophthalmologist or optometrist and mydriatic seven-field stereoscopic retinal photography.⁵⁹¹ The latter is optimal for research but is not widely available in the clinical setting. Other methods are mydriatic and nonmydriatic two-field fundal photography, direct ophthalmoscopy, indirect ophthalmoscopy, fundus fluorescein angiography, and optical coherence tomography. Rapid advancements in photography and optics combined with AI and machine learning have opened up new, innovative, and more efficient techniques for screening for DR that could be adopted for routine use in the clinical arena in the near future.⁶¹⁸

Current recommendations are that screening for DR should start from age 11 years with 2 to 5 years diabetes duration.⁵⁹¹ A comprehensive initial eye examination should also be considered to detect cataracts, major refractive errors, or other ocular disorders. For those with diabetes duration less than 10 years, mild nonproliferative retinopathy (microaneurysms only) and good glycemic control, biennial screening assessment by biomicroscopic examination or fundal photography may be sufficient. The frequency of retinopathy screening should be more frequent if there are high-risk features for visual loss. Initial worsening of DR can occur with the initiation of improvement in glycemic control especially in patients with long-term uncontrolled

diabetes and severe underinsulinization.^{619,620} Careful retinal examination should be performed in all such patients before initiating intensive insulin therapy. To date, there is no evidence that controlling the speed or magnitude of HbA1C decreases will reduce the risk of DR in patients with diabetes.⁶¹⁹ Pregnancy is a recognized risk for acceleration and progression of retinopathy⁶²¹; hence screening for retinopathy should be undertaken preconception, every trimester and 1 year postpartum.

Treatment for Retinopathy

Treatment options for sight-threatening retinopathy include laser photocoagulation and/or antivascular endothelial growth factor (VEGF) therapy. Pan-retinal laser photocoagulation (PRP or commonly known as *laser therapy*) has been proven to reduce the progression of visual loss by more than 50% in patients with PDR.⁶²² However, photocoagulation is not indicated for eyes with mild or moderate nonproliferative retinopathy. Complications of laser therapy are vitreal and choroidal hemorrhages or visual sequelae of misplaced burns. For PDR, intravitreal injection of anti-VEGF monoclonal antibody (e.g., aflibercept) is now increasingly used and shows better 12-month results for visual acuity than PRP.⁶²³ This treatment is not destructive but does require repeated visits and injections for efficacy (e.g., monthly injections for the first 5 months with up to nine injections in the first year), and carries the rare risk of ocular infection. For diabetic macular edema involving vision loss, anti-VEGF monoclonal antibody (e.g., bevacizumab) is now considered standard of care and has shown superior outcomes over 5 years compared with laser treatment.⁶²⁴ Surgical treatment, such as vitrectomy, may be indicated for persistent vitreous hemorrhage, tractional retinal detachment, or extensive fibrosis.⁶²⁵

Diabetic Neuropathy

Diabetic neuropathy is a major complication of diabetes. In contrast to adults, children and adolescents with diabetic neuropathy, because they are early on in the disease process, are asymptomatic.⁶²⁶ The importance of recognizing and diagnosing diabetic neuropathy in children and adolescents is that early detection of subclinical neuropathy during childhood will enable earlier intervention, with the possibility of reducing or delaying the incidence of clinical neuropathy later in life.

Classification of Diabetic Neuropathies (Modified from Pop-Busui et al.⁶²⁷)

A. Diffuse neuropathy

- Distal symmetric polyneuropathy (DSPN)
 - Primarily small-fiber neuropathy
 - Primarily large-fiber neuropathy
 - Mixed small- and large-fiber neuropathy (most common)
- Autonomic
 - Cardiovascular
 - Gastrointestinal (including gastroparesis, enteropathy, colonic hypomotility)
 - Urogenital (including diabetic cystopathy, erectile dysfunction, female sexual dysfunction)
 - Sudomotor dysfunction (including hypohydrosis/anhidrosis, gustatory sweating)
 - Hypoglycemia unawareness
 - Abnormal pupillary function

B. Mononeuropathy—Isolated cranial or peripheral nerve (e.g., cranial nerve [CN] III, ulnar, median, femoral, peroneal)

C. Radiculopathy or polyradiculopathy—lumbosacral polyradiculopathy, proximal motor amyotrophy

The most common type of childhood diabetic neuropathy is DSPN. Large nerve fiber dysfunction manifests as loss of distal tendon reflexes and altered perception of vibration, proprioception, and/or tactile sensation. Small fiber dysfunction manifests as hyperesthesia and decreased pain and temperature sensation. More than half of the children with early diabetic DSPN may be asymptomatic.⁶²⁸ The reported prevalence rates for diabetic neuropathy in children vary from under 10% to 30%.^{628,629} This wide variance possibly reflects differences in patient selection, clinical status, the type of diagnostic tests used, and the criteria used to define diabetic neuropathy. Abnormal nerve conduction studies can be detected as early as within 6 months after diagnosis of T1D, with improvement after correction of hyperglycemia.⁶³⁰ The presence of diabetic autonomic neuropathy is likely underestimated owing to suboptimal screening. Subclinical diabetic autonomic neuropathy has been reported to be between 8% and 43% in children with T1D.⁶³¹ Diabetic neuropathy is also an early complication of T2D. Recent studies have reported that prevalence of DSPN was significantly higher in youth with type 2 compared with those with T1D (25.7% vs. 8.2%).⁶²⁹

All patients should be assessed for DSPN 5 years after the diagnosis of T1D and at diagnosis of T2D, and at least annually thereafter.⁶²⁷ Assessment should include a history and physical examination, and either temperature or pinprick sensation (small-fiber function) and vibration sensation using a 128-Hz tuning fork (large-fiber function).⁶²⁷ All patients should have an annual 10-g monofilament testing to assess for feet at risk for ulceration and amputation. Electrophysiological testing or referral to a neurologist is rarely needed for screening, except in situations where the clinical features are atypical or the diagnosis is unclear. Atypical features include motor greater than sensory neuropathy, rapid onset, or asymmetrical presentation. Tight glucose control is the cornerstone of prevention of diabetic neuropathy. Despite the advances in elucidating the pathogenesis of diabetic neuropathy, there is a paucity of treatment options that alter the natural history of DSPN or reverse DSPN once established.⁶³² Pharmacological agents, such as pregabalin and duloxetine, have been proven to be of benefit in the treatment of neuropathic pain.⁶²⁷

A final point regarding neural changes in children with diabetes is the accumulating evidence that acute hyperglycemia impairs brain function manifest as lower spatial working memory along with changes in relevant areas of functional MRI in adolescents with T1DM.⁶³³ Also, chronic hyperglycemia in younger children is associated with altered white matter development, which might contribute to their documented mild cognitive deficits.⁶³⁴

Macrovascular Disease

Cardiovascular disease is a leading cause of mortality in patients with T1D. Whereas overt diabetes-related cardiovascular disease complications are rare until adulthood, the early markers and the pathophysiological foundations of these complications are manifest in adolescents and young adults with T1D.⁶³⁵ In general, progress in reducing macrovascular complications has lagged behind similar efforts targeted toward the management of microvascular complications of T1D. The reasons for this disparity may relate to differences in the pathogenesis and the longer time needed to develop macrovascular complications.⁶³⁵ Because cardiovascular events (such as stroke, myocardial infarction) are absent or rare in childhood and adolescence, studies have had to rely on surrogate parameters and indices (such as carotid intima thickness). Traditional risk factors for cardiovascular disease are hyperglycemia, hypertension, dyslipidemia, and diabetic kidney disease. However, the precise relationship of these risk factors to macrovascular disease in the pediatric age group is unclear at the present time. Hence in contrast to studies in the adult, pediatric studies have

failed to demonstrate a clear relation between HbA1c concentrations and measures of vascular health.⁶³⁶ Obesity is a risk factor for early death because of cardiovascular event and the rates of obesity are increasing significantly in children and adolescents with T1DM. The role of lifestyle and behavioral factors, such as exercise, diet, smoking, stress, sleep, and depression is also important in the pathogenesis of macrovascular disease in patients with T1DM.

Hyperglycemia, hypertension, and dyslipidemia are major contributory factors for cardiovascular disease. However, achieving reduction of these risk factors in children and adolescents remains a challenge for a variety of reasons.⁶³⁶ The insidious nature of the effect of these risks factors, compounded with the long time needed for the development of cardiovascular disease masks the importance of these risk factors. Lack of rigorous studies in the pediatric age group is another factor that detracts from assigning a high priority to these risk factors in children and adolescents. The majority of the evidence available in the pediatric age group are inferred from adult studies.

In T2D, comorbidities may already be present at the time of diagnosis of T2D in youth. Therefore blood pressure measurement, a fasting lipid panel, assessment of random urine albumin to creatinine ratio, and a dilated eye examination should be performed at diagnosis. Thereafter, screening guidelines and treatment recommendations for hypertension, dyslipidemia, urine albumin excretion, and retinopathy are similar to those for youth with T1D. Additional problems that may need to be addressed include polycystic ovary disease and other comorbidities associated with pediatric obesity, such as hepatic steatosis, sleep apnea, orthopedic complications, and psychosocial concerns.

TYPE 2 DIABETES MELLITUS

Typical

T2DM, formerly known as *NIDDM*, is a heterogeneous disorder characterized by defective insulin secretion that progressively fails to compensate for insulin resistance.⁶³⁷ The cause of insulin resistance is usually obesity,^{637–642} although agents such as growth hormone and cortisol also antagonize insulin action and may unmask inadequately compensated insulin secretion. The high concentrations of placental growth hormones during mid to late gestation likewise may unmask inadequate insulin secretion, resulting in gestational diabetes—a harbinger of permanent diabetes later in life.

The mechanism of insulin resistance caused by obesity may in part relate to changes in fatty acid metabolism that interfere with normal glucose metabolism, and in part to factors synthesized within fat cells that antagonize insulin action.⁶⁴³ Most notable are the hormones adiponectin, leptin, and resistin,⁶⁴³ which are produced by fat cells and are a likely major link between obesity and diabetes. Genetic regulation of the ability to compensate for insulin resistance may be another mechanism that predisposes or protects from T2DM.^{644,645} Thus in addition to the genetic components responsible for impaired insulin secretion (which are being investigated, progressively identified, and presently cannot be changed),^{646–650} the key modifiable factor responsible for the epidemic of T2D in children is the epidemic of obesity increasingly recognized throughout the world.^{650–654}

T2DM is being increasingly recognized in children, particularly obese adolescents and especially but not exclusively in certain ethnic groups, such as Native American Indians, non-Hispanic black Americans, Hispanic Americans, Pacific Islanders, and Southeast Asians in the developing world.^{650–654} Here, too, a genetic predisposition for insulin resistance together with the epidemic of obesity is responsible for a rapid increase in the proportion of patients with T2D—representing up to half of the newly presenting cases in one major medical center in the

United States.^{650,651} In these vulnerable groups, rates of T2DM have almost doubled from 2002 to 2012.⁴⁷

In addition to obesity, these patients often have a family history of T2D, indicative of genetic predisposition. They also may have acanthosis nigricans, are more commonly female, and often have poor metabolic control that predisposes them to the earlier appearance of microvascular and macrovascular complications.⁶⁵¹ There is an accelerated tempo in the development of complications associated with DM; impaired renal function manifest as albuminuria occurs in ~6% within 5 years of diagnosis and about 2.3% have end-stage renal failure by 10 years after diagnosis. Microvascular changes, for example, retinopathy, also appear earlier, and reduction of brain volume with microstructural changes in white matter and decreased cognitive function have been reported.⁶⁵⁵ In the TODAY study, those with a BMI 35 kg/m² or more demonstrated rapid progression of cardiovascular risk factors despite treatment; hypertension tripled over 4 years from 11% to 34%; microalbuminuria increased from 6% to 17% within 3 years; and high-risk LDL (LDL >130 mg/dL or taking medication) increased from 4.5% to 11% after 3 years.⁶⁵⁶ As previously noted, lifestyle intervention and metformin failed and the introduction of insulin promotes further weight gain.^{657,658} For the carefully chosen patient and in the appropriate facility, bariatric surgery offers promising results with amelioration in all manifestations of disturbed metabolism and associated vascular abnormalities, although vitamin and iron deficiencies, as well as surgical complications remain.⁶⁵⁹

Patients with T2DM may present initially in DKA suggesting T1D, but after recovery they may manifest a prolonged honeymoon phase—the so-called *atypical DM*, a form of T2D, as documented by significant insulin or C-peptide levels not consistent with T1D. They also lack markers of islet autoimmunity and the classic HLA associations.⁶⁵¹

In those with a family history of T2DM, insulin resistance (as shown by impaired insulin-stimulated glucose disposal and higher insulin values during oral glucose tolerance or so-called hyperglycemic clamps) is demonstrable in the first decade of life before clinically demonstrable changes in glucose tolerance.^{650,651} The sites of this presumably genetic impairment in insulin sensitivity have not yet been identified but clearly precede clinical DM brought about by obesity-induced insulin resistance.^{650,651} There may be other factors that induce insulin resistance.

There is also an emerging number of newly identified genetic factors associated with impaired insulin secretion and action. Genome-wide scans have consistently identified three major genetic linkages: the K_{ATP}, especially the Kir 6.2 subunit encoded by the *KCNJ11* gene; the peroxisome proliferator-activated receptor γ (*PPARG*); and transcription factor 7 like 2 (*TCF7L2*).^{653,654,660} The development of sophisticated arrays that permit genotyping of literally hundreds of thousands of polymorphisms has revealed additional loci of genetic markers in T2DM, including a polymorphism in the zinc transporter SLC30A8 (expressed only on pancreatic β cells) and genes potentially involved in pancreatic development (*IDE*, *KIF11*, *HHEX*) or function (*EXT2-ALX4*).^{647–654} These sophisticated genetic screening approaches are likely to identify more of the complex genetic traits that underlie T2DM. However, the complexity of the genetic contributions to T2DM remain challenging.^{661,662}

From a practical point of view, T2DM in children and adolescents should be viewed as a major public health issue—and without effective lifestyle interventions (such as weight reduction combined with regular exercise), treatment options are limited and only modestly successful.^{650,651} Bariatric surgery is successful in adults and in small population samples has been a durable and effective means to reverse metabolic disturbances, including hyperlipidemia, diabetes, hypertension

albuminuria.⁶⁵⁹ Exogenous insulin may be necessary to control blood glucose initially, but its appetite-stimulating effects challenge attempts at weight reduction. Sulfonylureas may be temporarily helpful, as may meglitinide—which acutely increase insulin secretion.

Metformin, which sensitizes tissue to insulin action and diminishes hepatic glucose production, is the most frequently used agent for treating T2D in children. The FDA has approved it for use for those over 10 years of age. The FDA has not approved for use in children thiazolidinediones (glitazones) that sensitize tissue to insulin, but nevertheless they have reportedly been used.⁶⁶⁰ These agents are potentially hepatotoxic, and the original product was withdrawn for this reason. Newer glitazones (such as rosiglitazone) are under investigation in adolescents with T2DM.⁶⁶⁰ Alpha-glucosidase inhibitors that slow carbohydrate absorption and lipase inhibitors to diminish fat absorption are available and are approved, but clinical trials in children/adolescents for efficacy and compliance have not yet been published. In addition, agents such as GLP-1 receptor agonists, dipeptidyl-peptidase (DPP)4 inhibitors, and SGLT2 antagonists used in adults with T2DM are undergoing trials in adolescents but are not yet approved for use in this age group. This represents a deficiency in our ability to treat T2DM in adolescents and youth.^{650,651} Compared with placebo, the addition of liraglutide, a GLP-1 analog, to metformin and insulin in adolescents with T2DM succeeded in lowering HbA_{1c}, and liraglutide is now approved for use in youth with T2DM.⁶⁶³ It is anticipated that similar studies examining the efficacy and safety of the variety of agents now approved for use in adults with T2DM will become available for use in adolescents and youth in the near future.

GENETIC DEFECTS OF BETA CELL FUNCTION

MODY Syndromes

The term MODY was originally conceptualized as a form of maturity-onset (i.e., type 2) diabetes. However, the MODY syndromes are best considered a group of disorders of monogenic defects in beta-cell function. Affected patients may have only modest elevation of glucose, may remain asymptomatic for many years, and may become clinically apparent during intercurrent illness or pregnancy that unmasks the limitation in insulin secretion.^{13,14} Clinical criteria used to establish the diagnosis include the following:

- Dominant inheritance with at least two (and preferably three) consecutive affected generations
- Onset before age 25 to 30 years
- Evidence of significant but impaired residual insulin secretion reflected in C-peptide levels whether or not the patient is being treated with insulin

Some 14 specific genetic defects have been identified (see also Chapter 10) but of these, the most common are MODY2, MODY3, MODY1, and MODY5 (Table 21.14), which together account for over 85% of all forms. Moreover, milder defects in the K_{ATP} genes *KCNJ11* and *ABCC8*, as well as defects in the insulin gene itself (*INS*), have been found in patients who fulfill the criteria for a diagnosis of MODY. Of these genetic defects that together account for no more than 2% to 5% of diabetes, about two-thirds (65%) are MODY 3 (*HNF1A*), together with MODY 2 (glucokinase defect), and the remainder constitute the other defects. MODY2 has a prevalence of approximately 1:1000 births and may remain entirely asymptomatic until discovered during routine laboratory evaluations, as for example, during pregnancy.^{25,119} Mild stable hyperglycemia may be present from birth and not require treatment except during stress, such as infections in an infant or child, or pregnancy in a young adult.

TABLE 21.14 Classification of Maturity-Onset Diabetes of Youth

Type	Gene	Chromosome	Treatment	Relative Frequency (%)
MODY 1	<i>HNF4A</i>	20q12–q13.1	Insulin/SU	5
MODY 2	Glucokinase	7p15–p13	Exercise/ diet	22
MODY 3	<i>HNF1A</i>	12q24.2	Insulin/SU	58
MODY 4	<i>IPF1/PDX1</i>	13q12.2	Insulin	<1
MODY 5	<i>HNF1β</i>	17q12	Insulin/SU	2
MODY 6	<i>NEUROD1/ Beta-2</i>	2q32	Insulin	<1
MODY 7	<i>KLF11</i>	2p25	Insulin	<1
MODY 8	<i>CEL</i>	9q34.3	Insulin	<1
MODY 9	<i>PAX4</i>	7q32	Insulin	<1
MODY 10	Insulin	11p15.5	Insulin	<1
MODY 11	<i>BLK</i>	8p23.1	Insulin	<1
MODY 12	<i>ABCC8</i>	11p15.1	SU	<1
MODY 13	<i>KCNJ11</i>	11p15.1	SU	<1
MODY 14	<i>APPL1</i>	3p14.3	Insulin	<1

ABCC8, ATP binding cassette subfamily C member 8; *APPL1*, adaptor protein, phosphotyrosine interacting with PH domain and leucine zipper 1; *BLK*, BLK proto-oncogene, Src family tyrosine kinase; *CEL*, carboxyl-ester lipase; *HNF*, hepatic nuclear factor; *IPF/PDX*, insulin promoter factor/pancreas-duodenum homeobox; *KCNJ11*, potassium channel family J number 11; *KLF*, Kruppel-like factor; *NEUROD1/Beta-2*, neurogenic differentiation factor 1/beta-cell E-box transactivator 2; *PAX*, paired homeobox; *SU*, sulfonylurea drugs.

- Maturity-onset diabetes of youth (MODY)1, 2, & 3 together constitute 85% of all known MODY syndromes; if MODY5 is included, almost 90% of all MODY syndromes are defined
- MODY2 is stable, rarely requires insulin treatment except during pregnancy to protect the fetus from hyperglycemia, and has an excellent prognosis for avoidance of vascular complications
- MODY1 & 3 frequently respond to sulfonylurea drugs initially but may progress to insulin dependence and risk for development of vascular complications dependent on metabolic control
- MODY constitutes about 1.5%–3.0% of new-onset childhood diabetes and should be suspected in those with a family history of multiple affected members in two to three generations, with onset before age 35 years, absence of markers of autoimmunity, “mild diabetes” requiring <0.5 U/kg insulin from the outset or unusually prolonged “honeymoon” phase

With glucokinase deficiency, microvascular complications of diabetes are rare.²⁵ In the other common forms of MODY, such as MODY3 and MODY1, however, onset is usually in the early teens to 20s, glucose intolerance may become progressively worse and hence require treatment, and microvascular complications may develop later in life. Renal cysts or other renopelvic anomalies may occur in MODY 5 (*HNF1β*). Notably, if the genetic defect in insulin promoter factor-1 (*IPF1*, MODY 4) is homozygous, pancreatic agenesis results and this is a cause for permanent neonatal diabetes associated with exocrine, as well as endocrine, insufficiency (see Chapter 10). Likewise, homozygous mutations in glucokinase have been associated with congenital diabetes. In contrast, gain-of-function mutations in glucokinase cause persistent hyperinsulinemic hypoglycemia of infancy (see Chapter 7). Thus the MODY syndromes are monogenic defects of islet cell formation (MODY 4) or of transcription factors (MODY 1, 3, 5, and 6)—or a defect in the functional glucose sensor glucokinase (MODY 2).^{13,14,664,665}

Table 21.15 compares and contrasts the four most common types of diabetes found in adolescents: type 1, type 2, atypical DM, and MODY. The monogenic MODY syndromes have been extensively reviewed in terms of chemical, biochemical, and molecular analyses,^{13,14,664,665} and are also discussed in Chapter 10. Other monogenic defects reportedly associated with a type 2 clinical picture include mutation in *GLUT2* and the glycogen synthase genes.^{660,664}

Other Forms of Monogenic Diabetes

Mitochondrial Diabetes

Mitochondrial genetic defects that are associated with diabetes are commonly but not invariably associated with neuromuscular disorders, including deafness, migraine, seizures, and mental retardation. For example, the MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) syndrome may initially present in childhood with short stature, go on to deafness in teen years, and develop diabetes and encephalopathy in midlife. DM may be the only manifestation of a mitochondrial disorder encoded by a gene defect within the mitochondria (all of which are maternally inherited) or a nuclear DNA-encoded gene necessary to the oxidative phosphorylation sequence within mitochondria.

This defective energy pathway leads to progressive impairment of insulin secretion, and thus an initially mild hyperglycemia may progressively worsen. This is the case with the most common form of diabetes caused by a mitochondrial gene mutation at nucleotide pair (np) 3243 of the mitochondrial genome, often associated with deafness. Remarkably, this same genetic defect may be associated with the MELAS syndrome. Initially, patients with np 3243 mutations can be controlled by diet alone but later may require insulin. DM presenting in infancy and severe from the outset and requiring insulin may be associated with mitochondrial DNA deletions, as seen in the Kearns-Sayre syndrome and Pearson syndrome.^{666,667} Fig. 21.7 identified the critical role of energy production, including the mitochondrial oxidative phosphorylation pathway for normal insulin secretion.

Defects in this pathway may be responsible for transient or permanent neonatal DM, especially those that involve activating mutations in the K_{ATP} channel subunits Kir 6.2 (*KCNJ11*) and its regulatory subunit sulfonylurea receptor SUR1 (*ABCC8*) as discussed in Chapter 10. Inactivating mutations in the K_{ATP} subunits cause neonatal hyperinsulinemic hypoglycemia of variable severity, as described in detail in Chapter 7. Diabetes in the mitochondrial syndromes is generally well controlled by exogenous insulin.⁶⁶⁷

Wolfram Syndrome

Wolfram syndrome is characterized by diabetes insipidus, DM, optic atrophy, and deafness (DIDMOAD).^{668,669} There is a selective loss of beta cells, which is responsible for the DM. Genetic linkage studies in consanguineous families with autosomal-recessive inheritance led to the positional cloning of a gene on the short arm of chromosome 4 (termed *WFS1*, and now identified as Wolframin).

Although the function of this gene is not entirely understood, it is expressed in many tissues (most abundantly in beta cells, compared with the exocrine pancreas). Mutations in Wolframin have been identified in many families with Wolfram syndrome. Affected individuals are usually compound heterozygotes. The Wolframin gene may have a role in beta-cell and neural tissue survival, and there does not appear to be a correlation between the observed mutation and severity of disease. Defects in Wolframin have been implicated in the idiopathic common nonimmune form of T1DM.⁶⁶⁸ A second locus of Wolfram syndrome has been mapped to the long arm of chromosome 4 in several consanguineous Jordanian families.⁶⁶⁸ In these patients, diabetes insipidus was not a feature—but upper gastrointestinal bleeding and ulceration were prominent.

Although a mitochondrial form of Wolfram syndrome has been proposed, a defect in mitochondrial DNA could not be confirmed in one large cohort.⁶⁶⁹ It has been suggested that DM (age <15 years) and progressive optic atrophy are highly predictive of Wolfram syndrome. The sequence of appearance

TABLE 21.15 Comparison of the Common Forms of Youth-Onset Diabetes

Characteristic	Type 1 Diabetes	Type 2 Diabetes	Classic MODY	Atypical Diabetes Mellitus
Age at onset	Peaks at 5 and 15 years of age	Teenage years, young adults	<25 years of age	>40 years of age
Predominant ethnic groups affected	White	Hispanic, African American, Native American	Occurs in all ethnic groups	African American
Male-to-female ratio	1.1:1	1:1.5	1:1	1:3
Severity at onset	Acute, severe, insulin required	Subtle, insulin not required	Subtle, insulin not required	Acute, severe, insulin required
Islet autoimmunity	Present	Absent	Absent	Absent
HLA-DR3, -DR4	Very common	No increased frequency	No increased frequency	No increased frequency
Ketosis, DKA	Common	Uncommon	Rare	Common at onset
Long-term course	Insulin-dependent	Noninsulin-dependent	Noninsulin-dependent	Noninsulin-dependent
Prevalence of obesity	Uncommon	≥90%	Uncommon	40%
Proportion of cases of 100% youth-onset diabetes	Most common form of youth-onset diabetes	Rising in frequency; ± as common as type 1 diabetes in specific populations	≤5% of youth-onset diabetes in whites	≤10% of cases of youth-onset diabetes in African Americans
Percentage of probands with an affected first-degree relative	≤15%	Variable but common	100%	>75%
Mode of inheritance	Nonmendelian, generally sporadic	Nonmendelian but strongly familial	Autosomal dominant	Autosomal dominant
Number of genes controlling inheritance	Polygenic	Polygenic	Monogenic	Monogenic
Pathogenesis	Autoimmune beta cell destruction: insulinopenia	Insulin resistance plus relative insulinopenia	Insulinopenia	Insulinopenia

DKA, Diabetic ketoacidosis; MODY, maturity-onset diabetes of the young.

(Modified from Winter, W E., Nakamura, M., & Hause, D. (1999). Monogenic diabetes mellitus in youth. *Endocrinol Metab Clin North Am*, 28, 765–785.)

of the stigmata is nonautoimmune T1D in the first decade of life; central diabetes insipidus and sensorineural deafness in two-thirds to three-fourths of the patients in the second decade; renal tract anomalies in approximately half in the third decade; and neurological complications, such as cerebellar ataxia and myoclonus, in half to two-thirds in the fourth decade. Other features include primary gonadal atrophy in the majority of males and a progressive neurodegenerative course with neurorespiratory death at a median age of 30 years. Depression has been reported as a frequent feature of relatives of patients with Wolfram syndrome.⁶⁶⁸

Thiamine-Responsive Diabetes Mellitus (Roger Syndrome)

This syndrome is characterized by megaloblastic anemia, DM, and sensorineural deafness—all of which may respond to vitamin B₁ (thiamine). DM is mild to moderate, insulin secretion may improve with thiamine therapy, and there are no associated autoimmune markers. It is caused by a defect in the thiamine transporter,^{670,671} which has now been identified as being caused by mutations in the *SLC19A2* gene. This gene encodes the membrane-bound thiamine transporter THTR-1.

Uptake of thiamine by the combined pathways of an active high-affinity carrier and a passive low-affinity carrier leads to accumulation of intracellular thiamine, which is then converted to its active form, thiamine pyrophosphate. This cofactor enables proper function of transketolase, which is important in the pentose phosphate shunt, the key to ribose synthesis and hence nucleic acid production and of pyruvate dehydrogenase, α ketoglutarate dehydrogenase, and branched chain acid dehydrogenase—all of which are key to oxidative decarboxylation. Mutations in the high-affinity transporter THTR-1 lead to cell death in those cells that have a high rate of nucleic acid turnover (such as bone marrow cells) and activity (such as pancreatic

beta cells), thereby explaining the association of thiamine-responsive anemia with diabetes in those affected by this mutation.

Drug or Chemical Induced

A number of drugs and chemical agents may be toxic to the beta cell. Best known for the diabetogenic effects are the immunosuppressive drugs cyclosporine, sirolimus, and tacrolimus, which are toxic to beta cells—causing insulin-dependent diabetes in a significant proportion of patients treated with these agents for organ transplantation. Their toxicity to pancreatic beta cells is compounded by the use of immunosuppressive glucocorticoids after transplantation, which antagonize insulin action and together with impaired β -cell number or function lead to diabetes.

Streptozotocin and the rodenticide Vacor are also beta-cell toxic, causing diabetes. Box 21.1 listed other agents that may induce diabetes. Among these, L-asparaginase (used in chemotherapy for leukemia) and diazoxide (used to treat persistent hyperinsulinemic hypoglycemia in infancy) may cause diabetes. All of these agents, especially glucocorticoids, may combine to unmask clinical DM.^{672–674}

Diseases of the Exocrine Pancreas

Cystic fibrosis (CF) is one of the most common inborn errors of metabolism, involving the chloride channel encoded on chromosome 7 and affecting approximately one in 2500 live-born white infants. The increasing survival of patients with CF and the increased use of glucocorticoids to suppress bronchopulmonary inflammation have brought to the fore an entity termed *cystic fibrosis-related diabetes* (CFRD), characterized by variable impairment of carbohydrate intolerance.

Some have mild DM clinically apparent only while receiving steroids, whereas others require insulin for a nonimmune form of insulinopenic DM. Up to 75% of adults with CF have CFRD. Islet amyloid is prominent, both insulin secretion and insulin sensitivity may be impaired, and DKA may occur—as may microvascular complications. When fasting hyperglycemia (7 mM = 126 mg/dL or higher) is documented, therapy with insulin is indicated. Insulin also facilitates optimal nutrition and growth and hence promotes a sense of wellbeing. The diagnostic and management criteria for CFRD have been extensively reviewed.^{16,675}

Ionizing Radiation to the Abdomen

Ionizing radiation to the abdomen during childhood for a condition, such as nephroblastoma, has been associated with the development of DM some 20 years later in 5% to 10% of children so treated.⁶⁷⁶

Pancreatectomy

Extensive pancreatectomy performed for the management of severe hyperinsulinemic hypoglycemia of infancy is associated with diabetes in approximately 50% or more of long-term survivors.²²

Virus Infections

Several viruses have been implicated in the cause of T1DM in children. Coxsackievirus B₄ has been shown in one case report as likely fulfilling Koch's postulates for a direct beta-cell toxic effect in causing acute fulminant DM. In other cases of coxsackievirus infections (as well as with the established association among rubella, cytomegaloviruses, and enteroviruses), molecular mimicry between antigenic determinants in the virus and certain islet cell antigens has been implicated as the mechanism leading to an autoimmune form of T1DM. Finally, a superantigen-triggered immune response has been suggested for some viral infections and may be the mechanism related to the acute onset of DM with the hemolytic-uremic syndrome.^{21,61,677,678} Patients with new-onset diabetes frequently have evidence of enteroviral infection in their islets.⁶⁷⁹ Peptides derived from a particular viral genus possess insulin-like properties, including binding and stimulation of insulin and IGF-1 receptors providing a further potential link between viral infection and the onset of DM via the mechanism of molecular mimicry; antibodies to the virus might also affect endogenous cells producing insulin.⁶⁸⁰

GENETIC DEFECTS IN INSULIN ACTION

Type A Insulin Resistance With Acanthosis Nigricans

This syndrome is characterized by severe insulin resistance, acanthosis nigricans in the absence of obesity, or lipotrophy. Affected females also have hyperandrogenism, possibly as a secondary manifestation of the hyperinsulinemia with stimulation of androgen synthesis by ovarian theca cells. Glucose intolerance is variable and includes symptomatic diabetes. The hyperandrogenism presents as clinical and biochemical findings suggestive of polycystic ovary syndrome (PCOS).

Some patients (predominantly black females with obesity, acanthosis nigricans, and accelerated growth suggestive of gigantism) may represent insulin resistance owing to obesity, with downregulation of the insulin receptor. The gigantism may represent a "spillover" effect of insulin acting through the IGF-1 receptor rather than the insulin receptor.^{681,682}

Type B Insulin Resistance

Type B insulin resistance is a rare syndrome associated with evidence of immune dysfunction (such as the defined autoimmune disease rheumatoid arthritis) or of nonspecific features of autoimmunity (such as elevated sedimentation rate or high levels of antinuclear antibodies). As with other autoimmune disorders, females are predominantly affected. An insulin-resistant diabetes develops together with acanthosis nigricans and features of PCOS (such as hirsutism).

The syndrome is caused by serum autoantibodies against the insulin receptor resulting in impaired function. However, the receptor may be activated by the presumed conformational changes induced by the antibody and cause severe hypoglycemia rather than diabetes. Treatment may require high doses of insulin to try to control the hyperglycemia, along with immunosuppressive drugs to suppress antibody production.⁶⁸²

Leprechaunism (Donohue Syndrome)

Leprechaunism is a syndrome characterized by intrauterine growth retardation, fasting hypoglycemia, and postprandial hyperglycemia in association with profound resistance to insulin in a patient whose serum concentrations of insulin may be 100-fold that of comparable age-matched infants during an oral glucose tolerance test. Various defects of the insulin receptor have been described, thereby attesting to the important role of insulin and its receptor in fetal growth and possibly in morphogenesis. Even a probable complete absence of functional insulin receptors caused by homozygous inheritance of missense mutation in the insulin receptor, however, resulted in normal organogenesis and a live-born infant who had a severe form of leprechaunism. Most of these patients die during the first years of life.^{683,684}

Rabson-Mendenhall Syndrome

The Rabson-Mendenhall syndrome is defined by clinical features that appear to be intermediate between those of acanthosis nigricans with insulin resistance type A and leprechaunism. Features include extreme insulin resistance, acanthosis nigricans, abnormalities of the teeth and nails, and pineal hyperplasia. It is not clear whether this syndrome is entirely distinct from leprechaunism. However, patients with Rabson-Mendenhall syndrome tend to live beyond the first year of life. Defects in the insulin receptor gene have been described in this syndrome.^{684,685}

Lipotrophic Diabetes

Lipotrophic diabetes presents an interesting paradox. Whereas classic T2DM is generally associated with an excess of fat and its metabolic consequences (as described previously), a paucity of fat also causes severe insulin resistance and marked metabolic disturbances. Table 21.16 lists the genetic syndromes associated with lipotrophic diabetes. A primary cause has been identified in the form called *familial partial lipotrophy* (also known as *Dunnigan syndrome*). This is a gene defect localized to chromosome 1q21-22 and its product lamin A/C.

This autosomal disease usually manifests peripubertally as subcutaneous fat in the extremities and trunk but with progressively more fat in the face and neck as puberty progresses. Visceral and interfascicular fat also increases. Females seem to develop DM and dyslipidemia earlier and more severely than males. It is unclear why and how the lamin A/C mutations cause this lipotrophy syndrome, especially as mutations in this gene also are associated with a progressive form of muscular dystrophy (Emery-Dreifuss syndrome), cardiomyopathy, and cardiac conduction defects.^{686,687} The gene altered

TABLE 21.16 Genetic Syndromes of Lipoatrophy

Syndrome	Lipoatrophy	Gene/Locus	Inheritance	OMIM
PRIMARY LIPOATROPHY SYNDROMES				
Congenital generalized lipoatrophy (Seip-Berardinelli)	Generalized	9q34	AR	269700
Dunnigan syndrome	See text for details	Gmg3lg; 11q13p		
	Familial partial	1q21–22	AD	151660
	See text for details	Lamin A/C		
Others	Numerous distributions	Unknown	AD/AR	N/A
COMPLEX SYNDROMES ASSOCIATED WITH LIPOATROPHY				
Mandibuloacral dysplasia	Congenital, partial	Unknown	AR	248370
	Involves extremities			
Werner syndrome	Congenital, partial	8p12	AR	277700
	Involves extremities	Werner helicase		
Cockayne syndrome	Congenital, partial	5	AR	216400
	Involves extremities	CSA		
Carbohydrate-deficient glycoprotein syndrome	Transient, partial	16p13.3	AR	212065
SHORT syndrome ^a	Buttocks	PMM1 and 2		
AREDYLD syndrome ^b	Generalized, congenital	Unknown	AR	269880
	Generalized, congenital	Unknown	Unknown	207780

AD, Autosomal dominant; AR, autosomal recessive; OMIM, Online Mendelian Inheritance in Man, database providing information about genetic syndromes; PMM1, PMM2, phosphomannomutase 1 and 2.

There is evidence for genetic heterogeneity because similar clinical features may be caused by different genetic mutations.

^aShort stature, hyperextensibility, hernia, ocular depression, Rieger anomaly, and teething delay.

^bAcrorenal field defect, ectodermal dysplasia, and lipoatrophic diabetes; not clear if this is a variation of Seip-Berardinelli syndrome.

(From Arioglu, E., Rother, K.I., Reitman, M.L., et al. (2000). Lipoatrophy syndromes. *Pediatr Diabetes* 1:155; Brown, R.J., Araujo-Vilar, D., Cheung, P.T., et al. (2016). The diagnosis and management of lipodystrophy syndromes: a Multi Society Practice Guideline. *J Clin Endocrinol Metab*, 101 (12), 4500–4511.)

in Berardinelli-Seip congenital lipodystrophy has been localized to chromosome 11q13.274.⁶⁸⁷ In addition, defects in genes encoding the enzyme AGPAT2, the endoprotease ZMPSTE24, the kinase AKT2, the nuclear receptor PPAR γ , and the protein BSCL 2 have been found in patients with lipodystrophies.^{686,687}

ACQUIRED DEFECTS IN INSULIN ACTION

These defects range from hormonal disorders, such as pheochromocytoma and Cushing syndrome that antagonize insulin action to disease to drug-acquired forms of lipodystrophy. Antiinsulin receptor antibodies may be found in some collagen vascular disorders and can cause a T2DM syndrome characterized by acanthosis nigricans and severe insulin resistance. This is generally referred to as *acanthosis nigricans with insulin resistance type B*. The type A syndrome consists of a variety of insulin receptor mutations, some of which were described earlier. The type B syndrome is rarely described in childhood.⁶⁸²

GENETIC SYNDROMES WITH DIABETES AND INSULIN RESISTANCE OR INSULIN DEFICIENCY

A number of genetic syndromes are associated with DM. In children, four relatively common genetic syndromes may be associated with diabetes. In trisomy 21 (Down syndrome) and Turner syndrome (a single normal X chromosome), there is an increased incidence of autoimmune disorders, especially of the thyroid. T1DM also has a higher prevalence in patients with Down syndrome than in the general population.

In Turner syndrome, insulin secretory reserve may be limited such that treatment with growth hormone (now common) can result in impaired glucose tolerance or T2D. In Klinefelter syndrome (XXY), insulin resistance is a major feature—but autoimmune associations have been described. In Prader-Willi

syndrome, the reported high frequency of DM may not be caused simply by the insulin resistance as part of the obesity of this syndrome but possibly by a primary defect in insulin secretion.^{688–692}

Alström syndrome consists of retinal dystrophy, sensorineural deafness, obesity and associated diabetes, cardiomyopathy, hypertriglyceridemia, liver disease, and urological abnormalities. Severe insulin resistance may lead to acanthosis and diabetes. Mutations in the gene *ALMS1* have been identified in these patients.⁶⁹³ Bardet-Biedl syndrome also has atypical retinitis pigmentosa as a key feature, along with central obesity, polydactyly, mental retardation, hypogonadism, and renal dysfunction. Eleven loci have been linked to this syndrome, with abnormalities in cilia-like structures a central theme.⁶⁹⁴ The association of these and other syndromes with diabetes (listed in Box 21.1) can be ascertained by searching the Online Mendelian Inheritance in Man database (OMIM, available at www.ncbi.nlm.nih.gov/omim).

Gestational Diabetes

Gestational diabetes is a disease of the second and third trimesters of pregnancy that is caused by congenital or acquired defects in insulin secretion that result in the inability to compensate for the increased demands of insulin as a result of the counterinsulin effects of placental growth hormones.⁶⁹⁵

Neonatal Diabetes

Discoveries in the molecular basis for pancreas formation and regulation of insulin secretion have propelled the syndromes of neonatal diabetes from the backwater of rarity to the forefront of research. These syndromes probably occur more frequently than previously considered, and they may have an overall incidence of about 1:100,000 births^{696–703} in European populations. Moreover, some of those with activating mutations in

K_{ATP} channel subunits Kir 6.2 or SUR1 lend themselves to treatment with oral sulfonylurea hypoglycemic drugs, such as glibenclamide—which results in endogenous insulin secretion with near-normal glycemic control and at least partial reversal of neuromuscular manifestations.^{13,664,665,696–712} These entities are described in detail in Chapter 10.

Impaired Glucose Tolerance

The term impaired glucose tolerance is used to characterize individuals who have a plasma glucose concentration in excess of 140 mg/dL but less than 200 mg/dL at 2 hours after initiation of the standard oral glucose tolerance test, but do not have symptoms of diabetes or fasting hyperglycemia. Such a constellation may represent the earliest phase of a gene defect in insulin secretion or action or be one step in evolving DM type 1 or 2. The hyperglycemia may be a chance discovery during an intercurrent illness, during therapy with corticosteroids, or as part of a screening of close relatives of patients with defined genetic syndromes.

In those who have impaired glucose tolerance but do not have fasting hyperglycemia, repeated oral glucose tolerance tests (OGTTs) are not recommended. Investigations in such children indicate that the degree of impaired glucose tolerance tends to remain stable except in those who have markedly subnormal insulin response.^{713,714} The arbitrarily designated response that identifies impaired glucose tolerance is defined as a fasting plasma glucose value of less than 100 mg/dL and a value at 2 hours of more than 140 mg/dL. The determination of serum insulin responses during the glucose tolerance test is not a prerequisite for reaching a diagnosis. Because the magnitude of the insulin response may have prognostic value, however, some investigators request measurements of insulin during the OGTT tests.⁷¹⁴

Pancreas and Islet Transplantation

In an attempt to cure insulin-dependent diabetes, transplantation of a segment of the pancreas or of isolated islets has been increasingly performed in humans.^{715–719} These procedures are technically demanding and associated with the risks and complications of rejection and its treatment by immunosuppression. Therefore segmental pancreas transplantation is generally performed in association with transplantation of a kidney for a patient with end-stage renal disease owing to DN in whom the immunosuppressive regimen is indicated for the renal transplant.

Several thousand such transplants have been performed worldwide since the late 1980s. With experience and newer immunosuppressive agents, functional survival of the pancreatic graft may be achieved for as long as several years—during which patients may be in metabolic control with no or minimal exogenous insulin and reversal of some of the microvascular complications. Because children and adolescents with DM are not likely to have end-stage renal disease as a result of diabetes, however, pancreas transplantation as a primary treatment cannot be recommended (nor its risks justified) in children. An exception may be reimplantation of autologous islets after pancreatectomy for recurrent pancreatitis.⁷¹⁹

Attempts to transplant isolated islets have been equally challenging because of techniques to harvest sufficient islets and the issue of rejection.⁷¹⁷ Some of the newer antirejection drugs, notably cyclosporine and tacrolimus, are toxic to the islets of Langerhans—impairing insulin secretion and even causing diabetes.⁷¹⁷ The Edmonton protocol for islet transplantation avoids steroid and uses an anti-IL-2 receptor antibody and tacrolimus instead of other immunosuppressants.⁷¹⁷ Initial

success had been promising, but long-term survival of the graft beyond 3 to 5 years is unusual—and there have been serious side effects of the procedure, as well as failure to restore hypoglycemia unawareness.⁷¹⁷ Hence this islet transplantation protocol cannot be recommended in children.

Research continues to improve techniques for the yield, viability, and loss of immunogenicity of islets of Langerhans for transplantation. Transplantation has been investigated of islets coated or microencapsulated with a film of protective chemicals that permit diffusion of insulin and nutrients but prevent T-cell contact and therefore avoid rejection.⁷¹⁸ These novel approaches have been frustrated in the long term by overgrowth of fibroblasts that progressively impair glucose sensing by the islets and insulin diffusion from them. Should these technical problems be overcome, or methods to avoid rejection become established, transplantation of pancreas or islets as primary treatment for diabetes may be entertained after their risks are carefully compared with and weighed against potential benefits—especially in children.⁷¹⁹ Islet regeneration by modulating the immune response is also under scrutiny.⁷²⁰

CONCLUDING REMARKS

Progress continues to be spectacular in understanding and treating DM. We have moved from a glimmer of understanding that diabetes is a syndrome of broad categories (insulin dependent and noninsulin dependent) to an understanding of disease susceptibility and disease causality at a molecular level. T1D is acknowledged to be an autoimmune disease with major susceptibility loci in various immune regulatory genes, especially the HLA complex, although the trigger(s) for this autoimmune process remains elusive; various viruses head the list but yet to be identified environmental factors also may be involved. Recent studies suggest immunization against rotavirus as protective; this remains to be proven. Evidence for autoimmunity via the presence of circulating antibodies to islet cell components precedes clinical manifestation by months to years; treatment with anti-CD3 antibodies appears to delay clinical onset of disease in those with two antibodies but no impairment of glucose tolerance. Positional cloning and genome-wide association techniques have identified other gene markers, and we now recognize the importance of mitochondrial gene defects in some types of insulin-dependent diabetes that may not be autoimmune. The predisposition of the beta cell to autoimmune destruction (homicide) versus a predisposition to apoptosis (suicide) is the topic of intensive debate and investigators raise questions about our accepted paradigms of this disease.^{1,44,45} More spectacular has been the unraveling of the molecular basis of monogenic defects, such as MODY and neonatal diabetes and their treatment, including the use of sulfonylureas. Not surprisingly, this knowledge is being rapidly applied to predict the likelihood of disease appearance in individuals whose susceptibility can be quantified by the presence of certain antibodies and by limitations in first-phase insulin response. Population surveys in individuals not known to be at risk for diabetes have just begun. We are in the early stages of attempts to prevent the disease, reminiscent of the early trials examining the relationship between control and microvascular complications.

The monumental DCCT and European studies have irrefutably established the link between control and complications, requiring new standards of care. Progress and understanding of insulin secretion and insulin action have been equally spectacular for the insights provided in defining non-insulin-dependent forms of diabetes at physiologic, biochemical, and molecular levels. Therapy with human insulin is now standard and a plethora of long-acting, as well as fast-acting

preparations are now available. Trials with improved insulin-delivery systems, including computerized artificial pancreas, as well as pancreas and islet transplantation, are in progress and have entered the realm of clinical practice. The FDA in the United States has approved two artificial pancreas systems for use, and improvements in these devices are bound to change the course and treatment of T1DM. The beneficiaries of these advances are our patients, whose interests will continue to be best served by bidirectional scientific inquiry from bench to bedside.

INTRODUCTION

The autoimmune polyglandular syndromes (APS) are uncommon constellations of organ-specific autoimmune diseases characterized by the occurrence of more than one autoimmune disease in an affected individual (Table 22.1). Although autoimmune endocrine disorders commonly affect single organs, multiorgan autoimmune involvement of both endocrine and nonendocrine organs and tissues, secondary to loss of self-tolerance, is a characteristic feature of APS.

Tolerance is a physiological state in which one's immune system recognizes self-antigens and does not mount an immune response to self-antigens.¹⁻⁴ If tolerance is not established or is lost, autoimmunity and subsequent disease may result. Although breakdown in self-tolerance remains mostly unexplained, improved understanding of the complex interplay between genetics and the environment, and the resultant aberrant immunological processes has identified a number of possible mechanisms. To comprehend these mechanisms, a brief overview of how self-tolerance is established and maintained is essential.

MECHANISMS UNDERLYING TOLERANCE

Introduction

The body's first line of immune defense, after physiological barriers against invading foreign pathogens, is the innate arm of the immune system.⁵ Innate immunity is a nonspecific response mediated by expression of germ line genes, which does not require prior exposure to an antigen and provides immediate defense.⁵ However, the innate immune system does not exhibit immunologic memory and does not provide long-lasting protection. The next line of defense against foreign antigens is the adaptive immune system.⁶ Although the adaptive immune system assumes all exogenous antigens are potentially harmful, it produces antigen-specific responses. In a normal adaptive immune response; the host organism must differentiate self- from nonself-antigens; mount an immune response; eliminate or remove the inciting antigen; and protect the host from injury, organ dysfunction, and even death.¹⁻⁴ Discrimination of self/nonself is carried out by the adaptive (specific) immune system by a mechanism that uses specific T- and B-cell surface receptors.⁷⁻⁹ T-cell and B-cell receptors recognize distinctive antigen peptides and epitopes, respectively, and are the keys to the specificity of the adaptive immune response. Whereas B cells and their receptors recognize soluble antigens on cell surfaces of pathogens, T cells and their receptors (TCRs) perceive short polypeptides only when presented by antigen presenting cells (APCs), using specialized cell-surface molecules encoded by the major histocompatibility complex (MHC).¹⁰⁻¹³ The human MHC is termed the *human leukocyte antigen* (HLA) complex. Class I MHC (e.g., HLA-A, HLA-B, and HLA-C molecules) is found on all nucleated cells, and presents endogenous peptides derived from the cytoplasm (such as from a pathogen infected cell) to CD8 T cells. Class II MHC (e.g., HLA-DP, HLA-DQ, and HLA-DR) molecules, on the other hand, present foreign antigens (peptides) that have been endocytosed and processed by APCs (such as B cells, dendritic cells, and macrophages) to CD4 T cells.

T cells are initially classified based on their cluster of differentiation (CD) surface proteins that bind differentially to antigens presented on class I (binds to CD8) and class II (binds to CD4) MHC. For example, CD8 T cells, also called *cytotoxic* T cells when activated, typically recognize antigens presented via class I MHC, and mediate an immune response specific to that antigen. Conversely, CD4 T cells, serving as helper or regulatory T cells, are activated when presented with peptides via class II MHC. Regulation of T-cell self-tolerance occurs at two distinct but interdependent levels: central tolerance and peripheral tolerance (described later) (Fig. 22.1). Central tolerance occurs in the thymus, whereas peripheral tolerance occurs in both lymphoid and nonlymphoid tissues. Although many of the mechanisms involved in self-tolerance remain poorly understood, almost 2 decades of characterizing the autoimmune regulatory gene (AIRE) has improved our understanding of the pathways in the establishment and maintenance of self-tolerance.¹⁴ The AIRE gene encodes a transcription factor in the thymic medulla, which plays a critical role in establishing

TABLE 22.1 The Autoimmune Polyglandular Syndromes I and II

	APS I	APS II
Comparative frequency	Less common	More common
Onset	Infancy/early childhood	Late childhood, adulthood
Heredity	Autosomal recessive	Polygenic
Gender	Males = females	Female predominance
Genetics	<i>AIRE</i> gene; no HLA association	HLA associated; DR/DQ
Hypoparathyroidism	77%–89%	<5%
Mucocutaneous candidiasis	73%–100%	None
Ectodermal dysplasia	77%	None
Addison disease	60%–86%	70%–100%
Type 1 diabetes	4%–18%	41%–52%
Autoimmune thyroid disease	8%–40%	70%
Pernicious anemia	12%–15%	2%–25%
Gonadal failure		
Females	30%–60%	3.5%–10%
Males	7%–17%	5%
Vitiligo	4%–13%	4%–5%
Alopecia	27%	2%
Autoimmune hepatitis	10%–15%	Rare
Malabsorption	10%–18%	Rare

HLA, Human leukocyte antigen.

central tolerance (described in detail in the later part of this chapter).^{15,16} Deletions in the mouse *AIRE* homologue result in multiorgan autoimmunity, whereas mutations in the human *AIRE* gene result in APS I.^{17,18}

Tolerance is initially developed in utero with T and B cells playing important roles. T and B cells are produced

continuously throughout life by hematopoietic stem cells of the bone marrow, with the T-cell precursors migrating to the thymus for further maturation. Although the thymus atrophies after puberty,¹⁹ residual thymic tissue may provide for T cell development throughout life.

Although T cells require exposure to small doses of antigen to achieve tolerance during their thymic development, larger doses of antigen are required to induce B-cell tolerance, and B-cell tolerance is often short lived. Tolerance is immunologically specific and induced in developing lymphocytes early in life; however, it can also be induced in mature lymphocytes when costimulatory signals are absent at the time of peptide interaction with TCR.

Central T-Cell Tolerance and AIRE

T cells are primarily educated to distinguish self and nonself when they develop in the thymus.^{20–23} In the thymic cortex, CD4+ CD8+ (double-positive) T cells bearing α/β TCRs that are able to bind to self-peptide/MHC complexes are selected to survive, whereas T cells whose TCRs fail to bind undergo apoptosis. As many as 99% of developing thymocytes undergo apoptosis and never reach the periphery (see Fig. 22.1). This is referred to as *positive selection* and is carried out by antigen-presenting cortical thymic nurse epithelial cells (cTECs), bearing MHC I and MHC II. T cells that bind to MHC I commit the developing T cell toward a CD8 T-cell pathway, whereas those that bind to MHC II develop into CD4 T cells. Positively selected cells migrate through the corticomedullary junction into the medulla where a secondary checkpoint occurs. Although T cells must be able to bind to MHC/self-peptide to establish tolerance, cells that bind too tightly to self-antigens are capable of inducing autoreactivity and therefore undergo negative selection and apoptosis.²⁴ This process of positive selection of T cells for positive selection of MHC binding T cells

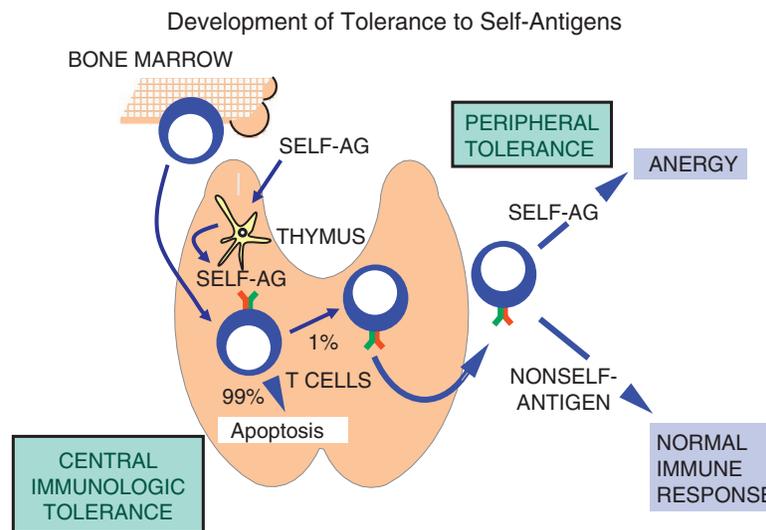

Fig. 22.1 Normal tolerance pathways. T-cell precursors initially arise in the bone marrow. These progenitors enter the thymus where developing T cells encounter self-antigens (*SELF-AG*) derived from circulating proteins or generated within the thymus (e.g., via the action of medullary thymic epithelial cells [mTECs]; drawn as a yellow-colored dendritic cell). Ectopic expression of various proteins in the thymus, including hormones such as insulin, is facilitated by the action of the autoimmune regulator gene (*AIRE*). Strong self-antigen stimulation of receptors on developing T cells induces apoptosis, with ultimately approximately 99% of all developing T cells dying in this manner. This is “central immunologic tolerance” (also known as “thymic” tolerance; *bottom left*) where strongly anti-self-reactive T cells are eliminated. One percent of T cells will progress to become either CD4 T cells or CD8 T cells. These naïve T cells that leave the thymus can be subsequently tolerized to self-antigens if they encounter self-antigens without the normal costimulatory signals (B7.1/B7.2-CD28; see Fig. 22.2). Induction of tolerance outside the thymus is termed “peripheral tolerance” (*top right*), and is a complementary mechanism to central tolerance. Peripheral tolerance is functionally expressed as anergy: autoreactive cells are present but are inactive (*top right*). However, if a nonself-antigen is encountered, a normal immune response ensues (*bottom right*).

(in the thymic cortex) and negative selection of T cells tightly bound to self-antigens (in the medulla), accounts for central (thymic) immunological tolerance.^{3,16,25} The single positive T cells expressing either CD4 or CD8 then migrate to the periphery and secondary lymphoid organs.

Medullary thymic epithelial cells (mTECs) are specifically involved in the process of negative selection of T cells and express an enormously diverse range of peripheral tissue-specific antigens (TSAs) for presentation to the developing T cells. This has been referred to as *promiscuous gene expression* (PGE) and is mediated by AIRE, a transcriptional regulator. Notably, AIRE is expressed in a small population of mature mTECs, with high levels of CD80 and MHC II. Unlike traditional transcriptional regulators, it does not bind to deoxyribonucleic acid (DNA) segments but activates ribonucleic acid (RNA) polymerases, and elongates TSA RNA transcripts. This process is also mediated by interaction of AIRE with other transcriptional regulators.²⁶ Another transcriptional regulator that is involved in negative T-cell selection in the thymus is the FEZ family zinc finger protein 2 (FEZF2), which is involved in AIRE-independent TSA expression in mTECs.²⁶ Studies have shown that AIRE and FEZF2 share complementary and parallel function in establishing and maintaining central tolerance. In addition to regulation of TSA expression in mTECs, AIRE is involved in thymic selection and differentiation of autoreactive CD4 T cells into regulatory T cells (Tregs),²⁷ and upregulation of chemokines that aid in thymocyte migration.¹⁴ Extrathymic expression of AIRE in tissues, such as the bone marrow, has also been shown to aid in peripheral tolerance by inducing energy of CD4 and CD8 T cells.²⁸

Peripheral T-Cell Tolerance

Once naïve T cells enter the circulation or secondary lymphoid organs (e.g., lymph nodes and spleen) and recognize specific antigens, they require additional cosignals to become activated.⁷ The first signal involves the interaction of antigen-peptides bound to the MHC molecules on the surface of APCs with TCRs on the surface of CD4 and CD8 T-cells. CD4 and CD8 molecules on these T-cell subsets serve as antigen-nonspecific coreceptors binding to nonpolymorphic portions of the class II and class I MHC molecules, respectively. The second signal is antigen non-specific and is provided by the B7.1 (CD80) and B7.2 (CD86) molecules of the APC interacting with the CD28 molecule on the T-cell surface (Fig. 22.3). In addition to CD80/CD86/CD28 interactions, there are other costimulatory signals that have important roles in T-cell development.²⁹

When T cells perceive both signals (MHC-antigen with TCR and B7-CD28), a cascade of intracellular signaling events occur, leading to T-cell activation. Activated cytotoxic CD8 T cells mediate direct lysis of target cells, whereas activated CD4 T cells lead to expression of numerous cytokines, cytokine receptors, and cytotoxic T-lymphocyte antigen 4 (CTLA-4). CTLA-4 is homologous to CD28 and competes with CD28 for binding to B7.1/B7.2. CTLA-4 expression by the activated T cell and its interaction with B7.1/B7.2 provide an immunosuppressive/immunoregulatory signal to the T-cell, thereby downregulating the T-cell responses. Thus CTLA-4 and CD28 though homologous, act antithetically: B7.1/B7.2-CD28 turns on T cells, whereas B7.1/B7.2-CTLA-4 downregulates the T cell (see Fig. 22.2).

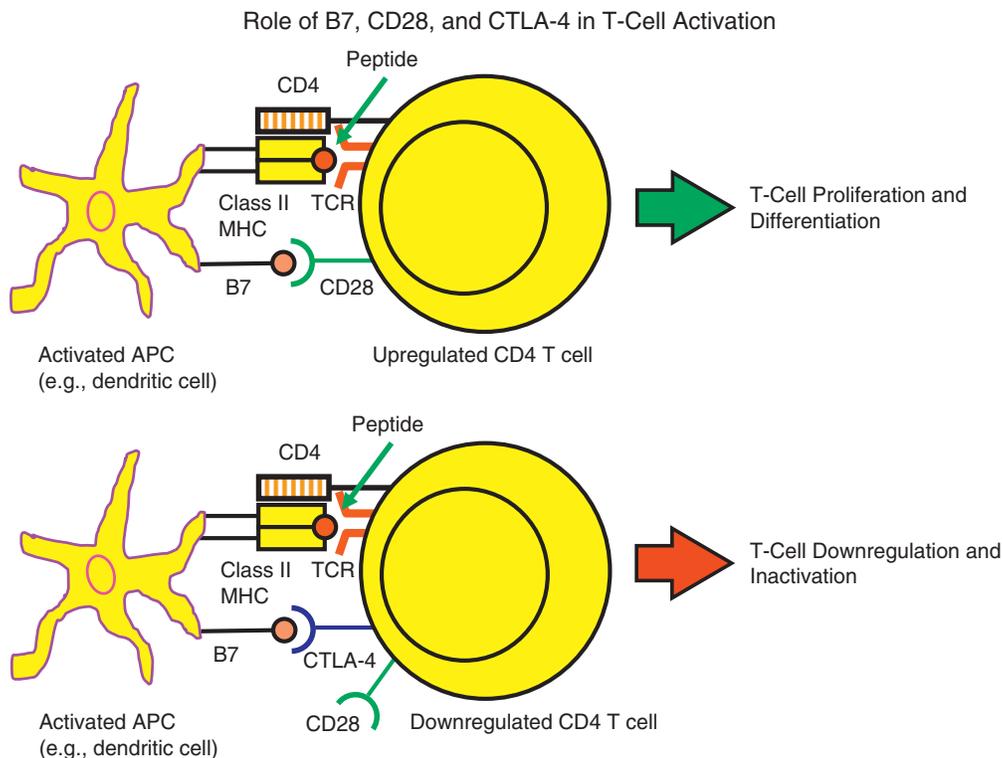

Fig. 22.2 Role of B7, CD28, and CTLA-4 in T-Cell Activation. Activated antigen presenting cells (APCs) present antigen peptides via major histocompatibility complex (MHC) molecules (in this drawing, class II MHC) and express B7 [including B7.1 (CD80) and B7.2 (CD86)] co-stimulators. When B7.1 or B7.2 is bound by CD28, and MHC plus peptide is bound by the T cell receptor, T cell proliferation and differentiation of naïve T cells ensues (top image). Conversely, activated T cells express CTLA-4 and bind to B7 (either B7.1 or B7.2) inducing down regulation and inactivation of T-cells (bottom image).

The requirement for two signals to activate naïve T cells mainly accounts for peripheral T-cell tolerance. When the naïve T cell perceives antigen peptide presented by MHC molecules without the necessary costimulatory signal (e.g., B7.1/B7.2-CD28), the T cell becomes unresponsive. This state of unresponsiveness is termed *anergy*; anergic T cells are generally not restimulated with antigen peptide displayed by the APCs. T cells may also undergo apoptosis (programmed cell death) to be removed completely from the T-cell repertoire. Tolerance may also exist because the TCR does not encounter the relevant peptide, and this has been termed *T-cell ignorance*.

Another mechanism whereby T-cell tolerance is mediated is the interaction of programmed death 1 (PD-1) receptor on T cells and its ligands PD-L1 and PD-L2.³⁰ These interactions bring about inhibition of T-cell effector functions in an antigen-specific manner. PD-1 signaling can also mediate the conversion of naïve T cells to Tregs.³¹

Helper CD4 T cells are classically divided into two distinct lineages: (1) Th1 cells, which activate cell-mediated and some antibody responses, and (2) Th2 cells, which predominantly activate antibody-mediated responses.³² However, additional T-cell lineages exist (i.e., Th17 cells, T-follicular helper cells, and regulatory T cells) and recent data have described remarkable plasticity in their cytokine expression, suggesting shifting T-cell functionalities, depending on environmental cues.³³ Although overtly simplistic, Th1 subsets secrete predominantly proinflammatory cytokines, such as interleukin (IL)-2, interferon-gamma (IFN- γ), tumor necrosis factor-beta (TNF- β), induce IL-12 secretion from dendritic cells,³⁴ and activate macrophages and CD8 T cells to eliminate intracellular pathogens. Upon activation, CD8 T cells, often with the help of Th1 cells supplying IFN- γ to upregulate B7 expression on APCs, become functional cytotoxic T killer cells.³⁵ Conversely, Th2 cells elaborate IL-4, IL-5, IL-6, IL-10, and IL-13, which aids antibody and eosinophil production.³⁵ There is also crosstalk between Th1 and Th2 cells; for example, IFN- γ from Th1 cells suppresses Th2 cells, and IL-10 from Th2 cells inhibits Th1 cells.

Tregs are a subset of T cells, which play a critical role in suppressing the activity of effector T cells that escape negative selection to self-antigens in the thymus.³⁶ Functional Tregs are able to anergize previously self-reactive T-effector cells, resulting in improved tolerance to self. Tregs originating from the thymus are termed as *central* or *natural Tregs* and carry surface CD4⁺CD25⁺ and intracellular forkhead transcription factor (FOXP3⁺) markers, which are specific to CD4⁺CD25⁺ Treg cell population. FOXP3 is a transcription factor that is required for developing α/β TCR-positive T cells to differentiate into Tregs in the thymus. First identified in the *Scurfy* mouse, a mouse model of immune dysfunction and polyendocrinopathy, abnormal FOXP3 expression is now known to be responsible for failure in immune tolerance in humans affected with a similar polyendocrinopathy, as further discussed later.^{37–39} Abnormal FOXP3 expression in humans leads to an extremely rare, X-linked inherited, and typically fatal autoimmune lymphoproliferative disease known as IPEX (Immune dysregulation, Polyendocrinopathy, Enteropathy, and X-linked inheritance).^{40,41} Defects in FOXP3 responsible for IPEX map to Xp11.23-Xq13.3.

B-Cell Tolerance

Naïve B cells, during the early stage of development in the bone marrow, express surface immunoglobulin (Ig)M, which serves as B-cell receptors (BCRs). Upon interacting with self-antigens, naïve immature B cells undergo negative selection, either through clonal deletion or anergy, whereby B cells enter a state of unresponsiveness and have a reduced life span.⁴² Another

process mediating B-cell central tolerance is receptor editing, whereby genetic rearrangement of the Ig chain leads to generation of BCRs with new antigen specificities. B cells with non-autoreactive BCRs are positively selected and continue to the periphery.⁴³ If self-reactive B cells escape into the periphery, they undergo anergy. Anergized B cells do not die immediately but have a shorter half-life. Naïve mature B cells require T-cell help for realization of their full potential through affinity maturation and class switching. The absence of T-cell help also leads to B-cell tolerance.

Autoimmune Diseases

The organ-specific nature of many autoimmune diseases results from abnormal immune system recognition of tissue-specific self-antigens. In many autoimmune endocrinopathies, the target molecule is either a tissue-specific or tissue-limited (i.e., the protein is not unique to one tissue but is clearly restricted in its distribution) enzyme or cell-surface receptor.^{44,45} (Table 22.2).

The criteria for classification of a disease as autoimmune are not universally agreed upon.⁴⁶ However, major criteria that are generally accepted as strong evidence of autoimmune disease include: (1) detection of autoantibodies or autoreactive T cells, including lymphocytic infiltration of the targeted tissue or organ;

TABLE 22.2 Autoantigens in Autoimmune Endocrine and Associated Diseases

Disease	Autoantigens	Putative Autoantigens
Mucocutaneous Candidiasis		IL-17A IL-17F IL-22
Hypoparathyroidism		NALP5 CASR
Addison disease	P450c21	P450c17 P450scc
Hashimoto thyroiditis	Thyroid peroxidase Thyroglobulin	
Graves disease	Thyrotropin receptor	
Diabetes	Insulin Glutamic acid Decarboxylase 65 IA-2 (ICA 512) IA-2 β ZnT8	Proinsulin Carboxypeptidase H ICA69 Glima 38
Premature gonadal failure	P450scc	P450c17 3 β hydroxysteroid dehydrogenase
Pernicious anemia	H ⁺ /K ⁺ ATPase pump Intrinsic factor	
Myasthenia gravis	Acetylcholine receptor α chain	
Vitiligo		Tyrosinase Tyrosinase-related protein 2 L-amino acid decarboxylase
Celiac disease	Endomysium transglutaminase	Reticulin Deamidate gliadin
Autoimmune hepatitis	Liver kidney microsome 1	L-amino acid decarboxylase Tryptophan hydroxylase

CaSR, Calcium sensing receptor; IA-2, protein tyrosine phosphatase-like protein; ICA, islet cell autoantigen; IL, interleukin; NALP5, NACHT leucine rich repeat protein 5; ZnT8, zinc transporter 8.

(2) disease transfer with antibodies or T cells; (3) disease recurrence in transplanted tissue; and (4) ability to abrogate the disease process with immunosuppression or immunomodulation. Few, if any, human autoimmune diseases meet all these criteria. Further information that is supportive of, but not diagnostic for an autoimmune disease, include: (1) increased disease frequency in women compared with men, (2) the presence of other organ-specific autoimmune diseases in affected individuals, and (3) increased frequencies of particular HLA alleles in affected individuals.

Defects in Tolerance That Cause Autoimmune Disease

Several different hypotheses explaining defects in tolerance have been proposed.⁴⁷ Autoimmunity may develop because (1) tolerance never developed to specific self-antigens or (2) established tolerance was lost (Fig. 22.3). If self-antigen is not efficiently presented in the thymus, tolerance may not be established during T-cell education within the thymic cortex.⁴⁸ For example, *AIRE* mutations lead to lack of expression of ectopic self-antigens by mTECs and their presentation to developing T cells. This leads to escape of autoreactive T cells into the periphery and ultimately multiorgan autoimmunity. Another example is the insulin gene (*INS*) VNTR (variable number of tandem repeats), which lies around 500 basepairs upstream of the *INS* gene promoter. The *INS* VNTR influences thymic insulin T-cell expression and education based on its length. Specifically, longer VNTRs are associated with increased thymic expression of insulin, and thus a decreased risk of developing type 1 diabetes, whereas shorter VNTR are associated with decreased thymic expression of insulin, failure to delete specific autoreactive T-cell clones, and an increased risk of developing diabetes.⁴⁹

If tolerance has not developed because of intracellular sequestration of an antigen, and thus not expressed in the thymus during T-cell ontogeny, T-cell reactivity in the periphery will not be abolished. However, several antigens initially thought to be sequestered intracellularly have now been shown to circulate in low concentrations in normal individuals. Thyroglobulin, a self-antigen in autoimmune thyroid disease, is known to circulate in low but appreciable quantities in individuals with no serologic evidence of thyroid autoimmunity.

Thyroid follicular cell destruction in Hashimoto thyroiditis is mostly cell mediated and not mediated by humoral factors.

If sequestered antigens do play a role in autoimmune disease, viral infections, trauma, ischemia, or irradiation are all possible mechanisms that could disturb cellular integrity and lead to release of intracellular antigens.⁵⁰ Some sequestered self-antigens may never encounter the immune system, unless there is a breakdown of anatomic barriers within the body. An example is the occurrence of autoimmunity to intraocular proteins, following orbital trauma. Although a rare consequence of orbital damage, initiation of an autoimmune response to released sequestered intraorbital proteins in adjacent lymph nodes can generate autoreactive T cells that can invade and damage the contralateral eye (sympathetic ophthalmia).^{51,52} Removal of the inciting damaged tissues and immunosuppression may be required to sustain vision in the undamaged eye. Similarly, transient autoantibody reactivity to cardiac myosin following myocardial infarction has been described albeit with no pathological consequences.⁵³

Alteration of self-antigens because of infection or neoplasia is another possible theory explaining some types of autoimmunity. As environmental triggers, viral infections could lead to modification of self-proteins and neoantigen expression. Alternatively, a self-antigen may be partially degraded, leading to a “new” antigenic target for the adaptive immune system. This new antigen is recognized as foreign by the immune system, and the immune response to these new antigens results in autoimmunity. Some cells/tissues may suffer unintended autoimmune damage when substances bind to the cells and elicit an initial immune response. For example, certain drugs bind to red blood cells and result in an immune hemolytic anemia. If an antibody response to the red-cell-bound drug is elicited, the antigen-antibody complex present on the red blood cell can lead to red blood cell destruction. This can occur either through red blood cell phagocytosis by the monocyte-macrophage system or via complement-mediated lysis of the red blood cell. Thus the red blood cell becomes an innocent bystander to the antidrug humoral immune response. Theoretically, this could also occur with viruses that serendipitously attach to tissues.

Molecular mimicry is another mechanism to explain development of autoimmunity.^{50,54} Following exposure to a dietary, viral, or bacterial antigen (e.g., infection) and similarity (molecular mimicry) between the self-antigen and the foreign

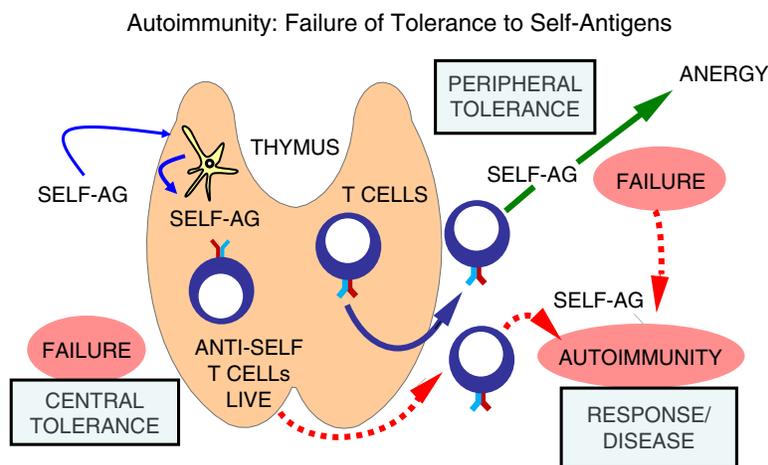

Fig. 22.3 Autoimmunity: Failure of Tolerance to Self-Antigens. With the failure of central tolerance (bottom left), anti-self T cells survive that should not normally survive. When such anti-self T cells leave the thymus, they are able to produce autoimmunity (red arrows). Alternatively, with a failure of peripheral tolerance (top right), if anergy (green arrow) does not occur after contact with self-antigen, an autoimmune response or disease can occur (red arrow).

antigen, the immune response to the foreign antigen leads to cross-reactivity with self-antigen, autoimmunity, and disease.^{54–57} For this theory to work, tolerance must not previously exist to the self-antigen. This might be true if the self-antigen is truly sequestered and the immune system has never developed tolerance to the self-antigen. Alternatively, the self-antigen peptides may be present in very low concentration to elicit an immune response and initial tolerogenicity has not occurred. Only after infection or novel dietary exposure would there be a sufficient degree of immunization to the exogenous antigen (which is similar to a self-antigen) and subsequent immune autoreactivity. If the self-antigen is a cell-surface antigen, the “pathogen-induced” autoantibodies could fix to self and produce disease via complement fixation, or the antibodies could act as opsonins for fixed or circulating phagocytes (antibody-dependent cell cytotoxicity). In rheumatic fever, associated comorbidities such as carditis and Sydenham chorea are thought to be autoimmune manifestations secondary to similarities in the structural components of group A *Streptococcus* with collagen (I and IV) and fibronectin in human cardiac connective tissues⁵⁸ and tubulin in human brain cells,⁵⁹ respectively.

Some cases of autoimmunity may result from superantigens, which can be secreted by certain pathogenic bacteria and viruses. Superantigens are polyclonal T-cell stimulators that can cross-link TCR β chains and MHC molecules, and activate as many as a third of T cells in the body. This can initiate a nonspecific T-cell immune response, including against self-antigens. In such cases, systemic disease can develop from massive cytokine release (e.g., systemic inflammatory response syndrome [SIRS]). This is the case in toxic shock syndrome, wherein a staphylococcal exotoxin acts as a superantigen. Mycobacterial antigens have also been proposed as possible superantigens in Crohn disease.⁶⁰ This theory requires that T cells bearing antiself TCRs have not been deleted or become permanently anergic. These T cells may be stimulated and proliferate to develop an autoimmune response if they encounter the specific self-antigen.

Similar to polyclonal T-cell activation, polyclonal B-cell stimulation has also been implicated in humoral autoimmunity. Autoreactive B cells arise routinely as part of the naïve B-cell repertoire, and can be found in healthy individuals. If an autoreactive clone of B cells encounters a self-antigen and a costimulator (which might be nonspecific, e.g., a virus, such as Epstein-Barr virus, or a bacterial product, such as lipopolysaccharide), autoantibodies could be produced, bypassing the need for T-cell help.

Autoimmune human disease likely results from an interaction of environmental and genetic factors.^{61–63} Environmental factors implicated include: wheat gliadin ingestion and celiac disease, penicillamine exposure and myasthenia gravis, methimazole and autoimmune hypoglycemia from insulin autoantibodies (reported primarily in Japanese patients), and amiodarone and thyroiditis. Cancer has also been associated with the development of autoimmunity: thymoma and myasthenia gravis,⁶⁴ ovarian teratoma and *N*-methyl-D-aspartate receptor-mediated encephalitis,⁶⁵ and breast cancer and stiff-person syndrome.⁶⁶ Despite remarkable improvements in our understanding of immunology, the mechanisms whereby the complex interaction of genes, environment, and immune system lead to autoimmunity remain to be fully elucidated.

Checkpoint Inhibitors and Autoimmunity

Tumor cells can manipulate the inherent immune tolerance mechanism to disrupt antitumor immunity. An efficient way of escaping antitumor activity is by increasing checkpoint pathways, which suppress T-cell responses. An example is the

interaction of CTLA-4 (present on activated T-cells) with B7.1/B7.2 of APCs that downregulates T cell response. CTLA-4 can also remove B7 molecules from APCs, through a process called *transendocytosis* and prevent binding of CD28 costimulatory molecules, and thus bring about T-cell anergy. Another example is the interaction of PD-1 on T cells with its ligands PD-L1 and PD-L2.^{67–71} PD-1/PD-L1/PD-L2 interactions inhibit T-cell proliferation and production of proinflammatory cytokines (TNF- α , IFN- γ , and IL-2), allowing immune checkpoint pathways to promote a tolerogenic environment.

Checkpoint inhibitors, now increasingly used in anticancer therapy, include monoclonal antibodies targeting the CTLA-4 and PD-1 pathway (both the PD-1 receptor and PD-L1 ligand) and thus removing the restraint on antitumor activity (Fig. 22.4). Blockade of CTLA-4 enhances costimulatory signals and leads to naïve T cells having increased effector T-cell responses to tumor cells, whereas PD-1 pathway blockade leads to increased T-cell proliferation and a proinflammatory milieu that aids in antitumor activity. In addition, there are other immune pathways impacted by blockade of these pathways. The discovery of immune checkpoint inhibitors was a breakthrough in anticancer therapy, resulting in the 2018 Nobel Prize for Medicine awarded to Drs. James Allison and Tasuku Honzo, two pioneers in this field.

Given that checkpoint inhibitors have the ability to eliminate a tolerogenic environment, it is not surprising that these immunomodulatory agents can bring about immune-related adverse effects (irAEs), and such irAEs have even been referred to as the *Achilles heel of cancer immunotherapy*.^{67,71,72} Hypophysitis, hepatitis, dermatitis, colitis, type 1 diabetes, thyroiditis, adrenalitis, and myocarditis have been reported following treatment with ipilimumab (CTLA-4 antibody) and/or PD-1 antibody (nivolumab) therapy. Other potential mechanisms leading to irAEs after use of checkpoint inhibitors include: (1) cross-presentation, where tumor antigens released after antitumor activity are picked up by APCs, initiating secondary immune responses, and (2) epitope spreading (after release of tumor antigens), whereby there is continuous acquisition of neo antigens and recruitment of untargeted T cells. Despite the success of checkpoint inhibitors as anticancer drugs, these irAEs remain a concern. There are few studies in cancer patients with and without preexisting autoimmune conditions, and the long-term effects of checkpoint inhibitor use remain unknown. Newer modes of anticancer immunotherapy that have been investigated to lessen irAEs include increasing the efficacy and the use of vaccines against tumor neoantigens.^{73,74}

Having provided a review of basic immunological concepts related to central and peripheral tolerance, we will shift our focus for the remainder of the chapter toward the clinical and pathological aspects of APS.

CLASSIFICATION OF THE AUTOIMMUNE POLYGLANDULAR SYNDROMES

APS I, also known as *autoimmune polyendocrinopathy candidiasis-ectodermal dystrophy* (APECED) is an autosomal recessive disorder characterized by several autoimmune disorders with significant heterogeneity in its presentation. The syndrome is caused by a mutation in the *AIRE* gene on chromosome 21q22.3.^{17,18}

The presence of two of the following three conditions are prerequisites for the diagnosis of APS I: (1) adrenocortical failure (Addison disease) or serologic evidence of adrenalitis (adrenal autoantibodies), (2) hypoparathyroidism, and (3) chronic mucocutaneous candidiasis.^{61,62,75–78} APS II is defined by the coexistence of at least two of these three endocrinopathies: (1) autoimmune adrenocortical insufficiency or serologic evidence of adrenalitis, (2) autoimmune thyroiditis, and/or

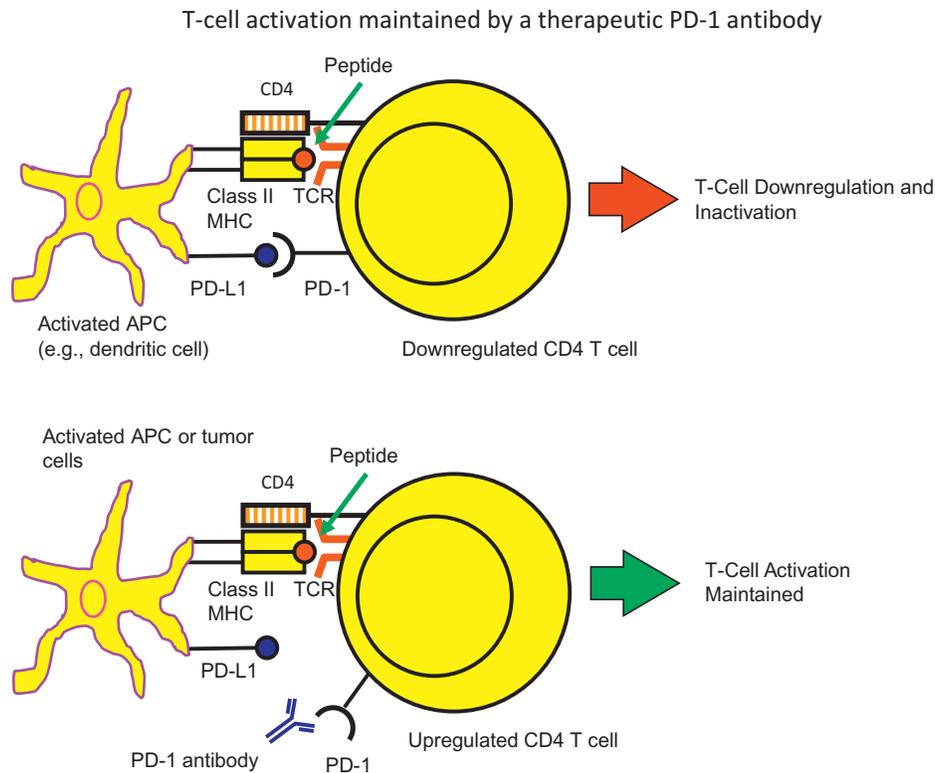

Fig. 22.4 T cell activation maintained by a therapeutic PD-1 antibody. Whereas the binding of PD-L1 on an APC to PD-1 (pictured) down-regulates activated T cells (CD4 T cells in this drawing; top half of the figure), interference in PD-1:PD-L1 signaling via a therapeutic monoclonal antibody to PD-1 (as pictured) or via a therapeutic monoclonal antibody to PD-L1 will maintain T cell activation (bottom half of the figure). Indeed therapeutic anti-PD-1 and anti-PD-L1 monoclonal antibodies have produced remarkable beneficial results in the treatment of some cancers.

(3) type 1 diabetes mellitus or serological evidence of islet autoimmunity.^{61,79–82} Traditionally, the presentation of autoimmune thyroid and adrenal disease has been termed *Schmidt syndrome*, whereas a complete triad of adrenal, thyroid, and islet autoimmunity (or type 1 diabetes mellitus) has been termed *Carpenter syndrome* (Fig. 22.5). The presence of thyroiditis, without adrenal disease, but associated with type 1 diabetes,⁸³ pernicious anemia, vitiligo, or alopecia has been referred to by some authors as *APS III*, whereas additional combinations of autoimmune disease have been referred to as *APS IV* (i.e., vitiligo plus alopecia, type 1 diabetes plus celiac disease, or type 1 diabetes and vitiligo).⁸⁴ Given that they share similar susceptibility genes and immunological features, these subtypes are often considered as extensions of APS II and not necessarily as separate entities.

GENETICS OF APS I AND APS II

APS I is caused by mutations in the *AIRE* gene, and is inherited in an autosomal recessive fashion.⁸⁵ The *AIRE* protein is expressed in the thymus, lymph nodes, and fetal liver, as well as in pancreas, adrenal cortex, and testes. The gene spans 11.9 kb, contains 14 exons, and encodes a 545 amino acid protein.¹⁸ The protein *AIRE* has four major domains—CARD (caspase recruitment domain), SAND (SP100, *AIRE1*, NucP41/P75 and DEAF1), PHD1 (plant homeodomain), and PHD2. The CARD domain is involved in multimerization of the *AIRE* protein into an active state, and its attachment to a target chromatin.⁸⁶ The SAND domain is required for *AIRE* to interact with a transcriptional repressive complex (ATF7ip), which in

turn is critical for *AIRE*-dependent gene expression.⁸⁷ The PHD domains function as sites for multiple binding events and aids *AIRE* transcriptional activity.⁸⁸

Over 98% of patients with APS I have mutations in the *AIRE* gene.^{77,89–91} So far, more than 100 mutations in the *AIRE* gene have been reported, and recessive mutations causing disease are distributed throughout the *AIRE* gene. Although the inheritance is traditionally accepted as autosomal recessive, there are some patients reported with heterozygous dominant mutations (in the gene encoding the SAND domain) and atypical or nonclassical manifestations of APS I.^{92,93} Because *AIRE* is active in multimeric forms, minor changes in amino acid sequences in critical domains of the *AIRE* secondary to heterozygous mutations can lead to defective multimers, and thus a negative dominant effect, whereby the altered gene product inhibits the functioning of the wild-type protein. Such an effect has also been reported for monoallelic mutations in the *AIRE* gene encoding the PHD1 domain.⁹⁴

Unlike APS I, APS II is not inherited as a single gene mutation but displays polygenic inheritance. APS II is much more typical of other autoimmune endocrinopathies, where cases can occur either sporadically, or within families with APS II. Often, different organ-specific manifestations share common genetic associations, and most of these genes code for key regulatory elements in immune system pathways. The *MHC* (*HLA* in humans) class II complex involved in antigen presentation is the most important gene associated with APS II.^{95,96}

A study in 1986 reported an association of *HLA-DR3* and/or *DR4* haplotypes⁹⁵ with Addison disease and type 1 diabetes. Subsequent studies have shown that variants in *DR3-DQ2*

Diagnostic relationships and common associations in the autoimmune polyglandular syndromes

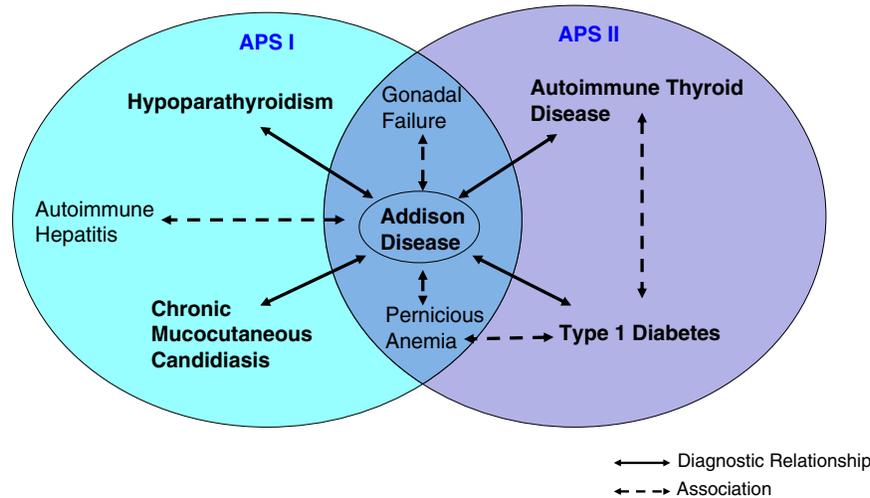

Fig. 22.5 Diagnostic relationships and common associations in the autoimmune polyglandular syndromes. The *solid lines* indicate diagnostic relationships. The *dashed lines* indicate common associations. The diagnosis of APS I depends on the coexistence of Addison disease (or adrenal autoantibodies) plus either hypoparathyroidism or chronic mucocutaneous candidiasis or both. The diagnosis of APS II depends on the coexistence of Addison disease (or adrenal autoantibodies) plus either autoimmune thyroid disease or type 1 diabetes or both (or their associated autoantibodies). Autoimmune hepatitis can occur in people affected with APS I. Gonadal failure or pernicious anemia can be seen in persons affected with either APS I or APS II. Pernicious anemia is also strongly associated with autoimmune thyroid disease (independent of APS II and Addison disease; note: for graphic simplicity, no line is drawn in the figure to indicate such “thyrogastric” autoimmunity).

and *DR4-DQ8* haplotypes confer a risk for type 1 diabetes and Addison disease, as well as autoimmune thyroid disease and celiac disease. This may indicate a common immunogenetic etiopathogenesis and highlights why multiple autoimmune disorders can develop in the same person.⁹⁷ Other components of APS II, such as Graves disease, have shown association with *HLA-DR3* as opposed to Hashimoto thyroiditis, which is associated with *HLA-DR4* or *DR5*.^{98,99} In addition to class II molecules, class I molecules (*HLA-A* and *B*) have also been implicated in the risk for type 1 diabetes.

Because the association of APS II with specific *HLA* alleles is only modest, the role of other susceptibility genes has been studied. Other non-*HLA* genes conferring APS II risk include genes that encode *CTLA-4*,¹⁰⁰ the transcriptional regulator protein *BACH2*,^{101–103} protein tyrosine phosphatase nonreceptor type 22 (*PTPN22*),¹⁰² and *CD25* (the high-affinity *IL-2* receptor).¹⁰⁴

CLINICAL ASPECTS

The major disease components, frequencies, and differences between APS I and II are shown in [Table 22.1](#). The overlap in some disease components between APS I and II are also highlighted in [Fig. 22.5](#).

APS I

Although the disease is not common, with an overall prevalence of less than 1:100,000, it is more prevalent in Finland (1:25,000), Sardinia (1:14,000), and among Iranian Jews in Israel (1:9000).^{75,76,78,105,106} The Finnish cohort of 91 subjects is the largest and most well-characterized APS I group of patients worldwide.⁷⁶

Persistent mucocutaneous candidiasis is usually the first sign (60% of all APS I patients) and appears during the first year or two of life. In the Finnish cohort, 50% developed candidiasis by age 5 years, 94% by age 20 years, and 100% by

40 years of age.⁷⁶ Candidal diaper rash is observed early in life, with vulvovaginal candidiasis often developing at puberty in females. Colonization of the gut by *candida* can lead to intermittent abdominal pain and diarrhea. Retrosternal pain in patients with oral candidiasis may suggest esophageal candidiasis and should be confirmed by esophagoscopy. Infection of the nails with chronic candidiasis may lead to a darkened discoloration, thickening, or erosion. Studies have shown that T cells from *AIRE*-deficient individuals still have a competent proliferative response against *C. albicans*. However, there is defective receptor-mediated internalization of yeast cell wall derivatives by monocytes in *AIRE*-deficient antigen presentation, and this leads to ineffective clearing of mucocutaneous candidiasis, and thus the chronicity. Thus, all patients with refractory mucocutaneous candidiasis should be thoroughly investigated not only for a T-lymphocyte abnormality (absolute lymphocyte count, enumeration of T-cell subpopulations, assessment of T-cell function where possible) but also for the presence of polyendocrinopathies. Chronic oral mucosal candidiasis must be treated aggressively, as there is increased risk of candidiasis associated squamous cell carcinoma (SCC) of the oral mucosa or esophagus; SCC was reported in seven of the 55 Finnish APS I patients over 25 years of age, albeit five of the seven were also smokers.^{75,107}

Oral mucous membranes must be protected from exposures that can increase susceptibility to *candida* infections. Specifically, patients should be advised to avoid hard, sharp, or spicy foods, as well as whitening toothpastes or abrasives. Dentures or orthodontics can provide additional surfaces for *candida* growth.⁷⁵ Fluconazole has good activity against *candida* and is the preferred treatment. Other azoles that have been used include ketoconazole, and miconazole. Data suggest that prolonged use can lead to resistance.^{108,109} With drug resistance, newer azoles, such as itraconazole, voriconazole, or posaconazole can be used. Patients should follow up closely with an infectious disease specialist. Physicians must be cognizant of the possibility of precipitating adrenal insufficiency

or worsening already present adrenal deficiency when using ketoconazole; ketoconazole can inhibit cortisol synthesis.^{110,111} In addition, there have been reports of adrenal insufficiency following use of other azoles (fluconazole, posaconazole) in sick patients.^{112,113}

Hypoparathyroidism is typically the first endocrinopathy to develop in APS I and eventually occurs in more than 85% of patients. Hypoparathyroidism usually presents after the onset of mucocutaneous candidiasis but before puberty, with 33% of APS I patients diagnosed by age 5 years, 66% by age 10 years, and nearly 85% by age 30 years.⁷⁶ Severe hypocalcemia, as evidenced by seizures, carpopedal spasms, muscle twitching, and laryngospasm may be presenting features of APS I, although these symptoms may be masked by the relative hypercalcemia associated with the cooccurrence of adrenal insufficiency. Some of the theories to explain the development of hypercalcemia in adrenal insufficiency include: (1) hypovolemia-induced reduction in glomerular filtration, and hence the amount of calcium filtered through the glomerulus, and (2) increased activity of 1- α hydroxylase, which is normally inhibited by glucocorticoids. Low or inappropriately normal intact parathyroid hormone (PTH) with concurrent hypocalcemia and hyperphosphatemia are diagnostic of hypoparathyroidism. Standard therapy consists of oral calcium salts and calcitriol administration (see Chapter 20 for management). Whereas recent data suggest that once or twice daily administration of subcutaneous recombinant parathyroid hormone (rPTH 1-34 and rPTH 1-84) may provide optimal therapy,^{114–116} especially in those who are poorly controlled on standard therapy, this approach is not yet approved by the US Food and Drug Administration for children in the United States.

Autoimmune adrenocortical insufficiency (Addison disease) is the third major component of APS I and typically occurs after mucocutaneous candidiasis and hypoparathyroidism have been diagnosed. Over 85% of APS I patients eventually develop adrenal insufficiency. Unfortunately, the clinical diagnosis of adrenal insufficiency is often missed initially with the diagnosis commonly made late, or at the time of a life-threatening adrenal crisis. In the Finnish cohort of APS I patients, 40% had Addison disease by 10 years of age and nearly 80% by 30 years of age.⁷⁶ Deficiencies of cortisol, aldosterone, and adrenal androgens may present simultaneously or may evolve over months to years. In addition, the initial symptoms of adrenal insufficiency are often nonspecific, mimicking psychiatric or gastrointestinal disease. These include fatigue, weight loss, myalgias, arthralgias, behavioral changes, nausea and vomiting, abdominal pain, and diarrhea. Cortisol deficiency leads to increased pituitary production of proopiomelanocortin or POMC, a precursor molecule that is cleaved into products including adrenocorticotrophic hormone (ACTH) and melanocyte-stimulating hormone (MSH). Over time, hyperpigmentation (because of elevated MSH) in non-sun-exposed areas, along with postural hypotension, can usually be found on careful examination. Unexplained hypotonic dehydration, with concomitant presence of the mentioned features, should raise the suspicion of Addison disease. Adrenal crisis with hyponatremia, hyperkalemia, acidosis, hypotension, and hypoglycemia may be fatal, unless recognized and treated appropriately and promptly with intravenous glucocorticoids and isotonic fluids (please see specific chapters for more details). As discussed in detail further in the chapter, adrenal autoantibodies are used to predict adrenal cortical failure. If antibody testing is positive, morning cortisol and renin measurements and/or an ACTH stimulation testing may be used diagnostically or monitoring asymptomatic patients.

Autoimmune gonadal failure occurs in over 50% to 60% of women with APS I by age 20 years, whereas less than 25% of males develop testicular insufficiency.^{76,97} Gonadal failure

often presents with primary amenorrhea in young women though menstrual irregularities, polycystic ovaries, or infertility may be presenting features.^{76,117} As with autoimmune adrenalitis, gonadal failure can be predicted by the presence of steroid cell autoantibodies.¹¹⁸

Ectodermal dystrophy, unrelated to hypoparathyroidism or mucocutaneous candidiasis, has been extensively documented in the Finnish cohort. Dental enamel hypoplasia of permanent (but not deciduous) teeth, as well as nail dystrophy (nail pits of 0.5–1 mm), are commonly found. There may be complete absence of the enamel or transverse hypoplastic bands alternating with zones of well-formed enamel. Nearly one-third of the Finnish patients also had calcification of the tympanic membranes¹¹⁹ and 20% to 25% developed keratitis.⁷⁶

As shown in Table 22.1, type 1 diabetes and thyrogastric autoimmunity (a descriptive term for the combination of autoimmune thyroid disease and atrophic gastritis) are associated with APS I, but occur far less frequently than in APS II. When present, thyroiditis is typically atrophic rather than goitrous. Gastric-parietal cell autoimmunity, which leads to atrophic gastritis, with resultant achlorhydria and intrinsic factor deficiency, typically presents as iron-deficiency or vitamin B₁₂-deficient pernicious anemia. Atrophic gastritis occurs in 15% to 30% of APS I cases with a mean age of onset of 16 years.^{76,119} Whereas iron-deficiency anemia is microcytic and vitamin B₁₂-deficient anemia is macrocytic, combined iron and vitamin B₁₂ deficiency can be normocytic. It is also important to recognize that the spinal cord comorbidities (subacute combined degeneration of the spinal cord) of vitamin B₁₂ deficiency can occur in the absence of anemia.

Nonendocrine organ-specific manifestations are less common (~5%–20%) and include alopecia, vitiligo, autoimmune hepatitis, and malabsorption among others. Progression to alopecia totalis (total loss of scalp hair) or universalis (total loss of all body hair, including eyelashes, eyebrows, and scalp hair) usually occurs before puberty. Vitiligo presents initially as small, pale pigment-lacking skin patches. These may be missed, unless specifically sought and ultraviolet light examination of the skin may be necessary. The appearance of clay-colored stools, dark urine, and jaundice suggests chronic active autoimmune hepatitis. Hepatitis occurs in 10% to 15% of APS I patients and is the leading cause of death. Consequently, all patients suspected of having APS I should have their liver function regularly monitored. Autoimmune hepatitis is typically treated with glucocorticoids initially, and later with azathioprine, once there is partial disease control. Malabsorption, which may occur intermittently (and typically of fat), has been linked to hypoparathyroidism (insufficient duodenal mucosal hormone and pancreatic enzymes because of hypocalcemia), bacterial and fungal overgrowth, gluten sensitivity (celiac disease), and IgA deficiency. There have also been rare reports of APS I with hypophysitis (diabetes insipidus, growth hormone deficiency, ACTH deficiency), and nonendocrine manifestations, such as rheumatoid arthritis, Sjögren disease, tubulointerstitial nephritis, autoimmune bronchiolitis, myopathy, and asplenia.^{75,120,121} Recent studies in a European cohort of 112 APS I patients have also uncovered a wide spectrum of phenotypic manifestations and genotypic changes in AIRE.¹²²

A study in a cohort of 35 North and South American subjects revealed that nonendocrine manifestations occur much earlier and more frequently when compared with European cohorts. These nonendocrine manifestations included urticarial eruptions (66%), hepatitis (43%), gastritis (48%), intestinal dysfunction (80%), Sjögren-like syndrome (43%), and pneumonitis (40%), and were present in 80% before the diagnostic dyad criteria of APS were met.¹²³ It is unclear if there are genotype-phenotype correlations that can explain the higher frequency of nonendocrine manifestations in the American cohort.

APS II

APS II is the most common of the autoimmune polyendocrinopathies (excluding the coincidences of type 1 diabetes and autoimmune thyroid disease), with a prevalence of 1 to 4:100,000 and with a polygenic inheritance. Unlike APS I, APS II usually has its onset in adulthood, particularly during the third or fourth decade and is at least 3 times more common in females than males, whereas APS I is equally common in males and females. This female bias in APS II is primarily explained by the coexistence of autoimmune thyroid disease (AITD), which is more common in women. In 1926 Schmidt first described the association of adrenocortical and thyroid gland failure and Carpenter extended this in 1964 to include type 1 diabetes mellitus.^{79,80} In 1957 the autoimmune nature of these diseases was suggested by Doniach and Roitt's discovery of thyroglobulin autoantibodies in patients with Hashimoto thyroiditis.¹²⁴

APS II presents with adrenocortical failure in approximately 50% of cases, though multiple disease components may be present at diagnosis. Although the disease usually has its onset between ages 20 and 50 years, it is not unusual to find cases before or after these ages.^{82,125,126} Type 1 diabetes coexists in nearly 50% of patients with Addison disease, whereas AITD coexists in about two-thirds of patients with Addison disease. Therefore type 1 diabetes and AITD must be pursued vigorously in any patient presenting with Addison disease.

The most common component of APS II is AITD and is seen in almost 70% to 75% of patients.¹²⁷ AITD affects nearly 4.5% of the US population,¹²⁸ with 80% to 90% of all cases occurring in females. AITD increases in incidence during the teen years, peaking in the fifth and sixth decades. Chronic lymphocytic thyroiditis (Hashimoto disease) is by far the most common form of AITD, although Graves disease may also occur. Postpartum thyroiditis has also been considered a transient manifestation of autoimmune thyroiditis following childbirth and can manifest as hypo- or hyperthyroidism. Several studies have reported on the coexistence of islet autoimmunity (3%–8%) or even overt type 1 diabetes and AITD,^{129,130} whereas less than 1% of patients, with otherwise isolated thyroiditis, have serological evidence of adrenal autoimmunity.

Although "polyglandular syndrome" involvement in patients with autoimmune thyroid disease is infrequent, thyroid autoimmunity or a family history of thyroiditis is common in patients with pernicious anemia, vitiligo, alopecia, myasthenia gravis, and Sjögren syndrome.^{131–133} Almost 20% to 40% of vitiligo patients have another component of APS II, with thyrogastic autoimmunity being the most common.^{134,135} Most patients with vitiligo are asymptomatic and evidence of concurrent autoimmunity can be ascertained only by autoantibody screening. Segmental vitiligo with involvement of dermatomal regions is not associated with autoimmunity.¹³⁶ Up to 15% of patients with alopecia (areata, totalis, universalis) and 5% of their first-degree relatives have thyroid disease. More patients with APS I than APS II have cutaneous manifestations, such as vitiligo or alopecia, but because APS II is far more common, most patients with either of the manifestations and another autoimmune disease are categorized as incomplete APS II.

Nearly 30% of patients with myasthenia gravis, an autoimmune disease characterized by presence of anti-acetylcholine receptor autoantibodies and muscle weakness worsening during muscular contraction, have AITD. Both Hashimoto thyroiditis and Graves disease may occur in patients with myasthenia gravis.^{137,138} Interestingly, patients with myasthenia gravis and concomitant AITD tend to have milder expression of their myasthenia, and a lower incidence of thymic disease and acetylcholine receptor α -chain autoantibodies. The incidence of ocular myasthenia is higher in patients with Graves disease.

Type 1 diabetes mellitus, a diagnostic component of APS II, has a peak incidence during the teen years with a smaller but increasing incidence occurring in the preschool years.¹³⁹ Nevertheless, the disease may have its onset at any age. Approximately 10% to 15% of APS patients, incorrectly labeled as type 2 diabetes because of diabetes onset after 40 years of age, actually have slowly progressive autoimmune diabetes (also referred to as *latent autoimmune diabetes of adults* or LADA).¹⁴⁰ Unlike APS II, in which there is a female gender bias despite the occurrence of type 1 diabetes, no gender bias is present in patients with isolated type 1 diabetes. AITD (denoted by the presence of thyroperoxidase and/or thyroglobulin autoantibodies) occurs in 20% to 25% of patients with type 1 diabetes with women representing nearly two-thirds of the autoantibody-positive patients.¹²⁵ Despite the high prevalence of thyroid autoantibodies, less than 20% of patients with thyroid autoantibodies have evidence of thyroid dysfunction defined as an elevated thyroid-stimulating hormone (TSH) concentration. Adrenocortical autoimmunity is much less frequent among patients with type 1 diabetes, with serological evidence reported in 1.5% of cases.^{141,142} Tissue transglutaminase autoantibodies suggestive of celiac disease are present in 3% to 7% patients with type 1 diabetes.¹⁴³ Celiac disease should be suspected in type 1 diabetes patients with unexplained diarrhea, weight loss, failure to gain weight, or failure to thrive, unexplained hypoglycemia should be confirmed by intestinal biopsy.^{144,145}

Gastric parietal cell autoantibodies (PCAs) are present in approximately 10% of females and 5% of males with type 1 diabetes.¹⁴⁶ Although pernicious anemia typically affects women after the fifth decade, children with PCA should be monitored closely for the development of pernicious anemia. Atrophic gastritis may lead to the development of megaloblastic anemia because of lack of intrinsic factor required for absorption of dietary vitamin B₁₂ from the gut. Iron-deficiency anemia may also occur in both adolescents and adults because of impaired ability to absorb iron consequent to decreased acid production (achlorhydria).¹⁴⁷

Approximately 10% of women younger than 40 years of age with APS II develop ovarian failure. Ovarian failure may present as either primary or secondary amenorrhea. In females with biopsy-proven lymphocytic oophoritis, adrenocortical failure or subclinical adrenal autoimmunity is often present.¹⁴⁸ In contrast, progression to gonadal failure is very rare among males with Addison disease.

Pituitary involvement is occasionally seen in APS II.^{149,150} Hypophysitis and empty sella syndrome have been described, leading to isolated failure of secretion of growth hormone, ACTH, TSH, follicle-stimulating hormone (FSH), or luteinizing hormone (LH).

Several nonendocrinological conditions have also been reported in association with APS II. These include ulcerative colitis,¹⁵¹ primary biliary cirrhosis,¹⁵² sarcoidosis,^{153,154} achalasia,¹⁵⁵ myositis,¹⁵⁶ and neuropathy.¹⁵⁷

IPEX Syndrome

IPEX is a syndrome caused by defective Tregs secondary to mutations in the *FOXP3* gene.¹⁵⁸ The *FOXP3* gene encodes a transcriptional factor of the same name. More than 70 *FOXP3* mutations associated with IPEX have been described to date. Because *FOXP3* is located in the X chromosome, the inheritance is X-linked recessive with males being affected, whereas females are carriers.

Patients who have *FOXP3* inactivating mutations resulting in *FOXP3* deficiency develop IPEX, which is characterized by multiorgan autoimmunity that begins very early in life and typically includes the triad of neonatal-onset type 1 diabetes, eczematous dermatitis, and enteropathy (watery diarrhea).

Other autoimmune disorders include thyroiditis, hemolytic anemia, thrombocytopenia, hepatitis, nephropathy, arthritis, and lung disease.^{159–162} Patients with IPEX syndrome often manifest autoantibodies early in life; those with type 1 diabetes often have glutamic acid decarboxylase autoantibodies (GADA), and other islet cell autoantibodies (ICAs) in the neonatal period. Other autoantibodies detected early in life include those against harmonin and villin, proteins found in the microvilli of the intestinal brush border and the renal proximal tubule, and may explain the enteropathy and nephritis found in these patients.

IPEX is often fatal in the first few years of life. To date, only long-term immunosuppression or bone marrow transplantation, with the goal of enhancing regulatory T-cell function, have been effective therapies for IPEX. Sustained expression of *FOXP3* may reprogram effector T cells to act as regulatory T cells.^{163,164} Novel approaches, including treatment with engineered Tregs^{165,166} or targeted gene editing of *FOXP3*,¹⁶⁷ are being investigated as treatment options for IPEX syndrome.

DIAGNOSTIC APPROACH AND FOLLOW-UP

The approach to diagnosing polyglandular syndromes is three-fold: (1) autoantibody screening to (i) verify the autoimmune

nature of the suspected endocrinopathy, and (ii) test for the involvement of other organs and tissues; (2) full assessment of endocrine function in patients with confirmed autoantibodies and autoantibody-negative subjects in whom disease is suspected clinically; and (3) mutation analysis to confirm the diagnosis, and screen siblings and other relatives for their potential carrier status.

Recognition of multiorgan autoimmune diseases before their symptomatic phases is vital to minimize associated morbidity and mortality. A thorough history and physical examination should always be performed, and a high index of suspicion should be maintained. In addition, family history of multiorgan autoimmune disease should increase the suspicion for potential APS.

As discussed later, perhaps the greatest single achievement in the last decade was the discovery of the association of autoantibodies to type 1 interferons and APS I, enabling early diagnosis of APS I patients.¹⁶⁸ Although not indicative of tissue-specific immune attack, autoantibodies to interferon (α and ω) provide a nearly 95% to 100% sensitive and specific screening test for APS I.^{169–171} The presence of autoantibodies to interferons should be followed by confirmatory testing for *AIRE* mutations, as well as testing for other tissue specific autoantibodies (Fig. 22.6). These include 21-hydroxylase or adrenal cortex

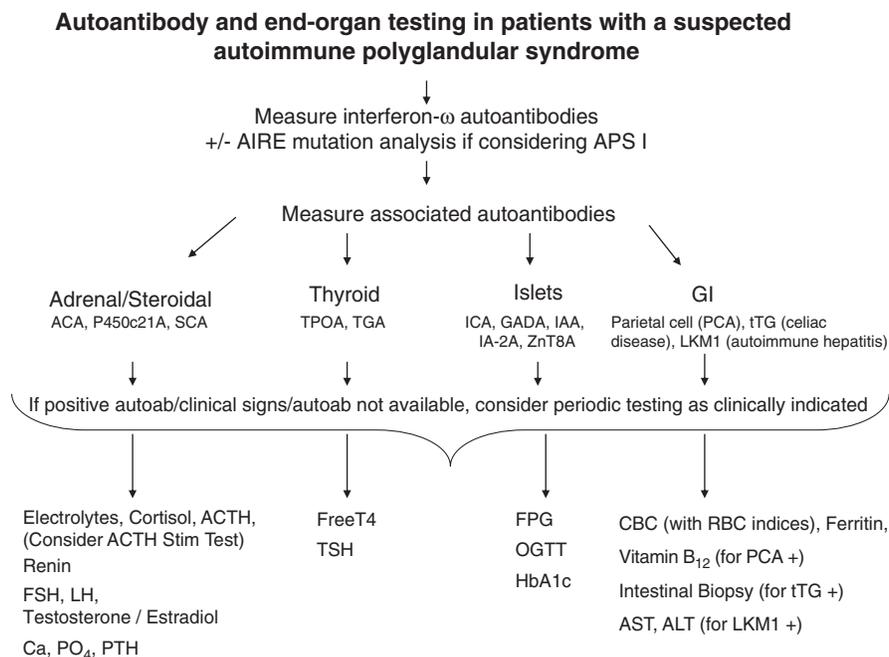

Fig. 22.6 Autoantibody and end-organ testing in patients with a suspected autoimmune polyglandular syndrome. This flow diagram indicates which autoantibodies should be obtained when APS is suspected. Given its sensitivity and specificity, primary screening with interferon- ω autoantibodies (if available) is likely adequate if APS I is suspected. That said, we recommend organ specific autoantibody testing in subjects with a suspected APS related disease (adrenitis, chronic mucocutaneous candidiasis, or autoimmune hypoparathyroidism) at the time of initial diagnosis. We also recommend autoantibody testing in subjects with 2 or more associated autoimmune diseases (i.e. T1D and autoimmune thyroiditis). Mutations in the *AIRE* gene can also be sought. Unfortunately, data are lacking to provide firm recommendations regarding the need for repeat autoantibody testing in patients who are initially autoantibody negative. However, if antibodies are negative, we recommend repeat autoantibody testing in early puberty if clinical signs or symptoms of APS persist. For those who are autoantibody positive, annual testing of end-organ failure should be obtained as shown. When autoantibody assays are unavailable, clinicians must use frequent testing of disease-specific endpoints to identify associated comorbidities. ACA = adrenal cytoplasmic autoantibodies detected by indirect immunofluorescence; P450c21A = Autoantibodies against the adrenal enzyme 21-hydroxylase; SCA = steroidal cell autoantibodies; TPOA = thyroperoxidase autoantibodies; TGA = thyroglobulin autoantibodies; ICA = islet cell cytoplasmic autoantibodies; GADA = glutamic acid decarboxylase autoantibodies; IAA = insulin autoantibodies; IA-2A = insulinoma associated-2 autoantibodies; ZnT8A = zinc transporter-8 autoantibodies; tTG = IgA transglutaminase autoantibodies; LKM1 = liver kidney microsomal type 1 autoantibodies; ACTH = adrenocorticotrophic hormone; FSH = follicle-stimulating hormone; LH = luteinizing hormone; Ca = calcium; PO₄ = phosphate; PTH = parathyroid hormone; T4 = thyroxine; TSH = thyroid stimulating hormone; FPG = fasting plasma glucose, OGTT = oral glucose tolerance test; HbA1c = hemoglobin A1c; CBC = complete blood count.

cytoplasmic autoantibodies (for autoimmune Addison disease), GADA, insulinoma associated autoantibodies (IA-2A), insulin autoantibodies (IAA), zinc transporter 8 (ZnT8) autoantibodies (for type 1 diabetes), thyroperoxidase and thyroglobulin autoantibodies (for AITD), steroidal cell autoantibodies (for ovarian failure), and transglutaminase autoantibodies (for celiac disease). In addition, although not readily available, autoantibodies to 17-hydroxylase, side-chain cleavage enzyme, and 3-hydroxysteroid dehydrogenase can be used to detect gonadal and adrenal autoimmunity. Autoantibodies to NACHT leucine-rich repeat protein 5 (NALP5) and calcium sensing receptor indicate underlying autoimmune hypoparathyroidism (CaSR).^{172,173} However, the specificity of CaSR and NALP5 for diagnosing autoimmune hypoparathyroidism is around 83% and 50%, respectively, whereas sensitivity has been reported to be 39% and 26%, respectively.¹⁷⁴

Other autoantibodies include antibodies to human pituitary enolase, and suggest autoimmune hypophysitis.¹⁷⁵

It should be noted that measurement of some of these autoantibodies might not be available to all clinicians, and require individualized approaches to screening and follow-up. In addition, data suggest a number of autoantibodies to cytokines (IL-17A, IL-17F, and IL-22) may be associated with mucocutaneous candidiasis.¹⁷⁶ Although there is a clear link between the presence of organ-specific autoantibodies and either the presence of preexisting disease, or subsequent progression to disease, the number of associated disorders that may develop and their age of appearance are unpredictable. Consequently, long-term follow-up is necessary in both autoantibody-positive and -negative subjects.

All patients with a single autoimmune disease must be considered at risk for other autoimmune diseases. Whether and when to screen for other autoantibodies is based on the likelihood of finding another autoimmune disease, cost-effectiveness, and the likelihood that screening will prevent morbidity and mortality from other future potential disorders, such as diabetic ketoacidosis, Addisonian crisis, or hypocalcemia with seizures, and so on.

Because of the high incidence of AITD in patients with type 1 diabetes, it is recommended that type 1 diabetes patients have thyroperoxidase and thyroglobulin autoantibodies measured shortly after diagnosis and thyrotropin (TSH) measured biannually.¹⁷⁷ Measuring both thyroid autoantibodies has close to 90% sensitivity for the detection of AITD. The frequency with which thyroid autoantibodies should be repeated remains somewhat controversial. In fact, some clinicians prefer to follow at-risk patients by means of TSH only, given that treatment is typically not initiated until the TSH becomes elevated.

Screening for all components of APS is not recommended in patients with isolated autoimmune thyroid disease. However, several reports have demonstrated an increased incidence of PCA in younger patients with autoimmune thyroiditis.^{147,178} Thus screening for PCA in children with AITD may be considered. In hypothyroid patients with confirmed APS, evidence for adrenal autoimmunity must be sought before starting thyroid hormone replacement therapy, because thyroid hormone

replacement can potentially precipitate an adrenal crisis in patients with marginal adrenocortical function (by increasing metabolism of glucocorticoid hormones).

Delayed diagnoses and even preventable deaths still occur in patients with undiagnosed adrenocortical failure. As mentioned previously, the presentation is often vague and nonspecific, until an Addisonian crisis ensues. In patients with type 1 diabetes, unexplained hypoglycemia or unexplained improvement in blood glucose control might be a clue to the diagnosis of Addison disease. Improved sensitivity to administered insulin and improved glycemia may represent the loss of counterregulatory activity associated with glucocorticoid deficiency. All patients with prolonged or unexplained chronic mucocutaneous candidiasis, or hypoparathyroidism, and females with premature ovarian failure should be evaluated for APS I, especially in the context of potential Addison disease.

Assessment of end-organ function in any patient with positive autoantibodies is recommended annually (see Fig. 22.6). Fasting and/or 2-hour postprandial blood glucose testing, calcium, phosphate plus PTH, and TSH levels can effectively assess islet, parathyroid and thyroid function, respectively, in asymptomatic individuals. Although hemoglobin A1c has a limited sensitivity as a screening tool for type 1 diabetes, publications in the literature have reported that it can predict the clinical onset in those who already have positive islet autoantibodies.¹⁷⁹ Elevated FSH and LH levels with concomitant low sex steroids confirm gonadal failure. Serial assessments of hemoglobin, hematocrit, and red blood cell indices can assess progression to atrophic gastritis in patients with gastric autoimmunity. The findings of a megaloblastic anemia with an elevated mean corpuscular volume suggest vitamin B₁₂ deficiency, whereas a microcytic hypochromic anemia suggests iron deficiency. Vitamin B₁₂ levels should be followed in all patients with PCA because neuropathy can develop without anemia. Before starting therapy, both vitamin B₁₂ level and an iron profile should be obtained. Methylmalonic acid levels are not routinely needed in patients with gastric autoimmunity but may be helpful if vitamin B₁₂ levels are borderline low.¹⁸⁰ Liver function tests and antimitochondrial autoantibodies should be obtained in patients with APS I. Patients with tissue transglutaminase or endomysial autoantibodies are frequently asymptomatic and should be referred to a gastroenterologist to discuss the need for an intestinal biopsy, and potential confirmation of celiac disease.

Low early morning cortisol levels, electrolyte abnormalities (hyponatremia/hyperkalemia), and hypoglycemia represent late changes occurring at or just before the onset of adrenal insufficiency. Just as the natural history of pretype 1 diabetes is well characterized (see Chapter 21), a similar pattern is seen before the development of adrenocortical insufficiency. Four stages have been described (Table 22.3) subsequent to the detection of adrenal autoantibodies: Stage 1: increased plasma renin activity with normal to low aldosterone; Stage 2: decreased cortisol response after parenteral ACTH administration; Stage 3: elevated basal ACTH; and Stage 4: low basal

TABLE 22.3 Stages in the Development of Autoimmune Addison Disease

Stage	Renin	Aldosterone	Basal Cortisol	Cortisol Post ACTH	Basal ACTH
1	Elevated	N or Low	N	N	N
2	Elevated	N or Low	N	Low	N
3	Elevated	N or Low	N	Low	Elevated
4	Elevated	Low	Low ^a	Low	Elevated

N = normal.

^aClinical Addison disease.

ACTH, Adrenocorticotropic hormone; N, normal.

cortisol.^{181,182} In individuals with adrenocortical autoantibodies, screening with a measurement of the morning cortisol concentration and ACTH should be done. A morning cortisol of less than 5 µg/dL with a concomitant plasma ACTH more than twofold above the reference range is highly diagnostic of primary adrenal insufficiency.¹⁸³ If these values are normal but the clinical suspicion is high, a confirmatory 250-µg ACTH stimulation test can be performed. Basal elevated renin values are also very suggestive of adrenocortical failure, and an ACTH stimulation test should be carried out for confirmation.

TREATMENT

Hormone or other replacement therapies for the component disorders of APS I and APS II, such as adrenal insufficiency, hypothyroidism, type 1 diabetes, iron-deficiency anemia, and pernicious anemia are similar whether the ailments occur in isolation or in association with other conditions. Specific endocrine disorder-related therapies are described in the individual chapters. Multidisciplinary teams must be involved in the evaluation and management of patients with APS I or II, given the multitude of pathologies that can manifest in the same individual. In addition, patients with APS I have been reported to have asplenia or functional hyposplenism,¹⁸⁴ and these patients are prone to fulminant infections. Timely immunizations and, if required, prophylactic antibiotics must be part of the management of these patients.

AUTOANTIBODIES IN AUTOIMMUNE POLYGLANDULAR SYNDROMES

Autoantibodies in APS are predominantly IgG antibodies that bind to self-antigens. Autoantibodies may be pathogenic, as observed in Graves disease or myasthenia gravis. In Graves disease, agonistic autoantibodies directed to the TSH receptor stimulate overproduction of thyroid hormone causing hyperthyroidism.¹⁸⁵ In myasthenia gravis, autoantibodies directed against the motor end plate acetylcholine receptor located on myocytes stimulate internalization of the acetylcholine receptor, producing muscular weakness. However, autoantibodies usually serve solely as serologic markers of autoimmunity, such as in type 1 diabetes where ICAs, IAA, GADA, IA-2A, and autoantibodies to the ZnT8A are indicators of ongoing autoimmunity.^{186,187} Interestingly, in patients with APS I, GADA are not as predictive of the subsequent development of type 1 diabetes.⁷⁵

As previously stated, detection of autoantibodies in APS serves several important functions. First, detection of autoantibodies allows for a specific autoimmune diagnosis to be established.¹⁸⁸ Secondly, autoantibody detection in asymptomatic individuals indicates an increased risk for the later development of clinical disease and patients are monitored more closely.¹⁴¹ Thirdly, the presence of an autoantibody or one autoimmune disease in an individual may suggest increased risk for other associated autoimmune diseases.

Nonorgan-Specific Autoantibodies

1) Antiinterferon Autoantibodies

Autoantibodies to interferons (α and ω) are highly specific and sensitive for APS I,¹⁶⁹ and some authors have advocated the use of these antibodies as screening assays rather than evaluating for AIRE mutations. These autoantibodies were first used clinically as indicators of risk for myasthenia gravis and thymoma, and high-titer AIA were unexpectedly found in 60/60 Finnish APS I patients and 16/16 Norwegian APS I patients.¹⁶⁸ Notably, AIA were detected in stored serum samples in known APS I patients before the onset of organ-specific autoantibodies. In

fact, several APS I patients developed AIA before the onset of mucocutaneous candidiasis or other organ manifestations. As further evidence of the specificity of AIA, subjects with AIRE mutations but lacking classic features of APS I (mucocutaneous candidiasis, hypoparathyroidism, or adrenal insufficiency) have also demonstrated high titers to AIA. As such, AIA are likely to become the primary screening test for APS I; AIA can be detected by a competitive immunoassay.¹⁷¹ Recent animal studies have also demonstrated that IFN- α autoantibodies have neutralizing effects in vitro and in vivo, with the potential to ameliorate autoimmune disease processes in APS I.¹⁸⁹ The authors of the same study also questioned if the lower rate of development of type 1 diabetes in APS I patients (10%–20%), despite many having GAD autoantibodies, may be associated with the presence of these neutralizing IFN- α autoantibodies.

2) Autoantibodies to IL-17A, IL-17F, and IL-22

Mucocutaneous candidiasis is often the presenting clinical abnormality in APS I. Although AIA can predict APS I, they do not predict the order or severity of the known APS I components. Disease or organ-specific autoantibodies are therefore needed to provide patients and physicians with optimal anticipatory guidance. Several groups have reported that autoantibodies to cytokines, such as IL-17A, IL-17F, and IL-22, may both predict and explain the mucocutaneous candidiasis associated with APS I. Under normal circumstances, these pro-inflammatory cytokines with antifungal and microbicidal properties are produced by Th17 cells.

In one study, 33/33 patients with APS I and mucocutaneous candidiasis demonstrated high-titer autoantibodies to IL-17A, IL-17F, and IL-22, whereas 0/37 controls, and 0/103 patients with isolated autoimmune diseases were positive for these antibodies.^{123,176,177} These observations have been confirmed in subsequent cohort studies.^{123,190,191} However, these autoantibodies are only used in the research setting currently.

Organ-Specific Autoantibodies

Adrenal Cytoplasmic Autoantibodies

Adrenal cytoplasmic autoantibodies (ACA) were first detected using a complement-fixation technique with saline extracts of adrenal tissue and soon afterward by indirect immunofluorescence.¹⁹² Usually all layers of the adrenal cortex (but not the medulla) fluoresce. The microsomal localization of autoantigens has been confirmed using ultracentrifuged cellular components.¹⁹³ Other assays for adrenal autoantibodies include solid-phase radioimmunoassays and nonradioactive enzyme-linked immunoabsorbent assays.^{182,194}

ACA are detected in all forms of autoimmune Addison disease, be it isolated Addison disease or as part of APS I or APS II. Approximately 50% of asymptomatic ACA-positive individuals develop Addison disease within 3 years, and up to 75% to 100% of those with recent onset or close to clinical onset of Addison disease exhibit ACA.^{181,194} In a follow-up of 20 ACA-positive children followed for up to 11 years, the cumulative risk for developing Addison disease was 100%.¹⁸¹ ACA are also predictive of the subsequent development of Addison disease in adults, although less frequently than in children. Higher titers of ACA and complement fixing ACA have been associated with an increased risk of progressing to clinical disease.¹⁹⁵

Autoantibodies to the surface of adrenal cortical cells have been described, and almost 90% of individuals with Addison disease were reported to exhibit these autoantibodies.¹⁹⁶ However, these assays are rarely done because of the difficulty in obtaining fresh human or animal adrenal tissue that are used in these assays.

Adrenal Enzyme Autoantibodies

Typical of many organ-specific autoimmune diseases, major autoantigens that serve as targets of autoantibodies in APS are enzymes. Examples of various autoimmune diseases where enzymes are the target of the immune system are illustrated in Table 22.2. A discussion of adrenal hormone synthesis can be found in Chapter 14.

21-Hydroxylase (P450c21) is a major autoantigen recognized by autoantibodies in sera from patients with Addison disease.¹⁹⁷ There is a strong correlation between positivity for ACA and P450c21 (21-hydroxylase) autoantibodies, and P450c21 autoantibodies appear to be an even more sensitive indicator of disease.¹⁹⁸ Nearly 75% of APS I and APS II patients have positive P450c21 autoantibodies.¹⁸⁰ Other enzymes have been identified as autoantigens in patients with either isolated autoimmune Addison disease or APS, including P450 cholesterol side-chain cleavage enzyme (P450scc), 17 α -hydroxylase (P450c17), and 3 β -hydroxysteroid dehydrogenase.¹⁹⁸

The autoantigenic epitopes of the P450c21 enzyme are located in the C-terminal end and in a central region of the enzyme.¹⁹⁹ It has been reported that two of four epitopes recognized by P450c17 autoantibodies cross-react with P450c21, indicating that reactivity to one of these autoantigens could actually reflect molecular mimicry between such epitopes.²⁰⁰ Except for the N-terminal amino acids 1–40 and the C-terminal amino acids 456–521, immunoreactive epitopes have been described throughout P450scc.²⁰¹

High titers of both ACA and P450c21 autoantibodies are associated with greater impairment of adrenocortical function and subsequent development of Addison disease.¹⁷⁹ As with many autoimmune diseases, an inverse correlation exists between autoantibody titer and duration of disease in patients with Addison disease.²⁰² This is consistent with the concept that once an autoantigen is completely destroyed, the immune system is no longer stimulated to produce autoantibodies.

When clinical or preclinical Addison disease is present, there is no unique combination of adrenal or gonadal antibodies that separate APS I from APS II.^{187,203,204} The differentiation of APS I from APS II is made either on clinical grounds or, in asymptomatic patients, by detecting concomitant autoantibodies associated with APS II. Furthermore, there are no unique epitopes recognized by P450c21 autoantibodies that allow differentiation of isolated Addison disease versus APS I or APS II.²⁰⁵ However, APS I can be definitely distinguished from APS II via molecular diagnostic tests for mutation in the *AIRE* gene and inferred by the presence (APS I) or absence (APS II) of interferon antibodies.

Steroidal Cell/Gonadal Autoantibodies

Some individuals with ACA have sera that cross-react with reproductive-steroid producing tissues, including the theca interna of the Graafian follicle, Leydig cells of the testis, and/or syncytiotrophoblastic layer of the placenta.^{206,207} Sera that recognize antigens in both adrenal and reproductive-steroid producing tissues whose immunoreactivity cannot be absorbed with adrenal extracts are termed *steroidal cell/gonadal antibodies* (SCA). Such variability in immunoreactivity likely represents differences in autoantigen density or epitope availability differences among the tissues.

In asymptomatic patients, SCA are associated with an increased risk of developing primary autoimmune gonadal failure. In women, this usually manifests as either primary amenorrhea or premature menopause; men are usually asymptomatic. SCA, depending on the assay used are found in 4% to 87% of women with premature ovarian failure.^{206,208,209} SCA have also been reported to be predictive

of gonadal failure in women with APS who had normal menses at the time of initial study. In a small cohort study of 11 APS I female patients, 100% (11 of 11) who were positive for SCA developed primary ovarian failure during a follow-up period of 12 years.²¹⁰ When ACA are present in the absence of SCA, gonadal failure is rare.²⁰⁷ However, approximately one-third of individuals with ACA have SCA (using ovary, testis, or placenta as the antigen source). A small study of five women with SCA who also had ACA, consistent with an APS I manifested ovarian failure.²¹⁰ SCA are more common in APS I than in APS II patients, and it is estimated that 60% of subjects with APS I and Addison disease have SCA, compared with 30% of patients with APS II.

Premature ovarian failure independent of APS may also occur as a consequence of autoimmunity.²¹¹ However, Addison disease coexists in approximately 2% to 10% of women with autoimmune premature ovarian failure, and thus should be sought.²¹² Like other organ-specific autoimmune diseases, autoimmune ovarian failure is characterized histologically by ovarian infiltration with inflammatory cells.²¹³

The nature of the ovarian autoantigens in premature ovarian failure is controversial. Autoantibodies reacting strongly to pig zona pellucida, as determined by indirect immunofluorescence, were observed in six of 22 women with infertility.²¹⁴ Because the adrenal cortex and gonad share several synthetic pathways common to cells producing both adrenocortical and sex steroids, humoral autoimmunity to shared autoantigens might be expected in patients with both Addison disease and gonadal failure. The synthesis of sex and adrenal steroids requires P450scc, 3 β -hydroxysteroid dehydrogenase, and P450c17. Data are, however, contradictory. In one study, SCA activity was removed by preabsorption with recombinant human 3 β -hydroxysteroid dehydrogenase, suggesting that this enzyme was a major autoantigen detected by SCA positive sera.²¹⁵ Another study suggested that SCA correlated best with reactivity to P450scc and a 51-KDa autoantigen that binds to the aromatic L-amino acid decarboxylase present in granulosa cells, placenta, liver, and pancreatic beta cells.²¹⁶

Autoantibodies in Hypoparathyroidism

Autoimmune hypoparathyroidism is unique to APS I. In the original report of parathyroid autoantibodies detected using indirect immunofluorescence, nearly 40% of patients with autoimmune hypoparathyroidism were positive for parathyroid cytoplasmic autoantibodies versus 6% of controls.^{217,218} However, other laboratories did not confirm the initial reports of the existence of such parathyroid cytoplasmic autoantibodies.^{219,220} It was shown that autoantibodies detected by indirect immunofluorescence directed against the parathyroid gland could be preabsorbed with human mitochondria, indicating that such autoantibodies were not tissue specific.²²⁰

Since then, several different antiparathyroid autoantibodies have been reported in patients with hypoparathyroidism. Screening of human parathyroid complementary DNA libraries with sera from patients with known APS I and hypoparathyroidism have identified NALP5 as an important parathyroid autoantigen. Autoantibodies were detected in 49% of patients with APS I and hypoparathyroidism, but were absent in all 293 controls.¹⁷¹ Although NALP5 autoantibodies are rarely (0.69%) seen in patients with idiopathic hypoparathyroidism,²²¹ their specificity for diagnosing APS I-associated hypoparathyroidism is only around 50% and sensitivity 26%.¹⁷² Activating autoantibodies to CaSR are also seen in patients with autoimmune hypoparathyroidism. The specificity of CaSR autoantibodies for diagnosing autoimmune hypoparathyroidism is 83%, which is better than that of NALP autoantibodies. However, the sensitivity of CaSR autoantibodies at 39% remains low.¹⁷²

Other Autoantibodies in APS I and II

In addition to the autoantibodies discussed earlier, autoantibodies to tyrosine hydroxylase have been reported in around 40% of patients with APS I and appear to correlate with alopecia areata,²²² whereas autoantibodies to tryptophan hydroxylase correlate with intestinal malabsorption.²²³ Antibodies to liver/kidney microsome type 1 (LKM1) are found in nearly 100% of patients with type 2 autoimmune hepatitis.²²⁴ Some 40% of such patients have associated autoimmune disease commonly seen in APS I. The hepatic autoantigens P450IA2 and P450A6 seem to be the targets of these antibodies. Autoantibodies to aromatic L-amino acid decarboxylase have also been recognized in APS I patients, and is associated with autoimmune hepatitis and vitiligo.²²⁵ Antibodies to human pituitary enolase are associated with autoimmune hypophysitis.¹⁷⁴ Finally, autoantibodies against bactericidal/permeability-increasing fold-containing B1 (BPIFB1) and the potassium channel regulator KCNRC have been associated with development of pneumonitis. BPIFB1 has been reported to be highly sensitive, whereas KCNRC has a low sensitivity, but 100% specificity for pneumonitis.¹²²

SUMMARY

The APS result from a loss of tolerance to self-antigens. APS I, an autosomal recessive disorder mapped to the *AIRE* gene, is defined by the presence of at least two of the following three findings: (1) adrenocortical autoimmunity, (2) hypoparathyroidism, or (3) mucocutaneous candidiasis. APS II is defined by the coexistence of autoimmune adrenocortical insufficiency or serologic evidence of adrenalitis with autoimmune thyroiditis and/or type 1 diabetes mellitus. The occurrence of any one component disease of an APS may be linked to the occurrence of others through shared autoimmunity background genes that are involved with loss of tolerance. As such, a high index of suspicion should be maintained whenever one autoimmune disorder is diagnosed. For example, in type 1 diabetes, it is routine to screen for thyroid autoimmunity and celiac disease.

Treatment of APS should be aimed at optimal management of the specific underlying diseases. Screening for the presence of associated autoimmune disorders should be performed regularly. In conclusion, an improved understanding of the interaction between susceptibility genes, environmental triggers, individualized genomic background and its relation to the development of impaired immune tolerance, new immunological applications (such as generation of thymic epithelial cells from stem cells or use of engineered Tregs) should prove to be the best path to improved diagnostic and therapeutic modalities in the care of patients with APS.

Autoimmune type 1 diabetes mellitus and other immune endocrinopathies before the age of 6 months of life, associated with enteropathy in a male, should raise consideration of the IPEX syndrome and mutational analysis of the *FOXP3* gene; without evidence of autoimmunity, for example, antiislet antibodies, a form of neonatal diabetes mellitus, should be considered because specific therapies for the latter include effective oral medications and may not require insulin (see Chapter 10).

The increasing use of immune checkpoint inhibitors is associated with various adverse reactions, including endocrinopathies, such as hypophysitis, leading to secondary adrenal insufficiency, or primary adrenal insufficiency, thyroiditis, and occasionally type 1 diabetes mellitus. These may occur in 10% to 20% of adult patients weeks to months after the use of the drugs, though the frequency in childhood and adolescence is not yet defined. However, physicians should be aware of these entities and treat with appropriate hormone replacement as indicated.^{226,227}

INTRODUCTION

Glucose is an obligate fuel for the brain under physiological conditions. The brain can neither synthesize glucose nor store more than approximately a 20-minute supply of glycogen; therefore brain survival requires a continuous supply of glucose.^{1,2} The brain can use alternative fuels from the circulation, provided their concentrations rise high enough to enter the brain in sufficient amounts; for example, elevated ketones during prolonged fasting³ or lactate during vigorous exercise⁴ and in untreated type 1 glycogen storage disease (GSD).⁵ Blood-to-brain glucose transport mediated by glucose transporter 1 (GLUT-1) is a direct function of the arterial plasma glucose concentration, and physiologic mechanisms normally maintain plasma glucose at levels that ensure adequate glucose delivery to the brain. At physiological (70–100 mg/dL¹) plasma glucose concentrations, the rate of blood-to-brain glucose transport exceeds the rate of brain glucose metabolism. At plasma glucose concentrations lower than 54 mg/dL,² however, the cerebral metabolic rate of glucose decreases,^{6,7} and at even lower plasma glucose concentrations, functional brain failure occurs, and profound and prolonged hypoglycemia causes permanent brain injury and eventually brain death.²

Beyond the newborn period and early infancy, hypoglycemia is uncommon and is usually caused by an acquired disorder of the endocrine system, prolonged fasting in susceptible individuals (e.g., an intercurrent gastrointestinal illness), congenital abnormalities, such as hyperinsulinism (HI) or inborn errors of metabolism, or accidental and rarely deliberate exposure to medication or toxins. As the interval between feedings increases in the growing infant, physiologic endocrine and metabolic processes normally ensure the maintenance of normoglycemia; however, hypoglycemia can first manifest later in infancy or early childhood when there are mild congenital defects of these systems. In contrast, hypoglycemia presenting in older children and adults is typically caused by an acquired disorder.

This chapter describes an approach to diagnosis based on identifying the specific cause of failure to maintain normal

glucose homeostasis. Key diagnostic information is often best derived from blood and urine specimens (referred to as *critical samples*) obtained at the time of hypoglycemia and immediately before reversing hypoglycemia.

PHYSIOLOGIC DEVELOPMENT OF GLUCOSE METABOLISM DURING INFANCY AND CHILDHOOD

Glucose Production and Utilization

Rates of glucose flux into and out of the circulation are normally tightly regulated and systemic glucose balance is maintained, while ensuring a continuous supply of glucose to the brain. After a typical carbohydrate-containing meal, increased insulin secretion (together with inhibition of counterregulatory hormone secretion) leads to rapid disposal of ingested glucose, either for immediate energy needs or storage via deposition of glycogen and conversion to fat, resulting in restoration of plasma glucose concentrations to basal levels within 2 to 3 hours. Bier et al. showed that in children, ranging from premature infants to age 6 years, mean glucose production rates are 5 to 8 mg/kg/min; thereafter, glucose production as a function of body weight decreases toward the mean adult value of 2.3 mg/kg/min.⁸ Furthermore, the rate of glucose production is linearly correlated with estimated brain weight at all ages.⁸ Because the brain accounts for the bulk of daily glucose utilization, it is not surprising that adult glucose production rates are reached by mid-childhood (body weight ~30 kg), when the child's brain weighs about 90% of the adult brain (Fig. 23.1).

During fasting, the brain initially uses glucose almost exclusively provided from a combination of glycogenolysis and gluconeogenesis in the liver. As liver glycogen stores diminish, adipose tissue lipolysis is activated to increase availability of free fatty acids (FFA) as fuel for peripheral tissues, such as muscle, and for ketogenesis in the liver, which makes ketones available as a brain fuel and partly replaces glucose utilization. Note that the time to reach the fasting hyperketonemia stage is markedly shorter in younger infants and children than in adults,

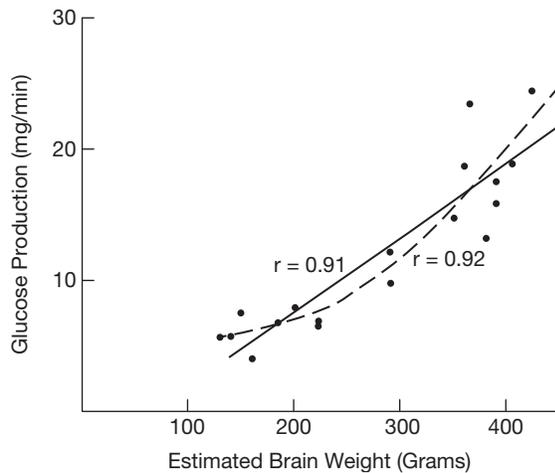

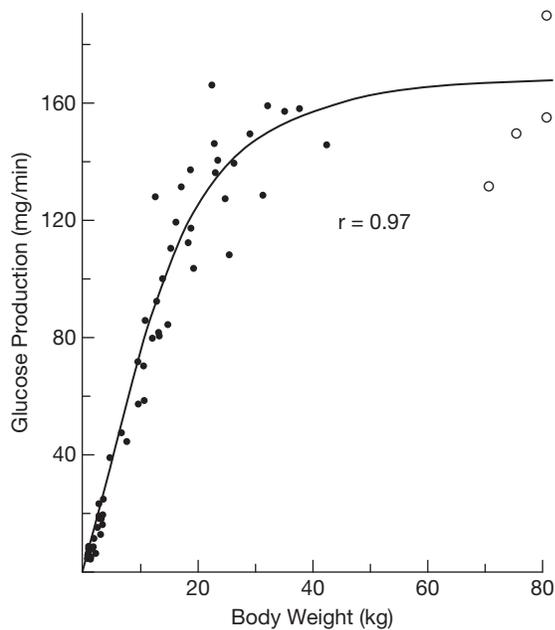

Fig. 23.1 Glucose production as a function of body weight (*top*) and estimated brain weight (*bottom*). Note the change in slope at approximately 30 to 40 kg of body weight, when brain growth is complete. (From Bier, D.M., Leake, R.D., Haymond, M.W., Arnold, K.J., Gruenke, L.D., Sperling, M.A., et al. (1977). Measurement of “true” glucose production rates in infancy and childhood with 6,6-dideuteroglucose. *Diabetes*, 26, 1016–1023.)⁸

because of their larger ratio of brain relative to muscle mass. As shown in Fig. 23.2, the change in sources of fuel for the brain is reflected in the changes in plasma concentrations of the major metabolic fuels. The substantially smaller muscle mass of infants and young children relative to brain mass limits their ability to tolerate prolonged fasting.⁹ Because brain growth is nearly complete by 10 to 12 years of age, plasma glucose can be maintained above 70 mg/dL for progressively longer fasting durations in adolescents and adults. Nonetheless, most full-term infants, from about 1 week to 1 year of age, are able to tolerate fasting for 15 to 18 hours before plasma glucose decreases below 70 mg/dL,^{10–12} and by 1 year of age, most normal children are able to fast for up to 24 hours.^{12–15} By 5 years of age, a fast of up to 36 hours may be tolerated, and most adults can maintain fasting plasma glucose above 70 mg/dL for 48 to 72 hours (Fig. 23.3).¹⁶ When hypoglycemia is induced by fasting for a shorter duration than would be expected for the child’s

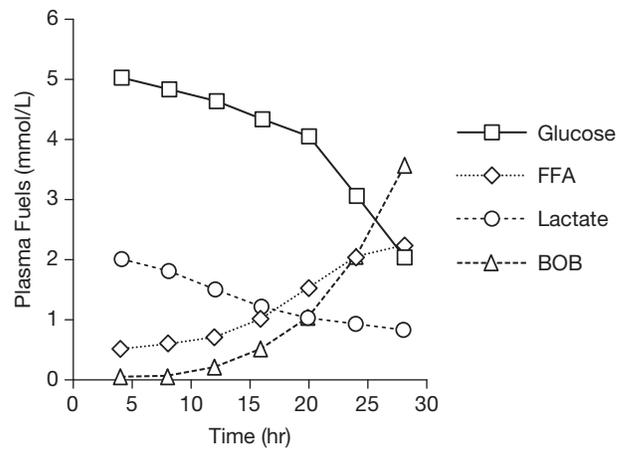

Fig. 23.2 Changes in plasma concentrations of glucose and major metabolic fuels during a fast in a normal child. Note that plasma glucose concentrations decline toward hypoglycemic values by 24 hours, as hepatic glycogen reserves are depleted. The level of lactate, a representative gluconeogenic substrate, declines gradually during fasting. Late in fasting, levels of plasma free fatty acids increase as lipolysis is activated—followed by an increase in beta-hydroxybutyrate as rates of hepatic fatty acid oxidation and ketogenesis increase. BOB, beta-hydroxybutyrate; FFA, free fatty acid.

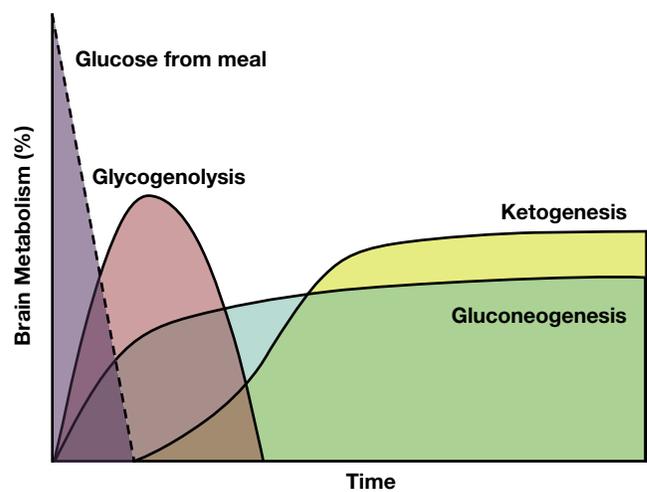

Fig. 23.3 Change in fuel sources during fasting. 1 month old—14- to 18-hour fast; 1 to 5 years old—16- to 24-hour fast; 6 to 12 years old—24- to 36-hour fast, adult—30- to 48-hour fast

age, the possibility of an underlying hypoglycemia disorder should be considered.^{12,17}

Adaptation to Longer Feeding Intervals

With feeding, plasma insulin concentrations in normal-weight children rise from basal levels of 3 to 10 μ U/mL to peak levels of 20 to 50 μ U/mL, which serves to stimulate hepatic glycogen synthesis, inhibit hepatic glycogenolysis and gluconeogenesis, and enhance peripheral (muscle and adipose tissue) glucose uptake and utilization (Table 23.1). Simultaneously, triglyceride synthesis is activated and lipolysis and ketogenesis are suppressed. In the postabsorptive state, a characteristic sequence of physiological responses are involved in preventing or correcting hypoglycemia. The earliest response to decreasing plasma glucose concentrations is a decrease in insulin secretion, as

TABLE 23.1 Hormonal Regulation of Fuel Metabolism

	Insulin	Glucagon	Epinephrine ^a	Cortisol	Growth hormone

Ketogenesis	-	+	+	+	

+ denotes stimulates, - inhibits; ^aincludes sympathetic nervous system activation ^bcortisol stimulates glycogen synthesis, and both cortisol and growth hormone exert permissive effects on the gluconeogenic and glycogenolytic effects of glucagon and epinephrine.

plasma glucose declines within the physiological range (80–85 mg/dL) followed by increased secretion of glucose counterregulatory hormones (glucagon, epinephrine, cortisol, and growth hormone [GH]), when plasma glucose falls just below the postabsorptive physiological range (65–70 mg/dL), and sympathetic neural activation occurs at 55 mg/dL (Fig. 23.4). The combined effects of suppressed insulin secretion, increased levels of counterregulatory hormones, and sympathetic neural activation mobilize stored fuels and reduce glucose utilization, thereby preventing hypoglycemia.^{18–20} With insulin levels suppressed, elevated glucagon secretion and sympathetic neural activation trigger glycogenolysis, the first phase in the metabolic defense against hypoglycemia. In infants, liver glycogen stores may provide glucose for up to 4 hours (see Fig. 23.3). As the child grows, hepatic glycogen content relative to brain glucose utilization is greater and may be able to provide glucose for up to 8 hours of fasting. Isolated glucagon deficiency is extremely rare and, with the exception of children on beta-blocker drugs, deficiency of sympathetic nervous activity is equally unusual. Therefore hypoglycemia occurring within 2 to 4 hours of a feed suggests either a primary disorder of glycogenolysis or excess (dysregulated) insulin secretion. As glycogen stores become depleted, maintenance of plasma glucose levels relies on gluconeogenesis and reduced tissue glucose utilization (resulting from increased oxidation of FFA and ketones) (see Fig. 23.3). The main gluconeogenic precursors are amino acids, especially alanine and glutamine, from skeletal muscle, and glycerol from adipose tissue lipolysis (Fig. 23.5). FFA become the body's major fuel source, as the duration of fasting becomes more prolonged.

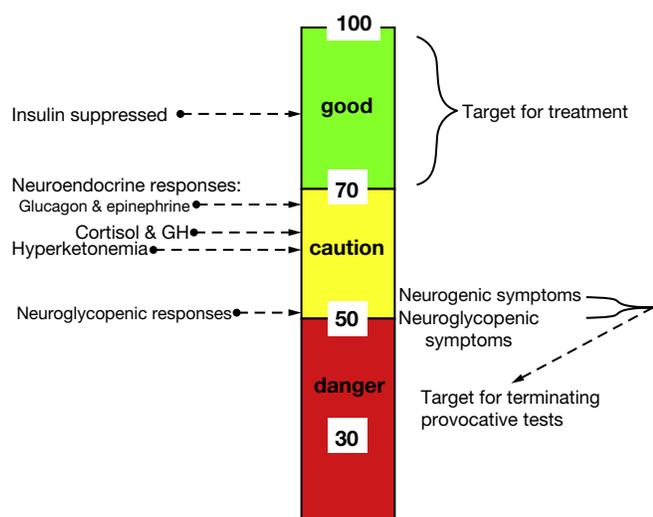

Fig. 23.4 Interpreting plasma glucose levels (mg/dL) and plasma glucose targets for treatment of hypoglycemia and for terminating provocative tests. *GH*, growth hormone. (Based on data from Cryer PE. *Banting Lecture. Hypoglycemia: the limiting factor in the management of IDDM. Diabetes. 1994;43(11):1378-89.*³⁹⁰)

Mitochondrial fatty acid oxidation in the liver produces ketone bodies (acetoacetate and β -hydroxybutyrate [BOHB]), which are used for energy production by the brain and skeletal muscle, including cardiac muscle (see Fig. 23.2).^{12,14,21,22} Oxidation of FFA and ketone utilization decreases peripheral glucose utilization, which helps to ensure an adequate supply of glucose to the brain and tissues that can only use glucose as fuel (e.g., red blood cells and renal medullae), while preventing excessive breakdown of muscle protein. Lipolysis of triglycerides in adipose tissue is triggered by low levels of insulin together with increased secretion of the counterregulatory hormones (especially GH²³) and sympathetic neural activation. In infants, elevation of plasma ketone concentrations begins within 12 to 18 hours of fasting; whereas, in older children, substantial ketonemia may not appear until 18 to 24 hours of fasting.^{12,24,25} Cortisol, secreted in response to stress, accelerates gluconeogenesis and lipolysis and decreases glucose utilization.²⁶

Defects in gluconeogenesis (e.g., fructose-1,6-bisphosphatase deficiency; see Fig. 23.5) usually become manifest only after glycogen stores have been depleted; accordingly, hypoglycemia typically does not occur in the recently fed state. Disorders of fatty acid oxidation also typically manifest after more prolonged fasting. In the first few months of life, the interval between feedings in the on-demand breastfed infant gradually increase from about 2 to 3 hours to 4 hours or more, and eventually to 8 to 12 hours as nighttime feedings are omitted. Therefore disorders of gluconeogenesis and fatty acid oxidation seldom present as hypoglycemia in the newborn period when feeding is frequent; rather, they present later in infancy as the interval between feeds becomes more prolonged. They may, however, present immediately after birth before lactation is established. Congenital or acquired deficiencies of cortisol and GH may also cause hypoglycemia either in the newborn period, if congenital and severe, or later in infancy when longer periods of fasting typically occur. Combined deficiency of cortisol (adrenocorticotropic hormone [ACTH]) and GH in hypopituitarism may cause earlier onset and more severe hypoglycemia than occurs with isolated deficiencies of either GH or cortisol.

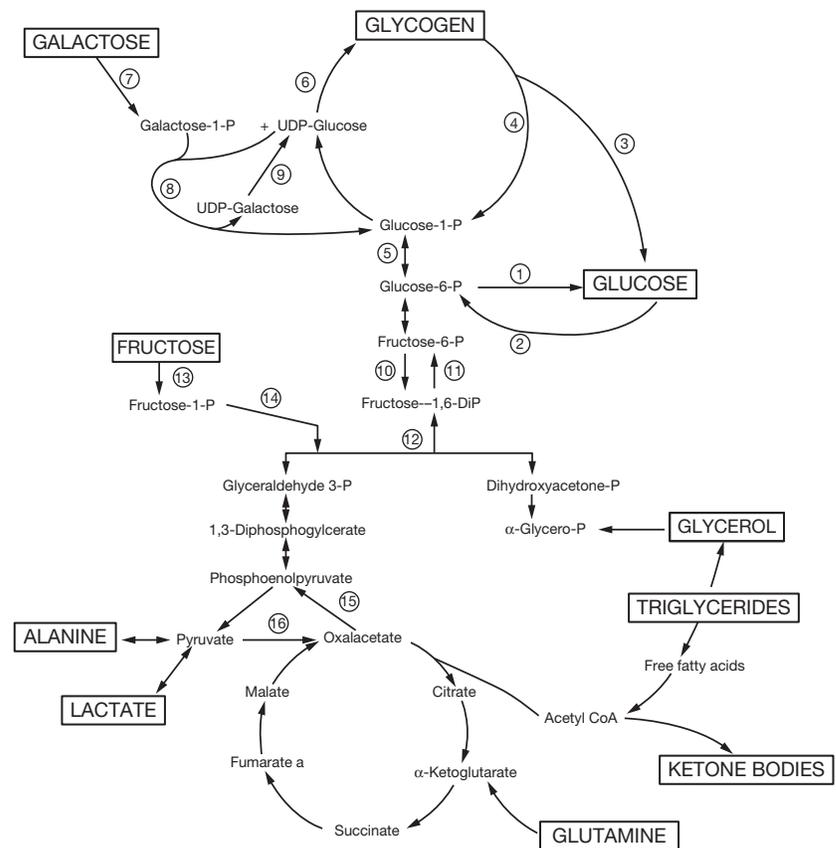

SYMPTOMS, SIGNS, AND EFFECTS OF HYPOGLYCEMIA

Control of the counterregulatory responses is at least partially local: a low glucose concentration and a decrease in intraislet β -cell insulin secretion stimulate glucagon secretion.^{27,28} Low plasma glucose concentrations are sensed in the hepatic portal vein,²⁹ as well as in the gut, carotid body, and oral cavity (and are transmitted to the brain) and also are directly sensed in the hindbrain and hypothalamus,³⁰ which initiates an increase in sympathoadrenal activity.

The trigger for counterregulatory responses is the plasma glucose level itself. The rate at which glucose decreases and the absolute level of insulin have little effect.^{20,31} The symptoms of hypoglycemia, which reflect the brain's response to glucose

Fig. 23.5 Key metabolic pathways of intermediary metabolism.

Disruption of the elements of these pathways may be pathogenetic in the development of hypoglycemia. Not shown is the hormonal control of these pathways. Indicated are: (1) glucose 6-phosphatase, (2) glucokinase, (3) amylo-1,6-glucosidase, (4) phosphorylase, (5) phosphoglucomutase, (6) glycogen synthetase, (7) galactokinase, (8) galactose 1-phosphate uridyl transferase, (9) uridine diphosphogalactose-4-epimerase, (10) phosphofruktokinase, (11) fructose 1,6- diphosphatase, (12) fructose 1,6-diphosphate aldolase, (13) fructokinase, (14) fructose 1-phosphate aldolase, (15) phosphoenolpyruvate carboxykinase, and (16) pyruvate carboxylase. *UDP*, Uridine diphosphate. (From Pagliara, A. S., Karl, I. E., Haymond, M., & Kipnis, D. M. (1973). Hypoglycemia in infancy and childhood. *J Pediatr*, 82, 365–379, 558–577.)

BOX 23.1 Symptoms of Hypoglycemia

NEUROGENIC SYMPTOMS CAUSED BY ACTIVATION OF AUTONOMIC NERVOUS SYSTEM

- Sweating
- Shakiness, trembling
- Tachycardia
- Anxiety, nervousness
- Weakness
- Hunger
- Nausea, vomiting
- Pallor
- Hypothermia

NEUROGLYCOPENIC SYMPTOMS CAUSED BY DECREASED CEREBRAL GLUCOSE USE

- Headache
- Visual disturbances
- Lethargy, lassitude
- Restlessness, irritability
- Difficulty with speech and thinking, inability to concentrate

- Mental confusion
- Somnolence, stupor, prolonged sleep
- Loss of consciousness, coma
- Hypothermia
- Twitching, convulsions, “epilepsy”
- Bizarre neurologic signs
- Motor disturbances
- Sensory disturbances
- Loss of intellectual ability
- Personality changes
- Bizarre behavior
- Outburst of temper
- Psychologic disintegration
- Manic behavior
- Depression
- Psychoses
- Permanent mental or neurologic damage

deprivation, have been extensively studied and well characterized in adults (Box 23.1).^{32,33} Autonomic (neurogenic) symptoms primarily arise from perception of the physiological changes caused by sympathetic (not adrenomedullary) neural activation and include both adrenergic (tremor, palpitations, anxiety/nervousness) and cholinergic responses (sweating, hunger, paresthesias).³³ Awareness of hypoglycemia chiefly depends on perception of the central and peripheral effects of these

neurogenic (in contrast to neuroglycopenic) responses to hypoglycemia. Neurogenic symptoms are perceived at a plasma glucose of less than 54 mg/dL, the threshold at which brain glucose utilization becomes limiting.^{6,7} In older children and adults, the search for food or assistance is a crucially important defense against more severe hypoglycemia. Plasma glucose below 50 mg/dL causes neuroglycopenic manifestations (the result of an insufficient supply of glucose to maintain brain energy), such

as impaired cognition, loss of motor coordination, confusion, coma, and seizures. Hypothermia often occurs with prolonged hypoglycemia in older children and adults and is thought to be the result of a neurogenic mechanism.^{34,35} It is noteworthy that young children (6–11 years old) with type 1 diabetes have poor ability to detect low blood glucose levels.³⁶

Activation thresholds for the neuroendocrine responses have been best established for healthy young adults and vary only slightly by sex,³⁷ age,³⁸ exercise,³⁹ sleep,⁴⁰ and nutritional status.⁴¹ There is no evidence that the definition of hypoglycemia should be lower in infants and young children. Indeed, both epinephrine and GH are released at a higher plasma glucose level in children than in adults, suggesting that the threshold for neuroendocrine responses to decreasing plasma glucose levels in children is not lower and may actually be higher than in adults. At comparable plasma glucose thresholds, epinephrine levels are also markedly increased in children as compared with adults.³⁸ Drugs alter the neuroendocrine responses to hypoglycemia, for example, beta-blockers, dampen the response, whereas caffeine amplifies the response.⁴² Prior exposure to hypoglycemia and hyperglycemia cause clinically important alterations of neuroendocrine response thresholds. Even a single episode of moderately severe hypoglycemia can blunt or lower the activation threshold for 24 hours or more;^{43,44} after prolonged or recurrent hypoglycemia, autonomic responses may be sufficiently attenuated that neuroglycopenic effects may be the sole clinical manifestation of severe hypoglycemia, a condition referred to as *hypoglycemia-associated autonomic failure (HAAF)*.⁴⁵ HAAF has been demonstrated in adults and children with type 1 diabetes, in nondiabetic adults with an insulinoma,⁴⁶ and in infants with recurrent hypoglycemia caused by congenital HI.⁴⁷ Conversely, chronic hyperglycemia is associated with higher glucose thresholds for counterregulatory responses.^{48,49}

The effects on cognition, behavior, and level of consciousness are typically completely reversed when the glucose level is raised, although subtle neuropsychological impairment may be measurable days later.⁵⁰ Severe and prolonged neuroglycopenia, however, causes brain injury and neuronal death.^{2,51} In experiments with primates, plasma glucose below 20 mg/dL for 5 to 6 hours reliably produces severe injury.² In both infants and adults, magnetic resonance imaging (MRI) shows characteristic changes caused by hypoglycemia-induced brain injury.^{52,53} Pathologic changes are observed particularly in cortical tissue and white matter; whereas, the cerebellum and brainstem tend to be spared.⁵⁴ Permanent cognitive impairment is common both in children and adults after recurrent, severe hypoglycemia.^{55–62}

DEFINITION OF HYPOGLYCEMIA

Clinical hypoglycemia is defined as a plasma glucose concentration low enough to elicit defensive neuroendocrine responses, which cause symptoms and/or signs, or impair brain function.⁶³ Because the signs and symptoms are nonspecific, hypoglycemia may be difficult to recognize, and a single low plasma glucose concentration may be an artifact. For example, when blood is drawn but plasma not immediately separated from the cellular elements, glycolysis in red cells causes glucose levels to decline at a rate of 6 mg/dL/h. This is a common cause of artifactually low glucose levels reported in metabolic panels measured at commercial laboratories. Point-of-care glucose meters, originally designed for diabetes management, are useful for screening purposes, but their accuracy is limited to approximately ± 10 to 15 mg/dL in the hypoglycemia range.⁶⁴ Whole blood glucose levels are approximately 15% lower than plasma concentrations, and it is preferable consistently to refer to plasma glucose concentrations. Before establishing a

diagnosis of hypoglycemia and undertaking a diagnostic evaluation, it is essential to confirm a low plasma glucose concentration using a clinical laboratory method. For these reasons, guidelines emphasize the value of Whipple's triad for confirming hypoglycemia^{63,65,66}: (1) symptoms and/or signs consistent with hypoglycemia, (2) a documented low plasma glucose concentration, and (3) relief of symptoms and signs when plasma glucose is restored to normal. Because infants and young children cannot dependably recognize or communicate their symptoms, recognition of hypoglycemia may require confirmation by repeated measurements of plasma glucose concentration and formal provocative testing.

It is important to appreciate that hypoglycemia cannot be defined as a single specific plasma glucose concentration because thresholds for specific brain responses to hypoglycemia occur across a range of plasma glucose concentrations, and these thresholds can be altered by the presence of alternative fuels, such as ketones, and also by recent antecedent hypoglycemia. It is also not possible to identify a single plasma glucose value that causes brain injury, and the extent of injury is influenced by other factors, such as the duration and degree of hypoglycemia, availability of alternative fuels, and potential artifacts and technical factors that lead to inaccuracies in glucose measurements.

Despite the frequency with which hypoglycemia is not accompanied by obvious symptoms in infants, evidence of injury to the brain from prolonged or recurrent hypoglycemia suggests the same clinical thresholds and treatment goals are applicable irrespective of age beyond the immediate (48–72 hours) newborn period. Two different hypoglycemia thresholds are recommended for use in clinical practice. To determine the etiology of hypoglycemia and terminate a diagnostic provocative fasting test, obtain critical samples when plasma glucose is less than 55 mg/dL. For therapeutic purposes, however, the lower limit of the plasma glucose range should be 70 mg/dL (see Fig. 23.4). This goal is important to avoid periods of low glucose that may blunt the neuroendocrine and symptomatic responses to hypoglycemia and lead to greater susceptibility to subsequent more severe episodes of hypoglycemia.

As noted earlier, the effects of specific plasma glucose levels on the central nervous system may vary among patients, especially after experiencing previous episodes of hypoglycemia.^{43,46–48,67–70} Because there is no exact correspondence between the risk of harm (including brain injury) and either severity of symptoms or specific plasma glucose levels, hypoglycemia should always be treated urgently.

FASTING SYSTEMS APPROACH TO THE DIAGNOSIS OF HYPOGLYCEMIA

To provide appropriate treatment for a hypoglycemia disorder, it is essential to establish a specific diagnosis of the etiology. Because most hypoglycemia disorders, especially in infants and children, involve a disturbance of fasting adaptation, the best approach to diagnosis is a closely monitored fasting test, which both reproduces the hypoglycemia and surveys the integrity of the major metabolic and endocrine systems shown in Figs. 23.3 and 23.5 and in Table 23.1. These "fasting systems" include the four metabolic systems (hepatic glycogenolysis, hepatic gluconeogenesis, adipose tissue lipolysis, and hepatic ketogenesis) and their regulation by the endocrine system. The endocrine system includes: (1) insulin, which suppresses activity of all four metabolic systems; and (2) the four counterregulatory hormones that oppose insulin action in specific tissues: (a) glucagon acts acutely on liver to stimulate glycogenolysis and gluconeogenesis and facilitate ketogenesis;

(b) adrenergic nervous system activation (reflected by increases in plasma epinephrine levels) acts acutely on adipose tissue and liver to stimulate lipolysis, ketogenesis, glycogenolysis, and gluconeogenesis; (c) cortisol has longer term effects required for maintaining liver glycogen stores and promoting gluconeogenesis; and (d) GH, which has longer-term effects on the capacity for adipose tissue lipolysis (see Table 23.1).

The operation of these metabolic and endocrine systems is reflected by changes in major circulating metabolic fuels during normal fasting, as shown in Fig. 23.2. As liver glycogen reserves become depleted, plasma glucose falls toward hypoglycemic levels, plasma lactate declines by 25% to 50% (a marker of enhanced gluconeogenesis), plasma FFA rise 4- to 6-fold (a marker of lipolysis), and plasma ketones rise 20- to 40-fold (a marker of ketogenesis, usually measured as BOHB the major ketone). Measurement of these fuels at the time of hypoglycemia (the critical samples) provides crucial information about which component of the fasting systems is responsible for causing hypoglycemia (Fig. 23.6). For example, abnormal elevation of plasma lactate suggests a defect in gluconeogenesis; abnormal suppression of BOHB, with a normal or excessive rise in FFA, suggests a defect in fatty acid oxidation; abnormal suppression of both FFA and BOHB suggests excessive insulin action; and a normal fall in plasma lactate accompanied by a rapid rise in FFA and ketone concentrations occurring after a relatively brief period of fasting (i.e., ketotic hypoglycemia) suggests a defect in glycogenolysis. Cortisol or GH deficiency usually manifest with ketotic hypoglycemia; however, in the neonatal period, combined pituitary hormone deficiencies, especially, may present as hypoketotic hypoglycemia, mimicking HI. Deficiency of sympathetic nervous activity (e.g., secondary to beta-blocker drugs) may present with hypoketotic hypoglycemia because of impaired lipolysis. Deficiency of

glucagon as a primary disease has not been described, whereas secondary deficiency is common in patients with recurrent hypoglycemia, such as congenital HI or type 1 diabetes (HAAF).

Additional tests may be done separately to further assess for specific disorders or can be conveniently added at the end of the fasting test by using extra blood obtained with the critical sample. Serum insulin levels are often not elevated enough for diagnosis of HI disorders; therefore insulin levels, within the normal range, do not exclude the possibility of HI; plasma C-peptide levels may more accurately reflect pancreatic insulin secretion because insulin delivered by the portal vein is variably extracted by the liver, whereas C-peptide passes through the liver without hepatic extraction.⁷¹ HI can be conveniently confirmed with a glucagon stimulation test: in normal children, there is little or no response at the time of hypoglycemia, because liver glycogen stores have been depleted; whereas in HI, there is an abnormally large glycemic response caused by inhibition of glycogenolysis.⁷¹ Plasma levels of cortisol or GH sometimes increase to values sufficiently high during hypoglycemia to exclude deficiency of either or both; however, before making a diagnosis of cortisol or GH deficiency, low values must be confirmed by additional specific provocative tests of these hormones.⁷² Plasma free and total carnitine levels, together with the profile of plasma acylcarnitines, are useful for the diagnosis of most, but not all, of the fatty acid oxidation defects.

Other tests may be considered if specific disorders are suspected. Plasma ammonia concentrations are elevated 3- to 5-fold in patients with the HI hyperammonemia syndrome caused by activating mutations of *GLUD1*.⁷³ Plasma C-peptide suppression in the face of elevated insulin levels may be helpful in demonstrating exogenous insulin administration. Plasma

Recommendations from the Pediatric Endocrine Society for evaluation and management of persistent hypoglycemia in neonates, infants, and children. *J Pediatr*, 167 (2), 238–245.)⁶⁶

insulin-like growth factor binding protein-1 (IGFBP-1) concentration usually rises 5- to 10-fold as insulin levels decline during fasting, so that low IGFBP-1 values support a diagnosis of HI.^{71,74} Specimens to test for drugs or toxins may be considered in cases of suspected ingestion of oral hypoglycemic drugs, plant toxins (unripe ackee-ackee fruit, litchi fruit),^{75,76} or surreptitious insulin administration (factitious hypoglycemia or Munchausen by proxy).

Detailed methods for performing fasting tests and other tests useful for diagnosis of hypoglycemia are provided at the end of this chapter.

MAJOR CAUSES OF HYPOGLYCEMIA IN THE TODDLER AND CHILD

Hyperinsulinism

HI is the most common and the most severe form of hypoglycemia in neonates and young infants, and is also one of the most common causes of hypoglycemia in toddlers and older children.^{77–80} Hypoglycemia caused by HI is particularly dangerous to the brain, because glucose deficiency cannot be compensated for by increased production of ketones to support brain metabolism.⁷¹ Although many neonates with severe congenital HI present in the first week of life, milder genetic forms of HI continue to be an important cause of hypoglycemia throughout infancy. Older children and adolescents with HI may have acquired insulin-secreting pancreatic adenomas.

Congenital HI may present beyond the first months of life as feeding intervals lengthen and overnight feedings are omitted. Such infants may have early morning lethargy or seizures and may have a history of previous seizures and unexplained developmental delay, or of hypoglycemia in the newborn period that was not fully evaluated or treated. In dominant forms of HI, there may be a history of hypoglycemic symptoms in a parent or other relatives; however, carriers may often not recognize symptoms.⁸¹ As outlined in Chapter 7, all of the genetic causes of HI may initially present in the neonatal period.

The diagnosis of HI is suggested when hypoglycemia is not accompanied by hyperketonemia and can be confirmed when injection of glucagon causes a large increase (>30–40 mg/dL relative to baseline) in plasma glucose concentration. HI may be suggested by increased rates of glucose utilization (glucose infusion rate [GIR] >8 mg/kg/min), but this is less consistently present in older children than in neonates. A critical specimen obtained during hypoglycemia, which demonstrates increased levels of insulin or C-peptide can be conclusive; however, it is often not possible to demonstrate clearly elevated insulin levels.^{71,82} Table 23.2 shows the diagnostic criteria for hyperinsulinemic hypoglycemia. In cases of surreptitious insulin administration, standard insulin immunoassays may not

detect exogenously injected insulin analogs, such as lispro, aspart, glargine, etc.⁸³ In suspected cases, specific assays must be requested.

Adenosine Triphosphate Sensitive Potassium Channel Hyperinsulinism

Mutations in the adenosine triphosphate-sensitive potassium (KATP) channel genes are the most commonly identified genetic defects in patients with congenital HI.⁸⁴ The *ABCC8* and *KCNJ11* genes on chromosome 11p encode the two subunits, SUR1 and Kir6.2, of the KATP channel in the plasma membrane of the beta-cell. Potassium efflux through this channel hyperpolarizes the beta-cell plasma membrane and is a key negative regulator of insulin secretion; genetic defects which impair KATP channel activity and preclude channel opening cause persistent depolarization of the plasma membrane and uncontrolled insulin secretion.⁸⁰ As described in Chapter 7, there are three distinct forms of KATP-HI:

- Biallelic inheritance of two recessive KATP mutations causes diffuse HI with severe neonatal onset that is unresponsive to diazoxide.^{85–88}
- Recessive KATP channel mutations also can cause focal congenital HI by a two-hit mechanism, involving a paternally transmitted recessive KATP mutation combined with an embryonic somatic mutation in the corresponding maternal gene, resulting in effective paternal 11p uniparental isodisomy for the region containing both KATP and the Beckwith-Wiedemann imprinted genes. The resulting focal area of islet cell adenomatosis contains beta cells with defective KATP channels, resulting in HI.^{89–91}
- Dominantly inherited KATP channel mutations act in dominant-negative fashion to produce diffuse HI with KATP channels that have varying degrees of impaired channel function. Most dominant KATP mutations are diazoxide responsive, but diazoxide-unresponsive mutations do occur.^{81,84,92}

The diffuse and focal forms of KATP-HI account for more than 90% of diazoxide-unresponsive cases of congenital HI in early infancy, and are similar in their clinical manifestations.⁸⁴ Both may require surgery to maintain safe glucose levels.

Beyond the neonatal period, dominant KATP mutations are more common and are often diazoxide-responsive.⁸⁴

Diazoxide (5–15 mg/kg/day) is the first-line drug for treatment of HI, but is often ineffective for KATP-HI, because it acts as a KATP channel opener. Octreotide may be given by subcutaneous injection at 5 to 15 mcg/kg/day.^{80,93} Longer acting somatostatin analogs, such as lanreotide, have recently been introduced, with some success in older infants.⁹⁴ Calcium-channel blockers are not effective.⁹⁵ If medical management cannot maintain the plasma glucose concentration greater than 70 mg/dL, with a normal feeding schedule, surgery may be necessary. Surgical treatment for focal KATP-HI can be curative, whereas for diffuse disease even a 95% to 99% pancreatectomy may not cure the hypoglycemia, and insulin-dependent diabetes is a frequent consequence.^{96,97} 18F-fluorodopa positron-emission tomography (¹⁸F-L-DOPA PET) scans have been accurate in preoperative localization of a focal lesion.^{91,98,99}

Glutamate Dehydrogenase Hyperinsulinism

HI can be caused by dominant activating mutations in *GLUD1* on 10q, which encodes glutamate dehydrogenase (GDH).¹⁰⁰ This disorder is also known as the *HI hyperammonemia syndrome*, because the increased GDH enzymatic activity in kidney

TABLE 23.2 Diagnostic Criteria for Hyperinsulinemic Hypoglycemia

- Glucose infusion rate >8 mg/kg/min
- Laboratory plasma glucose ≤50 mg/dL
- Detectable serum insulin
- C-peptide ≥0.5 ng/mL
- BOHB <1.8 mmol/L^a
- FFA <1.7 mmol/L
- Response to glucagon ≥30 mg/dL
- IGFBP-1 ≤110 ng/mL

^a100% sensitive.

BOHB, Beta-hydroxybutyrate; FFA, free fatty acids; IGFBP-1, insulin-like growth factor binding protein 1.

(Modified from Ferrara, C., Patel, P., Becker, S., Stanley, C.A., Kelly, A. (2016). Biomarkers of insulin for the diagnosis of hyperinsulinemic hypoglycemia in infants and children. *J Pediatr*, 168, 212–219.)⁷¹

tubules results in increased renal ammoniogenesis.¹⁰¹ Hypoglycemia in GDH-HI is usually milder than in KATP-HI, and less likely to present in the newborn period.^{102,103} As is common with dominant genetic disorders, up to 80% of cases with GDH-HI have a de novo mutation. The hyperammonemia in GDH-HI appears to be asymptomatic. However, affected children frequently have brain manifestations, possibly because of increased GDH activity in neurons and altered levels of glutamate or other neurotransmitters: these include absence seizures (generalized epilepsy), behavior disorders, and mild to moderate developmental delay.¹⁰⁴

In GDH-HI, activating mutations of GDH in the beta cell amplify leucine-triggered production of ATP, leading to closure of KATP channels and insulin release, independent of glucose levels. In affected children, ingestion of high-protein feedings can induce hypoglycemia (leucine-sensitive or protein-sensitive hypoglycemia).^{105,106} In the kidney, the same mutations increase oxidation of glutamate to alpha-ketoglutarate with the release of ammonia.¹⁰⁷

The diagnosis of GDH-HI is similar to that of other forms of HI; however, persistently elevated plasma ammonia levels (typically 80–120 $\mu\text{mol/L}$) are specific for this disorder.¹⁰⁵ Because the hyperammonemia is of renal origin, plasma ammonia levels are unrelated to either insulin secretion or plasma glucose levels and are also not related to protein feeding. Thus elevated ammonia levels can be readily demonstrated in casual (random) specimens of plasma. Most patients respond well to diazoxide and do not need surgery.^{102,108}

Glucokinase Hyperinsulinism

Glucokinase (encoded by *GCK*) is the enzyme that serves as the glucose sensor in the beta cells of the pancreas.¹⁰⁹ Gain-of-function glucokinase mutations result in a lower glucose threshold for insulin secretion, leading to persistent hypoglycemia (in contrast, *GCK* loss-of-function mutations produce a higher glucose threshold for insulin release, causing a common form of mild monogenic diabetes (MODY2)).¹¹⁰ At least 15 different dominantly expressed *GCK*-HI mutations have been reported.¹¹¹ Alterations in the enzyme kinetics of individual mutations predict widely different degrees of lowering of glucose threshold, but do not correlate with clinical severity and course.¹¹¹ In some cases, *GCK*-HI mutations present with neonatal hypoglycemia, severe enough to require pancreatectomy to control hypoglycemia; however, some mutation carriers have escaped recognition even into adulthood.

GCK-HI may be especially challenging to diagnose, because fasting plasma glucose levels tend to stabilize at a glucose threshold between 50 and 65 mg/dL. During fasting, if plasma glucose remains at this threshold for an extended period, levels of FFA and BOHB can rise, suggesting a form of ketotic hypoglycemia rather than HI.¹¹² Plasma ammonia levels are normal in *GCK*-HI patients and they do not have protein-sensitive hypoglycemia. The response to diazoxide has been only partial and transient in most patients with *GCK*-HI and some have required pancreatectomy.¹¹³ One report has described good results using a ketogenic diet to prevent symptomatic hypoglycemia;¹¹⁴ the long-acting somatostatin analog, lanreotide, might be useful in older patients, but experience is limited.

Hexokinase 1 Hyperinsulinism

Hexokinase 1 (*HK1*) is closely related to glucokinase and carries out the first step in glucose oxidation by phosphorylating glucose to glucose-6-phosphate in most tissues of the body, except for beta cells. In contrast to glucokinase, which has a low affinity for glucose ($K_m \sim 5 \text{ mM}$) that sets the threshold for glucose stimulation of insulin secretion at around 4 to 4.5 mM (70–80 mg/dL), *HK1* has a very high affinity for glucose

($K_m \sim 1 \text{ mM}$), and its expression in beta cells is therefore normally disallowed.¹¹⁵ Two reports of congenital HI possibly because of beta-cell expression of *HK1* have recently been published. The first report described a large, dominant pedigree with diazoxide-responsive congenital HI, in which linkage analysis identified a shared haplotype on chromosome 10 that included 3 noncoding mutations in the *HK1* locus.¹¹⁶ This family was in one of the original descriptions of congenital HI by McQuarrie in 1953.¹¹⁷ It was suggested that one or more of these mutations caused *HK1* to be expressed in beta cells and to reduce the glucose threshold for insulin secretion to around 55 to 60 mg/dL. In the second report,¹¹⁸ increased beta-cell expression of *HK1* was detected by immunohistochemical staining of islets from several infants who underwent surgery for diazoxide-unresponsive congenital HI; these infants were also suggested to have HI because of a failure of *HK1* silencing in beta cells. As described later, failure to silence expression of a “disallowed” beta-cell gene has also been suggested as the mechanism of exercise-induced HI: expression of the pyruvate plasma membrane transporter, MCT1.^{119,120}

Short Chain 3-Hydroxyacyl-Coa Dehydrogenase Hyperinsulinism

Short chain 3-hydroxyacyl-CoA dehydrogenase ([SCHAD], encoded by *HADH* on chromosome 4 at q22-26) is a mitochondrial fatty acid oxidation enzyme that catalyzes oxidation of short chain 3-hydroxyacyl-CoAs.¹²¹ Levels of SCHAD protein are relatively high in pancreatic beta cells, where it appears to negatively regulate the activity of GDH, the target of the gain-of-function mutations responsible for GDH-HI (the hyperammonemia HI syndrome).¹²² Homozygous inactivating mutations of the *HADH* gene are associated with increased beta-cell GDH activity and cause a form of HI similar to GDH-HI, but without hyperammonemia or specific brain defects. The systemic defect in fatty acid oxidation in SCHAD deficiency leads to accumulation of upstream substrates resulting in diagnostic elevations of urinary organic acids (3-hydroxyglutarate) and plasma acylcarnitines (3-hydroxybutyryl-carnitine). Patients with HI caused by SCHAD deficiency have responded well to treatment with diazoxide.

Hepatocyte Nuclear Factor 4a Hyperinsulinism

Hepatocyte nuclear factor 4a (HNF4A) is a transcription factor important for pancreatic beta-cell development and insulin secretion. Heterozygous inactivating mutations of *HNF4A* are a well-recognized cause of monogenic diabetes (MODY1). Recently, it was recognized that these same mutations also cause excessive insulin secretion in early life, as manifested by fetal macrosomia and persistent diazoxide-responsive neonatal hyperinsulinemic hypoglycemia. The HI is usually transient, lasting only a few weeks to a few months after birth; however, it may persist for several years into childhood.¹²³ In the second and third decades, these children may develop the MODY1 form of diabetes, which is responsive to treatment with sulfonylureas. In most cases of *HNF4A* HI, birthweight has been above average, hypoglycemia occurred within the first days of life, and one parent had a history of MODY-type diabetes.^{124,125} Children with a specific *HNF4A* mutation, p.Arg76Trp, have additional manifestations, including renal Fanconi syndrome and hepatomegaly and elevated transaminases, suggesting that expression of the GLUT2 transporter in kidney tubules and in liver was impaired by the defect in *HNF4A*.¹²⁶

Hepatocyte Nuclear Factor 1A Hyperinsulinism

Hepatocyte nuclear factor 1a (HNF1A) is another transcription factor important for beta-cell development. Heterozygous

inactivating mutations of *HNF1A* cause the most common form of monogenic diabetes, MODY3. Several cases of *HNF1A* mutations causing congenital HI have been reported,^{126–128} several of which also were associated with MODY diabetes in older patients. An interesting, unexplained discrepancy between *HNF4A* and *HNF1A* HI is that large for dates birthweight has only been associated with *HNF4A*, but not *HNF1A* mutations.

Uncoupling Protein 2 Hyperinsulinism

Uncoupling protein 2 (UCP2) transfers Krebs cycle intermediates out of the mitochondria and favors oxidation of amino acids versus glucose in beta cells, liver, and other tissues. Loss-of-function mutations of UCP2 may enhance ATP generation from glucose and consequently amplify insulin responses to glucose stimulation, sufficiently as to cause hyperinsulinemic hypoglycemia. Several cases have been reported, which have generally responded to treatment with diazoxide.¹²⁹

Exercise-Induced Hyperinsulinism

A total of 13 patients belonging to three families have been found with dominantly inherited exercise-induced hyperinsulinemic (EIHI) hypoglycemia following periods of intense anaerobic exercise.¹²⁰ Clinical presentations have varied, with some cases having severe hypoglycemic episodes from infancy; some presenting with hypoglycemic syncope after exercise, as adolescents; and some only mildly affected, as adults. Most patients maintained normal glucose levels during prolonged fasting. Provocative testing, with brief, intense bicycle exercise, induced the expected rise in plasma lactate and pyruvate levels, but markedly increased plasma insulin concentrations for about 10 minutes after the exercise, causing hypoglycemia over the next 45 minutes.¹³⁰ Intravenous infusion of pyruvate stimulated a similar rise in insulin, suggesting that the defect reflected an abnormal beta-cell responsiveness to pyruvate. Recurrent hypoglycemia was only partially preventable with diazoxide treatment.

Excessive insulin secretion in EIHI occurs because of mutations upstream of the promoter region *SLC16A1* that allows the MCT1 monocarboxylate transporter to be expressed on the beta-cell plasma membrane. Normally, expression of MCT1 is “disallowed” in beta cells to prevent pyruvate and lactate from acting as insulin secretagogues.

Syndromic Forms of Congenital Hyperinsulinism

Beckwith-Wiedemann Syndrome. Beckwith-Wiedemann syndrome (BWS) is an overgrowth syndrome caused by embryonic mosaic mutations of an imprinted region on 11p, which is close to the location of the beta-cell KATP channel genes, *SUR1* and *Kir6.2*. The BWS locus includes growth-inhibiting genes expressed on the maternal chromosome (H19, P57) and growth-promoting genes (*IGF2*) expressed on the paternal chromosome; expression of these genes is controlled by two imprinting control sites. Although BWS has been associated with HI for many years, recently it has been found that most cases of BWS with persistent HI are associated with paternal isodisomy for the 11p region (11pUPD overgrowth), which is the cause of around 20% of BWS cases.¹³¹ The histopathology in these cases shows islet cell overgrowth (adenomatosis), which may involve nearly the entire pancreas. Some cases are responsive to diazoxide, but hypoglycemia in some may not be controllable with diazoxide and may require more intensive medical management with octreotide and continuous feedings or pancreatectomy. Some cases of 11pUPD BWS also have a paternally transmitted recessive KATP channel mutation; these cases can have severe HI and unusually high glucose requirements. The possibility of 11pUPD BWS should be suspected

in infants with HI who have features of BWS, such as hemihypertrophy, macroglossia, or umbilical hernia.

Kabuki Syndrome. Kabuki syndrome is associated with recognizable dysmorphic features including facial features resembling a Kabuki actor mask and caused by somatic mosaic mutations in either *MLL2* (*KMT2D*) or *KDM6A*, two genes which regulate chromatin methylation.¹³² A proportion of infants with Kabuki syndrome have persistent hypoglycemia caused by HI, which may either be responsive or nonresponsive to treatment with diazoxide.

Turner Syndrome. Turner syndrome has been reported to be associated with congenital HI for several decades. A recent study found that the frequency of Turner syndrome in a large series of children with HI was increased ~50-fold, indicating that the risk of HI in Turner syndrome was around 1 in 1000 compared with the risk of HI in the general population of 1 in 40,000.¹³³ Some of the Turner syndrome cases were diazoxide responsive, but others failed to respond to diazoxide and required pancreatectomy. The only consistent chromosomal anomaly in Turner syndrome girls with HI was a 45 XO karyotype, suggesting that loss of a gene on the X-chromosome was the cause of the HI. A possible candidate gene is *KDM6A*, a pseudoautosomal X-chromosome gene, because inactivating mutations of *KDM6A* are one of the causes of Kabuki syndrome in which there is also an increased frequency of HI.

Carbohydrate-Deficient Glycoprotein Hyperinsulinism

Congenital disorders of glycosylation (CDG) are caused by recessively inherited loss-of-function mutations in genes that regulate glycosylation of proteins.^{134,135} Most produce syndromic diseases affecting multiple organ systems, including brain, skeleton, liver, and kidney. Hypoglycemia resulting from HI has been reported in children with three of the identified defects of N-glycosylation: CDG Ia, Ib, and Id (OMIM IDs: 601785, 602579, and 601110). Most cases of CDG-HI have been identified in the newborn period, but some have been diagnosed later in infancy or early childhood. CDG-HI is usually suspected in a child with a dysmorphic facies and manifestations affecting multiple other organ systems, including—especially the brain, liver, gut, and skeleton. In all three types, cases have been reported in which hyperinsulinemic hypoglycemia was the presenting or dominant problem.^{136–138} The mechanism of excessive insulin production has not been determined.

Phosphomannomutase 2 (PMM2)-CDG (CDG-Ia) is the most common type of CDG and involves deficient activity of phosphomannomutase 2 resulting from mutations of *PMM2*. Most patients have severe developmental delay, cerebellar hypoplasia, hypotonia, and seizures. Protein-losing enteropathy and liver disease contribute to failure to thrive. Deficient levels of antithrombin III can cause thromboses. Dysmorphic features are common and may be subtle or obvious, including unusual fat distribution and inverted nipples. Hyperinsulinemic hypoglycemia occurs in only a minority of patients, but can be mild or severe enough to warrant pancreatectomy.^{136,139}

Phosphomannose isomerase (MPI)-CDG (CDG-Ib) involves deficient activity of phosphomannose isomerase resulting from mutations of *MPI*. Unlike CDG-Ia, the central nervous system is spared and hyperinsulinemic hypoglycemia is a common feature, presenting in the first days of life or later in the first year.^{137,140} Liver disease and protein-losing enteropathy are usually the dominant clinical problems.¹⁴¹ Some children have had cyclic vomiting. Clinical severity is variable, and mildly affected adults have been diagnosed. Oral mannose in doses of up to 150 mg/kg/day can correct most of the clinical

abnormalities, making MPI-CDG the only CGD with a specific treatment.¹⁴²

ALD3-CDG (CDG-Id) involves deficient activity of mannosyltransferase 6 resulting from mutations of *ALD3*. Clinical features resemble those of PMM2-CDG, with severe central nervous system damage. One case with severe neonatal hyperinsulinemic hypoglycemia has been reported, but whether it was a direct result of the CDG or a consequence of perinatal stress is unknown.

PMG-1 reversibly converts glucose-6-P to glucose-1-P and is required both for glycogen formation and degradation. Recessive inactivating mutations of *PGM1* cause a syndrome of dysmorphic features, short stature, and fasting hyperketonemic hypoglycemia.¹⁴³ In addition to abnormalities in protein glycosylation (hence the designation of CDG-It), hyperinsulinemic hypoketonemic hypoglycemia occurs when patients are fed. Deficiency of *PGM1* impairs both the synthesis and breakdown of liver glycogen (hence the fasting hyperketonemic hypoglycemia and the labeling of the disorder as *GSD type 14*). However, deficiency of *PGM1* in the beta cell appears to cause an exaggerated insulin response to a glucose load, leading to postprandial hyperinsulinemic hypoglycemia. The diagnosis can be made by screening tests for abnormalities in transferrin glycosylation. Treatment with diazoxide has not been effective in controlling postprandial hyperinsulinemic hypoglycemia, but low glycemic index feedings, uncooked cornstarch (UCS), or continuous low-dose glucose infusions have been more successful. Because the defect potentially impairs synthesis of galactose, treatment with galactose supplements have been tried with some success in correcting abnormalities of transferrin glycosylation.¹⁴⁴

AKT2 Hypoglycemia

Three children with hypoglycemia caused by gain-of-function mutations of *AKT2* have been described.¹⁴⁵ *AKT2* is a serine/threonine kinase that is one of the downstream steps in post-insulin receptor signaling; loss of *AKT2* activity is associated with insulin resistance, whereas activation of *AKT2* causes an increase of insulin sensitivity. Beginning around 6 months of age, all of the reported cases had episodes of severe, symptomatic, hypoketotic hypoglycemia resembling HI, but associated with low levels of insulin, proinsulin, and FFA. Hypoglycemia was primarily postprandial and could be controlled with low dose continuous dextrose feedings. Other clinical features included large birth weight and postnatal asymmetric overgrowth of body or face. Each of the three unrelated patients had the same *de novo* mutation of *AKT2*. The mutations were postzygotic and mosaic, which probably explains the localized nature of the overgrowth.

Phosphatidylinositol-3-Kinase Hypoglycemia

Phosphatidylinositol-3-Kinase (PI3K) is an enzyme step in the pathway of postinsulin receptor signaling upstream from *AKT2*. Postzygotic gain-of-function mutations of two PI3-kinase-related enzymes, *PIK3CA* and *PIK3R2*, were recently reported to cause a syndromic form of hypoketotic hypoglycemia with low insulin concentrations, similar to gain-of-function mutations of *AKT2* described earlier. Features included asymmetric overgrowth, megalencephaly, and developmental delay. Diazoxide was ineffective and treatment with continuous dextrose at a low glucose infusion rate was needed to control the hypoglycemia. The hypoglycemia appears to be caused primarily by increased postinsulin receptor activity in the liver.¹⁴⁶

Hyperinsulinemic Hypoglycemia Associated With Insulin Receptor Defects

Inactivating mutations of the insulin receptor (*INSR*), which cause insulin resistance and diabetes mellitus, can also be associated with postprandial hyperinsulinemic hypoglycemia of varying severity. Severe defects in the *INSR* present in early infancy and childhood with dysmorphic features because of marked deficiency of adipose tissue (lipodystrophy) and, in order of severity, include Donohue syndrome (leprechaunism) (OMIM ID: 246200) and Rabson-Mendenhall syndrome (OMIM ID: 262190); milder defects may present later in childhood or early adulthood as type A insulin resistance (OMIM ID: 610549).¹⁴⁷ More severe forms of insulin resistance may be caused by biallelic *INSR* mutations, and monoallelic defects may be associated with milder forms of insulin resistance; mutations in the *INSR* beta subunit tend to be milder than mutations in the alpha subunit. Plasma insulin levels are increased 10 to 100 times normal. Hypoglycemia in these patients is usually postprandial and has been suggested to be caused by delayed insulin clearance¹⁴⁸ (a similar delay in insulin clearance has also been suggested to be responsible for postprandial hypoglycemia in autoimmune hypoglycemia caused by antiinsulin antibodies). Fasting hypoglycemia has been associated with the more severe insulin resistance seen in neonates and infants with Donohue syndrome and has been suggested to be caused by the very high insulin levels, having an insulin-like action by cross-reaction with the insulin-like growth factor-1 (IGF-1) receptor, although an earlier report demonstrated a pattern of accelerated hyperketonemic fasting adaptation, suggesting a possible impairment in hepatic glycogen storage.^{149–151} Infants with Donohue syndrome present in the newborn period and most die of infection in the first years of life. Features include intrauterine growth retardation, markedly diminished subcutaneous fat, typical facial appearance reminiscent of a leprechaun (“leprechaunism”), enlargement of breasts and clitoris or phallus, hypertrichosis, acanthosis nigricans, and postprandial hyperglycemia. Hypoglycemia, a few hours after meals, may be noted within the first days after birth and persists throughout life. Frequent feedings have been the mainstay of management for the hypoglycemia; diazoxide has generally not been effective.^{152,153}

Children with Rabson-Mendenhall syndrome are somewhat less severely affected than those with Donohue syndrome, but share many of the features, including reduced adipose tissue, acanthosis nigricans, hypertrichosis, and enlargement of the genitals in both males and females. Many of these children also have postprandial hypoglycemia. Diabetes tends to be progressive and insulin resistance can be severe. Adolescent females may have evidence of hyperandrogenism similar to polycystic ovarian syndrome. Death in childhood from diabetic ketoacidosis is common. Treatment with leptin (metreleptin) has been reported to modestly improve glucose control in some patients with Rabson-Mendenhall syndrome.¹⁵⁴

Postprandial (reactive) hypoglycemia has also been reported in adolescents with type A insulin resistance in which diabetes mellitus develops more gradually, sometimes as the adolescent reaches adulthood.¹⁵⁵ Features may include reduced adipose tissue, acanthosis nigricans, and elevated triglyceride levels. Insulin resistance may lead to eventual beta-cell failure and insulin insufficiency.

Reactive hypoglycemia has also been reported in insulin-resistant conditions because of postreceptor disorders,¹⁵⁶ and should be considered in other insulin resistance syndromes, such as congenital lipodystrophy (Berardinelli-Seip syndrome), because of recessive defects in *AGPAT2*, *BSCL2*, or *PTRF*.

Factitious Hyperinsulinism

Instances of factitious HI have been reported in infants and children, typically the result of a parent or other caregiver administering insulin or an insulin secretagogue.¹⁵⁷ This form of child abuse is referred to as *Munchausen by proxy*¹⁵⁸ and may cause needless pancreatic surgery and can be lethal.¹⁵⁹ In most reported cases, the parent (often the mother) was a nurse or other medical professional or had access to insulin or sulfonylureas being used at home for treatment of diabetes. Typically, classic symptoms of HI are present, but can occur irregularly. As in other forms of HI, hypoglycemia is accompanied by suppression of plasma ketones and FFA and an abnormal positive response to glucagon. Fasting tests in the absence of the caregivers will be normal; however, extreme caution is required to ensure no interference by the suspected agent. An extremely high plasma insulin concentration (e.g., >100 $\mu\text{U}/\text{mL}$) is sometimes a clue (especially likely to be found after administration of short- or intermediate-acting insulin, such as regular or isophane (NPH); in contrast, plasma insulin levels are usually only mildly elevated in HI from endogenous causes. Insulin administration has become increasingly difficult to detect by standard insulin assays because these can vary in their ability to detect insulin analogues (lispro, aspart, glargine, glulisine, detemir, degludec).^{83,160,161}

The most conclusive evidence of exogenous insulin is a discrepancy between elevated plasma insulin, but very low plasma C-peptide concentration, indicating that endogenous insulin production has been suppressed.¹⁶² Insulinomas may be associated with elevated plasma insulin, but values are rarely greater than 100 $\mu\text{U}/\text{mL}$ and levels of C-peptide and proinsulin should be correspondingly elevated.

Surreptitious (or, more commonly, accidental) administration of long-acting oral hypoglycemic agents that induce insulin secretion, such as glyburide or other sulfonylureas, cause elevation of both insulin and C-peptide and may cause persistent hypoglycemia for 24 hours or longer. Routine toxicology screens of blood and urine may not detect sulfonylureas, but specific testing can be arranged if a specific drug is suspected.

If surreptitious insulin or oral hypoglycemic drug administration is suspected, specimens of plasma/serum, from the time of hypoglycemia, should be obtained for testing of plasma insulin and C-peptide concentrations and preserved for other tests that may become necessary to document the involvement of an exogenous agent. Consultation with the laboratory is helpful in interpreting and selecting appropriate tests. Treatment of the hypoglycemia with intravenous glucose is usually sufficient, but continuous intravenous glucagon may be needed in severe cases and diazoxide or octreotide may be helpful in cases of prolonged insulin hypersecretion.

Autoimmune Hypoglycemia

Two types of autoimmune hypoglycemia have been reported: one mediated by antibodies to insulin and the other by antibodies to the insulin receptor. Hypoglycemia caused by antiinsulin antibodies has been reported most often from Japan ("Hirata disease"),¹⁶³ but cases have been described in both sexes, all ages, and from many regions of the world.¹⁶⁴ Nearly all autoimmune hypoglycemia in infants and children have been of this type.^{165–168} The presumed mechanism of hypoglycemia is slow dissociation of insulin from antibodies during the postprandial or postabsorptive periods. The hypoglycemia is most often postprandial, but may be fasting, and has sometimes been severe enough to cause seizures or coma.¹⁶⁹ Metabolic features are those of HI, with low plasma ketone and FFA levels. Assays of plasma insulin can give very high values that remain constantly high over

time because of the interference by endogenous insulin binding antibodies (this may vary, depending on the assay method); in contrast, plasma C-peptide values may be suppressed, suggesting the possibility of surreptitious insulin or sulfonylurea administration. The disorder may be triggered by infections with common viruses or by exposure to drugs containing sulfhydryl or thiol groups, such as methimazole or lipoic acid, and appears to be associated with other autoimmune endocrine disorders, such as hyperthyroidism. In Japan, an association with the HLA allele HLA-DRB1*04:06 has been reported; a high incidence of HLA-DRB1*04:03 has been described in Europeans with the disorder. Among various treatments reported to improve the hypoglycemia have been courses of glucocorticoids, plasmapheresis, and intravenous immunoglobulin infusions. The disorder often resolves over time as autoantibody titers wane.

The second form of autoimmune hypoglycemia is caused by antibodies that bind to and activate the insulin receptor (analogous to thyroid-stimulating immunoglobulins in Graves disease). Childhood onset is rare, but cases as young as 8 months old have been seen.¹⁶⁸ In children, there may be severe fasting hypoglycemia with very elevated rates of glucose utilization that is unresponsive to diazoxide or octreotide. In adults, the disorder has been associated with type B (autoimmune) insulin resistance, or a malignancy or severe inflammatory disorder. Some patients have had both antiinsulin and antireceptor antibodies.¹⁷⁰ C-peptide and insulin levels are typically undetectable and diazoxide and octreotide are ineffective in controlling hypoglycemia. Treatment with glucocorticoids, plasmapheresis, or intravenous immunoglobulin may be considered.

Insulinoma

Insulinomas are the most common cause of acquired persistent hypoglycemia in adults and older children and may rarely occur in children as young as 2 years of age.¹⁷¹ Most often, insulinomas are solitary, small tumors, 0.5 to 1 cm in size, which are slow-growing and rarely become malignant or metastasize; multiple tumors and recurrent insulinomas may occur, especially in patients with multiple endocrine neoplasia type 1 (MEN1) syndrome because of dominant inactivating mutations in *MEN1* on 11q. Children with insulinomas present with recurrent episodes of symptomatic hypoglycemia, which are often initially mild and may go unrecognized for several months before severe manifestations, such as a seizure, occurs. The diagnosis of HI is most easily made with a fasting test to demonstrate hypoketonemic hypoglycemia, together with an inappropriately large glycemic response to glucagon. In younger children, especially, it may not be possible to distinguish clinically between an insulinoma and a genetic form of diffuse HI.

The majority of pediatric insulinomas appear to be associated with paternal 11p uniparental isodisomy, although this appears not to be so common in adult insulinomas.¹⁷¹ The frequency of genetic mutations in *MEN1* appears to be higher in children (42% of childhood insulinomas at Children's Hospital of Philadelphia) than in adults with insulinomas (~8%). This is important, because the presence of multiple tumors at first surgery and recurrence of tumors is more likely in patients with MEN1 than in cases of sporadic insulinomas.

Initially, diazoxide may provide good control of hypoglycemia in patients with an insulinoma, especially in early stages, while the tumor is small; but diazoxide may become ineffective as the tumor grows. Surgical resection is the treatment of choice; therefore careful preoperative imaging to locate the lesion (or lesions) before surgery is important. In a series of eight pediatric cases, imaging was successful localizing the

insulinoma in 40% by MRI, 40% by endoscopic ultrasound, 30% by computed tomography, and only 20% by abdominal ultrasound.¹⁷² Octreotide scan and F-DOPA PET scans occasionally provide additional diagnostic utility. At surgery, palpation and inspection and intraoperative ultrasound were generally successful in identifying and resecting the insulinoma. Patients with MEN1, caused by dominant mutations of *MEN1*, are at risk for other endocrine tumors, including functioning or nonfunctioning adenomas of the parathyroids, pituitary, and pancreas and require regular monitoring, as well as testing to identify affected family members.

Postprandial Hypoglycemia After Gastrointestinal Surgery (“Late Dumping Syndrome”)

Gastrointestinal hormones and signals—the enteroinsular axis—play an important role in regulating insulin secretion in response to meals. Disruption of this system by gastric surgery can result in hypoglycemia from excessive postprandial insulin release.¹⁷³ In children, the most common cause is gastric surgery for gastroesophageal reflux (e.g., Nissen fundoplication); in adults, the most common cause is gastric bypass bariatric surgery for severe obesity. This “alimentary hypoglycemia” is exclusively postprandial (i.e., reactive), rather than fasting, and is caused by an amplified release of glucagon-like peptide 1 from the small intestine.^{174–177} The disorder is sometimes called *late dumping syndrome* to contrast it with *early dumping syndrome*, which is caused by rapid gastric emptying that induces osmotic shifts and symptoms, such as hypotension, sweating, and diarrhea, immediately after a feeding.

In young children, postprandial hypoglycemia after Nissen fundoplication may be accompanied by bowel symptoms of early dumping syndrome, but more often presents as isolated neuroglycopenic and autonomic symptoms 1 to 3 hours after meals.^{174,178} Hypoglycemia may be confirmed in association with symptoms after a regular feeding or can be elicited by a formal mixed meal or oral glucose tolerance test. Although the glucose tolerance is somewhat unphysiologic, and normal individuals may develop hypoglycemia 3 to 4 hours after a glucose load, the glucose tolerance test is preferred by some as a more standardized test. Patients with late dumping syndrome hypoglycemia have an unusually large rise in plasma insulin to as high as 200 to 300 $\mu\text{U}/\text{mL}$ in the first 30 to 60 minutes after ingesting glucose, which is followed by hypoglycemia at 3 to 4 hours. There is often also a marked hyperglycemic spike shortly after glucose ingestion because of rapid gastric emptying; however, this does not always occur and is not the cause of the hypoglycemia.

Treatment of late dumping syndrome hypoglycemia may include dietary measures that slow gastric emptying and the release of free glucose into the small bowel, such as frequent small feedings of complex carbohydrates, small snacks between meals, avoidance of simple sugars, and providing fat and protein along with carbohydrates.¹⁷⁹ In more severe cases, acarbose, an alpha-glucosidase inhibitor that slows digestion of starch and other complex carbohydrates, may be effective using doses between 25 and 100 mg, with each feeding.¹⁸⁰ In some cases, continuous intragastric or intrajejunal tube feedings have been required.¹⁸¹

Hyperinsulinemic Hypoglycemia as a Prodrome to the Onset of Diabetes Mellitus. Instances of fasting, but more commonly postprandial hypoglycemia, have occasionally been described before the onset of type 1 diabetes or during the “honeymoon” remission phase when insulin requirements are low.^{182,183} In the Diabetes Prevention Trial-Type 1, closely observed first- and second-degree relatives of patients with type 1 diabetes who were at increased risk of diabetes (i.e.,

individuals with prediabetes) were found to have chemical hypoglycemia detected by quarterly glucose profiles at a rate of 7.5 episodes per 100 person-years. Episodes of hypoglycemia, with documented blood glucose lower than 50 mg/dL, occurred at a rate of 2.6 episodes per 100-person years. There were no reported episodes of severe hypoglycemia.¹⁸⁴ The mechanism most likely involves excessive second-phase insulin release as a consequence of a defective first-phase insulin response; other potential mechanisms have also been proposed, including delayed action of insulin, because of antiinsulin antibodies or insulin release secondary to inflammatory destruction of beta cells. A relationship between reactive hypoglycemia and onset of type 2 diabetes (“dysinsulinism”) was postulated as early as 1930,¹⁸⁵ and widely recognized among diabetologists in the middle of the 20th century.^{186–189} Early type 2 diabetes is also often characterized by loss of the first-phase insulin response to food, resulting in higher glucose excursions, followed by lower glucose nadirs. In most cases of prodromal hypoglycemia in both type 1 and type 2 diabetes, plasma glucose does not reach levels low enough to cause neuroglycopenic symptoms. If necessary, treatment to avoid excessive postprandial hyperglycemia, such as low glycemic index meals, may be effective. In type 1 diabetes during the remission phase, raising the dose of insulin to reduce postprandial hyperglycemia may be helpful.

Hypoglycemia in Cystic Fibrosis Related Diabetes. In cystic fibrosis (CF) first-phase insulin secretion is impaired and glucagon secretion decreases with worsening glucose tolerance.¹⁹⁰ Both fasting and reactive hypoglycemia during a routine glucose tolerance test is relatively common before the onset of cystic fibrosis-related diabetes (CFRD);^{191–193} however, the frequency of reactive hypoglycemia may not be more common than in individuals without CF.¹⁹⁰ In one study, the occurrence of hypoglycemia following an oral glucose tolerance test (OGTT) was associated with a lower 10-year risk of progression to CFRD, as compared with those without hypoglycemia.¹⁹³

Nonislet Tumor Hypoglycemia

Certain noninsulin-secreting tumors are occasionally associated with paraneoplastic hypoglycemia.¹⁹⁴ Most cases have involved large, malignant tumors of mesenchymal, epithelial, or hematopoietic origin. Cases in children are rare, but have been reported with neuroblastoma and Wilms tumor.¹⁹⁵ The hypoglycemic episodes typically occur with fasting and are associated with inappropriately low plasma ketones and FFA, and with increased glucose utilization, which mimic insulin excess. Plasma levels of insulin, proinsulin, and C-peptide are low, and drugs which suppress insulin secretion (diazoxide, somatostatin) are ineffective, suggesting activation of insulin receptors by other circulating factors.¹⁹⁶ In most cases, levels of IGF-2 have been found to be elevated and are postulated to cause hypoglycemia by cross-reaction with both insulin and IGF-1 receptors.¹⁹⁷ IGF-2 is normally produced in the liver and limited amounts are secreted into the circulation bound to IGFBP-3 and the acid-labile subunit (ALS). Tumor-produced IGF-2 may be more active because of incomplete processing and less efficient binding to IGFBP-3 and ALS or may be structurally abnormal—a large molecular form called *big IGF-2*. In addition to stimulation of the insulin receptor, stimulation of the IGF-2 receptor may downregulate GH secretion, resulting in low levels of IGFBP-3.¹⁹⁸

The demonstration of elevated plasma IGF-2 with suppression of both IGF-1 and insulin levels confirms tumor hypoglycemia of this variety. If the tumor cannot be completely removed, a possibly effective intervention is treatment with GH to raise IGFBP-3 levels and reduce the free IGF pool, thereby ameliorating hypoglycemia.¹⁹⁵

It should be noted that not all paraneoplastic hypoglycemia is mediated by IGF-2. Hypoglycemia associated with lactic acidemia, attributed to increased anaerobic glucose metabolism, has been reported in lymphomas and leukemias.^{199,200}

Glycogen Storage Diseases

The GSDs or glycogenoses comprise several inherited diseases caused by deficiencies of enzymes that regulate the synthesis or degradation of glycogen, resulting in increased storage of glycogen in several tissues, especially liver and muscle. Glycogen is the storage form of carbohydrate in humans: hepatic glycogen serves as a crucial glucose reservoir in the intervals between meals; glycogen in muscle and other tissues cannot be released as free glucose, but is used for endogenous needs. Hepatic glycogenolysis provides a large fraction of the glucose that enters the circulation, beginning within a few hours after eating, and continuing until the store of glycogen is depleted.

Glycogen is a highly branched polymer of glucose residues, most of which form straight chains linked by α -1,4-glycosidic bonds. Branches are created by α -1,6-glycosidic bonds, which occur on the average of once every 10 residues. After carbohydrates have been ingested, plasma glucose and insulin levels rise and new glycogen is synthesized.

Glycogen synthesis and degradation in the liver follow distinct pathways that begin and end with glucose 1-phosphate (see Fig. 23.5). The liver is freely permeable to glucose, which is first converted to glucose 6-phosphate before it can enter one of several metabolic pathways. Glucose 6-phosphate can be reversibly converted to glucose-1-phosphate, which is the starting point for glycogen synthesis. Alternatively, glucose-6-phosphate can be hydrolyzed to glucose by glucose-6-phosphatase (G6Pase), or it can be metabolized via the glycolytic pathway to pyruvate and lactate, or via the pentose phosphate pathway, to ribose-5-phosphate, a precursor of nucleotide synthesis. Glycogen synthase catalyzes the formation of α -1,4-linkages. A branching enzyme forms the α -1,6-linkages that make glycogen a branched polymer.

Glycogen breakdown (glycogenolysis) requires the sequential interaction of several enzymes. First, hepatic phosphorylase successively cleaves the 1,4 links to within four glucosyl units of the branch point. Then 4- α -glucanotransferase exposes the 1,6-linked branch points by transferring three glucosyl residues to elsewhere on the glycogen molecule. Amylo-1,6-glucosidase, the debranching enzyme, then splits the 1,6-linked glucosyl units. Thus the sequential actions of phosphorylase and debrancher enzyme liberate the stored glucose units; the action of phosphorylase yields glucose 1-phosphate and the debrancher enzyme liberates free glucose. During fasting, the debrancher

TABLE 23.3 Hepatic Glycogen Storage Diseases

Disorder	Affected Tissue	Enzyme	Inheritance	Gene	Chromosome	Fasting Hypoglycemia
Type 0 GSD	Liver	Glycogen synthase	AR	<i>GYS2</i>	12p12.2	Mild to moderate
Type Ia GSD	Liver, kidney, intestine	Glucose 6-phosphatase	AR	<i>G6PC</i>	17q21	Severe
Type Ib GSD	Liver	Glucose 6-phosphate transporter (T1)	AR	<i>SLC37A</i>	11q23	Severe
Type IIIa GSD	Liver, muscle, heart	Glycogen debranching enzyme	AR	<i>AGL</i>	1p21	Mild to moderate
Type IIIb GSD	Liver	Glycogen debranching enzyme	AR	<i>AGL</i>	1p21	Mild to moderate
Type IV GSD	Liver	Branching enzyme	AR	<i>GBE</i>	3p12.2	With liver failure
Type VI GSD	Liver	Glycogen phosphorylase	AR	<i>PYGL</i>	14q21–22	Mild
Type IXa GSD	Liver, erythrocytes, leukocytes	Liver isoform of α subunit of phosphorylase kinase	X-linked	<i>PHKA2</i>	Xp22.1–p22.2	Mild to moderate
Type IXb GSD	Liver muscle, erythrocytes, leukocytes	β subunit of liver and muscle phosphorylase kinase	AR	<i>PHKB</i>	16q12–q13	Mild to moderate
Type IXc GSD	Liver	Testis/liver isoform of γ subunit of phosphorylase kinase	AR	<i>PHKG2</i>	16p11–p12	Mild

AR, Autosomal recessive; GSD, glycogen storage disease.

TABLE 23.4 Biochemical Characteristics of the Most Common Hepatic Glycogenoses

Type	At Time of Hypoglycemia			Response to Oral Glucose		Response to Glucagon 4–8 Hours After a Meal ^a		Response to Glucagon 2 Hours After a Meal ^b	
	Triglyceride	Uric acid	Lactate	Glucose	Lactate	Glucose	Lactate	Glucose	Lactate
GSD-0	N	N	N	↑↑	↑↑	0-↑	0	↑	↓
GSD-I	↑↑↑	↑↑	↑↑↑	↑	↓↓	0	↑↑↑	0	↑↑
GSD-III	↑	N	N	↑	↑	0	0	↑	0
GSD-VI, IX	0-↑	N	N	↑	↑	0-↑	0	↑	0

0, No increase; 0-↑, variable increase; ↑, mild increase; ↑↑, moderate increase; ↑↑↑, marked increase; ↓, mild decrease; ↓↓, moderate decrease.

GSD, glycogen storage disease; N, normal.

Subjects with suspected GSD-I should not be permitted to fast for more than 4 hours.

^aAfter a glucose-containing meal.

^bSee text to explain why there is a mild glycemic response early after a meal in the GSD types listed.

enzyme mobilizes approximately 8% of hepatic glycogen as free glucose; the remainder requires activity of hepatic G6Pase.

The hallmark of the hepatic glycogenoses is fasting hypoglycemia. The types of hepatic glycogenoses, their specific enzyme deficiencies, affected tissues, their modes of inheritance, and the chromosomal localization of the relevant genes are shown in Table 23.3. Table 23.4 summarizes the major biochemical characteristics of the hepatic glycogenoses (types 0, I, III, VI, and IX) that typically cause hypoglycemia.

Glycogen Synthase Deficiency (Type 0 GSD)

Mutations in the glycogen synthase gene (*GYS2*) on chromosome 12p12.2 cause a rare autosomal recessive disorder characterized by inability to store hepatic glycogen, resulting in markedly reduced hepatic glycogen content 4 to 6 hours after a meal (~0.5 g/100 g wet weight of liver as compared with 5 g/100 g in a normal child), but normal muscle glycogen content. Ingested glucose is preferentially converted to lactate. Symptoms of morning hypoglycemia appear when nocturnal feeding ceases.²⁰¹ Type 0 GSD has a characteristic biochemical phenotype: fasting hypoglycemia and hyperketonemia alternating with transient hyperglycemia with glucosuria and hyperlacticacidemia during the daytime, especially after high-carbohydrate meals.²⁰² During fasting hypoglycemia, plasma levels of the counterregulatory hormones are appropriately elevated, insulin levels are appropriately low, and ketones are elevated.

Unlike the other hepatic GSDs, the liver is not enlarged; therefore referral to glycogen synthase deficiency as a storage disease is a misnomer. Despite its rarity, the disorder should be considered in the differential diagnosis of "ketotic hypoglycemia."^{203,204} After an overnight fast, oral glucose (1.75 g/kg) causes hyperglycemia and hyperlacticacidemia, whereas glucagon (0.03 mg/kg intramuscularly [IM]) typically has no appreciable effect on the plasma glucose level. Genetic testing for mutations in *GYS2* is commercially available.

The goal of treatment is to prevent hypoglycemia and ketonemia during the night, and hyperglycemia and hyperlacticacidemia during the day. Fasting hypoglycemia and ketosis may be prevented by bedtime feedings of UCS, 1 to 1.5 g/kg.²⁰¹ During illness, administration of a similar dose of cornstarch every 6 hours can be used to prevent hypoglycemia. During the day, patients are fed frequently (e.g., every 4 hours); because gluconeogenesis is intact, the diet should contain an increased amount of protein to provide substrate for gluconeogenesis and a decreased amount of carbohydrate (predominantly complex, low glycemic index carbohydrates) to minimize postprandial hyperglycemia and hyperlacticacidemia. This dietary regimen relieves symptoms, reverses the biochemical abnormalities, and improves growth.

Glucose-6-Phosphatase Deficiency (Type I GSD, Von Gierke Disease, Hepatorenal Glycogenosis)

First described in 1929, type I GSD is an autosomal recessive disorder caused by lack of activity of the hepatic enzyme G6Pase, either because of a deficiency of G6Pase itself or a deficiency of the transporter enzyme G6P translocase (*G6PT*). G6Pase catalyzes the final step in the production of glucose from glucose-6-phosphate. Deficiency of this enzyme impairs glucose production both from glycogenolysis and gluconeogenesis (see Fig. 23.5). Decreased production of glucose causes hypoglycemia in the intervals between meals, and increased production of lactate, uric acid, and triglycerides. Glycogen and triglycerides accumulate in the liver, resulting in marked

hepatomegaly; glycogen also accumulates in the kidney and intestinal mucosa.

The G6Pase enzyme system is located in the endoplasmic reticulum (ER) membrane and consists of several subunits. The catalytic subunit, which converts glucose-6-phosphate to glucose, faces into the ER. Three transport systems transport the substrate, Glucose-6-phosphate, and the products, phosphate, inorganic orthophosphate, and glucose, across the ER membrane. glucose-6-phosphate transporter transports glucose-6-phosphate into and phosphate out of the ER; GLUT2 transports glucose out of the ER.²⁰⁵

Approximately 80% of patients with GSD-I have deficient catalytic activity of the G6Pase system leading to type Ia GSD (GSD-Ia). Approximately 100 different mutations have been found in the G6Pase gene, *G6PC*, located on chromosome 17q21. Patients with GSD type Ib, which is caused by failure to transport glucose-6-phosphate into the lumen of the ER, have mutations (about 80 mutations have been described) in the *G6PT* gene, *SLC37A4*, on chromosome 11q23.²⁰⁵

The estimated incidence of GSD-I is one in 100,000 births in the general population; its prevalence is one in 20,000 in Ashkenazi Jews. The presenting symptoms vary according to age. Symptomatic hypoglycemia may appear soon after birth; however, most patients are asymptomatic, as long as they receive frequent feedings that contain sufficient glucose to prevent hypoglycemia. Symptoms of hypoglycemia typically appear only when the interval between feedings increases, such as when the infant starts to sleep through the night or when an intercurrent illness disrupts normal feeding patterns. The condition may not be recognized until the child is several months old and an enlarged liver and protuberant abdomen are noted during a routine physical examination. Patients may present with hyperpnea (from lactic acidosis) and a low-grade fever without a demonstrable infection. Untreated patients may have a cushingoid appearance (a round cherubic or "doll-like" facies), growth failure, and delayed motor development. Social and cognitive development typically are not affected unless the infant suffers brain injury from recurrent severe hypoglycemia.

During infancy, the blood glucose concentration typically drops to less than 50 mg/dL within 3 to 4 hours of a feeding. Longer intervals of fasting cause even more severe hypoglycemia accompanied by hyperlacticacidemia and metabolic acidosis. Despite plasma glucose values in the range of 20 to 50 mg/dL, patients experience few autonomic or neuroglycopenic symptoms of hypoglycemia reflecting the brain's ability to use lactate as an alternative fuel and the downregulation of autonomic responses after recurrent prolonged hypoglycemia.⁵ Serum insulin is appropriately suppressed and the counterregulatory hormones are elevated in a futile attempt to stimulate glycogenolysis and gluconeogenesis, resulting instead in lactic acidosis and exaggerated lipolysis, which causes marked hyperfattyacidemia. Fructose-1-6-bisphosphatase deficiency in infancy may resemble GSD I, with recurrent hypoglycemia and lactic acidosis (see Fig. 23.6); however, in contrast to GSD-I, glucagon administration elicits a brisk glycemic response in the recently fed state and genetic testing for *FBP1* confirms the diagnosis (see Table 23.4).

The serum of untreated patients may be lipemic, with extremely high triglyceride concentrations (typically >500 mg/dL) and moderately increased levels of phospholipids and total and low-density lipoprotein-cholesterol; the high-density lipoprotein-cholesterol concentration is low. High triglyceride levels are caused by increased hepatic synthesis (mobilization of FFA from adipose tissue in response to hypoglycemia), impaired ketogenesis, and reduced clearance of triglycerides, secondary to decreased lipoprotein lipase activity.²⁰⁶ Eruptive xanthomata may appear on the extensor surfaces of the

extremities and on the buttocks and severe hypertriglyceridemia (>1000 mg/dL) may cause acute pancreatitis.

Untreated or poorly controlled GSD I is associated with marked elevations of plasma uric acid. The hyperuricemia is caused by increased degradation of adenosine monophosphate (AMP) to inosine and uric acid because of de/inhibition of AMP deaminase as a consequence of accumulation of glucose-6-phosphate and lowering of both ATP and inorganic phosphate in hepatocytes. A similar mechanism causes hyperuricemia in fructose-1,6-bisphosphatase deficiency (see later section on Genetic Disorders of Gluconeogenesis) because of accumulation of fructose-1,6-phosphate and is the reason fructose is not used in intravenous fluids.

Although symptomatic hypoglycemia becomes less severe with increasing age, nonetheless, without adequate therapy growth is stunted, and puberty is delayed. However, when continuous glucose therapy is started early in life and long-term good metabolic control is maintained, patients can grow and develop normally.²⁰⁷

Impaired platelet function causes a bleeding tendency manifested as recurrent epistaxes or oozing after dental or other surgery. Reduced platelet adhesiveness, abnormal platelet aggregation, and impaired release of adenosine diphosphate (ADP) in response to collagen and epinephrine have been observed. The defects in platelet function are secondary to the systemic metabolic abnormalities and are corrected by improving the metabolic state.

Anemia is common in children with GSD I. The etiology of the anemia is multifactorial and includes iron and other nutritional deficiencies, chronic lactic acidosis, blood loss from menorrhagia, end-stage renal disease (ESRD), and enterocolitis (in patients with GSD Ib). Patients with liver adenomas may have iron refractory anemia secondary to aberrant hepcidin expression.²⁰⁸ Intestinal symptoms are usually not a prominent feature but can include diarrhea.

Kidney enlargement is readily demonstrated by ultrasonography. Deficiency of G6Pase leads to glycogen deposition in the kidneys and disturbs the metabolism of renal tubular cells, resulting in a relative energy deficiency.²⁰⁹ Increased renal blood flow and glomerular filtration rate (GFR) may be a compensatory mechanism for the intracellular energy deficit. Renal manifestations include proximal and distal renal tubular dysfunction, as well as glomerular injury that can lead to ESRD.²¹⁰ Proximal tubular dysfunction (glucosuria, phosphaturia, hypokalemia, and a generalized aminoaciduria) is reversible when biochemical control of the disease improves.²¹¹ Some patients have a distal renal tubular acidification defect associated with hypocitraturia and hypercalciuria, which predisposes to renal calculi and nephrocalcinosis. Increased urinary albumin excretion may be observed in adolescents. Progressive severe renal injury with proteinuria, hypertension, and decreased creatinine clearance because of focal segmental glomerulosclerosis and interstitial fibrosis, may be seen in young adults. Patients with persistently elevated blood lactate, serum lipid, and uric acid concentrations appear to be at increased risk of developing nephropathy. Normalization of metabolic parameters decreases proteinuria, and optimal therapy instituted at or before age 1 year may delay, prevent, or slow the progression of renal disease.^{212,213}

Development of hepatic adenomas is a common complication, occurring in up to 75% of patients by the time they reach adulthood. Although adenomas are usually first observed in the second and third decades of life, they may appear before puberty. Adenomas may hemorrhage or become malignant hepatocellular carcinomas.²¹⁴ Ultrasonography is the preferred method of screening for hepatic adenomas. When malignancy is suspected, MRI and measurement of serum alpha-fetoprotein should be performed.

Radiographic studies have demonstrated osteopenia, and pathologic studies have shown osteoporosis, without evidence of abnormalities in calcium, phosphate, parathyroid, or vitamin D metabolism. Bone mineral content is decreased compared with age-matched normal children. Endocrine and metabolic disturbances, including hypercortisolemia, resistance to GH, delayed puberty, and lactic acidosis, may account for decreased bone mineralization.

Menstrual irregularities and hirsutism caused by hyperandrogenism are uncommon; however, in all types of hepatic GSDs, ultrasonography has shown a high prevalence of morphologically polycystic ovaries (even in prepubertal children), the clinical significance of which is still unclear.

Although the heart itself is not affected in GSD I (unlike GSD III), hypertension may develop in association with renal disease. Pulmonary hypertension presenting in the second or third decade of life and leading to death from progressive heart failure has also been described.

Patients with GSD Ib have symptoms similar to GSD Ia, but with the addition of either constant or cyclic neutropenia of variable severity, ranging from mild to complete agranulocytosis, and is associated with recurrent bacterial infections.²¹⁵ Neutropenia is a consequence of disturbed myeloid maturation and is accompanied by functional defects of circulating neutrophils and monocytes.²⁰⁵ A recent case series suggests that vitamin E supplementation may improve neutropenia and reduce infection rates.²¹⁶ Patients frequently develop an inflammatory bowel disease resembling Crohn disease, which is responsive to treatment with granulocyte colony-stimulating factor (G-CSF). Children with GSD Ib are prone to oral complications (recurrent mucosal ulceration, gingivitis, and rapidly progressive periodontal disease), painful perianal abscesses, and have an increased prevalence of thyroid autoimmunity and primary hypothyroidism.

Diagnostic Studies. During infancy, plasma glucose typically decreases to less than 50 mg/dL within 3 to 4 hours of a feeding and is accompanied by hyperlactacidemia and metabolic acidosis. The serum may be cloudy or milky, with very high triglyceride and moderately increased levels of cholesterol. Serum uric acid, aspartate aminotransferase, and alanine aminotransferase levels are usually increased. The simplest method of determining the probable nature of the enzymatic deficiency in a child suspected of having a GSD I is to obtain serial blood samples for measurement of metabolites (glucose, lactate, FFA, ketones, and uric acid) for up to 6 hours (or until the plasma glucose decreases to ≤ 50 mg/dL), following oral glucose (1.75 g/kg), or 30 minutes after stopping a continuous overnight intravenous or intragastric glucose infusion. Hypoglycemia, together with elevated blood lactate levels, combined with an abnormal fed glucagon stimulation test, clinches the diagnosis. In the normal child, a 2-hour postprandial (fed) glucagon stimulation test causes the plasma glucose to increase by 30 mg/dL or more within 30 minutes without a change in lactate concentration, whereas in GSD I, the glucose response is minimal and there is a marked increase in lactate. Because administration of glucagon can lead to pronounced worsening of metabolic acidosis and decompensation in GSD I, it is no longer recommended in the diagnostic evaluation of suspected GSD I. Mutation analysis of *G6PC* (GSD Ia) and *SLC37A4* (GSD Ib) genes is recommended to confirm type I GSD.^{217,218} Because GSD Ia is more common, unless neutropenia is present, complete *G6PC* sequencing is recommended first. Note that although neutropenia suggests GSD Ib, it has also been occasionally seen in GSD Ia and the neutrophil count can be normal in patients with GSD Ib in the first years of life. A liver biopsy for measurement of G6Pase activity may be necessary in the rare patient who does not have an identifiable gene mutation. In most

individuals with GSD Ia, G6Pase enzyme activity is <10% of normal. G6Pase activity must be assayed in both intact and fully disrupted microsomes, as enzyme activity normalizes when freezing disrupts the integrity of the ER. For this reason, G6Pase enzyme activity on snap-frozen liver biopsy tissue will not detect GSD Ib, and fresh (unfrozen) liver biopsy tissue is needed to assay G6PT activity accurately. The glycogen itself has a normal appearance. Ultrasound of the abdomen shows hepatomegaly and nephromegaly without splenomegaly. Nephromegaly is characteristic of GSD I and is not a feature of the other GSDs.

Treatment consists of providing a continuous dietary source of glucose to prevent the plasma glucose from falling below the threshold for glucose counterregulation.²¹⁸ When hypoglycemia is prevented by providing an appropriate amount of glucose throughout the day and night, the biochemical abnormalities are ameliorated, liver size decreases, the bleeding tendency is reversed, and growth improves. Recommended biochemical targets: plasma glucose greater than 70 to 75 mg/dL, triglycerides less than 500 mg/dL, and uric acid less than 7.5 mg/dL.

Various methods may be used to provide a continuous source of glucose at a rate sufficient to satisfy glucose requirements in the intervals between meals: intravenously, via the gastrointestinal tract by intragastric infusion (either nasogastric or gastrostomy tube), or by use of low glycemic index foods.²¹⁸ Of the latter, UCS has the most suitable properties described to date. The *minimum* amount of glucose required in the basal state may be obtained by using the formula for calculating the basal glucose production rate: $y = 0.0014x^3 - 0.214x^2 + 10.411x - 9.084$, where $y = \text{mg glucose per minute}$ and $x = \text{ideal body weight in kilograms}$.⁸ The amounts and/or schedule of glucose or UCS administered are modified, if necessary, based on the results of clinical and biochemical monitoring.

Infants with GSD I usually require feeds every 2 to 3 hours of a formula that does not contain either lactose or sucrose. The formula must contain a polymer of glucose (corn syrup solids, maltodextrins) that will yield an amount of glucose equal to the calculated glucose production rate.²¹⁹ If nighttime feedings are challenging, continuous overnight feedings, using the same formula, may be given via nasogastric or gastrostomy tube controlled by an infusion pump.

Orally administered UCS acts as an intestinal reservoir of glucose that is slowly absorbed into the circulation. In many centers, UCS has replaced frequent daytime feedings of glucose or glucose polymers and overnight continuous intragastric infusion of glucose. It has been used successfully in infants as young as 8 months of age.²¹⁹ The UCS is given in a slurry of water or an artificially sweetened beverage (e.g., Kool-Aid) or in formula for infants, at 3- to 5-hour intervals during the day, and at 4- to 6-hour intervals overnight. The amount given is determined by multiplying the time interval between feedings by the calculated hourly glucose requirement for ideal body weight. One tablespoon (8 g) of UCS contains 7.3 g of carbohydrate. The optimum schedule and amounts of intermittent UCS feedings for patients of different ages is determined empirically by metabolic monitoring to ensure that the biochemical goals are being achieved.²²⁰

Extended Release Waxy Maize Cornstarch (Glycosade, Vita-flo, International Ltd., Liverpool, England) was approved in England in 2009 for the management of GSD I and was released in the United States as a medical food in 2012. Efficacy studies in children as young as 5 years old have shown prolongation of fasting tolerance from an average of 4.1 to 7.8 hours, using extended release cornstarch as compared with standard UCS.^{221,222} Gastrointestinal intolerance and exacerbation of

inflammatory disease are common side effects of the extended release formulation.

When adequate exogenous glucose is provided, significant hyperuricemia and hyperlipidemia are usually restored to near normal. If severe hyperuricemia persists, allopurinol, a xanthine oxidase inhibitor (5–10 mg/kg/day as a single daily dose or divided q12 hours), effectively lowers serum uric acid to normal levels. Lipid-lowering agents (gemfibrozil or fenofibrate) are indicated when persistent severe hyperlipidemia, despite optimal glucose therapy, poses a significant risk of acute pancreatitis.

Dietary fat should be restricted to less than 20% of the total energy intake, equally distributed among monounsaturated, polyunsaturated, and saturated fats. Dietary cholesterol is restricted to less than 300 mg/day. Carbohydrate typically provides 60% to 65% of the daily calories. Of the total daily calories, 30% to 45% is prescribed (both the amount and schedule) in the form of UCS. Most of the remaining dietary carbohydrate should, ideally, be low glycemic index starches. With the glucose requirements prescribed, the total caloric intake is determined by the child's appetite, as long as the rate of weight gain is not excessive. The dietitian must ensure that the patient is consuming an adequate amount of protein, fat, minerals, and vitamins to support optimal growth. When adequate glucose is prescribed to maintain normoglycemia, milk products and fruit, despite their content of galactose and fructose, respectively, may be used sparingly to supply essential nutrients, minerals, and vitamins.

Renal disease. Angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers have been reported to improve GFR in patients with hyperfiltration. Thiazide diuretics and oral citrate can help prevent nephrocalcinosis and renal calculi.²²³ Loop diuretics should be avoided because of the risk of hypercalciuria.

Anemia. Iron, vitamin B₁₂, and folic acid intake should be optimized. Patients with hepatic adenomas may develop iron refractory anemia caused by aberrant tumor expression of hepcidin, a key regulator of iron metabolism.²⁰⁸ Erythropoietin supplementation may be required in patients with ESRD.

Neutropenia. G-CSF is efficacious for treatment of neutropenia and infections in patients with GSD-Ib; monitoring for splenomegaly should be performed because it is the most serious complication of G-CSF therapy in this population.^{224,225}

Monitoring. Frequent plasma glucose monitoring before meals, before cornstarch administration, and before and after exercise is essential to establish good metabolic control. If the cornstarch dose is changed, plasma glucose should also be monitored frequently after cornstarch administration to establish the effective duration of action. Clinical studies of continuous glucose sensors, in both adults and children, show that they can be used safely and reliably in patients with GSD I, and can help reduce duration of hypoglycemia, as well as detect asymptomatic hypoglycemia.²²⁶

Routine monitoring should include: complete blood count with differential white cell count, serum uric acid, triglycerides, and cholesterol. Triglyceride concentrations are considered the most useful parameter of metabolic control, given the rapid fluctuations in the levels of plasma glucose, lactate, and transaminases. Significantly increased adenoma progression has been reported in patients with mean triglyceride greater than 500 mg/dL.

The American College of Medical Genetics and Genomics has provided guidelines for screening patients with GSD I for complications.²¹⁸ These include measurement of serum creatinine, urea, electrolytes, calcium, phosphate, liver function tests, protein, and

albumin every 6 months. Urine microalbumin, protein, creatinine, calcium, and citrate should be checked every year from 0 to 5 years of age and every 6 months if older than 5 years of age. Creatinine clearance (GFR estimate) should be performed yearly for those older than 5 years of age. An abdominal ultrasound examination to evaluate liver, kidneys, spleen, and ovaries should be performed annually if younger than 10 years of age, and every 6 months after age 10 years. Bone densitometry should be obtained every 1 to 2 years for those older than 5 years. Periodic echocardiography (ECHO) and electrocardiogram (ECG) should be performed to screen for pulmonary hypertension starting at 10 years of age and repeated at least every 3 years.

A clinical study to evaluate the efficacy and safety of gene therapy to replace hepatic G6Pase in human subjects, using adeno-associated virus carrying the human *G6PC* gene, is currently in progress.

Amylo-1,6-Glucosidase Deficiency (Type III GSD, Debranching Enzyme Deficiency, Limit Dextrinosis, Cori Disease, Forbes Disease)

Type III GSD is caused by deficient activity of the glycogen debranching enzyme (GDE) (see Fig. 23.5), leading to impaired glycogen degradation, reduced glycogenolysis, and accumulation of abnormal glycogen (limit dextrin). It is an autosomal recessive disease resulting from mutations of the *AGL* gene on chromosome 1p21, which encodes four GDE isoforms. Isoform 1, the most widely distributed and the predominant form in the liver, is defective in GSD-IIIa. Isoforms 2, 3, and 4 are exclusively located in skeletal and cardiac muscle. GDE has two enzymatic functions: a transferase that exposes the 1,6-linkage and amylo-1,6-glucosidase, which produces free glucose. Without GDE, glycogen breakdown cannot proceed past the outermost branch points, resulting in limit dextrin, an abnormal form of glycogen with short side chains. Only the outer 5% to 10% of glucose residues can be released by phosphorylase. In the United States, 80% to 85% of patients with GSD-III lack GDE activity in both liver and muscle (GSD-IIIa), 15% lack GDE activity in the liver alone (GSD-IIIb); rarely, patients lack activity in muscle alone (GSD-IIIc). In contrast, in Israel the majority of patients lack enzyme activity only in the liver (GSD-IIIb).

Clinical and enzymatic variability is a feature of GDE deficiency. During infancy and childhood, the presentation may be indistinguishable from GSD-I. Hepatomegaly, fasting hypoglycemia with ketosis, hyperlipidemia, and growth retardation are the predominant features. About 70% of patients have muscle weakness, but this is usually not clinically significant in childhood.

Because small amounts of glucose can be produced from 1,4-segments beyond the outermost glycogen branch points and from gluconeogenesis, patients with GDE deficiency may be able to tolerate longer periods of fasting, and hypoglycemia usually is less severe than in those with G6Pase deficiency. Infants with GSD-III may be asymptomatic on their usual frequent feeding schedules and typically do not become as severely ill with infections and other stresses that disrupt feeding as do children with GSD-I.

Infants with GSD-III develop fasting hyperketonemia as a result of an accelerated transition to the fasting state. Blood lactate and uric acid levels are normal, because the gluconeogenic pathway is intact and hepatic glycolysis is not increased (see Fig. 23.5). Hyperlipidemia is less severe in GSD-III than in GSD-I. The presenting clinical finding may be hepatomegaly and growth failure. An enlarged spleen may be seen at 4 to 6 years of age in patients who develop hepatic fibrosis. The kidneys are not large and renal dysfunction does not occur.

Untreated infants and children grow slowly and puberty is delayed. Patients who lack GDE in muscle usually have minimal, clinically insignificant muscle weakness during childhood. With the exception of myopathy, symptoms and signs characteristically ameliorate with increasing age. Myopathy, however, usually becomes prominent in the third or fourth decade of life, manifesting as slowly progressive muscle weakness involving the proximal muscles. In some patients, the small muscles of the hands are also affected. Cardiac involvement is common as a result of limit dextrin accumulation in the heart causing a cardiomyopathy that resembles idiopathic hypertrophic cardiomyopathy. Significant concentric left ventricular hypertrophy usually develops after puberty and manifests as ventricular hypertrophy on ECG and increased left ventricular mass and wall thickness on an echocardiogram.²²⁷ Ventricular changes are more commonly seen in patients with GSD-IIIa, but have also been reported in patients with GSD-IIIb. Symptomatic cardiomyopathy may occur and sudden death has been attributed to cardiac arrhythmias; glycogen accumulation in the cardiac conduction system has been observed at autopsy.

The size of the liver tends to decrease during puberty. Biopsy usually shows hepatic fibrosis, and some adult patients develop cirrhosis. Hepatic adenomas have been found in 4% to 25% of patients, compared with 22% to 78% of GSD-I patients. The development of hepatocellular carcinoma is rare, but has been described in patients more than 30 years old.

Typical biochemical features are fasting hypoglycemia with ketosis (i.e., ketotic hypoglycemia), but without elevation of blood lactate or serum uric acid concentrations (see Fig. 23.6). Hypertriglyceridemia and hypercholesterolemia occur in approximately two-thirds and one-third of patients, respectively. Hypertriglyceridemia is most commonly found in younger children (<3 years old) and does not reach levels high enough to cause pancreatitis. Liver transaminases are consistently elevated in children (at least twice the upper limit of normal, and often >500 IU/L), but decline at puberty and may be normal in adults. Creatine kinase (CK) is often markedly elevated in patients with GSD-IIIa.

After an overnight fast, plasma glucose and lactate concentrations do not increase after administration of glucagon (see Table 23.4). However, when the test is performed 2 hours after a high-carbohydrate meal (before the outer branches of glycogen are degraded), a glycemic response can be elicited. Diagnosis of GSD-III is made by mutation analysis of the *AGL* gene or, alternatively, by liver and/or muscle biopsy.²²⁸ Biopsy results show a 3- to 5-fold elevation of structurally abnormal (highly branched) glycogen content in the involved tissue. Definitive subtyping of GSD-III requires a biopsy of both liver and muscle. Although muscle involvement can be inferred from the presence of high levels of serum CK, a normal level does not rule out muscle enzyme deficiency. At the time of diagnosis, muscle biopsy is the only way to predict accurately whether skeletal muscle disease or heart muscle involvement is likely to develop in the future, unless a GSD-IIIb specific mutation is identified.

Because only a limited amount of glucose can be mobilized from glycogen, hypoglycemia develops during an overnight fast in infancy and early childhood. This occurs despite increased gluconeogenesis and enhanced hepatic uptake of gluconeogenic amino acids, which results in low plasma levels of several amino acids, such as alanine. As in GSD-I, continuous provision of an adequate amount of glucose, using UCS, combined with a normal intake of total calories, protein, and other nutrients, corrects the clinical and biochemical disorder and restores normal growth. UCS 1 to 1.75 g/kg at 6-hour intervals (e.g., at midnight, 6 AM, etc.) maintains normoglycemia, increases

growth velocity, and decreases serum aminotransferase concentrations.²²⁸ Infants less than 12 months old may not produce sufficient amylase to digest UCS and experience bloating, flatulence, and diarrhea. If these side effects occur, a slow rate of introduction of UCS or addition of pancrelipase (which contains amylase) may improve tolerance. UCS can be mixed in any beverage, although addition to milk or yogurt is preferable, as it adds protein and fat. Addition of whey protein is recommended to prolong normoglycemia. Excessive UCS should be avoided because it leads to excess glycogen deposition and weight gain. For patients who have significant growth retardation and myopathy, continuous nocturnal feeding of a nutrient mixture composed of glucose, glucose oligosaccharides, and amino acids combined with intermittent feedings during the day of meals with a high protein content may be beneficial. Adolescents and adults with GSD IIIa should aim for a high-protein (25% of total calories) and low complex carbohydrate (<50% of total calories) diet and should avoid simple sugars and fasting. A high-protein diet may improve muscle function by enhancing muscle protein synthesis and reducing glycogen storage. It has also been reported that a high-protein diet (~30% of total calories) may reverse and possibly prevent cardiomyopathy.²²⁹ Patients with GSD-IIIb may be able to transition to a regular well-balanced diet.

Plasma glucose monitoring should be performed before meals or UCS, before bedtime and breakfast, with addition of extra monitoring during times of illness. Liver function tests should be performed every 6 months. As in patients with GSD-I, annual hepatic ultrasound examinations should be performed to screen for hepatic adenomas. MRI of the liver should be performed every 6 to 12 months in older patients and in children, when an ultrasound examination shows an adenoma has increased in size. Routine ECG and ECHO should be performed to evaluate for dysrhythmias, ventricular hypertrophy, and systolic or diastolic dysfunction. Cardiac ECHO should be done every 12 to 24 months in patients with GSD-IIIa and every 5 years in those with GSD-IIIb. ECG should be done every other year in patients with GSD-IIIa. No exercise restrictions are recommended for patients with GSD-III, unless they have significant cardiac disease. Exercise helps prevent worsening myopathy and low bone mineral density. Physical therapy evaluation is recommended every 6 months.

Hepatic Phosphorylase Complex Deficiency (Type VI GSD, Hepatic Phosphorylase Deficiency, Hers Disease; Type IX GSD, Phosphorylase Kinase Deficiency)

Hepatic phosphorylase, the rate-limiting enzyme of glycogenolysis, is activated by a cascade of enzymatic reactions triggered by glucagon and epinephrine. First, adenylate cyclase catalyzes the formation of cyclic adenosine monophosphate (cAMP), which then activates a cAMP-dependent protein kinase. Protein kinase then phosphorylates a phosphorylase kinase (PHK), which converts inactive hepatic phosphorylase to its active form. Active phosphorylase hydrolyzes the α -1,4-linkages and mobilizes glucose from glycogen (see Fig. 23.5).

The GSDs caused by a reduction in liver phosphorylase activity are a heterogeneous group of disorders (see Table 23.3). Hepatic PHK or type IX GSD, which occurs in approximately one in 100,000 births and accounts for about 25% of all cases of GSDs is the most common form; whereas, deficiency of hepatic phosphorylase (type VI GSD) itself is rare.

PHK of liver and muscle is a complex enzyme consisting of four subunits: α , β , γ , δ . The enzyme is regulated by phosphorylation of specific serine residues of the α and β subunits and by calcium through the δ subunit, a member of the calmodulin family. The γ subunit is catalytically active. Mutations in three

different genes of PHK subunits (*PHKA2*, *PHKB*, and *PHKG2*) can result in deficient activity of hepatic phosphorylase. GSD IXa, because of mutations in *PHKA2*, is the most common variant (see Table 23.3).

GSD IXa is an X-linked disorder restricted to boys. Patients seldom have symptomatic hypoglycemia during infancy, unless they fast for a prolonged period.²³⁰ They can develop hyperketonemia similar to, but usually milder than, that seen in type III GSD. Metabolic acidosis is rare. The disorder is usually discovered when an enlarged liver and protuberant abdomen are noted during a physical examination.^{231,232} Physical growth is usually impaired, and motor development may be delayed as a consequence of hypotonia. With increasing age, clinical and biochemical abnormalities gradually ameliorate, and catch-up growth may occur; most adult patients are asymptomatic. GSD IXc, because of *PHKG2* mutations, tends to have a more severe phenotype that includes liver fibrosis and cirrhosis in childhood. Recent reports indicate that liver fibrosis may also occur in GSD VI and IXa. Mild cardiomyopathy has been identified using ECHO on long-term follow-up of patients with GSD VI and IXb.²³³

Hypoglycemia is unusual and blood lactate and uric acid levels are normal. Mild hypertriglyceridemia, hypercholesterolemia, and elevated transaminase levels may be present. Ketonemia occurs with fasting.²⁰⁴ Functional tests are not especially useful in evaluating these patients. After an overnight fast, blood lactate level is normal, and administration of glucagon elicits a brisk glycemic response, without a rise in the blood lactate concentration. The glycemic response to glucagon cannot be used to distinguish between phosphorylase kinase deficiency and lack of phosphorylase itself. Thus the definitive diagnosis of type IX GSD requires genetic testing or determination of phosphorylase kinase activity in erythrocytes or leukocytes. The diagnosis of type VI GSD can also be established by genetic testing or, alternatively, by assaying the activity of phosphorylase in purified blood cell fractions, and usually does not require a liver biopsy. Muscle phosphorylase activity is normal; muscle histology and glycogen content are normal.

In the past, specific treatment other than avoidance of prolonged fasting was considered unnecessary. Recent research, however, suggests that therapy with a high-protein diet and UCS in patients with GSD IX improves linear growth, general wellbeing, decreases hepatomegaly, and may be associated with regression of ultrasound findings of liver fibrosis. UCS, 2 g/kg at bedtime, typically prevents hypoglycemia and ketosis in these patients.²³²

Plasma glucose and ketone monitoring should be done routinely. Growth and pubertal progression should be carefully monitored. Annual liver ultrasound examinations should be performed starting at age 5 years. Because there is increased risk of osteoporosis, bone densitometry is recommended once growth is complete.

Glycogen Branching Enzyme Deficiency (Type IV GSD, Andersen Disease)

There is minimal impairment of glycogenolysis and gluconeogenesis is normal; accordingly, hypoglycemia is rare; however, fasting hypoglycemia may occur when severe cirrhosis develops.²³⁴

Fanconi-Bickel Syndrome (Type XI GSD)

GSD XI is a rare autosomal recessive disorder characterized by hepatorenal glycogen accumulation caused by deficiency of the facilitative GLUT2 that mediates the bidirectional transport of

glucose and galactose in hepatocytes, pancreatic beta cells, enterocytes, and in the proximal tubules of the kidney.²³⁵

Patients usually present in infancy with failure to thrive, chronic diarrhea from carbohydrate malabsorption, hepatomegaly, and fasting hypoglycemia, as the interval between feeds increases. A general renal proximal tubulopathy with severe glucosuria and hypophosphatemic rickets are characteristic features. Older patients have a moon-shaped face, a protuberant abdomen, short stature, and delayed puberty. Kidneys are enlarged (detectable by ultrasound) as a result of glycogen accumulation.²³⁶ Clinical findings are of variable severity.^{237,238}

Fasting ketotic hypoglycemia and postprandial hyperglycemia and hypergalactosemia (caused by impaired hepatic uptake of the two sugars) are characteristic biochemical features. Decreased insulin secretion (because of an impairment of beta-cell glucose sensing) may also contribute to impaired hepatic glucose uptake and postprandial hyperglycemia. Other laboratory findings include hypergalactosemia, glucosuria, renal bicarbonate wasting, proteinuria, phosphaturia, generalized aminoaciduria, and elevated serum alkaline phosphatase level. Mutation analysis of the *GLUT2* gene confirms the diagnosis.

Frequent feeds using slowly absorbed carbohydrates and restriction of galactose are recommended. Supplementation with UCS has a beneficial effect on metabolic control and growth. Fructose metabolism is not affected; therefore this monosaccharide may be used as an alternative carbohydrate source. Water and electrolytes must be replaced. Alkali may be necessary to compensate for renal tubular acidosis, and hypophosphatemic rickets requires supplemental phosphate and vitamin D.

Ketotic Hypoglycemia. Ketotic hypoglycemia has been recognized for nearly a century²³⁹ as the most common type of childhood hypoglycemia between 1 to 6 years of age, with a well-characterized presentation and course, but an incompletely understood etiology.^{240–243} Usually, this condition presents as recurrent episodes of morning hypoglycemia in the second or third year of life—but onset as early as 6 months has been reported. The condition usually remits spontaneously by the age of 8 to 9 years. The classic history is of a child, often a male with a history of low birthweight, who has eaten poorly the previous day or misses an evening meal, is difficult to rouse from sleep the next morning, and displays neuroglycopenic symptoms that may range from lethargy to seizure. Hypoglycemic episodes are especially likely to occur during an illness, when food intake is limited. Treatment to avoid prolonged overnight fasting usually limits recurrent attacks to less than one to two a year.

At the time of hypoglycemia, high levels of ketones are found in plasma and urine, and plasma insulin concentrations are suppressed, indicating that HI is not responsible for the hypoglycemia. It remains unsettled whether these children display an accelerated, but qualitatively normal, metabolic response to fasting (i.e., the lower end of the normal distribution of fasting tolerance, “accelerated starvation”) or whether ketotic hypoglycemia represents a heterogeneous group of disorders of limited substrate availability awaiting further delineation.^{244,245} For example, fasting tolerance is much shorter in young infants because of their larger ratio of brain versus body mass and therefore are more vulnerable to becoming hypoglycemic, when fasted for longer than 12 hours, especially if normal feeding has been impaired by anorexia, vomiting, or diarrhea because of an intercurrent illness. On the other hand, in children previously diagnosed as having ketotic hypoglycemia, an increasing number of specific metabolic defects have been recognized, such as mild forms of glycogen storage disorders (Type IXa GSD)²⁰⁴ or of ketone utilization.²⁴⁶ Thus ketotic

hypoglycemia should be considered a diagnosis of exclusion and further investigation should be considered in any child with ketotic hypoglycemia who has recurrent episodes.

Several studies have shown that ketotic hypoglycemia reflects underproduction rather than overutilization of glucose.^{247,248} Infusions of alanine, fructose, or glycerol produce a rise in plasma glucose concentration, without significant changes in blood lactate or pyruvate levels, indicating that the entire gluconeogenic pathway from the level of pyruvate is intact, and suggesting that a deficiency of substrate rather than a defect in gluconeogenesis is involved.^{247,249}

Glucagon induces a normal glycemic response in affected children during the fed state, but not at the time of hypoglycemia, indicating that glycogenolytic pathways are also intact. Plasma glycerol levels are normal in these children, in both the fed and fasted states. The metabolic response to infusion of BOHB does not differ from that of normal children. Finally, the levels of hormones that counter hypoglycemia are appropriately elevated, whereas insulin levels are appropriately low.^{14,249,250}

Children with ketotic hypoglycemia have plasma alanine concentrations that are reduced in the basal state, after an overnight fast, and fall still farther with prolonged fasting.^{21,251} Alanine is the major amino acid used for gluconeogenesis. Its formation and release from muscle during periods of caloric restriction is enhanced by the presence of a glucose-alanine cycle, as well as by de novo formation from other substrates, such as branched chain amino acids. Hypoalaninemia in ketotic hypoglycemia probably reflects “accelerated starvation,” rather than a specific defect in alanine metabolism. As pointed out in the original description of ketotic hypoglycemia, the children are frequently smaller than age-matched controls and often have a history of transient neonatal hypoglycemia.²⁴⁰ Thus ketotic hypoglycemia may simply reflect the reduced reserve of a small muscle mass at an age when glucose demands per unit of body weight to support brain metabolism are relatively high; children with ketotic hypoglycemia may represent the lower end of the normal range for fasting tolerance.²⁴⁴ Spontaneous remission of ketotic hypoglycemia by age 8 to 9 years might be explained by the increase in muscle bulk relative to brain size, with a resultant increase in the supply of endogenous substrate, and the relative decrease in glucose requirement per unit of body mass, with increasing age.

The diagnosis of ketotic hypoglycemia is confirmed by a supervised fast. Hypoglycemia with elevated plasma FFA, BOHB, and acetoacetate develops within 14 to 24 hours in most of these children, whereas normal children of similar age can withstand fasting without developing hypoglycemia for at least 24 hours.

Episodes of ketotic hypoglycemia can be prevented or minimized by avoidance of prolonged fasting. The overnight fast should be shortened to less than 10 to 12 hours, with a bedtime snack containing carbohydrate and prompt breakfast. When episodes have been triggered by illness, parents may test the child’s urine for ketones or, preferably, plasma BOHB. The appearance of hyperketonemia precedes the hypoglycemia by several hours and indicates a need for high-carbohydrate liquids. If these cannot be tolerated, the child should be taken to the emergency department for intravenous glucose. A letter of explanation and treatment recommendation may expedite the emergency department response.

Ketotic hypoglycemia should be considered only a diagnosis of exclusion, as episodic hypoglycemia with ketosis can occur with deficiencies of several hormones or a variety of defects of gluconeogenesis or glycogen metabolism, especially hypopituitarism and GSDs.²⁰⁴ Recurrent episodes of ketotic hypoglycemia that cannot be explained by intercurrent illness

should trigger reevaluation for a possible underlying disorder that had previously been missed. Among the disorders that deserve special consideration are the milder glycogen storage disorders (e.g., Type IXa GSD caused by X-linked phosphorylase kinase deficiency, *PHKA2*); adrenal insufficiency because of inhaled or intranasal glucocorticoids; or defects in ketone utilization, such as deficiency of MCT1 encoded by *SLC16A1*.²⁴⁶

Hormone Deficiency

GH and cortisol both augment glucose production, decrease glucose utilization, and accelerate lipolysis and ketogenesis.^{23,26} In contrast with glucagon and epinephrine, which raise plasma glucose levels within minutes, the actions of GH and cortisol are delayed for several hours and neither has a primary role in the defense against acute insulin-induced hypoglycemia. They are important, however, in preventing hypoglycemia during prolonged fasting.

Deficiency of Growth Hormone and Hypopituitarism

Deficiency of GH is an important cause of fasting hypoglycemia, especially in infants and young children. Although less common, symptomatic and asymptomatic hypoglycemia, usually precipitated by stress, starvation, or exercise, may also occur in older children and adults with either isolated GH deficiency or multiple pituitary deficiencies.^{252–254}

Hypopituitarism in the newborn period can cause persistent or recurrent severe hypoglycemia,²⁵⁵ and some infants may require a glucose infusion rate comparable to that required to treat congenital HI, in addition to mimicking HI by having suppressed FFA and ketone levels, and a glycemic response to glucagon.²⁵⁶ A microphallus suggests coexistent gonadotropin deficiency.²⁵⁷ Infants with congenital hypopituitarism may have cholestatic jaundice with elevated liver enzymes consistent with neonatal hepatitis.^{258,259} The diagnosis of GH deficiency cannot be based on a single GH value obtained at the time of spontaneous or fasting-induced hypoglycemia. Studies have shown that a single low GH value, at the time of fasting hypoglycemia, has poor specificity for the diagnosis of GH deficiency.^{72,260} Confirmation of the diagnosis should be based on a firm foundation of clinical evidence, including demonstration by imaging of abnormal pituitary gland development or other midline defects.²⁶¹

Isolated GH deficiency in young children may cause morning hypoglycemia with hyperketonemia (“ketotic hypoglycemia”).^{262–264} Plasma insulin levels are appropriately suppressed and the glycemic response to glucagon during spontaneous hypoglycemia is poor. The degree of ketosis at the time of hypoglycemia may be lower than expected in the more common type of idiopathic ketotic hypoglycemia, perhaps reflecting increased insulin sensitivity and impaired lipolysis. It has been suggested that the relative hypoketonemia (i.e., impaired generation of alternative fuels) may contribute to the development of fasting hypoglycemia in young children with GH deficiency.²⁶⁴ After early infancy, slow growth and low IGF-1 levels are more reliable indicators of GH deficiency, and the definitive diagnosis of GH deficiency should be confirmed by demonstrating low GH responses to standard provocative stimuli.

Growth Hormone Resistance and Insulin-like Growth Factor-1 Deficiency

Recurrent fasting hypoglycemia is common in GH resistance because of molecular defects in the GH receptor, leading to

an inability to generate IGF-1, commonly referred to as *Laron dwarfism*.^{265,266} The hypoglycemia tends to improve in adolescence, although still can occur with prolonged fasting. Similar frequencies of hypoglycemia ($\geq 45\%$) have been reported in the two largest populations with this condition, in Israel and Ecuador. The vulnerability to fasting hypoglycemia improves with treatment with synthetic IGF-1; however, one of the insulin-like effects of IGF-1 treatment is hypoglycemia, which can occur within an hour of an injection, if the child has not eaten.

Deficiencies of Cortisol and Adrenocorticotropin

Cortisol is crucially important in supporting glucose production during fasting by increasing glycogen storage and gluconeogenesis, and for mobilizing FFA;²⁶ cortisol also has an indirect role in the defense against hypoglycemia by enabling epinephrine to be synthesized normally in the adrenal medulla. Activity of phenylethanolamine N-methyl transferase, the enzyme that converts norepinephrine to epinephrine, depends on intraadrenal cortisol.²⁶⁷

Cortisol deficiency increases sensitivity to insulin; for example, an increased frequency of hypoglycemia and diminishing insulin requirement are characteristic manifestations of Addison disease in type 1 diabetes.²⁶⁸

Fasting hypoglycemia can occur in patients with both primary and secondary glucocorticoid deficiency and is more common in neonates, infants, and young children than in adolescents and adults, and in those with more severe cortisol deficiency.²⁶⁹ Hypoglycemia is most likely to occur after prolonged fasting or during the stress of illness, especially if the usual daily glucocorticoid replacement has been interrupted by illness.^{270,271}

ACTH deficiency combined with GH deficiency, especially in congenital hypopituitarism, is more likely to cause hypoglycemia than primary adrenal insufficiency. Congenital ACTH deficiency, presenting with early hypoglycemia, has been reported with mutations of several genes involved in pituitary development (*POU1F1*, *PROPI*, *TPIT*).²⁶¹ ACTH insufficiency is not always clinically apparent in early infancy but may manifest later in childhood.

An increasing number of specific genetic defects resulting in isolated ACTH deficiency or resistance have been identified. Red hair and severe early-onset obesity are characteristic features of children with ACTH deficiency caused by proopiomelanocortin (POMC) mutations.²⁷² Hypoglycemia in an infant caused by ACTH deficiency has been attributed to a defect of prohormone cleavage.²⁷³ Idiopathic ACTH deficiency can be acquired in childhood, adolescence, or later adult life.²⁷⁴ Circumstantial evidence, such as an association with autoimmune thyroiditis, suggests autoimmune hypophysitis as a common cause and in some instances antipituitary antibodies have been demonstrated.²⁷⁵ In ACTH resistance, hyperpigmentation accompanies other manifestations of adrenal insufficiency.²⁷⁶

Iatrogenic suppression of adrenal function is a common cause of glucocorticoid insufficiency, but it may be overlooked because the typical electrolyte abnormalities of mineralocorticoid deficiency are absent. An adrenal crisis with prostration, vomiting, hypotension, and hypoglycemia can be triggered by a stressful event, in a child recently weaned from high-dose glucocorticoid therapy, and has also been reported on alternate day low-dose therapy. More often, hypoglycemia is caused by inhaled and nasal glucocorticoid preparations that are the mainstay of asthma and allergy treatment for millions of children.²⁷⁷ A serum cortisol level of less than 3 mcg/dL between 7 and 9 AM in a child receiving topical or inhaled glucocorticoids is diagnostic of adrenal insufficiency; if the level is 3

mcg/dL or higher, an ACTH stimulation test is required to evaluate adrenal function.²⁷⁷

Hypoglycemia may be a presenting feature of primary adrenal insufficiency,²⁷⁸ and often occurs during illness or starvation in patients being treated with replacement glucocorticoids.^{269,270} Primary adrenal insufficiency is associated with deficient epinephrine responses to hypoglycemia, and hypoglycemia manifested by neuroglycopenic rather than adrenergic symptoms may be less recognizable.²⁷⁹ Hypoglycemia is relatively frequent in treated patients with congenital adrenal hyperplasia.^{269,280}

As has been noted earlier for GH deficiency, the diagnosis of cortisol or ACTH deficiency, as the cause of a child's hypoglycemia, cannot be based on a single low cortisol value during hypoglycemia, and requires additional clinical evidence (such as a concomitant markedly elevated plasma ACTH concentration in the case of primary adrenal insufficiency) or a standard adrenal stimulation test.⁷²

Deficiency of Glucagon and Epinephrine

The importance of glucagon and epinephrine in the counterregulatory responses to hypoglycemia suggests that isolated deficiency of either hormone would be likely to cause hypoglycemia, and yet no instances of hypoglycemia caused by isolated, primary deficiency of either hormone have been well documented in children.

Although there have been case reports of reduced epinephrine excretion in patients with hypoglycemia, evidence from patients with type 1 diabetes and insulinomas suggests that reduced epinephrine excretion is likely to be the consequence rather than the cause of recurrent hypoglycemia. The defective epinephrine response that accompanies adrenal insufficiency can be at least partly restored by glucocorticoid replacement. Severe fasting hypoglycemia has been reported in a young child receiving the beta-blocker, propranolol.²⁸¹

Despite its crucial importance in acute glucose counterregulation, there have been no well-documented cases of childhood hypoglycemia caused by isolated glucagon deficiency. One case, often cited as an example of isolated glucagon deficiency, was subsequently proven to be an instance of familial SCHAD-HI.^{282,283}

Genetic Disorders of Gluconeogenesis

In the early postabsorptive period, the plasma glucose level is maintained by both glycogenolysis and gluconeogenesis. As fasting continues beyond 6 to 10 hours and liver glycogen is depleted, gluconeogenesis contributes an increasing proportion of circulating glucose (see Fig. 23.3). Alanine from muscle is a principal substrate for gluconeogenesis, but lactate derived from peripheral tissue glycolysis also contributes to glucose production via the Cori cycle, and in later stages of fasting glycerol, derived from lipolysis of adipose tissue triglycerides, becomes a major source of gluconeogenic substrate (FFA cannot be converted to glucose). Genetic defects of the four enzymes of gluconeogenesis required to bypass irreversible steps in glycolysis (pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose 1,6-diphosphatase [FDPase], and G6Pase) cause hypoglycemia, characterized by marked elevations of lactate (see Fig. 23.5; deficiency of G6Pase is described previously under the Glycogen Storage Disorders).

Pyruvate Carboxylase Deficiency

Pyruvate carboxylase is a biotin-containing protein consisting of four subunits that converts pyruvate to oxaloacetate, as the first step in the gluconeogenic pathway.²⁸⁴ Activation is dependent on acetyl CoA and occurs principally during mobilization

of FFA during fasting. Several forms of deficiency have been described, typically presenting as severe lactic acidosis and encephalopathy in early infancy, usually triggered by metabolic decompensation during illness.^{284,285} Hepatomegaly is common. Hypoglycemia is not invariably present in pyruvate carboxylase deficiency.^{286,287} Urine contains large amounts of alpha-ketoglutarate. The diagnosis can be confirmed by direct sequencing of the *PC* gene on 11q13. Management consists of frequent carbohydrate meals and intravenous dextrose support during illness.

Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase (PEPCK) catalyzes the conversion of oxaloacetate to phosphoenolpyruvate as the second key step in gluconeogenesis. Cytosolic and mitochondrial isoforms are encoded by *PEPCK1* and *PEPCK2*, respectively. Deficiencies of both forms have been reported in rare patients, but the clinical phenotype remains uncertain. It is only recently that patients with deficiency of the cytosolic form of PEPCK have been confirmed at the molecular level.²⁸⁸ These patients presented with intermittent episodes of hypoglycemia, without marked elevations of plasma lactate, but with increased urinary concentrations of tricarboxylic acid cycle intermediates. Several patients with deficiency of the mitochondrial form of PEPCK have been described based on enzymatic data, but have not been confirmed at the molecular level. These patients presented with hypotonia, hepatomegaly, failure to thrive, lactic acidosis, and hypoglycemia.

Fructose 1,6-Diphosphatase Deficiency

FDPase, or fructose 1,6-bisphosphatase, catalyzes the conversion of fructose 1,6-diphosphate to fructose-6-phosphate. FDPase is encoded by *FBP1* on chromosome 9q22.32. Deficiency of FDPase impairs the formation of glucose from lactate; glycerol; gluconeogenic amino acids, such as alanine; and fructose.

Hypoglycemia caused by FDPase deficiency was first described in 1970 by Baker and Winegrad.²⁸⁹ FDPase deficiency may present with hypoglycemia and lactic acidosis in the first days of life, but up to 50% of cases present later. Typical manifestations include hyperventilation because of lactic acidosis and ketoacidosis, seizures and coma from hypoglycemia, and hepatomegaly. Attacks are precipitated in infancy and childhood by prolonged fasting during intercurrent illness. Uric acid is elevated similar to type 1 GSD, secondary to sequestration of phosphate as fructose phosphates in the liver, and increased degradation of adenine nucleotides. The diagnosis should be suspected when fasting leads to hypoglycemia and lactic acidemia, with a poor glycemic response to glucagon. The diagnosis may be confirmed by genetic mutation analysis of *FBP1*.²⁹⁰ Treatment of acute attacks of hypoglycemia is with intravenous glucose and bicarbonate infusion. Chronic treatment is avoidance of prolonged fasting and a reduction, but not total elimination, of fructose from the diet.²⁹¹

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) was first described as an idiosyncrasy to ingestion of fructose,²⁹² and was later determined to be caused by recessive mutations of aldolase B (*ALDOB* at 9q31.1).^{293,294} Aldolase B plays an essential role in fructose metabolism by converting fructose-1-phosphate to dihydroxyacetone phosphate and glyceraldehyde, which are substrates for either gluconeogenesis via fructose 1,6-diphosphate or oxidation via conversion to pyruvate. Ingestion of fructose (e.g., as sucrose in fruit) in patients with aldolase B deficiency causes accumulation of fructose-1-phosphate in

liver, kidney, and intestinal cells, leading to intracellular phosphate depletion and both acute symptoms and potentially long-term organ damage. Phosphate depletion induces hypoglycemia by impairing glycogenolysis and, as noted earlier in G6Pase deficiency and FDPase deficiency, also causes hyperuricemia because of increased adenine nucleotide degradation.²⁹⁵ The hypoglycemia of HFI occurs immediately after fructose ingestion, rather than with fasting.

HFI presents in infancy, after fructose is introduced to the diet in fruits or as sucrose (table sugar). Fructose ingestion induces vomiting, abdominal pain, diarrhea, and hypoglycemia.²⁹⁶ With ingestion of substantial amounts of fructose, plasma lactic and uric acid levels rise and phosphorus, potassium, and bicarbonate levels fall. The severity of symptoms is proportional to the amount of fructose ingested; in early infancy, large amounts (e.g., in milk or formula made with sucrose) may produce shock, acute liver failure, and death. Older children are less likely to ingest toxic amounts because of abdominal pain induced by fructose. Acute treatment of hypoglycemia by intravenous glucose rapidly reverses symptoms and affected patients remain healthy if fructose exposure is discontinued. Chronic fructose ingestion causes failure to thrive and increasing liver dysfunction. The earliest renal effect is proximal tubular damage with glucosuria and phosphaturia; prolonged exposure to fructose can lead to kidney failure.

Fructose challenge is potentially dangerous and is not needed to make the diagnosis, because genetic mutation testing of *ALDOB* is available. Chronic treatment is the avoidance of all fructose-containing foods (fruits, sucrose, high-fructose corn syrup); because sorbitol is metabolized to fructose, it needs to be excluded as well.²⁹¹

Defects of Fatty Acid Oxidation

Fatty acid oxidation is the major source of energy for the heart and working skeletal muscle and, apart from the brain, becomes the body's dominant fuel during prolonged fasting. Lipolysis of adipose tissue triglyceride stores releases glycerol, as a substrate for hepatic gluconeogenesis, and FFA, which are used directly as fuel for peripheral tissues and, indirectly, to spare glucose consumption. FFA are converted by mitochondrial β -oxidation in liver to ketones (BOHB and acetoacetate), which are an alternative fuel for the brain. The key steps in transport of fatty acids into mitochondria, the β -oxidation cycle, and the ketone synthesis pathway are outlined in Chapter 7. Genetic disorders in all of these steps have been identified which, in general, present with life-threatening attacks of hypoketotic hypoglycemia, coma, and cardiovascular collapse induced by fasting stress. Defects interfering with early steps in long chain fatty acid oxidation tend to have more systemic features, including chronic cardiomyopathy and skeletal muscle weakness, whereas defects in later steps affecting shorter chain fatty acid oxidation, such as medium chain acyl-CoA dehydrogenase (MCAD) deficiency, may present chiefly with acute episodes of illness triggered by fasting. As a group, genetic disorders of fatty acid oxidation are relatively common (the incidence of MCAD deficiency is ~ 1 in 15,000 births in the United States, and 1 in 5000 in Northern Germany),²⁹⁷ and must be considered in the differential diagnosis of any child with hypoglycemia. Newborn screening programs exist in most countries, which can identify most of the genetic defects in fatty acid oxidation, based on analysis of acylcarnitine profiles (exceptions include HMG-CoA synthase deficiency). However, pediatric endocrinologists must also be able to recognize these fatty acid oxidation disorders, because many cases may present as new onset hypoglycemia at ages ranging from

the newborn period through infancy, and up to several years of age.

Hypoglycemia can manifest in the first days of life (see Chapter 7) in babies exposed to early fasting stress because of failed breastfeeding. However, typically, patients may not present until several months of age, when feeding intervals overnight lengthen to 8 to 12 hours of fasting. Genetic disorders of fatty acid oxidation are especially likely to become clinically apparent during the accelerated starvation of gastrointestinal illness. Because fatty acid oxidation disorders impair ketogenesis, hypoglycemia associated with these disorders is hypoketoneic; however, in contrast to HI disorders, plasma concentrations of FFA are increased. Acute attacks of illness may be accompanied by coma, fatty liver, and encephalopathy, which mimic Reye syndrome, and may not immediately respond to glucose.^{298,299} Episodes may be rapidly fatal and can resemble sudden infant death syndrome.³⁰⁰ Hypertrophic or dilated cardiomyopathy and skeletal muscle weakness are prominent features of certain defects, such as long chain acyl CoA dehydrogenase deficiency, carnitine transport deficiency, and carnitine-palmitoyl transferase 2 deficiencies.³⁰¹ In patients with primary carnitine deficiency caused by the plasma membrane carnitine transporter (*SLC22A5*), treatment with high-dose carnitine supplementation is required; the value of carnitine supplementation in other disorders is controversial.³⁰² Diagnosis can be based on an abnormal plasma acylcarnitine profile and confirmed by genetic mutation analysis.

The primary treatment of these disorders of fatty acid oxidation is avoidance of fasting. In younger children, fasting should be limited to less than 8 to 10 hours; older children may tolerate fasting as long as 10 to 12 hours. Episodes of acute illness with fasting should be treated by rapid institution of intravenous dextrose to raise plasma glucose to the high normal range.

Hypoglycemia Induced by Exogenous Agents

In children, hypoglycemia caused by exogenous agents usually represents accidental ingestions. Ethanol, salicylates, quinine, and beta-blockers, such as propranolol, are the agents most frequently implicated in childhood hypoglycemia.^{303,304}

Alcohol-Induced Hypoglycemia

Ethanol is a notorious cause of severe fasting hypoglycemia in young children and malnourished alcoholic adults, and occasionally in healthy adolescents who are intoxicated.³⁰⁵ Oxidation of ethanol in the liver causes an increase in the nicotinamide adenine dinucleotide (NAD):NAD⁺ ratio that impairs conversion of lactate to pyruvate and, thus, inhibits gluconeogenesis. This inhibition of gluconeogenesis can lead to hypoglycemia in the setting of fasting for long enough to deplete liver glycogen stores. Young children fasted overnight are particularly vulnerable, as are adolescents who have become intoxicated with alcohol without eating. The hypoglycemia is associated with lactic acidemia and hyperketonemia. Treatment with intravenous dextrose is required to reverse the hypoglycemia.

Salicylate Intoxication

In high doses, aspirin and other salicylates have been reported to cause hypoglycemia in both children and adults.³⁰⁶ Suggested mechanisms include stimulation of insulin release or inhibition of hepatic gluconeogenesis. Infants appear to be more susceptible than older children to salicylate-induced hypoglycemia. Because of concerns about a possible role of

salicylates in causing Reye syndrome, their routine use in young children has been largely abandoned.

Hypoglycin A and Jamaican Vomiting Sickness

Hypoglycemia caused by ingestion of unripe ackee fruit was first described as Jamaican vomiting sickness occurring in young children who were seeking potential foods because of undernutrition/starvation. The responsible toxin was identified as hypoglycin A, which is metabolized to a tricyclic compound that is a suicide-substrate for medium chain acyl-CoA dehydrogenase.⁷⁵ A similar illness has been recently linked to ingestion of unripe litchi fruit, which contains a related toxin (methylene cyclopropyl-glycine).⁷⁶ The toxins in both fruits produce a condition similar to MCAD deficiency (described earlier and in Chapter 7).

Hypoglycemia in Fasting, Starvation, Illness, and Stress

During prolonged fasting, FFA and ketones supply a progressively greater proportion of fuel and plasma glucose levels may fall below 50 mg/dL (2.8 mM), without autonomic or neuroglycopenic symptoms, or apparent ill effects because elevated levels of ketones provide adequate alternative fuel for the brain (see Fig. 23.2).^{16,25,307} This is especially likely to be seen in healthy young children and young women, because of their relatively smaller body stores of fuel and smaller body mass relative to brain size. Biochemical hypoglycemia, for example, is occasionally observed in younger children with excessive preoperative fasting.^{308,309}

The risk of biochemical, occasionally symptomatic, hypoglycemia is further increased in children during a wide variety of stressful illnesses, such as rewarming after profound hypothermia and near-drowning.^{310,311}

Hypoglycemia During Starvation and Malnutrition

Chronic malnutrition compromises the ability to maintain euglycemia, and hypoglycemia in malnourished infants and adults can be difficult to reverse.^{312,313} In African children with kwashiorkor, hypoglycemia has been reported to be a common terminal event.³¹⁴ In the developed world, anorexia nervosa is an important cause of severe malnutrition, and hypoglycemia is common and may occasionally be severe.^{315–318}

Hypoglycemia With Prolonged Exercise

Muscle uses glucose at a high rate during exercise; however hypoglycemia is normally prevented during prolonged exercise by a decrease in insulin secretion and increased secretion of glucagon and catecholamines.^{319–321} Nevertheless, hypoglycemia occasionally occurs during intense exercise, even in presumably healthy adults, and can be prevented by ingestion of complex carbohydrates, but not extra sugar.³²² Cases of hypoglycemia severe enough to cause seizures after a marathon or comparable endurance exercise have been reported.^{323,324} Exercise-induced HI because of promoter mutations of MCT1 (described previously) may explain at least some cases of hypoglycemia associated with exercise.³²⁵

Diarrheal Illness

Hypoglycemia is uncommon in previously healthy children with acute viral gastroenteritis, unless there has been a period of starvation (as occurs after prolonged consumption of water or sugar-free fluids) or of severe diarrhea.^{326,327} Hypoglycemia

in these settings is typically ketotic and has a good outcome. Because hypoglycemia is uncommon in otherwise healthy children, and previously unsuspected metabolic or hormonal disorders may present to an emergency department with hypoglycemia, it is important that a history of prolonged starvation be confirmed and that underlying conditions, especially the disorders of fatty acid oxidation, be ruled out.³²⁸

When diarrhea (e.g., cholera or shigella) develops in severely malnourished children, hypoglycemia is a grave prognostic sign and may be fatal because of depletion of gluconeogenic substrates and alternative fuels.³²⁷

Sepsis

Infectious diseases rarely cause hypoglycemia; indeed, hyperglycemia because of adrenergic stress responses is much more likely. However, septicemia, especially meningococemia (unrelated to adrenal insufficiency), may present with severe hypoglycemia.^{329,330} Research in animals suggests that cytokines, such as tumor necrosis factor may amplify glucose uptake.³³¹ Limited data in humans indicate appropriate suppression of insulin and elevation of counterregulatory hormones, as well as cytokines.³³²

Hypoglycemia in Specific Infections

Hypoglycemia has been reported to occur in approximately one-third of children with severe malaria and is a risk factor for increased mortality.³³³ Insulin levels are appropriately low, whereas lactate and alanine levels are high, suggesting that hepatic gluconeogenesis is impaired.³³⁴ Management should include provision of glucose and monitoring of plasma glucose concentrations. In addition, drugs for malaria treatment (in particular quinine) may aggravate hypoglycemia because of their ability to stimulate insulin release.³³⁵

Hypoglycemia has been repeatedly reported in infants with pertussis infection, which is caused by hyperinsulinemia and is not simply caused by fasting. Hyperinsulinemia, but without hypoglycemia, has also been shown to occur in mice after pertussis immunization.³³⁶ Evidence suggests that pertussis toxin amplifies the insulinogenic response to glucose rather than stimulating insulin secretion per se.^{337,338}

Hypoglycemia in Organ System Disease

Hypoglycemia is common in critically ill patients of all ages^{339,340} and can occur in failure or severe disease of nearly every major organ system. The liver is the principal source of glucose during the postabsorptive period, and under experimental conditions, hypoglycemia occurs after loss of 80% of the liver. Hypoglycemia in human liver disease is less predictable. In cirrhosis and progressive liver failure, glucose levels usually remain normal, even in patients with hepatic coma. However, fasting hypoglycemia can occur sporadically in many forms of liver disease, most likely caused by impaired glycogen reserves, with little dependence on the severity of liver impairment by other measures. Hypoglycemia has been reported in adults and children, with drug-induced hepatic injury, poisoning,³⁴¹ and in patients with infectious hepatitis³⁴² and other causes of hepatic injury.³⁴³ Hypoglycemia can also occur as a complication of various rare genetic diseases affecting the liver. For example, citrin deficiency has an intermediate, childhood-onset form characterized by growth retardation, episodic neurologic and behavioral abnormalities with hyperammonemia, and sometimes hypoglycemia.³⁴⁴

Renal gluconeogenesis also normally contributes to maintenance of blood glucose during fasting, and hypoglycemia may occur in patients with end-stage chronic renal failure.^{345–347} Because autonomic responses to hypoglycemia are often impaired in chronic renal failure, neuroglycopenic manifestations typically predominate. In many cases of hypoglycemia with renal disease, the hypoglycemia reflects a complication of dialysis or other procedures and the existence of a specific “uremic hypoglycemia” has been challenged.³⁴⁸

Many cases of fasting hypoglycemia associated with both acute and chronic pancreatitis have been reported in adults and children.^{349–351} Both hypoglycemia and hyperglycemia are recognized complications of mumps pancreatitis in children.³⁵²

The causes of hypoglycemia associated with severe heart disease, both cyanotic congenital heart disease in young children,³⁵³ and congestive heart failure in older children and adults^{354–356} are complex, with evidence of both increased glucose uptake and impaired gluconeogenesis. In infants, hypoglycemia can cause heart failure that improves with restoration of normal glucose levels.³⁵⁷

Skeletal muscle contributes substrates to gluconeogenesis during fasting, and fasting hypoglycemia occurs with several forms of muscular dystrophy and spinal muscle atrophy characterized by reduced muscle mass.^{358–361} A novel mechanism for hypoglycemia, resulting from intracranial disease, would be alteration of the afferent or efferent limbs of hypothalamic glucose sensing; this has been demonstrated in rodents and has been invoked in rare cases of hypoglycemia accompanying brain tumors and trauma.³⁶²

Hypoglycemia accompanied by lactic acidosis has been reported as both uncommon presentations and end-stage events in patients with acute and chronic leukemias, and lymphomas.³⁶³ Children on prolonged chemotherapy regimens have been found to have a high rate of fasting hypoglycemia caused by depleted glycogen and gluconeogenic precursors and to direct effects of oral purine analogs.^{364–366}

Hypoglycemia in the Intensive Care Unit

Hypoglycemia is common in critically ill children,³³⁹ is often asymptomatic and, especially when associated with increased glucose variability, is associated with poorer outcomes (increased morbidity, length of stay, and mortality rates).³⁶⁷ In addition to processes specific to the underlying diseases, other contributing factors may include substrate depletion, accelerated glucose consumption, undernutrition, impaired gluconeogenesis, cytokine effects, and adrenal insufficiency. Iatrogenic factors, such as misplaced infusion lines, changes in the rate of intravenous dextrose administration, or drug effects need to be considered.³⁶⁸ Abrupt discontinuation of parenteral nutrition may lead to hypoglycemia, particularly in children younger than 3 years of age; accordingly, a gradual taper of the infusion rate is recommended to reduce the risk of reactive hypoglycemia.³⁶⁸ Factors affecting reliability of glucose measurement (e.g., altered hematocrit, oxygenation, line draws, drugs) are more common in the intensive care unit (ICU).³⁶⁹ As noted earlier, it is important to not forget the possibility that an acute illness is unmasking a previously compensated disorder of glucose metabolism, especially in a young child.³²⁸

Insulin use aiming for tight glycemic control to improve outcomes in critically ill children has recently become the most common cause of hypoglycemia in the ICU.^{370,371} However, a recent multicenter randomized clinical trial showed that critically ill children with hyperglycemia did not benefit from tight control, 80 to 110 mg/dL, as compared with target plasma glucose levels of 150 to 180 mg/dL.³⁷²

Reactive Hypoglycemia and “Spells”

Reactive hypoglycemia refers to symptomatic hypoglycemia occurring 1 to 4 hours after a meal, and is rare in children, apart from those who have had gastric surgery (fundoplication for gastroesophageal reflux or gastric bypass surgery for obesity). However, children with symptoms attributed to hypoglycemia are not infrequently referred to endocrinology clinics. Whipple’s triad (symptoms typical of hypoglycemia, associated with a documented low plasma glucose level and relieved by treatment to raise glucose) is suggested by guidelines from the Pediatric Endocrinology Society and the Endocrine Society as necessary before entertaining a diagnosis hypoglycemia, because the symptoms of hypoglycemia are very nonspecific.^{63,66} Although home blood glucose meters may be helpful in testing the possibility of hypoglycemia, caution is needed in considering their use because of problems with accuracy of the results (see later in Artfactual Hypoglycemia). An OGTT should not be relied on to diagnose reactive hypoglycemia, because many normal individuals develop asymptomatic low glucose 2 to 4 hours after the glucose load. Minor dietary modifications to avoid high glycemic index foods and inclusion of foods that are more slowly digested, together with protein and fat, are usually sufficient to control symptoms in reactive hypoglycemia.

Artfactual Hypoglycemia

A low plasma glucose level discovered unexpectedly in an apparently “well” child, who had an outpatient chemistry profile for reasons unrelated to carbohydrate metabolism, is most often a spurious result. The most common cause of artfactual hypoglycemia is improper handling of samples before their arrival in the laboratory. If blood is drawn and allowed to stand, glucose is consumed by both erythrocytes and leukocytes.³⁷³ If a whole blood sample is allowed to clot at a room temperature, the serum glucose concentration may decrease by 7 to 20 mg/dL/h. The rate of glycolysis is temperature dependent and immediate refrigeration of samples reduces but does not completely eliminate glucose consumption.³⁷⁴ Use of collection tubes that separate cells from serum also prevents glycolysis. Fluoride inhibits but does not eliminate glycolysis, and glucose levels may decrease by 20% or more when processing is delayed for even a few hours.³⁷⁵ Postphlebotomy glycolysis consumes a relatively higher proportion of glucose when the specimen contains a low glucose level at the time it was obtained, and spurious hypoglycemia is more common when either the red cell or white cell counts are elevated, and has also been described in a hemolytic crisis with a high count of nucleated red blood cells.^{376,377}

In 2013 the International Organization for Standardization (ISO) stated that blood glucose meters are acceptably accurate if 95% or more of measurement results are within ± 15 mg/dL or $\pm 15\%$ (whichever is larger) of reference values. Thus according to ISO, if the true blood glucose is 60 mg/dL, measured glucose could be 45 to 75 mg/dL. The 2014 US Food and Drug Administration (FDA) guide for over-the-counter blood glucose meters requires 95% or more of results to be within $\pm 15\%$ of reference values and 99% or more of results within $\pm 20\%$ across the whole glycemic range. Based on the FDA criteria, if the true blood glucose is 60 mg/dL, measured glucose would be considered acceptably accurate in the range of 51 to 69 mg/dL.³⁷⁸ Recent evaluations of commercially available blood glucose meters show considerable differences in performance in the low glucose range.^{379–382} Moreover, accuracy in the low glucose range varies considerably among meters; for example, one study showed that when the reference plasma glucose was less than 70 mg/dL, mean absolute differences of

various meters ranged from 2 to 11 mg/dL and mean absolute relative differences (MARD) ranged from 4.3% to 24.2%.³⁷⁹ In another study, MARD ranged from 8.9% to 39.2%, when reference plasma glucose was less than 70 mg/dL.³⁸²

Continuous glucose monitoring (CGM) devices are increasingly being used to track patterns of glucose, but absolute nadirs may be inaccurate and their usefulness in evaluating hypoglycemia is still uncertain.^{383,384} There are concerns about accuracy of CGM at low glucose concentrations; nonetheless, in one study using a glucose monitoring system, a majority of parents of children with congenital HI found the glucose trend to be useful.³⁸⁵ CGM has also been used to signal impending hypoglycemia in studies of tight glycemic control, in critically ill children,^{372,386} and although potentially useful, their use has not been systematically evaluated in the diagnosis and management of diverse hypoglycemia disorders. Several reports have suggested that use of CGM may decrease the frequency and duration of hypoglycemia in high-risk newborn infants.^{384,387,388} Trials are needed in patients with congenital HI before CGM can be recommended as a routine alternative method for monitoring glucose levels during treatment. There are also no data on the use of CGM for diagnosis of hypoglycemia, such as using it in the outpatient setting as an alternative to an inpatient fasting test.

Despite the aforementioned considerations, it is important to stress that unexpected low glucose levels should not be ignored because of the possibility that a “fluke” laboratory test may detect an unrecognized chronic hypoglycemic condition.

EMERGENCY TREATMENT OF HYPOGLYCEMIA

Once the critical sample has been obtained, a minibolus of 0.2 g/kg of dextrose should be administered by intravenous infusion over 1 minute (2 mL/kg of 10% dextrose). This should be followed by a continuous intravenous infusion of 8 mg/kg/min using dextrose 10% solution. This rate of glucose administration may be rapidly and conveniently calculated by using the simple formula that 5 mL/kg/h of a 10% dextrose solution provides approximately 8 mg/kg/min of glucose. Glucose levels should be determined 15 minutes after the bolus has been given and while the maintenance glucose infusion is running. If hypoglycemia recurs, a bolus of 0.5 g/kg may be given (5 mL/kg of dextrose 10%) and the glucose infusion increased by 25% to 50%. For details of specific treatments of individual disorders, see the sections on each condition.

TABLE 23.5 Protocols for Fasting Studies

Type of Fast	Purpose	Fasting Duration Based on Age	Plasma Glucose and BOHB Monitoring	End of Fast
Diagnostic fast	Establish diagnosis underlying patient's hypoglycemia	<1 month: 18 h 1–12 months: 24 h >12 months: 36 h >13 years: 72 h	Bedside meter glucose and BOHB: Q3 until PG <70, then Q1 until <60, then Q30 min until <50 mg/dL	End fast for: duration, PG <50 mg/dL, BOHB \geq 2.0 mmol/L \times 2, or symptomatic ^a GST: when PG <50 mg/dL, give 1 mg glucagon IV/IM and then monitor PG at 10, 20, 30, 40 min (omit if BOHB >2 mmol/L)
Safety fast	Test efficacy of existing regimen	Diazoxide <1 month: 8–12 h; 1–12 month: 12 h; >1 year: 18 h Octreotide: 6–8 h (skip a feed) Lanreotide: 18 h if off dextrose; 12 h if on continuous intra-gastric dextrose	Bedside meter glucose and BOHB: Q3 until PG <70 mg/dL	End fast for: duration, PG confirmed <70 mg/dL, BOHB \geq 2.5–3 mmol/L \times 2
Cure fast	Prove resolution of disease in those who have received definitive therapy or are off of medication	<1 month: 18 h; 1–12 months: 24 h; >1 year: 36 h; >13 years: 48 h Insulinoma >13 years: 72 h	Bedside meter glucose and BOHB: Q3 until PG <70, then Q1 until <60, then Q30 min until <50 mg/dL	End fast for: duration, PG confirmed <50 mg/dL, BOHB \geq 3 mmol/L \times 2, or symptomatic Obtain HI draw: PG, FFA, BOHB, insulin, IGFBP-1, C-peptide GST: when PG <50 mg/dL (if BOHB <3 mmol/L), give 1 mg glucagon IV/IM and then monitor PG at 10, 20, 30, 40 min

^aAt the end of the diagnostic fast, obtain the critical sample. If PG <50 mg/dL and BOHB <1.5 mmol/L, this is most compatible with HI. Therefore **HI labs are the most important to draw first:** PG, FFA, BOHB, insulin (consider also C-peptide, cortisol, GH, ammonia, lactate, acylcarnitine profile, carnitine, IGFBP-1). A GST is indicated if HI is suspected.

If BOHB \geq 2 mmol/L at conclusion of fast, this suggests some form of ketotic hypoglycemia. Therefore ketotic hypoglycemia labs are important to draw first: PG, FFA, BOHB, cortisol, GH, lactate, acylcarnitine profile, carnitine, insulin, C-peptide, ammonia, IGFBP-1. GST is NOT indicated.

BOHB, Beta-hydroxybutyrate; FFA, free fatty acids; GST, glucagon stimulation test; HI, hyperinsulinemia; IGFBP-1, insulin-like growth factor binding protein 1; IM, intramuscular; IV, intravenous; PG, plasma glucose.

APPENDIX: USEFUL TESTS FOR DIAGNOSIS OF HYPOGLYCEMIA DISORDERS

Diagnostic Fasting Test: Maximum duration of fast is based on age: younger than 1 month 18 h, 1–12 months 24 h, 1–12 years 36 h, older than 13 years 72 h. Time intervals between the samples are based on the plasma glucose (PG) levels: monitor PG and plasma BOHB using respective bedside meters every 3 hours until PG is less than 70 mg/dL, then every hour until PG is less than 60 mg/dL, then every 30 minutes until PG is under 50 mg/dL. Ending criteria for fast include: maximum duration (based on patient age), plasma glucose confirmed less than 50 mg/dL, BOHB 2.0 (or more) mmol/L \times 2, or severely symptomatic. After confirming that PG is under 50 mg/dL (e.g., in STAT laboratory measurement), draw the critical blood samples for laboratory tests (monitoring at intermediate time points of insulin, lactate, BOHB, FFA is often useful, especially if acute changes might occur in response to patient developing adrenergic symptoms; Table 23.5).

The Critical Sample: refers to laboratory tests drawn at the time of a PG under 50 mg/dL to help determine the etiology of hypoglycemia. The critical sample may include a comprehensive metabolic panel, insulin, BOHB, FFA, lactate, GH, cortisol, C-peptide, ammonia, acylcarnitine profile, free and total carnitine, IGFBP-1, urine ketones, urine organic acids. Normal responses to fasting hypoglycemia (PG <50 mg/dL) in infants, children, and adults are similar: insulin less than 2 to 3 μ U/mL (lower limit of assay), lactate lower than 1.5 mmol/L, BOHB greater than 2.0 mmol/L, FFA greater than 1.0 mmol/L (see Ferrara et al.⁷¹)

Glucagon Stimulation Test: At the end of the fasting test, after the critical samples have been obtained (and if the fast was ended for a PG <50 mg/dL and BOHB <2.0 mmol/L), give 1 mg of glucagon intramuscularly or intravenously. PG on bedside meter should be 50 to 55 (or less) mg/dL before administering glucagon (time zero). Check PG at time zero, 10, 20, 30, and 40 minutes. If PG has not risen by more than 20 mg/dL after 20 minutes, consider terminating the study. A positive (abnormal) response is a rise in PG by at least 30 mg/dL within 40 minutes, indicating that excess insulin action restrained glycogen breakdown that was overcome by the action of the high dose of glucagon.^{71,389}

Oral Protein Tolerance Test for Protein-Sensitive Hyperinsulinism

- Patient must be fasting (nothing by mouth [NPO]) for more than 3 hours
- Verify patient allergies because protein powder contains cow milk protein (whey)
- Beneprotein protein powder 1.16 g/kg (mix protein powder in 4 ounces of Crystal Light)
- Administer protein drink by mouth or by nasogastric (NG) tube within less than 5 minutes
- Laboratory specimens: PG, insulin at times –15, 0, +15, +30, +45, +60, +90, +120, +150, and +180 minutes
- Terminate test if PG is less than 50 mg/dL during oral protein tolerance test
- Interpretation: Positive (abnormal) response is a fall in PG of more than 12 mg/dL and below 70 mg/dL.¹⁰⁵

Oral Glucose Tolerance Test for Postprandial Hypoglycemia

- Patient must be NPO 4 hours before the start of study

- Administer dextrose (e.g., Glucola) 1.75 g/kg PO within 15 to 20 minutes or via NG tube—maximum 75 g.
- Laboratory specimens at times –15, zero, +30, +60, +90, +120, +150, +180, +210, and +240 minutes for PG and insulin

Interpretation: Children with late dumping hypoglycemia caused by Nissen fundoplication have an exaggerated insulin increment ($220 \pm 310 \mu$ IU/mL [1610 ± 2250 pmol/L]), followed by a hypoglycemic nadir PG (47 ± 11 mg/dL [2.6 ± 0.6 mmol/L]) after oral glucose. They also usually, but not always, have an exaggerated rise in PG (180 ± 87 mg/dL [10 ± 4.9 mmol/L]) compared with controls: insulin increment $36 \pm 22 \mu$ IU/mL (255 ± 160 pmol/L); nadir PG 86 ± 21 mg/dL (4.8 ± 1.2 mmol/L); PG rise 58 ± 40 mg/dL (3.2 ± 2.2 mmol/L).¹⁷⁴

INTRODUCTION

The global prevalence of pediatric obesity has increased by a staggering eightfold over the past 4 decades with a current estimate of 124 million children, ages 5 to 19, having obesity worldwide.¹ The concept of the adipocyte functioning as an endocrine organ rather than simply serving as a repository for lipid storage emerged a quarter of a century ago when leptin was identified as the first of many adipokines produced by fat tissue.² Thus given that the pathophysiology of obesity is a form of endocrine derangement at its core, and because many of the complications associated with obesity have an endocrine component in nature, pediatric endocrinologists are increasingly receiving referrals for the treatment of obesity and its comorbidities. Type 2 diabetes, which was once rare in children and is typically associated with obesity, now comprises approximately one-third of all new diagnoses of pediatric diabetes and continues to rise by nearly 5% in annual incidence rate among youth.³

This chapter provides a framework for understanding the regulation of energy balance and summarizes approaches for

assessing and managing pediatric patients with obesity. On the flip side of the energy-balance coin, disorders of energy inadequacy are also discussed in this chapter, and they provide insight on the converse problem of nutritional insufficiency. Although the relative dearth of current knowledge on how best to ameliorate the complex biologic, behavioral, and environmental contributors to energy imbalance poses a therapeutic challenge, recent advances in novel “precision medicine” approaches that target specific defects in energy homeostasis provide insights into potentially effective treatments for both obesity and underweight disorders.

ENERGY BALANCE

The major components of energy balance are energy intake, energy expenditure, and energy storage. Sources of energy intake include carbohydrate (4 kCal/g), protein (~4 kCal/g), fat (9 kCal/g), and alcohol (7 kCal/g), typically negligible in children, but possibly significant in some adolescents. Energy expenditure is comprised of basal metabolic rate ([BMR],

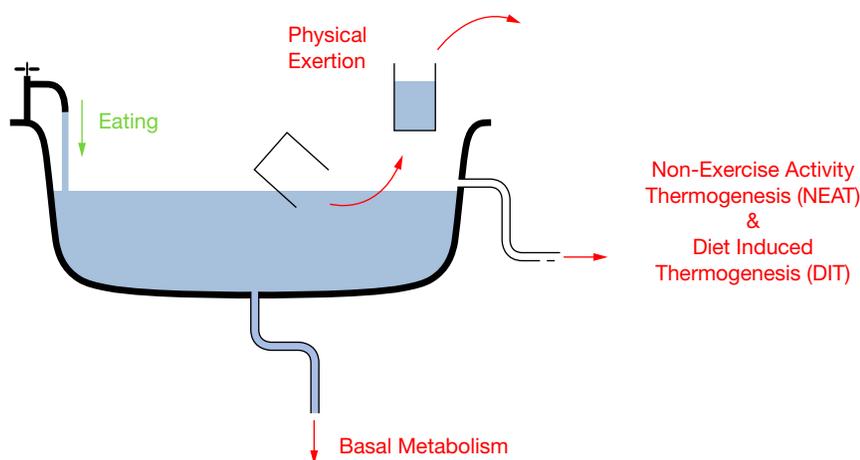

Fig. 24.1 Determinants of total body energy stores as represented by water in a bathtub. (Figure by Clint Kinney, PhD, modified from Rogers, P.J., Brunstrom, J.M. (2016). Appetite and energy balancing. *Physiol Behav*, 164, 465–471).

energy needed to maintain bodily functions, highly correlated with lean muscle and organ mass, and affected by various disease states), thermic effect of food (energy used to digest food, diet-induced thermogenesis [DIT]), and physical activity (exercise and nonexercise activity thermogenesis [NEAT], which includes activities of daily living, fidgeting, and posture maintenance). Energy storage, primarily in the form of fat, occurs when intake exceeds expenditure.⁴ Using a bathtub (Fig. 24.1) as an analogy for energy balance with the water level representing total energy stores, the water volume (total body fat) is determined by intermittent addition of water from the faucet (meals), episodic removal of water buckets (physical exertion), continual drainage of water from a bottom drain (BMR), and overflow drainage of water from an upper drain (NEAT and DIT) that is positioned at the set point for maximal water level (individual homeostatic set point).⁵ Changes in faucet flow rate, size of buckets, aperture diameter of the drains, and height of overflow set point together determine the water level in the bathtub.

Human energy balance is regulated by intricately connected homeostatic and non-homeostatic mechanisms. The homeostatic system maintains body fat stores within a fairly tight range for each individual, remarkably within around 10 kCal/d on average,^{6,7} such that even small perturbations in balance can lead to cumulative weight gain over time.⁸ The non-homeostatic system mediates environmental and cognitive factors that motivate eating, including the reward aspects of food intake and learned behaviors that lead to food consumption for reasons other than fulfillment of nutritive needs. The neural circuitry and neuroendocrine hormones of the homeostatic and non-homeostatic processes interact and overlap to form a complex system that integrates temporal, spatial, and contextual signals of metabolic status and higher-order brain function.⁹ Because survival depends on an adequate supply of energy, the evolutionary calibration of energy balance favors food consumption and promotes excess energy storage to protect against starvation when food is scarce.⁵ Consequently, in our modern era, in places where food is readily available in abundance, especially highly palatable, energy-dense foods, the inhibitory mechanisms for appetite regulation may be inadequate for preventing overconsumption.

Regulation of Food Intake

Human meal patterning is typically characterized by discrete bouts of food consumption interspersed with periods of fasting. The time-course of each meal follows a cycle, comprised

of cephalic, gastric, and intestinal phases followed by a postabsorptive state.¹⁰ The cephalic phase consists of the physiologic responses to the thought, sight, smell, and taste of food in anticipation of ingestion. In the gastric phase, ingested food enters the stomach and digestion formally begins. As food leaves the stomach, the intestinal phase begins, where secreted pancreatic enzymes enhance digestion and nutrient absorption. Finally, in the postabsorptive state, nutrient absorption from the meal is complete and circulating glucose concentrations are maintained by glycogenolysis and gluconeogenesis until initiation of the next meal.

Short-term regulation of appetite determines satiety (time period between meals before hunger prompts meal initiation) and satiation (sensation of having eaten enough, leading to meal termination). Food intake is driven by a combination of hunger, social context, and sensory inputs.⁷ Hunger is mediated by a drop in anorexic (appetite-suppressing) signals in the postabsorptive state following the prior meal, and by a rise in ghrelin, an orexigenic (appetite-stimulating) peptide secreted by the enteroendocrine cells of the stomach during fasting. Nutrient ingestion leads to a rise in anorexic signals, including gastric wall stretch and mechanical contact with food, secretion of intestinal peptides (e.g., cholecystokinin [CCK], peptide YY, glucagon-like peptide 1 [GLP-1], etc.), and entry of digested nutrients into circulation.¹⁰ The vagal nerve is the primary neural connection between the gastrointestinal (GI) tract and the central nervous system (CNS).¹¹ It is the longest cranial nerve and contains both sensory and motor fibers involved in the regulation of parasympathetic (“rest and digest”) homeostasis.¹² Vagal sensory afferents from the gut terminate in the hindbrain where connections to cortical, forebrain, and midbrain regions are involved in vagal motor efferent regulation of GI motility and secretory functions for digestion.¹³ Importantly, the GI tract is also innervated by the spinal nerves, which convey sensory inputs from the intestinal tract to the homeostatic centers. Satiation is reached when ghrelin drops; gastric distension triggers anorexic vagal afferents to the hindbrain; and increases in glucose, insulin, and anorexic peptides lead to slowing of gastric motility and signaling of fullness to the CNS. Satiety, which determines the interval until the next meal, is influenced by the quantity and composition of the prior meal and additional physiologic contributors, such as gut microbiota, fermentation products, and bile acids.¹⁴

Nonnutritive aspects of meal regulation include food palatability and neuropsychologic factors, such as mindfulness, stress, cognitive demands, and alertness.¹⁵ Food craving is linked to the hedonic aspects of eating because of activation

of the mesocorticolimbic reward pathway. Opioid receptor activation mediates the reward sensation of food and the pleasure of eating, whereas dopaminergic activation mediates the reward value of food and the motivation to obtain food.¹⁶ Social context (gatherings and events where food consumption is expected) and sensory inputs (sight and smell of palatable food) can drive food intake in the absence of hunger, making environmental contingencies and stimulus control just as critical to address as physiologic cues for obesity management.⁵

HOMEOSTATIC SYSTEM FOR ENERGY BALANCE

The CNS is the control center for energy homeostasis. Afferent signals from the periphery deliver energy status information to the brain, which processes these cues and then delivers efferent signals to modulate energy intake and expenditure. The system is directed by several hypothalamic nuclei, which receive an array of hormonal, neural, environmental, and cortical inputs. These signals activate, based on their directionality, anorexigenic or orexigenic signal transduction pathways. The output of the system is conveyed via the autonomic nervous system and is translated by peripheral organs into food-seeking behavior, energy conservation/wasting, and physiologic adaptations (a simplified vision of these pathways is shown in Fig. 24.2). The physiologic target of energy homeostasis is to maintain stable levels of total body fat rather than overall weight per se. Therefore leptin, which is secreted in proportion to total fat mass, functions suitably as a key circulating signal to convey adiposity status to the CNS.^{17–19} Binding of these hormones to their respective receptors within the hypothalamic arcuate nucleus (ARC) upregulates anorexic/catabolic signals from proopiomelanocortin (POMC)/cocaine-amphetamine-related transcript (CART) expressing neurons and downregulates orexigenic/anabolic signals from Agouti-related peptide (AgRP)/neuropeptide Y (NPY) expressing neurons. A schematic of these energy homeostasis pathways is shown in Fig. 24.3, and further details about individual hormones are described later.²⁰

The Afferent System

Monitoring of metabolic status occurs in multiple regions of the body and assesses circulating forms of energy that are available for immediate use and fluctuate over the course of a meal cycle, as well as more constant stored forms of energy, namely fat. Direct detection of circulating forms of energy uses specific receptors for micronutrients²¹ or cellular detection systems, such as glycolytic flux generating varying amounts of adenosine triphosphate (ATP) depending on glucose availability.²² Indirect surveillance involves paracrine and endocrine hormones that reflect energy status and also stretch receptors in the GI tract that detect volume of material within the gut, nutritive or otherwise, rather than micronutrients specifically. The bloodstream and the autonomic nervous system, mainly the afferent vagus nerve, are the primary routes for transmission of metabolic information from the periphery to the CNS. The mediobasal hypothalamus (MBH), contains the ARC, ventromedial hypothalamic nucleus [VMH], and median eminence [ME] and dorsal vagal complex (DVC, contains the nucleus of the solitary tract [NTS], the area postrema [AP], and dorsal motor nucleus of the vagus nerve [DMV]) of the brainstem medulla have a special fenestrated blood-brain barrier (BBB),²³ allowing circulating hormones and micronutrients to diffuse into these brain regions for detection by specific receptors and sensing mechanisms.^{22,24–26} The DVC also receives sensory afferents from the vagal nerve, which innervates the GI tract from the esophagus to the colon and delivers information from chemical and mechanical sensors in the gut to the CNS.²⁷

Positive Regulation

In addition to intrinsic neurocircuitry that favors positive energy balance by default, currently, one additional positive regulatory signal from the periphery is known to enhance this drive.

Ghrelin. Ghrelin is an octanoylated 28-amino-acid peptide that is a ligand of the growth hormone secretagogue receptor

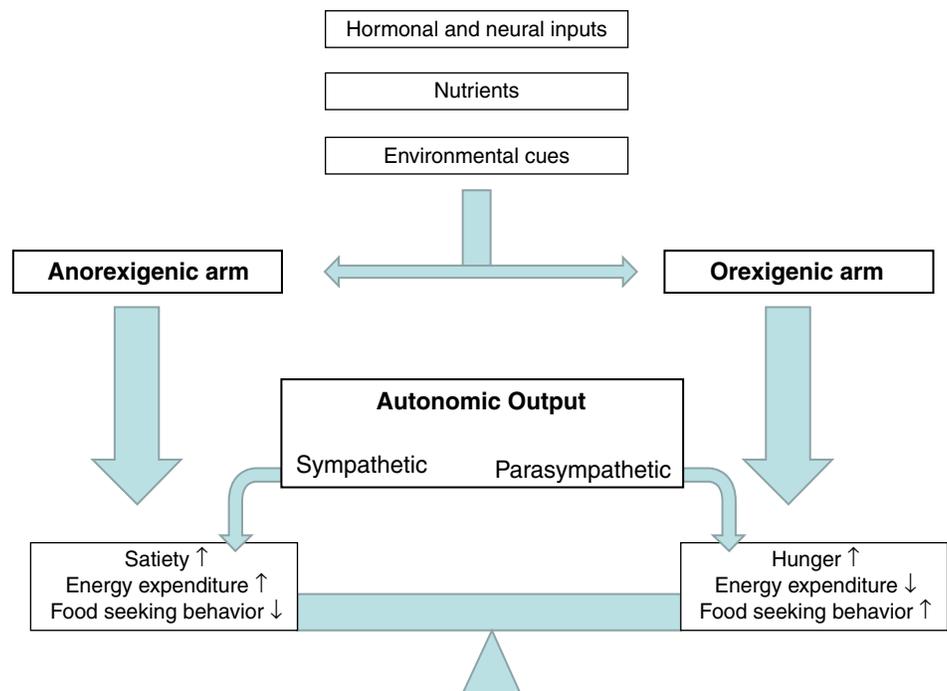

Fig. 24.2 Simplified view of the homeostatic energy system and its inputs/outputs. Hypothalamic nuclei govern homeostasis. Their inputs include hormones (such as leptin or ghrelin), neural inputs (directly from the gastrointestinal tract), nutrients, and environmental cues. The integration of these signals leads to an autonomic output that determines the dominance of the orexigenic or anorexigenic arms.

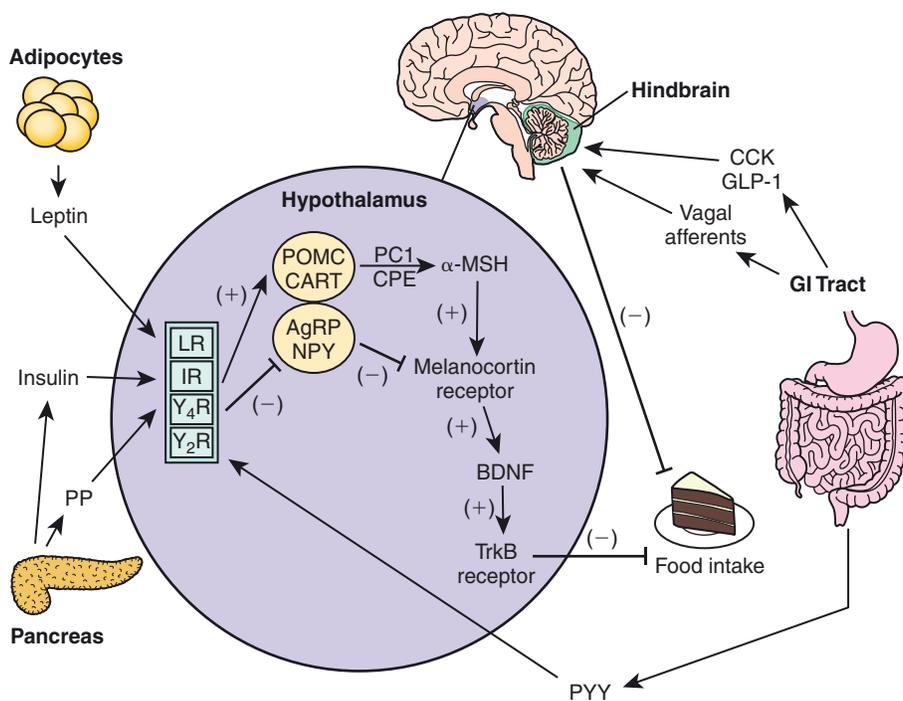

Fig. 24.3 Schematic of energy homeostasis pathways. Lines with arrowheads show stimulatory action. Lines with perpendicular end-blocks show inhibitory action. *AgRP*, Agouti-related peptide; *BDNF*, brain-derived neurotrophic factor; *CART*, cocaine-amphetamine-related transcript; *CCK*, cholecystokinin; *CPE*, carboxypeptidase E; *GI*, gastrointestinal; *GLP-1*, glucagon-like peptide 1; *IR*, insulin receptor; *LR*, leptin receptor; *MSH*, melanocyte-stimulating hormone; *NPY*, neuropeptide Y; *PC1*, prohormone convertase 1; *POMC*, proopiomelanocortin; *PP*, pancreatic polypeptide; *PYY*, peptide YY; *TrkB*, tropomyosin-related kinase B; *Y₂R*, type-2 neuropeptide Y receptor; *Y₄R*, type-4 neuropeptide Y receptor. (Figure modified from Han, J.C., Lawlor, D. A., Kimm, S.Y. (2010). Childhood obesity. *Lancet*, 375(9727), 1737–1748.)

(GHSR) and endogenously secreted by the stomach and duodenum in the fasting state.²⁸ Ghrelin circulates within the bloodstream to the CNS, where it binds GHSRs in the hypothalamus and brainstem, accessed through fenestrations and selective transport across the BBB.^{29–31} Pituitary GHSR stimulation induces growth hormone (GH) release whereas VMH GHSR stimulation promotes positive energy balance through increased hunger, food intake, fat deposition, and reduced energy expenditure.^{32–35} To date, ghrelin is the only known peripherally produced orexigenic peptide hormone. Ghrelin secretion by the stomach terminates upon entry of nutrients into the stomach and intestines after meal consumption.¹² Ghrelin rises in conjunction with increasing hunger, and ghrelin peaks at the conclusion of satiety when voluntary food consumption begins.³⁶ Exogenous ghrelin infusion induces food intake, supporting the role of ghrelin in triggering meal initiation.³⁷ Individuals with obesity compared with normal weight controls have a globally lower plasma ghrelin concentration but retain a similar circadian pattern of rise in ghrelin with fasting and decrease with meal intake,³⁸ suggesting that ghrelin is responsive to, rather than a cause of, obesity. Weight loss because of dietary restriction leads to a rise in ghrelin whereas gastric bypass surgery results in decreased ghrelin,³⁸ which may contribute to the differences in weight regain after weight loss by these different approaches. Importantly, ghrelin is activated from its prohormone form by binding of octanoic acid to a serine residue by ghrelin O-acetyltransferase (GOAT). The unacylated form is active as a homeostatic signal yet does not bind to the GH receptor.³⁹

Negative Regulation

Satiation, satiety, and expenditure of excess energy are achieved by negative regulatory elements that respond acutely to intake and to long-term energy stores.

Stretch Receptors. Ingested material entering the stomach applies pressure to the gastric wall although mechanosensitive receptors formed by vagal afferents whose cell bodies reside in the nodose ganglion and terminals lie within the NTS of the

brainstem DVC. The stretch signal slows gastric emptying, which promotes retention of food in the stomach allowing satiation to be reached.¹²

Glucose. Digestion of carbohydrates leads to liberation of glucose and other sugars, which are readily absorbed into the hepatic portal vein and taken up by liver hepatocytes. A significant portion of the incoming glucose also enters into systemic circulation,⁴⁰ and blood glucose levels are detected by glucose-sensing neurons in the brain that are involved in regulation of glucose homeostasis, as well as energy balance.^{41–43} A subset of glucose-excited neurons responds to postprandial increases in glucose by stimulating energy expenditure through thermogenesis,⁴² whereas a subset of glucose-inhibited neurons respond to increased glucose by reducing the activity of hunger circuitry with the CNS.⁴⁴

Insulin and Amylin. Glucose entry into circulation from meal absorption triggers a proportional release of the peptide hormones insulin and amylin from pancreatic β -cells.⁴⁵ Circulating insulin induces cellular uptake and utilization of glucose and glycogen synthesis,⁴⁶ and enters the CNS through active transport across the BBB⁴⁷ or through fenestrations in the BBB at the MBH and DVC to promote satiety and increasing energy expenditure.⁴⁸ Amylin enhances satiation by slowing gastric emptying⁴⁹ and mediates satiety through its actions in AP of the DVC.⁵⁰

Cholecystokinin. As food enters the proximal small intestine, enteroendocrine I-cells in the duodenum and proximal jejunum respond to nutrients, most strongly to long-chain free fatty acids (FFAs), by secreting CCK, an 8-amino-acid peptide with paracrine and endocrine hormone actions. Locally, CCK binds receptors in the pylorus to promote delayed gastric emptying, and stimulates vagal afferent receptors within the proximal intestine that transmit signals to the NTS and AP of the DVC to induce satiation.⁵¹ CCK also circulates within the bloodstream to the BBB-fenestrated MBH and DVC to suppress hunger and promote meal termination.⁵²

Peptide YY, Glucagon-Like Peptide-1, and Oxyntomodulin. As food enters the lower GI tract, enteroendocrine L-cells residing primarily in the ileum and colon become activated

and secrete the peptide hormones peptide YY (PYY), GLP-1, and oxyntomodulin into circulation.⁵³ The segment of intestine that secretes PYY, GLP-1, and oxyntomodulin is both downstream and considerably longer than that of the region where CCK is released, and thus the passage of food through this later segment of the gut leads to prolonged satiety between meals.⁵⁴

PYY circulates within the bloodstream to the brain as peptide fragments, predominantly as the 34-amino-acid PYY₃₋₃₆,⁵⁵ and binds type-2 neuropeptide Y receptors (Y2Rs), predominantly in the ARC,⁵⁶ where it suppresses orexigenic NPY signaling and activates anorexigenic POMC signaling, together inducing satiation and satiety. PYY also acts in a paracrine fashion by locally activating intestinal afferent vagal neurons that transmit anorexigenic signals to the DVC.⁵⁷

GLP-1 is produced by prohormone convertase 1 (PC1)-mediated proteolytic cleavage of proglucagon within L-cells, and acts on the stomach to slow gastric emptying, contributing to satiation through food retention. GLP-1 also circulates to the MBH and DVC where it activates its receptor to induce satiation and satiety. In addition to these effects on energy homeostasis, GLP-1 also acts as an incretin (enhancer of glucose-dependent insulin secretion) upon binding of GLP-1 receptors expressed in pancreatic β -cells, thereby enhancing insulin-mediated negative energy balance.⁵⁸

Oxyntomodulin is also produced through PC1-mediated proteolytic cleavage of proglucagon as a separate product from GLP-1.⁵⁹ Oxyntomodulin activates the GLP-1 receptor, but appears to act as a biased agonist that preferentially engages different intracellular signaling pathways from that of GLP-1, resulting in extended actions on satiation and satiety.⁶⁰ Oxyntomodulin also activates the glucagon receptor, which stimulates energy expenditure through increased thermogenesis.⁶¹

Pancreatic Polypeptide. Food ingestion stimulates, via CCK and vagal efferent signals delivered to the pancreas, the secretion of pancreatic polypeptide (PP) from pancreatic PP-cells into circulation.^{62,63} Circulating PP slows gastric emptying and mediates satiety by activating type-4 NPY receptors (Y4Rs) in the hypothalamus that increase anorexigenic POMC neuronal activity and decrease orexigenic NPY expression.^{64–66} Postprandial PP levels remain elevated for several hours, likely persisting into the postabsorptive phase and mediating satiety.⁶⁷

Bile Acids and Fibroblast Growth Factor 19. Bile acids are synthesized from cholesterol in the liver and are secreted into the duodenum after a meal, serving as lipid emulsifiers and signaling molecules of nutritional status via the G-protein-coupled receptor 19 (GPCR19) and farnesoid X-activated receptor (FXR). GPCR19 and FXR are expressed in the small intestine, liver, and adipose tissue. Activation of GPCR19 stimulates GLP-1 secretion and increases colonic peristalsis. Activation of FXR induces fibroblast growth factor 19 (FGF19) secretion into the bloodstream. FGF19 regulates lipid and glucose metabolism within the liver and also acts within the CNS to reduce food intake and increase energy expenditure.¹²

Leptin. Adipocytes secrete the 167-amino-acid peptide hormone leptin in proportion to the amount of stored body fat.^{68,69} Typically, this secretion follows a circadian pattern with higher levels at night during sleep.⁷⁰ However, when the post-absorptive phase progresses into extended fasting and subsequent starvation, leptin levels rapidly decrease, leading to potent food-seeking behavior.^{71–76} This striking effect indicates that an acute drop in leptin serves as a starvation signal and confirms leptin's primary role as a protector of energy stores rather than as a preventer of obesity.⁷⁷ Importantly, this acute effect is achieved regardless of basal leptin levels, thus starvation or extended fasting induces the same metabolic adaptations and behaviors in individuals with and without obesity.

Leptin secretion is enhanced by markers of nutrient availability, including glucose, insulin, and cortisol, which all rise with meal intake,^{78–80} and is suppressed by catecholamines released with activation of the sympathetic nervous system (SNS, consistent with the “fight or flight” response requiring diversion of attention away from “rest and digest” behaviors).⁸¹ Leptin is a pre-requisite signal of sufficient energy stores to permit initiation of high-energy processes, such as puberty and pregnancy.^{82,83} Programming of relative leptin concentrations by early caloric intake may be one mechanism that links early over nutrition with later obesity.⁸⁴

Leptin accesses the CNS through the BBB fenestrations of the MBH and DVC and is also actively transported across the BBB.^{85,86} Leptin's primary site of action is the MBH but it also acts in other regions in the CNS and periphery. Leptin receptors are expressed by white adipocytes suggesting paracrine autoregulation,⁸⁷ liver hepatocytes,⁸⁸ pancreatic islet cells including insulin-secreting β -cells,⁸⁹ neurons throughout the brain, and a portion of brain vascular endothelial cells (cerebrovascular cells) that form the BBB.^{90–92} The leptin receptor (a member of the cytokine receptor superfamily) has four isoforms, formed by differential messenger ribonucleic acid (mRNA) splicing: ObRa, an isoform with a shortened intracellular domain, which may function as a transporter; ObRb, the intact full-length receptor; ObRc, also with a short intracellular domain; and ObRe, without an intracellular domain, but which may function as a soluble receptor.⁹³ Leptin receptor (LepR) activation leads to three primary neuronal signals. The first is the opening of an ATP-sensitive potassium channel, which hyperpolarizes the neuron and decreases its firing rate.⁹⁴ The second is the activation of a cytoplasmic Janus kinase 2 (JAK2), which phosphorylates a tyrosine moiety on proteins of a family called *signal transducers and activators of transcription* (STAT-3).⁹⁵ The phosphorylated STAT-3 translocates to the nucleus, where it promotes leptin-dependent gene transcription.⁹⁶ However, leptin also activates the insulin receptor substrate 2/phosphatidylinositol-3-kinase (IRS-2/PI3K) second messenger system, which increases neurotransmission of the central anorexigenic signaling pathway.⁹⁷

LepR activation in hypothalamic and brainstem regions suppresses the activity of orexigenic neurons and activates anorexigenic activity that increases energy expenditure.^{98–102} LepR activation increases SNS efferent tracts connected to adipocytes and acts to reduce leptin secretion, suggesting that leptin, like classic hormones, may be autoregulated by an endocrine feedback loop.¹⁰³ Leptin also appears to have a role in regulating energy thermogenesis through reduction in the thermoregulatory tolerance of colder temperatures, in essence increasing the body's thermostat to a higher temperature set-point.^{104,105} Thus when leptin levels are reduced during fasting, body temperature is not defended as strongly and thermogenic energy expenditure is therefore decreased to conserve energy stores.

Central Processing

The peripheral afferent signals outlined earlier reach the CNS and act primarily within the hypothalamus and brainstem, where they are integrated by a gated neural circuit, designed to promote net catabolic or anabolic effects (see Fig. 24.2).

Central Catabolic Signals

POMC/CART Neurons. The ARC houses neurons that coexpress POMC and CART. POMC is a peptide that is proteolytically cleaved by PC1 and carboxypeptidase E (CPE) to form different peptides depending on neuron type and location. Cleaved products include β -endorphin, adrenocorticotrophic hormone (ACTH), and, in ARC POMC-expressing neurons

(ARC^{POMC}), α -melanocyte-stimulating hormone (α -MSH). Both overfeeding and peripheral leptin infusion induce the synthesis of POMC and α -MSH within the ARC.¹⁰⁶ ARC^{POMC} neurons are also directly activated by insulin, glucose, and serotonin.¹⁰⁷ ARC^{POMC} neurons are inhibited by ghrelin and AgRP neurons.¹⁰⁸ α -MSH induces anorexia by binding to receptors within the paraventricular hypothalamic nucleus (PVN) and lateral hypothalamus (LHA). CART is a hypothalamic neuropeptide induced by leptin and reduced by fasting. Intrahypothalamic infusion of CART blocks appetite, whereas antagonism of endogenous CART increases caloric intake.¹⁰⁹

Melanocortin Receptors. The cleaved peptide products of POMC bind to and activate various 7-transmembrane G-protein-coupled melanocortin receptors (MCRs): MC1R in skin and hair stimulates production of the dark pigment, melanin; MC2R in the adrenal glands stimulates production of glucocorticoids; and melanocortin-4 receptor (MC4R) and melanocortin-3 receptor (MC3R) in the CNS induce negative energy balance. Activation of MC4R in the PVN and LHA results in a state of satiety, whereas intracerebroventricular (ICV) administration of MC4R antagonists in rodents stimulates feeding.¹¹⁰ MC4R-null mice display severe hyperphagia and obesity. MC3R-null mice display milder obesity and are not hyperphagic but appear to have higher feeding efficiency and greater fat partitioning.^{111–113}

Brain-Derived Neurotrophic Factor. Brain-derived neurotrophic factor (BDNF) is an activity-dependent neurotrophin that regulates synaptic plasticity.¹¹⁴ BDNF has additionally been shown to play an important role in energy homeostasis as a downstream mediator of the leptin-melanocortin pathway.¹¹⁵ BDNF expression in the VMH is regulated by nutritional state and MC4R signaling.^{116,117} Selective deletion of BDNF from VMH and dorsomedial hypothalamic nucleus (DMH) of adult mice causes hyperphagia and obesity,¹¹⁶ whereas infusion of BDNF into VMH of wild-type (WT) rats reduces food intake and increases energy expenditure.^{118,119} In the anterior PVN, BDNF suppresses food intake and increases locomotor activity, whereas in medial and posterior PVN, BDNF stimulates thermogenesis through increased SNS outflow.¹²⁰ BDNF haploinsufficiency in both humans and rodents is associated with obesity, which in mice, can be prevented with pair-feeding, suggesting hyperphagia as the primary driver of weight gain.^{121–125} BDNF dysfunction may also contribute to overeating behaviors found in Prader-Willi syndrome (PWS) and Smith-Magenis syndrome (SMS), as well as in common eating disorders.^{126–131} The BDNF Val66Met polymorphism, which impairs activity-dependent BDNF secretion, is linked to binge episodes in bulimia nervosa and binge eating disorder,¹³² and BDNF hypermethylation is associated with bulimia nervosa.¹³³ The intronic BDNF rs12291063 variant (homozygous in ~10% of individuals with African ancestry) is associated with reduced VMH BDNF expression and increased adiposity.¹³⁴ Together these observations indicate that BDNF insufficiency may underlie common, as well as rare causes of overeating behaviors.

Tropomyosin-Related Kinase B Receptor. Tropomyosin-related kinase B (TrkB) is encoded by the *NTRK2* gene and is the cognate receptor for BDNF. Chemogenetic activation of TrkB-expression neurons in the DMH suppresses feeding during the dark cycle when mice are physiologically hungry, whereas chemogenetic inhibition of these neurons promoted feeding during the light cycle when mice are physiologically satiated. Selective *Ntrk2* deletion in the DMH of adult mice induces hyperphagia, decreased energy expenditure, and obesity.¹³⁵

Norepinephrine. Norepinephrine (NE) neurons in the locus coeruleus synapse on VMH neurons to regulate food intake.¹³⁶ In rodents, the actions of NE on food intake seem paradoxical, as intrahypothalamic NE infusion stimulates food intake through

effects on central α_2 - and β -adrenergic receptors,¹³⁷ whereas central infusion of α_1 -agonists markedly reduces food intake.¹³⁸

In human studies using molecular neuroimaging, NE transporter availability was negatively associated with perceptions of hunger and the strength of this association was stronger among individuals with obesity compared with normal-weight controls, suggesting that NE has a role in modulating hunger.¹³⁹

Serotonin (5-hydroxytryptamine). 5-Hydroxytryptamine (5-HT) has been implicated in the perception of satiety based on many lines of evidence: (1) injection of 5-HT into the hypothalamus increases satiety, particularly with respect to carbohydrate¹⁴⁰; (2) central administration of 5-HT_{2c} receptor agonists increase satiety, whereas antagonists induce feeding¹⁴¹; (3) administration of selective 5-HT reuptake inhibitors induce early satiety¹⁴²; (4) leptin increases 5-HT turnover¹⁴³; and (5) the 5-HT_{2c}R-KO mouse exhibits increased food intake and body weight.¹⁴⁴ The role of 5-HT in the transduction of the satiety signal may have both central and peripheral components, as intestinal 5-HT is secreted into the bloodstream during a meal, where it may have an impact on GI neuronal function and muscle tone, and may bind to 5-HT receptors in the NTS (discussed previously) to promote satiety.¹⁴⁵ Molecular neuroimaging in humans suggests that obesity is driven by decreased serotonin-mediated homeostatic feedback in response to food intake.¹⁴⁶

Central Anabolic Signals

AgRP/NPY Neurons. NPY and AgRP colocalize to a different set of neurons within the ARC, immediately adjacent to those expressing POMC/CART.¹⁴⁷ The ARC houses the only population of neurons that express AgRP, and the majority of these neurons coexpress NPY.¹⁴⁷ These two orexigenic peptides are secreted from nerve terminals as peptide neurotransmitters, in addition to the inhibitory small-molecule neurotransmitter gamma-aminobutyric acid (GABA). AgRP is the human homolog of the protein agouti, which is present in abundance in the Agouti yellow mouse (A^y-a).¹⁴⁸ AgRP is an endogenous competitive antagonist of all MCRs, accounting for the yellow color in these mice because of its inhibitory actions at the MCR1 receptors of the fur. AgRP also antagonizes MC4R and MC3R, thereby attenuating the ability of α -MSH to suppress appetite and fat deposition.¹⁴⁹ AgRP neurons also suppress SNS-mediated “browning” of white adipose tissue which would otherwise increase energy expenditure,^{150,151} thus reducing thermogenesis and promoting positive energy balance. AgRP neurons are directly activated by the orexigenic hormone ghrelin¹⁵², dopamine, which may originate from dopamine neurons residing within the ARC¹⁵³; and several glutamatergic projections from other hypothalamic nuclei including the DMH (which exhibits leptin BBB transport and activity) and the PVH.¹⁵⁴ AgRP neurons are inhibited by leptin,¹⁵⁵ insulin,¹⁵⁶ PYY,⁵⁵ and by GABAergic projections from the DMH and other arcuate neurons.¹⁵⁷

NPY has numerous functions within the hypothalamus, including initiation of feeding, regulation of gonadotropin secretion, and modulation of adrenal responsiveness.^{158,159} NPY acts as an orexigen and it also stimulates adipogenesis.¹⁶⁰ ICV infusion of NPY in rats rapidly leads to hyperphagia, energy storage, and obesity,^{161,162} mediated through Y₁ and Y₅ receptors. Fasting and weight loss increase NPY expression in the ARC, accounting for increased hunger, whereas PYY_{3–36} (through Y₂ receptors) and leptin decrease NPY mRNA.^{55,163}

Melanin-Concentrating Hormone. Melanin-concentrating hormone (MCH) is a 17-amino-acid orexigenic peptide expressed in the zona incerta and LHA. MCH-knockout mice are hypophagic and lean,¹⁶⁴ whereas transgenic MCH-overexpressing mice develop obesity and insulin resistance.¹⁶⁵ ICV

administration of MCH stimulates food intake, similar to that seen with NPY administration.¹⁶⁶ Interestingly, endogenous MCH circulation within the cerebrospinal fluid (CSF) may in fact represent an alternative neural communication mechanism in the regulation of food intake with rise in CSF concentrations of MCH driving the initiation of food intake.¹⁶⁷

Orexins A and B. Orexin A and B are orexigenic peptides (33 and 28 amino acids in length, respectively) produced within the hypothalamus and modulate both energy balance and autonomic function in mice.^{168–170} Orexins stimulate release of NPY, corticotropin-releasing hormone (CRH), and SNS outflow leading to increased food intake, wakefulness, blood pressure, and energy expenditure. The orexins also appear to bridge the homeostatic and non-homeostatic mechanisms that regulate food intake and may play a role in reward-based learning and memory.¹⁷¹ Orexin neurons in the LHA process the hedonic aspects of food and drugs of abuse, whereas orexin neurons in the perifornical and DMH regulate arousal and stress response.¹⁷²

Endocannabinoids. Tetrahydrocannabinol, the main psychotropic component of marijuana, has long been known to stimulate food intake. The endogenous endocannabinoid (EC) receptor, CB₁, is expressed in corticotropin-releasing hormone (CRH) neurons in the PVN, in CART neurons in the VMN, and in MCH- and orexin-positive neurons in the LHA and perifornical region.¹⁷³ Fasting and feeding are associated with high and low levels of ECs in the hypothalamus, respectively. For example, CB₁ receptor-knockout mice have increased CRH and reduced CART expression. In the leptin-deficient *ob/ob* mice, hypothalamic EC levels are increased, whereas leptin infused intravenously reduces these levels, indicating that a direct negative control is exerted by leptin on the EC system. Glucocorticoids increase food intake by stimulating EC synthesis and secretion, whereas leptin blocks this effect.¹⁷⁴ Also the presence of CB₁ receptors on afferent vagal neurons suggests that EC may be involved in mediating satiety signals originating in the gut.¹⁷⁵

The Efferent System

The MCRs in the PVN and LHA transduce the anorexigenic and orexigenic information coming from the VMH, to modulate activity of the SNS, and the efferent vagus, which promotes energy storage (Fig. 24.4). In this way, peripheral energy balance can be modulated acutely to provide requisite energy for metabolic needs, and store the rest.

The Sympathetic Nervous System and Energy Expenditure

Anorexigenic pressure increases energy expenditure through activation of the SNS.¹⁷⁶ For instance, leptin administration to leptin-deficient *ob/ob* mice promotes increased brown adipose tissue lipolysis, thermogenesis, renovascular activity, and increased movement, all associated with increased energy expenditure and enhanced weight loss.¹⁷⁷ Similarly, insulin administration acutely increases SNS activity in normal rats and in humans.^{178,179} The SNS increases energy expenditure in four ways: (1) by innervating the hypothalamus and appetite centers in the medulla to reduce appetite, (2) by increasing thyroid-stimulating hormone (TSH) secretion to increase thyroid hormone release and energy expenditure, (3) by innervating skeletal muscles to increase energy expenditure, and (4) by innervating β_3 -adrenergic receptors in white adipose tissue to promote lipolysis.

Activation of the SNS increases energy expenditure by the skeletal muscle, by activating β_2 -adrenergic receptors,¹⁸⁰ which in turn increase the expression of numerous genes in skeletal muscle,¹⁸¹ especially those involved in carbohydrate metabolism. SNS activation stimulates glycogenolysis, incites

myocardial energy expenditure, increases in glucose and fatty acid oxidation, and increases protein synthesis.¹⁸²

Activation of the SNS in rodents stimulates the β_3 -adrenergic receptor of brown adipose tissue to promote lipolysis.¹⁸³ In humans, activation of the β_3 -adrenergic receptor increases cyclic adenosine monophosphate (cAMP), which activates protein kinase A (PKA). PKA acts in two separate molecular pathways to increase energy expenditure. First, PKA phosphorylates the cAMP response element binding protein (CREB), which induces expression of peroxisome proliferator-activated receptor (PPAR) γ -coactivator-1 α (PGC-1 α). PGC-1 α then binds to enhancer elements on the uncoupling protein-1 (UCP1) gene, which increases the expression and activity of uncoupling proteins (UCPs) 1 and 2.^{184,185} UCPs reduce the proton gradient across the inner membranes of mitochondria, thereby diverting protons from storage in the form of ATP to heat production. Originally, UCPs were discovered in brown adipose tissue and were found to be responsible for thermogenesis. UCP1 is an inner membrane mitochondrial protein that uncouples proton entry from ATP synthesis;¹⁸⁶ therefore UCP1 expression dissipates energy as heat, thus reducing the energy efficiency of the adipose tissue. However, UCP2 has been found in most tissues and UCP3 in skeletal muscle. Second, PKA activation activates the enzyme hormone-sensitive lipase (HSL), which is responsible for lipolysis of intracellular triglyceride to its component FFAs. The FFAs also induce UCP1, further increasing energy expenditure. The FFAs released from the adipocyte also travel to the liver where they are used for energy by being metabolized into two-carbon fragments. Lipolysis reduces leptin expression; thus a negative feedback loop is achieved between leptin and the SNS (see Fig. 24.4).

The Efferent Vagus and Energy Storage

In response to declining levels of leptin or persistent orexigenic pressure, the LHA and PVN send efferent projections residing in the medial longitudinal fasciculus to the DMV, activating the efferent vagus.¹⁸⁷ The efferent vagus opposes the SNS by promoting energy storage in four ways: (1) by slowing the heart rate, myocardial oxygen consumption is reduced; (2) the vagus nerve promotes alimentary peristalsis, pyloric opening, and energy substrate absorption; (3) through direct effects on the adipocyte, the vagus nerve promotes insulin sensitivity to increase the clearance of energy substrate into adipose tissue; and (4) through effects on the β -cells, the vagus increases postprandial insulin secretion,^{12,188–191} which promotes energy deposition into adipose tissue.

Retrograde tracing of white adipose tissue reveals an abundance of efferents originating at the DMV.¹⁹¹ These efferents synapse on the M₁ muscarinic receptor on the adipocyte, which increases insulin sensitivity of the adipocyte. Denervation of white adipose tissue results in a reduction of glucose and FFA uptake, and an induction of HSL, which promotes lipolysis—both of which reduce the efficiency of insulin-induced energy storage. Thus vagal modulation of the adipocyte augments storage of both glucose and FFAs by improving adipose insulin sensitivity¹⁹² (see Fig. 24.4).

The DMV also sends efferent projections to the β -cells of the pancreas.¹⁹³ This pathway is responsible for the “cephalic” or preabsorptive phase of insulin secretion, which is glucose independent and can be blocked by atropine.¹⁹⁴ Overactive vagal neurotransmission increases insulin secretion from β -cells in response to an oral glucose load through three distinct but overlapping mechanisms¹⁹⁵ (see Fig. 24.4):

1. Vagal firing increases acetylcholine availability and binding to the M₃ muscarinic receptor on the β -cell, which is coupled to a sodium channel within the pancreatic β -cell membrane.¹⁹⁶ As glucose enters the β -cell after ingestion of a

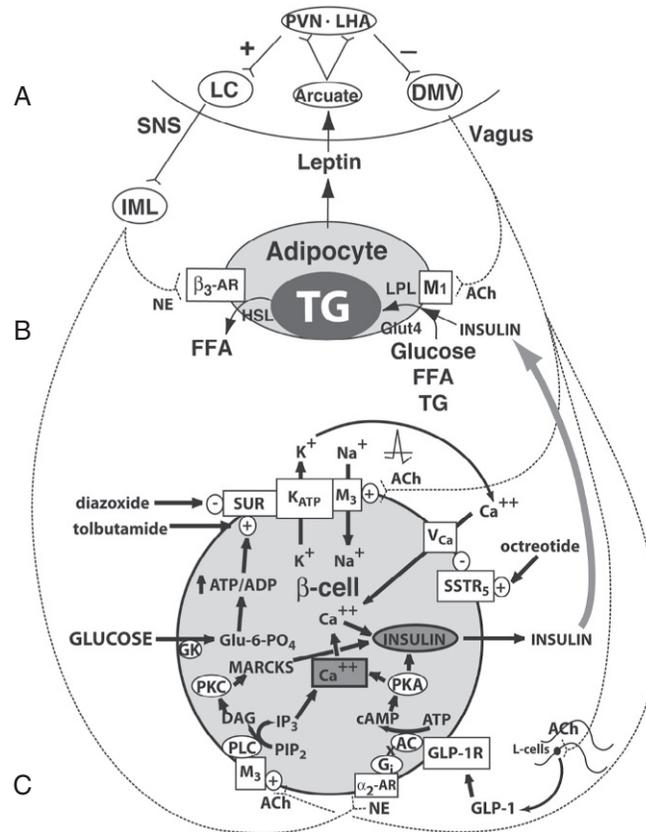

Fig. 24.4 Central regulation of leptin signaling, autonomic innervation of the adipocyte and β -cell, and the starvation response. (A) The arcuate nucleus transduces the peripheral leptin signal as one of sufficiency or deficiency. In leptin sufficiency, efferents from the hypothalamus synapse in the locus coeruleus, which stimulates the sympathetic nervous system. In leptin deficiency or resistance, efferents from the hypothalamus stimulate the dorsal motor nucleus of the vagus. (B) Autonomic innervation and hormonal stimulation of white adipose tissue. In leptin sufficiency, norepinephrine binds to the β_3 -adrenergic receptor, which stimulates hormone-sensitive lipase, promoting lipolysis of stored triglyceride into free fatty acids. In leptin deficiency or resistance, vagal acetylcholine increases adipose tissue insulin sensitivity (documented only in rats to date), promotes uptake of glucose and free fatty acids for lipogenesis, and promotes triglyceride uptake through activation of lipoprotein lipase. (C) Autonomic innervation and hormonal stimulation of the β -cell. Glucose entering the cell is converted to glucose-6-phosphate by the enzyme glucokinase, generating adenosine triphosphate (ATP), which closes an ATP-dependent potassium channel, resulting in cell depolarization. A voltage-gated calcium channel opens, allowing for intracellular calcium influx, which activates neurosecretory mechanisms leading to insulin vesicular exocytosis. In leptin sufficiency, norepinephrine binds to α_2 -adrenergic receptors on the β -cell membrane to stimulate inhibitory G-proteins, decrease adenylyl cyclase and its product cyclic adenosine monophosphate (cAMP), and thereby reduce protein kinase A levels and insulin release. In leptin deficiency or resistance, the vagus stimulates insulin secretion through three mechanisms.⁸⁰⁵ First, acetylcholine binds to an M_3 muscarinic receptor, opening a sodium channel, which augments the ATP-dependent cell depolarization, increasing the calcium influx, and insulin exocytosis. Second, acetylcholine activates a pathway that increases protein kinase C, which also promotes insulin secretion. Third, the vagus innervates L-cells of the small intestine, which secrete glucagon-like peptide-1, which activates protein kinase A, contributing to insulin exocytosis. Octreotide binds to a somatostatin receptor on the β -cell, which is coupled to the voltage-gated calcium channel, limiting calcium influx and the amount of insulin released in response to glucose (reprinted with kind permission of Springer Science and Business media). α_2 -AR, α_2 -Adrenergic receptor; β_3 -AR, β_3 -adrenergic receptor; AC, adenylyl cyclase; ACh, acetylcholine; DAG, diacylglycerol; DMV, dorsal motor nucleus of the vagus; FFA, free fatty acids; G_i , inhibitory G-protein; GK, glucokinase; GLP-1, glucagon-like peptide-1; GLP-1R, GLP-1 receptor; Glu-6-PO₄, glucose-6-phosphate; GLUT4, glucose transporter-4; HSL, hormone-sensitive lipase; IML, intermediolateral cell column; IP₃, inositol triphosphate; LC, locus coeruleus; LHA, lateral hypothalamic area; LPL, lipoprotein lipase; MARCKS, myristoylated alanine-rich protein kinase C substrate; NE, norepinephrine; PIP₂, phosphatidylinositol pyrophosphate; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; PVN, paraventricular nucleus; SUR, sulfonylurea receptor; SSTR₅, somatostatin-5 receptor; TG, triglyceride; V_{Ca}, voltage-gated calcium channel. (From Lustig, R.H. (2006). Childhood obesity: behavioral aberration or biochemical drive? Reinterpreting the first law of thermodynamics. *Nat Clin Pract Endo Metab*, 2, 447–458. With permission from Nature Publishing Group.)⁹⁰⁴

meal, the enzyme glucokinase phosphorylates glucose to form glucose-6-phosphate, increasing intracellular ATP, which induces closure of the ATP-dependent potassium channel. Upon channel closure, the β -cell experiences an ATP concentration-dependent β -cell depolarization^{197,198} and the opening of a separate voltage-gated calcium channel within the membrane. Intracellular calcium influx increases acutely, which results in rapid insulin vesicular exocytosis. Concomitant opening of the sodium channel by vagally mediated acetylcholine augments β -cell depolarization,

which in turn augments the intracellular calcium influx and results in insulin hypersecretion.^{199–201}

2. Vagally mediated acetylcholine increases phospholipases A₂, C, and D within the β -cell, which hydrolyze intracellular phosphatidylinositol to diacylglycerol (DAG) and inositol triphosphate (IP₃).¹⁹⁵ DAG is a potent stimulator of protein kinase C (PKC),²⁰² which phosphorylates myristoylated alanine-rich protein kinase C substrate (MARCKS), which then binds actin and calcium-calmodulin and induces insulin vesicular exocytosis.²⁰³ IP₃ potentiates the release of calcium

within β -cells from intracellular stores, which also promotes insulin secretion.²⁰⁴

3. The vagus also stimulates the release of GLP-1 from intestinal L-cells, which circulates and binds to a GLP-1 receptor within the β -cell membrane. Activation of this receptor induces a calcium-calmodulin-sensitive adenylyl cyclase, with conversion of intracellular ATP to cAMP, which then activates PKA. PKA causes both the release of intracellular calcium stores and the phosphorylation of vesicular proteins, each contributing to an increase in insulin exocytosis.^{205,206}

In the efferent pathway, insulin is responsible for shunting blood-borne nutrients into adipose for storage. Indeed, the primary hormonal signal for adipogenesis is insulin.²⁰⁷ Within the adipocyte, insulin increases: (1) glucose transporter 4 (GLUT 4) expression, (2) acetyl-CoA carboxylase, (3) fatty acid synthase, and (4) lipoprotein lipase.²⁰⁸ Thus the net effect of insulin on the adipocyte is the rapid clearance and storage of circulating glucose and lipid thereby promoting energy storage.

NON-HOMEOSTATIC REGULATION OF ENERGY BALANCE

The non-homeostatic determinants of energy balance are higher order functions that integrate cognitive functioning and environmental cues that prompt nonnutritive reasons for eating. Homeostatic feeding is needed for survival, whereas hedonic feeding is driven by the reward aspects of palatable food.²⁰⁹ In contrast to rodents or other mammals, hedonistic drives in humans may override homeostatic drives and dictate eating behavior.

The Nucleus Accumbens and the Hedonic Pathway of Food Reward

The hedonic pathway comprises the ventral tegmental area (VTA) and the nucleus accumbens (NA), with inputs from various components of the limbic system, including the striatum, amygdala, hypothalamus, and hippocampus. These pathways also mediate the hedonic response to drugs of abuse, such as nicotine and morphine. In fact, administration of morphine to the NA increases food intake in a dose-dependent fashion.²¹⁰ When functional, the hedonic pathway helps curtail food intake in situations where energy stores are replete; however, when dysfunctional, this pathway can increase food intake leading to obesity.

The VTA appears to mediate feeding on the basis of palatability rather than energy need. The dopaminergic projection from the VTA to the NA mediates the motivating, rewarding, and reinforcing properties of various stimuli, such as food and addictive drugs. Leptin and insulin receptors are expressed in the VTA, and both hormones have been implicated in modulating rewarding responses to food and other pleasurable stimuli.²¹¹ For instance, fasting and food restriction (when insulin and leptin levels are low) increase the addictive properties of drugs of abuse, whereas ICV leptin can reverse these effects.²¹² In rodent models of addiction, increased addictive behavior (and pleasurable response from a food reward), as measured by dopamine release and dopamine receptor signaling, is greater after food deprivation.²¹³ In humans with leptin deficiency, alterations in activity in the NA can be seen using functional magnetic resonance imaging (MRI) scanning, and these changes subside with administration of exogenous leptin.²¹⁴ Acutely, insulin increases expression and activity of the dopamine transporter, which clears and removes dopamine from the synapse; thus acute insulin exposure blunts the reward of food.²¹⁵ Furthermore, insulin appears to inhibit the ability

of VTA agonists (e.g., opioids) to increase intake of sucrose.²¹⁶ Finally, insulin blocks the ability of rats to form a conditioned place preference association to a palatable food.²¹⁷ However, insulin resistance of this pathway may lead to increased reward perception of food by way of reduced dopamine clearance from the synapse and prolongation of the postsynaptic hedonistic response.

One question that has garnered increasing interest is whether any macronutrient has addictive properties. In animal studies, sugar has been shown to induce the four criteria for addiction: (1) bingeing, (2) withdrawal, (3) craving, and (4) cross-sensitization with other drugs of abuse.²¹⁸ Within fast food, sugar and caffeine satisfy the criteria presented in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) for dependence in humans.²¹⁹ However, the question of whether food addiction exists, and whether it can explain patients with obesity, remains contested,²²⁰ although a recent systematic review of the literature supports this notion of “highly-palatable food addiction” based on the criteria of impaired control, social impairment, risky use, and tolerance/withdrawal, at least as a paradigm for consideration in treatment strategies.²²¹

The Amygdala and the Stress Response

The VMH and VTA-NA mediate satiety when energy stores are replete, but they appear to be easily overridden by amygdala activation and resultant stress, a state of physiologic insulin resistance (Fig. 24.5). Numerous lines of evidence suggest that the stress glucocorticoids corticosterone (in the rodent) or cortisol (in the human) are essential for the full expression of obesity, which helps to explain the disruptive role of stress in weight regulation.²²²

Stress and glucocorticoids are integral in promoting adiposity and the metabolic syndrome. Adrenalectomized rats maintained pharmacologically with high levels of corticosterone demonstrate that exogenous fat intake is directly proportional to circulating corticosterone concentrations,²²³ whereas amygdala activation by stress is dampened by the ingestion of energy-dense food.²²⁴ In intact rats, corticosterone stimulates eating, particularly of high-fat food, and in humans, cortisol administration increases food intake.²²⁵ Human research shows increased caloric intake of “comfort foods” (i.e., those with high energy density) after acute stress,²²⁶ and that the stress response contributes to leptin resistance (discussed later).²²⁷ Several studies in children have observed relationships between stress and unhealthy dietary practices, including increased snacking, and an elevated risk for problems with weight during adolescence and adulthood.²²⁸ In a controlled study of 9-year-old children who scored high on dietary restraint and who felt more stressed by laboratory challenges tended to eat more comfort food.²²⁹ Adverse childhood experiences are also associated with later development of obesity and cardiometabolic risk factors suggesting a role of stress in longitudinal weight gain and metabolic health.²³⁰

DYSREGULATION OF ENERGY BALANCE

Leptin Resistance

Most children with obesity have high leptin levels but do not have receptor mutations, manifesting what is commonly referred to as *functional leptin resistance*. Leptin resistance prevents exogenous leptin administration from promoting weight loss.²³¹ The response to most weight-loss regimens plateaus rapidly because of the rapid fall of peripheral leptin levels which induces a “starvation response” immediately, regardless of baseline values, and potentially because of reaching a

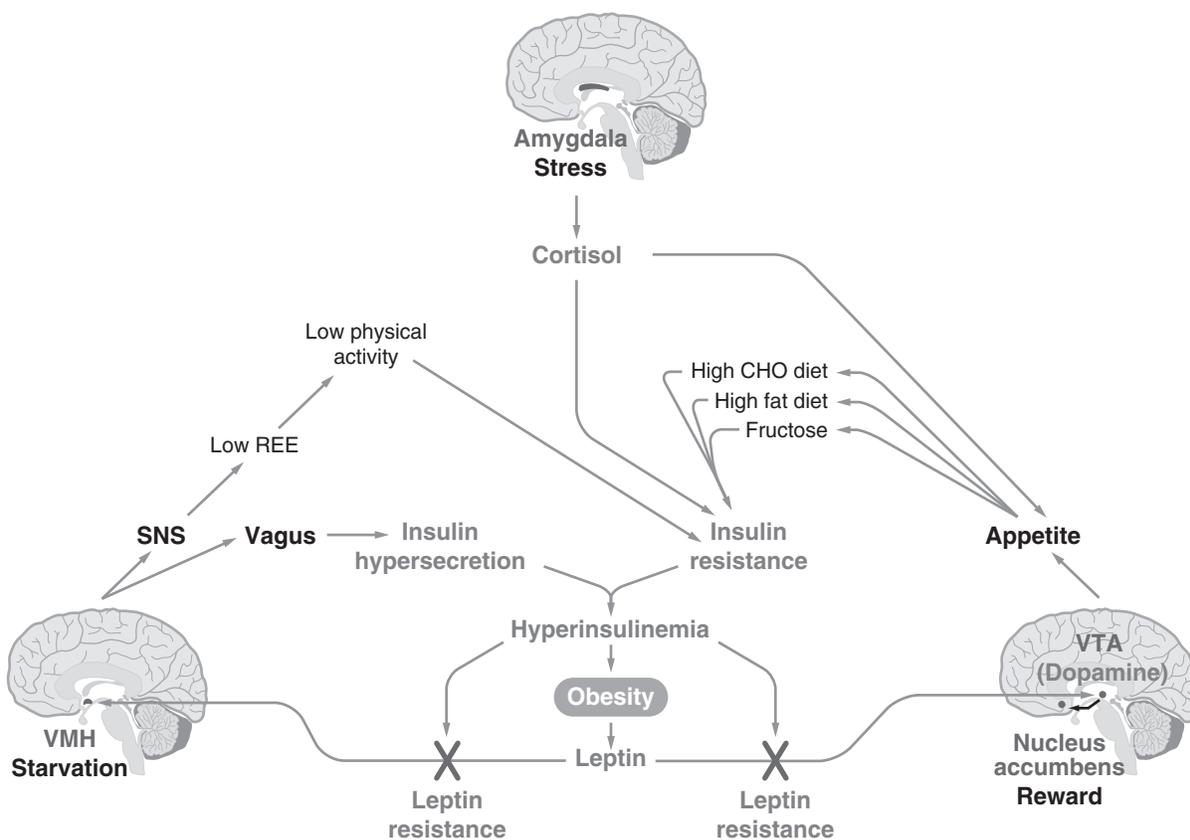

Fig. 24.5 The “limbic triangle.” Three areas of the CNS conspire to drive food intake and reduce physical activity, resulting in persistent weight gain. The ventromedial hypothalamus (VMH) transduces the leptin signal from adipocytes to reduce energy intake and increase energy expenditure; however, hyperinsulinemia prevents leptin signaling, promoting the “starvation response.” The ventral tegmental area (VTA) transduces the leptin signal to reduce dopamine neurotransmission to the nucleus accumbens, reducing food intake; however, hyperinsulinemia prevents leptin signaling here as well, increasing dopamine and promoting the “reward” of food. The amygdala transduces fear and stress, which results in increased cortisol release from the adrenal cortex. The elevated cortisol also drives energy-rich food intake and promotes insulin resistance, further interfering with leptin signaling at the other two central nervous system sites. Thus activation of any aspect of the limbic triangle turns on a positive feedback loop, promoting continued weight gain and obesity. (From Mietus-Snyder, M.L., Lustig, R.H. (2008). Childhood obesity: adrift in the “limbic triangle.” *Ann Rev Med*, 59, 147–162.)⁹⁰⁵

personal “leptin threshold,”²³² which is likely genetically determined. Leptin decline causes the VMH to sense a reduction in peripheral energy stores, which modulates a decrease in resting energy expenditure (REE) to conserve energy, analogous to a starvation response,²³³ but occurring at elevated leptin levels.

The cause of leptin resistance is unknown, but it may have several etiologies.²³⁴ Leptin crosses the BBB via a saturable transporter, which limits the amount of leptin reaching its receptor in the VMH^{235,236}; this transporter operates more efficiently at lower levels of leptin, while preventing increased signaling at higher levels.²³⁷ Activation of the leptin receptor induces the intraneuronal expression of suppressor of cytokine signaling-3 (SOCS-3), which limits leptin signal transduction in an autoregulatory fashion.²³⁸ Because the presence of hyperleptinemia has been shown to be a prerequisite for development of leptin resistance, it has been postulated that leptin-induced expression of leptin signaling inhibitors may be an initial step in the process. Other studies suggest that obesity itself induces hypothalamic inflammation, gliosis, and endoplasmic reticulum (ER) stress that impair responsiveness to leptin.²³⁴

The standard method for producing insulin resistance and obesity in rodents is a high-fat diet. Dietary fat promotes leptin resistance through its effects on hypertriglyceridemia,⁸⁵ which limits access of peripheral leptin to the VMH, and also by interfering with leptin signal transduction upstream of STAT-3, its primary second messenger.²³⁹ One likely modulator of this pathway is the enzyme PI3K, which is the downstream effector

of insulin action in POMC neurons²⁴⁰ and which appears to account for the effects of dietary fat on leptin resistance and obesity.²⁴¹

Two clinical paradigms have been shown to improve leptin sensitivity. After weight loss through caloric restriction, exogenous administration of leptin can then increase REE back to baseline and permit further weight loss,^{242,243} suggesting that the weight loss itself improves leptin sensitivity. Second, suppression of insulin correlates with improvement in leptin sensitivity and promotes weight loss,²⁴⁴ suggesting that hyperinsulinemia promotes leptin resistance by interfering with leptin signal transduction in the VMH and VTA.²⁴⁵ Indeed, insulin reduction strategies can effectively promote weight loss in children with hyperinsulinemia by improving leptin sensitivity.²⁴⁶

Counterregulatory Mechanisms That Oppose Weight Loss

Because the homeostatic system for energy balance was developed to protect against starvation, body fat stores are avidly protected. Therefore dietary restriction, even before the onset of weight loss, triggers counterregulatory mechanisms to oppose the perceived threat of starvation, regardless of baseline adipose tissue stores.⁷¹ Gastric secretion of ghrelin acutely rises, which increases pituitary GH release, to stimulate lipolysis to

provide energy substrate for catabolism. Ghrelin stimulates NPY/AgRP to antagonize α -MSH/CART. Decline of leptin reduces α -MSH/CART as well. This leads to decreased MC4R and MC3R occupancy leading to reduced anorexigenic and catabolic signaling with a net effect of increased feeding behavior and higher energy efficiency (with reduced fat oxidation). Appetite proportionally increases leading to food consumption above baseline by approximately 100 kCal/d per kilogram of lost weight.²⁴⁷ Meanwhile, total and resting energy expenditures decline in an attempt to conserve energy.²³³ Specifically, UCP1 levels within adipose tissue decline²⁴⁸ as a result of decreased SNS activity.²⁴⁹ In spite of decreased SNS tone at the adipocyte, there is clearly an obligate lipolysis (because of insulin suppression and upregulation of HSL), which is necessary to maintain energy delivery to the musculature and brain in the form of liver-derived ketone bodies. In addition, in the weight-reduced state, vagal tone is increased to slow the heart rate and myocardial oxygen consumption, increase β -cell insulin secretion in response to glucose, and increase adipose insulin sensitivity—all directed to increase energy storage.²⁴⁹ These counterregulatory mechanisms together serve to drive weight regain and can even persist for years after the initial onset of weight loss,²⁵⁰ therefore rendering maintenance of reduced body weight exceedingly challenging especially in light of the feed-forward mechanisms described later. In other words, the metabolic adaptations aimed at conserving energy and returning to the body weight before weight loss are maintained for years following the weight loss and achievement of weight plateau rendering the individual prone to weight gain. Upon comparison of two individuals with similar weight and body composition, a weight-stable patient and a patient who lost weight to achieve this measurement, to maintain the current body weight—the patient who lost weight will have to consume less energy and spend more energy in comparison with the weight-stable counterpart.

Feed-Forward Mechanism That Promote Weight Gain

Feed-forward signaling bridges homeostatic and hedonic mechanisms of appetite regulation, a concept developed based on the observation that a hungry mouse will have appropriately elevated AgRP neuronal firing in the fasted state but these AgRP neurons are then acutely suppressed when the mouse is presented with food, even before the onset of eating.⁷ In addition, gut signals are also released that anticipate the imminent arrival of ingested food, setting in motion, digestive processes before actual food intake. Because hunger is an aversive experience, rapid reduction in AgRP firing and the sudden removal of hunger sensations induce an acute reward experience, perhaps serving as a positive reinforcer of the environmental cue of food availability. For example, readily visible and appealing packaging of processed foods encourages hedonistic consumption and establishes a learned behavior that prompts subsequent return to the environment where such foods were available. Along the same lines, fast food restaurants and advertising targeting youth rely heavily on connecting images of food with other pleasurable stimuli (toys, games, fun, etc.), further compounding the reward effect of already highly palatable food.²⁵¹ This feed-forward mechanism has potential implications as we consider the role of the built environment and its role in promoting food consumption.

ENERGY EXCESS—OBESITY

The rise in the prevalence of obesity in children and adolescents is one of the most alarming public health issues facing the

world today. Although the rise in the prevalence of obesity in children and adolescents seems to have leveled in some parts of the world,²⁵² many others, especially developing countries and migrant populations,²⁵³ are still experiencing a steady increase. Obesity is associated with significant health problems in children and is an early risk factor for much of adult non-communicable disease morbidity and mortality,²⁵⁴ and an important factor in increasing healthcare expenditures.²⁵⁵ Childhood obesity tends to track into adulthood,²⁵⁶ and those who continue to have obesity as adults have a significant risk for the development of obesity-driven morbidity with an excess risk associated with the length of exposure to obesity.²⁵⁷ In contrast, children with obesity who lost weight and became non-obese adults do not have an increased risk for such morbidity.²⁵⁸ These observations identify obesity in early childhood as a major window of opportunity for obesity prevention efforts with a potential lifelong impact.

Definition

The theoretical definition of obesity is a degree of somatic overweight that affords detrimental health consequences.²⁵⁹ Based on morbidity and mortality statistics, and with a desire to prevent future risk of morbidity, we practically define obesity as a statistical magnitude of overweight for a population, keeping in mind that morbidity and mortality vary with degree of overweight in different racial, ethnic, and socioeconomic groups.²⁶⁰

The majority of obesity in adulthood has its origins in childhood,^{261,262} making obesity a pediatric concern and the prevention and treatment of obesity a pediatric goal. Body mass index (BMI) is also the accepted marker in children.²⁶³ In childhood, comparison of BMI with normal curves for age²⁶⁴ allows for categorization of BMI above the 85th percentile as overweight, and above the 95th percentile as obesity (Fig. 24.6A and B). The World Health Organization (WHO)²⁶⁵ categorizes adult overweight into four subgroups based on BMI (weight [kg] \div height [m]²): BMI 25 to 30 (overweight); BMI 30 to 35, Grade 1 (moderate obesity); BMI 35 to 40, Grade 2 (severe obesity); and BMI over 40, Grade 3 (morbid obesity). A similar degree of obesity categorization can also be used in the pediatric population using BMI centiles where the 95th centile for age and sex is used as a reference point and 100% to 120% of the 95th percentile for age and sex is grade 1, 120% to 140% is grade 2, and over 140% is grade 3.²⁶⁶ Such categorization demonstrates that cardiometabolic risk increases with rising degrees of obesity.²⁶⁶

Although BMI is the standard indicator of obesity for statistical purposes and within populations, it should be noted that BMI does not take into account body composition parameters such as total body fat, (as well as both subcutaneous and visceral fat), muscle, and bone. Furthermore, BMI in children is age, sex, and puberty dependent, thus BMI z-score is a more accurate assessment of childhood adiposity. Lastly, waist circumference (an indirect measure of intraabdominal visceral fat) has emerged as a more accurate indicator of metabolic disturbance in children.²⁶⁷ These limitations of BMI indicate that it is a useful index for population and epidemiologic studies yet should be used with caution when assessing an individual child in the clinical setting.

Prevalence and Epidemiology

The prevalence of childhood obesity in the United States has increased dramatically during the past 30 years,^{268,269} and continues to do so, although the comparison of longitudinal and cross-sectional data is difficult because of different definitions and measurement parameters between epidemiologic studies. The most recent estimates of obesity prevalence and trends in

the United States are based on data from the 2011 to 2014 National Health and Nutrition Examination Survey (NHANES V).^{252,270} NHANES demonstrates that the epidemic of childhood obesity in the United States seems to have stabilized in some age groups but not in others. Overall, in 2013 to 2014, 9.4% (95% confidence interval [CI], 6.8–12.6) of infants and toddlers and 17% (95% CI, 15.5–18.6) of children and adolescents from 2 through 19 years of age had obesity. Of note, the prevalence of extreme obesity (>120% of 95th percentile for age and sex) was 5.8% (95% CI, 4.9–6.8). Trend analyses over a 25-year period indicated a significant increase in obesity prevalence among children aged 2 to 5 years between 1988 and 1994 and 2003 and 2004 that slightly declined in 2013 to 2014 (7.2%, 13.9%, and 9.4%, respectively). Among children aged 6 to 11 years old, the prevalence of obesity increased from 1988 to 1994 to 2007 to 2008 and remained stable in 2013 to 2014 (11.3%, 19.6%, and 17.4%, respectively). Among adolescents 12 to 19 years of age, the prevalence of obesity significantly increased from 1988 to 1994 to 2013 to 2014 (10.5% and 20.6%, respectively, $P < .001$). Of note, the prevalence of extreme obesity increased among children 6 to 11 years old between 1988 and 1994 to 2013 and 2014 (3.6% and 4.3%, respectively, $P = .02$) and among adolescents aged 12 to 19 years (2.6% and 9.1%, respectively, $P < .001$). Importantly, no significant trends were observed between 2005 and 2006 and 2013 and 2014. The practical implication of these trends is for example in 1988 to 1994, the 95th percentile of BMI among 17-year-old males was 31.5 kg/m² (i.e., 5% of males had a BMI >31.5), and in 2011 to 2014 the 95th percentile was 36.2 kg/m² (i.e., 5% of males had a BMI >36.2). Thus between 1988 and 1994 and 2013 and 2014, the prevalence of obesity increased until 2003 to 2004 and then decreased in children aged 2 to 5 years, increased until 2007 to 2008 and then leveled off in children aged 6 to 11 years, and increased among adolescents aged 12 to 19 years. In 2013 to 2014, 17.4% of children met criteria for class I obesity, including 6.3% for class II and 2.4% for class III. A clear, statistically significant increase in all classes of obesity continued from 1999 through 2014.²⁷¹ In the United States, obesity and severe obesity among children significantly increased with greater age and lower education of household head, and severe obesity increased with lower level of urbanization. Compared with non-Hispanic white youth, obesity and severe obesity prevalence were significantly higher among non-Hispanic black and Hispanic youth. Severe obesity, but not obesity, was significantly lower among non-Hispanic Asian youth than among non-Hispanic white youth.²⁷² Lastly, projections argue that by 2030, 42% of American adults will have obesity.²⁵⁵

Global Prevalence

Obesity has overtaken acquired immunodeficiency syndrome and malnutrition as the number one public health problem in the world.²⁷³ The global prevalence of childhood obesity has been increasing worldwide at an alarming rate during the past 20 years. Rates have increased 2.7 to 3.8-fold over 29 years in the United States,²⁶⁹ 2.0 to 2.8-fold over 10 years in England, 3.4 to 4.6-fold over 10 years in Australia, and 3.4 to 3.6-fold over 23 years in Brazil. European data,²⁷⁴ using slightly different obesity cutoff definitions (a childhood BMI corresponding to >25 and 30 kg/m² in adults signifying overweight and obesity, respectively), suggests that among European countries, prevalence of overweight/obesity combined ranges between 16% and 22% whereas that of obesity ranges between 4% and 6% (corresponding to 2.9–4.4 million children with obesity in the European continent). Rapid increases in the prevalence of overweight schoolchildren are being seen in all European countries for which data are available. The numbers

indicate a lag of 10 to 15 years behind the United States. Using data from the mid-70s to 2016 in 200 countries, it was shown that trends in mean BMI have recently flattened in northwestern Europe and the high-income English-speaking and Asia-Pacific regions for both sexes, southwestern Europe for boys, and central and Andean Latin America for girls. In contrast, the rise in BMI has accelerated in east and south Asia for both sexes, and southeast Asia for boys.¹ In developed countries, the urban poor are more susceptible for developing obesity, presumably because of poor dietary practices and limited opportunity for physical activity.^{275,276} In contrast, obesity is more frequent in upper socioeconomic class of developing countries, probably because of a nutrition transition to a more Western diet with more energy-dense items consisting of higher fats and sugar, which tend to be more palatable at a lower cost.^{277–279} This may be also caused by specific properties of processed food, which may promote leptin resistance.²⁸⁰

Racial and Ethnic Considerations

The NHANES surveys only list prevalence among non-Hispanic whites, non-Hispanic blacks, and Asians, despite the fact that Native Americans, Pacific Islanders, and other racial/ethnic groups are experiencing rapid increases in obesity prevalence as well. Across racial groups, there is a marked dichotomy in the prevalence, and in the rate of increase of childhood obesity.^{281,282} For instance, the prevalence among African American (24.4%), Hispanic (21.7%) and Mexican American adolescents (22.2%) is significantly higher than among white adolescents (15.6%). Importantly, the prevalence of severe obesity (BMI >97th percentile) among African American (18.5%), Hispanic (15.2%) and Mexican American adolescents (15.2%) by far exceeds that of non-Hispanic white adolescents (10.5%). The rate of increase in the prevalence of obesity among African American and Hispanic adolescents almost doubled between 1988 and 1994 and 1999 and 2000, from 13.4% to 23.6% in African Americans, and from 13.8% to 23.4% in Hispanics. The 1994 Pediatric Nutrition Surveillance System (PedNSS) indicated that 12% of 2- to 4-year-old Native American children were overweight, which is similar to Hispanic children at the same age (12%) but much higher than white children (6%). The prevalence of overweight at 5 to 6 years in Native Americans is twice that in US youth in general, and the prevalence of obesity is even 3 times higher.²⁸³ Overall, both American Indian and Alaska Native children and adolescents have a greater prevalence of obesity compared with US children overall.²⁸⁴ Among infants and toddlers less than 2 years of age, the prevalence of obesity is highest in African Americans (18.5%), as compared with 10.1% in non-Hispanic whites and 13.7% in Hispanics. It is possible that different dietary practices may account for some of these differences. For instance, a study of 2-year-old Latino children in California correlated obesity with early consumption of sugar-sweetened beverages.²⁸⁵

Within racial populations, ethnic variability in the prevalence of childhood obesity has also been noted. Only 25% of first-generation Hispanic adolescents were overweight based on BMI in the 85th percentile or higher, as compared with 32% of second- and third-generation Hispanics. The prevalence of overweight in Asian American adolescents in this study was 20.6%, with comparable prevalence among Filipinos (18.5%) and Chinese (15.3%). Again, only 12% of first-generation Asian Americans were overweight, compared with 27% and 28%, of second and third generations, respectively. In Native Americans, there is great variation in the prevalence of obesity from 12% to 77%, based on tribes, age groups, measurement tools, and cut off values, among the studies performed between

1990 and 2000.²⁸³ These studies indicate that obesity in Native Americans begins very early in childhood.

Predictive Factors

The higher the BMI during childhood, the more likely adult obesity will manifest. In general, children with a BMI in the 95th percentile or higher have a very high risk for adult obesity.²⁸⁶ Obesity in adolescence is a primary risk factor for obesity in adulthood, with an increased odds ratio from 1.3 for obesity at 1 to 2 years of age to 17.5 for obesity at 15 to 17 years of age.²⁸⁷ The strongest predictor of adolescent obesity is rapid weight gain between 2 and 6 years of age.²⁸⁸ The change of BMI during and after adolescence is the most important predictive variable for adult obesity.²⁸⁹ Children and adolescents with BMI in the 95th percentile or higher have a 62% to 98% chance of having obesity at 35 years of age, with a 50% chance in males aged 13 years or older and 66% chance in girls age 13 years or older.²⁹⁰ Importantly, an elevated BMI in adolescence (even one that is considered well within the “normal” range) constitutes a substantial risk factor for obesity-related disorders in midlife.^{291,292} Although the risk of diabetes is mainly associated with increased BMI close to the time of diagnosis, the risk of coronary heart disease is associated with an elevated BMI both in adolescence and in adulthood.²⁹³

The age of adiposity rebound, that is, the point of the BMI nadir before body fatness begins to rise (between 5 and 6 years of age), typically more pronounced in girls (see Fig. 24.6A and B), is also an important predictor for adult obesity.²⁹⁴ Children with early adiposity rebound have a fivefold greater chance of having obesity as adults, compared with those with late adiposity rebound. At the age of adiposity rebound, children already overweight have a sixfold greater risk for adult obesity, as compared with lean children. Weight accumulation at an earlier age confers longer exposure to the obesity-related metabolic milieu and thus increases the risk for the development of obesity-related morbidity.²⁵⁷ Therefore the earlier the onset of childhood obesity, the greater is the risk for adult obesity.

Infant overnutrition plays an extremely important role in the future development of obesity. Numerous studies have implicated bottle feeding as a specific risk factor.²⁹⁵ The prevalence of obesity in children who were never breastfed was 4.5%, as compared with 2.8% in breastfed children, and a clear time-response effect was identified for the duration of breastfeeding on the decline in prevalence of obesity as well.²⁹⁶ Early overnutrition has been correlated with elevated leptin concentrations in later life.²⁹⁷ Differences in both volume and composition of commercial formula versus breast milk have been proposed as etiologic factors. An emerging paradigm posits that the gut microbiome plays a critical factor in the development of obesity in childhood as well as in adulthood. Early exposures to maternal factors including breast milk and to other dietary constituents in infancy (such as introduction of solids, exposure to artificial sweeteners etc.) may be key determinants of the profile of the microbiome impacting metabolism and weight balance during childhood and adulthood.²⁹⁸

Parental obesity is also an important predictor of childhood obesity. Children with at least one overweight parent at the age of adiposity rebound have a fourfold to fivefold greater chance of becoming adults with obesity. Lean children aged 5 years or younger have a 13-fold risk of adult obesity if both parents have obesity. Excessive BMI gains of parents during childhood and adulthood are also associated with a higher BMI and risk of obesity in the offspring.²⁹⁹ Conversely, older children with obesity (10–14 years of age) have a 22.3-fold increased risk to become adult with obesity regardless of parental weight,²⁶² suggesting that parental obesity is more important in early childhood weight gain.³⁰⁰ Upon studying associations of

parental and child obesity status, stronger associations were shown in older children than in younger children, in both parents than in father or mother only, in parental obesity and child obesity compared with overweight status of both.³⁰¹ Parental obesity is also related to early adiposity rebound, although it remains unclear whether the relation between parental and childhood obesity is genetic, epigenetic, or environmental.

METABOLIC IMPACT OF CHILDHOOD OBESITY

Many of the metabolic and cardiovascular (CV) complications of obesity are already evident during childhood and are closely related to the development of insulin resistance-hyperinsulinemia, the most common biochemical abnormality seen in obesity.³⁰² The obesity-related comorbidities that emerge early in childhood are alterations in glucose metabolism, dyslipidemia, and hypertension. Although an accelerated atherogenic process is present in children with obesity, thrombotic CV events do not usually appear until adulthood. The clustering of these manifestations is termed the *metabolic syndrome*, or the *insulin resistance syndrome*, suggesting that peripheral insulin resistance may be the driving force of the majority of the obesity-related morbidity.³⁰³

Insulin Resistance

Insulin resistance is defined as the decreased tissue response to insulin-mediated cellular actions and is the inverse of insulin sensitivity. The term insulin resistance, as generally applied, refers to whole-body reduced glucose uptake in response to physiologic insulin levels and its consequent effects on glucose and insulin metabolism. However, it is now clear that not all insulin-responsive tissues are equally sensitive to insulin. Generalized insulin resistance would result in global metabolic dysfunction, such as leprechaunism or Rabson-Mendenhall syndrome. Thus the insulin resistance of obesity must of necessity affect different tissues quantitatively (see Chapter 3 and Chapter 21 on diabetes mellitus and insulin receptor mutations).

Hepatic Insulin Resistance. The liver plays a major role in substrate metabolism and is the primary target of insulin action. After insulin's release from the β -cell following a glucose load, it travels directly to the liver via the portal vein, where it binds to the insulin receptor and elicits two key actions at the level of gene transcription. First, insulin stimulates the phosphorylation of FOXO1, which prevents it from entering the nucleus,^{304,305} and thus diminishes the expression of genes required for gluconeogenesis, mainly phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase. The net effect is diminished hepatic glucose production. Second, insulin activates the transcription factor sterol regulatory element-binding protein (SREBP)-1c, which in turn increases the transcription of genes required for fatty acid and triglyceride (TG) biosynthesis, most notably ATP-citrate lyase, acetyl-coenzyme A carboxylase, and fatty acid synthase; which together constitute the process of de novo lipogenesis (DNL). TGs synthesized by DNL are then packaged with apolipoprotein B (apoB) into very low-density lipoproteins (VLDL) for export to the periphery for storage or utilization by reciprocal activation of lipoprotein lipase (LPL) on the surfaces of endothelial cells in adipose or muscle tissues.³⁰⁶

For reasons that remain unclear, insulin-resistant subjects typically have “selective” or “dissociated” hepatic insulin resistance; that is, they have impaired glucose homeostasis (mediated by the FOXO1 pathway) but normal insulin-mediated hepatic DNL (mediated by the SREBP-1c pathway³⁰⁷ and the GSKR gene³⁰⁸). The increase in FFA flux within the liver, either by DNL or FFA delivery via the portal vein, impairs hepatic

insulin action via fatty acyl-CoA intermediates within the hepatocyte,³⁰⁹ leading to increases in hepatic glucose output, the synthesis of proinflammatory cytokines, and excess TG secretion by the liver, low high-density lipoprotein (HDL) cholesterol levels, and an increase of relatively cholesterol-depleted LDL particles.³¹⁰ Furthermore, the intrahepatic accumulation of FFA and lipid are also detrimental to liver insulin sensitivity as this leads to the generation of toxic lipid-derived metabolites, such as DAG, fatty acyl CoA, and ceramides.³¹¹ These in turn trigger activation of protein kinase C- ϵ (PKC ϵ , and serine/threonine phosphorylation of insulin receptor substrate 1 (IRS-1), which attenuates hepatic insulin signal transduction.³¹² Intrahepatic insulin resistance results in greater first pass insulin clearance in the liver, resulting in lower amounts of insulin reaching the systemic circulation.

Adipose Tissue Insulin Resistance. The expanded adipose tissue mass that accompanies obesity often leads to increased lipolysis and FFA turnover. Normally, insulin inhibits adipose tissue lipolysis; however, in the insulin-resistant state, the lipolytic process is accelerated, leading to increased FFA release into the circulation. Moreover, visceral adipocytes are more sensitive to catecholamine-stimulated lipolysis than subcutaneous adipocytes, further increasing FFA flux.³¹³ Macrophages also infiltrate into adipose tissue and contribute to both adipocyte hypertrophy and cytokine release.^{314–316} These circulating cytokines also affect insulin action in other tissues, such as liver and muscle. Within the normal glucose tolerance range, an increase in adipose insulin resistance is related to an increase in 2-h glucose levels. A tight relation exists between visceral fat ($r = 0.34$; $P < .001$) and the visceral/subcutaneous fat ratio and adipose tissue resistance to insulin. Greater FFA concentration following an oral glucose load is also evident with worsening glucose tolerance indicating reduced suppression of lipolysis and lower FFA clearance.³¹⁷

Muscle Insulin Resistance. Downstream of an insulin-resistant liver, increased plasma FFA flux into skeletal muscle results in fatty acyl-CoA derivatives altering the insulin signal transduction pathway and resulting in reduced insulin-mediated glucose transport in skeletal muscle, facilitating the development of hyperglycemia.³¹¹ The ectopic deposition in skeletal muscle of fat as intramyocellular lipid may also play a direct role in the pathogenesis of whole-body insulin resistance and metabolic syndrome via lipid metabolite-induced activation of PKC ϵ with subsequent impairment of insulin signaling.³¹² Greater intramyocellular lipid deposition is tightly associated with insulin resistance and is typically detected in children with obesity who have altered glucose metabolism.^{318,319} The manifestation of impaired insulin signal transduction in skeletal muscle is reduced translocation of GLUT4 to the cell membrane leading to reduced systemic glucose uptake.

Assessment of Insulin Resistance. The euglycemic hyperinsulinemic clamp is the gold standard for measuring insulin sensitivity; the frequently sampled intravenous glucose tolerance test (FSIVGTT) and steady-state plasma glucose (SSPG) methods are also valid measurements. The clamp is performed by infusing a body-surface-area-adjusted continuous insulin drip while maintaining fasting plasma glucose concentrations by modifying a glucose infusion. Greater glucose infusion rates needed to maintain euglycemia indicate greater insulin sensitivity.³²⁰ Euglycemic hyperinsulinemic clamp studies have shown that insulin resistance is determined primarily by the response of skeletal muscle, with over 75% of infused glucose taken up by muscle and only 2% to 3% by adipose tissue.³²¹ All three methods are generally time consuming, require intravenous infusions and frequent blood sampling, are burdensome for participants, costly, and require a research setting. In an attempt to simplify the measurement of insulin sensitivity, a

number of methods using single simultaneously obtained samples of fasting insulin and glucose have been developed, such as the homeostatic model for assessment of insulin resistance (HOMA-IR). Each of these uses a mathematical formula that adjusts for individual variability in insulin and glucose secretion and clearance. Although the goal for these methods was to improve the accuracy of fasting insulin alone by the addition of fasting glucose, it is now agreed that they yield similar results to fasting insulin. When correlated with gold standard methods in children, fasting insulin is a poor measure of whole-body insulin sensitivity in an individual child.³²¹ Although the primary interest has been in insulin resistance, the adverse effects related to insulin resistance are more likely mediated via compensatory hyperinsulinemia. The fasting triglyceride to HDL-cholesterol ratio, a surrogate of insulin resistance that does not use insulin measurements, has been proposed and correlate quite well with clamp-derived insulin resistance, yet its utilization needs validation in ethnically diverse populations.³²²

The two most important biologic conditions associated with insulin resistance in childhood are ethnicity and puberty. Studies show that African American, Hispanic, Pima Indian, and Asian children are less insulin sensitive compared with non-Hispanic white children with similar anthropometric measures.³²³ Insulin resistance in minority ethnic groups is manifested as lower insulin-stimulated glucose uptake, concomitant with hyperinsulinemia, evidence of increased insulin secretion from the β -cell, and decreased insulin clearance. During puberty there is around 25% to 50% decline in insulin sensitivity with recovery when pubertal development is complete.³²⁴ The compensatory increase in insulin secretion during puberty may be blunted in African American and Hispanic youth, thus increasing their risk for type 2 diabetes (T2DM) around the time of puberty. The development of T2DM is covered in depth in Chapter 21, yet it is worth noting that impaired glucose tolerance (IGT), known as prediabetes, is a relatively common condition in children and adolescents with obesity.³²⁵ IGT in youth with obesity is typically characterized by obesity with an unfavorable pattern of lipid partitioning, with increased deposition of fat in the visceral, hepatic, and intramyocellular compartments.³²⁶

Lipid Partitioning

The term lipid partitioning refers to the distribution of body fat in various organs and compartments. The majority of excess fat is stored in its conventional subcutaneous depot, yet other potential storage sites exist as well, such as the intraabdominal (visceral) fat compartment and insulin-responsive tissues, such as muscle and liver. One hypothesis to explain the relation between obesity and insulin resistance is the “portal-visceral” paradigm.³²⁷ This hypothesis claims that increased adiposity causes accumulation of fat in the visceral depot, leading to an increased portal and systemic FFA flux³²⁸ (Fig. 24.7). Associations between visceral adiposity, insulin resistance, and comorbidities have been demonstrated across most age groups and ethnicities.³²⁹ Of note, studies of in vivo FFA fluxes from the visceral and the subcutaneous truncal and abdominal depots have failed to demonstrate a substantial difference in net fluxes between these depots.

Subcutaneous fat, which does not drain into the portal system, is strongly related to insulin resistance in healthy men with obesity and in men with diabetes.³³⁰ Similarly, truncal subcutaneous fat mass has been demonstrated to independently predict insulin resistance in women with obesity. Visceral and subcutaneous fat differ in their biologic responses³³¹ because visceral fat is more resistant to insulin and has increased sensitivity to catecholamines. These observations emphasize that both visceral and subcutaneous abdominal fat can contribute to insulin resistance, possibly by different mechanisms.³³²

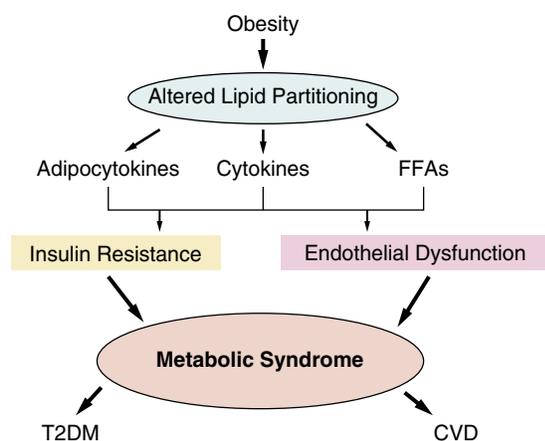

Fig. 24.7 A hypothesis on the relation between obesity and the metabolic syndrome. The metabolic impact of obesity is determined by the pattern of lipid partitioning. Lipid storage in insulin-sensitive tissues, such as liver or muscle, and in the visceral compartment is associated with a typical metabolic profile characterized by elevated free fatty acids and inflammatory cytokines alongside reduced levels of adiponectin. This combination can independently lead to peripheral insulin resistance and to endothelial dysfunction. The combination of insulin resistance and early atherogenesis (manifested as endothelial dysfunction) drives the development of altered glucose metabolism and of cardiovascular disease.

Studies performed in adolescents with obesity highlight the fact that the ratio of visceral to subcutaneous fat may be the determinant of their metabolic impact rather than their absolute quantity of fat. Indeed, adolescents with obesity who have a high visceral to subcutaneous fat ratio, despite having a comparable degree of obesity, demonstrate a markedly adverse metabolic phenotype of severe insulin resistance and alterations in glucose and lipid metabolism.³³³ Moreover, intrahepatic fat, although strongly associated with high levels of visceral fat, is also associated with the insulin-resistant state in adolescents with obesity, independent of all other fat depots.³³⁴

A more unifying paradigm is the “adipose tissue expandability” hypothesis claiming that total body fat is not the culprit of adverse health in obesity rather the relative proportion of lipids in various fat depots is what determines the metabolic phenotype and its derived metabolic risk.³³⁵ This theory claims that as adipose tissue expands, “ectopic lipid deposition” in insulin-responsive tissues is the culprit of adverse effects on metabolism.³³⁶ This theory is based on the observations that lipid content in liver and/or muscle is increased in obesity and in T2DM and is a strong predictor of insulin resistance.^{337,338} Moreover, in conditions such as lipodystrophies, all fat is stored in liver and muscle because of lack of subcutaneous fat tissue, causing severe insulin resistance and diabetes.³³⁹ In adults with obesity (BMI >30), muscle attenuation on computed tomography ([CT]; representing lipid content) is a stronger predictor of insulin resistance than is visceral fat.³⁴⁰ Studies performed in vivo using proton nuclear magnetic resonance (¹H-NMR) spectroscopy demonstrated increased intramyocellular lipid (IMCL) content to be a strong determinant of insulin resistance in adults³⁴¹ and in adolescents with obesity.³⁴² Alternatively, lipid deposition in hepatocytes to produce intrahepatocellular lipid (IHCL) is highly predictive of insulin resistance, even more so than visceral fat.³⁴³ Thus obesity-driven morbidity may begin when the subcutaneous adipose tissue reaches its capacity to store excess fat and begins to shunt lipid to ectopic tissues, such as liver and muscle, leading to peripheral insulin resistance³⁴⁴; or possibly when liver or muscle accumulates

lipid produced de novo in response to dietary manipulation (see later). Another postulated cause of IMCL and IHCL accumulation is a reduction of fat β -oxidation,³⁴⁵ related to low aerobic capacity, a reduced number or malfunction of mitochondria, or reduced SNS tone. The effect of IMCL or IHCL accumulation on peripheral sensitivity is postulated to be caused by an alteration of the insulin signal transduction pathway in muscle, caused by derivatives of fat, such as long-chain fatty acyl-CoA and DAG within the hepatocyte or myocyte. These derivatives activate the serine/threonine kinase cascade and cause serine phosphorylation of IRS-1, which inhibits insulin signaling.³⁴⁶ A comparable mechanism has been demonstrated in the liver, where accumulation of lipids, in particular DAG, activates the inflammatory cascade by inducing c-jun N-terminal kinase 1 (JNK-1), which causes serine rather than tyrosine phosphorylation of IRS-1, leading to inhibition of hepatic insulin signaling.^{347,348}

Vascular Changes

Early stages of the atherosclerotic process may be detected in children with obesity. In recent years, it has become clear that endothelial dysfunction represents a key early step in the development of atherosclerosis.³⁴⁹ The hallmark and cause of endothelial dysfunction is impairment in nitric oxide (NO)-mediated vasodilation.³⁵⁰ This is caused by decreased NO production by endothelial nitric oxide synthase (eNOS), which has been postulated to result from high levels of FFAs and inflammatory cytokines (interleukin [IL]-6, tumor necrosis factor [TNF]- α) in insulin-resistant individuals with obesity, increased reactive oxygen species, or increased uric acid, which inhibit eNOS activity.³⁵¹ Decreased NO bioavailability leads to an imbalance between vasodilating and vasoconstricting factors (such as endothelin), which leads to impaired vascular smooth muscle relaxation, increased adhesion of inflammatory cells to the endothelium, increased expression of plasminogen activator inhibitor-1 (PAI-1; a prothrombotic molecule) and increased vascular smooth muscle cell proliferation. Thus decreased NO bioavailability is thought to create a proinflammatory, prothrombotic environment which promotes atherosclerosis.³⁵² Endothelial function represents an integrated index of the overall CV risk burden in any given individual. During the last decade, noninvasive techniques for the assessment of endothelial function, including high-resolution external vascular ultrasound to measure flow-mediated endothelium-dependent dilatation (FMD) of the brachial artery during hyperemia have been developed.^{353,354} Impaired FMD correlates with arterial wall stiffness, coronary dilatation, and endothelial dysfunction in children with obesity.³⁵⁵ Similarly, anatomic changes in peripheral arterial vessels, such as increased intimal medial thickness (IMT), have also been demonstrated in children and adolescents with obesity,³⁵⁶ which mimics early coronary pathology and predicts adverse CV outcomes.

There are no longitudinal studies that directly measure in vivo insulin sensitivity and its relationship to the development of atherosclerotic abnormalities in children. Very limited observations suggest a relationship between HOMA-IR and arterial stiffness and fasting insulin levels in youth. However, a role for insulin resistance in the early abnormalities of vascular smooth muscle is proposed based on the observation that circulating biomarkers of endothelial dysfunction (intercellular adhesion molecule and E-selectin) are highest, whereas adiponectin, the antiatherogenic adipocytokine, is lowest among the most insulin-resistant youth. The landmark Bogalusa heart study demonstrated that CV risk factors present in childhood are predictive of coronary artery disease in adulthood.^{302,357} Among these risk factors, LDL-cholesterol and BMI measured in childhood were found to predict IMT in young adults.³⁵⁸

There is now substantial evidence that the insulin resistance of childhood obesity creates the metabolic platform for adult CV disease.^{359–361} Obstructive sleep apnea (OSA), typically present in children with obesity, is also tightly associated with the presence of endothelial dysfunction.³⁶² Moreover, the constellation of peripheral insulin resistance, an unfavorable adipocytokine profile, subacute inflammation, and endothelial dysfunction work in parallel to promote the pathologic processes of aging.

Adipocytokines

Leptin. The discovery of leptin in 1994 has dramatically changed the view of adipose tissue in the regulation of energy balance.³⁶³ Adipocytes secrete several proteins that act as regulators of glucose and lipid homeostasis.³⁶⁴ These proteins have been collectively referred to as *adipocytokines* because of their structural similarity with cytokines. Circulating leptin levels correlate with the degree of obesity. As stated earlier, the primary role of leptin is to serve as a long-term energy storage sensor to protect against starvation. Leptin probably has a permissive role in high-energy metabolic processes, such as puberty, ovulation, and pregnancy, but its role in states of energy excess is less known. In obesity, the development of leptin resistance may result in a breakdown of the normal partitioning of surplus lipids in the adipocyte compartment.³⁶⁵

Adiponectin. The cytokine adiponectin is peculiar in obesity because, in contrast with the other adipocytokines, its level is reduced in individuals with obesity.³⁶⁶ The adiponectin gene is expressed exclusively in adipose tissue and codes a protein carboxyl terminal globular head domain and an amino terminal collagen domain, which is structurally reminiscent of the complement factor 1q.³⁶⁷ The gene is located on chromosome 3q27, a location previously linked to the development of type 2 diabetes and the metabolic syndrome. Several single nucleotide polymorphisms (SNPs) in the adiponectin gene have been reported to be associated with the development of type 2 diabetes in populations around the world, suggesting that adiponectin plays a major role in glucose metabolism.³⁶⁸ Adiponectin circulates in plasma in three major forms: a low-molecular-weight trimer, a middle-molecular-weight hexamer, and a high-molecular-weight 12- to 18-mer.³⁶⁹ Circulating plasma high-molecular-weight adiponectin concentrations demonstrate a sexual dimorphism (females have greater concentrations), suggesting a role for sex hormones in the regulation of adiponectin production or clearance.³⁷⁰ Dietary factors, such as linoleic acid or fish oil versus a high carbohydrate diet or increased oxidative stress, have been shown to increase or decrease adiponectin concentrations, respectively. These observations suggest that the circulating levels of adiponectin are regulated by complex interactions between genetic and environmental factors.³⁷¹

The receptors for adiponectin have been characterized in rodent models and cloned. Two receptors, named ADIPOR1 and ADIPOR2, have been characterized. ADIPOR1 is expressed in numerous tissues including muscle, whereas ADIPOR2 is mostly restricted to the liver.³⁷² Both receptors are bound to the cell membrane, yet are unique in comparison to other G-protein-coupled receptors in the fact that the C-terminal is external, whereas the N-terminal is intracellular.³⁷³ Both ADIPOR1 and ADIPOR2 are receptors for the globular head of adiponectin and serve as initiators of signal transduction pathways that lead to increased PPAR α and increased adenosine monophosphate (AMP) kinase activities, which promote glucose uptake and increased fatty acid oxidation. Adiponectin has been shown to have potent antiatherogenic functions, as it accumulates in the subendothelial space of injured vascular walls to reduce the expression of adhesion molecules and the recruitment of macrophages.³⁷⁴

Studies in children and adolescents with obesity have shown that adiponectin is inversely related with the degree of obesity, insulin sensitivity visceral adiposity, IHCL, and IMCL, whereas weight loss increases adiponectin. In adolescents with obesity and type 2 diabetes, low baseline adiponectin and a reduced elevation in response to treatment have been shown to predict treatment failure.³⁷⁵ All of these observations along with human clinical data support a pivotal role for adiponectin in the prevention of the comorbidities of the metabolic syndrome.

Family studies using parent-offspring regressions revealed that most adipocytokines show evidence for significant inheritance. There are three main common axes of variation in the heritability of adipocytokines. The main axis, which explained 21% of the variation, was most strongly loaded on levels of leptin, TNF- α , insulin, and PAI-1, and inversely with adiponectin. This axis was significantly associated with BMI and phenotypically stronger in children, and showed a heritability of 50%, after adjustment for age, gender, and generational effects. Thus adipocytokines are highly heritable and their pattern of covariation is significantly correlated with BMI as early as the preteen years.³⁷⁶

Myokines and Natriuretic Peptides. Skeletal and heart muscles may serve as an endocrine organ as well. Some of the effects of exercise on skeletal muscle are mediated by the transcriptional coactivator PPAR- γ coactivator 1 α (PGC-1 α). In the mouse, PGC-1 α expression in muscle stimulates an increase in expression of FNDC5, a membrane protein that is cleaved and secreted as a newly identified hormone, named *Irisin*. Irisin acts on white adipose cells in culture and in vivo to stimulate UCP1 expression and induces “beiging” of white adipocytes into cells metabolically more active.³⁷⁷ Irisin is induced with exercise in mice and humans, and mildly increased irisin levels in the blood cause an increase in energy expenditure in mice with no changes in movement or food intake, resulting in improvements in obesity and glucose homeostasis. This novel myokine is actually the first hormonal link between exercise and the adipose tissue changes it may induce.³⁷⁸ Importantly, this molecule has a negative correlation with brain executive function³⁷⁹ and thus probably has multiple effects yet to be discovered. Atrial natriuretic peptides (ANP) also have been implicated in fat metabolism. These natriuretic peptides are produced with exercise, cardiac wall stress, weight loss, and cold exposure, and inhibited by obesity and insulin resistance. ANP binds to its natriuretic receptor, facilitating the formation of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP). cGMP phosphorylates cGMP-dependent protein kinase, which activates lipolysis, and phosphorylates p38 mitogen-activated protein kinase to enhance mitochondrial biogenesis with increased energy expenditure and increased heat generation, as part of the brown-fat thermogenic program. Thus both skeletal and cardiac muscle may respond to exercise by inducing changes in fat metabolism to enhance caloric expenditure and limit obesity. These new findings are likely to open new avenues of clinical research to limit the consequences of the “obesity epidemic.”^{380,381}

Inflammatory Cytokines. Accumulating evidence indicates that obesity is associated with subclinical chronic inflammation.³⁸² Adipose tissue serves not merely as a simple reservoir of energy stored as TGs, but also as an active secretory organ releasing many peptides, including inflammatory cytokines, into the circulation. This is probably because of infiltration of adipose tissue by cells of the immune system, mainly macrophages. In obesity, the balance between these numerous peptides is altered, such that larger adipocytes and macrophages embedded within them produce more inflammatory cytokines (i.e., TNF- α , IL-6) and less antiinflammatory peptides, such as adiponectin.³⁸³ One hypothesis posits that as energy

accumulates in adipocytes, the perilipin border of the fat vacuole breaks down, causing the adipocyte death.³⁸⁴ Cell death recruits macrophages into the adipose tissue, especially within the visceral compartment, which in the process of clearing debris, also elaborate inflammatory cytokines, initiating a proinflammatory milieu that predates and possibly drives the development of systemic insulin resistance, diabetes, and endothelial dysfunction.^{385,386} Systemic concentrations of C-reactive protein (CRP) and IL-6, two major markers and participants of the inflammatory process, are increased in children and adolescents with obesity. CRP levels within the “high-normal” range have been shown to predict CV disease³⁸⁷ and development of T2DM³⁸⁸ in adults. Elevated levels of CRP correlate with other components of the metabolic syndrome in children with obesity.^{389,390} Thus inflammation may be one of the links between obesity and insulin resistance, potentially driving myocyte and hepatic resistance within the insulin signal transduction pathway.

Reactive Oxygen Species (ROS). The “Free Radical Theory” holds that imbalance between ROS generation and antioxidant defenses is a major factor in the determination of lipid peroxidation and protein misfolding, with resultant deoxyribonucleic acid (DNA) and cellular damage.³⁹¹ Excessive intracellular ROS formation occurs via three pathways: (1) inflammatory cytokines derived from visceral fat accumulation,³⁹² (2) dysfunctional mitochondrial energetics,³⁹³ and (3) glycation. Excessive nutrient processing by mitochondria can result in uncoupling of oxidative phosphorylation and increased generation of ROS; this, in turn, leads to altered mitochondrial function and further ROS generation.³⁹⁴ ROS

accumulation can also impair ER function, causing ER stress and the compensatory unfolded protein response (UPR). The UPR can itself be overwhelmed by persistent excessive nutrient processing and ROS generation, leading to cellular shutdown, defective insulin secretion, and T2DM^{395,396} (Fig. 24.8).

Because ROSs are inherent by-products of cellular metabolism, endogenous cellular antioxidants (e.g., catalase and glutathione) quench the ROS before they have a chance to promote peroxidation. These antioxidants are found primarily in peroxisomes, which collaborate with the mitochondria in ROS processing. Reduction in peroxisomal activity results in mitochondrial dysfunction and ER stress. Furthermore, cytokines, such as TNF- α , can reduce peroxisomal number and function, rendering cells even more vulnerable.^{396,397}

Comorbidities Related to Insulin Resistance

The Metabolic Syndrome

The association and clustering of T2DM, hypertension, dyslipidemia, and CV disease in adults has led to the hypothesis that they may arise from a common antecedent. The WHO argues that this antecedent is insulin resistance, and defines this association as the metabolic syndrome.^{398–401} A consensus definition of the metabolic syndrome for the pediatric age group has been published⁴⁰² and declares that children younger than 10 years of age should not be defined as having this condition. For children older than 10 years of age, the obesity component of the definition is waist circumference and not BMI, indicating the clinical importance of intraabdominal fat. The metabolic

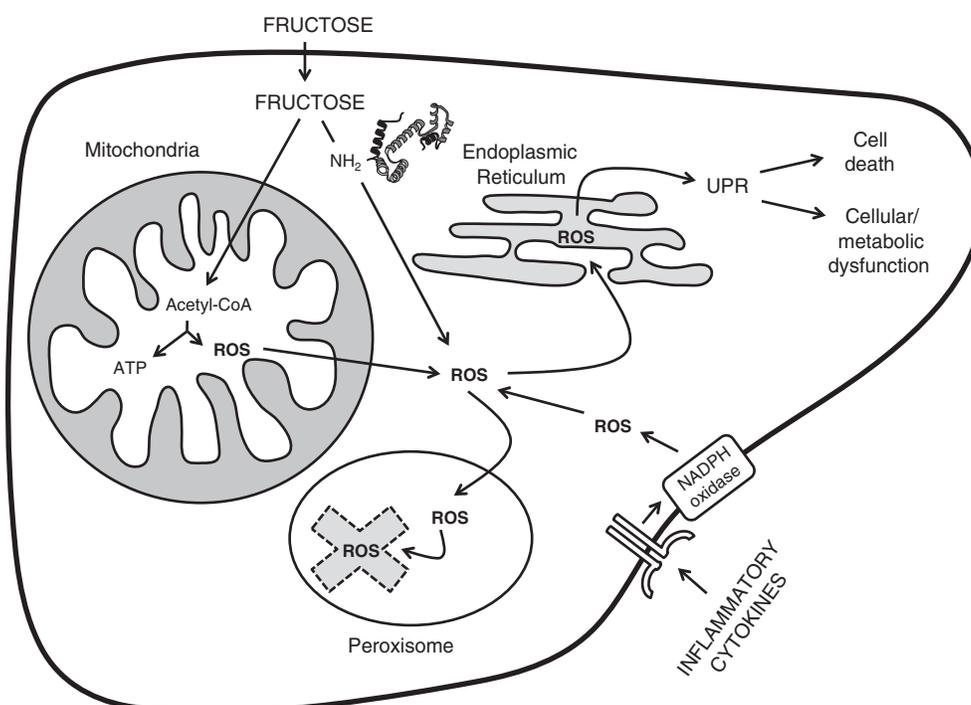

Fig. 24.8 Mechanisms of subcellular metabolic dysfunction, using fructose as an example. The formation of acetyl-CoA leads to lipid deposition and activation of inflammatory pathways, which results in serine phosphorylation of IRS-1, leading to insulin resistance. Furthermore, metabolic processing in the mitochondria, the glycation of protein ϵ -amino groups via the Maillard reaction, and circulating inflammatory cytokines, because of their receptor-mediated activation of NADPH oxidase, all increase intracellular levels of reactive oxygen species (ROS). In the absence of sufficient peroxisomal quenching and degradation, the ROS moieties lead to endoplasmic reticulum (ER) stress, promoting the unfolded protein response (UPR), and cause either cell death (apoptosis) or cellular/metabolic dysfunction. ATP, Adenosine triphosphate; CoA, coenzyme A; NADPH, nicotinamide adenine dinucleotide phosphate. (From Bremer, A.A., Mietus-Snyder, M.L., Lustig, R.H. (2012). Toward a unifying hypothesis of metabolic syndrome. *Pediatrics*, 129(3), 557–570. Courtesy American Academy of Pediatrics.)

syndrome affects approximately 25% of the US adult population.⁴⁰³ Because of its wide prevalence, the metabolic syndrome is of enormous clinical and public health importance, even at its earliest stages. Although still debated, one scheme of the pathophysiology of the metabolic syndrome is shown in Fig. 24.7. According to this paradigm, the impact of obesity is determined by the pattern of lipid partitioning—that is, the specific depots in which excess fat is stored. This pattern of lipid storage determines the adipocytokine secretion profile, on circulating concentrations of inflammatory cytokines and on the flux of FFA. The combined effect of these factors determines the sensitivity of insulin target organs (such as muscle and liver) to insulin and impacts the vascular system by affecting endothelial function. Peripheral insulin resistance and endothelial dysfunction are the early promoters of overt pathology, culminating in T2DM and CV disease. Regardless of the metabolic syndrome definition used, insulin resistance and high insulin levels are associated with the clustering of cardiometabolic risks associated with metabolic syndrome in a variety of ethnic groups. It should be noted that when studying a population (not necessarily an individual), increasing degrees of obesity in childhood are associated with greater risk for the presence of CV risk factors, yet this risk seems to plateau above a threshold of obesity which corresponds to 40 kg/m² in adults.⁴⁰⁴

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) represents fatty infiltration of the liver in the absence of alcohol consumption.⁴⁰⁵ The spectrum of NAFLD ranges from pure fatty infiltration (steatosis) to inflammation (nonalcoholic steatohepatitis, or NASH), to fibrosis and even cirrhosis.⁴⁰⁶ NAFLD was found in the NHANES III survey to be more prevalent in African American and Hispanic males with obesity, T2DM, hypertension, and hyperlipidemia.⁴⁰⁷ These associations have led to the hypothesis that NAFLD is an early marker of the presence of insulin resistance and appears before the development of overt diabetes. NAFLD is now the most common liver disease among children in North America.^{408,409} NAFLD in children is associated with increased visceral fat deposition,⁴¹⁰ and may progress to cirrhosis and related complications.⁴¹¹ The association between abdominal obesity and fatty liver may be partially explained by sustained exposure of the liver to an increased flux of FFA from the visceral depot.³³² NAFLD may represent an early manifestation of ectopic lipid deposition in the liver and represents a challenge to the clinician because of the contrast of its minimal early manifestations and its potential serious outcomes. Studies using the hyperinsulinemic euglycemic clamp methodology demonstrate that NAFLD is associated with hepatic and peripheral insulin resistance.

Insulin plays a key role in regulating transcription factors, such as SREBP-1c, which are abundantly expressed in the liver.⁴¹² SREBP-1c is pivotal in the control of hepatic lipogenesis and is increased in proportion to circulating insulin levels.⁴¹³ These data raise the possibility that fasting hyperinsulinemia may contribute to hepatic steatosis, rather than vice versa. Alternatively, inflammatory cytokines released by visceral fat or by the hepatic immune-reactive cells may contribute to altered hepatic lipid metabolism.⁴⁰⁵ It has been shown that specific SNPs, such as the rs58542926 SNP in the *TM6SF2* gene, are associated with pediatric NAFLD, explaining why some but not all children with obesity develop this phenotype.⁴¹⁴ The majority of patients probably experience NAFLD without progressing on to NASH. It is likely that subsequent inflammation from increased ROS formation without appropriate quenching is necessary to promote progression to NASH (the so-called *second hit* theory).^{411,415} For the time being, NAFLD can be

surmised by an elevated alanine aminotransferase (ALT) in children with obesity. However, ALT does not have to be very elevated; the 95th percentile for ALT in children is 25.8 U/mL for boys and 22.1 U/mL for girls.⁴¹⁶ Importantly, a normal ALT concentration does not rule out the presence of NAFLD.

Polycystic Ovarian Syndrome

The association of hyperandrogenism and oligomenorrhea or amenorrhea in females, termed *polycystic ovarian syndrome* (PCOS), is a frequent comorbidity of obesity, which can extend down to childhood. This disorder is covered in detail in Chapter 16. The diagnosis of PCOS must be based on the presence of at least two of the following three criteria: chronic anovulation, hyperandrogenism (clinical or biologic), and polycystic ovaries.⁴¹⁷ PCOS is the most common cause of infertility because of anovulation and a major risk factor for development of the metabolic syndrome and altered glucose metabolism in females. The antecedents of PCOS have been identified in prepubertal girls, suggesting a developmental lesion.⁴¹⁸

Adolescent girls with PCOS can have moderate to severe insulin resistance with increased risk for altered glucose metabolism and the impairment in insulin sensitivity is more pronounced in those with obesity compared with girls with PCOS who were lean. Typically, girls with PCOS and obesity demonstrate altered lipid partitioning including high visceral and hepatic lipid content, as well as decreased lipid mobilization, diminished fat oxidation, and metabolic inflexibility.⁴¹⁹ In some ethnic groups, girls with premature pubarche, a potential antecedent of PCOS, have relatively increased insulin levels, thus a causal link between hyperinsulinemia and androgen hypersecretion (of adrenal or ovarian origin) has been hypothesized. Population studies of normal girls have shown that rapid weight gain is associated with higher adrenal androgens and body fatness, and that hyperinsulinemia is related to early menarche. Thus the association of higher insulin levels with premature pubarche and subsequent PCOS may be driven, at least in part, by obesity. Obesity characterizes about 50% of women with classic PCOS,⁴²⁰ although it is even more common among adolescents. Increased peripheral insulin resistance occurs in approximately 50% of patients with PCOS, and almost certainly plays a role in the pathogenesis of this condition. On the other hand, almost all forms of severe insulin resistance, such as T2DM or rare lipodystrophy syndromes, are also associated with PCOS. Of note, insulin-resistance has not been included as a diagnostic criterion for PCOS mainly because of the difficulty of its measurement. Fasting hyperinsulinemia and an increased insulin secretory response to an oral glucose load have been demonstrated in girls with PCOS.⁴²¹ Indeed, adolescent girls with PCOS and obesity have been shown to be 50% more insulin resistant than weight-matched controls without PCOS.⁴²² The constellation of metabolic abnormalities typically seen in insulin resistant individuals is commonly encountered in adolescents with PCOS and obesity, including NAFLD⁴²³ and T2DM.⁴²⁴ The increased prevalence of the metabolic syndrome may be related to the hyperandrogenism independent of obesity-related insulin resistance.⁴²⁵ Early markers of accelerated atherogenesis are already present in young females with PCOS,⁴²⁶ indicating that early intervention aimed at reducing CV risk may be beneficial. Importantly, weight loss in women with PCOS is associated with improved menstrual function.⁴²⁷

Metabolic examination of patients with PCOS demonstrates hepatic and muscle resistance, but not ovarian insulin resistance; possibly accounting for insulin stimulation of theca cell androgen production.⁴²⁸ The correlation between insulin resistance and hyperandrogenism begs a unifying hypothesis as to

their pathogenesis, which is proffered by the “serine phosphorylation hypothesis,” which suggests that both P450c17 and the insulin receptor are aberrantly serine phosphorylated; in the case of P450c17, this leads to excess activity and increased androgen production,⁴²⁹ and in the case of the insulin receptor, this leads to tissue-specific insulin resistance.⁴³⁰ However, this hypothesis remains to be proven.

Other Endocrine Comorbidities

Obesity causes changes in other hormonal systems, some of which confer specific morbidities. The age of pubertal initiation has been creeping earlier, particularly in African American girls. This advancement is explained in part by the increasing overnutrition and BMI seen in this population.⁴³¹ Infertility in older adolescents and adult women may occur either as a manifestation of PCOS because of excessive ovarian androgen production in females, or because of excessive aromatization of androgen to estrogen by peripheral adipose tissue with suppression of the hypothalamic-pituitary gonadal axis in both sexes.⁴³² The hyperestrogenemia may also promote gynecomastia in males.⁴³³ In addition, the hypercapnia associated with OSA can suppress hypothalamic gonadotropin hormone (GnRH) function, leading to a syndrome of delayed puberty.⁴³⁴

Obesity is associated with decreased GH secretion, and indeed most subjects with obesity, despite normal or excessive statural growth, fail GH stimulation testing.⁴³⁵ However, caloric restriction for 24 hours can restore normal GH responsiveness.⁴³⁶ Despite the functional GH inadequacy, statural growth is accelerated, bone age is advanced, and peripheral total and free insulin-like growth factor (IGF)-1 levels are normal or elevated in obesity, suggesting normal or accentuated GH sensitivity,⁴³⁷ or possibly because of the suppression of insulin-like growth factor-binding protein (IGFBP)-1, and the effects of hyperinsulinemia on activation of the growth plate IGF-1 receptor.⁴³⁸ Free thyroxine levels tend to be lower and TSH higher in children with obesity, although mostly within the normal range along with some TSH levels within the subclinical hypothyroidism category; the mechanism is unknown. The elevated TSH levels in obesity seem a consequence rather than a cause of obesity. Therefore treatment of hyperthyrotropinemia with thyroxine seems unnecessary in children with obesity.⁴³⁹ Lastly, obesity can be associated with increased cortisol exposure, possibly because of conversion of circulating cortisone to cortisol by the enzyme 11- β -hydroxysteroid dehydrogenase type 1 (11 β HSD1) located within adipocytes.⁴⁴⁰

Other Nonendocrine Comorbidities

Childhood obesity is associated with numerous other comorbidities. Pseudotumor cerebri⁴⁴¹ is a rare and poorly understood condition leading to intracranial hypertension, whose manifestations include papilledema and headache. Treatment includes serial lumbar punctures, acetazolamide to reduce CSF production, in severe cases there is a need for a ventriculoperitoneal shunt, and occasionally optic nerve sheath fenestration is necessary to save eyesight. OSA occurs frequently in children with severe obesity; presumably because of the large amount of retropharyngeal fat that compresses the upper airway during sleep.⁴⁴² Affected patients snore, often stop breathing for more than 20 seconds during sleep, and wake up during the night with headache. Treatment includes nocturnal positive airway pressure and, when appropriate, tonsillectomy; however, symptoms often recur. Children with obesity manifest numerous orthopedic difficulties, including fractures, knee pain, anatomic lower limb malalignment, and impairment in mobility.⁴⁴³ Cholelithiasis occurs in approximately

2.5% of adolescents with obesity, especially in females, but is not usually seen in prepubertal children with obesity.⁴⁴⁴ Lastly, psychologic distress, including clinical depression, is clearly manifested in children with obesity⁴⁴⁵ and specifically in those with severe obesity. These various comorbidities all appear to be associated with BMI z-score in a curvilinear fashion⁴⁴⁶; thus the more their obesity, the more likely patients will manifest comorbidity.

FACTORS ASSOCIATED WITH THE CURRENT EPIDEMIC OF OBESITY

Genetics

The association between obesity and genetics owes to two separate lines of investigation: (1) the discoveries of monogenic disorders of the energy balance pathway (see later) and (2) studies of specific racial and ethnic groups, in which obesity seems to segregate, such as the Pima Indians and Hispanics in the Southwest United States.^{447,448} These observations are combined with an attractive theory on the natural selection of individuals in response to drastic environmental/ecologic pressure (i.e., famine), termed the *thrifty gene hypothesis*,⁴⁴⁹ to yield a very strong driving force for the elucidation of specific genetic loci in the pathogenesis of obesity.⁴⁵⁰ However, the rapid timescale of increased prevalence of childhood obesity cannot possibly reflect a population genetic change. Therefore the current model is that obesity is a result of gene-environment interactions; an ancient genetic selection to deposit fat efficiently may have provided a survival advantage in earlier times but is maladaptive with our current food overabundance. An evolutionary approach to obesity development involves a genomic/anthropologic dimension. For millions of years, the lifestyle of hunter-gatherers comprised intense physical activity and a high-protein/low-carbohydrate diet and the genomes of our ancestors were adapted to low insulin sensitivity. Upon development of farming, a diet high in carbohydrates emerged and since the industrial revolution, our genome is rapidly adapting to such diet. Our current genome represents a mixture of the two. Upon exposure to energy excess induced by the current food environment, these genomes may manifest as development of obesity at different timing and may respond differently to specific diets.⁴⁵¹

In the common forms of obesity, relating SNPs with associated risks for obesity is difficult because the effects are uncertain, and the results not always confirmed. Several SNPs in specific genes have been identified, such as the fat mass and obesity associated (*FTO*) gene. Variation in the *FTO* gene has provided the most robust associations with common obesity to date yet the *FTO* variant that confers a predisposition to obesity does not appear to be involved in the regulation of energy expenditure but may have a role in the control of food intake and food choice, suggesting a link to a hyperphagic phenotype or a preference for energy-dense foods.⁴⁵² The large genome-wide association studies (GWAS) have yielded to date more than 300 loci that may be relevant to the development of adult obesity, yet explain less than 5% of the phenotype.^{453,454}

Epigenetics and Developmental Programming

Follow-up studies of newborns born small-for-gestational age (SGA), large-for-gestational age (LGA), and premature, have noted markedly increased risks for obesity and the metabolic syndrome. The “fetal origins hypothesis”⁴⁵⁵ states that some aspect of the in utero environment contributes to the development of obesity and chronic disease in later life. Importantly, each of these three antenatal conditions is associated with insulin resistance. The “developmental model” of chronic diseases

postulates that early-life events affect individual differences in vulnerability to lifestyle and environment. One possible mechanism for such developmental programming includes epigenetic changes, which may contribute to alterations in gene expression. For instance, the pattern of DNA methylation noted in cord blood predicts the degree of adiposity at age 9 years.⁴⁵⁶

Documentation of the relationship of SGA with adult obesity and CV disease started with studies of the Dutch famine during World War II and its aftermath.⁴⁵⁷ Several studies of newborns born SGA demonstrate that they are hyperinsulinemic and insulin resistant at birth, exhibit rapid catch-up growth in the early postnatal period, and develop obesity in childhood, which remains and promotes persistent insulin resistance. An analysis of Indian newborns born in India versus the United Kingdom⁴⁵⁸ demonstrated that despite those born in India weighing 700 g less at birth, their glucose and insulin levels are markedly elevated. After adjustment for birth weight, the India-born babies demonstrate increased adiposity, 4 times higher insulin, 2 times higher leptin levels than the UK-born babies. Thus these babies are insulin resistant even at birth, which translates into increased adiposity. Following such babies into childhood, there are numerous studies documenting insulin resistance during early childhood.^{459–461}

Babies born LGA are often hyperinsulinemic at birth.⁴⁶² Although most LGA babies are caused by gestational diabetes mellitus (GDM) and exposure to maternal obesity and hyperglycemia throughout the pregnancy, this is not always the cause. Follow-up of LGA babies without GDM demonstrates a doubling of prevalence of insulin resistance and metabolic syndrome, whereas LGA babies resulting from GDM manifest a threefold increase.^{463,464} It has been shown that adolescents with obesity who were exposed in utero to GDM are more insulin resistant and have impaired β -cell function compared with peers with equal degree of obesity without such exposure.⁴⁶⁵ Indeed, the “vertical” transmission of maternal diabetes to the offspring in the form of later obesity and diabetes has been documented in studies of Pima Indians.^{466,467} Lastly, weight gain during pregnancy increases birth weight, the risk for LGA, and obesity in the offspring^{468,469} (Fig. 24.9).

The protective effect of breastfeeding against development of future obesity has long been known,²⁹⁶ and there appears to be a dose–response; the longer the breastfeeding, the more

protective.⁴⁷⁰ However, this may be complicated by confounding factors, such as socioeconomic status, maternal smoking in pregnancy, and maternal BMI.⁴⁷¹ The mechanism of breastfeeding’s antiobesity effect is also unclear. Some think infant feeding self-regulation is most relevant, whereas a recent study suggests that leptin in breast milk may contribute to this protection,⁴⁷² and finally, maternal breastfeeding may shape the offspring intestinal microbiome into a profile different than that induced by consumption of formula.^{298,473}

Environmental Factors

Numerous environmental factors have also been associated with the obesity epidemic, particularly in children. However, most of these associations are derived from cross-sectional rather than longitudinal studies, and in many instances, mechanism remains lacking.⁴⁷⁴ Several longitudinal studies in adults have clearly demonstrated that specific dietary and other lifestyle behaviors are independently associated with long-term weight gain, with a substantial aggregate effect. For instance, on the basis of increased daily servings of individual dietary components, 4-year weight change was most strongly associated with the intake of potato chips (0.767 kg), potatoes (0.58 kg), sugar-sweetened beverages (0.45 kg), unprocessed red meats (0.43 kg), and processed meats (0.42 kg) and was inversely associated with the intake of vegetables (-0.1 kg), whole grains (-0.168 kg), fruits (-0.224 kg), nuts (-0.25 kg), and yogurt (-0.37 kg) ($P \leq .005$ for each comparison).⁴⁷⁵ Similarly, the sociodemographic environment has been shown to affect the chance of having obesity in adulthood. Indeed, the opportunity to move from a neighborhood with a high prevalence of poverty to one with lesser poverty was associated with modest but potentially important reductions in the prevalence of extreme obesity and diabetes.⁴⁷⁶ Similar relationships are likely, but not proven, for children and adolescents.

Stress and Cortisol

In humans, elevated cortisol or markers of the hypothalamus, pituitary, and adrenal (HPA) axis dysregulation correlate with abdominal fat distribution and the metabolic syndrome.⁴⁷⁷ Although circulating cortisol is clearly important in determining visceral adiposity, the recent identification of reduction of circulating cortisone to cortisol within visceral fat tissue by the enzyme 11 β HSD1 has also been linked to the metabolic syndrome.^{440,478} These data suggest that cortisol is important both in increasing visceral adiposity and promoting the metabolic syndrome. The mechanistic link between stress and obesity has not been clarified, partly because of the inherent complexity of evaluating a potentially bidirectional effect of stress on eating and body weight. Studies focusing on brown adipose tissue metabolism support a dichotomous relation to explain the impact of stress on obesity: stress promotes obesity in the presence of hyperphagia and stable brown adipose function, whereas stress results in weight loss or protection from obesity development in the presence of hypophagia or when increased calorie intake is associated with brown adipose recruitment and enhanced thermogenesis (being of white adipocytes).⁴⁷⁹

Evidence of associations between elevated cortisol and psychological distress with abdominal fat distribution in adults is compelling. For instance, urinary glucocorticoid excretion is linked to aspects of the metabolic syndrome, including blood pressure, fasting glucose, insulin, and waist circumference.⁴⁷⁷ It seems that some individuals seem to be “high-responders” to a stress stimulus and demonstrate higher cortisol secretion. These individuals seem more prone for an alteration in satiety recognition and consume larger amounts of calories following the stress exposure (see Fig. 24.5). These data suggest that cortisol

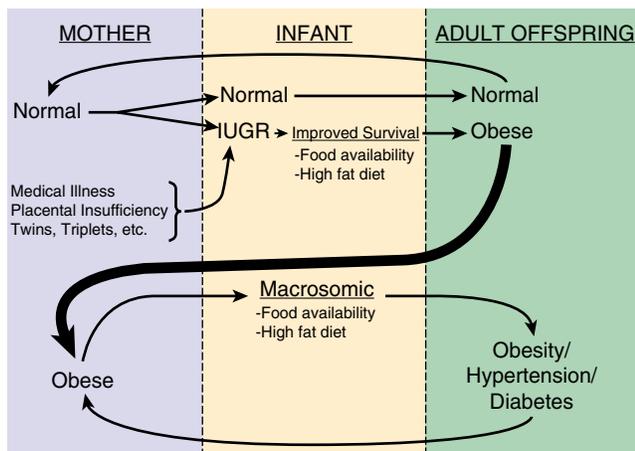

Fig. 24.9 Postulated mechanisms by which developmental programming (either intrauterine growth retardation or neonatal macrosomia) can lead to adult obesity in the offspring. (From Ross, M.G., Huber, I., Desai, M. (2010). Intrauterine growth restriction, small for gestational age, and experimental obesity. In: Lustig, R.H., ed. *Obesity Before Birth: Maternal and Prenatal Effects on the Offspring*. New York, Springer, p. 215–239.⁹⁰⁶ Courtesy Springer, Inc.)

is important both in increasing visceral adiposity and promoting insulin resistance, equivalent to “Cushing syndrome of the abdomen.”⁴⁸⁰

Sleep Deprivation

Adults in the United States currently average less than 7 hours of sleep per night—almost 2 hours less than in 1980—and about one-third of them get less than 6 hours per night.⁴⁸¹ Analyses of data from the NHANES I, revealed that adults (ages 32–49 years) who got less than 7 hours of sleep were more likely to have obesity 5 to 8 years later than those who got 7 or more hours of sleep.⁴⁸² The link between short sleep duration and obesity has also been observed among children.⁴⁸³ Longitudinal studies in children, with subjects from diverse backgrounds, suggested an inverse association between sleep duration and BMI. In 24,821 participants, pediatric subjects sleeping for short duration had twice the risk of having overweight/obesity, compared with subjects sleeping for long duration (odds ratio 2.15; 95% CI, 1.64–2.81).⁴⁸⁴ Like adults, increasing numbers of children are chronically sleep deprived. This is especially true of children with obesity, who have been found to get less sleep than those of normal weight. In addition to its other effects, sleep is one of the most powerful cross-sectional⁴⁸⁵ and longitudinal⁴⁸⁶ predictors of childhood obesity in prepubertal children.

Television Viewing and “Media Time”

Television watching is considered one of the most modifiable causes of childhood obesity.⁴⁸⁷ There are four possible mechanisms linking television watching and obesity. Firstly, television watching may increase stress levels and cortisol (see earlier), causing increased food intake, and promotion of obesity.⁴⁸⁸ Second, television watching displaces physical activity. Most, but not all studies find inverse correlations between television watching and physical activity and fitness.^{489,490} Third, television watching increases calorie consumption from eating during viewing or from the effects of food advertising. Television viewing is also associated with increased high-fat food intake, decreased fruit and vegetable consumption, and increased soft drink intake.⁴⁹¹ “Junk food” is the most frequently advertised product category on children’s television. Lastly, REE and NEAT appear to be decreased during television watching.⁴⁹² According to NHANES III, the prevalence of childhood obesity is lowest among children watching television for 1 hour or less a day, and highest among those watching 4 hour or more a day.⁴⁹³ Several experimental studies of reducing television watching have been conducted and their results support the suggestion that reduced television watching may help to reduce the obesity risk or help promote weight loss in children with obesity.⁴⁹⁴ These studies represent the strongest direct evidence that altering television watching alone is a promising strategy for prevention of childhood obesity. Other forms of screen time, such as cell phones, are also implicated in obesity pathogenesis. It has been shown that parental monitoring of child media exposure predicted lower child BMI z-scores at age 7 years and less steeply increasing child BMI z-scores from 5 to 9 years, thus parental behaviors related to children’s media consumption may have long-term effects on children’s BMI in middle childhood.⁴⁹⁵

Dietary Factors

Calories from any food have the potential to increase risk for obesity and cardiometabolic disease because all calories can directly contribute to positive energy balance and fat gain. However, various dietary components may promote obesity and cardiometabolic disease by additional mechanisms that

are not mediated solely by their caloric content.⁴⁹⁶ Regarding the health effects of specific dietary elements, it has been shown that food-specific saturated fatty acids and sugar-sweetened beverages promote cardiometabolic diseases by mechanisms that are additional to their contribution of calories to positive energy balance. Metabolic effects and responses to certain dietary components are influenced by the individual’s metabolic status, developmental period, or genotype; by the responsiveness of brain regions associated with reward to food cues; and possibly by the microbiome.

Dietary Fat Versus Carbohydrate

Fat is generally considered more obesogenic than other macronutrients, because it is more energy dense, highly palatable, and more effectively converted to body fat.⁴⁹⁷ A high-fat meal induces less thermogenesis and a higher positive fat balance than an isocaloric and isoprotein containing low-fat meal.⁴⁹⁸ Excessive fat intake is believed to cause weight gain,⁴⁹⁹ but the relationships between dietary fat intake and childhood adiposity remain controversial.⁵⁰⁰

The prevalence of overweight in the United States has increased despite a decreased percentage of dietary energy derived from fat. A metaanalysis of 12 studies in adults with overweight or obesity adults who were given dietary advice on low-fat diet and followed for 6 to 18 months suggested that low-fat diets are no better than calorie-restricted diets in long-term weight loss.⁵⁰¹ Similarly, in children, total fat consumption expressed as a percentage of energy intake has decreased.⁵⁰² This decrease in fat consumption is largely caused by increased total energy intake in the form of carbohydrates. Much of this imbalance is attributed to changing beverage consumption patterns, characterized by declining milk intakes and substantial increases in soft-drink consumption,⁵⁰³ which may have its own etiopathogenesis (see later). Most interventions with a low-fat, heart-healthy diet, have not been successful in childhood overweight prevention.⁵⁰⁴

Reduction in carbohydrate intake is taken to the extreme in the ketogenic diets, such as the Atkins diet, which restricts adult subjects to less than 25 g/d of ingested carbohydrate. Adult evaluations of the diet have been disappointing long term,^{505,506} and the popular diet has been abandoned recently. There are currently no data in children or adolescents. However, it should be noted that the ketogenic diet used for seizure control is similar in composition to the Atkins diet. A 2-year study of the ketogenic diet demonstrated persistent decreases in weight z-scores in children who were above average upon diet initiation, without significant compromise in general nutrition or in height.⁵⁰⁷

Trans Unsaturated Fatty Acids (Trans-Fats)

Trans-unsaturated fats in processed foods have been a staple in the Western diet since the early 20th century. This is because the trans-isomerization of the double bond prevents fatty acid breakdown by bacteria, prolonging the shelf life of food products. Like its bacterial predecessors, human mitochondria cannot subject trans-fats to β -oxidation in the liver,⁵⁰⁸ contributing to ectopic intrahepatic lipid accumulation. Fortunately, because of the recognized association between trans-fat consumption and CV disease in the mid-1980s and more stringent labeling requirements since 2006, the percent of calories from trans-fats consumed in the Western diet has been gradually declining.⁵⁰⁹ Trans-fats have no health benefit and cause hepatic steatosis and insulin resistance⁵¹⁰; however, their current consumption trends are temporally disparate with the current increasing prevalence of metabolic syndrome, suggesting that other factors are involved.

Glycemic Index and Fiber

Not all sugars exert the same insulinogenic response. Complex carbohydrates can take two forms: either a combination of α 1-4 linkages and α 1-6 linkages, which gives the starch a globular structure called *amylopectin*, as seen in bread, rice, pasta, potatoes, and glycogen; or a linear polymer of α 1-4 linkages called *amylose*, as seen in beans, lentils, and other legumes. Digestion and absorption of the former in the intestine is rapid because of the simultaneous actions of both α 1-4 and α 1-6 glucosidases, whereas that of the latter is much slower because the α 1-4 glucosidase can only cleave single glucose moieties on either side of the polymer. This phenomenon constitutes the basis of the glycemic index (GI),⁵¹¹ which refers to the relative glucose area under the curve after consumption (in comparison with dextrose). High-GI foods lead to an accentuated insulin response, which can shunt energy substrate to adipose tissue.⁵¹² In children, controlled studies with a high-GI diet demonstrate that energy intake is 53% higher than on low-GI diet.⁵¹³ One adolescent study demonstrated that an *ad libitum* low-GI diet was more effective in promoting weight loss than an energy-restricted low-fat diet.⁵¹⁴ Therefore the GI may be a simple concept to institute, although the “toxic environment” of American food products may make it difficult to maintain.

Dietary fiber consists of the nonstarch, polysaccharide portion of plant foods, including cellulose, hemicellulose, pectins, β -glucans, fructans, gums, and algal polysaccharides. Major sources of dietary fiber include whole grains, fruits, vegetables, legumes, and nuts. Fiber content accounts for 50% of the variability in glycemic load (GL; GI \times volume) between foods. Cohort studies of adults demonstrate that fiber intake is inversely associated with weight gain, fasting insulin levels, and risk of T2DM.^{515,516} Fiber may influence body weight regulation by several mechanisms involving intrinsic, hormonal, and colonic effects, which eventually decrease food intake by promoting satiation (lower meal energy content), satiety (longer duration between meals), or by increasing fat oxidation and decreasing fat storage.⁵¹⁷ A fiber-rich meal is processed more slowly and has less caloric density and lower in fat and added sugars. Fiber-containing foods engender slower glucose absorption, which lessens the postprandial insulin surge and decreases lipogenesis.⁵¹⁸ In addition, high-fiber meals allow for delivery of undigested triglyceride to the colon, where fermentation to short-chain fatty acids and their absorption improve lipids and insulin sensitivity.⁵¹⁹ Archeologists surmise that our ancestors consumed 100 to 300 g of fiber/d.⁵²⁰ However, the dietary fiber intake throughout childhood and adolescence currently averages approximately 12 g/d, and has not changed during the past 30 years.⁵²¹ Therefore parents and school foodservice personnel should strive to offer fiber-rich foods to children so their acceptance and consumption of them will be increased.⁵²²

Fructose

The most commonly used sweetener in the US diet is the disaccharide sucrose (e.g., table sugar), which contains 50% fructose and 50% glucose. However, in North America and many other countries, nondiet soft drinks are sweetened with high-fructose corn syrup (HFCS), which contains up to 55% of the monosaccharide fructose. Thanks to its abundance, sweetness, and low price, HFCS has become the most common sweetener used in processed foods. It is not that HFCS is biologically more ominous than sucrose; rather, it is that its low cost has made it available to everyone, especially low socioeconomic groups. HFCS is found in processed foods ranging from soft drinks and candy bars to crackers to hot dog buns to ketchup. Average daily fructose consumption has increased by over 25% over the past 30 years. The growing dependence on fructose in the Western diet may be fueling the obesity and T2DM epidemics.⁵²³ The highest

fructose loads are soda (1.7 g/30 mL) and juice (1.8 g/30 mL). Although soda has received most of the attention,^{289,524} high fruit juice intake is also associated with childhood obesity, especially by lower income families.⁵²⁵ Animal models demonstrate that high-fructose diets lead to increased energy intake, decreased resting energy expenditure, excess fat deposition, and insulin resistance,⁵²⁶ which suggest that fructose consumption is playing a role in the epidemics of insulin resistance and obesity and T2DM in humans.^{527,528}

Fructose in the gut is transported into the enterocyte via the fructose transporter GLUT5, independent of ATP hydrolysis and sodium absorption. Once inside in the enterocyte, a small portion of the fructose load is converted to lactic acid and released in the portal circulation, another small portion may also be converted to glucose. However, the majority of ingested fructose is secreted into the portal circulation and delivered to the liver. There, fructose is rapidly metabolized to fructose-1-phosphate (F1P) via fructokinase, an insulin-independent process, which also bypasses the negative feedback regulation of phosphofructokinase in the glycolytic pathway. Thus fructose metabolism generates lipogenic substrates (e.g., glyceraldehyde-3-phosphate and acetyl-CoA) in an unregulated fashion, which are delivered directly into the mitochondria. This excessive mitochondrial substrate then drives hepatic DNL, leading to intrahepatic lipid deposition and steatosis.⁴¹⁵ Hepatic DNL also limits further fatty acid oxidation in the liver via excess production of malonyl-CoA, which reduces entry of fatty acids into the mitochondria by inhibiting carnitine palmitoyl transferase 1 (CPT-1). F1P also stimulates SREBP-1c via peroxisome proliferator-activated receptor gamma coactivator (PGC)-1 β ,⁵²⁹ independently of insulin, which activates the genes involved in DNL; moreover, fructose has been shown to induce activation of carbohydrate-response element binding protein (ChREBP), which also increases the expression of all the enzymes of DNL. Furthermore, F1P activates dual-specificity mitogen-activated protein kinase 7 (MKK7), which subsequently stimulates Janus kinase 1 (JAK1), a hepatic enzyme considered to act as a bridge between hepatic metabolism and inflammation.⁵³⁰ In addition, the lipogenic intermediate DAG (formed during fructose metabolism in the liver) activates PKC ϵ , which phosphorylates serine residues on IRS-1, inactivating it, and leading to hepatic insulin resistance.⁴¹⁵ This impairs insulin-mediated phosphorylation of FOXO1, leading to increased expression of the genes required for gluconeogenesis and promoting increased hepatic glucose output, also contributing to hyperglycemia and the development of T2DM. The excess TGs secreted from the liver into the circulation as fat-laden VLDL particles following the ingestion of fructose, coupled with a fructose-induced reduction in LPL activity, cause sustained postprandial dyslipidemia, thereby augmenting the risk for CV disease.^{531,532} (Fig. 24.10A,B).

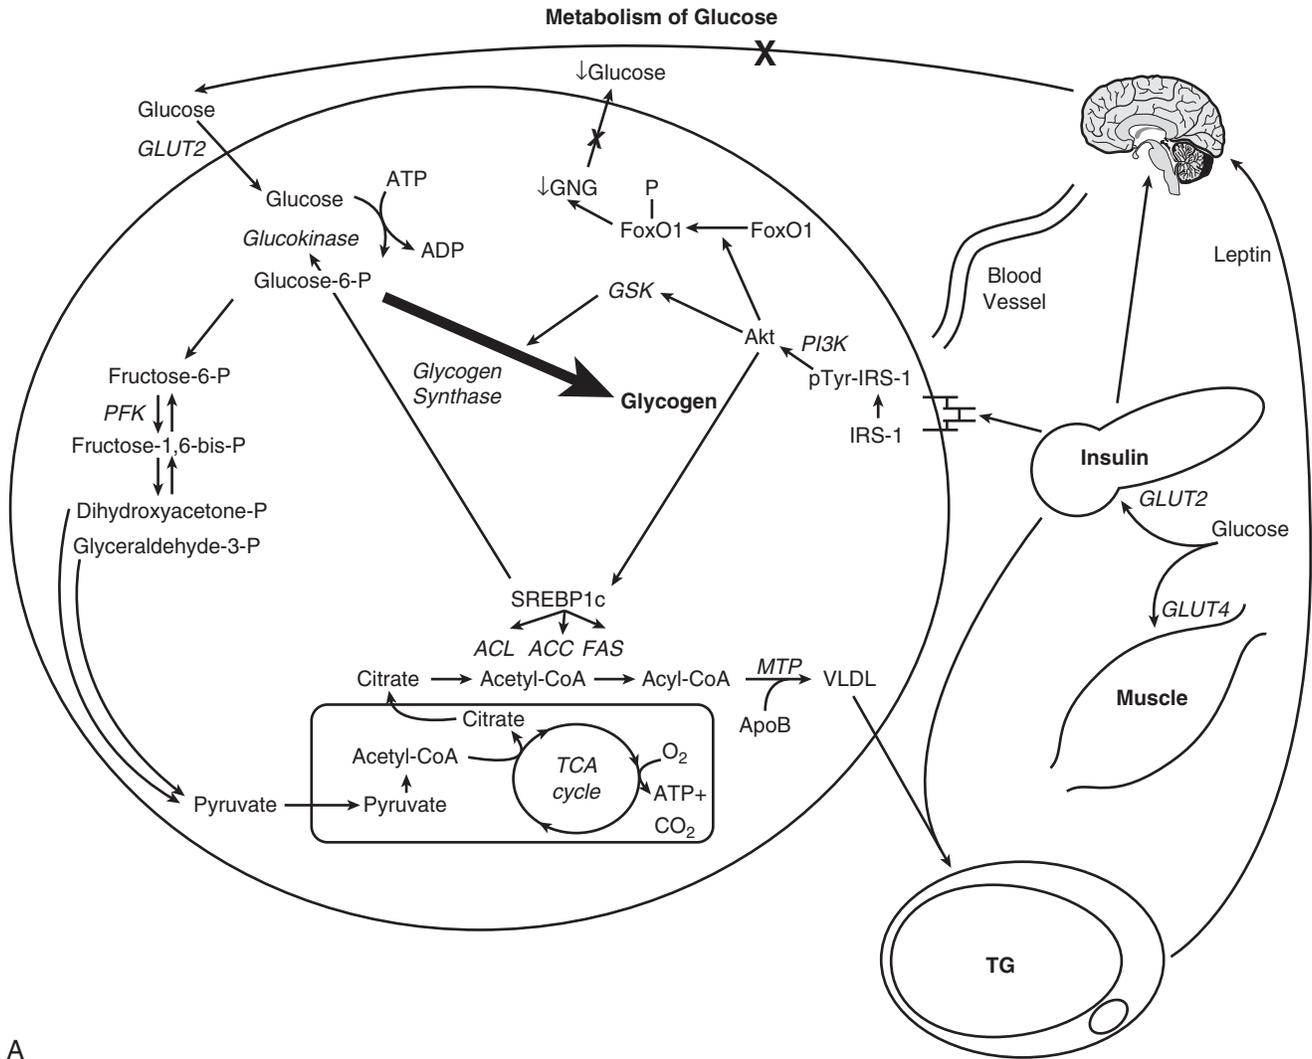

Because of its unique stereochemistry, the ring form of fructose (a five-membered furan with axial hydroxymethyl groups) is under a great deal of ionic strain, which favors the linear form of the molecule, exposing the reactive 2-keto group, which can readily engage in the nonenzymatic fructosylation of exposed amino moieties of proteins via the Maillard reaction, in the same way that the 1-aldehyde position of glucose is reactive.⁴¹⁵ Each Maillard reaction generates one ROS, which must be quenched by an antioxidant or risk cellular damage. In an *in vitro* study, incubation of hepatocytes with fructose yielded no direct damage; however, when these hepatocytes were preincubated with sublethal doses of hydrogen peroxide to reduce their peroxisomal ROS-quenching ability, fructose then became as hepatotoxic as other organic aldehydes.⁵³³ Mild reduction of fructose in an isocaloric diet intervention for a few days was shown to reduce intrahepatic fat, glucose, and insulin levels indicating its unique metabolic impact, independent of its caloric value.⁵³⁴

Branched-Chain Amino Acids

Branched-chain amino acids (BCAAs: valine, leucine, and isoleucine) are essential amino acids that account for more than 20% of the amino acids in the typical “Western diet.”⁵³⁵

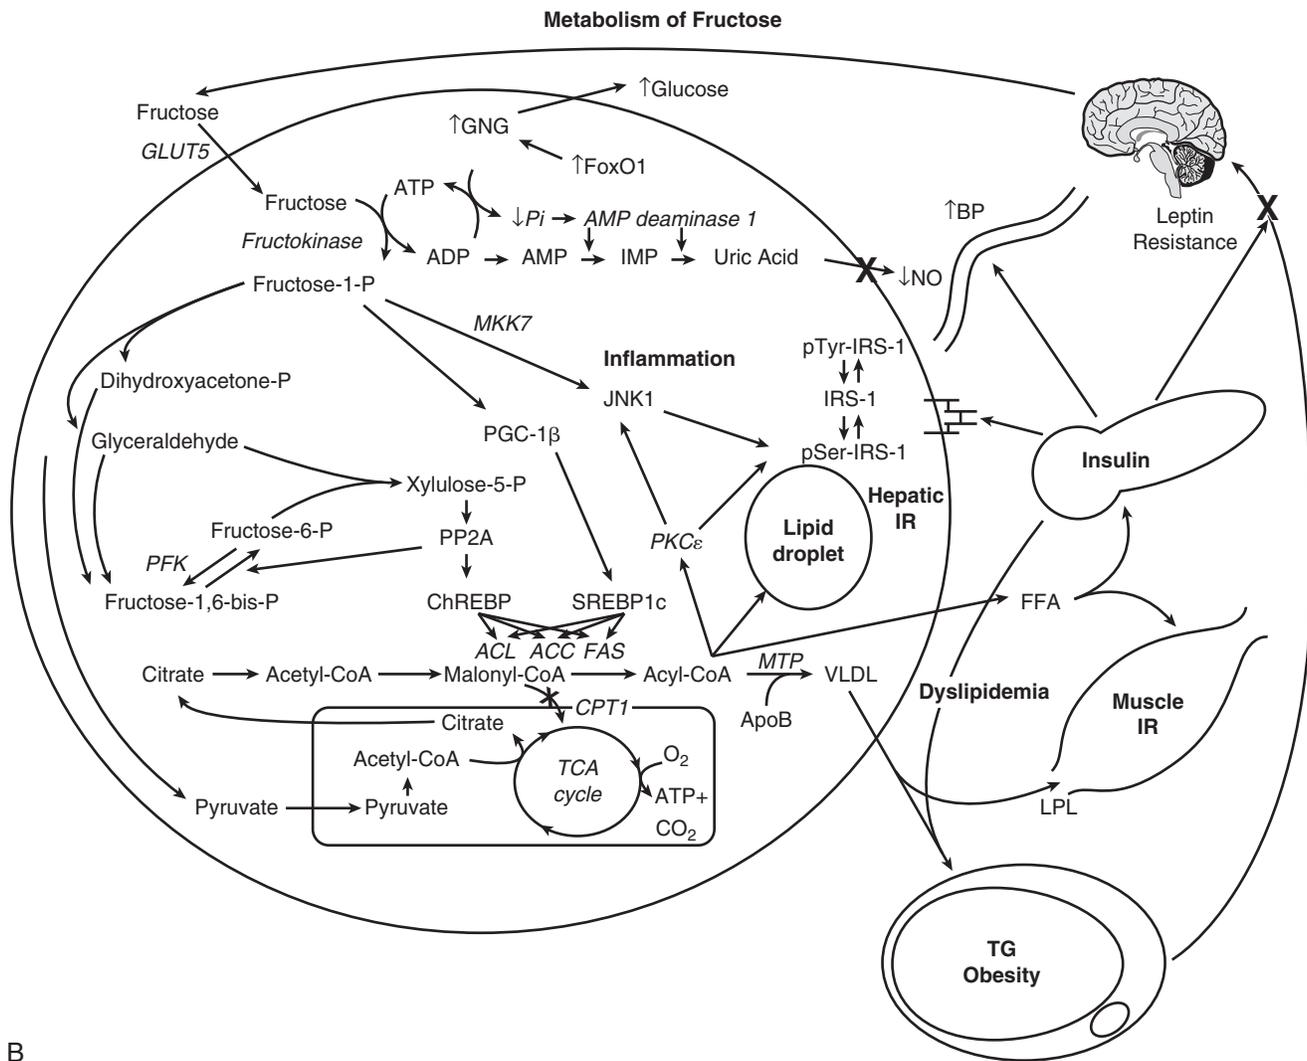

Although normally used for protein biosynthesis and cell growth, when provided in excess they are diverted away from protein synthesis and toward energy utilization.⁵³⁶

In the liver, BCAAs increase transcription of ChREBP and SREBP-1c,⁵³⁷ facilitating DNL. Furthermore, BCAAs limit

A

Fig. 24.10 Hepatic (A) glucose and (B) fructose metabolism. Of an ingested glucose load, 20% is metabolized by the liver; thus in a 120-kCal glucose load (two slices of white bread), 24 calories are hepatically metabolized. Under the action of insulin, glycogen synthase is increased, and the majority of the glucose load is stored as glycogen. Although insulin activation of sterol regulatory element-binding protein 1c (SREBP-1c) activates the lipogenic pathway, there is little citrate formed to act as substrate for lipogenesis. In addition, insulin action on the liver phosphorylates forkhead protein-1 (FOXO1), excluding it from the nucleus, and suppressing the enzymes involved in gluconeogenesis (GNG). In comparison, virtually 100% of a fructose load is hepatically metabolized; thus in a 120-kCal sucrose load (an 8-oz. glass of orange juice), a bolus of 72 calories reach the liver. In contrast to glucose, fructose induces: (1) substrate-dependent hepatocellular phosphate depletion, which increases uric acid and contributes to hypertension through inhibition of endothelial nitric oxide synthase and reduction of nitric oxide (NO); (2) stimulation of de novo lipogenesis and excess production of VLDL and serum triglyceride, promoting dyslipidemia; (3) accumulation of intrahepatic lipid droplets, promoting hepatic steatosis; (4) production of FFA, which promotes muscle insulin resistance; (5) c-jun N-terminal kinase (JNK-1) activation, which serine phosphorylates and the hepatic insulin receptor, rendering it inactive, and contributing to hepatic insulin resistance, which promotes hyperinsulinemia and influences substrate deposition into fat; and (6) central nervous system hyperinsulinemia, which antagonizes leptin signaling (see Fig. 24.5) and promotes continued energy intake. ACC, Acetyl-CoA carboxylase; ACL, ATP citrate lyase; ACSS2, acyl-CoA synthetase short-chain family member 2; ApoB, apolipoprotein B; ChREBP, carbohydrate-response element binding protein; CPT-1, carnitine palmitoyl transferase-1; FAS, fatty acid synthase; FFA, free fatty acids; GLUT2, glucose transporter 2; GLUT4, glucose transporter 4; GLUT5, glucose transporter 5; GSK, glycogen synthase kinase; IR, insulin resistance; IRS-1, insulin receptor substrate-1; LPL, lipoprotein lipase; MKK7, MAP kinase 7; MTP, microsomal transfer protein; PFK, phosphofructokinase; PGC-1 β , peroxisome proliferator-activated receptor- γ coactivator-1 β ; PI3K, phosphatidylinositol-3-kinase; PKC ϵ , protein kinase C- ϵ ; PP2A, protein phosphatase 2a; SREBP-1c, sterol regulatory element binding protein-1c; VLDL, very low-density lipoprotein. B

Fig. 24.10, cont'd

insulin-induced PI3K signaling and stimulate the activation of the mammalian (aka molecular) target of rapamycin (mTOR), promoting the serine phosphorylation of IRS-1 and impairment of insulin signaling. In addition, just as there are obesity-related changes in adipokines and CV risk markers, there also appear to be obesity-associated changes in BCAA metabolism and subsequent serum levels. In particular, valine and leucine/isoleucine levels have been reported to be 20% and 14% higher, respectively, in subjects with obesity compared with those with normal weight.⁵³⁶ Mechanistically, this appears to be accounted for by a high rate of flux through the BCAA catabolic pathway, resulting in the increased production of alanine. Because alanine is a highly gluconeogenic amino acid, increased BCAA catabolism may thus contribute to increased hepatic glucose output.⁵³⁸ Furthermore, the increased α -ketoacids generated by increased flux of the BCAAs through their catabolic pathways also potentially suppress mitochondrial β -oxidation.

Furthermore, chronic BCAA elevation impairs the transport of aromatic amino acids into the brain; the reduced production of serotonin (derived from tryptophan) and catecholamines (derived from phenylalanine and tyrosine) may drive hunger.⁵³⁶ The "BCAA overload" hypothesis suggests that in the context of a dietary pattern that includes high fat consumption, BCAAs may make an independent contribution to the

development of insulin resistance, a hypothesis supported by metabolomics studies demonstrating high BCAA levels in normoglycemic individuals that subsequently develop insulin resistance and diabetes.^{539,540}

Ethanol

Although adult epidemiologic studies associate light to moderate ethanol consumption with improved insulin sensitivity and red wine consumption with reduced CV risk, other cross-sectional and prospective studies implicate a dose-dependent effect of alcohol in metabolic syndrome, and suggest that chronic consumption of large amounts of ethanol worsen insulin sensitivity. Ethanol bypasses glycolysis by being converted by alcohol dehydrogenase-1B to form acetaldehyde, which promotes ROS formation and must also be quenched by hepatic antioxidants, such as glutathione or ascorbic acid. Acetaldehyde is then metabolized by the enzyme aldehyde dehydrogenase-2 to acetic acid, which in turn is metabolized by the enzyme acyl-CoA synthase short-chain family member 2 to form acetyl-CoA. The acetyl-CoA can then enter the mitochondria, or, in the presence of other caloric substrates, it is preferentially used for the synthesis of fatty acids through DNL. The excess malonyl-CoA produced from ethanol

metabolism inhibits CPT-1 and thus limits mitochondrial fatty acid β -oxidation. Ethanol also blocks fatty acid β -oxidation by inhibiting PPAR- γ , which suppresses microsomal triglyceride transfer protein, thereby altering the liver's lipid export machinery.^{541–543} Buildup of intrahepatic lipid metabolites leads to subsequent activation of the enzyme JNK-1 and serine-phosphorylation of the IRS-1, driving further hepatic insulin resistance. Thus ethanol metabolism results in intrahepatic lipid accumulation and liver injury,^{544,545} driving hepatic insulin resistance and promoting the metabolic syndrome.⁵⁴⁶ However, although clearly a concern in adults, it is unlikely that ethanol contributes significantly to metabolic syndrome in children.

Calcium and Dairy

There have been several reports of an *inverse* relationship between dietary calcium and obesity indices.^{547,548} Dietary calcium plays an important role in energy metabolism regulation. Increased calcitriol (1,25-dihydroxyvitamin D) in response to low-calcium diets stimulates Ca^{2+} influx in human adipocytes, which may lead to stimulation of lipogenic gene expression and lipogenesis, as well as inhibition of lipolysis.⁵⁴⁸ This may result in an expansion of adipocyte triglyceride stores, which can promote adiposity. Increased dietary calcium reduces calcitriol levels and leads to reduction of fat mass without caloric restriction in mice,⁵⁴⁹ and this antiobesity effect of dietary calcium is supported by human clinical and epidemiologic studies.⁵⁵⁰ Vitamin D deficiency correlates with increasing BMI, especially in African Americans⁵⁵¹; however, it is not known if this is caused by substitution of soft drinks for dairy, lactose intolerance, or other factors. One adult study⁵⁵² revealed a consistent effect of higher calcium intake on lower body weight and body fat; however, pediatric studies are lacking.

Intestinal Microbiome

Despite establishing a strong association between the gut microbiota and obesity in humans, a causal relationship and discovery of the underlying mechanisms remain to be identified. Studies have shown that fecal transplants from humans with obesity and normal weight to gnotobiotic mice result in adoption of the donor obesity phenotype by the formerly germ-free rodents. This suggests that the microbiome is indeed implicated in the development of obesity, and perhaps in the development of adiposity-related comorbidities. The gut acquires its microbial profile by colonizing bacteria from birth and during the first year of life. Intestinal crosstalk with colonizing bacteria in the developing intestine affects the infant's adaptation to extrauterine life (immune homeostasis) and may provide protection against disease development (such as obesity) later in life. Disrupted colonization (dysbiosis) caused by maternal dysbiosis, cesarean section delivery, and use of perinatal and neonatal antibiotics may adversely affect the gut development of host defenses and predispose to inflammation rather than to homeostasis, leading to increased susceptibility to development of diseases later in life.⁵⁵³ It has been shown that the gut microbiome responds to diet, antibiotics, and other external stimuli in ways that impact a variety of metabolic conditions, including obesity and NAFLD. The predominance of certain human intestinal flora species (*Firmicutes* vs. *Bacteroides*) may predispose both animals and humans to obesity,⁵⁵⁴ possibly by increasing efficiency of energy absorption⁵⁵⁵; however, factors that determine their predominance are unknown.

Medications

Numerous medications promote excessive weight gain in children. The most commonly prescribed are pharmacologic doses

of glucocorticoids (e.g., prednisone, methylprednisolone, dexamethasone) used for their antiinflammatory and antineoplastic activities. Patients so treated frequently develop obesity,^{556,557} and develop many of the features of Cushing syndrome (e.g., visceral adiposity, hyperlipidemia, hypertension, glucose intolerance), which typify the metabolic syndrome.⁵⁵⁸ Sex hormone administration also promotes excessive weight gain, presumably by inducing insulin resistance.⁵⁵⁹ In patients with type 1 diabetes, strict glycemic control is usually accompanied by slight overinsulinization of the patient, leading to greater occurrence of mild hypoglycemic episodes requiring nonhunger-driven calorie consumption, and potentially to excessive weight gain.⁵⁶⁰ Lastly, more and more children are being placed on the atypical antipsychotics risperidone, olanzapine, quetiapine, clozapine, aripiprazole, and ziprasidone to affect mood and behavior.⁵⁶¹ These antipsychotics are generally associated with weight gain. Studies assessing the weight-protective effects of augmentation therapy with metformin or topiramate demonstrate lower yet still substantial weight gain upon addition of these agents.⁵⁶²

DISORDERS OF OBESITY

The concept that obesity is a phenotype of numerous pathologies is evident from the examination of specific disorders leading to obesity in early childhood (Box 24.1, Fig. 24.11). Some involve neural mechanisms, others involve classic hormonal mechanisms, whereas others involve dysregulation of increased energy intake, decreased energy expenditure, or increased energy storage at the adipocyte. Remember that even in referral centers for pediatric obesity, children with an "organic" cause of their obesity represent a small minority of the population. Less than 1% will have a "classic" endocrinopathy and less than 3% will have an identifiable genetic etiology in general cohorts with obesity, and approximately 7% will have an endocrinopathy or identifiable genetic cause in pediatric cohorts with severe obesity.⁵⁶³

"Classic" Endocrine Disorders With an Obesity Phenotype

In children, linear or statural growth accounts for up to 20% of ingested calories. Endocrine states that allow for normal energy intake for age, but inhibit linear growth, will of necessity lead to excessive energy storage. This is the case for the four "classic" endocrine disorders associated with obesity. These can be distinguished from other causes of pediatric obesity on the basis of their suboptimal growth rate, as opposed to overnutrition, which tends to increase the rate of both growth and skeletal maturation, probably caused, at least in part, by excess insulin cross-reacting with the IGF-1 receptor.⁵⁶⁴

Hypothyroidism. Insufficient triiodothyronine (T_3) hormone causes lower REE and decreased physical activity caused by fatigue. Moreover, T_3 is permissive for the anabolic effects of GH. The decrease in total energy expenditure, despite a relatively low caloric intake, promotes persistent energy storage and increases adiposity. Signs, symptoms, and diagnostic evaluation of hypothyroidism are discussed in Chapter 13. Thyroid hormone replacement is sufficient to increase growth, REE, and physical activity to resolve the obesity over time. Of note, hypothyroidism as a cause of weight gain should not be confused with mild elevations in TSH that occur as a consequence of obesity, thought to be mediated by increased thyrotropin-releasing hormone (TRH) secretion induced by leptin. Thyroid hormone supplementation is generally not indicated in such cases, and TSH usually normalizes with weight loss and reduction in adiposity, which in turn reduces circulating leptin concentrations.

BOX 24.1 Classification of Childhood Obesity Disorders**CLASSIC ENDOCRINE DISORDERS (SHORT STATURE/GROWTH FAILURE PROMINENT)**

- a. Hypothyroidism
 1. Primary
 2. Central
- b. Cushing syndrome (glucocorticoid excess)
 1. Adrenal adenoma/carcinoma
 2. Adrenal micronodular hyperplasia
 3. Pituitary ACTH-secreting tumor
 4. Ectopic ACTH-secreting tumor
 5. Exogenous glucocorticoid administration
- c. Growth hormone deficiency
- d. Pseudohypoparathyroidism 1a
 1. Maternal transmission (AHO + multihormone resistance)
 2. Paternal transmission (Pseudopseudohypoparathyroidism, AHO only)

LEPTIN-MELANOCORTIN PATHWAY DEFECTS (HYPERPHAGIA PROMINENT)

- a. Leptin deficiency
- b. Leptin receptor deficiency
- c. *POMC* mutation (adrenal insufficiency and hypopigmentation/red hair)
- d. Prohormone convertase-1 deficiency (proinsulin excess)
- e. Carboxypeptidase E deficiency
- f. *MC3R* mutation
- g. *MC4R* mutation (tall stature)
- h. *SIM1* mutation (autonomic dysfunction, intellectual disability)
- i. Melanocortin receptor accessory protein 2 (MRAP2) deficiency
- j. Brain-derived neurotrophic factor (BDNF) haploinsufficiency/11p14.1 deletion
- k. *NTRK2* mutation
- l. *SH2B1* haploinsufficiency/16p11.2 deletion

SYNDROMIC OBESITY DISORDERS (MULTIPLE SYSTEM INVOLVEMENT AND DISTINCT PHYSICAL FEATURES)

- a. Prader-Willi syndrome
 - neonatal failure to thrive then rapid weight gain after infancy
 - hypotonia
 - intellectual disability
 - hypogonadism
 - short stature
- b. Bardet-Biedl syndrome
 - retinal dystrophy
 - polydactyly
 - intellectual disability
 - kidney disease
 - male hypogonadism

- c. Alström syndrome
 - retinal dystrophy
 - hearing loss
 - pulmonary fibrosis
 - kidney disease
 - severe insulin resistance
 - hypothyroidism
 - male hypogonadism
- d. Smith-Magenis syndrome
 - intellectual disability
 - maladaptive and self-injurious behaviors
 - sleep disturbance
- e. WAGR syndrome
 - Wilms tumor
 - aniridia
 - genitourinary anomalies
 - range of developmental delays/intellectual disability
 - reduced pain perception
- f. Cohen syndrome
 - microcephaly
 - hypotonia
 - intellectual disability
 - progressive myopia
 - retinal dystrophy
 - joint hypermobility
 - neutropenia
 - prominent incisors
- g. Carpenter syndrome
 - craniosynostosis
 - intellectual disability
 - brachydactyly, polydactyly, syndactyly
 - congenital heart disease
 - cryptorchidism
 - umbilical hernia
 - situs inversus

HYPOTHALAMIC OBESITY INSULIN DYNAMIC DISORDERS

- tumor
- surgery
- radiation
- trauma
- infiltrative disease
- inflammation ROHHAD syndrome (rapid-onset obesity with hypothalamic dysfunction, hypoventilation, autonomic dysregulation, neural crest tumor)

ACTH, Adrenocorticotrophic hormone; *AHO*, Albright hereditary osteodystrophy; *POMC*, proopiomelanocortin.

Whether thyroid hormone supplementation may aid weight loss or ameliorate CV comorbidities and hepatic steatosis is uncertain.⁵⁶⁵

Glucocorticoid Excess. Cushing syndrome is state of glucocorticoid excess that arrests growth and induces hyperphagia,²²⁵ along with a decrease in REE and physical activity caused by muscle wasting. Exogenous glucocorticoid therapy can result in a similar obesity phenotype. Cushing syndrome is discussed further in [Chapter 14](#). A reduction of circulating glucocorticoid through medical or surgical treatment reverses obesity, but central adiposity often persists.⁵⁶⁶ Although Cushing syndrome as a cause of obesity occurs very rarely, functional hypercortisolism (pseudo-Cushing syndrome) is common in

obesity and is thought to be caused by increased HPA-axis activation and greater conversion of inactive cortisone to cortisol by 11 β HSD1 in adipose tissue. This chronically higher glucocorticoid tone in obesity and other pseudo-Cushing conditions, such as depression, diabetes, add sleep disorders, may contribute to metabolic health risk and exacerbate visceral adiposity, leading to a viscous cycle of worsening central obesity.⁵⁶⁷ Transgenic mice that overexpress 11 β HSD1 selectively in adipose tissue develop insulin-resistant diabetes, hyperlipidemia, and hyperphagia.⁵⁶⁸ 11 β HSD1 enzyme activity is higher in visceral versus subcutaneous adipose tissue and correlated with BMI in normal weight prepubertal children.⁵⁶⁹ In adults, however, the associations of 11 β HSD1 polymorphisms and

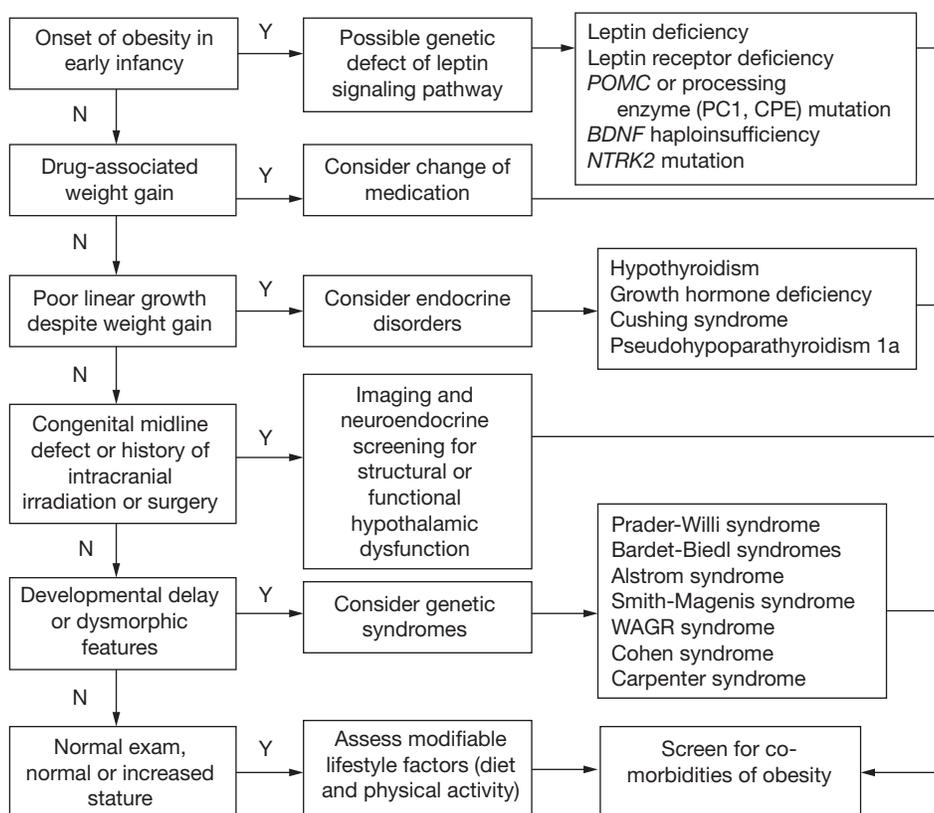

Fig. 24.11 Assessment of childhood-onset obesity. (Figure modified from Han, J.C., Lawlor, D.A., Kimm, S.Y. (2010). Childhood obesity. *Lancet*, 375 (9727), 1737–1748.)

BMI or waist : hip ratio were weak at best,⁵⁷⁰ and enzyme activity was not elevated in obesity.⁵⁷¹ Nonetheless, specific inhibitors of 11 β HSD1 are being investigated as potential drug targets for treatment of obesity and type 2 diabetes.⁵⁷²

Growth Hormone Deficiency. Inadequate GH prevents lipolysis and promotes visceral adiposity, although the severity of obesity is usually mild, such that diagnosis of GH deficiency typically precedes the onset of significant obesity. GH deficiency is also associated with fatigue and decreased physical activity. GH deficiency is often accompanied by other pituitary hormone deficiencies (e.g., central hypothyroidism), which can also decrease REE. GH therapy is able to reverse these energy expenditure deficits, increase muscle mass, and promote weight loss. Diagnostic testing for GH deficiency is discussed in Chapter 11, but it should be mentioned here that obesity itself affects GH secretion such that peak responses during stimulation testing are lower in children with obesity compared with those with normal weight.^{435,573} The mechanism for reduced GH secretion in obesity is not known but postulated contributors include hyperinsulinemia and elevated circulating FFAs.⁵⁷⁴ Therefore interpretation of GH stimulation testing results should account for altered thresholds in obesity. Moreover, the potential benefit of GH supplementation in relative GH insufficiency remains to be determined.

Pseudohypoparathyroidism Type 1a (PHP1a) and Albright Hereditary Osteodystrophy (AHO). PHP1a and AHO are caused by an autosomal dominant mutation of *GNAS1*, which encodes the G α subunit necessary for peptide hormone signal transduction of GPCRs (affected ligands include parathyroid hormone, TSH, growth hormone-releasing hormone, and α -MSH).^{575,576} Maternal transmission of the *GNAS1* mutation leads to PHP1a (multihormone resistance, described further in Chapter 3 and Chapter 20) along with AHO, of which a cardinal feature is obesity, caused by reduced MC3R and MC4R anorexigenic/catabolic signaling within the hypothalamus and reduced

ability to stimulate cAMP in response to β -adrenergic stimulation within adipocytes.⁵⁷⁷ In addition to obesity, other typical manifestations include hypocalcemia, short stature, mild intellectual disability, round face, low nasal bridge, short nose and neck, delayed dental eruption with enamel hypoplasia, short fourth and fifth metacarpals and metatarsals, and short distal phalanges of the thumb. Paternal transmission leads to AHO without multihormone resistance, also known as pseudopseudohypoparathyroidism. Besides hormone replacement and prevention of hypocalcemia, no specific treatments for the obesity aspect of this condition are currently available.

Genetic Obesity Disorders

Approximately 5% to 10% of children with hyperphagia and early-onset (first 3 years of life) obesity are estimated to have an identifiable genetic condition,⁵⁶³ and the prevalence increases to as high as 22% when screening children with syndromic obesity.⁵⁷⁸ Genetic obesity disorders can be categorized as monogenic conditions with obesity as the main phenotype and pleiotropic syndromes that include other characteristics, such as intellectual disability and dysmorphic physical characteristics. There are approximately 80 genetic syndromes that include obesity as a feature, but less than one-fourth of these syndromes have had their genetic etiology fully elucidated.⁵⁷⁹ In this chapter, we will focus primarily on the monogenic disorders of the leptin-melanocortin pathway and on a few of the better elucidated pleiotropic syndromes. Further descriptions of the many other syndromes are reviewed in detail elsewhere.^{580–582}

Leptin-Melanocortin Pathway Defects

Since the 1994 discovery of leptin deficiency as the cause of obesity in the *ob/ob* mouse,² the leptin-melanocortin pathway has been extensively elucidated in animal models, whereas in

parallel, monogenic defects along this same pathway have been identified in human obesity disorders. Each disorder will be described in sequential order based on the sequence of the pathway steps as shown in Fig. 24.3. Several pleiotropic obesity syndromes also appear to converge on the leptin-melanocortin pathway, and these conditions will be listed alongside their monogenic disorder counterpart.

Leptin Deficiency. Autosomal recessive mutations of the leptin gene in humans recapitulate the phenotype of the *ob/ob* leptin-deficient mouse.⁵⁸³ Only a few such patients have been described, primarily of Pakistani and Turkish descent, and for the most part they were born to consanguineous parents. Birth weight is normal followed by rapid weight gain during infancy and obesity as early as the first few months of life. Hyperphagia manifests at birth as insatiable hunger with constant demands to be fed in infancy and aggressive food-seeking behavior in childhood. The lack of leptin induces the starvation response in the form of central hypothyroidism, lower body temperature, hypogonadotropic hypogonadism, and defective T-cell-mediated immunity.⁵⁸⁴ Despite hypothyroidism, normal stature and skeletal maturation are generally preserved until the usual age of puberty because obesity-induced hyperinsulinemia allows excess insulin to cross-react with the IGF-1 receptor to maintain growth. However, because of the important role of leptin in initiating and maintaining puberty, untreated adult patients with leptin deficiency are short because of the lack of a pubertal growth spurt. The diagnosis is made by demonstrating extremely low or unmeasurable serum concentrations of leptin. It should be noted that some mutations of the leptin gene can produce nonfunctional protein that is still detected in standard antibody-based assays so bioactivity measurement may be necessary.^{585,586} In either circumstance of reduced or dysfunctional leptin, treatment with recombinant leptin effectively restores leptin signaling, thereby reducing hyperphagia, resolving obesity, and restoring normal pubertal progression and immune function.⁵⁸⁴ Heterozygous carriers of leptin gene mutations display an intermediate phenotype with lower serum leptin concentrations and predisposition for obesity.⁵⁸⁷

Leptin Receptor (LEPR) Deficiency. Autosomal recessive mutations of the leptin receptor gene produce similar symptoms and signs as leptin deficiency. In a large cohort of patients with severe, early-onset obesity, the prevalence of homozygous or compound heterozygous pathogenic variants of *LEPR* was 3%. Affected individuals had hyperphagia, severe obesity, delayed puberty because of hypogonadotropic hypogonadism and altered immune function. Overall, however, their clinical features were less severe than those of patients with congenital leptin deficiency. Serum leptin concentrations were elevated and correlated with fat mass but shifted higher for the degree of adiposity when compared with control subjects with obesity with normal *LEPR*. The generally higher circulating leptin concentration in *LEPR* deficiency is attributed to disruption in the leptin-SNS feedback loop that connects the CNS with peripheral adipocytes.¹⁰³ However, because of the fairly high degree of overlap in values, leptin concentrations cannot be used to diagnose *LEPR* deficiency reliably, so gene sequencing is required.⁵⁸⁸ Heterozygous carriers had higher adiposity but were otherwise asymptomatic.⁵⁸⁸ Variable presentations depending on type of *LEPR* mutation have been reported. Three members of a family in France of Algerian ancestry with a homozygous truncating mutation of *LEPR* (lacking both the transmembrane and the intracellular domains) had additional symptoms of low IGF-1, IGFBP-3, and growth retardation; the cause of these additional features is not known.⁵⁸⁹ Treatment of *LEPR* deficiency requires targeting downstream mediators of the leptin-melanocortin pathway. Because *LEPR* activation normally would increase POMC and hence the POMC-cleaved

product, α -MSH, which binds MC4R, a logical therapeutic target would be melanocortin receptor agonists. One promising candidate drug is setmelanotide, which functions as a biased agonist for MC4R, favoring $G\alpha_q$ signaling regulated by mitogen-activated protein kinase (MAPK),⁵⁹⁰⁻⁵⁹² thus avoiding the hypertensive side effect of previously developed MC4R agonists that primarily increased $G\alpha_s$ signaling.⁵⁹³ An initial case report of three patients with homozygous *LEPR* mutations who received setmelanotide described substantial weight loss with increased skin and hair pigmentation (because of MC1R activation) as the only major side effect.⁵⁹⁴ Whether this drug may be beneficial in individuals with heterozygous *LEPR* mutations remains to be determined.

POMC Deficiency and Splice Site Mutations. Autosomal recessive mutations in the *POMC* gene that interfere with protein translation or cleavage of the protein into ACTH and α -MSH products results in fair skin and red hair (because of lack of MC1R activation by α -MSH), adrenal hypoplasia and glucocorticoid deficiency (because of lack of MC2R activation by ACTH) with preserved aldosterone and catecholamine production, and obesity (because of lack of MC4R and MC3R activation by α -MSH). Birth weight is normal but hyperphagia drives rapid weight beginning in infancy.⁵⁹⁵ Although red hair is a common feature, a Turkish patient with an early nonsense mutation of *POMC* was reported to have dark hair, indicating that pigmentation can be variable.⁵⁹⁶ The diagnosis can be established based on clinical presentation, ACTH deficiency, and hypocortisolemia. Heterozygous carriers have normal pigmentation and cortisol, but higher predisposition for obesity.⁵⁹⁶ Methylation variants of *POMC* in the general population are correlated with individual body weight, suggesting a wider role of *POMC* in determining obesity risk.⁵⁹⁷ A case report in two patients with *POMC* deficiency showed significant weight loss with setmelanotide treatment, suggesting that MC4R agonism may be beneficial for this condition as well.⁵⁹⁸

Prohormone Convertase-1 Deficiency. Autosomal recessive mutations in the *PCSK1* gene that encodes the PC1 enzyme lead to the inability to process various prohormones to their active ligands, such as POMC to ACTH and α -MSH, proinsulin to insulin, and various gut propeptides to active hormones.^{599,600} Only a handful of patients have been described in the literature, and they are reported as displaying severe early-onset obesity, ACTH deficiency, hypogonadotropic hypogonadism, hyperproinsulinemia, and small intestinal dysfunction because of the inability to cleave intestinal propeptides to their mature form. Hypothyroidism and diabetes insipidus have also been reported.⁶⁰¹ Because of impaired proinsulin cleavage, postprandial hyperglycemia followed by hypoglycemia several hours after a meal is observed. This is caused by initially insufficient insulin secretion followed by reduced clearance of proinsulin, which has mild potency at the insulin receptor, inducing hypoglycemia in the postabsorptive state. The diagnosis can be made by finding extremely high levels of proinsulin, and molecular diagnostics may be required to confirm the gene defect.⁶⁰¹ The potential benefit of using the MC4R agonist setmelanotide to treat obesity in patients with *PCSK1* mutations is currently being investigated.

Carboxypeptidase E Mutation. One adult patient with homozygous truncating mutation of the *CPE* gene has been reported.⁶⁰² *CPE* processes various neuropeptides and prohormones, including POMC and gonadotropins. This patient manifested hyperphagia, severe obesity since childhood, type 2 diabetes, and hypogonadotropic hypogonadism. She also had intellectual disability, which is not a typical characteristic of the other proximal leptin-melanocortin pathway defects discussed thus far. Mice with *CPE* deficiency display hippocampal degeneration and memory deficits, suggesting a role of *CPE* in cognitive function.

Melanocortin-3 Receptor Mutation. α -MSH is the endogenous ligand for both MC3R and MC4R, with MC4R being the more critical receptor for regulation of appetite and energy balance whereas MC3R has only a modest role.¹¹² A heterozygous missense mutation of *MC3R* was identified in two family members of an ethnically Indian family in Singapore, manifesting as severe early-onset obesity in the child but only mild obesity in the father.⁶⁰³ The common MC3R variant T6K+V81I is associated with greater adiposity in children and adults. In vitro, this variant appears to decrease MC3R expression. Humanized knock-in mice display increased feeding efficiency and higher triglyceride storage in adipocytes.⁶⁰⁴ Diagnosis of *MC3R* variants can only be made by gene sequencing. No specific treatment currently exists.

Melanocortin-4 Receptor Mutation. Mutations in the *MC4R* gene appear to account for approximately 5% of severe early-onset obesity cases.^{605–610} Individuals with heterozygous mutations, severe obesity, increased lean mass, increased linear growth, hyperphagia, and severe hyperinsulinemia; individuals with homozygous or compound heterozygous mutations are even more severely affected.^{606,611} Functional severity varies based on the specific mutation, with patients who have mutations retaining residual signaling capacity having a less severe obesity phenotype.^{592,612,613} Thus mutations in *MC4R* result in a distinct obesity syndrome that is inherited in a codominant manner.⁶⁰⁶ Blood pressure is typically lower compared with control subjects with obesity and normal *MC4R*, consistent with the role of the melanocortin system in mediating SNS outflow to the renal and CV systems.⁶¹⁴ Intellectual function is typically normal, although a possible association with attention deficit hyperactivity disorder has been reported in children with homozygous mutations.⁶¹⁵ The diagnosis is made by gene sequencing. There is currently no specific treatment for this disorder, but clustered regularly interspaced short palindromic repeat (CRISPR) activation technologies in mice have successfully upregulated the expression of the remaining intact allele in the heterozygous *Mc4r* knockout to restore normal body weight.⁶¹⁶ Whether this type of gene editing approach can be translatable into humans remains to be determined.

SIM1 Mutation. Single-minded 1 (*SIM1*) is a human homolog of the *Drosophila* single-minded gene that is involved in neurogenesis in both species. In humans, *SIM1* is involved in the development and function of the PVN, the region of the hypothalamus that expresses MC4R and prodynorphin neurons.⁶¹⁷ *SIM1* is believed to function as a downstream mediator of the anorexigenic functions of both these neuronal subpopulations.^{618,619} In a cohort of 2100 individuals with severe obesity, the prevalence of heterozygous *SIM1* mutations was 1.3%,⁶²⁰ and microarray analysis of 279 individuals with syndromic obesity identified one subject with a microdeletion involving *SIM1*.⁵⁷⁸ Patients with *SIM1* haploinsufficiency present with hyperphagia, severe early-onset obesity, normal basal metabolic rate, autonomic dysfunction (lower systolic blood pressure, reduced SNS tone, reduced heart rate variability between sleep and awake states), and varying degrees of neurobehavioral abnormalities and intellectual disability.^{620–624} Increased methylation at the *SIM1* locus is associated with higher BMI in adolescents, suggesting that intermediate phenotypes exist in the general population. The diagnosis of *SIM1* mutation is made by gene testing. There is currently no specific treatment for this disorder, but CRISPR activation technologies in mice have successfully upregulated the expression of the remaining intact allele in the heterozygous *Sim1* knockout to restore normal body weight.⁶¹⁶ Whether this type of gene editing approach can be translatable into humans remains to be determined.

Melanocortin Receptor Accessory Protein 2 (MRAP2) Mutation. MRAP2 protein directly interacts with MC4R and enhances generation of cAMP upon ligand binding of

MC4R.⁶²⁵ Whole-body and brain-specific knockout of *Mrap2* in mice causes severe obesity. Heterozygous pathogenic mutations of *MRAP2* have been identified in four patients with nonsyndromic severe early-onset obesity without additional syndromic features.⁶²³

Brain-Derived Neurotrophic Factor Haploinsufficiency. The *BDNF* gene is located in the 11p14 region. Homozygous loss of function is incompatible with survival but heterozygous loss of *BDNF* is observed in WAGR syndrome, 11p14 microdeletion, and chromosome 11 paracentric inversion, and *BDNF* gene variants.

WAGR/11p Deletion Syndrome: The Wilms tumor, aniridia, genitourinary abnormalities, and range of developmental delays syndrome is a rare genetic disorder (prevalence ~1 in 1,000,000) caused by contiguous gene deletions on the short arm of chromosome 11.¹²⁴ Haploinsufficiency of *WT1* and *PAX6*, which are involved in genitourinary and eye development, respectively, cause the core features of the syndrome. *BDNF* resides at 11p14.1, which is 4 Mb from the 11p13 WAGR critical region that contains *WT1* and *PAX6*, and is included in the deleted segment of approximately half of patients with WAGR syndrome.¹²⁴ In a cohort of 33 patients with WAGR syndrome, *BDNF* haploinsufficiency was associated with higher BMI z-score, fivefold higher frequency of developing childhood obesity (100% vs. 20% for patients with and without *BDNF* deletion, respectively), reduced serum *BDNF* concentrations, and higher scores on a parent-reported hyperphagia questionnaire.⁶²⁶ In this cohort of patients with WAGR syndrome, having *BDNF* haploinsufficiency versus intact *BDNF* was also associated with 20-point lower IQ,⁶²⁷ greater social impairment and higher rate of meeting criteria for autism on the Autism-Diagnostic Interview-Revised,⁶²⁷ lower parent-reported behavioral responses to typically painful stimuli,¹²⁴ and lower self-reported perception of pain in response to hot and cold temperature stimuli.⁶²⁸

11p14 Microdeletion: Microdeletions causing *BDNF* haploinsufficiency while sparing the WAGR region have been reported in 11 individuals with obesity and neurodevelopmental abnormalities.^{130,629,630} Combining the reports, the 1-Mb common region shared by the deletions of all 11 individuals includes only one gene, *BDNF*.

11p Paracentric Inversion: Another form of *BDNF* haploinsufficiency can be caused by loss of expression from one *BDNF* allele even if the allele is still present. Gray et al.¹²⁵ described an 8-year-old girl with a heterozygous paracentric 11p13p15.3 inversion that encompassed *BDNF* without disrupting the sequence of the gene itself but interfered with expression of the inverted *BDNF* allele. Her serum *BDNF* concentration was significantly reduced compared with control subjects with obesity and normal weight, and she displayed hyperphagia, obesity, impaired nociception, and intellectual disability.¹²⁵

***BDNF* gene mutations/variants:** Sequencing of 765 children with early-onset nonsyndromic obesity revealed five heterozygous *BDNF* rare variants predicted to be deleterious in silico that were not present in 480 control subjects without obesity.⁶³¹ The common *BDNF* Val66Met polymorphism, which impairs activity-dependent *BDNF* secretion, is linked to binge episodes in bulimia nervosa and binge eating disorder,¹³² and *BDNF* hypermethylation is associated with bulimia nervosa.¹³³ Associations of *BDNF* Val66Met with BMI and obesity are inconclusive, but the preponderance suggests that the Met allele is protective.^{632–641} The intronic *BDNF* rs12291063 variant (homozygous in ~10% of individuals with African or Latino ancestry; rare in European non-Hispanic whites) is associated with reduced VMH *BDNF* expression and increased adiposity.¹³⁴ Together these observations indicate that *BDNF* insufficiency may underlie common, as well as rare, causes of hyperphagia and obesity.

***NTRK2* Mutation.** The *NTRK2* gene encodes the ligand-specific subunit of TrkB, which is the receptor for BDNF. A case report describes one 8-year-old boy with a heterozygous mutation of *NTRK2* that prevents autophosphorylation of the receptor upon ligand binding. The child manifested normal weight at birth, hyperphagia and severe weight gain beginning at age 6 months, and neurologic abnormalities including seizures, hypotonia, developmental delay, and decreased nociception.^{642,643}

***SH2B1* Haploinsufficiency.** Chromosome 16p11.2 has been shown to account for 0.7% of a large cohort of patients with severe obesity⁶⁴⁴ and 4% of a pediatric cohort that included children with developmental delay in addition to obesity.⁶⁴⁵ A candidate gene for this locus is *SH2B1*, which encodes a signaling adapter protein that is needed for BDNF-stimulated neurite outgrowth.⁶⁴⁶ Heterozygous mutations in *SH2B1* were described in 1.7% of a cohort of patients with severe obesity. The affected patients also displayed neuropsychiatric abnormalities.⁶⁴⁷

Syndromic Obesity Disorders

Several obesity syndromes were included in the earlier section for leptin-melanocortin pathway disorders because the causative genes are thought to be connected with that pathway. Subsequently, additional syndromes with etiologies are not as well delineated.

Prader-Willi syndrome. PWS is a hyperphagic obesity disorder (prevalence ~1 in 20,000) caused by lack of expression of paternally derived genes on chromosome 15q11-13, because of heterozygous deletions of paternal alleles (70%), uniparental disomy in which two copies of maternal alleles are inherited (20%–30%), or imprinting defects in which paternal alleles are silenced because of inappropriate methylation (2%–5%).⁶⁴⁸ In classical PWS, major diagnostic features include neonatal hypotonia, feeding problems in infancy, rapid weight gain after infancy, hyperphagia, developmental delay, hypogonadotropic hypogonadism, and characteristic facial features (narrow face, almond-shaped eyes, small mouth, thin upper lip, and downturned corners of mouth). Minor diagnostic features include decreased fetal movement, weak cry and lethargy in infancy, behavior problems, sleep disturbance, short stature (GH deficiency), hypopigmentation (in the deletion cases that involve *OCA2*, an albinism-related gene in the region), small hands and feet, and skin picking. Other common features include high pain threshold, decreased vomiting, temperature instability, scoliosis, early adrenarche, and unusual skill with jigsaw puzzles.⁶⁴⁹

Attempts to isolate the causative genes for PWS suggest that involvement of more than one gene is likely necessary for the full syndrome to be manifested. Many features of PWS can be observed in patients with inactivating mutations of *MAGEL2*, and screening for *MAGEL2* mutations is recommended for patients presenting with atypical PWS, also known as *Schaaf-Yang syndrome*. This syndrome is characterized by infant hypotonia, feeding difficulties, developmental delay, and autism spectrum disorder, but only one-third of patients develop hyperphagia.^{650–652} *Magel2*-null mice have neonatal growth retardation, excessive weight gain after weaning, and develop increased adiposity, so these mice can be used as a model to study obesity parameters in PWS.⁶⁵³ The cause of hyperphagia in PWS is unknown and likely multifactorial. Hyperghrelinemia is observed in patients with PWS,^{654–656} but pharmacologic suppression of ghrelin has not been therapeutically successful at reducing hyperphagia or body weight, calling into question the pathophysiologic role of ghrelin in PWS.^{657,658} Higher circulating EC have also been observed in patients with PWS.⁶⁵⁹ *Magel2*-null mice have increased

expression of EC receptors and administration of an EC antagonist induces weight loss.⁶⁵⁹

Serum leptin concentrations in patients with PWS are appropriately increased in proportion to their higher fat mass and at levels similar to patients with nonsyndromic forms of obesity.⁶⁶⁰ Therefore leptin production is preserved in PWS. *NPY* and *AgRP* expression appear to be appropriately suppressed in postmortem hypothalamic tissue from patients with PWS, indicating that overexpression of these orexigenic peptides is unlikely to be the cause of hyperphagia in PWS.⁶⁶¹ However, several lines of evidence point to defective signaling along the POMC/CART branch of the leptin-melanocortin pathway. *Magel2*-null mice are resistant to the appetite-suppressing effect of leptin administration,^{662–664} with development of leptin insensitivity occurring between 4 to 6 weeks of age, concomitant with a decline in the number of arcuate POMC neurons, suggesting that the transition from failure to thrive in infancy to hyperphagia in early childhood for patients with PWS may be attributable to a neurodegenerative process. Reduced *PC1* expression has been reported in induced pluripotent stem cells derived from human patients with PWS, which if also true in vivo, would exacerbate any deficiencies in POMC by further reducing processed α -MSH from *PC1* cleavage of POMC.⁶⁶⁵ Consistent with the hypothesis that disruption of POMC signaling could be the etiology of hyperphagia in PWS is the observation that patients with PWS have reduced serum and plasma BDNF concentrations compared with control subjects with obesity and normal weight.¹²⁶ Considering BDNF's role as a downstream mediator of MC4R signaling and its function in neurocognition and pain perception,^{628,666} insufficiency of BDNF could potentially account for the hyperphagia, intellectual disability, behavior abnormalities, and high pain tolerance associated with PWS. Although hyperphagia is the primary driver of weight gain, lower lean muscle mass in PWS reduces REE by 40%, further contributing to energy imbalance.⁶⁶⁷ GH deficiency also leads to defective lipolysis, further promoting adiposity, but this can be reversed with GH supplementation.⁶⁶⁸

Bardet-Biedl Syndrome (BBS). BBS is an autosomal recessive syndrome (prevalence ~1 in 100,000) characterized by hyperphagia, obesity, retinal dystrophy, polydactyly, cognitive impairment, kidney disease, and hypogonadism in males.^{669,670} Over 20 genes encoding proteins involved in the formation, stability, and function of cilia have been implicated in BBS.⁶⁷¹ Mouse models of BBS have defective cilia^{672–675} and impaired leptin receptor trafficking⁶⁷⁵ and signaling.⁶⁷⁶ These mice are unresponsive to leptin administration with lack of STAT-3 phosphorylation and a lack of reduction in food intake. Hyperleptinemia precedes onset of obesity in some but not all studies, calling into question whether leptin resistance develops before or after the onset of obesity, and the role of cilia in adipocyte differentiation suggests that primary fat deposition may also be a contributing cause of obesity in BBS.⁶⁷⁷ In patients with BBS, serum leptin concentrations are higher than those of BMI-matched control subjects, suggesting that in humans, leptin resistance out of proportion to degree of adiposity may play a role in the pathophysiology of ciliopathy-associated obesity.⁶⁷⁸ Supporting the hypothesis that insufficient melanocortin signaling contributes to hyperphagia in BBS, a pilot study of the MC4R agonist setmelanotide showed suppression of hunger and induction of weight loss in patients with BBS.⁶⁷⁹

Alström Syndrome. Alström syndrome (AS) is a rare (<500 reported cases) monogenic form of obesity caused by recessive mutations in the centrosome-body and basal body-associated gene *ALMS1*.⁶⁸⁰ AS is characterized by retinal dystrophy, sensorineural hearing loss, cardiomyopathy, pulmonary fibrosis, renal disease, childhood obesity, severe insulin resistance, higher susceptibility to type 2 diabetes, elevated triglycerides, and steatohepatitis.⁶⁸¹ Frequent endocrinopathies include

hypothyroidism (one-third central, two-thirds primary), central adrenal insufficiency, male hypogonadism (one-third central, two-thirds primary), female hyperandrogenism, and short stature/low IGF-1 concentrations.⁶⁸² In contrast with BBS, patients with AS do not have polydactyly and generally retain normal intellectual functioning. The function of the *ALMS1* protein is not known but is believed to be important for the formation, stability, and function of cilia. *Alms1* knockout mice have reduced number of hypothalamic neuronal cilia,⁶⁸³ and have hyperphagia and obesity.⁶⁸⁴ Because POMC neuronal function is dependent on cilia and intraflagellar transport, reduced POMC function is hypothesized to contribute to the hyperphagia of AS.^{671,685} Consistent with this hypothesis, a pilot study of the MC4R agonist setmelanotide showed suppression of hunger, induction of weight loss, and improved glucose homeostasis in patients with AS.⁶⁸⁶

Smith-Magenis syndrome. SMS (prevalence ~1 in 25,000) is caused by heterozygous retinoic acid–induced 1 (*RAI1*) mutation or deletion. *RAI1* is a transcriptional regulator of *BDNF* involved in craniofacial and nervous system development.⁶⁸⁷ In frogs, knockdown of *Rai1* using antisense morpholinos results in lower *Bdnf* mRNA expression and abnormal brain and face development.⁶⁸⁸ Heterozygous *Rai1* knockout mice have diminished hypothalamic *Bdnf* expression and display hyperphagia and obesity after age 20 weeks on normal chow,⁶⁸⁷ and by 16 weeks on high-fat or high-carbohydrate diets.⁶⁸⁹ SMS in human patients is characterized by intellectual disability, maladaptive and self-injurious behaviors, sleep disturbance, and dysmorphic facial features (brachycephaly, broad face, frontal bossing, synophrys, hypertelorism, upslanting eyes, midface hypoplasia with a depressed nasal bridge, a tented upper lip, prognathism, and low-set or abnormally shaped ears). Hyperphagia and obesity are typically not observed until later childhood or adolescence, mimicking the older onset of these symptoms in mice, and are more pronounced in patients with *Rai1* mutations compared with those with deletions.⁶⁹⁰ Examination of functional effects of mutations found in patients has revealed that the mutated *RAI1* protein fails to localize to the nucleus and does not activate expression of a reporter gene driven by an endogenous *BDNF* promoter.^{127,691} Presence of the mutated protein may have a dominant negative effect on the remaining normal protein, thus leading to a more severe obesity phenotype in patients with mutations.

Cohen Syndrome. Cohen syndrome (<1000 cases reported) is caused by autosomal recessive mutations in *VPS13B* and characterized by microcephaly, hypotonia, intellectual disability, progressive myopia, retinal dystrophy, joint hypermobility, neutropenia, truncal obesity that develops in later childhood, insulin resistance/type 2 diabetes, and dysmorphic features (thick hair and eyebrows, long eyelashes, downslanting and wave-shaped palpebral fissures, bulbous nasal tip, smooth or shortened philtrum, prominent upper central teeth, open mouth, narrow hands and feet, and slender fingers). *VPS13B* encodes a Golgi apparatus protein that is involved in protein glycosylation and intracellular transport in neurons and adipocytes.^{692–697}

Carpenter Syndrome. Carpenter syndrome (<100 cases reported) is caused by autosomal recessive mutations in *RAB23* (involved in vesicle trafficking) or *MEGF8* (involved in cell adhesion) and is characterized by acrocephalic or cloverleaf craniosynostosis, intellectual disability, childhood-onset obesity, flat nasal bridge, downslanting palpebral fissures, low-set and abnormally shaped ears, micrognathia, small primary teeth, cutaneous syndactyly of third and fourth fingers, brachydactyly, polydactyly, umbilical hernia, hearing loss, heart defects, deformed hips, kyphoscoliosis, genu valgum, cryptorchidism, situs inversus, dextrocardia, and transposition of the great arteries.^{698–704}

Hypothalamic Obesity

Hypothalamic damage can occur because of CNS tumor, surgery, radiation, trauma, inflammation, or infiltrative diseases. Injury to the VMH and ARC of the MBH are the critical regions that lead to the phenomenon of hypothalamic obesity, which is characterized by extremely rapid weight gain. For example, it is typical in the first 6 to 12 months after craniopharyngioma surgery for tumors involving the floor of the third ventricle (the hypothalamic homeostatic centers described earlier) for patients to increase weight by greater than 50%. Mechanistically, it has been well known that bilateral electrolytic lesions or deafferentation of the VMH in rats leads to intractable weight gain, even upon food restriction.^{200,201,705–708} Originally, weight gain was thought to be solely a problem with hyperphagia and increased energy storage.⁷⁰⁹ However, we now understand that a dysfunction of leptin-melanocortin pathway signaling can alter both the afferent and efferent pathway of energy balance and lead to severe and intractable weight gain that is caused by more than just overeating.^{710,711} The hypothalamic insult prevents the integration of peripheral afferent signals, and therefore the CNS is unable to detect nutrient sufficiency within the periphery and therefore responds as if in the starvation state. Caloric restriction alone is insufficient because patients also have reduced sympathetic activity, which reduces energy expenditure and lipolysis, and heightened parasympathetic (vagal) tone, which promotes insulin hypersecretion and energy storage.^{710,712–716} In both animals and humans, vagal hyperreactivity can be prevented by pancreatic vagotomy.^{201,717–719} Therapy for this disorder remains extremely problematic, as the brain seems to be “locked” in an orexigenic balance favoring energy consumption and storage. As the crucial period of weight gain is within the first year following the brain insult, it is crucial to focus on preventive measures during this narrow window of opportunity. Comprehensive treatment should include psychologic care to address cognitive, behavior, and sleep disturbances that commonly occur; endocrine hormone replacement for deficiencies; and intensive lifestyle (nutrition and exercise) management. Medical therapies, such as insulin sensitizers, insulin secretion blockers, GLP-1 analogues, stimulants, and oxytocin have all been investigated and each show modest benefits, but the intractable nature of the disease makes management exceedingly challenging.⁷²⁰ It is accepted practice today that all efforts should be made to avoid surgical trauma of the hypothalamic homeostatic centers, even at the price of leaving remnant tumor tissue (in cases of craniopharyngioma which typically involves this region).

ROHHAD (rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysfunction) syndrome is a form of hypothalamic obesity that is not well understood and has a very poor prognosis. Median age of diagnosis is 4 years and presents as extremely rapid weight gain in an otherwise previously healthy child.⁷²¹ ROHHAD appears to be a progressive neurodegenerative condition that evolves from hyperphagic obesity to global hypothalamic dysfunction (including GH deficiency, hypogonadotropic hypogonadism, central hypothyroidism, and ACTH abnormalities), central hypoventilation or altered respiratory control, autonomic dysfunction (bradycardia requiring pacemaker placement), thermal dysregulation, and risk for the development of tumors of neural crest origin (e.g., ganglioneuromas and ganglioneuroblastomas).⁷²² Although *BDNF* and *NTRK2* have been screened as candidate genes for ROHHAD, no mutations in these genes have been identified to date.⁷²³ However, one patient, an 11-year-old boy with BMI of 62 kg/m² with a clinical diagnosis of ROHHAD, was found to have a heterozygous truncating mutation of *RAI1*, which is a transcriptional regulator of *BDNF*

and is implicated as the causative gene for SMS.⁷²⁴ In addition to severe obesity, this patient also exhibited intellectual disability, autism spectrum disorder, dysmorphic facial features (macrocephaly, hypertelorism, flat nasal bridge, prominent forehead, and anteverted nares), high pain tolerance, excessive sweating, lack of fever with infections, obstructive and central sleep apnea, and hypoventilation leading to tracheostomy placement. Pituitary hormone abnormalities and neural crest tumors were lacking in this patient. Thus he could be categorized as atypical ROHHAD or possibly atypical SMS, and screening for *RAI1* haploinsufficiency should be considered in the differential for patients presenting with features of ROHHAD. Without treatment, ROHHAD has a high mortality rate from respiratory failure. Immunomodulator therapies have been attempted and show some benefit in slowing disease progression but there are no curative treatments known.⁷²⁵

EVALUATION AND TREATMENT OF PEDIATRIC OBESITY

Diagnostic Approach

The key to successful obesity therapy is accurate diagnosis. Our diagnostic armamentarium is not yet fully developed, so matching treatment to diagnosis is still uncertain. Specific points in the evaluation and their rationale are listed in Table 24.1. In eliciting the history, birth weight, parent's BMIs, exposure to gestational diabetes, prematurity, history of breast-feeding, and neonatal complications (especially CNS injury) are all relevant. The younger the patient's obesity is noted, the more likely an organic reason will be identified. Neurodevelopmental abnormalities and signs of dysmorphism may signify the need for a genetic referral. The medication list must be reviewed, especially for glucocorticoids and atypical antipsychotics. Orthopedic pain, headache, and snoring must be assessed. Dietary history must include skipping breakfast, daily ingestion of sodas and juices, and frequency and type of snacking. A corollary is the number of caretakers of the child because this increases stress, family chaos, and lack of child supervision.

On physical examination, linear growth is key, as classical endocrine evaluation (e.g., hypothyroidism, Cushing, GH deficiency, PHP) is not necessary if linear growth is not attenuated. However, hyperinsulinemia and insulin resistance may cause accelerated growth, because of cross-reactivity of insulin with the IGF-1 receptor.⁴³⁸ Important physical features to assess include acanthosis nigricans and waist circumference (both of which are associated with insulin resistance and the metabolic syndrome); fundoscopic examination to rule out pseudotumor cerebri if symptoms are suggestive; liver enlargement to suggest hepatic steatosis; hirsutism to suggest PCOS; and muscle tone to evaluate hypotonia and myopathy, which reduce energy expenditure. Early-onset obesity (during infancy and toddlerhood) along with dysmorphic features should raise the suspicion of an underlying genetic disorder.

Laboratory evaluation includes tests of obesity-related morbidity (e.g., aspartate aminotransferase, ALT, lipids, fasting glucose and hemoglobin A1c) and z knee and hip x-rays (in cases of suspected Blount deformity). Specific diagnostic studies must be tailored to the individual patient. For instance, growth attenuation (typically of accelerated weight gain along with deceleration of linear growth) requires endocrine evaluation, including thyroid function tests, IGF-1 and IGFBP-3, 24-hour urinary cortisol or midnight serum cortisol, and possibly MRI of the hypothalamus and pituitary. Luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone levels may be appropriate when evaluating for delayed puberty in males or PCOS in females. Patients with developmental delay will require karyotype and MRI. Severe obesity in a toddler may require a

TABLE 24.1 Diagnostic Evaluation of Childhood Obesity and Its Comorbidities

HISTORY	
Genetic etiology	Parent BMI, race, intellectual disability
Epigenetic etiology	Birth weight, gestational difficulties, prematurity
CNS etiology	CNS insult, intellectual disability or developmental delay
Endocrine etiology	Slowdown in linear growth, red hair
Medication etiology	Medication history, esp. atypical antipsychotics
Dietary etiology	Calorie recall, esp. sugar-containing liquids, breast-feeding Hx
Physical activity etiology	Exercise history, television, computer, and cellphone recall
Stress etiology	Socioeconomic status, number of caregivers, television recall, sleep status, atypical depression
Sleep apnea	History of snoring, headache, waking up with headache
PCOS	Hirsutism, oligomenorrhea, amenorrhea
Type 2 diabetes	Polyuria, polydipsia, nocturia, recent weight loss
Orthopedic morbidity	Knee or hip pain, limitation of motion
Depression	Affect, activity level, school performance
PHYSICAL	
Insulin resistance	Acanthosis nigricans, skin tags, waist circumference
Hypertension	SBP or DBP >90 th percentile for age
Pseudotumor cerebri	Papilledema
Hepatic steatosis	Hepatomegaly
PCOS	Hirsutism
Precocious/delayed puberty	Gonadal and pubic hair status
Sleep apnea	Tonsillar hypertrophy
Myopathy	Decreased muscle tone, hyporeflexia
Syndromic obesity	Specific neurocutaneous stigmata (see Box 24.1), intellectual disability
LABORATORY	
Hepatic steatosis	ALT, hepatic ultrasound
Glucose intolerance	Fasting glucose > 100 or 2-h glucose >140
Type 2 diabetes mellitus	Fasting glucose >125 or 2-h glucose >200; HbA1c >6.5%
Dyslipidemia	Lipid profile with increased VLDL, TG:HDL >2.5
Insulin resistance	Fasting insulin, glucose
Insulin hypersecretion	3-hour OGTT with insulin levels
CNS lesion	MRI, esp. with hypothalamic coned-down views

Also uric acid: >5.5 as a proxy for sugar consumption
 Free thyroxine, thyroid-stimulating hormone to rule out hypothyroidism
 ALT, Alanine aminotransferase; BMI, body mass index; CNS, central nervous system; DBP, diastolic blood pressure; HbA1c, hemoglobin A1c; HDL, high-density lipoprotein; MRI, magnetic resonance imaging; OGTT, oral glucose tolerance test; PCOS, polycystic ovarian syndrome; SBP, systolic blood pressure; TG, triglyceride; VLDL, very low-density lipoprotein.

leptin level and genetic testing for an MC4R or leptin receptor mutation. The correlation between fasting insulin and euglycemic-hyperinsulinemic clamp-derived whole-body insulin sensitivity in children is poor, indicating that it is an inappropriate surrogate of whole-body insulin sensitivity.⁷²⁶ This may have to do with the fact that fasting insulin levels likely reflect hepatic rather than total body insulin sensitivity.⁷²⁷ An oral glucose tolerance test (OGTT) may become necessary in a child with obesity, to evaluate for type 2 diabetes in cases where a suggestive history and the presence of familial risk factors is present.

Lifestyle Modification

Lifestyle modification remains the cornerstone of obesity therapy, especially in children. This approach is based on common sense, and on a handful of early studies demonstrating efficacy of lifestyle in a select handpicked group of children with intensive follow-up.⁷²⁸ Data supporting the long-term efficacy of lifestyle modification in the “real world” is not particularly persuasive. A recent analysis of numerous methodologies concluded that although there are limited quality data to recommend one treatment program to be favored over another, combined behavioral lifestyle interventions compared with standard care or self-help can produce a significant and clinically meaningful reduction in overweight in children and adolescents.⁷²⁹ Importantly, follow-up studies of numerous large-scale interventions often find a rapidly diminishing effect once the study is completed. Finally, a metaanalysis of 39 published intervention studies designed to prevent childhood obesity showed that 40% of the 33,852 participating children had reduction in BMI, whereas the remaining 60% exhibited no effect.⁷³⁰

It has been shown that 1 year after initial weight reduction, levels of the circulating mediators of appetite that encourage weight regain after diet-induced weight loss do not revert to the levels recorded before weight loss. Moreover, following significant weight reduction, whether induced by conservative or invasive measures, the metabolic and hormonal profile maintains a “starvation response” (a metabolic adaptation aiming at returning to the previous weight) even years after the intervention.²⁵⁰ This emphasizes the problem of long-term weight loss maintenance and the difficulties facing those who wish to lose weight and maintain it.⁷³¹ Optimistically, the effectiveness of interventions to prevent, rather than reverse, obesity in childhood (particularly for programs targeted to children aged 6–12 years) seem to be much more effective.⁷³²

Although weight loss is the conventional goal for intervention among adults, weight maintenance is the recommended target for the majority of children. The prevention of weight gain is easier, less expensive, and more effective than treating obesity itself,⁷³³ and the prevention of overweight among children before the presence of risk-related behaviors is crucial to stem the obesity epidemic. The primary goal of obesity prevention should be to promote physical activity and healthy diet with emphasis on improving overall health, rather than weight loss.⁷³⁴ There are at least four reasons to promote interventions to improve nutrition and physical activity in children.⁷³⁵ First, the child may receive immediate benefits, such as better fitness or energy or micronutrient intake. Second, intervention at critical periods may improve adult health. Third, modifying chronic disease risks in childhood may lead to lower rates and risk factors in adults. Lastly, modification of children’s behaviors may lead to improved behaviors in adulthood that would protect against chronic diseases.

Behavioral-cognitive therapy is designed to deal with both parent and patient, with behavior restructuring and reinforcement. Behavior changes include counseling sessions, teaching parenting skills, praise and contracts, self-monitoring tools, stimulus control within the home, role-modeling of behaviors by parents, and vigorous and long-term exercise programs. These programs have been successful in small studies with hand-picked subjects by specific investigators,^{736,737} but have not yet been successful when attempted in clinic populations. One new clinical approach involves motivational interviewing,⁷³⁸ a method for helping patients work through their ambivalence about behavior change. This method has been shown to be effective for substance abuse and in adult diabetes; whether it will be successful in pediatric obesity remains to be seen.⁷³⁹

Dietary Intervention

Dietary intervention is essential to reduce not just caloric intake, but to reduce the insulin response that promotes excessive energy deposition into adipose tissue. A myriad of studies demonstrate an association between consumption of high-calorie, high-fat, high-carbohydrate, low-fiber foods and the development of pediatric obesity.⁵⁰⁴ Specific maneuvers that have been successful in reducing the insulin response and promoting weight loss or stability in children include (1) elimination of sugar-containing beverages (including both soda and juice)^{740,741} and (2) a shift to a low glycemic load diet.⁵¹⁴ Not only does dietary modification to reduce the insulin response assist in promoting weight loss,⁷⁴² but it also promotes increased energy expenditure during the weight maintenance phase,⁷⁴³ presumably by improving leptin sensitivity, which would help prevent weight regain. However, dietary intervention alone is not a successful strategy for reducing pediatric overweight, unless the treatment is very intensive,⁷⁴⁴ in which case, the majority drop out. Furthermore, studies of non-supervised dieting have demonstrated the opposite effect, that is, increased attempts in female adolescents predict a greater increase in weight and risk for obesity.⁷⁴⁵

Importantly, diets are a crucial part of weight maintenance and not only aimed at weight loss. Specifically, following a successful weight loss—a weight maintenance diet is crucial to prevent weight regain because of the metabolic “starvation response” mentioned earlier. Thus the dietary changes proposed to the child should be adapted for life as a “healthy eating” strategy rather than a short-term weight plan. Comparison of dietary approaches to weight maintenance following weight loss in children has shown that among young adults with overweight/obesity compared with preweight-loss energy expenditure, isocaloric feeding following 10% to 15% weight loss resulted in decreases in REE and total energy expenditure (TEE) that were greatest with a low-fat diet, intermediate with the low-glycemic index diet, and least with the very low-carbohydrate diet. This suggests that a low carbohydrate diet may attenuate the “starvation response” induced by weight loss and help sustain the new weight achieved.⁷⁴³

Physical Activity Intervention

In adults, exercise is not an effective means of inducing weight loss unless combined with reduction of caloric intake. The role of exercise may have a greater impact on weight maintenance, rather than weight loss.⁷⁴⁶ Similarly, there is the question as to whether physical activity regimens for children can stabilize or reduce BMI.^{747,748} Short-term studies show that vigorous exercise can result in short-term reductions in adiposity⁷⁴⁹ and improved insulin sensitivity.⁷⁵⁰ This amounts to a minimum of 30 minutes of vigorous exercise, 5 days per week, as recently proposed activity guidelines from the Institute of Medicine.⁷⁵¹ However, such interventions eventually plateau in their effectiveness, and even short-term cessation rapidly reverses any accrued benefit.⁷⁵² To succeed, physical activity interventions must be long-term, sustained, and incorporated into behavioral modifications aimed at the individual, at the family, at the school, and within the community in general.^{749,752} In other words, to make physical activity work, it must become a priority.

Lifestyle programs including supervised exercise can improve fasting insulin levels as quickly as 2 weeks before measurable weight loss occurs. Furthermore, lifestyle intervention improved body composition without a change in body weight. Available studies suggest that fitness may play a more important role than BMI reduction on improvement in insulin sensitivity in adolescents with obesity. Appropriate interventions include (1) making school-based physical education mandatory for

every child and school; (2) increasing access to after-school recreation; (3) increasing culturally appropriate activities; (4) reducing the competitive nature of sports, so more children will participate; (5) increase incorporation of physical activity into daily life (e.g., stairs, walking to school as appropriate); and (6) increase participation of parents in physical recreation, for their own weight management and as role models for their children. Lastly, the effects of reducing sedentary behavior by restricting television viewing has been efficacious in both small and large studies, and in diverse ethnic groups,⁴⁸⁷ although fitness is not improved. Restriction of television also has a secondary effect of reducing caloric intake while watching television.

The results of the TODAY study have shown that the addition of an intensive exercise intervention to pharmacologic and dietary regimens in adolescents with type 2 diabetes had no additional benefit in any clinical outcome.⁷⁵³ This observation probably reflects the “real life” compliance to such interventions among the relevant target populations. Results using either dietary or exercise intervention alone are not encouraging. Those studies that use behavioral, dietary, and exercise components together appear to be more successful,^{504,754} although long-term efficacy is lacking.

Family Intervention

Invariably, the patient is not the only member of the family with obesity. There is frequently a familial environment that promotes obesity in other family members. Various caretakers (e.g., grandmothers, babysitters, etc.) will feed children and allow unrestricted television time as a method of confining their activities indoors, particularly in dangerous neighborhoods. Some parents will not alter their shopping for less healthy food because they believe other sibs should not be deprived of it. Divorced parents will often use food as reward to buy the child's love and loyalty. Thus the family itself must be the target of lifestyle intervention. Parental involvement is critical, and the concept of “food is not love” must be emphasized. Families need training to modify behavior to make healthy dietary choices, increase activity, and to reduce perceived stress. A recent meta-analysis of randomized trials of combined lifestyle interventions for treating pediatric obesity yielded a significant although underwhelming decrease in BMI of 1.5 with targeted family intervention, and a nonsignificant decrease in BMI of 0.4 in those that targeted the patient alone.⁷⁵⁵

Pharmacotherapy

Indications for Pharmacotherapy

Pharmacologic therapies in children must currently be considered adjuncts to standard lifestyle modification. The main problem is that presently most drugs are not approved for use in children. In addition, several limitations preclude physicians from early implementation of drug therapies for the treatment of childhood obesity, including (1) the youngest child for whom any obesity pharmacotherapy is currently US Food and Drug administration (FDA) approved is 10 years; (2) the long-term use of pharmacologic intervention has not always proven to be more efficacious than behavior modification; (3) there exists a limited number of well-controlled studies of safe and effective pharmacologic intervention in children with obesity; (4) the relative risk for the development of adverse events in children must be weighed against the long-term potential for improvement of morbidity and mortality, which is difficult to estimate in children; and (5) targeting the pathology is still in its infancy. Also, we must not forget that many drugs used for treatment of adult obesity resulted in unforeseen complications, which resulted either in their restriction (thyroid hormone, amphetamine) or recall (e.g., sibutramine,

rimonabant, dinitrophenol, fenfluramine, dexfenfluramine, phenylpropranolamine, ephedra).⁷⁵⁶⁻⁷⁶¹ Despite these concerns, the negative health impact of childhood obesity may justify long-term medication to control its progression.

In the current pharmacopoeia of childhood obesity (Table 24.2), only a nonspecific fat absorption reduction approach is available for obesity per se. Targeting obesity-related insulin resistance adds additional agents yet their effect in regard to weight reduction is disappointing.

Reduction of Energy Absorption: Orlistat

This drug is a modified bacterial product that specifically inhibits intestinal lipase and can reduce fat and cholesterol absorption by approximately 30% in subjects eating a 30% fat diet.⁷⁶² Orlistat irreversibly binds to the active site of the lipase, preventing intraluminal deacylation of triglycerides, resulting in an approximate 16 g/d increase in fecal fat excretion.⁷⁶³ Orlistat does not inhibit other intestinal enzymes. It has minimal absorption and exerts no effect on systemic lipases.^{764,765}

Although there have been several open-label trials of orlistat in adolescents, only two randomized control trials (RCTs) have been published.^{766,767} The side effects with orlistat are predictable from its mechanism of action on intestinal lipase.⁷⁵⁶ Orlistat appears to be well tolerated in adults, with the principal complaints being borborygmi, flatus, and abdominal cramps. The most troubling side effects are fecal incontinence, oily spotting, and flatus with discharge, which are highly aversive in the pediatric population. Orlistat does not affect the pharmacokinetic properties of most other pharmaceutical agents. Absorption of vitamins A and E and β -carotene may be slightly reduced, and this may require vitamin therapy in a small number of patients. Orlistat must be taken with each meal, which reduces its attractiveness in children, who are in school during lunchtime. Orlistat is currently approved for treatment of children as young as 12 years. An over-the-counter lower dose preparation recently obtained FDA approval, and should be available soon.

Improvement of Insulin Resistance: Metformin

Metformin is a bisubstituted, short-chain hydrophilic guanidine derivative used for the treatment of children and adults with T2DM.⁷⁶⁸⁻⁷⁷¹ Metformin also decreases fasting hyperinsulinemia, may prevent T2DM⁷⁷² and promotes weight loss in some but not all individuals with obesity,^{773,774} by improving hepatic and muscle insulin sensitivity. Metformin has little effect on energy expenditure.⁷⁶⁹ Although some believe that metformin promotes weight loss through a primary anorectic effect (because initial side effects of nausea and gastrointestinal distress limit caloric intake acutely),⁷⁷⁵ most believe that the decline in caloric intake observed with metformin is related to its enhancement of glucose clearance, through reduction of hepatic glucose output, and reduction in fasting hyperinsulinemia.^{776,777} Metformin improves hepatic insulin resistance by inducing hepatic AMP kinase,⁷⁷⁸ which reduces hepatic gluconeogenesis; therefore pancreatic insulin secretion and peripheral insulin levels fall. Metformin also restores PI3K and MAPK activity in muscle cells, improving muscle insulin sensitivity.⁷⁷⁹ Another possible mechanism of metformin action is through stimulation of GLP-1,^{780,781} which may inhibit food intake through central actions on the VMH.⁷⁸²

Thus far, results of two RCTs in children and adolescents have been reported.^{783,784} Examination of the open-label responses to metformin in a multivariate analysis demonstrated two predictors for efficacy: race (white >black American) and the degree of insulin resistance before therapy (among youth with obesity, those with insulin resistance

TABLE 24.2 Medications for the Treatment of Pediatric Obesity

Drug	Dosage	Efficacy	Side Effects	Monitoring and Contraindications
Orlistat Not FDA approved for <12 years of age	120 mg PO TID	Open-label: Wt–5.4 kg, BMI–2.0 kg/m ² at 6 months; RCT: Wt–2.6 kg, BMI–0.85, W –2.7 cm over placebo at 12 months	Borborygmi, flatus, abdominal cramps, fecal incontinence, oily spotting, vitamin malabsorption	Monitor 25OHD ₃ levels. MVI supplementation is strongly recommended. A lower dose preparation has been approved for over-the-counter sale
Metformin Not FDA approved for treatment of obesity Approved for ≥10 years of age for type 2 diabetes mellitus	250–1000 mg PO BID	RCT: BMI z-score –0.35 SD vs. placebo at 6 months RCT: Wt–2.7% vs. placebo at 6 months; Post-hoc analysis: efficacy dependent on degree of insulin resistance; BMI z-score –0.23 SD in first 4 months, –0.12 SD in next year	Nausea, flatulence, bloating, diarrhea; usually resolves. Lactic acidosis not yet reported in children	Do not use in renal failure or with intravenous contrast MVI supplementation is strongly recommended
Octreotide Not FDA approved for treatment of obesity, otherwise ≥18 years of age	5–15 mcg/kg/d SQ ÷ TID	Open-label: Wt–4.8 kg, BMI–2.0 kg/m ² in 6 months; RCT: –7.6 kg, BMI–2.5 kg/m ² over placebo at 6 months Posthoc analysis: BMI z-score –0.70 SD in 6 months, dependent on insulin secretion and sensitivity	Gallstones, diarrhea, edema, abdominal cramps, nausea, bloating, reduction in thyroxine concentrations	Monitor fasting glucose, FT ₄ , HbA _{1c} . Useful only for hypothalamic obesity Ursodiol coadministration strongly recommended
Leptin Not approved by FDA	Titration of dose to serum levels, SQ	Anecdotal: BMI–19.0 kg/m ² over 4 years	Local reactions	Useful <i>only</i> in leptin deficiency
Topiramate Not FDA approved for treatment of obesity	96–256 mg PO qd	RCT: Wt–8.0% over placebo at 6 months	Paresthesia, difficulty with concentration/attention, depression, difficulty with memory, language problems, nervousness, psychomotor slowing	No pediatric data
Growth hormone Not FDA approved for treatment of obesity	1–3 mg/m ² SQ qd	Decreases in percentage body fat, with increases in absolute lean body mass	Edema, carpal tunnel syndrome, death in patients with preexisting obstructive sleep apnea	Recommended only in Prader-Willi syndrome primarily to increase height velocity. It also decreases fat mass but should only be used in those have been after screening to rule out obstructive sleep apnea. Must closely monitor pulmonary function, glucose, HbA _{1c}

Should be considered only after an unsuccessful 6-month trial of lifestyle intervention.

All drugs effective only when combined with appropriate lifestyle intervention.

BID, Twice a day; BMI, body mass index; FDA, US Food and Drug administration; FT₄, free thyroxine; HbA_{1c}, hemoglobin A1c; MVI, multivitamins; PO, orally; qd, every day; RCT, randomized controlled trial; SD, standard deviation; SQ, subcutaneously; TID, three times a day; wt, weight.

respond better than those who are insulin sensitive).⁷⁸⁵ Metformin has also been used “off-label” for treatment of PCOS and NASH, with varying degrees of success.^{786–791} One particular use for metformin may be to combat the weight gain associated with atypical antipsychotics.⁷⁹² However, cessation of metformin therapy leads to a rebound hyperinsulinemia and rapid weight gain, which may negate any beneficial effects seen during the medication window.

Side effects with metformin include nausea, flatulence, bloating, and diarrhea at initiation of therapy, which appears to be self-limited and resolves within 3 to 4 weeks of initiation of the drug. Approximately 5% of pediatric patients discontinue metformin therapy because of the severity of side effects. The most feared complication of metformin in adults is lactic acidosis, which is estimated to occur at a rate of 3 per 100,000 patient-exposure years, primarily in patients with

contraindications to the use of metformin; however, no documented cases in children have been reported. Metformin increases the urinary excretion of vitamins B₁ and B₆, which are important in the tricarboxylic acid cycle, and which may hasten the lactic acidosis.⁷⁹³ Vitamin B₁₂ deficiency also has been reported in as many as 9% of adult subjects using metformin. Therefore prophylactic multivitamin supplementation is recommended with metformin use. Contraindications to metformin use include renal insufficiency, congestive heart failure or pulmonary insufficiency, acute liver disease, and alcohol use sufficient to cause acute hepatic toxicity. Metformin also should be withheld when patients are hospitalized with any condition that may cause decreased systemic perfusion, or when use of contrast agents is anticipated.⁷⁷⁶ It should be noted that metformin is FDA approved for treatment of T2DM in children but is unlikely to be approved for childhood obesity or insulin resistance.

Suppression of Insulin Hypersecretion: Octreotide

It is well known that bilateral electrolytic lesions or deafferentation of the VMH in rats leads to intractable weight gain,^{794–798} even upon food restriction.⁷⁹⁹ In humans, hypothalamic damage, either caused by CNS tumor, surgery, radiation, or trauma, can alter both the afferent and efferent pathway of energy balance, and lead to severe and intractable weight gain.^{800,801} In this syndrome of “hypothalamic obesity,” hypothalamic insult confers an “organic leptin resistance” as the VMH senses starvation;^{797,802} therefore energy intake is high, and expenditure is low.⁸⁰³ Children with hypothalamic obesity exhibit weight gain, even in response to forced caloric restriction,⁸⁰⁴ secondary to (1) overactivation of the vagus, which promotes an obligate insulin hypersecretion and energy storage and (2) defective activation of the SNS, which retards lipolysis and energy expenditure.^{805,806} Insulin hypersecretion with normal insulin sensitivity is noted on oral glucose tolerance testing in these children.⁸⁰⁷ This same phenomenon of insulin hypersecretion has also been documented in a subset of adults who have obesity without CNS damage.⁸⁰⁸

The voltage-gated calcium channel of the β -cell is coupled to a somatostatin-5 receptor (SSTR₅).^{809,810} Octreotide binds to this receptor, which limits the opening of this calcium channel, reduces influx of calcium into the β -cells, and in turn reduces calmodulin activation and vesicle exocytosis, thereby acutely decreasing the magnitude of insulin response to glucose⁸¹¹ (see Fig. 24.3), which results in weight loss or stabilization. Two RCTs and an observational prediction study using octreotide for obesity have been performed.^{246,812} An examination of BMI responses to octreotide in pediatric hypothalamic obesity in a multivariate analysis demonstrated that insulin hypersecretion with concomitant retention of insulin sensitivity before therapy augured for success.⁷⁸⁵ A larger scale study of patients following a brain insult showed limited efficacy, probably because of the timing of the intervention—the majority of weight gain in cases of hypothalamic obesity occurs early following the insult. Pharmacotherapy that begins too late may fail to reverse this condition whereas early initiation of treatment may prevent excessive weight gain.

Octreotide is usually well tolerated. The most common side effects include diarrhea, abdominal cramps, nausea, and bloating, which are self-limited, and usually resolve in 3 to 4 weeks.^{813,814} Other adverse events include gallstones (which are preventable by coadministration of ursodiol), edema, development of sterile abscess at the injection sites, B₁₂ deficiency, suppression of GH and TSH secretion, and mild hyperglycemia, especially in those with severe insulin resistance.⁸¹⁵

Other Targeted Therapies

Leptin. Mutations of the leptin gene in humans recapitulate the phenotype of the *ob/ob* leptin-deficient mouse.⁸¹⁶ Approximately 11 such patients have been described; they manifest hyperphagia from birth, with obesity documentable as early as 6 months of age. Leptin deficiency induces the starvation response,⁸¹⁷ with increased energy intake and decreased REE. The diagnosis is made by extremely low or unmeasurable serum leptin levels. In children with leptin deficiency, leptin therapy results in extraordinary loss of weight and fat mass,^{818,819} along with reduction in hyperphagia, resolution of obesity, induction of puberty, and improvement in immunity.⁸¹⁷ Although leptin administration in adults did not prove effective by itself because of leptin resistance,⁸²⁰ leptin may serve as an adjunct in combination with other medications after leptin sensitivity is ameliorated through weight loss.^{821,822}

GLP-1 Analogs. Several long-acting GLP-1 analogs have been recently introduced, some with an antiobesity indication.

GLP-1 is a gut-derived incretin that also serves a satiety signal as described earlier. As its half-life in the circulation is brief (~2 minutes) because of degradation by the enzyme dipeptidyl peptidase-4 (DPP-4), stable analogues have been designed, aiming initially at β -cell enhancement but also showing some significant weight loss effects.⁸²³ The safety of GLP-1 analogues has been demonstrated in children with obesity,⁸²⁴ efficacy trials are presently performed and should be published soon.

The Future of Pediatric Obesity Pharmacotherapy

In response to the relative lack of efficacy of lifestyle interventions, the ever-expanding knowledge of the physiology of energy balance, and particularly as a business decision of potential financial reward, many pharmaceutical companies have launched obesity research programs. The following agents are currently in human study; however, use of any of these new agents in children will depend on proof of safety and efficacy based on experience in adults. **Topiramate** is an anticonvulsant that blocks voltage-dependent sodium channels, enhances the activity of the GABA_A receptor, and antagonizes a glutamate receptor other than the *N*-methyl-D-aspartate (NMDA) receptor.⁸²⁵ Topiramate promotes weight loss in a dose-dependent fashion.⁸²⁶ An RCT in adults demonstrated a 9.1% weight loss in subjects taking topiramate 192 mg/d along with significant improvements in blood pressure, waist circumference, and fasting glucose and insulin.⁸²⁷ However, almost 33% of the subjects dropped out because of adverse events, which included paresthesias, somnolence, anorexia, fatigue, nervousness, decreased concentration, difficulty with memory, and aggression. There are currently no studies of topiramate in childhood obesity. **Oxyntomodulin** is an analog of PYY₍₃₋₃₆₎, which has been shown in a 4-week RCT to reduce energy intake and weight in adults.⁸²⁸ There are no studies in children. Current weight-loss formulations that have been approved in adults include combination phentermine-topiramate (*QSymia*[®]); combination naltrexone-bupropion (*Contrave*[®]); lorcaserin, a serotonin 2c-agonist (*Belviq*[®]); and liraglutide, a GLP-1 agonist (*Saxenda*[®]). There are no published clinical efficacy trials in children as of yet.

Bariatric Surgery

In comparison with adults, stricter and more conservative criteria must be applied to adolescents because only 85% of adolescents with obesity will become adults with obesity including the slightly improved rate of lifestyle and pharmacotherapeutic efficacy versus adults; a longer time interval before comorbidities become life-threatening; and their inability to give legal consent. For all these reasons, an expert panel with representation from the American Pediatric Surgical Association and the American Academy of Pediatrics has suggested that bariatric surgery for adolescents should be done only in institutions committed to long-term management of these patients⁸²⁹ and is justified in situations when obesity-related comorbid conditions (like OSA) threaten the child’s health. They provided stringent recommendations that bariatric surgery be limited to those adolescents with BMI over 35 or 120% of the 95th percentile with presence of severe comorbidity (severe OSA, pseudotumor cerebri, type 2 diabetes or steatohepatitis) or BMI over 40 or 140% of the 95th percentile with a less severe comorbidity.^{830–832} Published data support the notion that bariatric surgery is effective in adolescents with obesity in regard to weight loss and improvement of comorbidities similar to adults.^{833,834} The majority also improve psychosocial parameters yet, importantly, some may develop depression, suicidal ideation, and overall lower psychosocial well-being.⁸³⁵ It is not clear what the bariatric procedure of choice should be

in this population and what fashion of preparation and follow-up will allow optimization of long-term results.

Gastric bypass has been performed more widely in children and adolescents since the 1990s, whereas sleeve gastrectomy has been adopted from the adult practice since 2010 and is now performed twice as frequently as gastric bypass.^{835a} These procedures appear to be safe and effective when candidates are carefully selected, and the bariatric surgeon has advanced laparoscopic skills. Thus far, we have very limited data on long-term complications, including those that might be associated with future pregnancy, bone health, and outcomes of repeated surgical procedures in case of weight regain. Nonetheless, the data thus far suggest potential benefit for obesity-driven comorbidities and improvement of quality of life in youth with severe obesity and obesity-related complications. However, how widespread bariatric surgery should be used as a solution remains to be determined until we have additional and longer term outcomes data.

Indications for Bariatric Surgery

An expert panel with representation from the American Pediatric Surgical Association and the American Academy of Pediatrics⁸²⁹ suggested that bariatric surgery in adolescence could be justified in situations when obesity-related comorbid conditions threaten the child's health. They provided stringent recommendations that bariatric surgery be limited to those adolescents with BMI over 35 with presence of severe comorbidity, or BMI over 40 with a less severe comorbidity. Such procedures should be performed only in centers of excellence that include a multidisciplinary team that can provide the endocrine, psychiatric, dietary and psychologic patient and family support before and after the bariatric procedure.

Special consideration should be taken to avoid bariatric surgery at very late stages of obesity, when the presence of obesity-related comorbidities, and the inaccessibility of imaging (most MRI scanners have a weight limit of 450 lbs or 200 kg) may affect surgical outcome. Indeed, a review of eight retrospective studies in adolescents found that bariatric surgery in adolescents can promote durable weight loss in most patients, but there appears to be a significant complication and mortality rate.⁸³⁶ Therefore guidance is needed to determine the ideal circumstances at which the balance of risk versus benefit favors health preservation and reversal of complications with the lowest risk of morbidity and mortality from the procedure.

Bariatric procedures for weight loss can be divided into purely restrictive, those that bypass a segment of the foregut, and combination procedures. Purely malabsorptive procedures aim to decrease the functional length or efficiency of the intestinal mucosa through anatomic rearrangement of the intestine. These procedures include the jejunoileal bypass, and the biliopancreatic diversion with duodenal switch. Because of the high morbidity and mortality of these procedures, they cannot be recommended in children, and will not be discussed further. The restrictive procedures reduce stomach volume to decrease the volume of food ingested. They include the bariatric intragastric balloon (no data in children) and laparoscopic adjustable gastric banding (LAGB). The Roux-en-Y gastric bypass (RYGB) is a combination procedure.⁸³⁷ The sleeve gastrectomy seems to be a restrictive procedure yet it probably shares some of the hormonal effects of the RYGB and is gaining increasing popularity.⁸³⁸

Restrictive: Laparoscopic Adjustable Gastric Banding

LAGB uses a prosthetic band to encircle and compartmentalize the proximal stomach into a small pouch and a large remnant.⁸³⁷ The theoretical advantage of this technique is

decreased risk of staple line dehiscence. The more recent introduction of a new laparoscopic approach and the use of an adjustable band (allowing the stomach size to change) make this procedure more attractive. Finally, this procedure is reversible (at least theoretically; there are some surgeons who scoff at this notion), or it can be modified into the RYGB at a later date. Results vary widely in adults. A single RCT comparing LAGB to conservative obesity management in children with obesity has shown superior weight loss that was maintained over 2 years. Among adolescent participants with obesity, use of gastric banding compared with lifestyle intervention resulted in a greater percentage achieving a loss of 50% of excess weight, corrected for age. There were associated benefits to health and quality of life.⁸³⁹ The significant side effects and limited long-term weight maintenance following LAGB have caused a reduction in its popularity in recent years.

Combination: Roux-en-Y Gastric Bypass

RYGB involves dividing the stomach to create a small (15–30 mL) stomach pouch into which a segment of jejunum approximately 15 to 60 cm inferior to the ligament of Treitz is inserted, whereas the proximal portion of the jejunum that drains the bypassed lower stomach and duodenum is reanastomosed 75 to 150 cm inferior to the gastrojejunostomy.⁸³⁷ This procedure combines the restrictive nature of gastrectomy with the consequences of dumping physiology as a negative conditioning response when high-calorie liquid meals are ingested. In addition, RYGB is associated with decline in the circulating level of ghrelin, which may be in part responsible for the decrease in hunger associated with this procedure.⁸⁴⁰ The procedure can not only lead to extraordinary weight loss, it can reverse type 2 diabetes as well.⁸⁴¹

RYGB appears to result in significant early weight reduction in adults^{837,842}; however, long-term studies demonstrate weight regain in many patients.⁸⁴³ RYGB seems to provide complete remission of T2DM in adolescents with obesity. Importantly, when performed in adolescents with severe obesity, the nadir BMI achieved is typically around 37% from baseline. If one performs the procedure on a patient with a BMI in the low 40s—the result may be a BMI within an acceptable healthy range. In contrast, performing the procedure in patients with BMI over 50 leaves them, even after an optimal result, in the obese BMI range without further reductions.⁸⁴⁴

The most common reported complications of RYGB include iron-deficiency anemia (50%), transient folate deficiency (30%), and events requiring surgical intervention (40%: cholecystectomy in 20%, small bowel obstruction in 10%, and incisional hernia in 10%).⁸³⁷ Because most of the stomach and duodenum is bypassed in this procedure there is an increased risk for deficiencies in vitamin B₁₂, iron, calcium, and thiamine. Although beriberi has been reported in teenagers after RYGB,⁸⁴⁵ compliance with daily lifetime supplementation and regular monitoring of patients can prevent such nutritional deficiencies.

Laparoscopic Sleeve Gastrectomy

The laparoscopic sleeve gastrectomy (LSG) procedure is becoming more widely used. It reduces gastric capacity, by cutting out the greater curvature of the stomach, in other words, turning the stomach into a tube. Sleeve gastrectomy is rising in popularity among children as well as adults with obesity because it is seemingly a simpler procedure technically with clinical outcomes comparable with those of RYGB.⁸³⁴ The limited data in adolescents indeed show similar weight loss in comparison to RYGB. The 5-year failure rate in regard to weight regain and return of comorbidities of this procedure in adults with obesity is about 50%,⁸⁴⁶ yet such data in children is still not available.

Who Should Perform Bariatric Surgery in Children?

Surgical outcomes in adults vary widely between surgeons and institutions.^{847–849} Furthermore, there is a very clear learning curve because the morbidity of bariatric surgery varies inversely with the number of procedures performed.⁸⁵⁰ The increased risk of readmission after bariatric surgery in adults⁸⁵¹ argues for close and careful follow-up and monitoring in adolescents. Therefore it is essential that bariatric surgery in adolescents be performed in regional pediatric academic centers with programs equipped to handle the data acquisition, long-term follow-up, multidisciplinary nature of these difficult patients.⁸⁵²

A multidisciplinary team with medical, surgical, nutritional, and psychologic expertise should carefully select adolescents who are well informed and motivated to become potential candidates for bariatric surgery. Attention to the principles of growth, development, and compliance is essential to avoid adverse physical, cognitive, and psychosocial outcomes following bariatric surgery.⁸⁵² It must be clear to the subject and the parent that bariatric surgery is in fact an adjunct to a sincere commitment to lifestyle, rather than a “magic bullet.” Indeed, evidence of relapse in adults after RYGB is now commonplace.

Subjects and families must be well informed as to the risks and complications of such surgery. The medical team will require endocrine, gastrointestinal, cardiology, pulmonary, and otolaryngologic support. Prophylactic tracheostomy is rarely required to maintain airway patency and to allow for resolution of the hypercapnia before surgery.⁸⁵³ Adolescents undergoing bariatric surgery require lifelong medical and nutritional surveillance postoperatively.⁸⁵⁴ Extensive counseling, education and support are required both before and after bariatric surgery; patients left to their own recognizance tend to regain weight over time. Indeed, studies in adults document an increased risk of hospitalization after RYGB, because of difficulties from the procedure.⁸⁵¹ Monitoring of long-term weight maintenance, improvements in CV morbidity, and longevity are all necessary to determine the cost-effectiveness of bariatric surgery in the pediatric population.

ENERGY INADEQUACY

Starvation Versus Cachexia

Although both are weight loss syndromes, understanding the neuroendocrine mechanisms that distinguish starvation from cachexia is integral to both understanding and treating these disorders properly. In starvation, the negative feedback energy balance pathway is intact. The signal of leptin inadequacy from the weight loss is transduced by the VMH neuron into reduced sympathetic activity (to conserve energy) and increased vagal activity (to store energy). However, in cachexia, this pathway is short-circuited by cytokine action on the hypothalamus. The VMH POMC neuron expresses receptors for various cytokines, including IL-1 and TNF- α .⁸⁵⁵ In response to cytokine exposure, POMC neurons are activated, resulting in anorexia, increased sympathetic activity, decreased vagal activity, and energy wastage.^{856,857} Proinflammatory cytokines increase epinephrine, GH, and cortisol, and reduce insulin. These long-term hormonal changes accelerate muscle proteolysis (cortisol), increase resting energy expenditure (SNS), contribute to insulin resistance (both epinephrine and cortisol), increase catabolism (cortisol), and suppress appetite and intestinal transit (vagus). This is clearly adaptive in the short term during times of infection (to generate body heat to eradicate the organism), but maladaptive in the long term, when chronic cytokine signaling can lead to cachexia. Thus even in the situations of leptin decline or inadequacy, cytokine activation of POMC neurons will promote continued cachexia and weight loss through persistent SNS activation.

Failure to Thrive

Failure to thrive (FTT) is not a disease per se but rather a sign of multiple organic and nonorganic conditions and the interactions between them leading to compromised growth at a young age. FTT still represents a common pediatric medical problem mostly managed in the outpatient setting. Although FTT can rarely be a manifestation of critical illness, the majority of cases are the result of undernutrition because of the combination of biologic, environmental, and psychologic factors. The diagnosis of FTT requires a thorough, prudent, and oriented history taking by the caregiver and is not always simple to establish. Moreover, this diagnosis may carry several legal implications that are not within the scope of this text.

Definition

There is no consensus on a single definition for FTT. The condition reflects inadequate physical growth recorded over time using standard growth charts. The commonly used definitions in clinical practice include length and/or weight below the 5th percentile for age and gender, a downward cross of two major percentile lines of the growth chart over time, or a weight per height below the 10th percentile of expected. The practicality of usually using weight and not length curves evolves from the fact that undernutrition and chronic disease tend to primarily affect weight gain while preserving linear growth. Ultimately, linear growth is also affected if these conditions persist. It is important to emphasize that single measurements without longitudinal follow-up growth points are inadequate to make the diagnosis of FTT, and a wrongful diagnosis may be established in infants who were born small for gestational age or prematurely, and in some healthy growing infants growing along the lower percentiles.

Classification and Etiology

The traditional classification of FTT is to segregate between organic and nonorganic causes. The nonorganic causes refer to environmental and psychologic factors, such as sensory deprivation, parental and emotional deprivation, and feeding difficulties of no organic source that occur in infancy. This traditional classification seems to lack the insight that the majority of cases suffer of a combination of the two reflecting a mixed etiology.⁸⁵⁸ A different approach is to classify the disorder based on the pathophysiology of the disorder, that is, inadequate caloric intake, inadequate absorption, excess metabolic requirements, defective utilization of intake, and reduced growth potential.⁸⁵⁹ Common causes of FTT based on this classification scheme are shown in Box 24.2.

Of note, normal growth variation can confound the diagnosis of FTT because some infants may be born large for gestational age as the result of intrauterine causes (such as gestational diabetes), and later experience a “catch down” pattern of growth during infancy toward the actual growth potential curves. Another cause of such negative crossing of percentiles can be constitutional growth delay. It is estimated that up to 25% of children can cross curves by more than 25 percentile lines (representing a cross of two major growth percentile lines) because of the aforementioned reasons.⁸⁶⁰ These infants reach a new point from which they display a normal growth rate and weight gain pattern, yet they do not have FTT.

Endocrine causes of FTT are uncommon, as typical hormonal deficiencies, such as GH deficiency or hypothyroidism, present as growth failure but with preserved or increased weight gain. Hyperthyroidism (representing a state of increased metabolic demands and characteristically manifested by increased linear growth) and disorders of salt metabolism, such as hypoadosteronism and pseudo-hypoadosteronism, may have

BOX 24.2 Differential Diagnosis of Failure to Thrive

1. Inadequate caloric intake
 - Poverty and low food resources
 - Mechanical feeding difficulties (altered swallowing ability, congenital anomalies, central nervous system damage, severe gastroesophageal reflux)
 - Wrongful preparation of infant formula (too diluted, too concentrated)
 - Unsuitable feeding habits by parent
 - Behavioral problems affecting eating
 - Child neglect
 - Poor parent–child interaction
2. Inadequate absorption of caloric intake
 - Reduced absorption surface area (short bowel syndrome, s/p necrotizing enterocolitis)
 - Chronic liver disease, biliary atresia
 - Celiac disease
 - Cystic fibrosis
 - Cow’s milk allergy
 - Chronic diarrhea
 - Vitamin or mineral deficiencies (acrodermatitis enteropathica)
 - Vomiting because of CNS abnormalities (tumor, raised ICP)
3. Increased metabolism
 - Hyperthyroidism
 - Chronic infection (because of immune deficiency)
 - Occult malignancy
 - Congenital heart defects or acquired heart disease (mainly right to left shunts and heart failure)
 - Chronic lung disease with hypoxemia (bronchopulmonary dysplasia)
 - Burns
4. Defective utilization of calories
 - Renal failure, renal tubular acidosis
 - Inborn errors of metabolism (storage diseases, amino acid disorders)
5. Reduced growth potential
 - Genetic disorders (trisomies, skeletal dysplasias, Russell-Silver syndrome)
 - Specific genetic syndromes
 - Primordial dwarfism

CNS, Central nervous system; ICP, intracranial pressure.

FTT as part of their clinical manifestations.⁸⁶¹ Hypophosphatemic rickets may also present as FTT.

Diagnosis and Evaluation

The key to making the diagnosis of FTT is in plotting anthropometric data (weight and length) during a reasonable follow-up period. Although a prudent and focused history and physical examination are the keys to diagnosis, often the correct diagnosis is made in retrospect. The lack of an organic etiology to explain the findings is not enough to establish a diagnosis of nonorganic FTT. A response to an active intervention, manifested at least as a limited period of adequate growth while altering a behavioral element by the caregiver or child, can help establish a diagnosis of nonorganic FTT.

History should focus on the dietary and feeding history, past and present medical history, social environment, and family history. The dietary history is aimed at assessing as accurately as possible the actual caloric intake of the patient. An important tool for this assessment can be the use of food logs of several days. The important details are regarding actual amounts of food, the way the food is prepared (specifically relevant for the dilution technique of infant formulas and to cereals added to the formula), and beverages consumed with specific emphasis on sweetened juices and formula. These details should allow the practitioner to estimate the caloric intake.

The important details regarding feeding begin with the location of the meals and their timing throughout the day. Who feeds the patient or supervises the feeding process is of major importance. The feeding technique should be appropriate for the developmental stage of the child. The timing is relevant in regard to frequent snacking in between meals that may cause early satiety during mealtimes.

A standard pediatric medical history should be taken from all patients, yet it should be focused on details that may be relevant to the diagnosis of FTT. The pregnancy and birth history are important for differentiation of infants who were born small for gestational age versus those who suffer from FTT. The timing at which poor weight gain began, especially in relation to changes in feeding, is critically important for the

diagnosis. Chronic medical conditions, such as congenital heart disease, asthma, multiple recurrent infections, and anemia can all be causes of organic FTT. Multiple hospitalizations and a history of injuries can raise the suspicion of parental neglect. Gastrointestinal manifestations of relevant medical conditions, such as frequent vomiting (in cases of milk allergy or gastroesophageal reflux) and stool frequency and consistency (to rule out malabsorption, celiac, inflammatory bowel disease or cystic fibrosis), should be elicited in detail.

The social history should focus on identifying the actual caregivers of the patient during the majority of the time and whether there are economic issues that may affect the ability to nourish the patient adequately. Potential external and intrafamilial stressors that may affect the supply of food to the child should be sought (any stressor or life event that can affect the functioning of the caregiver in a way that could compromise the well-being of the child). The family history should focus on the body habitus of parents and siblings to obtain clues regarding genetic potential for height and weight. Medical conditions in siblings and relatives can suggest a predisposition to genetic disorders. The caregivers should be asked about mental illnesses, such as depression, that may hamper their ability to provide adequate care for the child. A family history of previous children who suffered from FTT should be investigated as well. A call to the local Department of Family Services may be warranted.

The physical examination begins with plotting the child’s length, weight, and head circumference on standard growth charts, along with previous measurements (if available). The severity of the FTT can be estimated by assessing the present weight in comparison to the expected weight for age. If the weight is less than 60% of expected by the 50th percentile for age and length, the condition is severe, whereas a weight between the 60th and 75th percentile of expected is considered moderate FTT. Microcephaly accompanied by neurologic signs may suggest a CNS lesion. It should be remembered that head circumference is the last parameter to change in FTT, and only in the severest cases. Detection of dysmorphism may suggest a genetic cause for impaired growth and development. Measures of nutritional status (such as thickness of skin folds and body fat distribution) can be examined. It is important to carefully

observe the interaction of the caregiver and the child during feeding. Impaired parent–child interactions can have a major impact on feeding habits, and their identification is critical to the design of effective behavioral interventions tailored for the patient and family.

The majority of children with FTT have no laboratory abnormalities, and no hormonal alterations. There is minimal literature available about comprehensive laboratory workups in children with FTT, although a classic manuscript about the workup of more than 180 infants in an in-patient setting found laboratory abnormalities in less than 1.4% of tests taken.⁸⁶² The choice of tests that may be beneficial should be based on the history and physical examination and usually is focused on the assessment of malnutrition in severe cases. A minimal workup, although not cost-effective, may include a blood count, chemistry panel (including liver and renal function tests, electrolytes, serum protein and albumin concentrations, as well as blood acid-base status) and a urinalysis with pH. Additional tests should be oriented at specific findings from the history and physical examination. No hormonal tests are warranted initially unless a clinical suspicion of a specific disorder arises. In children older than 6 months, screening for iron deficiency and lead poisoning is warranted. Hospitalization and in-patient workup does not add any yield to the workup,⁸⁶³ unless the degree of FTT is severe, or if there are concerns of child safety and neglect.

Management

The management of FTT is based on the identification of the underlying cause and its correction. The vast majority of cases are handled by a combination of nutritional and behavioral intervention. Importantly, the intervention should begin before the workup is complete, that is, from the first evaluation. All medical problems are treated independently of nutritional and behavioral interventions and should not delay or hamper them. The mainstay of treatment of all infants with FTT is a calorie-rich diet accompanied by frequent and close monitoring of weight response. An effective intervention will document a catch-up weight and height gain that is maintained over time.

Feeding and eating behaviors should be addressed walking the fine line between encouragement and pressure to promote eating. Timing meals and snacks and eating as a family in a pleasant environment of low stress may be important for the acquiring of improved eating and feeding practices. The feeding intervention is dependent on the infants' age at presentation. For breastfeeding infants, it is beneficial to attempt to increase breast-milk supply⁸⁶⁴ by pumping milk, treatment with metoclopramide to induce oxytocin secretion,⁸⁶⁵ improving maternal nutrition and fluid intake, and making adaptations at the home and workplace that can promote and simplify the breastfeeding process. Suckling problems in neurologically impaired infants can be solved by providing expressed human milk via bottle-feeding. Bottle-fed and older infants allow more interventions to promote increased caloric content of the diet. Infants with FTT should receive around 150% of the recommended daily caloric intake based on their expected weight (rather than based on their actual weight).⁸⁶⁶ The enrichment of formula may be achieved by adding cereals, and toddlers may benefit from the addition of palatable high-energy density foods (such as cheese and peanut butter) to their diet. High-calorie milk-based drinks (such as PediaSure that provides 30 calories per ounce, in comparison with whole milk which provides 19 calories per ounce) can be added alongside vitamin supplementation. Zinc supplementation has been shown to increase IGF-1 levels without affecting IGFBP-3 in infants with nonorganic FTT, yet this effect did not actually promote growth.⁸⁶⁷

Prognosis

The vast majority of infants and children with FTT show improvement with intervention. Others may even show progression when they achieve a more independent stage of development where they can attain their own food. Those who require gastrostomy feeding because of neurologic dysfunction may require assisted enteral nutrition for life. The cognitive and intellectual function outcomes of those who suffered from FTT seem worse than their peers, although this association has *only* been well established in cases of iron-deficiency anemia.⁸⁶⁸ It seems conceivable that deficiencies of other elements critical for brain development during infancy may have a similar adverse impact on intellectual properties at later ages, although this has not been studied systematically. The effects of nonorganic factors (such as emotional deprivation) on intellectual development, often coexisting with organic factors, may also contribute to decreased cognitive ability at later ages.

Cancer Cachexia

Cancer cachexia is characterized by a chronic wasting syndrome, involves skeletal muscle and adipose tissue loss, and is typically resistant to conventional nutritional support. Cachexia is responsible for a significant reduction in quality and length of life of patients with cancer, also in the pediatric age group. Similar to cachexia caused by chronic infections or inflammatory diseases, cancer patients may manifest both malnutrition and metabolic stress. Both carbohydrate utilization pathways, as well as amino acid incorporation, are decreased in the muscles of cancer cachexia patients. Tumor cells may affect patient metabolism in two ways: their own metabolism of nutrients into other metabolites and by circulating factors they secrete or induce the host to secrete. Accelerated glycolysis and lactate production, and the resultant increase in Cori cycle activity, are the typically observed metabolic effects.⁸⁶⁹ A large number of procachexia circulating metabolites and factors have been found, such as TNF- α , IL-6, myostatin, and PTH-related protein, yet no single molecule has been shown to be a determinant factor that can be targeted individually to treat cancer cachexia in humans. Cancer activates a complex set of CNS metabolic pathways, which result in cachexia (Box 24.3).⁸⁷⁰

BOX 24.3 Metabolic Changes in Cachexia

EXPRESSION OF CYTOKINES

- Increased production of acute phase proteins (APP)
- Upregulation of transcription factor NF Kappa B and AP-1
- Increased interleukin (IL)-1, IL-6, and tumor necrosis factor- α and interferon- γ
- Increased expression of tumor specific cachexins (proteolysis inducing factor, lipid mobilizing factor, and anemia inducing substance)
- Increased expression of ubiquitin, E₁, E₂, E₃, and proteasome components (cell death and removal)

INCREASED SYMPATHETIC NERVOUS SYSTEM TONE

- Increased expression of hormone-sensitive lipase in adipose tissue
- Upregulation of uncoupling proteins (UCP2 and UCP3) in muscle and adipose tissue
- Increased hepatic gluconeogenesis

REDUCED VAGAL TONE

- Reduced lipoprotein lipase expression in adipose tissue
- Reduced intestinal transit
- Reduced hunger

Peripheral cytokines gain access to the CNS through the central circumventricular organs, which bypass the blood-brain barrier, or by stimulation and amplification of CNS microglial cytokine or eicosanoid production. For instance, TNF- α stimulates VMH POMC neurons, which stimulate the SNS, which in turn increases resting energy expenditure, increases cortisol and glucagon levels, and contributes to insulin resistance. IL-1 decreases neuropeptide Y within the VMH and thus decreases appetite. IL-1 also increases CRH, which indirectly inhibits appetite. IL-6 bears striking similarity to ciliary neurotrophic factor (CNTF), which has been shown to reduce weight by activating VMH POMC neurons through a leptin-independent mechanism.⁸⁷¹ Conversely, because of reduction in vagal activity, gastrointestinal motility is impaired in cancer cachexia and is clinically manifest by early and inappropriate satiety, which occurs in 40% to 60% of cancer patients.

In addition, cytokines have adverse peripheral effects. Uncoupling proteins are upregulated by cytokines and contribute to increased energy expenditure. Cancer cachexia leads to overexpression of UCP1 in brown adipose tissue; UCP2 in brain, skeletal muscle, and liver; and UCP3 in skeletal muscle. Levels of UCP2 and UCP3 in the liver and muscle are regulated by prostaglandins, and UCP3 is also regulated by TGs, all of which are increased in cancer.⁸⁷²

Cytokines cause insulin resistance in skeletal muscle, liver, and adipose tissue. TNF- α decreases insulin receptor and PPAR activity. TNF- α has a direct catabolic effect on skeletal muscle and causes wasting of muscle by the induction of the ubiquitin-proteasome system (UPS). TNF- α drives the increase in liver gluconeogenesis, loss of adipose tissue, and proteolysis, while causing a decrease in protein, lipid, and glycogen synthesis. It has been associated with the formation of IL-1 and increases the UCP2 and UCP3 expression in skeletal muscle in the cachectic state.⁸⁷³ In addition, there is an inverse correlation between IL-6 levels and insulin sensitivity.⁸⁷⁴ Adipose tissue insulin resistance increases fat oxidation, and decreases lipoprotein lipase activity, resulting in continued lipolysis.⁸⁷⁵ The insulin resistance of cancer is not related to defective insulin clearance, and is therefore different than other forms of primary insulin resistance.⁸⁷⁶

Cancers are uniformly anaerobic and depend upon glucose for survival; thus the glucose manufactured from gluconeogenesis secondary to hepatic insulin resistance is essential for tumor growth. Cancers release large amounts of lactate, which is converted in the liver back to glucose. Such gluconeogenesis consumes ATP, which also increases energy expenditure.⁸⁷⁷ Additional raw materials for gluconeogenesis are alanine derived from skeletal muscle proteolysis and glycerol from lipolysis.

Given the complex multifactorial nature of the cachexia-associated hormonal/metabolic profile and the individual differences between cancer patients, targeting any single circulating factor would always be insufficient to treat cachexia for all patients with cancer. There currently is no specific pharmacologic agent that can effectively address cancer cachexia, and treatment relies on dietary supplementation and psychological support.

The Diencephalic Syndrome

The diencephalic syndrome includes clinical characteristics of severe emaciation, normal linear growth, and normal or precocious intellectual development in association with CNS tumors. Originally described by Russell in 1951,⁸⁷⁸ this rare disorder presents in infants younger than age 1 year, and is an indication of a hypothalamic lesion, usually an anterior hypothalamic glioma, or other neoplasm affecting hypothalamic function. Although the clinical spectrum is variable,

emaciation with paucity of subcutaneous fat, but with normal linear growth and head circumference is inviolate. Other frequent features include hyperalertness, hyperkinesis, nystagmus, and vomiting.^{879,880}

Numerous patients have been anecdotally reported and characterized; however, the cause of the emaciation remains unclear. Subjects with diencephalic syndrome have extremely elevated baseline GH levels, but with normal IGF-1 levels, suggesting a variant of GH resistance.⁸⁷⁹ It has been suggested that the high GH leads to lipolysis and accounts for the emaciation, but this finding is not consistent in all patients. Only one evaluation of energy balance has been performed, which demonstrated 30% to 50% greater REE in comparison to normal babies, and 13% greater energy expenditure compared with intake.⁸⁸¹

Treatment recommended is surgical excision of the lesion whenever feasible. Radiation is usually reserved for the very young patient. Frequently, these patients postoperatively manifest hypopituitarism, and ultimately develop hypothalamic obesity.⁸⁸⁰

Anorexia Nervosa

Definition

Anorexia nervosa (AN) is an eating disorder that typically begins during adolescence and consists of persistent dieting and intense physical activity, usually accompanied by compulsive behavioral traits and sometimes with binge eating and purging behaviors. Individuals with AN also manifest a disturbed body image and a persistent fear of weight gain, both of which promote further weight loss. The result of this behavior is a pathologic weight loss, with pathophysiologic consequences. The risk of developing AN among females in Western societies is estimated to be between 1.7% and 3.6%.⁸⁸² There are two subtypes of anorexia: the restrictive type, characterized by very low caloric intake and/or excessive exercise, and the binge-eating/purging type, characterized by varying levels of food purging, usually by way of self-induced vomiting and/or laxative abuse. Alongside the emotional and behavioral elements, the definition in the DSM-5 includes having a significantly low weight (defined as BMI <5th percentile for age and sex in children or BMI \leq 17 in adults).

Medical complications driven by the chronically reduced caloric intake, purging behavior, and excessive exercise may affect several organ systems. Typically, patients develop a marked loss of subcutaneous fat tissue, impaired menstrual function, bradycardia and orthostatic hypotension, hypothermia, and increased hair loss. Importantly, AN that develops during adolescence may create adverse clinical effects that persist into adulthood,⁸⁸³ including osteopenia and osteoporosis,⁸⁸⁴ higher rates of miscarriage, and reduced offspring birth weight.⁸⁸⁵ Anorexia may also alter cognitive abilities as during extreme weight loss in cases where a significant reduction of both gray and white cerebral matter occurs; conversely, during weight restoration cerebral white matter returns to premonitory levels, but gray matter does not.⁸⁸⁶ Anorexia carries an increased mortality risk, specifically for suicide, yet also from medical causes, such as starvation per se, as well as purging-induced, electrolyte-mediated arrhythmias. Full recovery of body habitus and of growth and development occurs in 50% to 70% of treated adolescents; yet achieving a full physiologic and psychologic recovery may take a comprehensive treatment intervention that may last as long as 5 to 7 years.⁸⁸⁷ Greater weight loss, lower sustained weight, and the coexistence of other psychiatric disorders adversely affect the probability of recovery. The outcomes for adults with AN are poorer than those who are diagnosed and treated in adolescence.

Endocrine Manifestations of Anorexia Nervosa

Obesity and malnutrition usually result in opposing effects on normal physiology and are both associated with changes in the hormonal profile. AN is associated with multiple, profound endocrine alterations which may be adaptive, reactive, or perhaps etiologic. The majority of these changes represent an adaptive response yet should be considered as part of the differential diagnosis of specific hormonal excess or deficiency disorders. Dysfunction of the hypothalamic-pituitary axis includes hypogonadotropic hypogonadism with relative estrogen and androgen deficiency, GH resistance, elevated cortisol, "sick euthyroid" syndrome, and reduced oxytocin. Levels of leptin are suppressed in patients with AN reflecting the reduced energy stores and levels of ghrelin, an orexigenic gut peptide, are elevated.⁸⁸⁸ Most, but not all, of these endocrine disturbances are adaptive to the low energy state of chronic starvation and reverse with treatment of the eating disorder. Despite this, these alterations contribute to impaired skeletal integrity, as well as neuropsychiatric comorbidities, in individuals with AN. Importantly, only 5% to 15% of patients with AN are male, and only limited data exist regarding the endocrine impact of the disease in adolescent boys. Fig. 24.12 demonstrates the typical hormonal profile of patients with AN, which reflect the organism's attempts at energy preservation and the cessation of energetically costly and nonvital processes.

Hypothalamic-Pituitary-Thyroid Axis. The starvation status of AN may resemble the sick euthyroid syndrome. In patients with AN, serum total and free T_4 , total and free T_3 , TSH and thyroxine binding globulin are significantly lower than normal, whereas reverse triiodothyronine (rT_3) levels are significantly greater than healthy controls.⁸⁸⁹ Most patients with AN have a hyporesponsive or delayed responsiveness of TSH to TRH stimulation. Of note, weight regain reverses the effects of AN on the hypothalamic-pituitary-thyroid axis to normal; thus the reduction in thyroxinemia may actually be a normal adaptive physiologic response to starvation. The differential diagnosis of hypothyroidism should be considered in patients with AN as both disorders are characterized by low T_4 and T_3 levels.

In primary hypothyroidism, TSH levels will be greater than those seen in patients with AN, although in mild secondary hypothyroidism this distinction may be difficult. Obtaining a serum rT_3 level may be helpful in distinguishing a true thyroid disorder from the euthyroid sick syndrome associated with systemic illness.

Growth Hormone-IGF-1 Axis. Patients with AN typically have GH hypersecretion accompanied by low IGF-1 levels. Whether this profile is caused by a primary hypothalamic dysfunction, peripheral target organ resistance to GH, or an impaired negative IGF-1 central feedback mechanism is unclear. An increased GH response to GHRH has been demonstrated in AN, possibly reflecting an impairment of beta-adrenergic suppression of GH secretion.⁸⁹⁰ The clinical presentation of weight loss, cessation of menses and cold intolerance alongside low levels of pituitary-derived hormones may resemble panhypopituitarism, yet patients with AN present with GH hypersecretion.

Hypothalamic-Pituitary-Adrenal Axis. Patients with AN typically present with elevated cortisol levels in the presence of normal ACTH levels.⁸⁹¹ The elevated cortisol levels are apparently because of increased cortisol secretion alongside a reduction in cortisol clearance. Elevated CRH levels found in CSF of patients with AN suggest that AN represents an overall state of activation of the hypothalamic stress response, manifested peripherally by hypercortisolemia. An abnormal response in the dexamethasone suppression test, mainly of reduced suppression, suggests that an element of decreased feedback sensitivity occurs in this disorder.

Bone Metabolism. Adolescence represents a critical period for the accumulation of bone mineral, thus building bone strength and density for later years. The achievement of peak bone mass is dependent on several hormonal effects characteristic of puberty, such as increased estradiol, and IGF-1 levels, as well as being dependent on adequate nutrition; all of which are compromised in patients with AN. Adolescents and adults with AN have a low bone mineral density. In adults this is caused by increased bone resorption and reduced bone formation; adolescents are characterized by an overall reduced bone

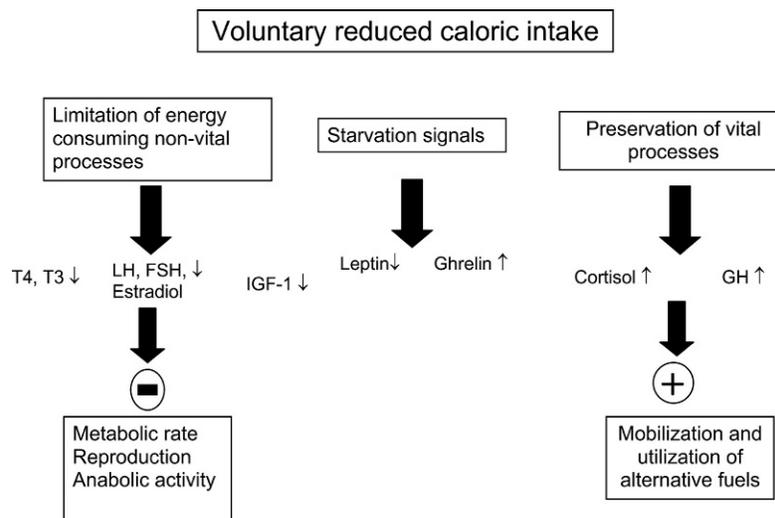

Fig. 24.12 Hormonal changes in anorexia nervosa. The hormonal profile of the patient with anorexia nervosa represents an adaptive response aimed at conserving energy. Processes that require significant energy, such as reproduction and growth, are limited by a complete suppression of the gonadotropic axis and by reduced insulin-like growth factor (IGF)-1 levels, respectively. A seemingly chronic stress response characterized by increased growth hormone (GH) and cortisol is aimed at efficient utilization of the limited energetic sources present. Reduced leptin serves as a signal for down regulating the hypothalamic-pituitary-gonadal axis. Reduced leptin also serves as a starvation signal, although this signal appears to be circumvented in this disorder.

turnover.⁸⁹² The reduced bone density is caused by the typical hormonal profile of AN, that is, reduced estrogens and androgens, low IGF-1, and relative hypercortisolemia. Moreover, the reduced lean body mass and lower mechanical forces acting on long bones may also contribute to the overall reduced BMD. Recent publications also suggest that elevated levels of gut-derived hormones PYY₍₃₋₃₆₎ and ghrelin may also contribute to impaired bone metabolism in AN.⁸⁹³ Importantly, resolution of AN with weight gain often does not bring full recovery of the bone mineral density status. Osteopenia resulting from undernutrition and the typical hormonal dynamics of AN is one of several long-term complications of AN during adolescence, and thus is a major treatment target.

Hypothalamic-Pituitary-Gonadal Axis. Amenorrhea is one of the hallmarks of AN, yet it is not always explained by the severe weight loss; thus hypothalamic amenorrhea in AN often precedes weight loss and may persist after refeeding and achievement of normal weight. Gonadotropin levels are reduced in patients with AN, and GnRH stimulation testing in patients with AN demonstrates a blunted LH response with a preserved FSH response and very low levels of estradiol. The normal pubertal pulsatile pattern of LH levels may revert to prepubertal patterns in adolescents who have previously achieved pubertal status. The amenorrhea of AN is also marked by strikingly reduced leptin levels. Leptin serves as a metabolic signal of energy status and nutritional reserve and thus may have a permissive role for the initiation of the complex hormonal dynamics necessary for normal reproductive function.⁸⁹⁴ Teleologically, conservation of energy for immediate and necessary metabolic demands while suppressing energetically expensive processes, such as reproduction, serves as a protective measure in severely malnourished individuals, as seen in AN. The rise in leptin upon weight gain is associated with increases in gonadotropin secretion, suggesting that leptin serves a permissive role for the activation of the hypothalamic-pituitary-gonadal axis.

Fat-Derived Hormones. Adipocytes secrete a wide array of adipocytokines, the normal profile of which is altered in AN. Patients with AN typically have very low plasma leptin concentrations alongside a marked disturbance of the leptin diurnal secretion profile.⁸⁹⁵ The concentration of leptin-binding protein (the soluble isoform of leptin receptor) has been reported to be increased in patients with AN, contributing to a further reduction in concentration of free leptin.⁸⁹⁶ Leptin has a major role in the neuroendocrine adaptations to the chronic starvation and undernutrition typical of AN, such as reduction in gonadotropins, reduction in thyroid hormone to conserve energy, a modified stress response manifested by hypercortisolemia, and elevated GH aimed at mobilizing and utilizing alternative energy sources.⁸⁹⁷ Weight gain in patients with AN may induce relative hyperleptinemia in comparison to controls matched for BMI; circulating leptin concentrations in AN patients thus traverse from subnormal to supranormal levels within a few weeks.

Adiponectin is the only adipocytokine whose plasma concentrations are inversely related to fat mass. Conflicting results regarding adiponectin concentration in AN, ranging from hyperadiponectinemia⁸⁹⁸ to hypo-adiponectinemia,⁸⁹⁹ have been reported. Interestingly, weight gain in AN is not necessarily associated with reciprocal changes in adiponectin concentration.⁹⁰⁰

Treatment

Indications for hospitalization and in-patient treatment of AN include dehydration, electrolyte disturbances (mainly hypokalemia), arrhythmias, CV instability (significant bradycardia, hypotension, and orthostatic changes), hypothermia, acute

food refusal, acute complications of malnutrition (seizures, pancreatitis, cardiac failure), and psychiatric emergencies.

Along with psychological interventions that may consist of psychotherapy and/or pharmacotherapy (based on the spectrum of psychiatric pathology), an increase in caloric intake must be part of the treatment protocol. Starting with 1200 to 1500 kcal per day and increasing by 500 kcal is aimed at a gain of 0.5 to 1 kg per week.⁹⁰¹ There is no single superior feeding regimen, as long as adequate caloric intake is consumed. Extreme cases may be handled through hospitalization in dedicated in-patient units; caloric intake in this setting may initially be provided by nasogastric tube and in extreme cases via parenteral feeding.

One major treatment decision facing the caregiver of patients with AN is whether to use estrogen replacement therapy to treat amenorrhea and protect the skeleton from osteopenia. There is a lack of a proven efficacious beneficial effect of estrogen replacement therapy in regards to improved bone mass in AN in comparison to placebo,⁹⁰² although this treatment modality is still commonly used.⁹⁰³ This treatment approach with estrogens may have several adverse effects on the treatment of adolescents as it masks the beneficial effect of weight gain on the resumption of menses and may provide an erroneous sense of security in patients that are still at critically low weight status. Increased calcium intake alongside 400 IU of vitamin D to accelerate absorption should be encouraged in all patients with AN as another potential protective measure of bone status.

CONCLUSIONS

Energy balance is complex and regulated by intricate mechanisms that evolved to finely tune and maintain body weight within accepted normal limits. Some of these mechanisms evolved to sustain and preserve life even in the face of famine. The impact of even relatively small imbalances in intake relative to expenditure can have appreciable cumulative effects on body weight over time, leading to obesity or underweight. Although important to consider in the differential diagnosis of childhood obesity, a classic endocrinopathy (glucocorticoid excess or deficiencies in thyroid or GH), genetic obesity syndrome, or hypothalamic lesion is seldom the etiology. Nonetheless, in an era of abundant nutrient surfeit, other subtle endocrine abnormalities, such as leptin concentration or action and insulin resistance, are hallmark features of obesity, and common variants of genes involved in the leptin signaling pathway may contribute to obesity risk in a sizable portion of the population. Furthermore, obesity, by virtue of its presence, indicates some degree of dysfunction in the neuroendocrine homeostatic mechanisms of the CNS that regulate energy balance. Therefore obesity and its consequences should be recognized as part of a spectrum of chronic endocrine dysfunction. The notion that obesity is caused by excessive caloric intake with concomitant inadequate caloric expenditure via work and exercise is simplistic and fails to address the underlying problem of a mismatch in regulatory mechanisms of energy intake and dissipation. It is this mismatch, unmasked in our era of abundant energy intake, that perpetuates the state of energy imbalance, and stigmatizes obesity as being merely caused by lack of discipline or will power. In fact, obesity is a pathologic condition that, in most patients, requires lifelong management. Similarly, in cachexia, investigation must extend beyond the lack of appetite to understand the reasons for the wasting and illness. Understanding the energy balance pathway, and where these various disorders impair its regulation, together with public health education of the consequences of obesity, are the keys to further research, and successful prevention and treatment.

ABBREVIATIONS

Abbreviation	Definition
α -MSH	alpha-melanocyte-stimulating hormone
11 β HSD1	11-beta-hydroxysteroid dehydrogenase type 1
5-HT	5-hydroxytryptamine (serotonin)
A ^y -a	Agouti yellow mouse
ACTH	adrenocorticotrophic hormone
AgRP	Agouti-related peptide
AHO	Albright hereditary osteodystrophy
ALT	alanine aminotransferase
AMP	adenosine monophosphate
AN	anorexia nervosa
ANP	atrial natriuretic peptides
AP	area postrema
apoB	apolipoprotein B
APP	acute phase proteins
ARC	arcuate nucleus
ARC ^{POMC}	proopiomelanocortin-expressing neurons of the arcuate nucleus
AS	Alström syndrome
ATP	adenosine triphosphate
BBB	blood-brain barrier
BBS	Bardet-Biedl syndrome
BCAA	branched-chain amino acids
BDNF	brain-derived neurotrophic factor
BMI	body mass index
BMR	basal metabolic rate
cAMP	cyclic adenosine monophosphate
CART	cocaine-amphetamine-related transcript
CCK	cholecystokinin
cGMP	cyclic guanosine monophosphate
ChREBP	carbohydrate-response element binding protein
CI	confidence interval
CNS	central nervous system
CNTF	ciliary neurotrophic factor
CoA	coenzyme A
CPE	carboxypeptidase E
CPT-1	carnitine palmitoyl transferase 1
CREB	cyclic adenosine monophosphate (AMP) response element binding protein
CRH	corticotropin-releasing hormone
CRISPR	clustered regulary interspaced short palindromic repeat
CRP	C-reactive protein
CSF	cerebrospinal fluid
CT	computed tomography
CV	cardiovascular
DAG	diacylglycerol
DIT	diet-induced thermogenesis
DMH	dorsomedial hypothalamic nucleus
DMV	dorsal motor nucleus of the vagus nerve
DNA	deoxyribonucleic acid
DNL	de novo lipogenesis
DSM-5	<i>Diagnostic and Statistical Manual of Mental Disorders, fifth edition</i>
DVC	dorsal vagal complex
EC	endocannabinoid
eNOS	endothelial nitric oxide synthase
ER	endoplasmic reticulum
F1P	fructose-1-phosphate
FDA	US Food and Drug administration
FFA	free fatty acid
FGF19	fibroblast growth factor 19
FMD	flow-mediated endothelium-dependent dilatation
FOXO1	forkhead protein-1
FSH	follicle-stimulating hormone
FSIVGTT	frequently sampled intravenous glucose tolerance test
FTO	fat mass and obesity associated gene
FTT	failure to thrive
FXR	farnesoid X-activated receptor
GABA	gamma-amino butyric acid
GDM	gestational diabetes mellitus
GH	growth hormone
GHSR	growth hormone secretagogue receptor
GI	gastrointestinal
GIx	glycemic index
GL	glycemic load
GLP-1	glucagon-like peptide 1
GLUT4	glucose transporter 4
GNG	gluconeogenesis
GnRH	gonadotropin hormone
GOAT	ghrelin O-acetyltransferase
GPCR19	G-protein-coupled receptor 19
GTP	guanosine triphosphate
GWAS	genome-wide association studies
HDL	high-density lipoprotein
HFCS	high-fructose corn syrup
HGP	Hepatic glucose production
HOMA-IR	homeostatic model for assessment of insulin resistance
HPA	hypothalamus, pituitary, and adrenal
HSL	hormone-sensitive lipase
ICV	intracerebroventricular
IGF	insulin-like growth factor
IGFBP	insulin-like growth factor-binding protein
IGT	impaired glucose tolerance
IHCL	Intrahepatic lipid
IHCL	intrahepatocellular lipid
IL-6	interleukin-6
IMCL	intramyocellular lipid
IMT	intimal medial thickness
IP ₃	inositol triphosphate
IRS-1	insulin receptor substrate 1
IRS-2	insulin receptor substrate 2
JAK1	Janus kinase 1
JAK2	Janus kinase 2
JNK-1	c-jun N-terminal kinase 1
LAGB	laparoscopic adjustable gastric banding
LEPR	leptin receptor
LGA	large-for-gestational age
LH	luteinizing hormone
LHA	lateral hypothalamus
LPL	lipoprotein lipase
LSG	laparoscopic sleeve gastrectomy
MAPK	mitogen-activated protein kinase
MARCKS	myristoylated alanine-rich protein kinase C substrate
MBH	mediobasal hypothalamus
MC3R	melanocortin-3 receptor
MC4R	melanocortin-4 receptor
MCH	melanin-concentrating hormone
MCR	melanocortin receptor
ME	median eminence
MKK7	mitogen-activated protein kinase 7
MRAP2	melanocortin receptor accessory protein 2
MRI	magnetic resonance imaging
mRNA	messenger ribonucleic acid
mTOR	mammalian target of rapamycin
NA	nucleus accumbens
NAFLD	nonalcoholic fatty liver disease
NASH	nonalcoholic steatohepatitis
NE	norepinephrine
NEAT	nonexercise activity thermogenesis

NHANES	National Health and Nutrition Examination Survey
NMDA	N-methyl-D-aspartate
NO	nitric oxide
NPY	neuropeptide Y
NTS	nucleus of the solitary tract
OGTT	oral glucose tolerance test
OSA	obstructive sleep apnea
PAI-1	plasminogen activator inhibitor-1
PC1	prohormone convertase-1
PCOS	polycystic ovarian syndrome
PedNSS	Pediatric Nutrition Surveillance System
PEPCK	phosphoenolpyruvate carboxykinase
PGC	peroxisome proliferator-activated receptor gamma coactivator
PGC-1 α	peroxisome proliferator-activated receptor gamma coactivator 1 alpha
PHP1a	pseudohypoparathyroidism type 1a
PI3K	phosphatidyl inositol-3-kinase
PKA	protein kinase A
PKC	protein kinase C
PKC ϵ	protein kinase C epsilon
POMC	proopiomelanocortin
PP	pancreatic polypeptide
PPAR	peroxisome proliferator-activated receptor
PVN	paraventricular hypothalamic nucleus
PWS	Prader-Willi syndrome
PYY	peptide YY
RAI1	retinoic acid-induced 1
RCT	randomized controlled trial
REE	resting energy expenditure
ROHHAD	Rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysfunction
ROS	reactive oxygen species
rT ₃	reverse triiodothyronine
RYGB	Roux-en-Y gastric bypass
SGA	small-for-gestational age
SIM1	single-minded 1
SMS	Smith-Magenis syndrome
SNP	single nucleotide polymorphism
SNS	sympathetic nervous system
SOCS-3	suppressor of cytokine signaling 3
SREBP-1c	sterol regulatory element-binding protein 1c
SSPG	steady-state plasma glucose
SSTR ₅	somatostatin-5 receptor
STAT-3	signal transducers and activators of transcription
T2DM	type 2 diabetes mellitus
T3	triiodothyronine
TEE	total energy expenditure
TG	triglyceride
TNF- α	tumor necrosis factor alpha
trans-fats	trans-unsaturated fatty acids
TRH	thyrotropin-releasing hormone
TrkB	tropomyosin-related kinase B
TSH	thyroid-stimulating hormone
UCP	uncoupling protein
UPR	unfolded protein response
UPS	ubiquitin-proteasome system
VLDL	very low-density lipoproteins
VMH	ventromedial hypothalamic nucleus
VTA	ventral tegmental area
WHO	World Health Organization
WT	wild-type
Y2R	type-2 neuropeptide Y receptor
Y4R	type-4 neuropeptide Y receptor

INTRODUCTION

Atherosclerotic cardiovascular disease (ASCVD) is a major cause of morbidity and mortality among adults in industrialized countries. Dyslipidemia (specifically elevated low-density lipoprotein [LDL] cholesterol, low high-density lipoprotein [HDL] cholesterol, and high non-HDL cholesterol and triglycerides [TGs]) has been identified as an independent risk factor in the development of ASCVD. There is strong evidence that lipoprotein levels track from childhood into adulthood and that abnormal levels of LDL cholesterol and perhaps other lipoproteins are associated with atherosclerosis, and therefore with related adverse outcomes.

This chapter reviews the evidence for the role of lipid abnormalities in the early natural history of atherosclerosis. In addition, a general overview of lipoprotein metabolism is

provided—followed by a review of genetic disorders in the metabolism of lipoproteins. Secondary causes of high cholesterol are explained, including the increasing prevalence of obesity and metabolic syndrome, as a cause of lipid abnormalities in the pediatric population. Standards and approaches to screening for hyperlipidemia in children are reviewed, as well as current approaches to the dietary and pharmacologic management of pediatric lipid disorders.

METABOLISM

Lipid disorders in children and adolescents can result from defects in the production, transport, or degradation of lipoproteins. To understand the diverse causes of lipoprotein abnormalities, a brief review of lipoprotein structure, function, and metabolism is provided. Table 25.1 summarizes the lipoprotein subclasses, the source of each one, and the constituent lipids and apolipoproteins associated with each particle.

TGs, cholesterol esters, phospholipids, and plant sterols within food post-ingestion are digested to fatty acids, 2-monoglycerides, lysophospholipids, unesterified cholesterol, and plant sterols. Absorption of these digestive end products occurs through two mechanisms: passive diffusion and carrier-mediated transport. In passive diffusion, nonpolar lipids are solubilized with the aid of bile acids and lysophospholipids into mixed micelles that can diffuse through the apical surface of the enteric membrane. Carrier-mediated transport involves several different transport proteins for fatty acids and sterols. CD 36/scavenger receptor B2 (SR-B2), a fatty acid translocase, promotes long-chain fatty acid and cholesterol absorption in the proximal small intestine.¹ At least two additional transporters, Niemann-Pick C1-like 1 protein (NPC1L1) and SR-B1, play a role in sterol uptake.^{2,3} As such, NPC1L1 and SR-B1 are targets for the cholesterol-lowering medication ezetimibe, a potent inhibitor of cholesterol and plant sterol absorption.

Most of the plant sterols ingested and about half of the absorbed cholesterol are excreted from the intestinal cell back into the lumen by two adenosine triphosphate (ATP)-binding cassette (ABC) half-transporters, G5 and G8, thus limiting the amount of sterols that are absorbed.^{4,5} A rare mutation of either ABCG5 or ABCG8, known as *sitosterolemia*, results in abnormally high plant sterol levels in plasma and tissues and deposition of sterols in the skin and arteries. Individuals with this disorder are at an increased risk of premature atherosclerosis.⁶ Sterols that remain in the enterocyte are converted to sterol esters by acyl-CoA cholesterol acyl transferase (ACAT), which attaches a fatty acid to the sterol for storage within the cytoplasm of the cell. Within the enterocyte, lipids are aggregated into lipoproteins through the action of a chaperone protein, microsomal triglyceride transfer protein (MTTP), and perhaps several additional proteins.⁷ MTTP conjugates TGs, phospholipids, cholesterol, and cholesterol ester with apolipoprotein B-48 (apoB-48) on the luminal side of the endoplasmic reticulum (ER) membrane to create a mature chylomicron.⁷ A similar process is used to aggregate TG, phospholipids, cholesterol, and cholesterol ester with apoB-100 in the liver to form very low-density lipoprotein (VLDL) particles. In the genetic disorder abetalipoproteinemia, mutations in the gene encoding MTTP result in an inability to produce chylomicrons and VLDL,

suggesting the essential nature of MTP in chylomicron and VLDL biogenesis.⁷ The recently approved drug lomitapide inhibits MTP, reducing lipoprotein assembly and secretion, and lowers plasma cholesterol by around 50% in patients with homozygous familial hypercholesterolemia.⁸

Chylomicrons once formed are too large to penetrate the capillary membrane. Consequently, they are secreted into the lymphatic system and enter the venous plasma compartment through the thoracic lymph duct. As the nascent particles are released into the plasma, several apolipoproteins (including apoC-II, C-III, and apoE) are preferentially transferred to the chylomicrons from circulating HDLs.⁹ Fig. 25.1 depicts chylomicron metabolism.

Chylomicrons transport dietary TG and cholesterol to sites of storage or metabolism.¹⁰ The size of the particles varies depending on the amount of fat ingested. They are rapidly cleared from the circulation through the action of lipoprotein lipase (LPL). LPL is a TG hydrolase found on the capillary endothelium of various tissues, with its highest concentration in muscle and adipose tissues.¹¹ Glycosylphosphatidylinositol-anchored high-density lipoprotein binding protein 1 (GPIHBP1) anchors LPL to the capillary endothelium.¹² LPL is activated by apoC-II and inhibited by apoC-III on the chylomicron. Loss-of-function mutations in LPL, apoC-II, and GPIHBP1 can result in marked

hypertriglyceridemia. Loss-of-function mutations in apoC-III are associated with increased LPL activity and decreased TG levels.^{12,13} As the TG contained within the chylomicron is hydrolyzed, free fatty acids are liberated for oxidation via a variety of cell types and the particle decreases in size. When approximately 80% of the initial TG has been removed, apoC-II dissociates from its surface.¹¹ The transfer of apoC-II from chylomicrons to HDL decreases the ability of LPL to further breakdown TGs. The TG-depleted chylomicrons, now considered chylomicron remnants, are taken up by the liver through the LDL receptor (LDLR), a receptor that recognizes apoE on the chylomicron surface and apoB100 on the surface of liver-derived lipoproteins.⁹ A smaller fraction of remnants may also be internalized via an LDLR-related protein-1 (LRP1)-mediated endocytosis.^{14,15}

VLDLs originate from the liver, and like chylomicrons they are TG-rich particles (Fig. 25.2). In contrast to the intestinally derived chylomicrons, the fatty acids contained within the VLDL TG come from de novo synthesis from dietary carbohydrate, lipoprotein remnants, or circulating fatty acids, internalized by the liver from plasma.⁹ Similar to chylomicrons, the size of the VLDL particles can vary depending on the quantity of the TG carried in the particle. When TG production in the liver is increased, the secreted VLDL particles are large. Within the hepatocyte, TG and cholesterol ester are assembled by an MTP and surrounded with a phospholipid membrane associated with apoB-100.⁸ The mature VLDL particles are released into the lymph and ultimately into the vascular space, where other apolipoproteins (including apoC-II, apoC-III, and apoE) adsorb to the VLDL surface. The metabolism of the VLDL particle follows a route similar to that of the chylomicron: apoC-II on its surface activates LPL, LPL hydrolyzes the VLDL TG, free fatty acids are liberated, the particle decreases in size (after an 80% loss of TG), and ultimately apoC-II dissociates—resulting in the formation of VLDL remnants (also known as *intermediate-density lipoproteins* [IDLs]). Approximately half of the IDL is then removed from plasma through the interaction of apoE with the LDLR and LRP1 on the surface of liver cells.⁹ The rest of the IDL is converted to LDL through further hydrolysis of TGs and phospholipids by hepatic TG lipase (HL).¹⁶ ApoE is transferred from IDL to HDL during the transition of the remnant to LDL.¹²

LDL, the major carrier of cholesterol in plasma, is taken up into peripheral tissues and liver cells by the LDLR assisted by an adaptor protein (AP). The AP binds to the LDLR and clathrin, suggesting a role for AP in the recruitment and retention of LDLR in clathrin-coated pits.¹⁷ Upon receptor binding, the LDL particle

bound to LDLR/AP is rapidly internalized into clathrin-coated pits by endocytosis. Within the cell, the newly formed endosome becomes acidified through the action of an ATP-dependent proton pump.¹⁸ Acidification causes degradation of the clathrin coat, dissociation of the LDLR from LDL, and subdivision of the endosomal membranes. The endosome containing the LDLR recirculates back to the cell membrane for additional LDL uptake. Alternatively, proprotein convertase subtilisin/kexin type 9 (PCSK9) binds LDLR, and short-circuits recycling of LDLR from the endosome, leading to its degradation.¹⁹ The remaining LDL-containing endosome fuses with a lysosome, where hydrolytic enzymes digest the lipoprotein into its component parts: unesterified cholesterol, fatty acids, and free amino acids.¹⁸

The amount of cholesterol released from endosomal uptake regulates hepatic synthesis of LDLR and cholesterol. When cellular concentration of cholesterol is low, sterol receptor binding proteins (SREBPs) move from the ER to the Golgi, where proteases cleave SREBPs into active transcription factors. SREBPs translocate to the nucleus, where they stimulate the transcription of LDLR and hydroxymethylglutaryl (HMG) CoA reductase, the rate-limiting enzyme of cholesterol biosynthesis.²⁰ If cholesterol levels in the cell are high, SREBPs remains in the ER in an inactive form and do not stimulate LDLR synthesis. In this way, intracellular hepatic cholesterol concentration regulates the amount of cholesterol internalized and synthesized by the cell.

When excess LDL and other small apoB-containing lipoproteins (chylomicron remnants and IDL) are present in the plasma, the capacity of the LDLR to remove them is exceeded and these particles become more susceptible to oxidation. Oxidized apoB-containing lipoproteins can be taken up by scavenger receptors

on macrophages in the subendothelium of arteries and may contribute to the formation of atherosclerotic lesions.²¹

HDL transfers cholesterol and other lipids from peripheral tissues (including arterial atheroma) back to the liver. The particles are synthesized predominantly in the liver (and to a lesser extent in the intestine) as lipid-poor precursor particles (pre-beta HDL) containing apoA-I (see Fig. 25.2).⁹ Nascent HDL interacts with the plasma membrane of cells, collecting lipid through an ABCA1 mechanism.^{5,7} The cholesterol and phospholipids transferred through this process adsorb to the HDL, forming a disk-shaped particle referred to as HDL₃. Dysfunction of ABCA1 will significantly decrease HDL levels and thereby dramatically impair cholesterol and lipid transport functions.⁹ A rare autosomal recessive disorder called *Tangier disease* is caused by lack of functional ABCA1 protein and is characterized by an absence of HDL along with hypertriglyceridemia and low LDL levels. Within the plasma, HDL₃ interacts with the enzyme lecithin cholesterol acyl transferase (LCAT)—which catalyzes the esterification of particle-associated cholesterol. ApoA-I on the HDL surface activates LCAT. Once formed, the cholesterol ester is more hydrophobic and moves to the interior of the particle—creating a sphere-shaped HDL particle known as HDL₂.²²

As HDL₂ increases in size, the particle becomes substrate for cholesterol ester transfer protein (CETP). This enzyme promotes the exchange of esterified cholesterol within HDL₂ for TG contained within apoB-100-associated lipoproteins.²³ This lipid exchange is the primary mechanism whereby HDL participates in reverse cholesterol transport from tissues back to the liver. The rest of the cholesterol ester is selectively taken up from HDL by hepatocytes via a SR-B1, without concomitant uptake

TABLE 25.2 Pediatric Lipoprotein Disorders

Lipoprotein Disorder	Lipoprotein Analysis	Blood Lipids	Genetic Defect
Familial hypercholesterolemia Autosomal recessive	↑↑LDL	↑↑Cholesterol	LDL receptor (<i>LDLR</i>)
hypercholesterolemia Autosomal dominant	↑↑LDL	↑↑ Cholesterol	<i>LDLRAP</i>
hypercholesterolemia	↑↑LDL (with increase in function mutations)	↑↑ Cholesterol	<i>PCSK9</i>
Familial ligand-defective apoB-100	↑↑ LDL	↑↑Cholesterol	ApoB-100

of the entire HDL particle. This latter process may require the action of HL.²⁴ The lipid-poor pre-beta HDL resulting from this process is released for recycling.¹⁷

Primary Dyslipidemias

Lipoprotein synthesis, transport, and metabolism occur in many steps and involve many specialized proteins. A number of genetic defects have been identified in these processes and are referred to as *primary dyslipidemias*. Most of these genetic defects present in childhood. Table 25.2 summarizes pediatric lipoprotein disorders with reference to the characteristic lipoprotein profile of each one. The genetic and metabolic etiologies of these disorders are detailed in the following material.

Disorders of Cholesterol Metabolism

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is the most common single gene disorder of lipoprotein metabolism. FH is inherited as an autosomal-dominant trait with relatively low prevalence in Western countries. The prevalence has been reported to be 10 times higher in certain populations with a presumed founder effect, such as the Lebanese, the French Canadians, and the South Afrikaners.²⁵ The heterozygous form is found in one in 250 persons, and the homozygous form is found in one in 1 million persons.²⁶ The disorder is caused by a mutation in the *LDLR* gene.²⁷ More than 1200 mutations in this gene have been identified, including those that affect receptor synthesis, intracellular transport, ligand binding, internalization, and recycling.²⁸ In the heterozygous form, inheritance of one defective *LDLR* gene results in plasma LDL cholesterol levels 2 to 3 times higher than normal.²⁷ TG and HDL cholesterol levels are usually unaffected by FH-causing gene mutations, but may be altered by obesity and insulin resistance.²⁸

Individuals with heterozygous FH are at an increased risk of developing early-onset ASCVD, usually between the ages of 30 and 60 years.²⁵ In the homozygous form, individuals inherit a mutant allele for FH from both parents, resulting in plasma LDL cholesterol concentrations that are 4 to 6 times higher than normal.²⁹ A more severe phenotype is found in individuals with receptor-negative mutations (those with 5% residual LDL receptor activity) compared with those with receptor-defective mutations (5%–30% of normal LDL receptor activity).³⁰ Because of the excessively high plasma cholesterol levels in individuals with homozygous FH, cholesterol deposits

are common in the tendons (xanthomas) and eyelids (xanthelasmas)—generally by the age of 5 years.³¹ In the heterozygous form, xanthomas occur less frequently and generally not until one reaches older adulthood. Children with homozygous FH have early-onset atherosclerosis and often have myocardial infarction in the first decade of life, and death from ASCVD in the second decade.³¹

Autosomal-Dominant and Autosomal-Recessive Hypercholesterolemia

Autosomal-dominant hypercholesterolemia (ADH) is another inherited disorder resulting in a phenotype that is expressed as marked elevations or low levels of LDL cholesterol. ADH is caused by mutations in a serine protease, *PCSK9*.³² This protein binds and favors degradation of the *LDLR* and thereby modulates the plasma levels of LDL cholesterol. Some of the naturally occurring *PCSK9* mutations result in an increase in the function of the protein and cause hypercholesterolemia by increasing the degradation of *LDLR*, whereas other mutations result in a loss of function, and hence increase in *LDLR* abundance, and are associated with low LDL cholesterol. The latter mutations appear to confer protection from developing ASCVD.

Autosomal recessive hypercholesterolemia (ARH) is caused by mutations in the *ARH* gene, which encodes the adaptor protein required for normal *LDLR*-mediated endocytosis in hepatocytes.³³ Several different mutations in this protein have been identified, all leading to a lack of or suboptimal internalization of the *LDLR*.³⁴ Cholesterol levels in individuals with ARH are 5 to 6 times higher than normal. Children with this disorder are clinically similar to those with homozygous FH. However, their parents usually have normal lipoprotein profiles.³³

Familial Ligand-Defective ApoB-100

Familial ligand-defective apoB-100 (FDB) is a monogenic disorder that clinically resembles heterozygous FH. The disease is characterized by moderate to markedly high plasma LDL cholesterol levels, normal TGs, and tendon xanthomas. The disorder is caused by poor binding of the LDL particle to the *LDLR*, because of a mutation in apoB-100.³⁵ Specifically two mutations, R3500Q and R3500W remain the most frequently identified mutations that cause FDB.³⁶ Deficient *LDLR* binding results in a decreased clearance of LDL from plasma. The disorder is most common in individuals of European descent (one per 1000).⁹ Patients with FDB are at moderate to high risk of developing ASCVD.³⁷

Sitosterolemia

Sitosterolemia is a rare autosomal-recessive disease caused by a mutation in either of two genes (*ABCG5* or *ABCG8*) encoding the ABC half-transporters.³⁸ These genes are expressed in enterocytes and hepatocytes. The ABC half-transporters limit the absorption of cholesterol and plant sterols (and possibly shellfish sterols) in the gut. They also promote biliary and fecal excretion of cholesterol and phytosterols.^{39,40} Defective proteins result in an abnormally high absorption of plant sterols (and, to a lesser extent, cholesterol) into the enterocyte, and decreased excretion of these sterols from the liver into the bile. Plasma cholesterol can be mildly, moderately, or markedly elevated, whereas plant sterol concentrations in the plasma are markedly increased. Patients with sitosterolemia develop premature ASCVD and xanthomas in childhood, and may develop aortic stenosis.³⁸

Disorders of Overproduction of Very Low-Density Lipoprotein

Familial combined hyperlipidemia (FCHL) is an autosomal-dominant disorder with a prevalence of 1% to 2% in Western populations.⁴¹ There is overlap in the lipid phenotype between FCHL and combined dyslipidemia (CD) of obesity, which likely has genetic underpinnings but is primarily influenced by lifestyle factors. CD is highly prevalent in youth, occurring in 30% to 60% of obese children and adolescents.⁴² Individuals with FCHL and CD generally share the same metabolic defect, which is overproduction of hepatic VLDL. Families with FCHL have multiple patterns of hyperlipidemia, including hypercholesterolemia, hypertriglyceridemia, and elevated apoB levels. A diagnosis of FCHL is based on the presence of increased levels of cholesterol, TG, or apoB in patients and their first-degree relatives.⁴¹ Veerkamp and colleagues have developed a nomogram to calculate the probability that a person is likely to be affected by FCHL.⁴³ FCHL can manifest in childhood, but is usually not fully expressed until adulthood.⁴¹ Patients with FCHL and CD often have concurrent problems with insulin resistance, central obesity, and hypertension and are at an increased risk of premature ASCVD.⁴⁴

Syndromes with a similar phenotype to FCHL and CD are hyperapobeta-lipoproteinemia, LDL subclass pattern B, and the clustering of ASCVD risk factors known as *metabolic syndrome in adults*.⁴¹ Of the three, the latter syndrome is much more prevalent in children. Rates of metabolic syndrome are continuing to rise with the prevalence of obesity in the pediatric population.⁴⁵ There appears to be a mechanistic link between central obesity, insulin resistance, and dyslipidemia—with central obesity generally preceding both glucose and lipid abnormalities. Currently, there is no agreed upon definition for metabolic syndrome in childhood.⁴⁶

Disorders of Marked Hypertriglyceridemia

Familial Hypertriglyceridemia

Familial hypertriglyceridemia (FHTG) follows an autosomal-dominant inheritance pattern expressed predominantly in adulthood, with a population prevalence of around 5% to 10%.⁴¹ The prevalence in children is increasing. Obesity is an important factor that can expedite the expression of FHTG, and patients often have concurrent glucose intolerance. The phenotype for FHTG is moderate to markedly high serum TGs (200–500 mg/dL range) and low to normal LDL and HDL cholesterol levels. The metabolic cause of the disorder is hepatic secretion of large TG-rich VLDL particles that are catabolized slowly.⁴⁷ The fundamental genetic defect for FHTG has not been identified.

Familial Chylomicronemia Syndrome

Chylomicronemia syndrome is a compilation of rare monogenetic disorders that cause marked impairment of LPL activity. These disorders are phenotypically expressed as hypertriglyceridemia (usually TGs >1000 mg/dL), because of diminished or absent hydrolysis of chylomicron and VLDL-associated TGs by LPL.⁴³ The estimated prevalence is one in 500,000 to 1,000,000.⁴⁸ Impairment of LPL activity may be related to LPL deficiency, apoC-II (cofactor for LPL) deficiency, or the more recently described apoA5 and GPIHBP1 loss-of-function mutations that result in poor hydrolysis of chylomicron and VLDL-associated TGs.^{49,50}

In homozygous chylomicronemia, fasting plasma has a viscous, creamy appearance because of the presence of large numbers of chylomicron particles. Risks for pancreatitis and hepatosplenomegaly are increased because of the markedly elevated serum TGs.⁴⁹ In addition, eruptive xanthomas and neurologic symptoms may be apparent. Individuals heterozygous for the syndrome may have a mild to moderate elevation in plasma TGs that can range from 200 to 750 mg/dL. Environmental factors, such as weight gain, may exacerbate hypertriglyceridemia. Premature cardiovascular disease (CVD) is generally not a feature of chylomicronemia, but cases have been reported.⁵⁰

HYPOLIPIDEMIAS

Low High-Density Lipoprotein Cholesterol

In clinical practice, patients with low HDL cholesterol levels commonly have concurrent high TGs, with or without elevations in small dense LDL cholesterol.⁴¹ These patients are usually obese, and the mechanistic explanation for this dyslipidemic triad is VLDL overproduction. Less common are familial disorders of HDL, including familial hypoalphalipoproteinemia, mutations of the apoA-1 protein, Tangier disease, and LCAT deficiency.⁵¹ These disorders are characterized by a low HDL cholesterol level, with no other lipid abnormality. Familial hypoalphalipoproteinemia follows an autosomal-dominant inheritance pattern.⁵² ApoA-1 levels are also often low because of decreased production of HDL.

A number of mutations have been described in the *apoA-1* gene and are associated with low HDL cholesterol and low apoA-1.^{51,53} Tangier disease is caused by mutations in the *ABCA1* gene.⁵³ Patients affected by this disease are not able to actively withdraw cholesterol from cells onto nascent HDL particles, causing rapid degradation of the nascent HDL. ApoA-1 is rapidly cleared before it is able to acquire cholesterol. In Tangier disease, HDL cholesterol levels are close to zero and the apoA-1 levels are less than 5 mg/dL. The risk of premature ASCVD in these patients is mild to moderate.^{52,53} LCAT deficiency is a very rare autosomal recessive disorder caused by mutations in LCAT, an enzyme synthesized by the liver and secreted into the plasma, where it associates with lipoproteins.⁵⁴ LCAT esterifies free cholesterol on the surface of HDL and enables the accumulation of cholesteryl esters in the core of HDL. In LCAT deficiency, lack of normal cholesterol esterification impairs formation of mature HDL particles, which are readily catabolized along with apoA-1. Remarkably, despite the extremely low levels of plasma HDL cholesterol (usually <10 mg/dL) and apoA-1, premature CVD is not a consistent feature of this disorder.

Abetalipoproteinemia

Abetalipoproteinemia is associated with low serum cholesterol (<50 mg/dL) and TGs (~2–45 mg/dL). Patients with this disorder present with steatorrhea and fatty liver. Without

treatment, ataxia follows (with acanthocytosis and retinitis pigmentosa). Abetalipoproteinemia is caused by a defect in MTP.⁵⁵ Without MTP, no chylomicrons, VLDL, or LDL appear in the plasma. In these patients, HDL takes over as the primary cholesterol carrier. Thus the defect is not fatal because of significant fat malabsorption, fat-soluble vitamin status is impaired.

In particular, because vitamin E absorption and cellular uptake require chylomicron and LDL transport, high doses of vitamin E are required to prevent retinal and sensory neuron degeneration. Additional dietary considerations include restricting long-chain dietary TGs to less than 15 g/day to alleviate the steatorrhea. Medium-chain triglycerides (MCT oils) can be used as an alternative source of energy.⁵⁰

Hypobetalipoproteinemia

Hypobetalipoproteinemia is an autosomal-dominant disorder resulting from a defect in the *apoB* gene that produces a truncated apolipoprotein B.⁵⁶ Cholesterol levels in patients with heterozygous hypobetalipoproteinemia are usually 50% of those of an unaffected family member. The heterozygous form of this condition is benign. However, homozygous hypobetalipoproteinemia is associated with severe hypocholesterolemia, significant steatorrhea, fatty liver, acanthocytosis retinopathy, and peripheral neuropathy.⁵⁷

Loss-of-Function Mutations for PCSK9

PCSK9 loss-of-function mutations are associated with very low LDL-cholesterol levels and reduced ASCVD risk (see section on Autosomal-Dominant and Autosomal-Recessive Hypercholesterolemia for mechanism for low LDL-cholesterol level). These mutations are found in approximately 2% of the population.⁵⁸ Compared with noncarriers, heterozygous carriers have a 28% reduction in LDL-C levels and an 88% reduction in ASCVD risk,⁵⁹ and may also protect carriers from myocardial infarction. Preventing PCSK9-mediated LDLR degradation with monoclonal antibodies is a novel strategy for LDL-cholesterol lowering in patients with severe forms of hypercholesterolemia.⁵⁹

Disorders With Lipoprotein Clearance via ApoE Pathways

Dysbetalipoproteinemia is characterized by elevated cholesterol and TG levels.⁴¹ The disorder results from the presence of a polymorphism of the *apoE* allele (*apoE2*, rather than the more common *apoE3* or less common *apoE4*).⁶⁰ Metabolically, this defect results in a poor uptake of remnant particles and abnormal remnant catabolism because of the abnormal *apoE*. Increased remnants, VLDL, chylomicrons, and apoE are all present. Xanthomas may occur, and premature ASCVD has been reported. This lipoprotein disorder is rare in children and often presents in young adulthood.⁴¹

SECONDARY CAUSES

Secondary dyslipidemias can result from a variety of diseases and conditions (Box 25.1). In the United States, the most prevalent cause of secondary dyslipidemia is overweight and obesity.⁶¹ The dyslipidemic triad (namely, elevated TGs and small dense LDL and low HDL cholesterol) is commonly associated with overweight (in particular, with central adiposity).^{61,62} In addition to dyslipidemia, insulin resistance and elevated blood pressure may be present. This cluster of abnormalities is known in adults as the *metabolic syndrome*. Empirical evidence in children also indicates that obesity during

childhood is associated with the same risk factor clustering seen in adults, that it continues into adult life, and that it is associated with an increased risk for accelerated early atherosclerosis.⁶³ The primary approach to treating this disorder in both adults and children is weight management. Improvement in weight status and a decrease in body fatness have been shown to be associated with improvements in the dyslipidemia and other comorbidities associated with obesity.⁶⁴

Metabolic lipid perturbations in adult patients with types 1 and 2 diabetes mellitus are similar to those found in patients with the metabolic syndrome, but often are more severe.⁶⁵ In general, in adults with diabetes, TGs are elevated and HDL cholesterol is low—and LDL cholesterol can be normal, mildly, or moderately elevated. Diabetes in adults is considered an ASCVD risk equivalent according to the National Cholesterol Education Program (NCEP). This means that the risk for developing ASCVD in patients with poorly controlled diabetes is equivalent to those with established ASCVD.⁶⁶ For this reason, the NCEP recommends aggressive treatment of dyslipidemia in adult patients with diabetes.

Although type 1 diabetes is currently the main form of diabetes seen in children, in the United States a growing number of patients with type 2 diabetes are under the age of 18 years.⁶⁷ Change in the prevalence of type 2 diabetes in youth is likely related to the growing obesity epidemic occurring in the pediatric population.^{67,68} Data on lipid concentrations in children and adolescents with diabetes are few, particularly in those with type 2 diabetes.

The Search for Diabetes in Youth Study assessed the prevalence of serum lipid abnormalities among a representative sample of US children and adolescents with type 1 and type 2 diabetes.⁶⁹ Findings from this study showed a substantial number of diabetic children over the age of 10 years with abnormal serum lipids: nearly 50% had an LDL cholesterol level above the optimal level of 100 mg/dL. For children with type 2 diabetes, 37% had elevated TG levels and 44% had low HDL cholesterol. These data highlight the importance of serum lipid screening in children with diabetes. A growing body of literature also shows early vascular dysfunction in children with diabetes, regardless of type.⁷⁰ This is thought to be caused by

glycemic and lipid abnormalities associated with poorly managed diabetes. For this reason, new treatment guidelines recommend intensive glucose and lipid management for children with diabetes.⁷¹ These guidelines are discussed later in the chapter.

Other causes of secondary dyslipidemia include hypothyroidism, nephrotic syndrome, other renal diseases, liver diseases, and infection.¹⁰ The risk of development of atherosclerosis with these conditions is unknown but is likely proportionate to the length of exposure and extent of elevation in serum LDL cholesterol levels. CVD is common in patients with chronic renal insufficiency.⁷² Dyslipidemias can also result from the ingestion of a variety of medications. These medications include progestins, estrogens, androgens, anabolic steroids, corticosteroids, cyclosporine, and retinoids. Secondary causes of dyslipidemias should be identified by patient historical data and a careful physical examination.¹⁰ Laboratory tests (including thyroid, renal, and liver function panels) can confirm the diagnosis.

The treatment of dyslipidemia in patients with secondary causes is focused on managing the underlying disease. Diet and physical activity changes may also be recommended to reduce elevated LDL cholesterol and TG levels.

VASCULAR CHANGES AND DYSLIPIDEMIA

It is well established that elevated concentrations of total cholesterol and LDL cholesterol in adult life are strong and reversible risk factors for ASCVD.⁶⁶ Whether dyslipidemia during childhood contributes to atherosclerotic lesions in coronary and other arteries has been a subject of debate, but accumulating evidence from pathology and in vivo imaging studies favors a relationship. Atherosclerotic lesions result from deposits of lipid and cholesterol in the intima of the arterial wall.⁷³ Early lesions, called *fatty streaks*, are formed from the accumulation of macrophages filled with lipid droplets (foam cells).

Fatty streaks do not disorganize the normal structure of the intima, do not deform or obstruct the artery, and are in and of themselves not considered harmful.⁷⁴ However, some continue to accumulate macrophage foam cells and extracellular lipid and smooth muscle cells—forming raised plaques. From these, more advanced lesions may develop—with further deposition of extracellular lipid, cholesterol crystals, collagen, and potentially calcium.⁷⁵ It is these raised lesions that result in a myocardial infarction because of their increasing size and obstruction of the arterial lumen or because of rupture of the fibrous plaque, which results in the release of thrombogenic substances from the necrotic core.⁷⁵

Pathobiological studies of the coronary arteries of young individuals who died from causes unrelated to heart disease have been useful in documenting the progression of atherosclerosis by age and risk factor determinants. Stary and colleagues studied more than 500 postmortem samples of coronary arteries from persons younger than 30 years of age and found the presence of fatty streaks in the majority of children younger than 9 years of age, raised lesions in about half of adolescents, and more advanced lesions in about one-third of the young adults studied.⁷⁶ In 93 autopsies of young adults for whom childhood risk factor data were available, Berenson and colleagues found that the extent of the surface of arteries covered with fatty streaks and fibrous plaques was positively associated with LDL cholesterol, TGs, blood pressure, and body mass index (BMI), and negatively associated with HDL cholesterol levels in childhood.⁷⁷

The Pathobiological Determinants of Atherosclerosis in Youth study reached similar conclusions from examination of more than 3000 postmortem samples of coronary arteries of young adults who died from noncardiovascular events and

BOX 25.2 Pediatric Risk Factors for Atherosclerotic Cardiovascular Disease

POSITIVE RISK FACTORS

- Elevated LDL cholesterol (≥ 130 mg/dL)
- Family history of premature (aged >55 years) coronary heart disease, CVD, or peripheral vascular disease
- Smoking
- Hypertension
- Obesity (≥ 95 th percentile weight for height on National Center for Health Statistics [NCHS] growth chart)
- Physical inactivity
- Diabetes

NEGATIVE RISK FACTORS

- High HDL cholesterol (60 mg/dL)

CVD, Cardiovascular disease, HDL, high-density lipoprotein, LDL, low-density lipoprotein.

who likewise had a variety of surrogates for antimortem risk factor measures available.⁷⁸ In general, pathology studies have made important contributions to the identification of risk factors for early aspects of the atherosclerotic process. In conjunction with findings from longitudinal studies, such as the Framingham Heart Study (in which risk factor assessments of participants preceded the development of CVD),⁷⁹ a group of risk factors, often referred to as the *traditional risk factors* for ASCVD has been established. A complete list of pediatric risk factors for ASCVD is found in Box 25.2.

Advances in vascular imaging technology have provided a means of measuring early pathologic changes and functional abnormalities against coronary and other arteries in response to adverse changes in CVD risk factors. The advantage in using this technology is that walls of superficial arteries can be imaged noninvasively in real time at high resolution, and changes to the arterial wall can be measured as a continuous variable from childhood to adulthood in patients with and without the presence of risk factors for ASCVD.⁸⁰ Computed tomography (CT) scanning is considered one of the most sensitive noninvasive tools for imaging the extent and location of coronary artery calcium present in atheroma.⁸¹

The presence of coronary artery calcium has been associated with adverse CVD outcomes in adults.⁸² In adolescents, several prospective studies have shown associations between risk factors for ASCVD in youth and coronary artery calcium in young adulthood. In the Muscatine Study, in which participants were assessed for CVD risk factors during their school-age years, and later assessed for cardiovascular changes by CT scan, 31% of men and 10% of women aged 29 to 37 years had significant coronary artery calcification.⁸³ In this study, childhood risk factors associated with calcification were obesity, increased blood pressure, and low HDL cholesterol. In the Cardiovascular Risk in Young Finns Study, elevated total and LDL cholesterol, Apo-B levels and systolic blood pressure measured in adolescence were associated with coronary artery calcium in middle-age, highlighting the role of lifelong risk factor exposure to the pathophysiology of CVD.⁸⁴ Gidding and colleagues showed significant coronary calcium by electron beam CT in 7 of 29 young adults with heterozygous familial hypercholesterolemia.⁸⁵ Overweight was found to increase the likelihood of calcium being present in individuals already at high risk.

Vascular ultrasound imaging has been used to assess alterations in brachial artery flow-mediated dilation, which is a measure of endothelial function, and carotid intima-media thickness (IMT).⁸¹ In adults, both measures have been

associated with adverse changes in traditional ASCVD risk factors,⁸⁶ respond to normalization of risk factors,⁸⁷ and are considered important early markers for the progression of atherosclerotic disease.^{86–89} Although fewer studies have used ultrasound technology to evaluate coronary arteries in the young, children with hypercholesterolemia have been assessed using measures of the carotid and brachial arteries and have been found to have abnormalities of carotid IMT^{90,91} and brachial artery vasodilation.^{92–94} Early initiation and longer duration of statin therapy in youth with FH was related to better carotid IMT at 10 years of follow-up, as demonstrated by no difference in rate of increased carotid IMT between youths with FH compared with their nonaffected siblings.⁹⁵ Regression of carotid IMT has also been demonstrated in youth with treatment of dyslipidemia,⁹⁶ whereas a study of statin therapy in low-risk adults demonstrated lack of progression of carotid IMT but did not result in regression of atherosclerosis.⁹⁷ In a systematic review of 51 studies evaluating over 4000 FH patients and 700 FCHL patients, impaired endothelial function, as measured by reduced brachial artery flow-mediated dilation (FMD), was significantly improved with statins. Consistent with studies of carotid IMT, improvement was proportional to duration and intensity of statin therapy.⁹⁸

In summary, these studies confirm the utility of vascular imaging for detecting early pathologic and functional changes to coronary vessels, and associations with modifiable CVD risk factors in the young. Clinically, vascular imaging by ultrasound may be a valuable means of estimating the benefit of treating multiple CVD risk factors in children and adolescents. However, the collection of more normative data across age, race, and gender groups, and longitudinal studies to determine age and puberty-related changes in these measures is needed before these methods could be adopted in clinical evaluation.^{99,100} In general, CT scans may be less useful in younger patients because calcium depositions are uncommon before young adulthood.

SCREENING FOR LIPID DISORDERS

Routine Screening

The approach to pediatric screening for dyslipidemia has been controversial. Since the 1990s, pediatric guidelines established by the NCEP have provided the standard of care, with respect to lipid screening and treatment of dyslipidemia in children.¹⁰¹ These guidelines recommend selective blood cholesterol screening in children, based on a positive family history of premature CVD (before age 55 years), presence of dyslipidemia in a parent (total cholesterol >240 mg/dL), or presence of additional CVD risk factors in the child, such as hypertension, diabetes, and obesity. If family history is unknown, recommendations suggest that lipid screening of a child be done at the discretion of the primary care provider. Selective screening is endorsed for young children between 2 to <9 years of age by the National Heart, Lung and Blood Institutes (NHLBI) Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents.⁶⁴

For older children ages 9 to 11 years and again after puberty (ages 17–21 years), the NHLBI Expert Panel recommends universal screening for dyslipidemia. This is based on evidence that targeted screening for dyslipidemia reportedly missed many children with moderate dyslipidemia (as many as 30%–60%) and failed to detect a substantial number who likely had genetic dyslipidemia who might require more intensive therapy.¹⁰² FH is a relatively common problem, with the heterozygous form occurring in one in 250 individuals.²⁶ FH has been clearly associated with an increased lifetime risk of ASCVD, and earlier treatment is associated with reduced

subclinical evidence of atherosclerosis.³⁰ To increase the likelihood of detecting young patients with FH and other genetic dyslipidemias, the American Heart Association (AHA)¹⁰³ and the National Lipid Association¹⁰⁴ also endorse lipid screening during childhood and adolescence. The US Preventive Services Task Force 2016 guidelines on pediatric lipid screening do not specifically advocate for or against pediatric lipid screening, but cite a lack of knowledge regarding the relationship between childhood lipid levels and hard cardiovascular outcomes, and the need for further evidence in this regard.¹⁰⁵

The NHLBI Expert Panel recommendations recognized that there is considerable variation in LDL cholesterol with age during growth and development, especially during puberty.^{106,107} Total and LDL cholesterol levels tend to decline during puberty, meaning that some adolescents will appear normal, when in fact they will have elevated levels after puberty.¹⁰⁸ For this reason, 9 to 11 years of age was selected as a good age to screen, before the effect of puberty lowers LDL cholesterol levels, but closer to an age when drug therapy may be appropriate.¹⁰⁹

The Expert Panel⁶⁴ also included non-HDL cholesterol as a screening tool for the identification of dyslipidemia in children. Non-HDL cholesterol is calculated by subtracting the HDL cholesterol from the total cholesterol. This measure reflects the amount of cholesterol carried by atherogenic apolipoprotein B-containing lipoproteins (VLDL, IDL, and LDL). In both adults and children, non-HDL cholesterol has been determined to be more predictive of persistent dyslipidemia and therefore atherosclerosis and future CVD events than total cholesterol, LDL cholesterol, or HDL cholesterol alone.¹⁰⁸ A major advantage of non-HDL cholesterol is that it can be accurately calculated in a nonfasting state and is therefore practical to obtain in a primary care setting. Percentiles for non-HDL cholesterol have been established (Table 25.3) and are based on data from the Bogalusa Heart Study,¹⁰⁹ where non-HDL cholesterol greater than or equal to the 95th percentile is considered “abnormal/high” and between the 75th to 95th percentile is considered “borderline.”

If a nonfasting non-HDL cholesterol is found to be abnormal, a fasting (12-hour) lipoprotein analysis is recommended⁶⁴ to allow quantification of total cholesterol, HDL cholesterol, TGs, and calculation of LDL cholesterol. The Friedewald equation—LDL cholesterol = total cholesterol – (HDL cholesterol + TGs/5)—can be used to calculate LDL cholesterol, as long as the serum TG level is less than 400 mg/dL.¹¹⁰ Direct measurement of LDL cholesterol concentration is available through some commercial laboratories and is indicated for individuals whose fasting TG level is 400 mg/dL or more.

TABLE 25.3 Normal Plasma Lipid and Lipoprotein Concentrations (mg/dL) for Children and Adolescents

Category	Low	Acceptable	Borderline	High
Total cholesterol	—	<170	170–199	≥200
LDL cholesterol	—	<110	110–129	≥130
Non-HDL cholesterol	—	<120	120–144	≥145
Apolipoprotein B	—	<90	90–109	≥110
Triglycerides	—			
0–9 y		<75	75–99	≥100
10–19 y		<90	90–129	≥130
HDL cholesterol	<40	> 45	40–45	—
Apolipoprotein A-1	<115	<120	115–120	—

Values for plasma lipids and lipoproteins are from the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents (2011). Summary report. Pediatrics, 128, S1–S44.

HDL, High-density lipoprotein; LDL, low-density lipoprotein.

The lipid/lipoprotein cut points to be used in screening are presented in Table 25.3. Cut points for total cholesterol and LDL cholesterol in children are from the Lipid Research Clinics Prevalence Study.¹⁰¹ The 75th and 95th percentiles for lipid values from this study were used to define “borderline” and “high” risk categories, respectively. If a lipoprotein analysis reveals LDL cholesterol to be borderline or high, there is consensus among guidelines that the test should be repeated and the average value of the two tests be considered for clinical decision making.⁶⁴

Although the Lipid Research Clinics Prevalence Study provided population percentiles for TG and HDL-C concentrations, recommended cut points for these variables were not established back in 1992.¹⁰¹ Measurement of these variables has become more important because they are part of the clustering of risk factors associated with the growing epidemic of pediatric obesity in the United States.⁶² Data from pathology and imaging studies show adverse changes in vascular structure and function in adulthood related to low HDL cholesterol and high TG levels in childhood.¹⁰⁰ Therefore the latest guideline⁶⁴ recommends cut points for TGs and HDL cholesterol based on percentiles provided by the NCEP.¹¹¹ The 75th and 95th percentiles for TG values were used to define borderline and high risk categories, respectively, and the 25th and the 10th percentiles were used to define borderline and high risk groups for HDL cholesterol (see Table 25.3).

Although well-standardized immunochemical methods are available for the determination of apoB and apoA-1 measurements, guidelines suggest that measurements of apolipoproteins for universal screening provide no additional advantage over measuring non-HDL cholesterol, LDL cholesterol, and HDL cholesterol levels, except in youth with premature CVD in parents.^{102,112} Cut points for apoB and apoA-1 from the National Health and Nutrition Examination Survey should be used in these cases¹¹¹ (see Table 25.3). Measurement of lipoprotein subclasses and their sizes in children and adolescents, by advanced lipoprotein testing, has been found to have no sufficient clinical utility to warrant routine use.⁶⁴

Clinical evaluation of children and adolescents at high risk for ASCVD, based on abnormal lipid levels, should include a careful review of the patient’s medical and family history, and physical examination to identify additional risk factors and secondary causes of dyslipidemia. Assessment should include the following: review of past medical or family history for hypertension, diabetes mellitus, medication use, obesity, poor dietary habits (including excessive intake of saturated fat), sedentary behavior, and tobacco use; measurement of height, weight, and calculation of BMI; Tanner staging to assess pubertal growth; blood pressure measurement; physical inspection of skin, eyes, and tendons for lipid deposition and palpitation of the thyroid gland and liver for signs of enlargement; and laboratory tests (including thyroid, renal, and liver function panels). Glucose and insulin levels should be measured to assess for the presence of metabolic syndrome or diabetes.

Genetic Testing

Increasingly, deoxyribonucleic acid–based tests are being used to confirm the diagnosis of FH in patients with a family member who has a mutation or in a young patient with high LDL cholesterol, with tendon xanthomas or atherosclerotic disease.¹¹³ Currently, three genes (*LDLR*, *apoB*, and *PCSK9*) have been identified in association with mutations that cause this disorder.¹¹⁴ In addition to *LDLR*, most laboratories test for the *apolipoprotein B* gene r500Q mutation. Rapid and relatively inexpensive methods have been developed to test a selected subset of the *LDLR* mutations. However, more expensive “complete gene scans” are needed for mutation-negative samples.¹¹⁴

Once a mutation is identified, relatives can be tested rapidly and cheaply.

It is expected that genetic testing will facilitate the diagnosis of FH and the initiation and intensity of recommended lipid-lowering therapy.¹¹⁵ Studies have shown that the degree of cholesterol lowering achieved by statins is influenced by the type of mutation (e.g., individuals with the *APOB* r3500Q mutation showed a strong positive response to statin therapy).^{116,117} In addition, the diagnosis of FH based on genetic testing improved uptake and adherence to treatment in several studies.^{118,119} Data from the CASCADE FH Registry (Cascade Screening for Awareness and Detection of FH) indicate that FH genetic testing is underused for patients in the United States, with genetic testing reported in 3.9% of individuals in the registry with a clinical diagnosis of FH.¹²⁰ Concerns remain about the long-term benefits and potential side effects from lifelong treatment with statins for identified children. As progress in this area continues, current treatment algorithms may need modification to describe the role of genetic testing in clinical practice.

DIET THERAPY IN MANAGING DYSLIPIDEMIA

New pediatric nutrition recommendations from the Expert Panel⁶⁴ support a two-pronged dietary approach to managing pediatric hypercholesterolemia: one geared to the population in general and the second focused on an individualized treatment of dyslipidemia, including an approach to elevated LDL-C and an approach to elevated TGs. On the population level for healthy infants, the Expert Panel⁶⁴ has recommended breastfeeding as optimal to 12 months of age if possible with supplementation of complementary foods when appropriate; the introduction of iron-fortified formula is recommended if breastfeeding is stopped or reduced before 1 year of age. Previous nutrition recommendations from the NCEP¹⁰¹ did not include recommendations for infants; however, evidence in favor of the sustained cardiovascular benefits of breastfeeding, including lower total cholesterol, BMI, and carotid IMT into adulthood, is now strong.^{121–123} These guidelines are in accordance with the Surgeon General’s Office, the World Health Organization, the American Academy of Pediatrics, and the American Academy of Family Physicians.

The 2015 Dietary Guidelines for Americans (DGA)¹²⁴ provide optimal nutrition guidance for primary care providers to use in promoting nutrient adequacy and CVD risk reduction in children over 2 years of age. In keeping with the goal of reducing chronic disease risk among all Americans, the DGA supports a dietary fat composition of 25% to 35% of calories, with less than 10% of calories from saturated fat and no or minimal trans fats included. Notably, the 2015 DGA no longer designates dietary cholesterol as a nutrient of concern for overconsumption. This is based on available evidence showing no appreciable relationship between dietary cholesterol intake and serum cholesterol. The DGA also emphasizes setting an appropriate daily calorie goal for healthy weight stability. This dietary pattern closely matches the former NCEP Step 1 diet,¹⁰¹ and is viewed as a primary preventive measure to optimize serum lipids, thereby reducing the risk of ASCVD in the pediatric population at large. Similar food-based dietary recommendations are available through the World Health Organization (<http://www.who.int/nutrition/topics/nutrecomm/en/>).

Within appropriate gender- and age-specific requirements for growth and development in normal children and children with dyslipidemia, the Expert Panel⁶⁴ has recommended an early transition (between 1 and 2 years of age) to reduced fat, unflavored milk (from whole to 2%), and a dietary composition that matches that recommended by the DGA.¹²⁴ Advice to transition early to a low-fat diet (minimum of 30% of total calories to age 2 years) is supported by data from the ongoing

TABLE 25.4 Estimated Calorie Needs per Day by Age, Gender, and Physical Activity Level

Gender	Age (Years)	Calorie Requirements (kcal) by Activity Level			
		Sedentary	Moderately Active	Active	
Child	2–3	1000–1200	1000–1400	1000–1400	
	Female	4–8	1200–1400	1400–1600	1400–1800
		9–13	1400–1600	1600–2000	1800–2200
Males	14–18	1800	2000	2400	
	4–8	1200–1400	1400–1600	1600–2000	
	9–13	1600–2000	1800–2200	2000–2600	
	14–18	2000–2400	2400–2800	2800–3200	

Estimated amounts of calories needed to maintain caloric balance for various age and gender groups at three different levels of physical activity are from the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents (2011). Summary report. *Pediatrics*, 128, S1–S44.

Special Turku Risk Intervention Program study,^{125–127} which showed that limiting total fat and saturated fat to DGA levels could be instituted safely after 6 months of age, under medical supervision and lowered total cholesterol, LDL cholesterol, and BMI more than a usual higher-fat diet. The Expert Panel⁶⁴ has cautioned that any dietary changes initiated during childhood should be tailored to the child to ensure optimal growth and development and administered under the guidance of the child's primary care physician. Estimated calorie requirements based on age and gender at three levels of physical activity from the Institute of Medicine¹²⁸ are found in Table 25.4.

The Expert Panel's⁶⁴ population approach for youth ages 4 years and older encourages consumption of a plant-based diet comparable to the Dietary Approaches to Stop Hypertension (DASH)¹²⁹ dietary pattern. This dietary pattern recommends 7 to 10 servings/day of fruits and vegetables and 6 to 10 servings of breads, cereals, and grains. Whole fruits and vegetables rather than juice, and whole grains rather than processed grains are encouraged. Key sources of saturated fat and cholesterol are moderated on the DASH dietary plan. For example, red meats are limited to modest amounts of lean cuts (e.g., 5 to 6 oz per day), and dairy products are limited to skim or low-fat varieties (16–24 oz/day). Plant-based foods should constitute the largest proportion of energy in children's diets. Most choices within these food groups are low in fat, cholesterol free, and high in fiber—and will help displace energy sources containing saturated fat.^{130,131} The major health benefits of a DASH style of eating are lowered blood pressure, improved lipids, and improved weight status.^{132,133} Box 25.3 highlights some practical dietary strategies for lowering saturated fat and cholesterol in the diets of the young.

In a recent systematic review of randomized controlled trials, aimed to reduce dietary saturated fat to modify CVD risk factors in children, the greatest lowering of LDL-C was achieved by replacing saturated fat with polyunsaturated fats (PUFA) or a mixture of PUFA and monounsaturated fats.¹³⁴ Similar to DASH, a Mediterranean-style diet, if appropriately planned, also emphasizes whole, unprocessed foods, a mixture of PUFA and monounsaturated fats, and plant sources of protein. This food pattern has been recognized as effective in modifying cardiovascular risk factors, including lowering blood pressure, improving blood lipids, and promoting weight loss.¹³⁵ Greater improvements in arterial distensibility measures were reported in obese adolescents with hypercholesterolemia on a 12-week Mediterranean-type diet intervention compared with a control group.¹³⁶

BOX 25.3 Practical Dietary Strategies for Lowering Saturated Fat and Cholesterol

- Eat 7 to 10 servings of fresh, frozen, or canned fruits and vegetables daily.
- Use vegetable oils and soft margarines low in saturated fat and trans fatty acids, instead of butter or most other animal fats in the diet.
- Eat whole-grain breads and cereals rather than processed grain products.
- Use nonfat (skim) or low-fat milk and dairy products daily.
- Eat more fish, especially oily fish (broiled or baked).
- Eat lean cuts of meat, and trim any obvious fat from red meat before cooking.
- Take the skin off chicken or turkey and eat only the white meat.
- Avoid processed meats, such as hotdogs, sausage, and bologna.
- Avoid creams or sauces made with butter or whole-milk dairy products.
- Choose low-fat snacks, such as ginger snaps, graham crackers, pretzels, plain popcorn, animal crackers, and vanilla wafers.
- Use recommended portion sizes on food labels when preparing and serving food.

For the individual child with identified dyslipidemia, a positive family history of premature CVD, obesity, or hypertension, the Expert Panel⁶⁴ has recommended initiating the same dietary approach recommended for the general population (as described previously). The Expert Panel has deemed this plan the Cardiovascular Health Integrated Lifestyle Diet (CHILD-1) and considers this the first line of therapy to remediate CVD risk factors, with a primary target of lowering LDL cholesterol levels. Meal plans for different calorie levels have been published for DASH and Mediterranean-style diet patterns¹²⁴ that conform to the CHILD-1 diet and can be modified for progressive saturated fat lowering and calorie and nutrient adequacy of children.¹³⁷ If LDL cholesterol levels remain abnormal (LDL cholesterol ≥ 130 mg/dL) after 3 to 6 months of dietary adherence to the CHILD-1, further restriction of dietary saturated fat (<7% of total calories) and cholesterol (<200 mg/day), referred to as the CHILD-2 (LDL), is recommended. Repeated studies have shown that a dietary saturated fat reduction to 7% of total calories and cholesterol to 200 mg/day is safe and efficacious in lowering LDL cholesterol in children with hypercholesterolemia.^{138–140}

Low-fat diets should be designed to be nutritionally adequate and consultation with a registered dietitian is particularly helpful in that regard. In some studies, lower intakes of calcium, zinc, vitamin E, and phosphorus on low-fat diets were reported for diets initiated without medical supervision.¹⁴⁰ To prevent overzealous implementation of a very low fat diet for children with dyslipidemia, which could lead to failure to thrive,¹⁴¹ the Expert Panel⁶⁴ has recommended 25% as the lower end of the range for total fat calories, consistent with the acceptable macronutrient distribution range stipulated by the DGA¹²⁴ for children 2 years of age and older. In most cases, dietary compliance to the CHILD-2 diet should normalize borderline-high LDL cholesterol levels. The reported response to diets with this composition of total fat, saturated fat, and cholesterol in children with LDL cholesterol levels over 130 mg/dL has ranged from 3% to 12%.^{141–144}

For children older than 2 years of age, with persistently high LDL cholesterol levels, additional dietary adjuncts can be used. These may include margarines containing plant stanol/sterol esters or water-soluble fibers, such as psyllium. About three servings of stanol containing margarine daily (equivalent to

approximately 2 g/day), consumed as part of a low-fat diet, can reduce LDL cholesterol by 5% to 15%.^{145–147} Psyllium at a dose of 6 g/day added to a low-fat diet may provide an additional 5% to 10% reduction in LDL cholesterol.^{147,148} The extent to which LDL cholesterol is lowered may depend on previous dietary intake and baseline LDL cholesterol levels. Dietary supplements are covered in more detail later in the chapter (see the section Dietary Additives and Supplements.).

For children with elevated TGs or low HDL cholesterol, the Expert Panel⁶⁴ has recommended following the CHILD-2 (TG) dietary pattern, which includes reducing one's intake of simple sugars from processed desserts, snacks, and sugared-sweetened beverages. CHILD-2 (TG) guidelines to minimize added sugars are consistent with a recent scientific statement from the AHA for children to consume no more than 25 g (100 calories or 6 teaspoons) of added sugars per day to lower cardiovascular risk factors.¹⁴⁹ Foods that are high in simple sugar generally add excess calories to the diet, which may contribute to weight gain and elevate serum TGs.¹⁵⁰ Weight management should be a goal of diet therapy for children with a BMI greater than or equal to the 85th percentile. Weight-reduction approaches should focus on decreasing the child's weight-for-height percentile, while maintaining linear growth.¹⁵¹ Although weight loss may temporarily lower HDL cholesterol, weight stabilization at a new lower level will lead to a gradual increase in HDL cholesterol over time.¹⁵² Fish oils from fatty fish, such as salmon and tuna, contain omega-3 fatty acids, which may also help to lower serum TGs.¹⁵³ Increased physical activity should be encouraged with a goal of 1 hour per day of moderate to vigorous activity, and sedentary activities (such as watching television and playing computer and video games) should be limited to no more than 2 hours per day.⁶⁴

For children with very high TG, such as those with hypercholesterolemia, a CHILD-2 (TG) diet and fat restriction as low as 15% of daily calories may be helpful in lowering TG and avoiding pancreatitis. MCT may also be considered as a source of calories in these cases. MCT are comprised of fatty acids, with a chain length of 10 to 12 carbons. MCTs are absorbed efficiently, without the need for emulsification, and do not require repackaging into chylomicrons for transport; therefore MCTs are particularly beneficial for disorders that have defects in bile secretion or chylomicron aggregation or clearance processes.¹⁵⁴

PHARMACOLOGIC MANAGEMENT

For many children with moderately or severely elevated LDL cholesterol, which usually results from a genetic dyslipidemia, diet alone will not lower their cholesterol levels to the acceptable or even borderline range. In these cases, lipid-lowering drug therapy will be required to achieve LDL cholesterol treatment goals in children age 10 years and older. Long-term drug therapy is associated with a decreased incidence of heart disease and overall mortality in adults.⁶⁶ Although no studies directly demonstrate the efficacy of administering lipid-lowering drug therapy in children to prevent CVD, there is evidence from vascular imaging studies that statins may delay the atherosclerotic disease process.^{155,156}

The Expert Panel⁶⁴ has recommended using medication in patients who are at least 10 years of age and whose postdietary (e.g., CHILD-1 → CHILD-2 after 6 months) LDL cholesterol level is 190 mg/dL (or higher) or whose LDL cholesterol level is 160 mg/dL (or higher), and there is a family history of early CVD, with at least one high-level or at least two moderate-level risk factors for CVD. In children with FH who have substantially elevated LDL cholesterol, medication management may need to be started earlier than age 10 years.¹⁵⁶ A lipid specialist should be consulted in these cases. A follow-up LDL cholesterol

TABLE 25.5 Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents Recommendations for Lipid Management of Children and Adolescents With Diabetes

Type 1 and Type 2 Diabetes Mellitus	
Screening	After glycemic control >2 years at diagnosis if other CVD risk factors; otherwise at 10 years; if normal, rescreen every 5 years At diagnosis regardless of age; if normal, rescreen every 2 years
Lipid goals	LDL-C ≤100 mg/dL Non-HDL-C <120 mg/dL Triglycerides <90 mg/dL
Treatment strategies	Glycemic control Diet (CHILD-1 → CHILD-2) Physical activity Weight reduction if appropriate Medication indications if initial management fails: <ul style="list-style-type: none"> • Age ≥10 years • If LDL >160 mg/dL • If LDL 130–159 mg/dL consider based on CVD risk profile • Statins with or without resins • Fibrates if TG >1000 mg/dL • Manage other CVD risk factors (see Box 25.2) if appropriate
Recommendations are from the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents (2011). Summary report. <i>Pediatrics</i> , 128, S1–S44. CVD, Cardiovascular disease; CHILD, Cardiovascular Health Integrated Lifestyle Diet; HDL, high-density lipoprotein; LDL, low-density lipoprotein; TG, triglyceride.	

assessment is recommended 6 weeks after starting drug therapy and every 3 months thereafter, until LDL cholesterol goals are met. Thereafter, follow-up can be less frequent.

For children in general, the goal for LDL cholesterol is less than 130 mg/dL. For children with diabetes, the goal for LDL cholesterol is lower than 100 mg/dL.^{68,157} The lower LDL cholesterol goal for children with diabetes reflects a synthesis of pediatric guidelines and treatment recommendations for adults with diabetes that now consider the presence of diabetes a coronary heart disease risk equivalent.⁶⁶ Table 25.5 summarizes the recommendations of the Expert Panel⁶⁴ regarding lipid screening and management of children and youth with diabetes. Medications used in the treatment of specific lipid abnormalities are summarized in Table 25.6 and are reviewed in the following material.

Bile Acid–Binding Agents

Bile acid–binding agents lower serum cholesterol indirectly by binding with bile acids in the gastrointestinal tract. This action prevents their reabsorption into the enterohepatic circulation, resulting in their loss from the body and removal from the cholesterol pool.¹⁵⁸ To compensate for this loss, the liver increases endogenous cholesterol synthesis and upregulates LDL-receptor synthesis—thereby lowering LDL cholesterol levels in the blood. In bile-acid resin trials in children, a dose of 8 g/day, while on a cholesterol-lowering diet, resulted in a decrease in LDL cholesterol ranging from 10% to 20%.^{159,160}

Bile-acid resins come in powder and tablet form. The powder is usually taken twice daily (4-g scoop) mixed with water or juice. Resins in this form tend to be gritty in texture and children complain that they are unpleasant to drink. Tablets are more palatable but are large and difficult for some children

TABLE 25.6 Drugs Used in the Treatment of Pediatric Lipid Disorders

Class of Medication	Common Name	Mechanism of Action	Change in Lipid Profile	Adverse Effects
Bile acid-binding agents	Cholestyramine	Binds intestinal bile acids; more cholesterol converted into bile acids; decrease hepatic cholesterol pool	↓ LDL	Constipation Abdominal cramping
	Colestipol		↑ TG	
HMG Co-A reductase inhibitors	Colesevelam	Inhibits cholesterol synthesis in hepatic cells; decreases cholesterol pool resulting in upregulation of LDLR	↓ LDL	Dyspepsia ↑ Liver transaminases ↑ CK Myositis
	Atorvastatin		↓ TG	
	Simvastatin		↑ HDL	
	Pravastatin			
	Rosuvastatin			
	Lovastatin			
Fibrates ^a	Fluvastatin	Increases degradation of VLDL cholesterol and TG; hepatic synthesis of VLDL may be decreased	↓ TG	Constipation Myositis
	Fenofibrate		↑ HDL	
Niacin ^a	Niacin extended release	Inhibits release of free fatty acids from adipose tissue; decreases VLDL and LDL cholesterol production and HDL cholesterol degradation	Gemfibrozil	Anemia
			↓ LDL	Flushing
PCSK9 Inhibitors ^a	Alirocumab	Binds to the extracellular domain of the LDL receptor and targets the receptor for degradation	↓ TG	Headache
			↑ HDL	↑ Liver transaminases
Cholesterol absorption blocker	Ezetimibe	Inhibits intestinal absorption of cholesterol and plant sterols	↓ LDL	Not reported in children or adolescents

^aNot US Food and Drug Administration approved for youths (as of this writing).

CK, Creatine kinase; HDL, high-density lipoproteins; HMG CoA, hydroxymethylglutaryl CoA; LDL, low-density lipoprotein; LDLR, low-density lipoprotein receptor; PCSK9, proprotein convertase subtilisin/kexin type 9; TG, triglycerides; VLDL, very low-density lipoprotein.

to swallow. Overall, studies report poor to fair compliance with the medication.^{158,161} Side effects are few and are mainly gastrointestinal in nature, including constipation and gas. These can be minimized with increased intake of water and fiber. Resins may increase TG levels and may interfere with the absorption of certain medications and fat-soluble vitamins.¹⁶² Supplementation with a multivitamin and folate (1 mg daily) is usually recommended.¹⁵⁸

HMG-CoA Reductase Inhibitors

HMG-CoA reductase inhibitors (also known as *statins*) lower LDL cholesterol in the blood by blocking hepatic HMG Co-A reductase, the rate-limiting enzyme in cholesterol biosynthesis.¹⁵⁶ This action depletes the intracellular cholesterol pool, leading to an upregulation of LDL receptors and a decrease in serum cholesterol. Doses ranging from 5 to 40 mg/day in children with FH have resulted in a 23% to 40% lowering of LDL cholesterol.^{154–156} Statins may be taken in combination with bile acid-binding agents for patients who fail to meet LDL cholesterol targets with statin monotherapy. No adverse effects of the combined therapies were noted in a pediatric trial of the medications, and the efficacy of the two medications taken together was additive.¹⁶³

In vivo imaging studies have demonstrated improvements in surrogate markers for atherosclerosis with statin therapy. Reversal of endothelial dysfunction and regression of carotid IMT have been reported in children treated with statins over a 2-year period.^{155,156} This latter finding suggests that the initiation of lipid-lowering statins in childhood may inhibit progression or might even lead to a regression of atherosclerosis.

Adverse effects of the medication are few but have included gastrointestinal complaints, elevated liver transaminase and creatine kinase (CK) levels, and myositis.^{158,162,164} For this reason, statins would not be recommended for patients with liver disease. Follow-up of patients treated with statins should include a laboratory assessment of liver transaminase and CK levels, and identification of adverse physical symptoms, such as muscle cramps.

Because statins are potentially teratogenic, it is essential that physicians determine that adolescent girls are not pregnant or likely to become pregnant before initiating therapy.¹⁵⁸ The longest statin trials have been 2 years in length. Thus whether statins adversely affect long-term growth and development and are safe for lifelong use has not been ascertained. Longer-term safety and efficacy studies are needed, particularly with a follow-up of vascular end points.

Inhibitors of Cholesterol Absorption

Ezetimibe is a cholesterol-lowering agent that prevents the absorption of cholesterol and plant sterols by inhibiting the passage of sterols across the intestinal wall.¹⁶⁵ The reduction in cholesterol absorption leads to a decrease in hepatic cholesterol uptake and availability. As a result, there is a compensatory increase in hepatic cholesterol biosynthesis, an upregulation of LDL receptor expression, and an overall decrease in blood LDL cholesterol levels. In children and adolescents, a daily intake of 10 mg/day reduced LDL cholesterol by approximately 20%.¹⁶³ Kusters et al. studied the safety and efficacy of ezetimibe in children aged 6 to 10 years of age.¹⁶⁶ They found that after 12 weeks of treatment LDL-C was reduced by 27% and non-HDL-C was reduced by 26%. Ezetimibe was well tolerated with few adverse effects. They concluded that ezetimibe could be used as monotherapy for lowering LDL-C in some children. Ezetimibe is US Food and Drug Administration (FDA) approved for use in individuals age 10 years and above.

Proprotein Convertase Subtilisin/Kexin Type 9 Inhibitors

In the early 2000s it was discovered that a gain of function of the gene for PCSK9 results in autosomal dominant hypercholesterolemia.¹⁶⁷ PCSK9 binds to the extracellular domain of the LDL receptor and targets the receptor for degradation. Loss-of-function mutations result in very low circulating LDL-C and also very low risk of CVD.¹⁶⁸ These findings have led to the development of agents that inhibit PCSK9 and lower

circulating LDL-C. These agents use monoclonal antibodies, which are fully human immunoglobulin G subtypes that bind with an approximate 1:1 stoichiometry to circulating PCSK9, which prohibits its binding to the LDL receptor. This results in an accumulation of LDL receptors on the membrane of hepatocytes. This increases clearance of LDL particles and reduces plasma levels of LDL-C.¹⁶⁹

PCSK9 inhibitors have been studied in adult populations, particularly individuals with prior CVD. They result in reduction of LDL-C by 55% to 72%, resulting in very low levels of plasma LDL-C.¹⁶⁹ These reductions in LDL-C have been associated with reduction of atherosclerotic CVD rates.¹⁷⁰

PCSK9 inhibitors have not been extensively studied in children and adolescents. They require injections, which may inhibit their use in pediatric patients. These agents are also costly and approval by insurance providers has proven difficult in adult patients. However, for patients with genetic dyslipidemia and marked elevation of LDL-C who may require more aggressive treatment using LDL apheresis, the PCSK9 inhibitors may prove to be valuable. Pediatric studies with PCSK9 inhibitors are underway, but long-term efficacy and safety data will take some time to acquire.

Fibric Acid Derivatives

Fibric acid derivatives (also known as *fibrates*) lower blood TG levels by increasing degradation and reducing the hepatic production of VLDL.^{158,165} The drug also increases the production of apoA-I, resulting in higher HDL cholesterol levels. Side effects are similar to those for statins and include gastrointestinal complaints, elevated liver transaminase activity, and myopathy.¹⁵⁸ For this reason, fibrates are not recommended for use with statins. These medications are not FDA approved for use with children and adolescents and should be used only in consultation with a lipid specialist for adolescents with genetic hypertriglyceridemia.⁶⁴

Niacin

Niacin decreases hepatic VLDL production, leading to decreased production of LDL cholesterol.^{158,165} Children with heterozygous FH treated with 1000 to 2250 mg of niacin daily, over an average of 8 months, showed a 23% to 30% reduction in LDL cholesterol.¹⁷¹ However, 76% of the children had adverse effects from therapy (e.g., flushing, headache, nausea, glucose intolerance, myopathy, abnormal liver function) and 38% discontinued the drug. Niacin is not recommended for children younger than 2 years of age and is generally not used to treat children with FH, unless LDL cholesterol is persistently elevated or unusual hypertriglyceridemia and low HDL cholesterol are present.⁶⁴ Niacin given in combination with statins has been used to treat homozygous FH. Niacin is available in immediate and slow-release forms (Niaspan, Slo-Niacin).

Dietary Additives and Supplements

Plant sterols and stanols consumed at levels of 2 g per day have been shown to reduce LDL cholesterol levels by 9% to 20% in adults.⁶⁶ Foods containing these additives (e.g., margarines and salad dressings) lower serum cholesterol by preventing dietary cholesterol absorption in the gastrointestinal tract.¹⁴⁵ In children with FH, use of 2 g/day of plant sterols decreased LDL cholesterol by 5% to 15%, but did not improve endothelial function.¹⁴⁶ This suggests that LDL cholesterol must be reduced to a certain threshold level before improvement of endothelial function can occur.

More studies examining the long-term effects of plant sterols on the vascular endothelium are warranted. Concern has been

raised about the potential for the malabsorption of fat and fat-soluble vitamins in children consuming plant sterols chronically.⁶⁶ The Expert Panel⁶⁴ recommends reserving the use of foods supplemented with plant sterols/stanols to children with moderate to severe elevation in cholesterol, and monitoring fat-soluble vitamin status.¹⁴⁰

Dietary supplements containing soluble fiber, garlic, and fish oils have been used to treat pediatric dyslipidemia with limited to moderate efficacy. In a randomized controlled trial, Davidson and colleagues studied the effect of psyllium fiber versus placebo on change in blood cholesterol levels of 6- to 18-year-old children with hypercholesterolemia.¹⁴⁸ Psyllium fiber (6 g/day) and the placebo were added to a ready-to-eat cereal. Compliance to treatment was excellent; consumption of the enriched cereal resulted in a modest 7% reduction in LDL cholesterol concentrations compared with the control cereal.

Garlic extract therapy was studied in a randomized controlled trial for effects on serum lipoproteins in 8- to 18-year-old children with FH.¹⁷² The extract was given in three daily doses of 300 mg versus a placebo for 8 weeks. No significant effects of garlic treatment versus placebo were noted on total, LDL, or HDL cholesterol.

Red yeast rice, a traditional Chinese culinary product, has been marketed to lower blood cholesterol. Although one pediatric trial showed significant LDL-C lowering with this product,¹⁷³ red yeast rice contains monacolin K, which is chemically identical to the cholesterol-lowering drug lovastatin. Therefore red yeast rice products may not be safe and are not recommended for children.

Omega-3 fatty acids, as found in fish oils, are known to reduce serum TG levels in adults.⁶⁶ In a randomized crossover study, children with FH and FCHL were supplemented with either 1.2 g/day of docosahexa-enoic acid (DHA) or a placebo for 6 weeks.¹⁵⁵ All children were given dietary counseling to reduce saturated fat intake to less than 7% of calories. Outcomes studied included TGs, LDL and HDL cholesterol, and endothelial function, as measured by FMD of the brachial artery. Findings showed that DHA supplementation was associated with increased levels of total, LDL, and HDL cholesterol, but no change in TGs compared with the placebo group. FMD improved significantly after DHA supplementation compared with baseline in both groups, and the change was greater in the DHA-treated group versus the controls. This finding suggests that in children, DHA may not be effective for positively modifying serum lipids. However, the endothelium may be a therapeutic target for DHA in hyperlipidemic children.

Low-Density Lipoprotein Apheresis

For children with homozygous FH and extremely elevated LDL cholesterol (>500 mg/dL), where LDL cholesterol cannot be reduced through the combination of diet therapy and multiple medication management, biweekly LDL apheresis has been used successfully to achieve significant lipid lowering, under the care of a lipid specialist. In this process, apoB-containing particles are selectively removed from the circulation through extracorporeal precipitation.¹⁷⁴ Apheresis reduced LDL concentrations up to 72% compared with maximal drug therapy in patients with homozygous FH. The procedure is FDA approved, and qualified medical sites that perform this procedure are listed on the National Lipid Association website (www.lipid.org).

CONCLUSIONS AND FUTURE DIRECTIONS

Increasing evidence indicates that extreme elevation in LDL cholesterol is associated with vascular pathology in youth. With new recommendations for universal screening of pediatric patients from the NHLBI Expert Panel, more patients with

significant hypercholesterolemia are likely to be identified. Fortunately, appropriate therapy is available to modify and potentially reverse vascular abnormalities. Pediatric clinical trials of lifestyle and drug therapy to treat dyslipidemia suggest similar effectiveness and safety to that observed in adults. Most studies, however, have been of short or medium term in design. Longer-term safety and efficacy studies are needed, particularly with follow-up of vascular end points. Also few clinical data are available to document at what age drug therapy should be appropriately and safely started. More work is needed in this regard to support clinical judgments on what age and dosage should be used in children at high risk for ASCVD.

 deficiency of
 causing hypocalcemia, 709t
 in infants, 754f, 755–756
 metabolism of, 239f
 repletion of, 241–242
- Vitamin D-dependent rickets type 1A (VDDR1A), 802t
- Vitamin D-interacting repressor, 221t
- Vitamin D receptor (VDR), 57–58, 221t, 223–226t, 227, 240, 242–245, 713, 802t
 calcitriol involvement with, 241–243
 genes regulating, 243–244, 244f
 mRNA, 242
 mutations in, 758f
- Vitamin D response element (VDRE), 221t, 242–243, 802t
- Vitiligo, 885t, 887t, 892–893
- VLDLs. *See* Very low density lipoproteins (VLDLs)
- V-Mak musculoaponeurotic fibrosarcoma oncogene family, protein B, 223–226t
- VMH, 944
- Voltage-gated calcium channel α 1, 223–226t
- Voltage-gated calcium channels, 220–226
- Volume regulation, physiology of, 357–368
- Volume sensor, effector pathways and, 364–368, 367f
- Von Hippel-Lindau (VHL) disease, 493f, 516–517
- V1 receptor (V1a KO), 362
- V3 (V1b) receptor, 362
- VTA. *See* Ventral tegmental area (VTA)
- W**
- WAGR/11p deletion syndrome, 968
- Water
 deprivation test, 369, 370f
- Water (*Continued*)
 metabolism disorders
 differential diagnosis of, 368–371, 370f
 specific disorders of, 371–383
- Weaver syndrome, 345
- Webbed neck, 628f, 634f
- Weight, 426–427
 of adrenal gland, 427f
 body
 glucose production *vs.*, 904–905
 gain, dysregulation, 949
 loss, dysregulation, 948–949
 at menarche, 578f
- Whipple's triad, 927
- White Addison disease (WAD)
 phenotype, 21–22
- Whole genome/exome sequencing, 21f
- Williams-Beuren syndrome (WBS), 732, 802t
- Williams syndrome transcription factor (WSTF), 221t, 242–243, 732, 802t
- WI-NAC, 243–244
- Wingless-type mouse mammary tumor virus (MMTV) integration site
 member 1, 223–226t
 member 9, 223–226t
- WNT4 gene, 117, 141
- WNT inhibitory factor 1, 223–226t
- WNT inhibitory factor (WIF), 221t
- Wnt signaling pathway, 248
 in bone mineralization, 248–249, 249–250f
- Wolcott-Rallison syndrome, 287
 etiology of, 287
 manifestations of, 287
 prognosis of, 287
 treatment of, 287
- Wolff-Chaikoff effect, 401
- Wolfram syndrome, 292, 862–863
- Wolman disease, 446–447, 464
- Women. *See also* Female reproductive system
 adolescent, bone deposition in, 259t
 mid-follicular phase, blood production rates in, 549t
- World Health Organization (WHO), 802t, 949, 956–957
- World Health Organization (WHO) Expert Committee on Biological Standardization, 1–2
- WSTF including nucleosome assembly complex (WINAC), 221t
- WSTF including nucleotide assembly complex (WINAC), 802t
- WT1 gene, 135
- WW domain-containing oxidoreductase (WWOX), 138–139
- X**
- X chromosome inactivation (XCI), 628–629
- X chromosomes
 diagnostic tests, 631–632
 differential diagnosis, 632–633
 genes, 628–631
 genomic imprinting, 631

- X chromosomes (*Continued*)
 genotype-phenotype associations,
 628–631
 and Turner syndrome, 628–631
 Xenotropic and polytropic retrovirus
 receptor (*XPR1*), 223–226*t*
XH2 gene mutations, 135–136
 X-LAG syndrome, 343
XLas, of *GNAS*, 717
 X-linked acrogigantism (X-LAG),
 513–514
 X-linked adrenal hypoplasia congenita,
 463
 X-linked congenital, diabetes insipidus,
 381, 382*f*
 X-linked dominant hypophosphatemic
 rickets (XLHR), 759, 802*t*
- X-linked hypophosphatemic rickets
 (XHR), 221*t*
 X-linked immunodysregulation,
 polyendocrinopathy, and
 enteropathy (IPEX), 462
 X-linked lissencephaly 2, 131
 X-linked recessive hypophosphatemic
 rickets (XLRH), 802*t*
 XX disorder of sex development/
 premature ovarian failure,
 139–141, 140*t*
 46,XX disorders, 136–137
 46,XX testicular disorder of sex
 development, 139
 45,X/46,XY mosaicism,
 131
 46,XY disorders, 136–137
- Y**
 Y chromosomes, patients with,
 647–648
- Z**
 Zearalenone. *See* Mycotoxin
 Zinc finger and ring finger protein 3
 (ZNF3), 139
 Zinc finger gene regulating apoptosis and
 the cell cycle (ZAC), 282
 Zinc finger protein, multitype 2 (ZFPM2),
 139
 Zona fasciculata, 36
 Zona reticularis, 36

ClinicalKey®

Confidence is ClinicalKey

Evidence-based answers, continually updated

The latest answers, always at your fingertips

A subscription to ClinicalKey draws content from countless procedural videos, peer-reviewed journals, patient education materials, and books authored by the most respected names in medicine.

Your patients trust you. You can trust ClinicalKey.

Equip yourself with trusted, current content that provides you with the clinical knowledge to improve patient outcomes.
