Foreword to the First Edition

The aim of the editor and contributors to this volume is to establish an effective bridge between the surging progress in biomedical science and the clinical practice of pediatric endocrinology. Half a century ago the biochemical elucidation of the structure and subsequent synthesis of steroid hormones provided the basis for a revolution in the diagnosis and treatment of a number of endocrine and nonendocrine disorders. That era was soon followed by a succession of fundamental discoveries: structure of peptide hormones, identification of releasing hormones from the brain, rapid and precise assay methods, and synthesis of peptide hormones by molecular biological techniques, to name but a few.

In no field has laboratory science been more effectively translated into clinical progress than in pediatric endocrinology.

A glance at the roster of contributors to this volume may well provide insight into why; many who are responsible for the dramatic advances in the laboratory also pursue active clinical careers.

This volume includes many new sections that were not presented in previous texts devoted to clinical pediatric endocrinology. It will serve as a valuable reference for family physicians, internists, pediatricians, and other health professionals, covering as it does the gamut of information from basic molecular biology to practical considerations in the diagnosis and treatment of pediatric endocrine disorders.

Solomon A. Kaplan, MD 1924-2017

Preface

PREFACE TO THE 5TH EDITION

In his foreword to the first edition in 1996, Solomon A. Kaplan, MD (1924-2017) stated “The aim of the editor and contributors to this volume is to establish an effective bridge between the surging progress in biomedical science and the clinical practice of pediatric endocrinology.” This has been the guiding principle of each edition and remarkably, the surging pace of progress in biomedical sciences remains unabated as does its application to pediatric endocrinology, justifying this updated and expanded fifth edition. Now, some 25 years later, a quarter century after the first edition, the vista of pediatric endocrinology is much expanded and vastly changed, especially by the application of molecular genetic techniques to the dissection of the etiology and potential remedy of congenital endocrine disorders. Although the disorder(s) manifest in childhood, adolescence, or even in adults, many have their origin in congenital or acquired genetic alterations, some possibly via environmentally induced epigenetic modifications.

To accommodate these changes, we have expanded the editorial team by including three outstanding physician-scientists as associate editors; each has made significant contributions to pediatric endocrinology in original research, leadership, and mentorship. We also introduced two new chapters dealing with maternal and fetal endocrinology in parturition and gender medicine, and included an expanded section on precision medicine in the chapter on “Molecular Endocrinology, Endocrine Genetics, and Precision Medicine.” Several of the chapters have entirely new authors, acknowledged leaders in their field, or new authors with expertise complementing established leader(s) in

the field; each chapter has been appropriately and often extensively updated, although it is possible that in this fast-moving era, the newest discoveries may have been published after finalized manuscripts were submitted. There also may be inadvertent errors that slipped by our careful attention; we apologize and thank those readers who brought them to our notice.

Nevertheless, we marvel at the vastly increased knowledge since the prior edition, and the changes in diagnostic and therapeutic armamentarium that have become available. For example, in childhood diabetes mellitus, closed-loop systems and continuous glucose monitoring are increasingly the norm in highly developed countries; glucagon-like peptide 1 agonists are approved for children with type 2 diabetes mellitus (T2DM); and gastric bypass surgeries are increasingly applied to adolescents with obesity and T2DM. Novelty abounds in each chapter, so we affirm that there is sufficient new material for both the serious student and/or the established endocrine practitioner/investigator to make this a “must have” book.

I have always considered that the editorship of this book is a great privilege, a labor of love well worth the enormous effort involved. On this occasion, I express my sincere thanks to the associate editors, Drs Majzoub, Menon, and Stratakis, who equally shared the work of editing and contributing. I extend sincere and warm-hearted thanks to all contributors; each of your contributions is highly respected and highly valued.

Acknowledgments

An enterprise of this nature requires the contribution and support of numerous individuals. I gratefully acknowledge the contributions of each of the authors, whose friendship and collegiality were—and continue to be—indispensable to bring this work to publication. Constructive critique was provided by colleagues, postdoctoral trainees, residents, and visiting scholars

to our departmental programs in endocrinology. A special thanks to Ms. Meghan Andress of Elsevier, whose experience, diligence, and patience enabled this project to move to timely conclusion. We express our thanks to Elsevier for giving us the privilege of editing this book.

HISTORICAL BACKGROUND

Endocrinology is a discipline of science that seeks to understand how chemical signals secreted by cells regulate the function of distant (endocrine) or local (paracrine) tissues, or even their own function (autocrine), to integrate vital processes of life, such as growth, reproduction, and metabolism (Fig. 1.1). Classical endocrinology derived from careful clinical observation such as, for example, the gigantism associated with pituitary tumors, or the characteristic bodily changes now known as *Cushing disease*, which is also associated with pituitary tumors; histology indicated the former was likely the result of a product made by “acidophilic cells,” whereas the latter was associated with the expansion of “basophilic cells.” The products of these acidophilic or basophilic cells had to traverse the bloodstream to reach their distant and often multiple targets. Hence these were internal (“endocrine”) secretions, unlike the chemical substances secreted into ducts leading to a target tissue, for example, salivary glands into the cheeks; pancreatic enzymes into the duodenum (“exocrine”). Cushing disease was associated with hypertrophy of the adrenal cortex and certain tumors of adrenocortical tissues mimicked the features of Cushing disease.¹ Therefore it was readily postulated that the pituitary secretes a substance that affects the adrenal glands and function; this substance was named *adrenocorticotrophic hormone (ACTH)* and it was deduced that the features of Cushing disease/syndrome were the result of a product or products from the adrenal gland. The destruction of adrenal tissue by tuberculosis or tumor was identified by Thomas Addison in 1855 and treatment of this entity with adrenal extracts, resulting in marked improvement, was first undertaken by William Osler in 1896.² However, the purification of these “internal secretions” began in earnest only at the turn of the 20th century with spectacular success, as reviewed by Dr. Delbert Fisher.² In the first quarter of the 20th century, epinephrine, thyroxine, insulin, and parathyroid hormone were purified, followed by the purification of the sex steroids from the ovary and testis, as well as

the pituitary and placental gonadotropins that stimulated the gonads to secrete sex steroids. These purifications required laborious chemical methods and the elucidation or measurement of their function required costly and cumbersome bioassays. For example, the assay of the potency of insulin, discovered in 1921, required the use of rabbits; the definition of 1 international unit (IU) of insulin was assigned to be the amount of insulin that lowers the blood glucose of a healthy 2-kg rabbit, fasted for 24 hours, to 45 mg/dL or less, within 5 hours of injection. Clearly, such potency estimates reflected the relative crudeness of the purification; today’s pure recombinant human insulin possesses approximately 29 IU/mg, whereas the potency of porcine insulin in the early 1980s was around 23 IU/mg and likely less at the dawn of insulin therapy for diabetes mellitus. The bioassay of pure human insulin preparations has been abandoned; the purity of human insulin permits insulin to be now standardized as “one international unit of insulin (1 IU) is defined as the biological equivalent of 34.7 µg pure crystalline insulin.” It should be noted that 1 IU for insulin is not part of the International System of Units of the modern metric system, but is the pharmacologic International Unit as defined by the World Health Organization (WHO) Expert Committee on Biological Standardization. In addition to their cumbersome nature, the lack of sensitivity in the early bioassays prohibited the ability to measure insulin in normal blood or other biologic fluids; refinements, such as measuring the incorporation of labeled glucose into the fat pad or diaphragm of a rat, represented only an incremental improvement.³ Similarly, growth hormone (GH), isolated in 1944, was initially bioassayed by its ability to increase the width of the tibia growth plate in rats, after a defined period of injections, and by comparing the unknown relative to a dose response of known concentrations administered *in vivo*.⁴ Attempts to improve sensitivity and specificity led to the “sulfation factor-somatomedin hypothesis” (Fig. 1.2), in which it was postulated that GH leads to the generation of a second substance, derived from the liver, which mediates the growth-promoting (somatotropic) effects and hence was named *somatomedin*.^{4,5} Subsequent studies demonstrated that this somatomedin substance was identical to a factor in serum which had insulin-like properties *in vitro*, and this insulin-like effect was retained even after all insulin was “quenched” by an excess of antibodies specific for insulin. The convergence of these two pathways eventually led to the discovery of the factor now known as *insulin-like growth factor (IGF)-1* and later as well as IGF-2 and a family of binding proteins that acted as carriers of the hormones in serum but also possessed biologic properties of their own, by which the actions of the IGFs were mediated and modulated.^{5,6} Despite these early bioassay limitations, the scientific curiosity of these chemical substances that regulated functions as diverse as blood pressure (epinephrine, cortisol), water metabolism (arginine vasopressin, cortisol), growth (GH, sex steroids, thyroid hormone), glucose (insulin, cortisol), and reproduction (sex steroids, follicle-stimulating hormone [FSH], luteinizing hormone [LH]), spurred the formation of medical societies focused on

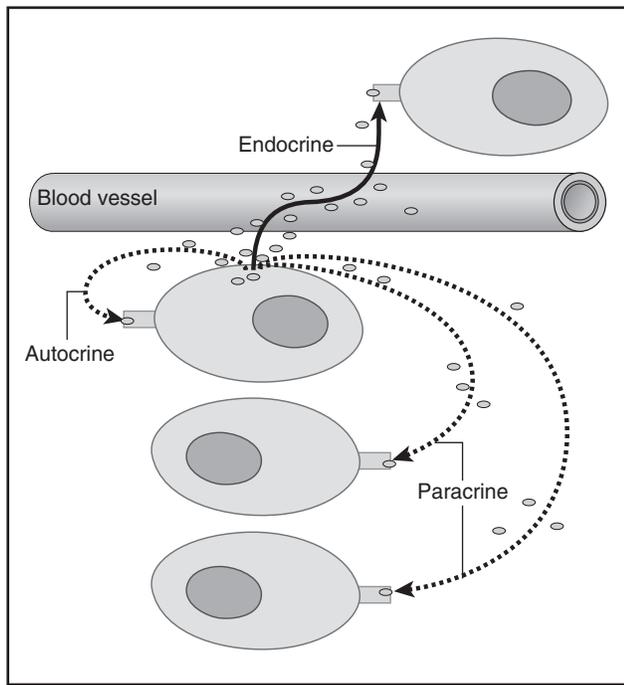

Fig. 1.1 Cellular signaling. Chemical signals synthesized and secreted by cells, may be released into the bloodstream to be distributed to target cells with specific capability to respond to the signal. These blood-borne chemicals constitute classical endocrine signals, also known as “*internal secretions*,” to distinguish them from the chemicals secreted into a duct that leads directly to another organ (e.g., pancreatic enzymes destined for the duodenum via the pancreatic duct [“*exocrine*”). However, the same cell may release the chemical that then affects nearby cells without traversing the bloodstream (these are known as *paracrine effects*) or act on a receptor on its own surface to modify the cells own functions (autocrine). (From King, T.C. (2006). *Elsevier’s Integrated Pathology*. Philadelphia: Mosby, Fig. 3.6.)

endocrine diseases. As detailed in the article by Fisher from which the following historical aspects are quoted,² the Association for the Study of Internal Secretions was established in 1918 in the United States and renamed the Endocrine Society in 1952.

Pediatric endocrinology began as a subspecialty only in the 1940s with the establishment of endocrine clinics at the Massachusetts General Hospital and at Johns Hopkins. These programs attracted postdoctoral trainees who then established their own pediatric endocrine units in the burgeoning growth of academic medical centers in the 1950s and 1960s. In the United States, the Pediatric Endocrine Society, initially named the *Lawson Wilkins Pediatric Endocrine Society (LWPES)*, was formed in 1972 and established as a subspecialty by the American Board of Pediatrics, with its first certification examination in 1978; there are more than 1000 board-certified pediatric endocrinologists today in the United States. The European Society for Pediatric Endocrinology was formed in 1966, followed by the Japanese Society for Pediatric Endocrinology in 1967 and the British Pediatric Endocrine Group in 1972, all preceding the LWPES in the United States. Several other regional pediatric endocrine groups were formed, including the Australian Pediatric Endocrine Group, the Sociedad Latino Americana de Endocrinología Pediátrica, and the Asia Pacific Pediatric Endocrine Society. All of these groups now meet jointly every 4 years at an International Pediatric Endocrine Congress.²

IMPACT OF HORMONAL ASSAYS AND MOLECULAR BIOLOGY

Two discoveries revolutionized the field of endocrinology and led to an explosion of basic, as well as clinically relevant, therapeutic knowledge in the second half of the 20th century. The first was the development of radioimmunoassay by Yalow and Berson, reported for insulin in 1960.⁷ Here was a method for measuring the low concentrations of a hormone, using as little as 10 to 50 μL of a biological fluid in an accurate, reproducible way, with precision and sensitivity adequate for *in vivo* studies in humans or other species, as well as *in vitro* studies, such as the regulation of insulin secretion by nutrients, hormones, ions, and pharmaceutical agents in whole animals, including humans, *in vivo*, or in isolated perfused pancreas, or in isolated islets. This was followed by the rapid development of assays for various hormones and an explosion of discovery, including the distinction between absolute and relative insulin deficiency as the difference between “juvenile” and “maturity onset” diabetes now known respectively as *Type 1 DM* and *Type 2 DM*, the regulation of GH secretion in normal individuals at different ages and in clinical disorders of growth, the changes in thyroid function at birth and the possibility of screening for neonatal hypothyroidism, and the changes in gonadotropins and sex hormones during the process of normal and abnormal puberty and later in aging. The discovery and purification of the hypothalamic-releasing hormones for thyroid-stimulating hormone (TSH), FSH/LH, GH, and ACTH were made possible by these precise assays using (rat) pituitary cells, perfused by protein fractions derived from the hypothalami of animals.⁸ The discovery that a hormone produced in a cell could affect the function of its neighboring cell(s), without traveling through the bloodstream (paracrine action) or even its own function (autocrine), was also enabled by the use of these sensitive and precise tools, expanding our concepts of a hormone as a chemical messenger that influences, directs, and coordinates cellular functions throughout the body (see Fig. 1.1). Similar principles enabled the identification of the receptor molecules at the cell surface or in its cytoplasm that permit the hormone signal to be transduced to a message for turning biological processes on, or off, in specific tissues.⁹ Refinements using the principles of radioimmunoassay (RIA), but without radioactivity, as well as newer techniques of liquid chromatography coupled with mass spectrometry, are the bases of modern laboratory methodologies for hormone measurement, as well as for other chemical substances, such as drugs; examples of modern application of these methods, as well as the pitfalls in performance and interpretation, are reviewed in Chapter 4. How these hormonal signals elicit a specific response after recognition and binding to a specific cell surface or cytoplasmic receptor, and the subsequent cascade of events known as the *signal transduction pathways* and their relevance to pediatric endocrinology are discussed in Chapter 3. The notion that a hormone may not be capable of eliciting a response, despite high concentrations, was implicit in the entity labeled *pseudohypoparathyroidism* by Dr. Fuller Albright,¹⁰ but receptors and their signal transduction pathways were only systematically investigated beginning in the 1970s. These systematic studies, still ongoing,⁹ continue to identify the mechanistic pathways by which a hormone, after binding to its receptor, may elicit a response in one tissue but not in another. There may be other reasons why a hormone does not elicit an appropriate tissue response despite apparent high concentrations in the circulation. For example, an abnormal sequence in a hormone may prevent its full action at the receptor, and feedback control increases the hormone’s secretion, leading to high concentrations of partially functioning hormone with only minor or moderate impairment of function. Examples of such abnormalities include disorders of

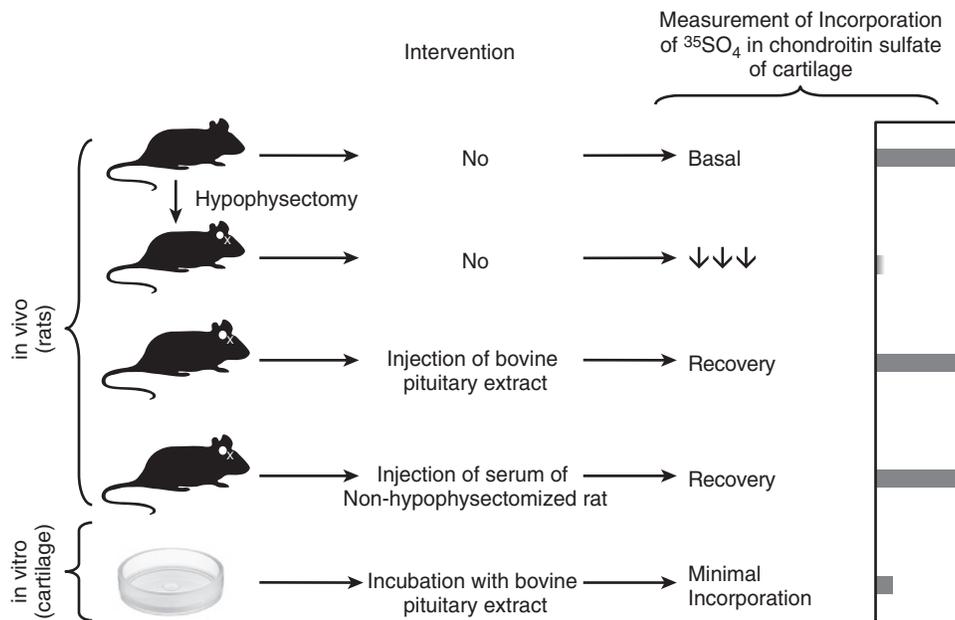

Fig. 1.2 “Sulfation factor” assay of growth hormone. The bioassay of growth hormone (GH) consisted of administering graded doses of bovine GH, with potency approximately 1.25 U/mg, via daily subcutaneous (SC) injections, for 4 days, to young, growing, prepubertal rats (approximately 31 days) that had been hypophysectomized 10 days previously. Approximately 5 animals per group and about 5 doses (0 plus 4 graded increments) were used to construct the “dose–response curve” of the increase in the width of the tibia growth plate; the unknown was 2 to 3 mL of plasma also administered SC to approximately three to five animals per test dose. The sulfation assay was an attempt to refine the technique by examining the dose–response relationship between the incorporation of $^{35}\text{SO}_4$ into chondroitin sulfate in vivo, or in vitro into uniformly prepared cartilage rings obtained from young rats. As shown in the figure, the in vivo component examined basal activity of the animal’s serum on the amount of radioactivity incorporated in vivo. Hypophysectomy almost completely abolished this ability to stimulate $^{35}\text{SO}_4$ incorporation, but injection of bovine pituitary extract or serum from a normal not hypophysectomized animal, restored this activity. However, in vitro incubation of cartilage rings with bovine pituitary extract resulted in only minimal incorporation. Thus it was proposed that GH acted on an internal organ to produce the “sulfation factor.” The sensitivity of these assays was, at best, in the 1 to 10 $\mu\text{g}/\text{mL}$ range, and precision and reproducibility were poor (Tweed, D.C., McCullagh, E.P. (1962). Assay of growth hormone-like activity in blood plasma: a comparison of two methods. *Clin Chem*, 8, 141–150; also see references 4 and 5). Today’s immunoassays permit measurement of plasma concentrations of GH with 1000-fold greater sensitivity than these early bioassays (ng/mL compared with $\mu\text{g}/\text{mL}$ previously mentioned) with high degrees of precision and reproducibility (see Chapter 4). (The author is indebted to Oscar Escobar, MD, Associate Professor, Department of Pediatrics, University of Pittsburgh School of Medicine, Division of Pediatric Endocrinology, Children’s Hospital of Pittsburgh, for creating this figure and granting permission for its use in this chapter.)

proinsulin conversion to insulin.¹¹ and OMIM #616214 Depending on the site of the abnormality in cleavage of proinsulin, both the measurement of insulin and proinsulin or its cleavage product C-peptide, may demonstrate higher than normal values that could be interpreted as “insulin resistance.” These studies also recognized that an activating mutation in a receptor will mimic the action(s) of a hormone, although the hormone concentration may be barely detectable, as exemplified by the precocious puberty in McCune-Albright syndrome or by an activating mutation of the LH receptor in males, which results in precocious puberty with high testosterone, but paradoxically very low concentrations of LH, an entity named *testotoxicosis* (see Chapter 18). In contrast, loss of function mutations cause the same clinical syndrome as hormone deficiency, even though the hormone concentration is markedly increased compared with normal, as exemplified in Laron syndrome, with poor growth and low IGF-1 concentrations, despite high circulating growth hormone concentrations (see Chapter 11). Thus the concentration of a hormone may not be directly related to its action. In summary, it is the ability to measure hormones, as well as intermediary molecules and metabolites, such as cyclic adenosine monophosphate at low concentrations (e.g., picomolar to nanomolar), in small volumes of biological fluids that enabled the rapid proliferation and understanding of endocrine regulation and function. It may be difficult for any reader who was not brought up in the era of bioassays to fully

appreciate the impact of the application of the tool of RIA and its modifications, as various competitive protein binding assays without radioactive markers, to modern endocrine concepts and practice. The theoretical basis for the competitive binding assays, pitfalls in their interpretation, and their application to studies of receptor–ligand interactions are detailed in Chapter 4.

The second revolution built on the discovery of the double helix by Crick, Watson, and Wilkins, a discovery for which they received the Nobel Prize in 1962. This discovery and its ongoing offspring propelled the ability to identify the molecular basis of cell function, the genes that regulate these processes, and the genetic mutations that underlie congenital or acquired disorders, including those of the endocrine system. Pediatric medicine is a particular beneficiary of these techniques because congenital malformations of the endocrine glands, the abnormalities of hormone signaling, as a result of defective hormone synthesis, hormone processing or receptor function to recognize and act on the hormonal signal are at the core of pediatric endocrinology, as reflected in this book. Chapters 2 and 3 provide an overview of the molecular and genetic methodologies applied in practice and research and also discusses the pitfalls in interpreting the results of genetic mutational analyses. This is a rapidly evolving field powered by the newer sequencing technologies (collectively termed *next-generation sequencing* [NGS]). These technologies enable the sequencing

of deoxyribonucleic acid (DNA) and ribonucleic acid much more quickly and cheaply than the previously used Sanger sequencing, and in concert with the ability to store and analyze huge data sets via computers have revolutionized the study of genomics and molecular biology and the direct clinical application of this knowledge. For example, whole exome sequencing and whole genome sequencing is increasingly being applied and is becoming part of established medical diagnostic practice in several situations, for example, neonates with multiple congenital malformations or metabolic disturbances in the newborn intensive care unit.^{12–14} Use of fetal DNA in maternal cell free plasma is becoming the standard for antenatal diagnosis of aneuploidy, without the need for invasive screening procedures, such as amniocentesis or chorionic villous sampling, and has been used to diagnose congenital adrenal hyperplasia in at-risk pregnancy of heterozygote carriers of this disease.^{15,16} NGS allows prompt genetic diagnosis of different mutations responsible for a specific disease or syndrome complex, for example, Neonatal Diabetes Mellitus, so that remedial treatment can be expeditiously provided,¹⁷ thereby altering what has hitherto been considered the natural history of the particular disorder. Direct therapeutic applications, such as, for example, choice of drug for maximum effectiveness, while avoiding drug interactions or excluding drug sensitivity, are also being explored. Gene therapy¹⁸ and gene editing¹⁹ for pediatric endocrine disorders are on the horizon and some show promise, but with many practical and ethical issues still to be resolved, as discussed in Chapters 2 and 3.

UNIQUE ASPECTS OF PEDIATRIC ENDOCRINOLOGY

Fetal Origins of Adult Disease

Pediatrics is all about growth and development of each aspect of human life—physical, emotional, cognitive, and sexual—from conception through birth, neonatal adaptation, infancy, childhood, puberty, and young adulthood. Changes in the mature organism continue, but the tempo is considerably slower than the rapid changes of early life. The endocrine system plays a central role in these adaptations and changes. It has long been known that environmental insults, such as viral infections (rubella, herpes, human immunodeficiency virus [HIV], cytomegalovirus, Zika) or drugs or other chemicals (thalidomide, phenytoin, alcohol), particularly in the first trimester, can result in distinct patterns of embryopathy. Only fairly recently has it been appreciated that developmental plasticity is influenced by the intrauterine nutritional environment that may predispose to the later development of diseases, such as type 2 diabetes. The notion that lack of nutrients during critical periods of development impart subsequent greater risk for development of adult diseases, such as hypertension, stroke, coronary disease, and diabetes emanated from careful epidemiologic observations of cohorts, such as those of the Dutch famine toward the end of the second world war²⁰ and a British cohort of citizens with health records from birth to death.²¹ The former documented that the effects of the famine appeared to depend on its occurrence during gestation, early gestation being the most vulnerable period, with effects on schizophrenia, depression, atherogenic lipid profile, and with an increased rate of hypertension and coronary heart disease later in life.²⁰ The latter demonstrated that a limited supply of nutrients, as reflected in intrauterine growth restriction, even in the absence of frank famine, could permanently alter the metabolism and other physiologic aspects in later adult life, including stroke and diabetes.²¹ Moreover, these effects could persist into future generations, suggesting modifications of the genome, giving rise to the concept of fetal origins of adult disease, as proposed

by Barker.²¹ As a hypothesis, the “fetal origins of adult disease” is now well supported by epidemiologic and experimental data,^{20–28} including the epigenetic modification of gene expression, via patterns of methylation or other modifications, some affecting the expression of genes regulating insulin secretion, cortisol, and other hormones.²⁹ These interactions are not restricted to early development—they may occur in the third trimester or beyond,^{30–33} but once “imprinted,” they may be passed on to succeeding generations. Thus the intrauterine and peripartum environment may permanently modify the expression of genes, including those of the endocrine system.^{30,33}

Acquisition of Patterns of Hormone Secretion and Action

At any given time, the plasma concentration of a hormone reflects its synthesis, secretion, and clearance, a concept that implies removal from the circulation in units of time. Indeed, the relationship between the production rate (PR) of a hormone (units/time), the serum or plasma concentration ($C = \text{units/mL}$), and its metabolic clearance rate (MCR) from the plasma (mL/time) is defined by the formula $PR = MCR \times C$, so knowing any two of these three variables permits one to solve the third. However, the concentration of a hormone may vary depending on such factors as time of day, stages of sleep, stage of puberty, renal or hepatic function, and the ingestion of other drugs. Hence each of these aspects represents complex interactions. For example, the secretion of ACTH and the chief product of its action, cortisol, are related in phase, the former preceding the latter and being highest in the early morning and lowest toward midnight. ACTH synthesis may have a basal rate determined by the impulses from its hypothalamic-releasing hormone, known as *corticotropin-releasing hormone (CRH)*, but both display a diurnal rhythm entrained by the light/dark cycle and relayed to the suprachiasmatic nucleus of the hypothalamus. As the fetus is not exposed to light/dark cycles and the newborn spends a majority of time asleep, it is important to know when the diurnal rhythm becomes established.^{34–37} This has importance for undertaking measurements of cortisol in the newborn to determine if the hormone is deficient, as, for example, in evaluating newborn hypoglycemia. Also, stress results in a rapid increase in the CRH-ACTH-cortisol axis and the secretion of cortisol. Such rapid adaptation is essential for the appropriate adjustments to physiologic stress resulting in the “fight or flight response.” It is known that the hypothalamic pituitary adrenal axis is established in utero and functional because inborn errors of metabolism, such as those found in congenital adrenal hyperplasia as a result of defects in enzymes responsible for cortisol synthesis, result in markedly elevated ACTH in utero, with hypertrophy of the adrenal cortex. However, after birth, there is a brief period during which adrenal secretion of cortisol is low, as reflected in the plasma levels,³⁶ and it is not known how rapidly the newborn can adjust to a stressful situation by appropriate increments in the ACTH-cortisol secretion rates.³⁷ Some hormonal cycles, such as GH secretion and FSH/LH secretion at the onset of puberty, are related to sleep rather than the light/dark cycle, as discussed for GH⁵ and separately for the gonadotropins in the relevant chapters of this book. But it is not known if these sleep-regulated patterns are operative in the newborn. Following birth, some inhibitory pathways of hormone secretion are not yet established, resulting in high hormone concentrations whose functional significance is not known. For example, inhibition of GH secretion by somatotropin release-inhibiting factor appears to develop only after birth, so that GH concentrations in serum are quite high in the newborn (averaging approximately

40 ng/mL), values that would be consistent with acromegaly in an adult.^{38,39} On the other hand, the expression of GH receptors on tissues and their linkage to postreceptor events is delayed and become fully operational only after several months, so that the effects of the high GH concentrations are muted.^{39–41} The practical implications of these findings are that GH deficiency in a full-term newborn will not be characterized by discernible small size at birth. Indeed, GH deficiency does not become manifest in a delayed growth velocity, until after 3 to 6 months when the GH–growth hormone receptor axis becomes established.^{39–41} Yet GH plays an important role in maintaining glucose homeostasis in the newborn, because GH deficiency may be associated with hypoglycemia, and this deficiency can be diagnosed without the need for stimulation tests if the GH concentration is lower than 10 ng/mL in the first week of life of a full-term newborn. Another hormone whose concentrations remain very high at birth and for several weeks thereafter is prolactin, presumably because the neurologic pathways responsible for dopamine secretion are not yet fully developed.³⁹ The physiologic implications of these adaptive processes in the secretion and action of prolactin in the newborn are not fully understood.³⁹

Adaptations in Endocrine Function at Birth

Separation of the newborn baby from its maternal blood supply after birth imposes a near-instantaneous need for adaptations in functions, such as the requirements of oxygen, maintenance of body temperature, and sources of nutrients. The endocrine system plays a vital role in several of these adaptations; three are briefly described here and are explored in more detail in relevant chapters in this book.

Maintenance of Body Temperature

The hypothalamic-pituitary-thyroid axis is intimately involved in the adaptations of body temperature regulation. The fetus, bathed in amniotic fluid and supplied by maternal blood, maintains a temperature of 37° C in utero. Delivery into an ambient temperature of approximately 20° to 25° C in a modern delivery room represents a significant fall in ambient temperature that contributes to activation of thyroid function. The concentration of TSH increases approximately 10-fold between birth and 15 to 30 minutes after cutting of the umbilical cord, to values of approximately 100 μ U/mL. Simultaneously, type 2 deiodinase is activated, converting thyroxine (T_4) to triiodothyronine (T_3) rather than the fetal pattern of type 3 deiodinase that converts T_4 to reverse T_3 . These rapid changes result in a surge of T_3 concentration, a decline in reverse T_3 concentration, and a somewhat later rise of T_4 concentration in the newborn's blood. Together, these coordinated changes in thyroid function enable T_3 to act on brown adipose tissue to activate nonshivering thermogenesis. Although TSH concentrations decline to values below 10 μ U/mL by day 2 to day 3 of life, T_3 and T_4 values remain elevated for days to weeks at concentrations that would be consistent with thyrotoxicosis in older children and adults (see Chapter 8 for details). Hence values of thyroid function reported for full-term or premature newborns must be reported as age specific; they may often be labeled erroneously as *hyperthyroid* in laboratories that only list reference values suitable for adults. Not only do premature babies have thyroid hormone-related concentrations that are lower than those of full term infants, but the acute stresses of prematurity, such as sepsis or respiratory distress syndrome, may lead to the "euthyroid sick syndrome" and further complicate the interpretation of thyroid function tests, as discussed in Chapter 8.

Glucose Homeostasis

The fetus obtains all of its glucose via placental transfer from the mother, with little, if any, endogenous glucose production until delivery. Following cord cutting, epinephrine and glucagon each rise approximately three- to five-fold, growth hormone is high at approximately 40 ng/dL (as mentioned previously), as are cortisol values, which are highest at about 2 hours after birth and, on average, remain in the range of 2.7 to 7.6 μ g/dL, mostly in the free form, in the first week of life.^{39,42–44} The coordinated effects of these four classic "counterregulatory" hormones, together with a small fall in insulin, stem the initial decline in blood glucose concentration, activate glycogen breakdown and gluconeogenesis, and initiate lipolysis with later activation of ketone body production by day 2 to day 3 of life.^{42–44} Understanding these critical adaptations is essential for the appropriate management of hypoglycemia in a newborn, as detailed in Chapter 7. All hormonal measurements must be age specific; a common problem with hypoglycemia in the newborn is the range of normal fasting insulin values from an adult reference range, generally in the range of 5 to 29 μ U/mL. A newborn with hypoglycemia who at the time of hypoglycemia has an insulin value greater than 5 μ U/mL likely has some form of genetic or acquired hyperinsulinism.

Gonadotropins and Sex Hormones

In males, testosterone concentrations on day 1 of life are high, ranging from 75 to 400 ng/dL, values that are consistent with Tanner stages 3 to 4 of male puberty. These high concentrations decline rapidly within the first few days after delivery but remain elevated at 20 to 50 ng/dL compared with males aged 1 to 10 years, in whom values are less than 10 ng/dL. A second rise in testosterone concentrations occurs between 1 week and 1 to 2 months, the mean values being approximately 200 ng/dL. Both FSH and LH also are relatively high in males at this age of life and decline to prepubertal levels only at about the end of the first year. In females, concentrations of estradiol are markedly elevated after birth and fall rapidly during the first week of life to prepubertal values, with a secondary rise occurring between 30 and 60 days followed by decline to prepubertal concentrations after 1 to 2 years. Values of FSH may range up to 14 mIU/mL in females and decline more slowly than in males, reaching prepubertal values only after 2 to 3 years. Likewise, LH values in females may be in the classical pubertal range in the first few months of life and decline to prepubertal values only after 1 to 2 years. This so called *minipuberty of infancy* is discussed in greater detail in Chapters 6, 16, and 18. A precise function for these perinatal changes in sex hormones and gonadotropins is unknown, but it has been proposed that they may have relevance to developmental patterning of male or female neural function. In addition, clinical relevance is related to the common problem of thelarche in newborn-infant females, as discussed in Chapter 16.

In summary, each of the major endocrine organs and systems undergo dramatic neonatal adaptations, so that knowledge of these endocrine adaptations following birth is essential for the appropriate evaluation of suspected abnormalities in endocrine function, and the interpretation of age- and sex-specific values of circulating hormones or other metabolic variables. A major deficit in healthcare systems is the application of standards of normal ranges for hormones or other biochemical indices derived from adult reference ranges to the newborn and infant; values must be relevant to the age- and sex-specific situation being evaluated.

EVALUATING ENDOCRINE DISORDERS IN INFANCY AND CHILDHOOD

A general principle of pediatric endocrinology is that the earlier the manifestation of either underactivity or excess hormone function, the more likely the cause is to be a genetic disorder, together with possible structural abnormalities. For example, the entity of septooptic dysplasia with underactivity of anterior and/or posterior pituitary function may be associated with typical structural abnormalities of optic nerve hypoplasia, absence of the septum pellucidum or corpus callosum, a small anterior pituitary, interruption or absence of the pituitary stalk, and an ectopic or absent posterior pituitary bright spot on magnetic resonance imaging (MRI) of the brain.^{45,46} In the majority of these patients, no genetic abnormality can be detected. However, mutations in three genes (*HESX1*, *OTX2*, and *OX2*) that play a role in the embryonic development of the pituitary gland, eyes, and forebrain, have been identified in a small subset of these patients.^{45,46} Hypothyroidism found on newborn screening is most commonly associated with an ectopic thyroid gland; total absence or goitrous hypothyroidism should suggest a defect in the genes responsible for thyroid gland formation (*TTF-1*, *TTF-2*, *PAX8*) or an “inborn error of thyroid hormone synthesis”⁴⁷ (see Chapter 8). To be sure, perinatal events and maternal illness or medication must be considered. For example, perinatal asphyxia or a difficult delivery may be associated with later evidence of hypopituitarism. Maternal ingestion of antithyroid medications would result in their transfer across the placenta and may cause transient neonatal hypothyroidism, as these agents affect the fetal thyroid in the same way as they affect the maternal thyroid gland. Similarly, transfer of immunoglobulin G antibodies that block or stimulate thyroid function will result in newborn hypothyroidism or hyperthyroidism that lasts for several weeks, until maternal antibodies are cleared from the circulation. A newborn with severe hyperthyroidism in the absence of any evidence of autoimmune disease in the mother almost certainly has an activating mutation of the TSH receptor⁴⁸ (see Chapter 8).

More subtle defects in endocrine function may appear later in childhood, but still have a genetic basis, for example, hypogonadotropic hypogonadism. This entity may be considered at birth in male infants because of underdeveloped penile and testicular size, but often does not become manifest or discovered until delayed puberty is investigated.⁴⁹ Macrosomia in an infant born to a mother with poorly controlled diabetes mellitus reflects secondary hyperinsulinism in the fetus, with hypoglycemia in the newborn when the maternal supply of glucose is curtailed. However, similar features in a baby born to a healthy young mother should immediately suggest the possibility of a genetic form of hyperinsulinism, most commonly the result of an inactivating mutation in the genes regulating the adenosine triphosphate (ATP)-regulated potassium channel (K_{ATP}).^{50–52} If the biochemical profile and clinical course are consistent with hyperinsulinism, but insulin concentrations are low, consider an activating mutation in the insulin receptor signaling pathway. Conversely, significant intrauterine growth retardation may be caused by many factors and is a major feature of neonatal diabetes mellitus, so early diagnosis via measurement of glucose may be lifesaving by providing insulin or sulfonyleurea drugs, to which some 90% of newborns with activating mutations of the *KCNJ11* gene respond with improved endogenous insulin secretion and restoration of near normal glucose metabolism⁵³ and as discussed in detail in Chapter 10. Severe intrauterine growth retardation also is a feature of inactivating mutations in insulin receptors, for example, Donohue syndrome or Rabson-Mendenhall syndrome.⁵⁴ Defects in the secretion or action of IGF-1 mimic the effects of insulin

secretion or action, both hormones and both receptors being structurally, as well as functionally related.^{55,56}

Autoimmunity, trauma, and chemo/radiotherapy for a childhood malignancy are the most common causes of acquired endocrine disorders. Thus as in all of medicine, a careful and thorough history, careful physical examination, and targeted investigation of hormonal measurements (taking into consideration age, time of day, and the value of obtaining a “free” hormone versus total hormone measurement) form the basis of the diagnostic approach. This may be followed by imaging of the suspected organ involved to diagnose the basis of the suspected endocrine dysfunction, in the particular patient being investigated. Increasingly, molecular diagnostics is becoming an integral component of this evaluation, both to establish the cause of the entity and to provide guidance for prognosis, such as multiple endocrine neoplasia 2 (see Chapter 15).

Definitive diagnosis may require stimulation tests (e.g., for growth hormone deficiency or with ACTH for suspected adrenal insufficiency) because a single random value is not sufficiently informative. Such stimulation tests are an integral and essential component of diagnosis and management of endocrine disorders at any age but particularly in the pediatric age range, where performance of the test must take into consideration its safety, easing anxiety and correct sample handling.

Finally, modern biology has provided pure synthetic compounds to replace what may be missing, such as thyroid hormone or cortisol, administration of pulsatile gonadotropin-releasing-hormone (GnRH) for syndromes of hypogonadotropic hypogonadism via programmable pumps, GnRH analogues for suppressing puberty, growth hormone for GH deficiency or other forms of approved short stature, various insulin preparations with ultrashort, short, intermediate, long-acting and ultralong acting forms for managing diabetes, and ultralong-acting somatostatin for childhood acromegaly as occurs in Carney complex,⁵⁷ or some patients with McCune-Albright syndrome.⁵⁸ Hormone replacement must also take into consideration administration via the dermal rather than the oral route to avoid “first pass” considerations in bypassing the liver, as, for example, giving sex hormones, such as estrogen to females with delayed puberty, including Turner syndrome (see Chapters 16 and 17).

CONCLUDING REMARKS

Endocrinology is the science of cellular communication that enables the biochemical integration of life’s vital processes. Pediatric endocrinology is the linchpin for these processes during the developmental epoch from fetus to mature adult. Evolving developments in molecular biology, bioinformatics, pharmacogenetics, and bioimaging will ensure that this specialty remains at the forefront of pediatric research and practice. This chapter is intended as an introduction to this important field, with greater detail to be found in the chapters that follow. Much has been learned since the prior edition of this chapter in 2014 and some of this newer knowledge is incorporated here; much remains to be learned.

INTRODUCTION

The study of the endocrine system has undergone a dramatic evolution since the 1990s, from the traditional physiologic studies that dominated the field for many years to the discoveries of molecular endocrinology and endocrine genetics.^{1,2} At the present time, the major impact of molecular medicine

on the practice of pediatric endocrinology relates to diagnosis and genetic counseling for a variety of inherited endocrine disorders. In contrast, the direct therapeutic application of this new knowledge is still in its infancy. Endocrine oncology has greatly benefited from the application of new drugs that were designed to target specific mutations in, for example, thyroid cancer. A notable recent therapeutic advancement that followed the identification of the molecular basis of an endocrine disorder is the development of monoclonal antibody biosimilars directed against the fibroblast growth factor-23 protein to treat X-linked hypophosphatemic rickets. This chapter is an introduction to the basic principles of molecular biology, common laboratory techniques, and some examples of the recent advances made in clinical pediatric endocrinologic disorders with an emphasis on endocrine genetics. Most new diagnostic testing, pharmacogenetics, and molecular therapies are discussed in the disease-specific chapters of this book, and only examples that highlight the principle/strategy under discussion are discussed in this chapter.

BASIC MOLECULAR TOOLS

Isolation and Digestion of DNA and Southern Blotting

The human chromosome comprises a long double-stranded helical molecule of deoxyribonucleic acid (DNA) associated with different nuclear proteins.^{3,4} As DNA forms the starting point of the synthesis of all the protein molecules in the body, molecular techniques using DNA have proven to be crucial in the development of diagnostic tools to analyze endocrine diseases. DNA can be isolated from any human tissue, including circulating white blood cells. About 200 µg of DNA can be obtained from 10 to 20 mL of whole blood, with the efficiency of DNA extraction being dependent on the technique used and the method of anticoagulation used. The extracted DNA can be stored almost indefinitely at an appropriate temperature. Furthermore, lymphocytes can be transformed with the Epstein-Barr virus (or other means) to propagate indefinitely in cell culture as “immortal” cell lines, thus providing a renewable source of DNA. For performing molecular genetic studies, transformed lymphoid lines are routinely the tissue of choice, because a renewable source of DNA obviates the need to obtain further blood from the family. Fibroblast-derived cultures can also serve as a permanent source of DNA or ribonucleic acid (RNA) (once transformed), but they have to be derived from surgical specimens or a biopsy. It should be noted that, because the expression of many genes is tissue specific, immortalized lymphoid or fibroblastoid cell lines cannot be used to analyze the abundance or composition of messenger RNA (mRNA) for a specific gene. Hence, studies involving mRNA necessitate the analysis of the tissue(s) expressing the gene, as outlined in the section on “RNA Analysis.” More recently, the problem of limited amounts of DNA obtainable from certain sources has been circumvented by the utilization of the polymerase chain reaction (PCR), a versatile way to faithfully multiply segments of the original DNA.

DNA is present in extremely large molecules; the smallest autosomal chromosome (chromosome 22) has about 50 million base pairs and the entire haploid human genome is estimated to comprise 3 to 4 billion base pairs. This extreme size precludes the analysis of DNA in its native form in routine molecular biology techniques. The techniques for identification and analysis of DNA became feasible and readily accessible with the discovery of enzymes termed *restriction endonucleases*. These enzymes, originally isolated from bacteria, cut DNA into smaller sizes on the basis of specific recognition sites that vary from two to eight base pairs in length.^{5,6} The term *restriction* refers to the function of these enzymes in bacteria. A restriction endonuclease destroys foreign DNA (such as bacteriophage DNA) by cleaving the DNA at specific sites, thereby “restricting” the entry of foreign DNA in the bacterium. Several hundred restriction enzymes with different recognition sites are now commercially available. Because the recognition site for a given enzyme is fixed, the number and sizes of fragments generated for a particular DNA molecule remain consistent with the number of recognition sites and provide predictable patterns after separation by electrophoresis.

The analysis of a few hundred base pairs of DNA in the region of interest is difficult when DNA from all human chromosomes is cut and separated on the same gel. These limitations are circumvented by the technique of Southern blotting (named after its originator, Edward Southern). Southern blotting involves digestion of DNA and separation by electrophoresis through agarose.⁷ After electrophoresis, the DNA is transferred to a solid support (such as nitrocellulose or nylon membranes), enabling the pattern of separated DNA fragments to be replicated onto the membrane (Fig. 2.1). The DNA is then

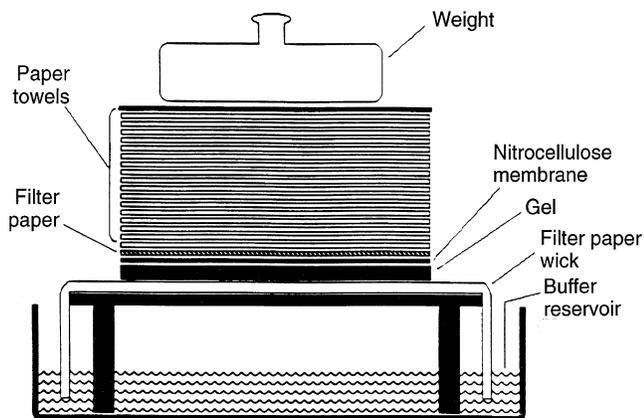

Fig. 2.1 Southern blot. Fragments of double-stranded deoxyribonucleic acid (DNA) are separated by size by agarose gel electrophoresis. To render the DNA single stranded (denatured), the agarose gel is soaked in an acidic solution. After neutralization of the acid, the gel is placed onto filter paper, the ends of which rest in a reservoir of concentrated salt buffer solution. A sheet of nitrocellulose membrane is placed on top of the gel and absorbent paper is stacked on top of the nitrocellulose membrane. The salt solution is drawn up through the gel by the capillary action of the filter paper wick and the absorbent paper towels. As the salt solution moves through the gel, it carries along with it the DNA fragments. Because nitrocellulose binds single-stranded DNA, the DNA fragments are deposited onto the nitrocellulose in the same pattern that they were placed in the agarose gel. The DNA fragments bound to the nitrocellulose are fixed to the membrane by heat or ultraviolet irradiation. The nitrocellulose membrane with the bound DNA can then be used for procedures, such as hybridization to a labeled DNA probe. Techniques to transfer DNA to other bonding matrices, such as nylon, are similar. (Modified from Turco, E., Fritsch, R., Trucco, M. (1990). Use of immunologic techniques in gene analysis. In: Herberman, R.B., Mercer, D.W. (eds.). Immunodiagnosis of cancer. New York: Marcel Dekker, p. 205.)

denatured (i.e., the two strands are physically separated), fixed to the membrane, and the dried membrane is mixed with a solution containing the DNA probe. A DNA probe is a fragment of DNA that contains a nucleotide sequence specific for the gene or chromosomal region of interest. For purposes of detection, the DNA probe is labeled with an identifiable tag, such as radioactive phosphorus (e.g., ³²P) or a chemiluminescent moiety; the latter has now almost exclusively replaced radioactivity. The process of mixing the DNA probe with the denatured DNA fixed to the membrane is called *hybridization*, the principle being that there are only four nucleic acid bases in DNA—adenine (A), thymidine (T), guanine (G), and cytosine (C)—that always remain complementary on the two strands of DNA, A pairing with T, and G pairing with C. Following hybridization, the membrane is washed to remove the unbound probe and exposed to an x-ray film either in a process called *radioautography* (also referred to as *autoradiography*) to detect radioactive phosphorus or in a process used to detect the chemiluminescent tag. Only those fragments that are complementary and have bound to the probe containing the DNA of interest will be evident on the x-ray film, enabling the analysis of the size and pattern of these fragments. As routinely performed, the technique of Southern analysis can detect a single copy gene in as little as 5 μg of DNA, the DNA content of about 10⁶ cells.

Restriction Fragment Length Polymorphism

Restriction fragment length polymorphism (RFLP) is a technique that is currently rarely used but is widely present in endocrine genetic literature, as a number of endocrine genetic discoveries over the last 2 to 3 decades were based on this technique. The number and size of DNA fragments resulting from the digestion of any particular region of DNA form a recognizable pattern. Small variations in a sequence among unrelated individuals may cause a restriction enzyme recognition site to be present or absent; this results in a variation in the number and size pattern of the DNA fragments produced by digestion with that particular enzyme. Thus this region is said to be polymorphic for the particular enzyme tested—that is, an RFLP (Fig. 2.2). The value of RFLP is that it can be used as a molecular tag for tracing the inheritance of the maternal and paternal alleles. Furthermore, the polymorphic region analyzed does not need to encode the genetic variation that is the cause of the disease being studied, but only to be located near the gene of interest. When a particular RFLP pattern can be shown to be associated with a disease, comparing the offspring’s RFLP pattern with the RFLP pattern of the affected or carrier parents can determine the likelihood of an offspring inheriting the disease. The major limitation of the RFLP technique is that its applicability for the analysis of any particular gene is dependent on the prior knowledge of the presence of convenient (“informative”) polymorphic restriction sites that flank the gene of interest by at most a few kilobases. Because these criteria may not be fulfilled in any given case, the applicability of RFLP cannot be guaranteed for the analysis of a given gene.

Polymerase Chain Reaction

PCR is a technique that was developed in the late 1980s and revolutionized molecular biology (Fig. 2.3). PCR allows the selective logarithmic amplification of a desired fragment of DNA from a complex mixture of DNA that theoretically contains at least a single copy of the target fragment. In the typical application of this technique, some knowledge of the DNA sequences in the region to be amplified is necessary, so that a pair of short (approximately 18–25 bases in length) specific oligonucleotides (“primers”) can be synthesized. The primers are synthesized in such a manner that they define the limits of the

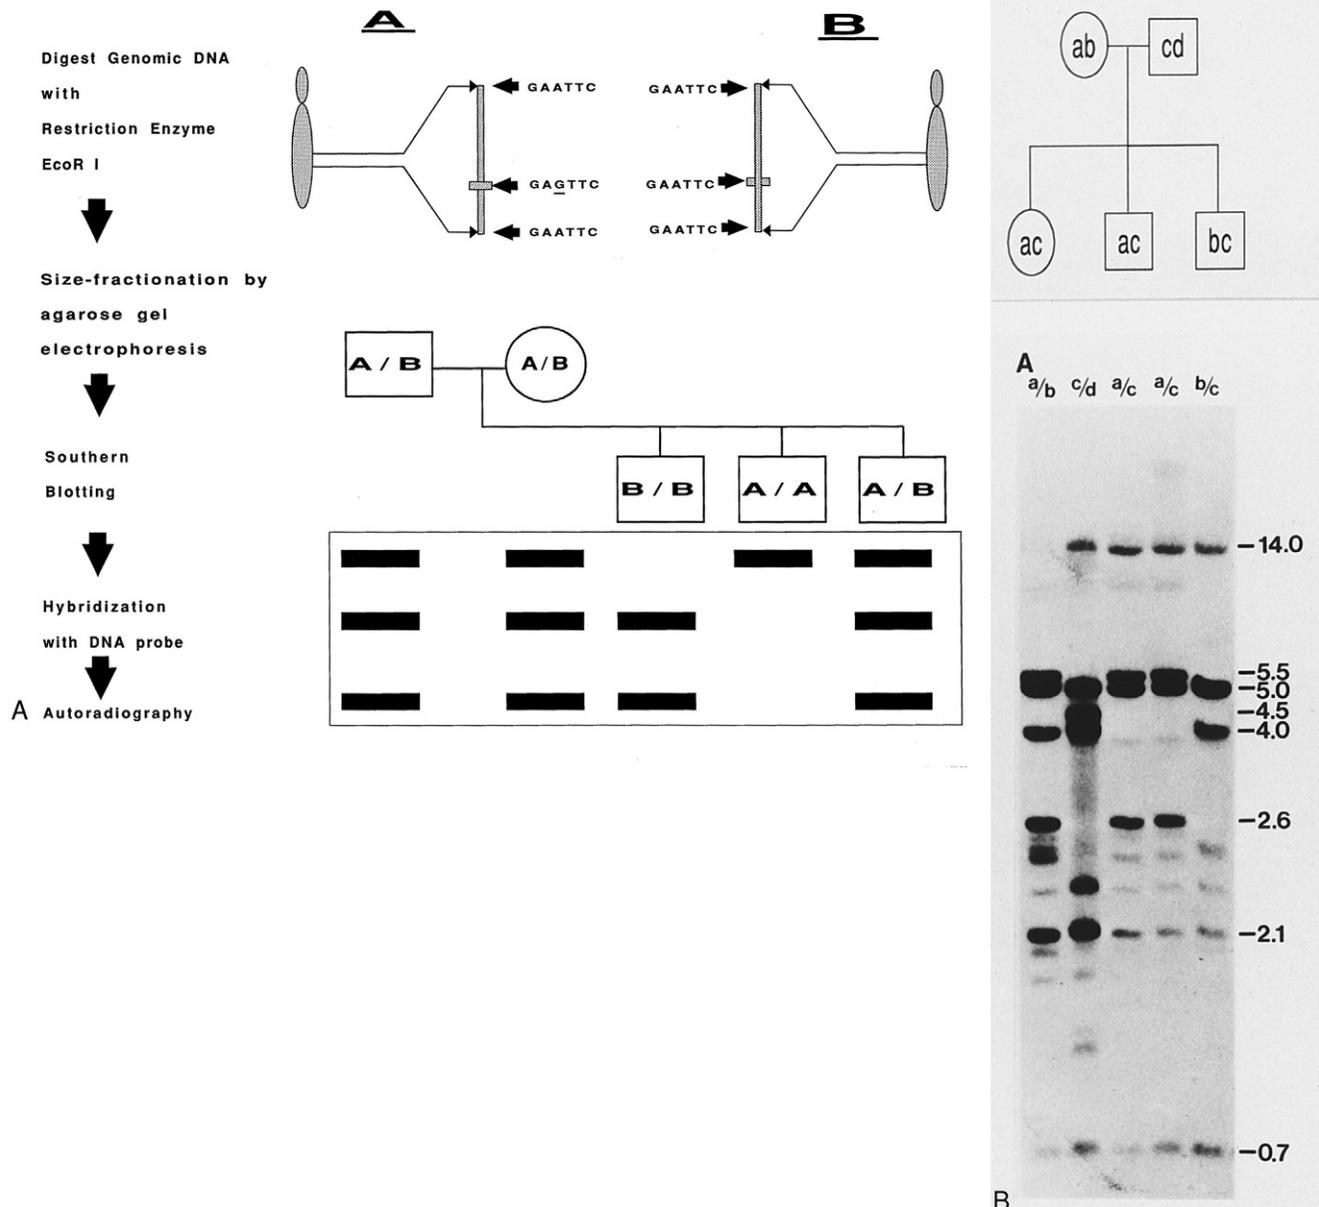

Fig. 2.2 Restriction fragment length polymorphism (RFLP). A, Schematic illustration. A and B represent two alleles that display a polymorphic site for the restriction enzyme EcoR I. EcoR I will cut deoxyribonucleic acid (DNA) with the sequence “GAATTC”; hence, allele B will be cut by EcoR I at three sites to generate two fragments of DNA, whereas allele A will be cut by EcoR I only twice and not at the site (indicated by horizontal bar) where nucleotide G (underlined) replaces the nucleotide A present in allele B. Following digestion, the DNA is size-fractionated by agarose gel electrophoresis and transferred to a membrane by Southern blot technique (see Fig. 2.1 for details). The membrane is then hybridized with a labeled DNA probe, which contains the entire sequence spanned by the three EcoR I sites. Radioautography DNA probe membrane will detect the size of the DNA fragments generated by the restriction enzyme digestion. In this particular illustration, both parents are heterozygous and possess both A and B alleles. Matching the pattern of the DNA bands of the offspring with that of the parents will establish the inheritance pattern of the alleles. For example, if allele A represents the abnormal allele for an autosomal recessive disease, then examination of the Southern blot will establish that (from left to right) the first offspring (B/B) is homozygous for the normal allele, the second offspring (A/A) is homozygous for the abnormal allele, and the third offspring (A/B) is a carrier. B, RFLP analysis of the *DQ-beta* gene of the human leukocyte antigen (HLA) locus. Genomic DNA from the members of the indicated pedigree was digested with restriction enzyme Pst I, size-fractionated by agarose gel electrophoresis, and transferred to nitrocellulose membrane by Southern blot technique. The membrane was then hybridized with a complementary DNA probe specific for the *DQ-beta* gene; the excess probe was removed by washing at appropriate stringency and was analyzed by radioautography. The sizes of the DNA fragments (in kilobases, kb) are indicated on the right. The pedigree chart indicates the polymorphic alleles (a, b, c, d) and the bands on the Southern blot corresponding to these alleles (a [5.5 kb], b [5.0 kb], c [14.0 kb], d [4.5 kb]) indicate the inheritance pattern of these alleles. (Modified from Turco, E., Fritsch, R., Trucco, M. (1998). First domain encoding sequence mediates human class II beta-chain gene cross-hybridization. *Immunogenetics* 28:193.)

region to be amplified. The DNA template containing the segment that is to be amplified is heat denatured, such that the strands are separated and then cooled to allow the primers to anneal to the respective complementary regions. The enzyme

Taq polymerase, a heat stable enzyme originally isolated from the bacterium *Thermophilus aquaticus*, is then used to initiate synthesis (extension) of DNA. The DNA is repeatedly *denatured*, *annealed*, and *extended* in successive cycles in a machine called

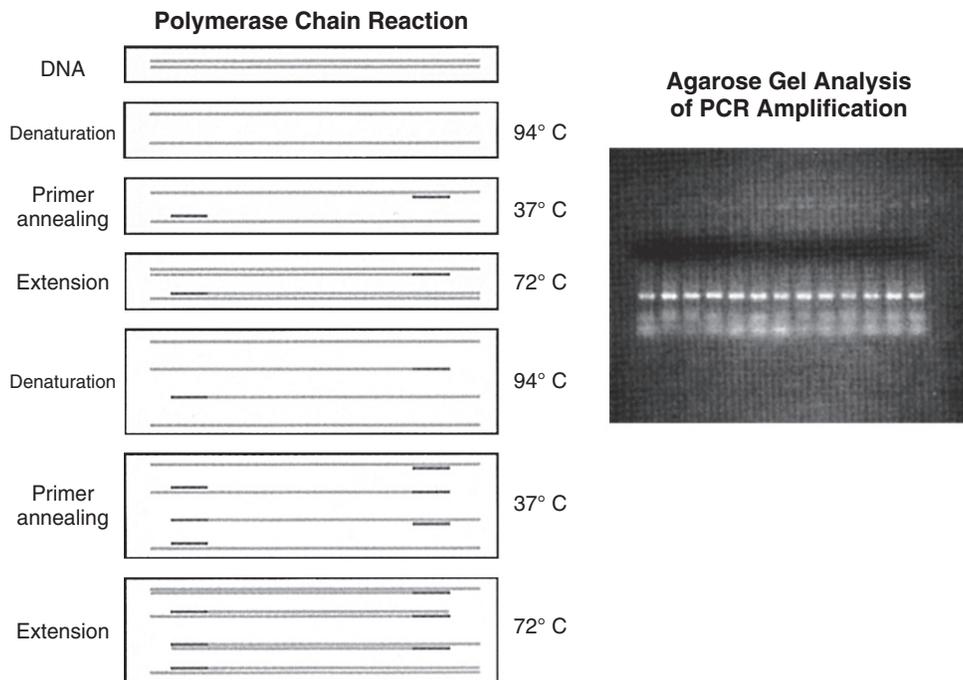

Fig. 2.3 Polymerase chain reaction (PCR). A pair of oligonucleotide primers (solid bars), complementary to sequences flanking a particular region of interest (shaded, stippled bars), are used to guide deoxyribonucleic acid (DNA) synthesis in opposite and overlapping directions. Repeated cycles of DNA denaturation, primer annealing, and DNA synthesis (primer extension) by DNA polymerase enzyme result in an exponential increase in the target DNA (i.e., the DNA sequence located between the two primers) such that this DNA segment can be amplified 1×10^6 – 7 times after 30 such cycles. The use of a thermostable DNA polymerase (i.e., Taq polymerase) allows for this procedure to be automated. Inset: The amplified DNA can be used for subsequent analysis (i.e., size-fractionation by agarose gel electrophoresis). (Modified from Trucco, M. (1992). To be or not to be ASP 57, that is the question. *Diabetes Care* 15:705.)

the *thermocycler* that permits this process to be automated. In the usual assay, these repeated cycles of denaturing, annealing, and extension result in the synthesis of approximately 1 million copies of the target region in about 2 hours. To establish the veracity of the amplification process, the identity of the amplified DNA can be analyzed by electrophoresis, hybridization to RNA or DNA probes, digestion with informative restriction enzyme(s), or subjected to direct DNA sequencing. The relative simplicity combined with the power of this technique has resulted in widespread use of this procedure and has spawned a wide variety of variations and modifications that have been developed for specific applications.^{8,9} From a practical point of view, the major drawback of PCR is the propensity to get cross-contamination of the target DNA. This drawback is the direct result of the extreme sensitivity of the method that permits amplification from one molecule of the starting DNA template. Thus unintended transfer of amplified sequences to items used in the procedure will amplify DNA in samples that do not contain the target DNA sequence (i.e., a false positive result). Cross-contamination should be suspected when amplification occurs in negative controls that did not contain the target template. One of the most common modes of cross-contamination is via aerosolization of the amplified DNA during routine laboratory procedures, such as vortexing, pipetting, and manipulation of microcentrifuge tubes. Meticulous care to experimental technique, proper organization of the PCR workplace, and inclusion of appropriate controls are essential for the successful prevention of cross-contamination during PCR experiments.

In general, PCR applications are either directed toward the identification of a specific DNA sequence in a tissue or body fluid sample or used for the production of relatively large amounts of DNA of a specific sequence, which then are used in further studies. Examples of the first type of application

are common in many fields of medicine, such as in microbiology, wherein the PCR technique is used to detect the presence of DNA sequences specific for viruses or bacteria in a biological sample. Examples of such an application in pediatric endocrinology include the use of PCR of the *SRY* gene for detecting Y chromosome material in patients with karyotypically defined Turner syndrome and the rapid identification of chromosomal gender in cases of fetal or neonatal sexual ambiguity¹⁰ (Fig. 2.4).

Most PCR applications, both as research tools and for clinical use, are directed toward the production of a target DNA or the complementary DNA of a target RNA sequence. The DNA that is made ("amplified") is then analyzed by other techniques, such as DNA sequencing.

RNA Analysis

The majority (>95%) of the chromosomal DNA represents noncoding sequences. These sequences harbor regulatory elements, serve as sites for alternate splicing, and are subject to methylation and other epigenetic changes that affect gene function. However, at present most disease-associated mutations in the human gene have been identified in coding sequences. An alternate strategy to analyze mutations in a given gene is to study its mRNA, which is the product (via transcription) of the remaining 5% of chromosomal DNA that encodes for proteins. In addition, because the mRNA repertoire is cell and tissue specific, the analyses of the mRNA sequences provide unique information about tissue-specific proteins produced in a particular organ/tissue.

There are many techniques for analyzing mRNA. The oldest and most widely used in the past, although now rarely used, is Northern blotting (so named because it is based on the same principle as the Southern blot), which is one of the original

to all the PCR reaction tubes serves as an internal control for the efficiency of the PCR process, and the yield of the mutant DNA in the various tubes can be used for the equalization of the yield of the DNA by PCR. It is important to ensure for accurate quantitation of the DNA of interest that the concentrations of the mutant and target template should be nearly equivalent. Because the use of mutated DNA for normalization does not account for the variability in the efficiency of the RT enzyme, a variation of the original method has been developed. In this modification, competitive mutated RNA transcribed from a suitably engineered RNA expression vector is substituted for the mutant DNA in the reaction before initiating the synthesis of the cDNA. Competitive RT-PCR can be used to detect changes of the order of two- to threefold of even very rare mRNA species. The major drawback of this method is the propensity to get inaccurate results because of the contamination of samples with the mRNA of interest. In theory, as the technique is based on PCR, contamination by even one molecule of mRNA of interest can invalidate the results. Hence, scrupulous attention to laboratory technique and set up is essential for the successful application of this technique.

In general, two types of methods are used for the detection and quantitation of PCR products: the “end-point”

measurements of products and the newer “real-time” techniques. End-point determinations (e.g., the competitive RT-PCR technique described earlier) analyze the reaction after it is completed, whereas real-time determinations are made during the progression of the amplification process. In general, the real-time approach is more accurate and is currently the preferred method. Advances in fluorescence detection technologies have made the use of real-time measurement possible for routine use in the laboratory. One of the popular techniques that takes advantage of real-time measurements is the TaqMan (fluorescent 5' nuclease) assay (Fig. 2.5).^{16,17} The unique design of TaqMan probes, combined with the 5' nuclease activity of the PCR enzyme (Taq polymerase), allows direct detection of PCR product by the release of a fluorescent reporter during the PCR amplification by using specially designed machines (ABI Prism 5700/7700). The TaqMan probe consists of an oligonucleotide synthesized with a 5'-reporter dye (e.g., FAM; 6-carboxy-fluorescein) and a downstream, 3'-quencher dye (e.g., TAMRA; 6-carboxy-tetramethyl-rhodamine). When the probe is intact, the proximity of the reporter dye to the quencher dye results in suppression of the reporter fluorescence, primarily by Forster-type energy transfer. During PCR, forward and reverse primers hybridize to a specific sequence

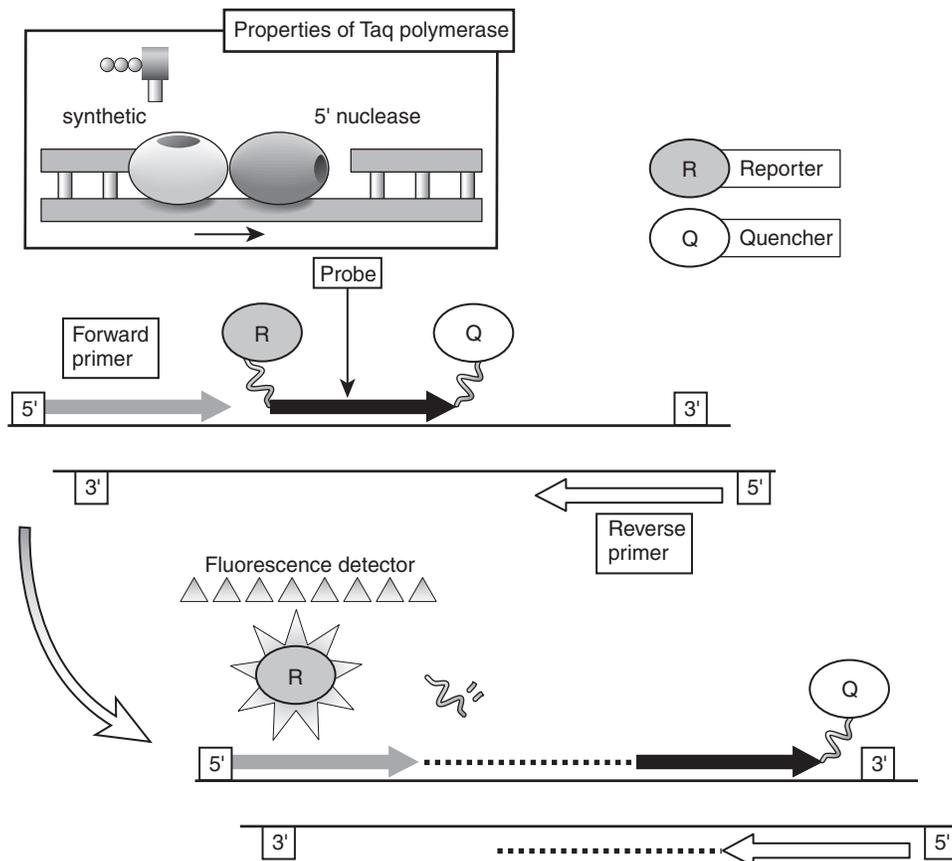

Fig. 2.5 Fluorescent 5' nuclease (TaqMan) assay. Three synthetic oligonucleotides are used in a fluorescent 5' nuclease assay. Two oligonucleotides function as “forward” and “reverse” primers in a conventional polymerase chain reaction (PCR) amplification protocol. The third oligonucleotide, termed the TaqMan probe, consists of an oligonucleotide synthesized with a 5'-reporter dye (e.g., FAM; 6-carboxy-fluorescein) and a downstream, 3'-quencher dye (e.g., TAMRA; 6-carboxy-tetramethyl-rhodamine). When the probe is intact, the proximity of the reporter dye to the quencher dye results in suppression of the reporter fluorescence, primarily by Forster-type energy transfer. During PCR, forward and reverse primers hybridize to a specific sequence of the target deoxyribonucleic acid (DNA). The TaqMan probe hybridizes to a target sequence within the PCR product. The Taq polymerase enzyme, because of its 5'-3' exonuclease activity, subsequently cleaves the TaqMan probe. The reporter dye and the quencher dye are separated by cleavage, resulting in increased fluorescence of the reporter dye as a direct consequence of target amplification during PCR. Both primers and probe must hybridize to the target for amplification and cleavage to occur. Hence the fluorescence signal is generated only if the target sequence for the probe is amplified during PCR. Fluorescent detection takes place through fiberoptic lines positioned above the caps of the reaction wells. Inset: The two distinct functions of the enzyme Taq polymerase: the 5'-3' synthetic polymerase activity and the 5'-3' polymerase-dependent exonuclease activity.

of the target DNA. The TaqMan probe hybridizes to a target sequence within the PCR product. The Taq polymerase enzyme, because of its 5'-3' nuclease activity, subsequently cleaves the TaqMan probe. The reporter dye and the quencher dye are separated by cleavage, resulting in increased laser-stimulated fluorescence of the reporter dye as a direct consequence of target amplification during PCR. This process occurs in every cycle and does not interfere with the exponential accumulation of product. Both primer and probe must hybridize to the target for amplification and cleavage to occur. The fluorescence signal is generated only if the target sequence for the probe is amplified during PCR. Because of these stringent requirements, non-specific amplification is not detected. Fluorescent detection takes place through fiber optic lines positioned above optically nondistorting tube caps. Quantitative data are derived from a determination of the cycle at which the amplification product signal crosses a preset detection threshold. This cycle number is proportional to the amount of starting material, thus allowing for a measurement of the level of specific mRNA in the sample. An alternate machine (Light Cycler) also uses fluorogenic hydrolysis or fluorogenic hybridization probes for quantification in a manner similar to the ABI system.

MicroRNA

One of significant advances in the early 2000s in the field of RNA biology is the discovery of small (20–30 nucleotide) noncoding RNAs.¹⁸ In general, there are two categories of small noncoding RNAs: microRNA (miRNA) and small interfering RNA (siRNA). miRNAs are expressed products of an organism's own genome, whereas siRNAs are synthesized in the cells from foreign double-stranded RNA (e.g., from viruses or transposons or from synthetic DNA introduced into the cell to study the function of a particular gene/process). In addition, there are differences in the biogenesis of these two classes of small nucleotide RNAs. These differences notwithstanding, the overall biological effect of these small nucleotide RNAs is translational repression or target degradation and gene silencing by binding to complementary sequences on the 3' untranslated region of target mRNA; positive regulation of gene expression via such a mechanism is distinctly uncommon. The complexity of the phenomenon is increased by the fact that in a cell- or tissue-specific context, a single miRNA can target multiple RNAs and more than one miRNA can recognize the same mRNA target to amplify and strengthen the translational repression of the target gene. It is estimated that this phenomenon is present in several cell types and the human genome codes for more than 1000 miRNAs that could target 60% to 70% of mammalian genes. miRNA-mediated events have been implicated in regulation of cell growth and differentiation, cell growth, apoptosis, and other cellular processes. To date, the major impact of the discovery of miRNA has been in the fields of developmental biology, organogenesis, and cancer.¹⁹ miRNA and miRNA-related events (e.g., proteins involved in miRNA processing) have been directly implicated in only a small number of non-neoplastic endocrine disorders (e.g., diGeorge syndrome and X-linked mental retardation). It is predicted that as we learn more about the basic biology of this process, small nucleotide noncoding RNAs will be implicated in the pathogenesis of a wider spectrum of endocrine diseases.

DETECTION OF MUTATIONS IN GENES

Changes in the structural organization of a gene that impact its function involve deletions, insertions, or transpositions of relatively large stretches of DNA, or more frequently single-base substitutions in functionally critical regions. High throughput or next-generation sequencing (NGS) has revolutionized the identification of mutations in genes.²⁰

Direct Methods

DNA sequencing is the current gold standard for obtaining unequivocal proof of a point mutation. However, DNA sequencing has its limitations and drawbacks. A clinically relevant problem is that current DNA sequencing methods do not reliably and consistently detect all mutations. For example, in many cases where the mutation affects only one allele (heterozygous), the heights of the peaks of the bases on the fluorescent readout corresponding to the wild-type and mutant allele are not always present in the predicted (1:1) ratio. This limits the discerning power of "base calling" computer protocols and results in inconsistent or erroneous assignment of DNA sequence to individual alleles. Because of this limitation, clinical laboratories routinely determine the DNA sequence of both the alleles to provide independent confirmation of the absence/presence of a putative mutation. DNA sequencing can be labor intensive and expensive, although advances in pyrosequencing (discussed later), for example, have made it technically easier and cheaper.

Although the first DNA sequences were determined with a method that chemically cleaved the DNA at each of the four nucleotides,²¹ the enzymatic or dideoxy method developed by Sanger and colleagues in 1977 became the most commonly used for routine purposes (Fig. 2.6).²² This method uses the enzyme DNA polymerase to synthesize a complementary copy of the single-stranded DNA ("template") whose sequence is being determined. Single-stranded DNA can be obtained directly from viral or plasmid vectors that support the generation of single-stranded DNA or by partial denaturing of double-stranded DNA by treatment with alkali or heat. The enzyme DNA polymerase cannot initiate synthesis of a DNA chain de novo but can only extend a fragment of DNA. Hence the second requirement for the dideoxy method of sequencing is the presence of a "primer." A primer is a synthetic oligonucleotide, 15 to 30 bases long, whose sequence is complementary to the sequence of the short corresponding segment of the single-stranded DNA template. The dideoxy method exploits the observation that DNA polymerase can use both dNTP and 2',3'-dideoxynucleoside triphosphates (ddNTPs) as substrates during elongation of the primer. Whereas DNA polymerase can use dNTP for continued synthesis of the complementary strand of DNA, the chain cannot elongate any further after addition of the first ddNTP, because ddNTPs lack the crucial 3'-hydroxyl group. To identify the nucleotide at the end of the chain, four reactions are carried out for each sequence analysis, with only one of the four possible ddNTPs included in any one reaction. The ratio of the ddNTP and dNTP in each reaction is adjusted so that these chain terminations occur at each of the positions in the template where the nucleotide occurs. To enable detection by radioautography, the newly synthesized DNA is labeled, usually by including in the reaction mixture radioactively labeled dATP (for the older manual methods) or, most commonly, currently fluorescent dye terminators in the reaction mixture (now in use in automated techniques). The separation of the newly synthesized DNA strands manually is done via high-resolution denaturing polyacrylamide electrophoresis or with capillary electrophoresis in automatic sequencers. Fluorescent detection methods have enabled automation and enhanced throughput. In capillary electrophoresis, DNA molecules are driven to migrate through a viscous polymer by a high electric field to be separated on the basis of charge and size. Although this technique is based on the same principle as that used in slab gel electrophoresis, the separation is done in individual glass capillaries rather than gel slabs, facilitating loading of samples and other aspects of automation. Whereas manual methods allow the detection of about 300 nucleotides of sequence information with one set of sequencing reactions, automated methods using

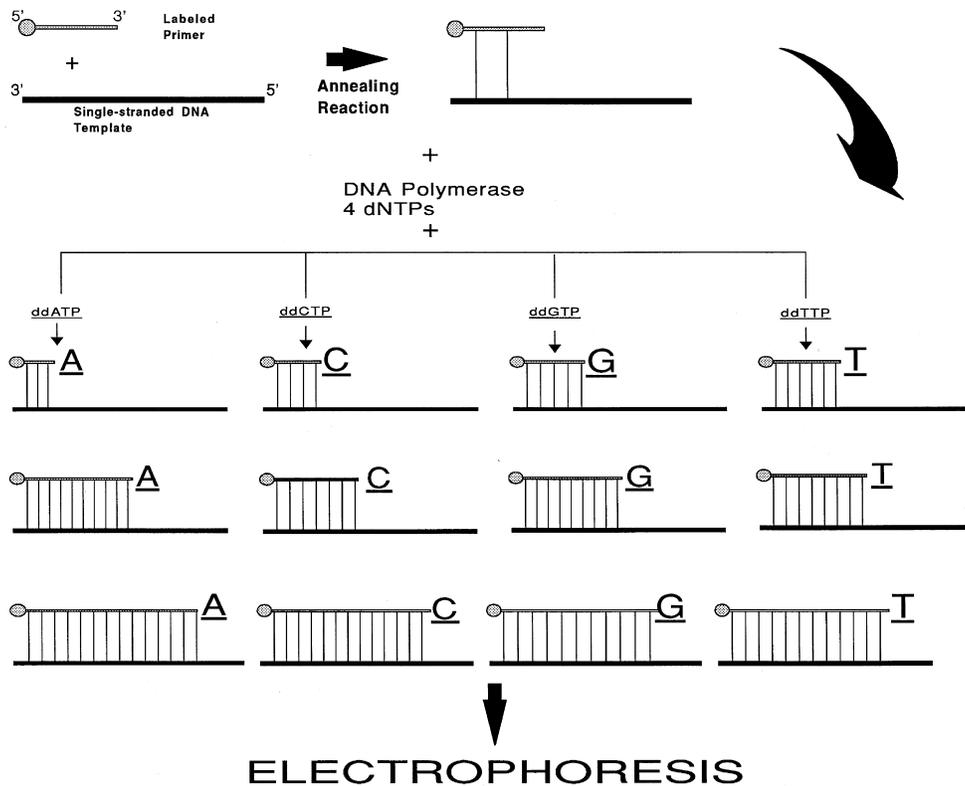

Fig. 2.6 Deoxyribonucleic acid (DNA) sequencing by the dideoxy (Sanger) method. A 5'-end-labeled oligonucleotide primer with sequence complementarity to the DNA that is to be sequenced (DNA template) is annealed to a single-strand of the template DNA. This primer is elongated by DNA synthesis initiated by the addition of the enzyme DNA polymerase in the presence of the four 2'-deoxynucleoside triphosphates (dNTPs) and one of the 2',3'-dideoxynucleoside triphosphates (ddNTPs); four such reaction tubes are assembled to use all the four ddNTPs. The DNA polymerase enzyme will elongate the primer using the dNTPs and the individual ddNTP present in that particular tube. Because ddNTPs are devoid of the 3' hydroxyl group, no elongation of the chain is possible when such a residue is added to the chain. Thus each reaction tube will contain prematurely terminated chains ending at the occurrence of the particular ddNTP present in the reaction tube. The concentrations of the dNTPs and the individual ddNTP present in the reaction tubes are adjusted so that the chain termination takes place at every occurrence of the ddNTP. Following the chain elongation-termination reaction, the DNA strands synthesized are size-separated by acrylamide gel electrophoresis and the bands visualized by radioautography.

fluorescent dyes and laser technology can analyze 7500 or more bases per reaction. To sequence larger stretches of DNA, it is necessary to divide the large piece of DNA into smaller fragments that can be individually sequenced. Alternatively, additional sequencing primers can be chosen near the end of the previous sequencing results, allowing the initiation point of new sequence data to be moved progressively along the larger DNA fragment.

One of the seminal technological advances has been the introduction of microarray-based methods for detection, and analysis of nucleic acids.²³ Microarrays contain thousands of oligonucleotides deposited or synthesized in situ on a solid support, typically a coated glass slide or a membrane. In this technique, a robotic device is used to print DNA sequences onto the solid support. The DNA probes immobilized on the microarray slide as spots can either be cloned cDNA or gene fragments (expressed sequence-tags [ESTs]), or oligonucleotides corresponding to known genes or putative open reading frames. The arrays are hybridized with fluorescent targets prepared from RNA extracted from tissue/cells of interest; the RNA is labeled with fluorescent tags, such as Cy3 and Cy5. The prototypic microarray experimental paradigm consists of comparing mRNA abundance in two different samples. One fluorescent target is prepared from control mRNA and the second target with a different fluorescent label is prepared from mRNA isolated from the treated cells or tissue under investigation. Both targets are mixed and hybridized to the microarray

slide, resulting in target gene sequences hybridizing to their complementary sequences on the microarray slide. The microarray is then excited by laser, and the fluorescent intensity of each spot is determined with the relative intensities of the two colored signals on individual spots being proportional to the amounts of specific mRNA transcripts in each sample (Fig. 2.7). Analysis of the fluorescent intensity data yields an estimation of the relative expression levels of the genes in the sample and control sample. Microarrays enable individual investigators to perform large-scale analyses of model organisms and to customize arrays for special genome applications.

The method of choice for global expression profiling depends on several factors, including technical aspects, labor, price, time, and effort involved, and, most important, the type of information that is sought. Technical advances in the development of expression arrays, their abundance and commercial availability, and the relative speed with which analysis can be done are all factors that make arrays more useful in routine applications. In addition, array content can now be readily customized to cover from gene clusters and pathways of interest to the entire genome: some studies examine series of tissue-specific transcripts or genes known to be involved in particular pathology; others directly use arrays covering the whole genome. Another factor that needs to be considered before embarking on any high-throughput approach is whether individual or pooled samples will be investigated. Series of pooled samples reduce the price, the time spent, and the number of the

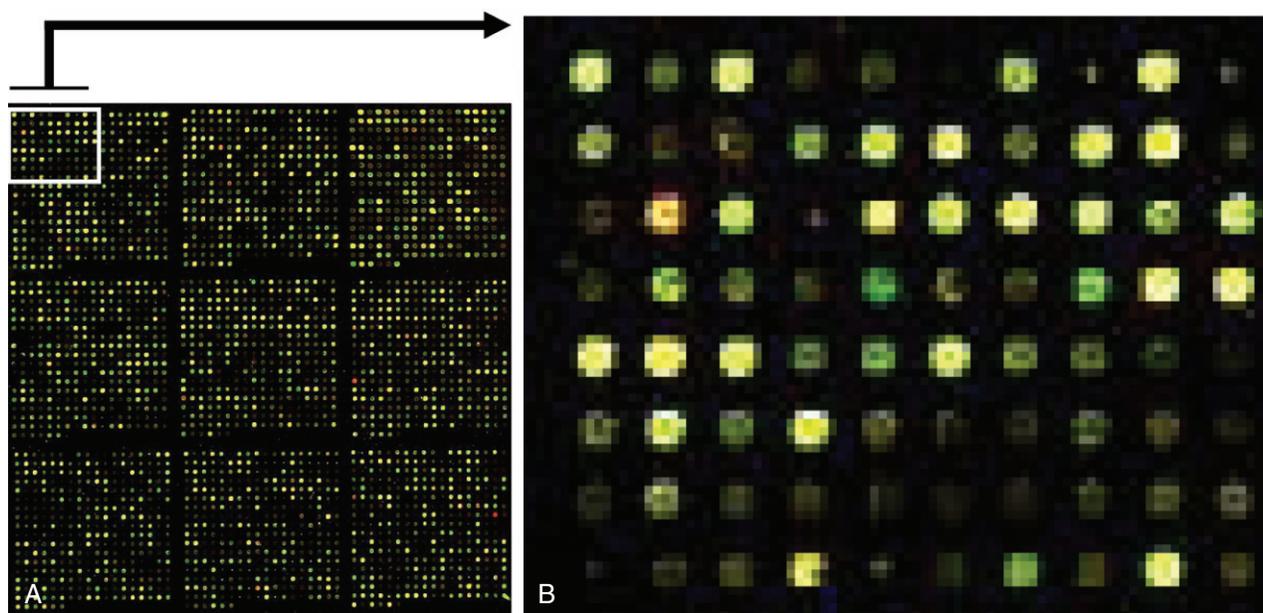

Fig. 2.7 A, Complementary deoxyribonucleic acid (cDNA) microarray, fluorescent labeled cDNA targets, adrenocorticotropic hormone (ACTH)-independent bilateral macronodular adrenal hyperplasia (Cy3), and ACTH-dependent hyperplasia (Cy5) were hybridized to glass slides containing genes involved in oncogenesis. Following laser activation of the fluorescent tags, fluorescent signals from each of the DNA “spots” are captured and subjected to analysis. experiments down to the most affordable. Investigating individual samples, however, is important for identifying unique expression ratios in a given type of tissue or cell. There are limitations of microarray-based techniques; for example, similar to direct DNA sequencing methods, microarray-based methods also suffer from the disadvantage of not being able to reliably and consistently detect heterozygous mutations. Furthermore, microarrays cannot be used to detect insertions of multiple nucleotides without exponentially increasing the number of oligonucleotides that must be immobilized on the glass slides.

A more reliable technique in mutation identification is pyrosequencing, which is based on an enzymatic real-time monitoring of DNA synthesis by bioluminescence²⁴ (Fig. 2.8). Pyrosequencing is performed by the addition of dNTPs individually, in a predefined dispensation order, so that the nascent nucleotide chain is extended one nucleotide residue per dispensation event. Detection of nucleotide sequence is performed by way of a chain of enzymatic reactions involving the activities of DNA polymerase, apyrase, ATP sulfurylase, and luciferase, respectively, allowing for the incorporation of complementary nucleotide, degradation of unused dNTP, generation of luciferase-substrate from pyrophosphate and adenosine 5'-phosphosulfate, and emission of light from the ATP-driven conversion of luciferin to oxyluciferin. Incorporation of a particular nucleotide is displayed graphically in the form of a chart recording of nucleotide dispensation event versus the intensity of emitted light. This cascade of enzyme reactions is quantitative, in that increased light intensity is produced upon incorporation of multiple nucleotides.

Pyrosequencing, introduced in the early 2000s, provided the background for the explosion of new techniques collectively known as *high-throughput NGS* or *massively parallel sequencing*. NGS provides longer read length and cheaper price per base of sequencing compared with Sanger sequencing. NGS is based on the uncoupling of the traditional nucleotide-identifying enzymatic reaction and the image capture and doing so in an ever-speedier way allows for essentially unlimited capacity.

The first discoveries of gene mutations for endocrine diseases exploiting NGS were published in 2011.²⁵ Currently, many similar systems are being used for NGS. Illumina[®] workflows, for example, include four basic steps: the first consists in the random fragmentation of the DNA (or cDNA) sample, followed by 5' and 3' adapter ligation. These adapter short sequences encompass binding sites, indices (necessary for performing multiplex reactions), and segments complementary to the oligos fixed on a flow cell. Adapter-ligated fragments are then PCR amplified and gel purified to generate a “library.” Then the generated library is loaded into the flow cell, where its fragments are captured on oligos complementary to the library adapters, immobilized onto a solid support at a dilute concentration. Each fragment is then further amplified into distinct, clonal clusters through bridge amplification. “Bridges” are formed by the annealing of the terminal, still free adapter sequence present at the other, not yet captured extremity of each single fragment, bending to the adjacent complementary immobilized oligo. A polymerase then generates a complementary strand. After denaturation, both strands bind again, pairing with other complementary primers anchored to the floor of the plate. This step is repeated a number of times, generating millions of each fragment’s copies. When this “cluster generation” is complete, the templates are ready for “sequencing.” Here also, as per conventional pyrosequencing, the reversible terminator-based method detects single bases as they are incorporated into DNA template strands, generating light emissions under excitation with a laser. Each colony of distinct fragments is sequenced through the capture of high-resolution images that reflect the base-by-base addition of nucleotides. In contrast to conventional pyrosequencing, all four reversible terminator-bound dNTPs are present during each sequencing cycle, each labeled with a different fluorescent dye. Natural competition minimizes incorporation bias, which reduces raw error rates. Finally, a sophisticated computer program aligns the newly identified sequence reads to a reference genome sequence, grouped, in the case of multiplex reactions, by the index

segments to each different DNA source. The extremely high number of equal sequences guarantees the correctness of the obtained results and the exclusion of the ones only sporadically represented. This dramatic rise of data output, together with the progressive reduction of sequencing cost, paved the way for “personalized medicine” in which the genome of each individual can be easily obtained and compared with normal genome sequences to detect possibly present, known, or new, disease-linked mutations.

Semiconductor and nanotechnology-based systems are currently under use in massive sequencing efforts and promise an even cheaper and faster way of determining mutations and other abnormalities of the human genome.

A requirement of all high-throughput screening approaches is confirmation of findings (expression level of a given gene/sequence) by other independent methods. A select group of genes are tested usually; these genes are picked from the series of sequences that were analyzed either because they were found to have significant changes or because of their particular interest with regard to their expression in the studied tissue or their previously identified relationship to pathology or developmental stage. The confirmation process attempts to support the findings on three different levels: (1) reliability of the high-throughput experiment (for this purpose the same samples examined by the microarrays are used); (2) trustfulness of the observations in general (to achieve that, larger number of samples are examined, assessment of which by high-throughput approaches is often unaffordable price- or labor-wise); and (3) verification of the expression changes at the protein level. A commonly used confirmatory technique is qRT-PCR. For verification at the protein level, immunohistochemistry (IHC) and Western blot are the two most commonly chosen techniques. IHC is not quantitative but has the advantage of allowing for the observation of the exact localization of a signal within a cell (cytoplasmic versus nuclear) and the tissue (identifying histologically the tissue that is stained). Modern Western blot methods require a smaller amount of protein lysate than older techniques and have the advantage of offering high-resolution quantitation of expression without the use of radioactivity.

Indirect Methods

In the mid-1980s, the need for rapid, high-throughput, accurate, and economical mutation analysis systems led to the development of several technologies, as an alternative to analysis by direct sequencing, that allowed detection of single mutations in long stretches of DNA (200–600 bp). However, screening for mutations by indirect methods has fallen out of favor because NGS and Sanger sequencing have become faster and cheaper methods for identifying gene mutations. We only refer to them here briefly and for historical purposes, because some of these techniques are still in use sporadically, and understanding the literature published since the 1980s requires the knowledge of the principles underlying these techniques.

Indirect methods of mutation identification included restriction endonuclease digestion of PCR products (PCR-RFLP), denaturing-gradient gel electrophoresis, single-strand conformation polymorphism, dideoxy fingerprinting, and heteroduplex mobility assay. Most of these methods used PCR to amplify a region of the DNA, a physical or chemical treatment of amplified DNA (e.g., by denaturation or restriction enzyme digestion), separation of the amplicons by denaturing or non-denaturing gel electrophoresis, and visualization of the separated sequence strands (by radioautography or fluorescence-based detection). Modifications in some of these techniques allowed simultaneous separation and detection of DNA fragments with the use of sophisticated equipment, such as HPLC and capillary electrophoresis.

CRISPR-CAS9 SYSTEM

The CRISPR-Cas9 system is a newly discovered relatively simple, yet very efficient approach to physically correct mutations present on selected genes or to mutate at will a target gene sequence²⁶ (Fig. 2.9). It is faster, cheaper, and more accurate than previous techniques of editing DNA and has a wide range of potential applications both for basic science and clinical medicine. This is a unique technology that enables geneticists and medical researchers to edit parts of the genome by removing, adding, or altering sections of the DNA sequence. It is based on a novel restriction system present in some bacteria that evolved to respond to invading pathogens. The system consists of two key molecules: an enzyme called *Cas9* and a segment of RNA called *guide RNA* (gRNA). *Cas9* acts as a pair of “molecular scissors” that can cut the two strands of DNA at a specific location in the genome, so that bits of DNA can then be added or removed in the same DNA site. gRNA is a short RNA sequence (about 20 bases long) able to bind to DNA at a predefined sequence. The gRNA binding to a specific sequence in the DNA, “guides” *Cas9* to the selected part of the genome where it should cut the DNA. The DNA repair machinery of the cell will then complete the repair process resulting in the refashioning of the targeted DNA segment that

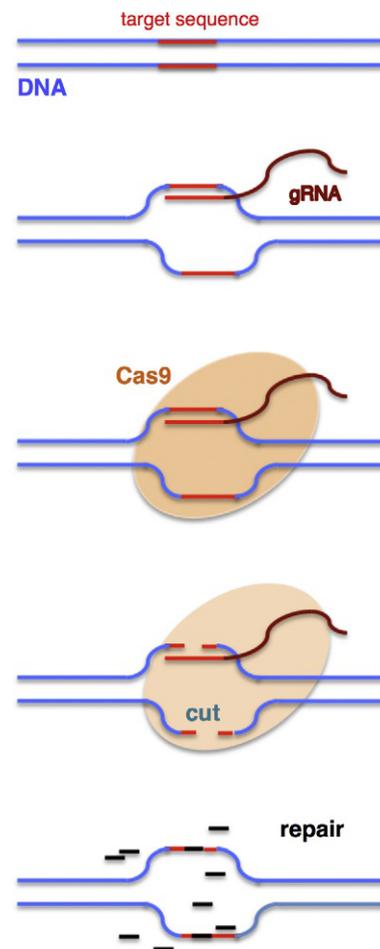

Fig. 2.9 CRISPR-Cas9 system. Cas9 enzyme acts as a pair of ‘molecular scissors’ that can cut the two strands of deoxyribonucleic acid (DNA) at a preselected location in the genome, guided in situ by a short ribonucleic acid sequence (gRNA). The machinery of the cell will then complete the DNA repair process introducing a segment of choice or disrupting the target sequence.

will not include the sequence to be eliminated or include a segment of choice.

Although the CRISPR-Cas9 system has a lot of potential as a tool for editing the genomes of somatic (nonreproductive) cells, there is considerable debate concerning its potential to edit germline (reproductive) cells. The conceptual possibility is tempered by ethical implications, as the gene changes will be transmitted to future generations of the treated individual. Furthermore, there are concerns about the specificity of the gRNA in guiding a targeted change in the DNA sequence of interest, as some data indicate that different and/or larger-than-intended DNA segments could be removed, introducing potentially unwanted DNA (off target) alterations that could be pathologic to the targeted cells(s). In several countries, for example the United Kingdom, the performance of these germline manipulations are for the time being prohibited in humans. The World Health Organization has convened a panel of experts to discuss the issue and give appropriate guidelines for possible future clinical considerations.

POSITIONAL GENETICS IN ENDOCRINOLOGY

The Principles of Positional Genetics

For the purpose of disease gene identification, the candidate gene approach relies on partial knowledge of the genetic basis of the disease under investigation. This process was successful in identifying disease genes whose function was obvious. For example, the genetic defects of most of the hereditary enzymatic disorders, including congenital adrenal hyperplasia (CAH) syndromes, became known in the late 1980s, when the introduction of PCR made the tools of molecular biology widely available to the medical and genetic research community. However, at about the same time, research on diseases without any obvious candidate genes (e.g., the multiple endocrine neoplasia [MEN] syndromes) or diseases in which the screening of obvious candidate genes failed to reveal mutations was ongoing. It was in these diseases that the application of “reverse genetics,” or more appropriately termed *positional cloning*, yielded information regarding the genetic basis of these disease states.^{27,28} Positional cloning is complemented by the Human Genome Project (HGP) and the worldwide web in

making available, in a fast and controlled manner, information that would otherwise be inaccessible.²⁹

The process of positional genetics is outlined in Fig. 2.10. The first step is the collection of clinical information from families with affected members, the determination of the mode of inheritance of the defect (autosomal dominant or recessive, X-linked, complex inheritance), and the phenotyping of subjects (or tissues), following well-established criteria for the diagnosis of the disorder. If inheritance is not known, formal segregation analysis needs to be performed to determine the autosomal, or X-linked, and the recessive or dominant nature of the inheritance.³⁰ Once this determination is made and the penetrance of the disorder is known, appropriate linkage software may be used.³¹ Linkage is examined with polymorphic markers that span the entire human genome²⁸; any marker that shows polymorphism and is known to lie close to or within a putative disease gene may be used. Genetic linkage can be defined as the tendency for alleles close together on the same chromosome to be transmitted together as an intact unit through meiosis. The strength of linkage can then be used as a unit of measurement to find out how close genetically different loci are to each other. This unit of map distance is an approximation of physical distance but is also highly dependent on other factors (e.g., the frequency of recombination is sexually dimorphic, and different among various chromosomes and along the length of a specific chromosome). The likelihood (logarithm of odds [or LOD]) score method is widely used for linkage analysis.

Once a locus on a chromosome has been identified, the region (which is usually several thousands of base pairs in length) is narrowed by analyzing informative recombinations in the cohort of patients and families available for study. The disease region may harbor already mapped genes. Online databases such as Gen Bank, ENSEMBL (www.ensembl.org), and others, and especially for clinicians, the Online Mendelian Inheritance in Man (OMIM),³² may provide all the necessary information. If a transcript is a reasonable candidate, mutation screening may identify the disease gene. If, however, these steps fail to identify the disease gene, screening new sequences from the area may be needed; today, this is done typically by NGS, followed by Sanger sequencing for confirmation. Chromosomal maps are linked by sequence-tagged sites (STSs) that are present in more than one genomic clone, thus providing

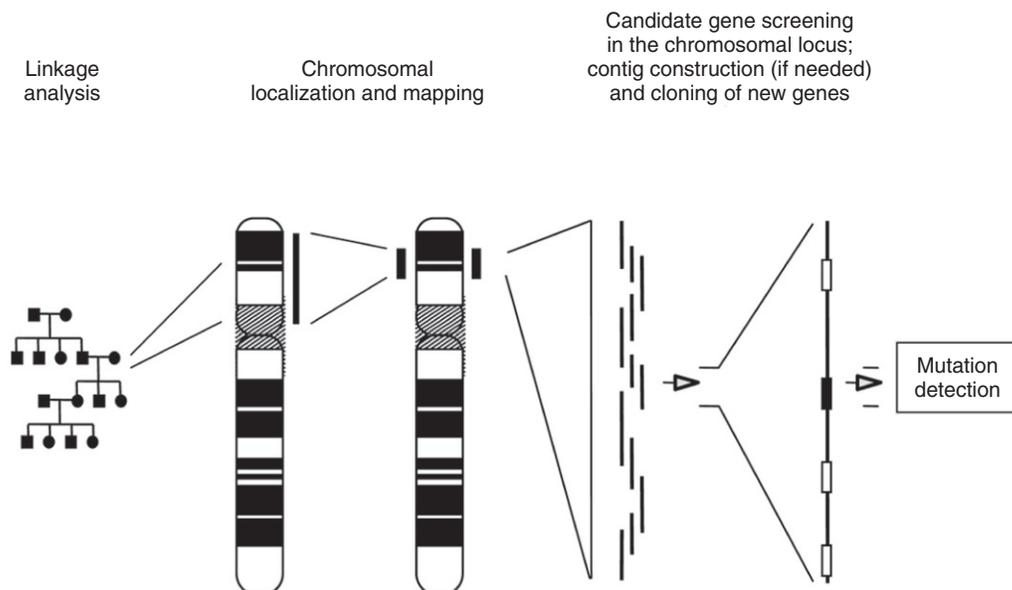

Fig. 2.10 The steps of positional cloning (see text).

critical information that allows for the proper aligning of DNA in a given locus. Polymorphic markers (including those that were used for the linkage part of the process) are the most useful STSs because they provide a direct link between the genetic and the physical mapping data. Individual clones can be sequenced; genes are identified in this process through their unique sequence features or through *in vitro* translation. In the past, ESTs provided information for what gene sequences are expressed from this area. Today, almost all the genes are fully sequenced; however, ESTs are still useful to look at, especially when one is trying to identify a new gene for a given disease-linked locus. Each one of the newly identified genes may be screened for mutations, as long as the expression profile of the identified transcript matches the spectrum of the tissues affected by the disease under investigation. Although this is helpful for most diseases, for others the expression profile may even be misleading; thus the presence of a transcript in an affected tissue is not always necessary. Complete segregation of the disease with an identified mutation, functional proof, or mutations in two or more families with the same disease are usually required as supportive evidence that the cloned sequence is the disease gene.

Genomic Identification of “Endocrine” Genes

In the 1990s positional cloning was used to identify a number of genes relevant to endocrinology; today, this is being achieved by NGS and other genome-wide methods. Endocrine tumor syndromes, despite their rarity and modest overall impact on everyday clinical endocrine practice, are seminal examples of diseases whose molecular etiology was elucidated by positional cloning. Identification of these genes was greatly assisted by the use of neoplastic tissue for studies, such as loss-of-heterozygosity (LOH), comparative genomic hybridization, and fluorescent *in situ* hybridization (FISH) applications. These techniques narrowed the genetically defined chromosomal regions and thus facilitated the identification of the responsible genes; LOH studies were critical in the identification of von Hippel-Lindau disease (*VHL-elongin*),³³ MEN1

(*menin*),³⁴ Cowden disease (*PTEN*),³⁵ Peutz-Jeghers syndrome (*STK11/LKB1*),^{36,37} and Carney complex (*PRKARIA*)³⁸ genes.

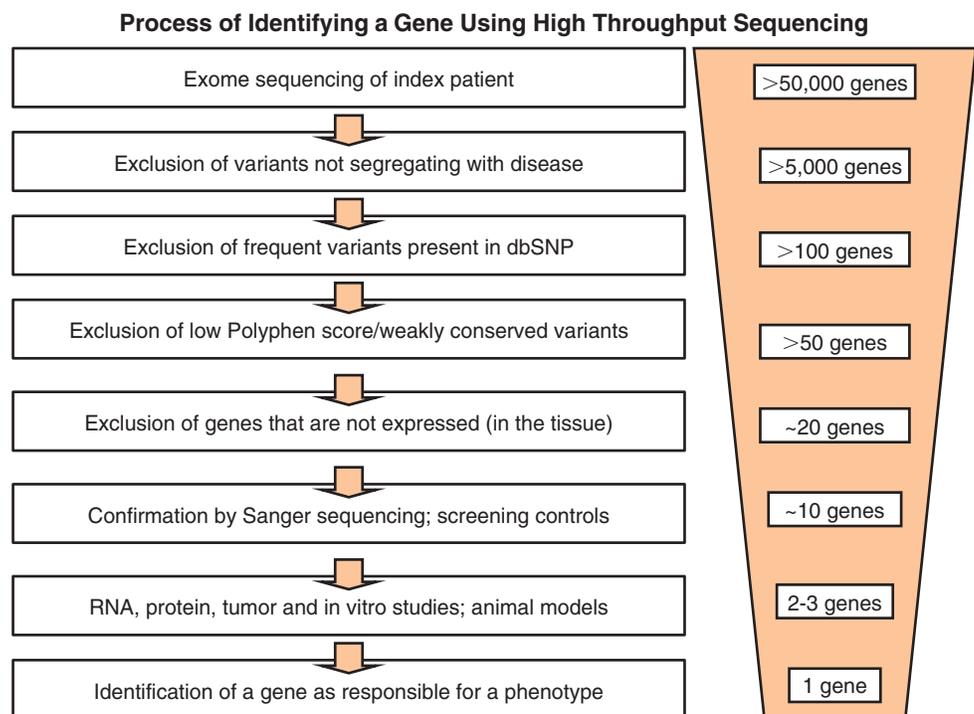

NGS is used today to sequence the entire genome (whole-genome sequencing [WGS]) or only the expressed genes (whole exome sequencing [WES]) of a proband (or his family members) with the intention to identify the mutations responsible for a disease after the methods described here have positionally identified a locus of interest. In the absence of linkage or other positioning information (such as, for example, in the absence of family history, tumor material, or additional DNA samples) an individual’s genomic DNA (or tissue derived from the individual) may be sequenced by WGS or WES. This, however, leads to the identification of many mutations and other variants that need to be excluded to identify the disease-specific gene(s). A typical flowchart for analyzing such studies is shown in Fig. 2.11.

Impact of Modern Sequencing in Clinical Practice

Genome-sequencing studies indicate that each human subject carries as many as 100 loss-of-function mutations, with more than 20 genes being completely inactivated.³⁹ Many genetic variants are found to have previously unsuspected functional redundancies; thus a patient may have many genetic variants within a singular signaling pathway leading to graded phenotypes.^{39,40}

An example of the application of the techniques of modern DNA sequencing in pediatric endocrinology that resulted in the elucidation of the disease mechanism is in the so-called *white Addison disease* (WAD) phenotype.⁴¹ It has been recognized that patients presenting with primary adrenal insufficiency (pAI) are not always pigmented; this variant of pAI was called WAD. Increased pigmentation in pAI is attributed to the binding of high levels of adrenocorticotropin (ACTH) to the melanocortin (MC) 1 receptor (MC1R). MC1R, a molecule with a high degree of sequence similarity to the MC2R, the ACTH receptor, binds to its regular ligand, α -melanocyte-stimulating hormone (α -MSH) and ACTH with an almost equal affinity.⁴² α -MSH stimulates melanogenesis in cultured human melanocytes

Fig. 2.11 Whole genome or exome sequencing is the currently preferred deoxyribonucleic acid (DNA) sequencing technology for gene identification. However, even in the genome of phenotypically normal human subjects, these sequencing techniques yield a multitude of sequencing variants, including bona fide protein-truncating mutations, hence the need to use a systematic and careful filtering process to identify the causative gene(s). The steps in the analysis of gene mutations identified by high-throughput sequencing techniques that culminate in the assignment of a gene to a specific phenotype are illustrated.

and acts specifically to increase the synthesis of eumelanin. Both α -MSH and ACTH are splice products of the same precursor pituitary protein, proopiomelanocortin (POMC), and play a role in determining pigmentation in humans, as homozygous or compound heterozygote mutations in the POMC gene are associated with hypopigmentation and red hair. In pAI that is not appropriately treated with glucocorticoids, POMC expression increases, and both α -MSH and ACTH increase. The important role of MC1R in the determination of human skin and hair pigmentation is beyond doubt: reduced function MC1R alleles lead to red hair, freckling, sun sensitivity, and an increased risk of cutaneous cancers, including melanoma.^{42,43}

Familial glucocorticoid deficiency (FGD) caused by ACTH resistance consists of at least three distinct genetic syndromes that are all inherited as autosomal recessive (AR) traits: inactivating mutations of the ACTH receptor (the *MC2R* gene) and its accessory protein (MRAP); isolated ACTH resistance (iACTHR) without *MC2R*, *MRAP*, or any other known mutation; and Allgrove syndrome.^{44,45} Turan and colleagues⁴¹ described a patient with FGD without pigmentation: she was born with red hair, which gradually darkened during early childhood; despite repeated episodes of hypoglycemia, she was not diagnosed with pAI and was thus exposed to high ACTH levels until she was 6 years old. *MC2R* sequencing showed a homozygous T152K mutation that is known to affect trafficking of the receptor, like most ACTH receptor defects causing FGD. *MC1R* sequencing showed a homozygous R160W mutation that is among the most common genetic variants of the receptor in red-haired individuals. In a fascinating confirmation of the roles of ACTH (and possibly other POMC-derived peptides) and MC1R in determining not only skin but also hair pigmentation, the patient's hair lightened and "reverted to a reddish color" following proper replacement with hydrocortisone and a decrease of serum ACTH levels.

With genetic variants responsible for even subtler effects (than, for example, red hair), DNA sequencing data challenge the practicing clinician to incorporate systems biology information in clinical practice. Clearly not all sequence defects identified by WGS or WES cause diseases; quite the opposite. The evidence is that there is redundancy and an exquisitely delicate and complex molecular balance in human biology. But clinicians have to incorporate genetics in their daily practice, and educators have to introduce molecular pathways and their genetic variability in classic physiology and pathophysiology lectures.⁴⁶

CHROMOSOME ANALYSIS AND MOLECULAR CYTOGENETICS

Chromosomes represent the most condensed state in metamorphosis of the genome during a cell cycle. Condensation of the genetic material at metaphase stage is a crucial event that provides precise and equal segregation of chromosomes between the two daughter's newborn cells during the next step, anaphase. This is followed by relaxation of the genetic content after cell division. This ability of the genome to transform from a molecular level (DNA) to a materialistic submicroscopic stage (chromosome) provides a unique opportunity to visualize the genome of an individual cell of an organism. Different chromosomal abnormalities related to particular diseases or syndromes can be detected at this stage by karyotyping chromosomes.

Chromosomes can be individually recognized and classified by size, by shape (ratio of the short/long arm), and by using differential staining techniques. In the past, identification of chromosomes was restricted to chromosome groups only. The introduction of the chromosome banding technique

revolutionized cytogenetic analysis.⁴⁷ The banding patterns are named by the following abbreviations: G for Giemsa, R for reverse, Q for quinacrine, and DAPI for 4'6'-diamino-2-phenylindole; the last two give a pattern similar to G-banding. Further development of high-resolution banding techniques enabled the study of chromosomes at earlier stages of mitosis, prophase, and prometaphase.^{48,49} Chromosomes are longer and have an enriched banding pattern at those stages, providing great details for the identification of chromosomal aberrations.

Outline of Methods

Preparation of good-quality chromosomes is an art. Many different methods for chromosome isolation have been developed in cytogenetics since the 1960s. The main principle behind all methods is to arrest cells at metaphase by disruption of the cell spindle. Metaphase spindle is a structure composed of tubular fibers formed in the cell to which the chromosomes are attached by kinetochores (centrosomes). The spindle separates the chromosomes into the two daughter cells. The agent commonly used for spindle disruption is Colcemid. The exposure time to Colcemid varies depending on the proliferative activity of cells. Cells with a high proliferative index need a shorter time of exposure to a high concentration of Colcemid, 0.1 to 0.07 $\mu\text{g}/\text{mL}$ for 10 to 20 minutes. Slow-growing cells require longer exposure, 1 to 4 hours or overnight with a lower concentration, 0.01 to 0.05 $\mu\text{g}/\text{mL}$. Prolonged exposure to Colcemid or the use of high concentrations increases the proportion of chromosomes at late metaphase, resulting in shortening of the chromosomes. Conversely, a short exposure with a high concentration of Colcemid reduces the total yield of metaphases. The optimum strikes a balance of these parameters. There are some additional modifications that allow for the enrichment of long (prometaphase) chromosomes by using agents that prevent DNA condensation, such as actinomycin D, ethidium bromide, or BrDU. Cell synchronization techniques can also significantly increase the total yield of metaphase chromosomes.

Applications

Chromosomes are invaluable material for the evaluation of the genome integrity and its preservation at the microscopic chromosomal level. The areas of application include prenatal diagnostics, genetic testing of multiple familial syndromes, including cancer, positional cloning of the genes, and physical mapping (assignment of the genes on chromosomes and subchromosomal regions). The number and morphology of all 23 chromosome pairs in humans can be examined using G-banding differential staining of chromosomes obtained from a peripheral blood sample. Aberrations in the number of chromosomes or visible chromosomal alterations, such as translocations, deletions, and inversions involving extended regions, can be detected by this method. Advances, such as spectral karyotyping, allow for better visualization of aneuploidy and translocations between different chromosomes. Subtle rearrangements, such as submicroscopic deletions or cryptic translocations (an exchange of the small distal telomeric regions between the two nonhomologous chromosomes), can be visualized using specific probes in the FISH technique (Fig. 2.12).⁵⁰

Future Developments

Chromosome analysis will remain a powerful analytic tool in clinical and research fields for the foreseeable future. Possible strategies to improve existing methods include automatization and linearization of the genetic content by increasing resolution to visualize at the level of the chromosome, chromatin,

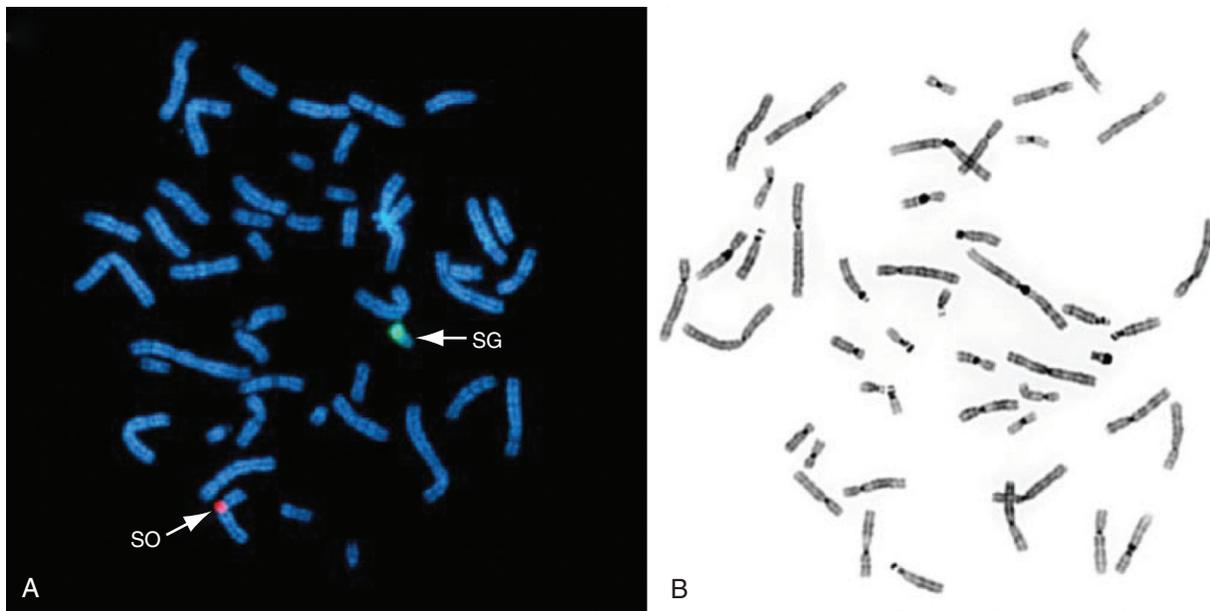

Fig. 2.12 Human metaphase chromosomes (A) after fluorescent in situ hybridization (FISH) using the chromosome X-specific centromeric probe labeled with Spectrum Orange (SO) and chromosome Y-specific heterochromatin labeled with Spectrum Green (SG) and (B) with the inverted DAPI banding (similar to G-banding) allowing chromosomal identification.

DNA, and gene. Another possible direction of development is functional analysis of the genome using constitutional chromosomes and labeled expressed sequences from particular tissues mapped directly to their original positions on chromosomes.

PRINCIPLES OF INTERPRETATION OF GENETIC TESTS IN THE DIAGNOSIS AND MANAGEMENT OF PEDIATRIC ENDOCRINE DISEASES

In the past, genetic tests were usually carried out by research laboratories that had a specific interest in the disease/syndrome under investigation. Under this scenario, the medical provider could generally rely on the expertise of the research laboratory to help with the identification of the appropriate test/test panel and interpretation of the results of the tests. However, with the increasing use of commercial laboratories for these tests, these responsibilities are being transferred to the medical providers. Hence it is now essential for medical providers to become familiar with issues, such as choosing of the appropriate test, the potential usefulness of the information provided by the test including false-positive and false-negative results, available preventive or treatment options, and social and behavioral issues related to genetic testing. The following are some of the points that should be considered when ordering or interpreting a genetic test for a pediatric endocrine disorder:

Limitations of commonly used PCR-based assays. In general routine PCR-based assays (whether they involve electrophoresis or DNA sequencing of the product) cannot reliably differentiate between the two alleles of an individual gene. Hence in a given instance, the detection of a mutation in an autosomal recessive disease could be either caused by the mutation being present in only one of the alleles (and thus not likely to have clinical manifestation) or the result of the mutation being present in a single allele with the other allele being absent (e.g., because of gene deletion) in which case the mutation in the one allele present would clinically manifest. In a similar manner, the inability to amplify a loss-of-function mutant allele by PCR could either be

caused by the presence of two normal alleles (hence excluding the genetic defect) or because of the absence of both the alleles (attributed to gene deletion) in which case the genetic defect would be symptomatic. In many cases, the latter scenario can be excluded by testing using alternative techniques, such as Southern blotting.

Germline versus somatic mutation. Germline mutations are present in every cell descended from the zygote to which that mutant gamete (ova/sperm) contributed. In contrast, somatic mutations occur in a somatic cell (e.g., liver or bone marrow or skin) and hence are not present in other cell types in the body. Most common examples of inherited mutations are germline mutations. Examples of somatic mutations causing endocrine disorders are rarer—for example, in McCune-Albright syndrome, the mutation in the *GNAS* gene may only be detectable in the skin (café au lait) or the bone (fibrous dysplasia) lesion.

Disorders of imprinting. In many instances, the genetic basis of the endocrine disorder is not caused by a mutation but rather by an abnormality in genomic imprinting. Genomic imprinting is the modification of gene expression dependent on whether the genetic material is inherited from the mother or the father. Classic examples are Prader-Willi syndrome (chromosome 15q12 deletion inherited from father) and Angelman syndrome (chromosome 15q12 deletion inherited from mother). Other examples of endocrine disorders in which imprinting is implicated are pseudohypoparathyroidism and Albright hereditary osteodystrophy, Russell-Silver syndrome, Beckwith-Wiedemann syndrome, the focal form of persistent hyperinsulinemic hypoglycemia of infancy, and transient neonatal diabetes.

Penetrance and expressivity. Penetrance is defined as the percentage of people who have the gene and who develop the cognate phenotype. Expressivity is the extent to which a gene is expressed in one person. For example, when a gene has 50% expressivity, only half the features are present or the disease severity is only half of what can occur with full expression. The variable penetrance of many of the neoplastic components of the MEN syndrome is an example of this phenomenon.

One gene, multiple diseases. Examples of mutations in the same gene causing different disease (e.g., *lamin A/C* gene [LMNA] mutation causing Emery-Dreifuss muscular dystrophy, Hutchinson-Gilford progeria, Charcot-Marie-Tooth type 2, familial partial lipodystrophy syndrome, and dilated cardiomyopathy). In many such instances, the variability can be attributed to specific mutation(s) for each of the different clinical manifestations or sets of mutations within different domains/regions of the gene. A similar example is mutations in the *RET* oncogene implicated in MEN2 syndromes, nonsynchondroma paraganglioma, and in Hirschsprung disease.

One disease, multiple genes (phenocopy). Phenocopy refers to the development of disease manifestations that are usually associated with mutations of a particular gene but instead are caused by another gene/etiology. Such a scenario could confound clinical diagnosis and management of a suspected hereditary endocrine disorder. For example, it has been reported that MEN1 syndrome, which is usually caused by mutation in the *MEN1* gene, can be mimicked by familial hypocalciuric hypercalcemia caused by an inactivating mutation in the calcium-sensing receptor, the hyperparathyroidism-jaw tumor syndrome resulting from a mutation in the gene responsible for hyperparathyroidism type 2 (HRPT2), and mutations in the p27 (*CDKN1B*) gene that cause a MEN1-like syndrome that has been called MEN4.

GENOMIC MEDICINE, GENOME SEQUENCING, AND APPLICATIONS IN GENETIC TESTING

As mentioned earlier, in the last 3 decades, there have been two major advances in modern molecular genetics. The first was theoretical; it was the introduction of the concept of “positional cloning,” which was explained previously. The second was technical; the technique of PCR was also extensively discussed in the preceding pages. Cancer medicine and traditional human genetics were the fields that benefited most from the first applications of the new genomic concepts and technologies. The HGP was completed in 2003 using mostly PCR-based Sanger sequencing. The latter was expensive, laborious, and impractical for studying whole genomes; thus HGP technologies that were grown out of necessity led to the development of NGS methods that are now widely available.⁵¹ The HGP also determined that the human genome is composed of 3.3 billion pairs of nucleotide bases and that all human beings share 99.9% similarity at the DNA level with only 0.1% genetic variation, the latter mostly caused by single-nucleotide polymorphisms (SNPs). Thus there are about 10 million SNPs in the human genome. On average, these SNPs occur once in every 300 nucleotides, mostly in noncoding DNA that is located between the approximately 20,000 to 25,000 coding genes. Decades after the first successful disease-causing gene identifications in endocrinology, the gene mutations in CAH syndromes, the insulin and steroid hormone receptors, and *RET*, *GNAS*, *menin*, *PTEN*, and *PRKARIA* in the various forms of multiple endocrine tumor syndromes, a number of other genetic causes have been identified in diseases affecting the pituitary, thyroid, parathyroid, pancreas, adrenal, the gonads, and so on.⁵² In fact, progress is so fast that we are already talking about postgenomic medicine or endocrinology.⁵³ However important these discoveries were in helping us understand cellular processes, glandular development, disease pathophysiology, even leading in some cases to new, molecularly designed treatments, it is only now that genomic medicine is in fact altering clinical practice. The changes are fast and far-reaching, from defining the genotypes of each one of us, to linking electronic medical records (EMRs) to genomic data, to direct-to-consumer genetic testing and its implications for patient-doctor interactions, disease

surveillance, ethics and beyond. Hippocrates, again, noted that “Medicine cannot be learned quickly because it is impossible to create any established principle in it, the way that a person who learns writing according to one system that people teach understands everything; for all who understand writing in the same way, do so because the same symbol does not sometimes become opposite, but is always steadfastly the same and not subject to chance. Medicine, on the other hand, does not do the same thing at this moment and the next, and it does opposite things to the same person, and at that things that are self-contradictory.”⁵⁴ The continuous shifting of ideas and practices is indeed very real in modern medicine and endocrinology and is caused by the advances of genetics.

GENETICS IN CLINICAL PRACTICE AND NEXT-GENERATION SEQUENCING APPLICATIONS

The vast majority of patients encountered in daily endocrine practice were not, up to recently, candidates for genetic testing. For most practicing endocrinologists, encountering a patient with familial glucocorticoid resistance (FGR), for example, would be almost unheard of. In these rare cases, a referral to a research academic center would be the solution; there the patient of our example, with FGR, would undergo genetic testing that could lead to the identification of the causative mutation in the glucocorticoid receptor gene.⁵⁵ The discovery would lead to a publication but would remain relatively obscure for the average clinician. This was the case up to recently for most of medicine.

However, today, there are more than 10,000 rare diseases and even though each is extraordinarily rare (like FGR), collectively, these diseases affect large numbers of patients and represent an exceedingly disproportionate share of healthcare costs.⁵⁶ The International Rare Disease Research Consortium estimates that a significant number of patients with rare diseases are seen and remain undiagnosed at clinical practices.⁵⁶ Several of our patients with complex symptoms and signs are now offered genetic testing in routine clinical settings. In addition, the chances are that most clinicians in developed countries will encounter patients that have already been the recipients of direct-to-consumer genetic testing (DCGT).⁵⁷ In February 2019 it was estimated that over 26 million people have taken home DNA tests. In 2015 a company known as “23andme” was granted approval by the US Food and Drug Administration (FDA) to include health risk assessments in genetic reports. There are several such companies today from those providing DCGT for ancestry and various traits, for a relatively inexpensive fee, to others that provide full genome sequence analysis data and discuss health risks for a higher price.

In another front, it is not unusual for the average clinician practitioner to encounter pharmacogenomics (PGx).⁵⁸ For example, in testing for abnormal cortisol levels in response to the 1 mg overnight dexamethasone (DEX) test, it is essential to know whether the patient is a rapid or slow DEX metabolizer. There are several testing sites that now test for the cytochrome P450 liver enzymes that are responsible for DEX metabolism. In areas of medicine other than endocrinology, PGx is already in daily practice from infectious diseases and the right choice of an antibiotic for a rapid or slow metabolizer, respectively, to how certain ethnic groups respond to a drug, based on gene-specific and ethnicity-related genetic variants. There are now more than 200 drugs that have PGx information included in their FDA-approved labels and new clinical practice guidelines, based on PGx, are now published frequently.⁵⁹

Finally, there is increasing use of genetic screening for preventive health and for prenatal diagnostic testing. There are several efforts across the United States and other countries and in

several health systems, private or government-run, to link cancer, cardiovascular, and other risk factors to medical records (EMR and other types of records) with the intent to lead to behavior, diet, and other modifications, diagnostic and even invasive procedures that prevent disease.⁵⁸ Noninvasive prenatal testing (NIPT) relies on the detection of cell-free DNA (cfDNA) on parental samples for the detection of trisomies and increasingly other genetic defects.⁶⁰ NIPT represents one of the fastest adopted tests by every day clinical practice in the history of medicine and has revolutionized the detection of fetal aneuploidies and other disorders, obviating the need for amniocentesis and a number of other procedures.^{51,60}

The aforementioned screening and testing strategies were possible because of advances emanating from the HGP, in particular massively parallel DNA sequencing technologies, which were first introduced in 2005 and keep improving and becoming cheaper every day.⁵¹ Collectively, these new DNA sequencing technologies can generate billions of short sequencing reads within hours; the current cost for a near-comprehensive determination of one's genome by NGS for both frequent and rare variants is approximately \$1000, whereas the cost is significantly less for exome-only versions and even less if specific regions or a collection of genes are targeted.^{61,62}

In addition to NGS, a product of HGP was high-density DNA microarrays based on SNPs. They were first introduced in the late 1990s; however, at the beginning, these microarrays were mostly used in population-based or other large cohort-based research studies of genotype human genomes for genetic variation and other association studies. Now, high-density DNA microarrays are also used in clinical practice for the identification of structural variants of the human genome and for the rapid identification of any sequence variation: in fact, the most popular genetic tests today are not sequencing-based tests, but genotyping tests using technology derived from the DNA microarrays that were first developed by HGP researchers.^{61,62} It is hard to predict where NGS is heading.⁵¹ It is safe to say, however, that it will expand in ways and applications that will intrude in every aspect of medicine and indeed life. It is therefore essential for endocrinologists to understand the basics of NGS, how it is applied today, and its impact on how we practice medicine.

Genome Versus Exome Sequencing, Variant Interpretation, Other Challenges

The goal of NGS is to provide a high-quality map of genome variation for each sample. WGS provides exactly that with short-read NGS technology, which is widely available today.⁶² Yet, it remains prohibitively expensive for clinical use and cumbersome in data management. Because nearly 99% of the roughly 3.3 billion nucleotides constituting the human genome do not code for proteins, and most human diseases are caused by variations of or defects of coding genes (the exome), the alternative approach, as mentioned earlier, is WES, which currently costs less than \$1000 and is widely available in developed countries.

Single nucleotide variants (SNVs) and small insertion or deletion variants (indels) that are less than 50 bp long represent the vast majority of variants in the human genome: there are 3 to 4 million SNVs and 0.4 to 0.5 million indels in every human sample compared with the reference genome.⁶² However, only a few more than 100 lead to a premature stop codon for a coding gene and only about 20 or so are potentially deleterious. Nevertheless, practically every variant can cause a phenotype not only through changing the protein by an amino acid substitution, a deletion, or an insertion, but also by changing binding of transcription factors, interactions with other molecules,

RNA stability, and so on. Sequence variants that are identified by WGS or WES are reported therefore as variants of unknown significance (VUS) because unless there is previously existing data documenting their function, they may not be called mutations and cannot be definitely linked to disease or even a risk factor.^{61,62}

Structural variation (SV) is another form of genome variation, by definition it is larger than 50 bp, which includes copy number variants (CNV) that represent amplifications or deletions of variable size DNA segments, chromosomal rearrangements, and mobile element insertions.⁶² SVs account for only about 0.2% of total variants, but they more frequently effect phenotype, representing, for example, as many as 4% to 12% of high-impact coding alleles. Their phenotypic effect is typically proportionate to their size, although exceptions to this rule exist. SVs are not easily detectable by short read WGS and even less so by WES. Their architectural diversity also poses additional challenges in their detection. For one to see the impact of methodology, a typical human genome contains as many as 10,000 SVs detectable by the commonly used short-read WGS but more than 20,000 SVs identified by long-read WGS. The complexity of variant interpretation increases when one considers repetitive elements, such as short or variable number tandem repeats and mobile element insertions.

Functional annotation for each one of the variants, whether it is a VUS, SV (CNV or otherwise), or a repeat variant, is constantly updated based on information in publicly available databases to which genotypic and phenotypic data are added daily.⁵⁸ It is estimated that up to 25% of patients with a rare disease may be found to have a causative defect upon first application and reading of a WES test in specific cohorts studied by experienced clinical centers.⁵⁶ Because of continuously available new information, reanalysis of previously "negative" WES data may increase yield by more than 10% and even higher when family and other data are added to the analysis.^{56,62}

Variants may be classified as pathogenic or likely pathogenic variants and benign or likely benign based on structural effect on DNA and/or the coding gene or protein, functional studies, in silico data, variant frequency in control populations, family studies (segregation analysis), and other factors.⁶³ There are stringent and explicit guidelines followed now by all genetic testing laboratories and endorsed by professional societies. Variant assessment also includes searching carefully the available literature but one has to be careful with older nomenclature, different gene symbols, sequence numbering, and phenotypic interpretations.

During NGS, one may also identify what have been called *secondary findings*, which is understandable given the number of variations in the human genome, as stated earlier. Currently, the American College of Medical Genetics and Genomics (ACMG) and other organizations have identified 59 medically actionable genes in which, if variants are found, they need to be reported as secondary findings and may lead to additional testing and even invasive procedures.^{61,63} Examples include the *BRCA1* and *BRCA2* genes, associated with early breast, ovarian, and other cancers; *BMPRIA* and *SMAD4* associated with increased risk for colorectal and other cancers; and other genes.⁶¹

NGS and Cell-Free DNA in Cancer Medicine and Prenatal Testing

Plasma-borne DNA was first described in 1948, but for years its origin and significance were unknown.⁶¹ In the 1980s, it was realized that tissues such as tumors, the placenta, and the human fetus, shed DNA and RNA. In cancer medicine, cfDNA

and cfRNA can lead to early detection, identification of the mutational profile of a given tumor, and provide means for follow-up as a tumor marker and in response to therapy. The notion of “liquid biopsy” is now well accepted in many oncological settings despite the challenges that remain: the relatively low proportion of tumor-derived cfDNA and cfRNA in the circulation, the difficulty in assessing such abnormalities early in the course of malignancy, and the high rates of false positives.⁶¹

On the other hand, sequence analysis of cfDNA and cfRNA fragments that circulate in the blood of pregnant women, along with the translation of this method into screening for fetal chromosome abnormalities, is clearly a great success story of modern genetics.^{51,60} As of late 2017, a total of 4 to 6 million pregnant women had had DNA from their plasma analyzed to screen for fetal aneuploidy.⁶⁰ During pregnancy, DNA fragments are released from the placenta into the maternal circulation; plasma contains both maternal and placental DNA and one calculates the ratio of placental to total cfDNA, which is known as the “fetal fraction” and increases as pregnancy advances. Testing is performed from the 10th week of gestation onward. The testing has revolutionized aneuploidy detection and obviated the need for more invasive procedures (i.e., amniocentesis). However, there are issues with a relatively high rate of false positives and the identification of secondary findings governed by the same ACMGG-sponsored guidelines referred to in the previous section.⁶³

Next-generation sequencing, mosaicism, and its applications in detecting somatic genetic defects

A “negative” WGS or WES in a tissue sample may be caused by some of the issues discussed earlier and caused by the increasingly frequent issue of mosaicism: most commercially available NGS technologies may not detect mosaicism for a pathogenic variant because the latter may not be present in the tissue tested (e.g., in peripheral blood in most cases). Picking a variant at low levels from the “noise” of a sequence is often impossible (unless one increases the “depth” of the sequence), and mosaicism levels for a variant change with aging at various tissues (sequence variants detectable in blood in infancy may not be there in adolescence).⁶¹ There are new diagnostic tools under development to detect mosaicism, but for most cases it remains a difficult issue to solve.

On the other hand, NGS is used frequently for the detection of the mutational spectrum in cancers.⁶¹ Tumors have a hugely variable genome that offers diagnostic and treatment opportunities if identified by NGS. Just like what was mentioned earlier in cfDNA analysis, challenges include the relatively high heterogeneity of tumor samples, low frequency of single clonal DNA changes, and the high rate of false positivity.

In endocrine diseases, McCune-Albright syndrome is a classic disorder caused by postzygotic mosaicism for an activating mutation of the *GNAS* gene.⁶⁴ NGS may be used for the detection of mosaicism in peripheral tissues, because frequently the mutation is not detectable in peripheral blood. It is expected that the wider application of NGS will lead to the identification of many more instances of mosaicism in endocrine diseases, just like it did in other areas of medicine.

PRECISION MEDICINE

As noted in the preceding section of this chapter, genetic testing for monogenic, mendelian disorders is becoming an increasingly important tool for the pediatric endocrinologist. It can by itself reveal a diagnosis and inform prognosis and treatment. For example, a heterozygous loss-of-function mutation in *ABCC8* inherited from the father may be evidence for congenital hyperinsulinism caused by a focal pancreatic lesion

treatable by resection of the lesion, whereas compound heterozygous loss-of-function mutations in the same gene inherited from both parents most likely would require near-total pancreatectomy. The diagnosis of monogenic diabetes may allow patients previously diagnosed with type 1 diabetes to transition from insulin to an oral sulfonylurea. In boys with primary adrenal insufficiency, the presence of a pathogenic mutation in *ABCD1* is diagnostic of adrenoleukodystrophy and predicts a very different prognostic and therapeutic trajectory than would be the case for an autoimmune etiology. Moreover, different mutations in the same gene may have different implications, as in CAH caused by mutations in *CYP21A2*, in which salt-wasting, virilizing, or nonclassical phenotypes can often be predicted by specific mutations. In addition, as specific gene- and cell-based therapies for endocrine diseases emerge, such as gene-editing, base-editing, and anti-sense oligonucleotide (ASO) therapies, it will become important to document a patient’s precise genetic lesion to correctly devise and deliver the appropriate treatment. Endocrinologists should understand the genetic basis of endocrine diseases and their treatments so they can advise their patients, participate in therapeutic decisions, and monitor the therapeutic consequences.

However, despite the growing importance of genetic testing in pediatric endocrinology, several barriers exist. First and foremost, many physicians have a knowledge deficit in genetic medicine. Most physicians, especially those who finished medical school in the past 25 years, have had robust education in basic and clinical genetics, but because this knowledge was not carried through residency, fellowship training, or faculty development, they are not comfortable applying clinical genetic principles to clinical practice. Physicians should (1) be proficient in recognizing when a patient might have a genetic basis for their disease when it appears at a very young age, when it is very severe, when it is part of a syndrome, and when its inheritance segregates within a family; (2) recognize different inheritance patterns of autosomal dominance, autosomal recessiveness, X-linked inheritance, and imprinted parental transmission from mother or father; (3) recognize consequences of loss of function, gain of function, and dominant negative mutations, and that different mutations in the same gene may have different consequences; (4) recognize the specific endocrine diseases that may have a monogenic basis, as well as the responsible genes; (5) understand what types of genetic tests are available (single gene, gene panel, exome, genome, microarray, cytogenetic/karyotype, PCR, FISH, etc.) and how to use these; (6) know how to interpret different DNA sequence results (benign versus pathogenic versus uncertain significance); and (7) understand that the interpretation of a patient’s test result may change over time as new knowledge emerges, and know how to recontact the original testing laboratory and search public databases (ClinVar, Human Mutation Gene Database, OMIM, etc.) for new information.

The proper interpretation of genetic test results by a testing laboratory requires it to have accurate phenotype information, which must be supplied by the physician who orders the test. For single genes and gene panel tests, different classes of mutations in the same gene have different consequences. For example, different variants in *CASR* cause either familial hypocalcemic hypercalcemia (loss of function) or hypocalcemia (gain of function). The testing laboratory would be reluctant to interpret the significance of a variant without knowing which phenotype to associate it with. When evaluating exome or genome DNA sequence results, the testing laboratory is guided by the phenotype (often documented in human phenotype ontology or HPO terms) to select which variants within the roughly 20,000 human genes to evaluate for pathogenicity. Incorrect or incomplete phenotype information may misdirect this analysis.

Patients (and if a child, their guardians) should provide informed consent for all genetic tests. Even for single gene and gene panel tests, they should be informed how the test may aid diagnosis, prognosis, or treatment. They should understand that a result may not be informative, may provide or confirm a diagnosis, may be of uncertain significance, or may require reanalysis at a future time. They should understand that if parental DNA is also analyzed (for example, a trio study using DNA from the patient and both assumed biological parents), there is a chance that nonpaternity may be revealed. They should understand that genetic test results may result in discrimination in obtaining life insurance, or provide evidence of preexisting disease, which under some future scenarios may result in denial of health insurance. Patients should also realize that exome and genome studies may reveal pathogenic findings outside of the scope of the purpose for the test, such as a predisposition to cancer, which they must decide either to be informed of or not. Finally, patients should understand their financial liability for genetic testing, as it is variably covered by health insurers. Before a genetic test is ordered, it is desirable to understand if the patient's health insurance provider will approve the testing, and if so, whether the patient will be responsible for copay or deductible costs.

When the physician discusses with the patient both the initial recommendation to perform genetic testing, as well as the test results, it is often helpful to do this in conjunction with a genetics counselor, who is trained in all of the aforementioned areas, including how to effectively discuss these issues with patients and their families.

Precision medicine therapeutics hold great promise for the future of pediatric endocrinology. Gene replacement of mutant genes coupled with autologous stem cell transplantation is being investigated in patients with adrenoleukodystrophy.⁶⁵ In vivo treatment of spinal muscular atrophy using an ASO approach⁶⁶ has recently been approved by the FDA.⁶⁷ In the future, direct correction of human gene defects in somatic cells in vivo may be possible by CRISPR-assisted gene- and base-editing strategies.⁶⁸ Knowledge of the specific genetic basis of a patient's disease will become the necessary first step in considering these future potential therapies.

RECOMBINANT DNA TECHNOLOGY AND THERAPY OF PEDIATRIC ENDOCRINE DISEASES

From a therapeutic point of view, recombinant DNA technology can be exploited to either tailor pharmacotherapy according to the genotype of a patient (i.e., targeted pharmacotherapy), manipulate genes within the human body (gene therapy), or engineer prokaryotic or eukaryotic cells to produce proteins, such as hormones, which can then be administered for therapy or diagnosis. Whereas targeted pharmacotherapy and gene therapy are mostly restricted to the research arena, the use of hormones produced by recombinant DNA technology is well established in clinical endocrinology. Historically, insulin was the first hormone synthesized by recombinant DNA technology to be approved for clinical use.^{69,70} At present, a variety of recombinant hormones including growth hormone (GH), luteinizing hormone, follicular-stimulating hormone, thyroid-stimulating hormone (TSH), parathyroid hormone, and erythropoietin are being used clinically or are in advanced stages of clinical trials.

On a theoretic basis, it should be possible to synthesize any protein hormone whose gene has been cloned and DNA sequence determined. Thus recombinant DNA technology makes it possible to insert the gene coding for a particular protein hormone into a host cell such that the protein is produced by the host cell's protein-synthesizing machinery. The

synthesized protein is then separated from the rest of the host cell proteins to obtain the pure form of the hormone of interest. Both prokaryotic and eukaryotic cells can serve as the host cell for the production of proteins by this technology. Because post-translational modifications, such as glycosylation, may be essential for the optimal action of a protein hormone, the choice of the specific cell system used for the production of a particular protein hormone is critical. Prokaryotic cell systems, such as *Escherichia coli*, are suitable for the production of protein hormones that do not need posttranslational modifications, such as GH.⁷¹ Eukaryotic cell systems, such as Chinese hamster ovary cells that are capable of posttranslational modification of the protein, are useful for the production of hormones, such as TSH, that require glycosylation for optimal bioefficacy.⁷² In addition, eukaryotic cells are capable of synthesizing proteins that undergo the appropriate folding, a step that is not carried out by prokaryotic cells. The advantages of the use of recombinant DNA for the production of these proteins include the possibility of a limitless supply of a highly pure form of a protein and the absence of the risk of contamination with biological pathogens associated with the extraction of proteins from human or animal tissue. In addition, this technology permits the development of hormone analog and antagonists with much greater ease than conventional protein synthesis protocols.

The influence of genetic factors on the metabolism of various drugs is a well-established phenomenon with the effect of various isoenzymes of cytochrome p450 on the circulating half-life of drugs, such as anticonvulsants, which are a classic example of this interaction. Another example of the role of genotype on the choice of pharmacotherapy is the phenomenon of drug-induced hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency. The genomic revolution has allowed for the exploitation of computational approaches to identify polymorphisms of known genes encoding proteins with different functional characteristics, as discussed previously. Investigators can now predict the response of a particular individual to a class of drugs/chemicals. This pharmacogenomic approach to clinical therapeutics has been successful in demonstrating an association between specific polymorphisms in the β -adrenergic receptor and response to β -agonists in patients with bronchial asthma, and polymorphisms in hydroxytryptamine receptors and response to neuroleptic drugs. The widespread application of the tools of molecular biology to unravel the molecular basis of action of hormones has also yielded benefits by allowing for customization of the pharmacotherapy of endocrine diseases and syndromes based on the specific individual genetic defect. One such example is the report of directed pharmacologic therapy of an infant with ambiguous genitalia, resulting from a mutation in the androgen receptor.⁷³ In this infant with an M807T mutation in the androgen receptor, in vitro functional studies had indicated that the mutant receptor exhibited loss of binding capacity for testosterone with retention of binding for dihydrotestosterone. Furthermore, this differential binding was also reflected in the better preservation of the transactivation potential of dihydrotestosterone (DHT) compared with testosterone. These in vitro findings were exploited to treat the infant with DHT, resulting in restoration of male genital development. This case illustrates that in selected cases, in vitro functional assays can help identify subsets of patients with ambiguous genitalia and androgen insensitivity who would respond to targeted androgen therapy. It can be anticipated that in the coming years, more examples of such innovative therapeutic strategies and "customized" hormonal treatment protocols will become routine and implemented in the practice of clinical pediatric endocrinology.

CONCLUDING REMARKS

The application of recombinant DNA technology has resulted in a tremendous increase in our understanding of physiologic processes and pathological conditions. Achievements, such as the full sequence of the human genome in normal subjects,⁷⁴ have resulted in a paradigm shift in the way that we think about genetic causes and predisposition to disease⁴⁶ and in the analysis of the function of hormones and related proteins.⁷⁵ In the traditional paradigm, investigators seeking to discover new genes or to analyze the function of known proteins needed to devote a significant part of their time to conducting “bench research” in “wet laboratories.” The new approach in this “postgenomic” era takes advantage of the unprecedented power of computational biology to “mine” nucleotide, protein sequence, and other related databases. In the future, most researchers will deal with abstract models and data sets stored in computer databases. Hence initial discoveries of novel genes or novel interactions between known proteins or intracellular signaling pathways could be made using the analytic power of computational software tools (functional genomics); these initial insights can then be verified and expanded upon by traditional laboratory bench methods. The advantages of this new paradigm are obvious with computational approaches taking a significantly shorter time, with less demand on manpower, and can easily expand the scope of the search to include multiple molecules and organisms (phylogenetic profiling). Several public-domain web-accessible databases are currently serving as the major repositories for this information. GenBank is the major repository for sequence information and is currently supported by the National Institutes of Health. One of the main sources of the physical location, clinical features, inheritance patterns, and other related information of specific gene defects is the OMIM operated by Johns Hopkins University in Baltimore, Maryland. Johns Hopkins University also operates the online Genome Data Base, which allows scientists to identify polymorphisms and identify contacts for gene probes and other related research tools. The ever-expanding number of endocrine (and other) disorders that can be attributed to changes in the nucleotide sequence of specific genes has also increased the necessity for the availability of accurate, reliable, and timely genetic tests, such as mutation detection. One source for such information is a collaborative website (www.genetests.org) that maintains an up-to-date catalog of commercially available and research-based tests for inherited disorders.

With the ubiquitous use of these powerful tools in laboratories around the world, genes are being cloned and genetic diseases are being mapped at a rapid pace. In all of these exciting developments, one still needs to keep in mind that whereas this “new” science has allowed for hitherto inaccessible areas of human biology to be probed and studied, a lot remains to be understood with respect to individual disease processes. Hence at the present time, we have only a rudimentary understanding of the correlations between phenotype and genotype in many of the common genetic diseases, such as CAH. These lacunae in our knowledge dictate that clinicians should be cautious about basing therapeutic decisions solely on the basis of molecular and genetic studies. This is especially true in the area of prenatal diagnosis and recommendation for termination of pregnancy based on genetic analysis. As we improve our understanding of the molecular and genetic basis of disease and translate this knowledge into gains at the bedside, it behooves us, both as individuals and as a society, to be cognizant of critical issues relating to the privacy of health data and to remain vigilant against misuse by inappropriate disclosure of this powerful knowledge.

INTRODUCTION

Hormones exert their actions by binding to specific receptor proteins, a process that induces conformational changes or compartmental redistribution of these proteins. The activated receptor is now capable of inducing positive (or negative) intracellular effects that ultimately are recognized as a physiologic response. The specificity of hormone action is determined by the affinity of hormones for different receptors, the cell-specific expression of the receptor, and the unique responses induced by ligand occupancy.

Since the early 2000s, our understanding of hormone action has advanced rapidly with the success of genomics and advanced molecular biologic techniques. This combined approach has led to the discovery and classification of an

unexpectedly large number of receptors, some quite novel and others even unanticipated, that are members of large families of genetically conserved proteins. Moreover, our understanding of receptor action has been clarified by the identification and detailed characterization of postreceptor signaling proteins and signaling mechanisms. Four major receptor superfamilies have been identified that are distinguished by protein structure, cellular localization, and effector systems. These families include the G protein–coupled receptors (GPCRs), cytokine receptors, tyrosine kinase receptors (RTKs), and nuclear receptors (Table 3.1). This chapter reviews major features of these important receptor families. Mutations influencing receptor function leading to endocrine disorders are also highlighted.

TABLE 3.1 Major Types of Hormone Receptors

Receptor Class	Hormone Receptors
G protein-coupled receptors	ACTH and other melanocortins, V2 vasopressin, LH, FSH, TSH, GnRH, TRH, GHRH, corticotropin-releasing factor, somatostatin, glucagon, oxytocin, gastric inhibitory peptide, type 1 PTH, free fatty acid, GPR54, orexin, ghrelin, melanin-concentrating, calcitonin, glucagon-like peptide-1, and calcium-sensing receptors
Type 1 cytokine receptors	Growth hormone, prolactin, and leptin receptors
Receptor tyrosine kinases	Insulin, IGF-1, and fibroblast growth factor receptors
Nuclear receptors	Thyroid hormone, vitamin D ₃ , PPAR γ , HNF4A, glucocorticoid, androgen, estrogen, mineralocorticoid, and DAX1 receptors

ACTH, adrenocorticotropic hormone; DAX1, dosage-sensitive sex-reversal adrenal hypoplasia congenital critical region on the X chromosome gene 1; FSH, follicle-stimulating hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; GPR54, KISS-1 derived peptide receptor 54; HNF4A, hepatocyte nuclear factor-4 α ; IGF-1, insulin-like growth factor-1; LH, luteinizing hormone; PPAR γ , peroxisome proliferator-activating receptor γ ; PTH, parathyroid hormone; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

BASIC PRINCIPLES OF RECEPTOR ACTION

A molecule that binds to a receptor is called a *ligand*. When ligand binding leads to activation of signaling processes inside cells that ligand is called an *agonist*. The response of a receptor to its ligand is generally assessed by two characteristics of the ligand: potency and efficacy. Potency describes the concentration of ligand needed to cause the biological effect by binding to the receptor. A potent agonist activates the receptors at a low concentration, typically in the nanomolar range. Efficacy describes the maximal effect induced by a ligand. Potency is generally described by using the EC₅₀, which is the concentration of ligand that induces a half-maximal effect. When a synthetic agonist exceeds the efficacy of the natural ligand it is called a *super agonist*. When receptor ligands (natural or synthetic) do not induce full activation, they are called *partial agonists*. An antagonist is a molecule that blocks the natural ligand from binding to its receptor. If it binds to the same site as the natural agonist it is called an *orthosteric antagonist*. If it binds to a different site than the natural agonist, it is called an *allosteric antagonist*. The potency of the antagonist is described by the IC₅₀, which is the concentration that causes half-maximal inhibition. A receptor that has constitutive basal activity can be bound by a ligand that inhibits the receptor's activity in the absence of the natural ligand. In this case the ligand is called an *inverse agonist*. A scale has been formulated to express the continuity in receptor ligand function—from -1 (representing a full inverse agonist), to 0 (representing a neutral antagonist), to +1 (representing a full agonist).^{1,2}

Receptors have multiple possible conformations that are constantly changing. Receptors exist in some conformations more than others, based on the free energy of each conformation. Agonists act as modulators that stabilize a given conformation of a receptor by reducing the energy needed to enter that conformation. This conformation is associated with activation of downstream signaling. Partial agonists stabilize the receptor in conformations less efficient at activation of downstream signaling. Super agonists stabilize the receptor in conformations more efficient at activation of downstream signaling. Conformational changes in a receptor can also affect the number and type of signals that a receptor generates. In the classic paradigm, a GPCR was believed to function as a binary switch that could be activated by agonist binding or inhibited by antagonist blockade of agonist binding. We now know that GPCR signaling is more complex than a simple binary switch model (i.e., "on" and "off"), and that different ligands can bind the same GPCR and selectively activate one downstream pathway versus another. This ability of different ligands to induce different conformations of a receptor that activate (or inhibit) selective downstream signals is called *biased signaling*. Ligands that bind to the native site of a receptor but produce different signaling events are termed *orthostatic ligands*. An example of this is provided by the follicle-stimulating hormone (FSH)

receptor, a classic GPCR.³ Fully glycosylated FSH is more acidic and acts as a full agonist at FSH receptors, activating Gs-coupled signaling and generation of cyclic adenosine monophosphate (AMP). Partially glycosylated FSH is more basic and acts as a partial agonist or a biased ligand as it activates both Gs and Gi pathways, which compete. Deglycosylated FSH has no effect on signaling but binds to the receptor and so acts as a competitive antagonist. These differently glycosylated variants exist in the circulation and are a means for fine-tuning the signal from the pituitary to the gonads. In certain cases, a neutral ligand can bind to the receptor at a different site than the natural ligand's binding site and by doing so, influence the conformation of the receptor such that the ligand's efficacy is increased, decreased, or biased. These are called *allosteric modulators*. They do not activate or inhibit the receptors on their own. Similarly, there are allosteric synthetic ligands for the FSH receptor that demonstrate signaling bias ranging from full agonists to reverse agonists.

Receptors are generally found associated with other proteins whether at the cell surface or in the cytoplasm. These associated proteins influence receptor conformation. An example is receptor activity modifying proteins or RAMPs. Calcitonin receptor and calcitonin-like receptor are GPCRs that can bind to several ligands (calcitonin, adrenomedullin, amylin, and calcitonin gene-related protein). RAMP1, RAMP2, and RAMP3 associate with both the calcitonin receptor and calcitonin-like receptor, and depending on which RAMP is associated determines selectivity for one of the aforementioned ligands.

Conformational fluidity of receptors and interactions with multiple ligands and modulators leads to greater complexity, specificity, and fine-tuning, as well as overall efficiency.

G PROTEIN-COUPLED RECEPTORS

More than 1% of the genome of vertebrates encodes a large protein family of receptors that sense molecules outside the cell and activate signal transduction pathways and, ultimately, cellular responses. These receptor proteins are embedded in the plasma membrane and are coupled to intracellular signal generating systems by heterotrimeric G proteins (i.e., GPCRs).⁴ GPCRs are also known as *seven-transmembrane domain receptors*, *7TM receptors*, *heptahelical receptors*, and *serpentine receptors*. They are called transmembrane receptors because they pass through the cell membrane, and they are called seven-transmembrane receptors because they have alpha helical regions that pass through the cell membrane 7 times. The human genome encodes roughly 950 GPCRs. GPCRs are involved in many diseases and are also the target of approximately 40% of all modern medicinal drugs.⁵ Approximately 150 of the GPCRs found in the human genome have unknown functions. Most GPCRs are odorant and pheromone receptors.⁴ Also important to note is that most hormones bind to GPCRs, and hence G protein-dependent signal transduction represents the most common mechanism for hormone action (Table 3.2).

TABLE 3.2 G Protein–Coupled Receptors and Clinical Conditions Associated With Receptor Mutations

Receptor	Germline Mutation	Endocrine Disorder
ACTH/melanocortin-2 receptor	Inactivating mutations (homozygous, compound heterozygous)	Familial glucocorticoid deficiency type 1
Melanocortin-4 receptor	Inactivating mutations (most heterozygous, some homozygous)	Obesity
V2 vasopressin receptor	Inactivating mutations (most X-linked recessive, rarely X-linked dominant)	X-linked nephrogenic diabetes insipidus
LH receptor	Inactivating mutations (homozygous, compound heterozygous) Activating mutations (heterozygous)	Males: types I and II Leydig cell hypoplasia Females: asymptomatic or hypergonadotropic hypogonadism with primary amenorrhea Males: male limited precocious puberty
FSH receptor	Inactivating mutations (homozygous, compound heterozygous)	Females: autosomal recessive hypergonadotropic ovarian dysgenesis or milder hypergonadotropic hypogonadism Males: variable impairment of spermatogenesis
TSH receptor	Inactivating mutations (most homozygous or compound heterozygous, rarely heterozygous) Activating mutations (heterozygous)	Resistance to TSH Autosomal-dominant inherited nonautoimmune hyperthyroidism/toxic adenomas
GnRH receptor	Inactivating mutations (homozygous or compound heterozygous)	Isolated hypogonadotropic hypogonadism
TRH receptor	Inactivating mutations (compound heterozygous)	Central hypothyroidism
GPR54	Inactivating mutations (homozygous, compound heterozygous)	Normosmic isolated hypogonadotropic hypogonadism
Ghrelin	Inactivating mutations (homozygous, possible heterozygous)	Short stature because of decreased growth hormone secretion
GHRH receptor	Inactivating mutations (homozygous/compound heterozygous)	Isolated growth hormone deficiency
Type 1 PTH receptor	Inactivating mutations (homozygous, heterozygous) Activating mutations (heterozygous)	Blomstrand chondrodysplasia if homozygous and rarely if heterozygous; enchondromatosis if heterozygous Jansen metaphyseal chondrodysplasia
Calcium-sensing receptor	Inactivating mutations (heterozygous, homozygous) Activating mutations (heterozygous)	Familial benign hypocalciuric hypercalcemia typical if heterozygous, neonatal severe hyperparathyroidism rarely if heterozygous, typical if homozygous Autosomal-dominant hypocalcemic hypocalciuria, Bartter syndrome type V

ACTH, Adrenocorticotropic hormone; *FSH*, follicle-stimulating hormone; *GHRH*, growth hormone–releasing hormone; *GnRH*, gonadotropin-releasing hormone; *GPR54*, KISS-1 derived peptide receptor 54; *LH*, luteinizing hormone; *PTH*, parathyroid hormone; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone.

The GPCR superfamily is divided into eight major classes.^{4,6} These receptors contain an amino-terminal extracellular domain that is frequently called the *ectodomain* or *exodomain*.⁷ These receptors also contain seven putative transmembrane spanning alpha helices (TM-I to TM-VII). The alpha helices are connected by three intracellular (i1–i3) and three extracellular (e1–e3) loops that are often collectively called the *serpentine region* (Fig. 3.1).^{7,8} The carboxy-terminal intracellular region is usually referred to as the *endodomain*.⁷

GPCRs are activated by a wide variety of signals, including proteins, nucleotides, amino acid residues, Ca²⁺, light photons, and odorants (see Fig. 3.1).⁴ It is postulated that ligand binding alters the conformation of transmembrane domains and intracellular loops, increasing the affinity of the receptor for specific heterotrimeric guanosine nucleotide binding proteins (G proteins) (see Fig. 3.1).^{9,10} G proteins share a common heterotrimeric structure consisting of an α subunit and a tightly coupled $\beta\gamma$ dimer.^{11,12} The α subunit interacts with detector and effector molecules, binds guanosine 5'-triphosphate (GTP), and possesses intrinsic GTPase activity. There are 16 genes in mammals that encode some 20 different α chains. The $G\alpha$ subunits are categorized in four classes and include $G\alpha_s$ (G stimulatory), $G\alpha_i$ (G inhibitory) and $G\alpha_o$ (G other), $Gq/11\alpha$, and $G12/13\alpha$. They behave differently in the recognition of the effector but share similar structures and mechanism of activation. The $G\alpha$ subunits consist of two domains: a GTP-binding domain and a helical insertion domain. The GTP-binding domain is homologous to Ras-like small GTPases and includes switch regions I and II, which change conformation during activation. The switch regions are loops of alpha helices with conformations

sensitive to guanine nucleotides. The helical insertion domain is inserted into the GTP-binding domain before switch region I and is unique to heterotrimeric G proteins. This helical insertion domain sequesters the guanine nucleotide at the interface with the GTP-binding domain and must be displaced to enable nucleotide dissociation.

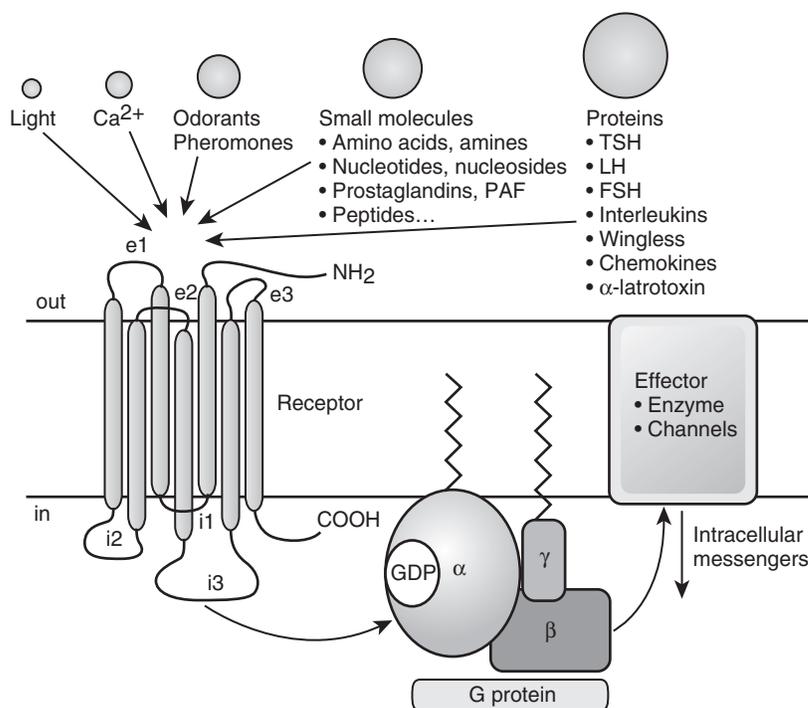

The α subunits associate with a smaller group of $\beta(5)$ and $\gamma(12)$ subunits.^{11,13} Combinatorial specificity in the associations between various G protein subunits provides the potential for enormous diversity and may allow distinct heterotrimers to interact selectively with only a limited number of GPCRs and effector proteins.^{9,10,14}

There are two principal signal transduction pathways involving the GPCRs: the cyclic AMP signal pathway and the phosphatidylinositol signal pathway. G protein–induced signal generation is regulated by a “molecular timer” that is determined by the rate of GTP exchange and hydrolysis. In the inactive state, G proteins exist in the heterotrimeric form with guanosine 5'-diphosphate (GDP) bound to the α chain. Interaction of a ligand-bound receptor with a G protein leads to release of GDP, with subsequent binding of GTP to the α chain. The binding of GTP to the α chain leads to dissociation of the α chain from the $\beta\gamma$ dimer, allowing the now free α -GTP chain to interact with target enzymes and ion channels. The $\beta\gamma$ dimers also participate in downstream signaling events through interaction with an everwidening array of targets, including certain forms of adenylyl cyclase and phospholipase C, potassium channels, and GPCR kinases.

G protein signaling is terminated by the hydrolysis of α -GTP to α -GDP by an intrinsic GTPase. A group of proteins, called

Fig. 3.1 G protein–coupled receptor (GPCR) structure and function.

GPCRs have an amino-terminal extracellular domain, seven putative transmembrane domains separated by three extracellular loops (e1–e3) and three intracellular loops (i1–i3), and a carboxy-terminal intracellular domain. Ligand binding results in the exchange of guanosine 5'-triphosphate (GTP) for guanosine 5'-diphosphate (GDP), which induces dissociation of the G protein into a GTP α subunit and a $\beta\gamma$ subunit. Then these subunits alter the activity of intracellular effector enzymes and transmembrane channels, resulting in the alteration of intracellular levels of second messengers that can include cyclic adenosine monophosphate and calcium. (Modified from Bockaert, J., & Pin, J. P. (1999). Molecular tinkering of G-protein–coupled receptors: an evolutionary success. *Embo J*, 18, 1724. With permission.)

regulators of G protein signaling (RGs), acts as GTPase-activating proteins (GAPs), specific for $G\alpha$ subunits. These proteins accelerate hydrolysis of GTP to GDP and terminate the transduced signal. In some cases, the effector itself may possess intrinsic GAP activity, which helps deactivate the pathway. This is true in the case of phospholipase C β , which possesses GAP activity within its carboxy-terminal region. This is an alternate form of regulation for the $G\alpha$ subunit. However, it should be noted that the GAPs do not have catalytic residues to activate the $G\alpha$ protein. Rather, GAPs reduce the required activation energy for the reaction to take place. After hydrolysis of GTP, the $G\alpha$ -GDP chain reassociates with the $\beta\gamma$ dimer; the reassociated heterotrimeric G protein is now capable of participating in another cycle of receptor-activated signaling.^{4,9,10,14}

Specificity in ligand binding is conferred by variations in the primary structures of the extracellular and intracellular domains.⁴ Specificity of effector responses is conferred by the variations in the primary structure of intracellular domains and isoforms of the $G\alpha$ subunits of G proteins.^{15,16} Some GPCRs couple predominantly with $G\alpha_i/G\alpha_o$ subunits that act primarily to decrease adenylyl cyclase activity.^{16–19} Other GPCRs couple predominantly with $G\alpha_s$ subunits that increase adenylyl cyclase activity or $G\alpha_q/G\alpha_{12}$ subunits that increase phospholipase C activity.^{16,20,23}

Interestingly, data show that cytoskeletal proteins may modulate receptor–G protein coupling. For example, the erythrocyte membrane cytoskeletal protein 4.1G can interfere with A1 adenosine receptor signal transduction.²¹ 4.1G also influences metabotropic glutamate receptor 1 α -mediated cyclic AMP accumulation, increases the ligand-binding ability of metabotropic glutamate receptor 1 α , and alters its cellular distribution.²² 4.1G may also play a role in receptor–receptor dimerization.

Receptor agonist-independent and agonist-induced homo- and heterodimerization have increasingly been recognized as important determinants of GPCR function.²⁴ For example, the GPCR somatostatin receptor 5 (SSTR5) primarily exist as monomers in the absence of an agonist. However, they form homodimers in the presence of an agonist.²⁵ Furthermore, it has been

shown that SSTR5 can form heterodimers with type 2 dopamine receptors (DRD2)—another GPCR—in the presence of hst2 agonist or dopamine.²⁶ Agonist-induced activation of SSTR5-DRD2 heterodimers in Chinese hamster ovary (CHO) cells expressing SSTR5 and DRD2 is increased, when compared with agonist-induced activation of monomers and homodimers in CHO cells expressing only SSTR5 or DRD2.²⁶ Heterodimerization of receptors may also lead to inactivation of one of the receptors in the complex. For example, heterodimerization of somatostatin receptor 2A (sst2A) with somatostatin receptor 3 (SSTR3) appears to lead to inactivation of the heterodimerized SSTR3, without inactivating the heterodimerized SSTR2.²⁷

GPCRs can form heterodimers with nonreceptor transmembrane proteins. Both the calcitonin receptor (CALCR) and the calcitonin receptor-like protein (CALCRL) can form heterodimers with three different accessory proteins that are termed “RAMPs”: RAMP1, RAMP2, and RAMP3.^{28–30} Whereas CALCRs can be activated by ligand in the absence of heterodimerization with a RAMP, CALCRLs are only activated by ligand if heterodimerized with a RAMP.^{28,29} RAMPs alter the ligand specificity of the heterodimerized receptor.

CALCRs that are not in heterodimers with RAMPs are activated by calcitonin and thus constitute the classic CALCR.^{28,29} However, CALCRs heterodimerized with RAMP1, RAMP2, and RAMP3 bind amylin and constitute amylin1, amylin2, and amylin3 receptors, respectively.^{28,29} CALCRLs dimerized with RAMP1 bind calcitonin gene-related peptide and constitute the calcitonin gene-related peptide receptor.^{28,29} CALCRLs dimerized with RAMP2 and RAMP3 bind adrenomedullin and constitute adrenomedullin1 and adrenomedullin2 receptors, respectively.^{28,29} RAMPs alter function of other GPCRs that transduce hormone action. The distribution and function of parathyroid hormone 1 and 2 receptors are altered by binding to RAMP2 and RAMP3, respectively.³¹ The distribution and function of the glucagon receptor is altered by binding to RAMP2.³¹ Dimerization/heterodimerization may occur in the endoplasmic reticulum (ER), shortly after protein synthesis occurs.³² The ER plays a role in determining whether or not a

protein will be expressed elsewhere in the cell, thus protecting the cell from misfolded and (likely) mutant proteins.³² The nonheterodimerized CALCRL is an orphan receptor because the CALCRLs cannot leave the ER for the cell membrane, unless heterodimerized with RAMPs.³³

The melanocortin receptors also use accessory proteins. Circulating adrenocorticotropin hormone (ACTH) binds to five different forms of the melanocortin receptor (types 1–5), but only the melanocortin 2 receptor (MC2R) in the adrenal cortex leads to release of adrenal steroids. MC2R interacts with Gs, which leads to activation of adenylyl cyclase and formation of cyclic AMP. The MC2R is the smallest GPCR known to date and belongs to a family of melanocortin receptors (types 1–5) that bind to various derivatives of proopiomelanocortin, especially α -melanocyte-stimulating hormone (α -MSH). The accessory protein melanocortin 2 receptor-associated protein (MRAP) is required for MC2R function, as it is critical for the translocation of the receptor from the ER to the cell surface.³⁴ Moreover, MRAP facilitates signaling of the MC2R.³⁵ Loss of function of MRAP thus prevents membrane expression of MC2R and completely prevents ACTH signaling. MRAP-deficient mice die at birth, unless rescued with glucocorticoids, but have normal mineralocorticoid and catecholamine production.³⁶ The adrenal glands of MRAP-deficient adult mice are small with abnormal adrenal morphology, abnormal cortex zonation, and abnormal adrenal progenitor cell differentiation. Interestingly, MRAP forms a unique antiparallel homodimer in close proximity to the MC2R.³⁷ The MRAP accessory protein can also interact with other melanocortin receptors, particularly MC5R, but exerts negative effects on their signaling. Expression of MRAP was shown to be predominantly present in the zona fasciculata in the rat adrenal gland, consistent with its facilitating role in glucocorticoid production. Hence mutations in MC2R³⁸ or MRAP³⁴ can lead to familial glucocorticoid deficiency secondary to ACTH resistance. In contrast, MRAP2, a protein with 39% amino acid homology to MRAP, shares the MC2R-trafficking function of MRAP but does not appear to play a major supportive role in adrenocortical ACTH signaling. On the contrary, *in vitro* studies have shown that overexpression of MRAP2 can suppress MC2R activation. MRAP2 appears to play a role in energy homeostasis as MRAP2 KO mice develop obesity.³⁹ MRAP2 interacts with MC4R in the paraventricular nucleus of the hypothalamus (PVN) where PVN-specific MRAP2 KO duplicates the global MRAP2 KO phenotype.

Failure of the ER to export mutant GPCR homodimers and mutant GPCR wild-type GPCR heterodimers to the cell membrane has been found to be the cause of dominant negative endocrine conditions. A dominant negative mutation is a heterozygous mutation that results in a phenotype that would be expected by a loss of function in both alleles. Some heterozygous MC4R mutations cause dominantly inherited obesity because of interaction of wild-type MC4R with the mutant receptor, and this specific effect of protein-protein interaction results in a dominant-negative effect.^{40,41} In addition, some heterozygous mutations in the gene encoding the V2 vasopressin receptor cause nephrogenic diabetes insipidus via production of mutant proteins that interfere with transit of normal receptors to the cell's membrane.⁴² These mutant receptors interfere with cell-surface expression of wild-type receptors by forming heterodimers with the wild-type receptors that cannot be exported from the ER to the cell membrane.⁴³ This finding explains why females heterozygous for these V2 vasopressin receptor gene mutations do not concentrate their urine with even high doses of desmopressin, a synthetic V2 vasopressin receptor agonist, in spite of being able to produce wild-type V2 vasopressin receptors.⁴⁴ A similar phenomenon explains dominant transmission of partial thyroid-stimulating hormone (TSH) receptor resistance in patients heterozygous for

some inactivating TSH receptor mutations.⁴⁵ In these patients, mutant TSH receptors form oligomers with wild-type receptors and prevent export of wild-type receptors from the ER to the cell membrane.⁴⁵

Similarly, misfolding and misrouting of some mutant gonadotropin-releasing hormone (GnRH) receptors in the ER (as well as oligomerization of these mutant GnRH receptors with wild-type GnRH receptors) decrease cell membrane expression of wild-type GnRH receptors.^{46–48} This phenomenon, however, has not been found to have clinical implications in patients who are heterozygous for mutations that cause autosomal recessive isolated hypogonadotropic hypogonadism (IHH), as the heterozygous individuals demonstrate an intact GnRH-gonadotropin axis and do not have clinical signs of IHH. Thus in these individuals, enough wild-type GnRH receptors do not oligomerize with mutant GnRH receptors and are transported to the cell membrane to maintain sufficiently normal GnRH-GnRH receptor interactions to avoid development of IHH.⁴⁷

Most GPCRs activate G proteins at very low levels in the absence of ligand binding. Some GPCRs have much higher constitutive (i.e., ligand-independent) activity, such as luteinizing hormone, TSH, thyrotropin-releasing hormone (TRH), glucagon-like peptide-1, melanocortin, and cannabinoid receptors. These receptors can activate G proteins in the absence of ligand binding,^{1,49} demonstrating constitutive activity that increases linearly with increased cell-surface expression of the receptors.⁵⁰ As described earlier, inverse agonists decrease the activity of these receptors.² In receptors without constitutive activity, genetic mutations that lead to substitution of a single amino acid can also greatly increase the interaction rate of the unliganded receptor for its G protein. It is possible that inverse agonists may play a role in treating medical conditions caused by GPCR mutations that lead to increased constitutional activation of the receptor.¹

Receptor desensitization and resensitization play a role in GPCR activity. Three processes for receptor desensitization have been described.^{51,52} The first receptor desensitization process is rapid uncoupling of the G protein from GPCRs.⁵² This process occurs within seconds to minutes after initiation of the process and occurs as a result of phosphorylation of GPCRs.⁵² G protein receptor kinases (GRKs) have been increasingly recognized as playing a major role when this process involves homologous desensitization.⁵¹ GRK-mediated phosphorylation of serine and threonine residues in the third intracellular loop, or the carboxy-terminal intracellular domain leads to activation of β -arrestins, which in turn inactivate adenylyl cyclase (Fig. 3.2).^{51–54} Second-messenger-dependent protein kinases also contribute to receptor desensitization when this process involves homologous desensitization, but they also participate in receptor desensitization when desensitization involves heterologous desensitization. Heterologous or agonist-independent desensitization occurs as a result of activation of a different receptor from the one that is desensitized.⁵²

The second receptor desensitization process is internalization/sequestration of GPCRs. This process is slower than receptor phosphorylation-induced uncoupling of the G protein from GPCRs and occurs within minutes to hours after initiation of the process. In addition to phosphorylation, both the GPCR and β -arrestins are modified posttranslationally in several ways, including by ubiquitination. This process is reversible because the receptors can be recycled to the cell surface (see Fig. 3.2).⁵² GRKs and β -arrestins play a role in initiating internalization/sequestration of β 2-adrenergic, luteinizing hormone (LH), FSH, TSH, TRH, vasopressin V2, angiotensin II type 1A, and other GPCRs in clathrin-coated vesicles (see Fig. 3.2).^{51,55–62} Dephosphorylation of the sequestered receptor, followed by disassociation of the receptor from β -arrestin, is necessary for

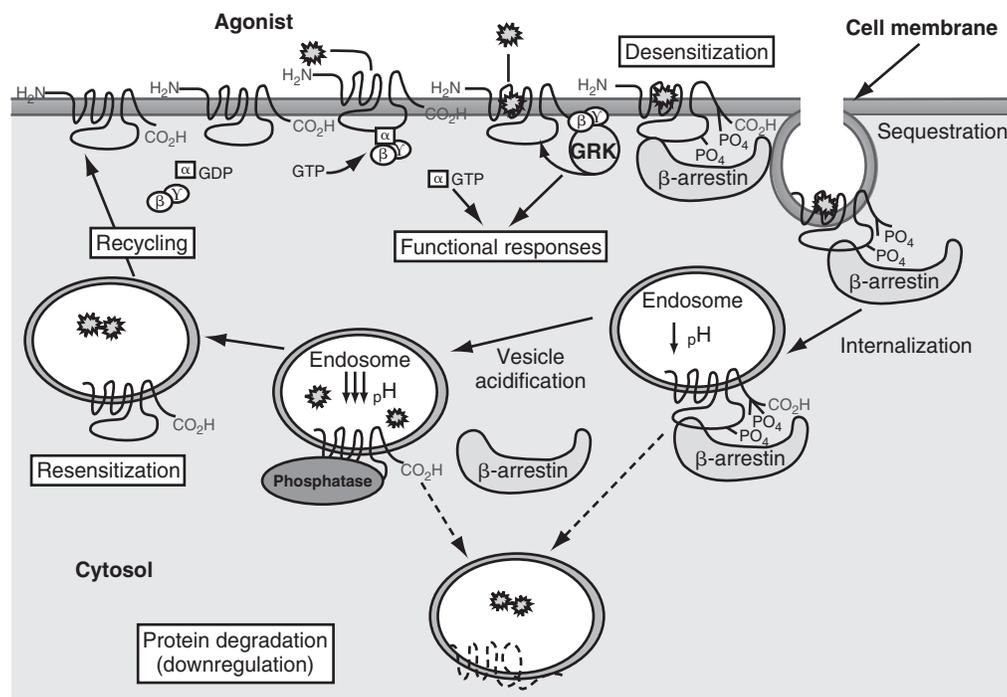

Fig. 3.2 Desensitization and recycling of G protein-coupled receptors (GPCRs). Shortly after an agonist binds a GPCR, G protein receptor kinases phosphorylation of serine and threonine residues in the third intracellular loop or the carboxy-terminal intracellular domain leads to activation of β -arrestin. Activation of β -arrestin inactivates adenylyl cyclase and initiates sequestration of the GPCR in clathrin-coated vesicles. Dephosphorylation of the sequestered receptor and subsequent disassociation of the receptor from β -arrestin is followed by recycling of the GPCR to the cell membrane. Alternatively, once sequestered, the GPCR can be destroyed in lysosomes. (Modified from Saunders, C., & Limbird, L. E. (1999). Localization and trafficking of α_2 -adrenergic subtypes in cells and tissues. *Pharmacol Ther*, 84, 200. With permission.)

the receptor to be recycled to the cell membrane and resensitized (see Fig. 3.2).²⁰

The third receptor desensitization process is downregulation. With downregulation, the number of intracellular GPCRs decreases because of increased lysosomal degradation and decreased synthesis of the receptors caused by alteration of transcriptional and posttranscriptional regulatory mechanisms (see Fig. 3.2).^{63,64} Downregulation is a slow process that occurs within several hours to days after initiation of the processes that lead to its development.⁶⁵ For many GPCRs, receptor ubiquitination promotes degradation of agonist-activated receptors in the lysosomes. Other proteins also play important roles in desensitization, including phosphodiesterases, RGS family proteins, and A-kinase-anchoring proteins. Together, this intricate network of kinases, ubiquitin ligases, and adaptor proteins orchestrate the acute and prolonged desensitization of GPCRs.

One of the ways the Arg137His V2 vasopressin receptor mutation interferes with mutant receptor function and causes X-linked nephrogenic diabetes insipidus is by altering desensitization and recycling of the mutant receptor.⁶⁶ In vitro studies have revealed that the mutant receptor is constitutively phosphorylated. Thus even in the absence of ligand binding, the mutant receptor is bound by β -arrestin—which in turn leads to sequestration of the mutant receptor within clathrin-coated vesicles. Recycling of the mutant receptor back to the cell membrane requires the mutant receptor to be dephosphorylated and disassociated from β -arrestin. However, the mutant receptor does not undergo dephosphorylation, while sequestered, and thus cannot be disassociated from β -arrestin and recycled to the cell membrane—thereby reducing cell membrane expression of the mutant receptor.

Of the eight classes of GPCRs, only classes A, B, and C contain receptors for mammalian hormones and

neurotransmitters (Fig. 3.3).⁶ Class A receptors contain the rhodopsin-like receptors and are divided into at least 15 groups.^{6,67} Four of these groups contain receptors activated by hormones. These are the peptide receptor, hormone protein receptor, GnRH receptor, and the TRH and secretagogue receptor groups.⁶

The peptide receptor group includes the angiotensin, ACTH/melanocortin, oxytocin, somatostatin, and vasopressin receptors.⁶ The hormone protein receptor group includes the receptors for glycoprotein hormones, including FSH, LH, and thyrotropin (TSH) receptors.⁶ These receptors have large extracellular amino-terminal domains and ligand-binding sites that include the first and third extracellular loops (see Fig. 3.3).^{4,6} There is also much similarity in amino acid sequence among these receptors (see Fig. 3.3).⁴ The GnRH receptor group only contains the GnRH receptor.⁵ The TRH and secretagogue receptor group includes the TRH receptor and the growth hormone (GH) secretagogue receptor.⁶

Class B GPCRs are structurally similar to members of the hormone protein receptor group (see Fig. 3.3).⁴ However, unlike the glycoprotein hormone receptors, class B GPCRs do not share similar amino acid sequences.⁴ This family contains receptors for higher molecular weight hormones, including calcitonin, glucagon, gastric inhibitory peptide, parathyroid hormone (PTH), and corticotrophin-releasing factor (CRF).^{4,6,68}

Class C receptors have a large extracellular domain, with two lobes separated by a hinge region that closes on the ligand (see Fig. 3.3).⁶⁹ This region has also been called the *Venus flytrap* domain or module because of the trapping mechanism of the hinge region.⁷⁰ This family includes the calcium-sensing receptor (CASR).⁷¹

Most GPCR-inactivating mutations can be classified into one of five classes.⁷² Class I inactivating mutations interfere with receptor biosynthesis. Class II inactivating mutations interfere

CLASS A

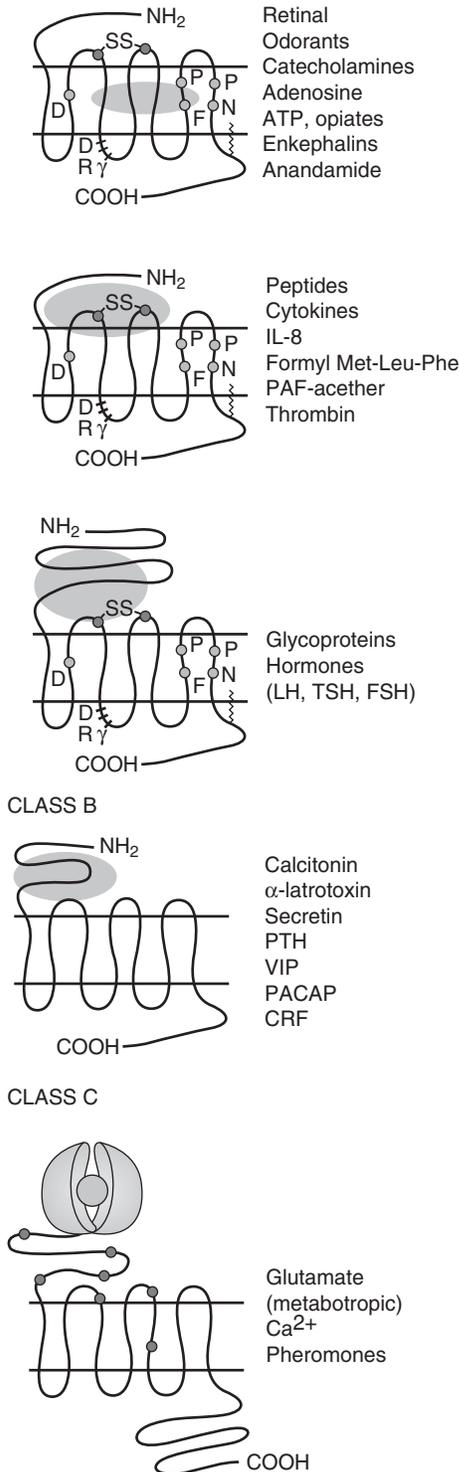

Fig. 3.3 Examples of class A, B, and C G protein-coupled receptors. The oval represents the ligand. These receptors can differ in amino acid sequence, in length of the amino-terminal extracellular and carboxy-terminal cytoplasmic domains, and in the receptor regions involved with ligand-receptor interactions. (Modified from Bockaert, J., & Pin, J. P. (1999). Molecular tinkering of G protein-coupled receptors: an evolutionary success. *Embo J*, 18, 1275. With permission.)

with receptor trafficking to the cell surface. Class III inactivating mutations interfere with ligand binding. Class IV inactivating mutations impede receptor activation. Class V inactivating mutations do not cause discernible defects in receptor biosynthesis,

trafficking, ligand binding, or activation, but may cause medical disorders. There are also inactivating mutations that interfere with receptor function via multiple mechanisms and thus cannot be placed into one class.

CLASS A RECEPTORS THAT TRANSDUCE HORMONE ACTION

The Peptide Receptor Group

Adrenocorticotropin and Melanocortin-2 Receptors

An alternative name for the ACTH receptor is *melanocortin-2 receptor* (MC2R) because the ACTH receptor is one of five members of the melanocortin receptor family of GPCRs, all of which couple to G_s to activate generation of intracellular cyclic AMP.⁷² For the purpose of clarity, when discussing interactions between ACTH and its receptor, the older name will be used for the remainder of this chapter. The ACTH receptor gene is located on small arm of chromosome 18 (18p11.2).⁷³ The ACTH receptor has a small extracellular and intracytoplasmic domain. Adrenocorticotropin-induced activation of the ACTH receptor in the zona fasciculata and zona reticularis of the adrenal cortex stimulates G_s , resulting in increased intracellular cyclic AMP levels that stimulate steroidogenesis by activating cyclic AMP-dependent kinases.^{74–76}

Hereditary isolated glucocorticoid deficiency, resistance to ACTH, and familial glucocorticoid deficiency (FGD) are the same names for an autosomal recessive syndrome that consists of glucocorticoid deficiency accompanied by normal mineralocorticoid secretion. FGD has been classified further as FGD types 1 and 2 and the triple A syndrome.³⁸ Patients with FGD type 1 have biallelic MC2R mutations, resulting in ACTH receptors with abnormal function, and account for 25% of FGD cases.^{38,77–82} In contrast, patients with FGD type 2 have ACTH resistance caused by mutations in MRAP.⁸³ Triple A (Allgrove syndrome) is an autosomal recessive syndrome characterized by ACTH-resistant adrenal insufficiency, achalasia, and alacrima—which is caused by mutations in the achalasia-adrenocortical insufficiency-alacrima syndrome (AAAS) gene encoding the protein ALADIN.⁸⁴ ALADIN is thought to regulate nuclear pore complexes, and nucleocytoplasmic transport⁸⁵ plays a role in modulating the oxidative stress response in adrenal cells.⁸⁶

The spectrum of disease in patients with FGD type 1 varies from presentation as a neonate with hypoglycemia, seizures, or circulatory collapse to presentation in childhood with fatigue and increased susceptibility to infection.^{79,87–91} Less commonly, patients may present with childhood asthma that resolves with treatment with physiologic doses of glucocorticoids.^{38,79,87} Hyperpigmentation thought to be caused by increased ACTH levels acting on the MC1R may be seen as early as the first month of life, but usually becomes apparent after the fourth month of life.^{77–79,87–89,92} There is one reported case of FGD type 1 without hyperpigmentation, despite elevated ACTH levels, in a patient with homozygous mutations in both the MC2R and the MC1R.⁹³ The assumption that hyperpigmentation is caused by increased ACTH levels acting on the MC1R (both in FGD type 1 and Addison disease) was substantiated in this patient whose MC1R mutation had previously been implicated in red hair and pale skin phenotypes. Neonates with FGD type 1 may also suffer from jaundice.^{79,89,91,94} Tall stature accompanied by an advanced or dissociated bone age, in spite of normal age of onset of puberty, appears to be common in children with FGD type 1.^{38,79,82,87,88,92} The pathophysiology of tall stature has not been definitively elucidated. One theory is that the anabolic effects of GH are unopposed by cortisol.

Patients with FGD1 exhibit absent adrenarche, confirming the importance of ACTH in the induction and maintenance

of adrenarache.⁸³ At presentation, plasma cortisol, androstenedione, and dihydroepiandrosterone levels are low or low normal—and plasma ACTH levels are elevated.^{38,79,87–91} When supine, patients with FGD type 1 have renin and aldosterone levels that are near normal.^{38,88,90,91} Histologically, the zona fasciculata and zona reticularis are atrophied with FGD.⁸⁷ However, demonstrating the lack of an essential role for ACTH in the embryologic development and maintenance of the zona glomerulosa, adrenal cortices in patients with all types of FGD contain zona glomerulosa cells.^{38,87,88,92,95,96}

FGD type 2 is caused by mutations in MRAP1 as described earlier and accounts for 20% of all FGD cases. Patients with FGD type 2 present with severe symptoms at an earlier age than patients with FGD type 1 (median age 0.08 years vs. 2 years).⁸³ Patients can present with severe neurologic disability, seizures, and microcephaly thought to be caused by unrecognized hypoglycemia.⁹⁷ Patients with FGD type 2 have normal heights.^{38,98} This is thought to be caused by early treatment with glucocorticoids. Mutations are splice site or nonsense mutations predicted to produce proteins without the transmembrane domain, which is necessary for interaction with MC2R.

Abnormalities in ACTH receptor expression may be seen in other conditions. Evidence suggests that the ACTH receptor- α_s -adenylyl cyclase-cyclic AMP cascade maintains differentiation of adrenocortical cells and that impairment of this cascade leads to dedifferentiation and increased proliferation of adrenocortical cells.^{99,100} Adrenocortical carcinomas from some patients have been found to have a loss of heterozygosity (LOH) for the ACTH receptor gene, resulting in markedly decreased ACTH receptor messenger ribonucleic acid (mRNA) expression.¹⁰⁰ Growth of the tumors with LOH for the ACTH receptor gene also may be more aggressive than the other tumors. An activating mutation of G₁₂ that constitutively suppresses adenylyl cyclase activity has also been found in adrenocortical tumors.⁹⁹ Thus decreased ACTH receptor activity may be associated with tumorigenesis.

Interestingly, many patients with ACTH-independent macronodular adrenal hyperplasia (AIMAH)—a cause of ACTH-independent Cushing syndrome caused by inactivating mutations of the putative tumor-suppressor gene *ARMC5*¹⁰¹—exhibit increased glucocorticoid levels in response to noncorticotropin hormones that do not normally induce glucocorticoid release.^{102–107} These hormones include gastric inhibitory peptide, exogenous arginine and lysine vasopressin, LH, human chorionic gonadotropin (HCG), angiotensin II, catecholamines, leptin, and serotonin receptor agonists.^{102–107} Increased expression of the receptors for these ligands in the abnormal adrenal glands has been implicated as a possible explanation for the abnormal induction of glucocorticoid release by these noncorticotropin ligands.¹⁰⁷ However, receptors for some of these ligands are expressed in normal adrenal glands.¹⁰⁷ Thus the mechanism for this phenomenon remains to be fully elucidated.

Other Melanocortin Receptors

Murine studies reveal that melanocortin-3 receptor (MC3R), another of the five members of the melanocortin receptor family, regulates fat deposition, as mice with MC3R deficiency or partially inactive receptors have normal resting energy expenditure and increased fat mass and reduced fat-free mass, including decreased bone formation.^{72,108} The role of the MC3R in humans is less clear. More than 24 human MC3R variants have been identified without evidence of obesity.^{109,110} However, patients with these variants were not phenotyped for fat mass to assess whether they phenocopy the mouse model, which exhibits normal body weight but greater energy intake and

altered energy partitioning that is biased toward lipid-accumulating cells' altered partitioning.^{110–112} Several coding variants (p.D158Y, p.T280S, p.I183N), which are likely pathologic because of significantly decreased cyclic AMP production, as well as noncoding variants, demonstrate early-onset obesity in all affected individuals.⁹⁷ Homozygosity for a pair of single-nucleotide polymorphisms of the MC3R gene (p.T6K+ p.V81I) that result in production of partially inactive MC3Rs was found to be associated with pediatric-onset obesity in Caucasian American and African American children.¹¹³ Subjects homozygous for the double mutation had higher body mass index (BMI)-z, fat mass and percent fat mass, as well as waist circumference. That is despite finding no differences in energy intake, resting energy expenditure, total energy expenditure, respiratory quotient, physical activity.^{114–117} A mouse model carrying the human MC3R T6K+V81I variants showed that the double mutant exhibited greater fat mass and feeding efficiency with reduced fat-free mass.¹⁰⁸ These findings are similar to the MC3R knockout mouse.

The melanocortin-4 receptor (MC4R) is another member of the melanocortin receptor family and plays a role in controlling appetite and weight.¹¹⁸ The MC4R has baseline constitutive (i.e., ligand-independent) activity that can be inhibited by the inverse agonist agouti-related peptide (AgRP).^{118,119} Activation of the MC4R by its natural agonist α -MSH produces anorexigenic effects.^{118,120,121} More than 150 naturally occurring MC4R mutations have been identified, causing hyperphagic obesity, increased lean body mass, increased bone density, and increased linear growth.^{122–127} Patients with homozygous mutations appear to have more severe obesity than their heterozygous relatives, consistent with codominant inheritance.^{10,128}

MC4R mutations are thought to be the most common monogenic cause of human obesity. The prevalence of pathogenic MC4R mutations in obese populations varies widely, ranging from 0.5% to 5.8%, depending on the screening criteria and population.^{124,129–131} AgRP gene polymorphisms appear to be associated with anorexia nervosa.^{125,126}

Little is known about melanocortin-5 receptors (MC5Rs) in animals and humans. There is only weak evidence from a single linkage and association study of families in Quebec that suggests that MC5Rs may also play a role in regulating body weight and fat mass.¹²⁷

Another member of the melanocortin receptor family, the MC1R, controls skin and hair pigmentation.^{132,133} Activation of MC1Rs in skin and hair follicle melanocytes by the proopiomelanocortin (POMC)-derived peptides α -MSH and ACTH stimulates the synthesis of eumelanin, a brown-black pigment.^{134,135} Inhibition of MC1R baseline constitutive activity by agouti protein, or specific mutations, leads to release of pheomelanin, a red-yellow pigment, from the melanocytes.¹³⁵

Inactivating homozygous mutations of the POMC gene cause hypoadrenalism, red hair, fair skin, and early-onset obesity. Hypoadrenalism is characterized by glucocorticoid deficiency because of lack of ACTH production from the POMC precursor. Fair skin and red hair are caused by a lack of ACTH and α -MSH-induced melanocyte release of eumelanin that results from activation of MC1Rs. Of note, nonwhite patients with homozygous POMC mutations do not appear to have the fair skin and red hair phenotype.^{130,136} In white individuals, eumelanin synthesis appears to be dependent on POMC-derived peptides, whereas in darker individuals, other genes may control eumelanin synthesis.¹³⁷ Obesity is caused by lack of α -MSH-induced anorectic effects, which normally result when α -MSH activates MC4Rs.¹³⁸ Heterozygosity for POMC gene mutations has been associated with hyperphagia, early-onset obesity, and increased linear growth.^{138–140} Both homozygous^{141,142} and heterozygous¹⁴³ mutations of

prohormone convertase 1 cause obesity in humans. Prohormone convertase 1 acts on POMC, proinsulin, and proglucagon. Patients with prohormone convertase 1 deficiency also have neonatal enteropathy and postprandial hypoglycemia. The cause of enteropathy is unknown but hypothesized to be related to the processing of GLP-2 by prohormone convertase 1. GLP-2 is known to stimulate proliferation and repair of intestinal epithelium.¹⁴⁴

Vasopressin Receptors

Nephrogenic diabetes insipidus (NDI) results from decreased responsiveness of the renal tubule to arginine vasopressin (AVP), with resulting excessive loss of free water. NDI is characterized by polydipsia and polyuria that is not responsive to vasopressin and vasopressin analogs.¹⁴⁵ Vasopressin binds to the V2 vasopressin receptor (AVPR2), a G_s-coupled receptor, in the basolateral membrane of collecting duct principal cells in the kidney and activates translocation of aquaporin-2 (AQP2) water channels to the apical membrane, thereby inducing water permeability. X-linked NDI is caused by inactivating mutations of the V2 vasopressin receptor (AVPR2) gene located at Xq28 and accounts for about 90% of genetically determined NDI.^{146–149} More than 200 AVPR2 mutations have been described, including missense, nonsense, insertions, deletions, and complex rearrangements.¹⁵⁰ Mutations have been categorized into five classes based on mechanism, including abnormal transcription, mRNA processing, translation, aberrant folding and intracellular retention, loss of the G protein binding site, loss of the AVP binding site, and defects in intracellular trafficking.^{145,151,152} Some patients with X-linked NDI are responsive to high doses of desmopressin. Autosomal recessive NDI (ARNDI) is caused by loss-of-function mutations in the gene for the AQP2 water channel and accounts for about 10% of genetic forms of NDI.^{151,153} More than 50 known mutations cause ARNDI. Autosomal dominant forms of NDI are also caused by mutations in AQP2 that are functional, but fail to be transported to the apical membrane. Eleven mutations have been described accounting for less than 1% of genetic forms of NDI and generally have a milder phenotype than ARNDI or X-linked NDI.

Gain-of-function mutations in the V2 vasopressin receptor have also been reported.¹⁵⁴ Deoxyribonucleic acid (DNA) sequencing of two patients' V2R gene identified heterozygous missense mutations in both, with resultant changes in codon 137 from arginine to cysteine (p.R137C) or leucine (p.R137L). These mutations resulted in constitutive activation of the receptor and clinical features of inappropriate antidiuretic hormone secretion (SIADH), which was termed *nephrogenic syndrome of inappropriate antidiuresis (NSIAD)*.¹⁵⁴ To date, around 30 cases of NSIAD have been reported, most of which are described in males as the condition is X-linked. Patients can present in infancy but sometimes do not present until adulthood. There have been several reports of female patients with NSIAD, some diagnosed in infancy and others in adulthood.¹⁵⁵ Patients with the p.R137L mutation demonstrated the expected decrease in AVP levels with a water-loading test, but urine AQP2 levels remained inappropriately elevated.¹⁵⁶

The Glycoprotein Hormone Receptor Group

The glycoprotein hormones include TSH, FSH, LH, and HCG. These hormones share common α subunits that dimerize with hormone-specific β subunits. TSH, FSH, and LH bind to the extracellular amino-terminal domain of the TSH, FSH, and LH receptors, respectively.^{4,6,157,158} The effects of HCG are mediated by the LH receptor, which is also known as the *luteinizing hormone/choriogonadotropin receptor (LHCGR)*.¹⁵⁹

Glycoprotein hormone receptors have a large (350 to 400 residues) extracellular amino-terminal domain, also known as the *ectodomain*, that participates in ligand binding (see Fig. 3.3).^{7,159} The ectodomain includes leucine-rich repeats that are highly conserved among the glycoprotein hormone receptors.^{7,159} There is 39% to 46% similarity of the ectodomain and 68% to 72% similarity of the transmembrane or serpentine domain among the three glycoprotein hormone receptors.⁷

The glycoprotein hormone receptors are coupled to G_s, and hormone binding stimulates adenylyl cyclase, leading to increased intracellular cyclic AMP levels and protein kinase A (PKA) activation.¹⁵⁹ Mutations leading to endocrine dysfunction have been reported for each of the glycoprotein hormone receptors.

Luteinizing Hormone/Choriogonadotropin Receptors

Both inactivating and activating mutations of the LH receptor have been found in humans.¹⁵⁹ The LH receptor gene is located in chromosome 2p21 and consists of 11 exons.^{160,161} Exon 1 encodes a peptide that directs the LH receptor to the plasma membrane.¹⁵⁹ Exons 2 through 10 encode the ectodomain.¹⁵⁹ The last exon encodes the transmembrane domains that are also known as the *serpentine regions*.^{7,159,160} Single nonsense mutations, amino acid changes, and partial gene deletions have been described that generate LH receptors with decreased activity.¹⁵⁹ Single-amino-acid changes have also been found that lead to activation of G_s in the absence of ligand binding.¹⁵⁹

Development of LH resistance requires biallelic mutations that inactivate the LH receptor gene, as one normal receptor allele is capable of producing adequate receptor protein to ensure physiologic signaling.¹⁵⁹ In contrast, activating mutations of the LH receptor gene cause endocrine disorders in the heterozygous state.¹⁵⁹

In the fetus, LH receptors are primarily activated by HCG.¹⁵⁹ Leydig cells begin to express LH receptors shortly after testicular differentiation at 8 weeks of gestation.¹⁵⁹ Thereafter, androgen production, caused by activation of these receptors by HCG, plays an important role in the development of male genitalia and testicular descent.¹⁵⁹ Thus male infants, with inactivating mutations of the LH receptor, may present with abnormally developed genitalia—including micropenis, cryptorchidism, and an XY disorder of sexual differentiation.¹⁵⁹

Males with mutations that completely inactivate the LH receptor exhibit failure of fetal testicular Leydig cell differentiation. This phenotype, which is known as *type 1 Leydig cell hypoplasia*, includes female external genitalia with a blind-ending vagina, absence of Müllerian derivatives, and inguinal testes with absent or immature Leydig cells.^{162–169} In addition, patients have elevated serum LH levels, normal serum FSH levels, and decreased serum testosterone levels that do not increase in response to HCG administration.^{162–169} Mutations that lead to this phenotype include a nonsense mutation (Arg545Stop) that results in a receptor that is missing TM4-7, an p.Ala593Pro change, and a TM7 deletion (p.Leu608del, p.Val609) that decreases cell-surface expression of the LH receptor.^{167,168,170} These mutant receptors are unable to couple to G_s.^{167,168,170}

Males with mutations that do not completely inactivate the LH receptor present with type 2 Leydig cell hypoplasia, which is characterized by a small phallus and decreased virilization.¹⁶⁶ A mutation that leads to this phenotype includes the insertion of a charged lysine at position 625 of TM7 in place of hydrophobic isoleucine that disrupts signal transduction.¹⁷¹ Another mutation (p.Ser616Tyr, found in patients with mild Leydig cell hypoplasia) is associated with decreased

cell-surface expression of the LH receptor.^{168,171} Other deletion and nonsense mutations have also been found to cause mild Leydig cell hypoplasia.¹⁵⁹

Males with inactivating mutations of the LH receptor may also present with a phenotype intermediate in severity between type 1 and type 2 Leydig cell hypoplasia. A compound heterozygote patient with p.Ser616Tyr on one allele and an inactivating deletion (Δ exon 8) on the other allele, presented with Leydig cell hypoplasia, micropenis, and hypospadias.¹⁷² The Cys131Arg mutation has also been found in patients with Leydig cell hypoplasia, small phallus, and hypospadias.¹⁷³ This mutation is located in the leucine-rich repeat segment of the LH receptor extracellular domain and interferes with high-affinity ligand binding.¹⁷³

Deletion of exon 10 of the LH receptor gene leads to an LH receptor that binds LH and HCG normally.¹⁷⁴ Interestingly, whereas HCG binding can elicit normal transmembrane signaling, LH binding fails to activate the receptor.¹⁷⁴ Because HCG is the principal hormone in utero that activates the LH receptor, and second-messenger response of the mutant receptors to HCG is not impaired, it is not surprising that a male patient found to be homozygous for the mutation was born with normal male genitalia.^{72,174} Pubertal progression and later gonadal function, however, are dependent on LH activation of the LH receptor.^{72,174}

Because deletion of exon 10 of the LH receptor gene results in a mutant LH receptor, with diminished intracellular signaling in response to LH, it is also not surprising that the patient homozygous for this mutation was found to have delayed pubertal development, small testes, and hypergonadotropic hypogonadism, when evaluated at the age of 18 years.¹⁷⁴ Prolonged HCG therapy resulted in normalization of testicular testosterone production, increased testicular size, and the appearance of spermatozoa in semen.¹⁷⁴ Similarly, inactivating mutations of the LH β subunit cause abnormal pubertal development, severe testosterone deficiency, and azoospermia, but normal external genitalia in males. In females, inactivating mutations of the LH β subunit are associated with normal pubertal development and menarche followed by oligomenorrhea, enlarged multicystic ovaries and infertility.¹⁷⁵

Females with loss of function mutations of the LH receptor may be asymptomatic or present with amenorrhea or oligomenorrhea.¹⁵⁹ Females with complete inactivating LH receptor mutations commonly have primary amenorrhea, inability to ovulate, and decreased estrogen and progesterone levels, accompanied by elevated LH and FSH levels.^{168,176} Affected individuals may have signs of low estrogen levels, including a hypoplastic uterus, a thin-walled vagina, decreased vaginal secretions, and decreased bone mass,^{168,176} although pubertal breast development is normal.¹⁷⁷ Homozygous LH receptor mutations (p.N400S, and p.Ala449Thr) have been associated with empty follicle syndrome, a disorder in which no oocytes are retrieved during in vitro fertilization.¹⁷⁸

Mutations that constitutively activate LH receptors cause male-limited precocious puberty (MLPP), also known as *testotoxicosis*—which may be familial or sporadic.^{169,179,180} Boys with this condition develop GnRH-independent precocious puberty before the age of 4 years, when p.Asp578Gly is present, and as early as the first year of life, when the p.Asp578Tyr mutation is present.^{159,181–183} Patients with this condition may also have an enlarged phallus at birth.¹⁸¹

During the first 5 years of life, patients with MLPP have very low LH and FSH levels but have testosterone levels in pubertal range.¹⁸⁴ During adolescence and adult life, testosterone levels do not increase above age-appropriate concentrations and gonadotropin levels normalize.^{159,184–186} Thus adolescents

and adults with MLPP do not usually manifest signs of androgen excess (such as hirsutism or severe acne).^{159,184} Most mutations that cause MLPP are located in the TM6 and i3, regions that participate in receptor-Gs protein coupling.¹⁵⁹ A milder phenotype was reported in a patient with a heterozygous activating mutation (p.C617Y) in TM7.¹⁸⁷ This mutation was inherited from the patient's mother who was apparently unaffected. Somatic activating mutations cause sporadic Leydig cell adenomas.^{118,188,189}

Activating mutations of the LH receptor do not appear to cause clinical disturbances in females. In prepubertal girls, this may be caused by low or absent LH receptor expression or because of insufficient aromatase expression in prepubertal granulosa cells. During puberty, activation of LH receptors on ovarian theca cells leads to the production of androgens that are converted to estrogens by aromatase in granulosa cells.¹⁵⁹ LH, along with FSH, also plays a role in inducing the differentiation of follicles into Graafian follicles and triggers ovulation and release of the oocyte.¹⁵⁹ Detailed phenotyping of the carrier mother of an MLPP male with the p.Asp578Gly activating mutation of the LH receptor failed to reveal any abnormalities in her menstrual cycles or fertility. LH dynamics, androgen, and FSH levels, as well as response to GnRH agonists, were normal.¹⁸⁴

Follicle-Stimulating Hormone Receptors

Inactivating and activating FSH receptor mutations have been described,¹⁹⁰ but they are far less common than LH receptor mutations.¹⁹⁰ The FSH receptor gene is located in chromosome 2 at p21 and contains 10 exons.¹⁹¹ The last exon of the FSH receptor gene encodes the transmembrane and intracellular domains.¹⁹²

FSH is required in females for normal follicle maturation and regulation of estrogen production by ovarian granulosa cells.^{190,193,194} FSH is required in pubertal males for Sertoli cell proliferation, testicular growth, and the maintenance of spermatogenesis.^{190,195}

The first inactivating mutation of the FSH receptor was found in Finnish females with autosomal recessive hypergonadotropic ovarian dysgenesis (ODG). ODG is characterized by primary amenorrhea, infertility, and streak or hypoplastic ovaries in the presence of a 46XX karyotype and elevated gonadotropin levels.¹⁹⁶ Twenty-two out of 75 Finnish patients with ODG were found to be homozygous for a c.C566T point mutation in exon 7 of the FSH receptor gene.¹⁹⁷ This mutation leads to the production of an FSH receptor with an p.Ala189Val substitution in an area of the extracellular ligand-binding domain that is thought to play a role in turnover of the receptor or in directing the receptor to the plasma membrane.¹⁹⁷ The mutated receptor demonstrates normal ligand-binding affinity but has decreased binding capacity and impaired signal transduction, when studied in transfected mouse Sertoli cells.¹⁹⁷ Males homozygous for this mutation have variable impairment of spermatogenesis and low to low-normal testicular volume, but are not azoospermic and can be fertile.¹⁹⁸ The c.C556T point mutation is uncommon outside Finland, where the carrier frequency is 0.96%.¹⁹⁹ Other mutations that alter signal transduction but not receptor expression or binding include p.Ala189Val, p.Asn191Ile, p.Ala419Thr, and p.Phe591Ser. The p.Ala189Val mutation causes primary hypergonadotropic amenorrhea in women and no spermatogenesis in men in the homozygous state and secondary amenorrhea in the heterozygous state.^{190,200} The nearby Asn191Ile mutation also causes hypergonadotropic amenorrhea in the homozygous state, but no clinical phenotype in the heterozygous state.²⁰¹ The Ala419Thr mutation was identified in a heterozygous

woman with primary amenorrhea.²⁰² The Phe591Ser mutation causes primary amenorrhea and premature ovarian failure (POF) in the homozygous state and a predisposition to sex cord ovarian tumors in the heterozygous state.²⁰³ Primary amenorrhea and POF have been described in women with homozygous mutations that totally impaired receptor binding to FSH²⁰⁴ or that resulted in reduced expression of the FSH receptor on the cell surface.²⁰⁵

A more recently published series described 13 Chinese families with nonsyndromic premature ovarian insufficiency.²⁰⁶ They found three novel mutations and 11 previously described homozygous mutations and 3 previously described compound heterozygous mutations. Clinical manifestations ranged from primary amenorrhea to normal menarche with oligomenorrhea or secondary amenorrhea. It was the first study to identify a frameshift mutation (p.Lys140Argfs*16 in the ectodomain) and a missense mutation in the signal peptide of the FSH receptor (p.Gly15Asp). The other novel mutation was p.Pro504Ser in the transmembrane domain.

Compound heterozygosity for mutations that cause partial loss of FSH receptor function may cause endocrine dysfunction in women.^{200,207} Women may present with infertility, secondary amenorrhea, osteoporosis, and a history of normal or delayed onset of puberty, accompanied by elevated LH and FSH, low-normal plasma estradiol, low plasma inhibin B levels, slightly enlarged ovaries with immature follicles, and a small uterus.²⁰⁷ This may be caused by FSH receptor gene mutations that result in an p.Ile160Thr mutation in the extracellular domain that impairs cell-surface expression and an p.Arg573Cys mutation in e3 that interferes with signal transduction.²⁰⁷ Other women present with primary amenorrhea and very elevated gonadotropin, low plasma estradiol and inhibin B levels, normal-size ovaries with immature follicles, and a normal-size uterus.²⁰⁰ This condition is associated with an p.Asp224Val substitution in the extracellular domain, leading to impaired cell-surface expression and a p.Leu601Val substitution in e3 impairing signal transduction.²⁰⁰

Activating mutations of the FSH receptor have also been described. Surprisingly, a hypophysectomized male was found to be fertile and to have serum testosterone levels above 4.9 nmol/L (141 ng/dL) and normal testis volume, in spite of undetectable gonadotropin levels.²⁰¹ This patient was found to be heterozygous for a c.A1700G mutation in exon 10 of the FSH receptor gene that resulted in a p.Asp567Gly substitution in an area of the third intracytoplasmic loop that is highly conserved among FSH, LH, and TSH receptors.^{201,208,209} The same substitution in corresponding areas of the LH and TSH receptors also results in constitutively active receptors and is found in MLPP and thyroid adenomas, respectively.^{201,208,210} Other activating mutations have been identified to cause spontaneous ovarian hyperstimulation syndrome (OHSS). OHSS is a common complication of treatment protocols used to induce ova for in vitro fertilization and is characterized by multiple follicular cysts lined by luteinized cells, which can result in abdominal discomfort and distention, as well as ovarian enlargement and fluid sequestration. One such mutation is the p.Asp567Asn, which was found in a woman with recurrent spontaneous OHSS.²¹¹ The p.Thr449Ile and p.Thr449Ala mutations cause a conformational change that leads to loss of specificity for FSH, leading to sensitivity to HCG²¹² and TSH,²¹³ causing spontaneous OHSS during pregnancy or with hypothyroidism. The p.Ile545Thr mutation caused spontaneous OHSS in a woman during the first trimester of pregnancy, despite a normal HCG level.²¹⁴ This mutant receptor displayed detectable constitutive activity, as well as promiscuous activation by HCG and TSH.

Thyroid-Stimulating Hormone Receptors

The TSH receptor gene is located on chromosome 14 and contains 10 exons, with the first nine exons encoding the large extracellular domain and the 10th exon coding the remainder of the receptor.^{215–218} At low extracellular TSH concentrations, TSH receptor activation leads to stimulation of $G\alpha_s$ —which activates adenylyl cyclase, resulting in increased intracellular cyclic AMP levels.^{219,220} At higher extracellular TSH concentrations, activation of the TSH receptor also stimulates the G_q and G_{11} proteins—activating phospholipase C and resulting in the production of diacylglycerol and inositol phosphate.²²⁰

TSH receptors differ from the other glycoprotein hormone receptors in that they exist in two equally active forms.^{221,222} These are the single-chain and two-subunit forms of the TSH receptor (Fig. 3.4). The single-chain form of the TSH receptor is made up of three contiguous subunits: the A subunit, C peptide, and B subunit.^{222–224} The A subunit begins at the amino-terminal of the extracellular domain and contains most of the extracellular domain.^{222–224} The C peptide is connected to the carboxy-terminal of the A subunit and continues the extracellular domain.^{222–224} The C peptide contains a 50-amino-acid sequence that is only found in TSH receptors.^{222–224} The B subunit is connected to the C terminal of the C peptide and contains the TMs and the carboxy-terminal cytoplasmic portion of the receptor.^{222–224} The two-subunit form of the receptor is missing the C peptide, which is cleaved from the protein during intracellular processing and consists of the A and B subunits attached by disulfide bonds.^{225–228} It is surprising that both receptor forms are activated equally by TSH because the C peptide and nearby regions of the A and B subunits participate in signal transduction.^{221–223,229,230}

Missense mutations of the TSH receptor gene, leading to replacement of Ser-281 near the carboxy-terminus of the A subunit, with Ile, Thr, or Asn, result in a constitutively active TSH receptor that may cause *intrauterine* or congenital hyperthyroidism, or toxic adenomas.^{224,231–233} Activating somatic mutations that cause toxic adenomas have also been found in different transmembrane domains of the TSH receptor.^{234–241} More specifically, clusters of mutations are located in the i3 and TM6 regions—found to be involved with signal transduction in all glycoprotein hormone receptors.^{234–236,238–240} The prevalence of activating mutations of the TSH receptor in toxic adenomas has been estimated to range from 2.5% in Japan to 86% in Brazil.^{237,238,240,242–245}

Activating somatic mutations of the TSH receptor have also been found in multinodular goiters.²⁴⁶ Interestingly, different activating mutations have been found in separate nodules in the same individual.²⁴⁶ Some well-differentiated thyroid carcinomas have activating mutations of the TSH receptor.^{247–249} Somatic activating mutations of the *GNAS* gene encoding $G\alpha_s$ have also been found in some toxic adenomas and differentiated thyroid carcinomas.^{99,250,251} Activating germline mutations of the TSH receptor can cause sporadic or autosomal dominant inherited nonautoimmune hyperthyroidism that presents in utero, during infancy, during childhood, and in some cases in adulthood.^{209,233,252–260} These mutations have been found in the amino-terminal extracellular and transmembrane domains.^{209,233,253–261}

Patients with heterozygous mutations that lead to constitutively active TSH receptors typically develop hyperthyroidism.²²² In contrast, biallelic loss of function mutations in the TSH receptor genes cause hypothyroidism.²²² Most known loss-of-function TSH receptor mutations are located in the amino-terminal extracellular domain.²⁶² A spontaneous p.Asp410Asn substitution, near the carboxy-terminus of the C peptide, results in a TSH receptor, with normal ligand

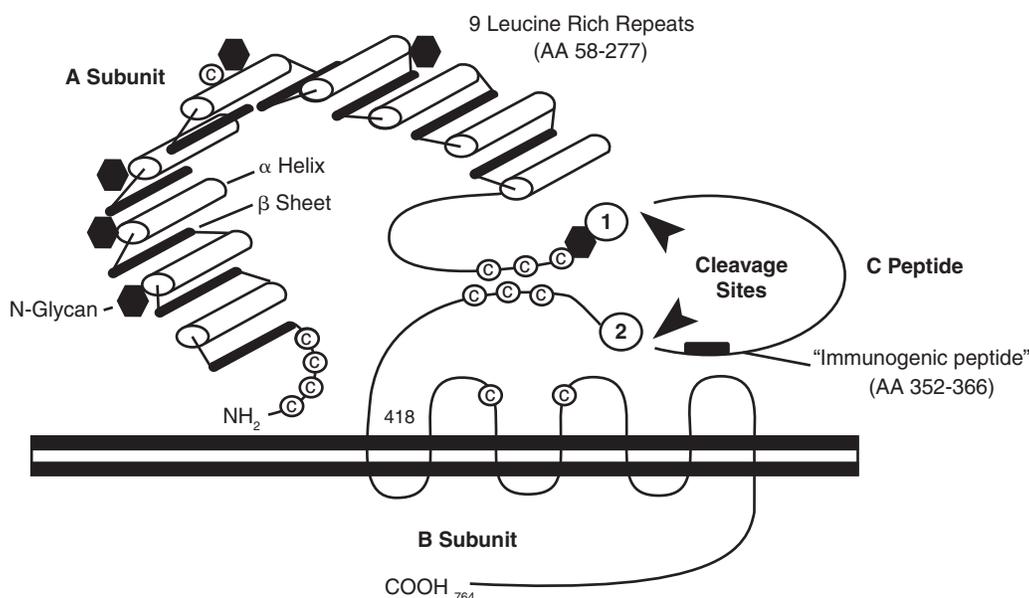

Fig. 3.4 The thyroid-stimulating hormone (TSH) receptor. There are two forms of TSH receptors. The single-chain form is made up of an A subunit, C peptide, and B subunit. Posttranslational cleavage of the C peptide from the single chain form results in the two-subunit form. This form consists of the A subunit joined to the B subunit by disulfide bonds between the carboxy-terminal cysteine residues of the A subunit and the amino-terminal cysteine residues of the B subunit. (From Rapoport, B., Chazenbalk, G. D., Jaume, J. C., McLachlan, S. M. (1998). The thyrotropin (TSH) receptor: interaction with TSH and autoantibodies. *Endocr Rev*, 19, 676. Copyright 1998, The Endocrine Society. With permission.)

binding affinity and impaired G_{α_s} -mediated signal transduction.²⁶³ Patients who are homozygous for this mutation present with compensated hypothyroidism.²⁶³

Patients homozygous or compound heterozygous for loss-of-function mutations of the TSH receptor present with the syndrome of resistance to TSH (RTSH). Loss-of-function mutations of the TSH receptor that cause RTSH have been identified in the amino-terminal extracellular domain, TM4, TM6,²⁶⁴ i2, e1, and e3.²⁶⁵ Clinical severity of RTSH may range from a euthyroid state accompanied by elevated TSH levels (fully compensated RTSH), to mild hypothyroidism unaccompanied by a goiter (partially compensated hypothyroidism), to congenital thyroid hypoplasia accompanied by profound hypothyroidism (uncompensated RTSH).^{76,263,266–270} In patients with uncompensated RTSH, a small bilobar thyroid gland is located at the normal site.⁷⁶ Loss-of-function mutations of the TSH receptor are a rare cause congenital hypothyroidism^{271, 272} more common in Japan and Taiwan ($\leq 7\%$ of children),^{273,274} where p.R450H is particularly frequent. Because expression of the sodium-iodide symporter is TSH dependent,¹⁷⁹ thyroid gland uptake of ¹²⁵Iodine and ^{99m}technetate is diminished or absent in patients with RTSH.^{76,275} In rare cases, iodine uptake is high-normal.²⁷⁶ These compound heterozygous mutations of the TSH receptor had some G_{α_s} activity and no G_{α_q} activity, suggesting that iodine uptake is solely controlled by G_{α_s} activity and not G_{α_q} activity. Some families have been found to have an autosomal-dominant form of RTSH that is not caused by a mutation of the TSH receptor.^{277,278}

Human Chorionic Gonadotropin and Thyroid-Stimulating Hormone Receptors during Pregnancy

Because of its structural similarity with TSH, at very high concentrations, HCG can activate the TSH receptor.²⁷⁹ During pregnancy, HCG activation of TSH receptors leads to elevation in thyroid hormones after the ninth week of gestation—and decreases in TSH levels between the 9th and 12th weeks of gestation.²⁸⁰ This phenomenon does not usually result in maternal hyperthyroidism (gestational thyrotoxicosis).^{280,281}

However, when HCG levels are abnormally elevated because of gestational trophoblastic disease caused by a molar pregnancy or choriocarcinoma, hyperthyroidism may occur.^{282–286} The prevalence of thyrotoxicosis in gestational trophoblastic disease correlates with HCG levels. In one study of 196 patients treated with chemotherapy for gestational trophoblastic neoplasia, the prevalence of thyrotoxicosis was 7%.²⁸⁷ Biochemical thyrotoxicosis only occurred in patients with HCG levels $>10^5$ and clinical thyrotoxicosis only occurred in patients with HCG levels greater than 10^6 . Serum TSH is consistently suppressed when HCG levels are above 4×10^5 mIU/mL.²⁸⁸

A mother and daughter were identified with recurrent gestational hyperthyroidism and normal serum HCG levels.^{211,213,214,289} These individuals were found to be heterozygous for a missense mutation in the TSH receptor gene, resulting in a p.Lys183Arg substitution in the extracellular domain of the receptor. It is believed that this substitution increases sensitivity of the receptor to activation by HCG, causing gestational hyperthyroidism.

The Gonadotropin-Releasing Hormone Receptor Group

Gonadotropin-Releasing Hormone Receptors

The GnRH receptor gene is located on 4q13 and includes three exons.^{290,291} Unlike glycoprotein hormone receptors, GnRH receptors lack an intracellular carboxy-terminal domain.^{292,293} In contrast to most GPCRs, the GnRH receptor is coupled to G_q/G_{11} and hence ligand-binding leads to stimulation of phospholipase C and not adenylyl cyclase.²⁹⁴ Phospholipase C cleaves phosphatidylinositol-4,5-diphosphate (PIP₂) to inositol 1,4,5-triphosphate (IP₃) and diacylglycerol, leading to increased protein kinase C activity.^{295,296}

Some patients with IHH are homozygous or compound heterozygous for loss-of-function mutations in the GnRH receptor gene.^{297–299} Unlike patients with Kallmann syndrome (KS), they have a normal sense of smell.^{297–299} GnRH receptor mutations were found in approximately 5% of patients with

normosmic congenital hypogonadotropic hypogonadism.³⁰⁰ GnRH receptor mutations that cause IHH result in decreased binding of GnRH or impaired GnRH receptor signal transduction, or decreased GnRH receptor cell membrane expression because of misrouting of GnRH receptor oligomers from the ER.^{47,48,297–299} Some mutations, including p.E90K, p.L266R, and p.S168R, that cause misfolding and retention, within the ER, exhibit a dominant negative effect because of retention of wild-type receptors.⁴⁸

Female patients with mutations that partially compromise GnRH receptor function may present with primary amenorrhea and infertility, associated with a normal breast development, normal or small uterus, and small ovaries with immature follicles.^{297,301} Males with the same mutations may present with incomplete hypogonadotropic hypogonadism (characterized by a delayed and incomplete puberty) or with complete hypogonadotropic hypogonadism (characterized by absent puberty).^{297,301}

Some patients with IHH caused by mutated GnRH receptors have partial or normal gonadotropin responses to exogenous GnRH.^{297,301} However, decreased amplitude in the pulsatile LH secretion can be observed in these patients.²⁹⁷ Females with a partial or normal gonadotropin response to exogenous GnRH are more likely than nonresponders to become fertile in response to pulsatile exogenous GnRH.^{297,302}

Activating mutations of the GnRH receptor have not been described in the germline or in pituitary adenomas.³⁰³

The Thyrotropin-Releasing Hormone and Secretagogue Receptor Group

Thyrotropin-Releasing Hormone Receptors

Like the GnRH receptor, TRH receptor activation leads to increased phospholipase C activity.³⁰⁴ To date, only inactivating mutations that cause endocrine dysfunction have been reported for the TRH receptor. One patient was identified with central hypothyroidism caused by mutated TRH receptors.³⁰⁵ He presented during the ninth year of life with short stature (−2.6 SD), accompanied by a delayed bone age (−4.1 SD), a low plasma thyroxine level, and a normal plasma TSH level. Exogenous TRH did not induce an increase in plasma TSH and prolactin levels. He was found to be compound heterozygous for TRH receptor gene mutations, resulting in receptors that failed to bind TRH or induce IP3 production. Another family was identified with complete resistance to TRH because of a nonsense mutation in the TRHR (p.R17X) producing a TRH receptor that lacked the entire transmembrane domain.³⁰⁶ The proband was homozygous and presented with short stature, growth failure, and fatigue at age 11 years. He had a low free T₄, with a low-normal TSH. TRH stimulation testing failed to stimulate TSH or prolactin. Surprisingly his 33-year-old sister who was also homozygous had escaped detection despite two normal pregnancies brought to term. She had no signs or symptoms of hypothyroidism but exhibited thyroid function tests similar to the proband. She breastfed normally. Both the proband and his sister had normal cognitive function. This report suggested that the TRH receptor is not essential for normal cognitive function or female fertility and lactation. The mouse model corroborates these findings.³⁰⁷

Other Class A Receptors That Transduce Hormone Action

Free Fatty Acid Receptor 1

At the time a new GPCR is discovered, the ligand for the newly discovered receptor is often unknown. Thus until a specific ligand is discovered, these GPCRs are known as orphan receptors. According to the Human Genome Organization (HUGO) Gene

Nomenclature Committee, these G protein-coupled orphan receptors should be named alphanumerically GPR followed by a number, until their ligand is known. Once a specific ligand is identified, a more specific name is given the receptor.

The ligands for GPR40 were unknown when the receptor was first discovered. The HUGO Gene Nomenclature Committee changed the name of the receptor to free fatty acid receptor 1 (FFAR1) when the ligands were identified as medium- and long-chain fatty acids. With rare exceptions that are clearly identified, this chapter follows HUGO Gene Nomenclature Committee recommendations (see www.gene.ucl.ac.uk/nomenclature/index.html for more information on receptor nomenclature).

FFAR1 is one of several GRCRs for lipid mediators. Lipid mediators are intercellular lipid messengers that include sphingosine 1-phosphate, sphingosylphosphorylcholine, dioleoyl phosphatidic acid, lysophosphatidic acid, eicosatetraenoic acid, bile acids, and free fatty acids.⁶⁷ FFAR1 is activated by medium- and long-chain fatty acids, whereas FFAR2 (formerly known as GPR43) and FFAR3 (formerly known as GPR41) are activated by shorter-chain fatty acids.⁶⁷ There is now evidence that FFAR1 activation by medium- and long-chain fatty acids has endocrine implications. FFAR1 is expressed in human pancreatic β-islet cells.³⁰⁸ FFAR1 is involved in cholecystokinin secretion from I cells in response to fatty acids.³⁰⁹ It has also been implicated in fatty acid stimulated GLP-1 and GIP secretion from L and K cells.³¹⁰ GPR120 is expressed in enteroendocrine cells and has a physiologic role in GLP-1 secretion.³¹¹ FFAR2 and FFAR3 are expressed in adipose tissue and FFAR3 has been implicated in leptin production.³¹¹

Fatty acid-induced stimulation of FFAR1 in β-islet cells leads to activation of the G_{αq}-phospholipase C second-messenger pathway, which in turn leads to release of calcium from the ER that augments insulin-mediated increases in intracellular calcium concentrations because of glucose-induced activation of voltage-gated calcium channels.^{312–315} Because an increased intracellular calcium concentration induces insulin release, FFAR1-mediated augmentation of glucose-mediated increases in the intracellular calcium concentration leads to amplification of glucose-stimulated insulin release.^{312–315}

A variant in FFAR1 (p.Gly180Ser), found in a Sicilian population, resulted in obesity, impaired glucose tolerance, and lipid stimulated insulin secretion.³¹⁶ Two other variants, p.Arg211His and p.Asp175Asn, are not associated with alterations in insulin release.^{316,317} TAK-875, an FFAR1 agonist, was shown to reduce hemoglobin A1c in patients with type 2 diabetes, in a phase 2 clinical trial.³¹⁸ Wild-type mice placed on an 8-week high-fat diet develop glucose intolerance, insulin resistance, hypertriglyceridemia, and hepatic steatosis—whereas FFAR1 knockout mice on the same diet do not develop these conditions.³¹⁹ The clinical relevance for patients is not yet clear. However, an Arg211His polymorphism in the FFAR1 gene may explain some of the variation in insulin secretory capacity found in Japanese men: Arg/Arg homozygotes had lower serum insulin levels, homeostasis model of insulin resistance, and homeostasis model of beta-cell function than His/His homozygotes.³²⁰

KISS1 Receptor/GPR54

Studies in animal models suggests that Kiss1-expressing neurons in the hypothalamus modulate GnRH expressing neurons to initiate puberty and modulate sex steroid feedback on GnRH release.^{321,322} Homozygous inactivating mutations in the gene encoding the KISS1 receptor (GPR54) were initially described in French and Saudi Arabian patients with IHH; in both cases the affected subjects came from consanguineous families.^{321,323–325} The Saudi patients carried a p.Leu148Ser

mutation, whereas the French patients carried a 155bp deletion. Leu148 is highly conserved among class A GPCRs.³²⁶ The mutation does not affect expression, ligand binding, or association with G_s , but impairs ligand-induced catalytic activation of G_s .³²⁶ At the same time, an African American patient with IHH was described who was compound heterozygous for inactivating GPR54 mutations.³²⁵ Since publication of these initial reports, additional patients have been described. A boy with a Jamaican father and a Turkish-Cypriot mother, and with cryptorchidism and micropenis at birth, and undetectable LH and FSH levels at 2 months of age, was found to have compound heterozygous GPR54 mutations.³²⁷ Another missense mutation (p.Leu102Pro) that exhibits complete inactivation of GPR54 signaling has been identified.³²⁸ Surprisingly, patients with this mutation exhibited spontaneous pulsatile LH and FSH secretion with normal frequency, and a blunted amplitude and family members had partial pubertal development.³²⁸ Biallelic loss of function mutations in GPR54 are a rare cause of normosmic IHH.^{321,327} A study of genetic causes of normosmic congenital hypogonadotropic hypogonadism showed that KISS1R mutations accounted for 2% of the variants.³⁰⁰

Unlike patients with KS, but similar to patients with GnRH mutations, patients with GPR54 mutations have an intact sense of smell. In contrast to patients with IHH caused by GnRH mutations, patients with GPR54 mutations increase serum gonadotropin levels in response to exogenous GnRH.

Ligands for GPR54 derive from a single precursor protein, kisspeptin-1.^{329,330} The longest derivative protein that acts as a ligand for GPR54 is metastatin, so called because it is a metastasis suppressor gene in melanoma cells.³²⁹ Metastatin consists of kisspeptin-1 69-121.^{329,330} However, shorter carboxy-terminal peptides derived from kisspeptin-1 bind and activate GPR54.³²⁹ Administration of metastatin to adult male volunteers increases LH, FSH, and testosterone levels.³³¹

An activating mutation in GPR54 was identified in a patient with central precocious puberty.³³² The adopted girl was found to have an Arg386Pro mutation, which led to prolonged activation of signaling in response to kisspeptin. Mutational analysis of 28 subjects with idiopathic central precocious puberty failed to find any variants in KISS1 or KISS1R.³³³ A larger study showed an association between several variants and central precocious puberty in Korean girls.³³⁴

Orexin Receptors

Orexins act on specific receptors that are located predominantly in the hypothalamus to control food intake and play a role in the regulation of sleep/wakefulness.³³⁵⁻³³⁷ There are two types of orexin receptors: the orexin-1 and the orexin-2 receptors.³³⁷ There are also two types of orexins, orexin A and orexin B, formed from the precursor peptide preproorexin.³³⁷ Orexins are also known as *hypocretins*, and orexin A is synonymous with hypocretin-1 and orexin B with hypocretin-2.^{336,337} Orexin A acts on orexin-1 and orexin-2 receptors, whereas orexin B only acts on orexin-2 receptors.^{335,338,339}

Like most class A GPCRs, orexin receptors couple with $G_{q/11}$ and G_i/G_o to activate phospholipase C and inhibit adenylyl cyclase, respectively.^{337,340-342} Surprisingly, evidence suggests that orexin receptors also couple with G_s —which increases adenylyl cyclase activity.³⁴² Orexins increase food intake and duration of wakefulness.^{335,336,343} Orexin A and activation of the orexin-1 receptor have greater orexigenic effects than orexin B and activation of the orexin-2 receptor.³⁴⁴ The orexin-2 receptor mediates the arousal effect of orexins.³⁴⁴ Most patients with narcolepsy with cataplexy have diminished levels of orexin A concentrations in cerebral spinal fluid and lack orexin-containing neurons.^{336,345-348} This is thought to be because

of postnatal cell death of orexin neurons in the hypothalamus.³⁴⁹ HLA DQB1*0602 is associated with narcolepsy with cataplexy and an autoimmune process has been suggested, but no autoantibodies have been identified. Thus far, no mutations in orexin receptors have been found in humans. A mutation in the orexin-2 receptor causes narcolepsy in dogs.³⁵⁰ There is one described mutation (p.Leu16ARG) in the *HCRT* gene in a child with early-onset narcolepsy with cataplexy.³⁴⁶ This mutation was shown to impair processing and trafficking of the mutant orexin, leading to undetectable orexin A concentrations in the cerebrospinal fluid.

Ghrelin Receptors

The ghrelin receptor is also known as the GH secretagogue receptor type 1a because activation of receptors in the hypothalamus and pituitary somatotrophs enhances GH secretion.³⁵¹ Ghrelin is a product of posttranslational modification of the ghrelin gene product proghrelin.³⁵² Ghrelin is mainly produced in the stomach.^{353,354} Activation of ghrelin receptors located in the hypothalamus induces growth hormone-releasing hormone (GHRH) secretion. At the level of pituitary somatotrophs, it stimulates GH secretion. The ghrelin receptor also stimulates the appetite (i.e., an orexigenic role).

Plasma ghrelin levels are elevated just before eating and decrease rapidly after eating.^{355,356} In addition, intravenous administration of ghrelin to humans increases appetite and food intake.³⁵⁷ Plasma ghrelin levels are elevated in individuals with Prader Willi syndrome.³⁵⁸ Thus hyperphagia in patients with Prader Willi syndrome may be caused at least in part by overactivation of ghrelin receptors by ghrelin. Screening of 184 extremely obese children and adolescents for mutations of the ghrelin receptor gene failed to identify a single mutation likely to cause obesity.³⁵⁹ In contrast, large-scale screening studies have identified mutations and single nucleotide polymorphisms (SNPs) scattered throughout the ghrelin receptor,³⁶⁰ and two SNPs and one mutation in the promoter region, associated with increased transcriptional activity, cosegregated with obesity.

Short individuals in two unrelated Moroccan kindreds were found to have a C to A transversion at position 611 in the first exon of the ghrelin receptor gene.³⁶¹ This transversion results in replacement of the apolar and neutral amino acid alanine at position 204 of the receptor by the polar and charged amino acid glutamate (p.Ala204Glu). This mutation interferes with normal constitutive activity of the receptor and decreases cell membrane expression of the receptor. Receptor activation by ghrelin, however, is preserved. Two-thirds of heterozygous individuals in the kindreds studied had short stature, with height more than or equal to 2 SDs below the mean. One heterozygous individual's height was -3.7 SDs below the mean. Before onset of GH therapy, the only individual in the kindreds homozygous for the mutation had a height -3.7 SD, and became overweight during puberty. The weight of the patients heterozygous for the mutation varied from underweight to overweight. Another patient who presented with severe short stature (-3 SD), vomiting, ketosis, hypoglycemia, and low BMI was identified to be a compound heterozygote for a p.W2X and an p.R237W mutation in the ghrelin receptor.³⁶² His serum insulin-like growth factor-1 (IGF-1) level was low at 44 ng/mL and he failed GH stimulation testing, but had a normal IGF-1 generation test. This patient had improvement in his height velocity and resolution of hypoglycemia after treatment with GH. Four more ghrelin receptor mutations were identified in a Japanese cohort with short stature (p.Q36del, p.P108L, p.C173R, and p.D246A).³⁶³ p.Q36del showed a minor reduction in activity. C173R led to intracellular retention. D246 caused impaired signaling, and P108L led to

reduced binding affinity to ghrelin. Two other mutations were identified in a cohort of patients with constitutional delay of growth and puberty in Brazil (Ser84Ile and Val182Ala).³⁶⁴ Both resulted in decreased basal activity. The patients were short at presentation (−2.4 and −2.3 SD) but reached a normal adult height without treatment.

Another product of posttranslational modification of proghrelin, obestatin, appears to play a role in controlling appetite and weight.³⁵² Activation of the obestatin receptor, previously known as *GPR39*, in rats results in decreased food intake and weight.

Melanin-Concentrating Hormone Receptors

Formerly known as *SLC-1* or *GPR24*, the type 1 melanin-concentrating hormone (MCH) receptor (MCHR1)—and the more recently discovered type 2 MCH receptor (MCHR2), formerly known as *SLT* or *GPR145*—may play a role in regulating feeding and energy metabolism in humans.^{365–367} When activated, MCHR1 couples with $G_{q/11}$ and $G_{i/o}$ to increase phospholipase C activity and inhibit adenylyl cyclase activity, respectively.^{365,366,368} MCHR2 couples with $G_{q/11}$, and MCH binding leads to increased phospholipase C activity.^{367,369}

Studies in rodents reveal that MCH is an orexigenic hormone, and treatment of rodents with MCHR1 antagonists decreases food intake, weight, and body fat.^{37,365,370–372} MCHR2 is not expressed in rodents.³⁷³ Deletion of the MCHR1 in mice prevents overeating in response to food cues under sated conditions.³⁷⁴ Two loss-of-function mutations were identified in MCHR1 in humans (R210H and P377S).³⁷⁵ Cells transfected with either mutant receptor failed to respond to MCH, despite normal cell-surface expression of the receptor, suggesting a receptor activation defect. These mutations were identified in two markedly underweight individuals and were not found in an obese cohort.^{375,376} Analysis of the *MCHR1* gene in more than 4000 obese German, Danish, French, and American children and adolescents revealed several SNPs and gene variations in the German children and adolescents that may be associated with obesity.³⁷⁶ Another study of 106 American subjects with early onset obesity failed to definitively identify MCHR1 and MCHR2 mutations as a cause of obesity.³⁷⁷

CLASS B RECEPTORS THAT TRANSDUCE HORMONE ACTION

Growth Hormone–Releasing Hormone Receptor

The GHRH receptor gene is located at 7p14.³⁷⁸ GHRH receptors interact with G_s to stimulate adenylyl cyclase, resulting in increased intracellular cyclic AMP levels that lead to somatotroph proliferation and GH secretion.³⁷⁹ Thus it is not surprising that activating mutations in G_{α_s} leading to constitutive activation of adenylyl cyclase have been found in some GH-secreting pituitary adenomas in humans.³⁸⁰

Many mutations in the GHRH receptor that cause isolated GH deficiency have been identified. These include six splice site mutations, two microdeletions, two nonsense mutations, one frameshift mutation, 10 missense mutations, and one mutation in the promoter.^{381–384} The first naturally occurring mutation in the GHRH receptor (p.D60G) was found in the little mouse, which has a dwarf phenotype.^{385,386} This mutation in a conserved amino acid in the extracellular domain impairs the ability to bind GHRH.³⁸⁷ The first human mutation in the GHRH receptor (p.Glu72X) was identified in a consanguineous Indian family.^{388,389} The same mutation was found in three apparently unrelated consanguineous kindreds from India, Pakistan, and Sri Lanka.^{378,390} A different mutation

(5′ splice site mutation in intron 1) was identified in a large Brazilian kindred of more than 100 individuals.³⁷⁹ Both mutations result in the production of markedly truncated proteins with no receptor activity.^{379,390} A frameshift mutation was identified in a patient with severe short stature and was the first documented case of early-onset anterior pituitary hypoplasia.³⁸³ In another family, two siblings with isolated GH deficiency were found to be compound heterozygous for inactivating GHRH receptor gene mutations.³⁹¹ Three more novel mutations were identified in families with severe short stature in the United Kingdom (p.W273S, p.R94L, and p.R162W).³⁸¹ The only mutation found in the promoter region of GHRH affects one of the Pit-1 binding sites.³⁹²

Studies of subjects in these large kindreds who are homozygous or compound heterozygous for inactivating GHRH receptor gene mutations have shown that affected children experience severe postnatal growth failure with proportionate short stature.^{378,379,390,391} Males have high-pitched voices and moderately delayed puberty.^{378,379,390} Unlike infants with complete GH deficiency, they do not have frontal bossing, microphallus, or hypoglycemia.^{378,390,393} Other features include a doll facies, reduced muscle mass, central adiposity, wrinkled thin skin, and delayed pigmentation of the hair in children and teens.³⁹⁴ Bone age is delayed with respect to chronological age, but advanced with respect to height age.³⁹⁰ Some patients have been found to have pituitary hypoplasia.^{378,390} Growth velocity increased with exogenous GH therapy.^{378,379,390,391} Remarkably, GH treatment of two siblings from Turkey, with the p.E72X mutation, allowed them to reach a normal adult height, despite pretreatment heights of −6.7 and −8.6 SD and initiation of GH around age 14 years.³⁹⁵

Further studies in the Brazilian cohort revealed that homozygotes had increased abdominal obesity, a higher low-density lipoprotein (LDL), and total cholesterol but normal carotid wall thickness and no evidence of premature atherosclerosis.³⁹⁶ Treatment of these patients with GH for 6 months improved body composition, reduced LDL and total cholesterol, and increased high-density lipoprotein (HDL). Surprisingly, this was associated with increased carotid intima-media thickness and atherosclerotic plaques.³⁹⁷ Reevaluation, 5 years after the discontinuation of GH, showed a return to baseline for these measures.³⁹⁸ Patients with a null mutation affecting the GHRH receptor also exhibited altered sleep patterns with abnormalities in both rapid eye movement and nonrapid eye movement sleep.³⁹⁹ Heterozygotes for the null mutation had normal adult heights and IGF-1 SD scores but exhibited reduced body weight, BMI, lean mass, fat mass, and increased insulin sensitivity.⁴⁰⁰

SNPs in the GHRH receptor have been shown to contribute to height-SDS variation,^{401,402} but mutations remain a rare cause of isolated GH deficiency.⁴⁰³

Gastric Inhibitory Polypeptide Receptors

The gastric inhibitory peptide receptor (*GIPR*) gene is located on the long arm of chromosome 19.⁴⁰⁴ Two functional isoforms exist in humans because of alternate splicing.⁴⁰⁵ GIPR activation induces G_{α_s} activation of adenylyl cyclase.^{405–407} Gastric inhibitory polypeptide (GIP) is also known as *glucose-dependent insulinotropic polypeptide* and is released by K cells in the small intestine in response to food. GIP has numerous physiologic actions, including stimulation of glucagon, somatostatin, and insulin release by pancreatic islet cells.^{408,409} Human mutations in the GIPR have not been identified to date. One study identified an SNP in the GIPR that is associated with insulin resistance in obese German children.⁴¹⁰ Another study identified an SNP in the GIPR that is associated with reduced fasting and induced C-peptide levels.⁴¹¹

The GIPR is implicated in food-dependent Cushing syndrome. Circulating cortisol levels in patients with food-dependent or GIP-dependent Cushing syndrome rise abnormally in response to food intake.^{102,103} GIP does **not** normally induce cortisol release from adrenocortical cells.^{412,413} These patients may have adrenal adenomas or nodular bilateral adrenal hyperplasia that overexpresses GIPRs that abnormally stimulate cortisol secretion when activated.^{412,414} Thus in these patients postprandial GIP release leads to activation of these abnormally expressed and functioning adrenal GIPRs, resulting in excessive adrenal cortisol secretion.^{412,413}

Parathyroid Hormone and Parathyroid Hormone-Related Peptide Receptors

Two types of PTH receptors have been identified. The type 1 PTH receptor (PTHr1) is activated by PTH and parathyroid hormone-related peptide (PTHrP) and mediates PTH effects in bone and kidney.⁴¹⁵ In spite of 51% homology to the PTHr1, the type 2 PTH receptor (PTHr2) is activated by PTH but not PTHrP.^{415–418} The PTHr2 is particularly abundant in the brain and pancreas but is also expressed in the growth plate; its natural ligand is TIP39.^{419–421} The function of the PTHr2 is largely unknown.^{415,416}

The PTHr1 has a large amino-terminal extracellular domain containing six conserved cysteine residues.⁴¹⁵ Ligand binding induces the PTHr1 to interact with G_s and G_q proteins, leading to activation of the adenylyl cyclase/PKA and phospholipase C/protein kinase C second-messenger pathways, respectively.^{422–428} Interestingly, mutations in i2 interfere with coupling of the PTHr1 to G_q, without interfering with coupling to G_s—whereas mutations in i3 disrupt coupling of the receptor to both G proteins.^{429,430} Binding of PTH to the PTHr1 leads to internalization of a portion of plasma membrane containing a ternary complex of activated receptor-G_s-adenylyl cyclase that exhibits sustained production of cyclic AMP.⁴³¹ In contrast, PTHrP binding to the PTHr1 receptor leads to formation of a complex that remains on the cell surface and generates cyclic AMP for only a short period of time.⁴³¹

Biallelic loss-of-function mutations in the *PTHr1* gene cause Blomstrand chondrodysplasia.⁴¹⁵ This lethal disorder is characterized by accelerated chondrocyte differentiation, resulting in short-limbed dwarfism, mandibular hypoplasia, lack of breast and nipple development, and severely impacted teeth.^{415,432} One patient with this rare condition was found to be homozygous for a point mutation that resulted in a p.Pro132Leu substitution in the amino-terminal domain that interferes with ligand binding.^{433,434} Another patient was found to be homozygous for a frameshift mutation that results in a truncated receptor lacking TM5-7, and contiguous intracellular and extracellular domains.⁴³⁵

A third patient was found to have a maternally inherited mutation that altered splicing of maternal mRNA, resulting in a PTHr1 with a deletion of residues 373 through 383 in TM5 (which also interferes with ligand binding).⁴³⁶ In spite of heterozygosity for the mutation, the patient was unable to produce normal PTHr1s, because for unknown reasons the paternal allele was not expressed.⁴³⁶ Heterozygosity for somatic or germline p.Arg150Cys missense mutations in the PTHr1 was identified in two out of six patients with enchondromatosis,⁴³⁷ a condition that is usually sporadic and which is attributed to a postzygotic somatic cell mutation. Enchondromas are benign cartilage tumors that develop in the metaphyses and may become incorporated into the diaphyses of long tubular bones, in close proximity to growth plate cartilage; there is an increased risk of malignant transformation to osteosarcoma.²⁰ Patients with multiple enchondromatosis

(OMIM ID: 166000) have Ollier disease (World Health Organization terminology), a disorder characterized by the presence multiple enchondromas with an asymmetric distribution of lesions that vary in size, number, and location. When multiple enchondromatosis occurs with soft tissue hemangiomas, the disorder is known as *Maffucci syndrome*. In vitro studies showed that the p.Arg150Cys mutation was mildly activating but led to stimulation of phospholipase C rather than adenylyl cyclase.⁴³⁷ A transgenic knockin mouse expressing the mutant PTHr1, under the control of the collagen type 2 promoter, showed development of tumors that are similar to those observed in human enchondromatosis.⁴³⁷ The clinical significance of these observations are uncertain, as most cases of enchondromatosis are caused by mutations in the *IDH1* and *IDH2* genes.^{438,439}

Biallelic loss of function mutations in PTHr1 are also the cause for Eiken syndrome,⁴⁴⁰ which is characterized by a skeletal dysplasia with severely retarded ossification, principally of the epiphyses, pelvis, hands, and feet, as well as abnormal modeling of the bones. Duchatelet et al.⁴⁴¹ mapped Eiken syndrome to chromosome 3p near the *PTHr1* gene. Affected individuals were homozygous for a nonsense mutation in the carboxy-terminal cytoplasmic tail of the *PTHr1* gene (p.R485X). In a 7-year-old boy with Eiken syndrome, who was born to unaffected first-cousin parents, Moirangthem et al.⁴⁴² identified a homozygous missense mutation at a conserved residue in the *PTHr1* gene (p.E35K). Finally, nonsyndromic primary failure of tooth eruption (PFE) is caused by heterozygous mutations in the *PTHr1* gene.⁴⁴³ Three distinct mutations, namely c.1050-3C > G, c.543+1G > A, and c.463G > T, were identified in 15 affected individuals from four multiplex pedigrees. All mutations truncate the mature protein and therefore should lead to a functionless receptor.

Some cases of Jansen metaphyseal chondrodysplasia have been found to be caused by constitutively activating mutations of the *PTHr1* gene.^{444–446} This autosomal-dominant disorder is characterized by short-limbed dwarfism caused by impaired terminal chondrocyte differentiation and delayed mineralization, accompanied by hypercalcemia.^{444,445} Interestingly, constitutive activation appears to result predominantly in excessive G_s activity because adenylyl cyclase activity is increased and phospholipase C activity is unchanged in COS-7 cells expressing mutated receptors.^{444–446}

Other Class B Receptors That Transduce Hormone Action

Other class B receptors that transduce hormone action include glucagon-like peptide-1, glucagon, calcitonin, and corticotrophin-releasing factor receptors.⁴⁴⁷ Class B receptors usually couple with heterotrimeric G_s proteins, leading to the activation of adenylyl cyclase—which in turn leads to elevated intracellular cyclic AMP levels.^{447,448} (See chapter on Diabetes Mellitus, for a discussion of the role of GLP1 in promoting insulin secretion and the use of GLP1 analogues or inhibitors of GLP1 breakdown in therapy.)

CLASS C RECEPTORS THAT TRANSDUCE HORMONE ACTION

Calcium-Sensing Receptors

The calcium-sensing receptor (CaSR) is located on the long arm of chromosome 3 (3q21.1).⁴⁴⁹ The CaSR has a large amino-terminal domain that contains nine potential glycosylation sites.⁴⁵⁰ Binding of ionized calcium to the CaSR leads to activation of phospholipase C via activation of G_{q/11} proteins.^{71,450,451}

The CaSR is an integral component of a feedback system that uses PTH and renal tubular calcium reabsorption to keep the serum concentrations of ionized calcium within a narrow physiologic range.⁴⁵² Increased extracellular ionized calcium concentrations activate CaSRs in parathyroid chief and renal tubular epithelial cells, leading to decreased PTH release and renal tubular calcium reabsorption.^{450,453} When ionized calcium concentrations fall, CaSR activation decreases—leading to increased PTH release and enhanced renal tubular calcium reabsorption.^{450,453}

The CaSR also binds magnesium, and thus PTH secretion can be inhibited by elevated serum concentrations of magnesium with consequent hypocalcemia.⁴⁵⁴ The CaSR may participate in magnesium homeostasis by altering reabsorption of magnesium in the thick ascending limb of Henle in the kidneys.^{455,456} It is probable that increased peritubular levels of magnesium activate renal CaSRs, leading to inhibition of reabsorption of magnesium from the thick ascending limb of Henle—which in turn leads to increased renal excretion of magnesium.^{455,456}

Both loss of function and gain of function mutations in the CaSR have been described in patients with hypocalcemia and hypercalcemia, respectively.⁴⁵⁷ Familial (benign) hypocalciuric hypercalcemia type 1 (FHH1) and neonatal severe hyperparathyroidism (NSHPT) are caused by loss-of-function mutations of the *CaSR* gene.^{458,459} Most of these mutations are located in the amino-terminal extracellular domain.^{460,461} With few exceptions, individuals heterozygous for loss-of-function mutations have FHH1, a benign condition characterized by very low urinary calcium excretion, mild hypercalcemia, normal or slightly elevated serum PTH levels, and few if any symptoms of hypercalcemia or hyperparathyroidism. In contrast, individuals homozygous for such mutations will develop NSHPT, a life-threatening condition characterized by severe hypercalcemia, markedly elevated serum PTH levels and skeletal defects.^{462,463} Therefore children of consanguineous FHH parents are at risk for NSHPT.^{460,464,465} Occasionally, infants with NSHPT are heterozygous for *CaSR* gene mutations that encode a dominant negative receptor protein.⁴⁶⁶ In most cases, FHH1 is transmitted in an autosomal dominant manner, but autosomal recessive inheritance has been described in one kindred in which the CaSR mutation was only weakly inactivating.⁴⁶⁷

Decreased CaSR function impedes calcium ion suppression of PTH release and renal tubular calcium reabsorption.⁴⁵⁹ Thus FHH1 is characterized by mild hypercalcemia that is accompanied by inappropriately normal or elevated serum PTH levels and by relatively low urinary calcium excretion.^{462,468,469} Individuals with FHH1 may also have hypermagnesemia as a result of decreased peritubular inhibition of magnesium reabsorption from the thick ascending loops of the kidneys by the CaSR.⁴⁵⁶ In addition to FHH1, there are two other variants, FBH type 2 (FBH2) and FBH type 3 (FBH3), that are caused by heterozygous loss of function mutations in *GNA11*⁴⁷⁰ and *AP2S1*,⁴⁷¹ respectively.

FHH1 is caused by heterozygous loss-of-function mutations of the *CaSR* gene on 3q21.1.⁴⁷² Two other chromosomal loci have been identified in patients with FBH who do not have *CaSR* gene mutations. FHH2 has been mapped to *GNA11*, which encodes the α subunit of G11, located 19p13.3 and is biochemically and clinically similar to FHH1.^{472,473} FBH3, which is also known as the Oklahoma variant (FHH_{OK}), is caused by mutations in the *AP2S1* gene located at 19q13.^{472,474} Adults with FHH3 have hypophosphatemia, elevated serum PTH levels, and osteomalacia, in addition to the clinical and biochemical findings found in individuals with FHH1 and FHH2.^{472,475} NSHPT is characterized by severe hypercalcemia accompanied by elevated circulating PTH levels,

undermineralization of bone, rib cage deformity, and multiple long-bone and rib fractures.⁴⁶²

Activating mutations of the *CaSR* gene cause autosomal-dominant hypocalcemia type 1 (ADH1), as increased CaSR function leads to increased calcium ion suppression of PTH release and suppression of renal tubular calcium reabsorption.^{451,472, 476–480} ADH1 is characterized by hypocalcemia and hypomagnesemia, accompanied by inappropriately normal or increased urinary calcium excretion and inappropriately normal or low serum PTH levels.^{451,478–480} Patients with ADH1 may be asymptomatic or may present with tetany, muscle cramps, or seizures during infancy or childhood.^{459,478–480} Similar to inactivating mutations, most activating mutations are located in the amino-terminal extracellular domain.^{476,478,479,481} Treatment of patients with ADH1 with activated forms of vitamin D (e.g., calcitriol) is complicated, as normalization of serum calcium levels is associated with worsening of hypercalciuria, hence further increasing the risk of nephrolithiasis, in nephrocalcinosis, and in renal impairment.^{478,479} In contrast, urinary calcium excretion is not excessive in patients with ADH2, who have activating mutations in *GNA11*.^{470,482,483} *GNA11* encodes the α subunit of G11, the principle G protein that couples to CaSR in parathyroid cells but not in the kidney.

Some patients with activating mutations of the *CaSR* gene will develop Bartter syndrome type V, which similar to other types of Bartter syndrome, is characterized by hypokalemic metabolic alkalosis and by hyperaldosteronism caused by elevated renin levels.^{484,485} Patients with Bartter syndrome type V, unlike patients with other types of Bartter syndrome, may also have symptomatic hypocalcemia and are at risk for developing nephrocalcinosis because of hypercalciuria.^{484,485} Evidence from in vitro functional expression studies suggests that patients with mild or moderate heterozygous gain-of-function mutations of the CaSR develop ADH1, whereas those with severe heterozygous gain-of-function mutations of the CaSR will also develop Bartter syndrome type V.^{484–486}

Some single-amino-acid polymorphisms of the *CaSR* gene appear to predict whole-blood ionized and serum total calcium levels and may increase the risk for bone and mineral metabolism disorders in individuals with other genetic and environmental risk factors for these disorders.^{487–489} Individuals heterozygous or homozygous for a Gln1011Glu *CaSR* gene polymorphism tend to have higher calcium levels than individuals with the polymorphism.^{489,490} The 15.4% of 387 healthy young Canadian women, with at least one *CaSR* gene allele with an Ala986Ser polymorphism, were found to have higher total calcium levels than the remainder of the women without the polymorphism.⁴⁸⁸

Another study of 377 unrelated healthy Italian adult males and females found that 24% of study subjects were heterozygous or homozygous for the p.Ala986Ser polymorphism and confirmed the finding that individuals without the polymorphism have lower whole-blood ionized calcium levels than individuals with the polymorphism.⁴⁸⁹ The p.Ala986Ser polymorphism has also been associated with Paget disease and primary hyperparathyroidism.^{490–492} Individuals with a less common Arg990Gly polymorphism tend to have lower whole-blood ionized calcium levels than individuals without the polymorphism.⁴⁸⁹ The p.Arg990Gly polymorphism has been found to be associated with hypercalciuria and nephrolithiasis.^{492,493}

Autoantibodies against the CaSR that interfere with binding of calcium to the receptor may cause autoimmune hypocalciuric hypercalcemia.⁴⁹⁴ These patients have primary hyperparathyroidism with the clinical and biochemical features of patients with FHH1.⁴⁹⁴ Conversely, autoantibodies that activate the CaSR are a cause of autoimmune-acquired

hypoparathyroidism.⁴⁹⁵ Both conditions may occur in association with other autoimmune conditions (such as autoimmune thyroiditis), with celiac disease in patients with autoimmune hypocalciuric hypercalcemia, and with autoimmune thyroiditis and autoimmune polyglandular syndrome types 1 and 2 in patients with autoimmune-acquired hypoparathyroidism.^{494–496} Autoantibodies that activate the CaSR were found in approximately one-third of individuals with acquired hypoparathyroidism.⁴⁹⁶

G PROTEIN GENE DISORDERS

A growing number of human disorders are associated with somatic or germline mutations in genes that encode the subunits of G proteins and lead to either a gain of function or a loss of function in the signaling protein.⁴⁹⁷ Here, we will limit discussion to disorders associated with mutations of the *GNAS* gene that encodes $G\alpha_s$, as this is the most common G protein to cause endocrine disorders.

Inactivating Mutations of the *GNAS* Gene

Pseudohypoparathyroidism type 1a (PHP1a; Albright hereditary osteodystrophy [AHO]) and pseudopseudohypoparathyroidism (PPHP) are caused by heterozygous inactivating mutations of the *GNAS* gene that encodes $G\alpha_s$.^{498,499} PHP1a is characterized by end organ resistance to PTH with consequent hypocalcemia, hyperphosphatemia, and elevated circulating PTH levels. In addition, patients also manifest resistance to other hormones whose receptors couple to Gs, such as GHRH, TSH, gonadotropin, calcitonin, and hypothalamic neurotransmitters. PHP1a patients also have neurocognitive impairment and obesity that reflect the effect of the $G\alpha_s$ in the brain. In addition, patients manifest a constellation of developmental defects that have been termed *Albright hereditary osteodystrophy* and which include heterotopic ossifications, short stature, craniofacial anomalies, and brachydactyly D/E of the hands and feet, characterized by shortened fingers and short fourth and fifth metacarpals.^{500–503} Patients with the associated condition PPHP share the same features of AHO as PHP1a, but do not have hormone resistance.^{500,501,504} The distinction between these two manifestations of the same gene defect is not stochastic but results from a complex mechanism of genomic imprinting that controls transcription of the *GNAS* gene. Hence, patients with a *GNAS* mutation on a maternal allele will develop a more severe form of $G\alpha_s$ deficiency with hormone resistance (i.e., PHP1a), whereas patients with identical mutations on the paternal *GNAS* allele will have a milder condition with normal hormone responsiveness (i.e., PPHP).^{500–504}

Although most cells express $G\alpha_s$ from both parental alleles, in some cells $G\alpha_s$ expression is suppressed from the paternal *GNAS* allele. Thus patients with PHP1a develop hormone resistance that is limited to the thyroid, pituitary somatotrophs, and proximal renal tubule cells because in these cells, $G\alpha_s$ is derived principally from the maternal *GNAS* allele.⁵⁰⁵ Thus patients with maternally inherited inactivating *GNAS* gene mutations express very little $G\alpha_s$ in these cells and develop hormone resistance.⁵⁰⁵ Because $G\alpha_s$ is not expressed from the paternal allele in imprinted tissues, PPHP patients with paternally inherited inactivating *GNAS* gene mutations do not experience a deficit in $G\alpha_s$ protein in these cells, as they will have a normal amount of $G\alpha_s$ protein that is produced from the wild-type maternal *GNAS* allele.⁵⁰⁵ Patients with either PHP1a or PPHP express only 50% of the normal amount of $G\alpha_s$ protein in cells in which $G\alpha_s$ transcription is not controlled by the imprinting mechanism, which leads to haploinsufficiency, and likely accounts for the similar features of AHO that occur in these two conditions. Subjects with paternally inherited *GNAS*

mutations have variable features of AHO without hormonal resistance and have been described to have PPHP, progressive osseous heteroplasia (POH),⁵⁰⁶ or osteoma cutis,^{507–509} based on the clinical phenotype. The basis for these distinctions is unknown.^{498,499}

Subjects with PHP type 1b (PHP1b; MIM 603233) lack typical features of AHO, but may have mild brachydactyly. PTH resistance is the principal manifestation of hormone resistance, but some patients have slightly elevated serum levels of TSH and normal serum concentrations of thyroid hormones as evidence of partial TSH resistance. It was initially thought that PHP1b is caused by inactivating mutations in the *PTHRI* gene.⁵¹⁰ However, no deleterious *PTHRI* gene mutations have been found in patients with PHP1b.^{511,512}

Epigenetic defects in imprinting of *GNAS* are the cause of PHP1b.^{498,499} There are three alternative first exons for *GNAS* (i.e., NESP55, XL α s, and exon A/B) that splice onto exons 2 through 13 and are associated with differentially methylated regions (DMRs). Most relevantly, the exon A/B DMR is methylated in the maternal germ cells and seems to be the principal control element for transcription from exon 1.^{505,513} Loss of methylation in the DMR upstream of exon A/B of the maternal allele is a consistent finding in patients with PHP1b, and this epigenetic defect accounts for decreased $G\alpha_s$ expression from the affected allele.^{514–516} Most cases of autosomal dominant PHP1b are caused by microdeletions on the maternal allele that include exons 3 to 5 or 4 to 6 of the gene encoding syntaxin-16 (*STX16*).⁵¹⁴ Three other maternally inherited microdeletions involving NESP55 and AS (delNESP55/ASdel3-4) or AS (delAS3-4) alone⁵¹⁷ have been identified, and these deletions produce a more global disruption of methylation that includes three *GNAS* DMRs (A/B, XL/AS, and NESP55). The genetic basis for most cases of sporadic PHP1b remains unknown and does not appear to be associated with the *GNAS* locus.⁵¹⁸ These patients have global epigenetic defects in methylation that affect all three DMRs. In some cases, partial⁵¹⁸ or complete⁵¹⁹ paternal uniparental disomy (UPD) for chromosome 20 has been identified, in which two normal copies of *GNAS* are both derived from the father. Paternal UPD would predict a near complete deficiency of $G\alpha_s$ in imprinted cells and tissues in which $G\alpha_s$ is not transcribed from the paternal allele.

$G\alpha_s$ is not expressed in the renal proximal tubules of these patients because of lack of a *GNAS* allele with a maternal epigenotype. In contrast, both of the *GNAS* alleles with paternal epigenotypes are normally expressed in nonimprinted cells in which expression of $G\alpha_s$ from the paternal allele is not suppressed.⁵²⁰

Activating Mutations of the *GNAS* Gene

When a GPCR is activated by a ligand, the activated receptor interacts with the heterotrimeric G protein and allows release of bound GDP from the $G\alpha$ subunit with replacement by GTP. The GTP-bound $G\alpha$ dissociates from the $G\beta\gamma$ dimer, and both complexes are free to associate with downstream signal generating molecules.^{9,10,14} The generation of second messengers is terminated by an intrinsic GTPase within the $G\alpha$ subunit that acts as a timer; hydrolysis of GTP to GDP inactivates $G\alpha$ and increases its affinity for $G\beta\gamma$ —leading to reassociation of an inactive heterotrimeric G protein that is ready for another cycle of receptor-induced activation.^{9,10,14} For $G\alpha_s$, the amino acids Arg201²¹⁴ and Gln227²⁴⁰ are critical to GTPase activity.⁵²⁰ *GNAS* mutations that result in substitutions of these amino acid residues lead to abrogation of GTPase activity and therefore prolong the active state of $G\alpha_s$, thereby leading to constitutive (i.e., receptor ligand-independent) stimulation of adenylyl cyclase.⁵²⁰ Somatic mutations of these residues that

disrupt GTPase activity are present in approximately 40% of GH-secreting and some ACTH-secreting and nonsecreting pituitary tumors; in some parathyroid, ovarian, testicular, thyroid, and adrenal tumors; and in some intramuscular myxomas.^{99,521,522}

More widespread mosaic Arg201²¹⁴ Gα_s mutations that decrease GTPase activity cause fibrous dysplasia or (when tissue distribution of the mutation is very widespread) McCune-Albright syndrome, which is characterized by the triad of café-au-lait spots, polyostotic fibrous dysplasia, and primary endocrine hyperfunction, particularly gonadotropin-independent precocious puberty.^{523–527}

Patients with McCune-Albright syndrome may also have excessive GH production, hyperthyroidism, and hypercortisolism, as well as nodularity of the pituitary, thyroid, and adrenal glands because of the growth-promoting effects of excessive cyclic AMP in these tissues.^{528,529} Hypophosphatemia, which is not uncommon in patients with McCune-Albright syndrome, appears to be caused by excessive production of the phosphatonin fibroblast growth factor (FGF)-23 by fibrous dysplasia skeletal lesions.^{530,531} Patients with McCune-Albright syndrome may also have non-endocrine problems, such as hepatobiliary abnormalities, cardiomyopathy, optic neuropathy, and sudden death.^{532–534}

CYTOKINE RECEPTORS

Cytokines are molecules produced by one cell that act on another cell.⁵³⁵ Thus the term *cytokine* can apply not only to molecules with immunologic functions, but also to hormones. Therefore GH, prolactin, and leptin are classified as type 1 cytokines.⁵³⁶ These and other type 1 cytokines (including interleukins [ILs] 2–9, 11–13, and 15; erythropoietin; thrombopoietin; and granulocyte-colony-stimulating factor) are characterized by a four α-helical bundle structure and signaling via type 1 cytokine receptors.⁵³⁶ Type 2 cytokines include the interferons and IL-10 and do not include hormones.⁵³⁶

Type 1 cytokines are divided into long-chain and short-chain cytokines.⁵³⁶ Prolactin, leptin, and GH belong to the long-chain subclass of type 1 cytokines because their helixes are 25 amino acids in length.⁵³⁶ The short-chain type 1 cytokines, including IL-2 and stem cell factor, have helixes of approximately 15 amino acids in length.⁵³⁶

Structure and Function of Type 1 Cytokine Receptors

All type 1 cytokine receptors have four conserved cysteine residues, fibronectin type 2 modules, a Trp-Ser-X-Trp-Ser motif in the extracellular domain, and a proline-rich Box 1/Box 2 region in the cytoplasmic domain.^{536,537} With the exception of stem cell factor, type 1 cytokine receptors do not contain catalytic domains, such as kinases.⁵³⁶

Type 1 cytokine receptors for long-chain type 1 cytokines require homodimerization for activation.^{536,538} First, the ligand binds a monomeric receptor.^{536,538} Then, the ligand interacts with a second receptor to induce receptor dimerization and activation.^{536,538} Activated receptors then stimulate members of the Janus family of tyrosine kinases (Jak kinases) to phosphorylate tyrosine residues on both the kinase itself and the cytoplasmic region of the receptors.^{536,539} Signal transducers and activators of transcription (STATs) then dock on the phosphorylated cytoplasmic receptor domains or Jak kinases via an SH2 domain, and are tyrosine phosphorylated.⁵³⁶ The phosphorylated STATs then dissociate from the receptors or Jak kinases, form homodimers or heterodimers, and translocate to the nucleus.^{536,540,541} In the nucleus, the STAT dimers bind and alter the activity of regulatory regions of target DNA.^{536,540,542}

There are four Jak kinases.^{540,543} Jak3 is only expressed in lymphohematopoietic cells, whereas Jak1, Jak2, and Tyk2 are expressed in every cell.^{536,544,545} There are seven STATs (Stat1, Stat2, Stat3, Stat4, Stat5a, Stat5b, and Stat6), which have different SH2 domain sequences that confer different receptor specificities.^{536,539–541}

Cytokine Receptors That Transduce Hormone Action

The actions of GH, prolactin, and leptin are mediated via specific type 1 cytokine receptors.⁵³⁶ Mutations of the growth hormone receptor (GHR) and the leptin receptor have been identified as the bases of specific endocrine disorders (Table 3.3).

Growth Hormone Receptors

The *GHR* gene is located on the short arm of chromosome 5 (5p13.1-p12), and 9 of the 13 exons of the gene encode the receptor.^{546–549} A secretion signal sequence is encoded by exon 2, the amino-terminal extracellular ligand binding domain is encoded by exons 3 through 7, the single transmembrane domain is encoded by exon 9, and the carboxy-terminal cytoplasmic domain is encoded by exons 9 and 10.^{546–549} Growth hormone binding protein (GHBP) is produced by proteolytic cleavage of the extracellular domain of the GHR from the rest of the receptor.⁵⁵⁰ Approximately 50% of circulating GH is bound to GHBP.⁵⁵⁰

Binding of GH to its receptor induces receptor dimerization and association with JAK2, a member of the Janus kinase family, which results in self-phosphorylation of JAK2 and a cascade of phosphorylation of cellular proteins, including Stat1, Stat3, and Stat5.^{551–555} The most critical of these proteins is STAT5b, which couples GH binding to the activation of gene expression that leads to the intracellular effects of GH, including synthesis of IGF-1, insulin-like growth factor binding protein 3 (IGFBP3), and acid labile subunit (ALS). The phosphorylated STATs translocate to the nucleus, where they regulate GH-responsive genes.^{552–555} In particular, GH indirectly controls growth by regulating production of IGF-1—which has direct effects on cell proliferation and hypertrophy.⁵⁵⁶ Jak2 also activates the mitogen activated protein (MAP) kinase and insulin receptor substrate pathways.^{557–559} However, the extent to which these pathways contribute to GH action is as yet unknown.⁵⁴⁹

Patients are considered to have growth hormone insensitivity (GHI) if they do not exhibit appropriate growth and metabolic responses to physiologic levels of GH.⁵⁵⁰ The phenotype of GHI is variable and ranges from isolated moderate postnatal growth failure to severe postnatal growth failure, accompanied by the classic features of Laron syndrome in Ecuadorian patients with GHR deficiency.^{550,560–564} Features of GHR deficiency include frontal temporal hairline recession, prominent forehead, decreased vertical dimension of face, hypoplastic

TABLE 3.3 Cytokine Receptors and Clinical Conditions Associated With Receptor Mutations

Receptor	Germline Mutation	Endocrine Disorder
Growth hormone receptor	Some inactivating (heterozygous) Inactivating (homozygous, compound heterozygous)	Partial growth hormone insensitivity with mild to moderate growth failure Growth hormone insensitivity/ Laron syndrome with moderate to severe postnatal growth failure
Leptin receptor	Inactivating (homozygous)	Obesity and hypogonadotropic hypogonadism

nasal bridge, shallow orbits, blue sclera, small phallus before puberty, crowded permanent teeth, absent third molars, small hands and feet, hypoplastic fingernails, hypomuscularity, delayed age of onset for walking, high-pitched voice, increased total and LDL cholesterol, and fasting hypoglycemia.^{550,564} All patients with GHI have normal or elevated circulating GH levels, markedly decreased circulating IGF-1 levels, and a delayed bone age.⁵⁵⁰

Patients homozygous or compound heterozygous for deletion of exons 5 and 6—or homozygous or compound heterozygous for numerous nonsense, missense, frameshift, and splice-point mutations throughout the *GHR* gene—have been found to have GHI characterized by severe postnatal growth failure and usually low or absent circulating GHBP levels.^{550,565–574} Patients homozygous or compound heterozygous for the p.Arg274Thr or the p.Gly223Gly splice mutations that result in a truncated receptor that cannot be anchored to the plasma membrane (or that result in the p.Asp152His missense mutation that interferes with GHR dimerization) have normal circulating GHBP levels.⁵⁵⁰

Patients heterozygous for mutations that alter the GHR have dimerization complexes that consist of two wild-type receptors, a wild-type receptor and a mutant receptor, and two mutant receptors. Thus heterozygosity for loss-of-function *GHR* gene mutations may have a dominant negative effect because the wild-type receptor/mutant receptor dimers may not be able to function normally.⁵⁷⁵ As expected from this phenomenon, some patients with moderate to severe growth failure have been found to be heterozygous for loss-of-function point or splice mutations of the *GHR* gene that alter the cytoplasmic or extracellular domains.^{550,576–579} In some cases, nonsense-mediated mRNA decay can lead to degradation of the aberrant mRNA and prevent a potential dominant negative effect.⁵⁸⁰

Some patients with severe short stature and GHI do not have GHR mutations. Rather, they have defects in GHR-mediated intracellular signaling—including impaired STAT activation.⁵⁸¹ Some patients with GHI were found to have STAT5b mutations.^{582–586} Unlike patients with GHR mutations, patients with STAT5b mutations also exhibited severe neurocognitive delay, chronic lung disease (lung fibrosis and/or lymphoid,

interstitial pneumonia, severe eczema, T-cell lymphopenia, and abnormal T-cell function.^{583,587} Patients with GHI can now be successfully treated with recombinant IGF-1,⁵⁸⁸ but this does not result in a normal adult height, in contrast to GH deficiency in which GH therapy can achieve normal adult height.

LEPTIN RECEPTORS

The leptin receptor (*LEPR*, also known as *Ob-R*) gene is located at 1p31. There are five isoforms of *LEPR* because of alternative splicing of the *LEPR* gene transcript (Fig. 3.5).⁵⁸⁹ Only the Ob-Rb isoform contains both the Jak kinase binding and STAT motifs necessary to maximally transduce the effects of leptin.⁵⁸⁹ The Ob-Ra, Ob-Rc, and Ob-Rd isoforms contain intact extracellular and transmembrane but are missing the STAT motif from their cytoplasmic domains.⁵⁸⁹ The Ob-Re isoform is missing the transmembrane and cytoplasmic domains.⁵⁸⁹ Thus the Ob-Rb isoform is thought to be the main isoform involved in mediating the effects of leptin.⁵⁸⁹

Three sisters from a consanguineous kindred were found to be homozygous for a splice mutation in the *LEPR* gene that resulted in expression of an 831-amino-acid protein (Ob-Rhd) that lacks transmembrane and cytoplasmic domains.⁵⁹⁰ They had been hyperphagic and morbidly obese since birth.⁵⁹⁰ They were found to have elevated circulating leptin levels, decreased TSH and GH secretion, and failure of pubertal development caused by hypogonadotropic hypogonadism.⁵⁹⁰ Heterozygous carriers of the mutation are not morbidly obese and do not have delayed or absent puberty.⁵⁹⁰

Nonsense or missense *LEPR* mutations were identified in 3% of a selected cohort of 300 subjects with early-onset obesity. Individuals with mutations had hyperphagia, severe obesity beginning in the first year of life with a mean BMISDS of +5.1, high rate of childhood infections, altered immune function, with moderately reduced CD4 counts (988 vs. 1100 cells/mL³), and delayed puberty because of hypogonadotropic hypogonadism. Childhood growth was normal but final height was at -1.7 to -2 SD because of the lack of a pubertal growth spurt. Importantly, circulating leptin levels were within the range predicted by the elevated fat mass, and clinical features

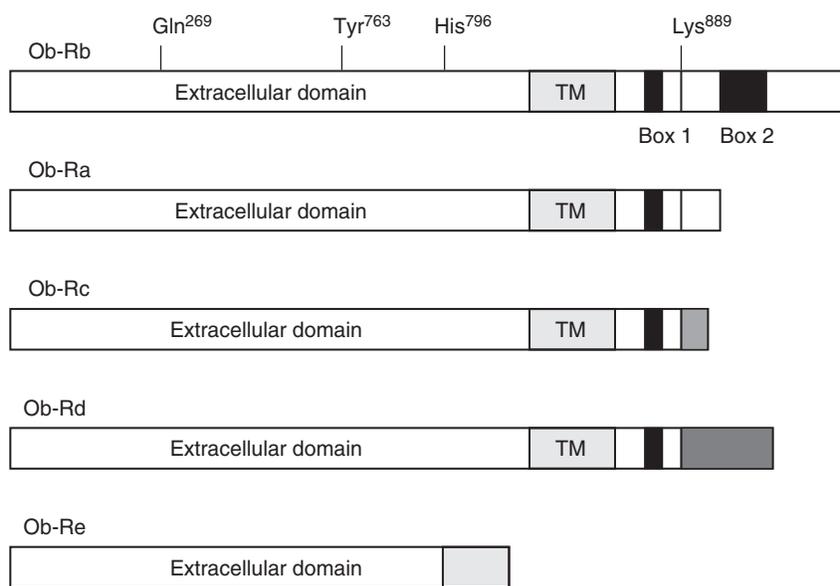

Fig. 3.5 Leptin receptor isoforms. There are five leptin receptor isoforms. Box 1 represents the Jak kinase binding motif, and box 2 represents the signal transducers and activators of transcription (STAT) motif. The Ob-Rb isoform is the only isoform that contains Jak kinase binding and STAT motifs, and it is thus thought to be the main isoform involved in mediating the effects of leptin. The Ob-Ra, Ob-Rc, and Ob-Rd isoforms are missing the STAT motif. The Ob-Re isoform is missing the transmembrane (TM) and cytoplasmic domains. (From Chen, D., & Garg, A. (1999). Monogenic disorders of obesity and body fat distribution. *J Lipid Res*, 40, 1737. With permission.)

were less severe than those of subjects with congenital leptin deficiency.⁵⁹¹ Heterozygous family members had an average BMISDS of +0.6 similar to that of family members with normal leptin receptors. Functional characterization of these missense mutations revealed defects causing intracellular retention, misfolding, or failure to signal to downstream pathways.⁵⁹² Additional novel mutations have been reported that cause similar phenotypes.^{593,594}

RECEPTOR TYROSINE KINASES

The receptor tyrosine kinase (RTK) superfamily consists of 15 receptor tyrosine kinase families (Fig. 3.6).⁵⁹⁵ With one exception, these families consist of receptors with one membrane-spanning domain (see Fig. 3.6).⁵⁹⁵ The single-membrane-spanning receptors typically contain an amino-terminal extracellular portion, a transmembrane helix, a juxtamembrane region, a tyrosine kinase (TK) domain, and a carboxy-terminal region (see Fig. 3.6).⁵⁹⁵ These receptors require dimerization to be maximally activated.⁵⁹⁵⁻⁵⁹⁷ Receptors belonging to the insulin RTK family differ from other RTKs, as they contain two membrane-spanning polypeptide chains, linked by disulfide bonds, to two intervening extracellular peptide chains and thus do not dimerize (see Fig. 3.6).⁵⁹¹

Activation of RTKs leads to phosphorylation of tyrosine residues in the activation loop (A-loop) in the TK domain(s), resulting in activation of the TK(s).^{591,598} Activation of the TK(s), in turn, induces the transfer of phosphate from adenosine triphosphate (ATP) to tyrosine residues in the cytosolic portion of the receptor and in cytosolic proteins that serve as docking sites for second messengers.⁵⁹¹

There is a growing body of evidence suggesting that members of the receptor TK superfamily can directly and indirectly interact with heterotrimeric G proteins. The insulin, IGF-1, and IGF-2 receptors appear to directly interact with G_{i/o} and G_{q/11}, G_{i/o}, and G_i, respectively.⁵⁹⁹ The FGF receptors (FGFRs) appear to directly and indirectly interact with G_s.⁵⁹⁹ Congenital alteration of function of receptors in the insulin and the FGF RTK families leads to endocrine disorders (Table 3.4).

INSULIN RECEPTOR TYROSINE KINASE FAMILY

The insulin RTK family includes the insulin receptor (INSR) and the IGF-1 receptor (IGF1R).⁵⁹⁹ These receptors are

TABLE 3.4 Receptor Tyrosine Kinases and Clinical Conditions Associated with Receptor Mutations

Receptor	Germ-Line Mutation	Endocrine Disorder
Insulin receptor	Inactivating (heterozygous)	Some cases of type A syndrome
	Inactivating (homozygous, compound heterozygous)	Rabson-Mendenhall, Donohue (leprechaunism), and some cases of type A syndromes
IGF-1 receptor	Gene deletion (heterozygous)	Pre- and postnatal growth failure
FGFR1	Inactivating mutation (heterozygous)	Kallmann syndrome, missing teeth, cleft palate
FGFR2	Inactivating mutation (heterozygous)	Apert, Pfeiffer, Crouzon syndromes
FGFR3	Activating mutations (heterozygous)	Achondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans, thanatophoric dysplasia types I and II, and platyspondylic lethal skeletal dysplasias (San Diego types)

FGFR, Fibroblast growth factor receptor; *IGF-1*, insulin-like growth factor-1.

heterotetramers consisting of two α and β subunits in an $\alpha\beta\alpha$ configuration (Fig. 3.7).⁶⁰⁰⁻⁶⁰² The cysteine-rich extracellular α subunits are linked by disulfide bonds, and each α subunit is linked to a plasma membrane-spanning and cytosolic β subunit by disulfide bonds.^{602,603} Each β subunit contains a TK domain and a carboxy-terminal region that contain tyrosine residues.⁵⁹¹

Both insulin and IGF-1 can bind INSRs and IGF1Rs. However, insulin has greater affinity for the INSR and IGF-1 has greater affinity for the IGF1R. Ligand binding alters the conformation of the receptor, resulting in *trans*-autophosphorylation of the carboxy-terminal tyrosine residues on one β subunit by the TK on the other β subunit.^{604,605} The phosphorylated tyrosine residues create motifs that can be bound by Src homology 2 (SH2)-domain-containing proteins, including Shc, Grb-2,

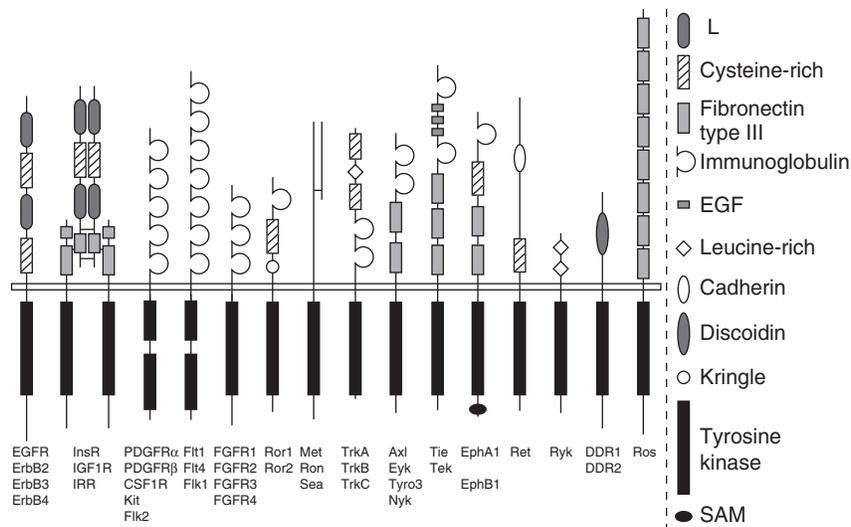

Fig. 3.6 The 15 tyrosine kinase receptor families. Each family has a characteristic extracellular portion and a cytoplasmic portion that contains a tyrosine kinase domain. (From Hubbard, S. R. (1999). Structural analysis of receptor tyrosine kinases. *Prog Biophys Mol Biol*, 71, 344. With permission.)

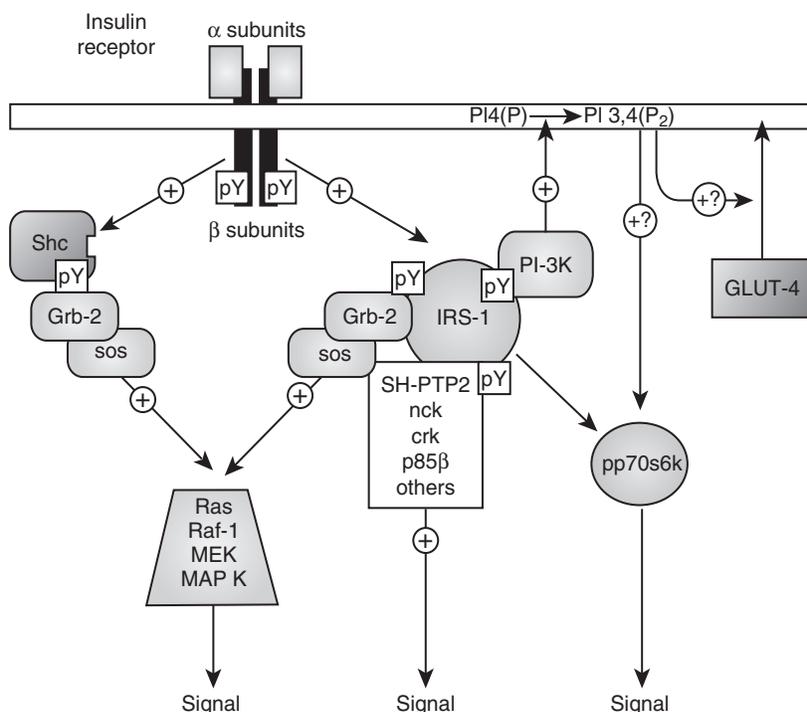

Fig. 3.7 Insulin receptor signaling. Insulin receptor substrate proteins, SH2-domain-containing proteins (including Grb-2 and Shc), and other proteins (including SOS) interact to activate the Ras/Raf-1/MAPK cascade, the PI-3K/PKB cascades, and other enzymes—including SH-PTP2 (SHP2) and p70 (s6k). (Modified from White, M. F. (1997). The insulin signaling system and the IRS proteins. *Diabetologia*, 40, S10. With permission.)

SHP2, nck, phosphatidylinositol-3-kinase (PI3K), and Crk.^{606–610} The receptor TK also phosphorylates tyrosine residues in insulin receptor substrate proteins (IRS), including IRS-1 and IRS-2, that bind INSRs and IGF1Rs.^{610–613} When phosphorylated, these tyrosine residues create motifs that are bound by SH2-domain-containing proteins.^{606,607,609,610,613}

Thus insulin receptor substrates can serve as docking proteins—allowing SH2-domain-containing proteins to indirectly interact with INSRs and IGF1Rs, when steric constraints do not permit direct interactions between the proteins and the receptors.^{606,607,610} Ultimately, IRSs, SH2-domain-containing proteins, and other proteins (including mSOS) interact to activate the Ras/Raf/MAPKK/MAPK and PI3K/protein kinase B (PKB) cascades (see Fig. 3.7).^{609,610,613}

Activation of the Ras/Raf/MAPKK/MAPK cascade increases mitogenesis and proliferation, and activation of the PI3K/PKB cascade increases glucose uptake and glycogen synthesis.^{602,614–619} Evidence suggests that IGF-1 has a greater effect on cell growth than on glucose metabolism because activation of the IGF1R stimulates the Ras/MAPK cascade more than INSR activation.^{602,618} Conversely, it appears that insulin has a greater effect on glucose metabolism because INSR activation stimulates the PI3K/PKB cascade more than IGF1R activation.^{602,619}

THE INSULIN RECEPTOR

The *INSR* gene is located on 19p and contains 22 exons.⁶²⁰ The $\alpha\beta$ half-receptor precursors are derived from proteolysis of a single proreceptor comprised of α and β subunits in tandem and disulfide linkage of these subunits.^{610,620,621} These $\alpha\beta$ half-receptor precursors then join to form a single $\alpha\beta\alpha$ heterotetrameric insulin receptor.⁶²¹ Interestingly, $\alpha\beta$ half-receptor precursors encoded by one allele may combine with $\alpha\beta$

half-receptor precursors encoded by the other allele to form a single insulin receptor.⁶²² This phenomenon explains how heterozygous mutations resulting in impaired β subunit TK activity can have a dominant negative effect because activation of the INSR requires *trans*-autophosphorylation of one β subunit by the other β subunit.⁶²²

Mutations in the insulin receptor lead to Donohue syndrome (leprechaunism), Rabson-Mendenhall syndrome, or type A insulin resistance syndrome. Patients with leprechaunism or Donohue syndrome are severely insulin resistant.^{623,624} They present during infancy with severe intrauterine and postnatal growth retardation, lipoatrophy, and acanthosis nigricans.^{623,625} They also have dysmorphic features that include globular eyes, micrognathia, and large ears.^{623,625} Affected male infants commonly have penile enlargement, whereas affected female infants often have clitoromegaly and hirsutism.^{623,625} In spite of hyperinsulinemia associated with glucose intolerance or diabetes mellitus, the major glucose metabolism problem for these patients is fasting hypoglycemia.^{623,625} Many patients with this condition do not survive past the first year of life.^{623,625} Unlike patients with Rabson-Mendenhall syndrome, patients with leprechaunism do not present with diabetic ketoacidosis.⁶²⁶

Patients with Rabson-Mendenhall syndrome present during childhood with severe insulin resistance.^{625–627} Although patients with this disorder may present initially with fasting hypoglycemia, eventually they develop severe diabetic ketoacidosis that is refractory to insulin therapy.⁶²⁶ Patients with this condition also have acanthosis nigricans, accelerated linear growth, dystrophic nails, premature and dysplastic dentition, coarse facial features, and pineal hyperplasia.^{625–628}

Patients with type A insulin resistance syndrome have acanthosis nigricans and severe inherited insulin resistance in the absence of INSR autoantibodies.^{629–631} Patients with this

syndrome tend to be lean and develop glucose intolerance.^{628,631} Females with this syndrome also exhibit signs of ovarian hyperandrogenism, including hirsutism, severe acne, clitoromegaly, oligomenorrhea, and infertility.^{629–631}

Patients with type B insulin resistance syndrome are distinguished from patients with type A insulin resistance syndrome by the presence of anti-INSR antibodies in the plasma that block insulin binding.^{629–632} Patients with type B insulin resistance syndrome present during adulthood with acanthosis nigricans, ovarian hyperandrogenism, and severe insulin resistance in association with signs of autoimmune disease—including alopecia areata, vitiligo, primary biliary cirrhosis, arthritis, and nephritis.^{629–632} Surprisingly, these patients may present with fasting hypoglycemia that may or may not be accompanied by postprandial hyperglycemia.^{629–632} Hodgkin disease and ataxia-telangiectasia are also associated with this syndrome.⁶³¹ The term *HAIR-AN* (hyperandrogenism, insulin resistance, and acanthosis nigricans) has also been used to describe women with features of types A and B insulin resistance syndromes in association with obesity.⁶³¹ However, this term is imprecise because many women who have been labeled as having *HAIR-AN* may actually have type A or B insulin resistance syndrome or severe polycystic ovary syndrome.⁶³¹

Mutations in the *INSR* have been found in all patients with leprechaunism and Rabson-Mendenhall syndrome, and in 10% to 15% of patients with type A insulin resistance syndrome.^{624,631,633} These mutations are divided into five classes.^{628,631,634} Class I mutations are frameshift or nonsense mutations that prematurely terminate translation and thus interfere with *INSR* synthesis. Class II mutations interfere with posttranslational processing and intracellular trafficking of the *INSR*. Class III mutations decrease insulin binding to the *INSR*. Class IV mutations are point mutations usually located on the intracellular region of the β subunit that decrease *INSR* TK activity. Class V mutations increase *INSR* degradation by increasing insulin-induced endocytosis and degradation of the receptors.

Patients with Rabson-Mendenhall syndrome and leprechaunism are homozygous or compound heterozygous for these mutations.^{623,624,626,631,633–645} Some patients with type A syndrome have been found to be heterozygous for dominant negative β -subunit mutations that reduce TK activity by 75%.^{634,639,646–650} Other patients with type A syndrome have been found to be homozygous or compound heterozygous for α -subunit mutations that interfere with receptor trafficking to the plasma membrane, β -subunit mutations that interfere with TK activity, or mutations that interfere with proreceptor cleavage into α and β subunits. Still other patients have been found to have decreased *INSR* mRNA levels that may be caused by a loss-of-function mutation in the *INSR* gene promoter.^{628,651–655} Interestingly, one patient with leprechaunism with parents with type A syndrome has been described.⁶³⁹ The proband was found to be homozygous for an *INSR* mutation that decreases TK activity, and the parents were found to be heterozygous for the mutation.⁶³⁹

THE INSULIN-LIKE GROWTH FACTOR-1 RECEPTOR

The growth-promoting effects of IGF-1 are mediated by IGF1Rs. IGF1R $\alpha\beta$ subunits are encoded by a single gene.⁶²¹ Like the insulin receptor, an $\alpha\beta$ half-receptor precursor is produced that then joins with a half-receptor precursor that may be encoded from the other allele to form a complete heterotetrameric IGF1R.⁶²¹ The IGF1R has 100-fold less affinity for insulin than for IGF-1.⁶⁵⁶

Patients who are heterozygous for a ring chromosome 15, which results in deletion of the *IGF1R* gene, have intrauterine growth retardation (IUGR) and postnatal growth failure. Other associated features include delayed bone age, mental

retardation, cardiac abnormalities, cryptorchidism, and dysmorphic features that include microcephaly, triangular face, frontal bossing, hypertelorism, and brachydactyly.^{657,658} Similarly, IUGR and postnatal growth failure are commonly found in patients heterozygous for deletion of distal 15q that results in deletion of the *IGF1R* gene. Patients with deletion of distal 15q often have microcephaly, triangular facies, hypertelorism, high-arched palate, micrognathia, cystic kidneys, and lung hypoplasia or dysplasia.^{656,659–661} However, the ring chromosome and deleted area of distal 15q may lead to loss of other genes—and it is unknown to what extent absence of the *IGF1R* gene contributes to the complex phenotype of these patients.^{656,658}

Complete loss of IGF1R function is lethal in the mouse model.^{662,663} Nevertheless, genetic screening of 42 short children, with a history of IUGR (approximately 10% of infants with IUGR remain small), revealed a girl who was compound heterozygous for missense mutations in IGF1R (p.R108Q and p.K115N).⁶⁶⁴ Fibroblasts cultured from the patient had decreased IGF-1 receptor function compared with that in control fibroblasts. Moreover, in a second cohort of 50 children with short stature who had elevated circulating IGF-1 concentrations, Abuzzahab et al.⁶⁶⁴ identified one boy with a heterozygous nonsense mutation (R59X) in IGF1R that reduced the number of IGF-1 receptors on fibroblasts. Children with IGF1R mutations have severe IUGR, microcephaly, and short stature, with biallelic mutations having a more severe phenotype.^{664–667}

In addition to defective *INSR* function, some patients with leprechaunism and Rabson-Mendenhall syndrome are resistant to the glucose lowering or growth promotion of IGF-1 and have abnormal IGF1R function—resulting in decreased ligand binding or altered intracellular signaling.^{656,668–672} No deleterious *IGF1R* gene mutation has been identified in patients with these syndromes, and many patients with leprechaunism and Rabson-Mendenhall syndrome have normally functioning IGF1Rs and no evidence of IGF-1 resistance.^{656,673}

Until recently, no activating mutations of the IGF1R had been found. Microduplication of 15q26.3, which includes the *IGF1R*, is believed to be the cause of an overgrowth phenotype. Recently, a heterozygous activating mutation of the IGF1R was discovered in a patient with extreme tall stature at +3.06 SD, 6'8".⁶⁷⁴ The proband had a birth length at +1.2 SD. His growth spurt started at age 16 years and he continued growing until age 20 years. He had very low levels of IGF-1 (-3 SD), with a delayed and prolonged growth spurt associated with decreased testosterone and SHBG levels in the setting of normal LH and FSH levels. His mother and father were at +1.1 SD and -0.3 SD in height. The variant was studied in mouse fibroblasts that lack the IGF1R and showed hyperstimulation of genes known to be regulated by the IGF1R compared with wild-type IGF1R. It also led to 50- to 70-fold increases in androgen receptor expression. The patient developed a meningioma of the sphenoid that was resected at age 40 years.

THE FIBROBLAST GROWTH FACTOR RECEPTOR FAMILY

There are four members of the FGFR TK family.⁵⁹¹ These are FGFR1, FGFR2, FGFR3, and FGFR4. These receptors consist of a single polypeptide chain that contains an amino-terminal extracellular region, a transmembrane region, and a cytosolic region (see Fig. 3.6).⁵⁹¹ The extracellular region contains three immunoglobulin-like domains: IgI, IgII, and IgIII (see Fig. 3.6).⁶⁷⁵ The cytosolic region contains a TK domain split into two segments (TK1 and TK2) by an intervening amino acid segment.⁶⁷⁵

FGFs are a family of growth factors involved in angiogenesis, wound healing, and embryonic development. The FGFs are heparin-binding proteins and interactions with cell-surface-associated heparan sulfate proteoglycans have been shown to be essential for FGF signal transduction. FGFs are key players in the processes of proliferation and differentiation of wide variety of cells and tissues. In humans, 22 members of the FGF family have been identified, all of which are structurally related signaling molecules.^{675,676} As monomers, FGFs can only bind a single FGFR—forming an inactive 1:1 complex.⁵⁹⁶ FGFR activation by dimerization occurs when two or more FGF molecules in 1:1 complexes are linked by heparan sulfate proteoglycans.⁵⁹⁶

Activation of FGFRs increases receptor TK activity.⁶⁷⁵ Increased TK activity leads to autophosphorylation of a tyrosine residue in the carboxy-terminal region, resulting in a binding site for the SH2 domain of phospholipase C γ (PLC γ).^{677,678} Once PLC γ is bound to this site, it is phosphorylated and activated.^{677,678} In chondrocytes, activation of FGFR3 also induces activation of STAT1.⁶⁷⁹

Fibroblast Growth Factor Receptor 1

Inactivating mutations of the *FGFR1* gene are a cause of autosomal-dominant KS.⁶⁸⁰ Individuals with KS have anosmia and isolated hypogonadotropic hypogonadism.^{681,682} The *FGFR1*, which is located on 8p12, plays a role in olfactory and GnRH neuronal migration from the nasal placode to the olfactory bulb, and in the subsequent migration of the GnRH neurons to the hypothalamus.⁶⁸⁰ Before identification of these *FGFR1* gene mutations, X-linked KS was thought to be caused only by inactivating mutations of the *KAL1* gene.^{681,683,684} *KAL1* encodes anosmin-1, the ligand for the *FGFR1* receptor.⁶⁸⁵ Like *FGFR1*s, anosmin-1 plays a role in olfactory and GnRH neuronal migration to the nasal placode, and in the subsequent migration of GnRH neurons to the hypothalamus.^{681,685,686}

There is a high penetrance for anosmia and signs of hypogonadotropic hypogonadism (including lack of puberty, microphallus, and cryptorchidism) in the 10% of KS patients with X-linked KS because of *KAL1* gene mutations.⁶⁸¹ Female carriers of *KAL1* gene mutations do not have anosmia or isolated hypogonadotropic hypogonadism.⁶⁸¹ In contrast to patients with KS caused by *KAL1* gene mutations, the approximately 10% of KS patients with *FGFR1* gene mutations (even within the same kindred) exhibit variable phenotypes, ranging from anosmia and complete hypogonadotropic hypogonadism (characterized by cryptorchidism and microphallus in males and absent pubertal development in both genders) to anosmia or delayed puberty.^{680,687,688}

It has also been noted that in most kindreds with *FGFR1* gene mutations, females present with more mild KS phenotypes than males.^{680,688} Female carriers may even be asymptomatic.^{680,688} Because the *KAL1* gene is located on the X chromosome, females may produce more anosmin-1 than males.⁶⁸⁰ Thus a possible explanation for milder KS phenotypes in females with *FGFR1* gene mutations may be that the increased anosmin-1 levels in females may lead to increased anosmin-1-induced activation of the mutant *FGFR1*s that may partially compensate for the mutation.⁶⁸⁰ Interestingly, missing teeth and cleft palate are not an uncommon finding in individuals with KS resulting from *FGFR1* gene mutations, whereas unilateral renal agenesis and bilateral synkinesia are associated with KS arising from *KAL1* gene mutations.⁶⁸⁷

Fibroblast Growth Factor Receptors 2–4

A diverse group of skeletal disorders are caused by activating mutations in the *FGFR1* gene, as well as in the related genes encoding *FGFR2* and *FGFR3*. In general, gain-of-function

mutations in *FGFR1* and *FGFR2* cause most of the syndromes involving craniosynostosis, whereas the dwarfing syndromes are largely associated with *FGFR3* mutations. Osteoglophonic dysplasia is a “crossover” disorder that has skeletal phenotypes usually associated with *FGFR1*, *FGFR2*, and *FGFR3* mutations.⁶⁸⁹ Osteoglophonic dysplasia is caused by missense mutations in highly conserved residues comprising the ligand-binding and transmembrane membranes of *FGFR1*, thus defining novel roles for this receptor as a negative regulator of long bone growth.⁶⁸⁹ Gain-of-function mutations in genes encoding the other FGF receptors cause related skeletal disorders: Pfeiffer syndrome (activating mutations of *FGFR1* and *FGFR2*), Crouzon syndrome (gain-of-function *FGFR2* mutations), Crouzon syndrome with acanthosis nigricans (an *FGFR3* mutation), Apert syndrome (*FGFR2* mutations), and craniosynostosis (gain-of-function *FGFR3* mutations).⁶⁷⁵ Several autosomal-dominant short-limb dwarfism syndromes—including achondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), hypochondroplasia, and three types of platyspondylic lethal skeletal dysplasias (PLSD) (thanatophoric dysplasia I [TDI], thanatophoric dysplasia II [TDII], and San Diego types [PLSD-SD])—are often caused by heterozygous constitutively activating *FGFR3* gene mutations.^{690–693}

Individuals with achondroplasia have activating mutations in the transmembrane domain of *FGFR3*, with the p.Gly380Asn found in more than 95% of achondroplastic patients.^{691,694–696} From 40% to 70% of individuals with hypochondroplasia have an activating p.Asn540Lys mutation in the TK1 domain.^{691,697–700} All individuals with TDII have an activating p.Lys650Glu mutation in the activating loop of the TK2 domain, and more than 90% of individuals with TDI and PLSD-SD have *FGFR3* mutations.^{691,693} Patients with SADDAN have an activating mutation in the same codon as patients with TDII.⁷⁰¹ Instead of the p.Lys650Glu mutation associated with TDII, patients with SADDAN have a Lys650Met mutation.⁷⁰¹ However, unlike patients with TDII patients with SADDAN do not have craniosynostosis and a cloverleaf skull—and often survive past childhood.⁷⁰¹

The *FGFR3* gene is primarily expressed in endochondral growth plates of long bones, brain, and skin pre- and postnatally.^{702,703} Constitutional activation of *FGFR3*s in chondrocytes leads to growth arrest and apoptosis.^{679,704,705} In addition, constitutive activation of *FGFR3*s is also postulated to alter neuronal migration because patients with SADDAN, TDI, and TDII have neurologic abnormalities that may include developmental delay, paucity of white matter, polymicrogyria, dysplastic temporal cortex, dysplasia of nuclei, and neuronal heterotopia.^{701,706–708} Furthermore, constitutive activation of *FGFR3*s in skin fibroblasts and keratinocytes is thought to cause the acanthosis nigricans seen in patients with SADDAN and Crouzon syndrome with acanthosis nigricans.⁷⁰⁹ However, it is not yet known why some activating *FGFR3* mutations affect the skeletal system, central nervous system, and the skin, whereas other activating *FGFR3* mutations only affect the skeletal system.⁷⁰¹

Loss-of-function mutations in *FGFR3* also have been associated with human disease. An uncommon syndrome characterized by camptodactyly, tall stature, scoliosis, and hearing loss (CATSHL syndrome) has been associated with a heterozygous missense mutation (p.R621H) in the TK domain and partial loss of *FGFR3* function.⁷⁰⁹ These findings indicate that abnormal *FGFR3* signaling can cause human anomalies by promoting, as well as inhibiting, endochondral bone growth.⁷¹⁰

NUCLEAR RECEPTORS

Using a phylogenetic tree based on the evolution of two highly conserved nuclear receptor domains (the DNA-binding C domain and the ligand-binding E domain), Laudet divided

nuclear receptors into six related subfamilies. Subfamily 0 contains receptors, such as the embryonic gonad (EGON) and DAX1 receptors, that do not have a conserved C or the E domain (Fig. 3.8).^{711,712} Subfamily 1 includes the peroxisome proliferator-activated retinoic acid, thyroid hormone, and vitamin D₃ receptors. Subfamily 2 includes the hepatocyte nuclear factor-4 α (HNF4A) and retinoid X receptors (RXRs). Subfamily 3 contains the steroid receptors. Evidence suggests that subfamily 3 (which includes the glucocorticoid, androgen, progesterone, and mineralocorticoid receptors) rapidly evolved from a common steroid receptor gene about 500 million years ago.⁷¹³

Subfamilies 4 to 6 contain several nuclear receptors, namely NR4A1-3, NR5A1-2, and NR6A1.⁷¹⁴⁻⁷¹⁶ The nomenclature is as follows: nuclear receptor subfamily 4, group A, and members 1 for NR4A1. NR5A1 is also known as *steroidogenic factor-1* or *SF-1*.⁷¹⁵

General Structure of the Nuclear Receptors

Nuclear receptors are made up of four domains: A/B, C, D, and E (Fig. 3.9).⁷¹¹ Supporting the notion that nuclear receptor subfamilies are derived from a common ancestral orphan receptor, the C and E domains are highly conserved among the subfamilies.⁷¹¹ Mutations of several nuclear receptors are associated with endocrine disorders (Table 3.5).

The A/B domain is located at the amino-terminal and contains the activation function 1 (AF-1)/ τ 1 domain.⁷¹⁷ The AF-1/ τ 1 domain regulates gene transcription by interacting with proteins (such as the Ada and TFIID complexes) that induce transcription.^{718,719} This transactivation function of the AF-1/ τ 1 domain is not dependent on binding of the nuclear hormone receptor to its ligand and is not specific in its choice of DNA target sequences.^{711,720-722} Thus specificity of action of the nuclear hormone receptor is determined by the function of other nuclear hormone receptor domains.

The C domain has characteristics that help to confer specificity of action on each nuclear hormone receptor. This domain consists of two zinc-finger motifs responsible for the DNA-binding activity of the receptor and the selection of dimerization partners.^{723,724} Each zinc-finger module consists of a zinc ion surrounded by the sulfurs of four cysteine residues, resulting in a tertiary structure containing helices.^{723,724} The P-box lies near the cysteines of the first zinc finger and contains the three to four amino acids responsible for specificity of binding to response elements.^{724,725} The D-box consists of a loop of five amino acids attached to the first two cysteines of the second zinc finger that provides the interface for nuclear receptor dimerization.⁷²⁴

The D “hinge” domain contains nuclear localization signals and contributes to the function of the adjacent C and E domains.⁷¹¹ Thus the amino-terminal portion of the domain contributes to DNA binding and heterodimerization and the carboxy-terminal portion contributes to ligand binding.⁷²⁵⁻⁷²⁸ The nuclear localization signal plays a particularly important role in the function of glucocorticoids and mineralocorticoid receptors because these receptors bind their ligand in the cytoplasm and must then localize to the nucleus to alter gene transcription.⁷¹⁷

The E domain is known as the *ligand-binding domain* (LBD) or the *hormone-binding domain*. In addition to ligand binding, the E domain has effects on dimerization and transactivation.⁷¹¹ The LBD consists of 11 to 12 α helices (named H1 through H12) and contains a ligand-binding pocket that is made up of portions of some of the different helices.⁷²⁹⁻⁷³³ For example, the thyroid receptor (TR) LBD has a ligand-binding cavity that includes components from H2, H7, H8, H11, and H12.⁷³³ The contribution of different parts of LBD to the ligand-binding pocket accounts for the finding that mutation of single-amino-acid molecules in different helices of the LBD can interfere with ligand binding.⁷¹⁷

Unlike the AF-1/ τ 1 transcriptional activating factor, the E domain activation factor 2 (AF2-AD) requires ligand binding to function (see Fig. 3.9).⁷³⁰⁻⁷³⁷ Often, when the receptor is not bound by its ligand, corepressor complexes simultaneously bind the LBD and transcriptional machinery consisting of protein complexes that place transcription factors on nucleosome binding sites (see Fig. 3.9).⁷³⁰⁻⁷³⁷ The corepressor complexes then suppress gene transcription by using histone deacetylases to compact the nucleosomes into inaccessible structures (see Fig. 3.9).⁷³⁸⁻⁷⁴¹ Ligand binding induces structural rearrangements in the E domain that lead to release of these corepressor complexes from the transcriptional machinery and the LBD, and exposure of the transcriptional machinery and the LXXLL motif of the AF2-AD to coactivator complexes (see Fig. 3.9).⁷³⁰⁻⁷³⁷ These coactivator complexes have histone acetyltransferase activity that acts to relax nucleosome structures, enabling transcription factors to access nucleosome binding sites (see Fig. 3.9).⁷⁴²

Most nuclear receptors are capable of binding their hormone response element and repress transcription when they are not bound by their ligand.⁷⁴³ However, in the absence of ligand, steroid receptors are bound to a complex of heat-shock proteins instead of their response element and do not appear to repress transcription.⁷⁴⁴

Agonists and antagonists have different effects on the interaction between the ligand binding pocket and AF2-AD. For example, when 17 β -estradiol binds to the estrogen receptor, the position of the AF2-AD containing H12 is altered so that coactivators can access the LBD-binding coactivator binding site.⁷²⁹ However, when the estrogen antagonist raloxifene binds at the same site, the coactivator binding site on H12 remains blocked by other portions of H12.⁷²⁹

Although some nuclear receptors are fully active when bound as monomers to DNA, the hormone receptors in the nuclear receptor superfamily are most active when bound as homodimers or heterodimers (see Fig. 3.9).⁷¹¹ RXRs, HNF 4, and the steroid hormone receptors can bind DNA as homodimers or heterodimers.^{711,745,746} The α isoform of the estrogen receptor (ESR1) is particularly promiscuous, and is able to heterodimerize with HNF4A and retinoic acid receptors, the β isoform of the estrogen receptor (ESR2), RXR, and the thyroid hormone receptors.^{745,746} As a homodimer, RXR binds the dINSRect repeat 1 (DR1).⁷⁴⁷ It can also join the thyroid, vitamin D₃, and peroxisome proliferator-activated receptors to form heterodimers.^{711,748-750}

Interestingly, it has also been suggested that some steroid hormones also act on transmembrane receptors—and these interactions may be responsible for the acute cellular effects of steroids.⁷⁵¹ Progesterone has been shown to interact with the G protein-coupled uterine oxytocin, nicotinic acetylcholine, γ -aminobutyric acid_A, *N*-methyl-D aspartate, and sperm cell membrane progesterone receptors.⁷⁵²⁻⁷⁵⁷ Cell membrane estrogen and glucocorticoids receptors have also been identified.⁷⁵⁸⁻⁷⁶¹

SUBFAMILY 1 NUCLEAR RECEPTORS: THYROID HORMONE, VITAMIN D₃, AND PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS

Thyroid Hormone Receptors

The two thyroid hormone receptor (THR) isoforms—thyroid hormone receptor α (THRA) and thyroid hormone receptor β (THRB)—are encoded by different *c-erbA* genes on chromosomes 17 and 3, respectively.^{728,762} Alternate splicing leads to expression of TR α 1, TR α 2, TR β 1, and TR β 2 with different tissue distributions. TR α 2 does not bind thyroid hormone and its function is not understood. TR α 1 is the predominant subtype in cardiac and skeletal muscle, bone, gastrointestinal tract, and the central nervous system. TR β 1 is the predominant

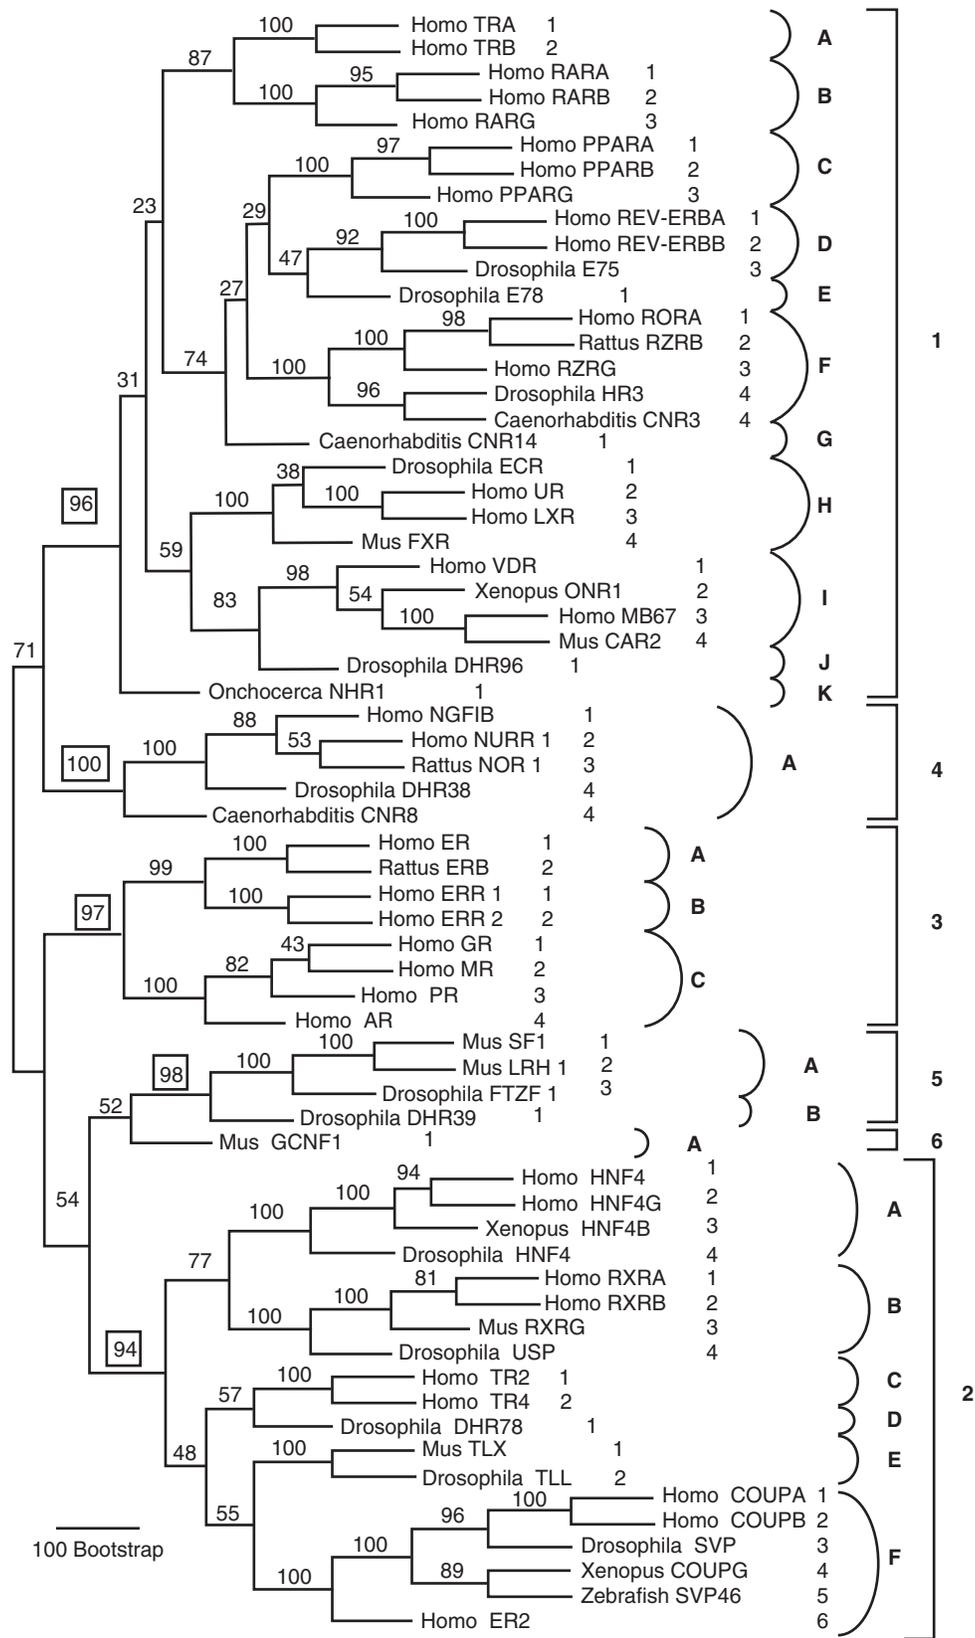

Fig. 3.8 Phylogenetic tree of nuclear receptors based on the evolution of the highly conserved C and E domains. Numbers at the right side of the figure represent subfamilies, and capital letters represent groups of more closely related receptors. The small numbers to the right of the receptor names are used in combination with the subfamily letters and group letters in a proposed nuclear receptor nomenclature. This nomenclature proposes that nuclear receptors should be named NR, followed by subfamily number, group letter, and individual receptor number. Thus the mineralocorticoid receptor is named NR3C2 and the peroxisome proliferator-activating receptor γ receptor is named NR1C3 according to this nomenclature. Numbers to the left of the receptor names represent bootstrap values. Values that define subfamilies with more than one member are boxed. (From the Nuclear Receptors Nomenclature Committee (1999). A unified nomenclature system for the nuclear receptor subfamily. *Cell*, 97, 161. With permission.)

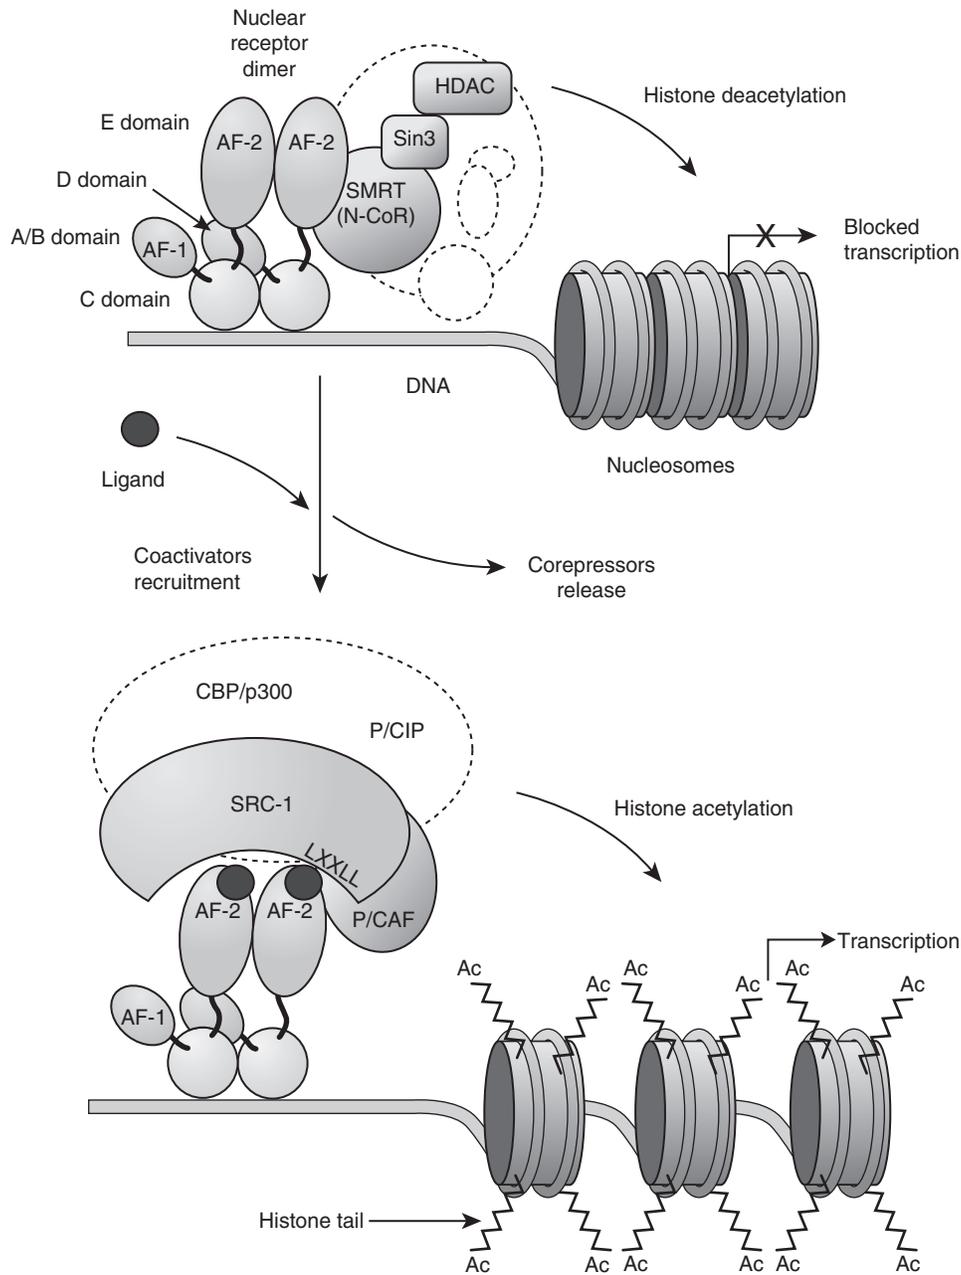

Fig. 3.9 Ligand-induced activation of transcription by nuclear receptors. Often, corepressors, including silencing mediator of retinoid and thyroid hormone receptors (SMRT) and nuclear receptor corepressor (*N-CoR*), bind a nuclear receptor that is not bound by its ligand. These corepressors then associate with Sin3, which in turn associates with a histone deacetylase (*HDAC*). Then, *HDAC* represses transcription by deacetylating histone tails—resulting in compaction of the nucleosomes into structures that are inaccessible to transcription factors. Ligand binding induces structural changes in the E domain that result in release of the corepressor/Sin3/*HDAC* complexes from the receptor and binding of coactivator complexes that may include steroid receptor coactivator 1 (*SRC-1*), p300/cyclic adenosine monophosphate responsive element binding protein (*CBP*), p300/*CBP*-associated factor (*P/CAF*), or p300/*CBP* cointegrator-associated protein (*pCIP*) to the LXXLL motif of the AF2-AD. Then the coactivator complexes induce transcription by acetylating (*Ac*) the histone tails—resulting in decompaction of the nucleosomes into structures that are accessible to transcription factors. Dashed lines are used to represent coactivator and corepressor complexes because their composition *in vivo* is yet unknown. (Modified from Robyr, D., Wolffe, A. P., & Wahli, W. (2000). Nuclear hormone receptor coregulators in action: diversity for shared tasks. *Mol Endocrinol*, 14, 339. Copyright 2000, The Endocrine Society. With permission.)

subtype in kidney and liver, whereas TR β 2 is expressed in hypothalamus and pituitary, as well as retina and cochlea. THR α s that are not occupied by the thyroid hormone triiodothyronine (T_3) exist as homodimers or heterodimers, with RXRs that are attached to DNA thyroid hormone response elements in association with corepressor proteins.⁷⁶³ Thyroid hormone binding induces the release of the corepressors from the THR.⁷⁶³ A coactivator, steroid receptor coactivator-1 (*SRC-1*), is then able to attach to the THR—enabling activation of transcription.⁷⁶³

Generalized resistance to thyroid hormones (GRTH) can be autosomal recessive or autosomal dominant, as the presence of a single normal THRB allele is sufficient for normal receptor function. Autosomal dominant GRTH is caused by the presence of an abnormal THRB that interferes with the function of the normal receptor in a dominant-negative fashion.^{762,764,765} The prevalence of dominant GRTH, based on newborn screening, was reported to be 1:40,000 live births.⁷⁶⁶ Patients with this syndrome have an impaired receptor response to T_3 .⁷⁶²

TABLE 3.5 Nuclear Receptors and Clinical Conditions Associated With Receptor Mutations

Receptor	Germ-Line Mutation	Endocrine Disorder
Thyroid Hormone Receptor β (TR β)	Inactivating mutations (heterozygous and homozygous)	Generalized resistance to thyroid hormones
Vitamin D ₃ receptor	Inactivating mutations (homozygous)	Vitamin D ₃ resistance
PPAR γ 2	Inactivating mutations (heterozygous)	Obesity or early-onset type 2 diabetes mellitus
HNF-4	Inactivating mutations (heterozygous)	Maturity-onset diabetes of the young (MODY) type 1 Hyperinsulinemic hypoglycemia in the newborn period followed in later life with MODY1 in some patients
Glucocorticoid receptor	Inactivating mutations (heterozygous)	Glucocorticoid resistance
Androgen receptor	Inactivating mutations (X-linked recessive)	Androgen insensitivity syndrome, Kennedy disease
Estrogen receptor α (ER α)	Inactivating mutations (homozygous)	Tall stature and incomplete epiphyseal fusion
Mineralocorticoid receptor	Inactivating mutations (heterozygous, homozygous)	Pseudohypoaldosteronism type 1
	Activating mutations (homozygous)	Syndrome of apparent mineralocorticoid excess
DAX1	Inactivating mutations (X-linked recessive)	X-linked adrenal hypoplasia congenita

DAX1, Dosage-sensitive sex-reversal adrenal hypoplasia congenital critical region on the X chromosome gene 1; *HNF-4*, hepatocyte nuclear factor-4; *PPAR γ 2*, peroxisome proliferator-activating receptor γ 2.

They have elevated T₃, reverse T₃, and thyroxine (T₄) levels with slightly high TSH levels.^{762,764,765} Consistent with the TSH elevation and goiter, serum thyroglobulin levels tend to be elevated and radioiodine uptake high. Unlike autoimmune thyrotoxicosis, the T₃:T₄ ratio is normal. The clinical manifestations are variable including some hyperthyroid and some hypothyroid symptoms. Findings include goiter in 65% to 85% of those affected, hyperactivity in 33% to 68%, tachycardia in 33% to 75%, failure to thrive, raised metabolic rate, low bone density, hearing defects, learning disabilities, developmental delay, and delayed bone age.^{762,764,765,767} GRTH can be detected by newborn screening if the program measures T₄, in addition to or in lieu of TSH only, as T₄ would be elevated and TSH would be elevated. The combination of findings normally associated with hyperthyroidism and hypothyroidism is caused by differential expression of TR α versus TR β . The hypothalamus and pituitary express TR β and this leads to elevated TSH levels. Cardiac tissues express TR α and this leads to tachycardia as elevated T₄ and T₃ act on the normal TR α receptor.

Mutations have been found in the D and E domains of THR β s of GRTH patients.^{762,768,769} These mutations alter ligand binding or transactivation.^{762,769,770} However, most mutant THR β s retain the ability to repress transactivation of target genes through interactions with corepressors.^{769,770} Some of the GRTH mutant receptors continue to associate with corepressors and are unable to bind the coactivator SRC-1 even when bound by T₃.^{770,771} Thus mutant THR β s have a dominant negative effect in the heterozygous state because they are able to interfere with the function of wild-type receptors by repressing transcription of target DNA.^{762,769,770}

Patients who carry biallelic loss-of-function mutations of THR β demonstrate more severe clinical abnormalities than patients with heterozygous dominant negative mutations. One patient with a deletion of both THR β alleles presented with deaf mutism, dysmorphic features, and stippled epiphyses.⁷⁷² Another patient homozygous for a THR β mutant ("kindred S receptor"), with an amino acid deletion in the ligand-binding domain, presented with mental retardation, very delayed bone age, and very elevated T₃ and T₄ levels.^{768,773} Heterozygous carriers of the kindred S receptor mutation have milder clinical manifestations of GRTH because this mutant THR β retains corepressor activity and thus has dominant negative effects.^{768,773,774}

Mutations in THRA were not identified until recently.⁷⁷⁵⁻⁷⁷⁷ The first described proband is heterozygous for a nonsense mutation (p.E403X) that inhibits the wild-type receptor in a dominant negative fashion.⁷⁷⁵ The patient had hypothyroid features (growth retardation, developmental delay, skeletal dysplasia, and constipation) that reflect the distribution of

target tissues in which THRA is expressed. This is associated with borderline low or normal T₄ and free T₄, low reverse T₃, borderline high or normal T₃ and free T₃, a low T₄:T₃ ratio, and normal TSH. After thyroxine treatment, normalizing T₄ levels, T₃ levels became elevated. It has been suggested that this may be related to increased type 1 deiodinase activity (which converts T₄ to T₃) and reduced type 3 deiodinase activity (which converts T₄ to reverse T₃ and T₃ to T₂).⁷⁷⁸ The mutant receptor failed to bind radiolabeled T₃ and failed to activate a thyroid hormone responsive reporter gene and inhibited the activity of the wild-type receptor. The second report described a one base insertion in a father and a daughter, causing a frameshift and premature termination at codon 406.⁷⁷⁶ Analyses of the mutant receptor in vitro, after expression in cultured cells, revealed that the mutant receptor fails to respond to stimulation by T₃ and exerts a strong dominant negative effect on the wild-type receptor. This and other subsequent reports^{777,779} identified more clinical features, such as macrocephaly, dysmorphic facies (round, flat face with coarse features) increased birth length and weight, anemia, and slightly elevated cholesterol. Several reports have recently documented different mutations, including missense mutations with partially active receptors.⁷⁸⁰⁻⁷⁸³ These studies demonstrated that the severity of clinical findings correlated with the degree of receptor impairment. The p.A263V mutation exhibited impaired transcription at low T₃ concentrations, but was active at higher T₃ concentrations and was associated with a milder phenotype. Another mutation (p.N359Y), which affects both TR α 1 and TR α 2, was associated with additional clinical features, namely, micrognathia, clavicular agenesis, metacarpal fusion, syndactyly, hyperparathyroidism, and chronic diarrhea.⁷⁸¹

Vitamin D Receptor

Severe rickets, hypocalcemia, secondary hyperparathyroidism, and increased 1,25-dihydroxyvitamin D (calcitriol) levels occur in patients with the autosomal recessive syndrome of "vitamin D resistance."⁷⁸⁴ These patients have defective vitamin D receptors (VDRs). Mutations causing this syndrome have been found in the zinc fingers of the DNA-binding domain (C domain), leading to decreased or abolished receptor binding to regulatory elements of target genes.⁷⁸⁵ Causative mutations have also been found that lead to the production of receptors that have decreased or abolished ability to bind calcitriol and heterodimerize with RXRs, which are required for the VDR to maximally transactivate target genes.^{785,786}

Less severe mutations in the VDR are associated with decreased gastrointestinal calcium absorption and bone

mineral density, even during childhood, and an increased risk for osteoporosis and fractures.^{787–792} However, it has not been possible to replicate these findings in some ethnic groups.^{793–797} Thus other factors (such as estrogen receptor genotype, dietary calcium, and age) probably contribute to the effects of VDR polymorphisms on bone mineral metabolism.^{790,792,798,799} Certain VDR polymorphisms are associated with decreased pre- and postnatal linear growth.^{800,801}

Other important associations have been found with VDR polymorphisms. Homozygous polymorphisms have been reported to be associated with primary hyperparathyroidism.⁸⁰² In addition, the presence of certain VDR alleles is associated with increased risk for the development of early-onset periodontal disease.⁸⁰³ Conversely, absence of such alleles has been associated with familial calcium nephrolithiasis.⁸⁰⁴ Absence of certain alleles may be a risk factor for the development of sarcoidosis.⁸⁰⁵ However, the presence of these alleles is associated with hypercalciuria and nephrolithiasis and increased risk in women for the development of metastatic breast cancer.^{806,807} VDR polymorphisms have also been associated with increased susceptibility to psoriasis, tuberculosis, leprosy, and other infections.^{808–812}

Peroxisome Proliferator-Activating Receptor γ

Peroxisome proliferator-activating receptor γ (PPAR γ) has a role in regulating adipocyte differentiation and metabolism. This formerly orphan receptor was adopted by the ligand prostaglandin J₂. Mutations in the gene encoding PPAR γ cause familial partial lipodystrophy type 3 (FPLD3).⁸¹³

Patients with FPLD3 exhibit fat loss in the arms and legs, severe insulin resistance, early-onset type 2 diabetes mellitus, and severe hypertriglyceridemia. Some heterozygous mutations have a dominant negative effect on the wild-type receptor (V290M and P467L).^{712,814} These mutations lead to amino acid substitutions that disturb the orientation of H12 in the E domain, leading to decreased ligand-dependent transactivation by AF-2/AD and coactivator recruitment.⁷¹² Other mutations are point mutations that cause FPLD3 simply because of haploinsufficiency without a dominant negative effect.^{815–822} In addition, a frameshift mutation that causes a similar phenotype was identified.⁸²³ Another mutation in PPAR γ expanded the phenotype to include muscular, immune, and hematologic features.⁸²⁴ This mutation is thought to induce a conformational change affecting transcriptional activation by the receptor.

A missense mutation leading to a p.Pro115Gln substitution near a site of serine phosphorylation at position 114 that suppresses transcriptional activation in PPAR γ 2 was found in some morbidly obese patients.⁸²⁵ The p.Pro115Gln substitution interferes with phosphorylation of the serine at position 114, leading to increased transcriptional activation by PPAR γ 2—which in turn leads to increased adipocyte differentiation and triglyceride accumulation.⁸²⁵

SUBFAMILY 2 NUCLEAR RECEPTORS: HEPATOCYTE NUCLEAR FACTOR AND RETINOID X RECEPTORS

This subfamily includes the HNF receptors and the RXRs. RXRs form heterodimers with other nuclear receptors (including the estrogen, vitamin D, and thyroid hormone receptors) and with PPAR γ (RXRs are discussed elsewhere in this chapter).

Hepatocyte Nuclear Factor Receptors

Alteration of another orphan nuclear receptor, HNF4A, also causes an endocrine disorder. Mutations of the *HNF4A* gene on chromosome 20 that alter the ligand-binding domain

(E domain) or the DNA-binding domain (C domain) have been found in patients with a form of monogenic diabetes, also known as maturity-onset diabetes of the young type 1 (MODY1).^{826–829} Patients with MODY usually develop diabetes mellitus by the end of the third decade of life. They have a defect in glucose-mediated stimulation of insulin secretion.^{827,830} Several studies have now described a biphasic phenotype of neonatal hyperinsulinism and macrosomia, with later onset of diabetes in patients with *HNF4A* mutations.^{831–835} In most cases, the hyperinsulinism is transient but can be persistent, requiring diazoxide treatment.^{833,834}

Patients who are heterozygous for the p.R76W *HNF4A* mutation also develop a Fanconi-Bickel like syndrome in addition to neonatal hyperinsulinism and macrosomia.^{836,837} The patients manifest the typical proximal tubulopathy of Fanconi-Bickel syndrome, including generalized aminoaciduria, low-molecular-weight proteinuria, glycosuria, hyperphosphaturia, and hypouricemia, plus additional features, including nephrocalcinosis, renal impairment, hypercalciuria with relative hypocalcemia, and hypermagnesaemia.⁸³⁶ The Fanconi-Bickel like phenotype has been recapitulated in a mouse model in which genetic ablation of *Hnf4a* was targeted to the kidney, indicating that *Hnf4a* is required for the formation of differentiated proximal tubules and that loss of *Hnf4a* decreased the expression of proximal tubule-specific genes.⁸³⁸ The p.R76W mutation occurs in the DNA-binding domain of HNF4A, and has been hypothesized to cause defective interaction with major regulatory genes; it remains unknown why patients with other HNF4A mutations do not develop the same renal phenotype.

Carriers of a glycine-to-serine substitution in codon 115 in the DNA-binding domain (C domain) appear to be at increased risk for developing low-insulin diabetes mellitus.⁸³⁹ Hepatocyte nuclear factors 3 (HNF-3 α , -3 β , and -3 γ) are also regulators of the early-onset type 2 diabetes genes *HNF1A*, *HNF4A*, and *IPF-1/PDX-1*—which are associated with MODY types 3, 1, and 4, respectively.^{840–843}

SUBFAMILY 3 NUCLEAR RECEPTORS: THE STEROID RECEPTORS AND GLUCOCORTICOID, ANDROGEN, ESTROGEN, AND MINERALOCORTICOID RECEPTORS

Glucocorticoid Receptors

Glucocorticoids strongly influence cardiovascular tone; have actions on liver, muscle, and adipose tissue; and exert potent antiinflammatory and immunosuppressive effects. Glucocorticoids are important in growth and development, as well as behavior and cognition. They influence multiple cellular processes, including proliferation, differentiation, and apoptosis. All of these actions are mediated by the glucocorticoid receptor (GR), which is a ligand activated transcription factor influencing transcription of approximately 20% of the genome. The gene for the glucocorticoid receptor is known as *NR3C1*. *NR3C1* is on chromosome 5 and consists of 10 exons. Multiple isoforms of the GR exist because of alternative splicing, insertions, deletions, and alternative translation initiation. The two main forms are hGR α and hGR β . hGR β does not bind natural or synthetic glucocorticoids; is expressed in few cell types, such as neutrophils and epithelial cells; and may exert inhibitory effects on the main glucocorticoid receptor hGR α . hGR α is ubiquitously expressed in all tissue but the suprachiasmatic nuclei of the hypothalamus.

Mutations in glucocorticoid receptors cause primary generalized glucocorticoid resistance (PGGR) or primary generalized glucocorticoid hypersensitivity (PGGH).⁸⁴⁴ PGGR is clinically characterized by the presence of elevated plasma cortisol and

ACTH levels, accompanied by the effects of hyperaldosteronism and hyperandrogenism in the absence of striae or central fat deposition.^{728,844–846} ACTH excess leads to adrenocortical hyperplasia, increased cortisol secretion, and increased production of adrenal steroids with androgenic (androstenedione, dehydroepiandrosterone [DHEA], DHEA-S) and mineralocorticoid activity (cortisol, deoxycorticosterone and corticosterone). The clinical spectrum is broad, ranging from asymptomatic to severe hyperandrogenism (characterized by severe acne, hirsutism, irregular menses, and infertility), mineralocorticoid excess (characterized by hypokalemic alkalosis and hypertension), and fatigue.^{845–847} Girls may present with ambiguous genitalia and both girls and boys may present with isosexual precocity.⁸⁴⁸ Clinical manifestations of glucocorticoid deficiency are infrequent and largely limited to fatigue.^{847,849,850} However, there were reports of childhood hypoglycemia.^{851,852}

Both homozygous^{850,851,853,854} and heterozygous^{854–858} mutations have been described. Heterozygous mutations that cause PGGR generally do so by exerting a dominant negative effect on the wild-type receptor.⁸⁴⁴

ACTH-secreting pituitary macroadenomas can also be caused by a frameshift mutation in the *GR* gene that interferes with signal transduction.⁸⁵⁷ Patients with this mutation manifest the symptoms of glucocorticoid resistance. The tumor develops as a result of impaired negative feedback regulation by glucocorticoids on the hypothalamic-pituitary axis.

PGGH was described in a 43-year-old female who presented with visceral obesity, hypertension, hyperlipidemia, and type 2 diabetes, and was found to have a mutation in the *GR* (D401H) that demonstrated increased transactivation of glucocorticoid responsive genes.⁸⁵⁹ The patient had evidence of glucocorticoid resistance in the hypothalamus–pituitary gland–adrenal gland axis and hypersensitivity at the vasculature, adipose tissue, and liver. This was associated with an elevated ACTH and am cortisol but normal urine free cortisol.

Androgen Receptors

The human androgen receptor (*AR*) gene is located on the X chromosome. Known disorders characterized by *AR* dysfunction caused by *AR* gene mutations are only expressed in patients with a 46 XY karyotype.⁸⁶⁰ These mutations may be transmitted from an asymptomatic carrier mother or can be de novo.

More than 1000 mutations have been described in the *AR* gene, with more than 500 mutations causing androgen insensitivity syndrome (AIS).⁸⁶¹ The phenotype of this syndrome can vary in severity and has been divided into mild, partial, and complete forms (MAIS, PAIS, and CAIS).⁸⁶² CAIS is characterized by intraabdominal testes, absence of müllerian structures, absence of androgen-induced body hair, such as pubic and axillary hair, and a female appearance.^{860, 863, 864} PAIS refers to individuals with ambiguous external genitalia with an enlarged clitoris or microphallus and patients with Reifenstein syndrome.⁸⁶³ Reifenstein syndrome is characterized by severe hypospadias with scrotal development and severe gynecomastia.⁸⁶³ MAIS refers to patients with *AR* mutations who are otherwise normal phenotypic males who present with adolescent gynecomastia or later infertility.

The phenotypic heterogeneity of AIS is caused by the varied locations of the mutations causing AIS. Functional consequences of each mutation causing AIS relate to the function of the domain in which the mutation is located. However, the degree of impairment of mutated receptor function in *in vitro* studies does not always correlate with the phenotypic severity of the syndrome.⁸⁶⁵

Mutations in exons that code for the *AR* hormone-binding domain decrease hormone-binding affinity.⁸⁶⁶ However, these

mutations do not abolish the hormone-binding capability of the receptor.⁸⁶⁶ Thus patients with these mutations usually present with PAIS or occasionally with CAIS.^{866–869} Patients with mutations in the hormone-binding domain do not appear to respond to treatment with high doses of testosterone.⁸⁶⁶ Mutations in the DNA-binding domain lead to failure of target gene regulation. Thus patients with these mutations usually manifest the CAIS.^{870, 871}

CAIS is also caused by a point mutation that results in a premature termination codon (p.Gln340ter), with apparent initiation of translation that is downstream of the termination codon. *In vitro* studies showed that the truncated *AR* is expressed at reduced levels.⁸⁷² Numerous other mutations have been described that cause truncation or deletion of the *AR* and complete AIS.^{873–876} Two patients with ambiguous genitalia and partial virilization were found to be mosaic for mutant *ARs*.^{877, 878}

Some patients with Reifenstein syndrome have been found to have a mutation in the DNA-binding domain that abolishes receptor dimerization.⁸⁷⁹ Other patients have been found to have a mutation in a different area of the DNA-binding domain that does not affect receptor dimerization, or to have mutations in the hormone-binding domain in the E domain.^{880–883} The Ala596Thr mutation in the D-box area of the DNA-binding domain has been associated with an increased risk of breast cancer.⁸⁸⁴

AIS is also a feature of Kennedy disease, which is an X-linked recessive condition causing spinal and muscular atrophy.⁸⁶⁷ This condition is caused by extension of a poly-CAG segment in the *AR* gene exon that codes for the N-terminus of the *AR*, leading to an increased number of glutamine residues in the A/B domain.^{885,886} *ARs* with a polyQ region increased to 48 glutamine residues accumulate abnormally in transfected cells because of misfolding and aberrant proteolytic processing.⁸⁸⁷ Because polyQ extension does not completely abolish transactivation, patients with Kennedy disease exhibit a mild partial AIS phenotype consisting of normal virilization accompanied by testicular atrophy, gynecomastia, and infertility.

Gain-of-function mutations in the *AR* have been described in prostate, breast, testicular, liver, and laryngeal cancers.⁸⁶¹

Estrogen Receptors

Two major full-length ESR isoforms have been identified in mammals. Estrogen receptor α (ESR1) was discovered first and mediates most of the known actions of estrogens.⁷²⁸ ESR1 is expressed primarily in the uterus, ovaries, testes, epididymis, adrenal cortices, and kidneys.⁸⁸⁸ Estrogen receptor β (ESR2) was discovered in 1996.⁸⁸⁹ ESR1 and ESR2 share 95% and 50% homology in the DNA-binding domain (DBD) and LBD, respectively.⁸⁹⁰ There is little homology in the amino-terminal between the two isoforms.⁸⁹⁰ ESR2 is expressed primarily in the uterus, ovaries, testes, prostate, bladder, lung, and brain.⁸⁸⁸ Although ESR2 has a high affinity for estrogens, it has less transactivating ability than ESR1 and has not yet been found to be involved in any pathologic condition.^{728,891,892}

There is evidence supporting the existence of other functional ESRs.⁸⁹³ Some of these putative ESRs localize to the cell membrane instead of, or in addition to, the nucleus. A 46-kDa amino-terminal truncated product of ESR1, named ER46, localizes to the cell membrane and mediates estrogen actions that are initiated at the cell membrane.⁸⁹⁴ Another of these putative ESRs has been named ER-X and is postulated to be a GPCR that localizes to the cell membrane.⁸⁹⁵ Another putative receptor is the aptly named heterodimeric putative estrogen receptor (pER), which has been found on the cell and nuclear membranes.⁸⁹⁶ The pER acts as a serine phosphatase.⁸⁹⁶ Five other

estrogen-binding proteins have also been identified, and at least three of them localize to the cell membrane.⁸⁹⁷⁻⁹⁰⁰

It had been thought that androgens provide the principal signals for closure of the epiphyses during puberty. In 1994, however, extensive studies of a 28-year-old man, with incomplete closure of epiphyses and tall stature, demonstrated that he was homozygous for a premature termination mutation of codon 157 in exon 2 of the *ESR1* gene. The patient had continued linear growth despite otherwise normal pubertal development, demonstrating that the ESR mediates epiphyseal closure.⁹⁰¹ Expression of this gene leads to the production of a nonfunctional ESR1 lacking both the DNA- and hormone-binding domains. He was also found to have increased estradiol levels, impaired glucose tolerance with hyperinsulinemia, and decreased bone density.

Further strengthening the association between ESR1 and epiphyseal closure is the observation that women with ESR1-positive breast cancer and a mutation in the B domain (B' allele) of ESR1 have an increased incidence of spontaneous abortion and tall stature.⁹⁰² These associations were not found in female carriers of the allele without breast cancer or with ESR1-negative breast cancer. Thus a second (as yet undiscovered) mutation is likely to play a role in the development of tall stature and spontaneous abortions in female carriers with ESR1-positive breast cancer.

Mineralocorticoid Receptors

Mineralocorticoid resistance is also known as *pseudohypoaldosteronism* (PHA). Both sporadic and familial cases with either autosomal-dominant or autosomal-recessive cases have been reported.⁹⁰³⁻⁹⁰⁷ Clinical presentation of patients with PHA ranges from asymptomatic salt wasting; to growth failure; to chronic failure to thrive, lethargy, and emesis; to life-threatening dehydration accompanied by severe salt wasting.^{904-906,908-910} Patients with the severe forms of PHA typically present within a year of birth and may even present in utero with polyhydramnios because of polyuria.⁹¹¹ Biochemically, the condition is characterized by urinary salt wasting, hyponatremia, elevated plasma potassium, aldosterone, and renin activity, and urinary aldosterone metabolism that are unresponsive to the mineralocorticoid treatment.⁹¹²⁻⁹¹⁴

Two forms of PHA are recognized (types I and II). Autosomal recessive (generalized) PHAI results from mutations in the epithelial sodium channel (ENaC), whereas autosomal dominant (renal) PHAI is caused by mutations in the mineralocorticoid receptor (MR). PHAII is the result of mutations in a family of serine-threonine kinases known as *WNK1* and *WNK4*, which are downstream of aldosterone action.⁹¹⁵ PHAI is characterized by renal tubular mineralocorticoid resistance, whereas PHAII results from mineralocorticoid resistance in the kidney, intestine, or salivary or sweat gland and is also known as *Gordon syndrome*.⁹¹⁶ Patients with these conditions present with hyperkalemia that only responds to treatment with nonchloride ions, such as bicarbonate or sulfate, which increase delivery of sodium to the distal tubule.⁹¹⁷ In general, patients with autosomal dominant PHAI have a mild salt-wasting syndrome and improve with age, whereas patients with autosomal recessive PHAI have severe salt wasting and hyperkalemia, as well as increased sweat and salivary sodium and frequent respiratory tract infections that fails to improve with age.⁹¹⁸

More than 50 different mutations of the MR causing autosomal dominant PHAI have been described (all heterozygous).⁹¹⁸⁻⁹²⁹ There is clear heterogeneity of clinical manifestations within families. Haploinsufficiency caused by mRNA or protein degradation is clearly sufficient to cause autosomal dominant PHAI.^{924,927,930} Yet some mutations have been shown to exert dominant negative effects on the wild-type receptor.⁹²⁷

Genetic disorders that are associated with increased activity of the MR cause severe early-onset hypertension. One such condition, characterized by excessive MR action, is termed the *syndrome of apparent mineralocorticoid excess*.⁹³⁰ Patients with this autosomal-recessive condition can exhibit pre- and postnatal growth failure, hypervolemic hypertension, medullary nephrocalcinosis, and hypokalemic metabolic alkalosis accompanied by hyporeninemic hypoaldosteronism.⁹³¹⁻⁹³⁴ Patients may also be asymptomatic and exhibit only biochemical abnormalities.⁹³⁵ Patients with this syndrome also have increased serum and urinary cortisol-to-cortisone ratios.⁹³⁴ This syndrome is caused by mutations in the 11 β -hydroxysteroid dehydrogenase type 2 (*HSD11B2*) gene that reduce enzymatic activity of the protein.^{933,934,936-938} The 11 β -HSD2 converts the active glucocorticoid cortisol to inactive cortisone; in contrast the type I isoform, encoded by the separate *HSD11B1* gene, has both 11- β dehydrogenase activity and 11-oxoreductase activity and can also convert cortisone to cortisol. The type I isoform is ubiquitously expressed, whereas the type II isoform has more restricted expression and is highly expressed in the kidney, where it is necessary to protect the renal MR from normally higher serum concentrations of cortisol, allowing aldosterone to regulate sodium homeostasis. Thus decreased activity of 11 β -HSD2 increases cortisol levels in kidney cells expressing MR tissues, leading to increased binding and activation of MRs by cortisol.^{933,934}

A transient form of mineralocorticoid resistance, probably because of abnormal maturation of aldosterone receptor function, also exists.⁹³⁹ This variant of PHA is known as *the syndrome of early-childhood hyperkalemia*. Children with this disorder present with failure to thrive or linear growth failure accompanied by hyperkalemia and metabolic acidosis. This condition resolves spontaneously by the second half of the first decade of life.

SUBFAMILY 0 NUCLEAR RECEPTORS: DAX1

Subfamily 0 nuclear receptors include DAX1.⁹⁴⁰ DAX1 plays a role in the regulation of steroid, mullerian-inhibiting substance, and gonadotropin production.

DAX1

The dosage-sensitive sex-reversal adrenal hypoplasia congenital critical region on the X chromosome gene 1 (*DAX1*) is an orphan nuclear receptor because its ligand has not yet been identified.⁹⁴¹ It has homologies in the E domain to other orphan receptors, including RXRs.⁹⁴² However, DAX1 has an unusual DNA-binding C domain that contains a tract of amino acid repeats instead of zinc-finger motifs.⁹⁴² DAX1 inhibits SF-1-mediated transcription. SF-1 is another orphan nuclear receptor that regulates transcription of adrenal and gonadal steroid hydroxylases, mullerian-inhibiting substance, and gonadotropin genes.^{943,944}

DAX1 gene mutations have been identified that cause X-linked adrenal hypoplasia congenita.⁹⁴² Patients with this condition have congenital adrenal insufficiency and are therefore deficient in glucocorticoid, mineralocorticoid, and androgen production.^{942,945} Some 40% of affected male patients present in the first 2 months of life with a salt-wasting adrenal crisis, and the remainder present later in childhood with mineralocorticoid insufficiency, resembling aldosterone synthase deficiency or PHA. Those who present with adrenal crisis can have hyperkalemia, hyponatremia, hypotension, or cardiac arrest, because of both mineralocorticoid and glucocorticoid deficiency in the setting of normal 17-hydroxyprogesterone levels. Patients may have normal cortisol levels. Imaging of

the adrenal by any modality at this age is not helpful, as the condition affects the definitive zone but not the fetal zone of the adrenal. The fetal zone is quite large at birth and does not atrophy until 6 to 12 months of age. Imaging cannot differentiate the fetal from the definitive zones and reports a normal adrenal gland in the first few months of life. Imaging after the first year of life would be expected to show a hypoplastic adrenal. Gonadotropin deficiency and azoospermia also occur in these patients but this does not present until puberty.^{940,945} Patients have findings consistent with hypogonadotropic hypogonadism (because of a combined hypothalamic/pituitary defect) and may have absent pubertal development or puberty that arrests at around Prader stage 3. Female carriers may have delayed puberty.⁹⁴⁰ All mutations that have been found to cause X-linked congenital adrenal hypoplasia are either located in or prevent transcription of the area of the E domain that inhibits SF-1-mediated transcription.^{941,946–948} Thus DAX1 mutations may cause X-linked congenital adrenal hypoplasia by altering SF-1 regulation of gonado- and adrenogenesis.⁹⁴⁶ DAX1 deletion may also occur in the setting of the contiguous gene deletion syndrome, resulting in complex glycerol kinase deficiency (cGKD) if individuals have deletions extending from the GK gene into the Duchene muscular dystrophy (DMD) gene, or involving a significant extension telomeric from DAX1.⁹⁴⁹

Duplications of Xp that include DAX1 in genetic males with XY karyotype lead to sex reversal. DAX1 overexpression represses all aspects of male differentiation beginning with the urogenital ridge progressing to a bipotential gonad, under the influence of WT1 and SF1, to differentiation into a testis under the influence of SF1, SOX9, SRY, and AMH and leads to female external genitalia with variable female internal organs from absent ovaries, uterus, and cervix to normal ovaries with rudimentary müllerian structures. Duplications in this region of the X chromosome are also associated with developmental delay, low-set ears, cleft palate, clinodactyly, hypotonia, thin upper lip, simian creases, and cardiac abnormalities.

SUMMARY

Understanding of receptors that transduce or influence hormone action has increased dramatically. As molecular biology techniques improve, it is expected that knowledge of receptor action will continue to increase at a rapid pace. It is likely that subtle defects in receptor function (such as regulatory or promoter region mutations that increase or decrease receptor gene expression, or mutations in second messenger proteins) will be found that cause endocrine disorders. It is also likely that new receptors will be discovered that transduce or influence hormone action and that endocrine roles will be found for receptors that were not previously thought to mediate or alter hormone action.

INTRODUCTION

What makes one an effective user of the clinical laboratory?
Such a user:

- Identifies at least one sympathetic ally in the clinical laboratory to whom one can reach out for advice about laboratory testing. None of us can be expert in all the areas we need to know for the best possible care of patients, so including a laboratory expert as an ad hoc member of the care team should be a best practice for all clinicians.
- Is at least somewhat conversant with the language of the clinical laboratory to make it easier to communicate with laboratory experts, as well as to understand key articles published in the clinical laboratory literature.
- Understands that diagnostic testing, like so much of medicine, is “playing the odds,” and has enough awareness of basic probability theory and statistics to know: (1) when and when not to order laboratory tests and (2) how confident to be about a positive or negative result.
- Has insight into how laboratory tests are validated (for quality purposes).

- Knows enough about laboratory methodology to decide which test is most appropriate for the patient.
- Is aware of test limitations and possible sources of error (many of which can occur even before the sample is actually tested).
- Accepts the reality that different versions/kits/brands of the same test can give markedly different results, and adjusts diagnostic strategy accordingly.
- Recognizes the limitations and statistical fuzziness of all reference intervals, particularly those in pediatrics, and interprets results carefully with this inexactitude in mind.

COLLABORATION AMONG CLINICIANS AND LABORATORIANS

Even with a laboratory test as seemingly simple as thyroid-stimulating hormone (TSH), a collaborative relationship between an endocrinologist and a clinical laboratory expert can be mutually beneficial. An experienced clinician may be well aware of the significant circadian rhythm of this hormone but may or may not be aware of the substantial interindividual difference in how much daily variability is present¹, nor how much TSH results may vary among different assays. The laboratorian in turn may be intimately familiar with how often interfering antibodies may lead to falsely elevated results but may or may not realize how common it is to see teenaged congenital hypothyroidism patients with high TSH and high free thyroxine (T₄) because of last-minute double-dosing after months of chronic noncompliance. A clinical laboratory expert can explain how heterophilic antibody interference differs from TSH autoantibody interference (we will cover this later), and which diagnostic maneuvers make the most sense given the clinical scenario presented by the clinician. There is a time commitment involved in arranging regular clinician-laboratorian communications, but without a doubt patients benefit tremendously from what experts can teach each other.

LEARNING TO SPEAK (SOME OF) THE LANGUAGE OF THE LABORATORY

The language used in the clinical laboratory can be a barrier to learning. “Labspeak” is not quite a foreign language but represents a dialect with many terms unfamiliar to clinicians. Imagine the following conversation:

Clinician: “The results for test X on this patient seem really different between laboratory Y and your laboratory.”

Laboratorian: “I agree with you that these two results show more discordance than I’d expect from normal analytical and biological variation because the total allowable error is only 15% even though we’re down near the LOQ. The assay QC looks fine, so we should check for potential preanalytical issues and consider possible heterophilic antibody interference as well. And let’s check the platforms used, because the assays for this analyte are definitely not standardized or even harmonized to date.”

Although those working in the clinical laboratory should be savvy enough to avoid speaking like this to a clinician (especially

TABLE 4.1 Selected Laboratory Terminology

Term and/or Concept	Associated Acronyms	Pertinent Section

CIA, Competitive immunoassay; *ELISA*, enzyme-linked immunosorbent assay; *EIA*, enzyme immunoassay; *GC-MS*, gas chromatography-mass spectrometry; *ICMA*, immunochemiluminometric assay; *IFMA*, immunofluorescence assay; *IRMA*, immunoradiometric assay; *LC*, liquid chromatography; *HAAA*, human antianimal antibody; *HAMA*, human antimouse antibody; *HPLC*, high-performance liquid chromatography; *MS*, mass spectrometry; *RIA*, radioimmunoassay; *UPLC*, ultraperformance liquid chromatography.

using acronyms like LOQ), the earlier paragraph is perfectly plausible for a conversation between two laboratorians, and in fact might be the most concise way to convey key points in the investigation to follow. Knowing even just a few commonly used laboratory terms shown in Table 4.1 can help bridge the communication gap and will certainly help a clinician better understand key articles in a useful journal, such as *Clinical Chemistry*.

Many of these terms will be defined in sidebars in the appropriate section, but there are a few general ones that are worth mentioning right away:

- “Analyte” is a very common word in laboratory medicine, simple in concept, yet unfamiliar to most clinical ears. It is a generic term for “the thing being measured/analyzed.” Feeling comfortable with this word will make it much easier to talk with the laboratory and scour the pertinent laboratory literature.
- “Aliquots” are smaller portions of a sample, prepared from the original, or “mother” tube. You can use an aliquot to send out to another laboratory for corroboration, or use a “fresh aliquot” to repeat the test, if you think the original one may have had too many freeze-thaw cycles, or was potentially contaminated.

- “Platform” is a general, albeit somewhat ambiguous term, most often used to describe the manufacturer and model of automated testing instruments, for example, the Beckman Access versus the Roche Elecsys. Why is this of any importance to the clinician? Because platforms differ in their performance characteristics and vulnerability to interferences. We will see later on that comparing results for the same sample on two different platforms is sometimes the fastest way to investigate certain types of interferences. A clinician faced with an unexpected result must be aware enough to ask the laboratory if they can corroborate that result “on a different platform” when appropriate.

LABORATORY STATISTICS: THE BASICS OF EVIDENCE-BASED DIAGNOSIS

Biostatistics and epidemiology are often taught during the early preclinical years of training, when students are hungry to gain clinical experience, and are sometimes dismissive of what seems like more didactic study. Yet, both experienced clinicians and those involved in clinical research realize quickly how important it is to have at least a basic awareness of medical statistics to avoid making significant errors in diagnostic or treatment decisions.

If you call your laboratory asking about the sensitivity and specificity of a test, you will be asked whether you want “clinical sensitivity and specificity” (covered here) versus the completely different “analytical sensitivity and specificity” (discussed in the following methodology/validation section). The clinical laboratory will certainly have data on the latter, but likely only limited studies for the former, because establishing clinical sensitivity and specificity typically require significant clinical studies beyond the reach of the clinical laboratory.

- “Clinical sensitivity” is how often the test will be positive in a patient who has the disease being tested for. An excellent mnemonic (useful for examinations) is to think of the abbreviation for “positive in disease” as “PID” and consider how important it is to be “sensitive” when you have a patient with clinical PID (pelvic inflammatory disease).²
- “Clinical specificity” is how often the test will be negative in a patient who is “healthy” (at least, who does not have the disease being tested for). The mnemonic in this case is “negative in health,” or “NIH”—consider how important it is to be very “specific” when writing an NIH grant proposal.

Perhaps more relevant to clinical practice is to understand the concepts of “positive predictive value” (PPV) and “negative predictive value” (NPV)

- PPV is the probability of disease in a patient with a positive test result.
- NPV is the probability of “health” (nondisease) in a patient with a negative test result.

Both NPV and PPV are affected by the underlying prevalence of disease, or more precisely, by the probability that the patient in question has the disease (“pretest probability”). Fig. 4.1 summarizes the definitions of these terms, whereas Fig. 4.2 demonstrates the dramatic effect of increasing pretest probability on the PPV of a diagnostic test, which should be a testament to the importance of a good history and physical examination before deciding on laboratory test ordering. The best way to improve diagnostic test performance is to be as certain as possible about the diagnosis even before ordering the test!

In clinical practice, most endocrine laboratory tests give continuous rather than “yes/no” results and are therefore rarely used as strict positive/negative tests. A TSH of either 6.0 mU/L or 60 mU/L are both “positive,” but neither value will be used as a diagnostic cutoff for the diagnosis of primary hypothyroidism. Using a TSH of 6.0 mU/L would ensure that virtually

all patients with primary hypothyroidism are detected (maximum sensitivity) but at the expense of many false negatives (very poor specificity) and unnecessary referrals to the endocrine clinic. On the other hand, using a cutoff of 60 mU/L would minimize the number of false negatives (excellent specificity) but at the expense of missing many true cases of primary hypothyroidism (clinically unacceptable low sensitivity). The choice of a cutoff somewhere in between these two extremes should be determined by the clinical scenario (e.g., perhaps lower in a 14-month-old infant than in an obese but otherwise healthy 13-year-old teenager) rather than an arbitrary universal threshold.

TP = True positive (positive test in a patient with disease)
 FP = False positive (positive test in a patient without disease)
 TN = True negative (negative test in a patient without disease)
 FN = False negative (negative test in a patient with disease)

$$\text{Clinical sensitivity} = \frac{TP}{TP + FN}$$

$$\text{Clinical specificity} = \frac{TN}{FP + TN}$$

$$\text{Positive predictive value (PPV)} = \frac{TP}{TP + FP}$$

$$\text{Negative predictive value (NPV)} = \frac{TN}{FN + TN}$$

Fig. 4.1 Definitions of basic diagnostic test statistics.

For tests that generate continuous results, the overall diagnostic effectiveness of a test can also be evaluated by plotting the true positive rate versus the false positive rate, producing a receiver-operating characteristics curve (ROC curve).

- An ROC curve plots, for various test results, the true positive rate (clinical sensitivity) of a test on the y-axis versus the false positive rate (1 – clinical specificity) on the x-axis (Fig. 4.3). The area under the curve (AUC) can be used to estimate the ability of the test to distinguish disease from nondisease, with an AUC of 0.50, indicating a test without diagnostic value, a test with an AUC of 0.90 or more generally considered as excellent, and one with an AUC of 0.70 considered to be a fair diagnostic test.

Two important caveats for evidence-based diagnosis:

- (1) Calculation of clinical sensitivity and specificity for a diagnostic test depends upon clear definition of who does have the disease in question and who does not. If there is no gold standard diagnostic test for comparison, or if the definition of the disease evolves and becomes less clear-cut over time (e.g., early definitions of severe/anatomically proven growth hormone deficiency [GHD] versus later, less well-defined cases of GHD), the definitions of sensitivity and specificity may be approximate at best.
- (2) Calculation of sensitivity, specificity, and true and false positive or negative rates will vary depending upon the nature of the population being studied. For example, a very good diagnostic test applied across the entire population of the United States will have a far higher false positive rate (as is seen with screening tests) than the same test applied to a carefully selected patient group who has been deemed

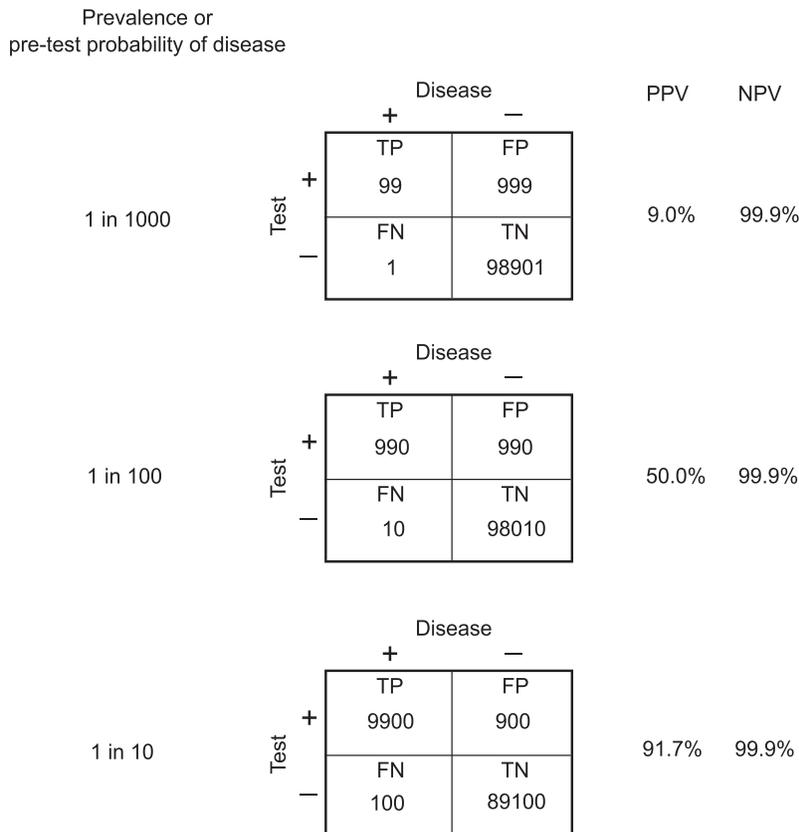

Fig. 4.2 Effect of disease prevalence/pretest probability on positive (PPV) and negative (NPV) predictive values, using a test with 99% clinical sensitivity and 99% clinical specificity. Numbers in boxes represent the distribution of 100,000 patients among true positives (TP), false positives (FP), false negatives (FN), and true negatives (TN).

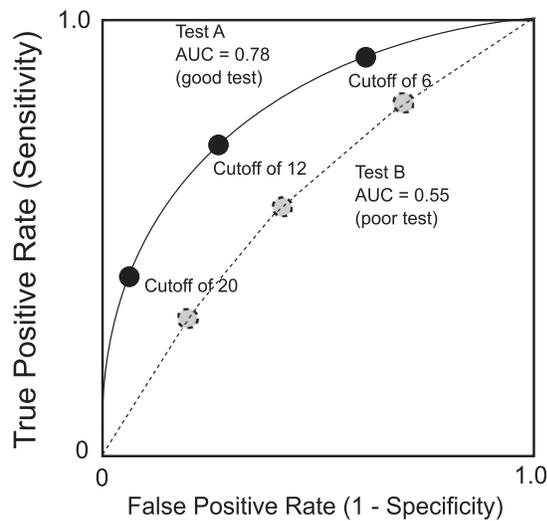

Fig. 4.3 Receiver-operating characteristic curves for two theoretical diagnostic tests.

likely to have the disease in question based on history and physical examination. This again emphasizes the need to increase pretest probability of disease as much as possible before ordering any diagnostic testing.

ANALYTICAL VALIDATION

Clinical Scenario 1

An investigator inadvertently runs two tubes containing nothing but water on a peptide classic radioimmunoassay (RIA) and is nonplussed when the results show a significant level of the peptide in these tubes.

Clinical Scenario 2

A laboratory declines to run a tumor marker immunoassay ordered on viscous cyst fluid because of a lack of analytic validation data but relents when the physician insists that the laboratory run the sample with a disclaimer "nonvalidated sample type; interpret with caution." Despite the disclaimer, the laboratory and the clinician are later both sued successfully for inappropriate diagnosis and unnecessary treatments based on what turns out to be a falsely positive result.

Both of these brief clinical vignettes illustrate why regulatory agencies and anyone concerned with quality laboratory testing place such emphasis on analytic method validation. A peptide RIA may give accurate results in serum, but totally inaccurate results in a protein-free fluid; perhaps the tracer (See Methodology: Immunoassays on page 91) in scenario 1 stuck to the sides of the plastic tube, leading to decreased tracer binding and an apparent detectable level of peptide where none was actually present. Scenario 2 represents a situation of misdiagnosis; the viscosity of the solution might have affected the interaction of the assay components, with substantial impact on the patient and legal consequences for all involved.

Analytical validation is meant to ensure that an assay method is accurate for its intended use. Components of an analytical validation include the following: (1) linearity/reportable range; (2) precision; (3) analytical sensitivity; (4) analytic specificity, interferences, and recovery; (5) accuracy/method comparison; (6) sample types and matrix effects; (7) stability; and (8) carryover. Determining reference intervals is an important part of many analytic validations and crosses over to clinical validation. Note that even though not all of these components are

always required from a regulatory point of view, all represent good-quality laboratory practice.

Linearity/Reportable Range

Also referred to as the analytic measurement range (AMR), this is the range of concentrations over which the assay is known to be reliable. Standards of known concentration (calibrators) are assayed and plotted against the signal generated in the assay. For the hypothetical study shown in Fig. 4.4, the upper limit of the AMR would likely be at the concentration represented by calibrator D, because the higher concentration represented by calibrator E does not result in a similar degree of increased signal. However, it may be possible to dilute the sample so that one can make a measurement within the AMR, thereby allowing for assay of concentrations above the upper limit of the AMR. The calibrator choice may alter the absolute value reported, particularly with peptides and proteins where the standard may represent only one of a mixture of differentially modified (e.g., glycosylated or cleaved) forms present in the circulation.

Precision

Also known as reproducibility or replicability, this defines whether the random error of the assay is small enough to make the assay clinically useful. A commonly used analogy is that of the target shooter: how close together are the bullet holes? Note that precision is distinct from accuracy (a different part of the validation study); precision addresses only if the shots are close together, not whether they are actually hitting the bulls-eye. Both intraassay (e.g., 20 measurements done on the same assay run) and interassay (1 measurement done daily for 20 days) precision are studied and the standard deviations (SDs) of the replicate measurements calculated. In general,

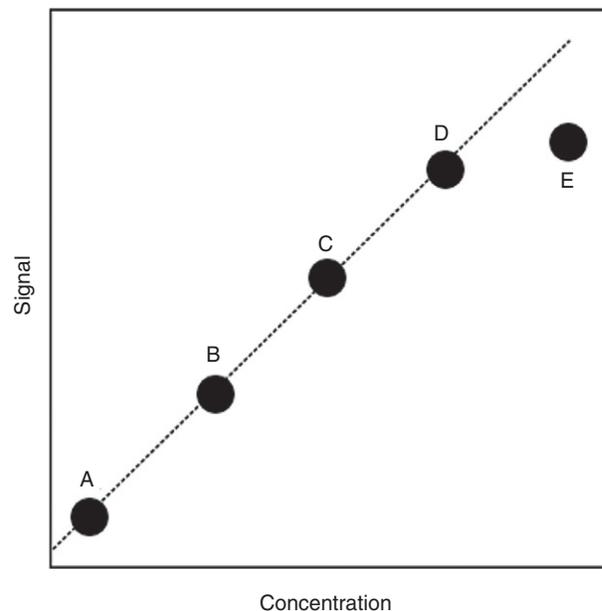

Fig. 4.4 Linearity study used to determine the analytic measurement range (AMR). The concentrations represented by points A and D represent the likely minimum and maximum concentrations of the AMR. Higher concentrations, such as that represented by point E, may still be measured if the sample can be diluted to bring the concentration to within the AMR, provided that previous studies have proven that the response remains linear when a dilution is performed.

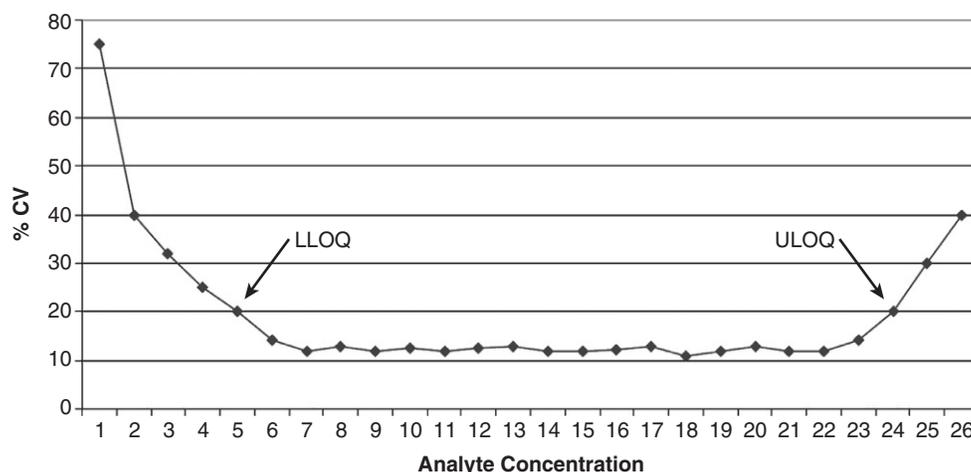

Fig. 4.5 Using a precision profile to determine the lower (LLOQ) and upper (ULOQ) limits of quantitation, based on acceptable interassay precision (commonly set at a coefficient of variation [CV] of 20% or less).

precision is presented as the coefficient of variation (CV), which is the SD divided by the mean, expressed as a percentage. For example, at a mean value of 100 ng/mL, an assay with an SD of 5 ng/mL would have a CV of 5%. Note that the concentration of the analyte factors into the assay's precision because CV values tend to be higher at either limit of the AMR (Fig. 4.5).

Analytic Sensitivity

This part of a validation study determines how low an analyte concentration can be measured with acceptable precision. It is distinct from clinical sensitivity (how often a result is positive in a patient with disease), which is a general part of a clinical validation study done well after the analytic validation has been completed. A frequent problem is the use of many different terms for analytic sensitivity, for example, minimal detectable concentration, limit of detection (LOD), limit of blank, or limit of absence, all of which describe the lowest possible concentration that can be confidently distinguished from zero. Although an assay developer might cite the LOD to make the assay look as sensitive as possible, the clinician should realize that values down near the LOD are hugely variable and not really quantitative. A more conservative and clinically useful analytic sensitivity limit is the limit of quantitation (LOQ), also known as *functional sensitivity* and typically defined as the lowest concentration that can be measured with a CV of less than 20%. Even this amount of variability is not trivial; if a testosterone assay has a CV of 20% at the LOQ of 30 ng/dL, one could obtain a result of either less than 30 ng/dL or 36 ng/dL on exactly the same sample, run on two different occasions.

Analytic Specificity, Interferences, and Recovery

Specificity in this context refers to the ability of the assay to measure a specific analyte without cross-reacting with other substances in the sample. Analytic specificity studies may involve the addition of known amounts of similar analytes to a sample; for example, a cortisol assay may be tested for cross-reactivity with cortisone, prednisone, prednisolone, dexamethasone, 17-hydroxyprogesterone, and other steroids. Closely related are interference studies to see if commonly encountered situations, such as hemolysis, hyperbilirubinemia, and lipemia affect the test results. Recovery studies are less often performed; here, a standard of known concentration is added into a sample, and the sample assayed to see what percentage of the added standard is detected (ideally 100%, but frequently less).

Accuracy/Method Comparison

Determining the accuracy of an assay is a multistep process, not all of which can be addressed in a typical analytic validation study. Accuracy may be part of the original test development decision-making process—for example, including an extraction and chromatography step to avoid otherwise problematic cross-reactions. Full determination of the clinical accuracy of a test may not be possible until the analytic validation is completed and the test released to investigators for clinical validation studies. Therefore so-called accuracy studies in an analytic validation are by necessity limited to just a small portion of the whole accuracy process. The interference and recovery studies mentioned earlier are pertinent to test accuracy, but the most common approach is to compare the new test method to another comparator method. Ideally, the method used for comparison will be some type of gold standard reference method, but often such a method is not available. As a proxy, the method under validation is compared with a well-accepted method, and the results shown (new method result on the y-axis, comparison method result on the x-axis) on a correlation plot (Fig. 4.6, upper panel). Also frequently used is a bias or difference plot (Fig. 4.6, lower panel), which better shows intermethod differences that may escape notice on a simple correlation plot.

Sample Types and Matrix Effects

Sample types are not automatically interchangeable. Ethylenediaminetetraacetic acid (EDTA) plasma from a lavender top tube may perform fine in an assay, whereas heparin plasma from a green top tube may not. One parathyroid hormone assay may give comparable results from both EDTA plasma and red top tube serum, whereas a different parathyroid hormone assay may not. These represent examples of a “matrix effect.”

- Matrix refers to the components of a sample other than the analyte being measured.

As noted in our vignettes, the matrix (e.g., protein-free, viscous, high-salt, containing high levels of paraproteins) may have a profound effect on the accuracy of a laboratory assay.

The matrix of serum is different than that of plasma, because of the absence of fibrinogen and anticoagulants, plus the presence of substances released by platelets. Differences in many analyte values may be more than is suggested by this apparently small difference; one study of metabolite profiles showed that 104 out of 122 metabolites had significantly higher concentrations in serum as compared with plasma.³ It is important to realize that an assay validated for one matrix cannot be automatically used for another.

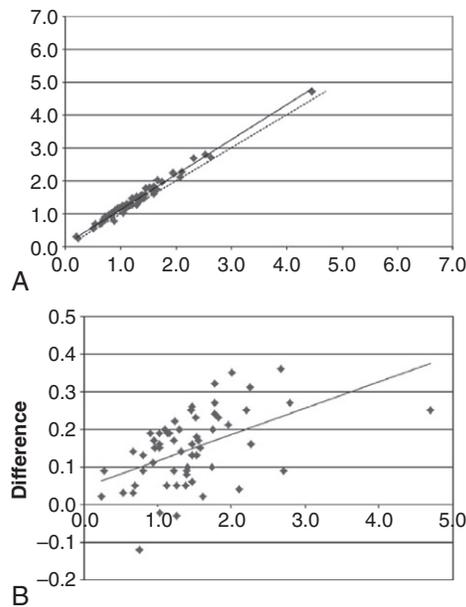

Fig. 4.6 Method comparison. A correlation plot (*upper panel*) versus difference/bias plot (*lower panel*). With a correlation plot (**A**), the values for a new assay (y-axis) are compared with values from an established assay (x-axis), showing a best fit (*solid line*) deviating slightly from the line of identity (*dotted line*). For the difference/bias plot (**B**), the difference between the values from the new versus the old assay is plotted on the y-axis, whereas the mean value of the results from both assays is plotted on the x-axis. The systematic upward bias of the new assay is seen more clearly on the difference/bias plot.

Stability

Typically, sample stability is studied at ambient (about 22°–26° C), refrigerated (about 2°–6° C), and regular frozen (around –18° to –20° C) temperatures. For assays used in clinical studies where specimens may be banked for prolonged periods, stability studies should also be performed at deeper frozen (e.g., –70° C) temperatures. Aliquots stored at these temperatures for varying periods of time are recovered and assayed to see if results are stable relative to baseline. Stability limits are an inherent property of the assay rather than the analyte: an osteocalcin assay designed to pick up only full-length molecules may have a short stability limit for samples at room temperature, whereas another assay that detects osteocalcin molecule fragments, as well as full-length protein, may have a much longer stability limit.

Carryover

Another important quality process is to ensure that there is no cross-contamination between samples, and that a sample with very high values will not carry over and falsely elevate results in the next sample to be assayed. Assays should be designed to minimize this problem, but there should also be awareness on the part of the laboratory staff to check for carryover whenever a sample with an extremely elevated value is encountered.

METHODOLOGY

Immunoassays

Immunoassay is an important methodology in the endocrine laboratory. Understanding the basic principles involved allows specialists to: (1) identify when a particular immunoassay is or is not appropriate for a particular clinical scenario,

(2) anticipate potential physiological and technical issues affecting the interpretation of laboratory results, and (3) understand how to work with the clinical laboratory to investigate unanticipated or clinically discordant test results.

Competitive Immunoassay versus Immunometric (Sandwich) Assay

There are two main immunoassay formats relevant to endocrinology laboratory testing, and understanding some of the basic differences between these formats helps both interpretation of results and troubleshooting of unexpected situations. The first class of assays is termed *competitive*, with the RIA as the archetypal example. A primary antibody against the analyte of interest is added to the patient's sample, together with a radiolabeled version of the analyte (tracer) that competes with the endogenous analyte for binding to the primary antibody (Fig. 4.7, upper panel). After a sufficiently long incubation time, the primary antibody is precipitated using a second anti-immunoglobulin (Ig)G antibody, polyethylene glycol, or (most commonly nowadays) by using primary antibody attached to a solid support, such as a bead, which allows a simple centrifugation step to collect the primary antibody. Any unbound tracer or analyte is washed away, and the amount of tracer in the precipitate is then quantified.

To convert this tracer signal into a concentration, a standard curve is prepared from samples where varying concentrations of a known amount of analyte have been added. For a competitive immunoassay, the amount of signal detected (amount of tracer bound to antibody) decreases as the analyte in the patient's sample increases. Importantly, anything that prevents the tracer from binding to the primary antibody would also decrease signal and increase apparent analyte concentration. For example, taking an immunoassay optimized for serum and using it for an extremely concentrated urine sample or in a body fluid where the protein concentration is extremely high can significantly alter the results. Because high-salt or high-protein concentration can inhibit tracer binding to antibody, tracer signal will be low and the apparent analyte concentration very high, even in the complete absence of any analyte.

The second class of immunoassays is termed *immunometric*, with the most important example being the noncompetitive, so-called *sandwich assay*. Typically, as shown in Fig. 4.7 (lower panel), an antibody attached to a solid support (plate, wall of a tube, or a bead) is used to capture the analyte of interest, followed by the addition of a second, labeled antibody that binds to a different site on the analyte, creating an antibody-analyte-antibody sandwich. After unbound detection antibody is washed away, and that which remains generates a radioactive (immunoradiometric [IRMA]), chemiluminescent (immunochemiluminometric [ICMA]), colorimetric (enzyme-linked immunosorbent assay [ELISA]), or fluorescent (immunofluorescence assay [IFMA]) signal, depending on the label chosen.

The immunometric assays offer certain inherent advantages over competitive immunoassays. First of all, the fact that two antibodies are involved, each binding to a separate epitope on the analyte, greatly increases analytic specificity, including the ability to select very specific isoforms of an analyte. For example, one antibody can be directed at the N-terminus of a peptide, whereas the other antibody can be directed at the C-terminus, ensuring that only full-length peptide is detected. A second advantage is that immunometric assays tend to be more analytically sensitive than their competitive assay counterparts.⁴ This arises from the fact that the sensitivity of a competitive immunoassay largely depends on the affinity of the antibody used in the assay—and developing very high-affinity antibodies is not an easy or predictable task. In contrast, the sensitivity of an immunometric assay can be improved by use of a

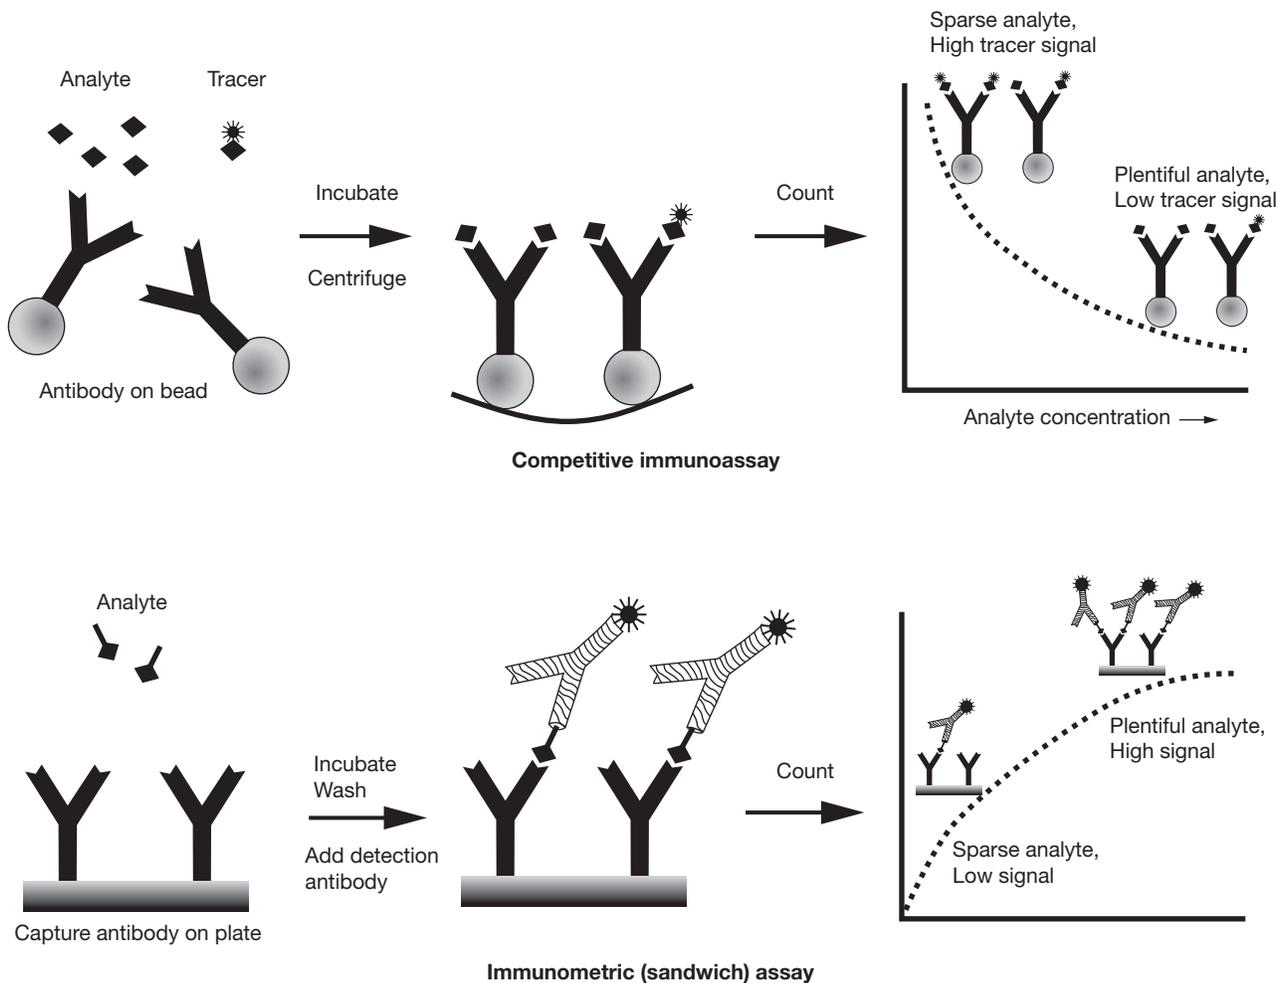

Fig. 4.7 Comparison of competitive versus immunometric (sandwich) assays. In competitive immunoassay (*top*), the labeled tracer (labeled analyte) and unlabeled analyte compete to bind to the assay antibodies. In the two-site immunometric method (*bottom*), the analyte of interest is sandwiched between the capture and signal antibodies.

higher activity signal, which is more easily detected even when analyte concentrations are very low. As signal detection technology continues to improve, increasingly sensitive immunometric assays can be developed. A third advantage of immunometric assays arises from the ability to use monoclonal antibodies, which can be more easily produced in quantity and have more predictable characteristics than polyclonal antibodies.

Limitations of Immunoassays

The ability of an antibody to bind a specific target with high affinity is remarkable, yet there are limitations. The small size and relatively poor immunogenicity of steroid molecules make it difficult to obtain an antibody that can clearly distinguish a specific steroid from other similar steroids. For example, an antibody raised against testosterone may show significant cross-reactivity with a conjugated form, such as testosterone glucuronide, or with the structurally similar dihydrotestosterone molecule. A solvent extraction step to remove water-soluble conjugates, such as glucuronides, coupled with a chromatographic step to separate out structurally similar molecules, will greatly improve the analytic specificity of the assay⁵ (Fig. 4.8A). The extraction step also separates testosterone from binding proteins that can interfere with accurate measurement.

Testosterone immunoassays that do not involve such extraction and chromatography steps, including the majority of assays found on most automated laboratory platforms, may

perform adequately at the higher levels found in adult males (>300 ng/dL) but will frequently measure inappropriately high values in the range most pertinent to women and prepubertal children (Fig. 4.8B). This overestimation (and poor low-end analytical sensitivity) is seen as well for other steroids, such as estradiol or 17-hydroxyprogesterone. Because in practice the lower values are more concordant with the clinical picture, endocrinologists caring for women and children have traditionally relied on immunoassays that involve extraction and chromatography steps, now largely replaced by assays involving chromatography and tandem mass spectrometry.

Free Hormone Assays

The concept that the “free” (not attached to any binding proteins) hormone level best reflects the endocrine status of a patient is still referred to as a *hypothesis*, because the clinical utility of free hormone assays varies from certain to speculative. A free T4 by equilibrium dialysis is clearly valuable for the evaluation of a patient with thyroxine-binding globulin (TBG) deficiency; a free testosterone may be helpful (although not always required) in some patients with findings not fully explained by the total testosterone level; and theoretically a free 25-hydroxyvitamin D (25-OHD) level might help explain why black Americans have lower average 25-OHD levels than white Americans, despite having a lower incidence of osteoporosis.⁶

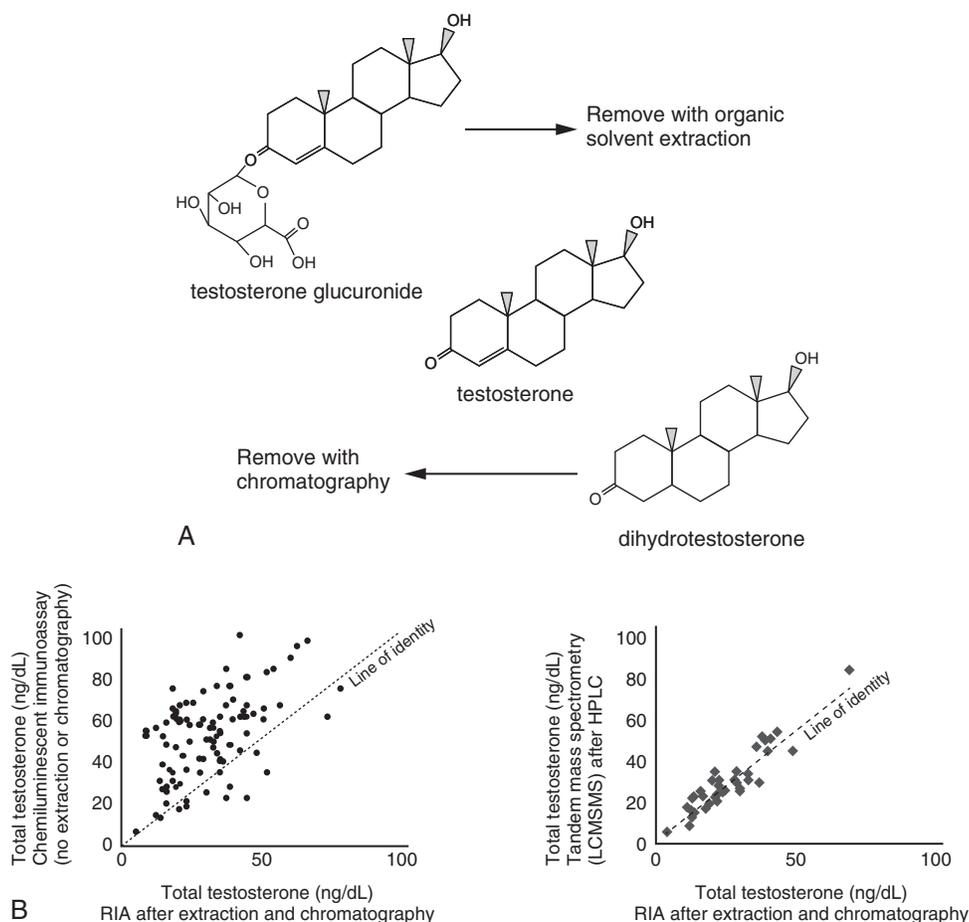

Fig. 4.8 A, Increasing analytical specificity via extraction and chromatography. After organic solvent extraction, water-soluble conjugates remain in the aqueous phase whereas steroid molecules generally remain in the organic phase. Similar steroid molecules can be separated by an additional chromatography step. **B**, Correlation of testosterone assays (extraction/chromatography/radioimmunoassay [RIA] versus nonextraction immunoassay or tandem mass spectrometry). Left panel: Steroid immunoassays without additional preparation steps before assay tend to give higher values than immunoassays after extraction and chromatography, likely because of steroid conjugates and compounds of similar structure (occasional lower values may reflect issues with incompletely removed steroid binding proteins). Right panel: Measurement of steroids by high-performance liquid chromatography [HPLC]-tandem mass spectrometry (MS) (which also involves extraction and chromatography) produces testosterone results very similar to those obtained with immunoassay after extraction and chromatography.

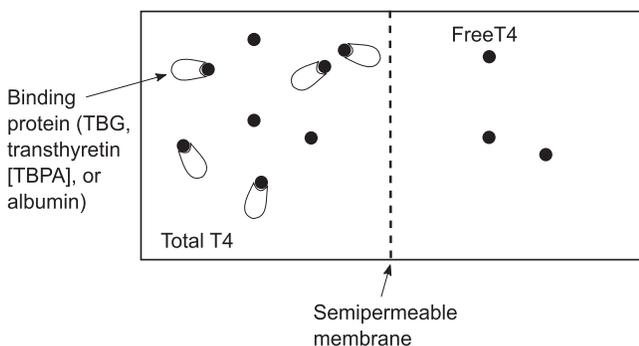

Fig. 4.9 Free T4 by direct measurement after equilibrium dialysis. See text for details.

Free T4 by direct measurement after equilibrium dialysis is the archetypal free hormone assay. As shown in Fig. 4.9, it involves incubation of a patient sample on one side of a dialysis buffer-filled chamber separated by a semipermeable membrane which free (but not bound) T4 can cross. After a period of time sufficient to reach equilibrium, the amount of free T4 can be directly measured by a highly sensitive detection

method (immunoassay using a very high-affinity antibody, or tandem mass spectrometry). This assay performs well at extremes of TBG (deficiency or excess), likely better than some of the alternative analogue-based assays described later. Disadvantages include a longer waiting time (turnaround time) for results, expense because of the additional labor required, and sensitivity to substances like nonesterified (free) fatty acids (NEFA) that can displace T4 from its binding proteins. The last issue can be seen when samples for free T4 are drawn through heparinized lines; heparin in the sample tube can accelerate the release of NEFA from triglycerides in the sample, artifactually elevating the measured free T4 level. Even in the absence of a heparin effect, there may be subtle to significant effects of NEFA on the free T4 by dialysis assay in patients who have hypertriglyceridemia, particularly if they have low thyroid hormone binding capacity (low TBG or very low albumin).

Free T4 and free serum cortisol are amenable to direct measurement after dialysis, because total T4 and total cortisol circulate in the micrograms per deciliter range. In contrast, total testosterone and total triiodothyronine (T3) are measured in the nanogram per deciliter range, with the resultant free hormone levels below what can be measured dependably by current immunoassays or mass spectrometry. A different approach (indirect measurement by tracer equilibrium dialysis) is thus

required. As shown in Fig. 4.10, the patient sample is placed in the dialysis chamber along with a known amount of radioactively-labeled hormone (the tracer). Some tracer is bound and some remains free. After equilibrium, the amount of radioactivity that has crossed the dialysis membrane (representing the fraction of tracer which remains free) can be measured to determine the “percent free hormone.” The total hormone (total T3 or total testosterone) level can be multiplied by this percent age of free hormone to get the resultant calculated free hormone level.

Because the dialysis-based free hormone assays are labor intensive and not amenable to automation, alternative “direct” approaches have been developed. The most common is free T4 by the labeled analogue method (Fig. 4.11). A labeled T4 analogue that does not bind to any of the TBGs (TBG, TBPA, albumin) is added to the patient sample; this analogue competes with the patient’s free T4 for the T4 antibodies (chosen to bind only free T4 molecules), with the resultant free T4 determined as with any competitive immunoassay (more signal from the bound analogue corresponds to less free T4 in the patient sample).

A clever variation involves labeling the antibody rather than an analog of free T4 (Fig. 4.12). T4 immobilized on a tube wall or plate well competes with the patient’s free T4 for the labeled

antibody. After incubation and a wash step, only the antibody bound to the immobilized T4 remains and the signal measured (as with any competitive immunoassay, more signal corresponds to less free T4 in the patient sample).

These direct assays are fast, relatively inexpensive, and easily automated. They have therefore become the dominant free T4 assays, displacing older approaches, such as calculation of the free T4 index. One concern is that the performance of the analogue assay is dependent upon the assumption that the analogue does not interact at all with TBG or other binding proteins, an assumption that may not be completely true, especially when TBG levels are high, or binding protein affinities are increased. These assays may therefore perform poorly at the extremes of thyroid hormone binding capacity (e.g., very low or very high TBG levels, extremely low albumin levels as in nephrotic syndrome, or in patients with altered thyroid hormone binding protein affinity). In general, the direct assays tend to underestimate free T4 when TBG or albumin levels are low⁷ and overestimate when binding protein levels are high. Nevertheless, analogue-based direct free T4 assays are widely accepted for general use, in contrast to the analogue free testosterone assays, which are specifically not recommended by the Endocrine Society.⁸

Mass Spectrometry

Mass spectrometry (MS) represents a detection paradigm completely different from antibody-based methods. It is a well-established method to achieve very high analytical sensitivity and specificity and accurate quantitation for small molecules like drugs, steroids, catecholamines, and various inorganic compounds. Using MS, proteins can be quantitated by measuring the amount of a “signature” peptide fragment after proteolysis, or (with more recent technological advances) by direct measurement of intact proteins up to about 20 kDa in size.

A typical mass spectrometry assay (Fig. 4.13) might include the following steps:

- Initial purification: most commonly an extraction step to remove binding proteins or other interfering substances from

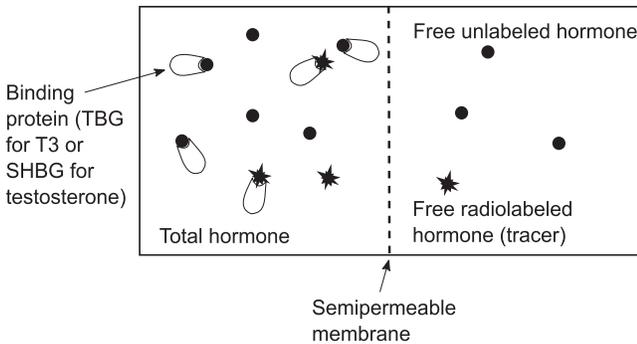

Fig. 4.10 Free hormone (e.g., free T3 or free testosterone) by tracer equilibrium dialysis. See text for details.

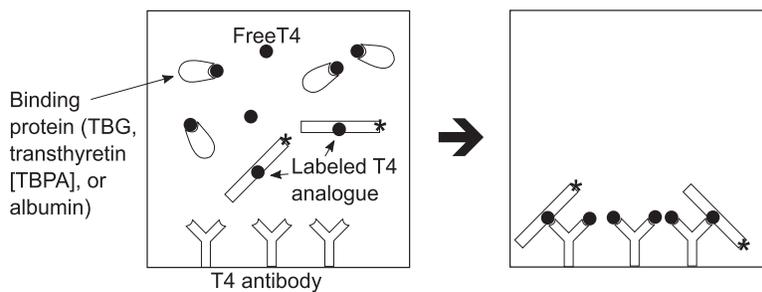

Fig. 4.11 Free T4 (nondialysis) by labeled analogue method. This method depends upon a T4 analogue that binds to the assay T4 antibody, but not to thyroxine-binding globulin (TBG). See text for further details.

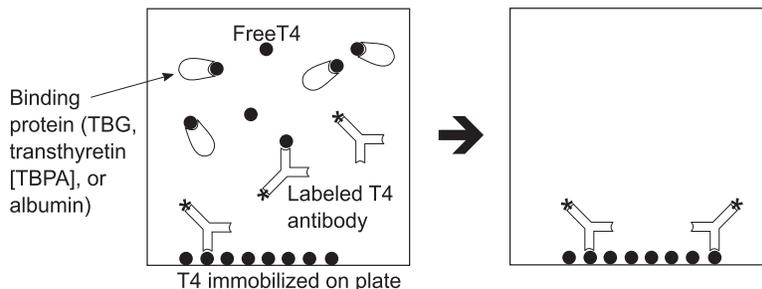

Fig. 4.12 Free T4 (nondialysis) by labeled antibody method. See text for details.

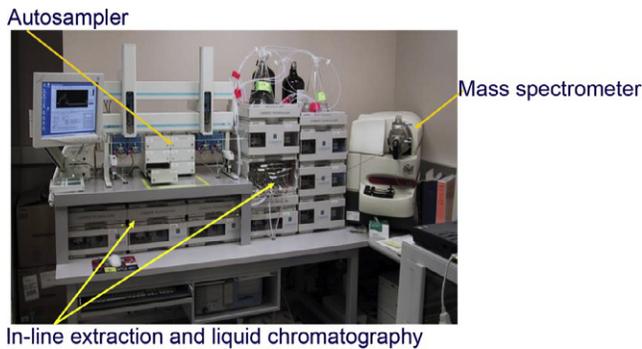

Fig. 4.13 An older but still representative setup for a quantitative high-performance liquid chromatography-tandem mass spectrometry assay. Note the extensive front-end equipment for the extraction and chromatography steps, with the mass spectrometer taking up only the small space at the extreme right.

the target analyte. Many clever techniques have been used to reduce the complexity of the overall sample and enrich the concentration of the target analyte.

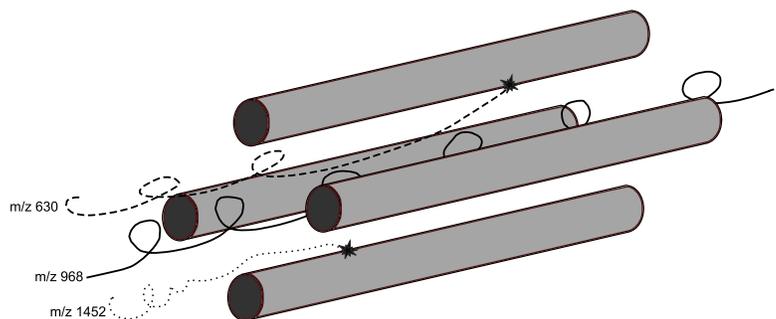

- Derivatization is a chemical modification of the target analyte that can make it easier to analyze accurately during the later detection step.
- Chromatographic separation, for example, gas chromatography (GC) or liquid chromatography (LC). GC typically uses very long columns and has the ability to resolve many different analytes with great accuracy, although it is both slow and generally not automation-friendly. LC is both faster and automatable, with high-performance liquid chromatography (HPLC) or ultraperformance liquid chromatography (UPLC) most commonly used. The target analyte has a typical retention time, which is the time between injection of the sample into the chromatography system and the detection of the analyte peak.
- Ionization of molecules in the partially purified mixture, typically using one or a combination of the following: heat, ion bombardment, high voltage, laser bombardment, or chemical ion transfer. The target analyte will have a characteristic mass to charge (m/z) ratio after ionization. The ionization techniques most commonly used in the clinical laboratory (because of compatibility with liquid chromatography systems) are electrospray ionization (ESI) for larger or polar molecules like peptides and proteins, and atmospheric pressure chemical ionization (APCI) for smaller, nonpolar molecules like steroids. Matrix-assisted laser desorption ionization (MALDI) is less often seen in the clinical chemistry/endocrinology laboratory because of difficulties in automation and achieving precise quantitation, but it has been invaluable in the microbiology laboratory to produce peptide fingerprints characteristic of different microorganisms.

- Mass analyzer separation of the ions produced earlier according to their m/z ratio. This can be accomplished by first accelerating the ions in an electrical field and then separating out the desired analyte ions using any one of several techniques. For endocrine testing, the most commonly encountered techniques are:
 - Quadrupole mass filtration: ions trace a complex path in an oscillating electrical field between four cylindrical rods (Fig. 4.14). The frequency of the oscillation can be tuned so that only ions with the desired m/z ratio make it to the end (where they will proceed to the detection step) without colliding with one of the rods, ending its journey.
 - Ion traps: ions are corralled in an oscillating electrical field that can be tuned to eject ions of a specific m/z ratio so that they reach the detector. They may allow higher resolution of different molecular weights than can be achieved by the typical quadrupole system.
 - Time of flight (TOF): all ions are subjected to the same electrical field, with lower molecular weight ions reaching the detector earlier than their heavier counterparts. These systems may allow analysis of larger mass ions than can be easily handled with the other approaches.
- Detection of ions (ion intensity) corresponding to analytes of interest within the desired m/z range (Fig. 4.15). Compounds can be further distinguished based on when they elute from the chromatography column (retention time).
- Data processing to convert the ion intensity data into quantitative laboratory results.

Further improvements in analytical specificity result when two mass analyzers are placed in tandem (Fig. 4.16). In a triple quadrupole tandem mass spectrometer (MS/MS), the first quadrupole mass analyzer/filter separates the initial molecular ions, of which only the ions with the desired m/z ratio are allowed to proceed onward. In the second chamber, where a quadrupole accelerates the ions but does not filter them, the selected ions collide with molecules of an inert gas, such as argon, breaking up these "precursor ions" predictably into characteristic fragments ("daughter ions"), which act like a molecular fingerprint for the analyte of interest. These daughter ions proceed to the third chamber, where a second mass analyzer/filter allows only ion fragments with a particular m/z ratio to pass onward to the detector.

Although the most important feature of MS for endocrinologists is the high analytical specificity, there are additional capabilities of interest. One of these is the ability to measure multiple analytes simultaneously, known as *multiplexing*. Immunoassays can be multiplexed as well; however, such assays tend to be much more difficult to design and often show undesirable interactions among the multiple different antibody-antigen reactions taking place in the same specimen tube. In contrast, provided that the analytes tolerate reasonably similar chromatographic and ionization conditions, multiple MS measurements can be taken from the

Fig. 4.14 Quadrupole mass filtration. An oscillating electric current is chosen to allow only ions with a certain mass to charge (m/z) ratio to pass through the quadrupole. Other ions trace an unstable path and collide with the quadrupoles, ending their journey.

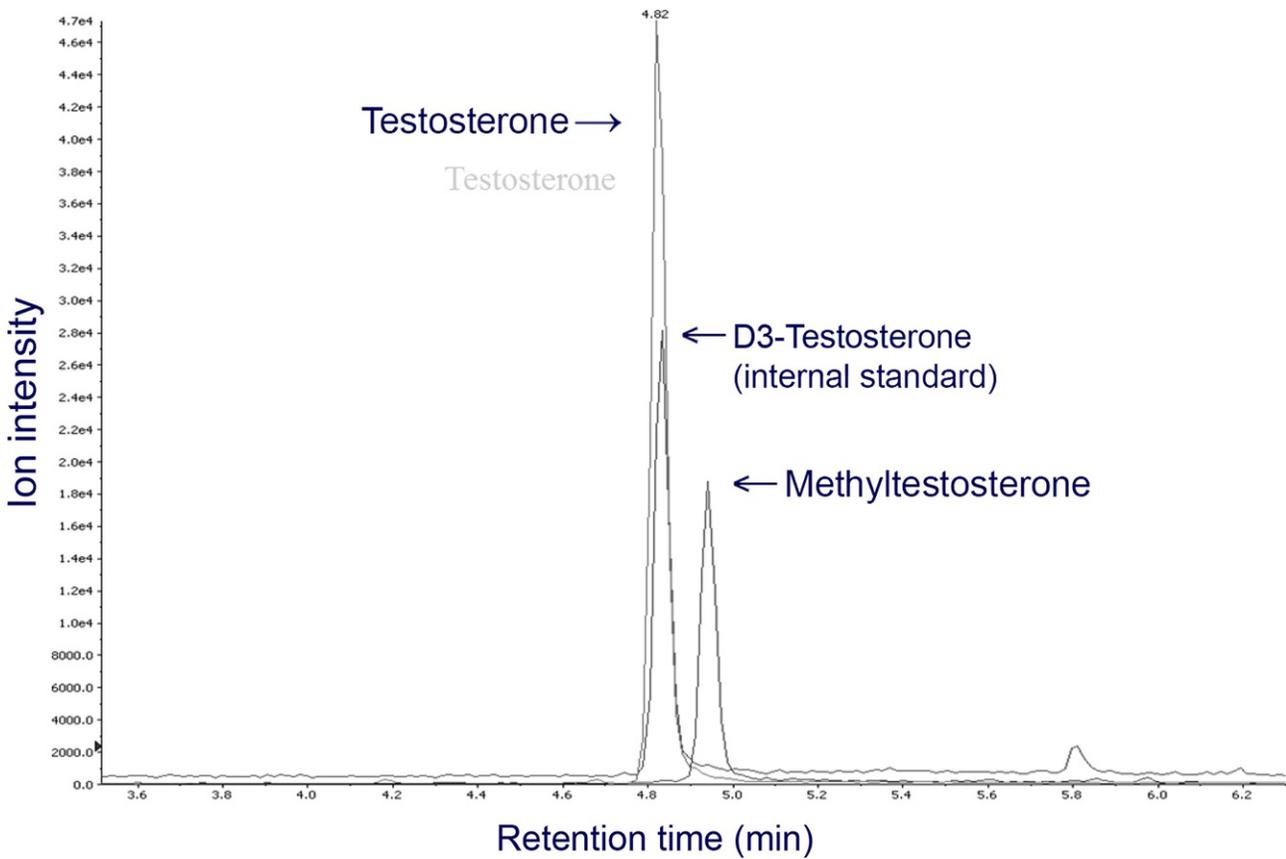

Fig. 4.15 Mass spectrometric quantitation of testosterone. Testosterone can be measured quantitatively by comparison to a known amount of an internal standard (deuterium-labeled testosterone that has a slightly higher mass and retention time compared with native testosterone) diluted into the sample. Methyltestosterone can also be measured separately, because of its distinctly higher mass and longer retention time on the chromatographic column before it reaches the mass spectrometer.

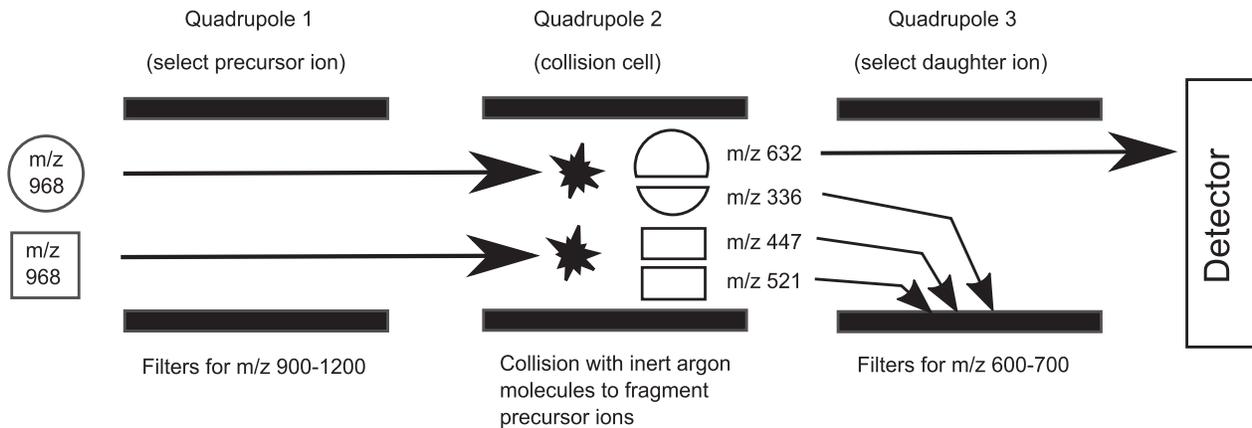

Fig. 4.16 Triple quadrupole configuration to achieve high analytical specificity. Even if two compounds have identical mass to charge (m/z) ratios and similar chromatographic retention times, they can be distinguished by measuring their unique “daughter ions” after a fragmentation step.

same sample without cross-interferences, greatly reducing the sample volume required, for example, for a panel of adrenal steroids.

Over the past several years, mass spectrometers have become increasingly able to handle larger and larger molecules at increasingly high resolution. Accurate quantitation of many peptide and protein hormones is now available. The earliest approach, which is still required for very large proteins, such as thyroglobulin (Tg, 660 kDa), involves thorough proteolysis and quantitation of an invariant “fingerprint” peptide fragment. This method, known informally as *bottom-up* proteomics,

is complemented by the more recent use of top-down proteomics,⁹ where smaller proteins (up to 20 kDa, with the upper limit continually increasing) can be directly analyzed and quantitated in their intact state (no proteolysis required). This top-down proteomic approach is particularly exciting, given that it allows examination of proteins in their native states, including their posttranslational modifications (e.g., glycosylation, sialylation, etc.). Thus there is the possibility of defining specific protein isoforms (perhaps the most bioactive ones?) for quantitation, if endocrine researchers can define which forms should be measured.

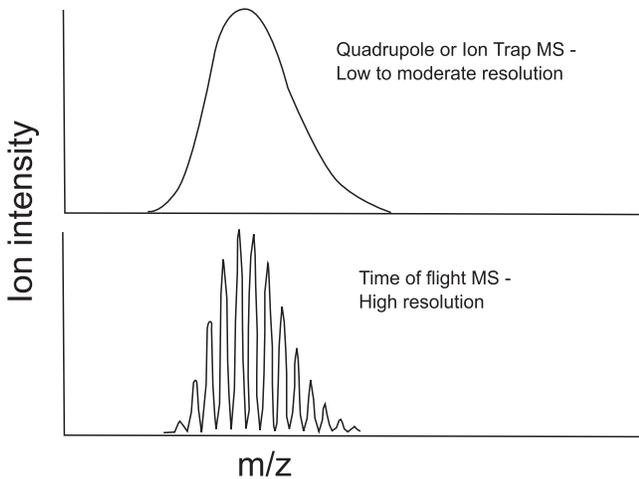

Fig. 4.17 High-resolution mass spectrometry reveals multiple peaks corresponding to proteins with different amounts of naturally occurring stable isotopes.

Top-down proteomics requires the use of mass spectrometers with high resolution, because the method of identifying a protein relies on an “isotopic fingerprint.” With a lower resolution instrument, a small protein like insulin (5.8 kDa) might appear as a single gently rounded peak whose identity as insulin is not 100% certain. As the resolution of the mass spectrometer increases, this peak is revealed to be composed of multiple sharper peaks, all with slightly different m/z ratios (Fig. 4.17). The reason that insulin does not have a single peak at one m/z ratio is because some of the insulin molecules contain naturally occurring stable isotopes like ^{13}C rather than ^{12}C and thus have a slightly higher mass. Based on the knowledge that about 1.1% of all carbon atoms are ^{13}C , and that insulin has 257 carbon atoms, one can use probabilities to calculate how many insulin molecules are likely to have 0, 1, 2, 3, or more ^{13}C . One can do the same for less abundant natural isotopes, such as ^{15}N , ^{18}O , and ^{34}S , and thus predict mathematically the distribution and ion intensity of insulin peaks at various m/z ratios, with experimental profiles matching quite closely (Fig. 4.18). These profiles act like fingerprints that identify the molecule definitively as insulin.

Isotope	Mass [Da]	% Abundance	Isotope	Mass [Da]	% Abundance
^1H	1.007825	99.985	^{16}O	15.994915	99.76
^2H	2.014102	0.015	^{17}O	16.999131	0.038
^{12}C	12. (exact)	98.90	^{18}O	17.999159	0.20

WHAT CAN GO WRONG? ERRORS, INTERFERENCE, AND THE LIKE

Errors can occur at any point in the diagnostic testing cycle, even before the sample is actually collected.

- “Preanalytical” refers to anything occurring before the actual testing of a sample (complemented by “analytical” and “postanalytical”). Because an estimated half to two-thirds of errors affecting laboratory test results occur in the preanalytical phase,¹⁰ it is important for the clinician to understand the many things that can go wrong even before testing starts.

One of the first questions to ask is whether the right test was ordered for the right patient at the right time. For example, a serum free cortisol drawn at 4 PM on a patient with suspected adrenal insufficiency has a high probability of being uninterpretable, both because of the odds of a noninformative low value (could easily be a normal finding) and because normative data using free cortisol is much more limited than that for total cortisol (particularly in pediatrics). This might be marginally more useful for a patient with suspected Cushing syndrome/disease, but even then better testing approaches exist. For some tests, there is no technical/physiological reason that an afternoon sample cannot be used—except that, if all normative data available are based on fasting morning samples or first morning urine voids, then interpretation will be that much more difficult.

The right test issue is particularly important for pediatric endocrinologists, who fortunately are usually well trained to seek out assays (at least for the most commonly used core tests) that most accurately answer their clinical questions. The issues surrounding accuracy of testosterone or estradiol assays in the low ranges typical for children has been well known by subspecialists for decades, yet to date, there is little or nothing in the U.S. Food and Drug Administration guidance or the College of American Pathologists checklists (used to assess laboratory quality) to discourage the use of testosterone immunoassays that do not involve extraction and chromatography steps (see Methodology section) to ensure accuracy of results in the lower ranges typically seen in children (note: this also applies to measurement of testosterone in adult women, or estradiol in men, so it is not a uniquely pediatric concern). A clinician must know enough about the laboratory tests ordered to know when to ask for something different than the standard offering on a laboratory form, and knowing the right test to order may not always involve asking for the gold standard version of a test; for example, when

screening a basically healthy obese patient for thyroid dysfunction, measuring a free T4 by equilibrium dialysis may be overkill, when the faster, more readily available, and likely much cheaper nondialysis free T4 may suffice (assuming that the endocrinologist knows the limitations of this test).

Was the correct sample type/collection tube type used? For many analytes, there are significant differences in serum versus plasma values, or between EDTA versus sodium or lithium heparin plasma values. A serum sample inadvertently sent for measurement of plasma renin activity (a surprisingly common occurrence) will show apparently suppressed values (one can easily test for this possibility by asking the laboratory to check the calcium level in the sample, which should be low in the proper EDTA plasma sample). Another very common issue is the use of serum separator (SST) tubes, which may cause interferences or affect measured levels of some steroids (e.g., estradiol and testosterone),¹¹ fat-soluble vitamins (vitamin A and vitamin D metabolites), and hydrophobic drugs. Because SST tubes are much more convenient for collection purposes (less waiting time for clotting of the sample, and much less labor involved in separating the serum from the cell mass), they tend to be the “default” tube type for serum collection; therefore those collecting the sample must pay close attention to specimen requirements when the tube can potentially affect test accuracy.

Were there factors during the sample collection process that could affect the results? Examples include hemolysis from a difficult blood draw (releasing insulin-degrading enzyme from red cells) or contamination of an antecubital puncture site by topical testosterone (potentially raising testosterone levels to many hundreds or even thousands of ng/dL). Another example would be elevation of free T4 by equilibrium dialysis results when samples are drawn through a heparinized line; heparin stimulates lipoprotein lipase to degrade triglycerides into NEFA + glycerol, with the NEFA displacing T4 from TBG in the sample tube.

Were there any issues in the processing, storage, and transport of samples after collection? For example, serum phosphoethanolamine (PEA) levels can be increased 2.7-fold in samples where the serum remains in contact with blood cells for 6 hours, instead of being separated within an hour; PEA levels can drop by 80% if properly separated serum is allowed to remain at room temperature for 24 hours.¹² Serum potassium increases dramatically when whole blood samples are refrigerated for as short a time as 6 hours before being spun and processed (Fig. 4.19), as compared with samples left at room temperature for the same period of time.

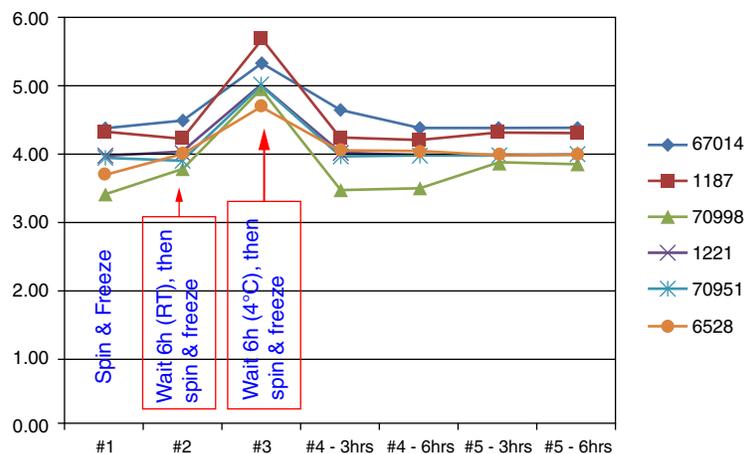

Fig. 4.19 Effect of refrigeration on release of potassium from intact red blood cells into serum. Six healthy volunteers had blood drawn into plain red top (no additives) tubes, with one aliquot (#1) centrifuged immediately and the serum frozen right away. Aliquot #2 was allowed to stand for 6 hours at room temperature (20° C) before centrifugation and frozen storage of serum. Aliquot #3 was placed in the refrigerator (4° C) for 6 hours before centrifugation/serum storage. All subjects showed a significantly higher serum potassium in aliquot #3. (Data from Quest Diagnostics Nichols Institute, San Juan Capistrano.)

Is there any chance of a sample switch/mix-up anywhere along the process from collection to reporting of a result? The implications of such an event on test accuracy are obvious.

Potential Confounders in Immunoassays

Sandwich immunometric assays are potentially vulnerable to what has been termed the *hook* or *prozone* effect that can lead to falsely normal or low values in the presence of large amounts of the analyte (Fig. 4.20). In general, as analyte concentration increases, more antibody-analyte-antibody sandwiches are formed, leading to more signal detected. At extremely high analyte concentrations, however, it is possible for both capture and detection antibodies to be saturated with analyte before formation of a sandwich complex, leading to the detection antibody being washed away and the low signal being misinterpreted as a low concentration of analyte. This phenomenon is not seen with competitive immunoassays. To minimize the chances of a hook effect, most immunoassays have now modified their methods as follows: analyte is allowed to bind to capture antibody, a thorough wash step removes excess unbound analyte, and only then is the detection antibody added. In the now extremely rare situation where a hook effect is still suspected, serial dilutions of the sample may be performed to see if the

apparent concentration of the analyte actually rises with increasing sample dilution.

There is some inconsistency in the literature around the terms *heterophilic antibody* and *human antianimal antibody* (HAAA) or *human antimouse antibody* (HAMA). Some authors use these terms interchangeably; others reserve the term *heterophilic* for low-affinity antibodies that spontaneously arise against multiple, poorly defined antigens and use HAMA or HAAA only for those patients who develop specific high-affinity antibodies because of treatment with a murine monoclonal antibody or because of recurrent exposure to a particular animal species (e.g., scratches endured by a rabbit handler). Regardless of the term used, any given patient may have antibodies present that bind to and interfere with animal (mouse monoclonal; rabbit, goat, or donkey polyclonal) antibodies used in a particular immunoassay,¹³ even without previous exposure to that particular animal. These antibodies can bridge the capture and detection antibodies in an immunoassay, as shown in Fig. 4.21 (left panel), creating a sandwich and a high signal (false elevation) even in the absence of analyte. Alternatively, they could attach at the binding site of the capture antibody and prevent binding of the analyte (Fig. 4.21, right panel), eliminating formation of the sandwich, and causing a falsely low value. Competitive immunoassays are less often affected, although

Fig. 4.20 Hook (prozone) effect leading to falsely low results. Extremely high analyte concentration leads to occupancy of all binding sites without creating the assay “sandwich” configuration. Signal antibody is washed away and the low signal is interpreted as a low concentration of analytes (*dotted line*). Dilution of sample may lead to increasing signal and an apparent increase in the measured analyte concentration.

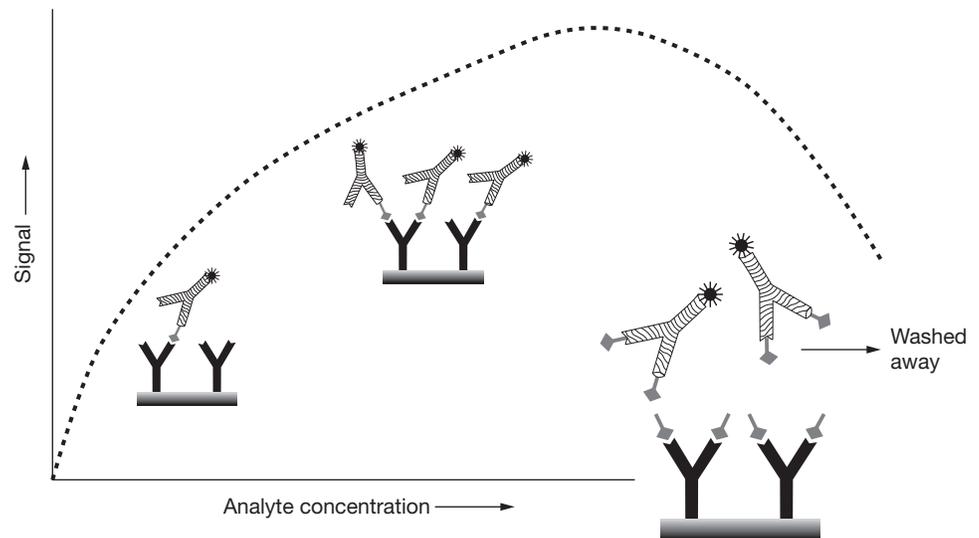

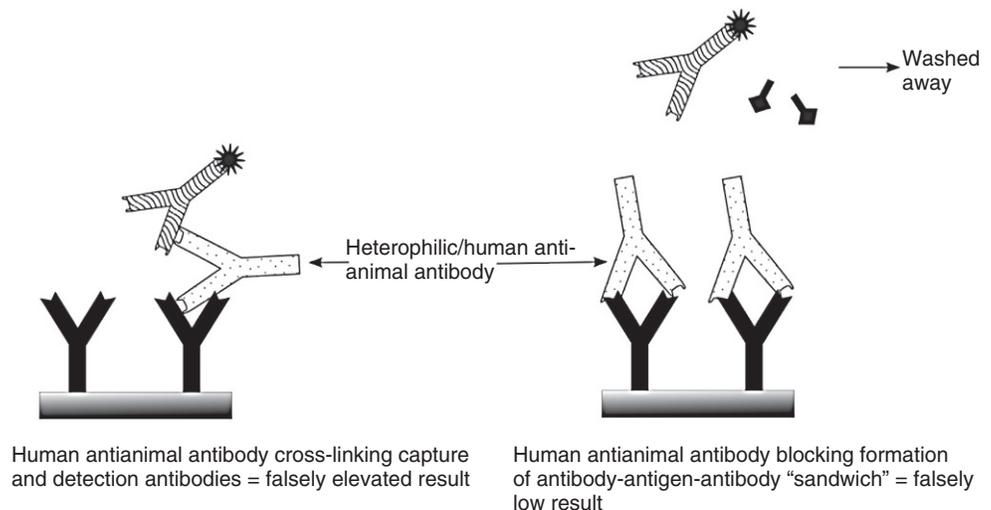

Fig. 4.21 Mechanism of immunoassay interference by heterophilic or human antianimal antibodies. See text for details.

they may show falsely high values if the interfering antibody outcompetes the assay antibody for tracer, or falsely low values if they bind preferentially to the analyte over the tracer.

When a heterophilic/HAAA/HAMA effect is suspected, the sample should be assayed on a different immunoassay platform because the interference is often specific for one manufacturer's assay but not another's. Only rarely¹⁴ does a heterophilic antibody interference affect multiple assays or different platforms. Such a maneuver is often the quickest to accomplish, but the sending laboratory must ensure that the second laboratory is truly using a different platform. Another option is to use heterophilic antibody blocking agents, which are a mixture of animal immunoglobulin fragments or other proprietary agents that soak up the interfering antibodies. A disadvantage of this approach for pediatrics is that a significantly larger volume of sample is required to assay both with and without use of the blocking agent. A third, more labor-intensive option is to assay the sample on serial dilutions, as those showing antibody interference effects tend not to show linear responses on dilution. Of note, the last option also requires previous proof (validation) that the assay continues to show a linear response on diluted samples, proof that is not always available.

Specific autoantibody interferences appear to be rare compared with the heterophilic/HAAA/HAMA interferences described in the previous section, with the notable exception of Tg antibody (TgAb) in patients with thyroid cancer. TgAb is present in about 20% to 25% of thyroid cancer patients and leads to false depression of Tg levels by immunometric assay (e.g., Tg-ICMA). In addition, different Tg antibody assays may report discordant (negative vs. positive) results in some cases. Although a competitive assay, such as Tg-RIA, is less often affected by TgAb interference than is the Tg-ICMA, if the autoantibody is of sufficiently high affinity to outcompete the assay antibody, a Tg-RIA may show false elevation in the presence of such TgAb.¹⁵ Overall, any Tg immunoassay result, whether performed by Tg-ICMA or Tg-RIA, must be viewed as potentially affected in a patient with TgAb present (and even possibly in patients whose TgAb is reportedly negative). Helpful proxies for Tg include following TgAb titer, which should fall over time in patients without cancer recurrence.¹⁶ Measurement of Tg concentration by LCMS is the method of choice for profiling Tg levels for thyroid cancer monitoring in the presence of anti-Tg antibodies. Imaging studies may also help assess the probability of recurrence. Although rare, autoantibodies may be of sufficiently high affinity to affect both competitive and immunometric assays alike. Consequently, they would be less likely to show differences when assayed on different platforms and are not affected by heterophilic antibody blocking agents. In these scenarios, diagnosis may require

measurement of specific autoantibody (e.g., a parathyroid hormone [PTH] antibody assay in someone with a discordantly high or low PTH level).

STANDARDIZATION/HARMONIZATION: CLINICALLY RELEVANT AND CRUCIAL

A frustrating reality is that different versions of a test with the same name more often than not give different results, sometimes surprisingly so. Sometimes the issue is methodological, related to differences in sample purity and analytical specificity, as we saw with testosterone immunoassays run directly on serum, versus mass spectrometric measurement of testosterone after extraction and chromatography. In other cases, it may relate to the complex biology of an analyte, such as human chorionic gonadotropin hormone (hCG), with at least seven different molecular isoforms (intact, nicked, hyperglycosylated, free subunits, beta core fragments, and more); the result of an hCG immunoassay will therefore depend upon what epitopes the assay antibodies recognize and what reaction conditions were used. In some cases, differences appear because of assay design: for example, an assay designed specifically to detect only full-length osteocalcin will be much more vulnerable to differences in processing, handling, and storage, as opposed to an assay targeting the more stable midmolecule region.

A premiere example of assay differences relevant to pediatric endocrinology is that of GH. Many of the early studies performed to establish diagnostic cutoffs for GHD used a competitive immunoassay with polyclonal antibodies. When a new monoclonal antibody-based immunometric (IRMA) GH assay was introduced by Hybritech, GH results were typically 60% of those seen in the original assay, leading to more patients diagnosed with GHD if the same diagnostic cutoffs were used. Although it was assumed that the lower values were caused by the higher analytical specificity of an immunometric format and monoclonal antibodies, this was not the entire answer, as another immunometric/monoclonal antibody GH assay (Wellcome IRMA) actually gave results about 30% higher than the original competitive/polyclonal GH assay,¹⁷ showing that other factors (e.g., use of animal versus human serum in the assay diluents, ionic strength of assay solutions, temperature and time of incubation) made a significant difference as well.

Another factor that contributes (even today) to GH assay differences is varying detection of alternate growth hormone isoforms.¹⁸ Although 22-kDa GH is the dominant isoform (90% of total GH), the other 10% includes 20-kDa GH and a small amount of other forms. To put this into perspective schematically, imagine that you are asked to count the number of stars in the box shown in Fig. 4.22. Unless everyone agrees on

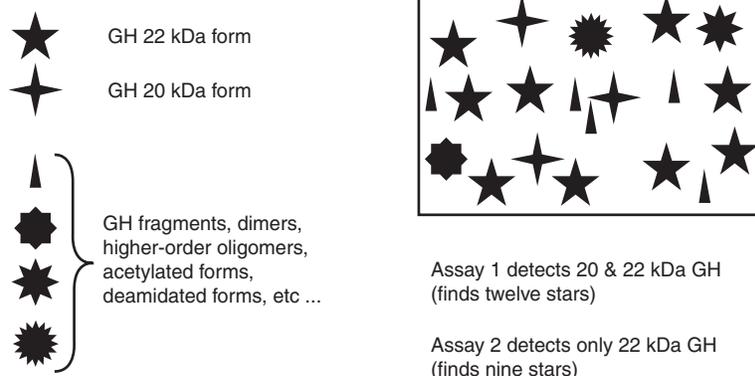

Fig. 4.22 How many stars are in the box? This shows the futility of quantitation if definitions are not first agreed upon.

the definition of a star (5-pointed only?) before counting, different observers may get different totals. The take-home lesson is that endocrinologists as a group need to define exactly what they want to measure, if there is any hope for getting assays to agree more closely in the future.

To convert a laboratory assay measurement (e.g., counts per minute, relative light units, or peak heights) to a quantifiable amount of hormone requires use of calibrators—known concentrations of the hormone being measured that can be measured along with patient samples. But how can we make certain that calibrators are similar among different assays?

The best available solution at present is to provide laboratories and diagnostic kit/instrument manufacturers with well-characterized reference materials. These reference materials should themselves be traceable back to a standard reference material (SRM) or international reference preparation (IRP), which is ideally as pure as possible and whose concentration is as exact as possible. The SRMs are often provided by organizations, such as the National Institute of Standards and Technology or the World Health Organization (WHO); SRMs from the WHO are often called *international standards* (ISs).

Several years ago, almost all GH assays switched to calibrators composed of pure recombinant 22-kDa GH (WHO International Reference Preparation 98/574). It was hoped that this would bring assays more closely in agreement. This did help somewhat, but it is not a definitive solution. For example, looking at three common GH assays all using IRP 98/574 as the reference standard for assay calibrators, there are still substantial differences. The GH assay manufactured by Siemens on the Immulite platform has varying degrees (40%–77%) of cross-reactivity with 20-kDa GH. The Beckman Coulter GH assay on the Access platform has essentially no 20-kDa cross-reactivity and gives results about 76% of those seen on the Immulite. The Roche Elecsys assay, with substantial cross-reactivity with 20-kDa GH runs about 11% higher than the Immulite.¹⁹

If GH assays do not agree, how can we establish universal diagnostic thresholds? One European group has proposed different platform-specific GH assay cutoffs (e.g., peak GH 7.77 ng/mL for the Immulite and 5.15 ng/mL for the Beckman Coulter Access/DxI platform) for GH stimulation testing, an approach that has not yet gained wide traction.²⁰

An alternative to assay-specific cutoffs is to standardize or harmonize the different assays:

- Standardization means getting assays to agree by clearly defining the analyte to be measured (e.g., 22 kDa GH rather than all GH isoforms), having a well-defined pure reference preparation (e.g., IRP 98/574), and a gold standard method to which all other methods can be compared. Only a handful of assays can meet these criteria.²¹
- Harmonization is a less stringent approach to improve assay agreement by choosing arbitrary reference materials (even if not pure and well defined) and designating a specific assay as the reference standard, even if not truly a gold standard method. Luteinizing hormone would be a good candidate for harmonization, but not standardization, given that it has dozens of different isoforms (differing by degree of sialylation, glycosylation, or sulfation),²² no pure reference preparation available, and no gold standard assay. Typically for a harmonization effort, a central laboratory prepares pools of sample with a defined value and distributes aliquots of this pool to other laboratories, who can then adjust their calibration to match these values.

There are active working groups within the international clinical chemistry community seeking to standardize assays for insulin (working with the American Diabetes Association), vitamin D metabolites, free T₄/TSH, and some bone markers

(C-telopeptide and procollagen type 1 N-terminal propeptide). The difficulty in accomplishing these tasks is illustrated by the Insulin Standardization Workgroup's greater than 15 years of working on this project²³ (badly needed given that insulin assays can vary easily by up to twofold at the high end and perhaps much more at the low end).²⁴ Current standardization and harmonization efforts can also be tracked at the website of the International Consortium for Harmonization of Clinical Laboratory Results (www.harmonization.net). Currently listed are:

- Alkaline phosphatase, alpha fetoprotein, C-peptide, ionized calcium, cortisol, fructosamine, glucose, GH, hemoglobin A1c, hCG, insulin, lipoproteins/triglycerides, magnesium, PTH, phosphate, T₄, free T₄, and free T₃.

There are also less-formal initiatives for harmonization of common steroid assays (testosterone and estradiol). Pediatric endocrinologists with clinical or research interests in any particular analyte may want to monitor the progress and decision-making of these working groups.

REFERENCE INTERVALS

Reference interval (RI) is the term preferred by laboratory professionals for what is more commonly referred to as a *reference range*, preferred because of the fact that range is formally defined in statistics as a single number (serum sodium may have an RI of 135–145 mmol/L, but the range is 10 mmol/L). Whatever terminology is chosen (as long as one does not use the term *normal range*!), the importance of this concept is obvious for the practice of pediatric endocrinology. What may not be as obvious is how surprisingly fragile are many of the existing RIs for frequently used tests, many of which are based on small numbers of subjects, older/different methodologies, or literature references that may or may not be applicable to the test in question. Also not apparent to most, are the number of subjective decisions that must be made when planning RI studies, analyzing the data, and deciding on the final RI citations. While good clinical judgment can compensate for the current limitations of RIs, it is critical that the pediatric endocrinology community participate with laboratorians, statisticians, and even regulators to ensure that the RI situation constantly improves, rather than worsens.

As a quick review, the first (and likely most obvious) point about RIs is that they apply to a reference sample group (chosen from what is hopefully an accurately defined reference population) and not necessarily to the patient in question. An obvious example would be a severely hypoglycemic individual whose insulin value of 9 uIU/mL is technically within the RI of less than 23 uIU/mL but is abnormal in that clinical context. The RI applies only to healthy fasting (and presumably normoglycemic) subjects, not hypoglycemic patients. A more difficult example would be applying a TSH RI generated from subjects of "normal" weight to obese children referred to the endocrine clinic, who clearly have a higher (than the reference sample group) incidence of TSH values above the upper RI limit. Most of those with slightly high TSH values will have normal free T₄ results and negative thyroid antibodies.

This leads to the importance of establishing clinical decision limits beyond the standard RIs provided on laboratory reports. Using the example earlier of TSH in obese children, some pediatric endocrinologists through experience may decide that obese children with TSH values only slightly above the upper RI cutoff should not be referred or have additional laboratory testing, particularly if growth and development will be followed regularly. However, subspecialists would likely agree that a child with a TSH above 10 mIU/L deserves formal evaluation and additional laboratory testing.

The generation of RIs is simple in theory:

- Obtain results from a random sample of healthy individuals drawn from a representative population.
- Exclude statistical outliers.
- Stratify and subgroup by appropriate dimensions (e.g., age, sex) as indicated.
- Analyze the data and generate a reference interval citation; on laboratory reports, flag anything that falls outside of the reference interval.

In practice, the choice of a representative reference population is surprisingly difficult/subjective. When deciding upon exclusion criteria for a testosterone RI, should we exclude slightly heavy Hispanic girls, who will have somewhat higher testosterone levels than, say, Asian girls with average body mass index? Should we insist that subjects participating in an RI study for C-peptide and insulin responses to an oral glucose tolerance test (OGTT) all be carbohydrate-loaded for the days before the study—when in clinical practice almost no one has this preparation before an OGTT? Ultimately, the investigators will have to make arbitrary decisions that will affect the RI citation.

A similar issue arises when deciding what represents a statistical outlier (and whether or not to exclude these). Fig. 4.23 shows the results of an osteocalcin and bone-specific alkaline RI study, where the point circled in red represents the same individual. This point is clearly a statistical outlier but represents a healthy individual who just happened to be at his peak growth velocity when the study was conducted. If we exclude this outlier, will we end up flagging as high many healthy teens at their peak growth spurts? If we include this point, will the RI be too wide?

A valid reply might be that the RI study is better stratified by Tanner stage of puberty, rather than age, given the wide variability of the age of pubertal onset. There are caveats, of course. First of all, getting accurately Tanner-staged subjects is difficult in practice, because of the frequent reluctance of subjects, parents, and Institutional Review Boards to allow breast palpation or external genital examinations of otherwise healthy children. Self-assessment of pubertal staging can be performed, but it is well documented to result in some significant inaccuracies.²⁴ Second of all, even when Tanner staging can be conducted by well-trained investigators, there are certain stages that can be surprisingly difficult to distinguish (e.g., male genital stage II vs. stage III), leading to some investigators preferring to use testicular volume or length for evaluating sexual maturity in boys, even though testicular size is not part of the original Tanner staging system. Even Tanner staging of breast development can be difficult at times; although the original Tanner staging was based solely on inspection, it is clear that in overweight

girls the examiner must actually palpate the breast in search of glandular tissue to distinguish true pubertal development from increased breast size because of fat accumulation. Breast Tanner stage II can be difficult to define, and there may even be confusion between Tanner III development in a large-breasted individual versus Tanner V development in a young woman with smaller breasts (although breast papillae/nipple diameter >1 cm might help more clearly define Tanner V development). Some women may always retain the secondary mound of the nipple and areola that defines Tanner IV, and thus never officially reach Tanner V breast staging.

Additional issues with Tanner staging include discordance of breast/genital development (driven by pituitary-gonadal activation) with pubic hair development (driven by both gonadal and adrenal activation). It is not uncommon for a girl to have Tanner III pubic hair but only Tanner II breast development. Ideally, we should be able to define the subject as “B II, PH III,” but to date, such a system has not been used for Tanner-based RIs. The pediatric endocrinology and clinical chemistry communities may want to come to an agreement that some hormones (e.g., estradiol) should be based on Tanner breast stage, whereas others (e.g., dehydroepiandrosterone [DHEAS]) should be based primarily on Tanner pubic hair staging.

One last point about Tanner stage stratification is that some stages are actually not at all homogeneous. An infant, toddler, preschooler, and a 7-year-old child may all be Tanner I by breast/genital/pubertal hair development, and yet have very different hormonal profiles. It is clear, for example, that adrenal activation (adrenarche) and rising DHEAS start even before age 6 years, at least 3 to 4 years before the appearance of pubic hair. Therefore a study that included Tanner I children age 1 to 7 years would have a much lower average DHEAS than a study that only used Tanner I children age 5 to 7 years. At present, there is no standardized definition of which subjects should be included in a Tanner I subgroup.

Even the much simpler stratification by age requires decision-making that can affect the final RI citation. A typical approach to generating age-related RIs is to take observed results, such as those shown in Fig. 4.24, divide them into age subgroups (e.g., 1- or 2-year-wide bins) that contain reasonably similar values and calculate individual RIs for each subgroup. For analytes that change rapidly with age, however, this tends to result in small subgroups that show significant variability from sampling error alone because of the small number.

An extreme hypothetical example is shown in Fig. 4.25. Here, the values vary continuously with age, and subgrouping these data would either result in untenably low n if the subgroups were small; subgrouping by a wider range of ages would

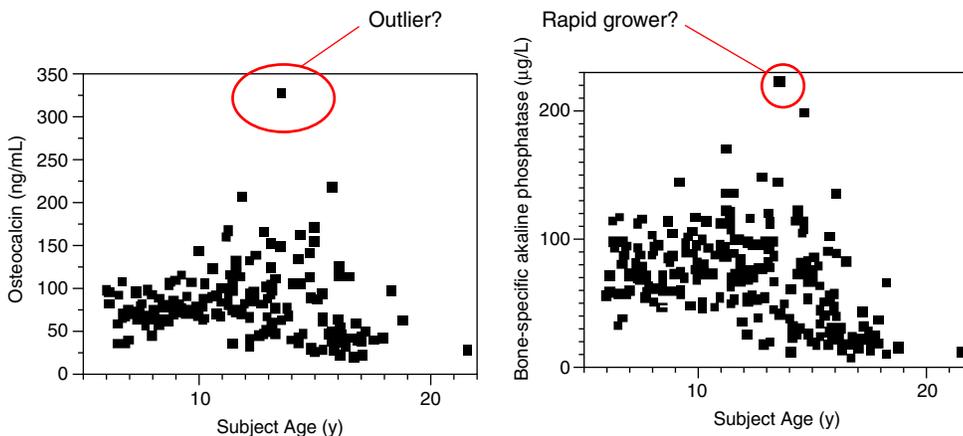

Fig. 4.23 Reference interval study of two bone formation markers (osteocalcin and bone-specific alkaline phosphatase). The same subject had results on both assays that were statistical outliers (circled in red), but clinical history revealed that this individual was at his peak growth velocity when the sample was drawn.

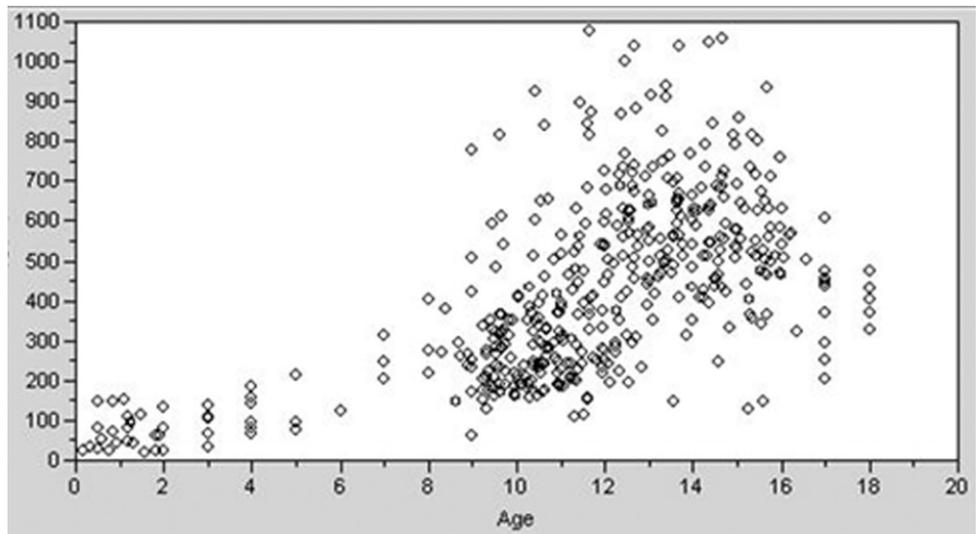

Fig. 4.24 Reference interval study for a hormone (insulin-like growth factor 1 [IGF-I]), which changes rapidly during the pediatric life cycle.

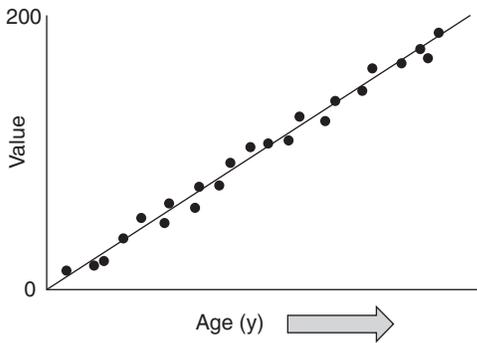

Fig. 4.25 Hypothetical example of an analyte that changes rapidly by age, demonstrating the need to do curve-fitting rather than dividing all of the data into tiny (e.g., 1 year) age subgroups.

lead to RIs that would overestimate values for the young end of the subgroup and underestimate values for those at the older end. In this case, it is obvious that a far better approach would be to fit a curve (in this case a straight line) to the data and use this to produce the RI based on age.

A more realistic example of this curve-fitting approach is shown in Fig. 4.26. Not only does this result in smoother, more physiological representations of the changes in value related to age, but it allows calculation of SD, or z-scores. Note that the z-score curves are not symmetrical about the mean value (the distance between the mean and +2 SD is more than the distance between the mean and -2 SD), which reflects the reality that most endocrine hormone values do not follow a normal/Gaussian (bell-shaped curve) distribution. Thus RI tables that provide a mean value and a single value for the SD may be misleading.

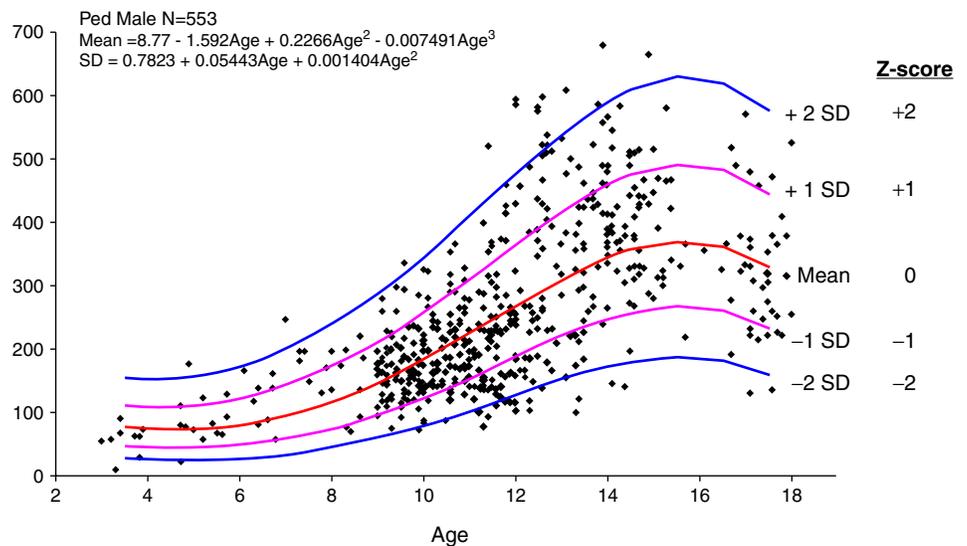

Fig. 4.26 Example of insulin-like growth factor 1 (IGF-I) z-scores derived after Box-Cox data transformation and curve-fitting.

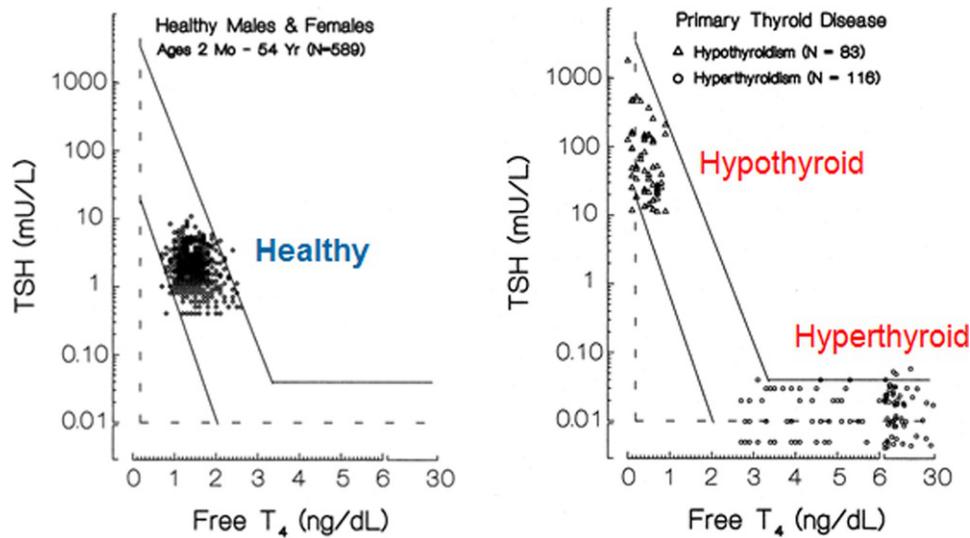

Fig. 4.27 Bivariate reference interval presentation: thyroid-stimulating hormone (TSH) versus free T₄ by equilibrium dialysis, in patients with an intact hypothalamic-pituitary axis.

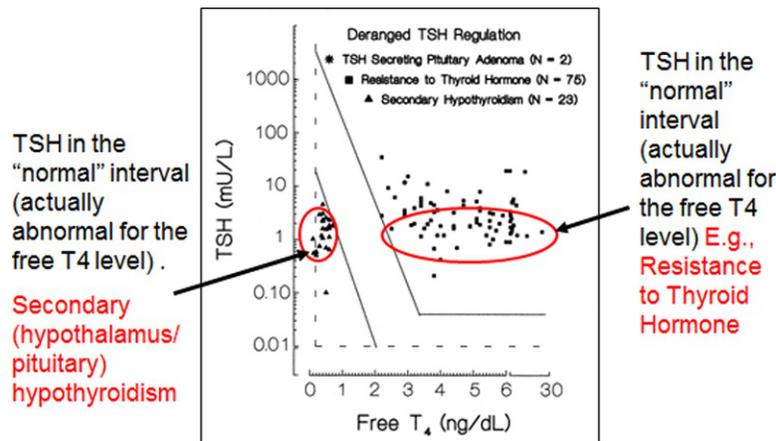

Fig. 4.28 Thyroid-stimulating hormone (TSH) versus free T₄ by equilibrium dialysis, in patients with secondary/tertiary hypothyroidism or resistance to thyroid hormone.

Another underused aid to improve understanding of laboratory results is to move from single (univariate) RIs to a bivariate presentation. For example, one can look at plots of TSH versus free T₄ for healthy individuals and for various disease conditions (Fig. 4.27). For any diseases that affect the thyroid but leave the hypothalamic-pituitary axis intact, the points will generally fall within the channel defined by the solid lines.

Diseases that affect the hypothalamic-pituitary axis will result in points falling outside of this channel (Fig. 4.28). Note that all of the points circled in red have TSH values within the RI, but when analyzed relative to the free T₄ level, these TSH values are inappropriately normal.

SUMMARY

Although it is not necessary for a pediatric endocrinologist to master all of the aspects of laboratory medicine mentioned in this chapter, having at least basic knowledge of the topics covered will help one make better test-ordering decisions and avoid interpretation errors. Knowing some of the “language of the lab” allows for better discussions with laboratory experts and makes it much easier to understand relevant publications

from the clinical chemistry community. Learning more about the statistics behind diagnostic decision-making, understanding how tests are validated for quality purposes, and understanding the various methods available (including the limitations and possible sources of error) are valuable for specialists at all levels of experience. An additional goal of this chapter has been to reveal some of the uncertainties involved with laboratory testing, to assuage some of the frustration experienced when one sees widely different results for the same test done at different laboratories, or to realize the current gaps in RI information. Hopefully, the pediatric endocrinology community will participate with the laboratory community to help harmonize testing and fill critical reference interval gaps. Most importantly, connecting with laboratory experts for consults involving diagnostic testing will help clinical subspecialists make the best decisions for their pediatric endocrinology patients.

OVERVIEW

Pregnancy is a complex physiological state consisting of a symbiotic relationship between two genetically distinct, but related, individuals: the mother and the fetus. The success of pregnancy requires dramatic alterations of maternal physiology to accept, protect, house, and nurture the fetal allograft. A successful pregnancy involves implantation of the developing embryo into the endometrium; its avoidance of immunological rejection by the maternal immune system; adaptation of the maternal uterus to sustain a pregnancy; and specific changes in maternal physiology to meet the nutritional, metabolic, and physical needs of the growing conceptus—along with the proper timing of parturition, so that birth occurs when the fetus is mature enough to survive outside the uterus and the mother is able to nurture her newborn child. Hormonal interactions between the fetal and maternal compartments control these processes. A unique and extremely important endocrine organ of pregnancy is the placenta. The hemochorial anatomy of the human placenta allows direct access of the fetal syncytiotrophoblast to the maternal circulation for hormonal secretion. Placental hormones flood the maternal systems and act on maternal target cells to adjust maternal physiology in favor of maintaining pregnancy and meeting fetal metabolic needs. Through this endocrine relationship, the fetus and mother maintain homeostasis and allows the fetus necessary time for growth and functional development. Defects in placentation, placental function, and aberrations in placental hormone production cause maternal and newborn pathophysiology, such as life-threatening preeclampsia and fetal growth restriction. The end of pregnancy usually occurs through the process of parturition and, in most cases, at a time, referred to as *term*, when the

fetus is sufficiently mature to survive as a neonate. Term for human gestation is between the 37th and 42nd completed week of gestation (measured from the last menstrual period). Preterm birth, defined as less than 37 completed weeks of gestation, is a major worldwide socioeconomic problem that accounts for the majority of neonatal morbidity and mortality. The hormonal control of parturition—such that it occurs at term—is therefore a major determinant on neonatal wellness and the success of pregnancy. This chapter addresses current understanding of the endocrinology of pregnancy and parturition from the perspective of fetal/placental wellness and the process and timing of parturition, including recent advances in unraveling the genetics of human gestation length and birth timing. The discussion will be prefaced by a contextual overview of the evolutionary biology of human pregnancy and birth timing.

Evolution of Human Pregnancy and Birth

Pregnancy is both a personal event between mother and baby and a sociological and public health concern, as is evidenced by high infant and maternal mortality rates, even in developed countries like the United States. Although scientific advances have allowed us to learn about potential causes of preterm birth and pregnancy complications, it is critical to look back, through an evolutionary lens, to more fully understand the process of pregnancy and birth.

Evolution optimizes reproductive fitness across generations—maximizing transmission of genes to the next generation. Pregnancy and parturition are key events in the reproduction of viviparous species and, as such, would have been subjected to strong selective pressure through evolution. Advances in genetic technologies allow in-depth examination of the influence of evolutionary dynamics on pregnancy—including the impact of genetics and hormones on conception, pregnancy maintenance, and triggers for parturition. Ultimately, genetic makeup reflects natural selection and, as such, evolutionary adaptations may contribute to extant pregnancy complications, because the current genetic makeup of the mother, or even the baby, may not be ideal for current environmental conditions. This mismatch may be the reason for diseases of pregnancy, such as preeclampsia and gestational diabetes—and, in fact, likely influences health throughout the life span.¹

“Nothing in biology makes sense except in light of evolution,” said geneticist and evolutionary biologist Theodosius Dobzhansky.² This concept is certainly reflected in the comparative biology of pregnancy and parturition among viviparous species. The common theme among viviparous species is that the fetal development requires a minimum gestation time and a supply of nutrients for the fetus to achieve functional maturity needed to survive as a neonate. Fetal organ systems (especially the pulmonary, renal, and gastrointestinal) and neuroendocrine axes (especially the hypothalamic-pituitary-adrenal [HPA] and thyroid systems) must be sufficiently developed at birth for the newborn to achieve and maintain homeostasis. Similarly, maternal physiology, which has been modified to provision pregnancy, must be prepared to nurture and protect the

newborn. Certain processes are common (e.g., the requirement for progesterone to establish and maintain pregnancy; the promotion of fetal organ maturation by glucocorticoids) to all species, but subtle differences exist that relate to specific selective pressures on pregnancy-related traits that improved reproductive efficiency against the backdrop of general habitus, environmental niche, and overall reproductive strategy.

Viewing conception through an evolutionary lens begs the question: *Why doesn't the mother's immune system attack the fetus?* The "inflammation paradox" hypothesis posits that inflammation may be a necessary process that evolved to aid implantation, rather than attack the fetus. This is just one part of the equilibrium that must be established in a healthy pregnancy between the needs of the mother and the needs of the fetus. This concept has been described as maternal-fetal "cross-talk," "tug-of-war," or a "modulation" of gene regulation or cell networks. This often-conflicting cadence between mother and fetus continues throughout pregnancy, highlighting nutritional needs and hormonal fluctuations that must remain balanced for a successful pregnancy to carry to term. Recent studies of individual cells at the maternal-fetal interface have identified regulatory interactions at the cell level between the mother and fetus that prevent immune cell attack of the conceptus.³ Through an evolutionary framework, preeclampsia, for example, could be the result of shallow trophoblast invasion and inadequate spiral artery remodeling—forcing the fetus to increase maternal blood flow to the placenta by increasing maternal peripheral vascular resistance and providing greater blood flow to the fetal interface.

Another "obstetric dilemma" is conferred by the combined traits of encephalization: the increase in brain mass relative to body mass that is unique to hominid lineages, and obligate bipedalism. Bipedalism evolved between 3 to 5 million years ago, leading to an increase in hominid brain size, estimated at about 1 million years ago. The size of the human brain has remained relatively constant for at least the last 100,000 years.⁴ Obligate bipedalism required changes in the pelvic anatomy that decreased the size of the obstetric outlet. This would have limited the extent of intrauterine encephalization and required that parturition occur before the fetal head becomes larger than the pelvic outlet. This trait appears to be unique among human lineages. No other primates face this level of cephalopelvic disproportion, as they have pelvic openings that are larger than the fetal head diameter. Women, however, must pass a large-headed fetus through a relatively small pelvic opening. This means that the fetus cannot grow too large, or it risks death for the baby and the mother. Evolutionary selection of ancestral lineages must have been at work to develop a gestation length optimal for fetal development, especially lung maturity, before parturition. In addition, recent research has found regional and ancestral variability in the shape of birth canal. Strict evolutionary theory might surmise that the birth canal should be similarly shaped. Instead, this new work shows that other evolutionary forces, such as genetic drift, migration patterns, or even climatic adaptation also may have been at work. Study authors Lia Betti and Andrea Manica state that thoroughly understanding this has implications for obstetric practice in multiethnic societies.⁵

Rapid fetal brain growth requires substantial energy, and therefore traits that increase energy transfer from the mother to the fetus would have been favored. This may explain the production of placental lactogen and placenta growth hormone (GH) that promote maternal insulin resistance, providing more glucose for fetal consumption. However, traits that favored fetal brain growth would have conflicted with the problem of birthing a large-headed fetus through a relatively small outlet. This problem may have been solved by altering the parturition timing mechanism to shorten gestation thereby avoiding

the *obstetric dilemma*. Allometric analyses of neonatal brain size to body ratios across primate species, and the fact that human neonates are altricial (referred to as *secondary altriciality*), whereas other extant primates are precocial, support the hypothesis that gestation was shortened in modern-day hominids.⁶ This is a reasonable hypothesis that explains much of the unique characteristics of human pregnancy and parturition. As natural selection generally operates at the population level and over many generations, traits that increase reproductive efficiency of the population (such as encephalization; fetal neuroendocrine plasticity) and are beneficial over the long term, may impart costs to an individual, such as increased risk for preterm birth or cardiovascular disease over the short term.⁷

Consideration of these traits through an evolutionary lens expands our perspective of pregnancy complications, such as preeclampsia, fetal growth restriction, gestational diabetes, and preterm birth, and normal processes, such as the plasticity of fetal neuroendocrine development in response to environmental cues.

Establishment of Pregnancy

Under normal circumstances, implantation of a viable embryo into a receptive uterine endometrium establishes pregnancy. During the menstrual cycle, the ovarian steroid hormones, estradiol and progesterone, induce structural and functional changes in the endometrium essential for the establishment of pregnancy. During the luteal phase, the endometrium converts to a secretory phenotype in response primarily to progesterone produced by the corpus luteum (CL). The secretory endometrium is spongy and highly vascularized and has a glandular epithelium that secretes factors into the uterus that favors embryo survival. At the same time, epithelial cells in the endometrium produce chemokines, growth factors, and cell adhesion molecules that attract the embryo to specific docking sites for implantation and, in addition, increased vascularization of the endometrial stroma provides an optimal substrate for placentation.

After fertilization, the zygote undergoes an intrinsic program of cell division and differentiation that is not dependent on the hormonal milieu of the fallopian tube or the uterus. At around the fourth day after fertilization, the embryo is a solid cluster of cells encapsulated by the remnant of the oocyte zona pellucida. In the next 24 to 48 hours, as the embryo moves through the fallopian tube toward the uterus, it develops a fluid-filled cavity, the blastocoel, and is referred to as a *blastocyst*. The outer layer of blastocyst cells, known as the *trophoblast*, will give rise to the placenta and chorionic membrane. An inner cell mass of the blastocyst will produce the fetus, amnion, and mesenchymal and vascular components of the placenta. The human blastocyst enters the uterus at around the fifth day after fertilization and floats freely in the uterine cavity for 2 to 3 days. By this stage, the zona pellucida degenerates, leaving the nascent blastocyst embryo in an optimal condition to implant into the endometrium.

Embryo implantation into the endometrium has temporal and spatial limits within the receptive uterus.^{8–11} Physical interaction of the blastocyst with the endometrial epithelium occurs at dome-like structures known as *pinopodes* that express chemokines and cell adhesion molecules that attract the embryo and appear to be the preferred site for embryo adherence and subsequent implantation.^{12,13} Embryo adherence and implantation is most successful between days 21 and 24 of the menstrual cycle (~85% success rate), whereas implantation before or after this optimal window has a low (~11%) success rate.¹⁴ After day 24 to 25, the endometrial stroma undergoes morphologic and functional changes collectively referred to as *decidualization*, which is dependent on progesterone and occurs independently of conception and implantation.^{11,15,16} The decidualized endometrium, composed of large polyhedral

cells, containing high levels of glycogen and lipids that secrete a tough pericellular capsule, is hostile to implantation. Therefore successful implantation must occur before the establishment of the decidual barrier. In an infertile cycle, menstruation occurs to eliminate the nonreceptive decidualized endometrium. In the subsequent cycle, the endometrium then renews to a receptive state.

For implantation, trophoblast cells proliferate and secrete proteases that degrade the extracellular matrix between endometrial cells forming a path for the blastocyst to enter the uterine stroma. The invading trophoblast cells are referred to as *cytotrophoblasts* (CTBs) and form columns penetrating to the basal membrane beneath the decidual cells and into the myometrium. Eventually, the entire embryo embeds in the uterine stroma, anchored by CTB columns. Some extravillous CTBs invade into maternal spiral arterioles, displacing endothelial cells and smooth muscle tissue, and dilating the vessels to create a low-resistance arteriolar system. This system directs maternal blood into spaces, known as *lacunae*, between the invading columns of CTB cells. During this time, some CTBs fuse their plasma membranes to become a *syncytiotrophoblast*. This becomes the outer layer of the functional placenta. Eventually, the syncytiotrophoblast forms chorionic villi that are bathed in maternal blood within the lacunae.

The embryo is semiallogeneic with respect to the mother, and therefore its invasion into the endometrium represents a major breach of the maternal immune system. For successful pregnancy, the placental syncytiotrophoblast and CTBs at the maternal-fetal interface must avoid attack and destruction by activated maternal immune cells. To this end, the trophoblast cells produce an immunogenic camouflage in the form of human leukocyte antigen (HLA)-G that has reduced polymorphism; therefore maternal immune cells do not recognize it as foreign.^{17–19} CTBs also express multiple factors: Fas ligand that induces apoptosis in immune cells that carry Fas receptor,²⁰ early pregnancy factor,²¹ and the progesterone-induced blocking factor²² that blocks lytic natural killer (NK) cell activity and several antiinflammatory cytokines (such as transforming growth factor [TGF]- β , interleukin [IL]-10, IL-4).²³

For the establishment of pregnancy, menstruation that normally occurs during a nonfertile cycle must be prevented. This happens when the trophoblastic cells of the early embryo secrete chorionic gonadotropin (CG) that prevents CL regression and maintains its secretion of progesterone. In nonfertile cycles, the CL usually regresses at about the second week after ovulation, and the subsequent decline in progesterone leads to menstruation. Thus one of the first endocrine interactions between the conceptus and the mother involves early embryo signaling to promote intrauterine conditions that will allow implantation and the establishment of pregnancy via maintenance of CL progesterone secretion.

Endocrine Placenta: Structure and Function

The placenta fulfills a variety of essential functions during prenatal life. Its global role is to maintain a protected environment that facilitates optimal growth and development of the embryo and fetus. The human, hemochorial placenta includes a chorionic plate and chorionic villi. The chorionic villi consist of stem villi (types 1 to 3) either anchored to the decidua basalis or floating free. Type 3 villi branch out into intermediate and finally terminal villi.²⁴ The surface of the terminal villi is covered in CTB progenitor cells, derived from the trophoblast of the early blastocyst, and anchored to a basal lamina. The low oxygen environment of the early placenta protects organogenesis and favors CTB proliferation.²⁵ However, as development progresses, differentiation of these trophoblast progenitor cells produces different cell phenotypes.

CTBs differentiate into an invasive phenotype, and extravillous trophoblasts (EVTs) invade the uterine wall anchoring some chorionic villi to the decidua basalis entering the maternal blood vessels. These invading CTBs plug maternal arterioles maintaining the state of physiological hypoxia.²⁵ EVT cells continue to move further up maternal spiral arterioles, replacing maternal endothelial cells, remodeling, and increasing the diameter of the arterioles to accommodate the massive increase in blood supply required for fetal growth. Furthermore, several maternal cell types maintain the balance between inflammation and tolerance in the decidua. In particular, innate lymphoid cells, such as NK cells, interact with trophoblasts, stromal cells, and neutrophils to play a key role in the induction and maintenance of pregnancy. Decidual NKs represent 50% to 70% of infiltrating lymphocytes during the first trimester, but numbers diminish throughout gestation. Decidual NK cells are involved in early remodeling of the maternal spiral arteries before trophoblast invasion, as well as secreting chemotactic factors critical for EVT migration and invasion (such as IL-8, CXCL10, and IL-6). An association exists between impaired trophoblast chemotaxis and improper spiral artery remodeling and abnormal placentation. Abnormal decidual NK (dNK) function also may lead to a loss of control of trophoblast invasion.

During this time, some CTBs fuse their plasma membranes to become a single multinucleated cell known as the *syncytiotrophoblast*, which becomes the outer layer of the functional placenta. By 10 to 12 weeks of gestation, the CTB plugs are broken down and maternal blood reaches the intervillous spaces (lacunae), resulting in a change in oxygen tension in the placenta and the syncytiotrophoblast comes into direct contact with maternal blood in the lacunae. Remodeling of the placental villi and their associated underlying vasculature, which connects to the umbilical cord, occurs throughout gestation and can be responsive to maternal signals/environmental exposures impacting placental function, fetal growth, and development, and potentially, disease development later in childhood and adulthood (a process known as *fetal programming*).

The placental syncytiotrophoblast facilitates oxygen and nutrient transfer from the maternal circulation to the fetus and disposes of fetal waste products. It synthesizes and secretes hormones, growth factors, cytokines, and other bioactive molecules mainly into the maternal compartment. It also metabolizes maternal hormones (such as glucocorticoid and insulin) to prevent fetal exposure, and thus, separates components of the maternal and fetal endocrine systems. Importantly, the hemochorial arrangement allows hormones produced by the syncytiotrophoblast to directly access the maternal circulation. In contrast, the syncytiotrophoblast prevents most maternal hormones from entering the fetal compartment. Most hormones the placenta produces are identical, or close structural and functional homologues, of existing maternal hormones. As such, they interact with cognate receptors on maternal cells. Consequently, placental hormones that are secreted in relatively large amounts to achieve high levels (compared with levels in the nonpregnant women) in the maternal circulation override maternal counterparts and have profound effects on maternal physiology. Placental hormones include members of the prolactin and GH family, steroid hormones, and neuroactive hormones.

Prolactin-Growth Hormone Family

The prolactin-growth hormone (PRL-GH) family is one of the major groups of hormones the placenta secretes during gestation. Members of this family consist of prolactin,²⁶ placental lactogens, and GH.²⁷ Their roles include mediating maternal metabolic adaptations to pregnancy. The placenta's

production of the PRL-GH family of hormones appears to be important in regulating both insulin production and the sensitivity of the mother in response to pregnancy. The PRL-GH family also is implicated in the regulation of appetite and body weight.

Steroid Hormones

The placenta is the primary source of steroid hormones during gestation. Placental steroid hormones include estrogens and progesterone.²⁸ Both estrogen and progesterone play roles in regulating insulin and glucose homeostasis, lipid handling, and appetite regulation, which may be important in promoting metabolic changes and mobilizing nutritional stores in the mother during pregnancy. Steroid hormones are implicated in pregnancy complications, such as gestational diabetes and preeclampsia. High progesterone and estrogen concentrations have been reported for women with gestational diabetes, whereas levels are reduced in preeclamptic pregnancies compared with healthy pregnancies.²⁹

Neuroactive Hormones

Major targets of placental hormones include the maternal brain, hypothalamus, and pituitary glands. These neuroendocrine effects enable the mother to respond to her environment and adapt to avoid adverse effects of stress and maintain homeostasis.³⁰ Neuroactive hormones also prepare and enable the future mother to adequately care for her offspring.³¹ Melatonin and its precursor, serotonin, are tryptophan-derived hormones with well-known neuroendocrine impacts. During gestation, circulating levels of melatonin and serotonin increase.^{32,33} The placenta also secretes neuroactive hormones, such as thyrotropin-releasing hormone (TRH) and kisspeptin, which may function in adapting maternal physiology to support pregnancy.^{34,35} The placenta secretes oxytocin and expresses its receptor. Both increase gradually in the late stage of pregnancy in the normal placenta.³⁶

Corticotropin-Releasing Hormone

The human placenta expresses the gene encoding corticotropin-releasing hormone (CRH) starting around the sixth to eighth week of gestation. Placental CRH can be detected in the maternal blood by the 15th week of gestation with levels increasing exponentially up to the time of delivery.^{37,38} For most of pregnancy, CRH circulates in association with a binding protein, which sequesters CRH and prevents its biological activity. At the end of pregnancy (4–5 weeks before parturition), levels of the CRH binding protein in the maternal blood fall. This is associated with an exponential increase in placental CRH production, resulting in increased CRH biological activity. Placental CRH production (based on in vitro studies of placental explants) is increased by prostaglandins (PGs) E₂ and F_{2 α} , norepinephrine, acetylcholine, vasopressin, angiotensin-II, oxytocin, IL-I, glucocorticoids, and neuropeptide-Y, and decreased by progesterone and nitric oxide donors.^{39–41}

Growth Factors

The human placenta secretes multiple growth factors and cytokines.^{42,43} Growth of the placenta involves trophoblast proliferation, migration, differentiation, and fusion, and as such, growth factors are likely to be involved in these processes. Development of the placenta also involves extensive angiogenesis and vascularization at the implantation site, and modulation of the maternal immune system to prevent rejection of the

allogeneic fetal tissue. These processes likely involve a complex autocrine/paracrine communication that involves a plethora of growth factors, angiogenic factors, and cytokines.

Insulin-Like Growth Factors

The human placenta produces insulin-like growth factor (IGF)-1 and IGF-2 from as early as the eighth week of gestation.⁴⁴ IGF-1 is present in syncytiotrophoblast and CTBs at all stages in gestation.⁴⁵ IGF-2, plays a role in modulating maternal sensitivity to glucose,^{46,47} insulin, and glucose levels.⁴⁸ Abnormal IGF-1 expression, levels, and signaling are highly associated with intrauterine growth retardation in humans.⁴⁹

Vascular Endothelial Growth Factor Family

CTBs, the syncytiotrophoblast, and villous stromal cells in the placenta express members of the vascular endothelial growth factor (VEGF) family of peptides.⁵⁰ Placental growth factor (PGF) is a member of this family, which shares about 50% homology with VEGF-A. It is expressed by villous and extravillous trophoblast cells, and in contrast to VEGF expression levels, are positively correlated with advancing gestation. Imbalance in circulating maternal levels of these peptides and their soluble receptor, soluble FMS-like tyrosine kinase (sFLT), is strongly, but not exclusively, associated with the etiology of preeclampsia.⁵¹ However, the contribution to these levels from maternal endothelium is unclear. Moreover, CTB and villous stromal expression of these peptides regulates villous vascular formation and remodeling throughout pregnancy, and if disrupted, impacts transfer of nutrients and oxygen into the fetal circulation.

Fibroblast Growth Factor Family

Villous trophoblasts and villous mesenchyme in the human placenta express members of the fibroblast growth factor (FGF) family,⁵² and placental mononuclear phagocytes (also known as *Hofbauer cells*) express FGF receptors.⁵³ FGF induces Hofbauer cells to produce multiple growth factors and cytokine involved in tissue repair.

Adipokines

The human placenta expresses adipokines, leptin, adiponectin, resistin, ghrelin, and visfatin, and secretes them into the maternal circulation. They are thought to regulate maternal metabolic adaptation to pregnancy, especially increased insulin resistance.^{54,55} In placental cells, leptin and adiponectin modulate trophoblast invasiveness and the nutrient supply.⁵⁶ Leptin is inversely correlated with birth weight in small-for-gestational-age newborns. Positive correlation of adiponectin with leptin and ghrelin expression suggests an interaction between these hormones in the placenta.⁵⁷

Transforming Growth Factor- β Family

TGF- β influences both the proliferation and differentiation of trophoblast cells acting through receptors that include endoglin (ENG), a coreceptor for TGF- β 1 and TGF- β 3, which the syncytiotrophoblast and endothelial cells express. Trophoblast cells produce a soluble truncated ENG (sENG) consisting of the extracellular domain. sENG expression is upregulated in preeclampsia and may act as a decoy to sequester and block TGF- β 1 binding to its endothelial cell receptor, preventing vasodilation. sENG appears to augment the endothelial dysfunction caused by elevated sFLT1.⁵³

Activins and inhibins are disulfide-linked homo- and heterodimeric members of the TGF- β family that derive their names from their ability to activate or inhibit, respectively,

pituitary follicle-stimulating hormone (FSH) secretion.⁵⁸ The syncytiotrophoblast expresses each of the activin/inhibin subunits and follistatin, and the levels of expression do not change with advancing gestation.⁵⁹ These factors are secreted into the maternal and fetal circulations and amniotic fluid and their production varies with stage of gestation.^{60,61} Activins and inhibins may affect placental CG production.⁶² In cultured trophoblast cells, inhibin suppresses gonadotropin-releasing hormone (GnRH)-induced CG expression, whereas activin augments the GnRH-induced release of CG. Thus at least in vitro, activin and inhibin via paracrine effects on placental GnRH production may contribute to the regulation of CG secretion in a manner similar to their effect on hypothalamic-pituitary gonadotropin secretion.⁶² Interestingly, levels of inhibin-A and activin-A in the maternal circulation have been reported to have predictive value for pathologies, such as placental tumors, hypertensive disorders of pregnancy, intrauterine growth restriction, fetal hypoxia, Down syndrome, fetal demise, preterm delivery, and intrauterine growth restriction.^{59,60,63,64}

Epidermal Growth Factor Family

CTBs and the syncytiotrophoblast in the human placenta express epidermal growth factors (EGFs) early in pregnancy, and the level of expression decreases with advancing gestation.⁶⁵ EGF is thought to promote trophoblast invasion during implantation and deficiency in EGF expression and/or signaling is associated with preeclampsia and fetal growth restriction.^{66,67}

Extracellular Vesicles

The placenta produces extracellular vesicles (EVs) in large quantities in both healthy and pathological pregnancies. EVs now are being recognized as important carriers for proteins, lipids, and nucleic acids, which may play a crucial role in fetomaternal communication and maternal adaptation to pregnancy.⁶⁸ Micro- and nanovesicles from both first trimester and term human placentae carried Flt-1, and levels significantly increased in EVs from severe, but not mild, preeclampsia compared with normotensive placentae.^{68,69} Placental exosomes can be detected in the maternal circulation from the sixth week of gestation, and their levels increase gradually with advancing gestation in proportion to the increased size of the placenta.⁷⁰ Microribonucleic acid (microRNAs) in placental exosomes affect the function of local immune cells to boost resistance to viral infection.^{71–74} Levels of exosomes (placental and non-placental) in the maternal circulation, and the composition of their cargo, have been associated with pregnancy complications, such as preeclampsia, preterm birth, intrauterine growth restriction, and gestational diabetes.⁷⁵

Cell-Free Fetal Nucleic Acids

Cell-free deoxyribonucleic acid (cfDNA) originates in trophoblast cells and can be assayed in the maternal blood as biomarkers of placental health and function.^{76,77} From around the seventh week of gestation, cfDNA is detectable in the maternal circulation, and the amount increases with advancing gestation, such that late in pregnancy, it represents around 4% of the cfDNA in maternal blood.⁷⁸ After delivery of the placenta, the amount of cfDNA in maternal blood rapidly decreases. The physiologic role of cfDNA—and why it is shed from trophoblast cells into the maternal compartment—is not known. The amount of cfDNA in maternal blood has been used as a biomarker of placental health, with increases in cfDNA noted in nonviable pregnancies, preeclampsia, and intrauterine growth restriction-associated with placental insufficiency.

Because it can be isolated and sequenced, cfDNA is used for noninvasive prenatal diagnosis and testing for conditions, such as X-linked genetic disorders and aneuploidies, as well as fetal sex determination.⁷⁹

Cell-free messenger RNA (mRNA) derived from the placenta has been detected in maternal blood by eight weeks of gestation.⁸⁰ The cell-free mRNA has been evaluated quantitatively for specific transcripts, particularly those encoding proteins expressed uniquely by the placenta (such as CG β -subunit, placental lactogen, placenta enriched -1 14). It has been found that some of these transcript levels in maternal blood are elevated in preeclampsia and intrauterine growth restriction.

MicroRNAs, short noncoding single-strand RNA molecules, are known to be epigenetic factors regulating gene expression by targeting specific sequences in mRNAs and destabilizing the transcripts and/or inhibiting or reducing translation. The microRNAs released from the placenta may be incorporated into microvesicles, including exosomes, in apoptotic bodies, or protein-bound. The placenta-derived microRNAs are thought to influence maternal gene expression, particularly in vascular endothelial cells. The placental-specific microRNAs include those encoded in clusters on chromosomes 14 and 19, with the best studied being the microRNAs from the chromosome 19 cluster (C19MC).⁸¹ Alterations in levels of specific microRNAs in maternal blood have been reported in nonviable pregnancies and preeclampsia.⁸²

Fetal Neuroendocrine Development

The neuroendocrine system, including the hypothalamus, anterior pituitary, and the major endocrine glands, is essential for physiologic homeostasis, growth, response to stress, and reproduction. Appropriate development of the neuroendocrine systems during fetal life is therefore critical for postnatal health and wellness.

The neuroendocrine system functionally develops by mid-gestation. The hypothalamus originates on the inner surface of the diencephalic neural canal at around the sixth week of gestation. By the tenth week, the median eminence can be distinguished and specific cells in the hypothalamus begin producing GnRH, TRH, CRH, GH-releasing hormone (GHRH), and somatostatin (SS). The primordium of the anterior pituitary appears at around the fourth week of gestation as an evagination of Rathke's pouch, in front of the buccopharyngeal membrane at the roof of the developing buccal cavity. By the seventh week, the floor of the sella turcica is in place and separates the anterior pituitary from its epithelial origins. Beginning during week 8, capillaries interdigitate among the mesenchymal tissue of Rathke's pouch and the median eminence of the hypothalamus, and by the 12th to 15th week of gestation, these vessels form the hypothalamic-hypophyseal vascular system. The mature anterior pituitary gland includes lactotropes that produce prolactin (PRL), somatotropes that produce GH, corticotropes that produce proopiomelanocortin (POMC) and that give rise to adrenocorticotrophic hormone (ACTH), β -lipotropin and β -endorphin, thyrotropes that produce thyroid-stimulating hormone (TSH), and gonadotropes that produce luteinizing hormone (LH) and FSH. Thus the fetal hypothalamic-pituitary axis is anatomically and functionally developed by midgestation and, for the remainder of pregnancy, the fetal anterior pituitary, under the control of the hypothalamus, produces tropic hormones and affects the fetal thyroid glands, adrenal glands, and gonads. Although, each endocrine axis exhibits varying levels of activity, the fetal HPA axis is remarkably active in preparation for its essential role postnatally.

Integrative Steroidogenesis During Pregnancy: Fetal Adrenal-Placental Crosstalk

The human placenta produces large amounts of progesterone and estrogens, especially after the first trimester. At 6 to 10 weeks of gestation, placental trophoblast cells and the syncytiotrophoblast gain the capacity to convert maternal cholesterol to progesterone. Placental cells also have high aromatase and 17β hydroxysteroid dehydrogenase (17βHSD) activity and convert C19 androgens to C18 estrogens (Fig. 5.1). However, the placenta cannot produce estrogens de novo from cholesterol, or from pregnenolone or progesterone because the cells lack the 17α-hydroxylase/17,20-lyase enzyme. Instead, the fetal adrenal cortex supplies C19 androgens. Thus the human placenta produces progesterone from maternal cholesterol (referred to as the *maternal-placental endocrine unit*) and estrogens from fetal adrenal C19 precursors (referred to as the *feto-placental endocrine unit*) (Fig. 5.2). Deficiency in placental aromatase may not affect implantation, but women report virilization in the third trimester, resulting in facial hair and acne. Female newborns had varying degrees of pseudohermaphroditism with clitoromegaly and hypospadias—resulting from the inability of the placenta to convert dehydroepiandrosterone (DHEA) to estrogen. Male offspring developed tall stature because of failure of epiphyseal fusion, along with delayed bone age, causing osteopenia and undermineralization, along with several other issues.^{83,84}

The human adrenal glands derive from a thickening of the celomic epithelium between the urogenital ridges that occurs at around the fourth week of gestation. Approximately 1 week later, the primordial adrenal cortical cells migrate toward the mesonephros where they aggregate and proliferate to form the anlage of the adrenal cortex.^{85–87} For most of pregnancy, the fetal-adrenal cortex displays two morphologically distinct zones: the large inner fetal zone and the narrow outer definitive zone. A third zone, the transitional zone, distinguished by ultrastructural and functional characteristics, exists between the fetal and definitive zones and is apparent early in the third trimester (Fig. 5.3). Thus late in pregnancy, the fetal-adrenal cortex resembles a rudimentary form of the adult-adrenal cortex. Soon after birth, the fetal zone involutes to become the

zona reticularis, the transitional zone becomes the zona fasciculata, and the definitive zone becomes the zona glomerulosa. Between the innermost fetal zone cells—that eventually will aggregate to form the adrenal medulla late in the third trimester—are clusters of immature neuroblasts.

At around week 12 of gestation, steroidogenesis in response to ACTH initiates in the fetal zone cells. This increase coincides with the initiation of fetal zone enlargement and the fetal pituitary gland secreting ACTH.⁸⁸ At midgestation, the fetal zone occupies 80% to 90% of the cortex and is the primary site of growth and steroidogenesis production. Remarkably, the adrenal glands are disproportionately enlarged because of fetal zone hypertrophy, and at 20 weeks, are larger than their adjacent kidney. Fetal zone cells are highly steroidogenic and in response to ACTH produce 100 to 200 mg/day of dehydroepiandrosterone sulfate (DHEA-S), a C19 steroid with weak androgenic activity, during the third trimester. The fetal adrenals produce DHEA-S that is used as substrate for placental estrogen synthesis. In the placenta, the steryl-sulfatase enzyme removes the sulfate and the 3βHSD, 17βHSD, and aromatase enzymes convert DHEA to estradiol and estrone. The fetal liver expresses the 16-hydroxylase enzyme and converts some DHEA-S to 16-hydroxy-DHEA-S (16OH-DHEA-S), which is then converted to estriol. Because 16-hydroxylase is not expressed postnatally, the amount of estriol in the maternal circulation indirectly reflects activity of the fetal HPA axis. For this reason, maternal estriol previously was used as an endocrine marker to evaluate fetal well-being. The fetal adrenal cortex continues to produce DHEA-S in response to ACTH for the remainder of pregnancy, increasing considerably during the second and third trimesters. By term, the human fetal adrenal produces around 200 mg DHEA-S per day. Thus the fetoplacental endocrine unit constitutes a cooperative interaction between the incomplete steroidogenic pathways in the fetal HPA axis and the placenta to produce a complete estrogen synthetic unit. Initial reports of steroid sulfatase deficiency suggested delayed onset of labor and lack of cervical dilation. However, subsequent research has shown normal gestation length with the possibility of spontaneous vaginal delivery.^{89,90}

The placenta’s production of CRH also influences the fetal HPA axis. A unique feature of primate pregnancy is that the

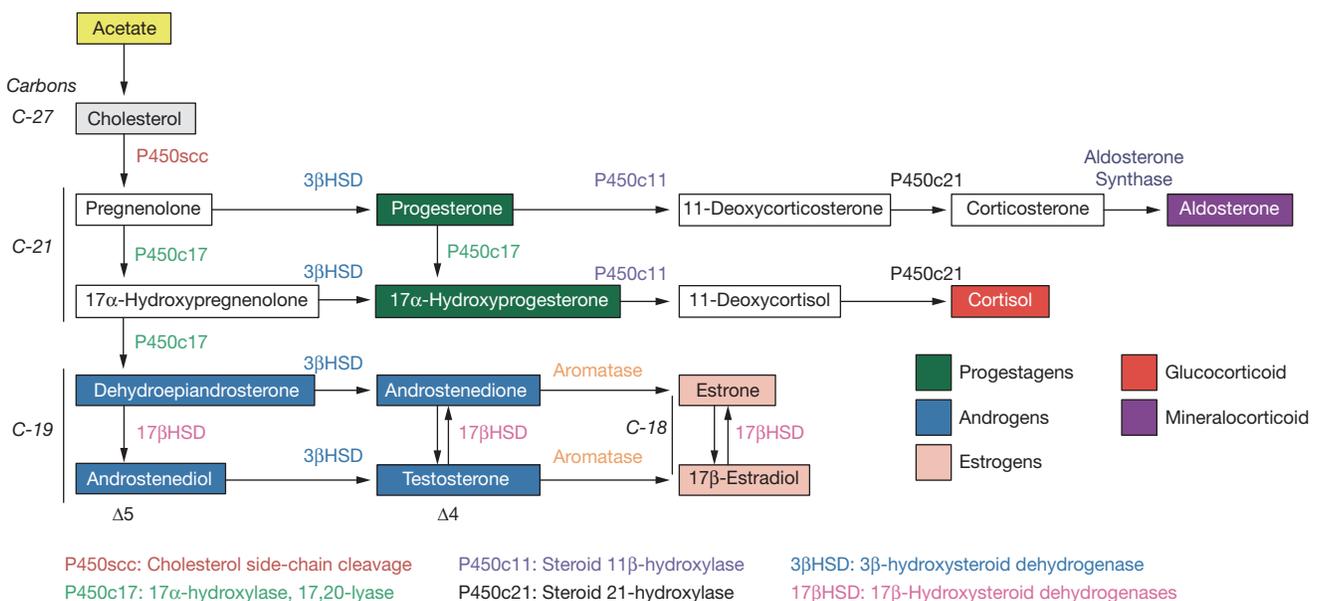

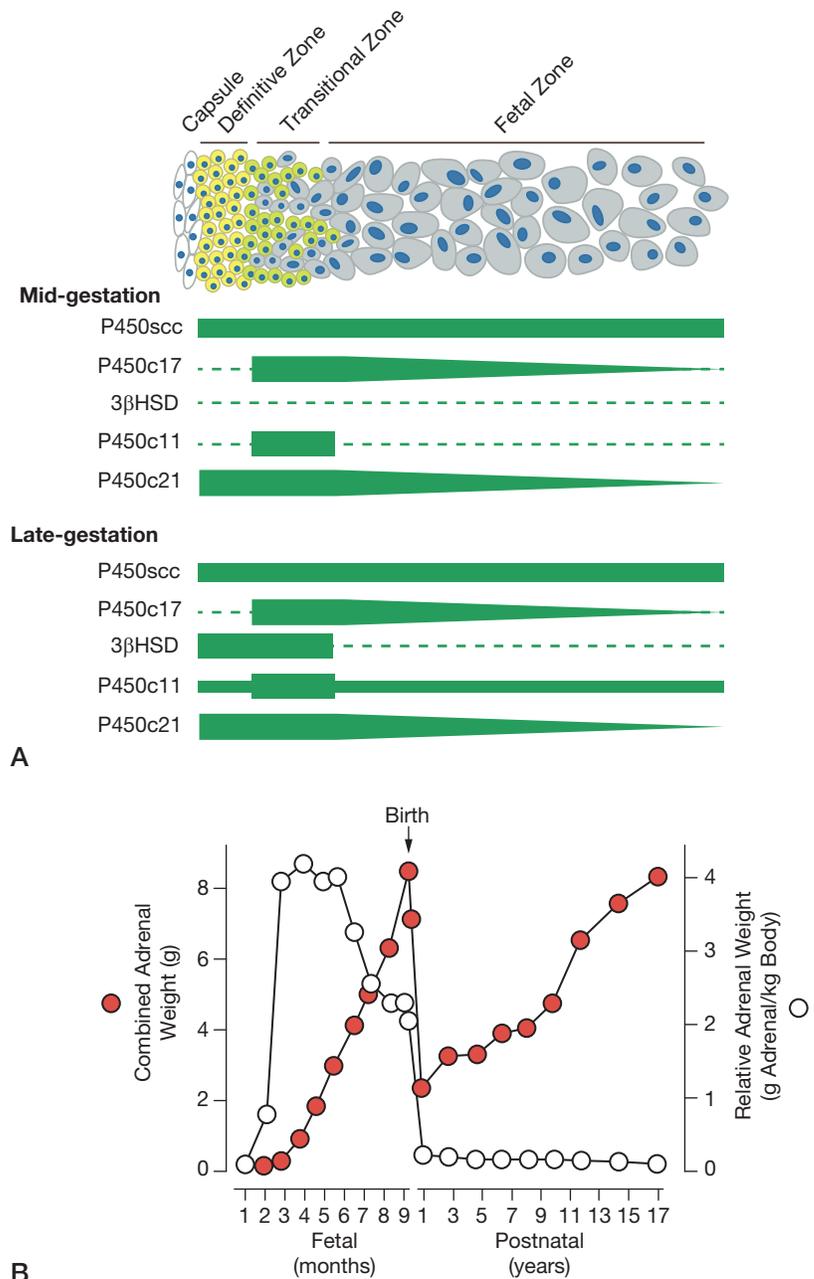

Fig. 5.1 Schematic diagram of steroid biosynthesis. Enzymatic steps and steroid intermediates progestogens, mineralocorticoids, glucocorticoids, androgens, and estrogens are shown.

Fig. 5.3 Morphologic zonation and steroidogenesis in the fetal adrenal and adrenal growth during development. A, Steroidogenic enzymatic activity by zones during mid or late gestation. B, Absolute adrenal weight and adrenal weight relative to body size during fetal and postnatal life. (Modified from Mesiano, S., Jaffe, R.B. (1997). Development and functional biology of the primate fetal adrenal context. *Endocr Rev*, 18, 378–403.)

negative feedback on pituitary ACTH secretion during the first trimester. Thus indirect data suggest that the fetal adrenals produce cortisol before 12 to 15 weeks, which then declines until 25 to 30 weeks' gestation, after which transitional zone cells express steroidogenic enzymes needed for cortisol synthesis de novo from cholesterol. Mineralocorticoid production by the human fetal adrenal cortex is low early in gestation but increases during the third trimester. At term, 80% of the aldosterone in human and rhesus monkey fetal blood appears to originate from the fetal adrenal.⁹⁷ In 18- to 21-week human fetal adrenals, the mineralocorticoid metabolic pathway localizes to the definitive zone, but its activity is low and unresponsive to secretagogues.^{98,99} Nonetheless, under normal conditions the steroidogenic capacity of the fetal adrenals to produce the cortisol and aldosterone is in place by the middle of the third trimester in preparation for the HPA axis to perform its vital function after birth.

Fetal Maturation and Parturition

At birth the fetus, as a newborn, must abruptly adapt to the extrauterine environment and independently establish and maintain physiological homeostasis. Success of this transition requires that organ systems needed for extrauterine life (such as lungs, gut, adrenals, thyroids, kidneys, liver, pancreas, immune system) are functionally mature before, or at least soon after, parturition. Maturation of the fetal lungs with the capacity for gas exchange is especially important. Cortisol is a key hormonal regulator of this process and promotes the functional maturation of multiple fetal organ systems before parturition. Interestingly, in some species, the cortisol responsible for fetal maturation also triggers parturition. For example, in sheep, activity of the fetal HPA axis increases during the week before parturition so that the fetal adrenals secrete a surge of cortisol that not only stimulates fetal organ maturation (especially

surfactant production by the lungs) but also triggers parturition by inducing the metabolism of placental progesterone to androstenedione, leading to a systemic decrease in maternal progesterone levels that induces labor.^{100,101} Thus in the central role, the fetal HPA axis produces cortisol to ensure that fetal maturation precedes parturition and that the two processes are coordinated. The discovery that cortisol promotes fetal lung maturation led to the widespread clinical uses of synthetic glucocorticoids that cross the placenta to promote fetal lung maturation in women with threatened preterm birth. This therapy increases the survival rates of preterm infants mainly by decreasing the severity of respiratory distress syndrome because of pulmonary insufficiency in premature infants. Thus as with most species, glucocorticoid stimulates maturation of the human fetus, preparing it for life outside the uterus. However, unlike the sheep, neither glucocorticoid or activity of the fetal HPA axis induces human parturition.

In sheep, the cortisol needed to induce fetal maturation and trigger parturition originates in the fetus, whereas maternal cortisol or cortisol therapy to the maternal side only, has no effect. The reason for this finding is that the sheep placenta inactivates maternal cortisol by expressing the 11β -HSD-2 enzyme that converts cortisol to the inactive cortisone.¹⁰² This is likely a safeguard to protect the developing fetal brain from adverse effects of glucocorticoid on neuronal development. Similarly, the human placenta prevents maternal cortisol from entering the fetal compartment throughout most of human pregnancy. This is why synthetic glucocorticoids that the placenta does not metabolize are used to treat women in preterm labor. This barrier, however, appears to collapse late in the third trimester. Evidence for this is that fetuses that have impaired cortisol production because of 21-hydroxylase deficiency are usually born at term without any apparent signs of organ immaturity.¹⁰³ This suggests that another source of glucocorticoid, possibly from the maternal adrenals, could contribute to fetal organ maturation. If this is the case, maternal cortisol must cross the placenta. Late in human pregnancy, the placental barrier to maternal cortisol appears to weaken. The evidence for this is that estriol levels in the maternal circulation during late pregnancy are inversely related to the circadian changes in circulating maternal cortisol levels,¹⁰⁴ suggesting that maternal cortisol crosses the placenta and exerts negative feedback on the fetal HPA axis, leading to a decrease in ACTH stimulation of DHEA-S production that, in turn, causes a decrease in placenta estriol production. Increased transfer of maternal cortisol to the fetus may represent a backup mechanism to ensure fetal lung maturation before term parturition.

The Hormonal Control of Human Parturition

The gravid uterus accommodates the growing conceptus physically and immunologically. For most of pregnancy the extracellular matrix of the uterine cervix is rigid and noncompliant, which effectively closes the uterine outlet. In contrast, the myometrium of the uterine wall relaxes, becoming compliant, growing mainly by cellular hypertrophy, and distending in response to the growing conceptus and amniotic fluid. The maternal immune system is also suppressed, especially at the maternal-fetal interface in the decidua, to prevent rejection of the semiallogenic fetal tissue. At parturition, the gravid uterus undergoes a series of temporally coordinated transformations, such that the myometrium becomes highly contractile and excitable and contracts rhythmically and forcefully to become the engine for birth, and the extracellular matrix of the cervix softens to allow dilation and opening of the gateway for birth. In addition, the fetal membranes weaken and rupture to release the fetus.¹⁰⁵ The process also is associated with immune activation in the decidua that produces extensive

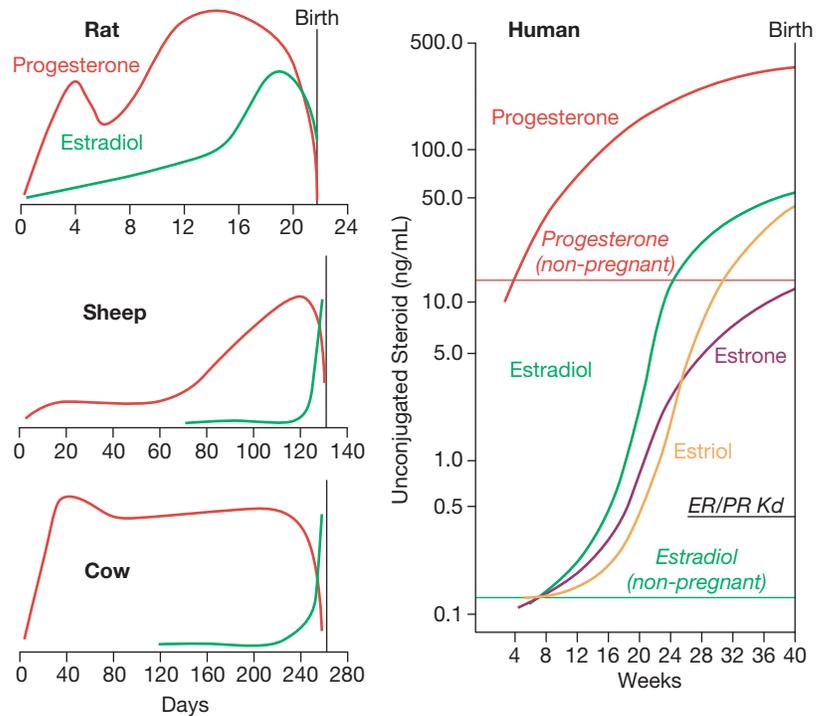

tissue-level inflammation and the local production of pro-labor uterotonic factors, such as prostaglandins. These events make up what we call *labor*, which is clinically defined as rhythmic and forceful contractions with softening and dilation of the cervix and rupture of the fetal membranes. The process culminates in the forceful expulsion of the fetus, placenta, and fetal membranes, including the decidua, and through hemostasis, involution, and endometrial regeneration, the uterus reverts to the nonpregnant state to resume menstrual cyclicality.

Hormones control the process and timing of parturition. Progesterone and estrogens affect the growth and contractility of the myometrium, the immunologic/inflammatory state of the decidua, and the mechanical integrity of the cervix. In this regard, the balance between the pro-pregnancy actions of progesterone that dominate for most of pregnancy, and the pro-labor actions of estrogens that occur as part of the parturition process, is critical. For most of pregnancy, progesterone and estrogen exert uterotrophic effects to promote myometrial cell hypertrophy and increase blood flow to the uterus and cervix. Progesterone exerts a relaxatory and antiinflammatory effect on the uterine tissues to block labor by maintaining closure of the cervix and quiescence of the myometrium. At parturition, the effects of progesterone are lost and estrogens dominate to promote the expression of genes in myometrial and cervical cells whose products increase uterine contractility and cervical softening.¹⁰⁶ Thus a general characteristic of viviparous species is that the withdrawal of the progesterone block triggers parturition, which permits stimulatory estrogenic actions to increase myometrial contractility and excitability and promote cervical softening and membrane weakening. Cortisol from fetal or maternal adrenals, does not appear to contribute to the hormone control of human parturition. Evidence for this is that parturition occurs normally at term in pregnancies where the fetus has CAH because of the inability to produce cortisol,¹⁰³ and glucocorticoid therapy does not hasten the parturition process.

Placental CRH may be involved in the regulation of human parturition. Maternal plasma CRH concentrations—reflecting CRH mainly of placental origin—increase exponentially with advancing gestation, and the rate of change as gestation progresses is predictive of the gestation length.⁹² The more rapid the increase in maternal CRH from midgestation, the earlier parturition occurs. A slower rate of increase is associated with postterm birth. The physiology and molecular biology underlying this association is not understood. In vitro experiments suggest some possibilities. CRH receptors have been identified in myometrial cells and fetal membranes.^{107–110} CRH stimulates PG secretion from decidua and amnion,^{111,112} and increases myometrial contractility by augmenting responsiveness to oxytocin and $PGF_2\alpha$.^{113–115} Paradoxically, placental CRH increases adenylate cyclase activity in myometrial cells, which promotes relaxation, but this effect is lost late in pregnancy, possibly because of changes in CRH receptor isoforms in myometrial cells.¹¹⁶

How progesterone withdrawal happens to achieve parturition differs between species, depending on the source of progesterone that maintains pregnancy. For example, in rodents the maternal CL produces progesterone during pregnancy and CL regression triggers parturition, leading to systemic progesterone withdrawal. In sheep, the placenta exclusively produces progesterone and its withdrawal is induced by a prepartum cortisol surge that induces the expression of the 17α -hydroxylase enzyme in placental cells that diverts progesterone from secretion to conversion to androstenedione, which is converted to estradiol. This enzymatic induction leads to a systemic decrease in maternal progesterone levels and a concomitant increase in estrogen levels that triggers parturition.¹¹⁷

Fig. 5.4 Patterns of maternal serum progesterone and estrogen concentrations through gestation in mammals. The rat, sheep, and cow all demonstrate systemic progesterone withdrawal preceding labor, whereas women do not. Estrogens increases in mammals as parturition approaches. In women the rapid increase in placental estrogen production is during the first trimester.

In contrast to rodents and sheep, parturition in women occurs without a systemic progesterone withdrawal (Fig. 5.4).¹¹⁸ Instead, the gravid uterus receives high levels of progesterone and estrogens—because of activity of the fetoplacental unit—for most of pregnancy and during labor and delivery. Although this suggests that progesterone withdrawal does not trigger human parturition, clinical studies show that disruption of progesterone signaling with agents, such as mifepristone, a selective progesterone receptor modulator/antagonist, increases myometrial contractility, and induces labor at all stages of pregnancy.¹¹⁹ That observation suggests that a functional, rather than systemic, progesterone withdrawal triggers human parturition, whereby uterine cells become refractory to progesterone.

Progesterone maintains pregnancy via its interaction with the nuclear progesterone receptor PR isoforms, PR-A and PR-B, expressed by myometrial, cervical, and decidual cells (Fig. 5.5).¹²⁰ The PRs function primarily as ligand-activated modulators of transcription by directly interacting with cis-elements in gene promoters or by modulating the activity of other transcription factors. Changes in PR transcriptional activity likely mediate functional progesterone withdrawal. Possible mechanisms include: (1) increased abundance and transrepressive activity of PR-A in uterine cells that decreases net progesterone-induced PR transcriptional activity^{121–131}; (2) decreased levels and/or activity of key transcriptional coactivators that modulate PR transcriptional activity^{132–134}; and (3) posttranslational modifications, especially site-specific serine phosphorylation, which suppress PR transcription activity.¹³⁵ Any, or all, of these PR-mediated functional progesterone withdrawal mechanisms may be responsive to prolabor parturition triggers. It is also possible that uterine cells metabolize progesterone to a form that does not bind the PR, leading to generation of unliganded PRs that may have prolabor actions.¹³⁴

Clinical^{136–143} and animal^{144–148} studies show that tissue-level inflammation within the uterine tissue compartments (myometrium, cervix, and decidua) is a major prolabor stimulus that plays a causal role in the process and timing of

parturition.^{149–154} Labor is also associated with increased production of uterotonic PGs by the decidua and fetal membranes; likely as a sequelae of tissue-level inflammation.¹⁵⁴ Increased levels of PGs (especially $\text{PGF}_2\alpha$ and PGE_2) in the uterine tissue have the potential to transform the myometrium to the laboring state and promote softening and dilation of the cervix. Thus a leading hypothesis is that parturition ensues from a local autocrine/paracrine process that involves tissue-level inflammation. By implication, this hypothesis predicts that antiinflammatory effects on the uterine and gestational tissues maintains pregnancy and blocks labor. Progesterone may mediate this via the PRs in myometrial, cervical, and decidual cells, as in vitro studies show that progesterone/PR signaling inhibits the response of uterine cells to prolabor/proinflammatory stimuli.^{126,135,155–159} Loss of progesterone/PR antiinflammatory activity would allow proinflammatory stimuli to prevail and induce tissue-level inflammation with the concomitant production of PGs that transform the myometrium and cervix to the laboring state. According to this model, physiological and/or pathological conditions that affect the capacity for PRs to mediate antiinflammatory actions of progesterone in uterine cells could trigger parturition. Studies suggest that in myometrial cells, prolabor/proinflammatory stimuli block progesterone/PR antiinflammatory activity by inducing site-specific serine phosphorylation of PR-A.^{135,160}

Throughout pregnancy, various physiologically relevant proinflammatory/prolabor stimuli affect the gravid uterus. Some may be intrinsic (such as fetal or maternal stress, placental senescence, uterine distention) and some may be extrinsic (such as intrauterine infection, maternal nutritional, and environmental psychosocial stress). The net effect is that the gravid uterus is exposed to an inflammatory load that increases as pregnancy advances. It is proposed¹³⁵ that for most of pregnancy progesterone/PR inhibits response of myometrial, decidual, and cervical cells to inflammatory load stimuli and that an inflammatory load threshold exists, above which specific protein kinase activity catalyzes PR phosphorylation and/or other mechanisms that

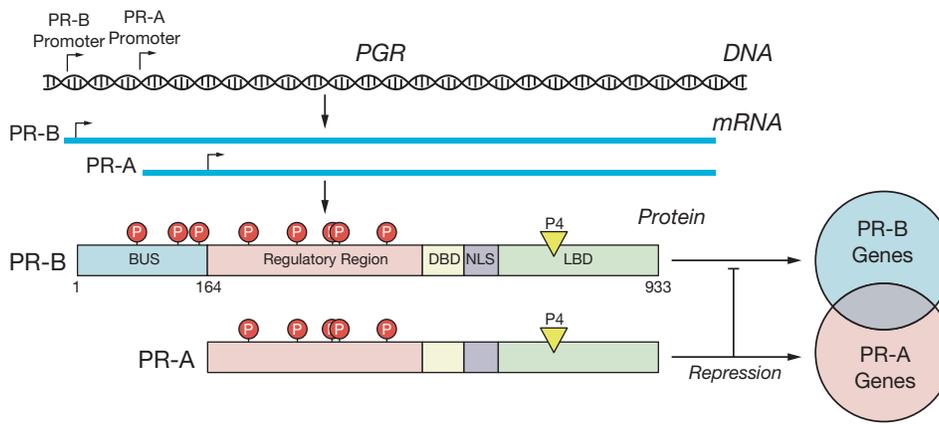

Fig. 5.5 Progesterone receptor isoform production. The progesterone receptor gene (*PGR*) generates two primary translation products, PR-A and PR-B. PR-A lacks N-terminal sequences encoding a transcriptional activation domain. Both isoforms undergo extensive posttranslational modifications with phosphorylation. The PRs function as ligand activated transcription factors to affect the expression of specific and common target genes. At some gene promoters PR-A represses that transcriptional activity of PR-B. *BUS*, B upstream segment; *DBD*, DNA binding domain; *LBD*, ligand binding domain; *NLS*, nuclear localization sequence.

cause PR-mediated functional progesterone withdrawal. The loss of progesterone/PR antiinflammatory activity would predispose the development of a positive-feedback proinflammatory state within the uterine tissues, leading to the production of PGs that activate the myometrium and dilate the cervix. This paradigm suggests that birth timing results from the inflammatory load trajectory, the set point for the inflammatory load threshold, and the capacity to induce PR-mediated functional progesterone withdrawal. Any of these parameters could be amenable to therapeutic strategies to clinically control birth timing and prevent preterm birth. Progestin prophylaxis in the form of 17-hydroxyprogesterone-caproate (intramuscular weekly) or progesterone (vaginal suppository daily) may decrease the risk for preterm birth in a subset of at-risk women by affecting the inflammatory load trajectory and/or augmenting the PR-mediated antiinflammatory activity.

Genetic and Genomic Approaches to Reveal Novel Endocrine Pathways Related to Birth Timing

As highlighted throughout this chapter, estrogen and progesterone are essential to the establishment, maintenance, and termination of pregnancy. These key reproductive steroid hormones have received considerable attention and certainly form a portion of the conserved signaling molecules in pregnancy, along with prostaglandins, across species. In attempting to understand the regulation of progesterone and estrogen synthesis, and activity at the end of pregnancy that allows term parturition to take place, it has been challenging to define molecular mechanisms. Typical animal models differ significantly from women in terms of progesterone and estrogen regulation associated with the initiation of parturition, as has been reviewed extensively elsewhere.¹⁰⁶ In women, circulating serum progesterone rises through gestation and does not decline with the onset of labor. Over the end of pregnancy, estrogen concentrations also rise, a pattern observed in most species. Various hypotheses regarding mechanisms of “functional” progesterone withdrawal in women have been put forward, including variation in progesterone receptor isoforms, progesterone receptor cofactors, posttranslational modification of the progesterone receptor, and increased estrogen-to-progesterone ratio, but no mechanism has been definitively proven.

In the last two decades, the ability to gain mechanistic insights into human physiology through nonbiased, genome-wide

analytic techniques has provided the opportunity to elucidate the control of human birth timing. Experimental manipulation of human pregnancy is not ethically acceptable, as it could result in harm to the mother or fetus. Genotype-based studies in mothers and infants, whether seeking common or rare variants, have the potential to produce new discoveries on the control of birth timing, including modulation of known endocrine signaling pathways and identification of new pathways. The ability to use genotypic information from mothers, fathers, and their offspring to identify loci associated with the length of gestation, as a continuous variable, or risk for preterm birth, as a dichotomous trait (term vs. preterm), is an especially important strategy, as human pregnancy has had to accommodate several species-specific constraints to optimize outcomes for both the infants and mothers.

Studying the genetics and genomics of pregnancy has several inherent challenges. The most unique of these is the potential for regulatory information to reside in two separate, but related, genomes, those of the mother and of the fetus. Moreover, although genetic factors affect birth timing and preterm birth, so, too, does a variety of environmental exposures, such as infection, psychosocial stress, nutrition, and health behaviors, that may act through similar or divergent mechanisms and pathways.

Abundant evidence has accumulated that genetic factors, particularly in the mother, contribute to determining gestational length for human pregnancy. Classic twin studies, investigating the concordance of birth timing for offspring of identical twins compared with dizygotic twins or other siblings, has suggested that maternal genetic factors contribute 30% to 40% of the variation in birth timing, with little influence from the paternal genome.¹⁶¹ Family-based segregation analysis findings come to a similar conclusion.^{162,163} Very large epidemiological studies also conclude that the heritability of preterm birth risk resides in the maternal genome, acting either in the mother or maternally transmitted information to the fetus.¹⁶¹ It should be noted that 60% to 70% of the risk for preterm birth resides in environmental factors, and that loci contributing to this common complex syndrome likely individually contribute risk of small effect size (odds ratio [OR] 1.10–1.25). Although these data support the utility of a genome-wide approach, they herald that large sample sizes will be required to detect loci that are statistically significant and associated with birth timing at the genome-wide level of $P < 5 \times 10^{-8}$.

GENOME-WIDE ASSOCIATION STUDIES

Studies have overcome the limitation of inadequate sample sizes for detection of this heterogeneous phenotype with presumably multiple loci of modest effect size. Important new findings have emerged from research, using a large discovery cohort assembled through a commercial direct-to-consumer genotyping company that included gestation duration information in one of their surveys, in conjunction with carefully phenotyped Northern European cohorts for birth timing and spontaneous preterm birth.

In 2017 Zhang and colleagues published the first well-powered, validated, and replicated study of the maternal genome that identified six loci that achieved genome-wide significance.¹⁶⁴ This study involved approximately 44,000 women in the discovery cohort and an additional 8000 in the replication cohort. The power of genome-wide association studies (GWAS) to explore preterm birth genetics has finally approached the magnitude of other complex common phenotypes, such as type 2 diabetes, obesity, hypertension, and other adult metabolic and cardiovascular disorders. As would be anticipated, retrospectively, logical associations of these gene regions with gestational duration are evident, but they were not previously a focus for targeted analysis. Of the six regions identified—those near the *EBF1*, *EEFSEC*, *AGTR2*, *WNT4*, *ADCY5*, and *RAP2C* genes—four of these have immediate endocrine signaling ramifications.

AGTR2 encodes the angiotensin II type 2 receptor. Responsive to the hormone angiotensin 2, this receptor is implicated in cardiovascular development and regulation and is, therefore, a plausible candidate for harboring variants that determine birth timing. In addition to its known cardiovascular effects, the endometrium upregulates *AGTR2* expression late in the decidualization process. Its specific actions at this time are not known, but the finding—taken in the context of *WNT4* ramifications to be discussed—raises the visibility and impact of the endometrium and the decidualization process as key factors in not only the initiation of pregnancy, but also the termination of pregnancy.

WNT4 and the *WNT* signaling pathway are part of the essential toolbox of general mammalian development. This paracrine signaling pathway is prominently involved in the development of the female reproductive tract, and also plays an essential role for proper decidualization. The single nucleotide polymorphism (SNP) identified in the GWAS study of birth timing was in the same linkage disequilibrium block as SNPs associated with risk for endometriosis, again suggesting the importance of the endometrial stromal cell. Functional studies of this locus revealed a putative causative variant in the nonreference allele that generated a new estrogen receptor binding site. Here, it is not the generation of estrogen that results in human variation in birth timing, but its action on pregnancy-relevant target tissues.

ADCY5 that encodes a member of the adenylyl cyclase family has been previously associated with variation in birth weight in the fetal genome. The gene region in the fetal genome, however, is not strongly linked to the region revealed in birth timing in the maternal genome. Adenylyl cyclases generate cyclic adenosine monophosphate, which plays an important role in promoting myometrial relaxation. The endocrine signals that activate *ADCY5* in pregnancy, if any, have not been determined and provide an important avenue for future research.

Perhaps the most intriguing locus emerging from the maternal GWAS analysis was *EEFSEC*, which encodes eukaryotic elongation factor for selenocysteine. Selenocysteine, the “21st amino acid,” is incorporated into a group of 25 human selenoproteins by a complex molecular machinery that identifies a translation stop codon instead as a selenocysteine insertion site

by adjacent selenocysteine insertion sequences. These selenoproteins exert antioxidant and antiinflammatory functions, and again could contribute to promoting or restricting signals that enhance uterine contractility and decidual function. In addition, iodothyronine deiodinase is a selenoprotein, and altered thyroid activity could affect myometrial contractility and birth timing. Perhaps most relevant in the identification of this locus in risk for preterm birth is the potential role for selenium itself, an essential micronutrient, in shaping preterm birth risk. Data suggest that selenium deficiency may predispose women to preterm birth, with the suggestion that selenium supplementation in selenium-deficient individuals could improve their pregnancy outcomes.¹⁶⁵

EBF1 demonstrated the strongest association with risk for preterm birth. This locus also was associated with birth weight in the maternal genome, likely caused by its effects on gestational duration. *EBF1* encodes early B-cell factor 1 that is involved in B-cell function, which has been recently linked to preterm birth risk,¹⁶⁶ and also is associated with a variety of cardiovascular and metabolic traits potentially influencing birth timing.

Lastly, *RAP2C*, which encodes RAS-related protein-2c and is a member of the RAS oncogene family, is most highly expressed in the uterus among other profiled tissues. Its role remains to be determined.

RARE VARIANT ANALYSIS

The GWAS described earlier analyzes the relationship of common human genomic variants with adverse pregnancy outcomes. The question subsequently arises as to whether rare, more highly penetrant mutations exist that also could contribute to preterm birth risk. Rare variants often can be shared with close family members and provide an additional avenue for genome sequencing to reveal new loci associated with birth timing. Until now, there have been few family-based rare variant and birth timing studies. Hallman and colleagues used linkage analysis to identify variants around the *IGF-1* receptor with risk for preterm birth in the infant genome.¹⁶⁷ Subsequently, McElroy et al. revealed an overrepresentation of variants associated with coagulation and complement pathways with risk for preterm birth.¹⁶⁸ The largest rare variant study to date, by Huusko and colleagues, demonstrated again the importance of steroid signaling variants and particularly found shared risk around variants in *HSPA1L*, which modulates steroid signaling.¹⁶⁹ This next-generation sequencing approach should also be useful for revealing many pathogenic variants related to adverse pregnancy outcomes beyond preterm birth.

MENDELIAN RANDOMIZATION AND CAUSATIVE PATHWAYS

One new avenue for investigation of genetic variants associated with birth timing is application of Mendelian randomization approaches to pregnancy outcomes. This approach seeks to determine the causative relationship of traits associated with a specific phenotype, in this case preterm birth. Zhang and colleagues reported in 2015 that maternal height was associated with risk for preterm birth.¹⁷⁰ They went on to show that construction of a genetic risk score based on known height-associated SNPs predicted maternal height and duration of gestation. Intriguingly, although transmission of growth promoting alleles determined fetal growth parameters from the mother to the fetus, the duration of gestation was most strongly shaped by maternal nontransmitted height variants, suggesting that maternal height is a causative factor for preterm birth risk and that genetic programming of maternal environment shapes pregnancy outcomes.

FETAL GENOME

Most genetic evidence suggests that the majority of the genetic risk for preterm birth resides within the maternal genome. The study mentioned earlier by Hallman and colleagues revealed the *IGF1R* locus had a predominantly fetal effect on preterm birth risk.¹⁶⁷ Recently, a preprint of a GWAS of the fetal genome has been deposited that implicates the proinflammatory locus around the *IL-1* gene as being involved in preterm birth risk in the fetus.¹⁷¹

This highly plausible target is supported with biochemical data. Although the evidence for the *IL-1* region is robust, it should be noted that in the cohort of approximately 80,000 pregnancies, only this single locus was substantiated. This finding is again consistent with the majority of risk for preterm birth being in the maternal genome.

CONCLUSION

Despite years of studying the symbiotic relationship between mother and fetus, there remains much that we do not completely understand about pregnancy and birth. Hormonally, estrogen and progesterone establish, maintain, and end pregnancy. By studying the birth process in other animals, changes refined by evolution throughout centuries, and new genetic knowledge, we can begin to decipher the mystery of what causes pregnancy complications and what triggers birth around 40 weeks in most women and prematurely in others. For example, we know the role of the fetal HPA axis and the abrupt fall of circulating maternal serum progesterone that sheep experience is not duplicated in women. In fact, shifts in progesterone during the birth process seem to be decidedly species specific. We do know, however, that despite the different roles in animals and humans, hormones and their function in maternal-fetal cross-talk, tug-of-war, or modulation of signaling throughout human pregnancy remain a key focus. Equilibrium must be established in pregnancy between the needs of the mother and the needs of the fetus, balancing the nutritional requirements and hormonal fluctuations that must endure for a healthy pregnancy and delivery at term.

We also recognize the critical importance of viewing pregnancy through an evolutionary frame: hormonal interactions have evolved through natural selection to increase a woman's chance of a successful pregnancy. Physiologically, encephalization and bipedalism are clear reasons a pregnancy should not continue past 40 weeks or risk the baby is too large to make it through the birth canal. Yet, some complications, such as gestational diabetes, may result from a mismatch between our ancestral and modern diets and environments. And, in fact, some researchers believe this disparity may contribute to the growing obesity epidemic, as well.

Finally, as we turn our focus on understanding contributions of the maternal and fetal genomes (and paternal contribution, although so far, that appears to not have an impact), GWAS have uncovered four genes in the maternal genome that have endocrine signaling ramifications: *AGTR2*, *WNT4*, *ADCY5*, and *EEFSEC*. Rare variant analysis and Mendelian randomization are two other tools researchers are using to discover causative pathways leading to preterm birth.

Preterm birth is the leading cause of infant mortality throughout the world, often affecting those infants who do survive with a lifetime of costly health issues. Some urban areas in the United States have premature birth rates higher than some developing countries. Maternal mortality—defined by the World Health Organization as the death of the mother within 42 days of giving birth—is also a growing concern because many deaths occur from preventable causes, such as hemorrhage or preeclampsia. It remains critical that we continue

working on understanding the causes of pregnancy complications and parturition timing. With emerging technologies and high-dimensional omics platforms, there has never been greater opportunity to study human pregnancy directly and further elucidate mechanisms.

None of these have major effects on birth timing. Evidence that pregnancy is prolonged in anencephaly and sulfatase deficiency is sketchy, and most steroidogenic enzyme deficiencies (placental aromatase and fetal adrenal enzymes) do not affect birth timing. Preeclampsia may increase risk for preterm birth via indirect mechanisms related to fetal/maternal stress. This is all speculation, however. Regarding placental aromatase deficiency, the major effect is to virilize the female fetus and mother.

INTRODUCTION

Throughout history, humans have sought to understand the differences between biological sexes and the mechanisms responsible for these biological differences.¹ Normal gonadal differentiation and sex development depend on the meticulous choreography and synchrony of a network of endocrine, paracrine, and autocrine signaling pathways. This network involves the actions and interactions of specific genes, epigenetic influences, transcription factors, and hormones. Perturbations of the intricate network of gene regulation and gene expression governing fetal gonadal development result in disorders of sex development (DSD). Approximately one in 4000 infants are estimated to be born with a DSD.^{2,3} However, this estimate increases if all variations of sex development including cryptorchidism and all forms of hypospadias are included. The prevalence for some subgroups have been merely accurately reported, such as 46,XY females at 6.4/100,000; 4.1/100,000 for androgen insensitivity syndrome (AIS); and 1.5/100,00 for gonadal dysgenesis.⁴

DSDs comprise a spectrum of disorders in which chromosomal, genetic, gonadal, hormonal, or anatomic aspects of sex are atypical. Understanding the developmental biology and embryology of the urogenital system is crucial to categorizing and identifying the molecular basis of the disorder in an individual patient. It has become apparent that multiple genes, epigenetic factors, environmental factors, and protein interactions are involved in the processes of gonadal differentiation and sex development. The pediatric endocrinologists' role in the care of an infant with ambiguous genitalia begins at the time of initial presentation—birth, childhood, adolescence, or before birth for infants identified through prenatal testing. The physician's responsibility for the management of this child starts early and continues until transition to adult care providers is deemed appropriate.

Following the 2006 Consensus Statement regarding the management of intersex disorders,⁵ knowledge regarding the molecular basis of sex differentiation/development has expanded. The number and capability of the genetic tools available to identify the molecular basis have increased. Considerations include a holistic approach to the child with a DSD, inclusion of the parents, recognition of psychological well-being, the role for support groups, and need for comprehensive longitudinal care.^{6,7} Outcome data collection, although still limited, expands medical knowledge and quality improvement. Development and evaluation of multidisciplinary care models focusing on quality of care is ongoing.⁸

TALKING WITH THE PARENTS

For parents, the birth of their child is a long-anticipated and exciting event. Because of the increased frequency of prenatal ultrasound examinations, parents have usually been told the sex of their child, may have selected their infant's name, and often hosted a "gender reveal" celebration. In some instances, abnormal genital development has been identified through ultrasound and the parents have been informed of this situation. In this scenario, parents and healthcare providers can confer regarding the likely diagnostic testing and treatment recommendations. In the absence of prior knowledge, the parents are suddenly confronted with a newborn with a birth defect involving the external genitalia and uncertainty regarding their infant's sex. Anxiety and apprehension regarding the baby's health and sex are particularly traumatic when parents had no prior awareness of the abnormal genital development.

Initially, the parents need to be congratulated on the birth of their child. They need to hear that their child has a condition affecting sex development and that this condition will be carefully and completely addressed. Appropriate discussions include sharing that abnormalities of sex development involve the complex system that directs the development of reproductive system, including external genital development. Explaining that the sex of their child cannot be established simply by examining the external genitalia is essential. It is important to emphasize that the atypical development is not the parents' fault and that they should not feel guilty or ashamed. Physician and healthcare professionals should not speculate or offer presumptive diagnoses. The parents can be reassured that all appropriate studies will be obtained to provide comprehensive information to best establish their child's sex of rearing. Use of genetic tools may ascertain the specific etiology of the DSD, with the caveat that a specific molecular etiology may remain unknown.

The goal is patient-centered care within the context of the family and a multidisciplinary team that includes pediatric endocrinologists, pediatric urologists/surgeons, geneticists, neonatologists, radiologists, behavioral health providers, and pediatric endocrine nurse educators. An initial treatment goal is to ascertain whether an underlying or associated life-threatening condition requires specific urgent treatment. One team member should serve as the principal communicator with the family.

Although contemporary society includes overt references to sex and sexuality, parents may have difficulty thinking of their child as a sexual being and feel embarrassed discussing their

child's sex, gender identity, and future sexuality. Cultural attitudes, preexisting expectations, and family support systems impact the parent's responses and may influence their choices for the infant.⁹ Parents need to be informed that the child's gender identity is a personal experience of one's gender. The medical team needs to promote an open and caring network to provide support for the parents. Importantly, the medical team needs to engage the parents in the medical decision-making process and discuss pertinent information. It is important to be aware that the clinicians' use of clinical uncertainty may misdirect parents and exacerbate their anxiety. For surgical decision-making, clinicians should strive for balance between caution and benefit and consideration of options beyond the dichotomy of "surgery" versus "no surgery."¹⁰

If the child's sex remains unclear, information needs to be obtained to assist the parents and healthcare team to determine the most appropriate sex of rearing. Usually, this can be accomplished within a matter of hours or days. In more complex instances, the diagnostic process may take longer. In situations in which it is impossible to identify the specific etiology, the general DSD category (see later) provides a basis for decision-making.

Factors relevant for the medical decision-making process include the extent of external and internal reproductive system development, evidence of gonadal functionality (potential for pubertal hormone secretion and fertility), and hormone responsiveness. In some instances, these factors are more relevant than the karyotype. Genes and gene products involved in sex development are mapped to autosomes and sex chromosomes. Genetic variants mapped to coding and noncoding regions influence sex differentiation and sex development of the fetus and child.

When consensus has been reached regarding a diagnostic category, available outcome information should be reviewed. Knowledge of a specific etiology, including immediate details and long-term outcome, enables optimal planning of therapeutic interventions and genetic counseling for future pregnancies. Healthcare providers need to be cognizant that available outcome data to assist in the decision-making processes are limited. Currently accessible information in published reports is largely based on retrospective studies obtained using diverse methods and strategies.¹¹ The extent, timing, and duration of prenatal androgen exposure, which can only be estimated, likely influences development of the central nervous system (CNS) and other tissues.¹² Prenatal androgen exposure may influence development of gender identity.

One multicenter cross-sectional study reported short-term outcome data on 92 children found to have genital ambiguity with karyotype distribution of 57%, 46,XX; 34% 46,XY; and 9% sex chromosome anomalies. Over 90% of 46,XX individuals had congenital adrenal hyperplasia (CAH); 65% of the 46,XY individuals lacked a molecular diagnosis; and most 46,XY individuals were being raised as males.¹³ Changing concepts regarding medical and surgical interventions urge caution regarding decision-making, while additional outcome studies are underway.¹⁴ Studies may address specific aspects, such as compliance with hormone therapy and patient satisfaction or psychological health, quality of life, and self-perceptions among males with CAH.

The first conversation with the parents should reinforce parental bonding with their infant. As much as possible, a positive and optimistic tone is helpful. Indeed, the emotional tone of this initial conversation is more meaningful than the factual information provided and is recalled by parents for many years. Respect for the family and individual viewpoints, together with a willingness to repeat or defer detailed explanations, are crucial. In the midst of the emotional distress associated with the uncertainty of their infant's sex, parents may be unable to

assimilate the vast amount of information that eventually needs to be shared. Repeated discussions with the parents will enable them to acknowledge their emotional and intellectual concerns regarding their infant. Familiarity and understanding will enable the parents to bond with their infant and interact with family members, friends, and colleagues.

Unless the natal sex is clear at this point, the healthcare team should recommend that the parents delay naming the infant, announcing the baby's birth, and registering the birth, until more information becomes available. The message should be clear that they will be actively involved in the process to establish the sex of rearing for their child. Until sex of rearing is established, it is best to refer to the infant as "your baby" or "your child." Terms such as *he*, *she*, and *it* should be avoided. The multidisciplinary team is responsible for educating ancillary staff regarding how to refer to the infant as "your baby."

Factual explanations regarding the process of sexual differentiation with a focus on their infant's situation should be initially outlined. The primary goal at this point is to provide the parents with a basic understanding that the internal and external genital structures for both boys and girls develop from the same primordial tissues. It is also helpful to explain that there are no exclusively male and female hormones. Rather, the environments in which male and female fetuses develop are characterized by differing relative amounts of these hormones. Using simple sketches, pictures, and diagrams can be helpful to explain the embryology of genital development to the parents. Some parents may benefit from practicing the words they will use to discuss the infant's health with other family members. Detailed explanations can be reviewed multiple times as the child ages, especially because the child is unable to actively participate in the initial discussions.

During the early conversations, examining the infant with the parents to identify the specific physical findings of their infant is often beneficial. Viewing their child's external genitalia can reduce their apprehension and reinforce the perception that their infant's needs are similar to all infants. Information can be presented to minimize anxiety and better equip parents to participate in the decision-making process. Discussion of the many concerns (particularly those related to gender identity, pubertal development, sexual orientation, sexual function, and fertility) may be helpful. Honestly addressing parents' concerns will ultimately create trust and positive feelings to help the parents promote their child's self-esteem. Ideally, each parent achieves a personal resolution with a commitment to a positive perspective for the child's future.

TERMINOLOGY

Under the auspices of the Pediatric Endocrine Society (NA) and the European Society for Pediatric Endocrinology, an international consensus statement was formulated that recommended a revised classification of the medical terminology used for disorders of sex development to avoid confusing and derogatory terms. This descriptive classification attempts to be sensitive to concerns of parents and flexible enough to incorporate novel molecular genetic information. The updated classification system integrates molecular genetic considerations into the nomenclature for "disorders of sexual differentiation (DSD)" and provides an approach to the diagnostic evaluation. There are objections to use of the word "disorders" because this implies pathology, with "differences" sometimes being used.

Terms, such as *pseudohermaphrodite*, *true hermaphrodite*, and *gender labeling* in the diagnosis should be eliminated.³ However, some patients still prefer to use the term *intersex*. To accommodate all types of DSD, the classification system is broad and includes some conditions that do not present with

TABLE 6.1 Sex Chromosomal Disorder of Sex Development

Syndrome	Karyotype	Chromosomal Defects
Turner syndrome	45,X mosaic 45,X/46,XX	X monosomy Mosaic monosomy X
Turner syndrome with structural X chromosome rearrangements	46,X,i(Xq) 46,X,del(Xp) 46,X,+mar	isochromosome Xq deletion Xp marker chromosome
Gonadal dysgenesis	45,X/46,XY XX/XY	Mosaic loss of the Y chromosome in XY, chimerism
XX male SRY gene positive Gonadal dysgenesis	46,XX or 46,X,der(X)t(X;Y)	Yp (SRY gene) translocation to the X chromosome or autosome
XX male SRY gene negative	46,XX	SRY gene is absent
Klinefelter syndrome and its variants	XXY mosaic 46,XXY/46,XY XXYY XX/XXY	Disomy X, Mosaic disomy X Disomy X and Y Mosaic loss of the Y chromosome in XXY

obvious abnormalities of genital development (Table 6.1). The primary goal of this classification system is to provide a framework for diagnosis, assessment, and care management based largely on sex chromosome status. Currently, microarray, candidate gene analyses, and whole exome/genome sequencing are increasingly used. The DSD categories include sex chromosome DSDs, such as 45,X/46,XY; ovotesticular DSD; 46,XY DSDs, such as disorders of testicular development, disorders of androgen synthesis and action, 46,XY sex reversal, and 46,XX DSDs; and 46,XX sex reversal. Some diagnoses are included in more than one category because of the complexities of chromosomal and gonadal development. The number of genes identified to be involved in sex development continues to increase. Nevertheless, despite many recent advances, the specific molecular etiology of the genital ambiguity in an individual cannot always be identified, especially among those with 46XY DSDs.

SEX DETERMINATION

Through Alfred Jost's experiments with fetal rabbits in the 1940s and 1950s, the critical requirements for a testis and testosterone for male sexual differentiation were established.¹⁵ Chromosomal composition of the human embryo, XX or XY, determines gonadal sex. Investigation of human sex chromosome evolution suggested that the human sex chromosomes evolved from a pair of ancestral autosomes approximately 300 million years ago. The emergence of the SRY locus, several Y chromosome inversions, and loss of X-Y crossing-over led to the current human situation.¹⁶

Studies of patients with disorders of sex development ultimately led to identification of the genetic locus primarily responsible for this binary switch, the sex-determining region on the Y (SRY) gene on the Y chromosome. Studies involving creation of transgenic SRY+ mice confirmed the essential role of SRY and provided further molecular understanding of testicular differentiation.^{17,18}

Genetic sex is established at fertilization followed by sex determination, the binary switch that launches the developmental destiny of the embryonic gonads to become testes or ovaries. Sex determination is largely influenced through transcriptional regulation, whereas secreted hormones and hormone receptors influence phenotypic development. Sexual

differentiation refers to the process through which male or female phenotype develops.¹⁹

The gonads, internal genital ducts, and external genital structures all develop from bipotential tissues. Each cell in the developing gonad has the potential to differentiate into either a testicular or ovarian cell, depending on how the transcriptome of the undifferentiated cell realizes its pathway to develop into an ovary or testis. In this bipotential state, pluripotency with genes poised for either activation or repression exists.²⁰ In other words, sex determination of the bipotential gonads depends on cell fate commitment to one pathway at a precise moment in development, while maintaining active repression of the alternative developmental pathway.

In the usual situation, the karyotype (46,XY or 46,XX) of the primordial gonad determines whether it differentiates into a testis or ovary, respectively. Inherent differences exist between XX and XY cells; approximately 85% of the second X chromosome in an XX cell undergoes X-inactivation and Y chromosome genes related to spermatogenesis are expressed in XY cells.²¹ Local factors (such as hormones secreted by the developing gonads or tissue-specific transcription factors) influence the ensuing differentiation of the internal and external genital structures. This process integrates sex-specific pathway signals that appear to antagonize each other.

Chromatin configuration and its spatial three-dimensional architecture influence gene expression by modulating the ability of transcription factors to bind to deoxyribonucleic acid (DNA).²² Histone modification and DNA methylation influence chromatin organization. The chromatin landscape actively modulates the unending ovary versus testis antagonism. Genes involved with male pathway development lose their repressive marks when the testis pathway is activated and vice versa for genes involved in the ovarian pathway. Cis-regulatory elements, such as silencers and enhancers, coordinate the specific spatiotemporal expression of genes within the transcriptional network; sex-specific regulatory elements are acquired during development.²³ Polycomb proteins are conserved transcriptional regulators that coordinate chromatin structure and chromosome architecture. Chromatin regulators, for example, polycomb proteins, represent critical nodes where biological signals modulate gene expression.

Divergence from the normal sequence of events leads to disorders of sex development that can manifest as abnormal gonadal differentiation, inconsistent internal genital differentiation, or ambiguity of the external genitalia. Although genital ambiguity is usually not considered to be a medical emergency, this type of birth defect is usually extremely distressing to the parents and extended family. When adrenal insufficiency accompanies the genital ambiguity, immediate evaluation and treatment are essential. Regardless, prompt referral and evaluation by a multidisciplinary team with expertise in disorders of sex differentiation is strongly recommended.

DEVELOPMENT OF THE REPRODUCTIVE SYSTEM

Urogenital Ridge and Bipotential Gonad Development

The urogenital ridge gives rise to the gonads, adrenal cortex, kidney, and reproductive tract. The gonads are derived from intermediate mesoderm and depend on the correct ingression, proliferation, and orientation of the coelomic epithelial cells (Fig. 6.1). In humans, at 4 to 6 weeks of gestation, the urogenital ridges develop as paired outgrowths of coelomic epithelium (mesothelium) on the ventral side of the mesonephros. As the coelomic epithelium proliferates, its basement membrane disintegrates to allow ingression of coelomic cells to form the developing gonad. Notch signaling ensures proper

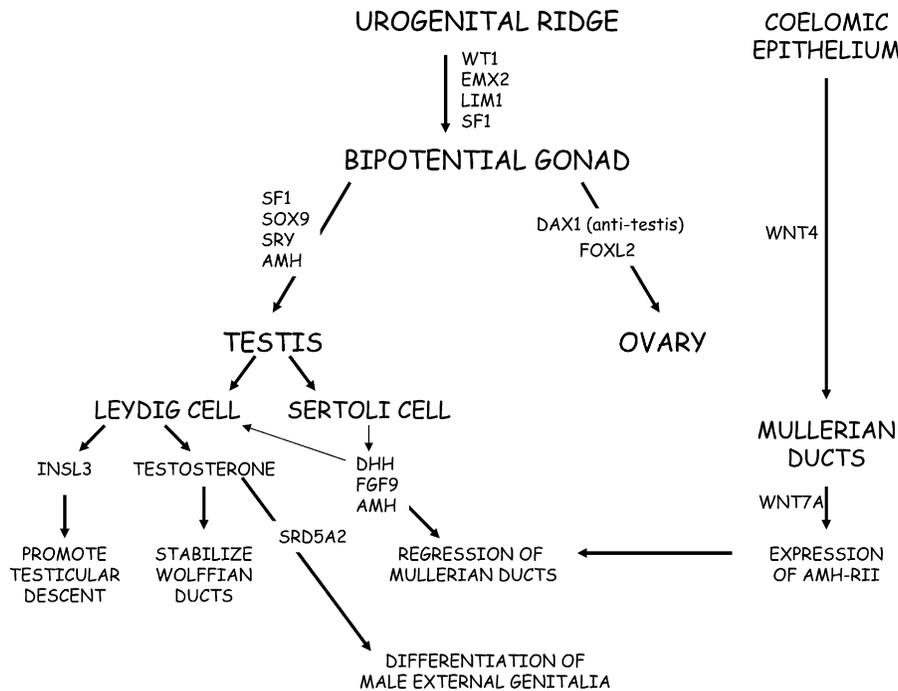

Fig. 6.1 Genes involved in the process of sexual differentiation. Wilms tumor (*WT1*), *EMX2*, *LIM1*, *CBX2*, and steroidogenic factor-1 (*SF1*) play roles in differentiation of gonad from urogenital ridge. Genes involved in testicular differentiation include *SF-1*, *SOX9*, sex-determining region on Y (*SRY*), and anti-Müllerian hormone (*AMH*). The dosage-sensitive sex-adrenal hypoplasia congenital critical region on X (*DAX1*) appears to function as an antitestis factor. *Wnt4* promotes development of the Müllerian ducts, whereas *Wnt7a* promotes expression of the receptor for *AMH* (*AMH-RII*). Sertoli cells secrete *AMH*, which (acting through its cognate receptor [*AMH-RII*]) promotes regression of the Müllerian ducts. Leydig cells secrete testosterone and insulin-like hormone-3 (*INSL3*). Testosterone stabilizes the Wolffian ducts and is converted to dihydrotestosterone (*DHT*) by 5α -reductase in target tissues to promote differentiation of the prostate and development of male external genitalia. *INSL3* is involved in transabdominal testicular descent. *FOXL2*, *RSPO1*, *WNT4*, and β -catenin are involved in ovarian development.

polarization of these cells. In the developing testis, the ingressing cells initially form the Sertoli cells, whereas the later ingressing cells develop into the interstitial cells, including Leydig cells.²⁴ In the ovary, ingressing cells give rise to both theca and granulosa cells.²⁵

The somatic cells of the bipotential gonad require expression of Wilms tumor (*WT1*), GATA binding protein 4 (*GATA4*), and steroidogenic factor 1 (*NR5A1/SF1*) genes. The *WT1* gene codes a zinc transcription factor, which is expressed in embryonic mesodermal tissues and appears to influence mesodermal-epithelial interactions.²⁶ *GATA4* is expressed in the somatic cells of the urogenital ridge and bipotential gonad before showing sex-specific expression. Chromobox homolog 2 (*CBX2*) is expressed in the developing gonad at 7 weeks of gestation and plays a role in early gonadal development.²⁷ *CBX2* functions upstream of *SRY*, promotes transactivation of *NR5A1* and *SOX9*, and represses forkhead transcription factor 2 (*FOXL2*).²⁸ *NR5A1* is expressed in the urogenital ridge and appears to upregulate *SRY* expression, furthering testis development. *FOXL2*, a forkhead transcription factor expressed in the ovary, orchestrates cell fate decisions; *FOXL2* favors ovarian development and represses testicular development. In addition to transcription factors and specific secreted factors (hormones), physical contact with the mesonephros appears to be important for subsequent gonadal differentiation.

Because of their origin within the developing urogenital system, ovaries, and testes are initially located high in the abdomen near the kidneys. Specific signaling molecules activate or repress gonad determination for both testes and ovaries. As noted earlier, ongoing mutual antagonism or competition between specific genes and proteins influences cell fate decisions in gonad development.²⁹ Transcription factors modulate

this “competition” by influencing gene expression. Specific examples include *FOXL2* versus *SRY*-box 9 (*SOX9*) and *SOX9* versus Wingless-type MMTV integration site family member 4 (*WNT4*)/ β -catenin, which are discussed later. Hence, sex determination and differentiation reflect mutual antagonism between the testes determining factors, *SRY*-*SOX9*-*FGF9*, and the ovary determining factors, roof plate-specific spondin-1 (*RSPO1*)-*WNT*- β -catenin-*FOXL2*. Curiously, the antagonism persists postnatally (see later). As would be anticipated, steroidogenic enzyme genes show higher expression in developing human testes compared with ovaries.³⁰

Human Testicular Development

Testicular differentiation begins earlier than ovarian development. The first evidence of testicular differentiation is the appearance of primitive Sertoli cells at 6 to 7 weeks’ gestation in the human fetal testis. Cells, mostly endothelial cells, migrate from the mesonephros and interact with the pre-Sertoli cells to promote development of the testicular cords, which is initiated at approximately 7 to 8 weeks of gestation with identifiable cords by 9 to 10 weeks of gestation.³¹ The testicular cords are precursors of the seminiferous tubules that will contain Sertoli and germ cells. Interactions between endothelial and mesenchymal cells appear to influence development of the testicular cords.³²

The binary switch responsible for testicular development is the *SRY* gene located on the short arm of the Y chromosome. The precise mechanism(s) responsible for triggering *SRY* expression are incompletely defined. In the human testis, *SRY* is expressed in supporting cells at approximately 6 weeks of gestation; low-level expression persists throughout

gestation.^{33,34} The SRY protein contains a high-mobility group (HMG) domain and is encoded by a single exon gene. Two nuclear localization signals are located in the HMG domain. The SRY protein is expressed in pre-Sertoli cells, where it triggers a molecular switch to induce Sertoli cell differentiation, thus, initiating the process of male sexual differentiation. The HMG domain of the SRY protein binds to the minor DNA groove, where it functions as a transcription factor by bending DNA to presumably permit other proteins access to regulatory regions and to promote assembly of nucleoprotein transcription complexes. A threshold SRY level must be achieved at a critical time during gestation to establish male sexual differentiation. Otherwise, the ovarian differentiation pathway is activated.

SRY expression is independent of the presence of germ cells. SRY increases the expression of the SRY-related HMG box-containing-9 (SOX9) gene. Phenotype-genotype studies of humans and mice demonstrate that SOX9 expression is a crucial step, downstream of SRY, in testis development. Upstream from the SOX9 transcription start site, at least three enhancers, eSR-A, eSR-B, and eALDI, synergize to promote SOX9 expression. Available data suggest that SRY and NR5A1 bind at eALDI to promote initial SOX9 expression. Once expression has been initiated, SOX9 positively autoregulates its own expression. Subsequently, SOX9 and NR5A1 bind to regions within all three enhancer loci to amplify testicular SOX9 expression.³⁵ Using both direct and indirect mechanisms, SOX9 interferes with genes promoting ovarian differentiation. These data are consistent with the suggestions that mammalian gene regulation depends on multiple redundant enhancers and that copy number variants in this region may cause sex reversal.³⁶

In addition to SRY, SOX9, and NR5A1, expression of other genes is required for normal male sexual differentiation. Fibroblast growth factor (FGF9) acting through FGF receptors (FGFRs) promotes expression of SOX9 and repression of WNT4 and FOXL2.³⁷ Genes found to have expression pattern similar to SOX9 during testis development include *CITED1*, *ANKRD18A*, *G6PD*, *SLC52A3*, *KEL*, *ZNF280B*, *PRPS2*, and *INHBB*.³³ In addition to activation of the testicular differentiation pathway, the developing testis expresses factors to actively repress ovarian development. Specifically, the developing testis represses the R-spondin-WNT signaling pathway. Transmembrane E3 ubiquitin ligases, ZNRF3 and RNF43, inhibit WNT signaling by targeting the Frizzled receptor for degradation.³⁹

By immunohistochemistry, NR5A1 and SOX9 proteins can be detected in human embryonic gonadal tissue at 6 to 7 weeks of gestation. At this time, SOX9 expression becomes limited to nuclei of Sertoli cells in a 46,XY fetus but remains cytosolic in a 46,XX fetus. Subsequently anti-Mullerian hormone (AMH) is expressed; with increased AMH protein expression Wilms tumor (WT1) and GATA-4 protein expression increase in the fetal testis.⁴⁰ Male-limited expression of doublesex-related and Mab-3-related transcription factor 1 (*DMRT1*) was found in 6- and 7-week-old human fetuses.⁴¹ *DMRT1* appears to be necessary to maintain testicular cords and prevent transdifferentiation to a female phenotype.⁴² The most rapid growth in Sertoli cell number appears to occur during the latter half of the first trimester and the second trimester.⁴³ After Sertoli cells have developed, fetal Leydig cells appear around the seventh to eighth week of gestation and produce androgens to promote internal and external male genital structures.⁴⁴

Leydig cells are comprised of two distinct populations; fetal Leydig cells differentiate in utero and adult Leydig cells emerge after birth. Fetal Leydig cell differentiation depends on paracrine signals, such as platelet-derived growth factor receptor-alpha (PDGFR- α), Desert hedgehog (DHH), PTCH1, and Aristaless-related homeobox (ARX). *NR5A1* is expressed in Leydig cells to promote steroidogenic enzyme gene expression. The number of fetal Leydig cells reflects gonadotropin

stimulation because the number is decreased in anencephalic male fetuses and increased in 46,XY fetuses, with elevated gonadotropin concentrations secondary to complete androgen insensitivity.⁴⁵

Expression of genes associated with testicular steroidogenesis increases around 8 weeks of gestation. Placental human chorionic gonadotropin (hCG) stimulates early testicular androgen secretion. Later in gestation, pituitary LH secretion drives testicular androgen secretion. By 11 weeks of gestation, the testicular compartments, tubular and interstitial components, and the cell types of interest (Leydig, Sertoli, and germ cells) can be visualized. In human fetal testes, *HSD17B3*, *CYP11A1*, and *PTC1* messenger ribonucleic acid (mRNA) levels increased significantly through the second trimester without significant changes in *CYP17A1*, *LHR*, or *INSL3* levels.

Human Ovary Development

Rather than ovarian differentiation being the default pathway occurring in the absence of SRY gene expression, it is clear that specific genes influence ovarian differentiation. Genes involved in ovarian differentiation include *WNT4*, *FOXL2*, follistatin (*FST*), bone morphogenic protein-2 (*BMP2*), *GATA4/FOG2*, and *RSPO1*. *RSPO1* is a secreted factor that activates the β -catenin WNT signaling pathway.³³ *FOXL2* represses male-specific genes, especially SOX9 beginning in the fetus; this active repression continues throughout adulthood.⁴⁶ Hence *FOXL2* and SOX9 expression are mutually exclusive in developing gonads, as well as postnatal ovaries and testes.^{47,48}

Normal ovarian development requires *FOXL2*, *RSPO1*, and canonical WNT/ β -catenin signals. *RSPO1* acting through *LGR4/5* cell-surface receptors sequesters the transmembrane E3 ubiquitin ligases ZNRF3 and RNF43, resulting in increased WNT signaling.⁴⁹ *RSPO1* and *WNT4* stabilize and amplify β -catenin signaling to activate target gene transcription.³⁹ *WNT4* suppresses androgen-secreting interstitial cells, inhibits coelomic vascularization, and supports Mullerian derivatives.

Two genes that factor in germline development, alpha (*FIGLA*) and newborn ovary homeobox (*NOBOX*), are expressed in fetal or neonatal germ cells, where they recruit developing granulosa cells to form primordial and primary follicles. Additional transcription factors involved in ovarian development include *SOHLH1*, *SOHLH2*, *NOBOX*, *LHX8*, *FIGLA*, and *LHX9*.⁵⁰ The second trimester human fetal ovary expresses proteins necessary to synthesize and respond to estrogenic, progestogenic, and androgenic signaling.⁵¹

Germ Cell Development

Despite the prerequisite for germ cell development to perpetuate the species, germ cells are not required for the initial development of ovaries or testes. The primordial germ cells originate in the epiblast. At approximately 6 weeks of gestation in the human, the primordial germ cells proliferate and migrate from the hindgut along nerve fibers to colonize the genital ridges.⁵²⁻⁵⁴ SOX17 is a pluripotency factor that is critical for human primordial germ cell specification through its action to promote germ cell-specific gene expression.⁵⁵ SOX17 appears to promote *BLIMP* expression, which appears to suppress endodermal and mesodermal genes.⁵⁵

Upon reaching the developing gonad, the local environment directs the fate of the primordial germ cells toward male or female development. Hence the terminal differentiation pathways for germ cells are sexually dimorphic. When this migration process goes awry, the gonadal germ cell population may be deficient. Aberrant migration can result in ectopic migration into other organs. Ectopic germ cells are primarily located in the CNS, but can also be found in the mediastinum,

thorax, and pelvic region. Germ cell tumors may develop in ectopic germ cells when the germ cells are not eliminated by apoptosis.

Developmental phases for female germ cells include initiation of meiosis, formation and breakdown of germ cell nests, and assembly of single oocytes into primordial follicles. For male germ cells, the characteristic phases are migration, mitosis, and cell-cycle arrest.⁵⁶ Oocytes undergo meiosis, whereas meiosis is actively inhibited in male germ cells.⁵⁷ The RNA binding protein deleted in azoospermia-like (DAZL) appears to license entry into meiosis; *DAZL* expression increased between 9 and 14 weeks' gestation.⁵⁸ Several RNA-binding proteins, such as LIN28, *DAZL*, and *BOLL*, are expressed during oogenesis.⁵⁹ Another protein, meiosis specific with coiled-coil domain (MEIOC) stabilizes mRNAs that encode proteins relevant for meiosis; its expression appears to be independent of retinoic acid.⁶⁰ *DAZL* inhibits *SOX17* expression limiting germ cell pluripotency. Hence *DAZL* plays dual roles: it initiates meiosis in ovaries and represses pluripotency factors.

The fetal ovary is characterized by a developmental gradient with existence of multiple subpopulations of germ cells at different developmental stages; the more differentiated germ cells are located in the center of the developing ovary. In the developing ovary, the germ cells initially form oogonial clusters connected by intracellular bridges. Selected oogonia enter meiosis and progress through meiotic prophase I (MPI). Somatic cells surround individual oocytes to form follicles. Around 16 to 20 weeks' gestation, the oogonial clusters break down to form primordial follicles.⁶¹ The oocytes within the primordial follicles undergo growth arrest at the diplotene stage, lasting until oocyte growth is reinitiated with the onset of puberty. The greatest number of follicles exists at midgestation. From a peak of 6.8 million oocytes at approximately 5 months of gestation, approximately 2 million are present at birth.⁶² Notch signaling mediates interactions between oocytes and granulosa cells, regulates oocyte survival, and promotes breakdown of the oogonial nests.⁶³ The internal environment throughout fetal ovary development has the potential to directly influence the fertility of the developing female fetus (controlling the size of the ovarian reserve) and the quality of the oocytes that will eventually become her child (by influencing the extent of selection and apoptosis).⁶⁴

The primordial follicles constitute the ovarian reserve. Postnatally, recruitment and maturation of the primordial follicles is largely governed by AMH, androgen, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) secretion. Premature germ cell loss can lead to gonadal dysgenesis or premature ovarian insufficiency (POI). Accelerated follicular atresia contributes to the follicular depletion characteristic of streak gonads in X monosomy. Although not typically associated with genital ambiguity, mutations in genes governing oocyte and ovarian development cause DSDs characterized by delayed puberty or POI. These genes influence germ cell mitosis, germ cell meiosis, and DNA repair.⁶⁵

In contrast, testicular germ cell development is less dynamic. The Sertoli cells envelop the germ cells to form seminiferous cords at approximately 7 to 9 weeks of gestation in the human XY gonad. The germ cells in the developing testis enter a state of mitotic arrest until the onset of puberty.

Early during gestation, primordial germ cells undergo epigenetic reprogramming, which modifies chromatin architecture. In other words, inherited imprints are erased and DNA methylation is decreased at CpG islands, transcription start sites, genes, and intergenic regions.⁶⁶ Demethylation affects almost the entire genome, including the inactive X chromosome by 10 to 11 weeks of gestation.⁶⁷ During meiosis, both X chromosomes need to be active to enable

efficient pairing.⁶⁸ Subsequently, maternal and paternal alleles undergo sexually dimorphic imprinting, such that developing oocytes and sperm are differentially marked reflecting "parent-of-origin"-specific methylation patterns. This process occurs late in fetal development in the male and postnatally in female germ cells.^{69,70} Study of parent-of-origin-dependent disorders, such as Beckwith-Wiedemann, Prader-Willi, and Angelman syndromes and neonatal diabetes mellitus has elucidated the importance of this imprinting process.

Human Adrenal Development

By 33 days postconception, the human fetal adrenal cortex is distinct from the developing gonad. Because of its role as the source of dehydroepiandrosterone sulfate (DHEA-S) for placental estrogen biosynthesis, the fetal adrenal cortex grows rapidly. By 50 to 52 days postconception, expression of several steroidogenic enzymes, steroidogenic acute regulatory protein (*StAR*), 11 β -hydroxylase (*CYP11B1*), 17 α -hydroxylase/17,20-lyase (*CYP17A1*), and 21-hydroxylase (*CYP21A2*) in the fetal adrenal cortex have been demonstrated immunohistochemically.⁷¹ Transitory fetal adrenal cortisol biosynthesis peaks at 8 to 9 weeks' gestation, which coincides with transient adrenal expression of both nerve growth factor IB-like (*NGFI-B*) and 3 β -hydroxysteroid dehydrogenase-2 (*HSD3B2*).⁷¹ At the same time, adrenocorticotropin hormone (ACTH) can be detected in the anterior pituitary, suggesting the presence of negative feedback inhibition during the first trimester. During the time male sexual differentiation begins, this negative feedback inhibition may serve to prevent virilization of female fetuses to ensure normal female sexual differentiation.⁷² Distinct expression profiles for fetal adrenal steroidogenic enzymes have been described with differences between the first and second trimesters.⁷³ Chromaffin cells derived from the sympathetic nervous system migrate into the adrenal cortex to form the adrenal medulla.

Development of Internal Genital Structures

The Wolffian duct originates as the excretory duct of the mesonephros and develops into the epididymis, vas deferens, ejaculatory duct, and seminal vesicle. The Mullerian or paramesonephric duct originates as an invagination of the coelomic epithelium and develops into the Fallopian tubes, uterus, and upper third of the vagina.

The Sertoli cells of the developing testis secrete AMH, also known as *Mullerian inhibitory hormone (MIH)*. In human 46, XY fetuses, AMH expression can be detected by 7 weeks of gestation, is not dependent on the presence of germ cells within the testis, and promotes regression of the Mullerian ducts. AMH, a member of the transforming growth factor- β (TGF- β) family, undergoes proteolytic cleavage to become biologically active. AMH binds to its receptor, AMH-RII, on the surface of the Mullerian duct mesenchymal cells to induce increased matrix metalloproteinase 2 expression. The net result is degeneration and loss of basement membrane integrity of the epithelial and mesenchymal Mullerian cells, leading to regression of the Mullerian ducts.

AMH expression is highly regulated; inappropriate expression in a 46,XX fetus would lead to uterine agenesis. In the 46,XX fetus with absence of both AMH and testosterone, the Mullerian duct derivatives persist and the Wolffian ducts regress. When a female fetus is inappropriately exposed to AMH (as in freemartin cattle), Mullerian duct regression and ovarian masculinization occur. The paired Mullerian ducts arise as coelomic epithelial invaginations. Around the eighth week of gestation, the Mullerian ducts fuse, followed by

degeneration of a midline epithelial septum. Variable persistence of this septum can lead to uterine malformations. Multiple factors influence the development of the uterus, cervix, and vagina.⁷⁴ *HOX* genes specify the development program for distinct uterine regions; *HOXA9* specifies the uterine tube, *HOXA10* and *HOXA11* specify the uterus, and *HOXA13* specifies the vagina.⁷⁵ The vaginal plate appears during the 11th week of gestation through occlusion of the Mullerian-derived uterovaginal canal and ultimately disappears as the vaginal plate lengthens and canalizes.⁷⁶

The fetal hypothalamic-pituitary-gonadal (HPG) axis is active by midgestation, with peak fetal testosterone concentrations occurring at approximately 15 to 16 weeks of gestation. Before this time, placental hCG stimulates testosterone production by the fetal Leydig cells. Secretion of testosterone by the fetal Leydig cells stabilizes the Wolffian ducts in 46,XY fetuses. Region-specific signaling molecules, such as BMPs, homeobox (*HOXA10* and *HOXA11*), growth differentiation factor 7 (*GDF7*), relaxin, an orphan G-protein-coupled receptor (*LGR4*), platelet-derived growth factor A (*PDGFA*), and its cognate receptor (*PDGFRA*) influence the development of the epididymis and seminal vesicle.

The prostate, a male accessory sex gland, contributes to seminal fluid plasma and develops from the urogenital sinus. After the initial testosterone-dependent induction of prostate differentiation, subsequent development involves epithelial-mesenchymal interactions that lead to cell differentiation and branching morphogenesis. The requisite signaling molecules, FGFs, sonic hedgehog (*SHH*), BMPs, *HOXA13*, and *HOXD13*, are similar to those required for external genital differentiation.^{77,78}

Development of External Genital Structures

The genital tubercle, urethral folds, and labioscrotal swellings give rise to the external genitalia. Androgens play a time-dependent role in formation, differentiation, and growth of the fetal male external genitalia at approximately 8 to 14 weeks of gestation, during the masculinization programming window (MPW).^{79,80}

During this period, a cylindrical 2-mm phallus with genital swellings develops by 9 weeks of gestation. Within the developing penis, the urethra forms by canalization of the urethral plate with subsequent fusion to form the penile urethra by 12 to 14 weeks of gestation.⁸¹ The genital tubercle develops into the corpora cavernosa of the penis, and the labioscrotal folds fuse to form the scrotum. By 14 weeks, the external genitalia are clearly masculine, apart from testicular location. Thereafter, the penis grows at a rate of 0.7 mm/week from 14 weeks to term.⁸² Deficiency of androgen or androgen action during the MPW reduces penis length, an effect that cannot be fully rescued by postnatal T therapy.⁸³ The MPW predetermines potential phallic size, whereas postnatal androgen action is required to realize normal potential.

In the 46,XX fetus, in the absence of androgens, the urethral folds and labioscrotal swellings do not fuse and develop into the labia minora and labia majora, respectively. The genital tubercle forms the clitoris, and canalization of the vaginal plate creates the lower portion of the vagina. By 11 weeks of gestation, the clitoris is prominent and the lateral boundaries of the urogenital sulcus have separated. Minimal clitoral growth, well-defined labia majora, hypoplastic labia minora, and separate vaginal and urethral perineal openings are present by 20 weeks of gestation.

Anogenital Distance

The anogenital distance (AGD), the distance from anus to the genital tubercle, indicates prenatal androgen action and, as

anticipated, is sexually dimorphic. Investigators have used different anatomic landmarks to assess AGD in humans. Salazar-Martinez and colleagues defined AGD as being from the anus to the perineoscrotal junction (anoscrotal distance) in males and from the anus to the anterior fourchette (anofourchettal distance) in females; this definition appears to improve interobserver reliability.⁸⁴ Salazar-Martinez and colleagues reported normative ranges for anoscrotal and anofourchettal distances to be 21 ± 3.0 mm in males and 11 ± 2 mm in females (Salazar). In both sexes, AGD increased up to 12 months and maintained the sex dimorphic pattern. AGD also showed positive correlation with penile length at birth and with the increase in AGD from birth to 3 months. AGD provides a biomarker of early fetal androgen exposure and masculinization. Measurement of AGD can be used as a diagnostic tool for in utero androgen exposure and assessing impact of potential environmental endocrine disruptors on external genital development.^{85–88} AGD at birth predicts adult anogenital distance, but correlations with adult male reproductive parameters are inconsistent.^{89,90}

Sexual Differentiation of the Brain

Clinical investigations suggest that the brain is sexually dimorphic and that testosterone is a masculinizing hormone in human. Males with aromatase deficiency manifest male psychosexual behavior and gender identity. Alternatively, 46,XY individuals with complete androgen insensitivity syndrome (CAIS) develop female gender identity. However, preliminary data implicate genetic differences, independent of sex steroid exposure, as the molecular basis for some aspects of sexual dimorphism of the brain and other nongonadal tissues.^{91,92} Androgens have organizational and activation effects on CNS function. Complex interactions between genetic factors and hormone contribute to human brain sex differences.⁹³

MOUSE MODELS

For many patients with DSDs, the specific molecular etiology is unknown. Hence investigation of animal models, especially transgenic mouse models, has been helpful to delve into the processes involved in sex development. Investigation of normal and transgenic mice confirmed the crucial role of the sex-determining region on Y (*SRY*) gene in male differentiation when XX mice carrying only a 14-kb fragment of the Y chromosome showed a male phenotype.⁹⁴ However, the molecular mechanisms responsible for sex differentiation/sex development and postimplantation development differ among rodents and humans. Despite these limitations, information gleaned from preclinical models provides useful information regarding molecular mechanisms of sex development.

Understanding gene regulation, epigenetic influences, and protein-protein interactions are essential to clarify regulation of the sex development pathways; this knowledge may identify factors relevant for patients with DSDs. The outcome of cell fate decisions involves antagonism between the male and female developmental programs. During the bipotential phase, both male- and female-specific genes are expressed. Subsequently, precise spatiotemporal expression of specific genes ensues. Abnormal gonadal development has been described in mice homozygous for targeted deletions of genes involved in urogenital differentiation, that is, *Wt1*, *Sf1*, *Emx2*, *Cbx2/M33*, *Six1/Six4*, and *Lim1/Lhx9*. The phenotype of *Wt1* knockout mice includes embryonic lethality, failure of gonadal and kidney development, and abnormal development of the mesothelium, heart, and lungs.⁹⁵ Homozygous deletion of *Emx2*, a homeodomain transcription factor, results in an embryonic lethal phenotype associated with absence of kidneys, ureters,

gonads, and genital tracts.^{96,97} As *Wt1* expression is initially normal in the metanephric blastema of *Emx2* knockout mice, *Emx2* is likely downstream of *Wt1*. Interestingly, adrenal gland and bladder development are normal in *Emx2* knockout mice. Although the phenotype of specific knockout mice have been reported, details regarding the regulatory mechanisms governing gene expression are often lacking.

Epigenetic mechanisms modify chromatin architecture to reversibly regulate gene expression in a developmental manner. These mechanisms include histone modifications, that is, methylation/demethylation, acetylation/deacetylation, ubiquitination, and DNA methylation.⁹⁸ The polycomb group proteins, consisting of multiple protein subunits, function to modify chromatin structure. One polycomb protein is *Cbx2/M33*. The phenotype of *Cbx2* knockout mice includes male-to-female sex reversal and hypoplastic gonads for both sexes. Although the testes were small, overexpression of *Sry* or *Sox9* in *Cbx2* knockout mice rescued sex reversal in XY mice.⁹⁹ Based on available animal studies, *Cbx2* modulates expression of *Sfl/Nr5a1*, *Sry*, *Sox9*, *Dax1*, *Gata4*, *Arx*, and *Dmrt1* in both sexes, and influences gonad proliferation and size.

Although the temporal expression patterns for human *SRY* and mouse *Sry* differ, understanding the regulatory mechanisms responsible for mouse *Sry* expression has been germane to human *SRY*. Epigenetic factors influence expression of the mouse *Sry* gene. Both demethylation and histone modification are essential for *Sry* expression. The histone demethylase JMJD1A positively influences *Sry* expression by regulating H3K9me2 marks; *Jmjd1a*-deficient mice show partial male to female sex reversal.¹⁰⁰ Another mechanism involves the GADD4G protein, which mediates DNA demethylation and mitogen-activated protein kinase (MAPK) signaling. Loss-of-function *Gadd45g* mutant mice manifest male-to-female sex reversal; GADD45G appears to activate the MAPK pathway by phosphorylating GATA4 to activate *Sry* expression.^{101,102} Mice with loss-of-function *Gata4* mutation show phenotype similar to *Gadd4g* mice with decreased *Sry* expression and XY sex reversal.¹⁰³

Another epigenetic mechanism involved in *Sry* regulation involves CREB-binding protein (CBP, CREBBP, KAT3A) and p300 (EP300, KAT3B). These proteins are histone/lysine acetyl-transferases that modify chromatin-associated proteins to regulate gene expression. Mice with loss-of-function mutations manifest male-to-female sex reversal.¹⁰⁴ These proteins can act as network hubs interacting with other proteins to influence gene transcription.¹⁰⁵

Investigation of mouse models has been used to learn more about Wolffian and Mullerian duct development. Development of Wolffian duct epithelium depends on signals from Wolffian duct mesenchyme. Testicular testosterone activates mesenchymal androgen receptors to initiate mesenchymal-epithelial cross talk, increase epidermal growth factor production, and antagonize COUP-TFII to promote Wolffian duct stabilization.^{106,107} Factors involved in Mullerian duct regression include AMH, AMHR2, and SMAD; however, the molecular mechanism(s) used by AMH to induce Mullerian duct regression remains to be defined.

SEX CHROMOSOME DISORDERS

45,X/46,XY Mosaicism

Most sex chromosome disorders, such as 45,X and cytogenetic variants and 47,XXY and cytogenetic variants, are not associated with abnormal external genital development and will not be discussed in this chapter (see Table 6.1). In contrast, individuals with 45,X/46,XY and 46,XX/46,XY karyotypes manifest a broad range of phenotypes.¹⁰⁸ Among individuals with

45,X/46,XY karyotype, internal and external genital structures range from normal male to ambiguous to female. Whereas the typical histological features consist of poorly developed seminiferous tubules surrounded by wavy ovarian stroma, gonadal differentiation can range from normal testis to streak gonads. At the time of puberty, virilization can occur.

The majority of individuals identified by prenatal karyotype as being 45,X/46,XY appear to be normally androgenized males; however, individuals diagnosed postnatally tend to have more clinical signs.^{109,110} A normal peripheral blood lymphocyte karyotype in individuals with gonadal dysgenesis suggests the presence of sex chromosome mosaicism within the gonad(s).¹¹¹ Individuals with sex chromosome DSDs because of gonadal dysgenesis have an increased risk of developing gonadal tumors, such as gonadoblastoma or dysgerminoma because a dysgenetic gonad carrying a Y chromosome has an increased risk for neoplastic changes. Although gonadal tumors typically do not develop until the second decade of life, they can occur at younger ages.

Among a series of 63 males with 45,X/46,XY, subjects were classified into two groups; one group presented with genital anomalies and the second group presented with other reasons, such as short stature or infertility. Individuals identified by genital anomalies tended to have lower rates of spontaneous pubertal development, shorter stature, and greater likelihood of germ cell neoplasia.¹¹² Although most gonads were classified as dysgenetic testes, some testes appeared relatively normal with evidence of spermatogenesis. No follicles were observed, suggesting that gonads labeled as ovotestis were mislabeled and consisted of undifferentiated/streak-like tissue.¹¹³ Based on these histological findings, it has been suggested that the etiology of the 45,X/46,XY karyotype is the loss of a Y chromosome in some cells.¹¹⁴ Focal spermatogenesis was identified in approximately 25% of these subjects. Thus when gonadectomy is considered because of risk for neoplasia, fertility preservation should be considered.¹¹²

DISORDERS ASSOCIATED WITH DISORDERS OF SEX DEVELOPMENT AND ADDITIONAL CONGENITAL ANOMALIES (TABLE 6.2)

ARX (X-Linked Lissencephaly 2)

X-linked lissencephaly 2 is characterized by genital ambiguity, lissencephaly, early-onset seizures, absence of the corpus callosum, intellectual disability, and hypothalamic dysfunction, and *Aristaless*-related homeobox (*ARX*) gene mutations. This gene is a member of the paired-type homeodomain transcription factor family and is mapped to Xp21.3. *ARX* contributes to many aspects of brain development including patterning, neuronal proliferation and migration, and cell maturation and differentiation, especially the generation and migration of GABAergic neurons.^{115,116} Findings in *Arx* knockout mice showed no expression in developing ovaries, but Leydig cell differentiation was impaired.¹¹⁷ Available data suggest that *Arx* is a positive regulator for the differentiation of fetal Leydig cells at the progenitor stage.¹¹⁸

CDKN1C (IMAGe Syndrome)

The IMAGe syndrome is characterized by intrauterine growth retardation, metaphyseal dysplasia, adrenal hypoplasia, cryptorchidism, and micropenis.¹¹⁹ Genital anomalies appear to be limited to affected males. Both sporadic and familial cases have been described. Heterozygous missense mutations in the *CDKN1C* gene have been detected in some cases. This gene is located at chromosome 11p15.5, encodes a 316-amino-acid protein, p57^{Kip2}, negatively regulates cellular proliferation, and

TABLE 6.2 Syndromic Disorders Associated With Disorder of Sex Development

Gene (CHR Band)	Syndrome	Karyo-Type	Genetic Defects	Mode of Inheritance	Characteristic Congenital Anomalies
<i>ARX</i> (Xp21.3)	Hydranencephaly with ABNORMAL GENITALIA (OMIM #300215)	XY	point mutations deletion/duplication	X-linked	lissencephaly, absent corpus callosum, early-onset intractable seizures, temperature instability
<i>ATRX</i> (Xq13.1)	Alpha-thalassemia mental retardation syndrome (OMIM # 301040)	XY	point mutations	X-linked	alpha-thalassemia, severe mental retardation, and genital abnormalities
<i>CDKN1C</i> (11p15)	IMAGe syndrome (OMIM # 614732)	XY	point mutations	AD maternal transmission	IUGR, metaphyseal dysplasia, adrenal insufficiency
<i>CHD7</i> (8q12.2)	CHARGE syndrome (OMIM#214800)	XY	point mutations (70%)	AD	coloboma, heart defects, choanal atresia, ear anomalies
<i>DHCR7</i> (11q13.4)	Smith-Lemli-Opitz syndrome (OMIM #270400)	XY	point mutations (96%) deletion/duplication (4%)	AR	characteristic facial features, postaxial polydactyly, 2-3 toes syndactyly, cleft palate
<i>EMX2</i> (10q26.11)		XY	microdeletion		sex reversal, kidney, developmental delay, schizencephaly
<i>GLI3</i> (7p14.1)	Pallister-Hall syndrome (OMIM #146510)	XY XX	point mutations (20%–25%) deletion/duplication (rare)	AD	hypothalamic hamartoma, mesoaxial polydactyly, bifid epiglottis
<i>HHAT</i> (1q32.2)	chondrodysplasia (PMID:24784881)	XY	point mutations	AR	dwarfism with generalized chondrodysplasia
<i>HOXA13</i> (7p15.2)	Hand-foot-genital syndrome (OMIM#140000)	XY XX	polyalanine expansions (60%) point mutations (35%) deletion/duplication (2%–5%)	AD	shortening of the thumbs and great toes, bicornuate uterus
<i>HSD17B4</i> ^a (5q23.1)	Perrault syndrome 1 (OMIM #233400)	XX	point mutations	AR	sensorineural deafness
<i>KAT6B</i> (10q22.2)	Genitopatellar syndrome (OMIM #606170)	XY	point mutations deletion/duplication (rare)	AD	patellar hypoplasia, club feet, microcephaly, flexion contractures, agenesis of the corpus callosum
<i>POR</i> (7q11.2)	Antley-Bixler syndrome (OMIM#201750)	XY XX	point mutations deletion/duplication (rare)	AR	radiohumeral synostosis, midface hypoplasia, choanal stenosis, joint contractures
<i>RSPO1</i> (1p34.3)	Palmoplantar keratosis/sex reversal (OMIM #610644)	XX	point mutations	AD	palmoplantar keratoderma, predisposition to squamous cell carcinoma of the skin
<i>SAMD9</i> (7q21.2)	MIRAGE syndrome (OMIM # 610456)	XY	point mutations	AD	myelodysplastic syndrome, IUGR, adrenal insufficiency, chronic diarrhea, pulmonary infections
<i>SOX9</i> (17q24.3)	Campomelic dysplasia (OMIM #114290)	XY	point mutations (90%) translocation (5%) deletion/duplication (2%)	AD	Pierre Robin sequence, cleft palate, short bowed limbs, 11 pairs of ribs
<i>TBX3</i> (12q24.1)	Ulnar-mammary syndrome (OMIM #181450)	XX	point mutations	AD	ulnar limb deficiencies, mammary gland hypoplasia, dental abnormalities
<i>TP63</i> (3q28)	Limb-mammary syndrome (OMIM #603543)	XX	point mutations	AD	hand/foot anomalies, mammary gland and nipple
<i>TSPYL1</i> (6q22.1)	SIDDT (OMIM #608800)	XY	point mutations	AR	bradycardia, hypothermia, laryngospasm, bronchospasm
<i>WT1</i> (11p13)	Denys-Drash, Frasier, and Meacham syndromes (OMIM #194080)	XY XX	point mutations	AD	Wilms tumor, nephropathy, gonadoblastoma, congenital diaphragmatic hernia
<i>ZEB2</i> (2q22.3)	Mowat-Wilson syndrome (OMIM#235730)	XY	point mutations (80%–85%) deletion/duplications (15%–17%) translocations (1%–2%)	AD	Hirschsprung disease, congenital heart defects, agenesis of the corpus callosum, microphthalmia, Axenfeld anomaly

^aadditional genes

AD, Autosomal dominant; AR, autosomal recessive; IUGR, intrauterine growth restriction; SIDDT, sudden infant death with dysgenesis of the testis syndrome.

inhibits cell cycle progression.¹²⁰ The gene is located within a complex genetic locus containing several genes including, *IGF2* and *H19*, subject to imprinting modulation through cis-acting elements; *CDKN1C* is maternally expressed. Mutations associated with the IMAGE or Silver-Russell syndromes appear to be localized to the proliferating cell nuclear antigen-binding domain, resulting in gain of function with excessive inhibition of growth and differentiation.^{121,122} Curiously, loss-of-function mutations affecting the cyclin-dependent kinase-binding domain of this protein are associated with overgrowth syndromes, such as Beckwith-Wiedemann syndrome.¹²³

CHD7 (CHARGE Syndrome)

The CHARGE syndrome is associated with mutations in the chromodomain helicase DNA binding protein-7 (*CHD7*) gene. Features of this syndrome include eye coloboma, heart malformations, choanal atresia, short stature, genital anomalies, ear abnormalities, and hearing loss. Micropenis and cryptorchidism are found in males. Hypogonadotropic hypogonadism can occur. Although usually sporadic, autosomal dominant cases have been described. The *CHD7* gene, located at chromosome 8q12.1-q12.2, codes for a large protein that participates in chromatin remodeling and transcription.

DHCR7 (Smith-Lemli-Opitz)

Several enzymes catalyze the conversion of lanosterol to cholesterol. Decreased activity of these enzymes leads to cholesterol deficiency. The enzyme, 7-dehydrocholesterol reductase, encoded by the 7-dehydrocholesterol reductase (*DHCR7*) gene, located at chromosome 11q12-q13, catalyzes the last step in cholesterol biosynthesis. Smith-Lemli-Opitz (SLO) is an autosomal recessive disorder caused by *DHCR7* loss-of-function mutations. As would be anticipated, elevated 7-dehydrocholesterol concentrations are required to confirm the diagnosis.

Clinical features include urogenital anomalies, mental retardation, failure to thrive, facial abnormalities, developmental delay, behavioral abnormalities, and autism symptoms.¹²⁴ The most common urogenital abnormalities include male-to-female sex reversal, hypospadias, and cryptorchidism. Facial abnormalities include microcephaly, broad nose, upturned nares, micrognathia, short neck, and cleft palate. Short thumbs, syndactyly of the second and third toes, and postaxial polydactyly are common.¹²⁵ CNS malformations include septum pellucidum anomalies, agenesis of the corpus callosum, or holoprosencephaly in severe cases.¹²⁶

Infants often have hypotonia, feeding problems, and failure to thrive. Tube feedings may be necessary because of the poor weight gain. Impaired cholesterol biosynthesis may be associated with adrenal insufficiency. However, overt adrenal insufficiency is uncommon.¹²⁷ Nevertheless, adrenal insufficiency, especially during stress, can occur.¹²⁸ Thus the hypothalamic-pituitary-adrenal axis function should be assessed and glucocorticoid stress dosing may be beneficial. Although the efficacy remains unclear, dietary cholesterol supplementation is often prescribed.¹²⁹

DHCR7 mutations are associated with decreased cholesterol and accumulation of sterol intermediates proximal to the defective enzyme. Decreased cholesterol concentrations lead to decreased steroid concentrations, with subsequent decreases in glucocorticoid, mineralocorticoid, and sex steroid biosynthesis. In addition to serving as the precursor for vitamin D and bile acids, cholesterol is involved in SHH signaling and cell membranes. Available data indicate that accumulation of sterol intermediates rather than cholesterol deficiency leads to some of the clinical findings. Impaired SHH signaling contributes to malformations, such as agenesis of the corpus callosum,

holoprosencephaly, and postaxial polydactyly. Using induced pluripotent stem cells from subjects with SLOS, data suggest that accumulation of 7-dehydrocholesterol and its isomer, 8-dehydrocholesterol, rather than cholesterol deficiency, likely contributes to the neurological manifestations.¹³⁰

Prenatal diagnosis can be performed by measurement of amniotic fluid 7-dehydrocholesterol concentrations. Women pregnant with affected fetuses have low plasma estriol; elevated blood 16 α -hydroxyestrogens concentrations; and elevated urinary $\Delta 7$ and $\Delta 8$ unsaturated C₁₈, C₁₉, and C₂₁ dehydrosteroid concentrations, presumably because of impaired fetal cholesterol production.¹³¹ The incidence of biochemically confirmed SLO is estimated at 1/20,000 to 1/60,000 live births.¹³² The rate of heterozygosity for *DHCR7* mutations is surprisingly high. Because the prevalence of SLO at 16 weeks of gestation is comparable to the prevalence at birth, early fetal loss and/or reduced fertility of carrier couples is likely occurring.¹³³

EMX2 Gene

One male patient presented with 46,XY DSD, a single kidney, and intellectual disability; he had a small microdeletion involving *EMX2*.¹³⁴

GLI3 (Pallister-Hall Syndrome)

Pallister-Hall syndrome is characterized by genital anomalies, hypothalamic hamartoma, postaxial polydactyly, and imperforate anus.¹³⁵ Hypospadias, micropenis, and bifid or hypoplastic scrotum are described in XY patients whereas hydrometrocolpos and/or vaginal atresia are described in XX patients.¹³⁶ This autosomal dominant disorder is caused by mutations in the Gli-Kruppel Family Member 3 (*GLI3*) gene, which is located at chromosome 7p14.1.¹³⁷ The protein acts as both a transcriptional activator and a transcriptional repressor of downstream targets in the SHH pathway. Pallister-Hall is typically caused by frameshift/nonsense and splicing mutations located in the middle third of the gene, which are predicted to generate a truncated functional repressor protein.¹³⁸ Curiously, mutations outside of this region are associated with Greigs cephalopolysyndactyly syndrome.¹³⁹ Preclinical data using mouse knockout models showed aberrant ureteric budding, hydroureter, hydronephrosis, and renal hypoplasia.¹⁴⁰

HHAT (Nivelon-Nivelon-Mabille Syndrome)

The Nivelon-Nivelon-Mabille syndrome is an extremely rare disorder characterized by primordial short stature, generalized chondrodysplasia, microcephaly, brachydactyly, facial dysmorphism, and XY sex reversal.¹⁴¹ This syndrome is caused by autosomal recessive loss-of-function mutations in the O-acyl-transferase hedgehog acyl-transferase (*HHAT*) gene mapped to chromosome 1q32.2. The HHAT protein palmitoylates the N-terminal domain of the hedgehog proteins. The hedgehog proteins, SHH, DHH, and Indian hedgehog (IHH), play major roles in embryo patterning and differentiation. Based on the phenotype of the knockout mouse, loss of *Hhat* leads to testicular dysgenesis characterized by decreased testicular size, decreased testis cord, and almost complete absence of fetal Leydig cells.¹⁴² Curiously, the phenotype described for XY patients with *DHH* mutations and *Dhh* knockout mice resembles the phenotype reported for *HHAT* patients and *Hhat* knockout mice.¹⁴²

HOXA13 (Hand-Foot-Genital Syndrome)

HOX genes are a group of transcription factors involved in embryonic development and patterning. These genes are organized into clusters characterized by specific spatiotemporal

expression patterns. The hand-foot-genital syndrome (HFGS) (OMIM #140000) is a rare, autosomal dominant disorder associated with mutations or deletions of the *HOXA13* gene on chromosome 7p15.¹⁴³ This syndrome is characterized by congenital genitourinary anomalies and variable skeletal anomalies. The skeletal anomalies mainly affect the hands and feet, such as short thumbs and halluces, shortening of the middle phalanges, fifth finger clinodactyly, and the fusion of distal and middle phalanges of the toes.¹⁴⁴ Although approximately 50% of affected individuals have urogenital anomalies, many experience normal fertility. Males may have hypospadias or cryptorchidism. Females may have incomplete Mullerian fusion or bicornuate uterus associated with increased risks for spontaneous abortion, preterm delivery, or stillbirth. In some instances, the skeletal phenotype can be mild.¹⁴⁵ Additional comorbidities include chronic urinary tract infections, ectopic ureteric orifices, chronic pyelonephritis, and renal failure.¹⁴⁶

KAT6B (Genitopatellar Syndrome)

The genitopatellar syndrome is a rare disorder characterized by skeletal dysplasia, flexion contractures, genital anomalies, craniofacial defects, and developmental delay associated with lysine acetyltransferase 6 (*KAT6B*) gene mutations. The skeletal features include hypoplastic or absent patellae, flat temporal bones, and brachydactyly. Genital anomalies include hypoplastic labia, clitoromegaly, scrotal hypoplasia, and cryptorchidism. Cardiac anomalies, hydronephrosis, and developmental delay have been described. The gene is located at chromosome 10q22.2 and contains 20 exons. The *KAT6B* protein is a component of the histone H3 acetyltransferase complex and functions as a histone acetyltransferase. The *KAT6B* protein functions as a chromatin modifier by catalyzing acetylation of specific lysines. Most mutations are de novo mutations.¹⁴⁷ The Say-Barber-Biececker-Young-Simpson syndrome is also associated with *KAT6B* mutations; specific facial features consisting of blepharophimosis/ptosis and an immobile mask-like face distinguish these syndromes.

NR2F2 Gene

This gene encodes chicken oval albumin upstream promoter transcription factor (COUP-TF2), a nuclear receptor. This protein appears to function as a proovary and antitestis factor. Mutations in this gene are associated with a syndromic 46,XX DSD characterized by genital virilization, congenital heart disease, and varying somatic findings. Frameshift mutations have been reported in three 46,XX patients who were identified by genital ambiguity. All three patients had congenital heart disease. One infant died of hypoplastic left heart; no gonadal histology was available. The other two patients carried de novo c.97_103delCCGCCCG predicted to generate frameshift mutation, p.Pro33Alafs*77; they also had blepharophimosis ptosis epicanthus inversus syndromes (BPES) and uterus. One patient had ovotesticular disorder; gonadal histology was not available for the other patient.

Immunohistochemistry studies performed on human ovaries showed positive COUP-TF2 staining in FOXL2-negative stromal areas consistent with COUP-TF2 functioning as a proovary and antitestis factor in developing female gonads.¹⁴⁸ Preclinical studies in mice showed that female embryos lacking *Coup-tfII* possess both Wolffian and Mullerian ducts; maintenance of the Wolffian ducts is androgen independent and is likely caused by enhanced phosphorylated extracellular signal-regulated kinase signaling in Wolffian duct epithelium.¹⁴⁹ These data suggest that COUP-TFII actively promotes Wolffian duct regression in female embryos.

RSPO1

The R-spondin 1 (*RSPO1*) gene codes for a secreted furin-like domain protein that stabilizes β -catenin in the Wnt-signaling pathway. Mutations in this gene, located at chromosome 1p34, are associated with 46, XX sex reversal. This gene was initially identified by investigating in individuals with palmoplantar hyperkeratosis with squamous cell carcinoma of skin and sex reversal in one family.¹⁵⁰ Affected XX, sex-reversed individuals lack Mullerian structures.¹⁵⁰ A 46,XY individual, homozygous for *RSPO1* mutations, fathered two children. An XX individual with ovotesticular disorder and palmoplantar keratoderma was found to be homozygous for a splicing mutation in the *RSPO1* gene.¹⁵¹ In addition to sex reversal and palmoplantar keratosis, reported features include microphthalmia and nail dystrophy.¹⁵¹

SAMD9 (MIRAGE Syndrome)

Mirage syndrome is characterized by myelodysplasia, infections, intrauterine growth restriction (IUGR), adrenal hypoplasia, XY male-to-female sex reversal, and enteropathy.^{152,153} Pulmonary disease, severe infections, and myelodysplasia contribute to deaths during the first 2 years of life. This disorder has been associated with heterozygous mutations in the sterile α motif domain-containing protein 9 (*SAMD9*) gene located at chromosome 7q21.2. The 1589-amino-acid protein is highly expressed in the fetal adrenal; immunohistochemistry showed *SAMD9* localization in the cytoplasm of adrenal definitive and fetal zone cells colocalized with cells positive for *NR5A1* expression. *SAMD9* is considered to be a tumor suppressor gene; mutations are gain-of-function mutations, leading to IUGR and consequences for adrenal gland and testes differentiation. Curiously, second mutations, such as acquired monosomy for chromosome 7, modify the phenotype and prolong survival. Buonocore and colleagues suggest that *SAMD9* is essential to control the balance between cell proliferation and cell differentiation; activating *SAMD9* mutations interfere with cell proliferation resulting in hypoplastic tissues.¹⁵⁴

SOX9

SOX9 is a member of the SRY-related HMG domain gene family located at chromosome 17q24.3-17q25.1 that encodes a 508-amino-acid protein. Heterozygous loss-of-function *SOX9* mutations are associated with autosomal-dominant campomelic dwarfism and male-to-female sex reversal.¹⁵⁵ Features of campomelic dwarfism include congenital bowing of long bones, hypoplastic scapulae, 11 pairs of ribs, narrow chest, congenital dislocated hips, and clubfeet. Facial features include micrognathia, cleft palate, large head, flat nasal bridge, and low-set malformed ears. When bone malformations are severe, postnatal survival may be limited. Affected 46,XY fetuses manifest sex reversal, with external genital differentiation, ranging from ambiguous to female. Gonadal dysgenesis and persistence of Mullerian duct derivatives are typical. Phenotypic heterogeneity with differing phenotypes, including ovotesticular DSD and complete sex reversal, has been described in affected siblings.¹⁵⁶ Acampomelic dysplasia has been described in which the typical limb anomalies are absent.¹⁵⁷ Patients with acampomelic dwarfism and sex reversal have been reported.^{158,159} Familial campomelic dysplasia associated with a deletion upstream of *SOX9* has been described in a mother and 46,XY child with female external genitalia, normal uterus, and streak gonads.¹⁶⁰

SOX9 mutations can affect DNA-binding affinity, DNA bending ability, nuclear import, transactivation, and nuclear export. Haploinsufficiency is the mechanism responsible for

many of the consequences of *SOX9* mutations. Somatic cell mosaicism, de novo germline mutations, and mitotic gene conversion events have been described. Mutations located upstream of *SOX9* in the regulatory regions have been identified in patients with varying degrees of sex reversal. Duplications of the eSR-A locus were associated with 46,XX testicular disorder and 46,XX ovotesticular disorder, whereas deletions have been identified in patients with 46,XY sex reversal.³⁵

***TBX3* (Ulnar-Mammary syndrome)**

The Ulnar-Mammary syndrome is characterized by cryptorchidism, micropenis, breast hypoplasia/aplasia, nipple hypoplasia/aplasia, delayed puberty, absent axillary hair, and skeletal anomalies. Skeletal anomalies include hypoplasia of humerus and ulna, oligodactyly, polydactyly, and finger anomalies. The *TBX3* gene plays a role in development of the dorsoventral limb axis. Additional endocrine features include hypogonadotropic hypogonadism, short stature, growth hormone deficiency, and obesity.¹⁶¹ Neuroimaging studies have identified pituitary and brain malformations.¹⁶²

WT1

The Denys-Drash syndrome is characterized by genitourinary anomalies, Wilms tumor, nephropathy, and Wilms tumor suppressor (*WT1*) gene mutations. Among affected 46,XY individuals, the external genitalia can range from ambiguous to normal female. Internal genital differentiation varies because of inconsistent Wolffian and/or Mullerian structure development and regression. Typically, the nephropathy begins during the first few years of life, manifests with proteinuria, and results in end-stage renal failure because of focal or diffuse mesangial sclerosis.^{163,164} Typically, the gonads are usually dysgenetic in 46,XY individuals. Affected 46,XX individuals typically have normal female external genital development.

However, a novel *WT1* mutation was reported in an XX individual identified at birth because of clitoromegaly and a single perineal opening. She was found to have an immature right uterine tube; gonadal histology revealed bilateral testes with seminiferous tubules containing predominantly Sertoli cells and rare germ cells. The karyotype of both gonads was XX. Genetic analysis revealed a de novo frameshift variant in exon 10, which encodes the fourth DNA finger. This variant is predicted to generate a deleterious mutation p.Arg485Glyfs*14, which appears to be a gain-of-function mutation increasing DNA binding affinity, promoting *NR5A1* overexpression and *SOX9* upregulation, and culminating in testicular development.¹⁶⁵

The Wilms tumor suppressor (*WT1*) gene, located at chromosome 11p13, plays an important role in both kidney and gonadal differentiation. Through alternative splicing, multiple translation start sites, and posttranslational RNA editing, over 30 isoforms are derived from this one gene. The carboxyl terminal domain of the *WT1* protein contains four zinc fingers that serve as the nucleic acid binding domain.

The two major isoforms differ by the inclusion or exclusion of three amino acids, lysine, threonine, and serine (KTS), between the third and fourth zinc-finger domains. Subnuclear localization studies have shown that the -KTS form colocalizes predominantly with transcription factors and preferentially binds to DNA, whereas the +KTS form colocalizes mainly with splicing factors and plays a role in RNA processing.¹⁶⁶ The ratio of the +KTS/-KTS isoforms appears to be tightly regulated. Hence depending on cell context, *WT1* can function as a transcriptional activator, a transcriptional repressor, or tumor suppressor. *WT1* plays a role in the balance between mesenchymal-epithelial transitions.¹⁶⁷

Patients with *WT1* mutations manifest phenotypic heterogeneity. Although Wilms tumor and genitourinary abnormalities can be associated with heterozygous *WT1* deletions, only 6% to 15% of sporadic Wilms tumors are associated with *WT1* mutations. Heterozygous deletions at chromosome 11p13 can be part of a contiguous gene deletion syndrome known as WAGR syndrome (Wilms tumor, aniridia, genitourinary anomalies, gonadoblastoma, and mental retardation). In general, missense mutations in exons 6–9 are associated with severe gonadal dysgenesis and early-onset nephropathy. The (-) KTS form appears to be protective from development of Wilms tumor, whereas mutations located in the N-terminal repression domain are associated with development of Wilms tumor.

Frasier syndrome is characterized by gonadal dysgenesis, progressive glomerulopathy, and an increased risk for gonadoblastoma. Wilms tumor is extremely rare in Frasier syndrome.¹⁶⁸ The typical renal lesion is focal glomerular sclerosis. The majority of cases are associated with a specific *WT1* point mutation in intron 9, associated with altered splicing and decreased amounts of the +KTS isoform.

Meacham syndrome is characterized by genital anomalies, cyanotic congenital heart defects, and pulmonary hypoplasia secondary to diaphragmatic abnormalities. In 46,XY infants, the spectrum of internal genital anomalies extends from presence of a uterus to a blind ending vaginal pouch. External genitalia have been described as ranging from normal female to ambiguous.¹⁶⁹

***XH2* (ATRX Syndrome)**

ATRX (α -thalassemia, mental retardation, X-linked protein) syndrome is an X-linked disorder characterized by mild alpha-thalassemia, severe mental retardation, and genital abnormalities because of mutations in the *XH2* gene located at chromosome Xq13.3. Urogenital anomalies, including ambiguous genitalia, cryptorchidism, hypoplastic scrotum, hypospadias, shawl scrotum, and small penis occur in approximately 80% of patients.¹⁷⁰ Additional features include short stature, psychomotor retardation, microcephaly, seizures, talipes equinovarus, and gastrointestinal problems. The facies are described as coarse with midface hypoplasia, short nose, and widely spaced incisors. The hemoglobin H inclusions associated with alpha-thalassemia can be demonstrated on brilliant cresyl blue stained peripheral blood smears.¹⁷¹ Typically, Wolffian duct structures are present, whereas Mullerian duct structures and germ cells are absent.¹⁷² Phenotype-genotype correlations are inconsistent. Most cases are inherited from carrier mothers and most, but not all, carrier females show preferential inactivation of the X chromosome carrying *ATRX* mutations.¹⁷³

This disorder, also known as Carpenter-Waziri syndrome, is caused by mutations in the *ATRX* (also known as *XH2* or *XHP*) gene located at Xq13.3.¹⁷⁴ The *ATRX* protein is a member of the SWI/SNF DNA helicase family and consists of three domains: an N-terminal containing a plant-homeodomain-like (PHD) domain, a coiled-coil motif, and C-terminal helicase domain.¹⁷⁵ The urogenital anomalies are typically associated with mutations located in the PHD domain and predicted to generate a truncated protein. During meiosis, *ATRX* maintains genomic integrity by modulating DNA damage response mechanisms.¹⁷⁶ *ATRX* mutations are associated with abnormal methylation of repetitive DNA sequences, failure to establish necessary epigenetic modification for X chromosome inactivation, and impaired silencing of imprinted genes.^{177,178}

Sertoli cell *ATRX* knockout mice had small testes, decreased seminiferous tubule volume, decreased Sertoli cell number, and increased Sertoli cell apoptosis associated with prolonged

G2/M phase during fetal life. This finding is consistent with the concept that ATRX protein expression impacts on G2-M progression with ultimate consequences on cell survival.¹⁷⁹ Tissue-specific consequences of the epigenetic regulation and disrupted cell cycle progression may explain the disparate features associated with *ATRX* mutations.

DISORDERS ASSOCIATED WITH 46,XX DISORDERS OF SEX DEVELOPMENT AND 46,XY DISORDERS OF SEX DEVELOPMENT (TABLE 6.3)

SF1/NR5A1 Gene

The *SF1/NR5A1* gene, located at chromosome 9q33, codes for a 461-amino-acid protein. This protein is a nuclear receptor transcriptional regulator involved in adrenal, gonadal, and hypothalamic development and function. The protein contains an amino terminal DNA binding domain containing two zincfingers, a hinge domain, and ligand-binding domain. The protein modulates expression of *SRY*, *SOX9*, *AMH*, and *AMHR*. In Leydig cells, *NR5A1* promotes expression of *LHCGR*, *STAR*, *CYP11A1*, and *CYP17A1*, which are required for testosterone biosynthesis.

Phenotypic heterogeneity is characteristic for patients with *NR5A1* mutations. Among 46,XY individuals, reported phenotypes range from impaired testicular development to male infertility. Among 46,XX individuals, reported phenotypes range from 46,XX ovotesticular disorder to primary ovarian insufficiency. Adrenal insufficiency may be the primary feature in some patients. Nonsense, frameshift, and missense changes have been identified. Most mutations are heterozygous. Familial cases have been reported.¹⁸⁰ Differing phenotypes have been described in a single family.¹⁸¹

Because of the multiple *NR5A1* actions in gonadal differentiation and function, several potential mechanisms of action are possible with *NR5A1* mutations. Among 46,XY individuals, *NR5A1* mutations cannot adequately activate the male pathway leading to undervirilization. Among XX (SRY-negative) virilized patients, based on in vitro studies, *NR5A1* mutations do not appear to abnormally activate the male pathway. Rather, in vitro studies showed that p.Arg92Trp or p.Ala260Val missense mutations repressed Wnt signaling, thus interfering with ovarian differentiation in virilized 46,XX (SRY-negative) patients.¹⁸² In other words, downregulation of the female “antitestis” genes decreases inhibition of the male developmental pathway, shifting cell fate determination to promote testicular differentiation in XX individuals.¹⁸³ Curiously, 46XX

TABLE 6.3 Nonsyndromic Disorders of Sex Development in XY Individuals

Gene	Location	Phenotype	Genetic Defects	Mode of Inheritance
<i>AMH</i>	19p13.3	Persistent Mullerian duct syndrome, gonadal dysgenesis (OMIM #261550)	Point mutations	AR
<i>AMHR2</i>	12q13.13	Persistent Mullerian duct syndrome (OMIM #261550)	Point mutations	AR
<i>AR</i>	Xq12	Androgen resistance, gonadal dysgenesis (OMIM # 300068)	Deletions, point mutations	X-linked
<i>AXIN1</i>	16p13.3	Cryptorchidism, caudal duplication anomaly (OMIM # 603816)	Point mutations	unknown
<i>CBX2</i>	17q25	Complete gonadal dysgenesis, ovotesticular DSD (OMIM #613080)	Point mutations	AR
<i>DHH</i>	12q13.12	Gonadal dysgenesis, partial or complete (OMIM #233420)	Point mutations	AR
<i>DMRT1</i>	9p24.3	Gonadal dysgenesis, partial or complete Additional anomalies in patients with 9p24.3 deletions (OMIM #154230)	Point mutations, 9p24.3 deletions (contiguous gene deletion syndrome)	AD
<i>ESR2</i>	14q23.2-q23.3	XY sex reversal (OMIM # 601663)	Point mutations	AD, AR
<i>FGFR1</i> , multiple	8p11.23, multiple	Hypogonadotropic hypogonadism with or without anosmia, see (OMIM # 147950) for additional loci	Deletions/duplications, point mutations	AD, AR, oligogenic
<i>GATA4</i>	8p23.1	Testicular anomalies with/without congenital heart disease (OMIM#615542)	Deletions/duplications, point mutations	AD
<i>KAL1</i>	Xp22.31	Hypogonadotropic hypogonadism with anosmia (OMIM #308700)	Deletions/duplications, point mutations	X-linked
<i>LHCGR</i>	2p16.3	Leydig cell hypoplasia (OMIM #238320)	Point mutations	AR
<i>MAMLD1</i>	Xq28	Micropenis, bifid scrotum, penoscrotal hypospadias (OMIM #300758)	Point mutations	X-linked
<i>MAP3K1</i>	5q11.2	Gonadal dysgenesis (OMIM #613762)	Point mutations	AD
<i>NR0B1(DAX1)</i>	Xp21.2	Complete gonadal dysgenesis, sex reversal (OMIM #300018)	Duplications, X-autosome translocations, deletions upstream	X-linked
<i>NR5A1 (SF1)</i>	9q33.3	Underandrogenization, complete gonadal dysgenesis, adrenal insufficiency (OMIM # 612965)	Deletions/duplications, point mutations	AD
<i>SOX8</i>	16p13.3	Ambiguous genitalia, complete gonadal dysgenesis (PMID:21373258) (28)	Point mutations, upstream duplications	AD
<i>SRY</i>	Yp11.2	Gonadal dysgenesis (OMIM #400044)	Deletions/duplications, point mutations	Y-linked
<i>WVVOX</i>	16q23.1-q23.2	Gonadal dysgenesis (PMID:22071891)	Deletions	AD
<i>ZFPM2 (FOG2)</i>	8q23.1	Gonadal dysgenesis with/without congenital heart disease (OMIM #616067)	Point mutations	AR
<i>ZNRF3</i>	22q12.1	Gonadal dysgenesis (OMIM# 612062)	Point mutations	AD

AD, Autosomal dominant; AR, autosomal recessive.

individuals with a different missense mutation, p.Arg92Gln, have been reported as having adrenal insufficiency and with or without ovotesticular DSD.^{184,185}

Incomplete penetrance and variable expression are recognized characteristics of *NR5A1* mutations. The *NR5A1* mutations illustrate how specific variants in a transcription factor act as a cell/organ switch to direct developmental outcomes.¹⁸⁶ With whole exome sequencing (WES), variants in other genes have been demonstrated. Hence, oligogenicity or modifier genes may influence phenotypic expression for *NR5A1* mutations.¹⁸⁷

SOX8

SOX8 is located at chromosome 16p.13.3. *SOX8* mutations are associated with 46,XY sex reversal and infertility in both 46,XX and 46,XY individuals. Heterozygous *SOX8* missense mutations were identified in individuals with 46,XY sex reversal.¹⁸⁸

NONSYNDROMIC 46,XY DISORDERS OF SEX DEVELOPMENT (GONADAL DYSGENESIS)

(SEE TABLE 6.3)

Chromobox Homolog 2 (*CBX2*)

The *CBX2* gene, mapped to chromosome 17q25, is a subunit of the chromatin-associated polycomb repressive complex 1. As noted earlier, the polycomb group proteins regulate chromatin structure, ultimately influencing gene expression. Two isoforms exist, *CBX2.1* and the shorter *CBX2.2*. Loss-of-function missense *CBX2.1* mutations were identified in a 46,XY infant identified by a mismatch between prenatal karyotype and female external genital appearance at birth. Subsequent evaluation identified a normal uterus and ovarian-like tissue on histology.¹²⁰ Two patients with *CBX2.2* mutations have been reported; both patients had 46,XY karyotypes. One patient had dysgenetic testes, whereas no gonadal tissue could be identified in the second patient.¹⁸⁹ Available data suggest that *CBX2.1* is involved in testis determination, whereas *CBX2.2* is involved in early gonad development. The factors that regulate alternative splicing of this gene are unknown.¹⁸⁹

Desert Hedgehog

The Desert hedgehog (*DHH*) gene is located on chromosome 12q12-q13.1 and encodes a protein consisting of 396 amino acids. *DHH* is a member of the Hedgehog family and is also expressed in the Schwann cells of the peripheral nervous system. This is an autosomal recessive disorder associated with XY gonadal dysgenesis and minifascicular neuropathy.^{190,191} However, neuropathy is an inconsistent feature. *DHH* promotes formation of the connective tissue sheath around peripheral nerves and is essential for their survival.¹⁹²

One 46,XY patient had female external genitalia, polyneuropathy, a testis on one side, and a streak gonad on the other side. Genetic analysis showed homozygosity for a single nucleotide substitution at the initiation codon, which is predicted to abolish initiation of translation at the normal start site. Histological analysis of the sural nerve revealed extensive formation of minifascicles within the endoneurium.¹⁹³ The associated minifascicular neuropathy has been attributed to developmental malformation of peripheral nerves and is characterized by the presence of many small fascicles with glove and stocking-type sensory impairment.¹⁹⁴ Gonadal tumors, including seminoma-in-situ, gonadoblastoma, and dysgerminoma have been reported.¹⁹⁵

Doublesex and Mab-3–Related Transcription Factor 1 (*DMRT1*) and Doublesex and Mab-3–Related Transcription Factor 2 (*DMRT2*)

Monosomy for distal chromosome 9p has been reported in male-to-female sex reversal. Most deletions associated with sex reversal involve the chromosome region 9p24.3 where three *DMRT* genes are located.¹⁹⁶ *DMRT1* appears to be involved in Sertoli and cell differentiation. External genitalia have been described as ambiguous or female. The external genitalia may appear symmetric or asymmetric. Differentiation of internal genitalia is highly variable, with the presence of Mullerian and Wolffian remnants being reported. In addition to sex reversal, clinical features include mental retardation, low-set ears, trigonocephaly, wide nasal bridge, single palmar creases, heart defects, epilepsy, and scoliosis. Genital anomalies reported in XY individuals include gonadal dysgenesis, ovotestis, hypospadias, penoscrotal inversion, and cryptorchidism.¹⁹⁷ Gonadoblastoma have been reported.¹⁴⁹ Although phenotype/genotype correlations are not apparent, haploinsufficiency for *DMRT1* appears to be sufficient to cause gonadal dysgenesis.¹⁵⁰ Female external genitalia and short stature were described in a patient with mosaic 46,XY karyotype characterized by ring chromosome 9 and *DMRT1* haploinsufficiency.¹⁹⁸

GATA4

The GATA proteins comprise a family of tissue-specific transcription factors that contain two conserved zinc-finger domains. The C-terminal zinc finger is required for DNA recognition and the N-terminal zinc finger contributes to stability; both zinc fingers are required for protein-protein interactions with other transcription factors.¹⁹⁹ The *GATA4* gene is mapped to chromosome 8p23.1. Heterozygous *GATA4* mutations are associated with congenital heart disease and XY disorders of sex development.²⁰⁰ The observed phenotypic heterogeneity has been attributed to incomplete penetrance and oligogenicity. Three males in one family were reported to manifest congenital heart disease and varying abnormalities in male sex development, whereas the female carrier had congenital heart disease without an ovarian phenotype. This specific mutation, p.Gly221Arg, abrogated the ability of the *GATA4* protein to interact with the ZFPM2/FOG2 protein and disrupted synergistic activation of the AMH promoter by *GATA4* and *NR5A1*.²⁰¹

Mastermind-Like Domain Containing 1 (*MAMLD1*)

MAMLD1 was identified during studies investigating the genetic basis of X-linked myotubular myopathy.²⁰² This gene is also known as chromosome X open reading frame 6 (*CXorf6*).²⁰³ However, some variants have been detected in normal individuals. In vitro, most *MAMLD1* variants acted similarly to the wild type with the exception of the L210X variant.²⁰⁴ The lack of a significant reproductive phenotype in transgenic knockout mice raises doubt whether *MAMLD1* is sufficient to cause a DSD.^{205,206} Hence these findings suggest that *MAMLD1* variations are insufficient to account for a patient's DSD phenotype.

Mitogen-Activated Kinase Kinase Kinase 1 (*MAP3K1*)

The *MAP3K1* gene is located at chromosome 5q11.2. This gene encodes a protein involved in MAPK signaling. Phenotypes of affected individuals include 46,XY complete gonadal dysgenesis, perineoscrotal hypospadias, cryptorchidism, and variable

Mullerian duct development.^{207,208} Gonadoblastoma and dysgerminoma have been reported.²⁰⁹ Inheritance appears to be sex-limited autosomal dominant. Variations associated with gonadal dysgenesis increase phosphorylation of the downstream targets, MAPK11 (p38), MAP3K (ERK1), and MAPK1 (ERK2) and increase binding of the cofactors RHOA and MAP3K4 (AXIN1); the net result is decreased SOX9 expression.²¹⁰ Hence these gain-of-function mutations repress the testis-promoting factors and stabilize beta-catenin, favoring the ovarian differentiation pathway.²¹¹

Nuclear Receptor Subfamily 0, Group B, Member 1 (*NROB1*)

This two-exon gene, *NROB1*, located at Xp21.2 encodes DAX1. The 460-amino-acid protein is an orphan nuclear receptor lacking a typical zinc-finger DNA-binding domain. The N terminus of the 470-amino-acid protein contains a novel DNA-binding domain, whereas the C terminus shows characteristics of a nuclear hormone receptor ligand-binding domain. *NROB1* is expressed throughout the HPG axis. The DAX1 protein functions as a transcriptional repressor of many genes, including NR5A1 and some steroidogenic enzyme genes.

Duplication of the *DAX1/NROB1* locus is associated with male-to-female sex reversal.¹³³ External genital differentiation ranges from female to ambiguous. Descriptions of internal genitalia include the presence of Mullerian and Wolffian structures. Gonads are typically described as streaks. Using high-resolution array comparative genome hybridization (CGH), a submicroscopic interstitial duplication of the *DAX1/NROB1* gene was discovered during thorough evaluation of two sisters. This 637-kb duplication included *NROB1*, four *MAGEB* genes, *CXorf21*, glycerol kinase (*GK*), and part of the *MAP3K7IP3* gene. The older sister had presented with primary amenorrhea, female external genitalia, 46,XY karyotype, and gonadal dysgenesis; the younger phenotypic female sister was prepubertal, but found to have 46,XY karyotype.¹³⁴

Loss-of-function mutations are associated with X-linked adrenal hypoplasia congenita (AHC). In this disorder, development of the fetal adrenal cortex is normal. However, the adult or definitive adrenal cortex fails to develop. Adrenal insufficiency may not be evident in the immediate neonatal period but may become obvious during early infancy. Although adrenal insufficiency generally manifests in infancy or early childhood, phenotypic heterogeneity in severity and age at presentation occurs.¹³⁵ Unilateral or bilateral cryptorchidism can also occur. At the age of expected puberty, hypogonadotropic hypogonadism caused by hypothalamic and pituitary dysfunction may occur among affected males.¹³⁶ Delayed puberty has been recognized in heterozygous females.¹³⁷ One female homozygous for *NROB1* mutations has been reported. Her phenotype was hypogonadotropic hypogonadism.¹³⁸ As part of a contiguous gene deletion syndrome, X-linked AHC can be associated with glycerol kinase deficiency, Duchenne muscular dystrophy, ornithine transcarbamylase deficiency, and mental retardation.¹³⁹

Nonsense mutations have been identified throughout the gene. Missense mutations account for 20% of mutations associated with AHC. These mutations tend to cluster in the carboxyl terminal of the protein corresponding to the putative ligand-binding domain and impair the transcriptional repression activity of the protein. One missense point mutation, located in the hinge region of the protein, was identified in an 8-year-old girl with clinical and laboratory features indicative of adrenal insufficiency. Additional studies showed that this mutation hindered nuclear localization of the protein. Curiously, the hemizygous father and heterozygous younger sister of the proband did not manifest the AHC phenotype.¹⁴⁰

PBX1 (Pre-B-Cell-Leukemia Factor 1)

Pre-B-cell-leukemia factor 1 (*PBX1*), located at chromosome 1q23.3, is a member of the Three Amino Acid Loop Extension (TALE) proteins. *PBX1* dimerizes with other proteins to generate nuclear complexes that promote binding specificity of HOX proteins to DNA.²¹² Mutations in *PBX1* have been reported among patients with congenital anomalies affecting the kidney and urinary tract, in association with developmental delay, ear anomalies, and congenital heart disease.^{213,214} A de novo *PBX1* mutation, p.Arg235Gln, located within the conserved homeo-domain, was identified in a 46,XY child with female external genitalia; the right gonad consisted of sparse seminiferous tubules with fibrous tissue and the left gonad consisted solely of fibrous tissue.²¹⁵ Expression studies showed that this missense mutation failed to localize in the nucleus, implying *PBX1* is necessary for testicular development and that this mutation is a loss-of-function mutation.²¹⁵

Protein Phosphatase Two Regulatory Subunit B"Gamma (*PPP2R3C*)

This gene, mapped to chromosome 14q13.2, has 13 exons encoding a 453 amino acid protein. In conjunction with scaffolding A and catalytic C subunits, the three proteins comprise a heterotrimeric protein phosphatase 2A, which functions in the reversible dephosphorylation of phosphoproteins. Four phenotypic female patients with 46,XY gonadal dysgenesis, flat facies, bilateral epicanthal folds, low-set posteriorly rotated ears, and single palmar crease have been described.²¹⁶ All four were homozygous for missense mutations; parents were heterozygous carriers. Curiously, three of the four heterozygous fathers were found to have impaired spermatogenesis characterized by teratozoospermia with severe head, acrosomal, and nuclear anomalies.

SRY

SRY is a single exon gene encoding a 204-amino-acid protein. The protein contains an HMG DNA-binding domain flanked by nuclear localization signals (NLS). The majority of sex-reversing *SRY* mutations are located in the HMG/NLS domain and affect DNA-binding affinity, DNA bending ability, or nuclear localization. Mutations located in the N-terminal and C-terminal domains have been identified in 46,XY sex reversed individuals. Mutations in the non-HMG domains may influence transcriptional activation, DNA binding, or protein-protein interactions.²¹⁷ Paternal mosaicism for *SRY* mutations in which different cells carry different *SRY* genes has been described.^{218,219} More puzzling are the pedigrees in which fathers and unaffected brothers carry the identical mutant *SRY* allele as the proband.²²⁰⁻²²² These paradoxical findings implicate involvement of other genes, gene-gene interactions, and gene-environment interactions in the process of sexual differentiation. Nevertheless, only 15% to 20% of cases of 46,XY DSD because of gonadal dysgenesis can be attributed to *SRY* mutations. Mutations in the *SRY* gene have also been reported in patients with stigmata typical of Turner syndrome and 45, X/46XY karyotype.^{223,224}

WW Domain-Containing Oxidoreductase (*WWOX*)

The *WWOX* gene is mapped to 16q23.1-16q23.2. This gene encodes a cytoplasmic protein that plays a role in growth, differentiation, and tumor suppression. One patient with 46,XY sex reversal was found to carry a heterozygous deletion of exons 6 to 8 (amino acids 173-352). This patient had unfused labioscrotal folds, bilateral nonpalpable gonads, clitoral

hypertrophy, a single perineal opening, and intraabdominal dysgenetic gonads.²²⁵ *WWOX* mutations have been identified in autosomal recessive cerebellar ataxia with epilepsy and mental retardation.²²⁶

Zinc Finger and Ring Finger Protein 3 (*ZNRF3*)

ZNRF3 mapped to chromosome 22q12.1 encodes a transmembrane E3 ubiquitin ligase that typically interferes with WNT signaling in the gonad to promote testicular differentiation. Heterozygous mutations have been reported in 5 XY patients with sex-reversal; four of five patients presented in late adolescence with delayed puberty.²²⁷

Zinc Finger Protein, Multitype 2 (*ZFPM2*)

The Friend of GATA 2 (*FOG2*) protein, encoded by *ZFPM2* and mapped to chromosome 8q23.1, is a transcriptional cofactor that modulates the activity of GATA4 by binding to its N-terminal zinc finger.²²⁸ One boy with a balanced translocation and breakpoint with intron 4 of the *FOG2* gene had congenital heart disease, retractile testes, and hypergonadotropic hypogonadism.²²⁹

OVOTESTICULAR DISORDER OF SEX DEVELOPMENT

Ovotesticular DSD is defined as the presence of ovarian tissue with follicles and testicular tissue with seminiferous tubules in the same individual. External genital appearance does not predict gonadal histology.²³⁰ The gonads can be an ovotestis, ovary, and/or testis. The most common histology is an ovotestis. An ovotestis is typically located on the right side and is often intraabdominal. An ovotestis can appear ovoid or bilobed on gross appearance. In most ovotestes, ovarian and testicular tissue show distinct separation in an end-to-end arrangement. In this situation, the testicular zone typically shows poor differentiation of the tunica albuginea with atypical interstitial tissue.²³¹ In some instances, oocytes are interspersed among seminiferous cords/tubules. The proportion of ovarian and testicular tissue differs among patients; uterine development also varies.

The most common karyotype is 46,XX. Mosaic karyotypes, such as 46,XX/46,XY, 46,XX/47,XXY, 45,X/46,XY, 47,XY/46,XY/45,X have been described.^{232,233} In some cases, the amount of Y chromosomal material in peripheral blood lymphocytes is limited, such as the *SRY* gene can be detected only by polymerase chain reaction (PCR) amplification. In other instances, *SRY* was apparently absent in peripheral blood lymphocytes and detected in testicular tissue.^{234,235} A deletion of the *SRY* promoter region was identified in the testicular tissue of a 46,XX patient with ovotesticular disorder.²³⁶ However, ovotesticular DSD in the absence of Y chromosomal material occurs.²³⁷ As noted elsewhere in this chapter, specific mutations, for example, *NR5A1*, *NR2F2*, *RSPO1*, and *SOX9*, have been identified among patients with ovotesticular disorder.

Most cases are sporadic. Nevertheless, pedigrees in which both XX males and XX individuals with ovotesticular disorder coexist have been described.^{238–240} Although most patients present in infancy or childhood, phenotypic males can present with bilateral gynecomastia.²⁴¹ One patient with 46,XX/46,XY karyotype presented in infancy with penoscrotal hypospadias, left descended gonad, and right undescended gonad; biopsies revealed normal prepubertal testis on the left and normal ovarian tissue on the right. Additional evaluation and management of this patient led to male sex of rearing accompanied by right salpingo-oophorectomy and hysterectomy. The patient subsequently presented at age 17 years with a painless scrotal mass, which was excised and found to be normal ovarian tissue. This case illustrates the potential for inconsistency in gonadal

development among patients with ovotesticular disorder with the possibility of sampling errors in gonadal biopsies.²⁴²

Limited outcome data regarding fertility are available. Among 33 patients followed longitudinally, germ cells identified in the testicular tissue during infancy degenerated, resulting in azoospermia.²³⁶ Histological findings among adults describe a dysgenetic Sertoli-only appearance with hyalinization of seminiferous tubules.²³⁴ Nevertheless, assisted reproductive techniques have been successfully used to achieve paternity in men with ovotesticular disorder.^{243,244} Several pregnancies have been reported among women with ovotesticular disorder.^{245,246}

NONSYNDROMIC XX DISORDERS OF SEX DEVELOPMENT (TABLE 6.4)

46,XX Testicular Disorder of Sex Development

Testicular DSD is characterized by a male phenotype with a 46,XX karyotype. The frequency of the XX male syndrome is approximately 1 in 25,000 males.²⁴⁷ This form of DSD can be subclassified as *SRY*-positive and *SRY*-negative groups. The *SRY*-positive 46,XX males generally have normal male external genitalia, small azoospermic testes, hypergonadotropic hypogonadism, and often present with infertility.²⁴⁸ In most instances, the *SRY* gene is located on an X chromosome because of recombination between the X and Y chromosomes.²⁴⁹ However, translocation to an autosome can occur. One example was the incidental finding small testes, azoospermia, and translocation of the *SRY* gene onto the terminal end of chromosome 16q in a 61-year-old 46,XX man.²⁵⁰

Approximately 10% of these patients are *SRY*-negative. The phenotypic spectrum ranges from genital ambiguity to normal male external genitalia.²⁵¹ Testes are typically small because of meiotic arrest and germ cell degeneration.²⁵² Molecular etiologies are more diverse for the *SRY*-negative 46,XX male. Duplication of *SOX9* was described in one family; all affected family members had normal male secondary sexual characteristics and azoospermia.²⁵³ Duplications approximately 600 kb upstream of *SOX9* have been identified in several *SRY*-negative XX males.²⁵⁴ Overexpression of the *SOX10* gene at 22q13 was found in one patient with 46,XX sex reversal in association with multiple congenital anomalies.²⁵⁵

SOX3 is a single exon gene mapped to Xq27. It plays a role in brain, pituitary, and craniofacial development.²⁵⁶ An *SRY*-negative 46,XX patient referred for evaluation of hypospadias and bilateral cryptorchidism was found to have bilateral ovotestes and *SOX3* duplication.²⁵⁷ Several other patients have been reported with *SOX3* duplications.^{258,259} Overexpression of *SOX3* in a preclinical transgenic XX mouse model resulted in testicular development and suggested the hypothesis that *SOX3* acts as a surrogate for *SRY* in this situation.²⁶⁰ Hypoplasia of the anterior pituitary and ectopic position of the posterior pituitary has been described in two patients.²⁶¹

XX DISORDER OF SEX DEVELOPMENT/PREATURE OVARIAN FAILURE

46,XX gonadal dysgenesis is a rare disorder associated with delayed puberty and premature menopause associated with hypergonadotropic hypogonadism (see Table 6.4). Affected individuals typically present with lack of spontaneous pubertal development, primary amenorrhea, and uterine hypoplasia.

As noted earlier, ovarian development is an active process involving multiple genes. However, mutations of genes involved in ovarian development are not typically associated with ambiguous genitalia; external genital development is typically female. Rather, these disorders typically present with

TABLE 6.4 Disorder of Sex Development and Gonadal Dysgenesis in XX (SRY-Negative) Individuals

Gene	Location	Phenotype	Genetic Defects	Mode of Inheritance
<i>BMP15</i>	Xp11.22	Ovarian dysgenesis ^a , primary amenorrhea (OMIM #300510)	Point mutations (paternally transmitted), deletions	X-linked

^aAlso associated with large X chromosome deletions/duplications. AD, Autosomal dominant; AR, autosomal recessive.

delayed puberty, primary amenorrhea, and POI.²⁶² In these disorders, follicles may fail to develop or may undergo premature atresia. Mutations in genes involved in ovarian development such as Forkhead box L2 (*FOXL2*), Newborn ovary homeobox (*NOBOX*), bone morphogenetic protein 15 (*BMP15*), and Factor in germline alpha (*FIGLA*) have been described. *BMP15*, a member of the TGF- β superfamily, influences granulosa cell growth and differentiation. Heterozygous missense *BMP15* mutations have been identified among women with POI and

associated with X-linked XX gonadal dysgenesis.²⁶³ Ovarian leukodystrophy is a leukoencephalopathy characterized by vanishing white matter and ovarian dysgenesis associated with mutations in the *EIF2B2*, *EIF2B4*, and *EIF2B5* genes. A mutation in the proteasome 26 subunit, adenosine triphosphatase (ATPase), 3-interacting protein (*PSMC3IP*) gene has been described in autosomal recessive 46,XX gonadal dysgenesis; this loss-of-function mutation reduces estrogen-induced transcriptional activation of the protein encoded by this gene.

Fragile X syndrome is caused by inactivation of the *FMR1* gene caused by DNA hypermethylation of the promoter and expanded 5'-UTR CCG repeat region; the premutation allele containing 55-200 CCG repeats is associated with POI.²⁶⁴ Prevalence of premutation alleles in the general population is estimated at 1 per 150 to 300 females.²⁶⁵

FOXL2

Forkhead box L2 (*FOXL2*) is a member of the winged helix/forkhead transcription family. The protein contains a DNA-binding domain, which is primarily located in the nucleus. The protein contains three α -helices. Mutations in *FOXL2*, located at chromosome 3q23, are associated with the autosomal dominant BPES. BPES is characterized by eyelid dysplasia consisting of small palpebral fissures (blepharophimosis), ptosis, epicanthus inversus, and a broad nasal bridge. The phenotype of BPES type 1 consists of eye findings and premature ovarian failure. Patients with BPES type 2 manifest only the eye features. Patients heterozygous for *FOXL2* mutations generally experience spontaneous pubertal development culminating in menarche, but undergo premature follicle depletion, leading to premature ovarian failure. The histological appearance of ovaries in patients with BPES type 1 is reported to vary from the presence of primordial follicles with some atretic follicles to the complete absence of follicles. Mutations generating nonsense mutations, predicted to generate truncated proteins lacking the transrepression domain, are associated with BPES type 1. Expansion of the poly-alanine tract is associated with BPES type 2.

One major role of *FOXL2* in the ovary appears to be transrepression of genes involved in steroidogenesis, such as *StAR*, *P450sc*, and *aromatase* to prevent premature differentiation and proliferation of granulosa cells.¹⁹⁶ Loss of the transrepressor activity because of nonsense mutations likely contributes to the premature depletion of ovarian follicles and premature ovarian failure. One patient with ovotesticular disorder was found to have expression of both *FOXL2* and *SOX9*. However, in general, expression of these proteins is mutually exclusive.

Curiously in goats mutations in this locus are responsible for the autosomal dominant phenotype characterized by the absence of horns in male and female goats (polledness) and XX female-to-male sex reversal in a recessive manner.

NOBOX

The Newborn Ovary Homeobox (*NOBOX*) gene is expressed in germ cells and primordial oocytes. *NOBOX* encodes a basic helix-loop-helix transcription factor involved in the transition from primordial to primary follicles. The protein is expressed in fetal and adult ovaries.²⁶⁶ The *NOBOX* gene is located at chromosome 7q35. The phenotype of patients with *NOBOX* mutations includes delayed puberty, with primary amenorrhea and secondary amenorrhea.²⁶⁷ POI associated with *NOBOX* mutations shows both autosomal dominant and autosomal recessive inheritance patterns.²⁶⁸

FIGLA

Factor in germline alpha (*FIGLA*) is a germ cell-specific transcription factor located at chromosome 2p13.3. *FIGLA* is expressed in the human fetal ovary. The phenotype of women with *FIGLA* mutations includes secondary amenorrhea and ovaries devoid of follicles.²⁶⁹ Both autosomal dominant and autosomal recessive inheritance have been described.²⁷⁰

SPIDR

Scaffolding protein involved in DNA repair (*SPIDR*), mapped to chromosome 8q11.21, encodes a protein involved in

homologous DNA repair. Sisters who presented with primary amenorrhea were found to have hypergonadotropic hypogonadism associated with homozygous mutation.

NUP107

Nucleoporins comprise nuclear pore complexes that serve as the gatekeepers of nucleocytoplasmic transport. One such protein is nucleoporin-107, encoded by *NUP107*, is mapped to chromosome 12q15. Missense variants in *NUP107* segregated with delayed puberty and hypergonadotropic hypogonadism associated with POI in two ethnically different families. Affected females were otherwise healthy; no male phenotype was evident.^{271,272}

WNT4 Gene

WNT4 is a secreted molecule that binds to members of the frizzled family of receptors, resulting in transcriptional regulation of target genes. *WNT4* increases follistatin expression, which inhibits formation of the coelomic vessel (antitestis action) and supports ovarian germ cell survival (proovarian action).¹¹⁰ Duplication of the *WNT4* gene, located at chromosome 1p31-1p35, has been associated with 46,XY male-to-female sex reversal. One such patient presented with ambiguous external genitalia accompanied by severe hypospadias, fibrous gonads, remnants of both Mullerian and Wolffian structures, cleft lip, microcephaly, and IUGR.¹¹¹ A female-to-male sex reversed patient with kidney, adrenal, and lung dysgenesis was found to have a homozygous loss-of-function *WNT4* mutation.¹¹² Loss-of-function *WNT4* mutations have been detected in 46, XX women with primary amenorrhea, secondary to Mullerian duct abnormalities and androgen excess.¹¹³⁻¹¹⁵ The phenotypes of these patients support the hypothesis that *WNT4* plays a role in ovarian differentiation.

VANISHING TESTES

The terms *testicular regression syndrome* and *vanishing testes* are used to describe testicular absence in boys with undescended testes. In some instances, this situation is associated with ambiguous genitalia and undervirilization, which presumably represents regression of testicular tissue occurring between 8 and 14 weeks of gestation. Physical findings reflect duration of testicular function. At operation, a rudimentary spermatic cord and nubbin of testicular tissue may be identified. Histological examination of the testicular nubbins often reveals hemosiderin-laden macrophages and dystrophic calcification.²⁷³ One potential mechanism involves an antenatal vascular accident, associated with antenatal testicular torsion, leading to testicular regression.²⁷⁴ Another possibility is anomalous vascular development.²⁷⁵ Although usually sporadic, familial testicular regression has been described.¹⁶⁰

DISORDERS OF CHOLESTEROL AND STEROID BIOSYNTHESIS

Abnormalities affecting the biosynthetic pathways involved in cholesterol, cortisol, and sex steroid biosynthesis can lead to genital ambiguity (Table 6.5). Steroidogenesis refers to the multiple enzyme-mediated processes through which cholesterol is converted to biologically active steroid hormones (Fig. 6.2). This process depends on the coordinated regulation of cholesterol uptake into cells, transfer into mitochondria, and actions of tissue-specific enzymes.²⁷⁶ Details regarding the complexities of steroidogenic processes continue to unfold. Three pathways have been characterized: (1) canonical/classical, (2) "alternative backdoor," and (3) 11-oxygenated C-19 androgens.

TABLE 6.5 Steroidogenic Disorders

Gene	Location	Phenotype	Genetic Defects	Mode of Inheritance
<i>AKR1C2</i> and <i>AKR1C4</i>	10p15.1	Complete gonadal dysgenesis, 3 α -Hydroxysteroid Dehydrogenase Isozyme Deficiency (OMIM #614279)	Point mutations	AR

<i>STAR</i>	8p11.23	Lipoid congenital adrenal hyperplasia (OMIM #201710)	Point mutations	AR

AD, Autosomal dominant; AR, autosomal recessive.

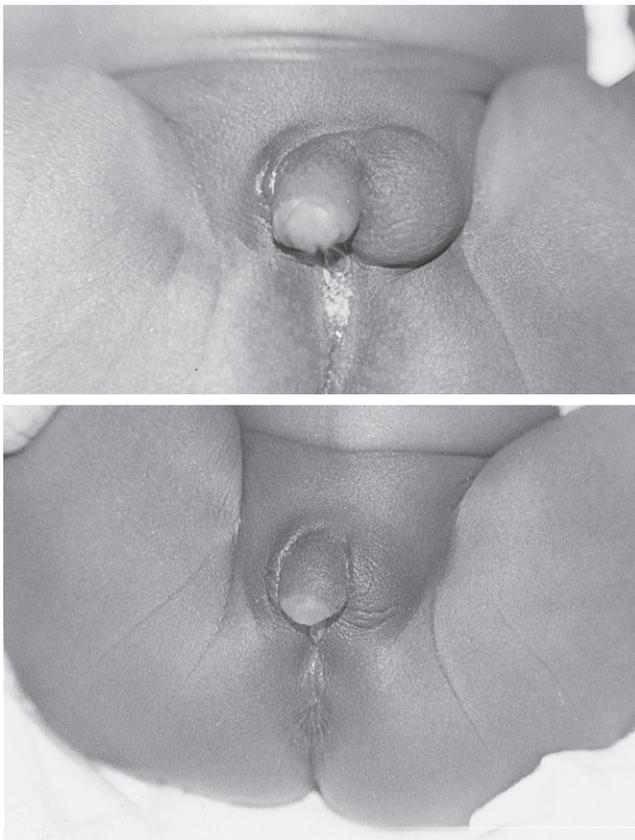

Fig. 6.2 Genital ambiguity with asymmetry in a patient with 46,XY disorder of sexual differentiation (mixed gonadal dysgenesis).

Many of the steroidogenic enzymes are cytochrome P450 heme-containing proteins that absorb light at 450 nm in their reduced state or hydroxysteroid dehydrogenases. The P450 enzymes receive electrons from the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) and use

their heme center to mediate catalysis. The type 1 enzymes are located in mitochondria and receive electrons from NADPH from a flavoprotein, ferredoxin reductase, and an iron-sulfur protein, ferredoxin. The type 2 enzymes are located in the endoplasmic reticulum and receive electrons from NADPH from another protein, P450 oxidoreductase.

The hydroxysteroid dehydrogenase enzymes use NAD⁺ and NADP⁺ as cofactors; these enzymes do not contain heme groups. The hydroxysteroid dehydrogenases are classified into two groups. One group is the short-chain dehydrogenase reductase family. The other group is the aldo-keto reductase family.²⁷⁷ These enzymes function as dehydrogenases and reductases. Although these enzymes can perform both dehydrogenase and reductase activities in vitro, most function unidirectionally.

During fetal life, steroidogenic enzymes are expressed in placenta, testis, and adrenal. Inborn errors of testosterone biosynthesis can lead to undervirilization and ambiguous genitalia in 46,XY fetuses. Loss-of-function mutations in adrenal cortisol biosynthesis leads to increased androgen concentrations in XX, fetuses with subsequent virilization of the external genitalia.

In the canonical/classical androgen pathway, the fetal testis secretes testosterone that is converted to dihydrotestosterone (DHT) in target tissues, such as the prostate and external genitalia. In the testis, cholesterol is converted to pregnenolone by cholesterol side chain cleavage enzyme P450_{sc} encoded by *CYP11A1*. Pregnenolone is converted to 17-hydroxypregnenolone by the 17 α -hydroxylase activity of P450_{c17} encoded by *CYP17A1* and then to DHEA by the 17,20-lyase activity of P450_{c17}. DHEA is converted to androstenedione by 3 β -hydroxysteroid dehydrogenase type 2 encoded by *HSD3B2*. Androstenedione is converted to testosterone by 17 β -hydroxysteroid dehydrogenase type 3 encoded by *HSD17B3*. In genital skin, testosterone is converted to DHT by 5 β -reductase type 2 encoded by *SRD5A2*.

Through investigations of the tammar wallaby and patients with disordered steroidogenesis, the presence of another pathway leading to DHT synthesis was uncovered.²⁷⁸ In this "alternate backdoor pathway" steroidogenesis bypasses

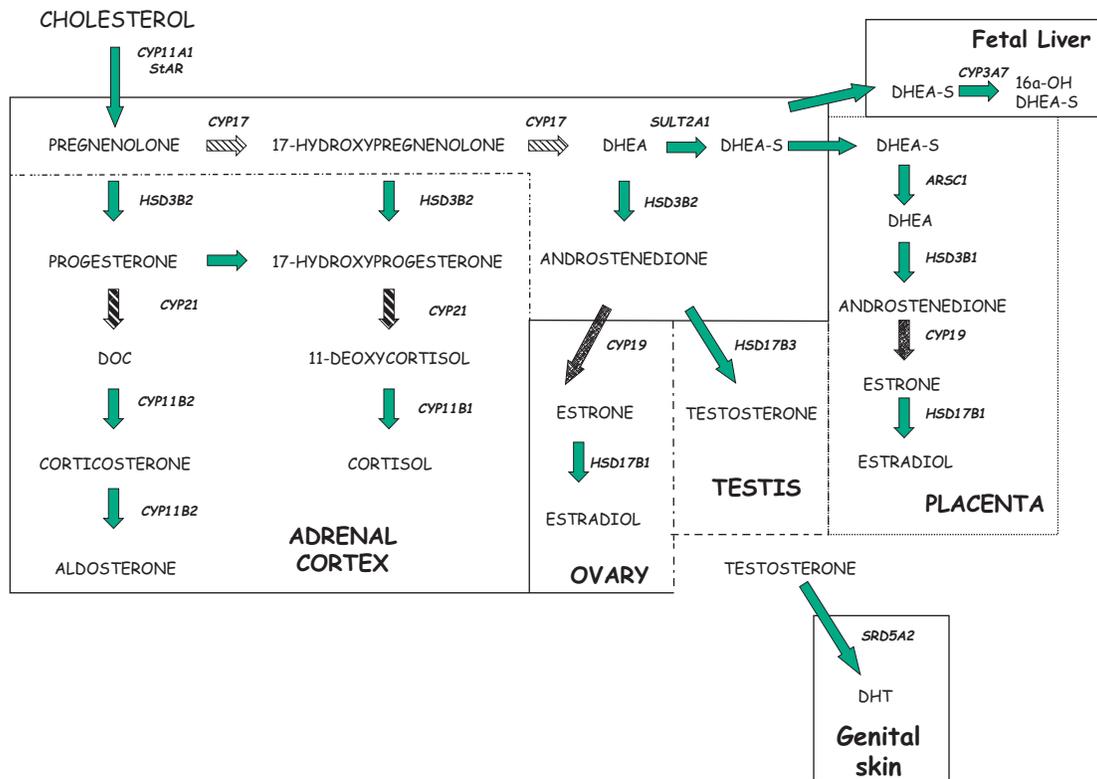

Fig. 6.3 Diagram of classical steroidogenic pathways. Substrates, products, and genes involved in adrenal, ovarian, testicular, and placental steroidogenesis are indicated. Genes are 17 α -hydroxylase/17,20-lyase (*CYP17*), 3 β -hydroxysteroid dehydrogenase (*HSD3B2*), 21-hydroxylase (*CYP21*), 11 β -hydroxylase (*CYP11B1*), aldosterone synthase (*CYP11B2*), aromatase (*CYP19*), 17 β -hydroxysteroid dehydrogenase type 1 (*HSD17B1*), 17 β -hydroxysteroid dehydrogenase type 3 (*HSD17B3*), 5 α -reductase type 2 (*SRD5A2*), sulfotransferase (*SULT2A1*), and steroid sulfatase/arylsulfatase C (*ARSC1*). *CYP3A7* is a cytochrome P450 enzyme expressed in fetal liver, where it catalyzes the 16 α -hydroxylation of estrone (E1) and dehydroepiandrosterone (DHEA). Its expression decreases postnatally. Steroidogenic enzymes that use P450 oxidoreductase (POR), a flavoprotein encoded by *POR*, to transfer electrons are indicated by hatched arrows DHEA-S, Dehydroepiandrosterone sulfate.

DHEA, androstenedione, and testosterone (Fig. 6.3). Rather, 17-hydroxyprogesterone (17-OHP) undergoes 3 α - and 5 α -reduction followed by 17,20-lyase, 17 β -hydroxysteroid dehydrogenase, and 3 α -oxidation steps to generate DHT.²⁷⁹

The third steroidogenic pathway involved the 11-oxygenated C-19 steroids, which have long been recognized as major androgens in teleost fish. The relevance of 11-oxygenated steroids for human health has been explored (see Fig. 6.3). This class of steroids depends on the activity of 11 β -hydroxylase (P450c11B1) encoded by *CYP11B1* and expressed in the adrenal zona fasciculata and zona reticularis. Androstenedione and testosterone are substrates for this enzyme and can be converted to 11 β -hydroxyandrostenedione and 11 β -hydroxytestosterone, respectively.²⁸⁰ Subsequent enzymatic steps can generate 11-ketotestosterone and 11-dihydroketotestosterone; both are potent androgens that activate the androgen receptor.²⁸¹ Whereas the 11-oxygenated C-19 steroids are established to be relevant in postnatal physiology, their contribution, if any, to fetal steroidogenesis is unknown.

Both the canonical androgen biosynthetic pathway and the “alternative backdoor pathway” are critical to promote normal masculinization of the XY fetus.²⁸² Proteins requisite for testosterone biosynthesis include NR5A1, LH receptor, steroidogenic acute regulatory peptide (StAR), P450scc, P450c17, 3 β -hydroxysteroid dehydrogenase type 2, 17 β -hydroxysteroid dehydrogenase type 3, P450-oxidoreductase, 5 β -reductase types 1 and 2, aldo-keto reductase type 1C2 (AKR1C2), and aldo-keto reductase type 1C4 (AKR1C4) (see Fig. 6.3). Enzymes, for example, SRD5A1, associated with the alternative backdoor pathway are primarily expressed in nongonadal

tissues, such as the liver and placenta.²⁸³ Based on a small number of midgestation human male fetuses, androsterone was reported to be the major backdoor androgen in the male fetal circulation; these data also suggested that placental progesterone provided the substrate for androsterone biosynthesis.²⁸³

Inborn errors of glucocorticoid biosynthesis are often associated with the virilizing CAHs. The fetal adrenal cortex is derived from coelomic epithelium and consists of two major zones: the fetal zone and the adult zone. The fetal zone is primarily responsible for DHEA synthesis, which is then sulfated to provide substrate for placental estrogen biosynthesis (see Fig. 6.3). The adult zone, which after birth differentiates into the three zones of the adult adrenal cortex, is primarily responsible for cortisol biosynthesis. By 10 weeks of gestation, the adrenal is secreting DHEA-S and the hypothalamic-pituitary-adrenal axis is functional. The extent of placental *CYP17A1* transcript expression is unresolved, but most recent data indicate minimal expression.^{284,285}

Luteinizing Hormone Choriogonadotropin Receptor Gene

Leydig cell hypoplasia is an autosomal recessive disorder characterized by failure of testicular Leydig cell differentiation, secondary to inactivating *LHCGR* mutations, with ensuing target cell resistance to LH.²⁸⁶ The *LHCGR* gene, mapped to chromosome 2p21, codes for a 674-amino-acid protein. The *LHCGR* is a seven-transmembrane domain G-protein-coupled receptor. Specific mechanisms through which the loss-of-function

mutations induce LH resistance include decreased receptor protein, decreased ligand binding, altered receptor trafficking, and impaired ability to activate G_s .

Inability to respond to hCG or LH decreases Leydig cell testosterone biosynthesis. The phenotype of affected 46,XY infants ranges from undervirilization to female external genitalia. Affected individuals raised as females often seek medical attention for delayed breast development. Mullerian duct derivatives are absent because AMH is secreted by the unaffected Sertoli cells. Testes are typically inguinal or intraabdominal. Laboratory studies show elevated LH, low testosterone, and normal FSH concentrations. There is no significant testosterone response to hCG stimulation. Testicular histology reveals absence of Leydig cells; seminiferous tubules and testicular volume are preserved because of normal FSH secretion and responsiveness. Undervirilization with hypospadias, micropenis, and cryptorchidism can occur with incomplete loss-of-function missense mutations.

Genetic females, sisters of affected 46,XY individuals, who carry the identical mutations show normal female genital differentiation and normal pubertal development but have amenorrhea and infertility.²⁸⁷ The uterus is small to normal in size. Ovarian cysts may develop. Estrogen concentrations generally fail to achieve the threshold required for ovulation. Genetic analysis may be helpful to distinguish LHCGR mutations from other disorders affecting testosterone biosynthesis.^{288,289}

Congenital Lipoid Adrenal Hyperplasia

This autosomal-recessive disorder is characterized by a severe defect in the conversion of cholesterol to pregnenolone, leading to impaired synthesis of all adrenal and gonadal steroid hormones. Impaired testosterone biosynthesis in utero prevents male sexual differentiation. Hence, all affected fetuses (46,XY or 46,XX) have female external genitalia. In the XY fetus, Sertoli cells are intact, AMH secretion is unaffected, and Mullerian duct elements regress. Low or undetectable steroid hormone concentrations, elevated ACTH concentrations, and elevated plasma renin activity (PRA) are consistent with this diagnosis. Elevated 17-hydroxypregnenolone or pregnenolone concentrations distinguish 3β -hydroxysteroid dehydrogenase deficiency from congenital lipoid adrenal hyperplasia.

Congenital lipoid adrenal hyperplasia is caused by mutations in the *StAR* gene mapped to chromosome 8p11.23.²⁹⁰ The *StAR* protein facilitates cholesterol transport across the mitochondria to P450_{scc}. In congenital lipoid adrenal hyperplasia, the impaired mitochondrial cholesterol transport leads to accumulation of cholesterol esters and sterol autooxidation products. Ultimately, the lipid accumulation alters the cell cytostructure provoking cell destruction and complete loss of *StAR*-dependent steroidogenesis.²⁹¹ Hence congenital lipoid adrenal hyperplasia has “two hits”: one is defective steroidogenesis and the other is destruction of the steroidogenic cell.^{292,293} Because the definitive zone of the adrenal cortex is relatively quiescent during gestation, aldosterone deficiency may not be obvious in the immediate newborn period. This two-hit mechanism enables spontaneous pubertal development in affected girls because significant estrogen synthesis does not take place until puberty. Ovarian follicular cells are sequentially recruited and damaged, resulting in hypergonadotropic hypogonadism.^{294,295}

Nonclassic lipoid CAH is a milder form with variable adrenal and gonadal function presenting in childhood and adolescence.²⁹⁶ Nonclassic lipoid CAH may present with isolated glucocorticoid deficiency and resembles familial glucocorticoid deficiency because of mutations in the ACTH receptor (*MC2R*) gene.²⁹⁷

In humans, because 17-OHP is not a favored substrate for the 17,20-lyase reaction, this pathway acquires functional importance in disorders of steroidogenesis associated with increased 17-OHP concentrations.

SIDE CHAIN CLEAVAGE CYTOCHROME P450 ENZYME

Side chain cleavage enzyme (also known as cholesterol desmolase) is a cytochrome P450 enzyme encoded by the *CYP11A1* gene located at chromosome 15q23-q24. This enzyme converts cholesterol to pregnenolone, is essential to steroidogenesis, and plays a crucial role in placental progesterone synthesis. Children affected with this autosomal-recessive disorder have adrenal insufficiency and female external genitalia irrespective of the karyotype. Postnatally, adrenal enlargement is typically not evident on ultrasound or magnetic resonance imaging. The absence of adrenal/gonadal tissue has been speculated to result from lipid accumulation similar to the cell destruction observed in patients with *StAR* mutations.²⁹⁸ The phenotypic spectrum includes adrenal insufficiency with hypospadias, normal external genital development, normal pubertal progression, or gonadal failure.²⁹⁹ *CYP11A1* mutations have been detected in patients with primary adrenal insufficiency.³⁰⁰ Genetic analysis may be necessary to distinguish this disorder from congenital lipoid adrenal hyperplasia.³⁰¹

VIRILIZING CONGENITAL ADRENAL HYPERPLASIAS

The virilizing CAHs are a group of disorders caused by mutations in the steroidogenic enzyme genes involved in cortisol biosynthesis. These genes are 3β -hydroxysteroid dehydrogenase type 2 (*HSD3B2*), 21-hydroxylase (*CYP21A2*), and 11 β -hydroxylase (*CYP11B1*). These three disorders share a common pathophysiology. Insufficient cortisol production leads to decreased negative feedback inhibition, increased ACTH production, accumulation of steroid intermediates proximal to the deficiency enzyme, and increased androgen concentrations.^{302,303} The specific manifestations and laboratory abnormalities vary depending on which enzyme gene is involved. Indeed, the magnitude of glucocorticoid and mineralocorticoid deficiencies varies generally in proportion to the severity of the enzyme deficiency.

Accumulation of steroid intermediates, such as 17-OHP, results in increased androgen concentrations. In the affected female, the increased androgen exposure promotes virilization of the external genitalia. Excessive 17-OHP can be converted through the alternate backdoor pathway to DHT. This alternate route involves 5α and 3α -reduction of 17-OHP to 5α -pregnane- $3\alpha,17\alpha$ -diol-20-one (pdiol), ultimately generating androstane-diol, which is the substrate for 3α -oxidation and conversion to DHT.³⁰⁴ (Fig. 6.4). During fetal life, accumulation of 17-OHP because of mutations in *CYP21A2*, *CYP11B2*, or P450-oxidoreductase (*POR*) may increase flux through this “backdoor pathway,” leading to elevated DHT concentrations.³⁰⁵

21-Hydroxylase Deficiency

The most common type of CAH (accounting for 90%–95% of cases) is 21-hydroxylase deficiency because of mutations in the 21-hydroxylase (*CYP21A2*) gene located at chromosome 6p21.3 in the human leukocyte antigen (HLA) class III region.³⁰⁶ The incidence of the classic forms is reported to range from 1:5000 to 1:15,000 and varies among ethnic/racial backgrounds.³⁰⁷ Decreased 21-hydroxylase activity impairs conversion of 17-OHP to 11-deoxycortisol in the zona fasciculata (the primary site of cortisol biosynthesis) and conversion of progesterone to deoxycorticosterone in the zona glomerulosa, the primary site of aldosterone biosynthesis. An extensive clinical practice guideline has recently been published.³⁰⁸

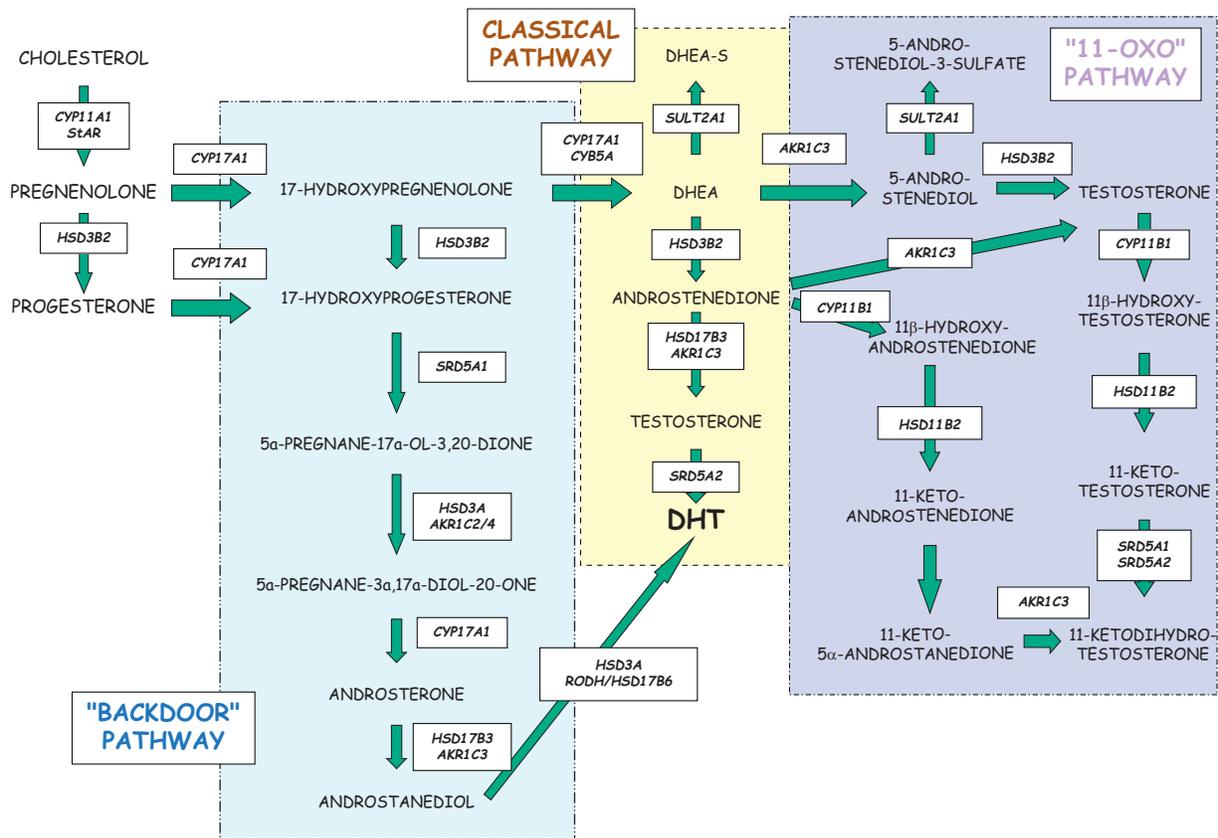

Fig. 6.4 Classical, backdoor, and 11-oxo-C19 steroidogenic pathways. The classic steroidogenic pathway relevant to the testis (*light background*), the "backdoor pathway" (*dark background*), and the 11-oxo-C19 androgens (*purple background*) are indicated. In the presence of elevated ACTH and 17-OHP concentrations because of *CYP21*, *CYP11B1*, or *POR* mutations, the backdoor pathway may contribute to the excessive androgen concentrations responsible for virilization of XX fetuses.

Infant girls with classic salt-losing 21-hydroxylase deficiency usually present in the immediate neonatal period because of genital ambiguity (Fig. 6.5). When the diagnosis is delayed, affected girls develop dehydration, hyponatremia, and hyperkalemia because of glucocorticoid and mineralocorticoid deficiencies. In affected females, the spectrum of genital virilization varies from clitoromegaly to perineal hypospadias to complete

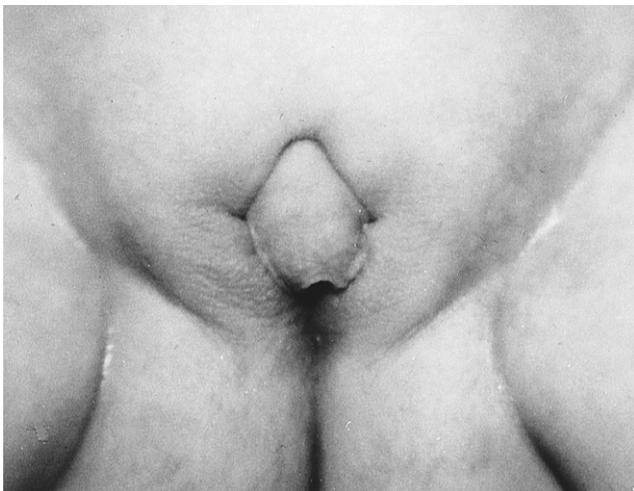

Fig. 6.5 Genital ambiguity in virilized female with 21-hydroxylase deficiency. The labioscrotal folds are fused, and the clitoris is enlarged.

fusion of labiourethral and labioscrotal folds, giving rise to a phallus with chordee and urethral meatus at the tip of phallus. The magnitude of external genital virilization may be so extensive that affected female infants appear to be males with bilateral undescended testes.^{309,310} Unless identified by neonatal screening, infant boys typically present at 2 to 3 weeks of age with failure to thrive, poor feeding, lethargy, dehydration, hypotension, hyponatremia, and hyperkalemia. When the diagnosis is delayed or missed, CAH is potentially fatal. Newborn screening programs decrease the morbidity and mortality associated with acute adrenal insufficiency.

In affected infants, random 17-OHP concentrations are usually elevated. Concentrations are greater than 5000 ng/dL and may be much higher.³¹¹ Androstenedione and progesterone concentrations are also typically elevated. In some instances, PRA can be helpful to assess mineralocorticoid status. Measurement of 21-deoxycortisol is extremely helpful, but availability of this hormone assay is limited. For female infants, a normal uterus is present and can be identified on ultrasound. Ovaries may be too small to be readily identified on ultrasound. Despite excessive antenatal androgen exposure, ovarian position is normal and internal Wolffian structures are not retained.

The spectrum of impaired 21-hydroxylase activity ranges from complete glucocorticoid and mineralocorticoid deficiencies to mild deficiencies manifested principally by compensatory excessive adrenal androgen secretion. Infants capable of adequate aldosterone synthesis do not usually manifest overt salt loss. Female infants capable of adequate aldosterone synthesis may still have sufficient androgen exposure in utero to virilize their external genitalia. In the absence of newborn

screening programs, affected males capable of aldosterone biosynthesis may not be identified until they present with genital overgrowth or premature pubarche. Infants with the milder forms of CAH are generally not identified by most newborn screening programs. Urinary steroid hormone gas chromatography/mass spectrometry analyses showed increased ratios of pdiol to metabolites of the Δ^4 and Δ^5 pathways, which indicates postnatal activity of the backdoor pathway, especially during early infancy.³¹²

CYP21A2 is located approximately 30 kilobases from a highly homologous pseudogene, *CYP21A1P*. The tenascin-XB (*TNXB*) gene encoding an extracellular matrix protein is located on the DNA strand opposite *CYP21A2*.³¹³ At this time, more than 200 *CYP21A2* mutations have been reported.³¹⁴ However, only a few mutations account for the majority of affected alleles. Most of the common mutations represent gene conversion events in which *CYP21A2* has acquired deleterious *CYP21A1P* sequences. The frequency of specific mutations varies among ethnic groups. Molecular genotyping can be a useful adjunct to newborn screening. Caveats to bear in mind are that multiple mutations can occur on a single allele and that different *CYP21A2* mutations can occur in one family.³¹⁵

11 β -Hydroxylase Deficiency

CAH because of 11 β -hydroxylase deficiency is characterized by glucocorticoid deficiency, excessive androgen secretion, and hypertension. This form of CAH is caused by mutations in the 11 β -hydroxylase (*CYP11B1*) gene. The enzyme is expressed in the zona fasciculata, where it converts 11-deoxycortisol to cortisol. CAH, caused by *CYP11B1* mutations, is rare (3%–5% of cases) apart from the high incidence among Moroccan Jews, for whom the incidence approaches one in 6000.³¹⁶ Despite the presence of the identical mutation (R448H), phenotypic heterogeneity for the magnitude of virilization and hypertension occurs even in a single family. Affected females may present with ambiguous genitalia. The typical laboratory finding is an elevated 11-deoxycortisol concentration. Serum concentrations of 17-hydroxyprogesterone, androstenedione, and testosterone may be mildly elevated. PRA concentrations are low or suppressed. Nevertheless, infants may experience salt loss presumably caused by mineralocorticoid resistance. Patients with nonclassic forms have been identified.³¹⁷ Although ACTH-stimulated hormone responses among heterozygotic carriers are usually normal, elevated 11-deoxycortisol and 11-deoxycorticosterone have been reported.

The *CYP11B1* gene is located at chromosome 8q22 in close proximity to a highly homologous gene *CYP11B2*, which codes for aldosterone synthase. Novel mutations associated with classical and nonclassical 11 β -hydroxylase deficiency have been identified. *CYP11B1* is expressed in the zona fasciculata, whereas *CYP11B2* is expressed primarily in the zona glomerulosa.

3 β -Hydroxysteroid Dehydrogenase Deficiency

CAH caused by 3 β -hydroxysteroid dehydrogenase type 2 deficiency, associated with mutations in the 3 β -hydroxysteroid dehydrogenase type 2 (*HSD3B2*) gene, leads to virilization of the external genitalia of 46,XX fetuses because of increased DHEA synthesis. Affected 46,XY fetuses have ambiguous genitalia characterized by undervirilization of the external genitalia secondary to testosterone deficiency. Despite decreased testosterone synthesis, affected 46,XY fetuses usually have intact Wolffian duct structures (including vas deferens). The NAD⁺-dependent enzyme 3 β -hydroxysteroid dehydrogenase/ Δ^5 - Δ^4 -isomerase catalyzes the conversion of the Δ^5 steroid precursors, pregnenolone, 17-hydroxypregnenolone, and DHEA into the respective Δ^4 -ketosteroids, progesterone, 17-OHP, and androstenedione.²⁵⁰

Two isozymes encoded by two different highly homologous genes have been identified and mapped to chromosome 1p13.1. The type 1 (*HSD3B1*) gene is expressed primarily in skin, placenta, prostate, and other peripheral tissues, whereas *HSD3B2* is primarily expressed in the adrenal cortex and gonads. Mutations in *HSD3B2*, but not *HSD3B1*, have been detected in patients with 3 β -hydroxysteroid dehydrogenase deficiency CAH. Acute adrenal insufficiency occurs in the newborn period when complete loss-of-function mutations impair biosynthesis of mineralocorticoids, glucocorticoids, and sex steroids. Typical presentations for the non-salt-losing forms include premature pubarche and (in 46,XY infants) perineal hypospadias. Confirmatory laboratory findings include elevated pregnenolone, 17-hydroxypregnenolone, and DHEA concentrations with elevated ratios of Δ^5 to Δ^4 steroids. Because enzymatic activity of the type 1 isozyme is unimpaired, elevated 17-OHP and androstenedione concentrations may be found.

DEFECTS IN SEX STEROID BIOSYNTHESIS

17 α -Hydroxylase/17,20-Lyase Deficiency

Synthesis of mineralocorticoids, glucocorticoids, and sex steroids is modulated by the enzyme, 17 α -hydroxylase/17,20-lyase. This enzyme, encoded by a single gene, *CYP17A1* mapped to chromosome 10q24.3, catalyzes two distinct steps in steroidogenesis, pregnenolone is 17 α -hydroxylated to 17 α -hydroxypregnenolone, which then undergoes 17,20-lyase activity to form DHEA. Factors favoring the 17,20-lyase reaction include availability of P450 oxidoreductase and cytochrome b₅ and serine/threonine phosphorylation of the P450c17 protein.³¹⁸

Loss-of-function mutations interfere with glucocorticoid and sex steroid biosynthesis. Affected males present with undervirilization of the external genitalia. Affected females have normal genital development and present with delayed puberty. Patients are often hypertensive because of the increased ACTH-stimulated mineralocorticoid synthesis. Serum levels of progesterone, deoxycortisone, corticosterone, 18-hydroxycorticosterone, and 18-hydroxy deoxycorticosterone (DOC) are elevated and can be suppressed glucocorticoid replacement. Low or absent glucocorticoids and sex steroids with poor ACTH-stimulated responses are consistent with this diagnosis. Mutations solely affecting the 17,20-lyase activity are extremely rare.³¹⁹ The phenotype of apparent isolated 17,20-lyase deficiency can be caused by mutations in other genes, such as cytochrome b₅, P450 oxidoreductase, and several aldo-keto reductase enzymes, as described later.

Cytochrome b₅ Deficiency

Cytochrome b₅ participates in electron transfer for some cytochrome P450 reactions. Although it is not an effective electron donor to P450c17, this protein enables the interactions between P450c17 and oxidoreductase to promote the 17,20-lyase reaction essential for sex steroid synthesis. One 46,XY infant found to be homozygous for a loss-of-function mutation in the cytochrome b₅ (*CYB5*) gene was described to have micropenis, bifid scrotum, scrotal hypospadias, undetectable DHEA-S concentration, low testosterone concentration, and elevated methemoglobin concentration.³²⁰ A mis-sense mutation associated with mild methemoglobinemia and undervirilized 46,XY siblings has been described.³²¹

3 α -Hydroxysteroid Dehydrogenase Isozyme Deficiencies

Reevaluation of the families originally reported to have isolated 17,20-lyase deficiency led to identification of alternative

pathways for androgen synthesis.³²² Investigation of one family revealed no mutations in *CYP17A1*, *NR5A1*, *POR*, or *CYB5*. Rather, mutations were detected in the 3 α -hydroxysteroid dehydrogenase type III (*AKR1C2*) gene, which is mapped to chromosome 10p15.1. The phenotype, undervirilization of affected 46,XY individuals, followed a sex-linked recessive inheritance pattern. A splicing mutation in another closely related 3 α -HSD gene, *AKR1C4*, was found in a second family. Digenic inheritance involving mutations in both *AKR1C2* and *AKR1C4* were found in this second family. Thus both the classic and backdoor pathways appear to be necessary for normal male external genital development.³²² However, details regarding the specific roles of these enzymes remains to be elucidated.

Cytochrome P450 Oxidoreductase Deficiency

In 1985 a disorder with biochemical evidence, suggesting decreased 17 α -hydroxylase and 21-hydroxylase activity, was initially reported.³²³ This disorder was found to be associated with mutations in the cytochrome P450 oxidoreductase (*POR*) gene, mapped to chromosome 7q11-12. *POR* codes for a protein that functions as a mandatory electron donor to microsomal steroidogenic and hepatic P450 enzymes. The *POR* protein plays a major role in glucocorticoid and sex steroid synthesis.

Clinical features included genital ambiguity, craniosynostosis, midface hypoplasia, and radiohumeral synostosis. At birth, genital ambiguity was noted in both male and female infants. However, progressive postnatal virilization does not occur. Insufficient testosterone synthesis likely causes the undervirilization of male infants. Virilization of female fetuses is attributed to shunting of the excessive 17-OHP to the "backdoor pathway," resulting in increased DHT synthesis. During pregnancy, some mothers developed signs associated with androgen excess, such as acne, hirsutism, and clitoromegaly.³²⁴ Typical laboratory findings include elevated 17-OHP, low sex steroid, and normal mineralocorticoid concentrations. Some affected individuals may benefit from daily glucocorticoid replacement therapy. Others may need glucocorticoid treatment only for stress dosing.

The skeletal malformations resemble those found in the Antley-Bixler syndrome, which is an autosomal dominant disorder associated with mutations in the *FGFR2* gene. Patients with Antley-Bixler syndrome caused by *FGFR2* mutations have normal steroidogenesis, whereas patients with *POR* mutations have abnormal steroidogenesis.³²⁵ The molecular basis of the skeletal anomalies is unclear but is suspected to be caused by impaired activity of enzymes involved in sterol biosynthesis, such as 14 α -lanosterol demethylase (*CYP51A1*) and squalene epoxidase or retinoic acid metabolism.³²⁶

17 β -Hydroxysteroid Dehydrogenase Deficiency

This disorder is caused by mutations of the 17 β -hydroxysteroid dehydrogenase type 3 gene (*HSD17B3*) located at chromosome 9q22. The enzyme is expressed almost exclusively in the testis, where it converts androstenedione to testosterone. Loss-of-function mutations result in testosterone deficiency and subsequent undervirilization of 46,XY fetuses. In this autosomal recessive disorder, external genitalia range from female with perineoscrotal hypospadias and a blind-ending vaginal pouch to ambiguous with labioscrotal fusion to hypospadias.³²⁷ Testes are present and may be palpable in the labioscrotal folds or incompletely descended. Despite the presence of female external genitalia, Wolffian structures are typically present.³²⁸

When unrecognized, patients are usually considered to be female at birth. At puberty, progressive virilization occurs. The extent of virilization ranges from hirsutism, deepening of

the voice, and clitoral enlargement. Virilization is attributed to extratesticular conversion of androstenedione to testosterone. Some affected individuals change gender role from female to male. Given the apparently low risk for gonadal neoplasia, there is no contraindication to changing gender role, gender marker, and retention of testes in a scrotal location.³²⁸ Increased conversion of androstenedione to estrogens may cause gynecomastia.

Appropriate male assignment can be made in infancy when the diagnosis is suspected and confirmed. Diagnostic laboratory features include increased basal and hCG-stimulated androstenedione to testosterone ratios. The clinical features are similar to those of 5 α -reductase deficiency and androgen insensitivity; molecular genetic analysis may be beneficial to confirm the diagnosis. Affected 46,XX girls are usually asymptomatic, have normal female internal and external genitalia, and normal pubertal development; infertility has been reported for some.³²⁹

5 α -Reductase Deficiency

This autosomal-recessive disorder is caused by mutations in the 5 α -reductase type 2 gene (*SRD5A2*), which is located at chromosome 2p23. This gene is expressed primarily in androgen target tissues, where it converts testosterone to DHT. Clusters of individuals with *SRD5A2* mutations have been described in regions of the Dominican Republic, Papua New Guinea, Turkey, and the Middle East.

Affected 46,XY individuals have genital ambiguity characterized by differentiation of Wolffian structures, absence of Mullerian-derived structures, small phallus, urogenital sinus with perineoscrotal hypospadias, and blind vaginal pouch. Patients raised as females may present with primary amenorrhea typically associated with genital ambiguity. Deletions, missense mutations, and uniparental disomy have been reported. Because of the extensive heterogeneity in the clinical features, phenotype/genotype correlations are not well established.³³⁰ Random testosterone/DHT ratios may not identify affected individuals; hCG-stimulated testosterone/DHT ratios may be necessary. Caveats regarding this diagnosis include the need for hCG stimulation in prepubertal patients and accurate hormone determinations in which cross-reactivity between testosterone and DHT is minimized.³³¹

At puberty, progressive virilization occurs with muscular development, voice change, and phallic enlargement. These features have been attributed to the actions of 5 α -reductase type 1 (*SRD5A1*). *SRD5A1*, located at chromosome 5p15, is expressed in postpubertal skin and scalp. Phenotypic heterogeneity occurs frequently. Some 46,XY individuals with this disorder who were raised as girls develop a male gender identity and changed gender role in adolescence or adulthood. Despite the virilization, facial hair tends to be scanty, the prostate is hypoplastic, semen tends to be viscous, and the amount of ejaculate is low. Affected men often have azoospermia or oligospermia. Intrauterine insemination with sperm from an affected male has resulted in pregnancy.³³²

Placental Aromatase Deficiency

Placental aromatase deficiency is a rare autosomal recessive disorder arising from mutation in the aromatase gene, *CYP19A1*, which is located at chromosome 15q21.2 and codes for a 503-amino-acid protein. Inactivating *CYP19A1* mutations impair conversion of androgens to estrogens, leading to increased androgens. During pregnancies with affected fetuses, progressive maternal virilization characterized by hirsutism, clitoral hypertrophy, acne, and frontal balding occurs. During pregnancy, testosterone, DHT, and androstenedione concentrations

are elevated and estradiol, estrone, and estriol concentrations are low. In the postpartum period, some clinical features of androgen excess regress and the elevated androgen concentrations return to normal levels.

At birth, 46,XX infants are variably virilized with labioscrotal fusion, clitoromegaly, and perineal scrotal hypospadias. Affected 46,XX individuals generally manifest delayed puberty characterized by minimal or absent breast development, primary amenorrhea, hypergonadotropic hypogonadism, multicystic ovaries, and decreased bone mineral density. At birth, affected 46,XY infants have normal internal and external genital development. Affected males have generally presented after puberty with tall stature, skeletal pain, delayed skeletal maturation, and infertility. Investigation of aromatase-deficient men suggests that estrogen deficiency is associated with abdominal obesity, insulin resistance, dyslipidemia, and relative infertility. Patients with less severe phenotypic features have been described.³³³

Aromatase is a cytochrome P450 enzyme that plays an important role in the biosynthesis of estrogens (C18 steroids) from androgens (C19 steroids). In addition to its role in estrogen biosynthesis in adolescents and adults, aromatase located in the human placenta converts fetal adrenal androgens to estrogens and protects the mother from the potential virilizing effects of the fetal androgens.

MATERNAL HYPERANDROGENISM

During pregnancy, maternal hyperandrogenism can occur secondary to luteomas of pregnancy, androgen secreting tumors, and exposure to exogenous androgen. The excessive maternal androgen concentrations can cause virilization of the external genitalia of 46,XX fetuses. Endocrine disruptors are exogenous chemicals or mixtures of chemicals that interfere with any facet of hormone action. Organochlorine pesticides, polychlorinated biphenyls (PCBs), and alkylpolyethoxylates are considered to be “endocrine disruptors” because of their estrogenic and/or antiandrogenic properties.

DISORDERS OF ANDROGEN ACTION

During the process of sexual development, androgen action is essential to promote retention of Wolffian duct derivatives, development of the prostate, and differentiation of male external genitalia. Androgen action is mediated by the androgen receptor (AR, also known as *NR3C4*), a member of the steroid/thyroid hormone family of hormone receptors. Similar to other members of this receptor family, the androgen receptor is a ligand-dependent transcription factor with a characteristic modular structure. The major modules of the protein include the amino-terminus transactivation (AF1), DNA-binding, and ligand-binding domains. Other features include a nuclear localization signal, another transactivation domain (AF2) in the carboxy terminus ligand-binding domain, and the hinge region.³³⁴ The AR protein has two polymorphic trinucleotide repeat regions located in the amino terminal domain encoding the polyglutamine (CAG) and polyglycine (GCN) repeat regions. In addition to the classical pathway, nongenomic rapid androgen actions occur.³³⁵

Androgen insensitivity is an X-linked recessive disorder because of AR mutations; AR is located near the centromere at Xq11-12.³³⁶ Approximately 30% of cases represent de novo mutations. Somatic cell mosaicism, when the mutation arises in the postzygotic stage, is associated with a lower recurrence risk.³³⁷ Complete androgen insensitivity (CAIS) is characterized by female external genitalia, absence of Mullerian duct derivatives, sparse sexual hair, inguinal masses, and primary amenorrhea in the adolescent girl. Wolffian duct derivatives

(e.g., vas deferens and epididymides) are absent because of deficient androgen action. Although rare exceptions have been described, Mullerian-derived structures are usually absent because Sertoli cell function is normal with in utero AMH secretion. It has been suggested that 1% to 2% of girls with bilateral inguinal herniae may have androgen insensitivity. The finding of a gonad within the hernia sac should prompt cytogenetic studies. The expected LH surge in testosterone concentrations during the first few months of life may be absent in some infants with CAIS.³³⁸ Spontaneous pubertal breast development because of aromatization of androgens to estrogens occurs if the gonads are in situ.

Partial androgen insensitivity (PAIS) is characterized by clinical features, suggestive of a partial biological response to androgens. Typical features include ambiguous genitalia with perineoscrotal hypospadias, microphallus, and bifid scrotum. Testicular position is variable, ranging from undescended to palpable in the scrotum. Infants with PAIS generally manifest the expected neonatal testosterone surge, suggesting that prenatal androgen responsiveness plays a role in imprinting of the HPG axis. Features of mild androgen insensitivity include gynecomastia and infertility in otherwise normal males. Older chronological age at presentation is typical. In all instances, karyotype is 46,XY.

Typical laboratory findings are elevated LH and testosterone concentrations because testicular testosterone synthesis is unimpeded. Yet, there is loss of negative feedback inhibition of gonadotropins. LH concentrations are usually higher than FSH concentrations because testicular inhibin secretion is not impeded. FSH concentrations may be elevated or normal. Infants with PAIS may require dynamic endocrine tests to assess hCG-stimulated Leydig cell testosterone secretion and importantly, end-organ responsiveness to androgens.

In the absence of ligand, the AR protein is located primarily in the cytoplasm, where it is bound to chaperone proteins. Upon ligand binding, the conformation of the androgen receptor changes. The ligand-receptor complexes dimerize and move to the nucleus. A key feature of androgen receptor dimerization is the intramolecular interaction between the N-terminal and C-terminal domains. Binding of ligand stabilizes the androgen receptor and slows its degradation. The increased potency of DHT is attributed to the greater stability of the DHT-receptor complex compared with the testosterone-receptor complex. In the nucleus, the complex binds to androgen response elements and alters target gene transcription.

Over 500 different AR mutations have been described.³³⁹ In general, the phenotype correlates with degree of impaired androgen action. However, clinical features can vary despite the presence of the identical mutation (even within the same family). CAIS or PAIS associated with the same AR mutation can occur in siblings. Different missense mutations at the same position can also be associated with differing phenotypes. Complete loss-of-function mutations and premature termination codons are typically associated with CAIS. Partial loss-of-function mutations are typically missense mutations. Receptors with mutations in the DNA-binding domain bind ligand normally but fail to transactivate target genes. Mutations in the ligand binding domain can be associated with decreased affinity for ligand and/or increased instability of the hormone-receptor complex. In addition to hormone determinations, diagnostic evaluation may include DNA sequence analysis of the AR gene (www.genetests.org and <http://www.androgendb.mcgill.ca>).

Mutations can be located in noncoding regions of the gene; WES identified an intronic mutation resulting in an alternatively spliced transcript in a large family with PAIS associated with neonatal hypospadias and pubertal gynecomastia.³⁴⁰ Two unrelated 46,XY girls diagnosed with CAIS were found

to have the same c.547C>T germline mutation in the *AR*-5'-UTR. This mutation introduced a translated upstream open reading frame in the 5'-UTR, resulting in decreased AR protein.³⁴¹ Two sisters with complete CAIS were found to have an intronic pseudoexon-activating point mutation in the intron between exons 6 and 7 of *AR*; this mutation leads to aberrant mRNA splicing and decreased protein production.³⁴²

AR transcriptional activity depends on other proteins, including coactivators and corepressors. These other proteins presumably modulate physical interactions, linking the basal transcription machinery, the ligand-receptor complex, and chromatin. For example, a missense *AR* mutation altered the interaction of the AR protein with the melanoma antigen A-11 (MAGE-11) protein by interfering with the stimulatory effects of the coregulator.^{343,344}

In addition to androgen insensitivity, Kennedy disease (also known as *spinal and bulbar muscular dystrophy*) is mapped to the *AR* locus. Kennedy disease, a progressive neurodegenerative disorder with onset in the 30s or 40s, is associated with excessive expansion of the CAG polyglutamine trinucleotide repeat region in exon 1 of *AR*.^{304,345} Repeat lengths greater than 35 are associated with spinal and bulbar muscular atrophy. The presumed mechanism for the neurodegeneration is related to the role of AR in the function of the ubiquitin ligase anaphase-promoting complex/cyclosome, which functions with its adaptor protein to influence cell cycle arrest and neuronal architecture. In the presence of the expanded CAG repeat, AR inhibits this complex, leading to abnormal cell cycle reactivation.³⁴⁶ Mild symptoms of androgen insensitivity can be detected with slight decreases in *AR* mRNA and protein concentrations.

MULLERIAN DUCT ABNORMALITIES

Persistent Mullerian Duct Syndrome

Persistent Mullerian duct syndrome (PMDS) is an autosomal recessive disorder because of mutations in the *AMH* gene located at chromosome 19p13.3 or its receptor (*AMH-RII*) gene located at chromosome 12q13.13.³⁴⁷ The phenotypes of patients with *AMH* or *AMH-RII* mutations are comparable. *AMH* is a member of the TGF- β family and signals through two different interacting membrane-bound serine/threonine receptors. The ligand, *AMH*, binds to the type II receptor, which leads to recruitment and phosphorylation of a type I receptor. The type II receptor is specific for *AMH*, whereas there are multiple subtypes of the type I receptors. *AMH* concentrations are low among patients with mutations in the *AMH* gene. Among patients with *AMH-RII* mutations, *AMH* concentrations are normal or elevated. Females who carry mutations on both *AMH* alleles appear to have normal fertility.

The typical clinical features of PMDS include cryptorchidism, testicular ectopia associated with inguinal hernia, and hernia uteri inguinalis. Testicular differentiation is usually normal, but the male excretory ducts may be embedded in the Mullerian duct remnants or incompletely developed. Infertility may ensue secondary to cryptorchidism, intertwining of vas deferens and uterine wall, or lack of proper communication between the testes and excretory ducts. Testicular torsion is not uncommon because the testes may not be anchored properly to the bottom of the processus vaginalis.

Mullerian Duct Abnormalities in 46,XX Individuals

Mayer-Rokitansky-Küster-Hausler (MRKH) syndrome refers to congenital absence of the uterus and upper two-thirds of the vagina; the lower portion of the vagina is usually unaffected. Ovarian development is generally normal. This disorder occurs in approximately 1:4500 girls.³⁴⁸ The typical presentation is an

adolescent girl with primary amenorrhea accompanied by appropriate breast and pubic hair development.

MRKH can be classified as type I or type II. Type I MRKH is characterized by isolated uterine agenesis.

Type II MRKH is characterized by uterine agenesis accompanied by extragenital malformation, commonly renal and skeletal malformations. Renal findings, identified in approximately 40%, include unilateral renal agenesis, horseshoe kidneys, renal ectopia, renal hypoplasia, and hydronephrosis. The MURCS syndrome is defined as Mullerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia; cardiac and nervous system anomalies may also be present.

Hydrometrocolpos, Mullerian hypoplasia, and polydactyly are associated with both the McKusick-Kaufman syndrome and Bardet-Biedel type 6. Both autosomal recessive disorders are associated with mutations in the *MKKS-BBS6* gene located at chromosome 20p12.³⁴⁹ The McKusick-Kaufman syndrome and Bardet-Biedel type 6 are similar; the major differentiating feature is occurrence of retinitis pigmentosa in Bardet Biedel type 6.³⁵⁰

No single gene defect has been identified for MRKH. Recurring copy number variants in specific chromosomal regions, such as 17q12, 16p11.2, 1q21.1, and 22q11.21, have been associated with MRKH.³⁵¹ Mutations in *WNT4*, *LHX1*, *HNF1B*, *TBX6*, *RBM8A*, and *WNT9B* have been associated with Mullerian aplasia.³⁵² Patients with MRKH associated with heterozygous *WNT4* mutations are reported to have clinical or biochemical hyperandrogenism.³⁵³ Mullerian duct hypoplasia has been associated with facioauriculovertebral anomalies, such as Goldenhar syndrome and DiGeorge syndrome.^{354,355} In the absence of a uterine transplant or surrogacy, affected individuals cannot carry pregnancies. Most cases are sporadic. Thus ascertaining genetic transmission has been challenging.

Pelvic ultrasound and magnetic resonance imaging (MRI) demonstrate abnormal development of the uterus, cervix, and upper vagina.^{356,357} Imaging studies should include assessment for renal anomalies and skeletal malformations.³⁵⁸ Ovarian morphology should be appropriate for pubertal stage. Because of the high frequency of associated anomalies, careful physical examination for skeletal malformations should be included in the diagnostic evaluation of women with abnormal development of the Mullerian duct system.

MICROPHALLUS, HYPOSPADIAS, AND CRYPTORCHIDISM

Hypospadias

Hypospadias is a congenital hypoplasia of the penis characterized by ventral displacement of the urethral meatus, chordee, and ventral foreskin deficiency.³⁵⁹ Distal hypospadias is much more frequent than proximal and accounts for approximately 70% of cases. Proximal hypospadias may be associated with chordee, cryptorchidism, and additional congenital anomalies. The reported incidence ranges from 1:100 to 1:1000. Familial hypospadias has been described. Genes involved in early genital tubercle patterning include *BMP4*, *BMP7*, *HOXA4*, *HOXB6*, *FGF8*, *FGF10*, and *FGFR2*. Deletions involving 19q13 are associated with IUGR, microcephaly, postnatal growth retardation, clinodactyly, and hypospadias; the Wilms tumor interacting protein (*WTIP*) gene is located in the deleted region.³⁶⁰

Cryptorchidism

Cryptorchidism (undescended testes) is the most common disorder of sexual differentiation, affecting 3% of male infants.³⁶¹ Cryptorchidism can be categorized as nonsyndromic/isolated or syndromic (Table 6.6).³⁶²

TABLE 6.6 Disorders Associated With Cryptorchidism or Small Penis in Males

Name	Gene	Location	
Aarskog syndrome	<i>FGD1</i> (OMIM # 305400) FGD1 FGD1	Xp11.22	Short stature, hypertelorism, shawl scrotum, brachydactyly
Beckwith-Wiedemann Börjeson-Forsman- Lehman syndrome	<i>CDKN1C</i> (OMIM# 130650) <i>PHF6</i> (OMIM # 301900)	11p15.4 Xq26.2	Beckwith-Wiedemann syndrome Hypogonadism, seizures, developmental delay, obesity
Carnevale syndrome Carpenter syndrome-1	<i>COLEC11</i> (OMIM # 265050) <i>RAB23</i> (OMIM # 201000)	2p25.3 6p12.1-p11.2	Hypospadias, horseshoe kidney, craniosynostosis, hypertelorism Acrocephaly, syndactyly, congenital heart disease, low-set ears, obesity
Carpenter syndrome-2	<i>MEGF8</i> (OMIM # 614976)	19q13.2	Craniosynostosis, polysyndactyly of the hands and feet, situs inversus, congenital heart disease
Cornelia de Lange syndrome	<i>NIPBL</i> (OMIM # 122470)	5p13.2	Hypoplastic male external genitalia, cryptorchidism, mental retardation, synophrys
Costello syndrome	<i>HRAS</i> (OMIM # 218040)	11p15.5	Short stature, coarse facies, hypertelorism, congenital heart disease, skin findings, developmental delay
Hajdu-Cheney syndrome	<i>NOTCH2</i> (OMIM # 102500)	1p12	Short stature, coarse facies, bowing of the long bones, vertebral anomalies, hypertelorism, bushy eyebrows, micrognathia
Juberg-Marsidi syndrome	<i>HUWE1</i> (OMIM # 309590)	Xp11.22	Hypotelorism, small palpebral fissures, dysplastic, large, or low-set ears, long face, high-arched palate, thin upper lip, brachydactyly, developmental delay
Johanson-Blizzard syndrome	<i>UBR1</i> (OMIM # 243800)	15q15.2	Short stature, failure to thrive, hypothyroidism, sensorineural hearing loss, imperforate anus, and pancreatic exocrine insufficiency
Lenz-Majewski hyperostosis syndrome	<i>PTDSS1</i> (OMIM # 151050)	8q22.1	Sclerosing bone dysplasia, loose skin, brachydactyly, progressive generalized hyperostosis, developmental delay
Leopard syndrome	<i>PTPN11</i> (OMIM #151100)	12q24.13	Short stature, ptosis, hypertelorism, low-set ears, webbed neck, congenital heart disease, multiple lentigenes
Lowe syndrome	<i>OCRL</i> (OMIM # 309000)	Xq26.1	Hydrophthalmia, cataract, mental retardation, vitamin D-resistant rickets, amino aciduria
3MC1	<i>MASP1</i> (OMIM # 257920)	3q27.3	Hypertelorism, blepharophimosis, blepharoptosis, and highly arched eyebrows
3MC2	<i>COLEC11</i> (OMIM # 265050)	2p25.2	Short stature, hearing loss, cleft lip/palate
3MC3	<i>COLEC10</i> (OMIM # 265050)	8q24.12	Short stature, ptosis, cleft lip/palate
McKusick-Kaufman syndrome	<i>MKKS</i> (OMIM #236700)	20p12.2	Congenital heart disease, hypoplastic lungs, polydactyly
Meckel-Gruber, type 1	<i>MKS1</i> (OMIM # 249000)	17q22	Polydactyly, polycystic kidneys
Meier-Gorlin syndrome ^a	<i>ORC6</i> (OMIM # 607213)	16q11.1	IUGR, short stature, microtia, microcephaly, cryptorchidism
MEND syndrome	<i>EBP</i> (OMIM # 300960)	Xp11.23	Short stature, cataracts, 2- to 3-toe syndactyly, seizure, development delay

^aThe classic triad for Meier-Gorlin syndrome is microtia, absent/hypoplastic patellae, and short stature. Mutations in *ORC1*, *ORC4*, *ORC6*, *CDT1*, and *CDC6* genes are associated with this phenotype. Cryptorchidism is typically associated with *ORC6* mutations. *IUGR*, Intrauterine growth restriction.

Because of spontaneous descent, the prevalence decreases to 1% by 6 months of age. Cryptorchidism can be associated with decreased number of germ cells, impaired germ cell maturation, and decreased number of Leydig cells.³⁶³ In some instances of unilateral cryptorchidism, abnormal histology may be evident in the contralateral normally descended testis.³⁶³ Usually cryptorchidism is an isolated finding, but it can be associated with hypothalamic hypogonadism, aberrant testicular differentiation, impaired testosterone biosynthesis, androgen insensitivity, holoprosencephaly, abnormal AMH production or action, abnormalities affecting *INSL3/LGR8* function, and possibly environmental factors. Other associations include prune belly syndrome, bladder exstrophy, and renal anomalies. Maternal diabetes mellitus, including gestational diabetes, may be a risk factor.

During sexual differentiation, the gonads are positioned between two structures: the cranial suspensory ligament and the gubernaculum. The gubernaculum is a mesenchymal structure that plays a major role in testicular descent. In females, the cranial suspensory ligament persists as the suspensory ligament of the ovary. Androgen action during the intraabdominal phase promotes regression of the cranial suspensory ligament. Testicular descent is divided into two phases: intraabdominal and inguinoscrotal.³⁶⁴ Factors involved in gubernaculum development during the intraabdominal phase include *INSL3* and its receptor, *LGR8/RXFP2*. *INSL3* is secreted by Leydig cells. Its receptor, *LGR8/RXFP2*, is a leucine-rich G-protein-coupled receptor expressed by the gubernaculum. By 13 or 14 weeks of gestation, the gubernaculum anchors the testis to the internal inguinal ring.³⁶⁵ At approximately 22 to 25 weeks of gestation, the testes and epididymis are located at the internal rings of the inguinal canal. Androgen influenced testicular descent through the inguinal canal is usually accomplished by the end of seventh months of gestation, with completion of the inguinoscrotal phase by the end of week 35.

Outcome concerns include risk for infertility and testicular neoplasia.^{366,367} In a prospective randomized study, orchidopexy at 9 months of age resulted in greater testicular volume and increased germ cell number compared with orchidopexy at 3 years of age.³⁶⁸ Hence surgical correction of cryptorchidism in early infancy is preferred.³⁶⁹

Heterozygous missense *INSL3* mutations have been identified in patients with cryptorchidism.³⁷⁰ Mutations have also been identified in the *LGR8* gene in males with cryptorchidism. Sequence variants have been identified in the *HOXA10* gene in boys with cryptorchidism.³⁷¹ Nevertheless, mutations in *INSL3*, *LGR8*, or *HOXA10* are rare causes of isolated

cryptorchidism.³⁷² Typically, the testes of patients with androgen insensitivity have completed the intraabdominal phase but fail to undergo inguinoscrotal descent because this second phase is androgen dependent. However, the more complete the androgen insensitivity, the greater likelihood of finding abdominal testes. Exposure of XX fetuses to androgen does not promote significant ovarian descent in humans, as evidenced by normal ovarian position in females with CAH.

Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism associated with GnRH deficiency is characterized by a spectrum of reproductive, olfactory, and nonreproductive clinical features. Inheritance patterns include X-linked, autosomal dominant, and autosomal recessive. Male infants with hypogonadotropic hypogonadism may be identified in the newborn period with microphallus and/or cryptorchidism. Genital ambiguity generally does not occur because placental hCG secretion is unaffected. Decreased gonadotropin secretion causes decreased testosterone secretion, resulting in microphallus and cryptorchidism. Additional anterior pituitary hormone deficiencies may be present.

The 1000 to 2000 GnRH neurons that reside in the postnatal hypothalamus are born in the olfactory placode and migrate during early fetal development from the nose through the forebrain to the hypothalamus. Investigation of families with inherited hypogonadotropic hypogonadism has led to identification of specific genes involved in this process (Table 6.7). Kallmann syndrome is the eponym used for the X-linked recessive form of hypogonadotropic hypogonadism associated with anosmia because of failed migration of GnRH neurons from the olfactory placode into the forebrain along branches of the vomeronasal nerve.³²⁴ Olfactory tract hypoplasia or aplasia has been found on MRI. The molecular basis of this X-linked form is mutations in the Kallmann (*ANOS1*) gene (located at Xp22.3). This gene escapes X-inactivation, codes for a 680-amino-acid protein, and helps target GnRH neurons to the hypothalamus.

Mutations in the *GNRHR*, *FGFR1*, *FGF8*, *NSMF*, *GNRH1*, *KISS1*, *KISS1R*, *PROK2*, and *PROKR2* genes are also associated with hypogonadotropic hypogonadism. Mutations in *TAC3* and its receptor *TACR3* are associated with hypogonadotropic hypogonadism; the prevalence of microphallus among males carrying *TACR3* mutations is high.^{329,373} Gonadal defects may occur in CHARGE syndrome because of *CHD7* mutations; additional features include ocular coloboma, heart defects, choanal atresia, short stature, and hearing loss.³⁷⁴ Rather than

AD, Autosomal dominant; AR, autosomal recessive.

being a single gene disorder, hypogonadotropic hypogonadism appears to be an oligogenic disorder.^{375,376}

ENVIRONMENTAL DISRUPTORS

Prenatal treatment with diethylstilbesterol (DES), a nonsteroidal synthetic estrogen, has been associated with urogenital abnormalities of both male and female fetuses with cryptorchidism occurring in 46,XY fetuses.^{377,378} The genital ambiguity, described in three 46,XY infants born in heavily agricultural areas, was attributed to fetal exposure to endocrine disruptors especially because no mutations were detected in the *SRY* or *SRD5A2* genes.³⁷⁹ Although no definite causation has been found, various environmental substances, such as herbicides, fungicides, pesticides, and plasticizers, have been considered to be potential endocrine disruptors. Potential mechanisms include binding to nuclear hormone receptors modulating gene expression or epigenetic changes. Reliable evidence confirming detrimental environmental effects on genital development is lacking.³⁸⁰

OTHER DISORDERS

The VACTERL association (VA) is characterized by several anomalies. These abnormalities include vertebral anomalies, anal atresia, cardiovascular malformations, tracheoesophageal fistula and/or esophageal atresia, renal anomalies, limb anomalies, and/or genital ambiguity. Mullerian hypoplasia/aplasia, renal agenesis, and cervicothoracic somite dysplasia (MURCS association) is characterized by primary amenorrhoea. Features of this disorder can include absence of uterus and fallopian tubes, cervical spine abnormalities, and renal anomalies.

Complete absence of penis also known as *aphallia* is rare and may be associated with additional congenital anomalies of the genitourinary and gastrointestinal systems.

EXSTROPHY OF BLADDER

The bladder-exstrophy-epispadias complex (BEEC) describes a primary field defect involving the pelvis, urinary tract, and external genitalia. This spectrum of malformations includes epispadias, bladder exstrophy, and persistent cloaca. Another variant is the OEIS complex (omphalocele, exstrophy, imperforate anus, and spinal defects). Additional findings can include ectopic kidney and renal agenesis as well as anomalies affecting the skeletal, genitourinary, and gastrointestinal systems.³⁸¹ Familial occurrence has rarely been described for this presumably multifactorial disorder.³⁸² Exstrophy of the cloaca is characterized by persistence of a common cloaca associated with failure of fusion of the genital tubercles. The underlying etiology remains to be identified. However, the 22q11.2 microduplication region has been repeatedly detected on array comparative genomic hybridization in several patients; a candidate gene is the Leucine zipper-like transcriptional regulator (*LZTR1*) gene that maps to this region.³⁸³

DIAGNOSIS

A comprehensive individualized approach is appropriate for a child found to have genital ambiguity.^{384,385} In some instances, the diagnosis is first considered when the child presents with delayed puberty. In addition to a thorough medical history and complete physical examination, endocrine assessment, and genetic evaluation provide valuable approaches.³⁸⁶ The list

of potential etiologies especially for 46,XY individuals continues to expand. Yet, despite identification of novel genes and innovative genetic technology, a definitive molecular diagnosis may not be established for all, especially for 46,XY individuals. Ahmed and colleagues suggest recommendations for boys with DSDs.³⁸⁷

History

A detailed family history should be obtained. The family history should include ascertainment of unexplained infant deaths, consanguinity, and infertility. Infants with CAH may have died before diagnosis. Family history may be negative in the case of autosomal recessive disorders. Infertility, POI, and gynecomastia may represent milder phenotypes for some DSDs. For X-linked disorders, such as androgen insensitivity, there may be affected maternal family members (i.e., either amenorrheic or infertile aunts or partially virilized uncles). Pertinent questions include prenatal exposure to exogenous or endogenous androgens, estrogens, or potential endocrine disruptors. Maternal virilization during pregnancy should be queried.

Physical Examination

DSDs encompass a spectrum of physical findings. Atypical genital development may occur as a component of a syndrome. Hence, careful examination of the facies, heart, limbs, and digits assessing for dysmorphic features should be performed. The specific physical findings range from micropenis, hypospadias, undescended testes, minimal clitoromegaly, and scrotalized labia to more extensive forms of genital ambiguity. Severe clitoromegaly with posterior labial fusion in a 46,XX patient may be distinguishable from perineal hypospadias, undescended testes, and a bifid scrotum in a 46,XY individual.

During the physical examination, attention should be focused on phallic size and shape, symmetry of the external genitalia, and presence and location of palpable gonads. The position of the urethra, and whether one or two perineal openings are present should be noted. The extent of virilization should be carefully documented, recording the configuration, stretched dorsal length, and diameter of the phallus (including the glans penis). The location of the urethral opening, degree of fusion of labiourethral folds, and extent of labioscrotal fold fusion and anogenital distance should also be noted. Labioscrotal folds fuse from posterior to anterior; the appearance can range from posterior labial fusion, to a partially fused hemiscrota, or to completely fused scrotum with labiourethral fusion, extending to a midline urethral opening.

Gonadal or adnexal structures may be identified upon careful palpation for content of the labioscrotal structures, scrotum or labia majora, inguinal region, and the lower abdomen. The groin area may be “milked” from anterior to posterior to maneuver the testis into the scrotum. The absence of palpable testes may indicate a virilized XX infant with adrenal hyperplasia or an XY infant with undescended or absent testes. Structures palpated within the labioscrotal folds are usually testes that typically have a characteristic ovoid structure. Rarely, ovaries, ovotestes, or even the uterine cervix can be found within the labioscrotal folds.

Symmetry or asymmetry of external genital differentiation provides clues to the etiology of the genital ambiguity (Figs. 6.6 and 6.7). Unilateral structures with asymmetry of other genital structures suggests ovotesticular or 45X/46,XY DSDs and is often associated with unilateral gonadal maldescent. Asymmetry implies differing local influences, which often reflect abnormalities in gonadal differentiation (see Figs. 6.6 and 6.7). Repeated examinations may be valuable.

Penile length measurements extend from the tip of stretched penis from the pubic ramus. As would be anticipated, penile

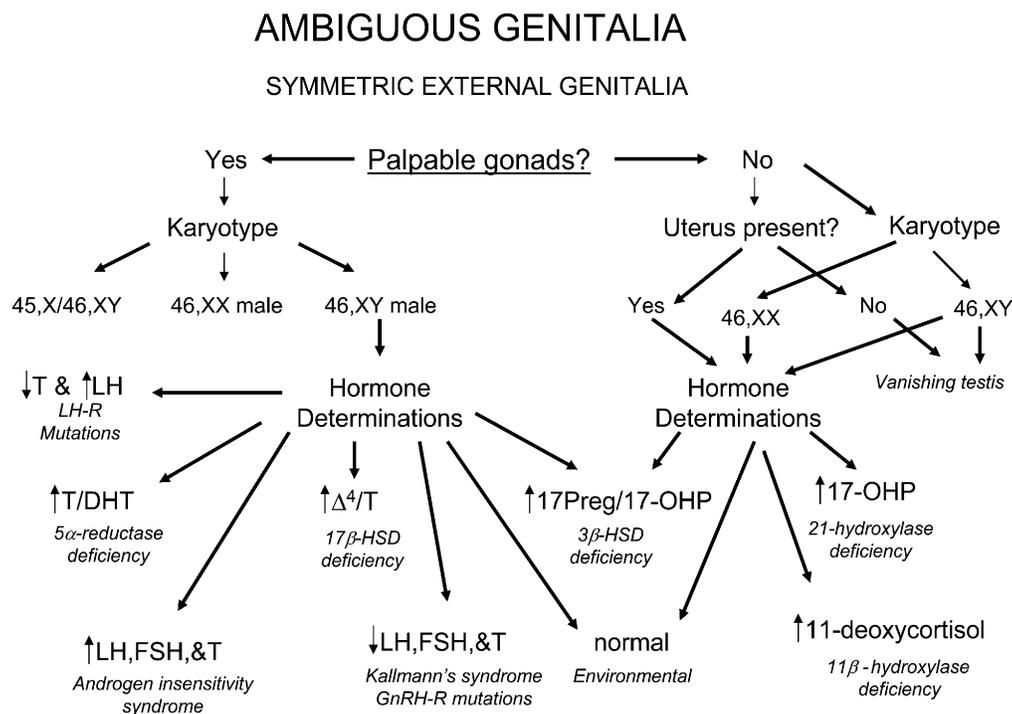

Fig. 6.6 Algorithm for the approach to the child with symmetric genital ambiguity. The configuration of the labioscrotal folds and presence/absence of palpable gonads is comparable on both sides. The presence or absence of palpable gonads directs the initial laboratory evaluation. Ultrasound examination to determine whether a uterus is present is helpful. For example, symmetric fusion of the labioscrotal folds, nonpalpable gonads, and presence of a uterus provide strong circumstantial evidence for the diagnosis of a virilized female with congenital adrenal hyperplasia.

AMBIGUOUS GENITALIA

ASYMMETRIC EXTERNAL GENITALIA

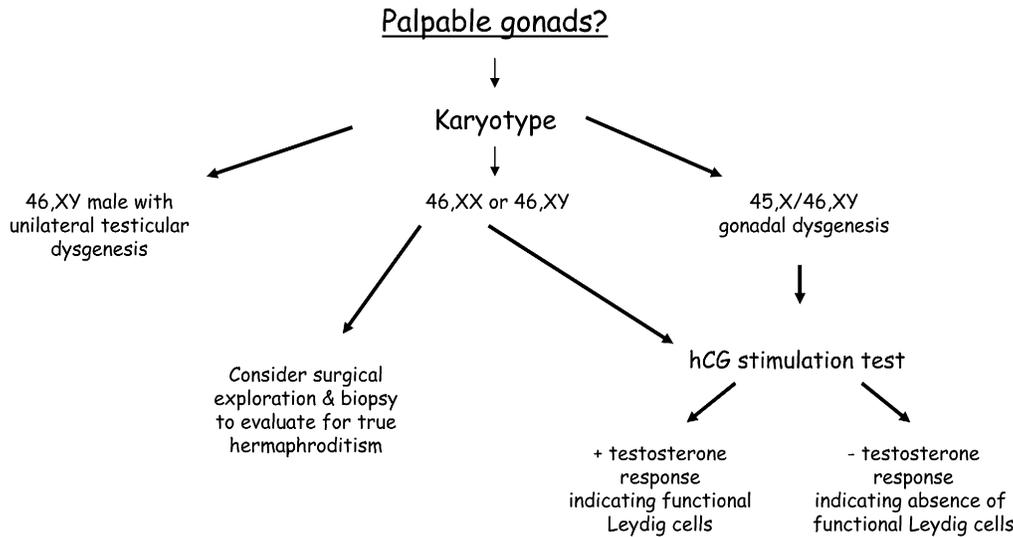

Fig. 6.7 Algorithm for the approach to the child with asymmetric genital ambiguity. In this instance, the labioscrotal folds may appear different or a gonad is palpable only on one side.

length depends on gestational age. For full-term male infants, the average stretched penile length is 3.5 ± 0.7 cm and average diameter is 1.1 ± 0.2 cm³⁸⁸; the lower limit (approximately – 2.5 standard deviation [SD]) at term being 2.0 cm. An isolated micropenis can be a consequence of decreased testosterone exposure in the second half of gestation because of Leydig cell failure, LH deficiency, androgen insensitivity syndrome, *LHCGR* mutations, or GH deficiency. The finding of both a micropenis and hypospadias can be classified as a DSD; additional evaluation is generally warranted.

Measurement of the clitoris requires a careful estimate of the proximal end with exclusion of overlying skin. Clitoral length is usually less than 1.0 cm, although rare variations exist. The length and width of the clitoris can be measured. For term female infants, mean clitoral length is 4.0 ± 1.24 mm and mean clitoral width is 3.32 ± 0.78 mm.³⁸⁹ The clitoral index is the product of length times width; mean clitoral index is 13.3 mm.³⁹⁰ The location of the urethral opening should be ascertained by visualization, witnessing the urinary stream, or with careful insertion of a firm catheter. If urination is observed, force, diameter, and direction of the urinary stream should be noted. The position of the inserted catheter may also provide crucial initial information. If directed toward the anal opening and palpable under the perineal skin, the catheter is likely in a urogenital sinus, as occurs often with virilization of a 46,XX fetus secondary to 21-hydroxylase deficiency. However, a penile urethra is anticipated if the catheter is directed anteriorly and is nonpalpable.

The anogenital ratio is measured as the distance between the anus and the posterior fourchette, divided by the distance between the anus and the base of the phallus. Because pelvic ultrasound is part of the initial laboratory assessment, a rectal examination may not be necessary. If present, a midline uterine cervix can often be palpated upon rectal examination.

The Prader scale is often used to classify the appearance of the external genitalia: (1) normal female genitalia with clitoromegaly; (2) partial labial fusion and clitoromegaly; (3) labioscrotal fusion, so that there is a single opening from the

urogenital sinus and clitoromegaly; (4) fusion of labioscrotal folds so that the single opening is at the base of the phallic structure; and (5) complete male virilization with penis-size phallus, complete labial fusion, and meatus on the glands. An external masculinization score is useful to assess virilization in male infants; this scoring system evaluates scrotal fusion, phallic size, location of urethral meatus, and position of the gonads.³⁹¹

In addition to the genital examination, the examination should include weight, length, and other features to ascertain whether findings are consistent with gestational age, particularly in the apparent female because the clitoris is more prominent in preterm infants. This appearance is caused by the scant subcutaneous fat and completion of clitoral growth before the last trimester of fetal life. A careful examination includes inspection for additional dysmorphic features because genital ambiguity may occur in association with other anomalies. These include midline facial defects, head size, and ear and digital anomalies. Bladder exstrophy and epispadias represent a nonendocrine malformation of the urological system. Infants with CAH, both male and female, may manifest hyperpigmentation of the genitalia and nipples because of adrenal insufficiency and ACTH hypersecretion.

In some instances, an older child or adolescent is referred for evaluation. The genital examination in children may be done subtly and quickly to avoid traumatizing the child. Palpation should be performed only if absolutely necessary. Before examining the child, especially a young child, it is important to remind the child that this is a private area, explain the reason for the examination, and obtain permission from both the child and the parent.³⁹²

Laboratory Studies

Initial laboratory studies to assess genital ambiguity should include karyotype, hormone determinations, and imaging studies. Ultrasound is the typical imaging modality because it does not require sedation, is noninvasive, and does not

require radiation or contrast material. Ultrasound can assess for the presence and location of the gonads, kidneys, adrenal, and uterus. Gonadal structures may be too small to definitively identify by ultrasound. Hence lack of visualization of gonads on ultrasound examination does not substantiate absence of gonads. In some instances, MRI can help evaluate Mullerian structures and abnormalities in the urinary tract. Limitations of MRI include inaccuracy in detecting intraabdominal gonads, streak gonads, or prepubertal uterus. Upon completion of other assessments, laparoscopy may be necessary to accurately evaluate intraabdominal structures and gonads, whereas cystoscopy may be needed to assess the urethra and vagina.³⁹³ When the diagnosis remains uncertain, laparoscopy to visualize the internal genital structures and obtain a biopsy of the gonadal tissue can assist with management recommendations. The extent of gonadal differentiation and germ cell status may predict gonadal function and clarify risk for germ cell tumors.

When gonads are not palpable, the external genitalia are symmetrically ambiguous, and a uterus and possibly ovaries are present, the most likely diagnosis is a virilized 46,XX fetus with CAH. However, the possibility of markedly dysgenetic testes cannot be excluded. If the differential diagnosis based on the presentation includes CAH, the initial laboratory studies should include electrolytes, PRA, serum 17-OHP, AMH, and cortisol concentrations.

Genetic Tests

The karyotype confirms chromosomal sex, even if prenatal chromosome testing was performed. Cytogenetic testing with G-banded karyotyping can detect the presence of two or more cell lines. Because of faster turn-around time, fluorescent in-situ hybridization (FISH) or PCR with markers specific for X and Y chromosomes is recommended.³⁹⁴ In general, peripheral blood karyotypes are sufficient to ascertain chromosomal karyotype. However, the patient may have a mosaic karyotype with one or more additional cell lines restricted to gonadal tissue. CGH microarray analyses are increasingly available and may identify submicroscopic genomic DNA imbalances or copy number variants.³⁹⁴ However, CGH and single nucleotide polymorphism (SNP) assays may fail to detect balanced chromosomal translocations and low-level mosaicism.

Molecular genetic analyses have become increasingly available to determine and confirm the molecular basis of the genital ambiguity and can be considered as part of the diagnostic process to be conducted in parallel to clinical phenotyping and hormone analyses.³⁹⁵ Identifying the specific mutation improves the accuracy of genetic counseling and the prediction regarding recurrence risk. The genetics laboratory can often perform FISH for the SRY gene, or other detailed chromosomal tests, such as CGH microarrays (Fig. 6.8). For some DSDs, molecular genetic analyses of specific genes are available through commercial laboratories. Information regarding the particular details can be obtained from a National Institute of Health-funded web-based resource, Genetests (<http://www.genetests.org>). In some instances, genetic testing is available through research laboratories.

Next generation sequencing (NGS) can benefit patient management by identifying specific disorders and inheritance patterns.³⁹⁶ WES and whole genome sequencing (WGS) are techniques for simultaneous analysis of the whole exome and whole genome, respectively. Whole exome genetic analysis is increasingly available. WES fails to identify variants in non-coding regions. WGS can detect mutations in noncoding regions, including introns, untranslated regions, and proximal and distal *cis*-regulatory regions; such variations can modify chromatin conformation changing structural positioning

between regulatory regions with subsequent misexpression of specific genes.³⁹⁷ Neither technique adequately detects larger Copy Number Variation (CNVs), repetitive sequences, aneuploidy, or epigenetic modifications (us). Subsequently, confirmation of the identified genetic variants by PCR, followed by Sanger sequencing or restriction fragment length polymorphism is necessary.

These NGS approaches generate much information; WES typically detects 15,000 to 20,000 variants and WGS detects 3 to 4 million variants, differing from the human reference genome.³⁹⁸ These tools generate vast amounts of genetic data, necessitating informed bioinformatics support. With identity of multiple variants, parsing the significant variants from benign variants is crucial. Variants can be identified as clearly pathogenic by the specific mutation, inheritance pattern, results of multiple in silico modeling software predictors, functional assays, and conservation between species.³⁹⁹ The American College of Medical Genetics and Genomics provides guidelines for interpretation of variants in the context of standard terminology (Table 6.8).⁴⁰⁰ Given the ongoing rate of gene discovery, reanalysis of variants of uncertain significance may be warranted.⁴⁰¹ Phenotypic heterogeneity and incomplete penetrance complicate interpretation of the genetic analyses. Clinicians also need to be aware of potential ethical issues, such as detecting a pathogenic mutation in a gene unrelated to DSD (incidental finding). Pretest counseling and informed consent are requisite before performing genetic studies.⁴⁰²

In some instances, infants with DSDs are detected through noninvasive prenatal testing (NIPT) using cell-free fetal DNA in maternal serum.⁴⁰³ This technique involves massive parallel sequencing or SNP analyses of the 150 to 180 base pair fragments of fetal DNA and avoids the risks posed by chorionic villus sampling and amniocentesis. At this time, false positive and false negative reports limit the usefulness of this technique. Traditional invasive diagnostic genetic testing is essential if NIPT results indicate a genetic abnormality or differ from ultrasound findings.^{404,405}

Hormone Determinations

Other initial studies depend on the physical findings. If the external genitalia are symmetrically virilized to any degree in the absence of palpable gonads, particularly if a normal uterus is present, additional studies should be directed toward causes of virilization of a female infant. Because 21-hydroxylase deficiency is the most common cause of virilization and genital ambiguity in 46,XX infants, initial laboratory studies should include determination of 17-hydroxyprogesterone (17-OHP) concentrations. In general, 17-OHP concentrations should be measured no earlier than 48 to 72 hours of age because of the potential for false positive results that may be caused by cross-reacting steroid sulfates.³⁵⁰ Nevertheless, extremely elevated 17-OHP concentrations may be detected at earlier timepoints in infants with classical CAH. If one or both gonads can be palpated, the intent of screening studies is to determine the adequacy of androgen synthesis and androgen action in a male infant. Determination of LH, FSH, and testosterone concentrations in infancy provides information regarding the function of the testes and the HPG axis (see Table 6.4).

The pattern of steroid hormone concentrations provides evidence for specific defects in steroidogenesis (see Table 6.4). The diagnosis of CAH arising from 21-hydroxylase deficiency is confirmed by finding elevated 17-OHP concentrations. Typically, 17-OHP concentrations are greater than 10,000 ng/dL (300 nmol/L) in the affected neonate. For 11 β -hydroxylase deficiency, 11-deoxycortisol and 17-OHP concentrations are elevated. For 3 β -hydroxysteroid dehydrogenase deficiency, pregnenolone,

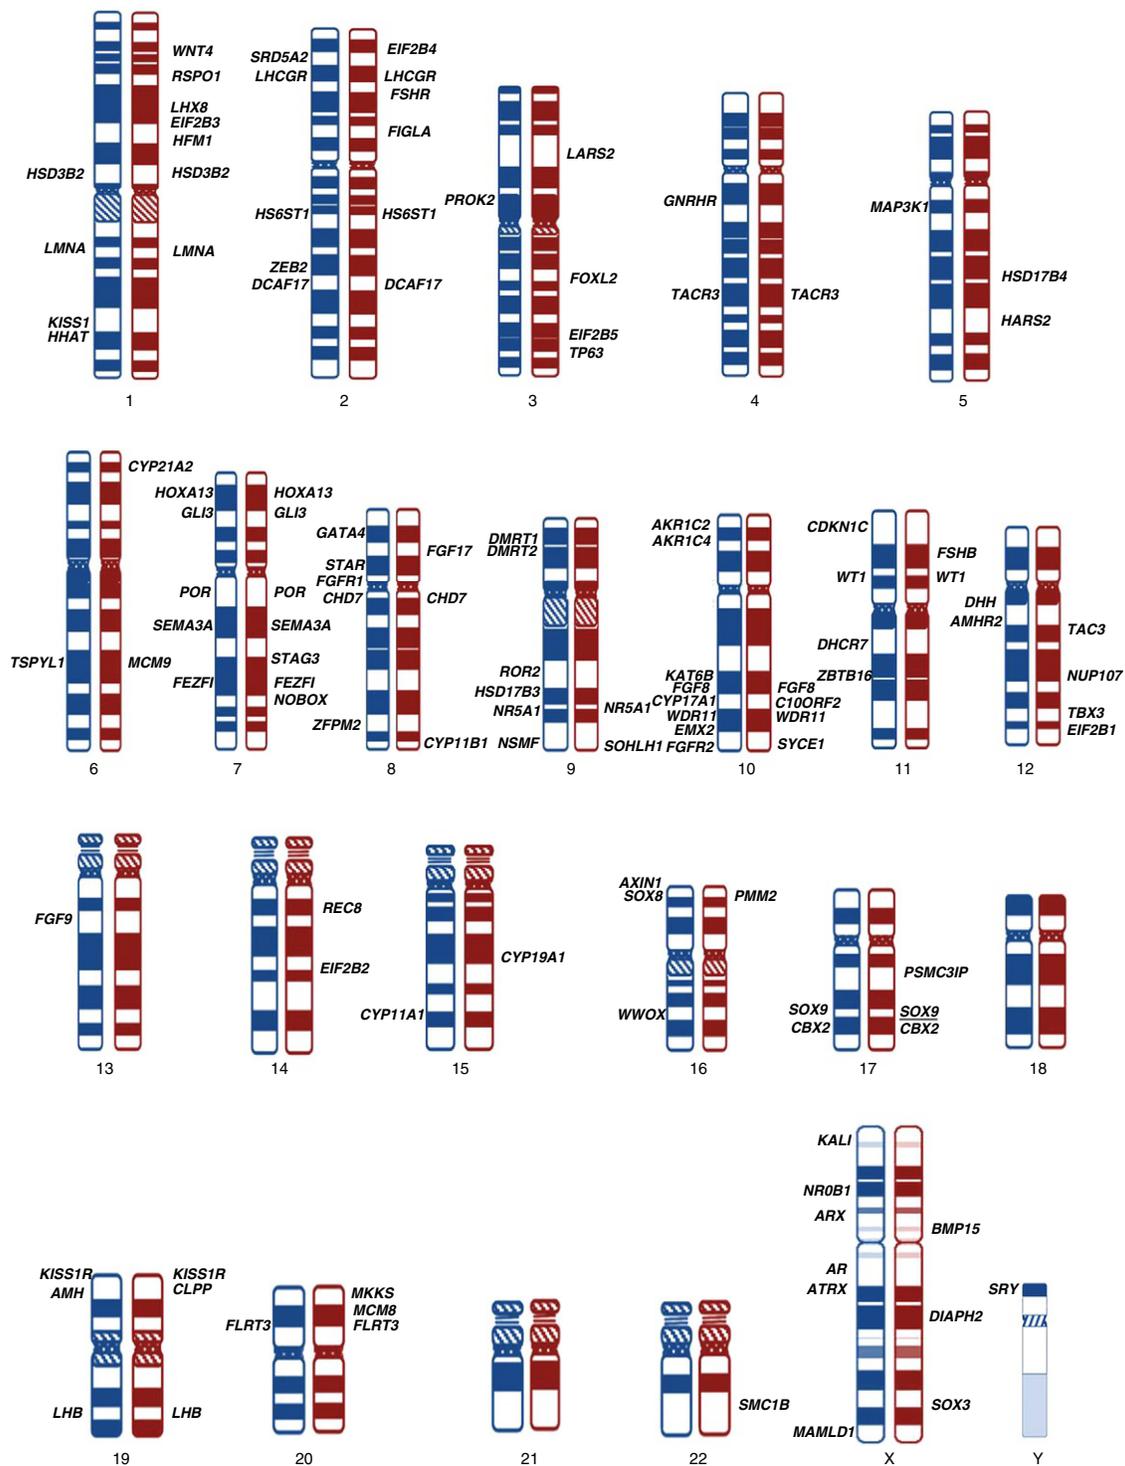

Fig. 6.8 Map of genes associated with disorders of sex development (DSDs). Genes known to cause gonadal dysgenesis, hypogonadotropic hypogonadism, disordered steroidogenesis, isolated urogenital anomalies, syndromic conditions associated with ambiguous genitalia, and primary and secondary gonadal insufficiency are listed along each chromosome. On the left, genes implicated in XY individuals, on the right, genes known to cause ovarian dysgenesis and DSD in XX individuals. (From Yatsenko, S.A., Witchel, S.F. (2017). Genetic approach to ambiguous genitalia and disorders of sex development: What clinicians need to know. *Semin Perinatol*, 41(4), 232–243.)

17-hydroxypregnenolone, and DHEA concentrations are typically elevated. Steroid concentrations are low for patients with congenital lipoid adrenal hyperplasia and CYP11A1 mutations. When salt-losing forms of CAH are included in the differential diagnosis, serum electrolytes and PRA should be monitored. Typically, despite mineralocorticoid deficiency, hyponatremia and

hyperkalemia are not present at birth and develop during the first week of life.

For the milder forms of CAH or other disorders affecting adrenal steroidogenesis, ACTH stimulation testing may be necessary to confirm the diagnosis. After a basal blood sample has been drawn, synthetic ACTH (0.25 mg) can be administered by

TABLE 6.8 Terms Used to Characterize Sequence Variants

Interpretation	Significance
Pathogenic	Contributes to disease
Likely pathogenic/ implicated	Data consistent with pathogenic role with a defined level of confidence
Benign	Available data indicate that variant does not contribute to disease
Likely benign	Data consistent with nonpathogenic role with a defined level of confidence
Variant of uncertain significance (VUS)	Data inadequate to classify variant
Associated	Variant is significantly enriched in affected individuals compared with matched controls
Damaging	Variant affects the normal levels or biochemical function of a gene product
Deleterious	Variant reduces reproductive fitness of carriers

intravenous bolus or intramuscular injection. A second blood sample to measure ACTH-stimulated hormone response can be obtained 30 or 60 minutes later. The milder forms of CAH generally do not affect external genital differentiation and are therefore not usually associated with genital ambiguity. Infants with late-onset CAH are generally not detected through newborn screening programs, presumably because the whole blood 17-OHP concentrations are determined from the newborn screening filter paper are lower than the values used as cutoffs.

In addition to the diagnostic evaluation for disorders of steroidogenesis, hormone measurements in the immediate neonatal period provide an index to the function of the HPG axis. Low testosterone and elevated gonadotropin concentrations in a 46, XY infant with ambiguous genitalia suggest inadequate testosterone biosynthesis. Elevated testosterone and gonadotropin concentrations in an infant with female external genitalia, bilateral labial masses, and 46,XY karyotype are consistent with the diagnosis of androgen insensitivity (see Table 6.5).

AMH concentrations reflect Sertoli cell function; concentrations are sexually dimorphic, with high values in boys (20–80 ng/mL) during the first 6 years of life and low values in girls.^{406,407} AMH concentrations may help distinguish between anorchia and cryptorchidism.⁴⁰⁸ In addition, AMH concentrations can be helpful in disorders of testicular dysgenesis or in virilized females to determine the presence of testicular tissue. Inhibin B concentrations, lower in females than in males, provide another marker of Sertoli cell function.³⁵⁷

Assessing testosterone secretion may be helpful, especially for patients with evidence of testicular tissue by palpation or ultrasound and AMH levels indicating testicular tissue. One approach involves administering hCG and measuring hormone responses. Compared with LH, the additional 24 amino acids on the carboxy-terminal of the protein increase the biological activity of hCG and the presence of a terminal sialic acid on the carbohydrate chain prolongs its half-life.⁴⁰⁹ Specific hCG preparations include hCG extracted from urine of pregnant women and recombinant hCG. Although recombinant hCG is usually more expensive, it shows good batch-to-batch consistency, high specific activity, and greater purity. Multiple protocols have been used with variation in dose and dosing frequency⁴⁰⁹ to assess for gonadal dysgenesis, Leydig cell hypoplasia, defects in testosterone biosynthesis, and androgen responsiveness. One protocol involves administering 1000 to 1500 units subcutaneously, either daily or every other day, for 1 to 5 days, with blood sampling on the day after the last injection. Intermittent injections can be given for up to 3 weeks to stimulate penile growth to demonstrate both testosterone

secretion and target tissue responsiveness. Total dosage should not exceed 15,000 units of hCG. Hormone determinations should include androstenedione, testosterone, and DHT. Testosterone concentrations should more than double.³⁸⁴ Post-stimulation hormone ratios are used to assess for defects in testosterone biosynthesis. Poststimulation, testosterone/androstenedione ratios less than 0.8 among infants and less than 1.0 among prepubertal and adolescent patients are suggestive for 17 β -hydroxysteroid dehydrogenase-3 deficiency.⁴¹⁰ Similarly, basal testosterone/DHT ratios greater than 10 and post-hCG stimulation greater than 20 are suggestive for 5 α -reductase deficiency. However, mutation testing may be needed to accurately differentiate between these disorders.

Newborn Screening

Newborn screening programs (NBS) have been established in all 50 states and many countries to identify infants with classic CAH.⁴¹¹ Typically, screening programs measure whole-blood 17-OHP concentrations eluted from a dried filter paper blood spot using a commercially available immunoassay, such as dissociation-enhanced lanthanide fluoroimmunoassay (DEL-FIA, Perkin-Elmer, Waltham, MA). Slightly increased whole-blood 17-OHP concentrations are detected often enough (especially in preterm infants) to complicate clinical decision-making regarding affected status and need to initiate glucocorticoid therapy. Etiologies of these false positive results include prematurity, cross-reacting steroids, sampling before 48 to 72 hours of age, heterozygosity for 21-hydroxylase deficiency, stressed infant, and late-onset CAH.^{412,413} False negative results can occur; with false negative results being more common in girls than boys.⁴¹⁴ Maternal treatment with glucocorticoids can also lead to false negative results. If the differential diagnosis includes CAH, specific laboratory testing is warranted even if the newborn screen results are reported as negative for 21-hydroxylase deficiency.

To avoid excessive false positive screening results, cutoff levels are typically selected to identify all infants with classic salt-losing or simple virilizing forms. Infants with late-onset CAH are generally not detected through NBS. Improved specificity can be achieved by use of additional procedures, such as organic extraction, chromatography, or liquid chromatography-tandem mass spectrometry (LC/MS/MS) analyses. This technique, LC/MS/MS, may be beneficial to either confirm or eliminate the diagnosis of CAH and can also be used to diagnose other disorders of steroidogenesis.^{351,415,416}

A challenge for NBS has been to ensure maximum sensitivity and specificity. Strategies to improve identification of affected children include a repeat blood sample or molecular genetic analysis. Currently, approximately 22% of American infants are routinely screened a second time.⁴¹⁷ Other approaches include use of gestational-age based cut-points, a second sample for 17-OHP immunoassay, 21-deoxycortisol concentrations, gas chromatography-mass spectrometry analysis, or hormone ratios, such as 17-OHP/11-deoxycortisol ratio.^{418–421}

Imaging, Endoscopy, and Laparoscopy

Endoscopic studies can be used to locate the vaginal-urethral confluence in relation to the bladder neck and the single opening of the urogenital sinus. Using a cystoscope and catheter placement, these distances can be determined before or in conjunction with retrograde contrast studies performed to outline the urethra and to demonstrate (if present) the vagina, uterus, cervix, and uterine cavity. Such information is needed to plan for reconstructive surgery, to assess the risk of medical complications, and in certain instances to provide information to determine the sex of rearing. If such procedures are unhelpful,

laparoscopy may be necessary to visualize and biopsy gonadal and internal genital structures. MRI may be helpful to define anatomic relationships.

TREATMENT

While awaiting results of the initial laboratory studies, and as needed, attention is focused on the main decision: the sex of rearing. In the ideal situation, a specific DSD team meets with the family.³⁸⁴ The DSD team usually includes a pediatric endocrinologist, a pediatric surgeon or pediatric urologist with expertise in urogenital reconstructive surgery, a behavioral health professional (psychologist, social worker, or psychiatrist), and a neonatologist. Input from an ethics consultant may be helpful. Using all available data, the DSD team shares the child's information with the family and educates them. At diagnosis and subsequent interactions, the family benefits from having opportunities to express their fears and concerns in nonthreatening environments in preparation for relevant decision-making.

Families struggle to understand complex medical information and deal with their child's anatomic differences. Additional consideration includes the potential for stigmatization by their community, anxiety about their child's gender identity, distress about their child's fertility potential, uncertainty regarding gonadal tumor risk, and the inconveniences inherent with multiple medical visits.⁴²² The initial participation of parents in discussions and decision-making regarding the options for sex of rearing, medical treatment, and possible surgical interventions should define the approach for subsequent discussion. Honest, sensitive, and candid discussions with the parents only help the child. The overriding goal is a positive strategy to promote the child's positive self-esteem.

Often, the neonatologist is the first physician to communicate with the parents about the genital ambiguity. In addition to talking with the parents, the neonatologist facilitates coordination of care and initiates laboratory studies. In some instances, the neonatologist coordinates transfer of the infant to a tertiary care facility. Long-term management needs to be delineated.

In many instances, the sex of rearing is apparent based on the initial physical examination and laboratory findings. However, for some infants, a decision regarding sex of rearing is necessary. Discussion regarding future gender identity and possibility for fertility are valuable. Consideration of family traditions and customs during the decision-making process reassures the child and family.⁴²³ Following an informed discussion, parents and healthcare providers choose sex of rearing.

Mental/behavioral/psychological health needs to be considered from the initial interactions with the family.⁴²⁴ Psychological impact can be assessed and addressed by relationships involving the members of the DSD team. The behavioral health professional should have thorough training and knowledge of resources available to patients and their families. In addition to the appointments necessary to the patient's medical, surgical, and psychological needs, additional sessions may benefit the parents to address their questions and concerns about their child. These evaluations should be performed promptly.

As the child matures, honest explanations regarding the medical condition are essential. All involved should be alert regarding the overall impact of the condition, as well as need for psychological counseling. The child should progress from a silent partner to a full participating member in this decision-making process, with the child's wishes taking precedence where appropriate.

When a specific diagnosis has been confirmed, decision-making and therapy can be guided accordingly. Considerations for medical care include decisions regarding sex of rearing,

possible need for surgery and a timeline for planned surgery, plan for medical treatment, and timely and appropriate psychological counseling and support.

Sex of Rearing

Decisions regarding the appropriate sex of rearing are based on the specific pathophysiology, external genital features, internal reproductive system anatomy, prognosis for spontaneous pubertal development, capacity for sexual activity and orgasm, and potential for fertility.⁴²⁵ With the use of fertility preservation and assisted reproductive techniques, the potential for future fertility is greater than in the past.^{426,427}

In instances where a decision regarding sex of rearing is necessary, each child warrants careful consideration of the physical findings, laboratory information, and available outcome data. Parents are often apprehensive because of fears regarding social stigmatization of their child and anxiety that the child will reject the assigned gender when older.⁴²⁸ Indeed, uncertainty regarding their infant can be so distressful and traumatic for some parents that their decision-making ability for the child breaks down.⁴²⁹ In most instances, children are raised male or female consistent with the karyotype acknowledging rare exceptions favoring sex reversal (when self-initiated gender reassignment is appropriate). Although the karyotype is informative, the patient's phenotype reflects the interactions of multiple factors. Longitudinal outcome studies are increasingly available regarding adult function, quality of life, and gender identity.^{430,431}

Gender identity refers to a person's self-experience. In most instances, gender identity is congruent with the sex of rearing (natal sex). The primary factors, critical steps, and sequence of psychosexual development that contribute to gender identity remain uncertain. Psychosexual development has three components: gender identity, gender role, and sexual orientation. Gender identity is established in infancy. Gender role, influenced by prenatal hormonal exposure, generally develops during childhood but may shift through life as a result of each individual's response to society's views and expectations. Sexual orientation is typically unknown before puberty and cannot be considered when contemplating sex of rearing.

The best predictor of gender identity among patients with DSDs appears to be sex of rearing.⁴³² Yet, as would be anticipated, an individual with a DSD may have complex feelings, questions, and thoughts about his or her own gender identity. In addition, society increasingly recognizes that gender exists on a nonbinary spectrum. Based on the large DSD-LIFE study, the number of individuals who change gender is higher among certain diagnoses. However, overall the number is low.⁴³³

Gender identity among most 46,XY patients with CAIS is female, whereas gender identity for those with PAIS can be female or male. Decisions regarding sex of rearing for individuals with PAIS may be challenging because androgen impact on CNS development and tissue responsiveness vary. The clinical response to exogenous testosterone can help with the decision-making process. Testosterone responsiveness can be ascertained by assessing penile growth, following one or more intramuscular injections of testosterone. Nevertheless, approximately a quarter of PAIS patients are dissatisfied with the sex assignment, regardless of whether they are raised as male or female.⁴³⁴

The majority of patients with 5 α -reductase deficiency identify as male, and about half of those diagnosed with 17 β -hydroxysteroid dehydrogenase self-reassign from female to male.⁴³⁵⁻⁴³⁷ If questions regarding sex of rearing arise for virilized 46,XX infants, female sex of rearing is usually recommended because most virilized 46,XX individuals with CAH identify as female. Typically, one major issue for virilized

46,XX females is that it relates to questions regarding genital surgery. Yet, among those completely virilized at birth and raised male with delayed diagnosis, male gender development with good long-term outcome has been reported.⁴³⁸ One report contemplates the option of male sex of rearing for extremely virilized 46,XX patients with CAH.⁴³⁹

Prenatal androgen exposure is believed to one factor that influences gender identity.^{440,441} Girls with CAH tend to choose male playmates and preferred male-typical play.⁴⁴² Among virilized 46,XX individuals with CAH, an increased rate of homosexual orientation has been reported primarily based on self-reported sexual imagery and sexual attraction, with reports of actual homosexual involvement being less well documented.⁴⁴³ In general, psychological adjustment has been found to be comparable for females with CAH and their unaffected siblings.⁴⁴⁴

Despite evidence that androgen exposure to the CNS alters general and cognitive behavior, much remains to be learned about the influences of nature and nurture on gender identity.^{445,446} In general, with the exception of CAIS, 46,XY individuals with fetal androgen exposure manifested as partial genital masculinization should be raised as males, unless there are extenuating individual circumstances. Ideally, 46,XY infants with 17 β -HSD3 or 5 α -reductase deficiency will be diagnosed in the newborn period and raised as males. Caution, reflection, and dialog are essential before those with a 46,XY, karyotype are assigned female sex of rearing because fetal androgen exposure appears to impact strongly on self-concept as male despite compromised external genital development.

Among individuals with DSD associated with gonadal dysgenesis, hCG-stimulated testosterone secretion and clinical response facilitates decisions regarding gender of rearing. The genital phenotype, ability of the Leydig cell to secrete testosterone, and extent of genital virilization in response to androgen stimulation are indicators regarding the potential for spontaneous pubertal development and need for hormone replacement therapy. Nevertheless, in gonadal dysgenesis, the impact of prenatal androgen exposure on gender development processes is often indeterminate and cannot be reliably predicted from routine diagnostic studies in the newborn period.

Within the past decade, the number of individuals with gender dysphoria (discordance between experienced gender and the sex assigned based upon biological sex) has increased among persons with typical binary sex development.⁴⁴⁷ Aspects of the care of transgender individuals may be applicable to those born with DSD who develop gender dysphoria.

Medical Treatment

A multidisciplinary team approach is recommended for the care of patients.⁴⁴⁸ With the exception of disorders affecting glucocorticoid and mineralocorticoid biosynthesis, most DSD conditions do not require specific medical therapy in infancy. At the time of expected puberty, patients with hypogonadism will need appropriate hormone replacement therapy. In general, hormone replacement therapy is initiated using low doses of the appropriate sex steroid hormone with incremental increases designed to mirror spontaneous pubertal development. It is helpful to review with families the anticipated frequency of outpatient visits and how the adequacy of replacement therapy will be assessed.

For females, induction of puberty involves low-dose estrogen therapy—usually initiated between 10.5 to 12 years of age to avoid excessive acceleration of skeletal maturation. The initial estrogen dosage is usually the lowest available, such as 0.3 mg of conjugated estrogens every other day or 5 mcg of ethinyl estradiol daily. Transdermal estrogen preparations that provide 0.007 to 0.025 mg daily can be used and are

recommended based upon early outcome data.⁴⁴⁹ Transdermal patches may be used only at night in an effort to mimic spontaneous puberty.⁴⁵⁰ Matrix transdermal patches can also be cut into smaller pieces to provide a lower estrogen dosage. Based on clinical response and the patient's perception, the dose of estrogen can be increased in 6- to 12-month intervals, such that complete replacement doses and development are achieved within 3 years.

Therapy involves the addition of a progestational agent after 12 months of estrogen therapy or when withdrawal bleeding occurs, whichever occurs sooner. Thereafter, cyclic estrogen-progesterone therapy should be used. Once full pubertal development has been reached, the estrogen dosage should be the minimum that will maintain normal menstrual flow and prevent calcium bone loss.⁴⁵¹ Options for cyclic estrogen-progesterone therapy include low-dosage estrogen birth control pills, transdermal estrogen with oral progestin, or estrogen-progestin transdermal patches.

For example, a daily oral estrogen regimen or the transdermal form for 21 days with the addition of progesterone, 5 to 10 mg of medroxyprogesterone acetate, or 200 mg of micronized progesterone daily added for 12 days (day 10–day 21) can be used. This is followed by a week of no hormones. At this point, the replacement regimen may be extended so that less frequent withdrawal bleeding occurs. In the absence of a uterus, progesterone therapy becomes optional. Among patients with low circulating androgen levels, sexual hair growth and libido may be improved by administering small doses of DHEA or methyltestosterone. Gonadotropins, hCG, and/or human menopausal gonadotropin/recombinant FSH are only used to stimulate ovulation or during assisted fertility attempts.

For males, testosterone hormone replacement typically begins at 12.5 to 14 years. In instances where treatment is indicated for psychological reasons, therapy may be initiated 1 to 2 years earlier. If therapy is begun earlier to reassure the patient concerning physical changes, the rate of skeletal maturation should be carefully monitored. Conversely, treatment may be delayed to allow for psychological or emotional maturity or catch-up growth. Testosterone therapy may be given by depot injections intramuscularly or subcutaneously or topically by a patch or gel. Depot testosterone (such as enanthate or cypionate) is begun at a dosage 50 mg every 4 weeks, followed by increased dosing and frequency over about 3 years, to a full replacement dosage of approximately 200 mg every 2 weeks. Availability of the gel in metered-dose pumps allows gradual increases of dosage from 1.25 g daily upward. Among those with differentiated testes and gonadotropin deficiency, assisted fertility techniques may involve intratesticular germ cell retrieval or hFSH/hLH stimulation.

For patients with CAH, carefully monitored hormone replacement therapy is essential.⁴⁵² The goal of glucocorticoid therapy is suppression of excessive adrenal androgen secretion, while maintaining normal growth and development. Typically, oral cortisol doses range from 8 to 20 mg/m²/d. This range is based on provision of 1.5 to 2 times the daily cortisol production rate, 7 to 12 mg/m²/d. Oral fludrocortisone (e.g., Florinef) is commonly used for mineralocorticoid replacement for patients with salt-losing CAH. Patients with simple virilizing CAH may benefit from mineralocorticoid replacement. The typical dose is 0.1 mg administered as a single daily dose. Neonates and infants may require higher fludrocortisone doses, as well as salt supplementation because of relative mineralocorticoid resistance, higher aldosterone production rates, and relatively lower sodium intakes. Topics of discussion with parents include how to crush and administer tablets, what to do if doses are accidentally missed, use of medical alert identification IDs, and when to administer "stress" dosages.

For children with CAH, adequacy of replacement therapy is monitored by periodic reassessment of growth velocity, extent

of virilization, and salt craving. Laboratory monitoring may include serum androgen and 17-OHP concentrations, skeletal maturation, and 24-hour urinary 17-ketosteroid excretion. Androstenedione concentrations are useful to assess adequacy of glucocorticoid replacement, whereas 17-OHP concentrations are useful to assess for overtreatment. Determination of testosterone concentrations is helpful in girls and prepubertal boys. In pubertal and postpubertal girls, menstrual cyclicity is a sensitive indicator of hormone replacement therapy. Adequacy of mineralocorticoid replacement can be judged using PRA. Boys with CAH need to be regularly assessed by ultrasound for the development of testicular adrenal rest tumors; these rest tumors may be too small to palpate on examination.⁴⁵³

At times of physiological stress (such as fever >101° F, persistent vomiting, significant trauma, and surgical procedures), the glucocorticoid dose should be increased. In general, 2 to 3 times the usual dose is sufficient to prevent adrenal insufficiency. Higher doses may be necessary for surgical procedures. All families should have at home and be able to administer injectable hydrocortisone (e.g., Solu-Cortef) intramuscularly in case of medical emergencies. Recommended intramuscular doses are 25 mg for infants, 50 mg for children less than 4 years of age, and 100 mg for all others.

During surgical procedures, additional hydrocortisone can be administered either as continuous intravenous infusion or intramuscular injection. Intravenous normal saline (0.9% NaCl) can be used if oral mineralocorticoid replacement is not tolerated by the patient. While receiving glucocorticoid replacement therapy (and occasionally in the newborn period), physiologically stressed individuals with 11 β -hydroxylase deficiency may develop hyponatremia and hyperkalemia and benefit from mineralocorticoid therapy. At times of physiological stress, individuals with SLO syndrome or P450 oxidoreductase deficiency may benefit from glucocorticoid treatment.

Considerations With Regard to Surgery

For the virilized female patient with female sex of rearing, the extent of ambiguity in combination with the magnitude of clitoromegaly and posterior fusion must be carefully evaluated to determine whether genitoplasty, including clitoral reduction or clitoroplasty, should even be considered. Although current surgical techniques spare more of the neurovascular bundle of the phallus, surgery should be done only after thoughtful consideration. If the urethral outlet is located high in the urogenital sinus, early surgery may be indicated to decrease the risk of recurrent urinary tract infections by providing a direct urinary outflow path. Girls with mild to moderate degrees of clitoromegaly generally do not need surgery because of the potential for compromising genital sensitivity. Despite surgery, lower urinary tract symptoms, such as stress incontinence and incomplete bladder emptying may persist among female DSD patients and among males with hypospadias.

One important point to share with parents of a virilized girl with CAH is that the “stimulated genital tissues” will regress after glucocorticoid therapy is begun. On one hand, the parents need to be informed that it may be appropriate to discourage genital surgery, until the child is old enough to make her own decision.⁴⁵⁴ On the other hand, parents must be empowered to make the choice with which they will be comfortable. This must be done with the understanding that their daughter may criticize them for this decision when she is older. Many parents of daughters with severe ambiguity still choose surgery.

A shared decision-making process may be helpful to encourage thorough discussion between the parents, as well as the healthcare providers.⁴⁵⁵ If surgery is anticipated, the operation should be described in a manner understandable to the parents. An experienced surgeon should discuss the options, risks,

and benefits of surgery, including the innervation of the clitoris or penis and the surgical approach to be used to attempt to spare the neurovascular supply.⁴⁵⁶ Although opinions vary as to whether surgery should be done in one or more stages and whether vaginal reconstruction should be attempted during infancy, the parents need to be informed that subsequent vaginoplasty or vaginal dilatation may be required after puberty.⁴⁵⁷ Among patients who underwent vaginal reconstructive surgery during infancy, the frequency of postoperative vaginal stenosis has been reported to range from 0% to 77%.⁴⁵⁸ Therapeutic goals for vaginal reconstruction surgery include adequate sexual function with minimal need for continual dilatation or lubrication. After the onset of puberty, those with MRKH syndrome and individuals with CAIS can usually achieve increased vaginal size with dilator treatment.⁴⁵⁹

When discussing surgery for boys with hypospadias, pertinent topics include common male concerns about the importance of being able to stand to urinate, adequacy of genital development, and capability of sexual activities. With hypospadias, the location of the meatus does not necessarily indicate that fusion is complete to that point because there may be more proximal inadequate development of the corpus spongiosum and surrounding tissues. Thus the extent of surgery may not be known until labiourethral fusion is better visualized at surgery. Because correction of hypospadias and chordee is generally performed in stages, this discussion also needs to cover the details of the surgical approach, the proposed schedule for follow-up visits, the likely number of surgical procedures, and the optimal age for each surgical stage. The surgeon should review the options, risks, and anticipated outcomes. If the precise location and differentiation status of the testes are unknown, the parents should be aware that exploration and biopsy may be performed. As would be anticipated, individuals with 46,XY DSD have sexual concerns, regardless of gender of rearing. In addition to reconstructive genital surgery, potential confounding factors include self-esteem, genital appearance, infertility, and need for hormone replacement therapy. Adequacy of counseling and support likely influence adult outcome.⁴⁶⁰

Outcome studies reflect the results of the type of surgery and timing of surgery. Although older surgical techniques resulted in impaired genital sensitivity, it is as yet unclear whether current surgical techniques sparing the neurovascular supply to the clitoris will result in better outcomes. It is anticipated (and hoped) that current surgical techniques will have better outcome; however, it will be years before this information is available. In the meantime, available outcome studies can be informative.^{461,462}

The goals of genital reconstruction surgery have been and continue to be a good cosmetic appearance and the potential for functionality involving sensitivity for sexual responsiveness. Function after surgery is related to severity of genital ambiguity at birth, extent of surgery, and complications of surgery. For example, among females diminished vaginal diameter correlated with greater prenatal virilization. Among 21-hydroxylase-deficient CAH females, the outcome of surgery appears to be related to the specific mutations. Those with the null genotype have more surgical complications and poorer scores regarding sexual function.⁴⁶³ Available outcome data indicate that most postsurgical patients have a female gender identity. Yet, studies show that a greater portion of women with CAH, even those with non-classical CAH (NCAH), are sexually attracted to other women compared with the general population. However, long-term outcomes are not well documented. Among 46,XX DSD patients, those living as females indicated that they preferred early surgery and felt that a satisfactory sex life was possible.⁴⁶⁴ Nonetheless, decreased sexual desire, difficulty achieving orgasm, and later sexual debut were common concerns. Fertility is

possible for women with CAH; reduction of progesterone concentrations is one important factor to ensure fecundity for women with classical forms of CAH.⁴⁶⁵

Although most males with 46,XY DSDs are satisfied with long-term results of genitoplasty, consequences of chordee and severe hypospadias can include penis size too short for vaginal penetration. Hence, outcome may be poor. Recurrent complaints not only include penile size and sexual activity, but also urinary symptoms. Despite improved understanding of DSDs and openness with patients and families, quality of life issues need to have further attention.⁴⁶⁶

Risks for Gonadal Tumors

The aberrant fetal gonadal environment and subsequent anomalous germ cell differentiation is associated with an increased risk for germ cell tumors. The presence of Y chromosome material, specifically the testis-specific protein Y-encoded (*TSPY*) gene, and a dysgenetic gonad increase the propensity risk for gonadal tumors. The relative risk for gonadal tumors directs the need for and timing of surgery. Germ cell neoplasia-in-situ (GCNIS) or gonadoblastoma are precursors for germ cell tumors. The prevalence reported for gonadoblastoma ranges from 15% to 30%, depending on age of the patient, gonadal histology, and diagnostic criteria used for GCNIS/gonadoblastoma. Gonadoblastomas are mixed germ cell sex cord-stromal tumors arising in dysgenetic gonads, are composed of immature germ cells and sex cord-stromal cells of indeterminate differentiation, and precede the development of the more invasive neoplasms, such as dysgerminoma, seminoma, and nonseminoma. Assessment of *FOXL2* and *SOX9* expression in the tumor tissue can help to discriminate between those with a Sertoli cell component from those with a granulosa cell component.⁴⁶⁷

Increased and prolonged expression of immunohistochemical markers, *POU5F1* (also known as *OCT3/4*) and *TSPY*, is common in GCNIS and gonadoblastoma. In one series, *TSPY* was abundantly expressed in germ cells within dysgenetic testes and undifferentiated gonadal tissue suggesting upregulation when germ cells are located in an unfavorable environment. It is hypothesized that the normal germ cell maturation process is interrupted, resulting in prolonged expression of *OCT3/4*, erased genomic imprinting, and subsequent immortalization of the cell.^{468,469}

In one series of patients with Turner syndrome, 14/171 (8%) were positive for Y-chromosomal material. Among these 14 patients, the prevalence of gonadoblastoma was 33%.⁴⁷⁰ In some instances, Y-chromosomal material is only detected using PCR methodology.⁴⁷¹ Frasier syndrome, associated with a specific *WT1* mutation, is characterized by steroid-resistant nephrotic syndrome, XY-sex reversal, and increased risk for gonadal tumors.⁴⁷²

Because of a hypothesized increased risk for gonadal tumors, gonadectomy has been typically performed in patients with CAIS. Despite the dearth of long-term outcome studies, available data indicate that the risk for gonadal tumors is extremely low in patients with CAIS during the adolescent years.^{473,474} An international survey highlighted the inconsistent approaches to treatment, low risk for germ cell tumors, and emphasized the need for individualized management recommendations for patients with CAIS.^{475,476}

Limited sample size, ascertainment bias, inconsistent diagnostic criteria for malignant cells, and confusing terminology leave many questions to be answered. For example, which patients with DSD benefit from gonadal biopsy to assess risk for neoplasia? Another consideration is how many biopsies are necessary to be representative of the histology of the gonad. Laparoscopy and video-assisted gonadectomy are invaluable tools when the risk for malignancy is high. Ultimately, the decision

regarding gonadectomy involves consideration of the patient's phenotype (internal and external genital anatomy), karyotype, gender of rearing, psychosocial factors, and gonadal histology.⁴⁰⁹

Transition From Pediatrics to Adult Care

Parents and pediatric healthcare providers envision that children with DSD will become productive adults who will find fulfillment and gratification in their lives. In view of the report from England regarding loss of follow-up of patients with CAH, a planned transition program from the pediatric healthcare team to the adult healthcare team is essential.⁴⁷⁷ This planned transition process needs to consider the medical, psychosocial, educational, emotional, cognitive, and vocational needs of the young adult. Differences in expectations between pediatric and adult healthcare situations should be reviewed. Explanation of the specific details of his/her diagnosis with the young adult is essential.⁴⁷⁸ For many of these patients, the specific details of their disorder were reviewed with the parents at the time of diagnosis when the individual was too young to participate in these discussions. The young adult needs to know the etiology, basic genetics, pathophysiology of his/her disorder, recurrence risk, and fertility status. The young adult, especially those requiring glucocorticoid replacement therapy, needs to understand the rationale for treatment.⁴⁷⁹

Long-Term Outcome Studies

Among 46,XX females with CAH, outcomes differ depending on the severity of the condition or the specific *CYP21A2* mutations. More recent surgical outcome has improved but is not always satisfactory, psychological effects vary, and hence fertility and sexual satisfaction varies. The key approach involves individualizing each patient.⁴⁸⁰ A study of outcome among phenotypic females with 46,XY DSD with an age-matched control group found: (1) overall increased morbidity but not after exclusion of those with specific diagnoses, pregnancy, and birth; (2) mortality similar to controls; and (3) education. Cohabitation and motherhood were reduced. Thus, such individuals appear to perform well in the work environment but family life is negatively impacted.⁴⁸¹ General health status is good, better related to early diagnosis and healthy lifestyle.⁴⁸² Fertility, as would be anticipated, is rare, related to initial genital phenotype, and partnerships (which occur among a minority). Assisted reproductive techniques (ART) are often used. Fertility is extremely rare among those with pure or mixed gonadal dysgenesis, ovotesticular DSD, and XX males.^{483,484} Better surgical techniques, improved socialization, focus on long-term treatment, and ART techniques may improve the potential for fertility in the future. Sexual satisfaction, including early reports of sexual function for females, because the sparing of the neurovascular hood of the clitoris, suggest similar results with the general population, with problems with socialization, interpersonal and intimate relationships continuing to be a factor. Severe forms of hypospadias, whether or not identified as a DSD continue to be a persistent surgical, functional, and psychosocial challenge.^{485,486} Clinical outcomes among boys with PAIS are poorer than with most other XY DSDs, hence the decision-making regarding sex assignment must be particularly cautious.⁴⁸⁷

Psychological and Genetic Counseling and Support and Ethical Considerations

Longitudinal continuity of care and provision for support systems are essential because of the medical and psychological aspects of DSDs. If an experienced social worker, psychologist, or psychiatrist is available, careful assessment and counseling are invaluable throughout childhood and adolescence. Although most such cases of 46,XY DSD may not require

medical therapy during early childhood, intermittent visits with the pediatric endocrinologist are helpful to address the patient's and parents' concerns, update parents concerning new therapy and outcome data, and ensure that appropriate psychological support needs are being met. These visits can foster a positive relationship between the child and the physician. Some parents may find disorder-specific support groups (e.g., AIS, www.aissg.org; CAH, www.caresfoundation.org; Turner syndrome, www.turnersyndrome.org) to be helpful.

Many DSD conditions are inherited. The most common inheritance patterns are autosomal recessive or X-linked traits. Genetic counseling is indicated because parents are often interested to learn about recurrence risks. Because phenotypic heterogeneity occurs in some DSD disorders, hormone determinations and genetic analyses (when available) for other family members may be recommended.

Ethical principles and recommendations have been published in an effort to provide a comprehensive view of the perspective of clinicians, patients, and families, based on the principles of fostering the wellbeing of the child and future adult, uphold their rights to participate in decisions that impact them now and later, and to respect family and parent-child relationships.⁴¹² The general media has noted that intersex babies currently may be caught in the "surgery battle over medical risks and ethical rights."⁴⁸⁸ This controversy highlights the ethical dilemma in which parents serve as surrogates for the best care of their minor children. Parents need to be educated and informed regarding all available information. Numerous critiques discussing various topics have been published; topics have included the struggle against medicalization, politicizing and democratizing standard of care, and legal/medical activism.⁴⁸⁹

CONCLUSIONS

Identification of genes involved in sexual differentiation has elucidated some of the molecular events responsible for normal and abnormal sexual differentiation. Knowledge of the genetic, hormonal, and environmental factors that influence sexual differentiation benefits the affected children, their parents, and their healthcare providers. This information enables better parental education regarding the etiology, natural history, and prognosis for their child. With understanding of factors that affect sexual differentiation, recurrence risks can be estimated.

The evaluation and subsequent management of a child with ambiguous genitalia is based on history, physical examination, and laboratory data. Understanding the family's background and situation enable the medical team to discuss the child's sex development, using terminology that they can understand at the time of diagnosis, as well as during the following years. Initial diagnosis and management are the beginning of a long-term relationship among the patient, family, and healthcare providers.

Despite the advances in characterizing the molecular basis of ambiguous genitalia, sensitivity and compassion demonstrated by the team of healthcare professionals in their interactions with the patient and family remain an essential aspect in the management of an infant with genital ambiguity. The initial evaluation and diagnostic processes are merely the beginning of an extended relationship with the child and family, ultimately culminating in successful transition to adult care providers. Respectful and empathetic interactions foster development of the infant with genital ambiguity to become an adult able to live a contented life. The healthcare providers need to remain cognizant that knowledge regarding all aspects of sex determination, sex development, and gender identity determinants remains to be elucidated, such that management of

individuals with DSDs will still involve uncertainties and likelihoods.

INTRODUCTION

One of the most important metabolic events to mark the transition from fetal to neonatal life is the adaptation from an environment that has a readily available and continuous source of glucose—transplacental passage of maternal blood—to an environment in which glucose is provided in a limited and intermittent supply via feeding. At birth, after separation from the placenta, the complex mechanisms involved in the maintenance of plasma glucose concentration must be activated and coordinated to avoid hypoglycemia and resultant damage to the central nervous system. A newborn or infant with hypoglycemia presents an urgent diagnostic and therapeutic challenge. The clinical features must be rapidly assessed and a plan of action developed based on the infant's age, maternal and parturition history, severity and persistence of hypoglycemia, and all other relevant clinical clues for definitive diagnosis and treatment. In this chapter, we review the normal physiology of glucose metabolism and the pathophysiology of the most common disorders resulting in hypoglycemia in the neonate (first 4 weeks of life) and infant (1 month to 1 year of life) with an emphasis on the approach to the diagnosis and management of these pathologies.

PRINCIPLES OF GLUCOSE METABOLISM

A systematic approach to hypoglycemia in the newborn, infant, or child requires an appreciation of the central role of glucose in the body's fuel economy.¹ Glucose metabolism accounts for approximately half of basal daily energy needs and is the principal metabolic fuel of the human brain. Glucose can be stored for energy in the form of glycogen and fat, although only glucose stored in liver glycogen is available for release into the circulation, and fatty acids cannot be converted back into glucose; glucose carbon can be used for synthesis of protein and for structural components (such as cell membranes). The aerobic oxidation of glucose yields high energy by producing 36 mols of adenosine triphosphate (ATP) for each mol of glucose. Although glucose is the predominant metabolic fuel for both the brain and the body in the period immediately after a meal, during longer term fasting, glucose utilization must be restricted to glycolytic tissues, such as red blood cells and the brain and the rest of the body must rely on oxidation of fatty acids released from adipose tissue triglyceride stores.²

All glucose extracted by the brain is oxidized, and thus cerebral glucose utilization parallels cerebral oxygen uptake. In 5-week-old infants, cerebral glucose utilization already represents 71% to 93% of the adult level in most brain regions (ranging from 13 to 25 $\mu\text{mol}/100\text{ g}/\text{min}$). Adult levels of cerebral glucose utilization (19–33 $\mu\text{mol}/100\text{ g}/\text{min}$) are reached by 2 years of age, and they continue to increase until 3 to 4 years of age—when they reach values ranging from 49 to 65 $\mu\text{mol}/100\text{ g}/\text{min}$, which are maintained to approximately 9 years of age and then gradually decline to adult levels by the end of the second decade.³

Glucose uptake by the brain occurs by means of a carrier-mediated facilitated diffusion process that is glucose concentration dependent, as well as energy, Na^+ , and insulin independent.⁴ This process is mediated by facilitative glucose transporter (GLUT) proteins. Several members of the GLUT family have been detected in the brain. GLUT1 is located at the blood-brain barrier,⁵ and although some neurons express GLUT2 and GLUT4, the majority use GLUT3 as their primary transporter.⁶ The main isoform present in insulin-responsive tissues is GLUT4.^{7,8}

Of major importance is that glucose entry into brain cells and its subsequent metabolism are not dependent on insulin but rather are dependent on circulating arterial plasma glucose concentration.⁹ Therefore a decrease in arterial glucose concentration or a defect in the glucose transport mechanism of the brain will result in intracerebral glucopenia and low cerebrospinal fluid glucose concentration (hypoglycorrhachia)—with attendant symptoms and signs of cerebral glucopenia as subsequently described.^{9–11} For example, genetic deficiency of the GLUT1 glucose transporter causes hypoglycorrhachia, seizures, and severe developmental delay.¹²

In normal adult humans and in the normal newborn infant after the first few days of life, plasma glucose concentrations range from 3.9 to 5.6 mmol/L (70–100 mg/dL). In experiments using rats, brain glucose consumption outstrips glucose transport, leading to a brain glucose concentration near zero at a plasma glucose

concentration of 2 mmol/L (36 mg/dL).¹³ To prevent circulating arterial plasma glucose from decreasing precipitously under normal physiologic conditions, and therefore to prevent impairment of vital function that depends on cerebral glucose metabolism, an elaborate defense mechanism has evolved.¹ This defense against hypoglycemia is integrated by the autonomic nervous system and by hormones that act to enhance glucose production through enzymatic modulation of glycogenolysis and gluconeogenesis, while simultaneously limiting peripheral glucose use.^{14,15} Similar defense mechanisms against hypoglycemia function in the normal full term human newborn after separation from the placenta.¹⁶ Thus hypoglycemia is the result of a defect in one of these systems that maintain a normal range of plasma glucose concentration, preventing its fall to less than 3.9 mmol/L (70 mg/dL) during fasting and its rise to more than 7.8 mmol/L (140 mg/dL) during feeding.

These mechanisms, most importantly, the regulation of β -cell insulin secretion, are not fully mature at birth, when there is an abrupt transition from intrauterine life to extrauterine life,¹⁶ and mean plasma glucose concentrations transiently fall by 25% before recovering by 2 days of life to normal adult values. Neonates who are born with various risk factors, including birth asphyxia, intrauterine growth restriction (IUGR), maternal toxemia, and prematurity may be particularly vulnerable to hypoglycemia,¹⁷ often with consequences to subsequent cerebral development or function that can be prevented by early detection and treatment.^{18,19}

PHYSIOLOGY OF PERINATAL GLUCOSE HOMEOSTASIS

Glucose Metabolism in the Fetus

Glucose provides 80% of fetal energy, with the remaining 20% derived mostly from oxidation of lactate and amino acids.²⁰ Free fatty acids are transported across the placenta in limited amounts sufficient for fetal growth, but do not contribute significantly to fetal energy demands. The glucose used by the fetus is derived entirely from the maternal circulation through facilitated diffusion across the placenta using primarily the GLUT1 glucose transporter.²¹ Placental glucose transport does not involve the GLUT4 glucose transporter, and therefore is not regulated by either maternal or fetal insulin concentrations. Because placental glucose transport is so rapid, the maternal and fetal glucose concentrations behave as a single pool and there is no endogenous glucose production in the fetus. This has important clinical consequences, for example, acute hypoglycemia in a mother will result in acute hypoglycemia in the fetus—with little or no ability of the fetus to acutely compensate for the abrupt reduction in glucose supply.

From early gestation to the time of delivery, maternal arterial and fetal umbilical vein concentrations of plasma glucose are very similar. The mean maternal-fetal plasma glucose concentration difference is essentially zero at 20 weeks of gestation and increases only slightly to 0.75 mmol/L (13 mg/dL) at term.²² The small increase in maternal-fetal gradient may reflect increased utilization by the growing placenta, because approximately 50% to 60% of maternal glucose taken up is consumed by oxidation in the placenta and only 40% to 50% transported to the fetus.²³ As gestation progresses, the increasing demand of the fetus for glucose oxidation and storage is accomplished by increasing uterine blood flow. There is excess capacity in uterine blood flow, and it may be reduced as much as 50% without causing any fetal harm. However, reducing blood flow from the placenta to the fetus causes significant impact on delivery of glucose and other nutrients to the fetus, with resultant IUGR.

In the second half of pregnancy, the fetal-placental unit secretes large quantities of placental lactogen, progesterone,

and estrogen, which cause increased maternal insulin resistance and may, in susceptible mothers, result in gestational diabetes. Maternal insulin secretion is responsible for controlling plasma glucose concentrations in the mother and, while insulin does not cross the placenta (unless bound by antibodies),²⁴ the maternal insulin also controls fetal glucose concentrations, because of the rapid facilitated transfer of glucose across the placenta. Although fetal insulin does not control fetal glucose concentrations, fetal insulin secretion is responsive to changes in fetal glucose concentrations. The role of fetal insulin is to maintain the rapid growth rate of the fetus. For example, maternal hyperglycemia (e.g., maternal diabetes) leads to fetal hyperinsulinemia and increased fetal growth; in contrast, maternal hypoglycemia (as in maternal malnutrition or in maternal hyperinsulinism caused by a glucokinase activating mutation) can suppress fetal insulin secretion, resulting in impaired fetal growth.²⁵

Changes at Birth: Transition Phase

The abrupt interruption of maternal glucose transfer to the fetus at delivery imposes a need for the newborn infant to independently control plasma glucose concentrations by adjusting insulin secretion and mobilizing counterregulatory responses. There is evidence that most of the counterregulatory mechanisms, including glucagon and epinephrine secretion and activation of hepatic glycogenolysis and gluconeogenesis, are functional at birth.²⁶⁻²⁸ Nevertheless, there is a transitional period immediately after delivery when mean plasma glucose concentrations fall in normal newborn infants from 70 to 80 mg/dL (close to maternal glucose values) to 55 to 60 mg/dL before returning by 2 to 3 days of life to the range of 70 to 100 mg/dL, which is normal for extrauterine life.^{17,29} This phenomenon, known as *transitional neonatal hypoglycemia*, in normal newborns has been recognized for many years, although its clinical significance remains uncertain, indeed controversial. There is increasing evidence that the mechanism of transitional hypoglycemia involves pancreatic regulation of insulin secretion and reflects persistence of the lower glucose threshold for β -cell insulin secretion in the fetus, which is required for maintaining fetal growth.³⁰ Evidence that transitional neonatal hypoglycemia should be considered as “transitional neonatal hyperinsulinism” includes observations that, during the period that plasma glucose is low in normal newborns, lipolysis and ketogenesis are suppressed and liver glycogen reserves are maintained, as shown by the large glycemic responses elicited by administration of glucagon or epinephrine.³⁰ As discussed later in this chapter, these findings are diagnostic hallmarks of insulin-induced hypoglycemia. The lower concentrations of plasma glucose in normal newborns are quite stable and relatively unaffected by durations of postnatal fasting of up to 24 hours, suggesting that transitional neonatal hypoglycemia reflects a lower glucose threshold for insulin secretion.³⁰ Recent studies in mice confirm a lower glucose threshold for insulin secretion in the immediate postnatal period. The mechanism responsible for the low glucose threshold in fetal beta-cells remains unclear, but suggested explanations include expression of genes that are normally “disallowed” in the beta-cell, such as hexokinase-1, the plasma membrane transporter for pyruvate and lactate, and lactate dehydrogenase or heightened sensitivity of insulin granule release to low glucose.³¹⁻³⁵ The phenomenon of transitional neonatal hyperinsulinism in normal newborns appears to usually be benign, but often complicates the recognition of infants who have persistent, pathological hypoglycemia disorders (see later).

Other challenges to the regulation of plasma glucose concentrations after delivery include the need to switch from a constant supply of glucose and amino acids provided from the maternal circulation to a variable and intermittent oral intake of nutrients. In breastfed infants, the composition of feedings

also changes over the first days of life, with colostrum being lower in carbohydrates and higher in fat than mature breast milk. Breastfed babies frequently may not achieve full nourishment initially and, beyond the period of transitional neonatal hyperinsulinism, may develop mild fasting hyperketonemia. Although this hyperketonemia was previously often attributed to the high fat content of colostrum (“suckling ketosis”), it appears to reflect a response to mild fasting stress.^{36–38} Impairments in adaptation to these changes in fuel supply in newborns may be manifested as symptomatic hypoglycemia, as described in later sections on specific hypoglycemia disorders in neonates and early infancy. Insulin secretion is glucose-responsive during late fetal development, but maximum capacity may be limited, especially in extremely premature infants who require intravenous (IV) feedings.

In summary, plasma glucose concentrations during intrauterine life are constant and are maintained to greater than 3.9 mmol/L (70 mg/dL). Following birth, plasma glucose falls to a mean glucose of 3.1 to 3.3 mmol/L (56–60 mg/dL), during the first 12 hours as a consequence of the low beta-cell glucose threshold for insulin secretion. As insulin regulation adapts to extrauterine life, glucose concentration rises to a mean of 3.5 mmol/L (63 mg/dL) by 12 to 24 hours of life; by 48 to 72 hours plasma glucose rises to a mean of 4.1 mmol/L (74 mg/dL).³⁹ The distribution of plasma glucose concentrations in neonates immediately after birth is not “normal” but is skewed toward lower values because of babies with various risk factors for hypoglycemia, as described later. For this reason, approximately 30% of “normal” newborns will have plasma glucose concentrations lower than 2.8 mmol/L (50 mg/dL) in the first 8 to 12 hours of life, but thereafter the frequency of glucose concentrations greater than 50 mg/dL drops to only 0.5% in newborns older than 24 hours of age.¹⁷ This drop in plasma glucose levels in the first 24 hours of life is *transitional hypoglycemia (transitional neonatal hyperinsulinism)*, which by definition occurs in normal healthy newborns. It should be differentiated from both transient and persistent pathologic causes of hypoglycemia.

Abnormalities of Transition

Studies of plasma glucose concentrations immediately after delivery in normal newborns show not only a lower mean concentration of glucose, but also a wider variance and, as noted earlier, a skewing of the distribution toward glucose values. This means that the simple mean \pm 2 standard deviations (SDs) is not a valid measure of the normal range of glucose in newborns, although this is used as the basis for many guidelines on neonatal hypoglycemia.^{40,41} The excess of low glucose concentrations reflects the fact that a large proportion of neonates are at increased risk of potentially pathologic hypoglycemia during the period of transitional neonatal hyperinsulinism. These at-risk infants have more severe and more prolonged hypoglycemia after delivery, which is caused by pancreatic insulin secretion and has been termed *perinatal stress-induced hyperinsulinism*. Perinatal stress-induced hyperinsulinism occurs with a number of fetal and maternal disorders, such as IUGR, birth asphyxia, maternal diabetes, and maternal hypertension (Box 7.1).^{42–44} Whether perinatal stress-induced hyperinsulinism is simply an exaggerated and more protracted form of transitional neonatal hyperinsulinism is not known. Affected neonates may require treatment to control hypoglycemia for several weeks or months after birth. Premature infants may not have developed adequate hepatic glycogen stores and may also have immaturities of liver enzyme systems for gluconeogenesis and ketone synthesis, which increase their risk of hypoglycemia but to a lesser extent than in infants with perinatal stress. It is important for the clinician to recognize these at-risk neonates and neonates whose glucose control is out of the

BOX 7.1 Neonates at Risk of Persistent Hypoglycemia (modified from PES guide)

Infants of Diabetic Mothers (including gestational diabetes)
 Large for Gestational Age (LGA) (even without maternal diabetes)
 Perinatal Stress-induced Hyperinsulinism
 Intrauterine Growth Restriction (IUGR), Small for Gestational Age (SGA)
 Birth Asphyxia; C-section for fetal distress
 Maternal preeclampsia or hypertension
 Meconium aspiration syndrome
 Erythroblastosis fetalis
 Polycythemia
 Premature or Postmature Delivery
 Family History of a Genetic Form of Hypoglycemia
 Congenital Syndromes Associated With Hypoglycemia
 Beckwith-Wiedemann Syndrome (especially 11pUPD)
 Turner Syndrome
 Kabuki Syndrome
 Midline facial malformations, microphallus

range of transitional hypoglycemia during this period and treat appropriately. In particular, it is important to recognize conditions in which insulin secretion is increased, as these infants will neither mobilize glycogen nor be able to oxidize fatty acids, thus putting their brains at risk of damage because of the combination of hypoglycemia and hypoketonemia.

Management of Hypoglycemia in the First 24 to 48 Hours

Management of hypoglycemia in the first 24 hours of life is important from two points of view. First, the management plan should avoid treatment of infants who do not need treatment. Second, it should include a plan for those who either have or are at risk of having a persistent hypoglycemic disorder, which both identifies those neonates and treats them adequately. It is not currently recommended that all newborns have plasma glucose concentrations measured. However, if an infant has symptoms consistent with hypoglycemia—such as lethargy, apnea, or seizures, or is unwell or in any of the at-risk categories (e.g., infants with siblings with known hypoglycemic disorders, preterm infants, large for gestational age infants, small for gestational age infants, infants of a diabetic mother, infants who had birth asphyxia, and other infants with disorders outlined in Box 7.1)—the infant’s glucose levels should be measured.

The recent recommendations of the Pediatric Endocrine Society suggest that beyond the period of normal transitional neonatal hypoglycemia in the first 24 to 48 hours after birth, the glucose thresholds and goals for management of low plasma glucose concentrations should be the same in neonates as in older children.⁴⁵ In addition, these same standards are recommended for neonates who either have or are at increased risk of having a persistent hypoglycemia disorder (e.g., family history or physical features of a hypoglycemia disorder, such as large for gestational age birthweight, suggesting hyperinsulinism or macroglossia, and hemihypertrophy, suggesting Beckwith-Wiedemann syndrome [BWS]). For neonates who are suspected to not have a persistent disorder and who are receiving normal feedings, the recommended glucose target for management is to maintain plasma glucose above 50 mg/dL during the first 48 hours of life and above 60 mg/dL beyond 48 hours, if the hypoglycemia is likely to resolve within a day or two.

Emergency treatment of hypoglycemia in neonates should be tailored to the presence or absence of symptoms and the degree of hypoglycemia. For mild asymptomatic hypoglycemia in the

first 48 hours of life, early feeding or oral glucose may be tried initially. However, symptomatic or severe hypoglycemia should be treated with IV dextrose (e.g., 0.2 g/kg bolus, followed by a glucose infusion rate [GIR] of at least 4–6 mg/kg/min initially, and adjusted as needed to maintain glucose >70 mg/dL). If the hypoglycemia is known to be caused by hyperinsulinism, glucagon may also be considered (0.5–1 mg IV, subcutaneous [SQ], or intramuscular [IM]). Follow-up frequent monitoring of plasma glucose should be done to determine whether formal diagnostic evaluation is required.

By 48 hours of age, the period of transitional neonatal hypoglycemia should normally be over and plasma glucose concentrations should be similar to older children and adults: a normal range of 70 to 100 mg/dL. Thus, formal evaluation to diagnose the cause of hypoglycemia should be considered after 48 hours of age for neonates in whom the possibility of having a persistent hypoglycemia disorder cannot be completely excluded. Such an evaluation to diagnose the cause of hypoglycemia should be undertaken before the baby is allowed to be discharged home. To address the issue of babies who may not have achieved complete resolution of transitional hypoglycemia before the time of discharge, the Pediatric Endocrine Society recommendations suggest considering a fasting challenge to ensure that plasma glucose can be safely maintained above 60 mg/dL for over 6 to 8 hours (the “skip a feed” test). This should only be considered for neonates who have no risk features for a persistent hypoglycemia disorder (i.e., no episodes of symptomatic hypoglycemia, no need for IV dextrose, no features to suggest genetic or syndromic form of hypoglycemia, or perinatal stress-induced hypoglycemia, etc.). For all other neonates, a complete formal fasting study should be considered. One should note that there is no evidence that proves these protocols recommended by the Pediatric Endocrine Society will identify 100% of infants, so caution should be made if

clinical circumstances warrant further thought. Finally, it is important to emphasize to anxious parents the consequences of missing a diagnosis of a hypoglycemic disorder. In our experience, most parents are willing to lengthen the hospital stay by 6 to 9 hours to ensure the long-term safety of their child.

HORMONAL AND METABOLIC SYSTEMS OF FASTING ADAPTATION

Hypoglycemia in neonates, infants, and children is essentially always a problem with fasting adaptation. Postprandial hypoglycemia is exceedingly rare and is limited to a few unusual situations, such as postprandial hypoglycemia after Nissen fundoplication, hereditary fructose intolerance, or the protein-induced hypoglycemia seen in some forms of congenital hyperinsulinism. Therefore a consideration of the four major hormonal and metabolic pathways that maintain fuel homeostasis during fasting provides an important framework for understanding the causes, diagnosis, and treatment of different forms of hypoglycemia.

Three metabolic systems regulate the physiologic response to fasting: (1) hepatic glycogenolysis, (2) hepatic gluconeogenesis, and (3) hepatic ketogenesis. The key enzymatic steps in these pathways are shown in Fig. 7.1. These metabolic systems are coordinated by (4) the endocrine system, consisting of suppression of insulin (the most important endocrine response to fasting, as insulin suppresses all three metabolic systems), and the secretion of the counterregulatory hormones: glucagon, epinephrine (a marker of sympathetic nervous system activation), cortisol, and growth hormone (GH). Table 7.1 summarizes the counterbalancing effects of these counterregulatory hormones on the three key metabolic systems. There is a hierarchic redundancy in the interaction of the counterregulatory hormones that provides a margin of safety (“fail-safe mechanism”) if only

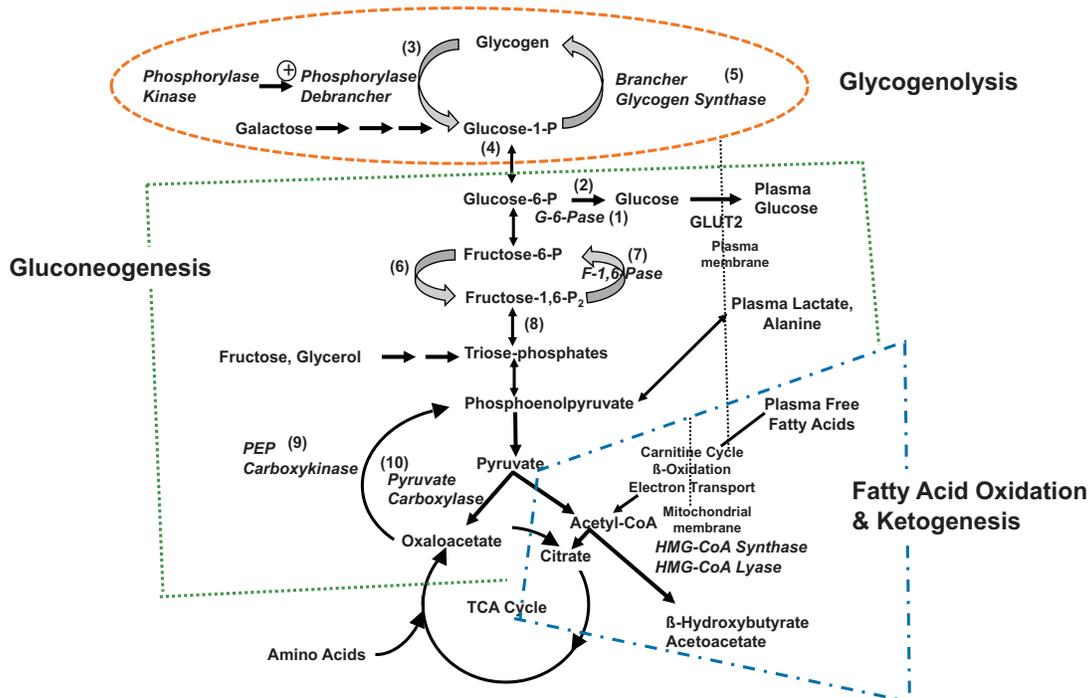

Fig. 7.1 Key metabolic pathways of intermediary metabolism. Disruption of the elements of these pathways may be pathogenetic in the development of hypoglycemia. Not shown is the hormonal control of these pathways. Indicated are (1) glucose 6-phosphatase, (2) glucokinase, (3) phosphorylase, (4) phosphoglucumutase, (5) glycogen synthetase, (6) phosphofructokinase, (7) fructose 1,6-diphosphatase, (8) fructose 1,6-diphosphate aldolase, (9) phosphoenolpyruvate carboxykinase, and (10) pyruvate carboxylase. (From Pagliara, A.S., Karl, I.E., Haymond, M., Kipnis, D.M. (1973). Hypoglycemia in infancy and childhood. *J Pediatr*, 82, 365–379 and 82, 558–577.)

TABLE 7.1 Hormonal Regulation of Fasting Metabolic Systems

Counterregulatory Hormone	Glycogenolysis	Gluconeogenesis	Lipolysis	Ketogenesis
Insulin	Inhibits	Inhibits	Inhibits	Inhibits
Glucagon	Stimulates	Stimulates		Stimulates
Cortisol		Stimulates		
Growth hormone			Stimulates	
Epinephrine	Stimulates		Stimulates	Stimulates

one counterregulatory hormone is impaired. Epinephrine (sympathetic activation) and glucagon are quick acting, each signaling its effects by stimulation of cyclic adenosine monophosphate (AMP). Deficiencies of glucagon, as occurs in long-standing type 1 diabetes mellitus, can be largely compensated for by an intact autonomic nervous system with appropriate α - and β -adrenergic, and cholinergic effects. Conversely, autonomic failure can be largely compensated for if glucagon secretion remains intact.¹

Hepatic glycogenolysis is sufficient to meet energy requirements for only a few hours. Beyond that time, glucose must be produced by hepatic gluconeogenesis from precursors, such as amino acids, glycerol, and lactate recycled from glycolysis. The major source of gluconeogenic precursors is amino acids from muscle protein. Although the pool of muscle protein is large, it is required for body function and thus in contrast to stores of glycogen in liver and fat in adipose tissue, there are no "reserves" of protein to draw on during fasting. To spare the use of essential protein during extended fasting, glucose consumption must be suppressed by switching on the mobilization of fatty acids from adipose triglyceride stores for oxidation in muscle and other tissues and of glycerol as substrate for hepatic gluconeogenesis. Fatty acids are also oxidized in liver to produce the ketone bodies, β -hydroxybutyrate and acetoacetate, which can be used by the brain as an alternative substrate to further spare glucose consumption.

The essential function of fasting adaptation is to maintain fuel supply to the brain. Glucose homeostasis is very limited in neonates and infants compared with adults, in part because of their smaller reserves of liver glycogen and muscle protein, but chiefly because of their relatively larger rates of glucose consumption because of their larger brain-to-body-mass ratio. For example, the fuel stores of a 10-kg infant are only 15% of those of an adult. However, the caloric needs are 60% of those of an adult and glucose utilization rates per kilogram body weight are 2- to 3-fold greater. As shown in Fig. 7.2, early in fasting after absorption of a meal is completed, glucose is the primary brain fuel and accounts for over 90% of total body oxygen consumption. Glucose is initially provided chiefly from hepatic glycogenolysis, supplemented by hepatic gluconeogenesis using amino acids released by muscle protein turnover and lactate from glycolytic tissues, such as red blood cells. After 8 to 12 hours in normal infants (24–36 hours in adults), glucose production declines, because the supply of liver glycogen is depleted and the rate of gluconeogenesis from amino acids remains constant. At this time, a transition to fat as the major fuel for the body begins, with accelerated adipose tissue lipolysis and increased fatty acid oxidation in muscle and ketogenesis in liver. Lipolysis also generates glycerol, which becomes an important gluconeogenic substrate once fasting adaptation is fully active. The brain cannot directly use fatty acids, because they do not pass the blood-brain barrier. However, the brain can substitute glucose consumption with the ketones acetoacetate and β -hydroxybutyrate, which are released by the liver as the end product of hepatic fatty acid oxidation. In late stages of fasting adaptation, fatty acid oxidation and ketone utilization account for 90% of total body oxygen consumption.

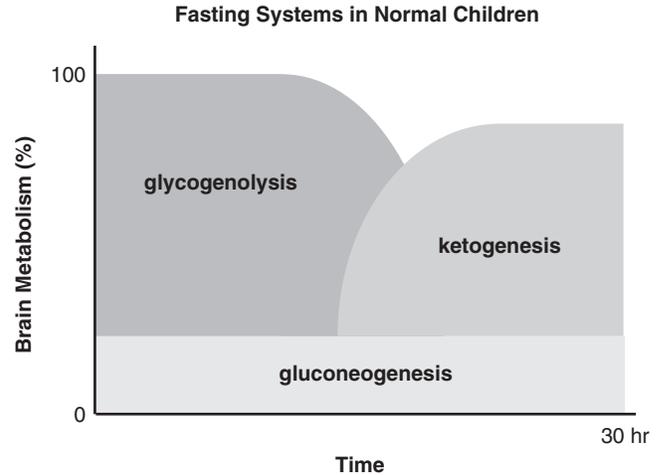

Fig. 7.2 Contribution of major fasting systems to brain metabolism over time in a typical normal infant. Note that glycogen stores are depleted by 8 to 12 hours and that ketogenesis becomes the major source of brain substrate by 24 hours.

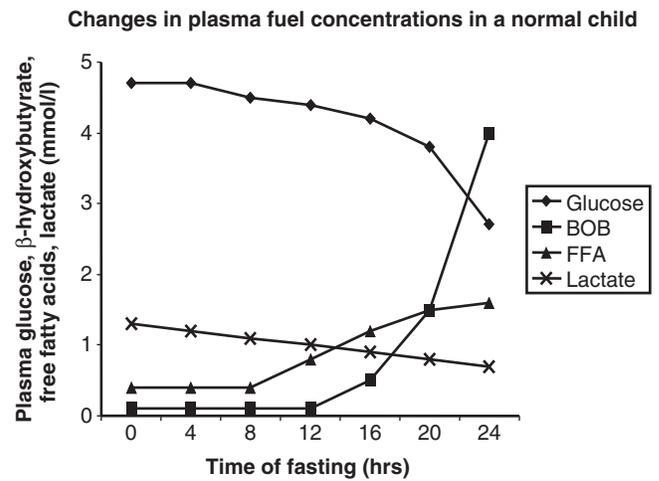

Fig. 7.3 In infants, a 24-hour fast is accompanied by a gradual fall in plasma glucose levels as hepatic glycogen stores are depleted, a progressive fall in concentrations of gluconeogenic substrate (e.g., lactate, alanine), as they are used for hepatic gluconeogenesis, a brisk rise in free fatty acids as lipolysis is activated, and a dramatic rise in β -hydroxybutyrate (the major ketone) as hepatic ketogenesis is turned on.

The operation of the metabolic and endocrine systems of fasting adaptation is evidenced by the changes in circulating levels of metabolic fuels and hormones during a fast. As shown in Fig. 7.3, in young infants, a 24-hour fast is accompanied by a gradual fall in plasma glucose levels as hepatic glycogen stores are depleted, a progressive decline

in concentrations of gluconeogenic substrate (e.g., lactate, alanine) as they are used for hepatic gluconeogenesis, a brisk rise in free fatty acids as lipolysis is activated, and a dramatic rise in β -hydroxybutyrate (the major ketone) as hepatic ketogenesis is turned on.⁴⁶

By the time that plasma glucose concentration has fallen to less than 2.8 mmol/L (50 mg/dL), all the metabolic systems and the hormonal responses described earlier will have fully engaged. A “critical sample” drawn at this time will therefore provide a snapshot of the integrity of the four metabolic and endocrine fasting systems (Table 7.2). The use of these critical samples in diagnosing the cause of hypoglycemia is discussed later.

DEFINITION HYPOGLYCEMIA IN NEONATES AND INFANTS

The definition of hypoglycemia is an important concept to assist in diagnosis and management of patients with suspected or proven hypoglycemic disorders. For this reason, we recommend using various different plasma glucose thresholds for different definitions. The diagnostic threshold is the level of glucose below or at which a diagnosis of the etiology of hypoglycemia may be made. The therapeutic threshold is the level of

glucose that indicates adequate therapy of a disorder of glucose dysregulation. Finally, there is the very controversial issue of what level of glucose causes brain damage.

A number of potential artifacts can interfere with measuring glucose levels in neonates and infants (Box 7.2). Whole-blood glucose concentrations are 10% to 15% lower than plasma glucose concentrations because erythrocytes have a higher concentration of protein (hemoglobin) versus plasma with its higher water content, and hence higher dissolved glucose concentrations. The difference may be greater in neonates with higher hematocrits. Blood samples that are not processed promptly can have erroneously low glucose levels, owing to glycolysis by red and white blood cells. At room temperature, the decline of whole-blood glucose can be 5 to 7 mg/dL/h. The use of inhibitors, such as fluoride, in collection tubes avoids this problem.

Hospital bedside glucose meters and similar home glucose meters are less precise than clinical laboratory methods and can be expected to have an error range of 10% to 15%. These methods are also prone to errors, such as outdated strips or inadequate sampling—most of which result in falsely low glucose values. For this reason, bedside monitors can be used for screening purposes—but any glucose value below 3.3 mmol/L (60 mg/dL) should be verified in the clinical laboratory. Falsely

TABLE 7.2 Differential Diagnosis of Hypoglycemia in Neonates and Infants

Disorder	Plasma Fuels at End of Fast (mmol/L)				Plasma Hormones at End of Fast				Physical Examination
	Glucose	Lactate	Free fatty acids	β -hydroxybutyrate	Insulin (μ mol/L)	Cortisol (ug/dL)	Growth hormone (ng/mL)	Glycemic response to glucagon (mg/dL)

BOX 7.2 Factors Affecting Measurement of Plasma Glucose Concentration

- Whole-blood versus plasma glucose concentration (plasma is 10%–15% higher)
- Duration between sample collection and sample measurement
- Presence or absence of glycolytic inhibitors in collection tubes
- Sample collection from indwelling lines without adequate flushing

(Modified from Sacks, D.B. (1994). Carbohydrates. In: Burtis, C.A., Ashwood, E.R. (eds.), Tietz Textbook for Clinical Chemistry, 2nd ed. WB Saunders, Philadelphia.)

low (or high) glucose values may occur with samples drawn from indwelling lines without adequate flushing of the saline (or glucose) infusate. Falsely low levels may also occur in critically ill infants with poor perfusion and use of bedside meters in the critical care setting is recommended only for venous or arterial samples.⁴⁷ Modern bedside monitors use whole-blood samples but generally are calibrated to give a result expressed as a plasma glucose.

Diagnostic Glucose Threshold

The classic definition of symptomatic hypoglycemia is Whipple's triad—symptoms, signs or both consistent with hypoglycemia, a low plasma glucose concentration, and resolution of symptoms/signs after the plasma glucose concentration is raised. These three criteria were originally used for diagnosing insulinomas in adults. However, in neonates and infants, who cannot dependably communicate their symptoms and in whom clinical signs of hypoglycemia are not specific, it may not be possible to satisfy Whipple's triad. In these cases, recognition of hypoglycemia may require confirmation by repeated measurements of plasma glucose concentrations, either in association with symptoms or signs of hypoglycemia or during screening of at-risk infants. If levels are found below the level of glucose that causes neurogenic symptoms (<3.3 mmol/L or <60 mg/dL), after the first 48 hours of life, further investigations should be carried out to determine the etiology.⁴⁵ In these instances, formal provocative testing should be performed to determine if the neonate is safe for discharge or to determine the etiology of hypoglycemia.

Beyond the first 48 hours of life, normal plasma glucose concentration in neonates and infants are not different than in older children and adults. Thus plasma glucose concentrations in the postabsorptive state range between 3.9 and 5.6 mmol/L (70 and 100 mg/dL), with a mean of 4.4 to 4.7 mmol/L (80–85 mg/dL). A plasma glucose level of 2.8 mmol/L (50 mg/dL) is conventionally used as an end point for provocative diagnostic tests for hypoglycemia. This value is low enough to strongly stimulate the endocrine and metabolic defenses against hypoglycemia for identifying the mechanism responsible for hypoglycemia. Falling glucose levels elicit a typical sequence of responses: plasma insulin levels begin to decrease when plasma glucose falls to the range of 4.4 to 4.7 mmol/L (80–85 mg/dL) and insulin secretion is generally "switched off" at glucose concentrations below 2.5 to 3 mmol/L (45–54 mg/dL); glucagon secretion increases when plasma glucose levels are in the range of 3.6 to 3.9 mmol/L (65–70 mg/dL); epinephrine, cortisol, and GH responses are activated in the range of 3.6 to 3.9 mmol/L (65–70 mg/dL). As the plasma glucose falls below 3.3 mmol/L (59 mg/dL), auditory and visual reaction time is prolonged and cognitive function begins to decline as

the plasma glucose concentration declines below 2.5 to 3.5 mmol/L (45–63 mg/dL), with some of this variability dependent of the testing used.^{48,49}

Therapeutic Threshold

Once a diagnosis of the etiology of hypoglycemia has been made or suspected, the goal of therapy is to maintain the plasma glucose concentration >3.8 mmol/L (>70 mg/dL). This target allows patients with hypoglycemia disorders to maintain glucose levels above the threshold for counterregulatory responses and prevent the development of hypoglycemia unawareness caused by repetitive hypoglycemia. For disorders of fatty acid oxidation and gluconeogenesis, maintaining glucose concentration in this range will prevent buildup of free fatty acids and lactate, respectively.

Plasma glucose concentrations between 2.8 and 3.9 mmol/L (50 and 70 mg/dL) should be regarded as suboptimal and below the goal for therapy for hypoglycemia and should lead one to evaluate if a therapy escalation is needed.

Hypoglycemic Brain Damage

"What level of glucose causes brain damage?" is one of the most frequently asked questions. Unfortunately, the answer is more complex than the lower the glucose, and the longer the glucose is low, the worse the risk. Brain damage likely occurs because of fuel deficiency in neurons. Neurons have many sources of energy, the most common of which are glucose, lactate, and β -hydroxybutyrate. Studies of normal newborn infants have shown that after 6 hours of fasting, ketones can account for 12% of energy production by the brain.

To fully oxidize these compounds to energy, the cell needs oxygen and adequate blood flow. Indeed, one of the early brain adjustments to hypoglycemia (at approximately 30 mg/dL) is to increase cerebral blood flow delivering more glucose and oxygen to the brain. Studies have shown that the addition of hypoxemia, asphyxia, or ischemia to hypoglycemia dramatically increase the extent of brain damage compared with hypoglycemia alone, and the presence of hypoglycemia increases the risk of brain damage from less degrees of hypotension. There are many reports attempting to address the long-term outcomes associated with a glucose concentration of 45 mg/dL versus 47 mg/dL versus 50 mg/dL and all are flawed because none of them look at all three fuels. Thus one cannot draw any firm conclusions from papers currently published about what level of glucose causes brain damage. However, there is evidence to suggest that severe hypoglycemia is associated with a bad outcome with studies that look at patients with a combination of brain imaging abnormalities and poor neurologic outcome finding that 95% of patients had glucose less than 30 mg/dL.

The same may be true for the development of neuroglycopenic symptoms, which typically occur before brain damage would occur. In some disorders, such as defects in ketogenesis, signs and symptoms may begin to appear during fasting at plasma glucose levels of 3.3 mmol/L (60 mg/dL). On the other hand, some patients (those with glucose 6-phosphatase deficiency causing GSD1) may have few symptoms of neuroglycopenia at plasma glucose levels as low as 1.1 to 1.7 mmol/L (20–30 mg/dL) because their high plasma levels of lactate provide an alternative substrate for the brain.

Conditions, such as hyperinsulinism have a very high rate (30%–50%) of brain damage,^{50–54} as they are deficient in glucose and β -hydroxybutyrate and lactate, whereas neonates

with GSD1 are often not even diagnosed until they are toddlers and rarely have significant brain damage.

In conclusion, there is no one cutoff for what level of hypoglycemia causes brain damage; rather, it is a complex interplay of fuel availability, oxygen levels, and blood flow that all combine to maintaining the integrity of the brain.

CLINICAL SYMPTOMS AND SIGNS ASSOCIATED WITH HYPOGLYCEMIA

The clinical features of hypoglycemia in infants may be associated with both neurogenic and neuroglycopenic components (Box 7.3). Symptoms are often subtle and nonspecific, therefore a high index of clinical suspicion must be maintained. Any alteration in clinical status in a newborn that suggests a change in neurologic behavior, fall in temperature, change in feeding pattern, or presence of tremors must be considered a possible initial presentation of a hypoglycemic episode. A seizure or apnea must always be considered a possible manifestation of hypoglycemia and plasma glucose should be measured immediately.

BOX 7.3 Hypoglycemia Signs in Neonates

NEUROGENIC (ADRENERGIC OR CHOLINERGIC)

- Jitteriness
- Tachycardia
- Pallor
- Hypothermia

NEUROGLYCOPENIC

- Lethargy
- Irritability
- Poor feeding
- Cyanosis
- Tachypnea
- Apneic episodes
- Weak/high-pitched cry
- Floppiness
- Eye-rolling
- Lip smacking
- Twitching, convulsions

DIAGNOSTIC APPROACH

Determining the specific underlying cause of hypoglycemia is critical for the establishment of specific treatment and thus prevention of further episodes of hypoglycemia. The diagnosis should be based on the combination of data obtained from the history, physical examination, laboratory findings, and, especially, the hormonal and fuel responses at the time of hypoglycemia.

Important elements from the pregnancy and perinatal history, in addition to the family history, are critical to determine the existence of risk factors that could point to specific diagnoses, for example perinatal stress-induced hyperinsulinism in a neonate with IUGR. Information regarding the duration of fasting that provoked hypoglycemia is also helpful, for example, onset within a few hours of a meal would be consistent with hyperinsulinism or GSD I, whereas onset after 10 to 12 hours would be consistent with a defect in fatty acid oxidation. Pituitary deficiency with GH or adrenocorticotropic hormone (ACTH)-cortisol deficiency might be suspected by the presence of midline facial malformations, microphthalmia, or microphallus (follicle-stimulating hormone [FSH]/luteinizing hormone [LH] deficiency in utero). Growth failure is also a prominent feature of GSD I or debrancher deficiency glycogen storage disease after the first 3 months of life. Both of these disorders are associated with massive hepatomegaly. Abnormal results of liver function tests (transaminases) and hyperammonemia, with or without elevated creatine kinase level, would suggest a possible fatty acid oxidation disorder (see Table 7.2).

A logical diagnostic approach is to analyze a hypoglycemic event as a maladaptation to fasting, and thus the most important information required for diagnosis, comes from tests on the blood and urine specimens obtained at the time of hypoglycemia (also known as the *critical samples*). Fig. 7.4 outlines an algorithm for diagnosis of different forms of hypoglycemia based on readily available laboratory tests on the critical samples. The first discriminant is a measure of acidemia at the time of hypoglycemia using the serum bicarbonate. If the acidemia is caused by elevations of the ketoacids (β -hydroxybutyrate and acetoacetate), possibilities include a normal child fasted for too long, a defect in glycogenolysis (glycogen storage disease type 3), or counterregulatory hormone deficiency (hypopituitarism). If the acidemia is caused by an elevation of lactic acid, a block of gluconeogenesis should be suspected (GSD I or fructose 1,6-diphosphatase deficiency or ethanol ingestion). If

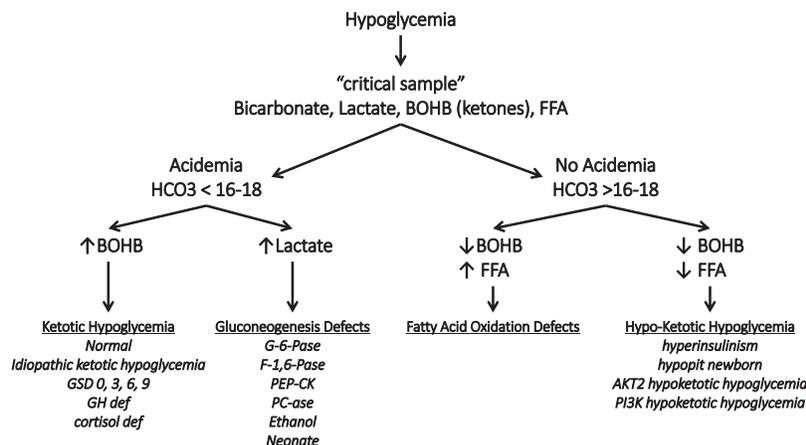

Fig. 7.4 Algorithm for diagnosis of hypoglycemia based on "critical" blood tests obtained during an episode of hypoglycemia. *BOHB*, β -hydroxybutyrate; *FFA*, free fatty acids; *GSD*, glycogen storage disorder; *HCO₃*, bicarbonate. (Modified from Stanley, C.A., Baker, L. (1978). Hypoglycemia. In: Kaye, R., Oski, F.A., Barness, L.A. (eds.), *Core Textbook of Pediatrics*. JB Lippincott, Philadelphia, p. 280–305.)

there is no acidemia (i.e., absence of the normal elevation of ketones) but free fatty acid levels are high, a defect in fatty acid oxidation and ketogenesis should be suspected (e.g., medium-chain acyl-CoA dehydrogenase deficiency [MCAD] deficiency). If ketones are not appropriately increased but the free fatty acid concentrations are also suppressed, hyperinsulinism should be suspected. In the neonatal period, the features of hyperinsulinism can be mimicked by congenital pituitary hormonal deficiency.

Further tests can then be planned using the initial critical specimens to confirm the suspected diagnosis. These may include physiologic tests (such as the glucagon stimulation test at a time of hypoglycemia to confirm hyperinsulinism) or specialized laboratory tests (such as a plasma acylcarnitine profile) to identify a defect in mitochondrial β -oxidation.

If a critical sample obtained during a spontaneous episode of hypoglycemia is not available, a formal fasting test may be necessary to diagnose the cause of hypoglycemia. The goal of this test is to reproduce the setting in which hypoglycemia occurs to identify the underlying cause. The fasting test should be considered a method of testing a hypothesis that has already been developed, based on available clinical and laboratory data about the cause of the hypoglycemia. Thus the test can be modified with additions or deletions to the basic protocol. This is important, because challenging an infant with fasting is not without risk—particularly if a genetic defect in fatty acid oxidation or adrenal insufficiency is present. Therefore fasting or other diagnostic challenges should be done only in the hospital under carefully controlled settings with an experienced physician and nursing staff readily available. Infants younger than 1 year are usually fasted for up to 24 hours, whereas in older children the maximum fast may be up to 36 hours. The fast is terminated when the plasma glucose falls below 2.8 mmol/L (50 mg/dL), but it may be ended sooner if plasma β -hydroxybutyrate rises to greater than 2.5 mmol/L or if there are any adverse signs or symptoms. Periodic blood samples are obtained for analysis of major fuels and hormones and for appropriate ancillary tests (e.g., serum total carnitine, acylcarnitine profile, liver transaminases, creatine phosphokinase, or urinary organic acids). If hyperinsulinism is suspected, the fasting test may be ended with glucagon (1 mg given IV) to evaluate the glycemic response.

Special note should be made that the most frequent cause of hypoglycemia in neonates, infants, and children (hyperinsulinism) often cannot be diagnosed based solely on the plasma insulin concentration. With very sensitive assays, serum insulin concentrations will be less than 1 to 2 μ U/mL at times of hypoglycemia (i.e., below the sensitivity of most insulin assays). However, serum C-peptide concentrations may be a useful marker with values of 0.5 ng/mL or higher strongly suggestive of hyperinsulinism, as shown in Table 7.3. Therefore the

diagnosis must often be made based on evidence of inappropriate insulin effects: hypoketonemia, hypo-free fatty acidemia, and a positive glycemic response to glucagon (see Table 7.3).

CLASSIFICATION OF CAUSES OF PERSISTENT HYPOGLYCEMIA IN THE NEONATE AND INFANT (BOX 7.4)

Hyperinsulinism and Similar Disorders

Suppression of insulin secretion is critical for maintaining euglycemia during fasting through the activation of hepatic glycogenolysis, gluconeogenesis, and fatty acid oxidation. Indeed, failure to suppress insulin secretion is the most common cause of persistent hypoglycemia in neonates and children. The clinical and biochemical hallmarks of increased insulin secretion/actions in the neonate are (1) increased birth weight because of the growth-promoting effects of insulin in utero; (2) increased glucose utilization; and (3) evidence that glycogenolysis, lipolysis, and ketogenesis are suppressed, as inferred by the finding of a glycemic response to glucagon (an increase of >30 mg/dL), and the suppression of plasma free fatty acids

BOX 7.4 Classification of Causes of Persistent Hypoglycemia in the Neonate and Infant

- A. Disorders of Insulin Excess or Actions
 1. Hyperinsulinism
 - a. Perinatal Stress-Induced Hyperinsulinism
 - b. Monogenic Hyperinsulinism
 - K*_{ATP} Hyperinsulinism

TABLE 7.3 Criteria for Diagnosing Hyperinsulinism Based on “Critical” Samples (Drawn when Plasma Glucose is Less Than 50 mg/dL)

Parameter	Sensitivity (%)	Specificity (%)
Insulin >2 μ U/mL ^a	82.2	100
C-Peptide ≥ 0.5 ng/mL	88.5	100
β -hydroxybutyrate <1.8 mmol/L	100	100
Free Fatty Acids <1.7 mmol/L	87	100
IGFBP-1 ≤ 110 ng/mL	85	96.6
Glycemic response to glucagon >30 mg/dL	89	100

^aDepends on sensitivity of insulin assay. *IGFBP*, Insulin-like growth factor binding-protein.

and β -hydroxybutyrate concentrations during hypoglycemia (see Table 7.3).

The lack of alternative fuels (ketones) during hypoglycemia heightens the risk of brain damage in infants with these conditions, thus, it is essential that the diagnosis and establishment of treatment are expedited. The differential diagnosis and mechanisms of disease are broad, but they can be grouped in two categories: (1) hyperinsulinism caused by dysregulated insulin secretion, and (2) mimickers of hyperinsulinism, in which insulin secretion by the pancreatic beta cells is appropriately suppressed during hypoglycemia, but the effects of insulin on insulin-responsive tissues is inappropriately turned on.

Hyperinsulinism

Hyperinsulinism is the most common cause of persistent hypoglycemia in neonates, infants, and children.⁵⁵ Hyperinsulinism is caused by dysregulated insulin secretion from the pancreatic β -cells and can be the result of perinatal factors (perinatal stress-induced hyperinsulinism); monogenic, because of mutations in genes important for the regulation of insulin secretion; or syndromic (as in BWS).⁵⁶

Transient Hyperinsulinism Resulting from Maternal Factors

Transient hyperinsulinism is a well-recognized complication in neonates after a pregnancy complicated by gestational diabetes. At birth, infants born to these mothers may be large and plethoric—and their body stores of glycogen, protein, and fat are replete. The classic clinical description of the effect of hyperinsulinism relates to the infant of the diabetic mother:⁵⁷

These infants are remarkable not only because like fetal versions of Shadrack, Meshack, and Abednego, they emerge at least alive from within the fiery metabolic furnace of diabetes mellitus, but because they resemble one another so closely they might well be related. They are plump, sleek, liberally coated with vernix caseosa, full-faced, and plethoric. The umbilical cord and placenta share in the gigantism. During their first 24 or more extrauterine hours, they lie on their backs, bloated and flushed, their legs flexed and abducted, their lightly closed hands on either side of the head, the abdomen prominent and their respiration sighing. They convey a distinct impression of having had such a surfeit of both food and fluid pressed upon them by an insistent hostess that they desire only peace so that they may recover from their excesses. On the second day, their resentment of the slightest noise improves the analogy when their trembling anxiety seems to speak of intrauterine indiscretions of which we know nothing.

The hypoglycemia in infants of diabetic mothers is caused by hyperinsulinemia triggered by maternal hyperglycemia.^{58,59} Infants born to diabetic mothers also have a subnormal surge in plasma glucagon immediately after birth, subnormal glucagon secretion in response to stimuli, and (initially) excessive sympathetic activity that may lead to adrenomedullary exhaustion because urinary excretion of epinephrine is diminished.^{60,61} Thus despite their abundance of tissue stores of available substrate, the normal plasma hormonal pattern of low insulin, high glucagon, and catecholamines is reversed. Their endogenous glucose production is inhibited and glucose utilization is increased compared with that in normal infants, thus predisposing them to hypoglycemia.

Mothers whose diabetes has been well controlled during pregnancy in general, have near-normal-sized infants who are less likely to develop neonatal hypoglycemia and other complications formerly considered typical of maternal diabetes. Nevertheless, treatment of infants born to mothers with diabetes

commonly requires provision of IV glucose for a few days, until the hyperinsulinemia abates.

During labor and delivery, maternal hyperglycemia should be avoided because it may result in fetal hyperglycemia—which predisposes to rebound hypoglycemia when the glucose supply is interrupted at birth. Other maternal factors that can result in transient neonatal hyperinsulinism include oral hypoglycemics (such as sulfonylureas) or other medications (terbutaline or propranolol).

By definition, transient hyperinsulinism, as a cause of neonatal hypoglycemia in an infant of a diabetic mother, should abate in 1 or 2 days. If the condition persists, prolonged or congenital hyperinsulinism must be considered.

Perinatal Stress-Induced Hyperinsulinism

The process of beta cell maturation after birth may be impacted by perinatal factors resulting in perinatal stress-induced hyperinsulinism, a distinct form of hyperinsulinism that spontaneously resolves within the first few weeks of life. Perinatal factors associated with perinatal stress-induced hyperinsulinism include birth asphyxia, maternal preeclampsia, prematurity, intrauterine growth retardation, and other peripartum stress.^{42–44} Up to 50% of neonates in these at-risk categories may be affected.⁶² The estimated incidence of perinatal stress-induced hyperinsulinism is 1:6,000 to 12,000 live births.⁴⁴

The clinical presentation of perinatal stress-induced hyperinsulinism is characterized by high glucose utilization, and the response to fasting hypoglycemia shows inappropriately detectable plasma insulin, low plasma β -hydroxybutyrate and free fatty acid concentrations, and inappropriate glycemic response to glucagon at the time of hypoglycemia. Unlike the transient hyperinsulinism seen in the infant of the diabetic mother, perinatal stress-induced hyperinsulinism may persist for several weeks. In a series of neonates with perinatal stress-induced hyperinsulinism, the median age of resolution was 6 months.⁴⁴ The mechanism responsible for the dysregulated insulin secretion is not known. Acute insulin responses show that, in general, the patterns of insulin response to secretagogues (calcium, tolbutamide, glucose, and leucine) in infants with perinatal stress-induced hyperinsulinism resembled those of normal controls.⁴⁴

Infants with perinatal stress-induced hyperinsulinism usually respond very well to medical therapy with diazoxide.^{42–44} Previously, it was common practice to use pharmacologic doses of glucocorticoids to treat such neonates with persistent hypoglycemia. However, the use of glucocorticoids as nonspecific therapy for neonatal hypoglycemia is not recommended because they are not only ineffective, but also can suppress the hypothalamic-pituitary-adrenal axis.

Monogenic Hyperinsulinism

Congenital hyperinsulinism, also known as *persistent hyperinsulinemic hypoglycemia of infancy*, represents a group of clinically and genetically heterogeneous disorders characterized by dysregulated insulin secretion and resulting in severe and persistent hypoglycemia. First described in 1954 by MacQuarrie⁶³ as “idiopathic hypoglycemia of infancy,” congenital hyperinsulinism is the most common cause of persistent hypoglycemia in neonates, infants, and children. Worldwide, the incidence of congenital hyperinsulinism is estimated at 1 in 50,000 live births, with higher incidence of up to 1 in 2500 in areas of high consanguinity.⁶⁴

To understand the pathophysiology of congenital hyperinsulinism, knowledge of the major pathways regulating insulin secretion by pancreatic β -cells is critical (outlined in Fig. 7.5). Glucose-stimulated insulin secretion involves glucose entry

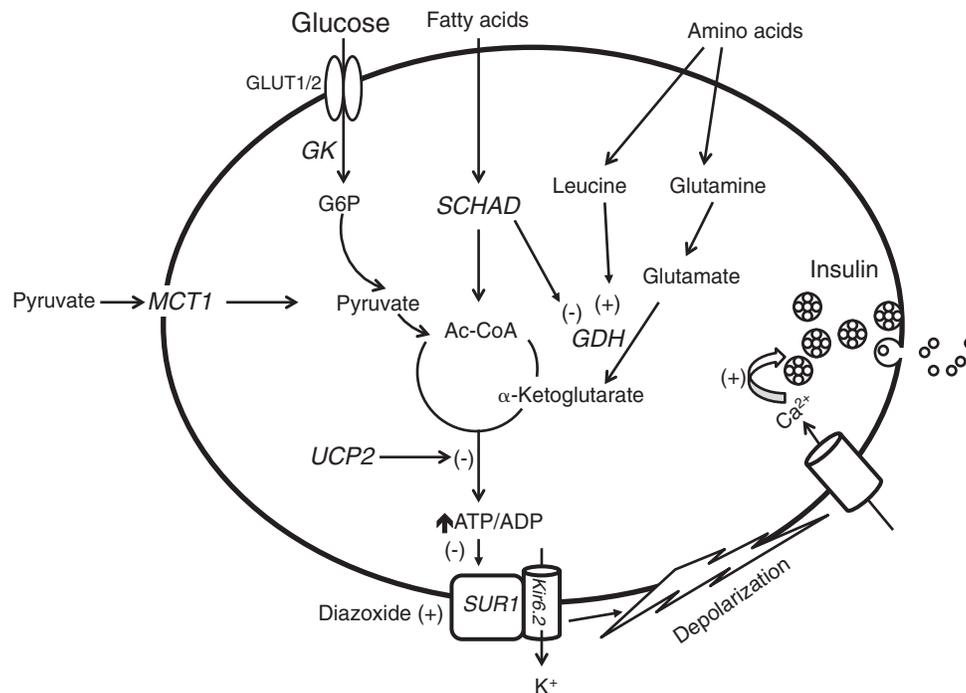

Fig. 7.5 Current model of mechanisms of insulin secretion by the beta cell of the pancreas. Glucose transported into the beta cell by the insulin-independent glucose transporter GLUT2/GLUT1 undergoes phosphorylation by glucokinase and is then metabolized, resulting in an increase in the adenosine triphosphate/adenosine diphosphate (ATP/ADP) ratio. The increase in the ATP/ADP ratio closes the K_{ATP} channel and initiates the cascade of events characterized by increase in intracellular potassium concentration, membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by allosterically activating glutamate dehydrogenase (GDH) and by increasing the oxidation of glutamate, thereby increasing the ATP/ADP ratio and closure of the K_{ATP} channel. Diazoxide inhibits insulin secretion by stimulating the K_{ATP} channel. The gene defects known to cause hyperinsulinism are shown in italics. Six are inactivating mutations: *SUR1* (sulfonylurea receptor), *Kir6.2* (potassium channel), *SCHAD* (short-chain 3-OH acyl-CoA dehydrogenase), *UCP2* (uncoupling protein 2), *HNF4A* (hepatic nuclear transcription factor 4 alpha), and *HNF1A* (hepatic nuclear transcription factor 1 alpha). Three are activating mutations: *GK* (glucokinase), *GDH* (glutamate dehydrogenase), and *MCT1* (monocarboxylate transporter 1). (–), Inhibition; (+), stimulation.

to the beta cell by facilitated diffusion through glucose transporters (mainly GLUT1 in human beta cells)⁶⁵ and phosphorylation by glucokinase (GK), leading to glucose oxidation and a rise in the ATP/adenosine diphosphate (ADP) ratio that results in closure of the plasma membrane ATP-dependent potassium (K_{ATP}) channel. The β -cell K_{ATP} channel is a heteroameric complex consisting of two subunits: a K^+ -selective pore-forming subunit (*Kir6.2*), and a regulatory subunit (sulfonylurea receptor 1 [*SUR-1*]). Four *Kir6.2* subunits form the central pore, coupled to four *SUR-1* subunits. The K_{ATP} channel is inhibited (closed) by sulfonylurea drugs (used therapeutically to stimulate insulin secretion in type 2 diabetes), and activated (opened) by diazoxide (the first-line medical treatment for congenital hyperinsulinism). In the unstimulated state, the β -cell ATP-sensitive potassium channels are open—keeping a resting membrane potential of approximately -65 mV. Following the uptake and metabolism of glucose, increase in the intracellular ATP/ADP ratio results in closure of ATP-sensitive potassium channels, depolarization of the cell membrane, opening of voltage-dependent Ca^{2+} channels, Ca^{2+} influx, rise in cytosolic free Ca^{2+} concentration, and activation of the exocytotic machinery.⁶⁶ Stimulation of insulin secretion by amino acids occurs through allosteric activation of glutamate dehydrogenase (GDH) by leucine, which results in increased oxidation of glutamate—leading to a rise in the ATP/ADP ratio, inhibition of K_{ATP} -channel activity, and membrane depolarization.

Mutations in genes encoding 10 factors involved in different steps of this pathway have been associated with congenital hyperinsulinism: *SUR-1*, a member of the superfamily of ATP-binding cassette proteins, encoded by *ABCC8*;⁶⁷ *Kir6.2*,

encoded by *KCNJ11*;⁶⁸ *GK*, encoded by *GCK*;⁶⁹ *GDH*, encoded by *GLUD1*;⁷⁰ the mitochondrial enzyme short-chain 3-hydroxyacyl-CoA dehydrogenase (*SCHAD*), encoded by *HADH*;⁷¹ monocarboxyl transporter-1 (*MCT-1*), encoded by *SLC16A1*;⁷² uncoupling protein-2 (*UCP2*), encoded by *Ucp2*;⁷³ hepatocyte nuclear factor 4 alpha (*HNF4A*), encoded by *HNF4A*;⁷⁴ hepatocyte nuclear factor 1 alpha (*HNF1A*), encoded by *HNF1A*;⁷⁵ and forkhead box A2 (*Foxa2*), encoded by *FOXA2*.⁷⁶ In this chapter, we review the forms more likely to present in the neonatal period. For a discussion of *MCT-1* hyperinsulinism, see Chapter 23.

K_{ATP} Hyperinsulinism. Inactivating mutations of the beta cell K_{ATP} channels are responsible for the most common and most severe form of congenital hyperinsulinism. According to the severity of the molecular defect and the phenotype, K_{ATP} HI can be classified into three subtypes: (1) recessive, diazoxide-unresponsive; (2) dominant, diazoxide-unresponsive; and (3) dominant, diazoxide-responsive. Recessive mutations interfere with protein expression or channel trafficking, resulting essentially in a complete absence of channels on the plasma membrane, and therefore diazoxide is not effective. Recessive mutations are the most common defects identified in children with congenital hyperinsulinism. Dominant mutations allow normal trafficking of the channels to the plasma membrane, but impair channel activity either completely or partially, resulting in a spectrum of phenotypes that go from severe, diazoxide-unresponsive to mild, diazoxide-responsive.⁷⁷

The clinical presentation of K_{ATP} HI then depends on the severity of the mutation effect. More commonly, these children are large for gestational age and have severe neonatal

hypoglycemia that does not respond to diazoxide, except for the cases with a dominant diazoxide-responsive subtype in which birth weight is normal and the clinical presentation tends to occur later in life.⁷⁸

The pathophysiology of K_{ATP} -HI has been illustrated by functional evaluation of islet function *in vivo* and *in vitro*.^{79–82} The absence of functional K_{ATP} channels results in uncoupling between plasma glucose and insulin secretion or β -cell “glucose blindness.” Thus insulin secretion is not turned off, as plasma glucose decreases and fails to increase in response to a rapid raise in plasma glucose (Fig. 7.6). The former defect dominates the clinical manifestations in early infancy, whereas the latter may play a role in later development of glucose intolerance and, possibly, diabetes. In marked contrast with the failure to respond to changing concentrations of plasma glucose, these β -cells are hyperresponsive to stimulation with amino acids,⁸² which results in protein-induced hypoglycemia.⁸³

Other clinical features of infants with K_{ATP} -HI include extremely high glucose requirements, frequently 4 to 5 times higher than normal to control plasma glucose (although in some cases the requirement may be normal), feeding aversion, and gastroesophageal reflux, likely consequences of force feeding. Treatment options for the diazoxide-unresponsive cases are limited. These infants may require pancreatectomy, within the first few weeks after birth, to manage the hypoglycemia. On the other hand, diazoxide is very effective for controlling hypoglycemia in cases with dominant diazoxide-responsive K_{ATP} -HI. Octreotide, a long-acting somatostatin analog, is a second-line medical therapy for infants unresponsive to diazoxide, although the US Food and Drug Administration (FDA) has not approved it for this indication, and because of concerns with a possible association with necrotizing enterocolitis, its use should be carefully considered.^{84,85} A nonsurgical approach in diazoxide-unresponsive hyperinsulinism consists of octreotide in combination with continuous or frequent enteral feedings or continuous dextrose through a gastrostomy.^{86,87} This approach is challenging for home management of these children, and it requires close supervision and frequent glucose testing.

There are two distinctive histologic forms of K_{ATP} -hyperinsulinism, focal and diffuse hyperinsulinism.

Focal K_{ATP} -Hyperinsulinism (Focal Adenomatosis). Approximately 40% to 60% of the cases of K_{ATP} -HI (which require surgery) have focal disease.⁸⁸ Focal lesions arise by a “two-hit” mechanism: (1) a paternally inherited mutation of the *ABCC8* or *KCNJ11* gene (located on the 11p15 chromosome), and (2) a deletion of maternally inherited 11p15 chromosomal region, compensated by a paternal uniparental disomy, as observed in some cases of BWS. The 11p15 region, which carries the *ABCC8* and *KCNJ11* genes, contains several imprinted genes: insulin-like growth factor 2 (*IGF2*), a growth-promoting protein is expressed from the paternal chromosome, whereas, *H19*, a long noncoding ribonucleic acid (RNA) growth suppressor and *CDKN1C*, a cell cycle regulator and growth inhibitor, are expressed from the maternal chromosome. Loss of these growth-suppressing genes, while the paternal growth-promoting gene is active, play an important permissive role in the clonal expansion of the cells expressing the mutated channel.⁸⁹

Diffuse Hyperinsulinism. In diffuse hyperinsulinism, all β -cells in the pancreas are affected. It results from the inheritance of two recessive mutations in *ABCC8* or *KCNJ11* or a dominant mutation in these genes.

Neonates with the diffuse hyperinsulinism are more likely to present at birth, whereas those with focal form may fail detection in the neonatal period and present at several weeks to months of life with hypoglycemia seizures.⁹⁰ However, because of significant overlap in clinical presentation, clinical features alone cannot be used to distinguish between the two forms. Genetic testing offers the best means of identifying infants with focal K_{ATP} -HI: a single recessive paternally inherited mutation in *ABCC8* or *KCNJ11* has a positive predictive value of 94% for focal hyperinsulinism.⁹¹

Histologically, diffuse and focal hyperinsulinism are distinct.⁹⁰ Diffuse hyperinsulinism is characterized by the presence of abnormally large islet cell nuclei distributed throughout the pancreas. In contrast, the pancreatic histology in focal hyperinsulinism is characterized by a lesion formed by the confluence of hyperplastic islets occupying more than 40% of the cross-sectional area of pancreatic lobules. In contrast to true adenomas, the focal adenomatous hyperplasia includes exocrine acinar cells intermixed within the lesion. The morphology of islets away from the focal lesion is

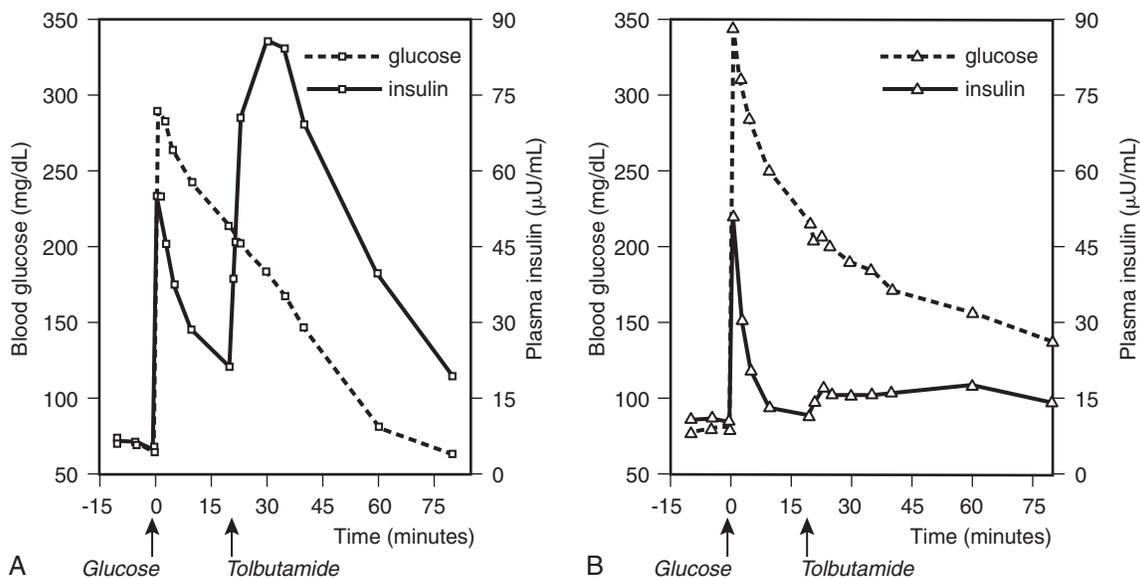

Fig. 7.6 Acute insulin response to glucose and tolbutamide in children with diffuse K_{ATP} hyperinsulinism (mean 11- and 13-minute increments). **A**, Normal adult control. **B**, Patient with diffuse K_{ATP} hyperinsulinism. (From Grimberg, A., Ferry, R.J., Kelly, A., et al. (2000). Dysregulation of insulin secretion in children with congenital hyperinsulinism caused by sulfonylurea receptor mutations. *Diabetes*, 50, 322.)

normal.⁹² The ability to interpret these histologic characteristics requires specialized training and is only available at centers with dedicated multidisciplinary teams to evaluate and treat hyperinsulinism.

Focal K_{ATP} HI is curable by surgery, whereas surgery is only palliative for diffuse K_{ATP} HI. Therefore efforts to diagnose and localize focal lesions in infants with diazoxide-unresponsive hyperinsulinism before surgery are critical. Conventional imaging techniques, such as computed tomography (CT) or magnetic resonance imaging, are unable to detect focal lesions. Interventional radiology studies, such as transhepatic portal venous insulin sampling⁹³ and selective pancreatic arterial calcium stimulation,⁹⁴ have only modest success, are technically difficult, and are highly invasive. The gold standard technique to localize the focal lesions is positron emission tomography (PET) scanning with fluorine-18 L-3, 4-dihydroxyphenylalanine (¹⁸F-fluoro-L-DOPA).^{95–97} Pancreatic β -cells take up L-DOPA,⁹⁸ and DOPA decarboxylase is active in pancreatic islet cells.⁹⁹ In children with focal hyperinsulinism, there is localized accumulation of ¹⁸F-fluoro-L-DOPA (Fig. 7.7). Coregistration of PET and CT images allows the anatomic localization of the lesion (Fig. 7.8).

Glutamate Dehydrogenase-Hyperinsulinism: The Hyperinsulinism Hyperammonemia Syndrome. Congenital hyperinsulinism caused by gain-of-function mutations of *GLUD1* (encoding GDH) is the second most common form of genetic hyperinsulinism and the most common form that responds to treatment with diazoxide.^{70,100–103} In approximately 70% of the cases, the mutations are de novo.¹⁰⁴ Among the 30% of familial cases, a clear autosomal dominant pattern of inheritance is evident.

GDH is a mitochondrial matrix enzyme that is a key regulator of amino acid and ammonia metabolism in pancreatic β -cells, liver, kidney, and brain. As shown in Fig. 7.5, GDH is allosterically activated by leucine to oxidize glutamate to α -ketoglutarate, which enters the Krebs cycle, resulting in an increased ATP/ADP ratio—which triggers insulin release. The HI/HA mutations affect either the inhibitory guanosine-5'-triphosphate (GTP)-binding site or the antenna loop of the enzyme, which communicates between adjacent subunits, impairing the inhibitory allosteric effect of GTP on GDH enzyme activity, thus leading to excessive insulin release.

The clinical presentation of HI/HA is characterized by fasting and protein-induced hypoglycemia and persistent but

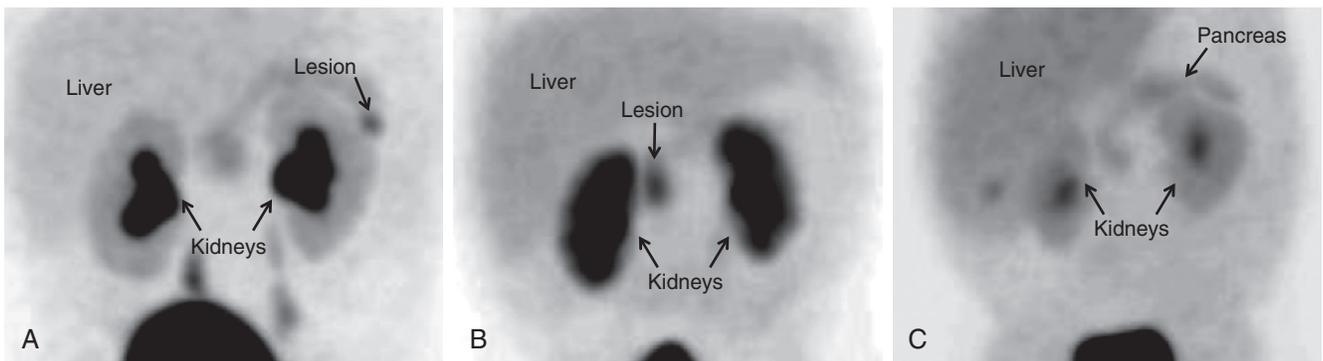

Fig. 7.7 ¹⁸Fluoro-L-DOPA PET scan images showing L-DOPA uptake in the liver, kidneys, and pancreas. Note increased uptake in the tail (A) and head (B) of the pancreas demonstrating focal lesions. In contrast, diffuse hyperinsulinism uptake throughout the pancreas is uniform (C).

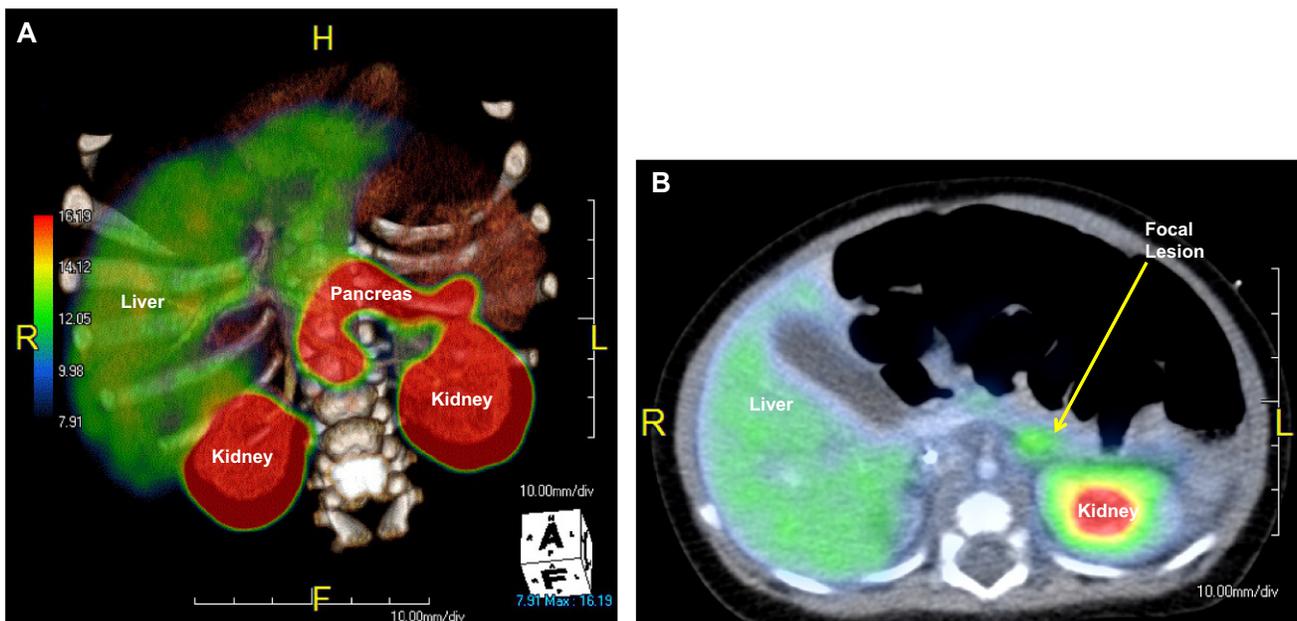

Fig. 7.8 A, Frontal view of fused positron emission tomography (PET)/computed tomography (CT) scan image of a diffuse case of hyperinsulinism showing L-3, 4-dihydroxyphenylalanine (L-DOPA) uptake in the liver, in the kidneys, and throughout the pancreas with equal intensity. **B**, Axial image of a contrast-enhanced CT scan fused with an ¹⁸Fluoro-L-DOPA PET scan showing a focus of increased uptake in the posterior body of the pancreas. asymptomatic elevation of plasma ammonia.¹⁰⁵ Infants with HI/HA have normal birth weight and typically are not diagnosed until later in infancy. Plasma ammonia levels in HI/HA are elevated 3 to 5 times above the normal range to approximately 60 to 150 $\mu\text{mol/L}$. Ammonia levels are quite constant, and in contrast to the urea cycle enzyme defects, do not increase with protein feeding. The hyperammonemia does not appear to cause symptoms and does not require treatment.

The clinical phenotype of HI/HA is dominated by the effects of the activating mutations in the pancreatic β -cells. Isolated islets from transgenic mice expressing a mutated human GDH exhibit normal glucose-stimulated insulin secretion but enhanced leucine- and amino-acid-stimulated insulin secretion.¹⁰⁶ In children with HI/HA, there is a dramatic increase in insulin following an IV bolus of leucine, but in contrast to children with K_{ATP} -HI, they do not respond to calcium stimulation.¹⁰⁷ The hypoglycemia in children with HI/HA is provoked by fasting and by protein-rich meals. The fasting hypoglycemia may be relatively mild. Children may be able to fast for 8 to 12 hours before experiencing hypoglycemia. However, these patients have dramatic protein-induced hypoglycemia—with plasma glucose concentration dramatically decreasing 30 to 90 minutes after a protein meal¹⁰⁵ (Fig. 7.9). Diazoxide therapy, 5 to 15 mg/kg/day, is usually effective in controlling both fasting and protein-induced hypoglycemia in HI/HA. Carbohydrate preloading may be helpful in avoiding the latter.¹⁰⁴

Initially, the hyperammonemia was presumed to be caused by the effects of the mutated enzyme in the liver; however, an alternative mechanism involving activation of renal GDH seems to be more likely.¹⁰⁸ The hyperammonemia is persistent and not associated to the classic signs of ammonia toxicity. It occurs in both the fed and fasted states and is unaffected by plasma glucose concentrations or protein intake.

In addition to hypoglycemia and hyperammonemia, patients with HI/HA syndrome have an increased frequency of seizures, learning disability, and behavioral disorders that are not directly linked to hypoglycemia.^{109,110} Studies describing the neurologic manifestations of HI/HA are limited; however, available evidence suggests that 42% to 64% of patients have generalized epilepsy that is characterized by high-amplitude generalized spike and wave discharges on

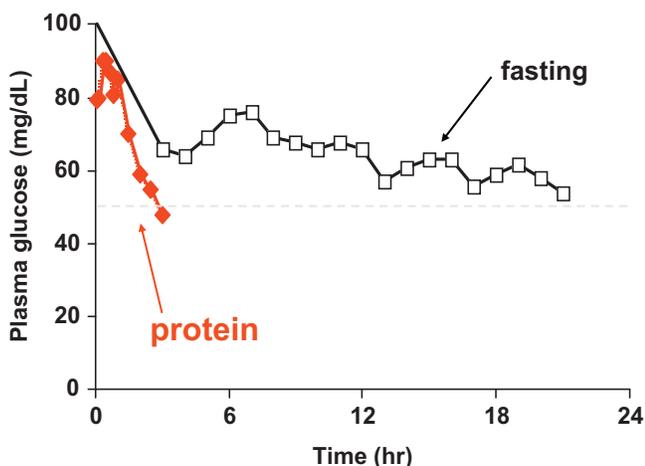

Fig. 7.9 Plasma glucose responses to fasting (open squares) and protein feeding (solid diamonds) in a 16-year-old girl with the hyperinsulinism/hyperammonemia syndrome caused by a dominantly expressed R269H regulatory mutation of glutamate dehydrogenase. (From Hsu, B.Y., Kelly, A., Thornton, P.S., et al. (2001). Protein-sensitive and fasting hypoglycemia in children with the hyperinsulinism/hyperammonemia syndrome. *J Pediatr*, 138, 383.)

electroencephalogram (EEG).^{109,111} The pathophysiology of the neurologic manifestations has not been elucidated. A proposed mechanism involves GDH overactivity in brain cells, leading to disruption of central nervous system glutamate pools, resulting in an imbalance between the major excitatory and inhibitory neurotransmitters, glutamine and γ -aminobutyric acid (GABA), respectively.¹¹¹

SCHAD-Hyperinsulinism. A less common form of congenital hyperinsulinism, also involving loss of regulation of GDH activity, is caused by inactivating mutations in *HADH* (the gene encoding the mitochondrial SCHAD).^{71,112,113} SCHAD-HI is an autosomal recessive disorder characterized by fasting hypoglycemia caused by inappropriate insulin regulation. The cause of dysregulated insulin secretion was elucidated with the discovery that in the β cell, SCHAD plays an inhibitory role in GDH activity.¹¹⁴ Thus the insulin dysregulation observed in SCHAD deficiency is caused by loss of this inhibition, explaining the clinical similarities between GDH-HI and SCHAD-HI.

In contrast to all other defects in fatty acid oxidation, children with SCHAD-HI have no signs of hepatic dysfunction or cardiomyopathy, or of effects on skeletal muscles. The clinical presentation of SCHAD-HI is heterogeneous, ranging from late onset of mild hypoglycemia to severe early onset of hypoglycemia in the neonatal period. In addition to fasting hypoglycemia, children with SCHAD-HI exhibit protein-induced hypoglycemia, similar to the children with GDH-HI.¹¹⁵ The biochemical hallmarks, in addition to markers of increased insulin action, are increased concentration of plasma 3-hydroxybutyryl-carnitine and increased urine concentration of 3-hydroxyglutarate, findings consistent with reduced SCHAD enzyme activity. In contrast to GDH-HI, children with SCHAD-HI do not have elevated ammonia, probably because of the lower expression of SCHAD in other tissues where GDH is expressed. Affected children are responsive to medical therapy with diazoxide.

Glucokinase-Hyperinsulinism. A less frequent form of congenital hyperinsulinism is caused by activating mutations in *GCK* (encoding glucokinase-GK). Glucokinase is a hexokinase that serves as the glucose sensor in pancreatic β -cells¹¹⁶ (see Fig. 7.5). In contrast to other hexokinases, GK has a much lower affinity for its substrate with half-maximal activity ($S_{0.5}$) at a glucose concentration of 7.6 mM. The properties of GK and the positive cooperative action of glucose on enzyme activity, with a curve that is steep in the range of 5 mM glucose, make GK well suited to tightly control plasma glucose in the normal physiologic range of 70 to 100 mg/dL.²⁵ Mutations in *GCK* alter the kinetics of glucokinase by increasing the enzyme affinity for glucose and cause hypoglycemia by lowering the threshold for glucose-stimulated insulin secretion in the beta cell.^{69,117,118} In contrast, heterozygous inactivating *GCK* mutations lead to maturity-onset diabetes of youth type 2 (MODY 2)¹¹⁹ and homozygous inactivating *GCK* mutations are a cause of permanent neonatal diabetes.¹²⁰ Some GK-HI cases are sporadic, and some are dominantly inherited. All of the mutations have reduced glucose $S_{0.5}$ ranging from 1.1 to 4.5 mM.

The clinical presentation of GK-HI is characterized by large for gestational age birth weight, reflecting the growth-promoting effects of increased fetal insulin secretion. Hypoglycemia may present in the neonatal period, but often it is not recognized until later in infancy or childhood. The severity of the phenotype is variable, with some mutations having a mild phenotype, with fasting hypoglycemia responsive to diazoxide, whereas others seem to lower the glucose threshold further and may be more difficult to treat. Based on our experience, diazoxide is uniformly unable to prevent hypoglycemia in children with GK-HI. Treatment with somatostatin analogues has been tried in some

children with GK-HI, with various success. Although some cases have undergone pancreatectomy, most children have continued to have hypoglycemia and required additional medical management after surgery. In some cases, it is necessary to provide continuous support with overnight feedings or glucose to prevent hypoglycemia.

From the few cases that have undergone a pancreatectomy, pancreatic histology has been reported to have little or no abnormal features.^{121–123} Others have reported nuclear enlargement and increased islet size and β -cell proliferation.^{124,125}

Uncoupling Protein-2 Hyperinsulinism. Loss-of-function mutations in the mitochondrial uncoupling protein UCP2 are associated with a dominant, diazoxide-responsive form of congenital hyperinsulinism.⁷³ UCP2 transports protons and phosphate from the cytosol across the inner mitochondrial membrane, in exchange for oxaloacetate and malate. By depleting the pool of mitochondrial tricarboxylic acid cycle intermediates, UCP2 activity restricts glucose oxidation in favor of the oxidation of glutamine and amino acids.¹²⁶ Inactivating mutations of UCP2 then, enhance the oxidation of glucose in pancreatic beta cells, leading to amplification of the insulin response to glucose. Indeed, the phenotype of UCP2-HI is characterized by glucose-induced hypoglycemia in addition to fasting hypoglycemia.¹²⁷

Hepatocyte Nuclear Factors and Hyperinsulinism: HNF1A and HNF4A-Hyperinsulinism. HNF1A and 4A are transcription factors expressed in hepatocytes, pancreatic β -cells, intestinal epithelial cells, and renal tubular cells. In β -cells and hepatocytes, they form a feed-forward loop, such that the haploinsufficiency of either causes decreased expression of the other.¹²⁸ Both HNF1A and HNF4A play an important role on pancreatic β -cell function and heterozygous mutations in the genes encoding them: *HNF1A* and *HNF4A*, respectively, are known to cause familial monogenic diabetes (MODY 3 and MODY 1). These autosomal dominant forms of diabetes are characterized by progressive impairment in glucose-stimulated insulin secretion leading to frank hyperglycemia, usually manifesting before the age of 25 years.¹²⁹

More recently, it has been demonstrated that the phenotype in individuals with inactivating mutations in *HNF1A* and *HNF4A* is biphasic, characterized by persistent hypoglycemia caused by hyperinsulinism early in life, followed by reduced insulin secretion leading to diabetes in early adolescence and young adulthood.^{74,75,130–133} Together, mutations in *HNF1A* and *HNF4A* account for approximately 5.9% of all cases of hyperinsulinism in which a mutation is identified.¹³³

The clinical phenotype of HNF1A- and HNF4A-HI is characterized by large birth weight, although some cases have normal birth weight, and persistent hypoglycemia that is for the most part diazoxide-responsive.¹³⁴ The hyperinsulinism is transient, with some cases resolving within the first few months of life,

whereas in others the hyperinsulinism phase may persist into childhood.

The phenotype in children with a particular mutation in *HNF4A* (p.Arg76Trp) involves extrapancreatic features, including hepatomegaly with elevated transaminases and renal Fanconi tubulopathy, similar to Fanconi-Bickel syndrome.^{75,135,136}

The precise mechanism by which mutations in *HNF1A* and *HNF4A* lead to hyperinsulinism is currently unknown, but it is likely that the defects in these transcription factors alter different gene expression patterns during early and later in life.

FOXA2 Hyperinsulinism. A novel form of hyperinsulinism associated with hypopituitarism was recently described in individuals with inactivating mutations in *FOXA2*.^{76,137} Foxa2 is a transcription factor that is involved in the development of multiple tissues, including the pituitary gland, and also plays an important role in insulin secretion by mature beta cells. The reported cases presented with hypoketotic hypoglycemia in the neonatal period that responded to replacement of pituitary hormones and treatment with diazoxide.

Syndromic Forms of Hyperinsulinism

Several genetic syndromes are now recognized to be associated with hyperinsulinism, including BWS, Kabuki syndrome, and Turner syndrome. Typical clinical features that distinguish these syndromes may be more subtle in the neonatal period, therefore a high index of suspicion and careful clinical evaluation are essential to make the diagnosis.

Hyperinsulinism in Beckwith-Wiedemann Syndrome. BWS is an overgrowth and cancer predisposition syndrome that results from various genetic and epigenetic changes involving two imprinted control centers on chromosome 11p15.5. This region can be divided into two distinct imprinted domains separated by a nonimprinted region. The distal domain 1 contains *IGF2*, a growth-promoting protein which is paternally expressed, and *H19*, a long noncoding RNA growth suppressor expressed from the maternal allele. In the proximal domain 2, the imprinted region contains three genes that have been implicated in BWS: *KCNQ1OT1*, paternally expressed untranslated transcript; *CDKN1C*, which is maternally expressed and encodes a negative regulator of cell proliferation; and *KCNQ1*, a maternally expressed potassium repolarizing channel (Fig. 7.10). Fifty percent of all BWS cases are caused by loss of methylation at the imprinted control region 2, 20% of cases are caused by paternal uniparental isodisomy involving both imprinted gene clusters, 5% are caused by gain of methylation at imprinted control region 1, and 5% are caused by maternally inherited mutations in *CDKN1C*.¹³⁸

The classical features of BWS include macrosomia, macroglossia, visceromegaly, abdominal wall defects, ear creases/pits, body asymmetry, and an increased risk for embryonal tumor development. Hypoglycemia caused by hyperinsulinism is

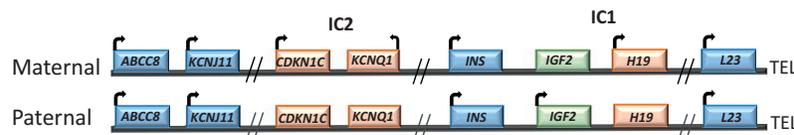

Fig. 7.10 Beckwith-Wiedemann syndrome locus on 11p15.5 outlining the normal parent of origin-specific allelic expression. Expressed genes are noted with an arrow. The genes encoding the K_{ATP} channels, *ABCC8* and *KCNJ11*, as well as insulin (*INS*) and *L23* are biallelically expressed, while *CDKN1C*, *KCNQ1*, *IGF2*, and *H19* are imprinted. IC1 is methylated on the paternal allele, resulting in paternal expression of *IGF2* and unmethylated on the maternal allele resulting in maternal expression of *H19*. IC2 is methylated on the maternal allele resulting in *KCNQ1* and *CDKN1C* expression and unmethylated on the paternal allele. *ABCC8*, ATP-binding cassette, subfamily C, member 8; *CDKN1C*, cyclin-dependent kinase inhibitor 1C; *IC*, imprinting center; *IGF2*, insulin-like growth factor 2; *INS*, insulin; *KCNJ11*, potassium channel, inwardly rectifying, subfamily J, member 11; *KCNQ1*, potassium channel, voltage-gated, KQT-like subfamily, member 1; *L23*, ribosomal protein L23-like; *TEL*, telomere.

present in up to 50% of cases.¹³⁹ The mechanism responsible for hyperinsulinism in BWS has not been elucidated, but may involve dysregulated insulin secretion and beta cell hyperplasia.^{140,141}

The hyperinsulinism in BWS may be mild and transient, although in some cases, it can be severe and persistent.¹³⁹ Some BWS infants respond to diazoxide, whereas others require pancreatectomy to control the hypoglycemia. Because the hyperinsulinism will resolve within the first year of life in most cases, pancreatectomy should be reserved for those cases in which the hypoglycemia cannot be medically controlled.

Hyperinsulinism in Kabuki Syndrome. Kabuki syndrome is the second most common cause of syndromic hyperinsulinism.¹⁴² Some 70% to 75% of cases of Kabuki syndrome are caused by autosomal recessive mutations in *KMT2D* (*lysine-specific methyltransferase 2D*), and X-linked mutations in *KDM6A* (*lysine-specific demethylase 6A*) account for 1% to 9% of cases.¹⁴³ Cardinal features of Kabuki syndrome include the typical “Kabuki Mask” facial characteristics (long palpebral fissure, arched eyebrows, eversion of the external third of the lower lid); skeletal abnormalities; dermatoglyphic abnormalities; neurodevelopmental delay and intellectual disabilities; and postnatal growth retardation. Endocrine manifestations include GH deficiency (22% of cases), hypothyroidism ($\leq 10\%$ of cases), premature thelarche (20%), and neonatal hypoglycemia (11%). The mechanism responsible for the neonatal hypoglycemia may be multifactorial: including hyperinsulinism and GH deficiency.^{144,145} Hyperinsulinism is a feature in up to 6% of Kabuki cases,¹⁴⁶ it is typically present from birth, diazoxide-responsive, and often appears to resolve during the first decade of life.

Hyperinsulinism in Turner Syndrome. It is well known that girls with Turner syndrome have a higher predisposition to both type 1 and type 2 diabetes,¹⁴⁷ but it has been less recognized that they are also predisposed to hypoglycemia.¹⁴⁸ There is increasing evidence that hypoglycemia in girls with Turner syndrome is caused by hyperinsulinism.^{149–153} Indeed, a higher than expected frequency of Turner syndrome among children with hyperinsulinism has been reported.¹⁵¹

Similar to other forms of hyperinsulinism, hyperinsulinism in girls with Turner syndrome more frequently presents shortly after birth and it is usually responsive to treatment with diazoxide, although, some of the reported cases have been unresponsive and severe requiring pancreatectomy. Although the mechanism responsible for hyperinsulinism in Turner syndrome has not been clearly established, a potential candidate gene on the X chromosome is *KDM6A*, a histone demethylase associated with Kabuki syndrome. Histological examination of the pancreas of a girl with Turner syndrome and hyperinsulinism showed increase islet cell nucleomegaly, similar to diffuse hyperinsulinism caused by inactivating K_{ATP} channel mutations. Islets isolated from this pancreas revealed an abnormal but distinct functional pattern, with increased basal cytosolic calcium and insulin, lower threshold for glucose-stimulated insulin secretion, increased sensitivity to stimulation by a mixture of amino acids, and preserved response to stimulation with glyburide.¹⁵¹

MANAGEMENT AND TREATMENT OF HYPERINSULINISM

Treatment of neonates with suspected congenital hyperinsulinism should be initiated promptly, as their risk of brain damage is high because their brain is deprived not only of glucose but also alternative fuels (ketones). Reports from multiple centers have demonstrated a high prevalence of developmental delays in patients with congenital hyperinsulinism, ranging from 30%

to 50%.^{50–54} Patients with hyperinsulinism, requiring surgical therapy, have a higher incidence of neurodevelopmental problems than diazoxide-responsive patients⁵³; however, abnormal neurodevelopment is also seen in up to 30% of infants with transient hyperinsulinism.¹⁵⁴ In general, the high risk of brain damage appears to be caused by delays in diagnosis and treatment rather than a consequence of the molecular defect itself, and thus is potentially preventable.

The goal of therapy is to restore plasma glucose to the normal range (>70 mg/dL) and to maintain it there. IV glucose at high rates, up to 5 times the normal glucose requirement, may be required and central lines may be needed for administration of highly concentrated dextrose. Glucagon, given as a continuous IV infusion (1 mg/day), can be used in infants requiring high glucose infusion rates as a temporary measure to reduce the risk of fluid overload.¹⁵⁵

The first line of therapy for hyperinsulinism is diazoxide, a K_{ATP} -channel opener that requires functional channels to be present at the cell surface to have an effect; thus most patients with K_{ATP} -HI do not respond to diazoxide. In contrast, patients with GDH-HI, HNF1A-HI, HNF4A-HI, SCHAD-HI, and those with perinatal stress-induced hyperinsulinism do respond to diazoxide. Patients with GK-HI are partially responsive to diazoxide and most require additional therapy. The pharmacologic dose range of diazoxide is 5 to 15 mg/kg/day, given orally twice a day. The major adverse event with diazoxide in neonates is fluid retention and therefore concomitant use of a diuretic (chlorothiazide or furosemide) is recommended, especially in infants receiving IV fluids. Pulmonary hypertension is the most serious potential complication; however, its occurrence is rare if appropriate steps are put into place to prevent it, particularly, therapy with diuretics. Other side effects associated with diazoxide include neutropenia, thrombocytopenia, and hyperuricemia.¹⁵⁶ Diazoxide therapy is also associated with significant hypertrichosis and coarsening of facial features.

Evaluation of whether the hyperinsulinism is responsive to diazoxide or not is critical because this determines the treatment path and also offers clues to the potential genetic cause of the hyperinsulinism. The half-life of diazoxide is 24 to 36 hours in adults; limited data indicate that in children, the half-life is 9.5 to 24 hours,¹⁵⁷ therefore the response to diazoxide should be evaluated after at least 5 days of therapy. Successful response should be demonstrated by showing maintenance of plasma glucose above 3.9 mmol/L (70 mg/dL) after fasting. The duration of the fast should be determined on a case-by-case basis, based in part on the age of the child.

Failure to respond to diazoxide suggests the possibility of K_{ATP} -HI and therefore genetic testing is critical to determine the likelihood of focal K_{ATP} -HI.⁹¹ Thus once the diagnosis is established and initial therapy is initiated, samples for the child and the child's parents should be obtained for deoxyribonucleic acid molecular analysis. Fig. 7.11 depicts the diagnostic and treatment approach for children with hyperinsulinism. A cardiac evaluation should also be considered in children with hyperinsulinism, as a large proportion of the cases have cardiac structural abnormalities, more commonly ventricular hypertrophy.¹⁵⁸

For children with diazoxide-unresponsive hyperinsulinism in whom focal hyperinsulinism has been ruled out, medical therapy with second-line agents should be considered, including somatostatin analogues. Somatostatin analogues inhibit insulin secretion by inducing hyperpolarization of β -cells, direct inhibition of voltage-dependent calcium channels, and more distal events in the insulin secretory pathway. The most frequently used somatostatin analogue is octreotide, which is administered SQ every 6 to 8 hours, at 5 to 20 μ g/kg/day. The initial response to octreotide is good in most infants with hyperinsulinism, but tachyphylaxis develops after a few doses,

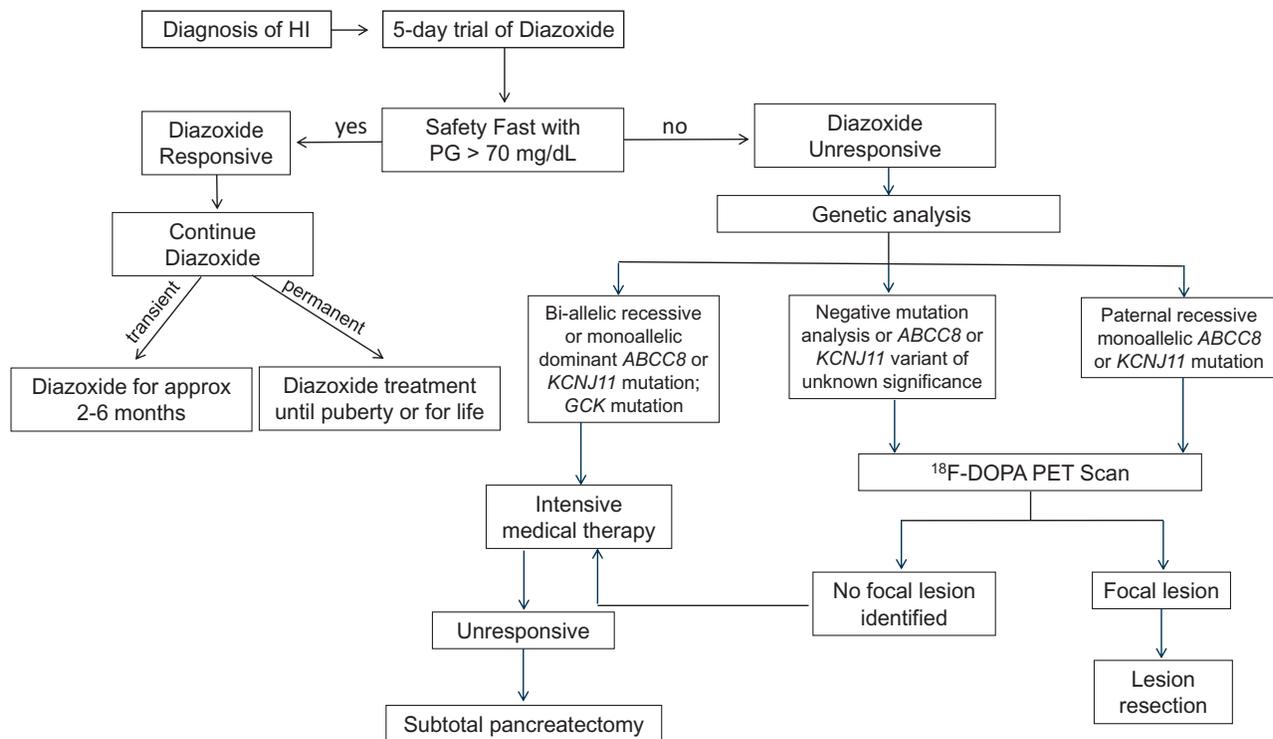

Fig. 7.11 Diagnostic and treatment approach in cases of hyperinsulinism.

rendering therapy inadequate for long-term use in most cases. An approach to avoid the need for multiple injections has been the use of SQ pumps for continuous administration of octreotide (e.g., off-label use of insulin pumps filled with octreotide).¹⁵⁹ A different approach limits dosing of octreotide to twice a day, used in combination with continuous overnight dextrose through a gastrostomy, in an effort to avoid tachyphylaxis.¹⁶⁰ The most frequent side effects of octreotide are transient elevation of liver enzymes, gall bladder pathology, and GH suppression.¹⁶¹ More serious side effects have also been reported, including necrotizing enterocolitis.^{85,162,163} Because of this association, the use of octreotide in infants less than 4 weeks of age or infants with other risk factors should be avoided. Long-acting somatostatin analogues, such as octreotide long-acting release and lanreotide autogel is favored for treatment of older children.^{164–166} Their use in younger children has been limited because dosing cannot be easily titrated with current formulations.

Hypoketotic Hypoglycemia Caused by Activating Mutations in Insulin Signaling Pathway

AKT2-Hypoketotic Hypoglycemia

Recessive gain-of-function mutations in *AKT2*, a key component of the insulin signaling cascade, cause a phenotype similar to hyperinsulinemic hypoglycemia, but without detectable plasma insulin levels, despite classical signs of increased insulin action (suppressed free fatty acids and ketones).¹⁶⁷ The phenotype in these children is characterized by severe, persistent hypoglycemia unresponsive to medical therapy and requiring continuous intragastric feedings. These children also had overgrowth with body asymmetry.

PI3K-Hypoketotic Hypoglycemia

Mosaic activating mutations in class 1A phosphatidylinositol-3-kinase (PI3K), which is upstream from *AKT2* in insulin

signaling, have also been described as a cause of hypoketotic hypoglycemia. The phenotype of the reported cases is characterized by early onset and severe hypoketotic hypoglycemia with undetectable insulin.¹⁶⁸

Acquired Postprandial Hyperinsulinemic Hypoglycemia after Fundoplication

The Nissen fundoplication and other modified fundoplication procedures, frequently performed for the treatment of gastroesophageal reflux in neonates and children, have been associated with late dumping syndrome, particularly postprandial hyperinsulinemic hypoglycemia. In a study in neonates, it was estimated that approximately 24% of those undergoing fundoplication developed postprandial hypoglycemia after the surgery.¹⁶⁹ Classically, dumping syndrome is characterized by early symptoms or “early dumping,” thought to be caused by the fluid shifts provoked by the osmotic load in the small bowel,¹⁷⁰ and “late dumping” or postprandial hypoglycemia.¹⁷¹ In our experience, dumping syndrome in children is characterized by severe postprandial hypoglycemia without the significant gastrointestinal symptoms observed in adults.¹⁷² Very frequently, children with postprandial hyperinsulinemic hypoglycemia, after fundoplication, experience seizures, lethargy, and other symptoms of hypoglycemia for several months before the diagnosis is made. In the neonate particularly, the hypoglycemia may not be recognized unless these infants are screened with postfeeding plasma glucose monitoring after the surgery.¹⁶⁹

The pathophysiology of hyperinsulinemic hypoglycemia after fundoplication is likely multifactorial. Studies of the motor and sensory function of the stomach after fundoplication have shown significantly reduced postprandial gastric relaxation and significantly accelerated gastric emptying.¹⁷³ The rapid emptying of a meal into the small intestine results in rapid absorption of glucose into the bloodstream, with early hyperglycemia followed by an exaggerated insulin surge and

subsequent hypoglycemia.¹⁷² Increased secretion of the potent insulinotropic hormone, glucagon-like peptide-1 (GLP-1), after a meal may be partly responsible for the postprandial hyperinsulinemia.¹⁷⁴ This is supported by evidence demonstrating that antagonism of the GLP-1 receptor with exendin-(9-39) blunts the insulin response, suggesting that the exaggerated insulin response to a meal is at least in part because of the effects of GLP-1 on the pancreatic beta cell.¹⁷⁵

The diagnosis of hyperinsulinemic hypoglycemia in neonates and children after fundoplication is established based on the glucose and insulin profile after a mixed meal tolerance test or an oral glucose tolerance test.¹⁷⁴ The typical response is characterized by hyperglycemia that can reach up to more than 11.1 mmol/L (200 mg/dL) within the first hour after the meal, followed by hypoglycemia at 90 to 120 minutes. Plasma insulin reaches a peak that is greater than 200 μ U/mL approximately 30 minutes after the meal. A variety of therapies have been used with varying success to treat dumping syndrome, including uncooked cornstarch,¹⁷⁶ pectin,¹⁷⁷ octreotide,¹⁷⁸ acarbose,¹⁷² and dietary manipulations.¹⁷⁹ Many of the patients suffering from postprandial hyperinsulinemic hypoglycemia continue to have severe symptoms, despite these interventions, and require a regimen of continuous enteral feedings to avoid hypoglycemia, but continue to be at high risk of hypoglycemic events if feedings are abruptly stopped. In most cases, the postprandial hyperinsulinemic hypoglycemia improves with time, especially after solids have been introduced to the diet.

Defects in Counterregulatory Response

Hypoglycemia associated with endocrine deficiency is usually caused by glucocorticoid or GH deficiency, more commonly the combination of both. In children with panhypopituitarism, isolated GH deficiency, or a combination of ACTH deficiency and GH deficiency, the incidence of hypoglycemia is as high as 20%. In the newborn period, hypoglycemia may be the presenting feature of hypopituitarism. In males, a micropallus and small testes may provide a clue to a coexistent deficiency of gonadotropin^{180,181} (Fig. 7.12). Newborns with hypopituitarism may also have liver dysfunction resembling cholestatic liver disease, and some have midline malformations, such as

Fig. 7.12 Micropenis and undescended testes in an infant with congenital hypopituitarism. The infant was hypoglycemic at 12 hours of age (glucose, 24 mg/dL). At 72 hours of age, he was jaundiced—and a liver biopsy demonstrated neonatal hepatitis. His endocrine evaluation was positive for hypothyroidism, low cortisol level, undetectable growth hormone level, and an elevated prolactin level (confirming hypothalamic hypopituitarism).

the syndrome of septooptic dysplasia.^{182–184} Clinically, such children may manifest nystagmus, or have mid-face hypoplasia syndromes, including cleft palate.

Although older infants and children with pituitary deficiency present with ketotic hypoglycemia in the neonatal period, the hypoglycemia may mimic hyperinsulinism, because mechanisms of ketogenesis are not fully developed in the immediate newborn period. However, their hypoglycemia is not responsive to diazoxide and only remits with replacement of deficient hormones (including thyroxine, as well as GH and cortisol). Of note, mutations in the transcription factor *Foxa2* cause both hypopituitarism and hyperinsulinism and present in the neonatal period with persistent hypoglycemia.^{76,137}

When adrenal disease is severe, as in congenital adrenal hyperplasia, bilateral adrenal hemorrhage, congenital absence or hypoplasia of the adrenals, or various syndromes of ACTH resistance,^{185–187} hyperpigmentation, disturbances in serum electrolytes with hyponatremia and hyperkalemia, or ambiguous genitalia may provide diagnostic clues. Abnormalities of the ACTH receptor or adrenal hypoplasia may be phenotypically difficult to distinguish from cortisol deficiency of other causes, with the exception of the marked elevations of serum ACTH concentration, noted if the ACTH receptor or adrenal gland is malfunctioning.^{188,189} However, all states with ACTH elevations may be clinically suspected by virtue of the associated hyperpigmentation (see Chapter 14). These cases of isolated adrenal insufficiency very rarely cause hypoglycemia in neonates, whereas in older infants and children, treated congenital adrenal hyperplasia and isolated ACTH deficiency may cause profound stress-induced hypoglycemia. Congenital ACTH deficiency caused by mutation in *TPIT*, which encodes *TBX19*, a transcription factor that is required for the expression of the proopiomelanocortin (*POMC*) gene and for terminal differentiation of the pituitary corticotroph lineage, is the exception, presenting in the neonatal period with severe and persistent hypoglycemia, until hormonal replacement is established.¹⁹⁰ It is important to have in mind that a low GH and cortisol level at the time of hypoglycemia is not diagnostic of a true deficiency¹⁹¹ and provocative testing may be needed to establish the diagnosis.

The mechanism of hypoglycemia in GH deficiency may be the result of decreased lipolysis. The mechanism of hypoglycemia with cortisol deficiency may be reduced liver glycogen reserves plus diminished gluconeogenesis, owing to a failure to supply endogenous gluconeogenic substrate in the form of amino acids from muscle proteolysis. Investigation of a child with hypoglycemia therefore requires exclusion of ACTH, cortisol, or GH deficiency—and if diagnosed, appropriate replacement with cortisol or GH. Cortisol replacement at stress dose concentrations should be the first line of treatment and GH replacement given only if glucocorticoid therapy alone fails to control hypoglycemia. There is evidence that the synthesis and secretion of GH in the newborn requires cortisol, so that apparent GH deficiency resolves with cortisol treatment alone.¹⁹²

Although glucagon deficiency^{193,194} had been described as a cause of hypoglycemia, the authors have retracted their conclusions and now believe these patients had SCHAD hyperinsulinism; thus this disorder is exceedingly rare and may be nonexistent. Epinephrine deficiency or deficiency of its action is also rare but must be a consideration in familial dysautonomia or in children treated with adrenergic receptor blockers, such as beta-blockers.

Defects in Glycogenolysis and Gluconeogenesis

Most of the disorders of glycogenolysis and gluconeogenesis that result in hypoglycemia are usually diagnosed in childhood

and will be discussed in [Chapter 23](#). The exception is GSD I, which impairs the release of glucose from glycogenolysis and gluconeogenesis and presents in the neonatal period, although in some cases, it is diagnosed later.

Glucose 6-Phosphatase Deficiency (GSD Type 1)

Glycogen storage disease type 1 is an autosomal recessive disorder caused by defects in the glucose 6-phosphatase (G6Pase) complex, which catalyzes the terminal steps of both hepatic gluconeogenesis and glycogenolysis, the hydrolysis of glucose 6-phosphate to glucose and inorganic phosphate. Deficiency of G6Pase activity in liver, kidney, and intestine results in the accumulation of glycogen in these organs, fasting hypoglycemia as a result of inadequate glucose production, and other secondary biochemical abnormalities, including hyperlacticacidemia, hyperuricemia, and hyperlipidemia.

G6Pase is a multicomponent complex consisting of a catalytic unit, G6Pase, localized on the luminal side of the endoplasmic reticulum, and a G6P-specific bidirectional translocase (G6PT) that allow the entry of glucose 6-phosphate to the catalytic unit.¹⁹⁵ The gene for the catalytic unit is located on chromosome 17,¹⁹⁶ whereas the gene for the glucose 6-phosphate translocase is located on chromosome 11.¹⁹⁷ Mutations in the catalytic unit cause GSD type 1a,¹⁹⁸ whereas mutations in G6PT cause GSD type 1b.¹⁹⁷ The phenotype for these two subtypes is identical, except that in type 1b, in addition to the liver phenotype, there are recurrent bacterial infections and inflammatory bowel disease associated with neutropenia and neutrophil dysfunction.¹⁹⁹

The estimated incidence of GSD type 1 is 1 in 100,000 live births, with GSD type 1a representing approximately 80% of cases. Clinically, GSD type 1 may present in the neonatal period with severe hypoglycemia, occurring 2 to 2.5 hours after a meal, and tachypnea secondary to respiratory compensation for the metabolic acidemia. However, because lactate and ketones may provide adequate brain substrate to protect central nervous system function (and because in early infancy regular feedings are consistently provided), the diagnosis may be delayed for months until massive hepatomegaly brings the infant to medical attention, although the hepatomegaly may be missed because the liver is soft. After infancy, affected patients may be seen walking with a waddling gait, secondary to their prominent abdomen and muscle weakness. Other consistent features are hyperuricemia, hypophosphatemia, a bleeding diathesis, secondary to impairment of platelet adhesiveness, and growth retardation.

Hypoglycemia may occur anytime these children are exposed to even brief periods of fasting. They are completely dependent on the provision of glucose from exogenous sources, with the exception of the small amount of free glucose—which is released as part of the process of debranching glycogen. Because less than 10% of glycogen consists of branch points, this mechanism provides little protection against hypoglycemia during fasting. Hypoglycemia in the setting of suppressed insulin and increased glucagon promotes glycogenolysis, but the absence of G6Pase commits the glucose-1-phosphate produced by phosphorylase to glycolytic catabolism, resulting in increased lactate production (see [Fig. 7.1](#)). Another consequence of the impaired activity of G6Pase is the shunting of G6P through the pentose phosphate pathway to yield ribose-6-phosphate, which ultimately yields uric acid, resulting in hyperuricemia. Hypertriglyceridemia results from increased triglyceride formation as a major route of disposal of pyruvate from lactate and amino acids, when glucose yield is blocked in G6Pase deficiency.²⁰⁰ Massive accumulation of fat in the liver is responsible for the massive hepatomegaly characteristic of GSD type 1.

Renal disease is a frequent complication of GSD type 1 (with an estimated prevalence of 30%).²⁰¹ Manifestations include proximal renal tubular dysfunction (Fanconi-like syndrome), distal tubular acidification defect, and hypercalciuria. There is an inverse relationship between age and citrate excretion, and the combination of low citrate excretion and hypercalciuria predispose these children to nephrocalcinosis and nephrolithiasis.²⁰² Citrate supplementation may prevent or ameliorate these complications.²⁰³ The widespread prevalence and serious prognosis of kidney involvement is manifested by severe glomerular hyperfiltration and microalbuminuria over time, systemic arterial hypertension, and consequently renal failure.^{204–206} The early implementation of treatment with angiotensin-converting enzyme inhibitors has been shown to delay the progression of renal damage.²⁰¹ The pathologic findings include focal segmental glomerulosclerosis with interstitial fibrosis. The etiology of the renal involvement is unclear, but it correlates negatively with metabolic control. It has been proposed that the dyslipidemia contributes to the kidney injury.²⁰⁷

In addition to the characteristic hepatomegaly, the liver undergoes adenomatous changes. Adenomas are usually first observed in the second and third decades of life but may appear before puberty.^{206,208} The adenomas may undergo malignant degeneration or hemorrhage and are frequently associated with chronic iron-resistant anemia.²⁰⁹ Other complications of GSD1 include osteopenia and growth retardation.

The diagnosis of GSD type 1 is based on the clinical and biochemical characteristics: hypoglycemia after a short period of fasting, hepatomegaly, lactic acidemia, and elevation of uric acid and triglycerides. Glucagon stimulation, 2 to 4 hours after a meal containing carbohydrates, results in increased lactate concentration, but plasma glucose does not rise.²⁰⁹ The diagnosis can be confirmed by mutation analysis.

The goal of treatment of children with GSD I is to completely eliminate hypoglycemia and suppress secondary metabolic decompensation. Continuous nasogastric or intra-gastric feedings during the night have been demonstrated to either reduce or eliminate the metabolic and clinical findings through complete avoidance of hypoglycemia.²¹⁰ However, this approach places children at risk of severe hypoglycemia, if feedings are abruptly stopped. A safer approach is the introduction of oral uncooked cornstarch, which helps prolonged the fasting tolerance,^{211,212} and can be used in older infants, usually older than 6 months of age. The doses of cornstarch used are approximately 1.6 g/kg per dose every 4 hours in infants and 1.7 to 2.5 g/kg per dose every 6 hours in older patients. A typical regimen consists of daytime feedings every 3 to 4 hours that are calculated to provide adequate carbohydrate calories to avoid the need for hepatic glucose output.²⁰⁹ Most of these calories consist of carbohydrates, primarily providing pure glucose as an energy source and avoiding disaccharides containing fructose or galactose. At night, the regimen consists of an intragastric infusion of glucose with or without protein designed to infuse at rates of about 125% calculated hepatic glucose output²⁰⁰ for normal young infants. For older children, a regimen of uncooked cornstarch can be implemented at nighttime.

Meticulous dietary control can lead to a significant clinical and metabolic improvement and prevention of complications. Adjunctive therapies should include careful monitoring of the uric acid level and treatment with allopurinol if the uric acid level is elevated. With increasing awareness of the renal tubular dysfunction, treatment of the hyperfiltration state with an angiotensin-converting enzyme inhibitor should be initiated promptly. Treatment with granulocyte-macrophage colony-stimulating factor to augment neutrophil production has been shown to ameliorate mouth ulcers and the enteritis in type 1b.²¹³

Disorders of Fatty Acid Oxidation: Medium-Chain Acyl-Coenzyme A Dehydrogenase Deficiency

The inborn errors of metabolism associated with deficiencies of fatty acid oxidation and ketogenesis (Fig. 7.13) are inherited in an autosomal-recessive fashion. All of these disorders may be provoked by fasting and exhibit acute life-threatening events characterized by coma, hypoketotic hypoglycemia, cardiorespiratory collapse, and fatty hepatomegaly; those disorders which impair early steps in oxidation of longer-chain fatty acids may also include chronic hypertrophic or dilated cardiomyopathy and muscle weakness or exercise-induced rhabdomyolysis.²¹⁴ Metabolic defects of fatty acid oxidation may be divided according to the site of the enzymatic defect (see Fig. 7.13)^{214,215}: (1) defects of mitochondrial carnitine cycle for transferring fatty acids into the mitochondrial matrix, (2) defects of the β -oxidation cycle, (3) defects of electron transfer to the electron transport chain, and (4) defects in the pathway of ketone synthesis. The age at presentation is usually beyond the neonatal period, but neonatal presentation may occur in breastfeeding babies who have not begun to receive adequate milk.^{216,217} Because of the life-threatening and the largely treatable nature of these disorders, newborn screening is universally available in all US states and many other countries using filter paper blood spots and tandem-mass spectrometric analysis of acylcarnitine profiles.²¹⁸ This detects most of the fatty acid oxidation disorders, with the exception of β -hydroxy-methylglutaryl-CoA synthase deficiency. This section reviews the diagnosis, clinical features, and treatment of MCAD deficiency; other fatty acid oxidation defects are reviewed in Chapter 23.

MCAD deficiency is the most frequent defect of fatty acid oxidation and is one of the more common inborn errors of metabolism.^{219,220} Neonatal screening in Pennsylvania has shown an incidence of 1 in 15,700 newborns and the disorder is especially common in northern European countries.²²¹

MCAD (encoded by *ACADM* on 1p31) is responsible for the first step in the β -oxidation cycle for medium-chain fatty acyl-CoAs, with a chain length between 4 and 12 carbon atoms. Deficiency of MCAD enzyme activity leads to accumulation of medium-chain fatty acid metabolites (between 6 and 10 carbons) in plasma (octanoylcarnitine-C8, hexanoylcarnitine-C6, decanoylcarnitine-C10, decenoylcarnitine-C10:1; and abnormal acylglycines—hexanoylglycine and suberylglycine). Urinary metabolic abnormalities include increased excretion of dicarboxylic acids. Metabolite profiles are usually diagnostic, but can be confirmed by genetic sequence testing. The most common mutation among Northern Europeans, 985A>G (p.Lys304Glu), is homozygous in 80% of cases presenting clinically, and in 60% of cases identified by newborn screening.

Children with MCAD deficiency may appear normal at birth, although symptoms may manifest before results from newborn screening are available, especially in breastfed neonates.²²² The typical clinical presentation (if not detected by newborn screening) occurs between 3 and 24 months of age and is precipitated in response to prolonged fasting (e.g., at the time of weaning from nighttime feedings or during an intercurrent illnesses). Manifestations can include vomiting, lethargy, coma, and hepatic encephalopathy. Acute decompensations can rapidly progress to coma and death and may resemble sudden infant death syndrome (SIDS) or Reye syndrome.

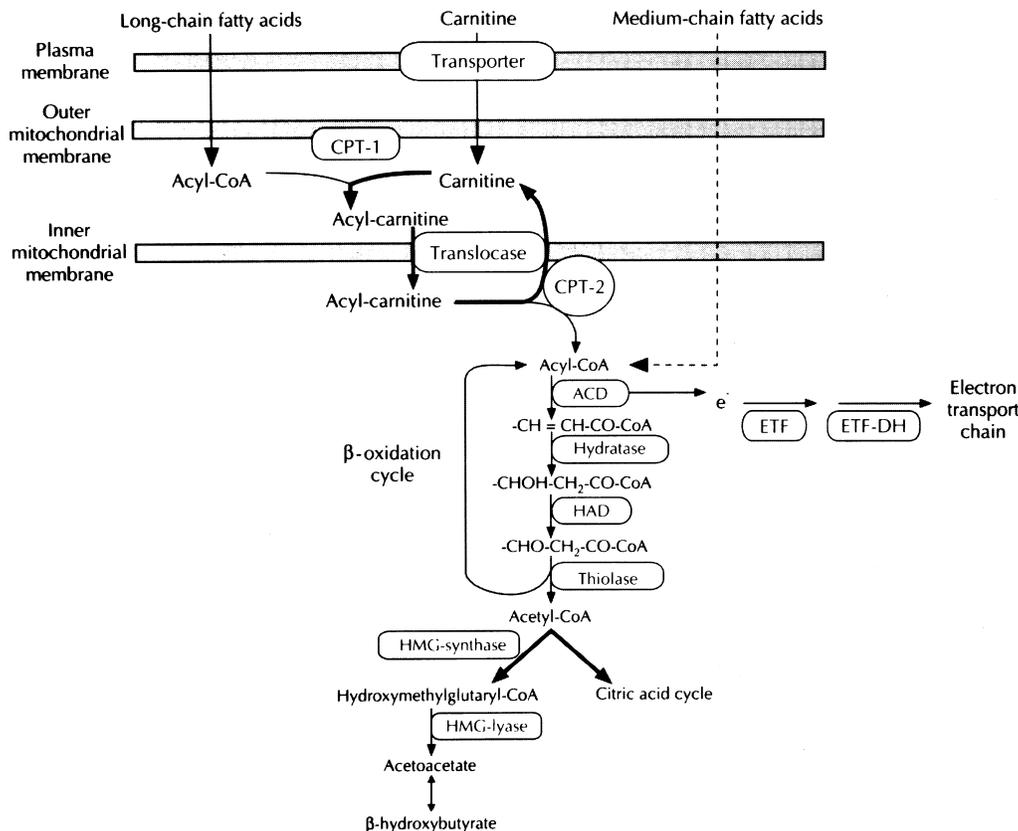

Fig. 7.13 The pathways of mitochondrial fatty acid oxidation and ketone body synthesis. *ACD*, Acyl-CoA dehydrogenase; *CPT-1* and *CPT-2*, carnitine palmitoyltransferase I and II; *ETF* 5, electron-transferring flavoprotein; *ETF-DH*, electron-transferring flavoprotein dehydrogenase; *HAD*, hydroxyacyl-CoA dehydrogenase. (From Stanley, C.A., Hale, D.E. (1994). Genetic disorders of mitochondrial fatty acid oxidation. *Curr Opin Pediatr*, 6, 476.)

In children not previously diagnosed, the mortality rate from the first episode is as high as 18%.²²³

Although there is significant heterogeneity in the presentation of MCAD, the most frequent clinical presentation is one of intermittent hypoketotic hypoglycemia with little or no acidemia, elevation of serum urea, ammonia, and uric acid, liver function abnormalities, and hepatic steatosis. The risk of severe complications, brain damage, and death is very high unless appropriate treatment to reverse the catabolic state is implemented.²²³ The diagnosis of these cases may be confused with Reye syndrome. Although hypoglycemia may be a prominent late feature with MCAD, the phenotype of a defect of a fatty acid oxidation disorder may not manifest if a fasting state is avoided. A high index of suspicion for fatty acid oxidation defects is important because appropriate therapy may result in an interruption and prevention of these potentially life-threatening episodes. Affected patients have also been misdiagnosed with idiopathic SIDS.²²⁴ Decreased plasma carnitine levels and an increase in the ratio of esterified to free carnitine is a frequently associated laboratory finding.²²⁵

Evaluation of suspected MCAD deficiency or other errors in fatty acid oxidation should first include a determination of the profile of plasma acylcarnitines by mass spectrometry and measurement of plasma total, esterified, and free carnitine. Table 7.4 shows the abnormalities of plasma acylcarnitines associated with specific fatty acid oxidation disorders are associated with specific abnormalities of plasma acylcarnitines—octanoylcarnitine in cases with MCAD deficiency.²²¹ Determinations of urinary organic acids with assessment of the presence or absence of dicarboxylic aciduria may also be useful. Other tests which may be useful in patients who require further evaluation include assays of fatty acid oxidation and specific enzyme assays in cultured skin fibroblasts or lymphoblasts. Since the early 1990s, the use of tandem mass spectrometry has made newborn screening possible for most fatty acid oxidation disorders, based on the acylcarnitine profile in blood spots. Presymptomatic identification of these individuals can prevent catastrophic events, such as sudden death. Genetic mutation analysis can be performed for all of these defects, which is particularly useful in MCAD, in which most cases are caused by a single common mutations (Lys304Gly).²²⁶

The primary treatment of disorders of fatty acid oxidation is a devoted avoidance of fasting.²¹⁴ For infants younger than 1 year old, 6 to 8 hours of fasting may be sufficient to precipitate an episode. On the other hand, as children become older,

they are able to tolerate periods of fasting of as long as 10 to 12 hours without decompensation. A high index of suspicion and rapid institution of IV glucose will often reverse an evolving episode. Glucose monitoring is not useful, because the presence of hypoglycemia is usually an event that occurs late in the evolution of an episode of metabolic decompensation. High-fat (e.g., ketogenic) diets should be avoided, although normal amounts of dietary fats are permissible. The use of uncooked cornstarch (as used for the treatment of type 1 glycogen storage disease) is rarely indicated.²²⁰

Defects of Glucose Transporters

GLUT1 Deficiency

GLUT1 deficiency syndrome is an autosomal dominant inborn error of glucose transport characterized by seizures, developmental delay, spasticity, acquired microcephaly, and ataxia. The biochemical hallmark is the finding of hypoglycorrachia (low cerebrospinal fluid glucose concentration), despite normal plasma glucose concentrations.

GLUT1, encoded by *SLC2A1*, is the fundamental vehicle that facilitates glucose entry into the brain. Diagnosis of GLUT1 deficiency is based on the finding of low cerebrospinal fluid glucose, in the absence of hypoglycemia, and identification of *SLC2A1* mutation (located on chromosome 1). The classic phenotype is a severe form of early-onset epileptic encephalopathy in approximately 90% of cases (classic form). A nonepileptic form represents 10% of cases, which includes a broad phenotypic spectrum that may present with paroxysmal nonepileptic manifestations that have been reported to include intermittent ataxia, choreoathetosis, dystonia, and alternating hemiplegia.²²⁷

Treatment efforts have been based on providing alternative brain fuel sources by a ketogenic diet.^{10,228} The ketogenic diet effectively controls the seizures and other paroxysmal activities, but it has less effect on the cognitive function.

GLUT2 Deficiency

Originally described by Fanconi and Bickel as a syndrome characterized by hypoglycemia and ketonuria in the fasting state and hyperglycemia in the postabsorptive state,²²⁹ Fanconi-Bickel syndrome is caused by recessive mutations of the GLUT2 plasma membrane transporter for glucose (encoded by

SLC2A2).²³⁰ The defect on GLUT2 results in hepatorenal glycogen accumulation, proximal renal tubular dysfunction, and impaired utilization of glucose and galactose.²³¹ GLUT2 is expressed in hepatocyte, pancreatic β -cells, and the basolateral membranes of intestinal and renal tubular epithelial cells.²³² The clinical manifestations reflect impairment of glucose release from liver and of glucose reabsorption from renal tubular cells. Galactose clearance and conversion to glucose is delayed.

Patients with GLUT2 deficiency usually present at an age of 3 to 10 months. The typical clinical signs are hepatomegaly caused by glycogen accumulation, a severe Fanconi-type renal tubulopathy with disproportionately severe glucosuria, glucose and galactose intolerance, hypophosphatemic rickets, and severely stunted growth.²³³ These patients may present with a combination of fasting hypoglycemia and postprandial hyperglycemia. The hypoglycemia during fasting is explained by altered glucose transport out of the liver, resulting in an increased intracellular glucose concentration that may inhibit glycogen degradation, leading to glycogen storage and hepatomegaly. The hypoglycemia is exacerbated by renal loss of glucose caused by a transport defect for glucose and galactose across the basolateral membranes of the tubular cells. Hyperglycemia (and hypergalactosemia) in the fed state is explained by decreased monosaccharide uptake by the liver and enhanced by an inappropriately low insulin secretion because of impaired glucose-sensing by the pancreatic β -cells.²³⁰

The therapeutic goal for patients with GLUT2 deficiency is to ameliorate the consequences of renal tubulopathy by replacing water, electrolytes, and alkali—and by providing phosphate and vitamin D supplementation. In terms of diet, an adequate caloric intake is recommended to compensate for renal and intestinal glucose loss—given as frequent feedings containing slowly absorbed carbohydrates (such as cornstarch) to avoid fasting hypoglycemia.

TREATMENT

A rational therapeutic approach to the treatment of hypoglycemia relies first on a systematic diagnostic evaluation that results in a specific diagnosis. Before that specific diagnosis being made, and before the implementation of individual therapy plans, the goal of therapy is to preserve central nervous system function and to prevent catabolic states in which intermediary metabolites, such as free fatty acids and their acylcarnitines, ketones, or lactate may cause secondary harm. IV glucose infusion remains the mainstay of emergency therapy, particularly for the child with severe hypoglycemia. It is important to follow an initial glucose bolus with a continuous glucose infusion to prevent further episodes of hypoglycemia, until specific therapies are established. For neonates in the first 24 to 48 hours of life see earlier (Physiology of Perinatal Glucose Homeostasis).

Initial glucose bolus may range from 0.2 to 0.5 g/kg glucose (2–5 mL/kg dextrose 10%) as an IV bolus, followed by an infusion of 8 mg/kg/min (approximately 5 mL/kg/h of dextrose 10%). This may be reduced if plasma glucose is greater than 5 mmol/L (>90 mg/dL), but should be rapidly increased if frequent glucose checks indicate failure to elevate plasma glucose to greater than 3.8 mmol/L (>70 mg/dL). This may be initially done in increments of 1.6 mg/kg/min (1 mL/kg/h of dextrose 10%), but if glucose fails to rise to greater than 3.8 mmol/L (>70 mg/dL) after 2 increments every 15 minutes, then increase by 3.2 mg/kg/h (2 mL/kg/h of dextrose 10%).

Ideally, once a specific diagnosis is made, treatment should maintain normoglycemia on a normal feeding schedule for the patient's age. In addition, allowance should be made for the effects of intercurrent illness on glucose regulation and

the longest fasting interval a patient should undergo routinely, should be defined for both the well state and during intercurrent illness. It is advisable to periodically reassess the efficacy of the treatment for any form of hypoglycemia by a formal fasting study on treatment. All patients should have an emergency letter stating their specific diagnosis, advice on prevention of hypoglycemia and information on acute treatment of a hypoglycemia episode, in addition to contact information for the physician of record for ongoing assistance.

CONCLUSIONS

Since the early reports of neonatal hypoglycemia in the 1950s by McQuarrie⁶³ and Comblath and colleagues,²³⁴ our understanding of the molecular genetics and pathophysiology of the different disorders that cause hypoglycemia in neonates and infants has progressed significantly. Discoveries since the prior edition of this book include the description of new forms of syndromic hyperinsulinism, particularly, Kabuki syndrome and Turner syndrome; a combined phenotype of hyperinsulinism and hypopituitarism caused by inactivating mutations in *FOXA2*; and activation of insulin receptor signaling via mutations in *PI3K*, complementing those in *AKT2* that present with a phenotype of hypoketotic hypoglycemia without hyperinsulinism. With the rapid advancement in the understanding of molecular genetics and genotype-phenotype correlations for the different types of congenital hyperinsulinism, the most common cause of persistent hypoglycemia in neonates, a model of personalized medicine is starting to emerge. The best example is the current approach to children with suspected focal hyperinsulinism—from the genetic analysis to determine the likelihood of focal hyperinsulinism, to the localization of the lesion with noninvasive imaging, using ¹⁸F-fluoro-L-DOPA PET, and the surgical removal of the lesion sparing the normal pancreas and curing the disease. These and future discoveries should result in continued improvement in outcomes.

INTRODUCTION

The thyroid axis is probably the best example of the physiological interactions between the mother, the fetus, and their environment. The discovery of the crucial role of maternal iodine intake for the normal development of the fetus also led to the first successful intervention in preventive medicine.¹ Two centuries ago, the idea to use iodine to treat endemic goiter, which predominantly affected women, encountered a lot of resistance because it was believed that iodine was toxic for humans. The demonstration that 10% of the insoluble fraction of the thyroid was iodine and that it could be used to treat myxedema and goiter was followed by the first systematic clinical trial to assess the efficacy of iodized salt in preventing goiter. Iodized salt at the population level was next introduced and resulted in a marked decrease in the prevalence of goiter in children and, even more importantly, in the disappearance of “endemic cretinism.” However, pregnant women require double the iodine intake of nonpregnant women to maintain normal thyroid hormone concentrations, so they and their fetuses

are most vulnerable to decreases in iodine intake at the population level. The iodine deficiency that resurfaces in adolescent girls in certain geographic areas is therefore worrisome and illustrates the need for continuous surveillance of intake of this essential nutrient.^{2,3} With this caveat, endemic goiter and cretinism have all but disappeared in the industrialized world and the most severe cases of congenital hypothyroidism (CH) are caused by developmental defects of the thyroid and, albeit much less frequently, to defective pituitary control of thyroid function. These are the focus of this chapter.

Development of the Thyrotrophic Axis

The Pituitary

As for all organs, anatomic development of the hypothalamic-pituitary-thyroid system occurs during the first trimester of gestation. By 3 weeks of gestation, a series of homeodomain proteins or transcription factors begin to drive the differentiation of the human embryonic forebrain and hypothalamus. Immunoreactive thyrotropin-releasing hormone (TRH) becomes detectable in human embryonic hypothalamus by 8 to 9 weeks of postconceptional age and is also produced by the fetal gut and pancreas.

Anatomically, the pituitary gland develops from two ectodermal anlagen: a neural component from the floor of the primitive forebrain, and Rathke’s pouch from the primitive oral cavity. The latter is visible by 5 weeks, evolving to a morphologically mature pituitary gland by 14 to 15 weeks. The pituitary-portal blood vessels are present by this time and mature further through 30 to 35 weeks. A wide spectrum of congenital malformations collectively named *midline defects*, including holoprosencephaly and septooptic dysplasia, may be associated with central hypothyroidism and other anterior pituitary deficiencies.⁴ The molecular mechanisms underlying these malformations have been identified in some cases.⁵ Within the pituitary itself, PROP-1 and PIT-1 are terminal factors in the differentiation cascade of pituitary cells and PIT-1 or PROP-1 deficiency results in profound defects in growth hormone, prolactin, and thyroid-stimulating hormone (TSH) secretion, as well as age-dependent pituitary hypoplasia.⁶

The Thyroid

The human thyroid gland also develops from two endodermal anlagen: the median anlage derives from the primitive pharyngeal floor and the two paired lateral anlagen from the fourth pharyngeal pouches. A branching morphogenesis program is essential for the thyroid to attain a normal size.⁷ The long-held belief that the lateral anlagen were the only source of calcitonin-producing cells has been challenged by the observation that sublingual thyroids, which are derived exclusively from the median anlage, contain calcitonin messenger ribonucleic acid (mRNA) and protein.⁸ Thyroid follicular cells can differentiate within the lateral anlagen, as illustrated by histological observations, as well as by patients in whom the only thyroid tissue is a lateral ectopy. Both the median and lateral structures are visible by day 16 to 17 of gestation; by 50 days, they have fused and the

thyroid gland has migrated to its definitive location in the anterior neck. The thyroglossal duct, from the foramen cecum to the final location of the thyroid, may persist and is constituted of degenerated thyroid follicular cells. Within the thyroid gland, iodine concentration, TSH receptors, thyroglobulin (TG), and thyroperoxidase (TPO) mRNA and protein can be demonstrated by 70 days.⁹

Thyroid embryogenesis depends on the expression of a programmed sequence of transcription factors, including thyroid transcription factors-1 and -2 (TTF-1 or *TiTF-1*, now designated as NKX2 homeobox 1 -NKX2.1-; and TTF-2, now Forkhead box E1 -FOXE1-) and paired box gene 8 (PAX8). In newborn mice, biallelic inactivation of *Nkx2.1* results in the absence of both pituitary and thyroid glands, with complete absence of both thyroid follicular cells and of calcitonin-producing C-cells, whereas that of *Pax8* results in a small thyroid gland composed almost exclusively of C-cells. FoxE-1 null mouse embryos have either an absent thyroid or an ectopic sublingual gland, but all newborn pups have athyreosis in addition to cleft palate. Mutations in the homologous genes, however, account for at most 2% of cases of thyroid dysgenesis in humans. Therefore genes extrinsic to the thyroid may be involved in the control of its migration.¹⁰

Interactions Between Cardiovascular and Thyroid Development

The coordination of the development of the brain and of its vasculature suggests that brain and vessels may follow the same extrinsic cues and/or that there are reciprocal interactions between the two.¹¹ By analogy, the lack of epithelial to mesenchymal transition during thyroid migration suggests it is not an active process but rather involves movement of the surrounding tissues and vessels.^{12,13} Further evidence that the development of the heart and vessels influences thyroid migration stems from the observation that a patient with cooccurring sublingual thyroid and congenital heart disease had a deletion of *NETRIN1* and that *ntn1a* zebrafish morphants had abnormal thyroid morphogenesis, resulting from a lack of proper guidance by the dysplastic vasculature.¹⁴

Maternofetal Transfers and Their Clinical Consequences (Fig. 8.1)

Iodine is an essential component of thyroid hormones. In this chapter, the term iodine will refer to both iodine itself (I^2) and iodide (I^-). The human placenta expresses the sodium-iodine symporter throughout gestation,¹⁵ which explains why the mother's iodine status is reflected in the fetus. If the mother's iodine intake is suboptimal, the fetal thyroid cannot constitute appropriate stores of iodine and fetal hypothyroidism will ensue. Worldwide, inadequate maternal iodine intake leading to late consequences remains a major public health problem, although an increasing number of emerging countries appear to have achieved iodine sufficiency.¹⁶ Prevention of intellectual disability in the offspring by supplying the mother with adequate iodine is a public health intervention with undisputed benefits.¹⁷

In contrast with iodine, thyroxine (T4) was for a long time thought not to cross the placenta in substantial amounts. However, several findings clearly indicate that maternal T4 must cross the placenta in physiologically relevant amounts. First, T4 is detectable in human embryonic tissues before the onset of fetal thyroid function and must therefore be of maternal origin. Second, the transfer of T4 from mother to fetus must continue later in gestation because the concentration in cord blood from neonates with complete absence of thyroid function is 30% to 50% of that of normal neonates.¹⁸ Third, birth weight and neonatal TSH levels are lower in infants born to a mother

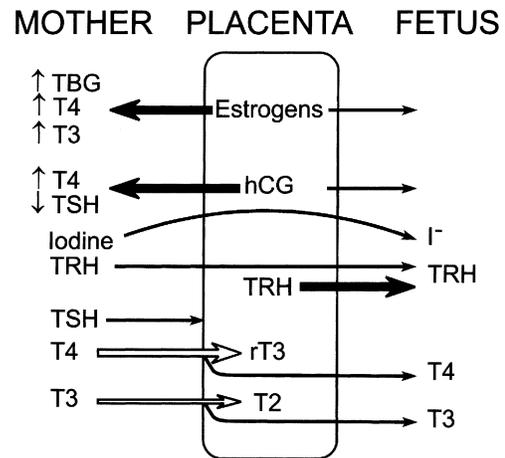

Fig. 8.1 The placental role in thyroid metabolism during human pregnancy. The placenta produces estrogens and a human chorionic gonadotropin (hCG), which increase maternal thyroxine-binding globulin (TBG) levels and stimulate maternal thyroid hormone production, respectively. Both activities tend to increase maternal thyroxine (T4) and triiodothyronine (T3) concentrations and inhibit maternal thyroid-stimulating hormone (TSH) secretion. Iodine and thyrotropin-releasing hormone (TRH) readily cross the placenta. In addition, the placenta synthesizes TRH. The placenta is impermeable to TSH and only partially permeable to T4 and T3. Placental type 3 iodothyronine monodeiodinase enzymes degrade T4 to reverse T3 and T3 to 3,3'-T2. The placenta is also permeable to the thiourea drugs used to treat maternal Graves disease.

who has chronically higher T4 concentrations because of a mutation inactivating the thyroid hormone receptor who have not inherited the maternal mutation than in those who have.¹⁹ These data indicate that maternal T4 crosses the placenta in physiologically relevant amounts throughout gestation and that, in excess, has a direct toxic effect on the fetus.¹⁹

However, low T4 concentrations in pregnant women do not appear to be causally related to a lower IQ in the children: two randomized controlled trials have shown a similar developmental outcome in the offspring of T4-treated versus placebo-treated hypothyroxinemic pregnant women.^{20,21} Moreover, in two case series of women with severe hypothyroidism diagnosed during pregnancy, but corrected by the third trimester, the intellectual outcome of the offspring was normal.^{22,23} Thus universal screening for thyroid dysfunction in the mother during pregnancy remains hotly debated. On the other hand, women with known hypothyroidism require closer monitoring during pregnancy, as 85% of women who are already receiving T4 therapy require a 30% to 50% increase in dose during pregnancy, because of the estradiol-induced increase in serum T4-binding globulin.²⁴

The transplacental transfer of T4 is not always sufficient to prevent the development of fetal goiter if the fetus has severe thyroid dyshormonogenesis (Fig. 8.2). Fetal goiters may be large enough to interfere with the flow of amniotic fluid into the oropharynx, causing progressive hydramnios and eventual lung hypoplasia. In such cases, levothyroxine injected into the amniotic fluid is swallowed by the fetus, leading to a decrease in the size of the fetal thyroid and in the degree of hydramnios.²⁵ The injection of thyroxine into the umbilical vein, which carries an even higher risk of triggering premature labor or fetal loss than amniocentesis,²⁶ should be restricted to fetuses with a goiter that continues to increase in spite of repeated intraamniotic injections. Invasive and potentially risky procedures should not be undertaken to protect the brain of affected fetuses:^{27,28} indeed, the fetal brain is, to a large extent, protected from the deleterious effect of hypothyroidism

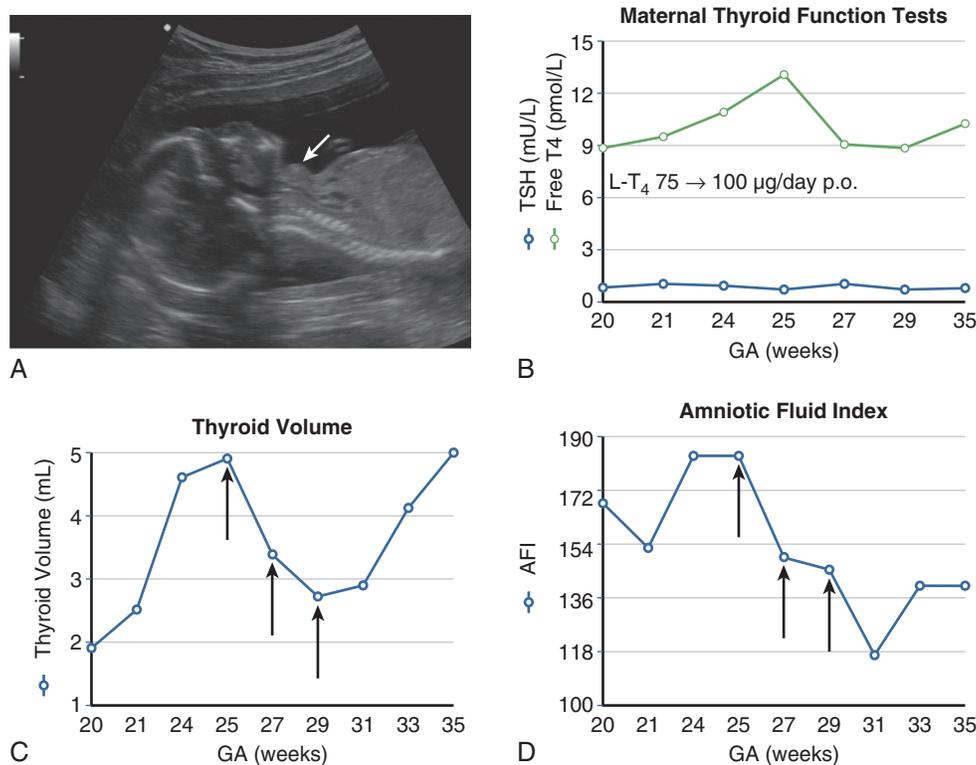

Fig. 8.2 A, Fetal goiter discovered at a routine ultrasound at 19 weeks (white arrow). The mother was euthyroid and had no autoantibodies. Cordocentesis showed a serum thyroid-stimulating hormone (TSH) of 90 mU/L. B, Initial management was through oral treatment of the mother with increasing doses of levothyroxine; this resulted in increased maternal free thyroxine (T4) concentrations, but presumably not enough to cross the placenta in sufficient amounts to prevent the progression of the fetal goiter (C) and the development of hydramnios (D). C, Effect of three intraamniotic injections of 200 μ g of levothyroxine (black arrows) on fetal thyroid size. D, Effect of three intraamniotic injections of 200 μ g of levothyroxine (black arrows) on amniotic fluid index. At birth, cord serum TSH was 224 mU/L and thyroglobulin was low at 3.55 μ g/L; thyroglobulin deficiency was confirmed by molecular genetic analyses. Treatment with 50 μ g of levothyroxine orally from day 1 has allowed this child, now aged 9 years, to have normal intellectual development. GA, Gestational age. (From Stoppa-Vaucher et al. (2010). *J Pediatr*, 156, 1026–1029.)

through upregulation of brain type 2 deiodinase, which converts the prohormone T4 into its biologically active derivative, triiodothyronine (T3). This likely accounts for the observation that even in CH with delayed bone maturation at diagnosis (indicating a prenatal onset), the intellectual outcome is within normal limits if continuous and adequate treatment is instituted shortly after birth.^{29,30} Thus the in utero treatment of fetal hypothyroidism should only be considered for goiter causing progressive hydramnios. Although the identification of a goiter by prenatal ultrasound may be increasing,³¹ it remains rare and even direct examination at birth often fails to detect goiters that are obvious on imaging. Goiters can also be detected in fetuses borne by women with Graves disease (see section on congenital hyperthyroidism).

Although a pro-TRH molecule is produced by the placenta, TRH concentrations in the maternal circulation are very low and thus have little effect on fetal thyroid function. However, TRH, a tripeptide, crosses the placenta readily and, when injected into the mother, increases thyroid hormone concentrations in the fetus. Because thyroid hormones stimulate fetal lung maturation, maternal TRH treatment to decrease neonatal respiratory distress syndrome has been attempted, but with negative results.³²

Immunoglobulin(Ig) of the IgG type cross the placenta, hence transient fetal/neonatal hyperthyroidism from transplacental transfer of TSH-receptor activating antibodies can occur in women with past or present Graves disease. On the other hand, when pregnant women are overtreated with antithyroid drugs, which also cross the placenta readily, their fetus may develop hypothyroidism; however, only one case of CH out

of about 30,000 births is attributable to this in the Québec database (unpublished observations). In addition, the antithyroid medication has a short half-life relative to that of immunoglobulin, so that a baby with apparently normal thyroid function tests at birth may develop hyperthyroidism within several days of birth, as the effects of antithyroid medication wanes, allowing the effects of thyroid-stimulating immunoglobulin (TSI) to become apparent. Lastly, transient neonatal hypothyroidism from maternofetal transfer of TSH-receptor blocking antibodies can also occur but only accounts for 2% of cases of neonatal hypothyroidism identified by screening,³³ and a specific screening strategy is not required for babies born to women with Hashimoto thyroiditis.

Thyroid function tests are often ordered clinically in newborns whose mothers have a history of thyroid disease and, if abnormal, require special consideration of optimal approach to therapy. For example, hypothyroidism at birth caused by treatment of maternal Graves disease with antithyroid medication may only require observation, in the expectation that the effects of the drugs will dissipate over a few days; hyperthyroidism may follow, albeit exceptionally. For hypothyroidism or hyperthyroidism resulting from maternal blocking or stimulating antibodies, respectively, treatment will be required as these effects may last several months.³⁴

Maturation of Thyroid Hormone Synthesis and Secretion (Figs. 8.3 and 8.4)

Maturation of thyroid function in the fetus reflects changes at the level of the hypothalamus, pituitary, and thyroid. Serum

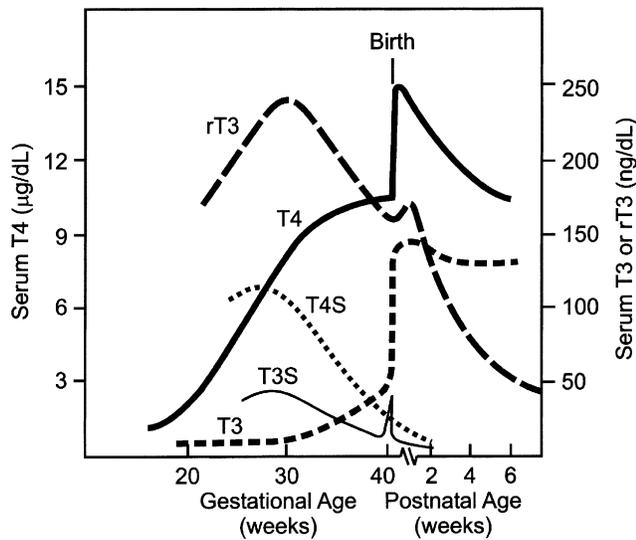

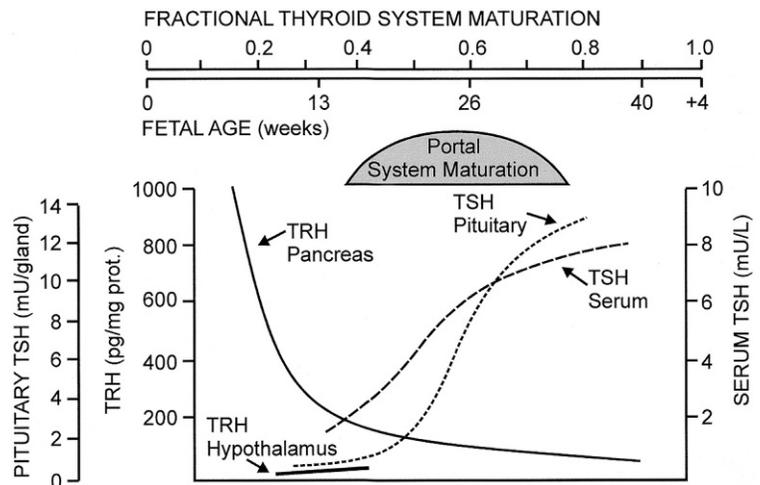

Fig. 8.3 The pattern of change in fetal and neonatal thyroid function parameters during pregnancy and extrauterine adaptation. Fetal serum thyroxine (T4) concentrations begin to increase at midgestation and increase progressively thereafter to term. This increase is caused largely by the increase in thyroxine-binding globulin concentration, but free T4 concentrations (not shown) also increase progressively between 20 and 40 weeks. T4 in the fetus is metabolized predominantly to inactive reverse triiodothyronine (rT3) and sulfated analogs (T4S, T3S). Monodeiodination of T4 to active triiodothyronine (T3) increases at about 30 weeks to levels approximating 50 ng/dL at term. The thyroid-stimulating hormone (TSH) surge (not shown), which peaks at 25 to 30 minutes after extrauterine exposure, stimulates thyroidal T4 and T3 secretion. Neonatal T4 and T3 peak at 2 to 3 days. Serum T3 concentrations remain at higher postnatal levels because of the increased T4-to-T3 conversion mediated by increased type 1 iodothyronine deiodinase activity in newborn tissues.

TRH concentrations are relatively high in the human fetus, because it is produced at both hypothalamic and extrahypothalamic sites and because the TRH-degrading activity of fetal blood is low. Fetal serum TSH increases from a low level at 18 to 20 weeks to a peak value of approximately 7 to 10 mU/L at term. After delivery, in response to exposure to the relatively colder extrauterine environment, there is an acute release of TSH with mean serum levels peaking at 30 minutes

Fig. 8.4 Changes in fetal thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH) levels in pancreas, hypothalamus, serum, and pituitary during human gestation. Hypothalamic TRH concentrations increase progressively after midgestation, but the pattern of change has not been documented in the human fetus. (From Fisher, D. A., Polk, D.H. (1994). Development of the fetal thyroid system. In: Thorburn, G.D., Harding, R. (eds.), *Textbook of Fetal Physiology*. Oxford, UK: Oxford University Press, 359–368. With permission.)

at concentrations of approximately 70 mU/L. A rapid decline follows within 24 hours, and levels return more gradually to 5 to 10 IU/L within the first week of life. The increase in serum T4 levels immediately after birth is TSH dependent. T3 rises as a result of both TSH-stimulated thyroidal production and peripheral conversion of T4 to T3. For newborn screening purposes, the percentage of samples with TSH greater than 15 mU/L, which is 9% in the first 24 hours, drops to 0.3%, as early as the second day,³⁵ so any sample obtained after 24 hours can be used.

Only free thyroid hormones enter cells, and hormones bound to serum thyroxine-binding globulin (TBG) and other transport proteins are not available to tissues. In addition, T4 is a prohormone and it is T3 that is biologically active within the cell, so that deiodination of T4 is essential for tissue euthyroidism. Both serum transport proteins and intracellular deiodination change during development. As previously mentioned, the fetal thyroid gland is capable of iodine concentration and iodothyronine synthesis as early as 70 days of gestation, a reflection of a sharp increase in the expression of the sodium-iodine symporter and of the appearance of a follicular architecture.³⁶ Starting at 18 to 20 weeks, TBG and total T4 concentrations in fetal serum increase steadily until the final weeks of pregnancy.

The study of free T4 (fT4) concentrations in fetal/neonatal blood has been hampered by the relative inadequacy of the commercially available immunoassay systems for measurements in these samples. The fetal serum T3 concentration remains low until 30 weeks because of two factors: first, the low activities of type I iodothyronine monodeiodinase result in relatively low rates of T4 to T3 conversion in fetal tissues; second, type III monodeiodinase in placenta and selected fetal tissues degrades T3 to T2. After 30 weeks, serum T3 increases slowly until birth. This prenatal increase in serum T3 is caused by progressive maturation of liver type I deiodinase activity increasing hepatic conversion of T4 to T3, and to decreased placental T3 degradation. Postnatally, T3 and T4 serum concentrations increase 2- to 6-fold within the first few hours, peaking on the second day of life. These levels then gradually decline to levels characteristic of infancy over the first 4 to 5 weeks of life. The deiodinase enzymes are described in greater detail later.

In the human, the fetal thyroid gland grows and its production increases under the influence of the increasing serum TSH level during the second half of gestation, as evidenced by the severely atrophic and hypofunctional glands observed in newborns with biallelic mutations that inactivate either the beta-subunit of TSH³⁷ or the TSH receptor.³⁸ On the other hand, the maturation of the negative feedback control

system appears to occur earlier than previously thought because an elevated TSH in serum obtained at cordocentesis can be seen in fetuses with primary hypothyroidism as early as 18 weeks.³⁹ Thyroid function in the premature infant is characterized by low circulating concentrations of T4 and fT4, a normal or low concentration of TSH, and a normal or prolonged TSH response to TRH, suggesting a degree of relative hypothalamic (tertiary) hypothyroidism (see Fig. 8.3).

In summary, fetal thyroid hormone secretion results from increasing hypothalamic TRH secretion and increasing thyroid follicular cell sensitivity to TSH and is regulated by increasing pituitary sensitivity to thyroid hormone inhibition of TSH release. The marked cold-stimulated TRH-TSH surge at birth is followed by a marked increase in T4 secretion and fT4 concentration with a new equilibrium reached by 1 to 2 months. During infancy and childhood, there is a progressive decrease in T4 secretion rate (based on a micrograms/kg per day) correlating with a decreasing metabolic rate.

Maturation of Thyroid Hormone Metabolism (Fig. 8.5)

The thyroid gland is the sole source of T4. Most of the circulating T3 after birth is derived from conversion of T4 to T3 via monodeiodination in peripheral tissues. Deiodination of the iodothyronines is the major route of metabolism, and monodeiodination may occur either at the outer (phenolic) ring or the inner (tyrosyl) ring of the iodothyronine molecule. Outer ring monodeiodination of T4 produces T3, the form of thyroid hormone with the greatest affinity for the thyroid nuclear receptor. Inner ring monodeiodination of T4 produces reverse T3 (rT3), an inactive metabolite. In adults, between 70% and 90% of circulating T3 is derived from peripheral conversion of T4 and 10% to 30% from direct glandular secretion. Nearly all circulating rT3 derives from peripheral conversion, with only 2% to 3% coming directly from the thyroid gland. T3 and rT3 are progressively metabolized to diiodo, monoiodo, and noniodinated forms of thyroxine, none of which possesses biologic activity.

Two types of outer ring iodothyronine monodeiodinases have been described.⁴⁰ Type I deiodinase (predominantly expressed in liver, kidney, and thyroid) is a high-K_m enzyme inhibited by propylthiouracil and stimulated by thyroid hormone. Type II deiodinase (predominantly located in brain,

pituitary, placenta, skeletal muscle, heart, thyroid, and brown adipose tissue) is a low-K_m enzyme insensitive to propylthiouracil and inhibited by thyroid hormone. Type I and II deiodinases contribute to circulating T3 production, whereas type II acts to increase local tissue levels of T3 as well. An inner ring deiodinase (type III deiodinase) has been characterized in most fetal tissues, including placenta. This enzyme system catalyzes the conversion of T4 to rT3 and T3 to diiodothyronine. All three deiodinase enzymes are selenoproteins.

Deiodination is developmentally and thyroid-state regulated. In the human fetal brain, type II deiodinase activity in the cortex increases between 13 and 20 weeks' gestation and by about 50% over the last third of gestation. There is a general inverse correlation of type II and type III activities. Both of these deiodinase species are thyroid hormone responsive.

Fetal thyroid hormone metabolism is characterized by a predominance of type III enzyme activity (particularly in liver, kidney, and placenta), accounting for the increased circulating concentrations of rT3 observed in the fetus. However, the persistence of high circulating rT3 concentrations for several weeks in the newborn indicate that type III deiodinase activity expressed in nonplacental tissues is important. The mixture of type II and type III deiodinase activities in the placenta provides for the conversion of T4 to T3 and of T4 and T3 to rT3 and T2, respectively.

Sulfated iodothyronines are the major thyroid hormone metabolites circulating in the fetus. Sulfokinase enzymes are present early in fetal life, and sulfation of the phenolic hydroxyl group of the iodothyronine molecule may be a normal prerequisite step for monodeiodination. The sulfated iodothyronines are preferred substrates for the type I deiodinase, and concentrations are high in fetal serum in part because of low type I deiodinase activity. However, increased production of sulfated metabolites is also involved. There is evidence that T3S has biologic activity, that is, it suppresses TSH *in vivo*, suggesting that it can be desulfated by one or more tissue sulfatase enzymes. The low production rates and low levels of T3 metabolites and the high ratio of inactive to active metabolites suggest that fetal thyroid hormone metabolism is largely oriented to inactivating T4, presumably to avoid tissue thermogenesis and to potentiate the anabolic state of the rapidly growing fetus. This is mediated by early activation of type III monodeiodinase, inactivation of type I monodeiodinase, and augmented iodothyronine sulfation.

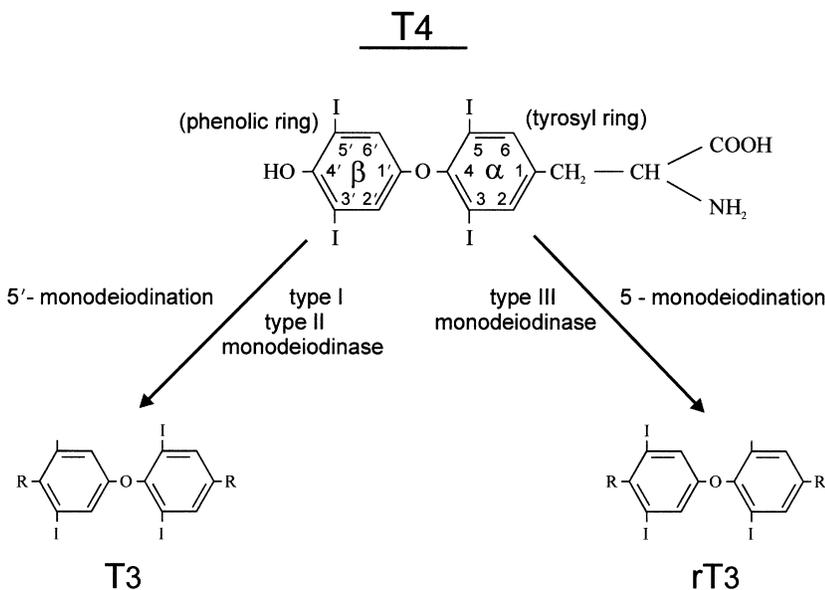

Fig. 8.5 The deiodination of thyroxine by types 1, 2, and 3 iodothyronine monodeiodinase enzymes. The type 1 enzyme is also capable of inner ring monodeiodination, particularly of the sulfated conjugates (not shown).

The developmental expression of type II deiodinase in brain and other tissues provides for local T3 supply to specific tissues (particularly in the event of T4 deficiency) and helps guarantee provision of T3 during gestation, when brain development is thyroid hormone dependent.

Thyroid Hormone Cell Membrane Transporters and Receptors

All thyroid-sensitive cell populations express iodothyronine membrane transporters, which are required for hormone entry into the cell. These belong to families of integrin, organic anion, amino acid, and monocarboxylate solute carriers. The importance of these transporters is highlighted by the role of mutations inactivating human monocarboxylate transporter 8 (MCT8) in an X-linked syndrome of severe psychomotor retardation (previously called the *Allan-Herndon-Dudley syndrome*) combined with mild abnormalities of thyroid function, characterized by high T3, low T4, and normal or high TSH.^{41,42} MCT8 is thought to play a role in the entry of T3 into neurons, after deiodination of T4 to T3 in neighboring astrocytes. In addition, MCT8 is involved in the transfer of T3 across the blood-brain barrier. Lastly, the abnormalities in thyroid hormone levels and TSH are also caused by the effect of MCT8 on deiodination.

Thyroid hormone effects are mediated predominantly via nuclear thyroid hormone receptors (TRs), which bind to deoxyribonucleic acid (DNA) to regulate gene transcription. Two mammalian genes code for TR, *TRalpha* and *TRbeta*, and alternative mRNA splicing leads to the production of four major thyroid hormone-binding transcripts: TRalpha1, TRalpha2, TRbeta1, and TRbeta2. The TRs exist as monomers, homodimers, and heterodimers with other nuclear receptor family members, such as the retinoid X receptors. TRalpha1 is the predominant subtype in bone, gastrointestinal tract, heart, and brain. TRbeta1 is expressed in liver, kidney, heart, lung, brain, cochlea, and pituitary. TRbeta2 is expressed in pituitary, retina, and cochlea. The receptors function redundantly, as indicated by knockout studies in mice, but predominant effects of one or another TR have been described.

In humans, the specific roles of TRalpha and TRbeta are illustrated by the phenotypes observed in patients with inactivating mutations in the corresponding genes. The syndrome of thyroid hormone resistance initially described in 1967 was later found to be caused by mutations inactivating TRbeta that occur either de novo or are inherited in an autosomal dominant fashion; however, in some patients with thyroid hormone resistance, TRbeta is normal and the molecular defect remains elusive. Mutations in TRalpha have also been described, occurring de novo in one patient and transmitted from father to daughter in one pedigree.⁴³

Thyroid hormone-programmed development of fetal tissues requires the interaction of local tissue monodeiodinase I and II, TRs, thyroid receptor coactivators, and thyroid-responsive genes. In most responsive tissues, the timing of maturation events is controlled by the TRs acting as a molecular switch. In the absence of T3, the unliganded receptor recruits corepressors, thereby repressing gene transcription. Local tissue maturation events are stimulated by the coincident availability of T3, liganded T3 receptor, T3-mediated receptor exchange of corepressors with coactivators, and activation of responsive gene transcription.⁴⁴

In the human fetus, low levels of TR binding have been detected in brain tissue at 10 weeks' gestational age—and liver, heart, and lung TR binding is observed at 16 to 18 weeks. TR levels in human fetal cerebral cortex and cerebellum increase markedly during the second and third trimesters. Information is limited regarding the timing of appearance of thyroid hormone tissue effects in the human fetus.

The birth length of the athyreotic human neonate is within normal limits: the linear growth of the human fetus is programmed independently of thyroid hormones by a complex interplay of genetic, nutritional, and hormonal factors, as well as by mechanical uterine constraint. However, 50% to 60% of athyreotic newborns manifest delayed epiphyseal maturation and have large fontanelles. In addition, neonates with severe CH may have large fontanelles, macroglossia, umbilical hernia, prolonged jaundice, and feeding difficulties. However, the classic clinical manifestations of CH appear progressively only during the early months of life. These include myxedema, a slow linear growth, and delayed attainment of psychomotor milestones, which can be mitigated by early diagnosis through neonatal screening programs with institution of thyroid hormone replacement. The normal IQ of athyreotic infants treated early through newborn screening³⁰ seems attributable to T4 of maternal origin coupled with upregulation of type II monodeiodinase in fetal brain tissue in the face of low fetal serum T4.

Postnatal thermogenesis is mediated via the brown adipose tissue prominent in subscapular and perirenal areas in the mammalian fetus and neonate. Heat production in brown adipose tissue is stimulated by catecholamines via beta-adrenergic receptors and is thyroid hormone dependent. The uncoupling protein thermogenin unique to brown adipose tissue is located on the inner mitochondrial membrane and uncouples phosphorylation by dissipating the proton gradient created by the mitochondrial respiratory chain. The type II monodeiodinase in brown adipose tissue mediates local T4 to T3 conversion. Full thermogenin expression in brown adipose tissue requires both catecholamine and T3 stimulation.⁴⁵ Brown adipose tissue matures progressively in the fetus but remains thermoneutral until stimulated by catecholamines in the perinatal period. Brown adipose tissue thermogenesis is immature in small premature infants, and brown adipose tissue mass decreases in the neonatal period in full-term infants, as the capacity for nonshivering thermogenesis develops in other tissues. Uncoupling protein-2 is found in many tissues but does not appear to be regulated by beta-adrenergic agonists or thyroid hormone. Uncoupling protein-3 is expressed in muscle and white adipose tissue, as well as brown adipose tissue. Muscle uncoupling protein-3 is regulated by beta3-adrenergic stimulation and thyroid hormone and presumably contributes to nonshivering thermogenesis in humans. mRNA levels for uncoupling protein-3 are also regulated by dexamethasone, leptin, and starvation, but the regulation differs in brown adipose tissue and muscle.

The critical role of thyroid hormones in central nervous system (CNS) maturation has long been recognized. Nervous system development involves neurogenesis, gliogenesis, neural cell migration, neuronal differentiation, dendritic and axonal growth, synaptogenesis, myelination, and neurotransmitter synthesis. Thyroid hormones have been shown to stimulate several developmentally regulated nervous tissue genes, but the role of these factors in the CNS developmental program remains undefined. Available evidence suggests that deficiency or excess of thyroid hormones alters the timing or synchronization of the CNS developmental program, presumably by initiating critical gene actions or other genetic CNS maturation events.⁴⁶

Perinatal Changes in Thyroid Function

After delivery, the neonate must rapidly convert from the fetal state of predominant thyroid hormone inactivation to a state of relative thyroidal hyperactivity. During the first hours after birth, there is an abrupt increase in circulating T4 and T3 levels. This is caused by the abrupt increase in hypothalamic TRH and pituitary TSH secretion stimulating increased thyroid hormone

TABLE 8.1 Estimated Birth Prevalence of Various Types of Permanent Thyroid Disorders in Iodine-Sufficient Populations, Based on Universal Newborn Screening With Either Thyroid-Stimulating Hormone or Thyroxine

Type of Permanent Congenital Disorder	Estimated Birth Prevalence
Thyroid Dysgenesis:	
– Ectopy	1:5,000
– Athyreosis	1:15,000
Thyroid Dyshormonogenesis	1:30,000
Hypothalamic-Pituitary Hypothyroidism	1:16,000
Thyroid Hormone Resistance	1:40,000

From Deladoey, J., Ruel, J., Giguere, Y., Van Vliet, G. (2011). Is the incidence of congenital hypothyroidism really increasing? A 20-year retrospective population-based study in Quebec. *J Clin Endocrinol Metab*, 96(8), 2422–2429; Van Tijn, D.A., de Vijlder, J.J., Verbeeten, B., Jr., Verkerk, P.H., Vulmsa, T. (2005). Neonatal detection of congenital hypothyroidism of central origin. *J Clin Endocrinol Metab*, 90(6), 3350–3359; Lafranchi, S.H., Snyder, D.B., Sesser, D.E., Skeels, M.R., Singh, N., Brent, G.A., et al. (2003). Follow-up of newborns with elevated screening T4 concentrations. *J Pediatr*, 143(3), 296–301.

orthotopic glands. In about 10%, there is a dumbbell-shaped image,⁶¹ suggesting that some cells have initiated migration and others not. The molecular mechanisms regulating migration of the embryonic thyroid are largely unknown. Ectopic thyroids are fully differentiated and have a normal follicular architecture and the associated CH likely reflects a reduced number of cells (lack of lateral lobes) and limited TSH-induced cell growth.⁶² The severity of CH is variable but is stable over time,⁶³ suggesting normal postnatal survival of the ectopic cells. The 25% of newborns with dysgenetic CH who have no visible uptake of tracer on scintiscan may have true athyreosis, in which cases serum TG is very low. When there is no visible tissue but serum TG is detectable, it seems appropriate to use the term *apparent athyreosis*, which may result from complete inactivation of the TSH receptor, either from the transplacental passage of blocking immunoglobulins (in which case CH is transient)⁶⁴ or from biallelic inactivating mutations of the

TSH receptor gene (in which case CH is permanent).³⁸ Orthotopic thyroid hypoplasia accounts for a smaller percentage of cases of overt CH. Lastly, congenital absence of a thyroid lobe, most often the left, is found in up to one in 500 normal children⁶⁵ but may be seen in association with permanent or transient CH.⁶⁶

A genetic susceptibility to thyroid dysgenesis was suggested by the observation that about 1% of affected patients have an affected first-degree relative,⁶⁷ giving a 40-fold increase in relative risk over the population prevalence of one in 4000 for dysgenetic CH. On the other hand, discordance between monozygotic twins is the rule⁵⁵ and the three to one female predominance of thyroid ectopy⁴⁷ are not compatible with standard Mendelian inheritance. To reconcile these contradictory epidemiological findings, a two-hit model has been proposed, in which thyroid dysgenesis requires the association of a germline susceptibility variant with a postzygotic event occurring at the somatic level, in developing thyroid tissue.⁶⁸ Because ectopic thyroids seldom need to be surgically removed, most of the work of the past 20 years has focused on leukocyte DNA, but disease-causing mutations have been found in a small percentage of patients with dysgenetic CH and in only a handful of those with the most common phenotype, thyroid ectopy. Clinically, a DNA diagnosis only needs to be sought if there are suggestive extrathyroidal manifestations or a family history of dominant or recessive transmission of dysgenetic CH (Table 8.2). In addition, generally mild CH, mostly associated with left hemithyroid, appears to occur more frequently in Di George⁶⁹ and Williams⁷⁰ syndrome than in the general population. In Di George syndrome, the deleted region on chromosome 22q11 generally encompasses *TBX1*, a gene involved in vessel development, further emphasizing the link between the development of the thyroid and of the cervical vasculature.⁷¹

Thyroid-Stimulating Hormone Receptor Mutations

The molecular cloning of the G protein-coupled TSH receptor⁷² was followed by the discovery of mono- or biallelic inactivating mutations in the *thyroid-stimulating hormone receptor* gene.⁷³ Monoallelic mutations account for 10% to 20% of persistent, mild, nonautoimmune hyperthyrotropinemia,⁷⁴

TABLE 8.2 Dysgenetic Congenital Hypothyroidism Associated With TSHR and Transcription Factor Mutations: Phenotypes (Thyroid and Other) and Mode of Inheritance

Gene	Transmission	Thyroid Phenotype	Other Features
<i>TSHR</i>	AR	From apparent athyreosis to normally appearing gland	None
<i>NKX2.1</i>	De novo or AD	From apparent athyreosis to normal gland, usually mild ↑ TSH	– RDS – Developmental delay/Hypotonia – Ataxia/Choreoathetosis
<i>FOXE1</i>	AR	True athyreosis	– Cleft palate – Choanal atresia – Kinky hair – Bifid epiglottis
<i>Pax8</i>	AD or de novo	From apparent athyreosis to normally appearing gland	Cysts within thyroid remnants
<i>GLIS3</i>	AR	From apparent athyreosis to normally appearing gland	– Congenital glaucoma – Deafness – Liver, kidney and pancreas abnormalities
<i>NETRIN</i>	de novo	Ectopy	Ventricular septal defect
<i>JAG1</i>	de novo	Ectopy, apparent athyreosis, orthotopic hypoplasia	Alagille syndrome
<i>BOR</i>	AR	Ectopy, athyreosis	None
<i>TUBB1</i>	AR	Ectopy, orthotopic hypoplasia, hemithyroid	Macroplatelets

AD, Autosomal dominant; AR, autosomal recessive; CH, congenital hypothyroidism; RDS, respiratory distress syndrome; TSH, thyroid-stimulating hormone.

which does not require treatment.⁷⁵ The phenotypic spectrum of biallelic mutations ranges from hyperthyrotropinemia with normal thyroid hormones and anatomy⁷³ to apparent athyreosis.^{38,76} There is no associated extrathyroidal phenotype.

Thyroid Transcription Factor Mutations

The thyroid transcription factors *NKX2.1* and *PAX8* are necessary and sufficient for the differentiation of stem cells into follicular cells,⁷⁷ whereas *FOXE1* may be involved in their migration.⁷⁸ Given their expression in extrathyroidal tissues, mutations mostly lead to syndromic phenotypes.

NKX2.1

The thyroid phenotype of patient bearing monoallelic inactivation of *NKX2.1* is typically restricted to mild hyperthyrotropinemia and it is the lung (lethal neonatal hypoplasia or recurrent infections of the lungs) and brain (hypotonia followed by choreoathetosis) manifestations of the “brain-lung-thyroid” syndrome that led to the diagnosis. These mutations may occur de novo or be transmitted in an autosomal-dominant fashion.⁷⁹

FOXE1

Only four homozygous mutations in *FOXE1* have been reported in athyreotic children with cleft palate and spiky hair, with or without bifid epiglottis and choanal atresia (Bamforth–Lazarus syndrome). Three mutations led to loss of function, and one led to gain of function.⁸⁰

Paired Box Gene 8

PAX8 is involved in thyroid and kidney development. The phenotypic spectrum of de novo or autosomal-dominantly inherited mutations varies widely both among individuals and within families carrying the same mutations, and ranges from normal thyroid morphology to hypoplasia, ectopy or athyreosis, with or without renal manifestations.⁸¹

GLIS3

Biallelic inactivation of GLI-similar3 (*GLIS3*), which is essential for TSH/TSHR-mediated proliferation of thyroid follicular cells and hormone biosynthesis, has been reported in a handful of cases. The patients present with a multisystem disorder dominated by athyreosis and neonatal diabetes, but also with glaucoma, sensorineural deafness, craniosynostosis, cardiac, liver, kidney, and exocrine pancreatic failure.⁸²

Hematopoietically Expressed Homeobox Protein

Thyroid follicular cells are characterized by the coexpression of *PAX8*, *NKX2.1*, *FOXE1*, and hematopoietically expressed homeobox protein (*HHEX*). However, the only patient with a monoallelic *HHEX* variant also had biallelic *TPO* mutations and a goiter, so the role of *HHEX* in thyroid development remains unclear.⁸³

NKX2.5

Because thyroid dysgenesis may be associated with defects in heart septation, monoallelic variants in *NK2* homeobox-5 (*NKX2.5*), a gene primarily known for its role in inherited heart conduction defects, have been investigated in patients with CH. However, the variants found in the probands were also carried by euthyroid parents with normal thyroid anatomy and, therefore, *NKX2.5* variants are not sufficient to cause thyroid dysgenesis.⁸⁴

NETRIN

In a single dysmorphic patient with thyroid ectopy, a ventricular and atrial septal defect, a patent ductus and a complex chromosome rearrangement, copy number variant analysis revealed a deletion of *NETRIN1* (*NTN1*), a gene encoding a laminin-related secreted protein that acts as an axon guidance molecule during neural development.¹⁴

JAG1

Alagille syndrome type 1 is a rare syndrome with liver and cardiovascular involvement generally caused by a heterozygous mutation in *JAG1*, a gene encoding a Notch pathway ligand or the receptor *NOTCH2*. Among 21 young patients with this syndrome, three were found to have severe CH caused by ectopy, apparent athyreosis, or orthotopic hypoplasia.⁸⁵

BOREALIN and *TUBULIN*

Mono- or biallelic mutations in these genes have been found in three families each with different forms of CH, including ectopy. In addition to CH, patients with *TUBB1* mutations have macroplatelets.^{86,87}

Thyroid Dyshormonogenesis

General Features

Functionally, the thyroid is an iodine pump that organifies this nutrient to make thyroid hormone. Iodine availability is the rate-limiting step for thyroid hormone synthesis, and thus a recycling mechanism exists to conserve it maximally. TSH is the main regulator of hormone biosynthesis: binding of the TSH receptor on the follicular cell surface triggers cyclic adenosine monophosphate (cAMP) activation, which in turn stimulates iodine transport across the cell membrane. Iodine is trapped in the follicular cell, diffuses to its apex, and is transported into the colloid. Next, oxidation and incorporation into tyrosine residues within the TG molecules takes place. TG is then endocytosed and fuses with intracellular phagolysosomes. Proteolysis leads to the release of iodotyrosines (monoiodotyrosine [MIT] and diiodotyrosine [DIT]) and iodothyronines (T4 and T3). Lastly, deiodination of MIT and DIT by dehalogenase leads to intracellular iodine recycling, while T4 and T3 are released into the circulation.⁸⁸ TG that escapes from the gland via the lymphatic system can be detected in blood and can be used as a marker for the presence of thyroid tissue. A schematic representation of thyroid hormone biosynthesis is shown in Fig. 8.7. Any defect in biosynthesis will, because of increased TSH secretion, result in a goiter. By analogy with the adrenal, thyroid dyshormonogenesis could therefore be conceptualized as “congenital thyroid hyperplasia.”

Dyshormonogenesis accounts for about 10% of CH,⁴⁷ except in consanguineous populations. In contrast to the mostly sporadic nature of dysgenesis, thyroid dyshormonogenesis follows a classically Mendelian, autosomal-recessive pattern. Decreased iodine trapping, defective organization of trapped iodine, abnormalities of TG structure, and deficiency of iodotyrosine recycling have all been described. *TPO* mutations appear to be most common in Caucasians⁸⁹ and *DUOX2* in Asians.⁹⁰

The goiter of patients with dyshormonogenetic CH can be seen as early as in utero²⁵ or at birth, but in many newborns, thyroid enlargement goes unnoticed, or onset of goiter occurs later. The diagnosis of the specific type of dyshormonogenesis does not affect initial treatment or counseling: a 25% recurrence risk for siblings of affected subjects can be given

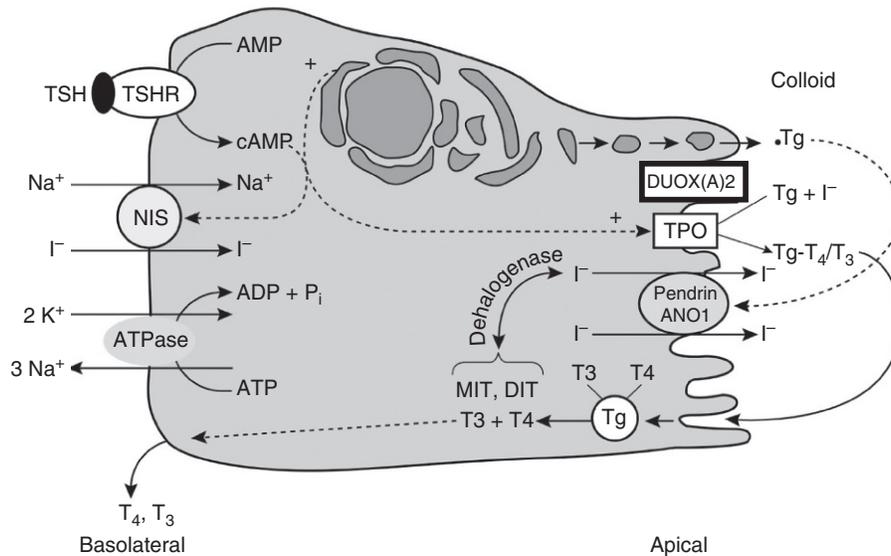

Fig. 8.7 Schematic representation of a thyroid follicular cell indicating all the important steps in thyroid hormone biosynthesis. *ANO1*, Anoctamin-1.

empirically. In cases with transient CH, *DUOX2*, or *DUOX(A)2*, mutations are likely.⁹⁰ Otherwise, a molecular diagnosis should only be sought when the inheritance pattern is other than autosomal recessive.⁹¹

Sodium-Iodine Symporter Defects

Mutations in the *SLC5A5* gene encoding the sodium-iodine symporter (NIS) impair the first step of thyroid hormone biosynthesis, whereby iodine is transported across the plasma membrane into the follicular cell cytosol. NIS is also present in several other tissues, including the salivary glands, gastric mucosa, mammary glands, ciliary body, choroid plexus, and placenta. Although these tissues can concentrate iodine (and thus be visible on iodine scintigraphy), the capacity to organify inorganic iodine is limited to the thyroid gland. Based on the degree of residual NIS activity, patients may present as neonates, infants, or during childhood. Diagnosis is based on detection of a goiter on physical or ultrasound examination with absent or reduced iodine uptake on scintigraphy. Infants may present after normal newborn screening and therefore risk neurodevelopmental delay.⁹²

Pendred Syndrome

Biallelic loss-of-function mutations in the *SLC26A4* gene encoding for the anion exchanger protein pendrin lead to a partial iodide organification defect caused by impaired iodide efflux. Pendrin is also expressed in the inner ear where it is involved in normal anion transport, and in the kidney where it functions as a chloride/bicarbonate exchanger. Clinical features of Pendred syndrome (PDS) include congenital bilateral neurosensory deafness and goiter, but no renal abnormalities. The thyroid phenotype is usually mild: the development of goiter and mild hypothyroidism depends on nutritional iodine intake and shows variable onset within the same families.⁹³ It is therefore seldom identified by newborn screening.⁹⁴ Anoctamin-1 is another apical iodide channel⁹⁵ but its role in human disease has not yet been proven.

Thyroperoxidase Defects

The heme protein TPO is membrane bound at the apex of follicular cells where it catalyzes the iodination of TG-bound

tyrosyl residues to form the iodotyrosines MIT and DIT, and the coupling of these in association with thyroid (nicotinamide adenine dinucleotide phosphate) oxidases. Over 100 mutations have been described.⁹⁶ Up to 17% of patients with monoallelic mutations have TPO deficiency and monoallelic expression of the mutant allele in the thyroid has been shown in three siblings born to a mutation-carrying but unaffected father.⁹⁷ Overall, no clear genotype-phenotype correlations have been established, and phenotypes may vary even within the same families. TPO deficiency manifests as goitrous CH with elevated levels of serum TG and high iodine uptake on scintigraphy, although a family with thyroid hypoplasia has recently been reported.⁹⁸

DUOX2 Defects

DUOX2, like TPO, is located at the apical membrane of thyroid follicular cells and its H_2O_2 -generating role is the rate-limiting factor for TG iodination during thyroid hormone biosynthesis. Originally, it was thought that biallelic mutations inactivating *DUOX2* or its maturation factor *DUOXA2* cause permanent CH, whereas monoallelic mutations cause transient CH.⁹⁰ However, there are many exceptions to this rule and the phenotype of *DUOX2* deficiency ranges from life-threatening goiter in utero to life-long euthyroidism.^{99–101} Compensation by *DUOX1* has been postulated to explain these findings.

Thyroglobulin Defects

Mutations in the *TG* gene affect the organification step of thyroid hormone biosynthesis through a variety of structural changes in the TG glycoprotein (abnormal folding, defective transport, lack of access to tyrosine residues, or defective iodotyrosine coupling). Clinically, the result is goitrous CH as early as in utero or at birth, with low or undetectable serum TG levels.¹⁰²

Dehalogenase Defects

The *dehalogenase* (*DEHAL1*) or *IYD* gene encodes iodotyrosine deiodinase, the enzyme responsible for iodine recycling in the follicular cell to avoid the leaking of iodine in the bloodstream and subsequent loss in the urine. In the few individuals described to date, the thyroid phenotype is variable and, as

in PDS and *DUOX2* deficiency, seems dependent on iodine intake and likely other yet unidentified modifiers. The biochemical hallmark of this condition is an increase in urinary MIT and DIT concentrations.¹⁰³

Transient Neonatal Hyperthyrotropinemia and Hypothyroidism

Transient CH is a temporary deficiency of thyroid hormone that occurs postnatally, with eventual restoration of normal thyroid function over time, typically within weeks to months. This may be primary hypothyroidism (elevated TSH, low T4) or isolated hyperthyrotropinemia (elevated TSH, normal T4). Identification and treatment of transient CH is likely the reason for the apparent increase in prevalence of congenital hypothyroidism because screening was implemented.^{47,104,105} The reported proportion of those diagnosed with CH who have transient dysfunction is widely variable, likely reflecting different screening algorithms and cutoffs, as well as the lack of a standardized definition and evaluation strategy for transient CH.

Iodine Deficiency

Worldwide, iodine deficiency likely remains the most common cause of transient CH. Even in industrialized countries, maternal iodine intake should be regularly monitored. The National Health and Nutrition Examination Survey (NHANES) demonstrated a decline in iodine nutrition from NHANES I to III with an apparent stabilization thereafter, but evidence of persistent mild deficiency exists.³ The American Thyroid Association recommends that women take a dietary supplement containing 150 µg of iodine daily during preconception, pregnancy, and lactation, but adherence to this recommendation has been poor.³ Premature newborns are at higher risk of iodine deficiency caused by inadequate time for accruing adequate iodine stores within the gland.

Iodine Excess

Excessive iodine exposure can also cause hypothyroidism caused by the Wolff-Chaikoff effect. Prenatal exposure may occur through maternal use of amiodarone, iodine antiseptics, or exposure to iodinated contrast agents. Postnatally, a systematic review found that neonates exposed to iodinated contrast media are at risk of abnormal thyroid function and development of hypothyroidism and that the risk might be higher in premature infants.¹⁰⁶ Exposure can occur through the use of iodinated skin preparations, as well as contrast media for cardiac catheterization, urinary and gut imaging, or treatment with amiodarone. This has led to many nurseries discontinuing the use of iodine containing antiseptics for skin preparation. Hypothyroidism may not be detected at newborn screening, as low T4 and high TSH levels generally appear 2 to 3 days after exposure. Some nurseries have recommendations for thyroid function testing after exposure to iodine. The duration of effect of iodine excess on thyroid function is variable.

Transfer of Drugs or Antibodies From Mother to Fetus

Maternal use of antithyroid drugs at the time of delivery can result in transient hypothyroidism in the neonate with return of normal thyroid hormone metabolism typically within 2 to 5 days.¹⁰⁷ Thyrotropin receptor blocking antibodies (TRABs) block the TSH receptor in the thyroid gland of the newborn, resulting in transient hypothyroidism. This resolves within 3 to 6 months because the antibodies of maternal origin disappear. This should be a diagnostic consideration in babies born to women with known autoimmune thyroid disease (Graves

disease or autoimmune thyroiditis) and families with a previous sibling detected with CH. Radionuclide uptake might be blocked partially or completely.

Diagnosis and Management of Transient Congenital Hypothyroidism

In newborns, permanent CH can only be diagnosed in those with either true athyreosis or ectopic thyroid on scintiscan. Those with an orthotopic gland of normal or even increased size may have transient CH. Practice guidelines¹⁰⁸ recommend treating all those with presumptive CH for a period of 3 years during the critical period of thyroid hormone-sensitive neurocognitive development, followed by a controlled withdrawal. During these 3 years, a low T4 requirement is suggestive of transience of CH, but there is overlap with permanent CH.¹⁰⁹

Transient Hypothyroxinemia of Prematurity

Transient hypothyroxinemia of prematurity (THOP; low T4 with normal TSH) is observed in up to 50% of infants born before 28 weeks. Multiple observational studies have shown a correlation between neuropsychological development and neonatal T4 concentrations, but a long-term randomized, placebo-controlled trial did not show evidence of benefit from thyroxine administration.¹¹⁰ On the other hand, premature infants have low intrathyroidal iodine stores and the T4-development correlation may be in fact a reflection of iodine deficiency. A multiple arm-trial comparing various treatment regimens including T4, iodine, and placebo has been ongoing for more than a decade, but definitive results on neurodevelopment have not been reported.¹¹¹

Likely because of their low intrathyroidal iodine stores, fetuses and premature neonates are prone to hypothyroidism from acute iodine overload (the Wolff-Chaikoff effect). This was initially reported in areas of borderline low iodine intake but is now known to occur elsewhere as well.¹¹² Thus iodine-containing disinfectants should be replaced with chlorhexidine in obstetrical and perinatal care and the use of iodine-containing contrast agents minimized, even in full-term infants.¹¹³ Infusion of dopamine, a potent suppressor of TSH secretion, is frequently (as high as 36%) used in infants born before 29 weeks of gestation.¹¹⁴ Both iodine overload and dopamine use contribute to the observations of a “delayed TSH rise” in premature infants and have led many programs to routinely obtain a second screening specimen. However, this problem is transient and the limited evidence does not suggest a benefit from treatment⁵⁶ so the routine second screen may not be justified.¹¹⁵

Consumptive Hypothyroidism

Hemangiomas may produce sufficient amounts of type 3 deiodinase to cause severe hypothyroidism.¹¹⁶ Hypothyroidism develops with the rapid growth of the hemangioma in the first weeks or months of life. It may be the presenting feature of the hemangioma, which may not be visible if located in the liver.¹¹⁷ Thus in severe early-onset hypothyroidism requiring high doses of thyroxine, an abdominal ultrasound is indicated. Consumptive hypothyroidism can be confirmed by the finding of low T4 and high reverse T3 in serum. The hypothyroidism resolves with spontaneous involution or with medical or surgical treatment of the hemangioma.

Defects in Thyroid Hormone Signaling Pathways

The first cases of thyroid hormone resistance had a mutation in the thyroid hormone receptor beta gene. Since then, mutations

in the thyroid hormone receptor alpha have also been described and other mechanisms of impaired sensitivity to thyroid hormone have been identified, including impaired conversion of T4 to T3 and defective transport of T4 and T3 into the cell. All these congenital defects are now collectively named “defects in thyroid hormone signaling pathways.”¹¹⁸ Although rare, thyroid hormone resistance may be detected through an increased TSH at newborn screening.¹¹⁹

Defects in Thyroid Hormone Metabolism

T4 is converted to biologically active T3 in the cell cytoplasm through deiodination by the selenoenzymes, DIO1 and DIO2, mainly in the liver and the thyroid itself. No disease has been reported in humans from mutations in DIO1 or DIO2, presumably because, through compensation, both DIOs would need to be affected for symptoms to develop. Consistent with this concept, biallelic inactivation in *SBP2*, which encodes a selenoprotein that affects both deiodinases, results in a phenotype of mild thyroid dysfunction (high-normal T4, low-normal T3, normal TSH). The clinical manifestations range from mild slowing of growth¹²⁰ to a severe multisystem disorder including hearing impairment, vertigo, muscle weakness, infertility, and mild developmental delay.¹²¹

Defects in Thyroid Hormone Transport Into Cells

T4 and T3 are actively transported into cells, where they bind to the intracellular thyroid hormone receptor. The expression of these transporters is tissue dependent. MTC8 plays an important role in the transport of T3 from glial cells to neurons. Individuals with an MTC8 defect have thyroid hormone deprivation in the brain during embryonic and early postnatal life resulting in varying degrees of psychomotor delay, typically severe and presenting during infancy or early childhood (known as the *X-linked Allan-Herndon-Dudley syndrome*). These patients have characteristically high serum T3 and low rT3 concentrations, low T4, and normal or slightly elevated TSH levels. The high T3 may cause symptoms of hyperthyroidism in peripheral tissues that are not dependent on MTC8, resulting in tachycardia, increased metabolic rate, and sleep disturbances.^{122,123} DITPA (diiodothyropropionic acid) treatment almost completely normalizes thyroid function tests and improves weight gain, but should probably be started very early—perhaps even in utero—to improve neurocognitive function.¹²⁴

Defects in Thyroid Hormone Receptors

The active hormone T3 binds with equal affinity to both TR- α and TR- β receptors with variable expression ratios in different tissues and individuals. For example, the pituitary thyrotrophs express primarily TR- β , whereas other brain areas express only TR- α and the heart expresses both. As a result, the clinical phenotype of hormone resistance depends on whether it is TR- α or TR- β that is mutated. In addition, the variable phenotypes of family members with the same mutations point to genetic or nongenetic modifiers.¹²⁵

The most common resistance to thyroid hormone (RTH) results from de novo or dominantly inherited mutations that inactivate the TR- β gene (*RTH-beta*), with more than 3000 patients reported and an estimated incidence of 1:40,000 as identified through a primary T4 screening program.¹²⁶ Many with RTH will be clinically euthyroid, but goiter is common. Hyperthyroid symptoms may occur in the tissues expressing predominantly TR- α , such as the heart (tachycardia) and some brain regions (hyperactivity) and increased metabolic rate. Hypothyroid symptoms predominate in TR- β -expressing tissues and may include growth failure, delayed bone maturation,

learning disabilities, and sensorineural deafness.¹²⁵ Treatment is usually not required.¹²⁷

RTH caused by inactivating mutations of TR- α , also de novo or dominantly inherited, have also been identified. Patients present clinically with developmental delay, constipation, and short legs and biochemically with low fT₄, high fT₃, and normal TSH.¹²⁸

Central Hypothyroidism

Central CH is an uncommon condition resulting from inadequate stimulation of the thyroid by TSH. Prevalence varies by ascertainment method but may be as high as one in 16,000 by biochemical screening.⁵² The majority of patients will have hypothalamic and/or pituitary pathology with multiple pituitary hormone deficiencies, with or without structural anomalies of the pituitary and additional syndromic features. Magnetic resonance imaging (MRI) generally shows a “classical triad” of ectopic posterior pituitary, thin or absent pituitary stalk, and hypoplastic anterior pituitary. A small minority of these individuals will have mutations in known transcription factors, such as *POU1F1*, *PROP1*, *HESX1*, *LHX3*, and *LHX4*. The exceptional cases of central hypothyroidism that are initially isolated can be caused by mutations in TSH β ,^{37,129} *TRHR*,^{130–132} *IGSF1*,^{133,134} and *TBL1X*,¹³⁵ the first two inherited in an autosomal recessive manner and the last two in an X-linked manner. The prolactin response to TRH is absent in patients with *TRHR* mutations¹³⁰ and present in those with TSH β mutations.³⁷ Prolactin levels may be low in patients with *IGSF1* mutations. X-linked loss-of-function mutations in *IGSF1* cause syndromic central hypothyroidism with testicular enlargement, and variable prolactin deficiency, although the macroorchidism is not present at birth.¹³³ Only central CH caused by TSH β mutations is severe enough at birth to cause intellectual disability; immunoreactive TSH may be slightly elevated³⁷ but not above screening cutoffs, so primary TSH screening will not identify it¹³⁶; given its rarity, population-based screening is not warranted, but a strong clinical suspicion of CH should prompt a measurement of serum fT₄ even if TSH is normal. Overall, primary T₄ screening was not superior to clinical ascertainment in the Indiana program, which therefore switched to a primary TSH screening strategy.⁴

Evaluation of Infants With a Positive Newborn Screening Test

Any positive CH newborn screening result should be acted on immediately to confirm the diagnosis and to promptly initiate treatment. Beyond acting on the screening result, it is important for the individual, as well as for public health purposes, to establish the etiology of CH and to document outcomes.

Thyroid autoimmunity in women of childbearing age is common but only accounts for 1% of cases of CH. The mother should be queried about an unusually high¹³⁷ or low iodine intake during pregnancy and the obstetrical and neonatal records should be scrutinized for the possibility of acute iodine overload.¹¹² Consanguinity increases the likelihood of dyschromonogenesis. Unexplained postmaturity and macrosomia are common in CH.¹³⁸ Unusually large fontanelles and macroglossia seen in CH can be identified immediately after birth¹³⁹ and hypotonia, umbilical hernia, and prolonged jaundice soon afterward. The neck of newborns is short and detecting a goiter is exceptional, even with the neck hyperextended. The general physical examination should focus on dysmorphic features and cardiac auscultation.

Confirmatory thyroid function tests including serum TSH and fT₄ should be obtained on any newborn with a positive

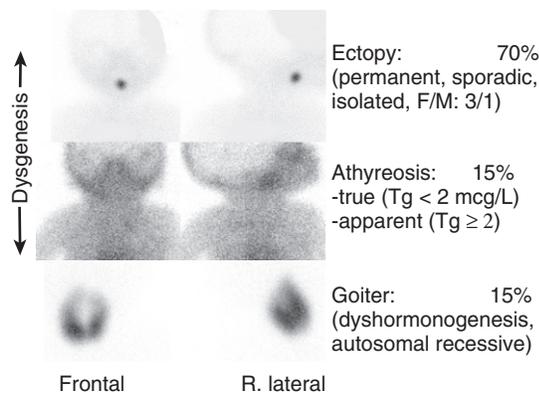

Fig. 8.8 The three most commonly seen etiologies of congenital hypothyroidism as evidenced by nuclear medicine scintigraphy using sodium pertechnetate.

screening result. However, treatment initiation should never be delayed while awaiting test results, especially if TSH on the screening sample is more than 40 mU/L.¹⁰⁸ TSH correlates with CH severity, but only pretreatment fT4 predicts neurocognitive sequelae, with lower values conferring greater risk.^{140,141} If radionuclide imaging reveals no uptake, TG will distinguish apparent from true athyreosis. In the former case, antibodies to, or inactivating mutations in, the TSHR will allow to predict the transience or permanence of the hypothyroidism.

Radionuclide scanning is the only imaging modality that will unequivocally detect ectopic glands, which account for two-thirds of cases of overt CH (Fig. 8.8). With 1 mCi of the readily available and cheap sodium pertechnetate, this etiology is established in 20 minutes and parents can be told that there is a 99% probability that their child's CH is sporadic and will be permanent. In contrast, imaging with ¹²³I, a less available and more expensive isotope, takes hours and only adds information about organification in cases of goiter, which does not alter management. Babies should be fed after the injection of technetium to avoid tracer accumulation in their salivary glands. Advantages of performing the scan at diagnosis include easier administration of the test in newborns who usually fall asleep following an oral feed (vs. a toddler who may not cooperate with the test). Ideally, scintiscanning should be performed before therapy is begun, although it should never delay initiation of hormone replacement. After starting treatment, the time window for scintiscanning depends on CH severity but is a few days, as long as TSH is more than 20 to 30 mU/L on the day of imaging.

Neck ultrasound has been extensively used by clinicians reluctant to use radionuclide imaging but often yields equivocal, false positive or false negative results.¹⁴² Absent knee epiphyses on x-ray in a term newborn documents a prenatal origin of CH, which should lead to an even greater attention to neurocognitive development.

Some clinicians opt to forego imaging altogether as it may be perceived as cumbersome to organize and does not alter immediate management. However, the inability to provide the parents with an etiological diagnosis of permanent CH likely contributes to the observation that up to 40% of the parents of the 1 in 2360 children, labeled as having CH by newborn screening in the United States, stop renewing their child's thyroxine prescriptions by age 4 years.¹⁴³

Treatment of Congenital Hypothyroidism

Thyroid hormone replacement in the form of levothyroxine should be commenced promptly after diagnosis, and at the

latest by 2 weeks of life, as delayed treatment initiation correlates with lower IQ. The goal of treatment is to restore normal thyroid function as quickly as possible and maintain it thereafter. The only randomized controlled trial of different starting doses showed that 50 mcg per day (~15 mcg/kg/d) resulted in the best neurodevelopment at 5 years.¹⁴⁴ Long-term observational studies^{145–147} support this approach, which is endorsed by professional society guidelines, although tiered dosing recommendations based on biochemical severity and imaging have been proposed.¹⁴⁸ Local T4 to T3 conversion is the major source of thyroid hormone in the brain and, consequently, the addition of T3 does not provide further benefit.¹⁴⁹ Thyroxine is well absorbed by the gut but, in situations, such as short bowel syndrome, intravenous thyroxine followed by very doses of oral thyroxine may be needed.¹⁵⁰

As clinical signs and symptoms are not sufficiently reliable to assess thyroid hormone status, thyroid function needs to be monitored closely following initiation of therapy, with progressively decreasing follow-up intervals over time. The first clinical and biochemical follow-up is recommended within about 2 weeks of initiating therapy. In general, subsequent visits are at least every 3 months for the first year of life, every 6 months until 3 years, and yearly until growth is completed.

Both undertreatment and overtreatment should be avoided, but the former is more closely linked to adverse outcomes at school age¹⁵¹ and in adulthood.¹⁵² The goal is to maintain TSH within the age-appropriate reference range and fT4 within the upper half of the normal range. Two weeks after starting at a dose of 15 mcg/kg/d, mean serum fT4 is 56 pmol/L (4.3 ng/dL)¹⁴⁴ but it should be kept in mind that mean serum fT4 of normal newborns at 1 to 4 days of age is 48 pmol/L (3.7 ng/dL).¹⁵³ Serum T3 is generally normal. Likely, a higher T4 suppression threshold for TSH exists in infants, that only resets later in childhood.¹⁵⁴ Especially early on, TSH is the main treatment target and, provided the TSH is not persistently suppressed or a child is clinically hyperthyroid, the dose does not need to be reduced.

Clinical monitoring during follow-up visits should focus on growth, developmental milestones, school progression, and behavior. If treated adequately, length and weight curves are within the normal range for family, and by age 3 years, complete catch-up growth, including normalization of the bone age is expected.²⁹ Head circumference tends to be slightly above average,^{155,156} likely reflecting an immaturity of the skeleton rather than true pathology. With appropriate treatment, children with CH usually have normal neurocognitive development, although the most severely affected may have hearing impairment.¹⁵⁷ A low socioeducational background of the family interacts with the biological effects of CH.¹⁴¹ Thus CH severity, treatment adequacy, and social determinants should all be considered in the management plan and educational interventions. Appropriate genetic counseling should be provided in families with a genetic defect of thyroid formation or function.

CONGENITAL HYPERTHYROIDISM

Graves Disease

In spite of the large number of women of childbearing age with past or present Graves disease, estimated at 0.1% to 2.5%,¹⁵⁸ the transplacental passage of immunoglobulins that stimulate the TSH receptor (TSIs) leading to symptomatic Graves disease occurs in only 1 in 50,000 to 1 in 100,000 fetuses or neonates. The reason why only 1 in about 1000 at-risk fetuses or newborns develop symptomatic hyperthyroidism is unknown. However, fetal/neonatal hyperthyroidism can be severe and, when it occurs, should be managed in centers with the necessary expertise in high-risk pregnancies.

Ideally, all women with Graves disease should have serum TSIs measured in early pregnancy. This applies to those currently treated for hyperthyroidism, as well as to those who are now euthyroid, spontaneously or on replacement after ablative therapy.¹⁵⁸ A high TSI titer in maternal serum makes hyperthyroidism more likely in the fetus or newborn. Unfortunately, this information is often not available at first evaluation¹⁵⁹ and clinicians are confronted at first with the classical signs heralding fetal hyperthyroidism, such as tachycardia and intrauterine growth retardation. In the hands of highly skilled radiologists, a fetal goiter may be the first sign, and its function may be predicted from its ultrasound characteristics, but whether this will be generalizable remains unproven.¹⁶⁰ The hyper- or hypothyroid nature of a goiter in a fetus can generally be guessed on the basis of maternal TSI concentrations or antithyroid drug dose being used, so that cordocentesis, which carries a 1% to 2% risk of fetal loss,²⁶ is usually not indicated.

Traditionally, the mainstay of treatment of hyperthyroidism during pregnancy has been the administration of propylthiouracil (PTU) because of the risk of methimazole (MMZ)-induced embryopathy.¹⁶¹ However, because of the greater liver toxicity of PTU,¹⁶² it has been suggested that MMZ should be preferred after organogenesis is complete but the practicality of switching from one drug to another has been questioned,¹⁶³ and recent data suggest PTU may be teratogenic as well.¹⁶⁴ Whichever drug is used, maternal antithyroid treatment should normalize fetal heart rate within 2 weeks. The antithyroid drug dose can usually be decreased progressively.

Graves disease in the newborn is manifested by irritability, tachycardia, hypertension, poor weight gain, thyroid enlargement, and exophthalmos. Thrombocytopenia, hepatosplenomegaly, jaundice, hypoprothrombinemia, and cardiac failure may occur. The diagnosis is confirmed by an undetectable serum TSH, high levels of serum T4, fT4, and T3. In contrast, on blood drawn on the second day of life in normal children, fT4 is high but TSH is not suppressed. In some neonates, the onset of symptoms and signs may be delayed as long as 8 to 9 days, if they were born to a mother treated with antithyroid drugs, and also reflecting the switch from an inactivating to an activating conversion of T4 to active T3 by liver and other tissues after birth. Neonatal Graves disease resolves spontaneously as maternal TSIs are cleared from the infant's circulation. The usual clinical course of neonatal Graves disease extends from 3 to 12 weeks.

Various biochemical parameters on serum collected from cord or in the first few postnatal days have been proposed to identify at-risk newborns who will develop clinically significant hyperthyroidism.³⁴ All at-risk newborns should, at a minimum, be carefully monitored for postnatal weight gain. Those who develop symptomatic hyperthyroidism should be admitted and their heart rate monitored. Treatment includes propranolol (1–2 mg per kilogram per day, divided in 4 doses) and methimazole in a dose of 0.5 to 1 mg/kg daily in divided doses at 8-hour intervals. Iodine is also often used, because it rapidly inhibits hormone release: Lugol's solution (5% iodine and 10% potassium iodide; 126 mg of iodine per milliliter) is given orally in a dose of one drop (about 8 mg) 3 times daily. A therapeutic response should be observed within 24 to 36 hours. If a satisfactory response is not observed, the dose of antithyroid drug and iodine can be increased by 50%. Glucocorticoids in high doses diminish T4 to T3 conversion and may therefore be helpful. In severe cases, sedatives and digitalization may be necessary.

Nonautoimmune Hyperthyroidism

Mutations that result in increased constitutive activity of the TSH receptor give rise to hyperthyroidism. Mutations can be present in the germline and be inherited in an autosomal

dominant manner or occur de novo or, much more rarely than in adults, at the somatic level, leading to the development of an autonomous adenoma. In all cases, persistent congenital non-autoimmune hyperthyroidism ensues, which is most severe in cases with a de novo germline mutation.¹⁶⁵ Premature delivery and low birth weight in these infants (as in unaffected children of mothers with thyroid hormone resistance),¹⁹ suggest that an increase in thyroid hormone levels in the fetus stunts growth and shortens gestation independent of autoimmunity. Hyperthyroidism is generally associated with a goiter, although this is not always present at diagnosis. Acceleration of bone maturation occurs very early and rapid linear growth, relative thinness, and microcephaly may be observed.¹⁶⁶

In contrast to neonatal Graves disease, nonautoimmune hyperthyroidism is life-long and thyroidectomy, the only curative approach, should be preferred in infants with a hyperfunctioning nodule. In those with a germline mutation and, consequently, a diffuse goiter, surgery is also often required.

DISORDERS OF SERUM THYROID HORMONE TRANSPORT

Several genetic abnormalities of the iodothyronine-binding serum proteins have been described and all are manifest at birth. These include complete TBG deficiency, partial TBG deficiency, TBG excess, transthyretin (prealbumin) variants, and familial dysalbuminemic hyperthyroxinemia. Total T4 is low or high but fT4 is normal and the patients are therefore euthyroid. Nowadays, these abnormalities are only picked up by screening programs that measure total T4, in which an elevated total T4 is at least 10-fold more likely caused by TBG excess than caused by Graves disease.¹²⁶ In serum, fT4, instead of total T4, is now almost universally measured but, depending on the assay method, fT4 can also be spuriously elevated in familial dysalbuminemic hyperthyroxinemia. The key difference between all of these conditions and true hypo- or hyperthyroidism is that serum TSH is normal.¹⁶⁷

Calcium (Ca), phosphorus (as phosphate [HPO_4^{2-}]), and magnesium (Mg) are essential nutrients that are indispensable for the structural integrity of the body and for the function of each of its cells.^{1–3} The genetic and physiological mechanisms that regulate normal mineral homeostasis and bone development, composition, and strength from the prenatal period through adolescence are complex. Lists some of the many genes that direct these processes. Figs. 9.1 and 9.2 schematically depict the factors that regulate calcium and phosphate homeostasis, respectively.

CALCIUM

Calcium is present in extracellular fluids, cell cytoplasm, and bone and is essential for the function of every cell in the body. Together, calcium and phosphate form the hydroxyapatite crystal [$\text{Ca}_{10}(\text{PO}_4)_{10}(\text{OH})_2$] of bone; hydroxyapatite accounts for 65% of bone weight and provides its mechanical and weight-bearing strength and also serves as a reservoir for calcium that may be quickly needed for homeostatic and functional purposes. Although 99% of total body calcium is present in the slowly exchangeable, deeply deposited skeletal crystal, it is the rapidly exchangeable 1% of body calcium in recently accumulated surface bone and in the vascular, extracellular, and intracellular (soft tissues) spaces with which it is in equilibrium

that modulates gene expression, intercellular communication and intracellular signal transduction, neural transmission, cell-to-cell adhesion, clotting, striated, smooth and cardiac muscle contraction, cardiac rhythmicity, enzyme action, synthesis and secretion of endocrine and exocrine factors, fertilization, and cellular proliferation and apoptosis.^{4,5} Approximately 50% of total serum calcium is bound to albumin and globulin; 5% is complexed/chelated to citrate, phosphate, lactate, bicarbonate, and sulfate; and 45% is present as biologically active and closely regulated ionized extracellular calcium (Ca^{2+}). Serum total and ionized calcium concentrations are related to levels of albumin, creatinine, parathyroid hormone (PTH), phosphate, and serum pH. For every 1 g/dL decline in the serum concentration of albumin below 4 g/dL, the total serum calcium level declines by 0.8 mg/dL. The measured Ca^{2+} level is dependent upon the serum pH (normal adult range 1.1–1.3 mmol/L at pH 7.4); increase in alkalinity (higher pH) raises calcium binding to albumin, thus decreasing the plasma Ca^{2+} value, whereas acidic changes (lower pH) decrease binding, thereby increasing the Ca^{2+} concentration. The relationship between pH and Ca^{2+} is best described by an inversely S-shaped third-degree function. The serum concentration of Ca^{2+} is maintained within narrow limits by an integrated system involving the plasma membrane Ca^{2+} sensing receptor (CaSR); PTH and its receptor (PTH/PTH-related protein [PTHrP]-1R); the thyroidal parafollicular C cell product calcitonin and its receptor; and the vitamin D hormone system acting upon the intestinal tract, bone, and kidney. Thus absorption of calcium in the small intestine is enhanced by 1,25-dihydroxyvitamin D3 (calcitriol); the proximal renal tubular reabsorbs calcium filtered through the renal glomerulus; PTH and calcitriol mobilize calcium from the hydroxyapatite apatite crystal, and calcitonin secreted by the parafollicular C cells of the thyroid gland suppresses PTH secretion (see Fig. 9.1).⁶

The intracellular concentration of cytosolic free Ca^{2+} (approximately 100 nM) is 10,000-fold less than that in serum and extracellular fluid (ECF), a gradient maintained by exchange of Ca^{2+} across the cell's plasma membrane and across the membranes of intracellular structures. Within the cell, Ca^{2+} is primarily (99%) stored within the endoplasmic reticulum (sarcoplasmic reticulum in muscle cells) and mitochondria, as well as within endosomes, lysosomes, the Golgi apparatus and secretory granules and bound to the interior of the cell plasma membrane from which sites it can be released by chemical signals, for example, inositol-1,4,5-trisphosphate (IP_3).⁷ Inositol-1,4,5-trisphosphate acts upon IP_3 receptors (encoded by *ITPR1*—see Table 9.1) located in the membrane of the endoplasmic reticulum to effect rapid egress of Ca^{2+} from storage, thereby quickly increasing intracellular Ca^{2+} levels.⁸ Ca^{2+} serves as a “second messenger” signal transducer that controls many cellular activities, including gene transcription, cell division and growth, cell movement, and secretion of synthesized products. Ca^{2+} enters the cell through transmembrane protein “pores,” such as voltage-gated and store-operated calcium channels. Voltage-gated Ca^{2+} channels are active in cells that are electrically excitable, such as cardiac, skeletal, and smooth muscle cells, neurons, gastric mucosa, and pancreatic β cells and that “open” in response to depolarization of the plasma membrane, permitting rapid influx of Ca^{2+} into the cell

Abbreviations

1,25(OH) ₂ D ₃	1,25-Dihydroxyvitamin D ₃ (calcitriol)	LRP	Low-density lipoprotein receptor-related protein
24R,25(OH) ₂ D ₃	24,25-Dihydroxyvitamin D ₃	μFE	Microfinite element
25OH ₂ D ₃	25-Hydroxyvitamin D ₃ (calcidiol)	MAPK	Mitogen-activated protein kinase
AA	Amino acids	MARRS-BP	Membrane-associated rapid response steroid-binding protein
Acan	Aggrecan	MATN3	Matrilin 3
ADHR	Autosomal dominant hypophosphatemic rickets	M-CSF	Macrophage colony-stimulating factor
AF	Activating function	MEPE	Matrix extracellular phosphoglycoprotein
AKT	see PKB	Mg ²⁺	Magnesium
AMP	Adenosine monophosphate	MITF	Microphthalmia-associated transcription factor
APC	Adenomatous polyposis coli	MMP	Matrix metalloproteinase
ARHR	Autosomal recessive hypophosphatemic rickets	MRI	Magnetic resonance imaging
ASARM	Acidic serine aspartate-rich MEPE-associated motif	Na ⁺	Sodium
ATP	Adenosine triphosphate	NAD	Nicotinamide adenine dinucleotide
ATPase	Adenosine triphosphatase	NADPH	Nicotinamide adenine dinucleotide phosphate
BAP	Bone alkaline phosphatase	NF-κB	Nuclear factor-κB
BMAD	Bone mineral apparent density (~volumetric BMD)	NFATC1	Nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1
BMC	Bone mineral content	NHERF	Sodium-hydrogen exchanger regulatory factor
BMD	Bone mineral density	NPT2	Sodium/phosphate transporter 2
BMP	Bone morphogenetic protein	NTX	Amino-terminal cross-link telopeptide of collagen type I
BMU	Basic multicellular unit	OMIM	Online Mendelian Inheritance in Man
BRU	Bone remodeling unit	OPG	Osteoprotegerin
BTT	Bone transmission time	OSCAR	Osteoclast-associated receptor
Ca ²⁺	Calcium—ionized	OSTM1	Osteopetrosis-associated transmembrane protein 1
CaMK	Ca ²⁺ /calmodulin-dependent protein kinase	P3H1	Prolyl 3-hydroxylase-1
CART	Cocaine amphetamine-regulated transcript	PHEX	Phosphate-regulating gene with homologies to endopeptidases on the X chromosome
CaSR	Calcium sensing receptor	PICP	Procollagen type I carboxyl-terminal propeptide
CGRP	Calcitonin gene-related peptide	PINP	Procollagen type I amino-terminal propeptide
Cl ⁻	Chloride	PIIINP	Procollagen type III amino-terminal propeptide
CNP	Natriuretic hormone type C	PI3K	Phosphoinositide-3-kinase
COMP	Cartilage oligomeric protein	PKA	Protein kinase A
CREB	Cyclic AMP-responsive element binding protein	PKB	Protein kinase B (AKT)
CTX	Carboxyl-terminal cross-link telopeptide α1 chain of type I collagen (see ICTP)	PLC	Phospholipase C
DAG	1,2-Diacylglycerol	PO ₄	Phosphate (HPO ₄ ²⁻)
DBP	Vitamin D binding protein	PPARγ	Peroxisome proliferator activator receptor gamma
DMP	Dentin matrix protein	PTH	Parathyroid hormone
DNA	Deoxyribonucleic acid	PTHrP	PTH-related protein
DPD	Deoxyripyridinoline	PTH1R	PTH/PTHrP-1 receptor (PTH/PTHrP-1R)
DRIP	Vitamin D interacting protein	PYD	Pyridinoline
DXA	Dual energy x-ray absorptiometry	QCT	Quantitative computed tomography
ECF	Extracellular fluid	QUS	Quantitative ultrasonography
EGF	Epidermal growth factor	RANK	Receptor activator of NF-κB
ER	Estrogen receptor	RANKL	RANK-ligand
ERK	Extracellular signal-regulated kinase	RDA	Recommended dietary allowance
FGF	Fibroblast growth factor	RNA	Ribonucleic acid
FGFR	Fibroblast growth factor receptor	RXR	Retinoid X receptor
FOS	FBJ osteosarcoma oncogene	SIBLING	Small integrin-binding ligand interacting N-glycoprotein (proteins)
FRP4	Frizzled related protein-4	SOS	Speed of sound
FRS	FGF receptor substrate	SOX	SRY-Box
GABA	Gamma (γ)-amino butyric acid	SPP1	Secreted phosphoprotein 1 (osteopontin)
GDNF	Glial cell line-derived neurotrophic factor	Src	SRC oncogene
GDP	Guanosine diphosphate	SRC	Steroid receptor coactivator
G _{ix}	Alpha subunit of inhibitory GTP-binding protein	STAT	Signal transduction and transcription
G _{sx}	Alpha subunit of stimulatory GTP-binding protein	SYK	Spleen tyrosine kinase
G _{qx}	Alpha subunit of a stimulatory GTP-binding protein	TALH	Thick ascending loop of Henle
GH	Growth hormone	TCF/LEF	T-cell factor/Lymphoid enhancer binding factor
Gla protein	Matrix gamma carboxyglutamic acid	TGF	Transforming growth factor
GMP	Guanosine monophosphate	TIO	Tumor induced osteomalacia
GPCR	G-protein-coupled receptor	TIP	Tuberoinfundibular protein (hypothalamic)
GRB2	GRB2-associated binding protein 2	TNF	Tumor necrosis factor
GRK	G-protein-coupled receptor kinase	TNSALP	Tissue nonspecific alkaline phosphatase
GSK3	Glycogen synthase kinase 3	TR	Thyroid (hormone) receptor
GTP	Guanosine triphosphate	TRAF	TNF receptor associated factor
H ⁺	Hydrogen ion (proton)	TRANCE	TNF-related activation induced cytokine
HNRPD	Heterogeneous nuclear ribonucleoprotein D	TRAP	Tartrate-resistant acid phosphatase
HRpQCT	High-resolution peripheral quantitative computed tomography	TREM2	Triggering receptor expressed on myeloid cells-2
HSP	Heat shock protein	TRP	Transient receptor potential (channel)
ICTP	Carboxyl-terminal cross-link telopeptide of collagen type I generated by matrix metalloproteinase (see CTX)	VDIR	Vitamin D-interacting repressor
IGF	Insulin-like growth factor (somatomedin)	VDR	Vitamin D receptor
IHH	Indian hedgehog	VDRE	Vitamin D response element
IL	Interleukin	VEGF	Vascular endothelial growth factor
IP ₃	Inositol-1,4,5-trisphosphate	WIF	WNT inhibitory factor
ITAM	Immunoreceptor tyrosine-based motif	WINAC	WSTF including nucleosome assembly complex
K ⁺	Potassium	WSTF	Williams syndrome transcription factor
		XHR	X-linked hypophosphatemic rickets

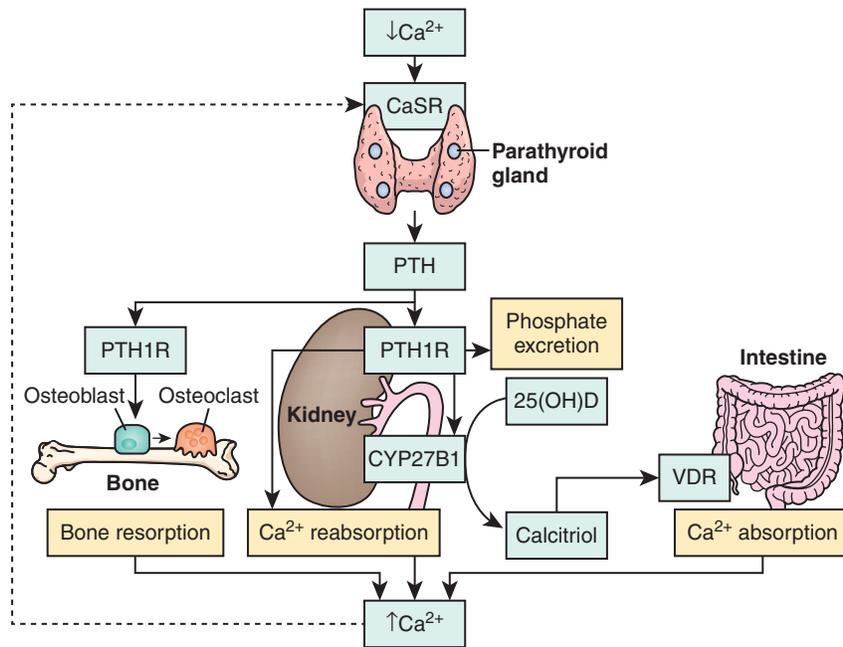

Fig. 9.1 Regulation of calcium homeostasis. Calcium (Ca^{2+}) is absorbed from the intestinal tract, kidney tubule, and bone in response to calcitriol [$1,25(\text{OH})_2\text{D}_3$] and/or parathyroid hormone (PTH). The Ca^{2+} -sensing receptor (CaSR) modulates Ca^{2+} -mediated activity of the parathyroid glands and the renal tubules. Both hypocalcemia and hypophosphatemia enhance renal tubular generation of calcitriol that increases intestinal absorption of calcium and phosphate. PTH increases renal tubular reabsorption of calcium while inhibiting renal tubular reabsorption of phosphate. Increasing serum concentrations of calcium inhibit secretion of PTH. Fibroblast growth factor-23 (FGF23), a phosphatonin secreted by osteoblasts and osteocytes, inhibits renal tubular reabsorption of phosphate and synthesis of calcitriol. Calcitonin, a product of the thyroid gland C cells, inhibits resorption of calcium from bone. (Please see Fig. 9.2 and text for further details.) (From Mannstadt, M., Bilezikian, J.P., Thakker, R.V., et al. (2017). Hypoparathyroidism. *Nat Rev Dis Primers*, 3, 17055. With permission.)

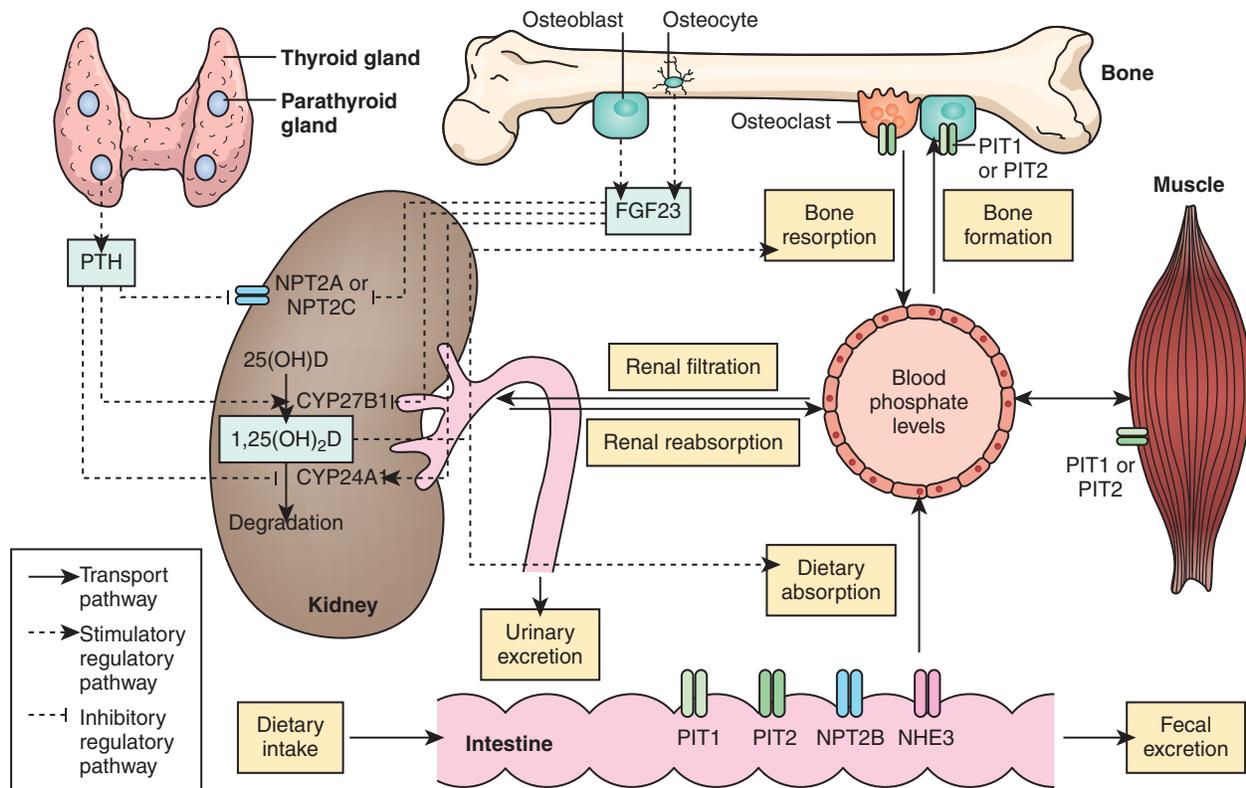

Fig. 9.2 Regulation of phosphate homeostasis. Ingested phosphate is absorbed from the gastrointestinal tract by passive paracellular mechanisms and through active phosphate cotransporters (NP2B, NHE3, PIT1, PIT2). Serum concentrations of phosphate are depressed by parathyroid hormone (PTH) and fibroblast growth factor-23 (FGF23), both of which increase urinary excretion of this cation by decreasing renal tubular expression of phosphate cotransporter proteins (NPT2A, NPT2C). Synthesis of FGF23, a product of osteoblasts and osteocytes, is depressed by low serum phosphate levels and by phosphate-regulating gene with homologies to endopeptidases on the X chromosome (PHEX), dentin matrix protein 1 (DMP1), and ectonucleotide pyrophosphate -phosphodiesterase 1 (ENPP1) all three of which proteins are also synthesized by bone cells. PTH increases whereas FGF23 depresses synthesis of calcitriol (1,25 dihydroxyvitamin D). (See text for details.) (From Minisola, S., Peacock, M., Fukumoto, S., et al. (2017). Tumour-induced osteomalacia. *Nat Rev*, 3, 17044. With permission)

Fibroblast growth factor-23	<i>FGF23</i>	12p13.32	605380
Fibroblast growth factor receptor-1	<i>FGFR1</i>	8p11.2-p11.1	136350
Fibroblast growth factor receptor-2	<i>FGFR2</i>	10q26.13	176943
Fibroblast growth factor receptor-3	<i>FGFR3</i>	4p16.3	134934
Fibroblast growth factor receptor-4	<i>FGFR4</i>	5q35—qter	134935
FK506-binding protein	<i>FKBP10</i>	17q21.2	607063
Four-and-a-half Lim domains	<i>FHL1</i>	Xq26.3	300163
Frizzled, drosophila, homolog of	<i>FZD1</i>	7q21.13	603408
Frizzled-related protein-4	<i>FRP4</i>	7p14-p13	606570
Gamma-carboxyglutamic acid protein, bone (Osteocalcin)	<i>BGLAP</i>	1q22	112260
GATA-binding protein 3	<i>GATA3</i>	10p14	131320
Glial cells missing, Drosophila, homolog of, 2	<i>GCM2</i>	6p24.2	603716
Glycogen synthase kinase 3-alpha	<i>GSK3A</i>	19q13.2	606784
Group-specific component (DBP)	<i>GC</i>	4q13.3	139200
Growth hormone 1	<i>GH1</i>	17q23.3	139250
Growth hormone receptor	<i>GHR</i>	5p13-p12	600946
Guanine nucleotide binding protein, alpha stimulating	<i>GNAS1</i>	20q13.2	139320
Guanine nucleotide binding protein, alpha 11	<i>GNA11</i>	19p13.3	139313
Hairless	<i>HR</i>	8p21.1	602302
Hematopoietic transcription factor PU.1	<i>SPI1</i>	11p11.2	165170
Heterogeneous nuclear ribonucleoprotein D	<i>HNRPD</i>	4q21.1-q21.2	601324
HNF1 homeobox B	<i>HNF1B</i>	17q12	189907
Indian hedgehog	<i>IHH</i>	2q35	600726
Inhibitor of kappa light polypeptide gene enhancer ... gamma	<i>IKBKG</i>	Xq28	300248
Inositol trisphosphate receptor	<i>ITPR1</i>	3p26.1	147265
Insulin-like growth factor-I	<i>IGF1</i>	12q22-q24.1	147440
IGF-I receptor	<i>IGF1R</i>	15q25-q26	147370
Integrin α v	<i>ITGAV</i>	2q31	193210
Integrin β 3	<i>ITGB3</i>	17q21.32	173470
Integrin-binding sialoprotein	<i>IBSP</i>	4q22.1	147563
Interferon-induced transmembrane protein family 5	<i>IFITM5</i>	11p15.5	614757
Interleukins-1-beta	<i>IL1B</i>	2q14.1	147720
Interleukin-6	<i>IL6</i>	7p15.3	147620
Interleukin 6-dependent DNA binding protein	<i>CEBPB</i>	20q13.13	189965
Klotho	<i>KL</i>	13q13.1	604824
Leptin	<i>LEP</i>	7q31.3	164160
Lipocalin 2	<i>LCN2</i>	9q34.11	600181
Low-density lipoprotein receptor-related protein 2 (Megalyn)	<i>LRP2</i>	2q31.1	600073
Low-density lipoprotein receptor-related protein 5	<i>LRP5</i>	11q13.2	603506
Low-density lipoprotein receptor-related protein 6	<i>LRP6</i>	12p13.2	603507
V-Mak musculoaponeurotic fibrosarcoma oncogene family, protein B	<i>MAFB</i>	20q12	608968
Matrilin 3	<i>MATN3</i>	2p24.1	602109
Matrix extracellular phosphoglycoprotein	<i>MEPE</i>	4q21.1	605912
Matrix gamma carboxyglutamic acid (Gla protein)	<i>MGP</i>	12p12.3	154870
Matrix metalloproteinase 9	<i>MMP9</i>	20q13.12	120361
Mediator complex subunit 4 (vitamin D interacting protein)	<i>MED4</i>	13q14.2	605718
Membrane-bound transcription factor protease site 2	<i>MBTPS2</i>	Xp22.12	300294
Methyl-CpG-binding domain protein 4	<i>MBD4</i>	3q21.3	603574
Mitochondrial RNA-processing endoribonuclease, RNA component of	<i>RMRP</i>	9p13.3	157660
Mothers against decapentaplegic, drosophila, homolog of, 2	<i>SMAD2</i>	18q21.1	601366
Natriuretic peptide precursor C	<i>NPPC</i>	2q37.1	600296
Natriuretic peptide receptor B	<i>NPR2</i>	9p13.3	108961
Natriuretic peptide receptor C	<i>NPR3</i>	5p13.3	108962
Noggin, mouse, homolog of	<i>NOG</i>	17q22	602991
Notch, drosophila, homolog of 1	<i>NOTCH1</i>	9q34.3	190198
Nuclear factor- κ B, Subunit 1	<i>NFKB1</i>	4q24	164011
Nuclear factor- κ B, Inhibitor (I κ B)	<i>NFKB1A</i>	14q13.2	164008
Nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1	<i>NFATC1</i>	18q23	600489
ORAI calcium release-activated calcium modulator 1	<i>ORAI1</i>	12q24.31	610277

TABLE 9.1 Human Genes Involved in Mineral Homeostasis and Bone Metabolism—cont'd

Protein	Gene	Chromosome	OMIM
Osteoclast-associated receptor	<i>OSCAR</i>	19q13.42	606862
Osteocrin	<i>OSTN</i>	3q28	610280
Osteopetrosis-associated transmembrane protein 1	<i>OSTM1</i>	6q21	607649
Paired box gene 1	<i>PAX1</i>	20p11.22	167411
Parathyroid hormone	<i>PTH</i>	11p15.2	168450
PTH-related/like protein	<i>PTHLLH</i>	12p11.22	168470
PTH 1 receptor	<i>PTH1R</i>	3p21.31	168468
PTH 2 receptor	<i>PTH2R</i>	2q34	601469
Patched 1	<i>PTCH1</i>	9q22.3	601309
Peptidyl-prolyl isomerase B (CypB)	<i>PPIB</i>	15q22.31	123841
Peroxisome proliferator-activated receptor gamma	<i>PPARG</i>	3p25.2	601487
Phosphate-regulating gene with homologies to endopeptidases on the X chromosome	<i>PHEX</i>	Xp22.1	300550
Phosphodiesterase 3A, cGMP-inhibited	<i>PDE3A</i>	12p12.2	123805
Phosphodiesterase 4D, cAMP-specific	<i>PDE4D</i>	5q11.2-q12.1	600129
Phospholipase C β -1	<i>PLCB1</i>	20p12.3	607120
Plastin 3	<i>PLS3</i>	Xq23	300131
Pleckstrin homology domain containing protein, family M, member 1	<i>PLEKHM1</i>	17q21.31	611466
Potassium channel, inwardly rectifying, subfamily 1, member 1	<i>KCNJ1</i>	11q24.3	600359
Potassium channel, inwardly rectifying, subfamily J, member 10	<i>KCNJ10</i>	1q23.2	602208
Potassium channel, voltage-gated, Shaker-related subfamily, member 1	<i>KCNA1</i>	12p13.32	176260
Pregnane X receptor	<i>NR112</i>	3q13-q21	603065
Procollagen-lysine,2-oxoglutarate 5-dioxygenase 1	<i>PLOD1</i>	1p36.22	153454
Procollagen-lysine,2-oxoglutarate 5-dioxygenase 2	<i>PLOD2</i>	3q24	601865
Prolyl 3-hydroxylase 1	<i>P3H1</i>	1p34.2	610339
Protein disulfide isomerase, family A, member 3 (MARRS-BP)	<i>PDI3</i>	15q14.3	602406
Protein kinase A	<i>PRKAR1A</i>	17q24.3	188830
Protein phosphatase 1, regulatory subunit 1B	<i>PPP1R1B</i>	17q12	604399
Protein phosphatase 3, catalytic subunit, alpha isoform (calcineurin A)	<i>PPP3CA</i>	4q24	114105
Receptor activator of NF- κ B (RANK)	<i>TNFRSF11A</i>	18q22.1	603499
RANK-Ligand (RANKL)	<i>TNFSF11</i>	13q14.11	602642
Retinoid X receptor α	<i>RXRα</i>	9q34.3	180245
Reversion-inducing cysteine-rich protein with kazal motifs	<i>RECK</i>	9p13.3	605227
Runt-related transcription factor 2	<i>RUNX2</i>	6p21.1	600211
Sclerostin	<i>SOST</i>	17q21.31	605740
Secreted frizzled-related protein 1	<i>SFRP1</i>	8p11.21	604156
Secreted phosphoprotein 1 (Osteopontin)	<i>SPP1</i>	4q22.1	166490
Secreted protein, acidic, cysteine-rich (Osteonectin)	<i>SPARC</i>	5q33.1	182120
Serpine peptidase inhibitor, clade H, member 1 (Heat shock protein 47)	<i>SERPINH1</i>	11q13.5	600943
Sirtuin 1	<i>SIRT1</i>	10q21.3	604479
Smoothed	<i>SMOH</i>	7q31-q32	601500
Sodium phosphate cotransporter Solute carrier family 34, member 1 (NPT2a/NaPi-IIa)	<i>SLC34A1</i>	5q35.3	182309
Sodium phosphate cotransporter Solute carrier family 34, member 2 (NPT2b/NaPi-IIb)	<i>SLC34A2</i>	4p15.2	604217
Sodium phosphate cotransporter Solute carrier family 34, member 3 (NPT2c/Na-Pi-IIc)	<i>SLC34A3</i>	9q34.3	609826
Solute carrier family 4 (anion exchanger), member 2	<i>SLC4A2</i>	7q36.1	109280
Solute carrier family 8 (sodium-calcium exchanger), member 1 – cardiac	<i>SLC8A1</i>	2p22.1	182305
Solute carrier family 8 (sodium-calcium exchanger), member 2 – skeletal	<i>SLC8A2</i>	19q13.32	601901
Solute carrier family 9, member 3	<i>SLC9A3</i>	5p15.3	182307
Solute carrier family 9, member 3, regulator 1 (NHERF1)	<i>SLC9A3R1</i>	17q25.1	604990
Solute carrier family 12 (sodium/potassium/chloride transporter), member 1	<i>SLC12A1</i>	15q21.1	600839
Solute carrier family 12 (sodium/chloride transporter), member 3	<i>SLC12A3</i>	16q13	600968
Solute carrier family 20 (phosphate transporter), member 2	<i>SLC20A2</i>	8p11.21	158378
Sonic hedgehog	<i>SHH</i>	7q36.3	600725
Sorting nexin 10	<i>SNX10</i>	7p15.2	614780
Sphingosine-1-phosphate	<i>S1PR1</i>	1p21.2	601974
SRY-box 9	<i>SOX9</i>	17q24.3	608160
Stromal interaction molecule 1	<i>STIM1</i>	11p15.4	605921
T-Box 1	<i>TBX1</i>	22q11.2	602054
T-cell factor/lymphoid enhancer binding factor	<i>LEF1</i>	4q25	153245
T-cell immune regulator 1	<i>TClRG1</i>	11q13.2	604592
Tartrate-resistant acid phosphatase	<i>ACP5</i>	19p13.2	171640
Transcription factor 3/VDR interacting repressor	<i>TCF3</i>	19p13.3	147141
Transcription factor Sp7 (Osterix)	<i>SP7</i>	12q13.13	606633
Transforming growth factor, Beta 1	<i>TGFB1</i>	19q13.2	190180
Transient receptor potential cation channel, subfamily M, member 6	<i>TRPM6</i>	9q21.13	607009
Transient receptor potential cation channel, subfamily M, member 7	<i>TRPM7</i>	15q21.2	605692
Transient receptor potential cation channel, subfamily V, member 4	<i>TRPV4</i>	12q24.1	605427

cytoplasm, leading to further depolarization of the membrane and activation of cell function.⁹ Voltage-gated channels 2+ may be activated by high or low electrical voltage. For example, the skeletal muscle high voltage-activated calcium channel is composed of five subunits: α_1 , α_2 , β , γ , and δ (one voltage-activated α_1 subunit is encoded by *CACNA1C*). The voltage-sensing, pore-forming Ca^{2+} -binding α_1 subunit has four repeated domains, each with six transmembrane spanning regions (or helices) and intracytoplasmic amino and carboxyl terminals; transmembrane helix 4 serves as the voltage sensor; and the α_1 subunit also has a sequence of amino acids between transmembrane helices 5 and 6 that is partially inserted into the membrane to serve as a “selectivity filter.”⁹ The assembly, intracellular movement, interaction with other proteins, activation, and kinetic properties of the α_1 subunit are modified by the extracellular, glycosylated α_2 subunit, the β subunit (a cytoplasmic globular protein), a small membrane spanning δ subunit that is disulfide-linked to form dimeric $\alpha_2\delta$, and a second transmembrane subunit γ . The voltage-gated calcium channels are designated in accord with their cloned specific α_1 subunits and have been termed *Cav 1.1*, *Cav 1.2*, *Cav 1.3*, ...*Cav 3.3*. The high voltage-dependent *Cav1.1* through *Cav 1.4* calcium channels are present in skeletal, cardiac, and vascular smooth muscle cells; endocrine cells, neurons; and fibroblasts. These calcium channels are activated by the guanine triphosphate (GTP)-binding α_q subunit of $G_{\alpha q}$ -proteins through stimulation of phospholipase C (PLC), leading to phosphorylation of the channel protein. The *Cav1.1* through *Cav 1.4* calcium channels modulate the growth and proliferation of fibroblasts and smooth muscle cells, the synthesis of extracellular matrix collagen proteins, and the activation of specific transcription factors.

Ca^{2+} also enters the cytosol through the plasma membrane store-operated Ca^{2+} channel—ORAI1 (encoded by *ORAI1*).^{8,10,11} Store-operated Ca^{2+} channels are active in cells that are electrically nonexcitable, such as lymphocytes and other immune cells.⁵ Both voltage-gated and store-operated Ca^{2+} channels often coexist in the same cell. The type of Ca^{2+} channel used in a specific cell is determined by the expression of *STIM1* (see Table 9.1) encoding stromal

interaction molecule 1—a protein that transverses the membrane of the endoplasmic reticulum. When the Ca^{2+} content (e.g., “store”) of the endoplasmic reticulum is depleted, *STIM1* unfolds and bridges the cytosolic distance between the endoplasmic reticulum and the cell’s plasma membrane where it binds to and opens the ORAI1 channel, thereby permitting Ca^{2+} influx into the cytoplasm and the restoration of Ca^{2+} stores within cytoplasmic organelles.¹⁰ At the same time that it activates the ORAI1 Ca^{2+} channel, *STIM1* inhibits the voltage-gated Ca^{2+} channel.^{5,12,13} Loss-of-function mutations in *ORAI1* have been identified in patients with severe combined immune deficiency and tubular myopathy.^{14,15}

In addition to traversing rapidly across the cell’s plasma membrane through voltage-gated and store-operated channels, Ca^{2+} enters the cytosol, but at a markedly slower rate, through bifunctional membrane-associated IP_3 receptors that also serve as calcium channels.^{8,16} Encoded by *ITPR1*, the tetrameric IP_3 receptor has six transmembrane domains and a pore-forming loop between the fifth and sixth transmembrane segments. Whereas many IP_3 receptor/channels are expressed in the membranes of the endoplasmic reticulum where IP_3 activation leads to depletion of Ca^{2+} stored in the endoplasmic reticulum, thereby triggering store-operated calcium channel activation, only one to two such channels are expressed in the plasma membrane of each cell. Ca^{2+} is translocated not only through specific Ca^{2+} channels but also through paracellular transport channels. Ca^{2+} is extruded from cell cytoplasm by calcium and energy-dependent adenosine triphosphate (ATP)-driven calcium pumps and in exchange for sodium (Na^+) through H^+ /ATPase and Na^+ / Ca^{2+} exchangers.⁴ The Ca^{2+} -ATPases are encoded by four genes: *ATP2B1* encodes a 1220-amino-acid (AA) membrane protein with a cyclic adenosine monophosphate (AMP)-dependent protein kinase domain and a carboxyl domain to which a calbindin (a calcium binding protein) attaches that links hydrolysis of ATP with transport of cations across membranes. The Ca^{2+} -ATPases have the capacity to transport Ca^{2+} against high concentration gradients. The Na^+ / Ca^{2+} exchangers are widely distributed plasma membrane Ca^{2+} export proteins.^{2,4} A homolog of the human Na^+ / Ca^{2+} exchanger is comprised of 10 transmembrane domains

consisting of two sets of five transmembrane helices in inverted reverse order, with the amino and carboxyl termini within the cytoplasm.^{17,18} Transmembrane helices 2, 3, 7, and 8 form an ion-binding pocket with three low-affinity Na^+ and one high-affinity Ca^{2+} binding sites symmetrically arranged in a diamond formation. Through conformational changes of the structure of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger, the Na^+ and Ca^{2+} binding sites are alternately exposed to either the intracellular or extracellular surfaces of the cell's plasma membrane. As Na^+ from the extracellular space occupies its three binding sites, the binding affinity for Ca^{2+} decreases, thereby releasing this cation into the cytosol and reversing the orientation of the $\text{Na}^+/\text{Ca}^{2+}$ channel; inasmuch as cytosolic levels of Na^+ are low, these cations are then released into the cytosol, restoring the affinity of the exchanger for Ca^{2+} . The human cardiac $\text{Na}^+/\text{Ca}^{2+}$ exchanger is encoded by *SLC8A1* and the human skeletal muscle $\text{Na}^+/\text{Ca}^{2+}$ exchanger by *SLC8A2*.¹⁷ Within the cell, cytosolic Ca^{2+} is transported across the membrane and into the endoplasmic reticulum of muscle cells through Ca^{2+} -ATPase channels encoded by *ATP2A2*; linkage of small ubiquitin-like modifier type 1 (sumoylation) to this Ca^{2+} -ATPase extends its half-life and increases its intrinsic activity.¹⁹

The circulating concentration of Ca^{2+} is detected by the CaSR, encoded by *CASR*, a G-protein-coupled transmembrane heptahelical receptor (GPCR) expressed on the plasma membrane of the PTH-secreting chief cells of the parathyroid glands, epithelial cells of the renal tubules, osteoblasts, and other tissues. When the ambient Ca^{2+} concentration declines, CaSR signaling in the parathyroid glands through $\text{Gq}_{11\alpha}$ (encoded by *GNA11*) activates the intracellular phosphatidylinositol 4,5 bisphosphate signal transduction pathway, leading to rapid release of Ca^{2+} from intracellular storage sites and subsequent increase in synthesis and secretion of PTH. In turn, PTH (and PTHrP) may act through binding to its stimulatory GPCR (encoded by *PTH1R*) present on the plasma membranes of osteoblasts to enhance expression of *TNFSF11* encoding the receptor activator of nuclear factor kappa-B (NF- κ B) ligand (RANK-ligand) thereby stimulating osteoclastogenesis and increasing the rate of bone resorption, thus releasing calcium and increasing its extracellular concentration. PTH also acts on epithelial cells lining the distal renal tubule to enhance renal reabsorption of filtered Ca^{2+} and synthesis of calcitriol (thereby increasing intestinal absorption of Ca^{2+}) while suppressing proximal renal tubular reabsorption of filtered phosphate directly and indirectly by enhancing osteocytic synthesis of fibroblast growth factor-23 (FGF23). Increased serum concentrations of Ca^{2+} reciprocally suppress CaSR activity and PTH synthesis. Intracellular signaling induced by PTH proceeds primarily through the stimulatory guanosine phosphate-binding protein composed of alpha (G_{src}), beta, and gamma subunits.²⁰ After substitution of GTP for guanosine diphosphate (GDP) on the α subunit, G_{src} dissociates from its linked $\beta\delta$ subunits. G_{src} then stimulates intracellular adenylyl cyclase (encoded by *ADCY3*) that converts ATP to cyclic AMP and releases it from the cytoplasmic surface of the plasma membrane of the PTH-responsive cell. Cyclic AMP in turn binds to the regulatory alpha subunit of protein kinase A (encoded by *PRKARIA*), thereby initiating intracellular signaling.²⁰ The catalytic subunits of protein kinase A phosphorylate a number of intracellular proteins, including the cyclic AMP response binding protein (encoded by *CREB1*) that in turn initiates transcription of cyclic AMP target genes. CREB1 is deactivated by one of several phosphodiesterases, including those encoded by *PDE4D* and *PDE3A*. By increasing activity of 25-hydroxyvitamin D-1 α hydroxylase, PTH stimulates renal synthesis of calcitriol, the active metabolite of vitamin D; calcitriol increases calcium absorption in the proximal small intestinal tract and distal

renal tubule, phosphate absorption in the intestine and kidney, and calcium mobilization from bone stores by enhancing osteoclastogenesis; calcitriol downregulates the synthesis and secretion of PTH (see Fig. 9.1).

In the gastrointestinal tract, calcium is absorbed by both active transcellular and passive paracellular processes.^{21,22} During growth in younger subjects and when calcium intake and consequently intraintestinal calcium concentrations are low, active transcellular absorption of calcium predominates; when calcium intake is adequate or high, passive paracellular absorption of calcium in the proximal intestine predominates.^{1,21,23} Transcellular gastrointestinal absorption of calcium is an active and saturable process that is primarily stimulated by the active metabolite of vitamin D₃ (calcitriol) by regulating the availability of transmembrane calcium "pumps" and channels on the luminal/apical and basolateral surface membranes of duodenal enterocytes.^{2,22} Calcitriol acting through the vitamin D receptor (VDR) increases duodenal expression of calcium transporter protein-1 (encoded by transient receptor potential cation channel 6 [*TRPV6*])—a luminal calcium channel with six transmembrane domains and intracytoplasmic amino and carboxyl terminals and a pore region between the fifth and sixth transmembrane domains that forms a homotetramer or heterotetramer combined with TRPV5; TRPV5 and TRPV6 specifically permit Ca^{2+} permeation at physiological levels of this cation.²³ Calcium is also actively absorbed in the intestinal tract by mechanisms that are independent of the VDR.²⁴ Thus the expression of *TRPV6* is increased by both estrogen and prolactin; prolactin increases transcellular absorption of calcium independently of calcitriol.²⁵ After entering the cytoplasm of the enterocyte, Ca^{2+} travels from its apical to its basolateral membrane either within a lysosomal vesicle bound to vitamin D-dependent calbindin D_{9k} (encoded by *S100G*), a protein with two high-affinity calcium binding sites, or within the cytoplasm linked to calmodulin (encoded by *CALM1*). Calmodulin 1 is a 149 AA protein with an amino-terminal "lobe" linked to a carboxyl-terminal "lobe" that can assume more than 30 three-dimensional conformations.⁹ Each lobe has two globular calcium binding domains consisting of two helix-loop-helix motifs connected by an α -helical linker; calcium binding exposes hydrophobic "pockets" that allow calmodulin to bind to and regulate the activity of target proteins.²⁶ When bound to a target protein, calmodulin can assume an exceedingly large number of conformations. This versatility enables calmodulin to act as a calcium sensor for many different proteins subserving distinct processes within a single cell, including voltage-gated calcium channels and calcium/calmodulin-dependent protein kinases. At the basolateral membrane, Ca^{2+} dissociates from calbindin and calmodulin and is then extruded into the extracellular space across the basolateral membrane through a basolateral Ca^{2+} - Mg^{2+} -dependent ATPase calcium channel (encoded by *ATP2B1*). When calcium intake is adequate or high, the bulk of ingested calcium is passively absorbed through paracellular channels between enterocytes in the jejunum and ileum. Calcitriol regulates synthesis of several tight junction proteins, including claudins-2 and -12, cadherin-17, and aquaporin 8.^{21,22,27}

Intestinal calcium absorption is influenced by vitamin D status, its food source (the bioavailability of calcium in cow milk formulas is 38%, that in human breast milk is 58%); the form of the calcium salt in dietary supplements; and the presence in food of inhibitors of calcium absorption, such as phytates, oxalates, or phosphates (e.g., cola beverages).²⁸ Intestinal calcium absorption is increased during adolescence, pregnancy, and lactation, and depressed in patients with nutritional or functional vitamin D deficiency, chronic renal disease, and hypoparathyroidism. The amount of calcium ingested

influences the net amount of calcium absorbed; the lower the calcium intake, the greater is the efficiency of its absorption. In the adult, when the dietary calcium intake is less than 200 mg/d, fecal calcium excretion exceeds intake; thus active absorption of calcium cannot compensate for very low intake. As dietary calcium increases from 200 to 1000 mg/d, active calcium absorption increases but at a progressively decreasing rate. When dietary calcium exceeds 1000 mg/d, active calcium absorption remains relatively constant at 400 mg/d, but passive absorption of calcium through paracellular channels continues to increase.² Thus hypercalcemia may result from dietary calcium excess as in the milk-alkali syndrome. PTH indirectly increases intestinal calcium absorption by enhancing renal 25-hydroxyvitamin D-1 α hydroxylase activity and hence calcitriol synthesis. Growth hormone (GH) and estrogens also increase intestinal absorption of calcium; glucocorticoids and thyroid hormone inhibit this process. Calcium is excreted into the intestinal tract in the ileum and in pancreatic and biliary secretions.

Low calcium intake is associated with increased fracture rate in children and adolescents, and therefore adequate dietary intake of calcium during infancy, childhood, and adolescence is necessary to attain a peak bone mass that may lessen the risk of fracture and the development of osteoporosis.²⁹ To ensure optimal mineralization of the developing skeleton, age-related dietary intakes of elemental calcium for infants, children, and adolescents have been recommended (Table 9.2).^{30,31} As a nutrient essential for bone mineralization, intake of calcium is optimal when skeletal calcium content is maximal for the age and gender of the subject.³ In normally weighted adolescents, a calcium intake of or above 1600 mg per day results in maximal calcium retention (approximately 35%).³² Calcium retention and bone mass increase as body mass index (BMI) rises when calcium intake is sufficient. The retention of oral calcium is dependent not only on the level of nutrient intake but also upon gender and race: white adolescent males retain more calcium than do white girls (37% vs. 30%); black adolescent girls retain more calcium than do white females (38% vs. 30%). Besides dietary intake of calcium and vitamin D status, the most significant modifiable determinant of bone mineralization is weight-bearing physical activity.³³

Calcium is excreted primarily by the kidney. After the ultrafiltrable portion (ionized, complexed, chelated) of plasma calcium crosses the renal glomerular basement membrane, more than 98% of filtered calcium is reabsorbed—primarily in the proximal convoluted tubule (60%) but also in the thick

ascending limb of the loop of Henle (TALH) (20%), distal convoluted tubule (10%), connecting tubule (3%), and collecting duct (10%).¹ In the proximal convoluted tubule, the bulk of calcium is passively reabsorbed through paracellular channels; a small amount of calcium is reabsorbed actively, a process regulated by both PTH and calcitonin. In the cortical TALH, resorption of filtered calcium is regulated in part through the influence of Na⁺-K⁺-2Cl⁻ ion channels and the CaSR upon the permeability of paracellular channels to calcium. Active transcellular movement of calcium in the TALH is stimulated by PTH and calcitonin.^{1,34} In the distal convoluted renal tubule, active transcellular reabsorption of 5% to 10% of filtered calcium occurs through a calcium channel encoded by *TRPV5* that is expressed on the apical membrane of renal tubular epithelial cells, a process regulated by calcitriol and PTH.²³ In the cytoplasm, calbindin D_{9k} then shuttles Ca²⁺ across the cell for extrusion by ATP2B1 channels and the Na⁺-Ca²⁺ exchanger type 1 (encoded by *SLC8A1*) on the basolateral membrane of the renal tubular cell. Calcitriol, PTH, low dietary calcium, estrogens and androgens, and acid/base balance increase expression of *TRPV5* and, thus renal tubular reabsorption of calcium. PTH also enhances posttranslational phosphorylation of TRPV5 and hence its movement to and insertion into the apical membrane of the renal tubular cell and inhibits its endocytosis, the paired effects thus resulting in increased numbers of TRPV5 channels on the apical surface of the renal tubular cell.²³ FGF23 and α kltho (encoded by *KL*), factors essential for normal phosphate homeostasis, increase the intracellular retention and hence decrease the abundance and hence the activity of the TRPV5 calcium channel on the apical surface of the renal tubular cell.^{22,35,36} Calmodulin, an intracellular Ca²⁺-binding protein that also binds to and inhibits the action of TRPV5, modulates renal tubular reabsorption of Ca²⁺, a process reversed by PTH-mediated phosphorylation of the TRPV5 calbindin-binding site.³⁷

In the TALH, calcium and magnesium are reabsorbed through voltage-driven paracellular channels (in part through paracellin-1, a tight junction protein channel). Paracellular transport of solute involves passive movement of ions along channels in the tight junctions between adjacent cells that are in complete contact with one another. Claudins are proteins present in the plasma membranes of the adjacent cells of the TALH that have formed tight junctions; claudins have four extracellular domains that associate with one another and selectively influence paracellular solute permeability and movement.³⁸ Claudins-14, -16, and -19 (encoded by *CLDN14*, -16, -19, respectively) are expressed in the tight junctions of the cells lining the TALH; the expression of *CLDN14* is partially regulated by the CaSR.^{1,34} Cells of the TALH also express *CASR* on their basolateral membrane; when activated by peritubular Ca²⁺, the CaSR decreases renal tubular reabsorption of calcium through the paracellular channels by inhibiting activity of the Na⁺-K⁺-2Cl⁻ transporter and lowering lumen-positive voltage. Increased glomerular filtration and/or decreased renal tubular reabsorption increase renal excretion of calcium, phosphate, and magnesium. Urinary excretion of calcium is augmented by increased dietary intake, hypercalcemia of diverse pathophysiology (with the exception of that associated with familial hypocalcemic hypercalciuria), expansion of extracellular volume, metabolic acidosis, and loop diuretics (e.g., furosemide).² PTH and PTHrP increase renal tubular reabsorption of Ca²⁺, whereas glucocorticoids, mineralocorticoids, and Ca²⁺ itself suppress Ca²⁺ reabsorption (see Fig. 9.1).

Plasma Ca²⁺ concentrations are monitored by the CaSR, a 1078 AA, seven transmembrane GPCR encoded by *CASR* whose extracellular domain recognizes and binds Ca²⁺,

TABLE 9.2 Recommended Dietary Intakes of Calcium and Vitamin D in Infants, Children, and Adolescents

Age (y)	Calcium (mg/day)	Calcium (Upper Limit)	Vitamin D (IU/day)	Minimum [25(OH)D] (ng/mL)
<0.5	200	1000	400	20
0.5–1	260	1500	400	20
1–3	700	2500	600	20
4–8	1000	2500	600	20
9–13	1300	3000	600	20
14–18	1300	3000	600	20
Pregnant or lactating	1300	3000	600	20

Amounts of calcium and vitamin D are the Recommended Dietary Allowances (RDA) for $\geq 97.5\%$ of population. (Modified from Golden, N.H., Abrams, S.A., and Committee on Nutrition. (2014). *Pediatrics*, 134, e1229–e1243.)

Mg²⁺, gadolinium, aromatic AA, antibiotics, and other compounds.^{39,40} The CaSR is expressed on the cell's plasma membrane as a homodimer linked by disulfide bonds between extracellular domain cysteine residues 129 and 131 of each CaSR; its extracellular domain of 612 AA binds Ca²⁺.³⁴ Homodimerization of the CaSR takes place in the endoplasmic reticulum after core N-linked glycosylation; homodimeric CaSR is then packaged within the Golgi apparatus where it is further glycosylated and transported to the cell membrane.⁴¹ The amino-terminal extracellular domain of the CaSR is composed of 612 AA with five Ca²⁺ binding sites constructed in a "Venus flytrap" configuration; there are 250 AA in the transmembrane domain composed of seven transmembrane helices and three alternating extracellular and intracellular loops, and 216 AA in the carboxyl-terminal intracellular domain.⁴⁰ The second extracellular loop contains sites (Asp758, Glu759, Glu767) that modulate the "sensitivity" of the CaSR to Ca²⁺. Within the intracellular domain of the CaSR are three protein kinase C phosphorylation sites; phosphorylation of Thr888 suppresses Ca²⁺-mediated CaSR intracellular signal transduction.³⁹ Through its binding of Ca²⁺, the CaSR finely regulates the extracellular concentration of this cation by modulating the secretion of PTH and the renal tubular reabsorption of filtered calcium. The CaSR is a member of the C family of GPCRs with extremely long extracellular domains (500–600 AA residues) and homologies with receptors that bind glutamate, γ -amino butyric acid (GABA), and pheromones, as well as with the taste receptors. The very long extracellular domain is extensively glycosylated, a posttranslational modification essential for efficient movement of the receptor to the cell surface. The CaSR is located on the plasma membrane of parathyroid chief cells, at the apical or basolateral membranes of most renal tubular cells—particularly those in the TALH and the collecting ducts, on the cell membranes of the calcitonin-synthesizing parafollicular C cells of the thyroid gland, in cartilage and bone, lungs, adrenal glands, breast, intestines, skin, lens, placental cytotrophoblasts, and nervous tissue.⁴² Expression of CaSR is regulated in part by glial cell missing homolog 2 (*GCM2*), encoding a transcription factor essential for formation of the parathyroid glands, and enhanced by calcitriol, high Ca²⁺ levels, and interleukin-1 β .⁴³ Insertion of the CaSR into the cell's plasma membrane is mediated by an agonist-driven insertional pathway antagonized by the cooperative interaction of β -arrestin 1 (encoded by *ARRB1*) and an adaptor-related protein complex 2 (*AP2S1*), the latter complex facilitating retrograde movement (endocytosis) of the CaSR from the cell surface and its return to the cytoplasm.^{34,44}

The intracellular signal of the CaSR is transduced by the G α_q and G α_{11} (*GNA11*) family of GPCRs that activates PLC β -1 (encoded by *PLCB1*), that then cleaves phosphatidylinositol 4,5-bisphosphate to diacylglycerol (DAG) and IP₃. In the parathyroid gland, IP₃ mobilizes stored intracellular calcium, whereas DAG activates the mitogen-activating protein kinase (MAPK) signal transduction pathway that leads to decrease in PTH secretion. Activation of the CaSR also stimulates activity of phospholipases A₂ and D and PKB (AKT) and PKC but inhibits that of adenylyl cyclase, the latter through stimulation of adenylyl cyclase-inhibitory G α_i activity.⁴⁰ Increases in plasma Ca²⁺ and rising cytosolic levels of Ca²⁺ within the parathyroid chief cells suppress expression of *PTH* and increase degradation of *PTH* messenger ribonucleic acid (mRNA), thereby limiting synthesis and secretion of *PTH*; CaSR signaling also inhibits proliferation of chief cells. Decline in Ca²⁺ leads to decrease in CaSR activity, lower intracellular Ca²⁺ values, and thence to increased *PTH* secretion, thus enabling the CaSR to exercise minute-to-minute control

over the release of *PTH* and hence of the plasma concentration of Ca²⁺.

The serum Ca²⁺ concentration is related to polymorphic variants of the CaSR; 70% of individuals are homozygous for alanine at AA 986 within the intracellular domain, 3% are homozygous for serine, and the remainder are heterozygous for the two amino acids. In heterozygous Arg986Ser and homozygous Ser986 subjects, Ca²⁺ levels are significantly higher than in those who are homozygous for Ala986.⁴⁵ The CaSR also serves as a Mg²⁺ sensor and modulates renal tubular reabsorption of this cation decreasing its reabsorption when Mg²⁺ levels rise. By binding to the CaSR, aromatic L-amino acids appear to "sensitize" the receptor to a given level of Ca²⁺.³⁹

In the kidney, CaSRs are present on the apical (luminal) brush-border membranes of cells in the proximal renal tubule where they are exposed to intratubular Ca²⁺, on basolateral cell membranes in cells in the TALH, and on the apical surface of cells in the distal renal collecting ducts.⁴⁰ Functioning through binding to local CaSRs, increasing peritubular concentrations of Ca²⁺ and Mg²⁺ inhibit renal tubular reabsorption of filtered Ca²⁺ and Mg²⁺, respectively. In the kidney, binding of Ca²⁺ to the CaSR decreases not only transcellular transport of filtered Ca²⁺ but also its paracellular transport in the TALH. Inactivating mutations in *CASR* result in familial hypocalciuric hypercalcemia, whereas gain-of-function mutations in *CASR* are associated with autosomal dominant hypoparathyroidism ("familial hypercalciuric hypocalcemia"). Stimulation of the CaSR suppresses *PTH*-mediated renal tubular Ca²⁺ reabsorption.^{40,46} In addition to effects on renal tubular cation transport, the Ca²⁺/CaSR complex inhibits antidiuretic hormone-induced renal tubular permeability to water by decreasing the number of apical aquaporin-2 water channels in the inner medullary collecting ducts, thus leading to polyuria. Stimulation of the CaSR expressed in cells of the renal distal collecting ducts also increases local H⁺-ATPase activity, resulting in urine acidification.⁴⁶

Acting through the CaSR, increasing serum Ca²⁺ concentrations stimulate release of calcitonin from thyroid C cells. The CaSR is expressed throughout the intestinal tract, where it may modulate the changes in intestinal motility that accompany low (increased) and high (depressed) serum Ca²⁺ values.³⁹ In addition, in gastric cells, stimulation of CaSR activity increases release of gastrin into the circulation and thereby intragastric acidity.⁴⁰ Expression of the CaSR in the brain suggests a mechanism whereby Ca²⁺ may influence neural function locally by modulating neurotransmitter and neuroreceptor function. The CaSR is present on cell membranes of osteoblasts, osteocytes, and osteoclasts, and agonist (Ca²⁺, neomycin, gadolinium) activation of the CaSR stimulates intracellular signal transduction in these cells. Increase in CaSR activity in osteoblasts enhances their proliferation.⁴⁰ The CaSR may mediate recruitment of osteoblast precursor cells to sites of high Ca²⁺ levels, the residue of local osteoclast activity, one of the factors linking the bone remodeling processes of resorption and formation.⁴²

Calcimimetics are agonist drugs that activate the CaSR; calcilytics are antagonists of the CaSR.⁴⁷ The CaSR binds and responds not only to Ca²⁺ but also to Mg²⁺, selected L-amino acids, and some antibiotics; the latter are designated type I calcimimetics. Synthetic compounds (e.g., phenylalkylamines) that bind to the second and third extracellular loops of the transmembrane domain of the CaSR and allosterically modulate (increase or decrease) the sensitivity of the CaSR to ambient Ca²⁺ are designated type II calcimimetic agonists or calcilytic antagonists, respectively.^{39,40} A widely used calcimimetic is cinacalcet

[N-[1-(R)-(-)-(1-naphthyl)ethyl]-3-[3-(trifluoromethyl)phenyl]-1-aminopropane hydrochloride]; this agent has been effective in decreasing secretion of PTH in patients with either primary or secondary hyperparathyroidism.⁴⁸ Calcilytics decrease the sensitivity of the CaSR to Ca^{2+} and thus increase the secretion of PTH and depress renal tubular reabsorption of Ca^{2+} . Variants of CASR may prevent its normal biosynthesis (class I), disturb movement of the CaSR protein to the plasma membrane (class II), interfere with binding of ligand to the CaSR (class III), impair activation of the CaSR (class IV), or disrupt receptor function by a currently unknown mechanism (class V).

PHOSPHATE

Second to calcium in abundance, phosphorus is present in humans in organic forms associated with fats, sugars, and proteins and in inorganic forms complexed to sodium, calcium, or magnesium.^{49,50} It is an essential component of deoxyribonucleic acid (DNA) and RNA nucleotides, critical for generation, storage, and utilization of energy as ATP, and irreplaceable as a part of cell membranes, signal transduction pathways, and bone mineral. Serum concentrations of phosphate reflect the balance between the amount of this anion ingested into and absorbed by the duodenum and jejunum of the gastrointestinal tract; the quantity filtered through the renal glomerulus and subsequently reabsorbed by the proximal renal tubule or excreted in urine; its movement between intracellular and extracellular spaces; and the intraosseous interactive dynamics of calcium, phosphate, and the formation and resorption of hydroxyapatite.

Some 85% of body phosphate is deposited in bone as hydroxyapatite. Some 14% of phosphate is intracellular (in the cytosol or mitochondria in the form of inorganic phosphate esters or salts, cell and organelle membrane phospholipids, and phosphorylated metabolic intermediate compounds involved in energy metabolism and formation of ATP and in signal transduction and in the cytosol and nucleus as an essential component of RNA and DNA) or in interstitial fluid or serum (approximately 1%). In serum, phosphate circulates as free orthophosphate anions HPO_4^{2-} and H_2PO_4^- (55%), bound to proteins (10%), or complexed to calcium, magnesium, or sodium (35%).^{2,51} At pH 7.4, serum HPO_4^{2-} and H_2PO_4^- are present in a molar ratio of 4:1; in alkalotic states the ratio increases, with acidosis it declines (at pH 7.4, 1 mmol/L of orthophosphate = 1.8 mEq/L = 3.1 mg/dL). The serum concentrations of calcium and phosphate are reciprocally related under normal circumstances, and the calcium \times phosphate product approximates 30. Intracellularly, cytosolic free phosphate concentrations approximate those in serum—3 to 6 mg/dL.

The serum phosphate concentration is determined by oral intake, intestinal absorption and excretion, renal tubular reabsorption and excretion of filtered phosphate, and release from bone by dissolution of hydroxyapatite by PTH and calcitriol, and fluctuates with age, gender, growth rate, diet, and serum calcium levels (see Fig. 9.2).^{1,2,50,52-54} In as much as phosphate is found in all cells and foods, dietary deficiency is unusual. Dietary phosphate is absorbed across the intestinal brush border as HPO_4^{2-} in direct proportion to its intake, principally in the duodenum and jejunum. Phosphate is absorbed through the apical membranes of cells lining the small intestine and proximal renal tubule by both passive and active transport pathways.^{49,50} Paracellular transport is a passive mode of phosphate movement from lumen to the extracellular space through the tight junctions between the sides of the epithelial cells that line the small intestine and proximal renal tubule. Phosphate is actively transported across the apical membranes of epithelial

cells lining the small intestine through the sodium/phosphate channel designated NPT2b encoded by *SLC34A2* (one of three type II sodium/phosphate cotransporters), the sodium-hydrogen exchanger 3 (NHE3 encoded by *SLC9A3*), and the sodium-dependent phosphate transporter encoded by *SLC20A2*—members of the type III sodium/phosphate cotransporter family. Expression of *SLC34A2* is increased by low dietary phosphate intake and calcitriol and suppressed by PTH. However, PTH also increases intestinal absorption of ingested phosphate (and calcium) by increasing expression of *CYP27B1* encoding renal 25-hydroxyvitamin D-1 α -hydroxylase, thereby enhancing synthesis of calcitriol, whereas *FGF23* has the opposite effect. When dietary phosphate intake falls below 310 mg/d in the adult, net phosphate absorption is negative. At low phosphate intakes, absorption is active in the duodenum, jejunum, and distal ileum, whereas at high intakes, 60% to 80% of ingested phosphate is absorbed primarily by diffusion. Phosphate absorption can be impaired by its intraluminal precipitation as an aluminum or calcium salt and by intestinal malabsorption disorders.

The kidney regulates moment-to-moment phosphate homeostasis. After passage through the renal glomerular membrane, 85% of filtered phosphate is reabsorbed by active transport against an electrochemical gradient across the apical membrane of the cells lining the proximal renal tubule through the type II sodium/phosphate cotransporters encoded by *SLC34A1* (NPT2a) and *SLC34A3* (NPT2c) with the aid of a Na^+ , K^+ -ATPase pump.^{2,51,55} Phosphate is also reabsorbed to a limited extent in the loop of Henle (10%), distal convoluted tubule (3%), and connecting tubule (2%). Expression of *SLC34A1* is increased by hypophosphatemia and suppressed by hyperphosphatemia. PTH, PTHrP, FGF23, and glucocorticoids decrease proximal renal tubular reabsorption of filtered phosphate by lowering expression of *SLC34A1* (NPT2a) and *SLC34A3* (NPT2c).^{49,56} In the mouse, NPT2a actively transports approximately 70% and NPT2c 30% of proximal renal tubular reabsorbed phosphate; in humans, however, NPT2c may be the major renal tubular transporter of phosphate. The Na^+ - H^+ exchanger regulatory factor 1 (NHERF1—encoded by *SLC9A3R1*) is a scaffolding protein that is essential for trafficking of NPT2a and NPT2c to the luminal membrane of cells in the proximal renal tubule; NHERF1 also interacts with PTH1R.⁵⁵ The family of phosphate transporters encoded by *SLC20A2* (designated PiT2) has also been identified in the renal proximal tubule. Phosphate exits the proximal renal tubular cell with sodium by cation exchange for potassium through channels (encoded by *XPR1*) located on the cell's basolateral membrane. The maximal tubular reabsorption of phosphate approximates the filtered load. Tubular phosphate reabsorption is increased by low phosphate intake and hypophosphatemia (because of decrease in filtered load), hypercalcemia (by decrease in the glomerular filtration rate), depletion of ECF volume, and metabolic alkalosis. Renal tubular reabsorption of phosphate is depressed by high phosphate intake, PTH (and PTHrP), and the phosphatonin FGF23—and is caused by rapid internalization and subsequent destruction of the NPT2a and NPT2c phosphate cotransporter proteins.⁵¹ The PTH-dependent degradative processes are mediated through the type 1 PTH/PTHrP receptor and transduced by intracellular signaling systems utilizing protein kinase A, protein kinase C, and MAPK. Phosphate is deposited in bone as hydroxyapatite dependent on local levels of calcium, phosphate and alkaline phosphatase activity and reabsorbed by osteoclasts whose activity is stimulated by PTH, calcitriol, and other osteoclast activating factors. There are age-related variations in serum concentrations (mg/dL) of phosphate: less than 5 days, 4.8–8.2;

1–3 years, 3.8–6.5; 4–11 years, 3.7–5.6; 12–15 years, 2.9–5.4; 16–19 years, 2.7–4.7; adult, 2.5–4.5.

Phosphatonins

The phosphatonins are a group of proteins that inhibit renal tubular reabsorption of phosphate. Increasing serum concentrations of phosphate and calcitriol stimulate osteocyte/osteoblast production of the predominant phosphatonin—FGF23—that then depresses synthesis of the phosphate cotransporters NPT2a and NPT2c and decreases renal expression of *CYP27B1* (encoding 25-hydroxyvitamin D-1 α -hydroxylase) and thus formation of calcitriol and consequently, intestinal absorption of calcium and phosphate. Simultaneously, FGF23 enhances expression of renal *CYP24A1* (encoding 25-hydroxyvitamin D 24-hydroxylase) and hence the synthesis and urinary excretion of water-soluble 24,25-dihydroxyvitamin D and 1,24,25-trihydroxyvitamin D.⁴⁹ FGF23 is generated as a 251 AA protein with a 24 AA signal sequence; for optimal biological function FGF23 must be posttranslationally glycosylated by UDP-N-acetyl-alpha-D-galactosamine:Polypeptide N-acetylgalactosyltransferase 3 (encoded by *GALNT3*). *GALNT3* is an enzyme that O-glycosylates the threonine-178 and serine-180 residues of FGF23; failure to glycosylate the threonine-178 site leads to accelerated degradation (and hence inactivation) of FGF23. FGF23 is proteolytically degraded by intracellular subtilisin-like proprotein convertase acting between AA 179 and 180 (... Arg₁₇₆-His₁₇₇-Thr₁₇₈-Arg₁₇₉-Ser₁₈₀ ...) that separates the amino-terminal FGF-like domain from the carboxyl-terminal tail. Spontaneously occurring gain-of-function mutations within this sequence of *FGF23* slow the inactivation of FGF23, thus prolonging its biological life, resulting in autosomal dominant hypophosphatemic rickets (ADHR). *FGF23* is expressed primarily by osteoprogenitor cells, osteoblasts, and osteocytes and to a lesser extent by the thymus, brain, thyroid, parathyroid glands, cardiac muscle, liver, and small intestines. In osteoblasts and osteocytes, expression of *FGF23* is stimulated by high serum levels or dietary intake of phosphate, PTH, and calcitriol acting through VDR.^{51,57,58} Inasmuch as calcitriol promotes synthesis of FGF23 whereas FGF23 inhibits production of calcitriol, there is a reciprocal feedback relationship between calcitriol and FGF23.

FGF23 links to the “c” isoform of tyrosine kinase FGF receptors (FGFR) 1, 2, and 3. The genes encoding the FGFRs consist of 19 exons that may be alternatively spliced to include or to exclude either exon 8 or 9 (encoding the third extracellular immunoglobulin-like domain of the FGFR which partially specifies the ligand bound by the receptor); when exon 8 is included in the mRNA transcript the “b” isoform of the FGFR is formed; when exon 9 is included in the transcript, the “c” isoform is produced. FGF23 acts through the dimeric coreceptor quaternary complex—FGF23/ α Klotho/FGFR1 (IIIc)/heparan sulfate—expressed on the plasma membrane of the target cell to depress renal tubular reabsorption of phosphate, intestinal absorption of phosphate, synthesis of calcitriol, and secretion of PTH.^{49,59,60} Although it is likely that FGF23 binds to multiple FGFR “c” isoforms, it is the multifunctional transmembrane protein α Klotho (encoded by *KL*) that serves as a coreceptor, thereby converting FGFR into specific FGF23 receptors in the parathyroid glands and kidneys.^{54,55,61}

α Klotho is a 1012 AA protein (encoded by *KL* whose expression is increased by calcitriol) with extracellular, transmembrane, and intracellular domains synthesized by renal tubular cells that serves as a coreceptor with FGFR1(cIII) for FGF23.⁶² Klotho was so named because its loss in mice is

associated with a phenotype of premature aging. There are membrane bound and soluble secreted forms of α Klotho; soluble α Klotho is a 549 AA protein composed of the ectodomain of the intact protein and is present in the circulation and excreted by the kidney.⁵⁹ The transmembrane form of α Klotho binds FGF23, FGFR1(IIIc), and heparan sulfate to form a quaternary complex that transmits the FGF23 signals that decrease renal tubular cell membrane expression of the genes encoding the phosphate transporters NPT2a (*SLC34A1*) and NPT2c (*SLC34A3*), thereby limiting renal tubular reabsorption of filtered phosphate and increasing its urinary excretion. The complex of FGF23/FGFR3,4/ α Klotho/heparan sulfate depresses transcription of renal *CYP27B1* encoding 25-hydroxyvitamin D-1 α hydroxylase necessary for synthesis of calcitriol while enhancing expression of *CYP24A1* encoding vitamin D-24 hydroxylase, thereby increasing the solubility and renal excretion of calcitriol and lowering its serum levels.^{59,60,62,63}

KL is also expressed in the parathyroid gland; there, FGF23 interacting with α Klotho and FGFR3,4 decreases transcription of *PTH* and thereby reduces PTH synthesis and secretion.⁶² Reciprocally, both calcitriol and PTH increase synthesis of FGF23 by bone cells, establishing a feedback loop regulating FGF23 synthesis and secretion.⁶⁴ After binding of the FGF ligand to the FGFR, the receptors dimerize, autophosphorylate, and then phosphorylate intracellular proteins involved in signal transduction, including PLC γ , growth factor receptor bound (GRB)-14, son of sevenless, FGF receptor substrate (FRS)-2—a docking protein that links the activated FGFR to the phosphoinositide-3-kinase (PI3K), and MAPK signaling pathways.⁶⁵ *FGF23* expression is increased by iron deficiency by interrupting the negative feedback effect of hypophosphatemia upon FGF23 synthesis.⁵⁶ The truncated, alternatively spliced form of α Klotho with 549 AA is secreted into the circulation, cerebrospinal fluid, and urine.⁶³ Soluble α Klotho regulates signal transduction by growth factors (insulin, insulin-like growth factor-1) independently of FGF23 through binding to sialogangliosides—components of intramembraneous lipid rafts. Soluble α Klotho enhances renal calcium absorption by cells lining the renal distal convoluted and connecting tubules by increasing the number of calcium transport channels encoded by *TRPV5* expressed on the apical membrane of these cells.⁶³

Serum values of FGF23 are increased in patients with X-linked hypophosphatemic rickets, autosomal recessive and dominant hypophosphatemic rickets, tumor-induced osteomalacia, and fibrous dysplasia associated with hypophosphatemia.⁶⁶ In patients with autosomal dominant hypophosphatemic rickets, gain-of-function mutations (e.g., Arg179Trp) in *FGF23* result in resistance to degradation of FGF23, a protein that is normally cleaved between Arg179 and Ser180, whereas in subjects with tumor induced osteomalacia, the rate of production of FGF23 is greatly increased. In familial tumoral calcinosis (OMIM 211900), loss-of-function mutations in *FGF23* lead to accelerated intracellular degradation of FGF23 that prevents secretion of intact protein resulting in decreased renal excretion of phosphate, hyperphosphatemia, relatively increased calcitriol levels, and diffuse ectopic calcification.^{54,67}

Phosphatonins were first identified by analysis of tumors associated with hypophosphatemic osteomalacia.^{54,68} Among other phosphatonins are matrix extracellular phosphoglycoprotein (encoded by *MEPE*) and secreted frizzled-related protein 4 (encoded by *SFRP4*).⁶⁹ *MEPE* is expressed by osteoblasts, osteocytes, and odontoblasts. Expression of *MEPE* is inhibited by calcitriol. *MEPE* is a 525 AA, 58-kDa protein that is a member of the short-integrin-binding, ligand-interacting

glycoprotein family whose genes are clustered on chromosome 4q22.1. MEPE modulates osteoblast and osteoclast function and may both inhibit and support bone mineralization.⁵⁴ MEPE enhances phosphaturia by increasing expression of *FGF23*.⁶⁴ MEPE (and other phosphatonins) contains within its structure an acidic serine aspartate-rich MEPE-associated (ASARM) peptide that may be released from its parent structure by cathepsins B and K in phosphorylated or nonphosphorylated forms. Phosphorylated ASARM and MEPE bind avidly to hydroxyapatite and prevent further deposition of calcium and phosphate; ASARM also inhibits phosphate uptake by the intestinal tract and the renal tubule (MEPE also is involved in the osteocytic response to a mechanical load). MEPE and ASARM are substrates for the X-linked phosphate-regulating endopeptidase (encoded by *PHEX*); inactivating variants of *PHEX* result in X-linked hypophosphatemic rickets.^{64,70}

Other SIBLING noncollagenous matrix proteins include dentin-matrix acidic phosphoprotein 1 (encoded by *DMP1*), dentin sialo-phosphoprotein (*DSPP*), osteopontin (also termed *secreted phosphoprotein 1* [SPP1]), and integrin-binding sialoprotein (*IBSP*).⁶⁴ In addition to sharing the ASARM sequence near their carboxyl terminals, these proteins have in common an Arg-Gly-Asp (RGD) tripeptide motif that interacts with and binds to integrins on the surface of interacting cells. The basic ASARM motif consists of 23 AA; several of its serine residues are specifically phosphorylated by casein serine kinase. Phosphorylated and nonphosphorylated ASARMS released by *DMP1*, *DSPP*, and *SPP1* are also resistant to proteolysis, except by the zinc metalloendopeptidase *PHEX*. Inactivating mutations of *PHEX* results in X-linked hypophosphatemic rickets, in part, by inability to degrade the ASARM peptide coating of hydroxyapatite.⁶⁴ *PHEX* may also be involved in the expression of *FGF23* and the stability of *FGF23*. Carboxyl to the ASARM motif of *DMP1* is an additional sequence of 35 AA that is termed the *minfostin* motif; a mutation in this region of *DMP1* results in one form of autosomal recessive hypophosphatemic rickets. The ASARM region of *DMP1* binds to *PHEX* sited on the plasma membrane of the normal osteocyte suppressing expression of *PHEX*; displacement of binding by excessive free ASARM peptides (as in patients with hypophosphatemic rickets) further increases *FGF23* expression.⁶⁴ In addition to patients with tumor-induced osteomalacia and X-linked hypophosphatemic rickets, increased serum concentrations of *FGF23* are found in subjects with autosomal dominant hypophosphatemic rickets because of activating mutations in *FGF23* and autosomal recessive hypophosphatemic rickets types 1 and 2 because of loss-of-function mutations in *DMP1* or *ENPP1*, respectively.^{52,54}

Secreted Frizzled-related protein 4 (*FRP4*) is a 346 AA glycosylated protein that shares the structure of the extracellular domain of the transmembrane Frizzled GPCR. The natural ligands of Frizzled receptors are wingless (WNT) proteins, and their coreceptors are cell-surface low-density lipoprotein receptor-related proteins; these heterotrimeric complexes stabilize intracellular β -catenin and the attendant signal transduction systems that are essential for many transformative processes including cartilage and bone formation. Secreted *FRP4* serves as a “decoy” receptor for WNT proteins and thereby competes with the Frizzled receptor for WNT binding and by so doing inhibits the function of the Frizzled receptor. *FRP4* is expressed in bone cells and in large amounts by tumors with associated osteomalacia. *FRP4* inhibits sodium-dependent renal tubular phosphate reabsorption by inhibition of WNT signaling leading to hypophosphatemia; it also reduces expression of *CYP27B1*, the gene encoding 25-hydroxyvitamin D₃-1 α -hydroxylase.⁷¹

Immunoreactive species of *FGF23* are measurable in normal adult sera but values vary depending on the epitopes recognized by the antibodies used, that is, whether they are specific for the full-length *FGF23* protein or only for its carboxyl-terminal fragment, and on the assay methodology (e.g., enzyme-linked immunosorbent assay or chemiluminescent immunoassay).⁷²⁻⁷⁴ In assays that recognize full-length *FGF23* and carboxyl-terminal fragments of *FGF23*, intact *FGF23* values vary diurnally and there is marked interindividual variability in *FGF23* levels.⁷³ The serum *FGF23* concentration is inversely related to that of phosphate, and values rise when dietary phosphate increases (or during infusion of phosphate) and decline with phosphate restriction.⁵⁴

MAGNESIUM

Magnesium (Mg^{2+}) is the fourth most abundant of the body cations. It is an intracellular and extracellular divalent cation that is critical for DNA and protein synthesis, neuroexcitability, intracellular signaling, oxidative phosphorylation, and bone hydroxyapatite development.¹ In serum, magnesium is present in the bound and free states. Approximately 1% of body magnesium is present in the ECF compartment, 14% in muscle and soft tissue, and 85% in bone, where it is found on the surface of the hydroxyapatite crystal and of which 50% is freely exchangeable.^{2,4,75} In blood, magnesium (1.7–2.4 mg/dL = 0.7–1.0 mmol/L) is partially bound to proteins (approximately 30%), complexed to phosphate and other anions (15%), and free Mg^{2+} (55%). As with calcium, magnesium levels rise as pH declines (with increased acidity). Intracellularly, magnesium (0.5 mmol/L) is bound to ATP and other molecules; 10% is in the ionic form and 60% is within mitochondria. Mg^{2+} is a cofactor in many enzymatic reactions, including those that consume or produce ATP. Magnesium alters free radicals and influences nitric oxide synthase, cyclic guanosine monophosphate generation, endothelin production, and immune function. Magnesium decreases membrane excitability in nerve and muscle cells and blocks the excitatory N-methyl D-aspartate receptor. It is a necessary cofactor for the regulation of neuromuscular excitability, nerve conduction, oxidative metabolism by mitochondria, glycolysis, phosphorylation, and transcription and translation of DNA. It is essential for the secretion (but not the synthesis) of PTH by the parathyroid chief cell.

Net intestinal magnesium absorption is directly related to dietary intake and independent of calcitriol.² The bulk of ingested magnesium is absorbed in the small intestine (and colon) in proportion to the intestinal luminal concentration of this cation through voltage-dependent paracellular channels within tight intercellular junctions, a process assisted by claudins. There is a small component of active, transcellular intestinal magnesium absorption through ion channels encoded by transient receptor potential cation channel, subfamily M, member 6 (*TRPM6*) linked to the transcript of *TRPM7*, a magnesium-permeable cation channel. The *TRPM6/TRPM7* heterooligomer is expressed on the surface of cells lining the intestinal tract.^{23,76} Loss-of-function mutations in *TRPM6* result in autosomal recessive hypomagnesemia with secondary hypocalcemia because of impairment of intestinal (and renal tubular) absorption of this cation. The intestinal absorption of magnesium may be impaired by high phosphate intake, intestinal dysfunction, or chronic laxative abuse. Magnesium is also excreted into the intestinal tract.

Some 70% of serum magnesium is ultrafiltrable and passes through the renal glomerular membrane; approximately 95% of filtered magnesium is reabsorbed—15% in the proximal

renal tubule, 70% in the cortical TALH, and 10% in the distal convoluted tubule.^{2,73} Thus 3% to 5% of filtered magnesium is excreted in the urine. In the proximal renal tubule and TALH, magnesium reabsorption is primarily passive through paracellular tight junction channels using claudins 10, 16, and 19. In the proximal renal tubule, reabsorption of water increases intratubular magnesium concentration, thereby facilitating its paracellular reabsorption. Tight junction claudin proteins bridge intercellular gaps and regulate the movement of ions across an epithelial sheet. Claudin 10 (encoded by *CLDN10*) is a 226/228 AA protein. Biallelic inactivating mutations in *CLDN10* result in the HELIX syndrome (OMIM 617671) of anhidrosis, alacrima, xerostomia, malformed teeth, hypermagnesemia, renal wasting of sodium and chloride, and secondary hyperparathyroidism. Paracellin-1 (encoded by *CLDN16*) is a 305 AA protein expressed in the renal cortical TALH and distal convoluted tubule; paracellin-1 has four transmembrane domains with intracellular carboxyl and amino terminals. Paracellin-1 is also employed for paracellular reabsorption of calcium in the TALH. Homozygous or compound heterozygous loss-of-function mutations of *CLDN16* lead to familial, autosomal recessive renal hypomagnesemia (type 3) characterized by renal wastage of magnesium in association with hypercalciuria and nephrocalcinosis (OMIM 248250).⁷⁷ Claudin 19 is a 224 AA tight junction protein. Biallelic inactivating mutations in *CLDN19* result in renal wasting of magnesium, hypomagnesemia, hypercalciuria, and nephrocalcinosis, leading to renal failure (hypomagnesemia type 5—OMIM 248190); in addition, because *CLDN19* is expressed in the eye, affected subjects have decreased vision because of retinal malformation.

In the TALH, magnesium reabsorption occurs through a paracellular pathway that is impermeable to water and is propelled by a transepithelial voltage gradient that is lumen-positive and generated by a $\text{Na}^+\text{-K}^+\text{-ATPase}$.⁶⁷ The voltage gradient requires the integrated action of a $\text{Na}^+\text{-K}^+\text{-Cl}^-$ -coupled cotransporter (NKCC2 encoded by *SLC12A1*), a Cl^- channel (CLC-Kb encoded by *CLCNKB*), and a K^+ channel (ROMK encoded by *KCNJ1*). Barttin, encoded by *BSND*, is an essential beta subunit of the CLCNKB Cl^- channel. Active transcellular movement of magnesium through the TALH is accomplished utilizing the NKCC2 cotransporter, a pathway inhibited by activation of the CaSR.¹ In the renal distal convoluted tubule, magnesium is actively reabsorbed through a channel composed of a heterooligomer of TRPM6 linked to TRPM7 expressed on the surface of cells lining this renal segment.^{23,75,78} It is primarily in the distal convoluted tubule that magnesium is actively transported through apical (luminal) membrane TRPM6 channels. The renal tubular expression of *TRPM6* and intracellular movement of TRPM6 is regulated by dietary magnesium, estrogens, acid-base balance, and proepidermal growth factor (pro-EGF). *TRPM7* is also expressed on the luminal surface of renal cells in the distal convoluted tubule where it too facilitates reabsorption of magnesium.⁷⁸ Other magnesiotropic proteins expressed in the distal convoluted tubule are the thiazide sensitive $\text{Na}^+\text{:Cl}^-$ cotransporter, potassium channels Kv1.1 and Kir4.1, and hepatocyte nuclear factor 1B (HNF1B). Biallelic inactivating mutations in *TRPM6* result in hypomagnesemia type 1 with secondary hypocalcemia (OMIM 602014); this disorder presents in early infancy with tetany and seizures and is caused by both impaired absorption of intestinal magnesium and reabsorption of renal tubular magnesium. Pro-EGF regulates the availability and activity of TRPM6 by enabling its movement from intracellular sites of storage to the luminal plasma membrane of renal distal convoluted tubular cells and colonic epithelial cells; biallelic loss of *EGF* leads to hypomagnesemia type 4 (OMIM 611718). Loss of *SLC12A3* and its encoded product—the thiazide sensitive $\text{Na}^+\text{:Cl}^-$

cotransporter—leads to reduced TRPM6 activity or abundance and the Gitelman syndrome (OMIM 263800) of hypomagnesemia, hypocalciuria, and hypokalemic metabolic alkalosis. Loss of the voltage-gated K^+ channel Kv1.1 (encoded by *KCNA1*) that colocalizes with TRPM6 alters the polarization of the renal epithelial cell of the distal convoluted tubule, a functional abnormality that impairs activity of TRPM6 and hence of magnesium transport resulting in autosomal dominant hypomagnesemia with episodic ataxia, tetany, muscular cramping, and myokymia (involuntary, localized quivering of a few muscle fibers within a muscle) (OMIM 160120). The pathogenesis of hypomagnesemia (OMIM 612780) that results from the loss-of-function mutations in *KCNJ10* encoding the inwardly rectifying K^+ channel—Kir4.1—is similar to that described for loss of *KCNA1*. Inactivating mutations of *KCNJ10* lead not only to hypomagnesemia but are also associated with the SESAME syndrome (seizures, sensory neural deafness, ataxia, mental retardation, electrolyte imbalance; OMIM 612780).

PTH increases magnesium reabsorption in the renal TALH and distal convoluted tubule; hypermagnesemia and hypercalcemia (acting through the CaSR) decrease renal tubular magnesium reabsorption as do expansion of ECF volume, metabolic alkalosis, phosphate depletion, loop diuretics, aminoglycoside antibiotics, and impaired renal function.²

ALKALINE PHOSPHATASE

The alkaline phosphatases are a group of transmembrane glycoproteins tethered to cell plasma membranes that remove phosphate groups from organic substrates; the extracellular (ecto) domain may be released from the cell membrane into the circulation by a phospholipase. There are three tissue-specific alkaline phosphatases (placental, germ cell, intestinal) and a tissue nonspecific alkaline phosphatase (TNSALP) (encoded by *ALPL*), the latter composed of several isoforms with similar protein composition of 507 to 524 AA but differing carbohydrate configurations that are present in the skeleton, teeth, liver, and kidney.⁷⁹ Bone TNSALP is generated by chondroblasts and osteoblasts by alternative processing of *ALPL* utilizing one of two leading exons during transcription and translation, permitting the osteoblast to synthesize and release a specific bone isoform. Functional as a homodimer, TNSALP removes phosphate residues (organically bound to a serine residue) from many phosphoprotein substrates including inorganic pyrophosphate, a substance that inhibits mineralization of bone organic matrix, phosphoethanolamine, and pyridoxyl 5'-phosphate, the precursor of pyridoxine in the absence of which seizures recalcitrant to treatment may develop.

Although TNSALP circulates as a homodimer, in tissue, it is a homotetrameric ectoenzyme (ectophosphatase) located on the cell surface of the osteoblast anchored through its carboxyl terminal to cell membrane phosphatidylinositol-glycan. In bone, alkaline phosphatase: (1) binds to collagen type I and prepares skeletal matrix for mineralization; (2) transports inorganic phosphate and free calcium into the cell; and (3) hydrolyzes organic phosphates, principally pyrophosphate and phosphoethanolamine, thereby increasing the local concentration of phosphate to values that exceed the calcium \times phosphate product encouraging deposition of calcium phosphate as hydroxyapatite on collagen type I fibers. Inactivation of pyrophosphate and other inhibitors of mineralization (e.g., phosphorylated ASARM derived from SIBLING proteins by removing their phosphate moieties by PHEX) permits formation of hydroxyapatite. The hepatic form of TNSALP is formed by alternative splicing of dual exons 1 of *ALPL*. Hepatic alkaline

phosphatase converts pyridoxyl-5'-phosphate (the major circulating form of vitamin B₆) to pyridoxal, a compound essential for normal synthesis of neural GABA, an inhibitory neurotransmitter; without pyridoxal-5'-phosphate central nervous system levels of GABA are low and seizures may occur. Loss-of-function mutations in *ALPL* lead to infantile, childhood, and adult forms of hypophosphatasia. The three genes encoding tissue-specific intestinal, placental, and germ cell alkaline phosphatase isoenzymes are clustered on chromosome 2q34-q37.

PARATHYROID HORMONE; PARATHYROID HORMONE-RELATED PROTEIN; PTH/PTHrP RECEPTORS

Parathyroid Hormone

PTH increases concentrations of plasma Ca²⁺, lowers serum phosphate values, stimulates synthesis of calcitriol, and exerts both anabolic and catabolic effects on bone. The chief cells of four paired parathyroid glands are derived from the endoderm of the dorsal segments of the third (paired inferior glands) and fourth (paired superior glands) pharyngeal pouches; occasionally, there may be a fifth parathyroid gland embedded within the substance of the thyroid gland or in the mediastinum.⁸⁰ The thymus is formed by the endoderm of the third pharyngeal pouch and calcitonin-synthesizing parafollicular C cells of the thyroid by endoderm of the fourth pharyngeal pouch. Transcription factors required for the development of the pharyngeal pouches and differentiation and organization of the parathyroid glands include T-box 1 (encoded by *TBX1*), GATA-binding factor/protein 3 (encoded by *GATA3*), glial cell missing, drosophila, homolog 2 (encoded by *GCM2*), and V-MAF musculoaponeurotic fibrosarcoma oncogene family, protein B (encoded by *MAFB*), a factor that aids in the movement of the parathyroid glands to sites on the periphery of the thyroid gland⁶ (Fig. 9.3). *GATA3*, *GCM2*, and *MAFB* are essential for the expression of *PTH* and synthesis of PTH postnatally.^{6,81} Variants of *GATA3* are associated with the syndrome of hypoparathyroidism, sensorineural deafness, and renal disease (OMIM 146255), whereas mutations in *GCM2* result in either familial hypo- or hyperparathyroidism (OMIM 146200/617413, respectively). In addition, four-and-a-half Lim domains (encoded by *FHL1*) is a gene that is also required for parathyroid gland formation as an inactivating variant of this gene is associated with aplasia of these structures.⁸² *PTH* is composed of three exons; exon 1 is transcribed but not translated; the second and third exons of *PTH* encode the prepro-PTH sequence of 115 AA that is processed to intact 84 AA PTH that is released from

the parathyroid glands in response to declining serum concentrations of Ca²⁺, detected by the CaSR expressed on the plasma membrane of the parathyroid gland chief cell.

PTH is recognized by the heptahelical PTH1R GPCR expressed on the plasma membranes of target tissue cells, including those that line the intestinal tract and renal tubules. In the distal renal tubule and collecting ducts, PTH increases reabsorption of filtered calcium. PTH inhibits reabsorption of filtered phosphate in the proximal renal tubule. PTH also stimulates expression of *CYP27B1* encoding renal 25-hydroxyvitamin D-1-alpha hydroxylase and consequently renal synthesis of calcitriol. In the intestinal tract, calcitriol increases absorption of calcium. PTH stimulates osteoblastogenesis and indirectly osteoclastogenesis, the latter by enhancing osteoblast expression of *TNFSF11* encoding the receptor activator of NF-κB-ligand (RANK-ligand) and suppressing that of *TNFRSF11B* encoding osteoprotegerin, a decoy receptor for RANK-ligand.⁸³ The intracellular message of PTH is transmitted by activation of signal transduction systems, including the cyclic AMP-protein kinase A, calcium-related protein kinase C, and MAPK pathways and those utilizing phospholipases A and C.

The synthesis and secretion of PTH by parathyroid gland chief cells is regulated by Ca²⁺ concentrations acting through the CaSR that either enhance (when Ca²⁺ concentrations are low) or repress (when they are high) transcription of *PTH* and secretion of PTH; Ca²⁺ values also modulate the rate of chief cell proliferation, a response also mediated by the CaSR. Calcimimetic drugs have inhibitory effects on PTH secretion, a property that has made these agents useful in the management of patients with excess secretion of PTH, such as mild hyperparathyroidism and autosomal dominant familial hypocalciuric hypercalcemia. Low serum concentrations of phosphate inhibit transcription of *PTH*, whereas rising serum phosphate values enhance production of PTH not only indirectly by lowering of Ca²⁺ values but also by stabilizing PTH mRNA, permitting greater translation of PTH and by stimulation of chief cell replication.⁸⁰ Calcitriol inhibits transcription of *PTH*, secretion of PTH, and proliferation of chief cells; FGF23 also decreases PTH secretion. In response to acute hypocalcemia PTH stored in secretory vesicles is rapidly released. When hypocalcemia is prolonged, the secretion of PTH¹⁻⁸⁴ is augmented by decrease in its rate of intracellular degradation and increase in the rate of transcription of *PTH*; when hypocalcemia is extended PTH synthesis and secretion are amplified by increase in chief cell number. When Ca²⁺ values rise, the secretion of PTH is decreased acutely by degradation of stored PTH¹⁻⁸⁴ by calcium-responsive proteases within the parathyroid glands; if prolonged, hypercalcemia leads to decrease in expression of *PTH* and to decline in the number of chief cells.⁸⁰

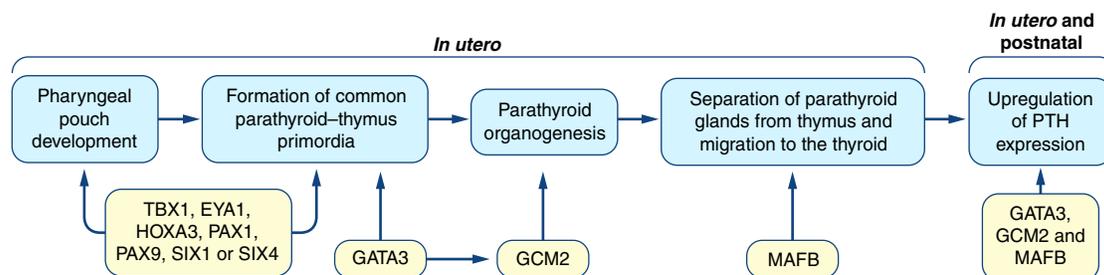

Fig. 9.3 Genetic regulation of the development and function of the parathyroid glands in the mouse. The parathyroid glands develop together with the thymus from the third pharyngeal pouch in mice (whereas in man, the parathyroid glands develop from the third and fourth pharyngeal pouches) under the sequential guidance of multiple transcription factors. *GCM2* is essential for initial differentiation of recognizable parathyroid tissue. GATA-binding protein 3 (*GATA3*), glial cell missing homolog 2 (*GCM2*), and V-Mak musculoaponeurotic fibrosarcoma oncogene family, protein B (*MAFB*) synergistically induce expression of *PTH*. (From Mannstadt, M., Bilezikian, J.P., Thakker, R.V., et al. (2017). Hypoparathyroidism. *Nat Rev Dis Primers*, 3, 17055. With permission).

The amino-terminal 25 AA signal sequence (encoded by exon 2) of 115 AA prepro-PTH is removed by furin, a prohormone convertase, as the polypeptide leaves the endoplasmic reticulum forming the 90 AA pro-PTH (encoded by exon 3) that is then further processed in the Golgi apparatus by furin to mature human 84 AA PTH¹⁻⁸⁴ that is stored in secretory vesicles and granules and from which it is either secreted by an exocytic mechanism or degraded by calcium-sensitive proteases (cathepsins B and H colocalized within the vesicles) to smaller amino and carboxyl-terminal fragments of PTH. PTH degradation represents an important mechanism that regulates the release of intact bioactive PTH¹⁻⁸⁴ and is accelerated when the plasma Ca²⁺ concentration is elevated. The full biological activity of PTH¹⁻⁸⁴ is found in its first 34 AA sequence and all of its skeletal and renal effects (vide infra) are localized within the segment PTH¹⁻³¹. Amino acids numbers 1 and 2 (ser-val) comprise an activation sequence that is essential for bioactivity of the amino-terminal portion of PTH¹⁻⁸⁴. Amino acids 20 to 26 constitute a core sequence necessary for binding to the amino-terminal ectodomain of PTHR1; within this seven AA sequence, Arg²⁰ and Trp²³ are critically important for binding of the PTH ligand to its receptor.⁸⁴ In addition to intact PTH¹⁻⁸⁴, the parathyroid glands secrete a phosphorylated form of PTH¹⁻⁸⁴ and carboxyl-terminal PTH fragments of varying length, but they do not secrete amino-terminal fragments of PTH¹⁻⁸⁴.^{85,86} The half-life of circulating PTH¹⁻⁸⁴ is approximately 2 minutes; it is rapidly metabolized by the liver and excreted by the kidney. In the hepatic Kupffer cells, PTH¹⁻⁸⁴ is cleaved usually either between AA 33 and 34 or between AA 36 and 37 to carboxyl-terminal PTH peptides with half-lives of approximately 15 to 20 minutes. In the kidney, intact and carboxyl-terminal fragments of PTH are filtered by the glomerulus, reabsorbed across the apical membrane of proximal renal tubular cells, and then degraded to smaller fragments. Megalin, a multifunctional low-density lipoprotein-related receptor (encoded by *LRP2*) expressed in coated pits on the luminal/apical surfaces (as well as endocytic vacuoles and lysosomes) of proximal renal tubular cells, specifically recognizes intact PTH¹⁻⁸⁴ and fragments of PTH and mediates the renal tubular endocytosis of PTH¹⁻⁸⁴ that has been filtered through the glomerulus.

The classical functions of PTH¹⁻⁸⁴, as well as its shorter amino peptide derivatives PTH¹⁻³⁴ and PTH¹⁻³¹ upon regulation of calcium and phosphate homeostasis are carried out through the seven transmembrane, G-protein-coupled type 1 PTH/PTHrP receptor sited on cell membranes in the renal tubule and osteoblast. Thus with equal potency PTH¹⁻⁸⁴, PTH¹⁻³⁴, and PTH¹⁻³¹: (1) inhibit renal tubular reabsorption of phosphate, thereby increasing its urinary excretion; (2) increase renal tubular reabsorption of Ca²⁺; (3) augment renal synthesis of calcitriol by enhancing expression of *CYP27B1* (encoding 25-hydroxyvitamin D₃-1 α hydroxylase), thereby amplifying intestinal absorption of calcium; (4) stimulate osteoblast production of RANK-ligand, thus enhancing osteoclastogenesis and osteoclastic reabsorption of calcium; and (5) mediate the anabolic effects of PTH on the volume and microarchitecture of bone.⁸⁷ PTH¹⁻⁸⁴, PTH¹⁻³⁴, and PTH¹⁻³¹ stimulate intracellular signal transduction through several G-protein-coupled pathways, including the G_{s α} -adenylyl cyclase-cyclic AMP-PKA and the G_{q/11}-PLC- β -inositol triphosphate (IP₃)/DAG-Ca²⁺-protein kinase C (PKC)-MAPK signal transduction pathways.⁸⁸ PTH¹⁻⁸⁴ and PTH¹⁻³⁴ also induce cell function through β -arrestin that does not involve a G-protein that in turn activates intracellular signaling pathways mediated by MAPK, protein kinase B (PKB), and PI3K.^{86,89}

Multiple carboxyl-terminal peptides derived from PTH¹⁻⁸⁴ are either secreted directly by the parathyroid chief cells

or return to the circulation after metabolism of intact PTH¹⁻⁸⁴ by hepatic Kupffer cells.⁸⁶ Indeed, carboxyl-terminal fragments of PTH¹⁻⁸⁴ are secreted in greater abundance from the parathyroid glands than is intact PTH¹⁻⁸⁴, and the proportion of carboxyl-terminal fragments secreted increases as the ambient Ca²⁺ concentration rises. Amino-terminal fragments generated by hepatic catabolism of PTH¹⁻⁸⁴ are degraded further within the liver and do not recirculate. PTH¹⁻⁸⁴ and the carboxyl-terminal fragments of PTH are filtered by the kidneys; the carboxyl-terminal fragments are reabsorbed by the renal tubules and further degraded intracellularly. Among the circulating carboxyl-terminal fragments of PTH are PTH⁷⁻⁸⁴, 24-84, 34-84, 37-84, 41-84, 43-84

In addition to their classical effects on mineral homeostasis, several nonclassical actions of PTH¹⁻⁸⁴ have been identified including: (1) rapid and direct stimulation of intestinal calcium absorption independent of its effects on vitamin D metabolism, (2) stimulation of hepatic gluconeogenesis, (3) acute natriuresis and calciuresis, and (4) enhancement of neutrophil movement in vitro.⁸⁶ Inasmuch as many of these nonclassical biological effects of intact PTH are not replicated by the amino-terminal fragment PTH¹⁻³⁴, it has been suggested that they may be related to the carboxyl-terminal portion of the protein. Indeed, the carboxyl-terminal fragments of PTH may have biological functions that oppose those of the amino-terminal portion of PTH, namely, hypocalcemic properties that are perhaps mediated by proapoptotic effects on both osteoclasts and osteocytes.⁴⁵

Because there are multiple circulating forms of PTH, its immunological measurement is dependent on the specificity of the antibody(ies) used in the assay. When a "first-generation" polyclonal PTH radioimmunoassay is used, both intact and carboxyl-terminal fragments of PTH are usually measured. Use of "second-generation" immunoradiometric and immunochemoluminometric assays using dual monoclonal antibodies, the first directed toward an epitope within the amino terminal of PTH (AA 20–25) and the second specific for an epitope in the carboxyl terminal of PTH (e.g., AA 59–78), improves the specificity of immunological assays for intact PTH¹⁻⁸⁴. Nevertheless, most of these assays detect both intact and selected carboxyl-terminal fragments of PTH and consequently measured PTH values may be inappropriately high, particularly in patients with chronic renal insufficiency in whom circulating levels of carboxyl-terminal fragments of PTH are high.⁹⁰ Furthermore, the comparability of PTH assays from different commercial sources is often limited.⁹¹ Using a two-site immunochemiluminescent assay, serum PTH concentrations average approximately 11 to 13 pg/mL and range between 2.3 and 24.5 pg/mL in children and adolescents 2 to 16 years of age; values do not vary with age but are a bit higher in girls than boys.⁹² Development of "third-generation" PTH assays that use antibodies that are directed to an epitope of the first four amino acids of PTH has improved the specificity and stability of assays for PTH¹⁻⁸⁴.^{93,94} A "fourth generation" of PTH assays uses immunoaffinity, in situ digestion, liquid chromatography, and tandem mass spectrometry to separate PTH¹⁻⁸⁴ from smaller PTH fragments.⁹⁰

The synthesis and secretion of PTH¹⁻⁸⁴ and its various fragments are modulated for the most part by the serum Ca²⁺ concentration acting through the CaSR expressed on the plasma membrane of the parathyroid chief cell. Rapidly declining, as well as steady-state low serum concentrations of Ca²⁺, increase PTH secretion by accelerating its release from storage sites in secretory vesicles; hypocalcemia also raises intracellular levels of PTH mRNA by increasing the transcription rate of *PTH* and enhancing the stability of PTH mRNA by its posttranscriptional binding to cytosolic proteins.^{4,80} Hypercalcemia decreases *PTH* transcription and destabilizes and thence lowers cellular levels of PTH mRNA. The serum Ca²⁺ concentration

also determines the form of PTH released by the parathyroid gland; during hypocalcemia PTH¹⁻⁸⁴ is the predominant form secreted; in hypercalcemic states, carboxyl-terminal fragments of PTH are released in abundance.

Low serum phosphate concentrations exert an independent and direct inhibitory effect on the transcription of *PTH*, post-transcriptional *PTH* mRNA stability, *PTH* secretion, and proliferation of parathyroid chief cells; hyperphosphatemia increases *PTH* secretion by lowering plasma concentrations of Ca^{2+} and by enhancing the stability of *PTH* mRNA.⁸⁰ Prolonged hyperphosphatemia contributes to hyperplasia of the parathyroid glands frequently encountered in patients with chronic renal disease. Calcitriol directly inhibits *PTH* transcription acting through the nuclear VDR. Calcitriol also controls expression of *CASR* and of *VDR* and decreases proliferation of parathyroid cells. However, chronic hypocalcemia overcomes the suppressive effects of calcitriol on *PTH* transcription by decreasing VDR number in the parathyroid chief cell. FGF23 released by osteocytes and osteoblasts directly impedes synthesis and secretion of *PTH*. Both hypomagnesemia and hypermagnesemia inhibit release but not synthesis of *PTH*. Other agents that increase *PTH* release include: β -adrenergic agonists, dopamine, prostaglandin E, potassium (by decreasing cytosolic Ca^{2+} levels within the parathyroid chief cell), prolactin, lithium (by “resetting” the set-point for *PTH* release), glucocorticoids, estrogens, and progestins. Prostaglandin F_{2 α} α -adrenergic agonists, and fluoride suppress *PTH* release by increasing cytosolic Ca^{2+} values.

PTH regulates the serum concentration of calcium by stimulating its reabsorption in the distal renal tubule and from the skeleton and indirectly by augmenting the intestinal absorption of calcium by increasing the synthesis of calcitriol. In bone, *PTH* enhances osteoclast differentiation and maturation indirectly by acting on and through stromal cells and osteoblasts to increase synthesis of RANK-ligand, an activator of osteoclastogenesis, and to suppress that of osteoprotegerin, a decoy receptor for RANK-ligand. When administered intermittently, however, PTH¹⁻⁸⁴ and PTH¹⁻³⁴ exert anabolic effects upon skeletal mass by increasing osteoblast number by accelerating their differentiation from progenitor cells and from inactive bone-lining cells. They do so in part by decreasing the stimulatory effects of the peroxisome proliferator activator receptor gamma (PPAR γ) upon mesenchymal stem cell differentiation into adipocytes permitting their differentiation into osteoblasts, by augmenting the rate of osteoblast proliferation, and by reducing the rate of apoptosis of osteoblasts.⁸⁷ The anabolic effects of *PTH* on bone formation are further mediated by enhancing synthesis and release of matrix-embedded growth factors, such as locally generated insulin-like growth factor-I (IGF-I), which has positive effects on differentiation and survival of osteoblasts, by stimulating the WNT-Frizzled- β -Catenin pathway of osteoblastogenesis, and by inhibiting antagonists to bone formation, such as sclerostin. In addition, through promotion of β -arrestin-mediated intracellular signal transduction, *PTH* increases trabecular number and volume.^{87,89} Thus *PTH* stimulates anabolism of bone mineralization whereas bisphosphonates exert an antiresorptive effect.⁹⁵ *PTH* stimulates calcitriol synthesis by increasing renal tubular expression of *CYP27B1*, the gene encoding 25-hydroxyvitamin D₃-1 α -hydroxylase, the enzyme that catalyzes the synthesis of calcitriol from calcidiol. *PTH* depresses proximal and distal renal tubular reabsorption of phosphate by decreasing expression of *SLC34A1*, encoding a Na⁺-HPO₄ cotransporter, thus increasing the urinary excretion of this anion. In addition, *PTH* directly stimulates secretion of bone-derived FGF23, thereby further increasing urinary phosphate excretion; *PTH* also indirectly stimulates FGF23 release by lowering serum phosphate concentrations and increasing those of calcitriol.⁹⁶

Parathyroid Hormone-Related Protein

PTHrP also termed *PTH-like protein (PTHLP)* (encoded by *PTHLP*) was initially identified as a major cause of humoral hypercalcemia of malignancy. *PTH* and PTHrP have evolved from a common ancestral gene through gene duplication, and they are structurally and functionally related.⁹⁷ Thus the sequence of AA in the preproportion of the translated products and the first eight of 13 AA at the beginning of their first coding exons are identical; although their AA sequences diverge thereafter, the predicted three-dimensional structures of the next 21 AA of both peptides are similar, as is the PTH1R to which the two proteins bind and through which they transmit their intracellular signals. However, *PTH* binds more avidly to PTH1R and elicits a greater hypercalcemic response than does PTHrP.⁹⁷ Following transcription, *PTHLP* is translated into isoforms composed of the first 139, 141, and 178 AA. PTHrP transmits its message both distally as an endocrine hormone and locally as both a paracrine and intracrine messenger. Variable parts of PTHrP are also secreted by keratinocytes, epithelial cells of the breast, and other tissues in sequences that include: AA 1 to 36 (which binds to and activates PTH1R), AA 38 to 94, and AA 107 to 138. Acting through the vitamin D nuclear receptor, calcitriol inhibits transcription of *PTHLP* and decreases the stability of PTHrP mRNA, thereby increasing the rate of intracellular degradation of the PTHrP protein.

Because transcription of *PTHLP* may begin in an exon downstream of the exon that encodes its signal peptide, after synthesis PTHrP can remain in the cytoplasm and be directly imported into the nucleus.⁹⁷ A nuclear localization sequence is present between AA 84 and 93 in the PTHrP molecule. After synthesis, PTHrP retained within the cytoplasm of the synthesizing cell is bound to importin β 1 and shuttled between cytosol and nucleus where it links to and regulates movement of targeted (m)RNA into the ribosome and translation of the selected gene(s), thus serving as an intracrine signaling transducer. PTHrP also transmits its message in a paracrine manner between cells within tissues. PTHrP is synthesized by many fetal and adult tissues (cartilage, bone, smooth, cardiac and skeletal muscle, skin, breast, intestines, parathyroid glands, pancreatic islets, pituitary, placenta, and central nervous system) and plays a crucial role in chondrocyte differentiation and maturation, formation of the mammary gland and eruption of teeth, and epidermal and hair follicle growth. In the fetus, periarticular chondrocytes located at the ends of long bones synthesize PTHrP in response to Indian hedgehog (encoded by *IHH*), a protein secreted by late proliferative-early prehypertrophic chondrocytes that functions through its receptor—Patched 1 (encoded by *PTCH1*).⁹⁸ PTHrP enters into and diffuses through the growth plate and signals prehypertrophic chondrocytes through PTH1R to slow their rate of differentiation to hypertrophic chondrocytes—thus prolonging the stage of chondrocyte proliferation and delaying ossification, thereby increasing the length of the cartilaginous growth plate and the long bone.⁹⁷ In addition to stimulating the secretion of PTHrP, the rate of growth plate chondrocyte proliferation is increased by *IHH*, which also directs differentiation of perichondrial cells to osteoblasts. PTHrP additionally influences osteoblast-induced bone formation and tooth eruption. PTHrP secreted by the fetal parathyroid gland and the PTHrP³⁷⁻⁹⁴ midregion fragment synthesized by the placenta increase placental calcium transport^{97,99} (Table 9.3). Both *PTH* and PTHrP are required for normal mineral homeostasis in the fetus.

Normal nipple and mammary gland formation is dependent upon local synthesis of PTHrP. In utero, this protein promotes differentiation of mesenchymal tissue surrounding the budding epithelial mammary ducts; PTHrP is also important for terminal differentiation of the mammary system during

TABLE 9.3 Parathyroid Hormone-Related Protein: Sites of Expression and Action

Site	Action
Mesenchyma Subarticular cells/ prechondrocytes	PTHrP depresses the rate of differentiation of late proliferating chondrocytes to hypertrophic chondrocytes and delays ossification, thus permitting increased longitudinal growth of the cartilaginous growth plate
Bone	Enhances or depresses bone resorption
Smooth muscle	Relaxation
Vascular system Myometrium Urinary bladder Cardiac muscle Skeletal muscle	Positive chronotropic and inotropic effects
Epithelia Skin Breast	Regulates proliferation of keratinocytes Induces ductal branching and formation of breast epithelium, secreted into milk, drives mobilization of calcium from maternal bone for transfer to nursing infant
Teeth	Stimulates resorption of overlying bone enabling eruption
Endocrine system Parathyroid glands Pancreatic islets Placenta	Stimulates transport of calcium Stored and cosecreted with insulin Enhances calcium transport from mother to fetus
Central nervous system	Neuroprotective by antagonizing excessive calcium

(ed). *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism*, 7th ed, The American Society of Bone and Mineral Metabolism, Washington DC, p 127–133; Wysolmerski, J.J. (2012). Parathyroid hormone-related protein: an update. *J Clin Endocrinol Metab*, 97, 2947–2956.)

puberty.⁹⁷ During lactation, mammary expression of *PTHLH* and secretion of PTHrP increases while production of estrogens declines permitting unopposed PTHrP-induced mobilization of maternal skeletal calcium necessary to meet the calcium requirement of the breastfed infant but substantially decreasing maternal bone mineral content, a process that is reversed when lactation ceases.¹⁰⁰

Biallelic loss of PTHrP in “knock-out” mice is lethal because of bony malformations. In *Pthlh*^{-/-} mice, there is decrease in the number of resting and proliferating chondrocytes; the columnar organization of the growth plate is disrupted, there is premature acceleration of chondrocyte maturation and apoptosis, and inappropriate ossification resulting in a dwarfing phenotype (a domed and foreshortened cranium, short limbs, small thorax) that is similar to that of Blomstrand chondrodysplasia (OMIM 215045), a disorder associated with loss-of-function mutations of *PTH1R*. Mice in which expression of *Pthlh* has been maintained only in chondrocytes survive but are short with cranial chondrodystrophy and failure of tooth eruption. In the heterozygous state (*Pthlh*+/-), mouse fetal development is normal but by 3 months of age, the trabeculae of the long bones are osteopenic; a similar bone phenotype is noted when loss of *Pthlh* expression is confined to osteoblasts.⁹⁹ For comparison, in mice in which *Pth* has been “knocked out,” there is decreased mineralization of cartilage matrix, expression of vascular endothelial growth factor (VEGF)

and neovascularization, osteoblast number, and trabecular bone volume.¹⁰¹ Thus both PTH and PTHrP are necessary for normal fetal endochondral bone development. Cortical thickness of long bones is increased in both *Pth*- and *Pthlh*-null mouse models, indicating that the regulation of endochondral and periosteal osteoblast function differs.

Serum concentrations of PTHrP are low except when it is secreted by tumors, leading to humoral hypercalcemia of cancer. There are high levels of PTHrP in breast milk and low concentrations of PTHrP may be measurable in the serum of lactating women.

Parathyroid Hormone/Parathyroid Hormone-Related Protein Receptors

PTH and PTH-rP bind to the PTH receptor, PTH1R.⁸⁸ PTH1R is a 585 AA protein that is a member of the Class B family of GPCRs whose ligands include calcitonin, GH-releasing hormone, secretin, glucagon, glucagon-like peptide 1, gastric inhibiting polypeptide, vasoactive intestinal polypeptide, corticotropin-releasing hormone, and pituitary adenylate cyclase activating protein that are characterized by long extracellular amino-terminal domains (~160 AA residues) with multiple cysteine residues forming disulfide bridges. PTH1R has an extracellular domain, seven transmembrane spanning segments connected by three extracellular and three intracellular loops, and an intracellular domain with which the signaling G-protein interacts. *PTH1R* is composed of 15 exons; there are three promoters that regulate expression of *PTH1R*. As a result of alternative splicing of its mRNA, there are several isoforms of the PTH/PTHrP receptor.

The amino terminals of both PTH¹⁻³⁴ and PTHrP¹⁻³⁶ bind to the transmembrane and the extracellular loop sequences of the transmembrane segments of PTH1R, whereas their carboxyl terminals bind to the amino-terminal extracellular portion of PTH1R.^{4,86,88,102} Ligand-bound PTH1R transmits its message through several intracellular signal transduction pathways, including the G_{sα}-adenylyl cyclase-cyclic AMP-PKA system, the G_{q/11}-PLCβ-inositol trisphosphate-cytoplasmic Ca²⁺-PKC path, the G_{12/13}-phospholipase D-transforming protein RhoA system, and the β-arrestin-MAPK pathway.⁸⁹ Interaction of the specific PTH1R ligand and PTH1R determines the signaling pathway and duration of response of these two components; thus PTH has a greater affinity for PTH1R than does PTHrP and coupling of PTH with PTH1R leads to a more stable, prolonged, and intense signaling response than does interaction of PTHrP and PTH1R. Indeed, even after internalization, PTH-PTH1R signaling continues.⁸⁸

After inducing intracellular signaling, PTH1R is phosphorylated by a GPCR kinase (GRK) and bound to β-arrestin-1 (encoded by *ARBB21*), leading to its internalization, and subsequent destruction or reutilization.⁸⁹ Once internalized, PTH1R may be degraded, recycled to the cell membrane, or directed to the nucleus by importins-α₁ and -β where it is present in the nucleoplasm.¹⁰³ The physiological functions of nuclear PTH1R and its ligands PTH and PTHrP are as yet unknown.

In the kidney, *PTH1R* is expressed on the apical and basolateral surfaces of cells in the proximal renal tubule; binding of PTH to apical PTH1R preferentially signals through cyclic AMP-PKA, whereas interaction of PTH with basolateral PTH1R activates the PLC-PKC signal transduction pathway. Through both PKA and PLC, PTH/PTH1R activates the MAPK signal transduction system of extracellular signal-regulated kinases (ERK)-1,2, allowing regulation of cell differentiation, division, growth, and apoptosis. In addition to participating in the internalization of the PTH-PTH1R complex, β-arrestin enables it to stimulate intracellular signaling in a manner that is

independent of G-proteins; the GRK-mediated patterns of proline phosphorylation of PTH1R and β -arrestin likely determine their conformations and functional activities.¹⁰⁴ Thus interaction of PTH-PTH1R with β -arrestin may also activate the MAPK signaling system and facilitate PI3K and PKB (AKT) intracellular signal transduction pathways.⁸⁹ PTH-PTH1R activation of the MAPK pathway through its GPCR is rapid but relatively brief lasting only a few minutes, whereas activation through the β -arrestin pathway is slow and sustained over hours. Another mechanism through which PTH/PTH1R interaction affects cellular function is by the binding of PTH1R to the Na^+ - H^+ exchanger regulatory factor 2 (NHERF2—encoded by *SLC9A3R2*) with consequent stimulation of PLC activity and inhibition of adenylyl cyclase activity.¹⁰⁵ In the kidney, PTH1R binds to NHERF1 (encoded by *SLC9A3R1*), an essential factor for trafficking of the phosphate channel NPT2a to the luminal membrane of cells in the proximal renal tubule.⁵⁴ In the proximal renal tubule, linking of PTH to PTH1R increases cyclic AMP production, leading to decrease in the internalization and expression of the sodium-phosphate cotransporters and increase in urinary phosphate excretion; association of PTH1R with NHERF1 blunts the phosphaturic effect of PTH. Therefore disruption of PTH1R-NHERF1 interaction leads to renal wasting of phosphate. Agonists of PTH have been synthesized that can “bias” the selection of the signal transduction pathway used; a “biased” agonist might stabilize a receptor conformation that stimulates a specific signal transduction sequence or activate one pathway while simultaneously inhibiting another.^{88,89,104}

PTH1R is expressed in renal tubular cells and osteoblasts, skin, breast, heart, and pancreas among other tissues—the latter sites reflecting the paracrine targets of PTHrP. PTH, PTHrP, and calcitriol decrease expression of *PTH1R*. Targeted loss of *PTH1R* is accompanied by impaired proliferation of chondrocytes and acceleration of chondrocyte maturation and calcification, an outcome mimicked by targeted loss of $\text{G}_{\alpha s}$ in chondrocytes.^{86,99} Clinically, inactivating mutations in *PTH1R* result in hypocalcemia and Blomstrand chondrodysplasia (OMIM 215045), whereas constitutively activating mutations of *PTH1R* lead to hypercalcemia and Jansen metaphyseal chondrodysplasia (OMIM 156400).

A second PTH receptor (PTH2R) is selectively activated by PTH but does not recognize PTHrP; PTH specificity is determined by Ile⁵ and Trp²³ in native PTH, sites that affect activation and binding, respectively.⁸⁶ *PTH2R* encodes a 539 AA GPCR with 50% homology to PTH1R that activates adenylyl cyclase; it is expressed predominantly in brain, testis, placenta, and pancreas, but not in bone or kidney; its physiological role is uncertain. In response to PTH¹⁻⁸⁴, PTH2R enhances both cyclic AMP generation and Ca^{2+} mobilization. However, the naturally occurring endogenous ligand for PTH2R is not PTH but the 39 AA PTH-related hypothalamic tuberoinfundibular peptide (TIP39); this protein is also expressed in the testis and various central nervous system regions.⁹⁷

Although as yet not molecularly characterized, receptors for carboxyl-terminal fragments of PTH¹⁻⁸⁴ have been functionally identified as renal and bone cell binding sites for PTH¹⁻⁸⁴ from which intact hormone can be only partially displaced by PTH¹⁻³⁴ but can be further displaced by PTH⁵³⁻⁸⁴ and PTH⁶⁹⁻⁸⁴.⁸⁶ In addition, in osteocytes, osteoblasts, and chondrocytes from which the PTH/PTHrP receptor has been “knocked out” and to which intact PTH¹⁻⁸⁴ but not PTH¹⁻³⁴ binds, labeled PTH¹⁻⁸⁴ can be displaced by carboxyl-terminal PTH¹⁹⁻⁸⁴, ²⁸⁻⁸⁴, ³⁹⁻⁸⁴ fragments. Important determinants for binding of PTH to the carboxyl-terminal selective receptor(s) appear to be AA 24 to 27 (Leu-Arg-Lys-Lys) and 53 to 54 (Lys-Lys). Furthermore, carboxyl-terminal fragments of PTH exert biological effects in intact and *PTH1R*-null cells, such as regulation of alkaline phosphatase

activity in osteosarcoma cells and osteoblasts (but not generation of collagen type I), stimulation of Ca^{2+} uptake by osteosarcoma cells and chondrocytes, and cell survival in vitro. Thus the physiological actions of PTH likely reflect the integrated sum of the individual functions of the intact hormone and its carboxyl-terminal fragments. Carboxyl-terminal fragments of PTHrP are not recognized by the sites that bind carboxyl-terminal fragments of PTH.

CALCITONIN

Calcitonin, a 32 AA peptide encoded by *CALCA*, is synthesized and released by the neural crest-derived parafollicular C cells of the thyroid gland in response to rising concentrations of Ca^{2+} (a reaction mediated by activation of the CaSR present on the plasma membrane of the C cell) and in response to several gastrointestinal hormones, including gastrin.^{4,106} *CALCA* is a six exon gene that by alternative transcription and translation forms a 141 AA protein from which calcitonin (exon 4) and katalcacin, a 21 AA hypocalcemic peptide adjacent to the carboxyl terminus of calcitonin, are derived, and a 128 AA protein from which is gleaned the 37 AA calcitonin gene-related-peptide (CGRP)- α (exon 5), a vasodilator and neurotransmitter that also interacts with the calcitonin receptor. Calcitonin lowers serum concentrations of calcium by inhibiting osteoclast-mediated bone resorption and by increasing renal calcium excretion. After binding of calcitonin to its GPCR expressed on the osteoclast cell membrane, the morphology of the ruffled membrane of the functioning osteoclast flattens causing it to withdraw from the bone reabsorption site, thereby decreasing this process and consequently lowering peripheral calcium concentrations.¹⁰⁷ Calcitonin also decreases renal tubular reabsorption of filtered calcium. However, calcitonin enhances proximal renal tubular synthesis of calcitriol and thereby increases intestinal absorption of calcium. In turn, calcitriol suppresses synthesis and secretion of calcitonin; thus calcitriol has the same reciprocal relationship with calcitonin as it does with PTH and FGF23.

Calcitonin is produced in excess by medullary carcinoma of the thyroid and, at times, by other neuroendocrine tumors. The calcitonins of multiple species share similar structures including: five of the first seven amino-terminal AA, a disulfide bridge between AA 1 and 7, glycine at AA residue 28, and a proline amide residue at carboxyl-terminal AA 32. In the interior of the peptide, species other than human have several basic amino AA that make them more stable and easily recognized by the human calcitonin receptor and thus more biologically potent, for example, therapeutically useful salmon calcitonin.

Calcitonin secretion is stimulated primarily by increasing concentrations of Ca^{2+} transduced by the CaSR expressed on the plasma membrane of the C cell.⁴ Members of the gastrin-cholecystokinin intestinal peptide hormone family (gastrin, glucagon, pancreaticozym, glucocorticoids, and β adrenergic agonists) are also potent calcitonin secretagogues.^{4,107} Calcium, pentagastrin, and glucagon are effective stimuli used to assess calcitonin secretion clinically. Somatostatin, calcitriol, and chromogranin A¹⁻⁴⁰ inhibit and chromogranin A⁴⁰³⁻⁴²⁸ stimulates calcitonin secretion. Calcitonin secretion declines as the Ca^{2+} concentration declines. The half-life of calcitonin is brief; it is metabolized primarily by the kidney and also by liver, bone, and thyroid gland. Serum levels of calcitonin are high in the fetus (when serum total calcium concentrations are normally 12–13 mg/dL) and newborn, fall rapidly after birth as Ca^{2+} values decline and then more slowly until 3 years of age remaining relatively constant thereafter (<12 pg/mL). After 10 years of age, serum concentrations of calcitonin are higher in males than in females. The physiological role of calcitonin is unclear as serum calcium concentrations are normal in patients with both decreased (primary congenital or acquired

hypothyroidism) and increased (medullary carcinoma of the thyroid) secretion of this peptide. However, disposal of a calcium load is slower in the calcitonin-deficient subject. Calcitonin values are slightly higher in males than in females. Immunoassayable concentrations of calcitonin are increased in patients with medullary carcinoma of the thyroid, chronic renal insufficiency, and pycnodysostosis.¹⁰⁷

The biological effects of calcitonin are mediated through its 490 AA class B GPCR encoded by *CALCR*. Intracellular signaling of the *CALCR* is transduced through the $G_{s\alpha}$ adenylyl cyclase-cyclic AMP-PKA and $G_{\alpha q}$ -PLC-IP₃ signal transduction pathways. Alternative splicing of *CALCR* results in two isoforms of the calcitonin receptor, one of which has an additional 16 AA inserted into its first intracellular loop between transdomains I and II. The calcitonin receptor is expressed in osteoclasts; when exposed to calcitonin, the osteoclast shrinks and bone resorbing activity declines quickly. Thus calcitonin lowers serum calcium and phosphate levels particularly in patients with hypercalcemia. In lactating women, serum levels of calcitonin rise and calcitonin is excreted in breast milk. Women who are breastfeeding their infants lose 5% to 10% of their trabecular bone mineral during 6 months of lactation that is recouped rapidly when lactation ceases, much more quickly than when

bone mass is lost because of other problems (e.g., glucocorticoid excess, bed rest). Inasmuch as calcitonin values increase during pregnancy and lactation, calcitonin may play a role in the remineralization of bone in lactating women after completion of breastfeeding.

VITAMIN D

Synthesis and Biological Activity of Vitamin D

Cholecalciferol (vitamin D₃) may either be generated endogenously by exposure of the skin to sunlight or consumed (in a diet consisting of oily fish, such as wild salmon, tuna, herring, cod, and mackerel; fungi, such as shiitake mushrooms; and egg yolks or as a dietary supplement). (Ergocalciferol [vitamin D₂] is a plant and yeast sterol that may either be consumed or ingested as a dietary supplement.) In the cutaneous stratae basale and spinosum, vitamin D₃ is synthesized from cholesterol: 7-dehydrocholesterol is photoisomerized to previtamin D₃ by ultraviolet B radiation at 290 to 315 nm and heat (37° C) from sunlight and then spontaneously isomerizes to cholecalciferol (vitamin D₃) (Fig. 9.4).^{23,108,109} Previtamin D₃ is also metabolized into products, such as lumisterol₃

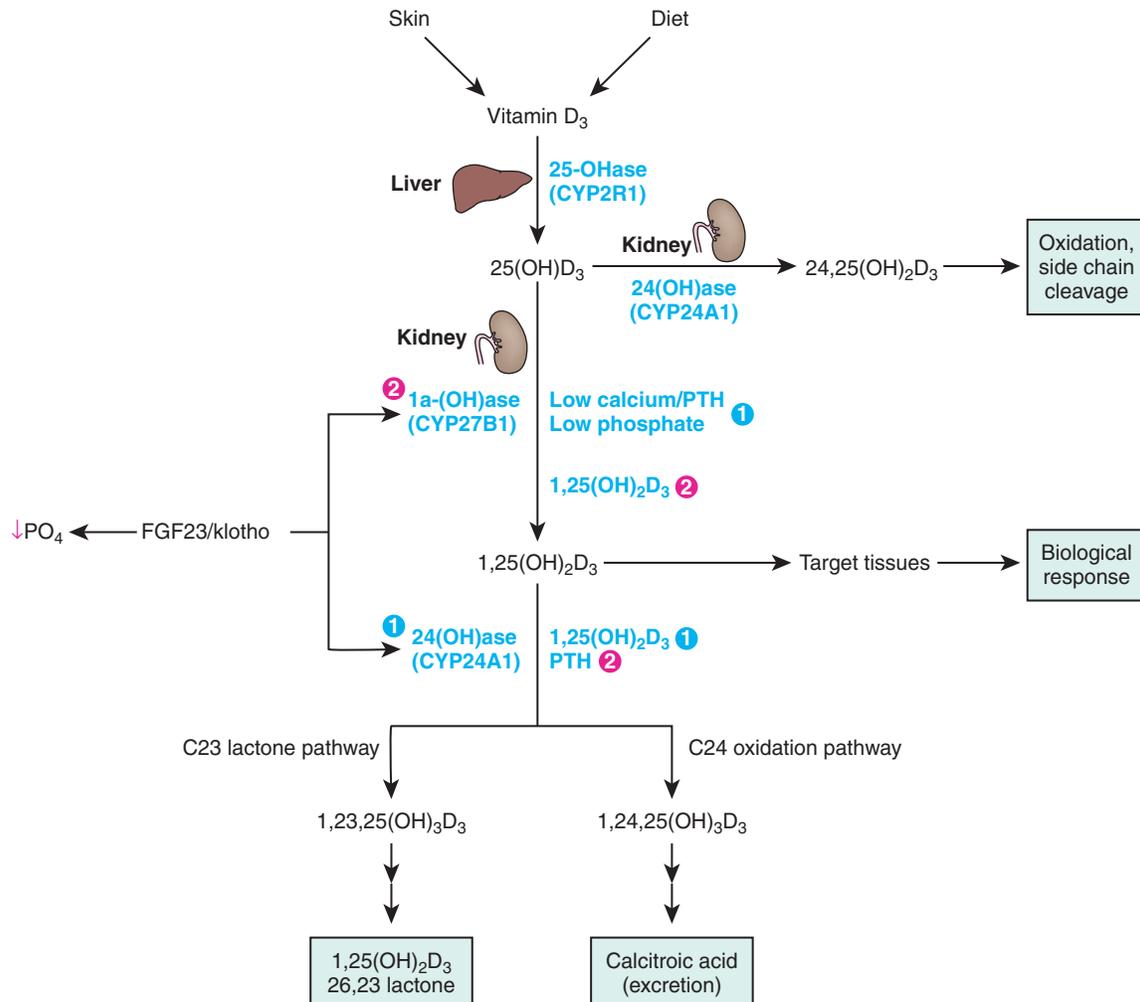

Fig. 9.4 Synthesis and metabolism of vitamin D. In skin, 7-dehydrocholesterol is metabolized to cholecalciferol (vitamin D₃) that is then hydroxylated at carbon 25 in the liver to form calcidiol (25OHD₃) and at carbon 1 in the kidney to form calcitriol [1,25(OH)₂D₃]. Calcitriol is inactivated by hydroxylation at carbon 24 or carbon 23. Parathyroid hormone (PTH) enhances synthesis of calcitriol and impedes its catabolism. Fibroblast growth factor-23 (FGF23) antagonizes synthesis of calcitriol and hastens its degradation. (From Christakos, S., Dhawan, P., Verstuyf, A., et al. (2016). Vitamin D: metabolism, molecular mechanisms of action, and pleiotropic effects. *Physiol Rev*, 96, 365–408. With permission).

and tachysterol₃ and to inactive photoproducts when exposure to sunlight is excessive, thereby preventing vitamin D intoxication by exposure to sunlight alone. Cutaneously synthesized vitamin D₃ enters the circulation directly. Ergocalciferol (vitamin D₂) derived from ergosterol differs structurally from vitamin D₃ by the presence of a double bond between carbons 22 and 23 and a methyl group on carbon 24. Vitamins D₃ and D₂ exert reasonably similar biological effects when ingested in equivalent physiological doses; however, the biological potency of vitamin D₂ is less than that of vitamin D₃ because it is rapidly cleared from the circulation, restricting its further processing into a biologically active form.^{108,110,111} The latitude, season of the year, and time of day influence the rate of cutaneous synthesis of vitamin D₃ in response to exposure to sunlight; in higher latitudes, the path through which ultraviolet B radiation from the sun travels is longer and more of the ultraviolet radiation is absorbed by the ozone layer; thus less reaches the surface of the earth. Exposure of the back of a white adult to intense summer sun (mid-July) for 10 to 12 minutes in the northeastern United States generates around 10,000 to 20,000 IU of vitamin D₃ over the next 24-hour interval.¹¹² (For persons of color, 30–120 minutes of exposure to sunlight may be required for comparable effects.) Sun-blocking topical creams and aging also decrease the cutaneous formation of cholecalciferol in response to sunlight. Both forms of vitamin D undergo similar chemical modifications to become bioactive metabolites. Orally ingested vitamin D is packaged into chylomicrons and absorbed into the intestinal lymphatic system and then enters the circulation. Vitamins D₃ and D₂ and their metabolites are transported in serum linked to vitamin D-binding protein (DBP), a polymorphic variant of the serum α 2-globulin synthesized by the liver and encoded by *GC*. DBP binds vitamin D and its hydroxylated metabolites with high affinity and capacity.¹¹³

Sequentially, vitamin D is twice hydroxylated, first in the liver at carbon 25 primarily by the vitamin D 25-hydroxylase encoded by microsomal *CYP2R1* to form 25-hydroxyvitamin D₃ (25OHD₃ = calcidiol), and secondly in the mitochondria of the proximal renal tubule at carbon 1 to form 1,25-dihydroxyvitamin D₃ [1,25(OH)₂D₃ = calcitriol].^{22,110} From serum, the 25-hydroxyvitamin D/DBP complex is transported into the cytoplasm of cells in the proximal renal tubule bound to a transmembrane protein termed *megalyn* (encoded by *LRP2*) and acted upon by mitochondrial 25-hydroxyvitamin D-1 α -hydroxylase (encoded by *CYP27B1*). The 1 α -hydroxyl group of calcitriol is essential for its binding to the VDR.¹¹⁴ The nine exons of *CYP27B1* encode a 507 AA protein with a mitochondrial signal sequence at its amino terminal and ferredoxin and heme-binding sites within its structure. As a class I mitochondrial cytochrome P450 enzyme, 25OHD-1 α -hydroxylase requires for its catalytic activity electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) that are ferried to the enzyme protein by the electron transport proteins—NADPH-ferredoxin and ferredoxin reductase.^{110,115} (*CYP27B1* is also expressed by the placental deciduous and trophoblastic cells, epithelial cells of the skin, parathyroid glands, pancreatic islet cells, thyroid, chondrocytes, and osteoblasts and by macrophages and T/B cells of the immune system.¹¹⁰)

Renal tubular expression of *CYP27B1* is stimulated by hypocalcemia, hypophosphatemia, PTH, calcitonin, GH, IGF-I, and prolactin and suppressed by calcitriol and FGF23/Klotho. In monocytes and macrophages, expression of *CYP27B1* may be induced by inflammatory cytokines, such as interferon- γ but is not regulated by concentrations of Ca²⁺, phosphate, PTH, or calcitriol.^{109,110} Reciprocally, hypercalcemia and hyperphosphatemia directly suppress expression of *CYP27B1*. Calcitriol exerts a direct autoinhibitory effect upon renal *CYP27B1* expression acting through the VDR and thus upon its own

synthesis; it also indirectly inhibits *CYP27B1* expression by impairing PTH synthesis in the parathyroid gland.¹⁰⁸ FGF23 depresses 25OHD-1 α -hydroxylase activity, whereas calcitriol increases *FGF23* expression effectively establishing a reciprocal control system for these compounds.^{57,64,116} Calcitriol acts in the parathyroid gland to increase expression of *CASR* thereby suppressing expression of *PTH* and indirectly that of *CYP27B1*. Both calcidiol and calcitriol are inactivated by hydroxylation at carbon 24 by renal tubular cells expressing *CYP24A1* (encoding vitamin D 24-hydroxylase) whose expression is stimulated by calcitriol and FGF23/Klotho and inhibited by PTH; calcitriol may also be inactivated by hydroxylation at carbon 23 and conversion to a lactone (see Fig. 9.4).²²

Inasmuch as calcidiol exerts only a minimal inhibitory effect on its production, serum concentrations of calcidiol reflect available body stores of vitamin D. However, genetic variants of *DHCR7* encoding 7-dehydrocholesterol reductase, *CYP2R1*, *GC*, and *VDR* encoding the VDR may affect the serum concentration of calcidiol.¹¹⁷ Although lacking consensus because of variability in calcidiol assay methodology, the current recommendation for interpretation of the 25OHD concentration is: less than 12 ng/mL deficiency of vitamin D; 12 to 20 ng/mL insufficiency; more than 20 to 50 ng/mL sufficiency; and toxicity over 100 ng/mL if associated with hypercalcemia, hypercalciuria, and suppressed serum PTH concentration.^{118,119} It is currently recommended that all infants (whether breast- or formula-fed) receive a vitamin D supplement of 400 IU/day and that children between 1 and 18 years of age receive 600 to 1000 IU of vitamin D daily, depending upon skin color and latitude of residence.^{118,120} It has been recommended that preterm infants ingest 200 to 800 IU of vitamin D daily, that the serum 25OHD concentrations of these subjects be measured serially, and that the dose of vitamin D readjusted as indicated. The recommended upper limit of vitamin D intake is 4000 IU/day for all age groups above 8 years (see Table 9.2).³⁰ In vitamin D-deficient pregnant women, vitamin D supplementation decreased the rates of premature delivery, maternal preeclampsia, and gestational diabetes mellitus.¹²¹ In middle-aged and older adults, intake of 400 to 800 IU per day of cholecalciferol can slightly reduce all-cause mortality.¹²² However, supplementation has had no effect upon the risk of cardiovascular disorders, neoplasia, altered glucose metabolism and adiposity, disorders of mood, and a number of other infectious and noninfectious diseases. Although subnormal serum concentrations of 25OHD may be recorded in many patients with a variety of illnesses, it is likely that hypovitaminosis D in these circumstances is the consequence of the disease rather than its cause.

Calcitriol circulates bound to DBP and enters the target cell (intestinal tract, kidney, parathyroid gland, bone, and other sites) where it binds to the cytosolic VDR, translocates to the nucleus, heterodimerizes with the retinoid X receptor (RXR), binds to the VDR response element (VDRE) of the selected gene, and stimulates or represses gene expression by recruiting site-specific transcriptional regulators. The VDREs have diverse nucleotide compositions and, while often present in the 5' sequence upstream of the target gene, may also be located far distant from the transcription start site.²²

The major functions of calcitriol are to increase intestinal and renal tubular absorption of calcium and phosphate, thereby increasing their serum concentrations and enhancing bone mineralization and to increase bone resorption by stimulating osteoblast production of RANK-ligand, thereby activating osteoclastogenesis.²² During periods of negative calcium balance, calcitriol impedes bone mineralization by increasing production of inhibitors of this process, such as pyrophosphate and osteopontin. Among the more than 1000 gene targets of calcitriol/VDR are: *TNFSF11* (RANK-Ligand—activator of

osteoclastogenesis), *LRP5* (lipoprotein receptor cofactor 5 for WNT/Frizzled receptor interaction), *TRPV6* (intestinal calcium channel), *FGF23*, *SLC34A3* (renal phosphate channel—NPT2c), *PTH*, *PTH1LH*, *KL* (Klotho), *CYP24A1* (25-Hydroxyvitamin D-24 hydroxylase), and *CA2* (Carbonic anhydrase 2).⁶²

Calcitriol is inactivated in bone, intestine, liver, and kidney by glucuronidation, sulfation, multisite (carbons-23, -24, -26) hydroxylation, and lactone formation to water-soluble compounds (such as calcitroic acid) that are excreted in urine and bile.^{108,109,110} In the kidney, 25OHD (calcidiol) and 1,25(OH)₂D (calcitriol) are converted to 24R,25(OH)₂D and 1,24R,25(OH)₃D, respectively, by mitochondrial 25OHD-24 hydroxylase encoded by *CYP24A1*, the first in a series of hydroxylations that increase the water solubility of the products, enabling their biliary and renal excretion (see Fig. 9.3). The expression of *CYP24A1* is increased by hypercalcemia, hyperphosphatemia, FGF23, and calcitriol, as well as retinoic and lithocholic acids, rifampicin, carbamazepine, and phenobarbital and suppressed by hypocalcemia and PTH.¹¹⁵ *CYP24A1* is also expressed by fibroblasts, lung, intestine, oocytes, brain, thyroid, and other tissues.¹⁰⁹ Cleavage of the side chain between carbons 23 and 24 that have been hydroxylated by hepatic cytochrome P450-3A (encoded by *CYP3A4*) dependent enzymes generates water-soluble calcitroic acid that is excreted in bile.^{108,109} Phenobarbital, phenytoin, carbamazepine, and rifampicin impair bone mineralization by inactivating calcitriol and do so by increasing its state of hydroxylation by binding to and activating the nuclear pregnane X receptor (*NR112*) that in turn increases expression of *CYP3A4*.¹²³ Calcitriol may also induce expression of hydroxylases that use cytochrome P450-3A, thereby enhancing its own hydroxylation and degradation. Inactivating mutations of *CYP24A1* lead to (idiopathic) hypercalcemia of infancy by reducing the rate of degradation and thereby prolonging the biological life of calcitriol.¹²⁴

Although emphasis has been placed on the vitamin D endocrine system in the regulation of mineral homeostasis and bone health, its role as a paracrine factor may also be considered. Adipocytes not only store vitamin D, these cells also express vitamin D-25 hydroxylase and 25-hydroxyvitamin D-1 α hydroxylase activities suggesting that fat may be a site of calcidiol and calcitriol synthesis.¹⁰⁹ The bulk of circulating calcitriol is bound to DBP, but it is its free fraction that is biologically active. Indeed, the serum level of DBP does not affect the calcitriol pool that enters the cell and regulates gene transcription.¹¹⁴ Approximately 0.04% of calcidiol and 0.4% of calcitriol are present in free form in serum. “Normal” ranges of calcitriol concentrations are: neonates 8 to 72 pg/mL, infants and children 15 to 90 pg/mL, and adults 21 to 65 pg/mL.

Calcitriol exerts its biological effects by binding to its cytosolic VDR, heterodimerizing with RXR α , entering the nucleus, and binding to the specific VDRE, thereby regulating the expression of more than 1000 target genes involved in mineral and bone metabolism and other processes that influence cell growth, musculoskeletal, cardiovascular, immune, skin, and pancreatic islet cell functions and energy metabolism.^{108,114,125,126} The nuclear effects of calcitriol take place over hours to days as the processes of transcription, translation, posttranslational modifications to the encoded protein(s), storage, and secretion occur in multiple cytosolic compartments. The VDR also associates with caveolae of the cell plasma membrane—flask-shaped invaginations of the membrane composed of sphingolipids and cholesterol where, after binding to ligand, the VDR is able to interact with intracellular signal transduction systems to exert rapid functional cell responses.^{127,128} The rapid cell responses to calcitriol generated by association with the caveolar VDR are evident within seconds to minutes after contact and include: immediate intestinal

absorption of calcium (transcaltachia), opening of voltage-gated calcium and chloride channels in osteoblasts, endothelial cell migration, and pancreatic β cell secretion of insulin. It is the flexible three-dimensional configuration of calcitriol that enables this ligand to exert both genomic and nongenomic (rapid response) actions.^{114,127} The protean three-dimensional structure of calcitriol is the result of: (1) rotation of side chain carbon pairs 17-20, 20-22, 22-23, 23-24, and 24-25; (2) rotation of the carbon 6-7 bond around the B ring; and (3) chair-chair interconversion with formation of either an α - or β - configuration of the cyclohexane-like A ring. Rotation about the carbon 6-7 bond of the B ring allows calcitriol to assume either an extended 6-*s-trans* configuration or a 6-*s-cis* conformation. It is the *trans* form of calcitriol with the β -chair configuration of the A ring that is recognized and bound by the hydrophobic pocket of the nuclear VDR. Ligand-bound VDR interacts with the RXR forming a heterodimer that is recognized by specific hexameric sequences of DNA bases (the VDRE) in the regulatory region of target genes.¹⁰⁹ The nucleotide sequences of the numerous VDREs are highly variable but in general consist of two halves of similar hexanucleotides connected by three (variable) nucleotides.¹¹⁰ The calcitriol/VDR-RXR-VDRE complex then recruits transcription-activating or transcription-repressing coregulatory proteins enabling its genomic transcriptional effects. The *cis* form of calcitriol permits its rapid cell membrane-related actions.

Calcitriol primarily controls intestinal, skeletal, and renal function by regulating expression of genes encoding calcium transporters (calbindin-D_{28K}, calbindin-D_{9K}), calcium channels (TRPV5—expressed primarily in the kidney; TRPV6—expressed predominantly in the intestinal tract), bone matrix proteins (osteocalcin, osteopontin, type I collagen, alkaline phosphatase), and osteoclast activators (RANK-ligand). Calcitriol promotes endochondral bone formation; it increases length of the long bones by amplifying volume, proliferation, and differentiation of epiphyseal chondrocytes and promotes mineralization of cartilage matrix.¹²⁹ Calcitriol increases trabecular and cortical bone formation by augmenting osteoblast number and function; it increases alkaline phosphatase activity, osteocalcin synthesis, and type I collagen formation and represses bone resorption by osteoclasts. Calcitriol directly suppresses transcription of *PTH* in the parathyroid gland acting through the VDR. Vitamin D is also important for normal muscle development and strength.

Mediated by the nuclear VDR, calcitriol stimulates the absorption or reabsorption of calcium in the intestines, bone, and kidney. In the duodenum and proximal small intestine, calcitriol increases the efficiency of calcium uptake from the intestinal lumen by increasing the number of epithelial calcium transport channels (TRPV6) in enterocytes, its movement through the cytoplasm, and its transfer across the basal lateral membrane into the circulation, in part by the induction of calbindin_{9k}, a calcium binding protein, alkaline phosphatase, Ca-ATPase, calmodulin, and other proteins.¹³⁰ Calcitriol also increases jejunal and ileal absorption of phosphate through a transcellular mechanism utilizing the type II Na⁺-HPO₄²⁻ cotransporter NPT2a (encoded by *SLC34A1*) expressed on the luminal surface of the enterocyte. When vitamin D stores are replete, 40% of dietary calcium and 80% of dietary phosphate may be absorbed. Even greater efficiency of mineral absorption is realized during periods of rapid growth, pregnancy, and lactation. A major task of calcitriol is to maintain calcium and phosphate concentrations in blood at levels sufficient to sustain mineralization of osteoid—collagen-containing bone matrix synthesized by osteoblasts. Paradoxically, in states of calcium deficiency, calcitriol acts indirectly within bone to induce monocytic stem cell differentiation into osteoclasts by stimulating osteoblast/stromal cell synthesis of

osteoclast activating factors, such as RANK-ligand. During periods of calcium deficiency, calcitriol is able to promote bone resorption through increased osteoblast production of osteopontin, a bone matrix noncollagenous protein to which osteoclast cell-surface integrin receptors bind enabling formation of the subosteoclastic lacuna essential for bone resorption. Calcitriol also stimulates osteoblasts to produce osteocalcin, bone-specific alkaline phosphatase, osteoprotegerin, and various cytokines.

A number of synthetic vitamin D₃ analogues have been prepared, including alfacalcidol [1α -(OH)D₃], paricalcitol [19-nor-1,25(OH)₂D₂] calcipotriol [1α ,25-(OH)₂-24-cyclopropyl-D₃], maxacalcitrol [1α ,25-(OH)₂-22-oxa-D₃], and tacalcitol [1α ,24R-(OH)₂D₃] and have been used in the treatment of patients with secondary hyperparathyroidism, osteoporosis, and psoriasis. These vitamin D analogues have been engineered to retain the noncalcemic actions of the parent compound while reducing their calcemic properties. Calcitriol and vitamin D₃ analogues exert many immunomodulatory effects.¹³¹ In animal models of autoimmune diseases, such as experimental autoimmune encephalitis, systemic lupus erythematosus, autoimmune thyroiditis, autoimmune diabetes mellitus, and inflammatory bowel disease, calcitriol exerts a protective effect. Calcitriol and its analogues inhibit T lymphocyte differentiation into Th1 cells that secrete interleukin-2, tumor necrosis factor (TNF)- α , and interferon- γ , thereby experimentally modifying disease induction, course, and severity. Calcitriol and analogues also exert differentiating and antiproliferative effects upon a variety of cells; thus calcitriol induces differentiation of promyelocytes into monocytes and macrophages. These agents enhance differentiation of keratinocytes and when administered orally or topically to patients with psoriasis vulgaris ameliorate the disease; they are particularly effective when coadministered with a topical glucocorticoid. In vitro, calcitriol and its analogues inhibit growth of prostate, breast, and colon cancer cell lines; in vivo, experimentally, calcitriol and its analogues prevent or reduce mammary tumor formation whereas in the absence of the VDR mammary tumor growth is enhanced.¹³¹ Calcitriol prevents hypertension and cardiac hypertrophy in mice in whom VDR or CYP27B1 has been “knocked out.” In humans, inferential data suggest that vitamin D plays a role in the pathophysiology of several nonskeletal disorders, including hypertension and cardiovascular disease, autoimmune disorders, multiple sclerosis, and infectious illnesses.^{62,125,126}

Vitamin D Receptor

The VDR is a 427 AA nuclear transcription factor that is encoded by the 11 exon gene—VDR that is expressed in the intestinal tract, kidney, parathyroid gland, osteoblast, skin fibroblasts and keratinocytes, cells within the brain and cardiovascular system, multiple cells of the immune system, including macrophages, T and B lymphocytes and T-regulatory cells, as well as liver and muscle cells.¹³² Regulation of VDR expression uses promoters that are both proximal to but may also be quite distant from the chromosomal site (chr. 12q12–q14) of VDR; some promoter sites are even located within its introns. Because in exon 2 there are two potential start site codons for transcription of VDR, there is a second isoform of VDR with 423 AA. At its 5′ terminus, VDR has three noncoding exons (1A, 1B, 1C) followed by exons 2 through 9 that encode the active protein enabling transcription of three unique mRNA isoforms, depending on the splicing pattern of exons 1B and 1C. As a member of the steroid-thyroid-VDR gene superfamily of nuclear transcription activating factors, the VDR has multiple domains: a short amino-terminal segment of 24 AA (domains A and B) that houses a ligand-independent

transcription activating function termed activation function-1 (AF-1) that interacts with the general transcription factor IIB, a DNA binding domain (C) with two zinc fingers (exons 2, 3), a “hinge” region (D), and a long carboxyl-terminal domain (E) with ligand and RXR α binding sites and a second transcription activating sequence (AF-2) (exons 7, 8, 9). Two nuclear localization signals are found within and immediately distal to the zinc-finger DNA binding domain, the first of which specifically recognizes the vitamin D response element, whereas the second zinc finger permits heterodimerization with RXR α . Structurally, the carboxyl-terminal E–ligand binding domain is composed of 12 α -helices (H1–H12) and has two ligand-dependent transactivating regions—E1, between AA 232 and 272 and AF2 between AA 416 and 424—that recruit transcriptional coactivating factors (the region is termed a *cistrome*) when the VDR is activated by binding to calcitriol; it also contains sequences that enable heterodimerization with RXR α .¹²⁶

Among the factors that enhance transcription of VDR are calcitonin, retinoic acid, estrogen, and transcription factor SP1. In part, estrogens increase expression of VDR through binding to estrogen receptors present in the caveolae of the cell membrane that then activate the MAPK signal transduction pathway.¹³³ PTH down regulates expression of VDR. The VDR is widely expressed in the intestinal tract, distal renal tubule, osteoblast, keratinocyte, hair follicle, fibroblast, smooth and cardiac muscle, lung, bladder, thyroid, parathyroid, pancreas, adrenal cortex and medulla, pituitary, placenta, uterus, ovary, testis, prostate, activated T and B lymphocytes, macrophages, monocytes, spleen, thymus and tonsil, brain, spinal cord, and sensory ganglia. Inactivating mutations of VDR result in vitamin D-resistant rickets (vitamin D-dependent rickets, type 2A—OMIM 277440).

Whereas most members of the superfamily of nuclear receptor transactivating factors pair as homodimers to bind to their specific hormone response elements of the target gene, the calcitriol-VDR complex teams through its E (ligand binding) domain with its obligate partner—unliganded RXR α (encoded by RXRA) to form a heterodimer that then binds to a VDRE. The endogenous ligand for RXR α is 9-cis-retinoic acid. When unliganded, the bulk of the VDR is cytoplasmic; binding of calcitriol to the VDR leads to heterodimerization with RXR α and translocation of the tripartite complex to the nucleus. Unliganded VDR can also be guided to the VDRE of its target gene by interaction with the Williams syndrome transcription factor (WSTF, encoded by BAZ1B), a component of a multiprotein, chromatin-remodeling complex termed WINAC (WSTF including nucleosome assembly complex); there the VDR remains inactive until bound to calcitriol.¹³⁴ There are several classes of VDREs located in the promoter region of target genes: generic positive, conventional negative, and E-box-like negative.¹³⁵ The generic positive or transcription activating VDRE is composed of two repeated hexanucleotide sequences linked by three nonspecific nucleotide bases—5′...(A/G)GGTCA-nnn-(A/G)TTCA ...3′ (113, 135). RXR α binds to the 5′ half of the VDRE and VDR to its 3′ segment. The conventional negative or transcription repressing VDRE is composed of a single copy of the generic positive VDRE with the nucleotide sequence—5′...(A/G)G(G/T)TCA...3′; it is through the conventional negative VDRE that calcitriol inhibits expression of PTH and PTHLH. The nucleotide sequence of the E-box-like negative VDRE is 5′...CANNTG...3′. After binding to the designated VDRE, the calcitriol-VDR-RXR α -WINAC complex recruits coactivating or corepressing modulating proteins (e.g., runt-related transcription factor 2 [encoded by RUNX2], steroid receptor coactivators [SRC] -1, -2, -3 /p160 family with histone acetyl transferase activity, the chromatin remodeling complex, SWI/SNF, interleukin 6-dependent DNA-binding protein

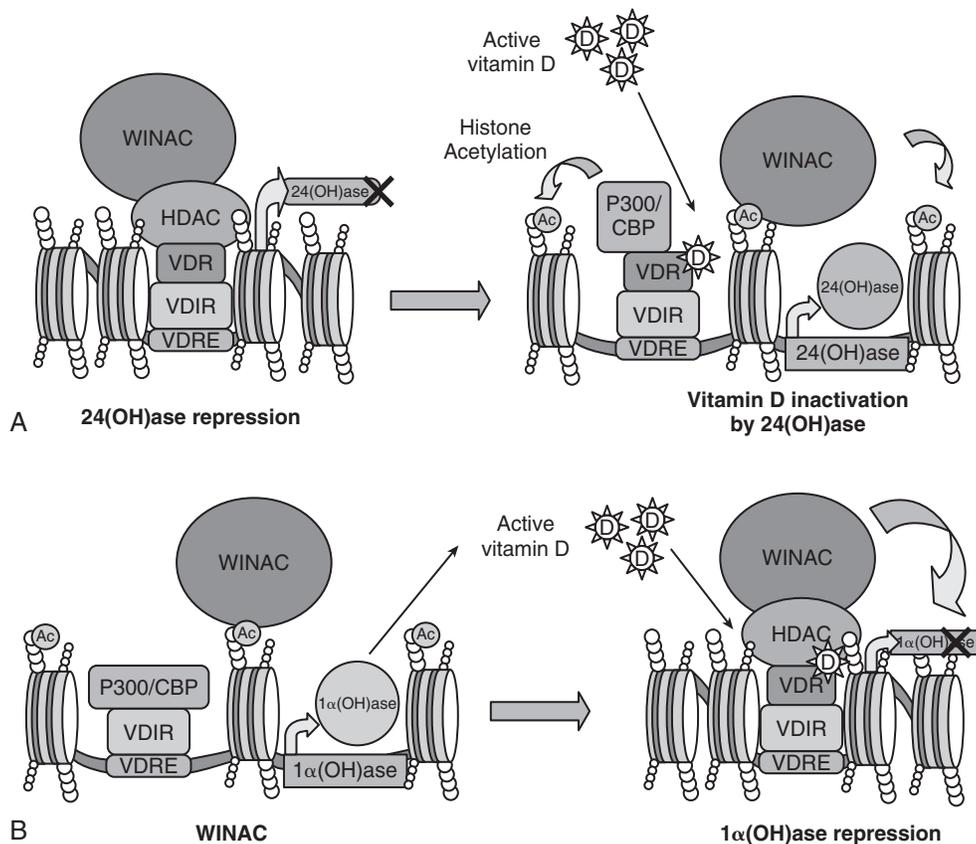

Fig. 9.5 Regulation of vitamin D receptor (VDR) action by interaction with WSTF including nucleosome assembly complex (WINAC) and VDR-interacting repressor (VDIR). A, Under basal conditions, histone deacetylase (HDAC), unliganded VDR-retinoid x receptor (RXR), and VDIR bind to the vitamin D response element (VDRE) of *CYP24A1* encoding 25-hydroxyvitamin D-24 hydroxylase and suppress gene expression; after calcitriol binds to VDR-RXR, HDAC is replaced by a histone acetyltransferase activation complex (p300/CBP), leading to active transcription of *CYP24A1*. B, The autoregulatory effect of calcitriol upon its own synthesis is mediated by its interaction with the VDR-RXR-VDIR-WINAC complex and replacement of histone acetyltransferase by histone deacetylase. (From Barnett, C., Krebs, J.E. (2011). WSTF does it all: a multifunctional protein in transcription, repair and replication. *Biochem Cell Biol*, 89, 12–23. With permission.)

[also designated C/EBP β - encoded by *CEBPB*], TRIP/SUG1, CPB/p300, TIF1) into the promoter site, as well as the general transcription **activating** apparatus of the target gene (TF-IIA, -B, TAF family).^{113,135,136}

Histones are lysine-containing protein components of chromatin, a complex of protein and DNA of which a chromosome is composed that may undergo epigenetic modification; 147 base pairs of DNA wrap around a histone octamer comprised of two copies each of histones H2A, H2B, H3, and H4 forming a nucleosome, a structure that regulates replication, repair, and expression of genes.¹³⁴ Epigenetic regulation of gene expression is achieved, in part, by histone modifying enzyme complexes that remodel chromatin by altering the state of histone methylation, acetylation, phosphorylation, ubiquitination, sumoylation, and proline isomerization.¹³⁷ WSTF is a component of three ATP-dependent chromatin remodeling complexes that alter nucleosome position and thus affect gene exposure to the primary transcription apparatus and accordingly gene expression or silencing; they are directed to sites of action by specific histone modifications.¹³⁴ Within the WSTF protein are a chromatin binding domain (PHD), a tyrosine kinase domain that enables it to phosphorylate histone tyrosine residues, and a binding site for the VDR. In addition to WSTF, the WINAC ATP-dependent chromatin remodeling complex is composed of 12 other subunits; it plays a role in chromatin assembly and cell cycle progression and facilitates activation of *CYP24A1* encoding 25-hydroxyvitamin D-24-hydroxylase

while repressing *CYP27B1* encoding 25-hydroxyvitamin D-1 α -hydroxylase (Fig. 9.5).

Gene activation by the calcitriol-VDR-RXR-WINAC complex is initiated by recruitment of a histone acetyl transferase-helicase complex (e.g., SRC/SWI/SNF) to the promoter segment of the target gene; acetylation of a lysine residue within a histone protein destabilizes the region enabling DNA to unwind, thereby granting basal transcription factors and RNA polymerase II access to the transcription start site thus bringing about RNA modeling of the target gene. Another VDR coactivator is the vitamin D interacting protein (DRIP—encoded by *MED4*) that links the VDRE and the initiation start site of the target gene to RNA polymerase II and its cofactors.¹²⁶ Corepressors cause chromatin to compact by removal of acetyl or addition of methyl groups to lysine residues within a histone protein, thereby silencing gene expression. Inasmuch as the E-box negative VDRE lacks the common hexameric VDRE, this VDRE binds to and gene transcription is inhibited (e.g., *CYP24A1* encoding vitamin D - 24-hydroxylase) by the interaction of unliganded VDR with the VDR-interacting repressor (VDIR encoded by *TCF3*), a process that involves recruitment of a histone deacetylase. Calcitriol inhibits activation of *CYP27B1* encoding 25-hydroxyvitamin D-1 α -hydroxylase by binding to VDR that links to the VDIR-WINAC complex, thereby replacing histone acetyltransferase with a histone deacetylase, thus halting transcription activation (see Fig. 9.5).^{134,135} In addition to regulatory effects upon gene

expression by alterations of histone lysine residues, calcitriol-VDR-RXR-induced methylation of DNA cytosine residues at CpG sites in the promoter region 5' to *CYP27B1* (another epigenetic modification) also represses expression of this gene. Positive and negative regulation of target gene expression by the VDR may also be achieved by interaction of the VDR complex with other transcription factors.¹³⁶ As illustrated in Fig. 9.5, WINAC is involved in both calcitriol-VDR-VDIR-mediated gene transcription and repression.¹³⁵ Deletion or inactivating mutations of *BAXBI* (encoding WSTF) impair the linkage between calcitriol, VDR, and WINAC and thus impede the inhibitory effects of calcitriol upon transcription of *CYP27B1*, resulting in increased synthesis of 25-hydroxyvitamin D-1 α hydroxylase and excessive synthesis of calcitriol, perhaps the pathophysiological process that leads to hypercalcemia in patients with Williams syndrome.

Some of the myriad of genes whose expression is regulated by the VDR are listed in Fig. 9.6.^{109,136} That there may be more than 2000 VDREs within the human genome indicates the potentially widespread effects exerted by the vitamin D system.¹³⁸ Calcitriol acting through the VDR stimulates transcription of genes encoding calcium transport proteins (TRPV5/6), bone matrix proteins (osteopontin, osteocalcin), bone resorption factors (RANK-ligand), and 25OHD-24-hydroxylase and represses those that encode PTH, PTHrP, and 25-hydroxyvitamin D-1 α hydroxylase. The calcitriol-VDR complex also suppresses expression of multiple cytokines (interleukin-2, interferon- γ , granulocyte macrophage-colony stimulating factor) by negatively interacting with transcription factors that enhance their transcription.

Although the VDR is necessary for the actions of calcitriol in the intestines, kidney, bone, skin, and elsewhere, its loss does not interfere with embryogenesis and fetal development in humans with loss-of-function mutations in *VDR* and vitamin D resistance or in mice in which *Vdr* has been "knocked out." In newborn mice, homozygous for targeted deletions that result in truncation of the VDR, osteoid surface is increased, bone mineralization decreased, and epiphyseal plate cartilage formation disorganized with irregular columns of

chondrocytes, increased matrix and excessive vascularity relative to wild-type or heterozygous (*Vdr*^{+/-}) mice.¹³⁹ In addition, hair loss begins at 4 weeks of age and is complete by 4 months of age in homozygous *Vdr*^{-/-} animals and is caused by a defect in the growth cycle of hair follicles, a phenocopy of the generalized alopecia associated with loss of hairless (*HR*), a transcriptional corepressor that interacts with the VDR.¹³⁶ (The hair follicle itself, although dependent on the VDR for physiological cycling, does not require calcitriol; thus maintenance of the normal hair follicle is a ligand-independent function of the VDR.^{62,140}) Maintenance of normal serum concentrations of calcium and phosphate by the feeding of high calcium-phosphate diets to *Vdr*^{-/-} pups beginning at 16 days of age prevents the development of all of the skeletal abnormalities, indicating that the main physiological effects of calcitriol and the VDR are upon the intestinal absorption of calcium and phosphate and the maintenance of normal serum concentrations of these ions.¹³⁹

Calcitriol also has rapid, nongenomic effects mediated through both a cell membrane-associated receptor and the designated nuclear VDR^{128,141} (Fig. 9.7). The cell membrane protein localized to the caveolae (invaginations) that binds 1,25-dihydroxyvitamin D has been designated "membrane-associated rapid response steroid-binding protein" (MARRS-BP encoded by *PDIA3*).^{126,141} After binding of calcitriol to MARRS-BP, its signal is transmitted by several classical intracellular signal transduction systems including: (1) adenylyl cyclase induction of cyclic AMP and PKA; (2) PLC and D-mediated increase in phosphoinositide turnover, resulting in generation of DAG and IP₃ that increase the permeability of Ca²⁺ channels and release Ca²⁺ from storage sites in the endoplasmic reticulum; (3) Gq-protein through PL- β 1 activation and intracellular redistribution of PKC isoforms (α , β , δ); and (4) Jun-activated kinase and the MAPK pathway.¹⁴¹ Within minutes after exposure of a vitamin D responsive tissue (e.g., intestine, chondrocyte, osteoblast) to calcitriol, there is increase in the intracellular concentration of Ca²⁺ (transcalcia) and activation of PLC, PKC, and MAPK.¹²⁷ The complex of calcitriol with its nuclear VDR also has rapid effects mediated

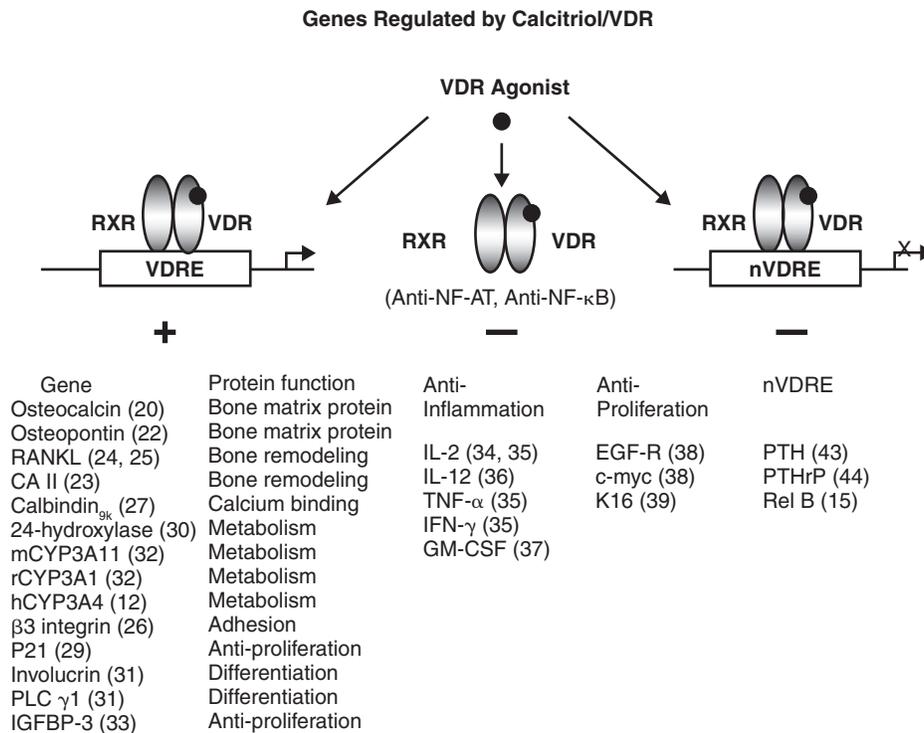

Fig. 9.6 Some of the more than 1000 genes regulated by calcitriol and the vitamin D receptor. (From Nagpal, S., Na, S., Rathnachalam, R. (2005). Noncalcemic actions of vitamin D receptor ligands. *Endocr Re*, 26, 662–687. With permission.)

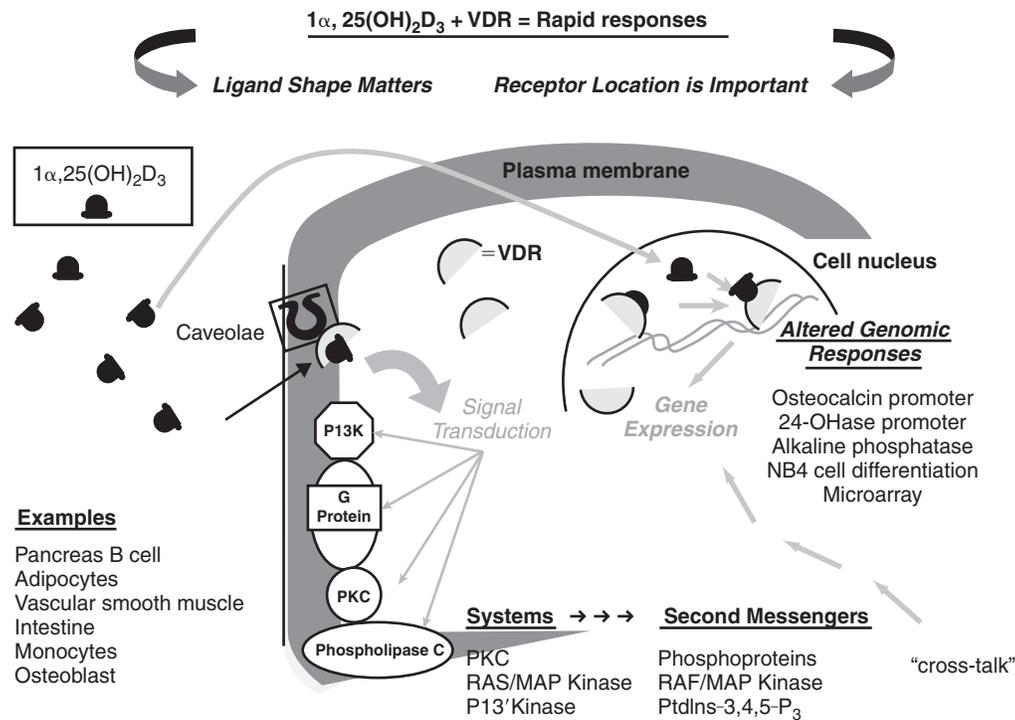

Fig. 9.7 Genomic and nongenomic (rapid) responses to calcitriol. (From Norman, A.W., Bouillon, R. (2010). Vitamin D nutritional policy needs a vision for the future. *Exp Biol Med*, 235, 1034–1045. With permission.)

by the colocalization of nuclear VDR to plasma membrane caveolae and the interaction of both ligand bound nuclear and membrane associated VDRs through linkage to caveolin-1 (encoded by *CAV1*).¹⁴¹ In osteoblasts from nuclear VDR^{-/-} mice and in fibroblasts from patients with inactivating mutations of nuclear VDR, the rapid actions of calcitriol are lost as is the association of the nuclear VDR with caveolae—evidence of the importance of the nuclear VDR for membrane-initiated responses to calcitriol. In chondrocytes, there is MARRS-BP-dependent enhancement of calcium flux, PKC activity, and matrix vesicle mineralization.¹⁴² The plasma membrane caveolae-associated VDR may link to G_{sα} and thence to a calcium channel or adenylyl cyclase or PLC or with caveolin, a protein that interacts with the nonreceptor tyrosine kinase—Src—and in turn with PLC or the kinase h-Ras.^{143,144} The rapid effects of vitamin D may optimize its genomic effects by phosphorylation of proteins required by the VDR transcriptional complex.

SKELETON: CARTILAGE AND BONE

Chondrogenesis and Skeletal Formation

The skeleton is the framework of the body. It is composed of cartilage and bone, specialized cells and forms of connective tissue that provide: (1) mechanical support for muscle/tendon insertion that enables movement; (2) protective shield for soft tissue organs; (3) repository for bone marrow; (4) reserve source of calcium, phosphate, magnesium, and other metabolically important ions; and serves as (5) an endocrine organ as the secreted products of bone cells regulate the function of distant organs—for example, the osteocyte secretes sclerostin (encoded by *SOST*), an inhibitor of bone formation, and FGF23, a factor that depresses renal tubular reabsorption of phosphate and the synthesis of calcitriol.^{116,145} Chondroblasts, osteoblasts, adipocytes, myoblasts, and fibroblasts are derived from a common mesenchymal cell.¹⁴⁶ Skeletal formation begins in utero with transformation of mesenchymal cells

from the lateral plate mesoderm into chondroblasts and chondrocytes that form the long bones of the skeleton (Fig. 9.8).^{146,147} Modeling of bone takes place during intrauterine and postnatal growth when the shape and size of a bone are determined. Mesenchymal stem cells become perichondrial cells, chondroblasts, and chondrocytes under the direction of fibroblast growth factor 2 (*FGF2*), bone morphogenetic protein 4 (*BMP4*), and SRY-Box 5, 6, 9 (*SOX5, 6, 9*). The expression of *SOX9* is stimulated by FGF/FGFR signaling through the MAPK pathway. *SOX9* is a 509 AA protein with an SRY homology domain that is also expressed in the testis where it is responsible for differentiation of Sertoli cells. Target genes of *SOX9* include those that encode collagen type II(α1) and aggrecan (*AGC1*), a chondroitin sulfate proteoglycan core protein that affects the biomechanical strength of cartilage.¹⁴⁸ *SOX9* is expressed not only in chondrocytes in the resting phase but also those in the proliferative phase but not in chondrocytes in the hypertrophic phase of maturation. Chondroblasts are primarily localized to the surrounding perichondrium where they secrete a matrix composed of type II collagen (*COL2A1*), elastin (encoded by *ELN*), and aggrecan. When embedded within cartilage matrix, these cells are termed *chondrocytes*. Chondrocytes pass through sequential developmental stages: (1) resting or basilar chondrocytes are adjacent to and below the secondary ossification center at the end of a long bone; (2) slowly and rapidly proliferating columnar chondrocytes that synthesize collagen type II composed of three cross-linked chains of collagen type II, alpha-1 (*COL2A1*) thus forming collagen type II; (3) prehypertrophic maturing chondrocytes; (4) hypertrophic chondrocytes that synthesize collagen type X consisting of three chains of collagen type X, alpha-1 (*COL10A1*); and (5) terminal chondrocytes that undergo apoptosis (Fig. 9.9). Chondrocyte differentiation, proliferation, and hypertrophy are enhanced by *IHH*, a 336 AA product of prehypertrophic and early hypertrophic chondrocytes that acts through its cell membrane receptor Patched 1 (encoded by *PTCH1*) and coreceptor Smoothed (*SMO*); *IHH* also stimulates the synthesis of

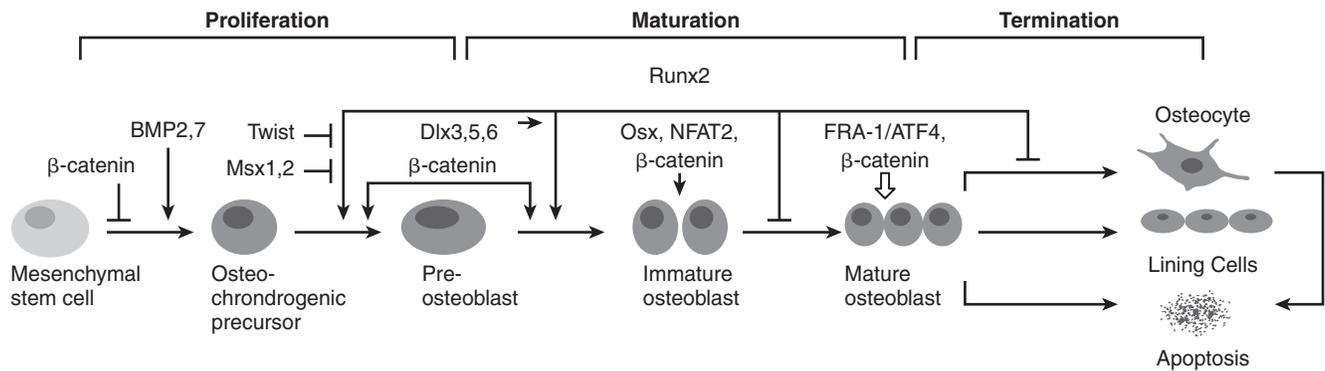

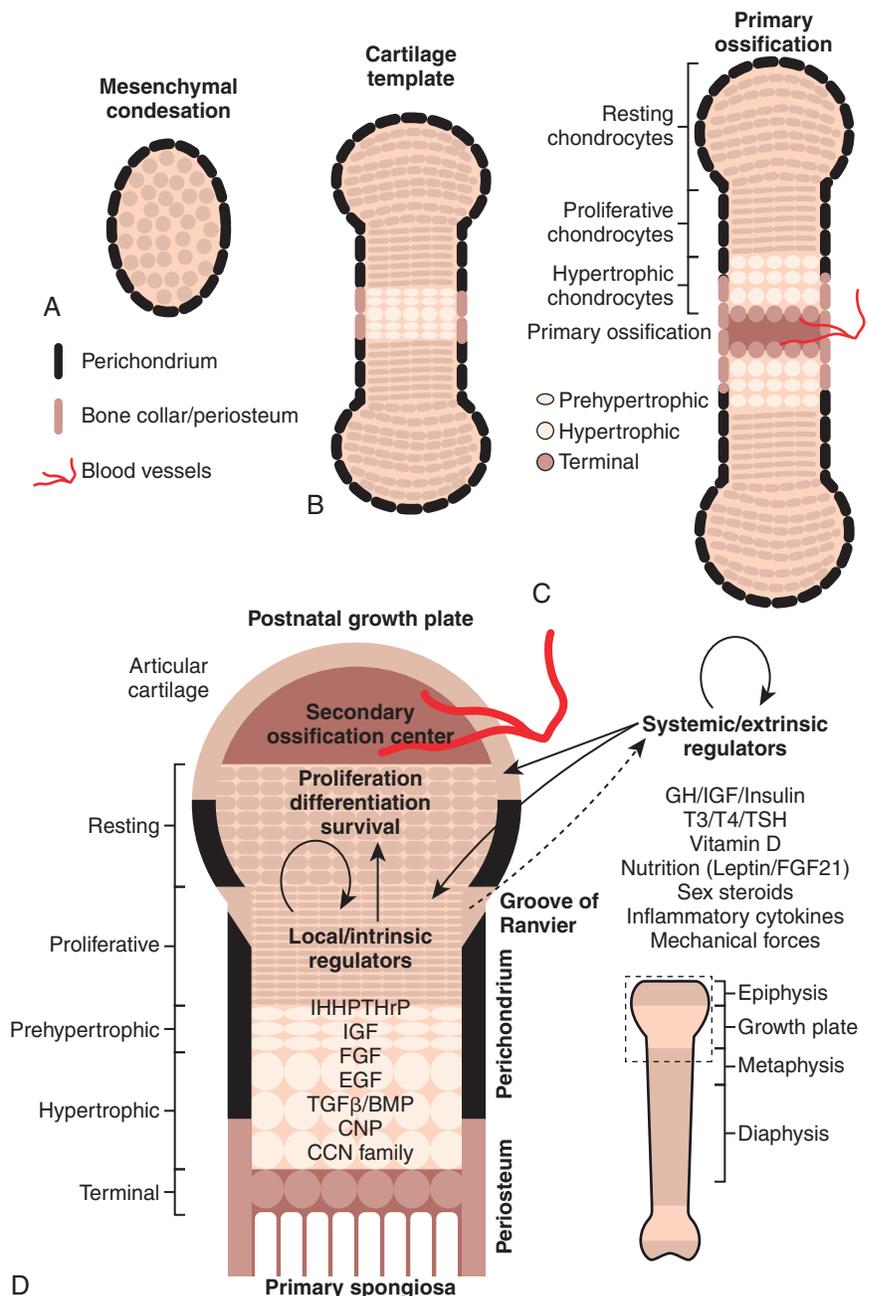

Fig. 9.8 Chondrogenesis/osteoblastogenesis. A common mesenchymal stem cell gives rise to chondroblasts, osteoblasts, myoblasts, fibroblasts, and adipocytes in response to specific differentiating factors. Bone morphogenetic proteins (BMP) are involved in the earliest steps leading to the differentiation of the common mesenchymal precursor cell into chondrocytes and osteoblasts. SRY-box 9 (SOX9) is critically important for differentiation and function of the common progenitor cell of chondrocytes and osteoblasts and for further maturation of osteoblasts. (Peroxisome proliferator-activated receptor γ 2 [PPAR γ 2] stimulates the differentiation of adipocytes. Osteoblasts and adipocytes may be interconverted depending on whether RUNX2 or PPAR γ 2 is the activated transcription factor. MyoD is a muscle-specific transcription factor necessary for development of myoblasts.) (From Krause, C., de Gorter, D.J.J., Karperien, M., ten Dijke, P. (2008). Signal transduction cascades controlling osteoblast differentiation. In: Rosen, C.J. (ed). *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism*, 7th ed. American Society for Bone and Mineral Research, Washington, DC, p. 10–16. With permission.)

Fig. 9.9 Differentiation and development of the long bones. The epiphyseal cartilage growth plate is composed of zones of resting, proliferating, prehypertrophic, hypertrophic, and terminal chondrocytes, the latter a transitional zone in which apoptotic hypertrophic chondrocytes and surrounding matrix are replaced by bone, a process mediated by both intrinsic and extrinsic regulatory factors. Indian hedgehog (IHH) is synthesized by prehypertrophic chondrocytes. Receptors for parathyroid hormone-related protein (PTHrP) are expressed by proliferating and transitional chondrocytes. IHH stimulates secretion of PTHrP by periarticular cells and this in turn blocks further differentiation and maturation of late proliferating chondrocytes to hypertrophic chondrocytes, thus prolonging the period of cartilage growth. IHH also acts through bone morphogenetic proteins (BMP) and the Wingless-type mouse mammary tumor virus (MMTV) integration site (WNT)- β -catenin pathway to enhance chondrocyte hypertrophy. Fibroblast growth factors (FGF) also influence chondrocyte proliferation and maturation. (See text for details.) (From Rosello-Diez, A., Joyner, A.L. (2015). Regulation of long bone growth in vertebrates; it is time to catch up. *Endocr Rev*, 36, 646–680. With permission.)

PTHrP by basilar chondrocytes. Differentiation of proliferating chondrocytes into prehypertrophic chondrocytes and of the latter into hypertrophic chondrocytes is inhibited in paracrine fashion by PTHrP functioning through PTH1R; PTHrP is secreted in utero by cells in the proximal periarticular perichondrium and postnatally by chondrocytes in the resting zone of the cartilaginous growth plate and diffuses into the zone of proliferating chondrocytes where it delays further differentiation, thus maintaining their replicative capacity.^{98,149,150} During the process of chondrocyte hypertrophy, individual cell length increases six- to tenfold; as the chondrocyte dies, collagenous fibers are enzymatically digested, the extracellular matrix calcifies, and VEGF is produced.¹⁵¹ Surrounding the cartilage anlagen is a periosteal collar of bone deposited by recently differentiated osteoblasts; in response to VEGF blood vessels, chondroclasts, osteoclasts, osteoblasts, stromal, marrow, and other cells invade the underlying cartilage and establish a primary center of ossification. (IHH is also able to stimulate the conversion of perichondrial cells into osteoblasts.¹⁵⁰) A secondary ossification center forms at the distal ends of long bones (defining the epiphyses) with intervening areas of cartilaginous growth plates that permit bone lengthening by continued proliferation and hypertrophy of chondrocytes and formation of extracellular matrix. Ultimately, the more distal late hypertrophic chondrocytes escape from the inhibitory effects of PTHrP, die, disintegrate, and discharge their contents attracting perichondrial blood vessels with their cellular cargo that invade the extracellular matrix. Chondroclasts and osteoclasts digest the extracellular matrix that has been degraded by proteolysis by matrix metalloproteinases, and crystals of calcium phosphate are deposited in the debris. These are later reabsorbed by osteoclasts after which osteoblasts secrete a matrix of collagen type I into which hydroxyapatite crystals are deposited to form bone. Ultimately, growth plate cartilage disappears as primary and secondary centers of ossification merge, a process regulated by estrogen which appears to accelerate the senescent process in late hypertrophic chondrocytes.¹⁵² Hypertrophic chondrocytes also mediate calcification of cartilage matrix, both of the distal secondary ossification centers at each end of the long bones adjacent to the growth plates and the central primary ossification center. Some hypertrophic chondrocytes develop into trabecular bone osteocytes. FGF18 (*FGF18*) stimulates chondrocyte proliferation, antagonizes chondrocyte differentiation, and induces chondrocyte autophagy.¹⁵³

Endochondral bone formation is the process by which cartilaginous bone is replaced by mineralized bone.¹⁵² The short cuboidal bones of the wrists and ankles, cranial base (ethmoid, sphenoid, occipital, frontal, temporal), and long bones of the limbs (humerus, radius, ulna, metacarpal, femur, tibia, fibula, metatarsal) develop from cartilage templates that are invaded by blood vessels accompanied by chondroclasts, osteoblasts that evolve from perichondrial cells situated in long bones adjacent to the zone of hypertrophic chondrocytes, and osteoclasts.¹⁴⁷ (The flat membranous bones of the skull, scapula, sternum, ribs, and ileum develop directly from osteoblast-mediated trabecular bone formation sandwiched between two layers of compact bone.) The shape of the skeleton is complete by the ninth week of gestation following which, there are many fold increases in skeletal dimensions, volume, and mass.^{152,154–156}

The pattern of endochondral bone development is directed by factors that are independent of bone formation; for example, in transgenic mice in which *Runx2* is inactivated, the cartilage “skeleton” forms normally but is not ossified.¹⁵⁷ Vertebrae evolve from the condensation and segmentation of paraxial mesoderm into somites under the direction and control of *NOTCH1*, *SHH*, and *PAX1* and Notch ligands encoded by *DLL3* and *JAG1*. The appearance of limb buds, proliferating

mesenchymal cells that grow out from the lateral body wall and are capped by an apical ectodermal ridge, heralds development of the cartilage anlagen of the long bones, a process of segmentation directed experimentally by multiple genes (*HOXA1*, *SHH*, *WNT7A*, *FGF4*, *FGFR1*, *BMP4*) among other signaling, receptor, and transcription regulating factors involved in differentiation, paracellular communication, and cell-to-cell interaction.¹⁵⁷ Mitochondrial RNA-processing endoribonuclease encoded by *RMRP* is a ribonucleoprotein that is essential for assembly of ribosomes and cyclin-dependent cell cycle activity, as well as chondrocyte proliferation and differentiation.

Chondrocyte differentiation within the resting zone of the cartilaginous growth plate is stimulated by anterior pituitary GH acting through the cytokine growth hormone receptor (GHR) and the JAK2/STAT5b signal transduction pathway to stimulate hepatic and local synthesis of IGF-I that in turn enhances chondrocyte proliferation and hypertrophy acting through the IGF type 1 receptor (*IGF1R*).¹⁴⁷ The insulin receptor is present in chondrocytes and also enhances their proliferation. Triiodothyronine stimulates chondrocyte maturation and fusion of the growth plate. Androgens act directly in the growth plate to stimulate proliferation of chondrocytes and by conversion to estrogens to accelerate chondrocyte division, their rate of maturation, and epiphyseal fusion. Glucocorticoids inhibit proliferation of chondrocytes and stimulate their apoptosis. In man, inactivating mutations of *PTH1R* result in rapid chondrocyte maturation and Blomstrand chondrodystrophy (OMIM 215045), whereas activating mutations in *PTH1R* lead to impaired chondrocyte maturation and Jansen metaphyseal chondrodysplasia (OMIM 156400). The rate of prehypertrophic and terminal hypertrophic differentiation of chondrocytes is regulated locally by both PTHrP and IHH, the latter by encouraging chondrocyte hypertrophy.¹⁴⁹ Nutritional effects on the growth plate are mediated, in part, by the adipocyte product leptin (*LEP*); obesity accelerates the rate of epiphyseal maturation whereas *FGF21*, whose synthesis is stimulated by suboptimal nutrition, impairs chondrocyte proliferation. Mechanical forces also increase the proliferation of growth plate chondrocytes because immobilization impedes limb growth acting through the MAPK/ERK signal transduction pathway. In addition, signaling through JAK2/signal transducer and activator of transcription (STAT) 5b, mammalian target of rapamycin (mTOR), and HIPPO pathways play important integrative roles in chondrocyte proliferation, hypertrophy, maturation, senescence, and apoptosis.¹⁴⁷

Although *RUNX2* inhibits the initial differentiation of the multipotential mesenchymal stem cell into the chondrocyte pathway, it is essential for progression of the chondrocyte through its later stages of differentiation, as well as for the early stages of osteoblastogenesis.¹⁵⁸ *RUNX2* is the alpha subunit of a transcription factor complex that binds to the promoter region of target genes such as *COLA1* and *MMP13*. As the chondrocyte progresses through its maturational stages of differentiation, proliferation, hypertrophy, and death, the patterns of expression of myriad genes change as do the components of secreted extracellular matrix.^{152,159} For example, experimentally the mesenchymal stem cell expresses among many other genes—*SOX9*, *COL2A1*; the resting chondrocyte—*SRFP5*, *SOX9*, *COL2A1*, *AGC1*, *PTH1R*; the proliferating chondrocyte—*SOX9*, *COL2A1*, *AGC1*, *FGFR3*, *RUNX2*; the prehypertrophic chondrocyte—*BMP*, *COL2A1*, *COL10A1*, *AGC1*, *PTH1R*, *RUNX2*, *VEGF*; the hypertrophic chondrocyte—*COL10A1*, *ALPL*, *IHH*, *RUNX2*, *VEGF*; and the terminal hypertrophic chondrocyte—*COL10A1*, *VEGF*, *MMP13*. During the transition from the resting to the proliferating chondrocyte, functional gene pathways that are involved include the VDR/RXR and BMP signaling systems: in the transition from the

proliferative to the hypertrophic chondrocyte prominent functional gene systems include BMP signaling and components of cellular growth and the cell cycle, such as p53; during the senescent phase of chondrocyte evolution the most prominently expressed signaling pathways are those involving VDR/RXR, MAPK, and WNT/ β -catenin. When the postproliferative chondrocyte begins to hypertrophy, the production of collagen type II declines and that of collagen type IX increases, whereas late hypertrophic and dying chondrocytes synthesize the collagenase—matrix metalloproteinase 13. In addition to IHH, transition from a proliferative to a hypertrophic chondrocyte is stimulated by triiodothyronine working in concert with IGF-I and FGFR3. Triiodothyronine acts through nuclear thyroid hormone receptor α to increase intracellular signaling through the WNT4/ β -catenin pathway. Triiodothyronine also inhibits expression of *PTHLLH*, thus shortening the proliferative phase of chondrogenesis. Increase in activity of FGFR3 accelerates the hypertrophic process. As discussed, IHH inhibits chondrocyte hypertrophy acting through PTHrP that in turn downregulates expression of *RUNX2* and impedes its regulation of hypertrophy associated genes.¹⁵²

FGFs-1, -2, -6, -7, -9, and -18 acting through one of four FGF receptors are also important for normal chondrocyte differentiation and development.¹⁵¹ Normal chondrogenesis is dependent on the balance between the positive regulation of chondrogenesis exerted through FGFR2 and FGFR4 and the negative regulation transmitted through FGFR1 and FGFR3. Mutations in *FGFR1* and *FGFR2* have been associated with syndromes of premature craniosynostosis (Jackson-Weiss, Pfeiffer, Crouzon, and Apert syndromes), whereas variations in *FGFR1* have also been identified in patients with hypogonadotropic hypogonadism. Gain-of-function mutations in *FGFR3*, expressed in chondrocytes in utero and postnatally, are associated with achondroplasia, hypochondroplasia, and related chondrodystrophies. Interestingly, congenital variants of *FGFR4* have not been identified to date. BMPs affect chondrogenesis by increasing production of IHH thus increasing chondrocyte proliferation, but also advancing chondrocyte maturation.¹⁵⁰

Osteoblastogenesis

Osteoprogenitor pluripotent stromal mesenchymal stem cells provide a continuous supply of bone-forming osteoblasts, the network of osteocytes embedded throughout bone that monitors bone integrity and strength, and bone surface lining cells. Osteoblasts are derived from mesenchymal stem cells whose differentiation is under the control of BMP and the WNT1- β -catenin signal transduction pathway.¹⁶⁰ (WNT was derived by combining the names of the *Drosophila* gene *Wingless* with the corresponding mouse gene *Int.*) Bone morphogenetic factors are members of the transforming growth factor (TGF)- β family that bind to TGF β /BMP transmembrane receptors and transmit messages through the MAPK and small mothers against decapentaplegic (SMAD) (*SMAD2*) intracellular signal transduction pathways. SMADs link to and then are released from the TGF β /BMP receptor(s); several may aggregate to form a transcription factor(s) for nuclear target genes that regulate cellular differentiation and growth.¹⁶¹ *WNT1* encodes a secreted glycoprotein that links to a Frizzled receptor (*FZD1*) with seven transmembrane domains on the surface of a mesenchymal multipotential stem cell and directs its differentiation into the osteoblast cell line. *NOTCH1* encodes a cotranscription regulating factor that inhibits initial commitment of the osteoblast precursor cell to further differentiation, but paradoxically enhances proliferation of already committed preosteoblasts, only to block their later progression to mature osteoblasts.¹⁶²

WNT1 also links to low-density lipoprotein receptor-related proteins 5 and 6 (*LRP5/6*), coreceptors that are long chain proteins with a single transmembrane domain expressed on the plasma membrane of the mesenchymal stem cell. LRP5 primarily acts locally to regulate differentiation of osteoblasts and mineralization of bone matrix by enabling the cytoplasmic protein β -catenin (*CTNNB1*) to enter the nucleus of the preosteoblast and further its maturation.¹⁶³ Experimentally, inactivation of both *LRP5* and *LRP6* results in low bone mass, but *LRP6* does so by increasing osteoclastogenesis rather than by decreasing osteoblastogenesis. LRP4, a third member of the LRP family, impairs skeletal mineralization by enabling the inhibitory proteins Dickkopf (encoded by *DKK1*) and sclerostin (encoded by *SOST*) to interact with LRP 5/6 and thereby block the association of WNT1 and LRP5/6 coreceptors. Activating mutations of *LRP5* are associated with an autosomal dominant form of relatively benign high bone mass (OMIM 601884) or in some patients autosomal dominant osteopetrosis type 1 (OMIM 607634), whereas inactivating mutations of *LRP5* result in the autosomal recessive osteoporosis-pseudoglioma syndrome (OMIM 259770) in which, in addition to decreased bone formation because of subnormal rate of osteoblast proliferation, the hyaloid vessels of the embryonic eye fail to regress.¹⁶⁴

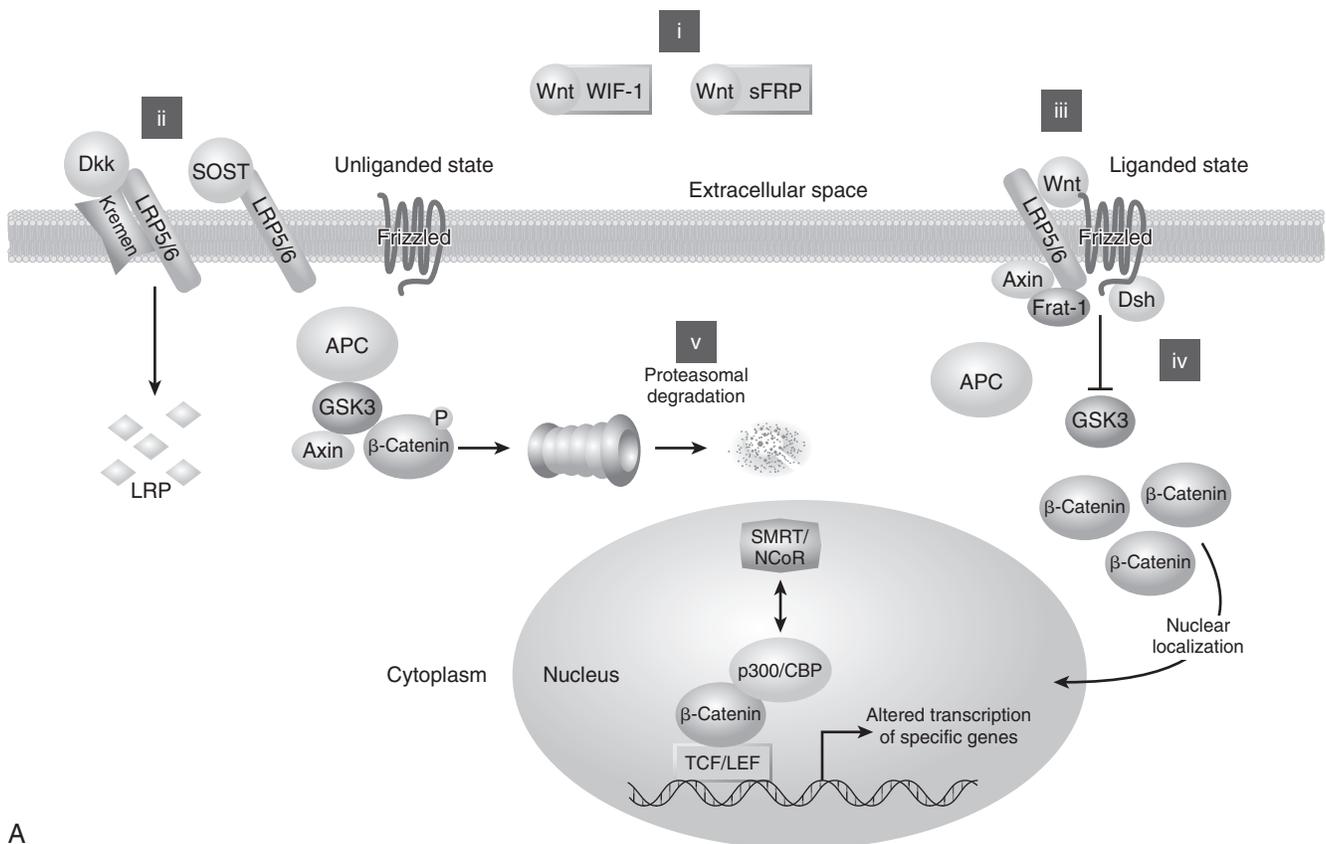

In the resting state of the mesenchymal stem cell, β -catenin is a cytoplasmic protein that is degraded by a “destruction complex” composed of axin (*AXIN1*), the product of *APC*, and glycogen synthase kinase-3 α (*GSK3A*); the latter phosphorylates β -catenin, thereby targeting it for destruction by the ubiquitin-proteasome pathway.^{165,166} When the WNT1 ligand links to the Frizzled membrane receptor and LRP5/6 coreceptors expressed on the plasma membrane of the preosteoblast, the β -catenin “destruction complex” is inhibited, freeing cytoplasmic β -catenin to enter the nucleus and bind to T-cell factor/lymphoid enhancer-binding factor 1 (*LEF1*), a nuclear transcription cofactor that activates WNT1-signaling target genes that result in osteoblast differentiation and function, initially *RUNX2* and its target genes, such as *SP7* (encoding osterix, a 431 AA zinc-finger nuclear transcription factor) (see Fig. 9.8). (Prostaglandin E₂ [PGE₂] is also able to activate *RUNX2* transcription,¹⁶⁷ whereas melatonin too increases differentiation of mesenchymal stem cells into osteoblasts and their synthesis of osterix.¹⁶⁸) Osterix binds to the 5′ promoter of *COL1A1* and is critical for its transcription and hence synthesis of collagen type I(α 1) as well as osteocalcin (*BGLAP*).^{157,158} Osteocalcin plays an important role in normal mineralization of bone matrix. Additional gene targets of *RUNX2* include those encoding *BMP4*, *FGFR1*, *Dickkopf*, *WNT10a*, *WNT10b*, *TGF β 1*, and *FGF18*.¹⁶⁹ *FGF18* is also essential for osteoblast differentiation and proliferation and normal bone development. Expression of *FGF18* is directly stimulated by the WNT-Frizzled-LRP 5/6- β -catenin-*RUNX2* pathway through association with TCF/LEF.¹⁷⁰ *RUNX2* increases expression of the gene encoding TGF β type 1 receptor through which TGF β enhances the transcriptional activity of TCF/LEF.¹⁶⁷ Also involved in the complex process of WNT1 selectivity for the signal transduction pathway(s), leading to osteoblastogenesis are extracellular, transmembrane, and intracellular cofactors, such as *RECK* (reversion-inducing cysteine-rich protein with kazal motifs), *ADGAR2* (adhesion G-protein-coupled receptor A2), and *DVL1* (Disheveled 1).¹⁷¹ WNT signaling also increases production of osteoprotegerin (OPG encoded by *TNFRSF11B*) by the stromal cell/osteoblast, a protein that inhibits osteoclastogenesis, thereby further increasing bone mass. *RUNX2* also mediates the effect of mechanical loading upon osteoblast differentiation and collagen synthesis. After initial osteoblast differentiation, the expression of *RUNX2* declines as the mature osteoblast evolves.

Stromal mesenchymal stem cells are able to differentiate not only into chondroblasts (under the direction of SOX9) and osteoblasts (through WNT-induced signaling of *RUNX2*, *DLX5* [distal-less homeobox 5], and *SP7* [Osterix]), but also into adipocytes (through *PPARG*), myoblasts, and fibroblasts. Committed osteoblasts and adipocytes are capable of redifferentiating into the other cell type depending on whether the expression of *RUNX2* or *PPARG* predominates; this process is directed by WNT10b, which enhances expression of *RUNX2*, *DLX5*, and *SP7* while suppressing that of *PPARG*.^{146,172} The nuclear nicotinamide adenine dinucleotide (NAD)-dependent protein deacetylase encoded by *SIRT1* also inhibits the adipocyte differentiating effects of *PPARG* by docking corepressors to this transcription factor, thereby diverting mesenchymal stem cells into the osteoblastogenic pathway.¹⁷³ BMP-2, -4, and -7 induce osteoblastogenesis acting through their heterodimeric cell surface receptors and transduce their intracellular signals through receptor-regulated SMADS 1, 5, and 8 that heterodimerize with DNA-binding SMAD 4 to induce expression of *RUNX2*, *DLX5*, and *SP7*; TGF β signals through SMADs 2 and 3 to promote *RUNX2* expression; platelet-derived growth factor, FGFs, and IGF-I also enhance the proliferation and further differentiation of committed osteoblast precursors.¹⁴⁶ WNT binding to Frizzled-LRP5/6 leads to intracellular signaling not only through the canonical (β -catenin) route but also

through a noncanonical (G α_q -protein and PLC) signal transduction pathway (Fig. 9.10).^{152,174,175}

There are additional factors of importance for bone differentiation and function. Serpin peptidase inhibitor, clade F, member 1 (encoded by *SERPINF1*) is expressed by osteoblasts and is also secreted by liver and bone; it is involved in the processes of endochondral ossification, osteoblast differentiation and maturation, and synthesis of the two subunits of collagen type 1—COL1 α 1 and COL1 α 2.¹⁷⁶ *IFITM5* encodes a protein (interferon-induced transmembrane protein family 5) confined to bone and expressed by osteoblasts whose primary function is uncertain, but may affect stability of *SERPINF1*.¹⁷⁷ Plastin 3 (*PLS3*) is an actin and calcium binding protein critical for the formation of the actin filaments that form the cytoskeleton of the osteocyte, the mature mechanosensory bone cell into which the osteoblast is transformed after being embedded within deeply deposited bone. Dentin matrix acidic phosphoprotein 1 (*DMP1*) is a member of the SIBLING family of secreted phosphoproteins that regulates expression of genes essential for osteoblast development, as well as mineralization of type I collagen.

Several endogenous factors antagonize BMP/WNT1-mediated osteoblastogenesis.¹⁶⁰ Sclerostin (encoded by *SOST*) sequesters and thus antagonizes the effects of BMPs; in the resting state sclerostin binds to the extracellular domains of

A

Fig. 9.10 Influence of Wingless-type mouse mammary tumor virus (MMTV) integration site, member 1 (WNT)- β -catenin signal transduction pathway on osteoblastogenesis. When a WNT ligand binds to its Frizzled receptor and its coreceptor lipoprotein receptor-related proteins (LRP) 5/6, phosphorylation and degradation of β -catenin ceases, enabling its transport into the nucleus where it serves as a cofactor for the T-cell factor/Lymphoid enhancer binding factor (TCF/LEF) transcription factor complex and enhances osteoblast differentiation. The WNT signaling system can be inhibited by binding of sclerostin (SOST) and Dkkopf (DKK) to the coreceptors and of WNT inhibitory factor (WIF1) and secreted Frizzled-related protein (sFRP) to the WNT ligand. (See text for details.) (From Krishnan, V., Bryant, H.U., MacDougald, O.A. (2006). Regulation of bone mass by Wnt signaling. *J Clin Invest*, 116, 1202–1209. With permission.)

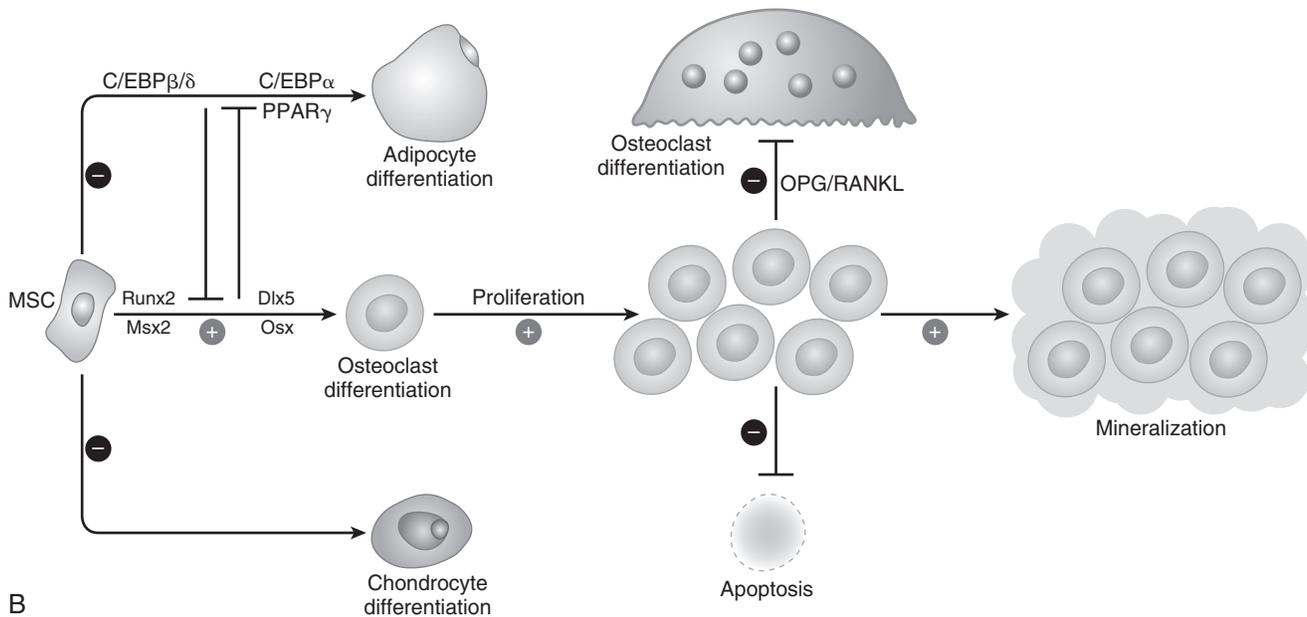

Figure 9.10, cont'd

coreceptors LRP5/6, thereby interfering with their binding to WNT and thus interrupting the WNT-Frizzled GPCR- β -catenin signal transduction pathway, leading to osteoblast differentiation and suppressing bone formation (see Fig. 9.10); sclerostin also binds to LRP4, a linkage that enhances the osteoblast antagonist effects of this 213 AA protein. Sclerostin also increases expression of *TNFSF11* (encoding RANKL), thereby promoting osteoclastogenesis.¹⁷⁸ Sclerostin is primarily expressed and secreted by cortical and trabecular osteocytes in response to decrease in mechanical forces ("unloading") exerted upon the skeleton; as a consequence, the rate of bone formation decreases and that of bone resorption increases.¹⁷⁹ The 232 AA protein noggin (*NOG*) binds to sclerostin, thereby neutralizing its effects on osteoblastogenesis; noggin also antagonizes activity of BMPs for which the inhibitory effect is itself mitigated by binding of sclerostin to noggin. In response to increased mechanical loading, osteocyte expression of *SOST* decreases and the rate of bone formation increases. The inhibitory effect of mechanical loading on osteocyte production of sclerostin may be mediated by paracrine factors, such as prostaglandins, nitric oxide, or oncostatin M. In addition to mechanical forces, the expression of *SOST* and/or synthesis of sclerostin is suppressed by PTH functioning through PTH1R. (There is a high density of binding sites for carboxyl fragments of PTH on osteocyte membranes, suggesting that these sequences may play a role in the mechanosensory activity of the osteocyte network.⁸⁶) Estrogens, cytokines produced by osteoblasts and osteoclasts (oncostatin M, leukemia inhibitory factor, cardiotrophin-1, interleukin-33), prostaglandin E₂, and hypoxia also suppress expression of *SOST*. Calcitonin, osterix, and TNF- α exert a direct stimulatory effect upon osteocyte expression of *SOST* and synthesis of sclerostin. Inactivating mutations in *SOST* result in autosomal recessive sclerosteosis 1 (OMIM 269500) characterized by skeletal overgrowth. Dickkopf-1 (*DKK1*) is a 266 AA protein that binds to the transmembrane LRP5/6 coreceptors for WNT and impedes WNT stimulation of the Frizzled GPCR- β -catenin-mediated signal transduction pathway, leading to osteoblast differentiation from mesenchymal stem cells and hence osteoblast function. Dickkopf-1 is also a ligand for NOTCH1, a single pass

transmembrane receptor that inhibits WNT signaling and RUNX2 activation preventing osteoblast maturation. The structure of the secreted frizzle-related proteins (*SFRP1*) is partially similar to that of the ligand binding domain of the Frizzled heptahelical transmembrane receptors, thereby enabling *SFRP1* to bind to WNT ligand, thereby inhibiting intracellular signaling of the WNT-Frizzled GPCR-LRP5/6- β -catenin complex and therefore osteoblast differentiation. WNT inhibitory factor 1 (encoded by *WIF1*) binds to WNT and also interferes with WNT binding to the Frizzled GPCR and to LRP5/6.

Osteoblasts have a life span of 3 months. They are heterogeneous and express diverse genes that may be dependent or independent of the stage of the cell cycle and extent of differentiation.¹⁷² The heterogeneity of osteoblasts may relate to the many different bone architectures and microenvironments in which they reside and must function. Actively bone-forming osteoblasts have a large nucleus, plentiful Golgi apparatus, and abundant endoplasmic reticulum. When the rate of bone formation is low, osteoblasts are small and quiescent and incorporated into the endosteum separating bone mineral from marrow or into the undersurface of the exterior enveloping periosteum. Differentiated, mature osteoblasts secrete collagenous and non-collagenous proteins including collagen type I, bone-specific alkaline phosphatase, and the calcium and phosphate binding proteins—osteocalcin, osteopontin, and osteonectin—thus making bone matrix competent for mineralization.¹⁸⁰

After the transcription and translation of *COL1A1* and *COL1A2* encoding the subunits of collagen type I, the nascent proteins are modified in the rough endoplasmic reticulum of the osteoblast, further processed in the Golgi apparatus, and then secreted into the matrix surrounding the osteoblast where they undergo further modification. Collagen type I is a trimer of two strands of COL1 α 1 and one strand of COL1 α 2; the helical chains of COL1 α 1 and COL1 α 2 are composed of repeated amino acid trimers of ...Glycine-X-Y... (where X and Y are primarily proline and hydroxyproline, respectively).¹⁷⁷ After synthesis, COL1 α 1 and COL1 α 2 are modified in the osteoblast's endoplasmic reticulum; there they undergo hydroxylation of selected lysine and proline residues, the latter are later converted to pyridinolines. These molecules are

assembled into trimers of two COL1 α 1 fibers and one COL1 α 2 fiber and further processed in the Golgi apparatus of the osteoblast. After being secreted into the matrix, flanking amino- and carboxyl-propeptide domains are removed, thereby exposing amino (N)- and carboxyl (C) terminal telopeptides that then form cross-linked fibers. The carboxyl-propeptide sequence is cleaved by a specific proteinase encoded by *BMP1*. Procollagen type I C- and N-terminal telopeptides (PICP, PINP, respectively) are present and measurable in the circulation enabling assessment of collagen synthesis and processing.

Posttranslational modifications of COL1 α 1 and COL1 α 2 are essential for formation of normal collagen type I and its mineralization. Hydroxylation of proline at AA 986 of COL1 α 1 and at AA 707 of COL1 α 2 forming 3-hydroxyproline is accomplished by the coordinated interaction of the responsible enzyme prolyl 3-hydroxylase 1 (*P3H1*)—also termed *LEPRE1*—interacting with its essential stabilizing cofactors, cartilage associated protein (*CRTAP*) and peptidyl-prolyl isomerase B (cyclophilin B) (*PP1B*). In the absence of this functional tripartite complex, the helical domain of COL1 α 1 is modified by other enzymes leading to alterations in cross-linking that adversely affect the strength of collagen type I.¹⁷⁷ Hydroxylation of lysine residues forming hydroxylysine by procollagen-lysine,2-oxoglutarate 5-dioxygenase 1 (*PLOD1*) at procollagen AA sequences of ...Gly-X-Lys ... in the helical regions of the three subunits that comprise collagen type I is essential for the stability of the pyridinoline cross-links of this molecule. In the telopeptide regions of collagen type I, *PLOD2* (*PLOD2*) is responsible for the formation of hydroxylysine.

Chaperone proteins play important roles as cofactors in the processing of COL1 α 1 and COL1 α 2 fibers.¹⁷⁷ Within the osteoblast's endoplasmic reticulum, stability of the three protein strands comprising collagen type I enabling its correct cross-linking is provided by heat shock protein (HSP) 47 encoded by *SERPINH1*. HSP47 binds to specified arginine residues within the collagen type I propeptides. The chaperone FK506-binding protein (*FKBP10*) may be involved in the hydroxylation of lysine residues of COL1 α 1 and COL1 α 2 and their subsequent cross-linking. *FKBP10* and HSP47 may also interact with one another during formation and maturation of collagen type I.

If the primary synthesis of the amino acid strands of the fibers of COL1 α 1 or COL1 α 2 or their initial glycosylation within the endoplasmic reticulum of the synthesizing osteoblast is incorrect, those strands are destroyed.^{177,181} However, if the corrective processes fail to occur or are overwhelmed, malformed and hence "misfolded" proteins accumulate within the endoplasmic reticulum, subjecting this organelle to "stress," leading to the "unfolded protein response," a process through which continued protein translation is attenuated and the abnormal product destroyed through the ubiquitin-proteasome pathway of protein degradation.¹⁸¹ When the destructive process becomes quantitatively overwhelmed, the endoplasmic reticulum is "stressed" and cellular activity declines eventuating in apoptosis of the stressed cell.¹⁸² Several factors are critical to the normal processing of newly translated subunits (COL1 α 1 and COL1 α 2) of collagen type I in the endoplasmic reticulum and their subsequent secretion into the bone matrix: (1) the cyclic AMP response element-binding protein 3-like 1 (*CREB3L1*) stimulates expression of *COL1A1* by binding to its 5' promoter and is also involved in the processing of osteoblast-synthesized bone matrix proteins and in its response to endoplasmic reticular "stress";¹⁷⁷ (2) membrane-bound transcription factor protease site 2 (*MBTPS2*) is an enzyme that alters several downstream factors that are then active in the endoplasmic reticular stress response; and (3) transmembrane protein 38B (*TMEM38B*), also designated *TRIC-B*, encodes a

homotrimeric intracellular cation (e.g., potassium) channel expressed on membranes of calcium storage sites that affects calcium transport from these organelles. Alteration in intracellular calcium levels affect function of the osteoblast, its endoplasmic reticulum, and the secretion of collagen type.¹⁸³

Osteoblasts, osteocytes, and osteoclasts also synthesize non-collagenous proteins and release them into the surrounding osteoid and into the circulation where they may act upon adjacent or distant tissues.¹⁸⁴ Among the secreted products of osteoblasts and osteocytes is FGF23, which decreases renal tubular reabsorption of phosphate, inhibits synthesis of PTH and calcitriol, and hastens degradation of calcitriol by enhancing synthesis of calcitriol-24 hydroxylase. Osteocalcin (encoded by *BGLAP*) is secreted by osteoblasts and exerts local effects upon bone and more distant effects upon energy metabolism and possibly reproductive function. Osteocalcin is a 49 AA peptide that is released into bone matrix but also into the circulation. It has three glutamic acid residues at AA sites 17, 21, and 24 that can be gamma carboxylated by a vitamin K-dependent gamma-carboxylase. The gamma-carboxylated residues of glutamic acid of osteocalcin bind to calcium on the surface of hydroxyapatite and facilitate formation of hydroxyapatite, growth of its crystals, and hence bone mineralization. During bone resorption many of the gamma carboxyl groups are removed, allowing osteocalcin to be released into the circulation where it may exert indirect and/or direct metabolic effects.^{184–187} Thus in vitro undercarboxylated osteocalcin enhances insulin release from pancreatic beta cells and systemically improves glucose tolerance and increases the synthesis and secretion of adiponectin (which augments insulin sensitivity) from white fat cells. Experimentally, osteocalcin also stimulates release of testosterone from testicular Leydig cells. Lipocalin-2 (*LCN2*) is secreted by osteoblasts and experimentally affects carbohydrate homeostasis by stimulating secretion of insulin and increasing insulin sensitivity; it reduces food intake through binding to hypothalamic melanocortin 4 receptors (*MC4R*) and activating an appetite-suppressing neural pathway.^{187,188}

Osteoblasts control mineralization of matrix, in part, by regulating local concentrations of phosphate through synthesis of cell membrane-bound alkaline phosphatase, which frees organically bound phosphate and by reducing levels of inhibitors of bone formation, such as pyrophosphates, the SIBLING proteins, and their intrinsic phosphorylated ASARM peptides. Calcium and phosphate can then precipitate in bone matrix as hydroxyapatite crystals. The hydroxyapatite [Ca₁₀(PO₄)₆(OH)₂] crystal is the major inorganic component of bone; magnesium, sodium, potassium, and carbonate are also present in bone mineral. Crystalline hydroxyapatite is formed within but at the periphery of the osteoblast from a supersaturated solution of initially amorphous calcium and phosphate, encapsulated within vesicles derived from the interior surface of the osteoblast cell membrane and then extruded into the organic matrix (osteoid). After destruction of the membrane of the matrix vesicle and in concert with the calcium and phosphate-binding proteins bone alkaline phosphatase, osteocalcin, osteopontin, osteonectin, and bone sialoprotein, growth of the hydroxyapatite crystal upon collagen type I fibrils, the organic matrix of bone that serves as a template for the orderly growth of hydroxyapatite crystals, proceeds. This process is antagonized by pyrophosphate, which structurally is two molecules of inorganic phosphate linked by an oxygen bridge. Pyrophosphate is dephosphorylated and hence destroyed by bone alkaline phosphatase, thereby allowing bone mineralization to proceed. Formation of the hydroxyapatite crystal is antagonized by members of the SIBLING family of proteins.

Ectonucleotide pyrophosphatase/Phosphodiesterase 1 (*ENPP1*) is an enzyme that transforms inorganic phosphate to pyrophosphate, an inhibitor of bone matrix mineralization

(thus, ENPP1 has a function opposite to that of alkaline phosphatase). ENPP1 is required for synthesis of Klotho in the setting of high phosphate intake.¹⁸⁹ Mutations in *ENPP1* are associated with autosomal recessive hypophosphatemic rickets type 2 (ARHR2). Family with sequence similarity 20, Member C (*FAM20C*) is a constitutively active serine/threonine kinase that phosphorylates members of the SIBLING family of proteins including DMP1. Loss-of-function variants of *FAM20C* are related to ADHR3 with elevated levels of FGF23 and hypophosphatemia and are also linked to the osteosclerotic phenotype of Raine syndrome (OMIM 259775).

Within the extracellular matrix of bone are noncollagenous, multifunctional proteins that organize, regulate, and coordinate mineralization, serum proteins (e.g., albumin, α 2HS-glycoprotein, growth factors—for example, IGF-I), proteoglycans—proteins with acidic polysaccharide side chains (e.g., chondroitin sulfates, such as aggrecan, perlecan, glypican), glycosylated proteins with cell attachments (e.g., alkaline phosphatase, osteonectin), SIBLING proteins (e.g., osteopontin, BSP, DMP1, MEPE), fibronectin, fibrillins 1 and 2, and γ -carboxylated (Gla) proteins (e.g., osteocalcin, matrix Gla protein, protein S).

Osteoblasts mature into flat, relatively inactive bone lining cells on bone surfaces where neither bone formation nor bone reclamation is occurring and into osteocytes buried deeply within bone.¹⁹⁰ Some bone lining cells extend processes into canaliculi to meet those formed by osteocytes. Bone lining cells express both *TNFSF11* (encoding RANK-ligand) and *TNFRSF11B* (encoding osteoprotegerin) and thus participate in osteoclastogenesis, as well as in bone remodeling. Osteocytes are extremely long-lived cells (25 years) that have matured from osteoblasts embedded in lacunae within formed bone; they are connected to one another and to bone surface osteoblasts by long dendritic filaments (cytoplasmic processes) coursing within canaliculi that link with one another across gap junctions. Osteocytes play a crucial role in *bone remodeling*, the process through which injured sites in existing bone are repaired and reformed through the coordinated and sequential processes of osteolysis and osteogenesis within a bone remodeling unit. Osteocytes summon both osteoclasts and osteoblasts to the site of injury by sensing the mechanical load placed on the bone in which the osteocytes reside by monitoring movement of fluid and pressure within canaliculi, within a basic multicellular unit (BMU) of osteoblasts and osteoclasts. The osteocyte detects the small areas of damaged bone (microfractures) that result from the forces that act continually upon the skeleton.¹⁹¹ For this and other purposes, osteocytes synthesize and release a number of products including: sclerostin, DMP1, IGFBP, RANKL, DKK1, TGF β , PHEX, MEPE, and FGF23.

The “mechanostat” function of the osteocyte is indispensable for maintenance of optimal bone strength, mass, size, and shape. The stimulus for the functional adaptation of bone is mechanical strain.^{192,193} The magnitude of a strain is determined by its force, frequency, and distribution and is also dependent upon the site on which the strain is exerted and by genetic characteristics of the individual upon whom the mechanical load is placed. In response to mechanical deformation, fluid shifts in the lacunae and canaliculi provoke the osteocyte to release nitric acid and prostaglandin-E₂ that recruit osteoblasts to the strain site where new bone is formed beneath the periosteum of long bones and on existing trabeculae (*formation modeling*). When mechanical force on bone is reduced (e.g., immobilization, bed rest, space flight), the rate of osteocyte apoptosis increases. The dying osteocyte releases both macrophage colony-stimulating factor (M-CSF) and soluble RANK-ligand, leading to increase in osteoclastogenesis and bone resorption primarily on the endosteal surface of long bones without comparable increase in osteoblast-directed bone formation, resulting in diminished cortical thickness

and bone strength (*resorption modeling*). At sites of microfractures, signals (M-CSF, sRANK-ligand) from dying osteocytes recruit osteoclasts that, in turn, attract osteoblasts for removal and reformation of bone, respectively (*targeted remodeling*).¹⁹³ Bisphosphonates, sex steroids, and PTH impede osteocytic apoptosis, a property that partially underlies the positive physiological effects of these compounds on bone mass. The strain placed upon long bones by muscular exertion and other forces (e.g., jumping) exerts a positive anabolic effect through stimulation of osteocyte function. The “functional muscle-bone unit” confers the ability of bone to modify its strength, mass, and shape in response to muscular force.¹⁹⁴

Cortical or compact bone is present in the cranium, scapula, mandible, ilium, and shafts of the long bones; both its periosteal and endosteal surfaces are lined with layers of osteogenic cells. Cancellous (trabecular or spongy) bone is located in the vertebrae, basal skull, pelvis, and ends of the long bones. Because only 15% to 25% of trabecular bone volume is calcified (compared with 80%–90% of cortical bone volume) and thus has a far greater surface area, trabecular bone is metabolically quite active; it has a high turnover rate making it more vulnerable to disorders that adversely affect bone mineralization. In flat bones (skull, ilium, mandible), intramembranous ossification begins with the local condensation of mesenchymal cells that differentiate directly into preosteoblasts and osteoblasts and initiate the formation of irregularly calcified (woven) bone that is then replaced by mature lamellar bone. Membranous bones grow by apposition, a process supported by development of new blood vessels induced by VEGF, a protein that also enhances bone formation.¹⁹⁵ The external surface of bone is enveloped by periosteum (containing blood vessels, nerve terminals, osteoblasts, and osteoclasts), whereas the interior of bone next to marrow is lined by endosteum. The periosteum is a fibrous network in which osteoblasts synthesize peripheral compact bone; cortical bone reinforces bone strength and complements and extends that provided by trabecular and endosteal bone. Tendons and ligaments insert and are fixed into cortical bone.

Osteoclastogenesis

Osteoclasts are multinucleated giant cells that adhere to the surface of bone and form a subosteocytic lacuna into which the osteocyte secretes hydrochloric acid to dissolve the mineral phase of bone (hydroxyapatite) and proteolytic enzymes to digest organic matrix.¹⁹⁶ Osteoclasts are derived from hematopoietic progenitor cells and macrophages through signaling by M-CSF, CSF1 acting through its receptor (CSF1R—also designated c-fms) situated on the cell membrane of the osteoclast precursor cell (Fig. 9.11A).¹⁶⁰ M-CSF induces transcription of hematopoietic transcription factor PU.1 (*SPI1*) that furthers osteoclast differentiation. In response to PTH (or PTHrP), calcitriol, prostaglandins, interleukins-6 and 11, TNF- α , and other cytokines, osteoblasts and bone marrow stromal cells synthesize both M-CSF and RANK-ligand (*TNFSF11*) expressed on their plasma membrane surfaces.¹⁹⁷ M-CSF also induces expression of *TNFRSF11A* (encoding RANK) on the surface of osteoclast progenitor cells that then enhances their further differentiation and activation. RANK-ligand is a 317 AA protein composed of cytoplasmic (48 AA), transmembrane (21 AA), and extracellular (248 AA) domains with the binding site for RANK extending between AA 137 and 158. *TNFSF11* is also expressed in lymphoid tissue (where it is critical for development of the immune system), striated and cardiac muscle, lung, intestines, placenta, thyroid, prechondroblast mesenchymal cells, and hypertrophic chondrocytes. In addition to furthering osteoclast differentiation, RANK-ligand enhances function of the mature osteoclast and inhibits its apoptosis. RANK-ligand

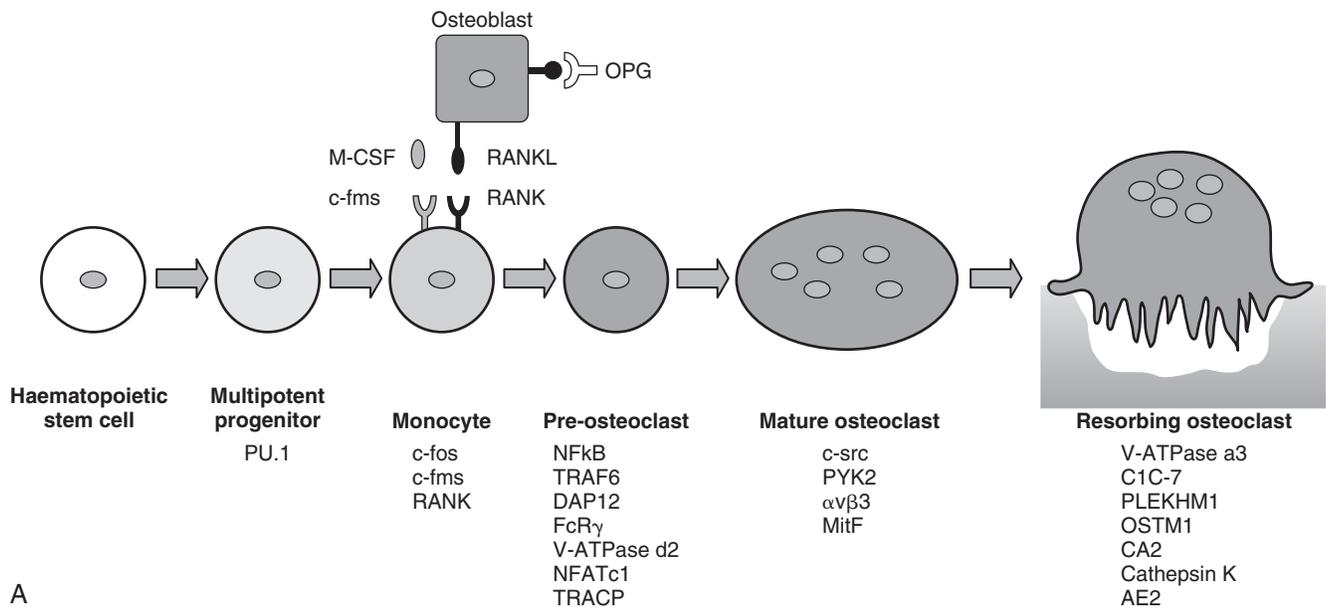

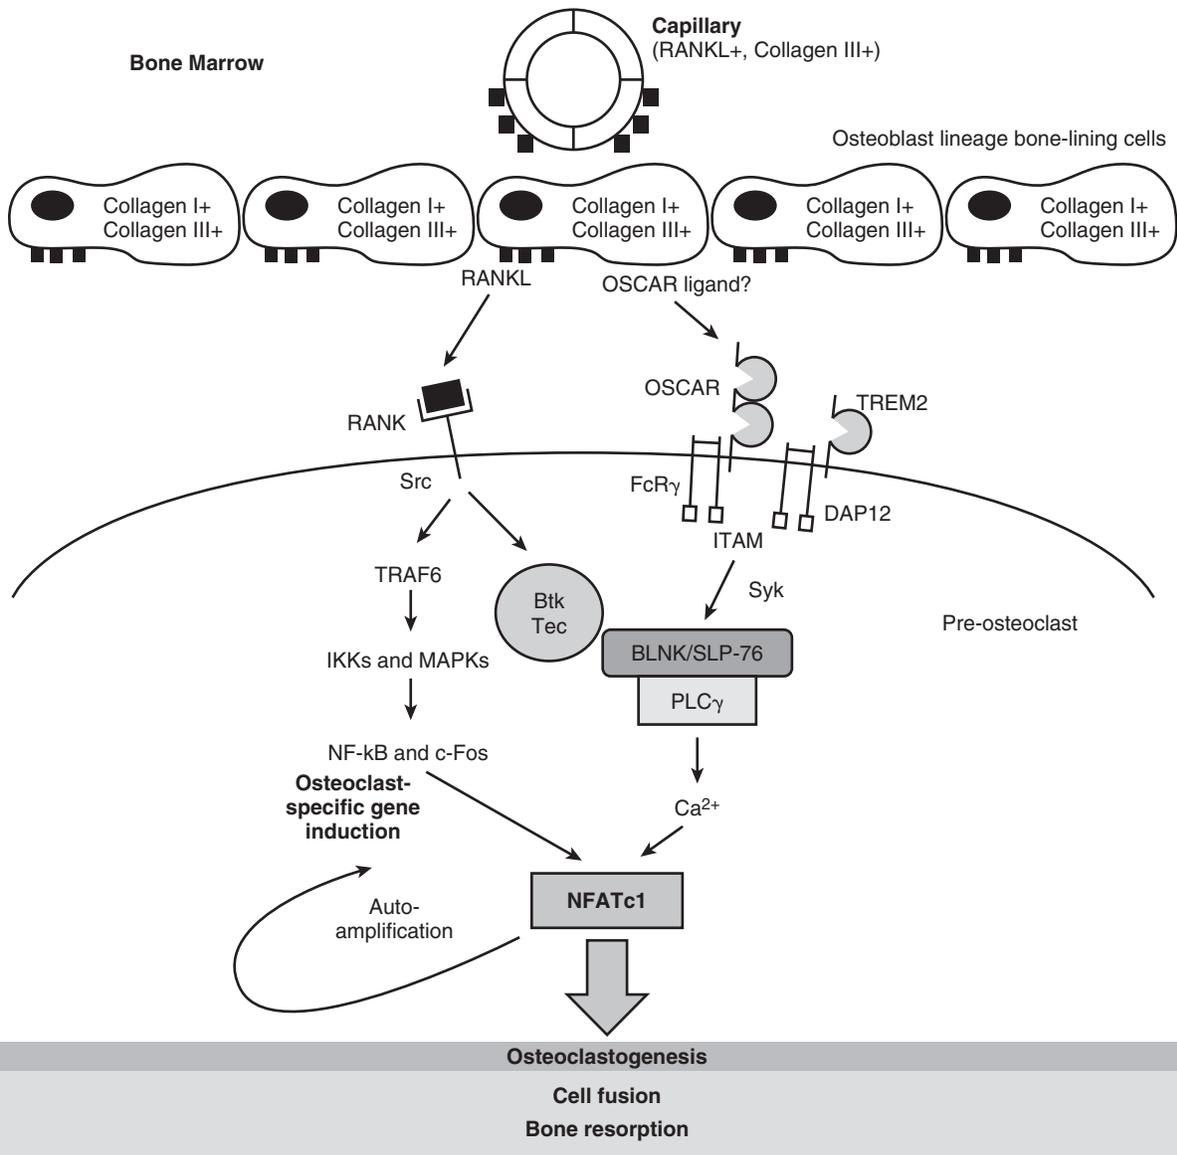

Fig. 9.11A Regulation of osteoclastogenesis. After initial differentiation following exposure of a mesenchymal stem cell to macrophage colony-stimulating factor (M-CSF), RANK-ligand synthesized by stromal cells and osteoblasts binds to RANK expressed on the plasma membrane of preosteoclasts, which signals through steroid receptor coactivator (SRC), tumor necrosis factor-associated factor 6 (TRAF6), and mitogen-activated protein kinase (MAPK) to enable nuclear factor (NF)-κB and c-Fos to translocate NFATc1 to the nucleus where it assists in the maturation of the preosteoclast into a mature osteoclast and serves as a transcription factor for osteoclast-specific proteins (tartrate-resistant acid phosphatase, cathepsin K, β_3 -integrin, calcitonin receptor). (From Henriksen, R., Bollerslev, J., Everts, V., Karsdal, M.A. (2011). Osteoclast activity and subtypes as a function of physiology and pathology—Implications for future treatments of osteoporosis. *Endocr Rev*, 32, 31–63. With permission.)

stimulates transcription of many osteoclast-specific genes and also enhances the development of calcium resorption lacunae and pits.¹⁹⁷

RANK is a 616 AA protein with a signal peptide (28 AA), cytoplasmic domain (383 AA), transmembrane domain (21 AA), and extracellular domain (184 AA) that is expressed in osteoclasts, fibroblasts, and B and T lymphocytes. Binding of RANK-ligand to RANK leads to transmission of an intracellular message through stimulation of the MAPK/ERK signal transduction pathway that activates NF-κB and c-Fos (encoded by *FOS*) (Fig. 9.11B).¹⁹⁸ *IKBKKG* encodes a phosphokinase that also activates NF-κB furthering osteoclastogenesis. The NF-κB family of five dimeric transcription factors includes NF-κB1 and NF-κB2 that are crucial for osteoclastogenesis; NF-κB is activated by degradation of the inhibitor of κB (IκB encoded by *NFKB1A*)—a protein that traps NF-κB in the cytoplasm and is itself destroyed through the ubiquitination/proteasomal pathway after phosphorylation of its serine residues. Free NF-κB then acts via c-Fos and the AP-1 complex of factors involved in movement of proteins to stimulate osteoclastogenesis in concert with the 827 AA master osteoclastogenic transcription factor encoded by *NFATc1*.^{196,198} Nuclear NFATc1 interacts within a transcriptional complex to stimulate expression of genes encoding osteoclast-specific proteins, such as tartrate-resistant acid phosphatase (TRAP, *ACP5*), matrix metalloproteinase 9 (*MMP9*), carbonic anhydrase II (*CA2*), cathepsin K (*CTSK*), the α_3 subunit of vacuolar $[H^+]$ -ATPase (encoded by *TCIRG1*), chloride channel 7 (encoded by *CLCN7*), osteopetrosis-associated transmembrane protein 1 (encoded by *OSTM1*), $\alpha_v\beta_3$ -integrin (*ITGB3*), and the calcitonin receptor (*CALCR*), leading to terminal differentiation of osteoclasts.¹⁹⁸ After binding of RANK-ligand to RANK and subsequent signal transduction, preosteoclasts fuse to become mature multinucleated osteoclasts. Osteoclastogenesis is also stimulated by cytokines, such as *TNF α* and interleukins-1-beta (*IL1B*) and -6 (*IL6*). *NOTCH1* encodes a cotranscription

regulating factor that inhibits initial commitment of the osteoclast precursor cell to further differentiation, but paradoxically stimulates further maturation of cells already committed to differentiation as osteoclasts.¹⁹⁹

The osteoblast also synthesizes, expresses on, and releases from its cell membrane osteoprotegerin (*TNFRSF11B*), a decoy protein that binds RANK-ligand and inhibits osteoclast differentiation. Mature B-lymphocytes also secrete osteoprotegerin.²⁰⁰ Osteoprotegerin is a member of the TNF receptor superfamily and is synthesized and secreted by the stromal cell/osteoblast; it acts as a decoy receptor by binding to RANK-ligand, thus inhibiting the interaction of RANK-ligand and RANK and thereby interfering with osteoclastogenesis.²⁰¹ The five exon gene (*TNFRSF11B*) encoding human osteoprotegerin is expressed also in the lung, liver, heart, kidney, intestinal cells, brain, thyroid, lymphocytes, and monocytes. Human osteoprotegerin is synthesized as a 401 AA propeptide; after cleavage of the 21 AA signal peptide, the mature protein of 380 AA contains four cysteine-rich amino-terminal domains and two carboxyl-terminal “death” domains; it is glycosylated and released into the paracellular space as a disulfide-linked homodimer. Osteoprotegerin synthesis is enhanced by interleukins-1 α and -1 β , TNF- α and - β , BMP-2, TGF β , and estrogen, and antagonized by calcitriol, glucocorticoids, and PGE₂. Through binding to RANK-ligand on the surface of the stromal cell/osteoblast or to its circulating secreted form, this decoy receptor inhibits the osteoclast activating and bone reabsorbing effects of calcitriol, PTH, and the interleukins. Overproduction of osteoprotegerin in transgenic mice leads to osteopetrosis whereas its knock-out is associated with loss of cortical and trabecular bone and osteoporosis, multiple fractures, and hypercalcemia; the latter model is the experimental counterpart of juvenile Paget disease (OMIM 239000).²⁰² The osteoblast and osteoclast also interact directly with one another; the osteoclast expresses on its cell surface the coupling factor ephrin-B1 (*EFNB1*) and secretes ephrin B2 (*EFNB2*), whereas the

B

Fig. 9.11B RANK-ligand produced by osteoblasts and stromal cells binds to RANK expressed on the surface of the osteoclast precursor cell; signal transduction through TRAF6 and NF-κB enables the translocation of NFATC1 into the nucleus and further maturation of the osteoclast. The costimulatory stimulus for osteoclastogenesis proceeds through OSCAR and TREM2, membrane proteins that recognize as ligands amino acid sequences within the structures of collagen types I and III. These receptors then signal through ITAM adaptors to stimulate phospholipase Cγ that converts membrane bound phosphatidylinositol to inositol trisphosphate (and DAG) resulting in mobilization of Ca²⁺ from storage sites in the endoplasmic reticulum and increase in cytosolic Ca²⁺ concentrations that also activate NFATC1 and stimulate osteoclastogenesis. (See text for details.) *BLNK*, B-cell linker protein; *ITAM*, immunoreceptor tyrosine-based activation motif; *NFATC1*, nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1; *OSCAR*, osteoclast-associated receptor; *PLCγ*, phospholipase Cγ; *RANK*, receptor activator of nuclear factor κB; *RANKL*, RANK ligand; *SLP-76*, SH2 domain-containing leukocyte protein-76 kD; *TREM2*, triggering receptor expressed on myeloid cells-2). (From Barrow, A.D., Raynal, N., Andersen, A.L., et al. (2011). OSCAR is a collagen receptor that costimulates osteoclastogenesis in DAP12- deficient humans and mice. *J Clin Invest*, 121, 3505–3516. With permission.)

osteoblast expresses the ephrin tyrosine kinase receptor (*EPHA1*); their interaction stimulates osteoblastogenesis.¹⁶⁰

Bone modeling, the initial process in bone formation, is accomplished by the independent action of osteoblasts and osteoclasts and is not dependent upon prior bone resorption.²⁰³ Bone remodeling is the process during which the strength, structure, and function of bone are renewed; bone resorption and deposition are sequentially linked. Bone remodeling is accomplished within the bone remodeling unit (BRU)

of designated osteoclasts and osteoblasts; it is a continuous process in which old cancellous and cortical bone is reabsorbed and replaced by new bone and takes place in the growing, as well as the mature skeleton. The bone remodeling unit is 1 to 2 mm in length, 0.2 to 0.4 mm in width, led by osteoclasts, and trailed by osteoblasts; in the adult skeleton, its life span is 6 to 9 months and 10% of the skeleton is “remodeled” each year. The site selected for remodeling is targeted by osteocytes sensing a mechanical or stress defect (microfracture), thereby

Schematic illustration of the differences between acid secretion and proteolysis during osteoclastic bone resorption, illustrating that the collagen matrix is removed by proteolysis after acidification

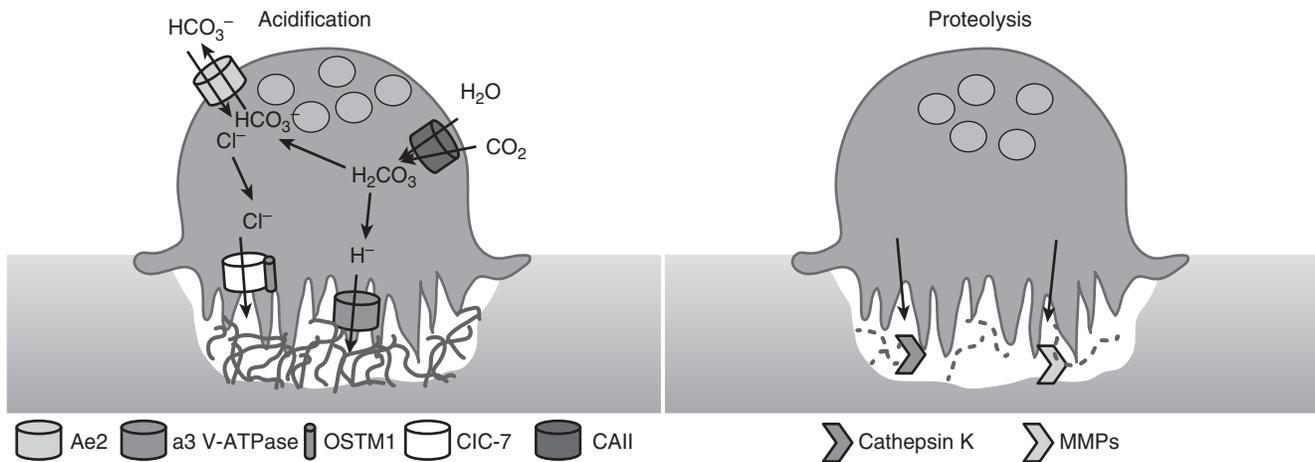

Fig. 9.12 Differentiated osteoclast form a ruffled border by adhering to bone surface through $\alpha\beta_3$ integrin receptors. A subosteoclast lacuna is formed by the dissolution of bone mineral by osteoclast secreted hydrochloric acid (*left panel*) and the resorption of organic bone matrix by cathepsin K and matrix metalloproteinases (*right panel*). Subsequently, osteoblasts are attracted to this pit (by the high local Ca^{2+} concentrations) as new bone is formed in the continuing process of bone remodeling. (From Henriksen, R., Bollerslev, J., Everts, V., Karsdal, M.A. (2011). Osteoclast activity and subtypes as a function of physiology and pathology - Implications for future treatments of osteoporosis. *Endocr Rev*, 32, 31–63. With permission.)

initiating bone remodeling. Osteoclasts are then summoned to the area of injured bone, bind to the insulated site, seal the microfracture using integrins present on the osteoclast's cell membrane, and develop a ruffled border below which a subosteocytic lacuna is formed by digestion of adjacent bone (Fig. 9.12). The mineral phase of bone (hydroxyapatite) is reabsorbed by acid (H^+) synthesized by *CAII* resulting in formation of rapidly dissociating carbonic acid (HCO_3^-) and the secretion of H^+ through the vacuolar H^+ -ATPase proton pump (encoded by *TCIRG1*) embedded within the ruffled border. To maintain neutrality in the lacuna, chloride (Cl^-) is also transported into this space through the H^+ - Cl^- -exchange channel encoded by *CLCN7*. The stability of *CLCN7* is maintained by osteopetrosis-associated transmembrane protein 1 (*OSTM1*). Osteoclasts also express *SLC4A2* encoding a $\text{Cl}^-/\text{HCO}_3^-$ exchanger that maintains normal acid/base balance within the cell.²⁰⁴ The osteoclast synthesizes and secretes into the lacuna several enzymes, including cathepsin K (*CTSK*) and zinc-dependent matrix metalloproteinases that digest and dissolve the organic matrix of bone. The digested debris within the lacuna is encapsulated within vesicles and transported across the osteoclast and released into the extracellular compartment. *SNX10* and *PLEKHMI* encode proteins that are necessary for vesicular maturation and transport within the osteoclast.²⁰⁵

RANK-ligand/RANK signaling also stimulates tyrosine kinases that form an osteoclastogenic signaling complex that activates PLC, leading to cleavage of membrane-associated phosphatidylinositol-4,5-bisphosphate to DAG and IP—the latter mobilizes Ca^{2+} from intracellular storage sites within the endoplasmic reticulum, resulting in increased cytosolic Ca^{2+} levels and activation of calcineurin and NFATC1.²⁰⁶ In the preosteoclast, there is an essential costimulatory signaling system of immunoglobulin-like receptors through which NFATC1 is also activated. The osteoclast-associated receptor (*OSCAR*) and the triggering receptor expressed on myeloid cells 2 (*TREM2*) are transmembrane c-stimulatory receptors expressed on the plasma membrane of preosteoclasts whose ligands are sequences of amino acids (...GPOGPX'GFX'...) derived from collagens types I, II, and III of extracellular matrix

to which preosteoclasts are exposed at sites of bone formation (see Fig. 9.11B).¹⁹⁸ The costimulatory receptors associate with intracellular adapter proteins that have been phosphorylated by RANK-ligand/RANK signaling. The complex of costimulatory receptors and other intracellular factors contribute to activation of *NFATC1*.^{196,198,206} *NFATC1* is capable of autoamplifying its own expression by linking to an NFAT-binding site within the promoter region of *NFATC1*, a site that is activated by epigenetic mechanisms that regulate histone acetylation and methylation.¹⁹⁶

During osteoclast differentiation, preosteoclast cell membranes fuse forming the mature multinucleated giant cell osteoclast. Maturing osteoclasts develop circumferential podosomes (adhesion structures with abundant actin that can degrade matrix) that are critical for cell-cell fusion.²⁰⁷ Syncytin-1 (encoded by *ERVW1*) is a plasma membrane protein that is involved in osteoclast fusion as are several adhesion factors and integrins.^{208, 209} In addition to the contribution of the endoplasmic stores of Ca^{2+} to cytosolic Ca^{2+} concentrations, extracellular Ca^{2+} enters the differentiating and mature osteoclast through TRPV4 and 5.¹⁹⁶ TRPV4 plays a role in osteoclast differentiation, whereas TRPV5 is important for the functional activity of the mature osteoclast. In the subosteoclast resorption lacuna, Ca^{2+} levels exceed 40 mM (serum Ca^{2+} values range between 1.1–1.3 mM); consequently, as intraosteoclast Ca^{2+} concentrations rise, bone resorbing activity is inhibited, and the osteoclast ages and dies. Concurrently, the high Ca^{2+} environment around the resorption lacuna is an attractant for osteoblasts that produce the bone needed to fill the lacuna. Thus, the processes of bone resorption and formation are coupled, in part, by lacunar levels of Ca^{2+} .

When mature osteoclasts attach to bone, the inferior surface of the osteoclast develops a ring structure composed of β -actin filaments and $\alpha_v\beta_3$ integrins that bind to matrix-embedded osteopontin and other components that contain the amino acid sequence – Arg-Gly-Asp (RGD) – thereby forming a sealed zone and creating an isolated microenvironment between the osteoclast's inferior cell membrane and the outer bone surface—the resorption lacuna (see Fig. 9.12).¹⁹⁷ The inferior

or apical surface of the osteoclast within the sealed zone develops an irregular ruffled border through which are secreted products of the osteoclast. Into the isolated sealed resorption lacuna the osteoclast pumps: (1) acid (H^+ or protons) generated from carbon dioxide by CA2 and actively transported via a vacuolar type ATPase proton pump (*TCIRG1*) and chloride ions passively transmitted through a chloride channel (*CLCN7*) to form a highly acidic (pH 4.5) milieu that dissolves hydroxyapatite, and (2) lysosomal proteolytic enzymes (such as the cysteine proteases—cathepsins K, B, and L—and collagenases, such as *MMP9*) that digest osteoid, the protein matrix of bone.^{197,210} Osteopetrosis-associated transmembrane protein 1 (encoded by *OSTM1*) is a 334 AA protein that is essential for normal processing of *CLCN7* and hence for normal acidification of the subosteocytic resorption lacuna and consequent dissolution of hydroxyapatite. Osteopetrosis associated with large numbers of osteoclasts develops in patients with loss-of-function mutations in the genes encoding CAII, the vacuolar ATPase proton pump, the *CLCN7* chloride channel, and associated proteins, whereas inactivating mutations in the gene encoding cathepsin K lead to pycnodysostosis.¹⁹⁷ After the osteoclast contacts bone, it functionally polarizes into two realms—the inferior portion of the osteoclast above the ruffled membrane transports protons, chloride ions, and enzymes from the interior of the cell into the subcellular space and reabsorbs the products degraded by these agents; the superior portion of the osteoclast processes and excretes the reabsorbed materials. TRPV5, the calcium channel required for intestinal and renal tubular absorption/reabsorption of calcium, is also found on the ruffled membrane of the osteoclast.²³ Multiple osteoclast subtypes have been described whose individual function depends on the genes the osteoclast expresses, the anatomic location of the osteoclast, and the functional response of the osteoclast to exogenous agents.¹⁹⁷ Thus there are subtle distinctions between endochondral and membranous bone osteoclasts, trabecular and cortical osteoclasts, and osteoclasts involved in targeted and stochastic bone remodeling. (Targeted bone remodeling occurs locally and involves replacement of damaged bone by new bone to maintain bone strength; stochastic bone remodeling occurs systemically in response to PTH secreted as the Ca^{2+} concentration falls.)

After digestion and resorption of injured bone have been accomplished, osteoblasts converge on the site of osteoclastic

activity. TGF β secreted by osteoblasts and stored in bone matrix is released by osteoclast-mediated bone resorption; it attracts mesenchymal precursor cells that differentiate into osteoblasts, thereby coupling bone resorption and formation and increasing osteocyte numbers.¹⁷⁷ IG-1 is a second osteoblast chemoattractant that is also stored in bone matrix and released by osteoclastic activity. In addition, osteoclasts secrete several “clastokines” that may be osteoblast differentiating factors, for example, WNT-Frizzled associated collagen triple helix repeat-containing protein 1 (encoded by *CTHRC1*) or chemoattractants that summon osteoblasts to the bone remodeling site—for example, sphingosine-1-phosphate (*S1PR1*).²¹¹ Thus the process of bone remodeling involves the sequential steps of activation (identification of the site of insulted bone by osteocytes), resorption (osteoblast-mediated recruitment and maturation of osteoclasts), reversal (removal of lacunar debris), formation (attraction of osteoblasts, leading to reformation of removed bone), and termination (conclusion of the remodeling cycle).²⁰⁰

Bone Extracellular Matrix

Organic matrix proteins comprise 35% of bone, and type I collagen makes up 90% of these proteins.¹⁸⁰ Type I collagen is composed of a coiled triple helix of two polypeptide chains of collagen type I(α 1) (*COL1A1*) and one of collagen type I(α 2) (*COL1A2*) that are cross-linked intramolecularly by disulfide bonds and intermolecularly at the amino (N) and carboxyl (C) telopeptides by pyridinium compounds that permit bundling of collagen molecules into fibrils and fibers (Figs. 9.13 and 9.14). The helical chains of COL1 α 1 and COL1 α 2 are composed of repeated amino acid trimers of ...Glycine-X-Y... (where X and Y are primarily proline and hydroxyproline, respectively).¹⁷⁷ Glycine permits the chains to coil. After their synthesis, the components of collagen type I (COL1 α 1/COL1 α 2) are modified in the osteoblast's endoplasmic reticulum; there they undergo hydroxylation of selected lysine and proline residues, the latter are later converted to pyridinolines. After the assembly of two molecules of COL1 α 1 and one of COL1 α 2, they are further processed in the Golgi apparatus of the osteoblast. After being secreted into the matrix, flanking amino- and carboxyl-propeptide domains are removed, thereby exposing amino- and carboxyl terminal telopeptides

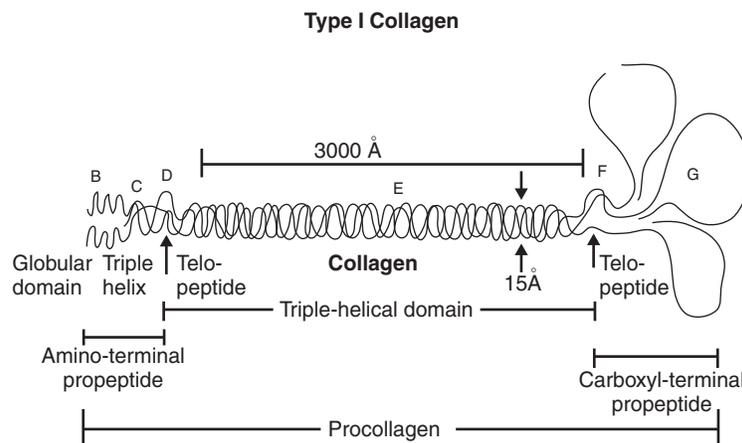

Fig. 9.13 Type I collagen is synthesized in the endoplasmic reticulum of osteoblasts as a larger procollagen molecule with amino (N) and carboxyl (C)-terminal extensions that are cleaved into carboxyl (PICP)- and amino (PINP)- terminal propeptides after secretion of procollagen type I into extracellular matrix. Mature type I collagen is a coiled triple helix of two polypeptide chains of collagen α 1(I) and one of α 2(I) that are cross-linked intramolecularly by disulfide bonds and intermolecularly at the N and C terminals by nonhelical pyridinium telopeptides. (From Byers, P.H. (1995). Disorders of collagen biosynthesis and structure. In: Scriver, C.R., Beaudet, A.L., Sly, W.S., Vale, D. *The Metabolic and Molecular Bases of Inherited Disease*, 7th ed. McGraw-Hill Inc, New York, p. 4029–4077. With permission.)

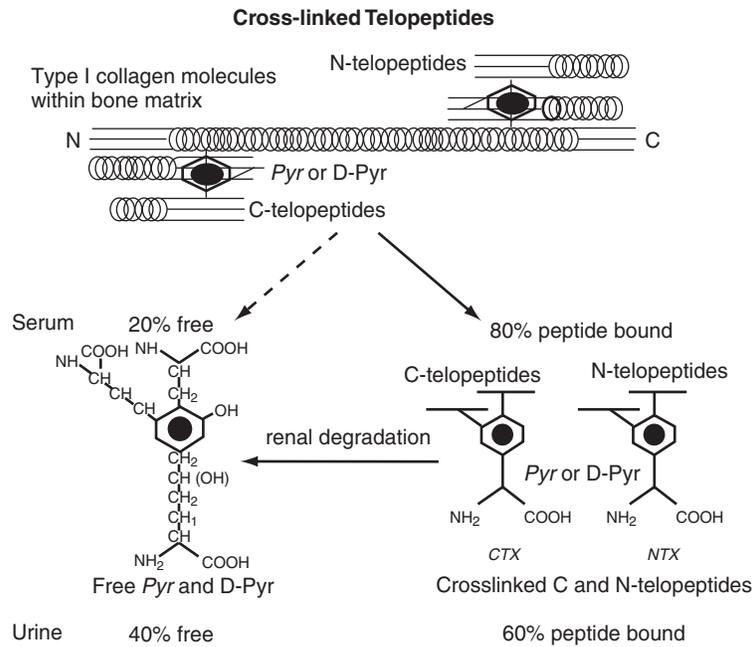

Fig. 9.14 Pyridinium and telopeptides of collagen. Pyridinoline (Pyr, hydroxylysyl-pyridinoline) and deoxypyridinoline (D-Pyr or Dpd, lysyl-pyridinoline) form nonreducible pyridinium cross-links between mature collagen fibers rendering them insoluble. Amino (–) and carboxyl (C) terminal regions (NTX, CTX) of collagen are proteolytically removed during degradation of mature collagen and secreted into extracellular space and serum. The carboxyl-terminal telopeptide of type I collagen (ICTP) is a marker of collagen type I degradation. (From Garnero, P., Delmas, P.D. (1998). Biochemical markers of bone turnover. Applications for osteoporosis. *Endocrinol Metab Clin NA*, 27, 303–323. With permission.)

that then form cross-linked fibers. Procollagen type I C- and N-terminal telopeptides (PICP, PINP respectively) are present and measurable in the circulation enabling assessment of collagen synthesis and processing.

Hydroxylation of proline at AA 986 of COL1 α 1 and at AA 707 of COL1 α 2 forming 3-hydroxyproline residues is accomplished by the coordinated interaction of the responsible enzyme prolyl 3-hydroxylase 1 (P3HI—also termed *LEPRE1*) interacting with its cofactors—cartilage associated protein (*CRTAP*) and cyclophilin B (encoded by *PP1B*). *CRTAP* and cyclophilin B are essential for the stability of P3HI activity. In the absence of this functional tripartite complex, the helical domain of COL1 α 1 is modified by other enzymes, leading to alterations in cross-linking that adversely affect the strength of collagen type I.¹⁷⁷ *CRTAP* is expressed in the proliferative zone of developing cartilage and at the chondroosseous junction; cyclophilin B is a peptidyl-prolyl cis-trans isomerase. That posttranslational modifications of COL1 α 1 are essential for normal bone formation is evidenced by the association of inactivating mutations of P3HI with osteogenesis imperfecta type VIII (OMIM 610915), of *CRTAP* with osteogenesis imperfecta type VII (OMIM 610682), and of *PP1B* with osteogenesis imperfecta type IX (OMIM 259440).^{212–214} Hydroxylation of lysine residues forming hydroxylysine by procollagen-lysine, 2-oxoglutarate 5-dioxygenase 1 (encoded by *PLOD1*), at procollagen AA sequences of ...Gly-X-Lys ... in the helical regions of the three subunits that comprise collagen type 1, is essential for the stability of the pyridinoline cross-links of this molecule. In the telopeptide regions of collagen type 1, procollagen-lysine, 2-oxoglutarate 5-dioxygenase 2 (*PLOD2*) catalyzes the formation of hydroxylysine.

Chaperone proteins play important roles as cofactors in the processing of COL1 α 1 and COL1 α 2 fibers.¹⁷⁷ Within the osteoblast's endoplasmic reticulum, stability of the three protein strands comprising collagen type 1 enabling its correct cross-linking is provided by HSP 47 (encoded by *SERP1NH1*). HSP47 binds to specified arginine residues within the collagen type I propeptides. The chaperone FK506-binding protein

(*FKBP10*) may also be involved in the hydroxylation of lysine residues of COL1 α 1 and COL1 α 2 and their subsequent cross-linking. *FKBP10* and *HSP47* may also interact with one another during formation and maturation of collagen type I.

After secretion of procollagen types I α 1 and α 2 subunits into bone matrix, their amino- and carboxyl-terminal propeptide domains are removed and secreted into extracellular space and serum. The carboxyl-propeptide sequence is cleaved by the proteinase activity of BMP1 (*BMP1*). Pyridinoline (PYR—hydroxylysyl-pyridinoline) and deoxypyridinoline (DPD—lysyl-pyridinoline) form nonreducible pyridinium cross-links between mature collagen fibers thus making them insoluble (see Fig. 9.14). Type I collagen predominates in bone but is also present in ligaments, tendons, fascia, and skin. Type II cartilage is composed of three procollagen type II(α 1) chains and is primarily deposited in cartilage. Type III collagen (three procollagen type III[α 1] chains) is present in bone, tendons, arteries, and intestine, and type IV (three procollagen type IV[α 1]) cartilage is a component of cell basement membranes.

Measurement of serum (and urine) concentrations of markers of bone formation and bone resorption provide information about bone turnover in adults and children (Fig. 9.15).²¹⁵ Serum levels of soluble (s)RANK-ligand and osteoprotegerin reflect osteoblast function as related to osteoclastogenesis.²¹⁶ Serum levels of sRANK-ligand are higher in male children and adolescents and increase with age in both genders; the median concentration in males is 0.27 pmol/L (range nondetectable–0.94) and in females 0.08 pmol/L (range nondetectable–1.42). Serum concentrations of osteoprotegerin do not vary with age or gender in children and adolescents; the median concentration of this analyte is 3.7 pmol/L (range 1.02–6.63). Determinations of the procollagen I extension peptides—PICP and PINP—reflect collagen synthesis and thus osteoblast function as does determination of the osteoblast products, osteocalcin and bone-specific alkaline phosphatase. Degradation of mature bone matrix collagen type I by osteoclast-secreted cathepsin K and matrix metalloproteinases releases PYR, DPD, and the amino-terminal (NTX) and

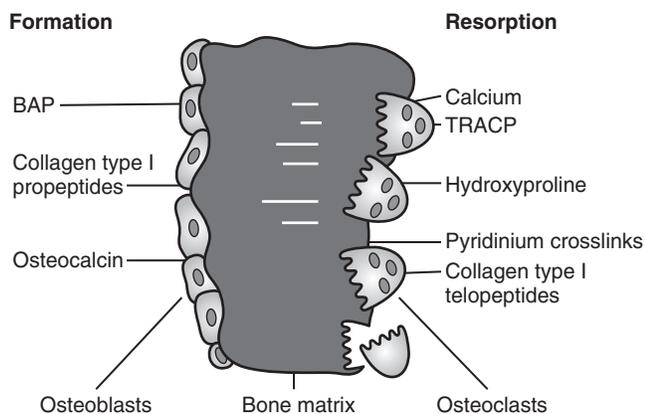

Fig. 9.15 Biochemical markers of bone formation and resorption. (From Jurimae, J. (2010). Interpretation and application of bone turnover markers in children and adolescents. *Curr Opin Pediatr*, 22, 494–500. With permission.)

carboxyl-terminal (ICTP) telopeptides of type I collagen. The urinary excretion of hydroxyproline and hydroxylysine and measurements of PYR, DPD, NTX, CTX, and ICTP in urine or serum reflect catabolism of collagen type I and thus bone resorption. Osteoclast activity is also reflected by measuring serum concentrations of TRAP5b.²¹⁵ In the normal pregnant woman, serum concentrations of sRANKL, osteoprotegerin, and ICTP are highest in the first trimester, whereas osteocalcin values are maximal in the first trimester—suggesting that early in normal pregnancy the rate of bone formation is increased whereas in the second trimester, the rate of bone resorption is amplified.²¹⁷ Serum levels of markers of both bone formation and resorption are higher in the fetus than mother (Table 9.4). Fetal umbilical cord plasma PICP concentrations are highest in mid-gestation and decline in the last trimester to term values; after birth, PICP values fall in preterm neonates during the first 3 days of life and then increase steadily to peak values at 36 weeks

postconceptual age; PICP levels in cord plasma are higher in males than females and correlate with gestational age and birth weight.²¹⁸ In general, values of bone formation and resorption markers are highest in infants, fall during childhood, increase slightly during adolescence, and then decline to adult levels (Tables 9.5A and 9.5B).^{215,219–224} In children and adolescents, serum concentrations of markers of bone turnover are unrelated to the BMI; however, age and gender significantly influence values of serum bone markers with higher levels in younger subjects and earlier decline in values in females than in males.

Serum concentrations of sclerostin reflect the function of osteocytes but vary with the assay used.^{225,226} Values of serum sclerostin are generally higher in healthy adult males than females (50 vs. 37 pmol/L) and rise two- to fourfold with aging; depending on age and gender, serum concentrations of sclerostin may correlate positively with bone mineral content and density (BMC, BMD) and negatively with serum levels of calcium, bone alkaline phosphatase, PINP, osteocalcin, and ICTP. Sclerostin values are decreased by physical activity and increased by immobilization. They are elevated in patients with hypoparathyroidism and decline after intermittent administration of PTH^{1–34}.^{227–230} Serum sclerostin concentrations are higher in boys (median ~23 pmol/L) than girls (median ~19 pmol/L), peak at 10 years of age in girls and 14 years in boys, and fall during puberty in both sexes.²³¹

The adult skeleton is composed of mineral (50%–70%), organic matrix (20%–40%), water (5%–10%), and lipids (<3%). Some 10% to 15% of bone matrix is composed of noncollagenous peptides secreted by the osteoblast, including proteoglycans (chondroitin sulfate, heparan sulfate), glycoproteins, growth stimulating proteins (BMP, TGF β , IGF-I), cell attachment peptides (integrin ligands—osteopontin, osteonectin, fibronectin), and Gla proteins or proteins derived from serum, for example, albumin.¹⁸⁷ Macromolecular proteoglycans are composed of glycosaminoglycans (acidic polysaccharide side chain) linked to a core protein and are important for normal synthesis of collagen and bone development. Osteonectin (encoded by SPARC) is a phosphorylated, 32-kDa glycoprotein that binds to Ca²⁺ in hydroxyapatite and to collagen fibrils enabling calcification of bone matrix. Bone alkaline

phosphatase is an isoform of tissue nonspecific alkaline phosphatase (encoded by *ALPL*), an 80-kDa glycoprotein essential for bone mineralization. Osteopontin (also termed *bone sialoprotein* or *secreted phosphoprotein 1* and encoded by *SPPI1*) is a 75-kDa sulfated and phosphorylated glycoprotein that contains the amino acid sequence — Arg-Gly-Asp (RGD) — necessary for linkage to integrins and hence for attachment of osteoclasts to bone; it also binds Ca^{2+} and hydroxyapatite and may play a role in the initiation of bone matrix mineralization. Osteopontin is secreted by osteoblasts in response to

calcitriol. Osteocalcin (encoded by *BGLAP*) is a 49 AA, Gla-containing 6-kDa peptide that plays an essential role in bone mineralization; it is produced only by osteoblasts in response to BMP-7 and calcitriol acting through RUNX2, whereas its posttranslational synthesis is dependent upon vitamin K.

Bone Formation and Mineralization

Bone is composed primarily of solid mineral [hydroxyapatite = $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$] that has been deposited on collagen fibrils

within extracellular matrix.²³² Bone extracellular matrix is comprised of the secreted products of the osteoblasts and is composed of collagenous fibrils (collagen types—I, III, V) upon which the mineral phase of bone is deposited. Type I collagen and alkaline phosphatase promote bone mineralization, a process modulated by vitamin K-dependent osteocalcin (encoded by *BGLAP*) and matrix Gla protein (encoded by *MGP*). Long bones consist of a central hollow shaft (diaphysis) distal to which are the metaphyses, cartilaginous growth plates, and epiphyses. The diaphysis is composed of cortical bone, and the metaphysis/epiphysis consists of trabecular bone enveloped by cortical bone. Some 80% of the adult skeleton is dense cortical bone; 20% is cancellous and composed of a network of trabeculae.

The skeleton is essential for posture and movement, shielding of vital organs, formation of all blood cells, and reservoir of the bone minerals (calcium, phosphate) quintessential for cellular function.¹⁹⁰ Very early in the first trimester the outlines of the future skeleton are present as patterns of cartilaginous anlagen that later form the long bones and skull base and undifferentiated mesenchymal fibers that condense to become membranous bone (face, skull, pelvis, clavicles). Bone modeling or ossification of these anlagen begins approximately 5 to 6 weeks after conception. Initially, mesenchymal stem cells differentiate into chondroblasts (and evolve into chondrocytes) or osteoblasts, some of which develop into osteocytes and bone lining cells, whereas osteoclasts derive from hematopoietic stem cells. The bulk of the skeleton forms from cartilage. Mesenchymal stem cells that differentiate into prechondroblasts then become chondroblasts that further develop into prehypertrophic and later into hypertrophic chondrocytes. The chondrocyte produces cartilage—an avascular matrix encased in a perichondrial membrane that is composed of collagen types II and X, hyaluronic acid, and chondroitin sulfate. When the chondrocytes in the midshaft of the long bone outgrow their available nutrients (supplied by diffusion through the cartilage matrix), they undergo apoptosis and necrosis permitting vascular invasion of this site from the periphery and inward movement of chondroclasts and osteoblasts. While the debris of apoptotic chondrocytes and cartilage matrix is being cleared, osteoblasts form a primary ossification center and begin to secrete collagen type I and associated bone matrix proteins, express alkaline phosphatase on their surface, and initiate deposition of calcium and phosphate later reconstituted into hydroxyapatite crystals. A periosteum forms and secondary ossification centers develop at the distal ends of the long bones (the epiphyses) separated from the primary ossification center by replicating chondrocytes in the epiphyseal growth plate (see Fig. 9.9). Ossification of membranous bones begins with gathering of pluripotential mesenchymal stem cells into an ossification center and their differentiation into preosteoblasts and then osteoblasts that secrete bone matrix—primarily composed of collagen type 1 into which calcium and phosphate are deposited as hydroxyapatite. Further differentiation leads to development of a periosteum beneath which develops a thin veneer of compact bone deep to which is cancellous or trabecular bone.

Although calcium and phosphate are co-stored in extracellular and intracellular fluid compartments, they are prevented from precipitating by inhibitors of their association such as polyphosphates (polymeric groups of phosphate anions linked together by oxygen bridges in linear chain or cyclic ring structures the first member of which is pyrophosphate composed of two phosphate groups linked by an oxygen bridge), organic ion chelators (oxalate, citrate), and skeletal proteins (e.g., osteocalcin and osteopontin, a SIBLING protein with the ASARM sequence).⁷ Pyrophosphate is generated by ectonucleotide pyrophosphatase/phosphodiesterase 1 (encoded by

ENPP1) mediated cleavage of nucleotides. Controlled formation and deposition of calcium and phosphate into the extracellular matrix of cartilage (composed of collagens type II and X) and then into the hydroxyapatite lattice in bone matrix (collagen type I) occurs as the inhibitors of biomineralization are degraded locally. In the first phase of bone formation, hypertrophic chondrocytes and osteoblasts initiate bone crystal formation by forming 100-nm subsurface matrix vesicles containing calcium, phosphate, TNSALP, calbindin-D_{9k}, CA, pyrophosphatases, osteocalcin, and osteopontin. After initial precipitation of calcium and phosphate as amorphous calcium phosphate within the matrix vesicles themselves and fusion of the vesicular and cell membranes, the precipitate is extruded into the extracellular matrix where further increases in local concentrations of phosphate and calcium, together with the structural properties of collagen type I, direct the formation of the hydroxyapatite crystal. TNSALP, synthesized by chondrocytes and osteoblasts, is tethered both to the interior of the matrix vesicle and to the exterior of the osteoblast plasma membrane. After pyrophosphate and other polyphosphates have been transported into the extracellular matrix, TNSALP removes their inorganic phosphate moieties, thereby increasing local phosphate concentrations and promoting hydroxyapatite formation and deposition in bone. Another phosphatase (encoded by *PPP1R1B*) also raises local levels of phosphate by releasing this anion from phosphoethanolamine and phosphocholine.

Inhibitors of bone mineral formation include osteopontin (*SPP1*) and matrix Gla (*MGP*). The function of osteopontin (a SIBLING protein with an ASARM sequence that binds to hydroxyapatite and inhibits deposition of mineral) is partially dependent upon the extent of its phosphorylation. Thus when 40% of the phosphorylation sites of osteopontin are phosphorylated bone mineralization is inhibited; however, when 95% of its sites are phosphorylated hydroxyapatite formation is promoted.^{187,233} Matrix Gla is an 84 AA, vitamin K-dependent peptide containing Gla (related to but distinct from osteocalcin) that has great affinity for Ca²⁺ and inhibits precipitation of calcium and phosphate; *MGP* is expressed in arteries and chondrocytes but not in osteoblasts; thus a normal function of *MGP* is to prevent calcification of cartilage; accordingly, in patients with biallelic loss-of-function mutations in *MGP*, there is extensive calcification of cartilage (Keutel syndrome, OMIM 245150).

Bone strength is determined by its size (height, width, depth), mineral mass, macro- and microarchitecture, and material properties (e.g., elasticity) of collagen that in turn are regulated not only by endocrine hormones and paracrine growth factors but also by mechanical forces exerted upon the skeleton by the environment (gravity), erect stance, and movement using the muscular system.^{194,234,235} Bone mass and strength are determined in part by the loads placed on bone by biomechanical forces exerted by muscles—the “mechanostat” model. In this model, osteocytes monitor the stresses and strains (deformations) that are the result of mechanical forces placed upon it. In response to mechanical force: (1) the osteocyte rate of apoptosis declines, (2) the osteocyte synthesizes less sclerostin, (3) the rate of WNT1-stimulated bone formation increases, and (4) stromal cells decrease their expression of RANK-ligand, thereby (5) slowing the rate of osteoclastogenesis. In addition, in response to mechanical stress, multiple growth factors generated by the osteoblast (FGFs, IGF-1, TGFβ) act in autocrine/paracrine manners upon their respective tyrosine kinase receptors expressed in the cell membrane of the osteoblast to activate multiple intracellular signals, including the adenylyl cyclase, PKA, PKB, PI3K, and MAPK signal transduction pathways. Generation of PLC leads to increase in cytosolic Ca²⁺ and osteoblast function as does influx of Ca²⁺ through transmembrane L-type calcium

channels.²³⁶ One of the target genes affected by mechanical stimulation is *RUNX2* whose transcript is essential for osteoblast differentiation and expression and synthesis of osteoblast-specific proteins. Repetitive bone strain (an applied deforming force that might be compressive, lengthening, or angulating) leads to enhanced quantity and quality of bone (bone strength). The mechanisms that lead to increased bone mass are inactivated by decreased weight bearing, such as immobilization or decreased gravity (e.g., space flight) and lead to bone loss (“disuse osteoporosis”). Although bone strength is in part dependent on bone mineralization, it is the size and integrity of bone that primarily determine its strength.²³⁷ Clinically, this paradox is illustrated by the increased rate of fractures in children with osteopetrosis or “marble bone disease” despite extremely dense bones with thick cortices and trabeculae.

Bone mineralization begins in utero with most calcium being deposited in the third trimester and progresses through childhood and puberty.³⁰ The skeleton accumulates 25 to 30 g of calcium in utero and accrues approximately 2500 g by adulthood. Bone mass increases throughout childhood and as puberty progresses and continues in the third decade of life. By 7 years of age, children have achieved approximately 70% of adult stature but have accumulated only approximately 35% of maximal whole-body bone mineral content.²³⁸ Approximately one-half of the skeleton mass is formed during puberty, and differences in bone mass between teenagers of similar genders and races is attributable to the velocity of sexual maturation as influenced by changes in secretion of GH, estrogens, and androgens during this phase of life.²³⁹ The rate of gain of bone mass is greatest 6 months after the peak height velocity of puberty has been achieved; the older the chronological age that the pubertal peak growth velocity is realized, the lower is peak adult bone mass. Females have lower peak bone mass than do males because of the smaller size of their bones, accounting in part for the greater number of vertebral fractures in adult females than in adult males. The average total body BMC of the adult male approximates 2800 g and of the adult female 2200 g with greater values in black than white individuals. Approximately 60% of total adult bone calcium is acquired during adolescence—25% in the 2 years before and after the peak velocity of BMC accrual; 30% of the mean BMC of the adult female lumbar spine (60 g) is deposited during this interval. In both males and females, peak bone mass achieved in young adulthood is inversely related to the age of pubertal onset.^{240,241}

Optimal bone mineralization requires good health and adequate nutrition—particularly intake of calcium and vitamin D, normal linear growth and weight gain, and frequent weight-bearing exercise as these increase periosteal bone mass.²³⁹ Recommended dietary intakes of calcium and vitamin D for children and adolescents are presented in Table 9.2. Calcium supplementation is usually unnecessary in the well child/adolescent; high intake of carbonated beverages should be discouraged as they lower intake of milk and calcium. Vitamin D supplementation has been recommended for breastfeeding infants, but older well children are usually able to consume sufficient vitamin D in a healthy diet and synthesize cholecalciferol endogenously if exposed to sufficient sunlight; vitamin D supplementation during winter months is appropriate for all children if exposure to sunlight is curtailed, as it is for children with malabsorption syndromes, those receiving anticonvulsant drugs or antiretroviral agents.³⁰

As evidenced by the close concordance of bone mineral status between mothers and daughters, identical and fraternal twins and siblings, 60% to 80% of the peak or maximum adult bone mass is determined by genetic factors. Thus an individual's expressed genetic composition exerts a substantial effect

on accrual of bone and the peak BMD achieved.²⁴¹ Genome-wide association studies have identified many genes that influence bone mineralization.^{241–243} Those that are related to the WNT- β -catenin osteoblast differentiation pathway are among the most prominent in this regard. Although many of these genes are involved in bone metabolism, others have not been known heretofore to be related to skeletal homeostasis. In addition to intrafamilial factors, ethnicity, sex, and body size and composition are important determinants of bone density. In black male and female youths, there is higher whole body less head BMC and areal (a) BMD and lumbar spine, one-third radius, total hip, and femoral neck BMC and areal BMD than in white, Asian, or Hispanic youth (Tables 9.6 and 9.7).^{239,244,245} Asian female children and adolescents have lower whole-body and femoral neck BMD than do white and Hispanic subjects. Hispanic males have lower lumbar spine BMD than do white and Asian youth. Radial and femoral neck (peripheral) and vertebral (axial) BMDs correlate with sex, age, height, weight, BMI, pubertal and postpubertal hormonal status, calcium intake, and exercise in children, adolescents, and adults. In young women only 16% to 21% of peak vertebral and femoral bone mass can be accounted for by weight, height, physical activity as an adolescent, and the VDR genotype emphasizing the essential roles of multiple factors in this process. Because adult peak bone mass is inversely related to the risk of osteopenia and osteoporosis in later adulthood (in adults, a 10% increase in BMD reduces the risk of femoral neck fracture by 50%), it is essential that bone mass be maximized during childhood and adolescence.

The rate of accumulation of bone mass increases during puberty, and peak bone mass is achieved early in the third decade of life; calcium intake accounts for perhaps 5% of accrued peak bone mass whereas exercise may contribute 10% to 22% of peak bone mass and is, therefore, one of the factors that can be modified in the pursuit of the goals of attaining and maintaining maximum peak bone mass.²⁴⁶ Thirty minutes of programmed weight-bearing exercise thrice weekly increases BMC of the femoral neck and lumbar spine in prepubertal boys and girls as may resistance training of moderate intensity performed 20 to 40 minutes once or twice per day 5 days per week; high-impact, weight-bearing exercises (ballet, tennis, volleyball, gymnastics, jumping, running, soccer, rugby, ice hockey) increase mass of weight-bearing bones, particularly in children and adolescents, an effect that may long outlast the period of exercise itself.²⁴⁶ Weight-bearing and high-impact exercises do so in part by augmenting periosteal bone acquisition and increasing the cortical thickness of long bones, particularly of the legs at their most distal extremes closest to the ground where weight bearing is maximal. At peak BMC velocity, the annual gain and total accumulation (>2 years) of total body bone mineral in active boys and girls are 80 g/year and 120 g/year, respectively, greater than in inactive adolescents. One year after peak BMC velocity, the total body, femoral neck, and lumbar spine BMCs are 9% to 17% greater in active than in relatively inactive subjects. Even greater normal activity (such as walking longer distances to school) convey long-lasting salutary effects on bone mineralization and later fracture risks.²⁴⁷ The effects of diminished physical activity on bone growth and strength are clearly illustrated by children with neurological insults that prevent normal motion (Erb paresis, hemiplegia, spinal cord insults) and thus restrain limb growth. An abrupt decrease in the mechanical load on bone (e.g., bed rest, space flight) evokes rapid loss of bone mineralization as the rate of bone formation declines whereas that of bone resorption is maintained. In patients with limited physical activity because of neurological or muscular insults, bone density may be increased by high frequency, low amplitude mechanical stimulation.²⁴⁶

Hormonal Regulation of Bone Mineralization

PTH; PTHrP; calcitriol; thyroid hormone; interleukins-1 β , -3, -6, and -11; TNF- α ; PGE₂; and glucocorticoids stimulate expression of RANK-ligand and M-CSF and depress that of osteoprotegerin and hence favor osteoclast development and bone resorption. Calcitonin; estrogens; androgens; interferon- γ ; interleukins-4, -10, and -18; TGF β ; and bisphosphonates antagonize these processes. Calcitonin acting through its GPCR dissociates the processes of bone resorption and bone formation by transiently depressing the bone-resorbing activity of osteoclasts; it does so by impeding formation of the ruffled membrane. Although osteoclasts do not express *PTH1R*, PTH¹⁻⁸⁴ enhances osteoclastogenesis by stimulating osteoblast and stromal cell production of RANK-ligand. However, when PTH¹⁻³⁴ is administered intermittently, it increases osteoblast activity and the rate of bone formation and slows the rate of osteoblast apoptosis, functioning in part through IGF-I. Carboxyl-terminal fragments of PTH¹⁻⁸⁴ can inhibit osteoclast formation and function and antagonize the osteoclast stimulating effects of PTH¹⁻⁸⁴, calcitriol, prostaglandins, and interleukins.⁸⁶

After binding to its receptor, pituitary GH enhances the differentiation and proliferation of chondrocytes and osteoblasts and extends the life of osteoblasts, thereby increasing bone mass and bone size.¹⁶⁰ GH increases the synthesis of BMPs, directly enhances differentiation of prechondrocytes within the resting zone of the cartilaginous growth plate, supports proliferation of chondrocytes in the reserve or resting zone, and increases local expression of *IGF1*. (In osteoblasts, the synthesis of IGF-I is also stimulated by PTH.) GHRs are expressed in chondrocytes in the reserve, proliferative, and hypertrophic zones and mediate chondrocyte proliferation, maturation, and synthesis of IGF-I.²⁴⁸ IGF-I is synthesized predominantly by proliferating chondrocytes; functions through the IGF type 1 receptor expressed in chondrocytes in the reserve, proliferative, and hypertrophic zones; and stimulates the clonal expansion of committed chondrocytes.²⁴⁹ IGF-I coordinates chondrocyte proliferation and inhibits their apoptosis; it modulates their differentiation and maturation and their synthesis of matrix heparan sulfate proteoglycan, a matrix component that is necessary for efficient signaling of FGF and their receptors.²⁵⁰ IGF-binding proteins (IGFBP)-1 through -6 are synthesized by growth plate chondrocytes; they regulate levels of bioactive IGF-I, as well as exert direct stimulatory/inhibitory effects on chondrocyte proliferation depending on the stage of chondrocyte differentiation.²⁵¹ In utero, both IGF-I and -II are essential for normal fetal growth as denoted by the in utero growth retardation experienced by the fetus with a loss-of-function mutation in *IGF1*, *IGF2*, or *IGF1R*.²⁵⁰ Neither GH nor IGF-I is necessary for patterning of the skeleton, however. Systemic loss of GH secretion or IGF-I synthesis or inactivation of their receptors impairs linear growth of long bones postnatally. Experimentally, selective loss of hepatic IGF-I production lowers its total circulating levels to 25% of normal but does not adversely affect growth in transgenic mice, indicating that it is the somatomedin synthesized by the cartilage growth plate that affects chondrocyte division by a paracrine mechanism. In patients with inactivating mutations of *GHR* encoding the GHR or deletion of *IGF1*, administration of IGF-I enhances linear growth, indicating that this growth factor is able to stimulate cartilage proliferation without the initial differentiating effect of GH but does so to a lesser extent than does GH in the GH-deficient subject, indicating that sufficient numbers of differentiated prechondrocytes are necessary for optimal somatomedin effect.²⁵² The GH secretagogue, ghrelin, is also synthesized and secreted by chondrocytes and affects their intracellular metabolism.²⁵³

Through expression of *GHR* by osteoblasts, GH stimulates their differentiation, proliferation and function-enhancing

synthesis and secretion of osteocalcin, bone-specific alkaline phosphatase, and type I collagen. GH also increases synthesis of IGF-I by the osteoblast as do estrogen, PTH, cortisol, and calcitriol. IGF-I is essential for GH-induced osteoblast proliferation in vitro; however, it also decreases expression of *GHR*, whereas estrogen enhances *GHR* expression. IGFBPs modulate activity of both IGF-I and -II; thus, IGFBP-5 binds to bone cells, matrix, and hydroxyapatite and enhances the actions of IGF-I on bone. Expression of *GHR* by the osteoblast is upregulated by IGFBP inhibition of somatomedin activity. GH increases synthesis of RANK-ligand and consequently osteoclastogenesis, osteoclast proliferation, and activity; human osteoclasts also have receptors for IGF-I, which stimulates osteoclast formation and function. IGF-I enhances differentiation of osteoblasts, as well as their function by stimulating the transcription of *COL1A1* and *COL1A2* encoding collagen type I, thereby increasing bone formation. GH also stimulates intestinal calcium absorption (through activation of 25-hydroxyvitamin D-1 α hydroxylase and synthesis of calcitriol) and renal phosphate retention. Interestingly, cortical bone structure is maintained by systemic (hepatic) IGF-I, whereas that synthesized by the skeleton stabilizes trabecular bone. Prolactin enhances bone formation, as well as osteoclastogenesis and bone resorption, the latter by increasing osteoblast production of RANK-ligand.

In children with GH deficiency and adults with childhood-onset or adult-onset GH deficiency, BMC and areal and volumetric BMDs are decreased and increase when GH is administered.²⁵⁴ Administration of GH to the hypsomatotropic patient increases serum and urine levels of markers of bone formation and resorption (e.g., osteocalcin, bone-specific alkaline phosphatase, procollagen type I amino and carboxyl propeptides, pyridinoline, deoxypyridinoline) with maximal values achieved 3 to 6 months after beginning treatment. There is a biphasic response of bone mass during GH treatment of deficient subjects; during approximately the first 6 months of GH administration BMD declines as bone resorption exceeds formation; over the next 6 to 12 months; this value increases steadily. In subjects with inactivating variants of *GHR* or *IGF1*, areal BMD and BMC are decreased, but volumetric BMD is not, suggesting that bone size but not bone mineral acquisition is impaired by isolated somatomedin deficiency. In acromegalic patients there is increased bone turnover, and variably increased lumbar spine and femoral neck BMD and iliac crest cortical and trabecular bone mass.

The thyroid hormones secreted under the control of pituitary thyroid-stimulating hormone (thyrotropin) and hypothalamic thyrotropin-releasing hormone exert major effects upon the chondrocyte, osteoblast, osteocyte, and osteoclast.^{148,160} Thyroxine is the primary product of the thyroid gland, but triiodothyronine is the biologically active thyroid hormone after conversion of thyroxine to triiodothyronine by types 1 and 2 monodeiodinase. The skeletal action of triiodothyronine is mediated by its binding to the cytoplasmic thyroid hormone receptors alpha 1 and beta (TR α 1/ β), transcription factors that translocate to the nucleus, pair with the RXR, bind to the thyroid response element in the 5' region of the target gene, link to corepressor or coactivating proteins, and stimulate or inhibit expression of selected genes. TR α and β are expressed in the reserve and proliferative zones of the growth cartilage. Triiodothyronine acting primarily through TR α 1 enables the differentiation of resting chondrocytes and their entrance into the proliferative phase, but there thyroid hormone inhibits further chondrocyte proliferation and promotes differentiation to terminal hypertrophic chondrocytes and secretion of collagen type X. They do so in part by disrupting the reciprocal interaction between IHH and PTHrP, thereby accelerating chondrocyte maturation, effects mediated by FGFR3 and by

downregulation of *IGF1* expression in chondrocytes.²⁵⁵ Thyroid hormone is essential also for vascular invasion of the growth plate's hypertrophic zone and induction of metaphyseal trabecular bone formation. Triiodothyronine stimulates osteoblast differentiation and proliferation and synthesis of osteocalcin, type I collagen, and alkaline phosphatase. In osteoblasts, TR β mediates intracellular nongenomic, rapid responses to triiodothyronine through activation of the PI3K signal transduction pathway and other routes. Thyroid hormone enhances bone resorption, but it is unclear if this a direct or indirect effect upon osteoclasts.^{148,160}

Thyroid hormones are necessary for fusion of the epiphyseal cartilage plate, although fusion may occur in the absence of thyroid hormone through estrogenic action. Through osteoblast-expressed receptors for thyroid hormone, triiodothyronine increases osteoblast production of osteocalcin, bone-specific alkaline phosphatase, and IGF-I. Thyroid hormones increase the rate of bone remodeling by expanding the number of osteoclasts and sites of bone resorption and the amount of bone resorptive surface; urinary calcium excretion is increased by thyroid hormones; in excess, thyroid hormones lead to net bone loss. Thyroid-stimulating hormone may directly impede osteoclast formation and bone resorption by reducing osteoblast expression of RANK-ligand and advance bone formation by enhancing WNT-mediated osteoblastogenesis.²⁵⁶

Estrogen and androgens promote chondrocyte maturation.²⁵⁷ Although many of the effects of androgens are mediated by their conversion to estrogens, nuclear androgen receptors are expressed by chondrocytes, and nonaromatizable androgens stimulate chondrocyte proliferation and long bone growth. Estrogens acting through estrogen receptors α and β (ER α , ER β) expressed in chondrocytes exert a biphasic effect on chondrocyte proliferation—increasing its rate at low doses and reducing it at higher levels; by decreasing chondrocyte proliferation and accelerating the rates of chondrocyte maturation, senescence, and apoptosis, estrogens lead to epiphyseal fusion.²⁵⁸ Complete maturation and fusion of the growth plate are mediated primarily by estrogens, as evidenced by the failure of growth plate fusion in young adult males with inactivating mutations of the genes encoding aromatase (the enzyme that converts androgens to estrogens) or ER α despite adult levels of testosterone and estrogen. Chondrocytes may also be capable of synthesizing estrogens from androgens as aromatase activity has been found in growth plate chondrocytes.²⁵⁷ This observation suggests that locally produced, as well as systemic estrogens, may contribute to chondrocyte maturation and growth plate fusion. Estrogens acting directly and indirectly upon osteoclasts through ER α maintain and augment bone mass, by inhibiting its dissolution, by suppressing T-cell production of osteoclast activating cytokines, such as interleukins-1 and -6, and TNF- α and by suppressing expression of RANK-ligand and increasing that of TGF- β . In addition, estrogens interfere with RANK-ligand/RANK stimulated intracellular signal transduction through the MAPK pathway and downregulate expression of genes encoding integrins thus impairing bone resorption.¹⁹⁷ Both estrogens and androgens depress the rates of apoptosis of osteoblasts and osteocytes. Androgens primarily promote mineralization by conversion to estrogens, as evidenced by the osteopenia noted in adult males with aromatase deficiency or loss-of-function mutations in the gene encoding ER α .²⁵⁹ Androgens also have a direct effect on bone mineralization; acting through the androgen receptor, they increase periosteal bone growth during puberty in both males and females; however, the stronger bones of men compared with women reflect not increased volumetric BMD but rather increased bone size because of greatly expanded periosteal bone width.²⁶⁰ Increased periosteal bone width in males is caused in part by the androgen-induced effect of increased

muscle mass, strain, and mechanical loading on bones.²⁶¹ Nevertheless, estrogens too are necessary for normal periosteal bone growth as despite normal testosterone secretion the aromatase-deficient adult male has decreased periosteal bone width, a situation that can be reversed by administration of estrogen. Thus gonadal sex hormones increase bone growth, maturation, and mineralization. At moderately high (menopausal) concentrations, follicle-stimulating hormone enhances osteoclast formation and decreases its rate of apoptosis, thereby increasing the rate of bone resorption.²⁵⁶

That sex hormones play major roles in the accretion of bone mineral in both females and males is evidenced by the increase in bone mineralization that occurs during puberty. The bulk of adult bone calcium stores are deposited during puberty when the peak rate of accrual of total body BMC occurs in boys and girls 0.7 years after attainment of peak height velocity (PHV) and 0.4 to 0.5 years after peak accrual of lean body mass (a surrogate measurement of muscle mass).²⁶² After controlling for size, the rate of total body and femoral neck accrual of bone mineral over the 2 years encompassing the PHV are greater in males than females; there is no gender effect on accrual of BMC of the lumbar spine, however. Both androgens and estrogens markedly influence rates of bone formation and resorption, although it is the effect of estrogen that predominates as evidenced by: (1) the marked osteopenia of adult males with androgen sufficiency but estrogen deficiency related to loss-of-function mutations in the genes encoding aromatase and ER α , (2) the beneficial effects of estrogen but not of testosterone upon bone mineralization in males with aromatase deficiency, (3) the very close association of BMD and serum levels of bioavailable estrogen in elderly men, and (4) the significant correlation in adult men treated with testosterone between changes in bone mineralization and increases in serum concentrations of estradiol but not of testosterone.²⁵⁸ Nevertheless, the osteopenia of adult (46XY) females with complete androgen insensitivity because of loss-of-function mutations of the X-linked androgen receptor, despite elevated serum testosterone and (endogenous or exogenous) estradiol concentrations, indicates that androgens, too, increase bone mineralization. Furthermore, nonaromatizable dihydrotestosterone has a direct anabolic effect on bone, as it stimulates the proliferation and maturation of osteoblasts, increases the production of procollagen I(α 1), and prevents bone loss in orchidectomized rats.

Estrogens increase bone mass primarily by suppressing bone resorption; they do so through inhibition of osteoclastogenesis and downregulation of osteoblast production of osteoclast activating factors, such as interleukin-6 (and its receptor), TNF- α , and M-CSF, increasing production of osteoprotegerin, and accelerating apoptosis of mature osteoclasts. Estrogens also prolong the life span of osteoblasts and osteocytes. During adolescence in the female, not only does the rate of bone deposition increase but that of bone resorption declines. There is maturation-related increase in BMC and areal and volumetric BMD and in metacarpal length, width, and cortical thickness. Data suggest that the pubertal increase in production of GH and IGF-I mediates, in part, longitudinal and periosteal skeletal growth and mineral acquisition during puberty.

Cortisol acts directly on chondrocytes, osteoblasts, osteocytes, and osteoclasts to affect cartilage and bone formation, remodeling, and dissolution.^{160,263} Glucocorticoids act through cytoplasmic receptors that translocate to the nucleus, form homodimers, and bind to specific 5' response elements in designated genes.²⁶⁴ The nuclear glucocorticoid receptor is expressed in proliferative and hypertrophic chondrocytes where cortisol inhibits chondrocyte proliferation, growth, synthesis of cartilage matrix, and maturation, but it also delays senescence of the growth plate, thereby permitting "catch-up"

growth when excess glucocorticoid exposure is temporary.^{265,266} Glucocorticoids depress expression of *GHR*, *IGF1*, and *IGF1R* in growth plate chondrocytes and, by regulating synthesis of IGF-BPs, they indirectly decrease the biological function of IGF-I. Paradoxically, glucocorticoids also increase expression of *SOX9* and the earliest phase of chondrocyte differentiation. Thus glucocorticoids exert dual but opposing effects on skeletal biology.²⁶⁴ In physiological amounts, glucocorticoids stimulate differentiation of osteoblasts from mesenchymal stem cells in part by inhibiting their differentiation into adipocytes. However, they also increase the rates of autophagy and apoptosis of osteoblasts and osteocytes, thereby decreasing their life span. Glucocorticoids stimulate osteoblast and osteocyte synthesis of osteocalcin, alkaline phosphatase, and sclerostin, the latter an antagonist of WNT/ β -catenin signaling and osteoblast differentiation. Excessive amounts of glucocorticoids impede osteoblastogenesis and accelerate osteoblast apoptosis by reducing expression and accelerating proteasomal degradation of *CTNNB1* (encoding β -catenin) and other osteoblast differentiating genes and increasing endoplasmic reticulum stress, thereby reducing the rate of bone formation, a process that may be impeded by calcitonin and bisphosphonates.

Glucocorticoids accelerate osteoclastogenesis by increasing expression of *TNFSF11* (RANK-ligand), which enhances osteoclastogenesis and osteoclast activation and by depressing expression of *TNFRSF11B* and hence the synthesis of osteoprotegerin, the endogenous antagonist of RANK-ligand.¹⁹⁷ They also prolong the life span of the osteoclast, further enhancing bone resorption. Physiological quantities of glucocorticoids have no substantial effect on osteoclast differentiation, function, or longevity. In excess, glucocorticoids also prolong the life span of the osteoclast further enhancing bone resorption. The overall effect of glucocorticoids on bone is to reduce the rate of trabecular bone formation and to increase the tempo of endocortical bone resorption. Other effects of glucocorticoids relative to bone formation include inhibition of calcium absorption by the intestine and enhancement of calcium excretion by the kidney, suppression of GH secretion and synthesis of IGF-I, decrease in muscular strength and hence of the mechanical forces exerted on the skeleton; and alteration of metabolic pathways that impinge on bone metabolism (e.g., obesity, glucose intolerance).

Transcripts of C-type natriuretic peptide (CNP, encoded by *NPPC*) and natriuretic peptide receptor 2 (encoded by *NPR2*), a guanylyl cyclase B, are expressed by chondrocytes. This ligand-receptor complex stimulates the growth of proliferative and hypertrophic chondrocytes, enhances osteoblast function, and induces endochondral ossification by generation of intracellular cyclic guanosine monophosphate (cGMP) and subsequent activation of the MAPK signal transduction pathway.²⁶⁷ CNP increases the thickness of the growth plate by enlarging chondrocyte size, but it does not affect differentiation of chondrocytes. Natriuretic peptide receptor C/3 (*NPR3*) lacks an intracellular domain but links to CNP and increases its clearance and that of other circulating natriuretic peptides. Osteocrin (*OSTN*) is a 133 AA peptide secreted by bone cells that competes with CNP for binding to NPR C/3, thus slowing its rate of clearance and prolonging its biological activity.²⁶⁸ Plasma concentrations of the amino-terminal pro-C-type natriuretic peptide are positively related to growth velocity in normal children and adolescents.²⁶⁹ Biallelic loss-of-function mutations in *NPR2* have been identified in patients with acromesomelic dysplasia—Maroteaux type (OMIM 602875), manifested by shortening and deformation of the forearms, forelegs, and vertebrae, resulting in severely compromised adult stature. Heterozygous inactivating mutations of *NPR2* have been recorded in subjects with short stature and nonspecific skeletal abnormalities (OMIM 616255).

Monoallelic gain-of-function mutations in *NPR2* have been associated with Miura type epiphyseal chondrodysplasia (OMIM 615923) manifested by tall stature, scoliosis, and enlargement of the great toes.

Another factor to which bone mass is closely related is body weight. Using data of 8348 children and adolescents who underwent studies of areal BMD and body composition by dual energy x-ray absorptiometry (DXA), a decline in whole-body and lumbar spine areal BMD with increasing percent body fat in both males and females of diverse ethnicities (white/non-Hispanic, African American/non-Hispanic, Hispanic, other ethnicities) has been recorded, whereas the effect of weight on pelvic areal BMD was more variable.²⁷⁰ Chondroblasts, osteoblasts, and adipocytes arise from a common mesenchymal stem cell and can be interconverted depending upon the transcription factor that is expressed in the stem cell (e.g., PPAR γ promotes adipogenesis); consequently, the fat cell synthesizes and secretes several adipokines that may affect bone development. Among these products is leptin (encoded by *LEP*), a 16-kDa protein with anorexigenic properties that acts within the ventromedial hypothalamic nucleus to depress appetite, increase the rate of energy utilization, enable fertility by enhancing gonadotropin secretion, and regulate thyrotropin secretion. Leptin acting through leptin receptors expressed by mesenchymal stem cells stimulates their differentiation into osteoblasts by inhibiting their transformation into adipocytes; leptin increases osteoblast proliferation, prolongs osteoblast life span, and assists their maturation into preosteocytes; leptin enhances synthesis of collagen type 1 and mineralization.^{271–273} Leptin also impairs osteoclast development by enhancing the expression of *TNFRSF11B* and synthesis of osteoprotegerin while decreasing that of *TNFSF11* encoding RANK-ligand.²⁷¹ However, leptin also acts indirectly upon the skeleton. Within the central nervous system, leptin is linked to osteoblasts through the sympathetic nervous system; mediated by the β_2 -adrenergic receptor expressed on the osteoblast cell membrane, leptin-stimulated increase in sympathetic input both inhibits osteoblast proliferation, hence decreasing bone formation, and increases osteoblast expression of *TNFSF11*, thereby favoring osteoclastogenesis.^{272,273} The dual central actions of leptin upon appetite and bone accrual may thus link the processes of energy metabolism and bone accretion.

Adiponectin (encoded by *ADIPOQ*), a 28-kDa product of the white adipocyte whose plasma values are inversely related to visceral fat mass, stimulates osteoclastogenesis by inducing osteoblast expression of *TNFSF11* and inhibiting that of its antagonist *TNFRSF11B*.^{271,274} However, acting through the sympathetic nervous system, adiponectin exerts the opposite effects, for example, suppression of *TNFSF11* expression and osteoclastogenesis and enhancement of osteoblastogenesis and bone mineralization.²⁷¹ Indeed, experimental loss-of-function mutations in *ADIPOQ* are associated with increase in bone mass.²⁷⁵ The storage site of fat within the body—subcutaneous, intraabdominal (visceral), bone marrow—also appears to influence bone mineralization. Thus subcutaneous adipose tissue has a positive effect and visceral adipose tissue a negative influence upon bone formation and size, cortical and trabecular bone mineral densities, and strength. Within bone marrow, the relative rates of differentiation of mesenchymal stem cells into either adipocytes or osteoblasts appears to influence bone mass.

Assessment of Bone Quality, Mass, and Strength

Evaluation of bone mineralization is indicated in children and adolescents with nontraumatic (low-impact—e.g., a fall from her/his standing height or less) or frequent fractures (two or more fractures before age 10 years, three or more fractures

between 11–19 years of age) or whenever a fracture of a vertebra occurs without local disease or high-energy trauma. Indeed, development of a vertebral fracture without local disease or high-energy trauma are criteria for the diagnosis of osteoporosis in a child or adolescent.²⁷⁶ Prospective evaluation of bone mineralization is also appropriate in patients with primary (e.g., osteogenesis imperfecta) or secondary bone disease, such as suboptimal nutrition (anorexia nervosa, cystic fibrosis, celiac disease or other malabsorptive illness) or disease-related risk factors (e.g., inflammatory bowel or joint disease, longer than 3 months exposure to therapeutic doses of glucocorticoids, GH deficiency, hypogonadism, immobility, e.g., cerebral palsy or myopathy, systemically treated childhood cancer survivors).²⁷⁷ Evaluation commences with historical review, documentation of physical findings (height, limb length, presence/absence of skeletal deformities) and appropriate laboratory studies (measurement of serum and urinary levels of calcium, phosphate, alkaline phosphatase, creatinine, PTH, and calcidiol together with other clinically appropriate analytes), and skeletal roentgenograms (radiogrammetry). If skeletal survey suggests abnormal mineralization, further evaluation is warranted. There are several invasive/noninvasive methods that may be used to evaluate bone mineralization, including direct assessment by bone biopsy and histomorphometric analysis of bone formation and resorption.^{278,279} Undecalcified transiliac biopsies permit limited assessment of bone modeling (changes in bone size, shape, mass) but detailed analysis of remodeling (bone renewal) as the iliac crest biopsy is primarily composed of trabecular bone with a circumscribed amount of cortical bone. During bone modeling, osteoblasts and osteoclasts are active on opposite bone surfaces across from one another. Thus the bone surface may change position, size, or mass during the modeling process. Usually modeling is associated with gain in bone mass as the rate of osteoblastic deposition of bone is more rapid than is the rate of osteoclastic resorption. During bone remodeling, osteoclastic resorption of bone is followed by osteoblastic replacement of the reabsorbed bone at the same surface with a net change of zero in bone mineral at the remodeling site under normal circumstances. Histomorphometry enables quantitation of structural parameters of bone size and amount (cortical width, trabecular number and thickness); static bone formation (thickness and surface of osteoid or unmineralized bone matrix, osteoblast surface); dynamic bone formation after labeling with a fluorochrome, such as tetracycline (mineral apposition and bone formation rates); and static resorption (osteoclast number and appearance and extent of eroded surfaces). Iliac trabecular thickness but not trabecular number increases substantially between 2 and 20 years of age, whereas remodeling activity peaks in young children, declines, and then increases again during puberty.²⁷⁸ Compact or cortical bone (present in the shafts of long bones and in the outer layer of vertebral bone) has a complex system of osteons (layers or lamellae of bone surrounding Haversian canals through which pass the intraosseous vasculature), lacunae in which the osteocytes reside, and canaliculi—passageways in bone through which extensions of osteocytes interconnect with one another, as well as osteoblasts and bone lining cells.^{280,281} Using small sections of excised bone examined by x-ray microcomputed tomography, it is possible to quantify several cortical bone microstructural components, including cortical porosity (the volume of the intracortical canals) and the diameter, separation, connectivity density, and canal surface to tissue volume of the intracortical canals.²⁸⁰ In normal children, there is a negative correlation between cortical porosity and BMD. “Noninvasive bone biopsy” is also achievable with the use of high-resolution peripheral quantitative computed tomography (HRpQCT) that permits construction of microfinite element models of bone strength, thus enabling quantitation of both cortical and trabecular bone dimensions.^{223,282} Micromagnetic

resonance imaging (μ MRI) is also a noninvasive technique that allows “virtual bone biopsy.”²⁸³

Noninvasive methods of assessment of skeletal mineralization besides skeletal roentgenograms include radiographic absorptiometry or photodensitometry, single photon or single x-ray absorptiometry, dual photon or DXA, spinal and peripheral quantitative computed tomography (pQCT), HRpQCT, quantitative ultrasonography (QUS), high-resolution quantitative MRI, quantitative μ MRI, and magnetic resonance microscopy.^{237,284} Automated radiogrammetry uses a standard radiograph of the hand measuring the dimensions of its metacarpals enabling calculation of cortical thickness, bone length, and bone width and predictions of bone fragility.

The most commonly used method for two-dimensional assessment of bone mineralization is DXA (Tables 9.6 and 9.7). The ratios of attenuation of x-rays of two energies (70 kV, 140 kV) traversing the same pathway through the patient reflect the “density” and mass of the tissue through which the x-rays have crossed; computer analysis of these captured energies then reconstructs the boundaries, density, and mass of the tissue. Because of variability between DXA instruments and analytical software programs (pediatric, adult) used, the report of the DXA scan should include not only the recorded data but also the type of DXA instrument and the software version used for analysis. This procedure provides two-dimensional densitometric analysis of cortical plus trabecular BMC (g) and areal BMC (g/cm^2). The microarchitecture of bone is a determinant of bone strength that is measured in part by assessment of the trabecular bone score that can be determined by differential analysis of the DXA pattern of radiation absorbed/transmitted by/through cancellous bone sites, primarily composed of trabeculae and their interconnected processes, and intertrabecular spaces (e.g., vertebrae, distal ends of the long bones, skull, ribs). The most useful DXA analyses in children are those that determine whole body minus (–) head (primarily cortical bone) and anterior/posterior lumbar spine vertebrae 1 to 4 (mostly trabecular bone).^{276,277,285} DXA is the most widely used densitometric technique because it is easily accessible, there are many standard data (related to gender, age, ethnicity), the procedure is rapid, and radiation exposure (5–6 μSv) is reasonably low.²⁷⁶

However, DXA does not measure “true” BMD—the mass within a volume of uniform composition that is expressed as grams of hydroxyapatite/ cm^3 (g/cm^3); rather DXA measures the two-dimensional areal or surface mass of mineral within a region of bone of nonuniform composition (cortex, trabeculae, osteoid, marrow); it is expressed as grams of hydroxyapatite/ cm^2 (g/cm^2). Because DXA does not take into account the depth of a bone, it may underestimate BMD in small children and overestimates it in large subjects.²⁸⁶ In children and adolescents, bone size (volume) increases with growth and maturation; the larger the three-dimensional structure of bone, the greater is the recorded areal BMD, even though the actual or volumetric (v) BMD may not change substantially. Therefore calculated or “apparent” (v) BMDs (BMAD) (g/cm^3) data have been generated in an attempt to correct this problem. Volumetric BMD increases as the cortex thickens, the number and width of trabeculae per unit volume rises, and the amount of hydroxyapatite per unit of trabecular volume accrues. Although during childhood and adolescence areal BMD of the femoral shaft increases with age, its vBMD remains relatively constant. Volumetric BMD of the lumbar spine increases in late puberty-early adulthood because of increasing thickness of trabeculae that is not gender specific but is greater in blacks than in whites after puberty.²⁸⁷ Cross-sectional areas of cortical and trabecular bone increase with age, with males achieving greater increase in periosteal apposition than do females during puberty. Cortical cross-sectional area is similar in white and black subjects.²⁸⁸ Heretofore the skull has been included in whole-body

DXA-generated BMD data; however, the skull has twice the BMD of that of the rest of the skeleton; whole-body BMD correlates better with height when the skull is excluded. Consequently, there are reference data for DXA whole-body BMC and BMD with inclusion or exclusion of the skull.^{244,245}

Inasmuch as DXA BMC and BMD values increase with height in both boys and girls, DXA-derived bone mass and density data should be adjusted for height (height age) when interpreting study results in children and adolescents.^{289,290} In the adolescent with markedly delayed skeletal maturation, it is helpful to consider DXA data in relation to skeletal maturation/bone age.²⁷⁷ The BMC and BMD of the total body—head, lumbar spine, hip, femoral neck, and distal one-third of the radius—are the most commonly measured indices of bone mass in childhood by DXA and recorded as g/cm². DXA data are reported as the standard deviation score (SDS) about the mean (SDS = 0) for gender, age, and ethnicity and interpreted individually for height SDS and/or bone age and/or Tanner stage(s) of pubertal maturation and/or body composition.²⁸⁵ Thus data derived from DXA may be “low, normal, or high” relative to the patient’s race, gender, and/or chronological age. These data are reported as a “Z score” using standard deviations about the mean, where Z=0 indicates that the value is at the mean for race, gender, and chronological age. To establish the presence of osteoporosis in a child/adolescence, it has been recommended that there be a history of a low-impact traumatic vertebral fracture in the absence of vertebral disease or two or more long bone fractures and that the total body (minus head) BMC/lumbar spine vertebrae 1-4 by DXA be equal to or below

2 SDs for gender, age, ethnicity, and height ($Z \leq 2.0$). The diagnosis of osteoporosis in a child/adolescent cannot be made on the basis of bone mineralization data alone; use of the term *osteopenia* in children is invalid.^{277,285,291}

In neonates and infants, whole/total body BMC is the primary measurement used to assess bone mineralization by DXA, although data for the lumbar spine and femur are also available (see Table 9.6).^{292,293} In neonates with appropriate weight for gestational age (AGA), whole-body BMC by DXA doubles between 32 and 40 weeks and increases 3.5-fold between birth weights of 1000 and 4000 grams; small for gestational age (SGA) neonates have lower whole-body BMC than do AGA neonates of comparable gestational age but they are similar to those of AGA infants with the same birth weights.²⁹⁴ In term infants, whole-body BMC, lumbar spine, and femur increase 200%, 130%, and 190% by their first birthday.²⁹² Total body—head BMC by DXA increases approximately four-fold between 7 and 17 years of age and is greater in males than females and in black relative to non-black youth (see Tables 9.7A and 9.7B).^{244,245} Lumbar vertebral areal BMD doubles between 7 and 17 years of age in both boys and girls (Tables 9.8A and 9.8B). The BMD of the femoral neck increases 1.5-fold between 7 and 17 years of age in both genders. The BMC of the distal one-third radius approximately doubles and its BMC increases 1.5-fold between 7 and 17 years.^{223,244,245} At all skeletal sites, BMC and BMD assessed by DXA are higher in males than females and in black relative to non-black children and adolescents (Tables 9.8C and 9.8D).^{244,245} In females, the rate of maximal increase in

CA, Age in years; 50th percentile (3rd–97th percentiles).(Modified from Zemel, B.S., et al. (2011). Revised reference curves for bone mineral content and areal bone mineral density according to age and sex for black and non-black children: results of the Bone Mineral Density in Childhood Study. *J Clin Endocrinol Metab*, 96, 3160–3169; Revised 2012; <https://doi.org/10.1210/jc.2012-3878>.)

whole-body BMC occurs in the year of menarche and follows the year of peak height velocity (Fig. 9.16).²⁹⁵ In girls with menarche before 12 years, there is greater peak BMD (at age 18–19 years) than in females with menarche after 14 years. BMD is greater in children with premature adrenarche than in preadrenarchal peers, but appropriate for the tall stature of the adrenarchal subjects.²⁸⁹ In adult males with a history of delayed puberty, there is lower lumbar spine BMD than in those with pubertal onset at 11 to 12 years. DXA measurements of bone mineralization are affected by the composition of soft tissues that surround the axial skeleton; variations in fat about the bone may significantly influence the recorded DXA measurements, thus limiting the use of DXA in extremely thin or obese children.²⁹⁶ In general, BMC, areal BMD, and/or BMAD below -2 SD for age and gender are considered abnormally

low. However, DXA measurements must always be interpreted in relationship to the patient's clinical status, for example, height, pubertal stage.²⁸⁶

There are several other techniques for assessment of bone mineralization.²⁹⁷ Quantitative ultrasonography of the heel, fingers, radius, and ulna avoids radiation exposure and enables measurement of the speed of sound, bone transmission time, and related data.²⁹⁸ Quantitative computed tomography (QCT) and peripheral (p)QCT separately measure the volume of cortical (cancellous) and trabecular bone of the lumbar vertebrae, midshaft of the femur, distal radius, and ulna enabling determination of volumetric BMD (g/cm^3), cross-sectional area of the bone, including cortex and vertebrae, and its periosteal and endosteal surfaces. HRpQCT can provide even finer detail.^{299,300} MRI of the vertebrae and long bones also permits

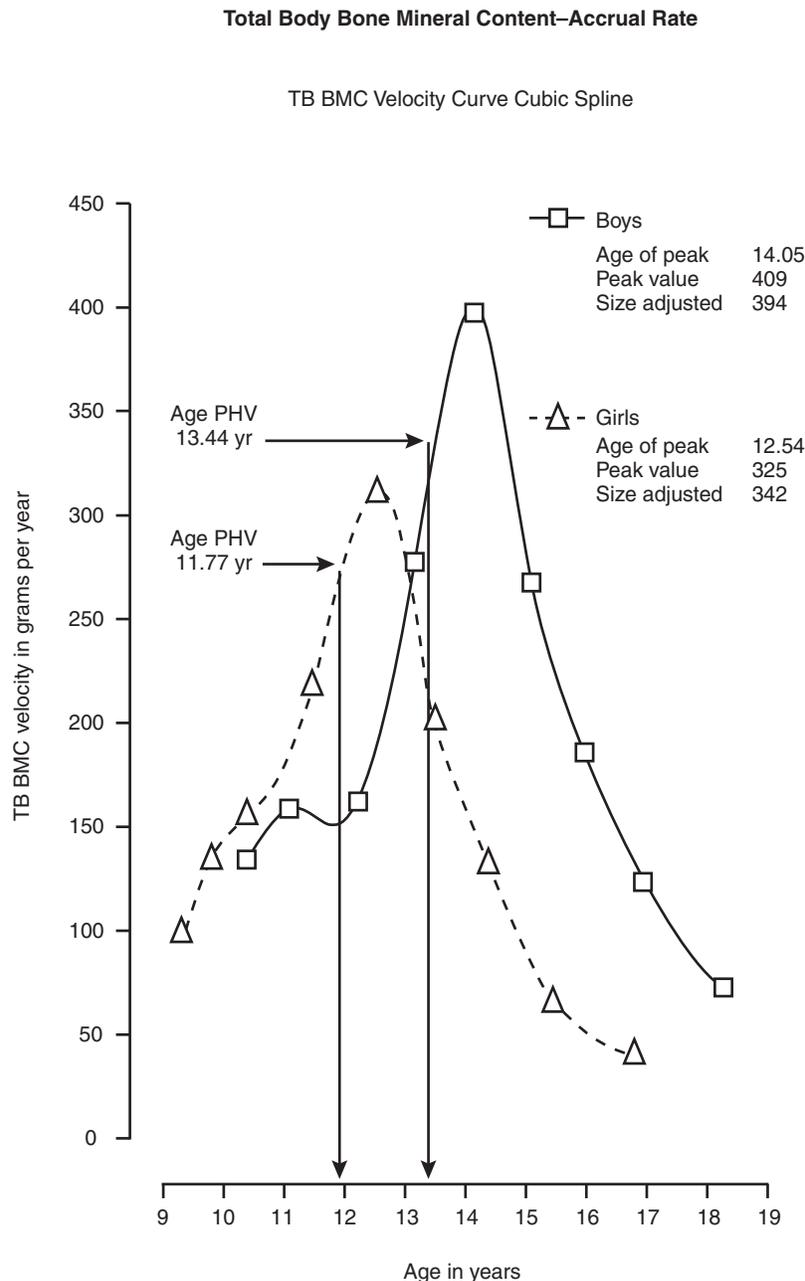

Fig. 9.16 During adolescence the peak rate of accrual of total body bone mineral content (BMC) occurs in boys and girls 0.7 years after attainment of peak height velocity (PHV). (From Bailey, D.A., McKay, H.A., Mirwald, R.L. et al. (1999). A six-year longitudinal study of the relationship of physical activity to bone mineral accrual in growing children: The University of Saskatchewan bone mineral accrual study. *J Bone Miner Res*, 14, 1672–1679. With permission.)

separate measurements of cortical and trabecular bone volume and mineral content and concentration, and estimation of apparent trabecular number, thickness, and spacing without exposure to ionizing radiation. Vertebral size and the presence of compression fractures may also be assessed by MRI, as well as by DXA.²⁹⁷

QCT of the spine, radius, and tibia provides three-dimensional measurements of cortical and trabecular bone mineralization and quantitation of cortical area and thickness and periosteal and endosteal circumference. QCT measures volumetric BMD of both trabecular and cortical bone at any site but has been commonly applied to the lumbar spine.²⁸⁷ However, the radiation dose delivered to the spine by this method is high (~30 μSv). During childhood, lumbar spine volumetric BMD measured by QCT is similar in black and white youth; during puberty, black males and females gain twice the volumetric BMD recorded in whites with no gender difference. Although BMD values of the lumbar spine acquired by DXA and QCT are reasonably well related, low bone density is reported in children far more often by DXA than by QCT, unless DXA measurements take into account body height and bone size.²⁹⁶ pQCT enables quantitation of bone mineralization in distal and/or proximal radial, femoral, or tibial sites (regions of both cortical and trabecular bone); the delivered radiation dose (10 μSv) is low. Forearm pQCT is assessed at 4% and 66% of the length of the nondominant forearm with a reference line being drawn through the most distal aspect of the cartilage growth plate when it is open, or through the

middle of the ulnar border of the articular cartilage when the growth plate is closed.^{299,301} pQCT permits measurement of total, cortical, and trabecular volumetric BMC and BMD, total and cortical cross-sectional bone area, cortical thickness, periosteal and endosteal circumferences, marrow area, and fat and muscle cross-sectional area (Table 9.9).

HRpQCT measurements may be obtained at the ultradistal tibia and radius in the interval between 1 and 10 mm above the proximal limit of the epiphyseal growth plate of the non-dominant limb and deliver a local absorbed radiation dose of 0.065 cGy and a total radiation exposure of <0.01 mSv.^{223,300} HRpQCT enables quantitative measurement of cortical and trabecular bone including: cortical bone volumetric BMD, cortical bone area, cortical bone thickness (Ct.Th— μm), periosteal and endosteal (endocortical) circumferences (μm), cortical pore volume (cortical areas of inverse density) and the “cortical porosity index” (cortical pore volume/cortical bone volume ratio), trabecular bone volumetric BMD, trabecular bone volumetric BMD/total bone volume ratio (BV/TV—%), trabecular number (Tb.N— mm^{-1}), trabecular thickness (Tb.Th— μm), and trabecular spacing (Tb.SP— μm) (Table 9.10). Determination of the “cortical porosity index” affords an estimate of strength of the distal wrist. HRpQCT also permits construction of microfinite element (μFE) models of bone strength enabling calculation of strain energies and loads supported by cortical and trabecular bone and “failure loads.”^{223,302} Fig. 9.17 depicts visually three-dimensional reconstructions of cortical and trabecular bone as derived by HRpQCT examinations.²²³

CSA, Cross-sectional area; DEXA, dual energy x-ray absorptiometry; vBMD, volumetric bone mineral density.

(Modified from Ackerman, K.E., Nazem, T., Chapko, D., et al. (2011). Bone microarchitecture is impaired in adolescent amenorrheic athletes compared with eumenorrheic athletes and nonathletic controls. *J Clin Endocrinol Metab*, 96, 3123–3133; Chevalley, T., Bonjour, J.P., van Rietbergen, B., et al. (2011). Fractures during childhood and adolescence in healthy boys: Relation with bone mass, microstructure, and strength. *J Clin Endocrinol Metab*, 96, 3134–3142.)

In boys, cortical bone volumetric BMD, Ct.Th, BV/TV, and Tb.Th increase in late puberty. In girls, cortical bone volumetric BMD and Ct.Th decline in midpuberty and then increase. Total bone strength increases in males and females through puberty. The percent of load borne by cortical bone decreases and the cortical bone porosity index increases in midpuberty, coincident with the point of peak incidence of adolescent radial fractures.

QUS enables evaluation of “bone quality” by measuring the speed of a longitudinal sound (SOS) wave as it is propagated along a bone; “speed of sound” and “sound wave attenuation” assess bone elasticity and connectivity and some aspects of bone architecture.²³⁷ This methodology has been applied to long bones (tibia, radius), to phalanges, the patella, and the os calcis. The rate of movement of sound through bone is dependent on its microstructural and macrostructural characteristics, mineral density, and elasticity and is thought to be a measure of bone strength. It is an attractive method for assessment of bone because it does not use radiation, is low in cost, and the measuring equipment is portable. Because of its safety, it is a measurement used in newborns and children. Transmitter and receiver ultrasound transducers placed on either side of the examination site (os calcis, patella, tibia, radius, phalange) quantitate transmission velocity or signal attenuation and convert these observations to SOS. In a study of 1085 children and

adolescents, SOS increased steeply at the tibia and radius during the first 5 years of life, more slowly between 6 and 11 years of age, and then again more rapidly during pubertal development.³⁰³ In 3044 healthy subjects ages 2 to 21 years, phalangeal QUS SOS and bone transmission time increased over time and with advancing adolescent development and were related to gender, age, height, and weight.³⁰⁴ QUS SOS is higher in postmenarchal than in premenarchal girls; adiposity (BMI) and serum leptin levels are inversely related to SOS in pubertal girls.³⁰⁵ The overlap of QUS data between various ages makes interpretation of a single SOS measurement problematic; serial assessment may be useful. Thus in a cohort of 29 preterm infants, tibial SOS values declined over time in neonates whose gestational ages were less than 29 weeks suggesting progressive loss of bone strength in this population and consistent with the development of “osteopenia of prematurity.”²⁹⁸ Although there is marginal correlation between vBMD determined by pQCT and SOS measurements in children and adolescents, QUS may complement radiographic methods.

MRI measures bone volume and cortical and trabecular bone microarchitecture; peripheral MRI has enabled assessment of bone structure and mineralization in the radius, ulna, femur, and calcaneus; MRI of the skeleton may also be used to assess bone geometry and estimate bone strength.³⁰⁶ Bone

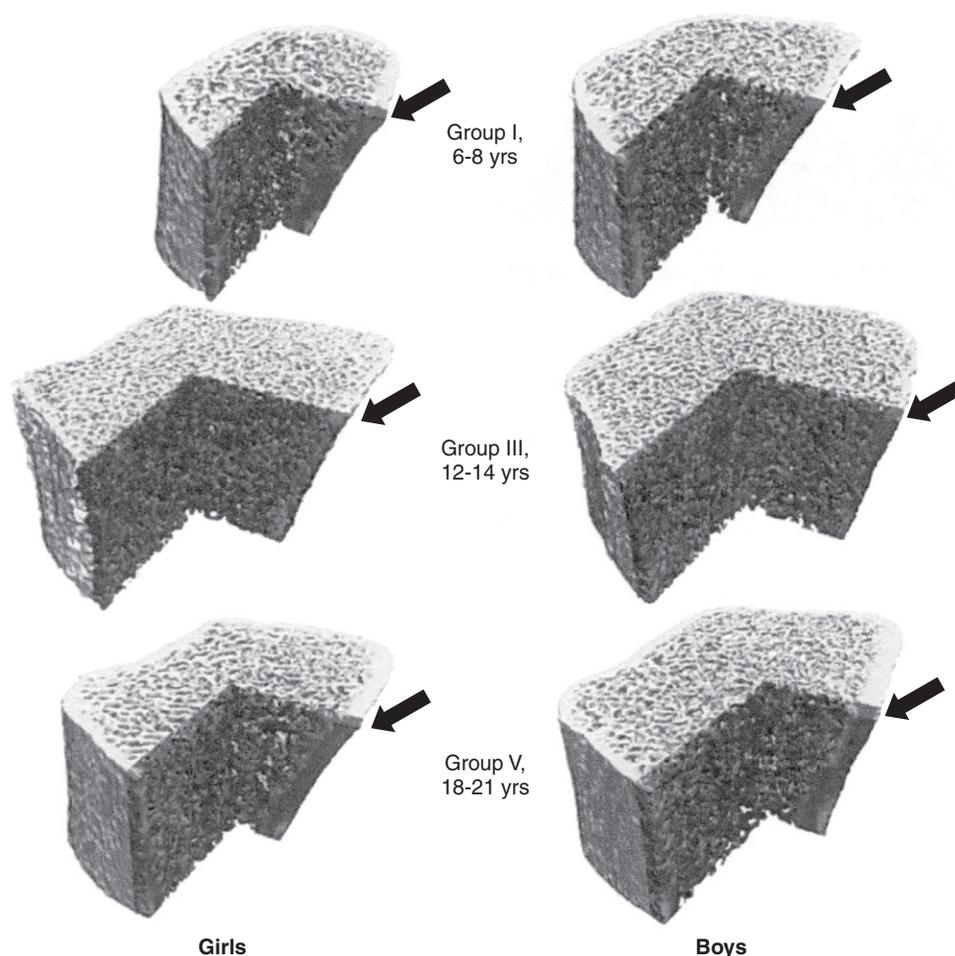

Fig. 9.17 Three-dimensional (3D) reconstructions of cortical and trabecular bone of ultradistal radius using high-resolution peripheral quantitative computed tomography (HRpQCT). Arrows point to cortical bone. (From Kirmani, S., Christen, D., van Lenthe, G.H., et al. (2009). Bone structure at the distal radius during adolescent growth. *J Bone Miner Res*, 24, 1033–1042. With permission.)

high-resolution MRI of the wrist and tibia measures cortical and trabecular bone structure including: trabecular number (mm^{-1}), thickness (mm), bone fraction (%), and separation (mm).³⁰⁷ Further, micro-MRI can be used to measure whole bone and trabecular bone stiffness, an indicator of whole bone mechanical competence, quality, and strength, and to obtain “virtual bone biopsies.”^{283,308} MRI of the vertebrae and long bones also permits separate measurements of cortical and trabecular bone volume and mineral content and concentration, and estimation of apparent trabecular number, thickness, and spacing without exposure to ionizing radiation. Vertebral size and the presence of compression fractures may also be assessed by MRI, as well as by DXA.²⁹⁷

INTRODUCTION

Diabetes is a heterogeneous disorder with many different possible causes, both genetic and acquired. Risk for the most common causes, type 1 and type 2 diabetes, depends on many different gene loci with intermediate or low effects and are thus considered polygenic. However, approximately 1% to 5% of all diabetes is caused by abnormalities at a single gene or locus and as a group, these entities are termed *monogenic diabetes*.^{1–6} Over 30 genes have now been described as causing the various forms of monogenic diabetes, where they typically fall into one or more of the three main overlapping phenotypic categories: neonatal diabetes, maturity-onset diabetes of the young

(MODY), and syndromic diabetes. In this chapter, we describe several of the more common causes of neonatal diabetes in some detail, and also provide brief descriptions of some of the main forms of MODY and syndromic diabetes, with a focus on diagnosis and treatment.

DEFINITION

Neonatal diabetes mellitus (NDM) was the initial term used to describe the presentation of diabetes within the first few days or weeks of life and was defined further in early reports as severe hyperglycemia occurring in the first month of life, lasting at least 2 weeks, and requiring insulin therapy to control blood glucose.⁷ These strict criteria have been progressively loosened as it became evident that the exact age at which the diabetes was diagnosed was more variable, even when an underlying cause, distinct from autoimmune type 1 diabetes mellitus (T1DM), was suspected, such as a genetic cause for pancreatic malformation, faulty insulin synthesis or secretion. Accumulated evidence has suggested an age under 6 months as being a particularly likely indication of NDM, because the majority of cases with an underlying monogenic cause will be diagnosed under 6 months, whereas autoimmune T1DM is highly unlikely during this window. Increasingly, however, it has become recognized that, for reasons that are poorly understood, several of the genetic forms can initially present with diabetes as late as 9 months to 1 year or even later.^{8–10} Indeed, pedigree analyses conclusively demonstrate that the same defect that causes permanent or transient NDM can be present in parents or other first-degree relatives with a phenotype consistent with MODY, but may have been misdiagnosed as T1DM or type 2 diabetes mellitus (T2DM) as subsequently detailed.^{11,12} Herein lies the importance of understanding the genetic basis of NDM, for although these entities are rare, they have taught us much about the genetic pathways involved in the formation of the exocrine and endocrine pancreas.^{13,14} For example, it has been shown that the specific combination of three transcription factors, *Ngn3*, *Pdx1*, and *Mafa*, known to be implicated in the determination of cell lineage during pancreas formation, can reprogram adult mouse exocrine pancreatic cells into cells that closely resemble pancreatic beta cells.¹⁵ Such information is essential for the ultimate ability to generate beta cells and whole islets as potential therapies for any form of diabetes, including T1DM.¹⁶ Equally important is the demonstration that activating mutations in the pore-forming potassium inward rectifying channel, family 6 subtype2-*KCNJ11* gene (*Kir6.2*) and its regulatory subunit sulfonylurea receptor 1-*ABCC8* gene (*SUR1*) of the K_{ATP}-regulated potassium channel, which keep the channel open and hence limit or preclude insulin secretion resulting in NDM (Fig. 10.1), can be overcome by high-dose sulfonylurea therapy, which restores endogenous insulin secretion in response to feeding.¹⁷ Because of the restoration of endogenous insulin secretion that can be triggered by the incretin effect in response to feeding, this oral treatment provides better metabolic control

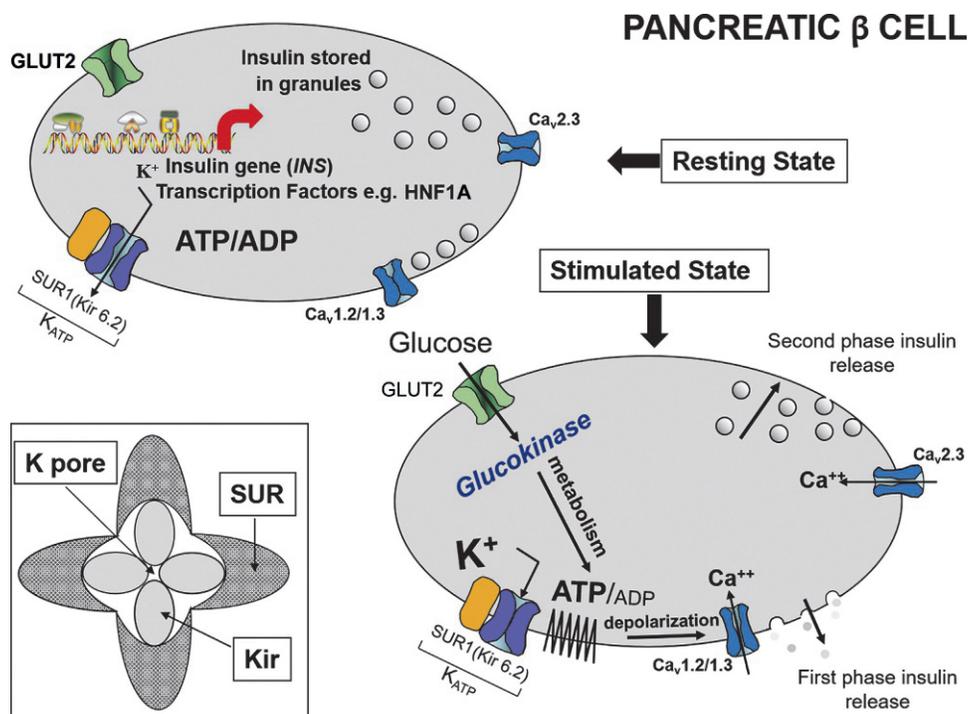

Fig. 10.1 Schematic representation of the role of K_{ATP} channels in nutrient regulation of insulin secretion. In the resting (nonfed) state, depicted in the upper left panel, insulin synthesis and storage are regulated by transcription from the insulin gene (*INS*) and by transcription factors, such as hepatocyte nuclear factor 1 α (*HNF1A*); mutations in *INS* or *HNF1A*, as well as many other beta cell genes can cause maturity-onset diabetes of the young (MODY) or transient or permanent neonatal diabetes mellitus (NDM). The K_{ATP} channel is composed of four subunits of the inward rectifying potassium channel 6.2 (Kir 6.2) encoded by the *KCNJ11* gene on chromosome 11 and four regulatory subunits of sulfonylurea receptor 1 (SUR1), encoded by the *ABCC8* gene, also located on chromosome 11 (inset lower left). In the fasting nonfed state, the K_{ATP} channel remains open. However, in the stimulated (fed) state (panel lower right) glucose concentration increases and enters the beta cell in a concentration-dependent, but insulin-independent manner via the GLUT2 glucose transporter encoded by the gene *SLCA2A*. Glucokinase (GCK) phosphorylates glucose to G6P and its metabolism generates ATP. The resultant change in ATP:ADP causes closure of the K_{ATP} channel, accumulation of intracellular potassium, membrane depolarization, leading to opening of voltage-gated calcium channels and secretion of stored insulin, as depicted in the lower right panel. Metabolism of amino acids, such as glutamate, also generates ATP, which stimulates insulin secretion as described for glucose. The amino acid leucine acts as an allosteric stimulus to glutamate dehydrogenase (GDH), which enables metabolism and generation of ATP. Activating mutations of the K_{ATP} channel maintain it in an open state to varying degrees, in spite of ATP generation, therefore preventing insulin secretion, which leads to diabetes mellitus, including NDM. Inactivating mutations in K_{ATP} genes prevent normal channel opening, maintaining varying degrees of channel closure, and hence constant insulin secretion that causes hyperinsulinism (see Chapters 7 and 23). ADP, Adenosine diphosphate; ATP, adenosine triphosphate; Ca^{++} , calcium; GLUT2, glucose transporter 2; K_{ATP} , ATP-regulated potassium channel; *HNF1A*, hepatocyte nuclear factor 1 α alpha; *INS*, insulin gene; K^+ , potassium; Kir6.2, potassium inward rectifying channel family6 subtype2; SUR1, sulfonylurea receptor1.

than multiple daily injections of insulin or insulin pumps and with a better quality of life.¹⁸ Successful transfer to sulfonylureas is best predicted by in vitro response of specific mutation and diabetes duration.¹⁹ These findings emphasize the benefits of research for understanding pathophysiology and choosing appropriate treatment. Indeed, for those whose NDM is caused by mutations in the K_{ATP} channel that respond to sulfonylureas, these treatments border on the miraculous.

INCIDENCE

Early estimates placed the incidence of NDM at approximately one in 500,000,⁷ but as increased awareness has led to these entities being recognized more frequently, the reported incidence has risen considerably. In populations with high rates of consanguinity, some studies report an incidence of NDM as high as one in 21,000 births.²⁰ A large representative database for pediatric diabetes reported that the incidence of NDM represented approximately one case in 89,000 live births in Germany, and a similar incidence occurred in Italy.^{21,22} In three other European countries, the incidence was reported to be one in 260,000 live births only for those with permanent NDM (PNDM) (suggesting a higher incidence if transient forms of NDM [TNDM] were also

included).²³ In the SEARCH for Diabetes in Youth Study involving 15,829 subjects aged under 20 years diagnosed with diabetes during the years 2001 to 2008, 39 were diagnosed before the age of 6 months. Among these 39 subjects with onset less than 6 months of age, 35 had permanent neonatal diabetes and an additional three had TNDM, leaving one subject whose status remained unknown.⁶ Hence, the total prevalence among children diagnosed with diabetes was approximately 0.246% or approximately 1 in 400. The majority were classified by their primary care providers as having T1DM and treated with insulin; only seven underwent mutational analysis for three of the most common genes (*KCNJ11*, *ABCC8*, and the insulin gene [*INS*]) and five of these seven had mutations in one of these three genes.⁶ The estimated population prevalence of PNDM in those aged less than 20 years in that study was one in 246,000 people.

CLINICAL PRESENTATION

Infants affected with diabetes may have diabetes in isolation, or the underlying genetic defect may also cause a variety of other clinical features (Fig. 10.2). Infants with NDM are more likely to be born small for gestational age, and in many cases there

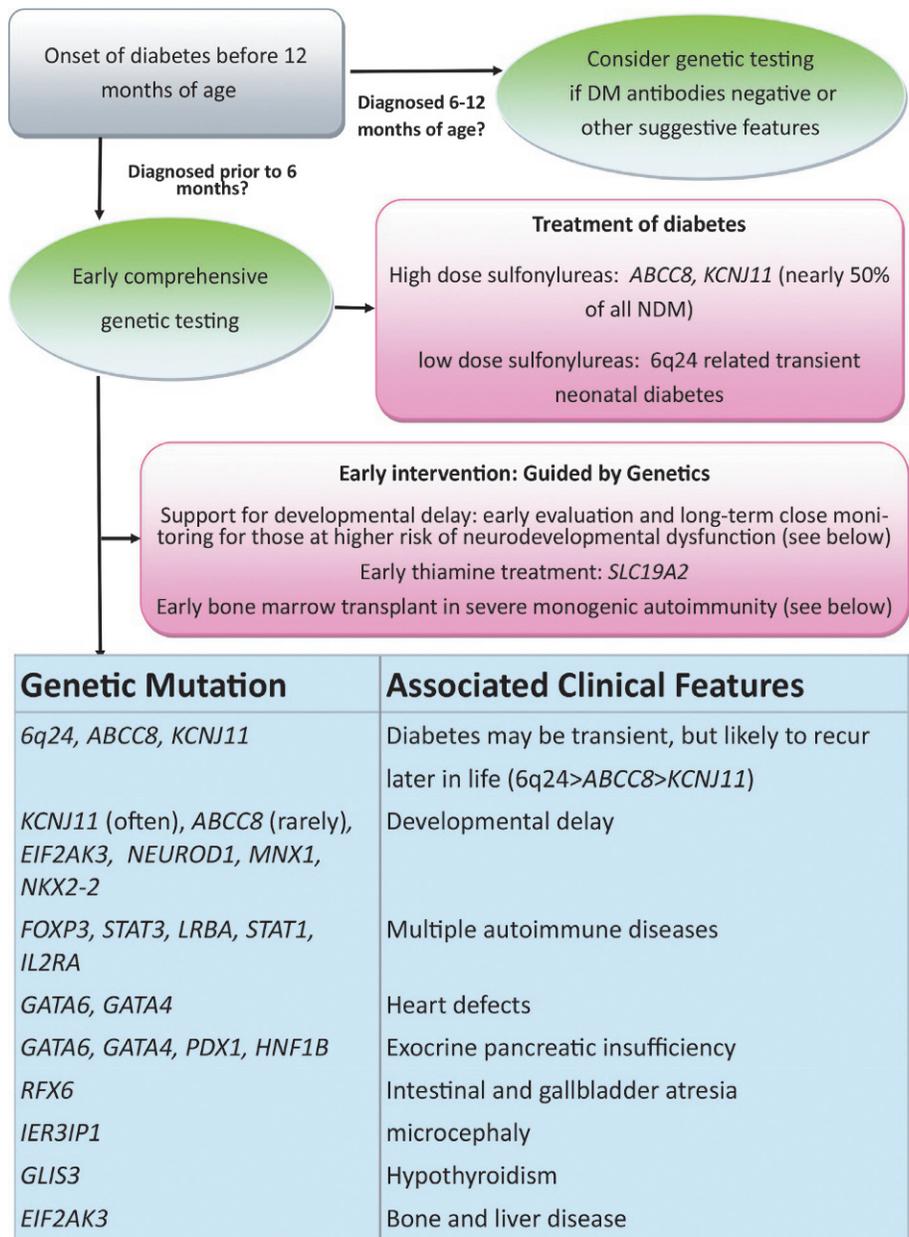

Fig. 10.2 Schematic representation of genetic diagnosis and management of neonatal diabetes mellitus. (Modified from Hattersley, A.T., Patel, K.A. (2017). Precision diabetes: learning from monogenic diabetes. *Diabetologia*, 60(5), 769–777.

may also have been concern for intrauterine growth retardation (IUGR) during their pregnancy, reflecting the in utero deficiency of insulin and emphasizing the role of insulin as a determinant of fetal growth.²⁴ Their small size and low birth weight markedly contrasts with the large birth weight and size of infants with inactivating mutations in the same K_{ATP} genes that instead of diabetes lead to hyperinsulinemic hypoglycemia (see Chapters 7 and 23). A disproportionate number of those with NDM are born prematurely at less than 37 weeks' gestation, which in some cases may be associated with induction of the delivery because of their IUGR status.²⁵ Hyperglycemia leads to osmotic diuresis and avid feeding from breast or bottle despite which the infants often fail to thrive. Delay in diagnosis from not considering the possibility of diabetes mellitus in a newborn may lead to severe dehydration and life-threatening diabetic ketoacidosis (DKA); in fact, a recent retrospective study of a large series of NDM cases in the United States showed that 66% of patients presented in DKA.²⁶ Rare syndromic forms may have severe congenital malformations, such as intestinal

and biliary atresia (*RFX6*), congenital heart defects (*GATA6* or *GATA4*), or brain malformations (*PTF1A*, *NEUROD1*, *IER3IP1*, *MNX1*, *NKX2.2*), or alternatively may have other features, such as skeletal dysplasia (*EIF2AK3*) that are difficult to recognize during the neonatal period. In addition to mutations in *FOXP3* responsible for the IPEX syndrome (immune dysregulation, polyendocrinopathy, enteropathy, X-linked), several additional genes (*STAT1*, *STAT3*, *LRBA*, *IL2RA*) have now been described to have mutations causing infancy-onset diabetes, along with other autoimmune disorders that result from dysfunction of immune regulation.^{27–30}

Patients with overexpression of genes at chromosome 6q24 present with TNDM and will often have more subtle features, such as macroglossia and umbilical hernia, reminiscent of Beckwith-Wiedemann syndrome. In addition, they rarely may have dysmorphic facies, as well as renal tract anomalies, such as hydronephrosis and vesicoureteral reflux, a variety of cardiac anomalies, hypothyroidism, or hand-finger anomalies.²⁵ A coarse facial appearance together with epilepsy and

later manifestations of developmental delay constitute the developmental delay, epilepsy, neonatal diabetes (DEND) syndrome associated with the most severe mutations of the *KCNJ11* gene¹⁷; however, in most cases of *KCNJ11* or *ABCC8* mutations that maintain the K_{ATP} channel in a variable open state and hence limit insulin secretion, there will not be any abnormal findings on physical examination. Even in those with the severe mutations causing significant neurodevelopmental dysfunction, the abnormalities may often not be recognized until patients are older. Clinical manifestations involving organs other than the pancreas may be part of the syndromes of a variety of genetic causes of NDM. These features in patients with NDM were previously incorporated in a retrospective categorization system to describe permanent, transient, and syndromic forms of NDM. However, now that the monogenic basis of NDM has been well established, genetic testing should be done immediately upon diagnosis of diabetes in the neonatal/infancy period, at which time it will be unclear whether the baby has a permanent or transient form of NDM (see Fig. 10.2). Furthermore, the extrapancreatic manifestations of genes causing syndromic NDM can be phenotypically quite variable and many of these features will often not be readily apparent during the neonatal period.³¹ Expert consensus has therefore shifted toward obtaining comprehensive genetic testing utilizing next-generation sequencing (NGS) panels (or a tiered approach) rather than iterative testing of fewer genes selected based on clinical features.³²

TRANSIENT NEONATAL DIABETES MELLITUS

TNDM is so named because hyperglycemia resolves spontaneously within the first few months of life and no longer requires treatment, although it may reappear later in life. About 70% of these cases will have TNDM1 (6q24-related TNDM), whereas the majority of the remaining cases of TNDM will be caused by mildly activating mutations in the K_{ATP} genes *ABCC8* (*SUR1*) and *KCNJ11* (*Kir6.2*), and only a small minority will be caused by recessive insulin gene mutations, mutations in the transcription factor *HNF1B*, or mutations in *SLCA2A*, the gene encoding the GLUT2 transporter.

6q24-Related Transient Neonatal Diabetes Mellitus (TNDM1)

TNDM1 (or 6q24-related TNDM) is caused by the overexpression of genes at the 6q24 chromosomal locus, including pleomorphic adenoma gene-like 1 (*PLAGL1*), which is a proapoptotic zinc finger protein, and (hydatidiform mole-associated and imprinted transcript (*HYMAI*), encoding an untranslated messenger ribonucleic acid (mRNA). TNDM1 arises as a result of uniparental paternal disomy of the entire—or only a segment that includes 6q24—chromosome 6 (UPD6), a paternally inherited duplication of chromosome 6q24, or relaxation of imprinting of the maternally methylated genes on chromosome 6 (Fig. 10.3). It is important to emphasize that these chromosomal changes cause altered expression of genes, rather than representing mutations. For example, *PLAGL1* (*ZAC*) has antiproliferative properties and is thought to function as a tumor growth suppressor expressed only on the paternal allele³³; overexpression in fetal life is believed to lead to underdevelopment of the pancreas. Although the precise mechanisms by which overexpression of *PLAGL1* lead to TNDM1 are not known, overexpression of *ZAC* in a clonal pancreatic beta cell line impairs glucose-stimulated insulin translation and secretion.³⁴ A transgenic mouse model expressing the human TNDM1 locus (6q24) is characterized by impaired glucose homeostasis with hyperglycemia in the neonatal period and impaired glucose tolerance with reduced insulin responses

to intravenous (IV) glucose as adults.³⁵ The pancreata of these animals display reduced expression of endocrine differentiation factors, notably *PDX1*, *NGN3*, and *PAX6*. There is also a reduction in the number of insulin staining cells and reduced insulin content or insulin secretion despite normal or elevated beta cell mass at all postnatal periods. Thus this model recapitulates TNDM1 and suggests that altered expression of *ZAC/HYMAI* cause impaired development of the endocrine pancreas, as well as impaired beta cell function.^{35,36} This mouse model also demonstrates resolution of abnormal insulin secretion with restoration of normal glucose tolerance during the “juvenile” phase of mouse development between 1.5 and 2 months of life, during which there is an approximate doubling of beta cell number that compensates for the reduced insulin synthesis and secretion of each cell. Also as in humans, the compensatory increase in beta cell mass is not sustained, resulting in a mild diabetes mellitus characterized by normal fasting glucose but hyperglycemia after glucose challenge. Overall, despite the recapitulation of the key features of the human disease, the mouse model displays milder features.^{35,36} One possible reason for this milder phenotype in mice is that pancreatic expression of the mouse ortholog *Zac1* declines drastically during gestation and early postnatal growth in mice, whereas expression of the *ZAC* gene in human pancreas declines between the second trimester and adult life.³⁷ More important, *ZAC* was specifically expressed only in the islets of the human fetus, whereas *Zac1* was predominantly expressed in mesenchyme of the mouse embryo, which may explain the milder features in the mouse model of TNDM1.³⁷

In patients with TNDM1 resulting from hypomethylation of the maternal differentially methylated region (DMR) of chromosome 6q24, there may be hypomethylation of other maternally imprinted loci (HIL) throughout the genome.³⁸ In cases displaying a more generalized HIL, the majority have a mutation in the transcription factor zinc finger protein 57 (*ZFP57*).³⁹ HIL also occurs in Beckwith-Wiedemann syndrome and this likely explains the macroglossia, umbilical hernia, and several congenital abnormalities described in TNDM1.⁴⁰ In a large multinational cohort involving 163 patients with TNDM1,²⁵ the authors describe IUGR with a mean birth weight of 2001 ± 417 g (mean \pm standard deviation) and adjusted Z score for birth weight of -2.5 . The mean age of presentation was 8 ± 12 days with a median of 4 days and a mode of 1 day. Mean gestation was 37.8 ± 2.4 weeks and prematurity was significantly more common than in the general population. Remission occurred at a mean age of 4.5 ± 5.8 months with a median at 3 months. Age at presentation was positively correlated to gestational age, but age at remission was negatively correlated with adjusted birth weight.²⁵ Thus the higher the birth weight, the earlier the remission and vice versa. This would be consistent with the effects of insulin on intrauterine growth, so that the larger infants would have the milder defect and therefore tend to enter remission sooner. Congenital anomalies were significantly more frequent in patients with UPD6 or HIL. Hypomethylation defects were overrepresented in patients born after assisted conception. Thus babies with TNDM1 generally present with diabetes mellitus within the first days of life, are small, and may have been born prematurely. The presence of one or more congenital anomalies suggests UPD or multiple HIL, and among the latter, almost one in seven had been conceived with assisted reproductive techniques. Macroglossia is present in about 50%, umbilical hernia in about 25%, and facial dysmorphism in about 20%. Cardiac and renal anomalies ($\sim 9\%$), hand abnormalities ($\sim 8\%$), and hypothyroidism ($\sim 4\%$) also may be present. Remission, when it occurs, is usually around 3 months and about half of these patients will revert to varying degrees of hyperglycemia in the teen years or later.²⁵ An unusual manifestation following

Mechanisms responsible for differential methylation patterns in TNDM1

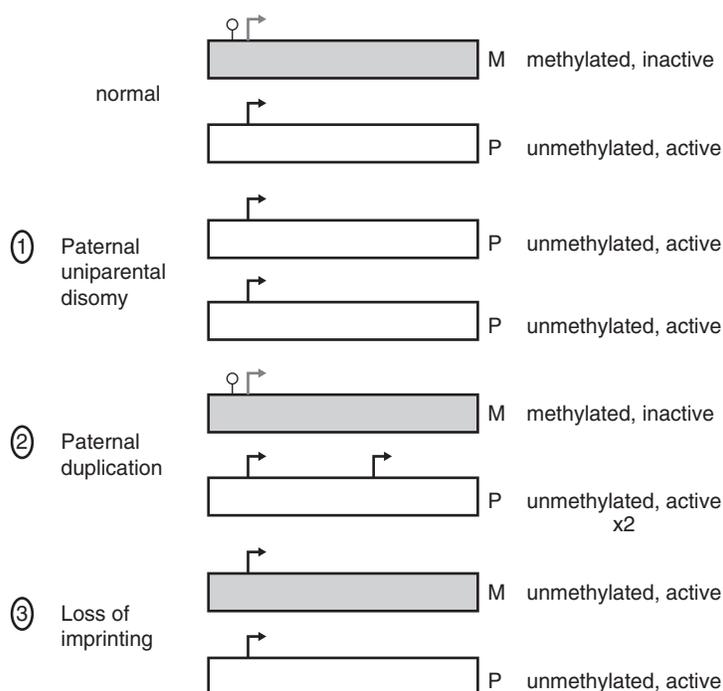

Fig. 10.3 Transient neonatal diabetes mellitus type 1 is caused by overexpression of imprinted genes on chromosome 6q24 (*PLAGL1* and *HYMAI*). Normally the maternal allele remains methylated and inactive, whereas the paternal allele is unmethylated and active. The differential expression of these genes can occur by one of three mechanisms, as illustrated: (1) paternal uniparental disomy, where both alleles are of paternal origin; (2) paternal duplication, so that two active paternal alleles are expressed; (3) loss of imprinting (or “relaxation of imprinting”), whereby the maternal 6q24 allele is also expressed. See text for details.

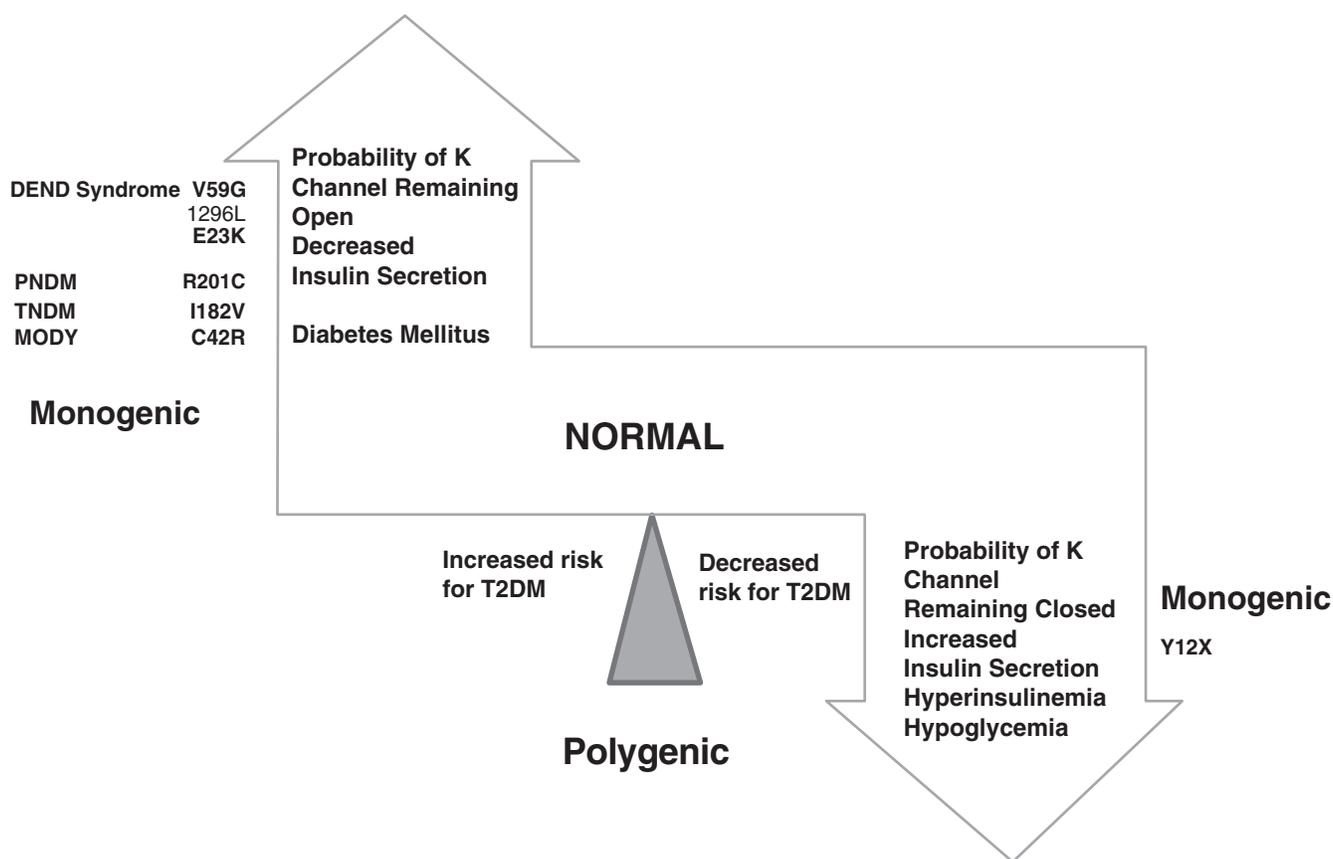

remission of diabetes in patients with 6q24 methylation defects is hypoglycemia with hyperinsulinemia, most often when the cause is UPD6.⁴¹ Modern molecular techniques permit diagnosis to be established which then influences treatment; however, many commercial sequencing panels for monogenic diabetes do not include testing that will reveal overexpression of genes at 6q24 as a cause of diabetes.

Patients with TNDM1 are sensitive to insulin and respond with excellent catch-up growth within several weeks of treatment. Progressive reduction of the insulin dose required to control blood glucose while avoiding hypoglycemia heralds the onset of remission. Although these patients do well with insulin treatment, some reports suggest a variable response to oral sulfonylurea treatment; though it is difficult to discern the extent to which the clinical improvement was caused by medical treatment versus spontaneous resolution of the condition in these observational studies.^{42,43} Of note, rare cases with 6q24-related TNDM will develop significant hypoglycemia within weeks or months after the remission of hyperglycemia. Most had evidence for hyperinsulinism as the cause of hypoglycemia and responded well to diazoxide treatment that was still required after several years in some cases.⁴¹ Even after resolution of diabetes during infancy, it is important that these patients understand that diabetes is highly likely to recur around the time of adolescence. Although a few papers report good response to other drugs besides insulin, the best approach to monitoring during remission, as well as to treatment after recurrence, remain uncertain. Because many questions remain about this condition, it is important that such cases be referred to research centers tracking long-term outcome, even if the diabetes has gone into remission.⁴³

K_{ATP} Channel-Related Transient Neonatal Diabetes Mellitus (TNDM2)

TNDM2 is one classification given to diabetes that remits during infancy and may recur later in life but is caused by mutations in genes regulating insulin secretion rather than expression of imprinted genes. The majority of these entities are caused by activating mutations in the K_{ATP} channel genes *ABCC8* and *KCNJ11*, which, respectively, code for the SUR_1 and Kir6.2 subunits of the K_{ATP} channel (see Fig. 10.1).^{32,44} Recessive loss-of-function mutations in the *INS* itself may occasionally be responsible for TNDM2⁴⁵; the autosomal dominant insulin gene mutations are associated with PNDM.^{8,32,44} There are rare reports of *HNF1B*⁴⁶ and *SLC2A2* mutations⁴⁷ also associated with TNDM.

The normal state of the K_{ATP} channel is to remain open, setting the resting membrane potential of the beta cell. Insulin secretion occurs when the channel closes in response to an increase in adenosine triphosphate (ATP) generated from the metabolism of glucose or amino acids, thereby changing the ATP:adenosine diphosphate (ADP) ratio. Closure of the channel with intracellular retention of K^+ causes depolarization of the plasma membrane, opening of voltage-gated calcium channels, influx of calcium, and secretion of insulin. Activating mutations in *ABCC8* or *KCNJ11* alter the ability of the channel to respond to the change in the ATP:ADP, so that the channel remains open to some extent, efflux of K^+ from the beta cell continues, permitting the cell membrane to remain hyperpolarized and therefore resulting in various degrees of impaired insulin secretion. These same mechanisms are also responsible for the most common form of PNDM, as subsequently discussed.^{32,44}

Relation Between KATP Channel Activity and Insulin Secretion

Fig. 10.4 This is a schematic representation of the relationship between K_{ATP} channel activity and insulin secretion. Activating mutations of the *KCNJ11* or *ABCC8* genes maintain the channel in an open state and hence limit insulin secretion. With progressively increasing probability of the potassium channel remaining open, the severity of the resulting hyperglycemia increases from a mild increased risk for type 2 diabetes mellitus (T2DM), to monogenic diabetes of youth (MODY), transient neonatal diabetes mellitus (TNDM), permanent neonatal diabetes mellitus (PNDM), and in the most severe state the DEND syndrome (developmental delay, epilepsy, neonatal diabetes) as illustrated on the left. In contrast, mutations that increase the probability that the channel remains closed also increase the likelihood of persistent insulin secretion and lead to hyperinsulinemia and hypoglycemia as illustrated on the panel on the right; in milder forms they may decrease the risk for T2DM by maintaining a higher insulin secretion. Common genetic defects are illustrated in each as examples. (Modified from Ashcroft, F.M. (2005). ATP-sensitive potassium channelopathies: focus on insulin secretion. *J Clin Invest*, 115, 2047–2058. Figure 6.)

It remains unclear how or why remission occurs, but it has been shown in vitro that mutations causing TNDM have a less pronounced effect on channel function compared with mutations that cause PNDM.⁴⁸ The ability of ATP to close the channel in vitro correlates with the severity of NDM, including the severe permanent form associated with the DEND syndrome, which demonstrates the greatest resistance to closure by ATP in vitro.^{48,49} Both resistance to closure caused by activating mutations, or resistance to opening of the channel because of inactivating mutations, segregate with certain mutations as illustrated in Fig. 10.4. As shown in the figure, near the fulcrum of this spectrum, those with minor defects may be prone to either develop milder type 2 diabetes or may be resistant to the development of diabetes by virtue of enhanced insulin secretion (see Fig. 10.4).

In comparison with TNDM1, patients with TNDM2 generally have greater birth weight, present or are diagnosed with diabetes mellitus later, remit later, and recur earlier (Table 10.1). Family members of patients with these forms of TNDM2 may have diabetes that was diagnosed in adulthood and was considered to be T1DM, T2DM, or MODY and yet harbor the same heterozygous mutations as the proband with NDM.^{10–12} This reflects the variable penetrance of these genes or upstream factors that may modify the expression of the gene

in different individuals. Confirming the presence of an *ABCC8* or *KCNJ11* mutation in a case of NDM is important for management because most of these K_{ATP} channel mutations respond to sulfonylurea treatment both at the time of initial diagnosis or later at the time of relapse.^{32,44} During their remission phase, these patients do not require therapy.

Recessive loss of function mutation in the *INS* gene has been reported in rare patients with TNDM.⁴⁵ These patients appear to enter remission at a median age of 12 weeks and insulin was required before remission and after later relapse that was reported in some cases.⁴⁵

Patients with mutations in the transcription factor hepatocyte nuclear factor 1 beta (*HNF1B*) are known to have diabetes associated with renal cysts with onset at a median of 20 years. However, two reported patients had neonatal diabetes: one was diagnosed at age 15 days and required insulin, initially intermittently and then permanently; a second patient diagnosed at the age of 17 days had remission 2 weeks after diagnosis but relapsed at the age of 8 years.⁴⁶ There have also been a few reported cases of mutations in *SLC2A2*, which encodes the glucose transporter type 2 (GLUT2).⁴⁷ Recessive inactivating mutations in this gene cause Fanconi-Bickel syndrome, characterized by glucosuria, galactosuria, aminoaciduria,

TABLE 10.1 Comparison of Clinical Characteristics of Patients With K_{ATP} Channel Mutations to Patients With 6q24 TNDM (data given in median [range])

Characteristic (median)	ABCC8 / KCNJ11 (n = 25)	6q24* (n = 23)	P-Value
Age at diagnosis (weeks)	4 (0–16)	0 (0–4)	<.001
Age at remission (weeks)	35 (2–208)	13 (5–60)	<.001
Age at relapse (years)	4.7 (3–15)	16 (4–25)	.073
Birth weight (g)	2570 (1360–3570)	1950 (1600–2670)	<.001
Percentile birth weight	12 (<1st–89th)	<1st (<1st–21st)	<.001

*Data previously reported (Temple IK, Gardner RJ, Mackay DJ, Barber JC, Robinson DO, Shield JP: Transient neonatal diabetes: widening the understanding of the etiopathogenesis of diabetes. *Diabetes* 49: 1359–1366, 2000). Differences between groups were calculated using Mann-Whitney U and χ^2 tests. Centile birth weights were calculated according to U.K. growth charts (Cole TJ, Freeman JV, Preece MA: British 1990 growth reference centiles for weight, height, body mass index and head circumference fitted by maximum penalized likelihood. *Stat Med* 17: 407–429, 1998) because the majority of patients were of U.K. white origin.

Modified from Flanagan SE, Patch AM, Mackay DJ, et al. Mutations in ATP-Sensitive K^+ Channel Genes Cause Transient Neonatal Diabetes and Permanent Diabetes in Childhood or Adulthood. *Diabetes* Jul 2007, 56 (7) 1930–1937; Table 2. <https://doi.org/10.2337/db07-0043>. Retrieved from: <https://diabetes.diabetesjournals.org/content/56/7/1930.long>.

proteinuria, and phosphaturia, as well as rickets, poor growth, and short stature with associated glucose and galactose intolerance and enlarged livers. Transient neonatal diabetes has been reported in these patients to occur in association with the classic Fanconi-Bickel syndrome.⁴⁷

PERMANENT NEONATAL DIABETES MELLITUS

The majority of genes that cause NDM result in PNDM without any significant treatment remission. Approximately 80% to 85% of infants with diabetes diagnosed before 6 months of age will have an underlying monogenic cause that can be identified, and the remainder may carry as-yet uncharacterized defects. Although diabetes resulting from monogenic causes can also be diagnosed between 6 and 12 months of age or later, and genetic testing can be considered, the majority of diabetes cases in this age range will have autoimmune diabetes (T1D) that can be suggested by positive anti-beta cell autoantibody testing or type 1 diabetes genetic risk scores (routinely done in most NDM research centers). Except in certain populations with higher frequency of consanguineous births, the vast majority of PNDM is caused by mutations in three genes: the two K_{ATP} channel genes *KCNJ11* coding for the pore-forming protein Kir6.2 (50%) and *ABCC8* coding for SUR1 (together account for 40%–45% of cases; see Figs. 10.1 and 10.2), and mutations in the gene encoding insulin itself (*INS*). Dominant mutations in *GATA6* or *GATA4* causing pancreatic hypoplasia are rarer than other dominant causes, as are X-linked mutations in *FOXP3* causing the IPEX syndrome, or milder IPEX-like syndromes, whereas the remaining gene causes of PNDM are very rare recessive disorders that often include a variety of extrapancreatic syndromic features (see Fig. 10.2).

K_{ATP} Mutations: *KCNJ11* and *ABCC8*

Until the discovery of the genes responsible for the K_{ATP} channel, patients with PNDM were considered to have insulin-dependent diabetes mellitus; now it is known that the majority of patients with K_{ATP} mutations causing PNDM respond to oral therapy with sulfonylurea.^{50,51} Early genetic testing is imperative because those who are responsive to sulfonylurea treatment and have earlier initiation of treatment have been reported to have improved response to therapy and may help improve quality of life.^{50,51} Typically treated with high-dose sulfonylureas, a cohort with this treatment has shown mild and infrequent hypoglycemia.⁵² Patients with PNDM caused by mutations in the K_{ATP} genes or the insulin gene usually present at 2 to 3 months of life, and sometimes later, and may be in severe DKA by the time of the diagnosis. Activating mutations in the Kir6.2 subunit of the K_{ATP} channel were first reported in 2004,⁴⁹ being found in 10 out of 29 subjects with PNDM.

Whereas the insulin secretory response to IV glucagon and glucose was minimal, there was a better response to oral glucose. Patients did respond with insulin secretion to IV tolbutamide, clearly hinting at possible therapy by the administration of sulfonylurea and confirmed by a landmark study published 2 years later.¹⁷ Expression of the mutated Kir6.2 subunit together with a normal SUR1 subunit in *Xenopus laevis* oocytes revealed that the ability to enable channel closure by ATP was greatly impaired. This provided a means to correlate the degree of *in vitro* abnormality with the clinical severity of the diabetes.¹⁷ The affected patients predominantly had *de novo* mutations, with only 20% of the mutations inherited from a parent. It was also noted that 4 of 10 of the patients had severe developmental delay, muscle weakness, and epilepsy, as well as dysmorphic facial features, which was termed the *DEND syndrome*. The degree of muscle weakness was partially ameliorated by treatment with sulfonylurea, raising the possibility that the developmental delay and epilepsy may also be ameliorated, or perhaps prevented, by early recognition and treatment with sulfonylurea.⁴⁴ Subsequently, it was demonstrated in mice that transgenic expression of an activating mutation in Kir6.2 in mouse pancreatic beta cells recapitulates neonatal diabetes⁵³ and that the muscle dysfunction caused by a human K_{ATP} channel mutation is neuronal and not muscular in origin.⁵⁴ K_{ATP} channels exist in other tissues and are known to modulate electric activity and neurotransmitter release at brain synapses in various regions of the brain.⁴⁸ Moreover, K_{ATP} channels in the ventromedial hypothalamic nucleus may be involved in the counterregulatory response to hypoglycemia⁵⁵; in the arcuate nucleus neurons, K_{ATP} channels may be involved in appetite regulation.^{55,56}

A spectrum of clinical disturbances occurs with different mutations ranging from the *DEND syndrome*, to relapsing diabetes,^{48,54,57} permanent diabetes appearing initially in childhood or later in adults.^{57–59} Mutations in adjacent locations may cause either neonatal diabetes or hyperinsulinism because they increase or decrease the open state of the channel.^{57–61} Likewise, mutations in the *ABCC8* gene encoding SUR1 cause transient or permanent NDM, or permanent diabetes diagnosed beyond the newborn period in children, or in adults, and mutations at a similar site in the gene can result in either hyperinsulinism or neonatal diabetes.^{11,62–65}

Initial reports noted certain mutations (such as *KCNJ11* V59M) are characterized by significant global developmental delay (often termed *intermediate DEND syndrome*, or *iDEND*) in about 20% of cases, and anecdotal reports suggested improvement of neurological symptoms of weakness, dyscoordination, and visuomotor impairment after treatment with sulfonylureas (replacing insulin) was initiated.^{66–68} Several groups have since undertaken careful characterizations of large groups of patients using standardized measures that reveal a wide range of dysfunction, including behavioral difficulties

and attention deficit hyperactivity disorder symptoms or diagnosis, lower educational attainment, and difficulties with executive functioning.^{69–73} In one study of 14 patients with mutations previously thought to cause diabetes in isolation, who did not have global developmental delay, IQ was found to be close to normal (91.1 ± 11.3) but significantly lower than 20 sibling controls (111.0 ± 8.3).⁷² Raising the importance of early proper diagnosis and treatment of these conditions, another study revealed better performance on a standardized measure of visuomotor functioning by the three patients who had been started on sulfonylurea treatment under a year, among eight patients with of V59M mutations in *KCNJ11*.⁶⁸

The safety and tolerability of high-dose sulfonylurea treatment, as well as its durability over more than 10 years of treatment, has also been reported in a few recent studies. A survey of 30 patients over a total of 166 patient years revealed no episodes of severe hypoglycemia, whereas mild to moderate hypoglycemia was unrelated to sulfonylurea dose.⁵² A recent follow-up study on 81 patients from a European cohort started on sulfonylureas before 2006 showed no episodes of severe hypoglycemia over 809 patient-years, with sustained excellent glycemic control on stable doses with infrequent mild side effects.⁷⁴

Insulin Gene Mutations

Insulin gene mutations as a cause of PNDM were first reported in 2007 and are now known to be the second most common mutations responsible for these entities.^{75–77} Inheritance was autosomal dominant in the familial cases, but the majority had de novo mutations. The mutations occurred in a critical region of the preproinsulin molecule, predicting misfolding and hence loss of normal trafficking of the proinsulin in the insulin secretory pathway. This misfolding was also proposed to induce the unfolded protein response, with degradation in the endoplasmic reticulum (ER), leading to severe ER stress and apoptosis of the beta cells, processes known to occur in mouse models of dominant insulin gene mutations.⁷⁵ Clinically, the age at diagnosis averaged 13 weeks compared with 5 weeks for *KCNJ11* and 7 weeks for *ABCC8* mutations. With a normal range of gestational ages of 36 to 41 weeks, mean birth weight was also normal at 2846 g. Thus these abnormalities appear to disturb intrauterine growth less than in 6q24 TNDM or those with K_{ATP} channel mutations. These dominant or de novo mutations are not usually associated with TNDM or remission,⁷⁵ whereas recessive mutations of the insulin gene can result in a remitting type of NDM as described earlier.⁴⁵ The initial suggestion of ER stress as a mechanism has been largely confirmed and the spectrum of disorders in the insulin gene extends to a MODY phenotype or onset in adulthood.^{9,76–80} Treatment of these patients is currently limited to insulin, whereby they can be managed very similarly to a patient with autoimmune T1DM. A few case series have demonstrated the effectiveness of insulin pumps and continuous glucose monitors in achieving good glycemic control as early as the neonatal period following diabetes diagnosis.^{81,82} One case study of two sisters suggested the theoretical benefit of early optimization of glycemic control to minimize the need for endogenous beta cells to respond to hyperglycemic excursions by producing mutated insulin that is toxic to beta cells. Limiting the toxic effects of protein production appeared to promote improved cell survival that might allow for at least low level production of insulin via the normal allele.⁸³

Other Genetic Forms of Permanent Neonatal Diabetes Mellitus

Two genes that cause MODY, the enzymatic metabolic gatekeeper glucokinase (*GCK*), and the islet formation transcription factor *PDX1* (previously called *IPF-1*), cause monogenic forms of

diabetes, respectively, known as *MODY2* and *MODY4*, when in the heterozygous state and can more rarely cause PNDM when in the homozygous or compound heterozygous state.

Glucokinase

Glucokinase (*GCK*) has been called the *glucose sensor* of the beta cell. It phosphorylates glucose to glucose-6-phosphate, permitting entry into the glycolytic pathway for metabolism and generation of ATP, which triggers insulin secretion (see Fig. 10.1). *GCK* is also known as *hexokinase IV* or *hexokinase D* and is most active in the physiological range of glucose at 4 to 10 mmol/L (72–180 mg/dL) with a K_m of ~ 8 mmol/L (144 mg/dL). The glucose-stimulated insulin release (GSIR) threshold occurs when glucose phosphorylating capacity reaches 30% of maximum, which generally occurs under normal circumstances at a glucose concentration of ~ 90 mg/dL and is maximum at glucose concentrations of 300 mg/dL or higher but not reaching more than $\sim 80\%$ of full (100%) glucose phosphorylating capacity.

Activating mutations of *GCK* exert these effects at lower glucose concentrations and hence cause hyperinsulinemic hypoglycemia (see Chapters 7 and 23). Inactivating heterozygous mutations in *GCK* cause a mild diabetes because the glucose phosphorylating capacity is shifted to the right, so that the 30% phosphorylating capacity needed for the GSIR occurs when glucose concentrations are around 120 mg/dL rather than 90 mg/dL and reach only a peak of 50% to 60% of the 100% phosphorylating capacity. This is enough to clear all glucose after a meal, but with periods of hyperglycemia before this occurs. *GCK* inactivating mutations are one of the most common forms of MODY (see later), often presenting asymptotically as an incidental finding discovered during blood tests done for other reasons, and there will often be a positive family history of diabetes.

Homozygous inactivating mutations in *GCK* were reported in two patients in 2001,⁸⁴ and the same authors reported an additional three cases in 2003.⁸⁵ The affected subjects were homozygous for the mutation or were compound heterozygous for two different mutations, being a splice site in one and a missense mutation in the other. Each of these five initial subjects was characterized by IUGR, permanent neonatal diabetes from day 1 of life, and hyperglycemia in parents, which was an important diagnostic clue. Apart from some other novel single case reports,^{86,87} an additional four novel cases of PNDM caused by homozygous mutations in *GCK* were reported in 2011.⁸⁸ Overall, these mutations are rare in NDM; in one large cohort of 54 cases of NDM, *GCK* mutations were found in only one case of European ancestry,⁸⁹ and the same was true for a study comparing the etiologies of PNDM in an Arab versus European population.⁹⁰

Pancreatic Duodenal Homeobox 1

Pancreatic duodenal homeobox 1 (*PDX1*), previously known as *insulin promoter factor 1* (*IPF1*), is a critical transcription factor that defines the pancreatic progenitor cell as it differentiates from the endodermal epithelium. Exocrine-duct lineage is then specified by the pancreas transcription factor 1 (PTF1), which defines the exocrine and duct cells. However, in the presence of NGN3, the progenitor cell differentiates into a series of endocrine pancreatic cells under the influence of other transcription factors, including PAX4. Thus *PDX1* is critical for the formation of both the exocrine and endocrine pancreas, and hence homozygous mutations will lead to an absence of pancreas formation with manifestations of neonatal diabetes and pancreatic exocrine insufficiency. The parents may be heterozygous carriers and therefore known to have a form of diabetes known as *MODY4*. The first case of pancreatic agenesis from a monogenic cause in 1997 revealed the etiology as a homozygous loss-of-function frameshift mutation in *PDX1*,⁹¹ whereas the second

case was reported in 2003,⁹² and the third case was reported in 2009⁹³; each of these patients were characterized by pancreatic agenesis with manifestations of both exocrine and endocrine abnormalities. In a more recent study, 103 patients in whom K_{ATP} and *INS* mutations had been excluded and who were not known to have abnormal development or clinical exocrine insufficiency of the pancreas, were tested and found to include four cases with homozygous or compound heterozygous *PDX1* mutations; thus it is possible to have PNDM caused by a mutation in *PDX1* without necessarily having complete pancreatic agenesis.⁹⁴ In this regard, it is important to note that neonatal diabetes may be associated with pancreatic, as well as cerebellar, agenesis as a result of mutations in the *PTF1A* gene (pancreas transcription factor 1A)⁹⁵ and that the *NEUROG3* gene (known as *Ngn3* in mice) can be associated with neonatal diabetes and congenital malabsorptive diarrhea consistent with the role of this gene in pancreas development as briefly described earlier.⁹⁶ Other genes that have been implicated in pancreatic agenesis or hypoplasia include *PTF1A*, *NEUROD1*, *EIF2AK3*, *HNF1B*, *RFX6*, *GATA4*, and *GATA6*, which may also be associated with other features, such as congenital heart defects or cerebellar agenesis.⁹⁷ As a diagnostic clue, if pancreatic imaging shows the absence or hypoplasia of a pancreas, the diagnostic search can be restricted to a series of genes as outlined.⁹⁸

Syndromic Neonatal Diabetes Mellitus

The syndromes associated with NDM together constitute a relatively small fraction of NDM that can vary considerably depending on the frequency of consanguineous unions in the population being studied.^{20,31} Although each form is rare, they are of interest in identifying the spectrum of genetic disorders that can result in abnormal pancreas formation, malfunction, or destruction. It is worth noting that the term syndromic is somewhat subjective but in this context helps to categorize very rare, usually recessive forms of PNDM. Even the most common forms of PNDM caused by K_{ATP} mutations could be considered syndromic based on their frequent variable neurodevelopmental dysfunction, especially with the most severe mutations causing DEND syndrome. In the past, syndromic features could be used to point to specific genes to be sequenced, but consensus opinion now suggests that all NDM patients should undergo comprehensive genetic testing for all known causes either all at once as part of an NGS panel or by using a tiered approach.³²

EIF2AK3: Wollcott-Rallison Syndrome

This rare condition is actually the most common genetic cause of PNDM in consanguineous families,^{90,99} and it may present as isolated nonautoimmune NDM diagnosed at 3 weeks of age or later. Typically, skeletal dysplasia and growth retardation are recognized in the first year or two of life; other manifestations include episodes of liver failure, renal dysfunction, and evidence of pancreatic exocrine insufficiency, neutropenia with recurrent infections, hypothyroidism, and mental retardation.¹⁰⁰ The basis for this condition are mutations in the *EIF2AK3* (eukaryotic translation initiation factor 2 alpha-kinase 3) gene (also known as *PKR-like endoplasmic reticulum kinase* or *PERK*), which participates in the unfolded protein response in the ER. Environmental factors and modification by other genes may influence the spectrum of clinical severity. Skeletal dysplasia with bone fractures and episodes of liver failure plus NDM are pathognomonic of this entity; a review in 2010 indicated that fewer than 60 cases had been reported worldwide¹⁰⁰; two novel mutations were subsequently reported.¹⁰¹ The prognosis is poor for affected patients. Treatment of the diabetes mellitus by pump therapy is recommended; parents should have genetic counseling for risks of recurrence, as this is an autosomal recessive condition.

FOXP3: IPEX Syndrome

The term *IPEX* is an acronym for immune dysregulation, polyendocrinopathy, enteropathy, X-linked and is caused by dysfunction of T regulatory cells caused by mutations in *FOXP3*, which normally is a transcriptional regulator for CD4 regulatory T cells, so that mutations result in the multiorgan autoimmunity. The clinical characteristics are early onset, insulin-dependent diabetes mellitus, or enteritis; eczema and elevated serum immunoglobulin (Ig)E also occur early. Later manifestations include primary hypothyroidism, nephritis, hepatitis, enteritis, and alopecia. Bone marrow stem cell transplant offers potential for cure, but it depends on the availability of a suitable donor.^{102,103} Scurfy mice serve as a model for this condition in humans.¹⁰⁴

Further study of patients with NDM has revealed cases carrying *FOXP3* mutations but without all features of the IPEX syndrome, as well as cases with multiple autoimmune conditions in addition to diabetes attributable to mutations in other genes important for immune regulatory function: *STAT1*, *STAT3*, *LRBA*, and *IL2RA*.^{27,28,105,106}

GLIS3: Neonatal Diabetes Mellitus With Congenital Hypothyroidism

GLIS3 is a member of the GLI-similar zinc finger protein family, which can function both as a repressor and activator of transcription and is specifically involved in the development of pancreatic beta cells, the thyroid, eye, liver, and kidney. An autosomal recessive syndrome, characterized by NDM, IUGR, congenital hypothyroidism, hepatic fibrosis with cholestasis, polycystic kidneys, and congenital glaucoma, was first described in 2003,¹⁰⁷ and the responsible mutation in the *GLIS3* gene was identified in 2006.¹⁰⁸ As noted, this gene is expressed in the early developmental stages of the thyroid, eye, liver, kidney, and the pancreas, particularly in beta cells. Thus mutations in *GLIS3* may have a role in other developmental anomalies and possibly in T1DM or T2DM. Novel mutations associated with the classical findings of NDM and hypothyroidism, plus bilateral sensorineural deafness, osteopenia, and pancreatic exocrine insufficiency, enlarge the clinical spectrum as reported.¹⁰⁹ In animal studies, it appears that *GLIS3* expression is required for pancreatic beta cell function and maintenance of beta cell mass in the adult, so that impaired function could lead to diabetes mellitus.^{110,111} Genome-wide association studies identify *GLIS3* as a locus that affects risk for T1DM,¹¹² and variants of *GLIS3* have been implicated in the predisposition to T2DM.¹¹³

PTF1A: Neonatal Diabetes Mellitus With Pancreatic and Cerebellar Agenesis

The gene *PTF1A* encodes pancreatic transcription factor 1 alpha known to be involved in pancreatic development. Mutations in this gene were identified in two families with NDM associated with pancreatic agenesis, as well as cerebellar agenesis, implicating this factor in normal cerebellar development, as well as pancreatic development, findings confirmed in knockout models of this gene in mice.⁹⁵

RFX6: Mitchell-Riley Syndrome With Biliary and Intestinal Atresia

In mice, it was shown that absence of the gene encoding transcription factor *Rfx6* prevents the formation of any pancreatic endocrine cells, except for pancreatic polypeptide producing cells; mutations in the human ortholog *RFX6* gene caused an autosomal recessive form of neonatal diabetes mellitus.¹¹⁴ In humans, the syndrome of NDM, intestinal atresia, and

hepatobiliary abnormalities had been known as the *Mitchell-Riley syndrome*.¹¹⁵ Clinically, patients are characterized by severe IUGR, fluctuations in glucose concentrations, stabilizing as persistent hyperglycemia and requiring insulin for treatment, cholestatic jaundice and anatomic findings of intestinal atresia, agenesis of the gall bladder, and abnormal formation of the pancreas. Quality of life may also be affected by mental retardation. Life expectancy for those who survive this critical neonatal period requiring intensive surgical and medical interventions is uncertain.¹¹⁶

MXN1 and *NKX2.2*

A fascinating report identified mutations in two other transcription factors previously known to be important for pancreatic beta cell development: *NKX2.2* homozygous mutations were found in two families with diabetes and severe developmental delay, hypotonia, cortical blindness, impaired visual tracking, and hearing impairment, whereas a more variable phenotype was found in two other families with homozygous *MXN1* mutations where both patients had diabetes, but only one had additional features, such as severe neurological complications, hypoplastic lungs, and sacral agenesis.¹¹⁷

NEUROG3: Neonatal Diabetes Mellitus With Congenital Malabsorptive Diarrhea

Neurogenin 3 (*NEUROG3*) is a critical transcription factor for the differentiation of islet endocrine cell types from the pancreatic endoderm. Mice lacking this factor are devoid of intestinal pancreatic endocrine cells and develop diabetes mellitus as newborns. In humans, homozygous mutations in the *NEUROG3* gene cause malabsorptive diarrhea and early-onset diabetes mellitus.^{96,118}

GATA6 and *GATA4*

Both *GATA4* and *GATA6* are critical factors with differential contributions for normal pancreatic organogenesis; double *Gata4* and *Gata6* knockout mice do not develop a pancreas and hence have diabetes.^{119–121} In humans, heterozygous inactivating mutations in *GATA6* were found to be the most common cause of pancreatic agenesis occurring in 15 of 27 subjects with pancreatic agenesis.¹²² These patients required both insulin plus pancreatic enzyme replacement.¹²² In a follow-up study,¹²³ the same investigators sought *GATA6* mutations in 171 subjects with NDM of unknown etiology, having already identified other mutations, including 15 with *GATA6* mutations, in 624 subjects out of a cohort totaling 795. In the new cohort of 171 remaining subjects, an additional nine new cases of *GATA6* mutations were identified for a total of 24 affected out of the original cohort of 795 subjects (3%). In these nine new cases, two had NDM but did not require pancreatic enzyme replacement, and one had TNDM. In addition, four parents were found to have *GATA6* mutations, but the diabetes was diagnosed between the ages of 12 and 46 years. Several of the nine new subjects had subclinical pancreatic enzyme deficiency. Except for one of the parents, subjects with *GATA6* mutations had extra pancreatic features, congenital heart malformations being found in 83%.¹²³ Mutations in *GATA4* were more recently shown to cause infancy-onset diabetes complicated by variable levels of pancreatic hypoplasia and exocrine insufficiency, pancreatic hypoplasia or complete agenesis, congenital heart defects, and neurodevelopmental delay.¹²⁴ Thus *GATA6* or *GATA4* mutations can cause PNDM or occasionally TNDM or adult-onset diabetes, with variable exocrine pancreatic insufficiency from complete agenesis, subclinical, or no deficiency at all.¹²³ Because the majority of cases manifest

congenital heart defects, it is reasonable to consider genetic testing in any individual with a congenital heart defect and diabetes, regardless of the age of onset of diabetes. In evaluating a patient with NDM, pancreatic imaging can be useful in that a finding of pancreatic agenesis or hypoplasia will suggest the need for clinical evaluation of exocrine pancreatic insufficiency or other features that are associated with a more restricted list of genes that include *GATA6*,¹²³ *GATA4*, *PDX1*, and *PTF1A*, as well as *EIF2AK3*, *HNF1B*, *GLIS3*, *NEUROG3*, and *RFX6*.⁹⁸

DIAGNOSIS AND TREATMENT OF NEONATAL DIABETES MELLITUS

NDM is extremely difficult to diagnose clinically, because the cardinal signs of diabetes resulting from osmotic diuresis—polyuria and polydipsia—are masked by the normal high-volume liquid diet of infancy, and clinicians may be reassured rather than worried when babies are feeding frequently and have lots of wet diapers. A diabetes diagnosis can be considered in neonates and infants who display IUGR in utero or at birth, or who fail to thrive despite apparent adequate intake with normal or copious urine output. A positive family history of diabetes mellitus (especially neonatal or infancy-onset) in one or both parents, or in prior siblings, points to a likely genetic cause; however, most cases will be caused by de novo mutations. The diagnosis is established by confirmation of sustained significant hyperglycemia and/or glycosuria, both readily available in hospitals or medical clinics. Recognition of diabetes mellitus within the first week of life often represents TNDM1, because of the differential expression of imprinted genes on chromosome 6q24, particularly if congenital defects, such as macroglossia and umbilical hernia, are present. Somewhat later recognition should also include consideration of defects in the K_{ATP} channel, involving *KCNJ11* and *ABCC8* genes, as well as the *INS* gene; diabetes-associated autoantibodies need not necessarily be determined, unless the baby is close to or older than 6 months of age at the time of diabetes diagnosis, or if other signs of immune dysfunction are present.

Genetic testing is mandatory in any infant diagnosed with diabetes under 6 months of age and should be considered in patients diagnosed up to a year of age or with other features suggestive of an underlying monogenic cause. Although a majority of cases will be related to 6q24 or mutations in *KCNJ11*, *ABCC8*, and *INS*, consensus guidelines recommend urgent comprehensive testing of all known genes either with NGS panels or through a tiered approach.³² A cause can be found in approximately 80% or more of cases diagnosed under 6 months of age, as well as a less certain fraction of cases diagnosed after 6 months of age. A molecular diagnosis is critical not only for guiding the possibility of completely different medical management, but also for guiding monitoring and evaluation of other possible associated features, informing long-term prognosis and outcome, as well as family genetic counseling. Current methodology permits molecular diagnosis to be completed relatively quickly with initial results often available within 1 to 2 weeks. Although commercial testing is available in many countries, consultation with regional centers of expertise can help guide testing decisions and interpretation, as well as allowing for the accrual of accumulated knowledge about best treatment and outcome for these rare disorders. If needed, many of these centers also enable genetic testing without charge as a result of funding from various national agencies (see Available Resources section later).

Insulin therapy is the mainstay of initial treatment in all cases, with the goal of rapidly correcting metabolic derangement and establishing normoglycemia. Because patients will

TABLE 10.2 Inpatient Transition to Oral Sulfonylurea

Day	Glucose Monitoring	Insulin Adjustments	Glyburide Dosing
Prep	Monitor capillary blood glucose (BG) before meals, 2 hours postmeals, bedtime, and 2 a.m. Monitor ketones any time BG is > 300 mg/dL (> 16 mmol/L) Have a plan for hypoglycemia	Maintain usual insulin regimen either via pump or customary basal-bolus injections Reduce basal insulin by 50% (If pump is being used, can be done just before day 1 breakfast; if long-acting insulin is being used, may be reduced on previous evening)	The experience of previous cases with the same mutation will help inform expected response Tablets (easily halved) available: 1.25, 2.5, or 5 mg For infants, tablets can be crushed and suspended in water/formula at the bedside or by any pharmacy
1	If BG before dinner dose is: > 126 mg/dL (7 mmol/L) → < 126 mg/dL (7 mmol/L) →	Administer rapid-acting bolus insulin as needed based on capillary BG: Give usual bolus insulin dose Give 50% of usual insulin dose	0.1 mg/kg before breakfast and dinner (total of 0.2 mg/kg/day), depending on BG: Give 0.1 mg/kg dose at dinner Dinner dose may be skipped
2-7	If BG before SU dose is: > 126 mg/dL (7 mmol/L) → < 126 mg/dL (7 mmol/L) →	Continue decreasing insulin as tolerated: Continue bolus dosing from previous day Decrease insulin bolus by 50%	Each day dose will increase by 0.2 mg/kg/day (0.1 mg/kg/dose) depending on BGs: Increase dose by 0.1 mg/kg/dose May continue dose from previous day
Last	On final day and after discharge continue checking BG at least 4–6 times per day to monitor response. Relative hypoglycemia may necessitate lowering of glyburide dose in following weeks-months	In most SU-responsive cases, insulin can be discontinued within 5–7 days, although mild hyperglycemia may still occur. Treat with rapid-acting bolus insulin as needed, as well as low-dose basal insulin in some cases. It may be possible to discontinue insulin in the following weeks-months	By the end of 5–7 day admission, the patient will either have clearly responded on a lower dose or will be on at least 1 mg/kg/day. The dose may continue to be increased after discharge if needed, with some patients requiring up to 2–2.5 mg/kg/day (which may be lowered eventually in the following weeks-months)
Notes	If expected response is uncertain, C-peptide levels pre- and 90–120 minutes postbreakfast (no insulin given) may be done on day 1 and a later day after the glyburide dose is at least 1 mg/kg/day (usually day 5) If levels pre-SU are nearly undetectable but show a significant increment on glyburide, consider increasing dose as high as 2–2.5 mg/kg/day	BG ranges and insulin adjustments are only a guideline; the physician should be guided by clinical judgment. If there is any indication that glyburide is helping to control BG levels overall, it is often better to decrease the insulin aggressively so as to avoid hypoglycemia If little/no insulin is given with meals, corrections for high BGs (per usual sensitivity/correction scale) may be given postmealtime or at any time	Patients with neurodevelopmental disability or those who are older at the time of transition may experience less responsiveness and require higher doses of glyburide. In such cases, the possible benefit of continuing a high dose for the long term should be carefully considered even if the patient still requires insulin

SU, Sulfonylurea.

Adapted from Pearson, E. R., Flechtner, I., Njolstad, P. R., et al. (2006). Switching from insulin to oral sulfonylureas in patients with diabetes due to Kir6.2 mutations. *N Engl J Med*, 355, 467–77. Contact monogenicdiabetes@uchicago.edu for more details.

often have DKA and/or be managed in intensive care units, an IV insulin drip is a viable and effective initial choice, but because this route requires IV access, it is not ideal for the long term. Subsequently, or in the absence of DKA, subcutaneous insulin can be used with regimens similar to older patients, although it should be understood that neonates and infants are often extremely sensitive to very small doses of insulin. A multiple daily injection insulin regimen similar to any type 1 diabetes patient will be effective, but in most cases will require dilution of the typical U100 rapid-acting insulin, which is typically done as a 1:10 dilution (U10, or 10 units/mL). When the appropriate diluent provided by the manufacturer is used, the diluted insulin should be as stable as typical insulin. A very small dose (often the minimal feasible dose of 0.5 unit) of long-acting basal insulin is favored over giving a larger dose that may be tolerated while the infant is feeding frequently but may ultimately be more than appropriate for basal requirements and cause significant hypoglycemia as the baby sleeps better and starts to space out the timing of feedings. Another excellent option if available is an insulin pump, with which it is usually not necessary to use diluted insulin because of the extremely low doses of bolus and basal insulin that can be programmed.¹²⁵

Once the patient is stable and genetic testing has been sent, some experts recommend that a brief glyburide trial could be considered while the family receives diabetes education and preparations are being made for discharge.⁴³ In

the absence of consanguinity or features suggestive of a rare syndromic cause, the chances of carrying a sulfonylurea responsive mutation approaches 50%.³¹ A standard protocol (Table 10.2) should be followed whereby the dose of glyburide is increased daily if hyperglycemia persists, and meanwhile correcting with appropriate modest doses of insulin to maintain reasonable glycemic control. It is important to discuss the relative risks and benefits with the family and be mindful of the high likelihood of failure. If no significant improvement of hyperglycemia is seen after a few days of increasing to a dose approaching 1 mg/kg/day, then the patient should resume insulin monotherapy pending genetic testing results.

MONOGENIC CAUSES OF DIABETES OF ADOLESCENCE/YOUNG ADULTHOOD: MATURITY-ONSET DIABETES OF THE YOUNG

MODY was described as a clinical phenotype distinct from other forms of diabetes by astute clinical scientists who recognized the high prevalence of diabetes occurring at a relatively young age within certain families that suggested an autosomal dominant pattern of inheritance. MODY is now understood to have somewhat different clinical presentations depending on the underlying gene cause and has now been reported to be caused by mutations in up to 12 to 14 different genes,¹²⁶

although some of these gene causes remain under dispute as to their actual pathogenicity (Table 10.3). The most common forms of MODY result from highly penetrant autosomal dominant rare mutations in genes important for beta cell function. Affected patients often have a mild disease presentation marked by modest elevation of glucose often without ketosis, that may be revealed by incidental laboratory testing in asymptomatic patients or may become clinically apparent during intercurrent illness, pregnancy, or puberty that unmasks the limited insulin secretion.^{44,127} Traditional clinical criteria used to define the phenotype of MODY are not absolute indicators of an underlying monogenic diagnosis but help to identify patients who may benefit from genetic testing:

- Dominant inheritance with at least two (and preferably three) consecutive affected generations (but de novo mutations can occur)
- Diabetes onset typically before age 25 to 30 years (some patients will not be diagnosed until older ages; consider whether other family members were diagnosed at younger ages)
- Evidence of significant but impaired residual insulin secretion reflected in C-peptide levels whether or not the patient is being treated with insulin
- Autoantibody tests associated with T1DM will in most cases be negative (very rare exceptions have been reported)
- A distinct phenotype of stable, mild, nonprogressive hyperglycemia in asymptomatic individuals suggests GCK-MODY

Overall, monogenic forms of diabetes may represent up to 2% to 5% of diabetes in those diagnosed under 30 to 35 years of age and may represent as much as 0.4% of all diabetes. GCK mutations appear to have a high population prevalence, with a higher fraction of GCK mutations found in those with suspected MODY who are younger because the stable mild hyperglycemia may be incidentally detected any time after birth. Microvascular complications are rare in GCK-MODY but will occur in those with *HNF1A/HNF4A* mutations (“transcription factor MODY”) because the disease is progressive over time. Diabetes in *HNF1A/4A*-MODY is most often diagnosed in adolescence and young adulthood and is rarely diagnosed before 10 years of age. *HNF1B*-MODY (MODY5) is characterized by renal cysts or other genitourinary anomalies with diabetes.^{44,127} Other rare but important causes of diabetes with a MODY phenotype include milder defects in the K_{ATP} genes *KCNJ11* and *ABCC8* (who will usually respond to oral sulfonylurea treatment), as well as defects in the *INS* itself (see Table 10.3).^{44,127}

Glucokinase Maturity-Onset Diabetes of the Young (MODY2)

GCK, a hexokinase family enzyme, acts in the pancreatic beta cells as the “glucose sensor,” catalyzing the first reaction in the glycolytic pathway by phosphorylating glucose to glucose-6-phosphate. Inactivating heterozygous mutations causing decreased GCK activity leads to insulin release occurring at slightly higher glucose levels, and individuals with these mutations consequently exhibit mild fasting asymptomatic hyperglycemia.^{128,129} There is an important contribution from the liver, which also requires normal levels of GCK, and the enzyme is also present in the appetite centers of the brain. Homozygous or compound heterozygous inactivating mutations, although rare, may result in permanent neonatal diabetes, requiring insulin therapy, whereas homozygous activating mutations can rarely result in neonatal hyperinsulinemic hypoglycemia (see Chapter 7).¹³⁰

The most characteristic feature of GCK-MODY that distinguishes it from other forms of monogenic diabetes is mild stable fasting hyperglycemia, reflected in mildly elevated hemoglobin (Hb)A1c levels that are rarely above 7.5%. In addition to fasting hyperglycemia, a relatively low 2-hour glucose value is seen following oral glucose tolerance test. This may be caused by the shifted glucose sensing defect causing insulin secretion at a higher set point, but peak insulin secretion is not blunted, and first-phase insulin secretion generally is preserved.^{128,129} In a cross-sectional study, patients with GCK-MODY were shown to have a low prevalence of clinically significant microvascular complications (1%) compared with control group (2%) and those with young-onset type 2 diabetes (36%).¹³¹

Some have reported the population prevalence of GCK-MODY as 1.1 in 1000 or 0.11%, and in pregnant women, 9 in 1000, or 0.93%.¹³² GCK-MODY commonly presents in pregnancy because this may be the first time a woman’s blood glucose level was ever checked. The prevalence in pregnancy highlights the importance of correctly diagnosing GCK-MODY because management options will differ from other types of gestational diabetes mellitus. Using the combination of body mass index less than 25 and fasting glucose of 100 or more, the Atlantic Diabetes in Pregnancy cohort used these tools for 68% sensitivity and 99% specificity for distinguishing GCK-MODY from GDM, with 2.7 needing to undergo genetic testing to diagnose one case of GCK-MODY.¹³² Treatment recommendations in GCK-MODY pregnancies are also affected by the fetal genetic status. An unaffected fetus born to a mother with GCK-MODY will have increased insulin secretion caused by mild maternal hyperglycemia, presenting a risk for increased birth weight and macrosomia, whereas an affected fetus will likely have normal birth because they share an altered set point for hyperglycemia resulting from the mutation. A fetus with paternally inherited GCK-MODY born to an unaffected mother would have a lower birth weight.¹³³ As invasive sampling is not currently recommended, routine ultrasounds beginning at 26 weeks allow for monitoring of accelerated fetal growth. If accelerated growth is noted, insulin therapy in the mother may be considered, but may not be effective in preventing macrosomia in a fetus presumed to be negative for mutations.¹³³

HNF1A/HNF4A: Transcription Factor Maturity-Onset Diabetes of the Young (MODY3/MODY1)

The most common MODY phenotype is caused by mutations encoding either of two important pancreatic transcription factors, *HNF1A* (MODY3) or *HNF4A* (MODY1). The patients are usually diagnosed with diabetes in adolescence or young adulthood (most often, but not always, >10 years of age and <30 years of age), and will often have an autosomal dominant pattern of diabetes in several generations of the family. Well-preserved beta cell function would be expected earlier in the disease course, with presenting HbA1c usually under 10%, and often under 7.5%. Although significant ketosis or DKA is unlikely, it has been reported in rare cases. *HNF4A* mutations are a much rarer cause of transcription factor MODY than *HNF1A*, but more often *HNF4A* patients and/or family members will have a history of higher birth weights and/or hyperinsulinemic hypoglycemia during the neonatal period (the mechanisms for which are poorly understood). A classic feature of *HNF1A* mutations that is often shared by those with *HNF4A* mutations is that they often do well with low-dose insulin treatment but are especially sensitive to treatment with low doses of sulfonylureas. In fact, some patients or family members will

TABLE 10.3 Genes Associated With MODY

Gene	OMIM # / Designation	Importance of Genetic Diagnosis	Comments
Genes for which genetic diagnosis has significant treatment implications; causal variants have high penetrance			
<i>GCK</i>	125851 / MODY2	Caused by highly penetrant heterozygous loss-of-function variants; most patients will not require ANY treatment, except possibly during pregnancy	Relatively high population prevalence of causal variants (approximately 1:1000) Inheritance of biallelic variants can cause neonatal diabetes
<i>HNF1A</i>	600496 / MODY3	Caused by highly penetrant heterozygous loss-of-function variants; usually responsive to low-dose oral sulfonylureas	Most common cause of treatment-requiring MODY. Glucosuria is common. Risk for benign hepatic adenomas (rarely can become large and/or complicated)
<i>HNF4A</i>	125850 / MODY1	Caused by highly penetrant heterozygous loss-of-function variants; usually responsive to low-dose oral sulfonylureas	Patient or family members may have history of large birth weights and/or hyperinsulinemic hypoglycemia
<i>HNF1B</i>	137920 / MODY5	Caused by heterozygous loss-of-function variants; renal manifestations appear to be more penetrant than diabetes; best treatment for diabetes not well established; genetic diagnosis will inform monitoring and management of other features	Other features may include genitourinary malformations (particularly renal cysts), altered liver function tests, hypomagnesemia, hyperuricemia, exocrine pancreatic insufficiency, and/or developmental delay (as part of chromosome 17q deletion syndrome)
<i>ABCC8</i>	600509 / MODY12	Caused by rare highly penetrant heterozygous missense mutations; usually respond to medium-high dose oral sulfonylureas	Same or similar mutations may also cause TNDM and similar but more severe mutations cause PNDM (most often heterozygous missense mutations)
<i>KCNJ11</i>	616329 / MODY13	Caused by rare highly penetrant heterozygous missense mutations; usually respond to medium-high dose oral sulfonylureas	Same or similar heterozygous missense mutations may also cause TNDM and similar but more severe mutations are the most common cause of PNDM
Genes with good evidence for causality but genetic diagnosis less likely to result in treatment difference; causal variants may have lower penetrance			
<i>INS</i>	613370 / MODY10	Very rare heterozygous variants cause MODY-like phenotype; best treatment not established	Pathogenic heterozygous variants more often cause neonatal diabetes, but certain rare variants are more often associated with a MODY-like phenotype
<i>RFX6</i>	N/A	Very rare pathogenic heterozygous variants associated with MODY-like diabetes with incomplete penetrance. Best treatment not established	Inheritance of biallelic variants can cause neonatal diabetes with other features
<i>NEUROD1</i>	606394 / MODY6	Very rare pathogenic heterozygous variants associated with MODY-like diabetes with incomplete penetrance. Best treatment not established	Inheritance of biallelic variants can cause neonatal diabetes with other features
<i>CEL</i>	609812 / MODY8	Very rare pathogenic heterozygous mutations in the VNTR of <i>CEL</i> associated with MODY-like diabetes. Best treatment not established	Very likely to include exocrine pancreatic insufficiency (can be assessed by fecal elastase)
<i>APPL1</i>	616511 / MODY14	Very rare pathogenic heterozygous variants associated with MODY-like diabetes with incomplete penetrance. Best treatment not established	Only two families reported, with diabetes onset in third to fourth decades of life
<i>PDX1</i>	606392 / MODY4	Very rare pathogenic heterozygous variants (e.g., 188delC, Pro63fs, ClinVar variation ID 8857) associated with MODY-like diabetes with incomplete penetrance. Best treatment not established.	Nonpathogenic variants, or those of uncertain significance (VUS) are more common than pathogenic variants. Inheritance of rare pathogenic biallelic variants can cause NDM with pancreatic hypoplasia
Genes for which the evidence for causality remains uncertain			
<i>KLF11</i>	610508 / MODY7	The few published reports describe MODY-like patients who carry variants that are present in genomic databases at frequencies higher than expected for variants causing monogenic diabetes	
<i>PAX4</i>	612225 / MODY9		
<i>BLK</i>	613375 / MODY11		

MODY, Maturity-onset diabetes of the young; *PNDM*, permanent neonatal diabetes mellitus; *TNDM*, transient neonatal diabetes mellitus.

Note: If a variant is extremely rare or even novel, it does not necessarily mean it is causal. Allele frequency depends greatly on particular genes, as well as specific populations, but in general, any variant present in population databases at a frequency greater than or equal to 0.0001 (0.01%) is highly unlikely to be causal for a monogenic form of diabetes. In case of any uncertainty, consider consultation with experts familiar with monogenic diabetes genes and interrogation of genomic information (see Available Resources section).

note a history of hypoglycemia with the use of sulfonylurea drugs, even from the initial dose. The long-term sustainability of sulfonylurea treatment has not been conclusively demonstrated, but several studies report the superiority of sulfonylurea therapy compared with insulin, particularly early in treatment.¹³⁴ A few small studies, and some case reports, have suggested the benefit of additional medications, such as GLP-1 receptor agonists if sulfonylurea monotherapy is not sufficient.¹³⁵ Glinide medications have a shorter half-life and may allow for a lower risk of hypoglycemia in some circumstances.¹³⁶ There are excellent recent reviews that provide guidance on management of *HNF1A*- and *HNF4A*-MODY during pregnancy.^{133,137}

***HNF1B*: Maturity-Onset Diabetes of the Young With Renal Cysts (MODY5—RCAD)**

Heterozygous mutations or large deletions of the pancreatic beta cell transcription factor *HNF1B* are a relatively rare cause of MODY that are characterized by renal cysts and/or developmental defects of the genitourinary system and diabetes.

HNF1B mutations seem to have a somewhat lower penetrance for diabetes than other forms of MODY, so some family members may exhibit renal abnormalities without a diabetes diagnosis.

These patients do not exhibit a similar sensitivity to sulfonylurea therapy as *HNF1A/HNF4A*-MODY, so the best

treatment approach, while not established, may well be insulin. In one large recent study of 201 *HNF1B* patients, 49% were treated with insulin at diabetes diagnosis, and 79% were treated with insulin at follow-up.¹³⁸ Over half (57%) exhibited some responsiveness to sulfonylurea or repaglinide within the first few years of diabetes diagnosis; however, switching from insulin to sulfonylurea or repaglinide was only successful in 30% of patients. One case report described successful treatment of a 17-year-old patient with oral medications (sitagliptin and glimepiride) for 6 years, but thereafter insulin was required.¹³⁹

Other Forms of Monogenic Diabetes

Mitochondrial Diabetes

Mitochondrial genetic defects that cause diabetes are commonly but not invariably associated with neuromuscular disorders, including deafness, migraine, seizures, focal segmental glomerulosclerosis, and mental retardation. For example, the MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) syndrome may initially present in childhood with short stature, go on to deafness in teen years, and develop diabetes and encephalopathy in midlife. Diabetes mellitus may be the only (or early) manifestation of a mitochondrial disorder encoded by a gene defect within the mitochondria (all of which are maternally inherited) or a nuclear deoxyribonucleic acid (DNA)-encoded gene necessary to the oxidative phosphorylation sequence within mitochondria, which would be predicted to have more devastating effects because all mitochondria should be affected. The variability of the syndrome is caused by heteroplasmy, as the number of mitochondria with the mutation (usually encoding the mitochondrial transfer [t]RNA-leu) varies from a few percent and up, and there is a variation from tissue to tissue.

This defective energy pathway leads to progressive impairment of insulin secretion, and thus an initially mild hyperglycemia may progressively worsen. This is the case with the most common form of diabetes caused by a mitochondrial gene mutation at nucleotide pair (np) 3243 of the mitochondrial genome in the tRNA-leu, often associated with (low-frequency) deafness. Remarkably, this same genetic defect causing maternally inherited diabetes with deafness (MIDD) may then later on be associated with the MELAS syndrome. Initially, patients with np 3243 mutations can be controlled by diet alone but later may require insulin. Metformin has been used but because it may be a mild mitochondrial toxin, it may not be the most appropriate therapy.

Diabetes mellitus presenting in infancy and severe from the outset and requiring insulin may be associated with large mitochondrial DNA deletions, as seen in the Kearns-Sayre syndrome and Pearson syndrome.^{140,141}

WFS1: Wolfram Syndrome

Wolfram syndrome 1 (the classic form) is characterized by diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (previously termed *DIDMOAD*).^{142–144} There is a selective loss of functional beta cells, which is responsible for the diabetes mellitus. Genetic linkage studies in consanguineous families with autosomal-recessive inheritance led to the positional cloning of a gene on the short arm of chromosome 4 (termed *WFS1*, and now named *wolframin*).

WFS1 encodes an ER protein, which has functions including regulation of ER stress signaling and calcium homeostasis.¹⁴⁵ Loss-of-gene function is believed to result in progressive decline of endocrine and neurological function by inducing chronic ER stress-mediated apoptosis of pancreatic beta cells and neuronal cells.¹⁴⁶

WFS1 is expressed in many tissues (most abundantly in beta cells, compared with the exocrine pancreas), including the

brain. Mutations in wolframin have been identified in many families with Wolfram syndrome. Affected individuals are often compound heterozygotes, but homozygous cases will be more common in populations with higher rates of consanguineous unions. The *WFS1* gene may have a role in beta cell and neural tissue survival, and there does not appear to be a correlation between the observed mutation and severity of disease. Defects in wolframin have been implicated in the idiopathic common nonimmune form (antiislet antibody negative) of clinically suspected type 1 diabetes mellitus.¹⁴⁴ A second locus of Wolfram syndrome (*WFS2*) was mapped to the *CISD2* gene on chromosome 4 based on several consanguineous Jordanian families.¹⁴⁴ In these patients, diabetes insipidus was not a feature—but upper gastrointestinal bleeding and ulceration were prominent.

Although a mitochondrial form of Wolfram syndrome has been proposed, a defect in mitochondrial DNA could not be confirmed in one large cohort.¹⁴⁵ It has been suggested that diabetes mellitus (before age 15 years) and progressive optic atrophy are highly predictive of Wolfram syndrome. The sequence of appearance of the stigmata may be variable but most often nonautoimmune clinical “type 1 diabetes” will occur first, within the first decade of life, whereas optic atrophy will usually occur early in the second decade; central diabetes insipidus and sensorineural deafness (low frequency deafness is seen) in two-thirds to three-fourths of the patients within the second decade; renal tract anomalies in approximately half within the third decade; and neurological complications, such as cerebellar ataxia and myoclonus, in half to two-thirds by the fourth decade. Other features include primary gonadal atrophy in the majority of males and a progressive neurodegenerative course with neurorespiratory death at a median age of 30 years. Depression has been reported as a frequent feature of relatives of patients with Wolfram syndrome.¹⁴⁴ Genetic testing can be considered among the 5% to 10% of young people with clinical type 1 diabetes who will be antiislet antibody negative, but such testing is more urgently indicated in any such patient who also exhibits other features, such as hearing or vision loss.

SLC19A: Thiamine-Responsive Megaloblastic Anemia and Diabetes (Rogers Syndrome)

This syndrome is characterized by megaloblastic anemia, diabetes mellitus, and sensorineural deafness—all of which may respond to vitamin B₁ (thiamine). Diabetes mellitus is mild to moderate, insulin secretion may improve with thiamine therapy, and there are no associated autoimmune markers. It may be caused by a defect in the thiamine transporter,^{147,148} which has now been identified as being caused by mutations in the *SLC19A* gene. This gene encodes the membrane-bound thiamine transporter THTR1.

Uptake of thiamine by the combined pathways of an active high-affinity carrier and a passive low-affinity carrier leads to accumulation of intracellular thiamine, which is then converted to its active form, thiamine pyrophosphate. This cofactor enables proper function of transketolase, which is important in the pentose phosphate shunt, the key to ribose synthesis and hence nucleic acid production and of pyruvate dehydrogenase, α -ketoglutarate dehydrogenase, and branched chain acid dehydrogenase—all of which are key to oxidative decarboxylation. Mutations in the high-affinity transporter THTR1 lead to cell death in those cells that have a high rate of nucleic acid turnover (such as bone marrow cells) and activity (such as pancreatic beta cells), thereby explaining the association of thiamine-responsive anemia with diabetes in those affected by this mutation.

Other Forms of Monogenic Diabetes. With the advent of NGS platforms, other genes have also been rarely implicated in monogenic diabetes and the list is growing. Consultations with experts in the field are strongly recommended. Another

reason for seeking consultation is that many genetic reports contain listings of variants of uncertain significance (VUS). Although these may be disease-causing, more often they are not, and have not yet been reported. Experts in genetic analysis of monogenic diabetes can provide important information, and changes should never be made in treatment based on a reported VUS sequence alteration.

It is important to note that we have focused in this chapter on genes that result in beta cell defects. Other genes that control insulin action, such as the insulin receptor itself (*INSR*), and genes associated with lipodystrophy may also lead to diabetes. As the availability of NGS testing increases, additional genes associated with monogenic diabetes are likely to be found.

AVAILABLE RESOURCES

The following resources offer advice on diagnostic management of patients with known or suspected monogenic diabetes and may also be able to provide genetic testing free of charge through funding from national governmental agencies:

www.diabetesgenes.org (Exeter, United Kingdom)

<https://monogenicdiabetes.uchicago.edu> (Chicago, United States)

www.mody.no (Norway)

Resource for finding laboratories offering clinical testing:

<https://www.ncbi.nlm.nih.gov/gtr/> (NCBI Genetic Testing Registry)

TRANSITION TO ORAL THERAPY

1. K_{ATP} (*KCNJ11/ABCC8*) mutations. Once the diagnosis of a mutation in the K_{ATP} channel likely to respond to sulfonylurea is established, transition to oral treatment from insulin treatment may be best accomplished on an inpatient basis, where blood sugars can be monitored frequently, the dose of insulin reduced quickly, and the dose of sulfonylurea increased rapidly. Depending on the age of the patient, whole or half-tablets, or a suspension of glyburide prepared in a pharmacy may be needed to facilitate the swallowing of the medication. The starting dose is typically 0.2 mg/kg/day in two divided doses, but

this starting dose may be decreased by half in newborns who may be especially insulin-sensitive and responsive to treatment. Table 10.2 outlines the sequential steps to be taken in transitioning the patient and is based on recommendations from NDM centers in both the United Kingdom and the United States.

2. *HNF1A* and *HNF4A*. *HNF1A/4A* mutations often respond dramatically to low-dose sulfonylureas, especially in younger patients. A starting dose equivalent to 0.625 mg of glyburide is often sufficient to allow for rapid withdrawal of insulin (so as to avoid hypoglycemia). Gradual increase of sulfonylurea dose may be necessary over time, based on blood glucose monitoring and possibly C-peptide levels. Additional agents, such as GLP-1 receptor agonists, may be helpful if glycemic control remains nonoptimal at sulfonylurea doses at the higher range recommended for type 2 diabetes (*HNF1A/4A* should not require very high doses as needed by K_{ATP} mutation patients).

FUTURE DIRECTIONS

The discovery of the genes responsible for various forms of NDM and MODY has been spectacular in its impact on the diagnosis and treatment of affected patients and its relevance to understanding the global burden of diabetes mellitus. The same genetic defects that cause NDM and/or MODY have been found in parents or unrelated individuals considered to have T2DM or classic-appearing T1DM that is nonautoimmune in origin. Thus these discoveries have informed potential mechanisms by which insulin secretion is impaired at the level of pancreas formation and development, insulin synthesis, and insulin secretion. In addition, this offers the possibility to overcome the defect through the pharmacogenetics of the K_{ATP} channel in which activating mutations can be overcome by sulfonylurea treatment. However, the cause of diabetes occurring under 6 months of age remains unknown in about 15% of cases, and many others diagnosed after 6 months of age may not have typical autoimmune type 1 diabetes. Whole genome sequencing¹⁴⁹ along with improved understanding of noncoding regulatory regions may reveal the basis for these undefined syndromes in the near future.

BOX 10.1 Neonatal Diabetes Mellitus

1. Genetic testing will reveal a monogenic cause for diabetes occurring under 6 months of age in about 85% of cases
2. A monogenic cause will be found in a lower fraction of those diagnosed 6–12 months of age or even later, whereas autoimmune type 1 diabetes becomes increasingly more likely. Genetic testing should be considered if islet cell antibodies are negative, there is a strong family history of diabetes, and/or other syndromic features (e.g., congenital heart defects, developmental delay or multiple autoimmune problems) are present
3. Comprehensive and rapid genetic testing is essential to guide specific treatment, anticipate possible remission and familial recurrence risk, and assess associated syndromes
4. Many infants with NDM will enter a remission phase for a variable period of time (transient diabetes mellitus); of these, about 2/3 will be caused by overexpression of genes on 6q24 (see Fig. 10.3), about 1/3 caused by mutations in the K_{ATP} genes *ABCC8* or *KCNJ11*, and very rarely resulting from other gene causes
5. Permanent diabetes mellitus is most commonly caused by heterozygous mutations in *KCNJ11*, *INS*, and *ABCC8* (see Fig. 10.2) that are most often de novo but can be inherited in an autosomal dominant fashion
6. Rarer causes often include syndromic features, such as heterozygous *GATA6/GATA4* mutations causing pancreatic hypoplasia with congenital heart defects, x-linked *foxp3* mutations causing NDM with other autoimmune dysfunction, and a long list of very rare recessive gene causes (see Fig. 10.2)
7. The majority of patients with mutations in *KCNJ11/ABCC8* respond to high-dose oral sulfonylurea medications with improved endogenous insulin secretion, improved HbA1c and quality of life; neurodevelopmental improvement may also occur, especially when treatment starts early
8. Up to 66% of new cases of neonatal diabetes will present in diabetic ketoacidosis (less likely with 6q24-related diabetes)
9. Any baby with diabetes is at greater risk of developmental delay and should be referred for early assessment and provision of any needed therapies (speech, physical, occupational, developmental), as well as ongoing monitoring during childhood for behavioral or learning difficulties, as well as seizures. Certain gene causes (including the most common: *KCNJ11* AND *ABCC8*) affect brain development and function and require close monitoring and support

BOX 10.2 MODY

1. MODY constitutes about 3%–5% of childhood diabetes (about 0.4% of all diabetes) and should be suspected in those with any of these features (none of which are absolute):
 - A. Autosomal dominant family history of diabetes with individuals affected across 2 to 3 generations
 - B. Onset before age 25 to 35 years (usually) but also usually after 8 to 10 years of age
 - C. Absence of markers of anti-beta cell autoimmunity
 - D. Absence of indicators of insulin resistance, such as acanthosis nigricans, characteristic dyslipidemia and/or significant obesity (note: individuals with these features could still have MODY)
 - E. “Mild diabetes” with initial HbA1c <10%, absence of significant ketosis, persistently low insulin requirements with surprisingly good glycemic control even 3 to 5 years after diagnosis
2. GCK-MODY (MODY2) has a distinct phenotype in addition to the earlier points
 - A. Mild, persistent, nonprogressive, fasting hyperglycemia (often 110–140 mg/dL)
 - B. HbA1c rarely in excess of 7.5%
 - C. Extremely low risk of any hyperglycemia-related complications
 - D. GCK-MODY does not require any treatment (not even diet modification)
 - E. The one exception is that treatment may be considered under certain circumstances during pregnancy (to try to prevent macrosomia in unaffected fetus)
 - F. Fasting hyperglycemia also present in children as this is a life-long condition
 - G. Caused by dominant mutations in glucokinase (GCK), with population frequency around 0.1%
3. *HNF1A* / *HNF4A* MODY (MODY3/MODY1)
 - A. Frequently respond to low doses of sulfonylurea (SU) drugs (less so with *HNF4A*)
 - B. Greater SU responsiveness (even hypoglycemia) earlier in the course of the disease
 - C. Beta cell dysfunction is characterized by insufficient insulin secretion and is progressive
 - D. Eventually additional hypoglycemic medications may be required (SGLT2 inhibitors may be contraindicated)
 - E. All diabetes-related complications may occur, dependent on metabolic control
 - F. Lipid profile better than in type 2 diabetes, but still at higher cardiovascular risk than unaffected relatives
4. Rarer forms of MODY are listed in Table 10.3 and include other causes for which treatment could change, such as *KCNJ11* and *ABCC8* that often respond to higher doses of SU drugs

MODY, Maturity-onset diabetes of the young; SGLT2, sodium glucose transport protein 2.

INTRODUCTION

Human growth is an astonishing process. Its beginnings are intertwined with the enormously intricate mechanisms that transform a single cell into a complex embryo. Once formed, the human fetus and then child continue to grow over the course of approximately 15 years, reaching a body mass more than 10,000,000 times greater than that of the zygote from which the child originated. The early growth rate is enormous. The fetus grows in length at more than 100 cm per year, but, by birth, the linear growth rate has slowed to 50 cm per year and by midchildhood to 5 cm per year. This decline in the growth rate is briefly interrupted by the pubertal growth spurt but then resumes, causing body growth to gradually grind to a halt as the child approaches adulthood. During the period of body enlargement, growth of the different organs, such as the kidney, heart, lung, liver, and bones, occurs synchronously, orchestrated to maintain body proportions.

In the majority of children, the largely mysterious mechanisms governing body growth proceed like clockwork, yielding an adult height most often between 1.5 and 2 m. However, in some children, body growth is either greater than or less than the normal range, often prompting the concerned family to seek medical evaluation.

The healthcare provider is then called upon to answer two questions. First, why is the child's growth outside the normal range and second what, if anything, should be done about it. The first question, "why," is important for several reasons. Many children are short or tall because they have inherited from their parents a large set of normal polymorphisms that place the child in one tail of the normal height distribution or the other. Such polygenic short or tall stature is generally benign. However, some children are short or tall because of a single gene abnormality that may have important health implications, such as a propensity to cardiac malformations or to malignancies. Other children are short because of a subtle systemic acquired disease, such as inflammatory bowel disease (IBD), autoimmune thyroiditis, or a central nervous system (CNS) tumor causing pituitary dysfunction. Thus the healthcare provider who evaluates children's growth faces the

challenge of sorting out the few children with important underlying pathology from the many children with a benign condition.

The second question, "what to do about it," can also be challenging. If the diagnostic evaluation uncovers an underlying, treatable disorder, such as celiac disease, the course is clear. But often, no simple treatable cause is found. Then, the provider and the family must try to assess whether the short or tall stature is sufficiently abnormal and sufficiently distressing to the child, or likely to be distressing in the future, so that the possible benefits of medical therapy outweigh the effort, costs, discomforts, and potential risks of intervening.

Addressing these two central questions requires a deep understanding of normal childhood growth and the many disorders that affect it, the determination to look diligently for underlying causes, as well as the willingness and ability to listen compassionately to the concerns of the child and family. In this chapter, we have tried to present the healthcare provider with a broad overview of the knowledge necessary for this endeavor.

CHILDHOOD GROWTH

The Biological Basis of Linear Growth

In children, many tissues and organs grow simultaneously. However, most children who present to the pediatric endocrinologist for evaluation of growth do so because the child's height is abnormal. The height is primarily determined by the length of the long bones in the lower extremities and the height of the vertebral bodies. These bone lengths in turn are determined by the action of the skeletal growth plates, thin layers of cartilage located near the ends of the long bones and vertebrae.

Within the growth plates, the chondrocytes are arranged in columns parallel to the long axis of the bone (Fig. 11.1A). In the upper portion (closer to the ends of the bone) of the columns, the chondrocytes proliferate (Fig. 11.1B). In the lower portion of the columns, the chondrocytes stop dividing and instead physically enlarge (Fig. 11.1B). These two processes, cell proliferation and cell hypertrophy, lead to chondrogenesis, the production of cartilage. In isolation, this chondrogenesis would cause progressive thickening of the cartilaginous growth plate. However, simultaneously, at the bottom of the growth plate, the newly formed cartilage is remodeled into bone. The net result is that new bone tissue is progressively created at the bottom of the growth plates, the overall bone grows longer, and the child grows taller.

Thus linear growth (height gain) in children results from growth plate chondrogenesis. Therefore short stature is caused by decreased growth plate chondrogenesis and tall stature is caused by increased growth plate chondrogenesis.

Regulation of Linear Growth

Because linear growth results from growth plate chondrogenesis, the regulation of linear growth results from the regulation of growth plate chondrocytes. Factors that stimulate growth

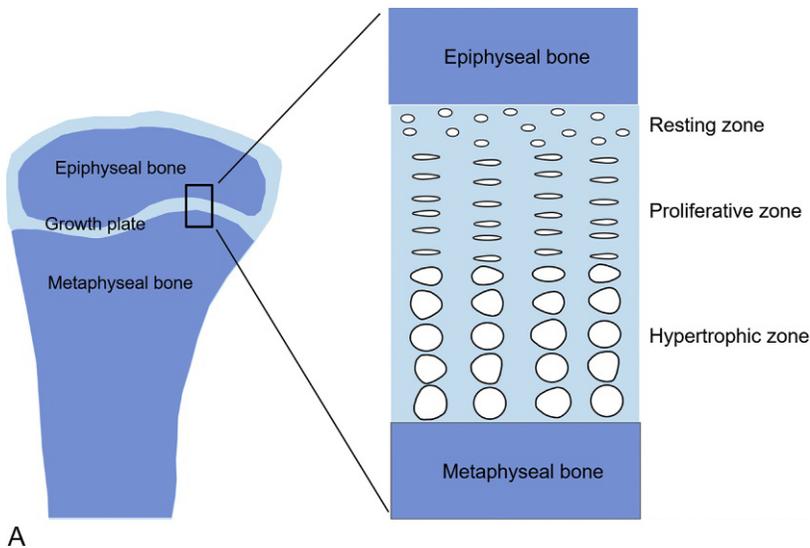

Fig. 11.1A Growth plate structure. In children, linear growth (height gain) results from growth plate chondrogenesis. The growth plate is a thin layer of cartilage found near the ends of long bones and in vertebrae. The growth plate is composed of three zones.

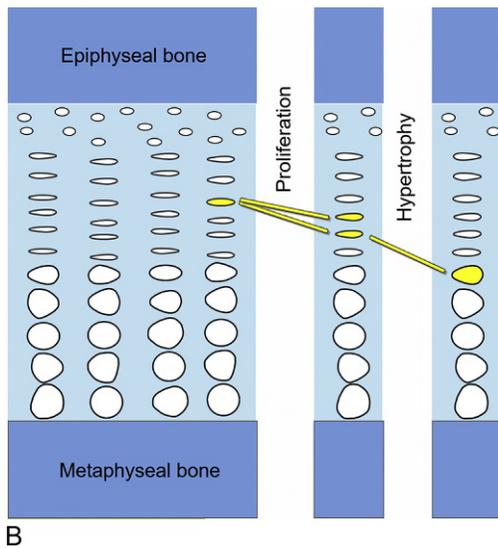

Fig. 11.1B Growth plate function. Within the growth plate, chondrocytes first proliferate and later hypertrophy. The result is the production of more cartilage (chondrogenesis). At the bottom of the growth plate, the newly formed cartilage is remodeled into bone (not shown). The net result is that new bone is created at the bottom of the growth plate, gradually pushing apart the ends of the bone, causing the bones to grow longer and the child to grow taller.

plate chondrocyte proliferation and hypertrophy stimulate linear growth, whereas factors that inhibit growth plate chondrocyte proliferation and hypertrophy inhibit linear growth. This regulation of growth plate chondrocyte function occurs at multiple different levels; endocrine signals, inflammatory cytokines, nutritional intake, paracrine/autocrine signals, extracellular matrix effects, and intracellular systems can all modulate chondrocyte proliferation and hypertrophy and therefore affect the rate of linear growth. Consequently, abnormalities at any of these levels can cause short or tall stature.

Endocrine Regulation of Linear Growth

Growth Hormone.

The Pituitary Gland. The pituitary gland lies in the sella turcica, the hypophyseal fossa of the sphenoid bone, which is

located in the center of the cranial base. The concept of the pituitary as a “master gland” controlling the endocrine activities of the body has become outdated and has been replaced by an appreciation of the importance of the brain, particularly of the hypothalamus, in regulating hormonal production and secretion. Nevertheless, the pituitary gland remains central to our understanding of the regulation of growth, metabolism and homeostasis, response to stress, lactation, and reproduction.

Embryologically, the pituitary gland is formed from two distinct sources, namely Rathke’s pouch, a diverticulum of the primitive oral cavity (stomodeal ectoderm), which gives rise to the adenohypophysis, and the neural ectoderm of the floor of the forebrain, which gives rise to the neurohypophysis, the posterior lobe. The adenohypophysis normally constitutes 80% of the weight of the pituitary and consists of the pars distalis (also known as the *pars anterior* or *anterior lobe*), the pars intermedia (also known as the *intermediate lobe*), and the pars tuberalis (also known as the *pars infundibularis* or *pars proximalis*).

Much of our knowledge of normal hypothalamopituitary development is derived from animal, particularly rodent, models. In the mouse, a thickening of the ectoderm in the midline of the anterior neural ridge, forming the hypophyseal placode, heralds the onset of pituitary development at 7.5 dpc (days postcoitum). The formation of a rudimentary Rathke’s pouch follows at 9 dpc, with formation of a definitive pouch by 12 dpc and subsequently, the anterior pituitary consisting of five different cell types secreting six different hormones (Fig. 11.2).

In humans, the pars distalis is the largest portion of the adenohypophysis and houses the great majority of hormone-producing cells. In contrast with the mouse, the pars intermedia is rudimentary and consists of several cystic cavities lined by a single layer of cuboidal epithelium as it largely disappears during embryogenesis. The pars distalis and intermedia are separated by a cleft, a vestigial structure of Rathke’s pouch from which it develops. This structure may often develop as a cyst (Rathke’s cleft cyst). The pars tuberalis represents an upward extension of the pars distalis onto the pituitary stalk and may contain a limited number of gonadotropin-producing cells. The posterior pituitary (neurohypophysis) consists of the infundibular stem or hypophyseal stalk, the median eminence of the tuber cinereum, and the infundibular process (posterior lobe, neural lobe). The posterior pituitary contains the terminal axonal projections of magnocellular neurons from the paraventricular and supraoptic nuclei of the hypothalamus; these

produce oxytocin, which is required during lactation and parturition, and vasopressin, which is required for osmotic regulation. It has no known function in the regulation of growth and will not be discussed further in this chapter.

Rathke's pouch, the origin of the adenohypophysis, can be identified in the 3-mm embryo during the third week of pregnancy in humans. Rathke's pouch then begins to develop, resulting in a complete pouch disconnected from the oral ectoderm by the end of the sixth gestational week. Growth hormone (GH)-producing cells can be identified by 9 weeks of gestation. It is at about this time that the vascular connections between the anterior lobe of the pituitary and the hypothalamus develop, although it has been demonstrated that hormonal production by the pituitary can occur in the absence of connections with the hypothalamus. Somatotropes are thus frequently demonstrable in the pituitary of an anencephalic newborn. Nevertheless, it appears likely that the initiation of development of the anterior pituitary is dependent on responsiveness of the oral ectoderm to inducing factors from the ventral diencephalon. Infrequently, the craniopharyngeal canal (marking the embryonic migration of Rathke's pouch) remains patent and may contain small nests of adenohypophyseal cells—giving rise to a pharyngeal hypophysis that may be capable of hormone synthesis.

Maintained apposition and interaction between the oral ectoderm and neuroectoderm is critical for normal anterior pituitary development.^{1,2} Experimental manipulation of embryos from several species, as well as Rathke's pouch explant experiments in rodents, have shown that signals from the diencephalon are essential not only for the induction and maintenance of Rathke's pouch, but also for the regionalization within the pouch that allows the emergence of the different endocrine cell types. During gestation, proliferating progenitor cells are enriched around the pouch lumen, and they appear to delaminate as they exit the cell cycle and differentiate. During late mouse gestation and the postnatal period, anterior lobe progenitors reenter the cell cycle and expand the populations of specialized, hormone-producing cells. At birth, all cell types are present, and their localization appears stratified, based on cell type. Current models of cell specification in the anterior lobe suggest that opposing gradients of fibroblast growth factor (FGF) and bone morphogenic protein (BMP) signaling pattern the progenitor cells within Rathke's pouch before they move

on to the anterior lobe where they differentiate. Several studies have revealed that normal pituitary development is dependent upon a complex cascade of transcription factors and signaling molecules that are expressed in a spatiotemporal manner.

Signaling molecules implicated in pituitary development are either intrinsic, emanating from the oral ectoderm, such as sonic hedgehog (Shh), or extrinsic from the neuroectoderm, such as Nkx2.1, FGFs (e.g., FGF 8), and BMPs (e.g., BMP4) (Fig. 11.3).¹ These molecules may activate or repress transcription factors, such as *Hex1*, *Lhx3*, and *Lhx4*. They may also act as morphogens creating the appropriate environment for cell differentiation, thus playing a critical role in cell fate. Such signaling molecules include members of the Shh family, FGFs, transforming growth factors- β (TGFs)/BMPs, *Wingless/Wnts*, and molecules in the Notch pathway to mention a few.

Recently, Davis and colleagues have challenged the current dogma of pituitary cell specification,³ showing evidence that, in mice, the pattern of cell specification that results in the rostral location of gonadotropes, the caudal location for somatotropes and a more intermediate location for corticotropes and thyrotropes, does not appear to be the result of an ordered cell cycle exit, as previously suggested. All anterior lobe cell types appear to begin the differentiation process concurrently (E11.5-E14.5), rather than in a temporally discrete manner.

To date, not many pituitary phenotypes have been reported in association with mutations in these signaling molecules. Importantly, the Wnt signaling pathway has recently been implicated in pituitary tumorigenesis. For example, there is clear evidence that the Wnt/ β catenin pathway is involved in the pathogenesis of craniopharyngioma, a rare tumor in the hypothalamopituitary region.^{4,5}

Multiple pituitary-specific transcription factors are involved in the determination of pituitary cell lineages and cell-specific expression of anterior pituitary hormones (see Fig. 11.3). Several homeodomain transcription factors have been shown to be involved in human anterior pituitary development and differentiation. Defects in several of these have now been associated with various combinations of pituitary hormone deficiencies (Table 11.1). Because additional gene defects have been implicated in abnormal murine hypothalamopituitary development,

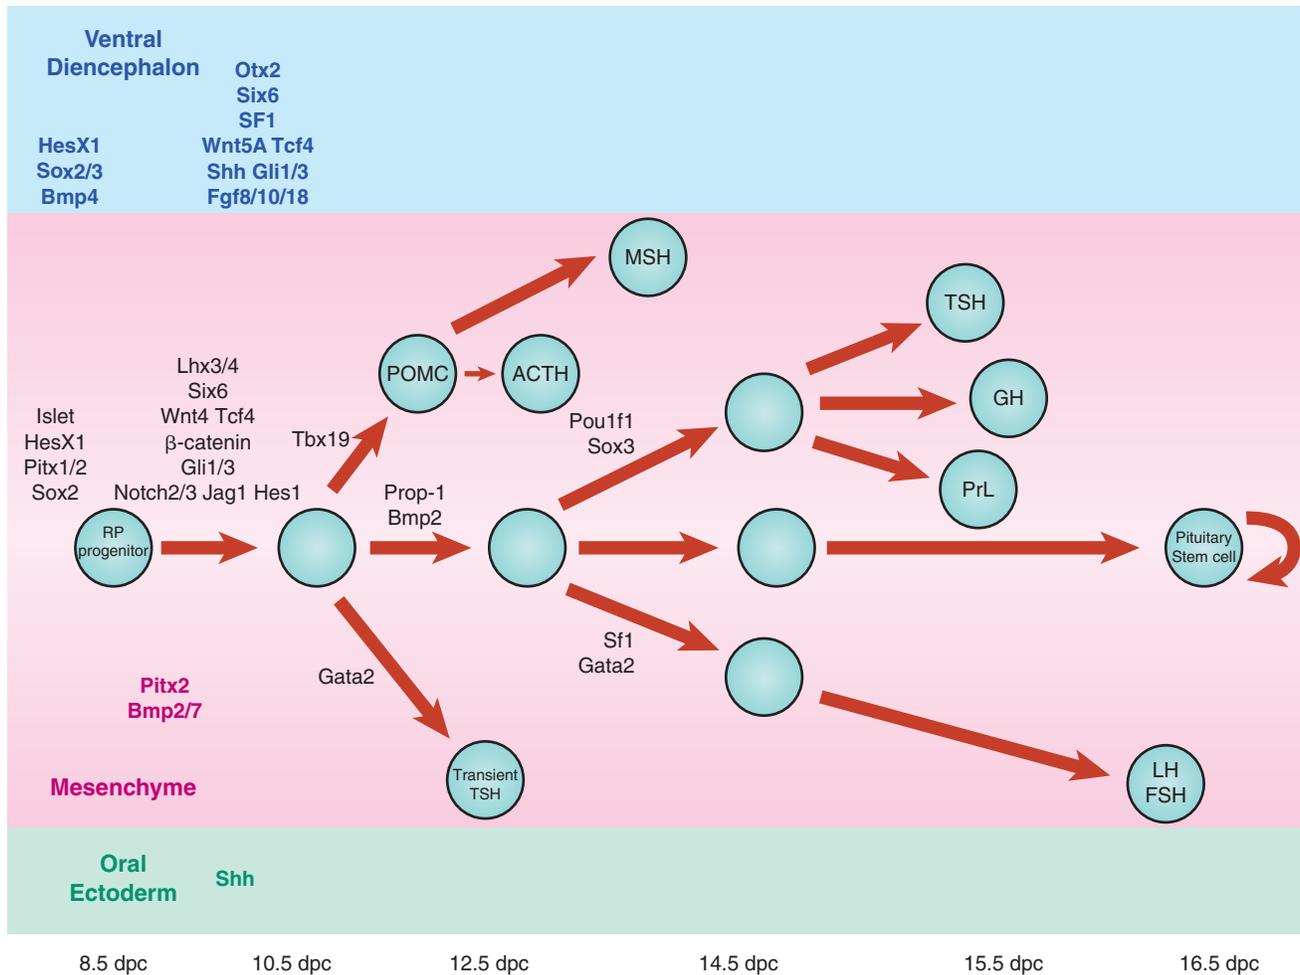

Fig. 11.3 Schematic representation of the developmental cascade of genes implicated in human pituitary development with particular reference to pituitary cell differentiation. (From Kelberman, D., Rizzoti, K., Lovell-Badge, R., et al. (2009). Genetic regulation of pituitary gland development in human and mouse. *Endocr Rev*, 30, 790–829.)

it seems likely that the number of known human genetic defects will expand.^{1,6}

In the human adult, the pituitary has a mean weight of 600 mg, with a range of 400 to 900 mg. Pituitary weight is slightly greater in women than in men, and typically increases during puberty and pregnancy. In the newborn, pituitary weight averages about 100 mg. The pituitary normally resides in the sella turcica immediately above and partially surrounded by the sphenoid bone. The volume of the sella turcica provides a good measure of pituitary size, which may be reduced in the child with pituitary hypoplasia. It is important, however, to recognize that considerable variation in pituitary size occurs normally. The pituitary is covered superiorly by the diaphragma sellae, and the optic chiasm is directly above the diaphragma. The anatomic proximity between the optic chiasm and the pituitary is important because hypoplasia of the optic chiasm may occur together with hypothalamic/pituitary dysfunction, as in the condition of septo-optic dysplasia (SOD), and because pituitary tumors may in turn impact on the optic chiasm, leading to visual impairment. The patient with congenital blindness or nystagmus should be initially evaluated and then subsequently monitored carefully for hypopituitarism, as this can evolve. In addition, suprasellar growth of a pituitary tumor may initially manifest with visual complaints or evidence of progressive impairment of peripheral vision, particularly bitemporal hemianopia.

The existence of a portal circulatory system within the pituitary is critical to normal pituitary function. The blood supply of the pituitary derives from the superior and inferior hypophyseal arteries, branches of the internal carotid. The anterior and posterior branches of the superior hypophyseal artery may terminate within the infundibulum and the proximal portion of the pituitary stalk. Hypothalamic peptides, produced in neurons that terminate in the infundibulum, enter the primary plexus of the hypophyseal portal circulation and are transported by means of the hypophyseal portal veins to the capillaries of the anterior pituitary. This portal system thus provides a means of communication between the neurons of the hypothalamus and the hormone-producing cells of the anterior pituitary. The blood supply of the neurohypophysis is separate, deriving from the inferior hypophyseal artery. Regulation of the posterior lobe of the pituitary does not involve the hypophyseal portal circulation but, rather, is mediated through direct neural connections.

The definitive Rathke's pouch comprises proliferative progenitors that will gradually relocate ventrally, away from the lumen as they differentiate. A proliferative zone containing progenitors is maintained in the embryo in the periluminal area and was recently found to persist in the adult. The exact nature of progenitor cells in the pituitary gland, however, remains unknown. Members of the Sox family of transcription factors are likely involved in the earliest steps of pituitary stem cell

TABLE 11.1 Genetic Defects of Pituitary Development and Their Phenotype³⁹⁵

Gene	Pituitary Deficiencies	MRI Phenotype	Inheritance	Other Phenotypic Features
<i>POU1F1</i>	GH, TSH, prolactin	Small or normally sized anterior pituitary	AR and AD	
<i>PROP1</i>	GH, TSH, LH, FSH, prolactin, evolving ACTH deficiencies	Small, normal or enlarged anterior pituitary – may evolve over time	AR	
<i>HESX1</i>	Isolated GH deficiency through to panhypopituitarism with TSH, LH, FSH, ACTH, and prolactin deficiencies	Optic nerve hypoplasia, absence of the septum pellucidum, ectopic posterior pituitary, anterior pituitary hypoplasia	AR and AD	Developmental delay, visual abnormalities, SOD
<i>LHX3</i>	GH, TSH, LH, FSH, prolactin with late ACTH deficiencies	Small, normal, or enlarged anterior pituitary	AR	Short neck with limited rotation
<i>LHX4</i>	GH, TSH, ACTH, and gonadotrophin deficiencies	Small anterior pituitary, ectopic posterior pituitary, cerebellar abnormalities, corpus callosum hypoplasia	AD (variable penetrance)	
<i>SOX3</i>	GH, TSH, LH, FSH, ACTH deficiencies. Most commonly isolated GH deficiency	Anterior pituitary and infundibular hypoplasia, ectopic posterior pituitary, corpus callosum abnormalities including cysts; persistent craniopharyngeal canal	X-linked recessive	Learning difficulties
<i>SOX2</i>	LH, FSH variable GH deficiency	Anterior pituitary hypoplasia, optic nerve hypoplasia, SOD, hypothalamic hamartoma	AD (usually de novo)	Microphthalmia, anophthalmia, micropenis, sensorineural deafness, gastrointestinal tract defects with esophageal atresia
<i>GLI2</i>	GH, TSH, and ACTH with variable gonadotrophin deficiencies	Anterior pituitary hypoplasia	AD	Holoprosencephaly, cleft lip and palate, anophthalmia, postaxial polydactyly, imperforate anus, laryngeal cleft, renal agenesis
<i>GLI3</i>	GH, TSH, LH, FSH, ACTH	Anterior pituitary hypoplasia	AD	Pallister-Hall syndrome Postaxial polydactyly, hamartoma
<i>OTX2</i>	GH, TSH, LH, FSH, and ACTH deficiencies	Normal or small AP, pituitary stalk agenesis, ectopic posterior pituitary, Chiari I malformation	AD (usually de novo)	Microcephaly, bilateral anophthalmia, developmental delay, cleft palate
<i>FGFR1</i>	GH, TSH, LH, FSH, and ACTH deficiencies	Normal or small anterior pituitary, corpus callosum agenesis	AD	ASD and VSD, brachydactyly, brachycephaly, preauricular skin tags, ocular abnormalities, seizures
<i>FGF8</i>	GH, TSH, ACTH, gonadotrophin, and ADH deficiencies	Absent corpus callosum, optic nerve hypoplasia, holoprosencephaly	AD or AR	
<i>PROKR2</i>	GH, TSH, ACTH and gonadotrophin deficiencies	Hypoplastic corpus callosum, normal or small anterior pituitary	AD	
<i>ARNT2</i>	GH, TSH, ACTH, LH, FSH, ADH deficiencies	Absent PP, thin stalk, thin corpus callosum, delayed myelination	AR	Hip dysplasia, hydronephrosis, vesicoureteric reflux, neuropathic bladder, microcephaly, prominent forehead, deep-set eyes, retrognathia
<i>TCFL7</i>	GH	Absent posterior pituitary, anterior pituitary hypoplasia, optic nerve hypoplasia, partial agenesis of corpus callosum, thin anterior commissure	AD	
<i>IGSF1</i>	GH (transient/partial), TSH, prolactin	Normal in the majority of cases. Frontoparietal hygroma, hypoplasia of the corpus callosum, and small stalk lesion reported	X-linked recessive	Macroorchidism, delay in puberty
<i>RNPC3</i>	GH deficiency		AR	Maternally inherited gingival fibromatosis
<i>KCNQ1</i>	GH, ACTH, TSH, and gonadotrophin deficiencies	Small anterior pituitary with normal stalk and ectopic posterior pituitary Normal/small AP	AR	

ACTH, Adrenocorticotropic hormone; *AD*, autosomal dominant; *ADH*, antidiuretic hormone; *AP*, anterior pituitary; *AR*, autosomal recessive; *ASD*, aortic septal defect; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *LH*, luteinizing hormone; *MRI*, magnetic resonance imaging; *PP*, posterior pituitary; *SOD*, septooptic dysplasia; *TSH*, thyroid-stimulating hormone; *VSD*, ventricular septal defect.

Adapted and updated from Alatzoglou KS, Gregory LC, Dattani MT. Development of the pituitary gland. *Compr Physiol*. 2020;10(2):389–413. <https://doi.org/10.1002/cphy.c150043>. PMID: 32163208.

proliferation and the earliest transitions to differentiation.^{7–9}

The transcription factor Prophet of Pit1 (*PROP1*) and the *NOTCH* signaling pathway may then regulate the transition to differentiation. It has been proposed that the niche of progenitors may be the marginal zone around the lumen of Rathke's pouch, between the anterior and intermediate lobes of mouse pituitary, because cells in this region are able to give birth to all five pituitary hormone cell lineages (see Fig. 11.3).

Stem cells have been shown to play a role in tumorigenesis in some tissues, and their role in pituitary hyperplasia, pituitary adenomas, and tumors is an important area for future

investigation. The ability to cultivate and grow pituitary stem cells in a predifferentiation state might also be helpful for the long-term treatment of pituitary deficiencies. Indeed, a seminal study resulted in the efficient self-formation of a three-dimensional anterior pituitary in an aggregate culture of mouse embryonic stem (ES) cells.¹⁰ Various endocrine cells were generated, and these cells were able to respond to trophic hormones. When these ES-derived cell aggregates were implanted under the kidney capsule in hypophysectomized mice, corticosterone was produced. These studies may therefore reflect the first step toward stem cell treatment.

Terminally differentiated secreting cells are not distributed randomly in a patchwork-like fashion throughout the pituitary gland. Instead, these cells appear to organize themselves in same-cell-type networks. The connectivity between the cells of this network is important to deliver coordinated secretory pulses of hormones to their target tissues and to facilitate the coordinated physiological response to stimuli.

Growth Hormone Chemistry. Human GH is produced from somatotrope cells within the anterior pituitary as a single-chain, nonglycosylated, 191-amino-acid, 22-kDa protein that comprises a core of four helices in a parallel/antiparallel orientation with two disulfide bonds between cysteines 53–165 and 182–189. The 217-amino-acid GH precursor is cleaved to remove the signal peptide before secretion.

GH is homologous with several other proteins produced by the pituitary or placenta, including prolactin, chorionic somatomammotropin (CS, placental lactogen), and a 22-kDa GH variant hGH-V, secreted only by the placenta. The latter differs from pituitary GH by 13 amino acids. The genes for these proteins have probably descended from a common ancestral gene, even though the genes are now located on different chromosomes.

GH1 is located on the long arm of chromosome 17 (17q22-24) within a cluster of five homologous genes encompassing a distance of about 65 kb (*CSHP* [CS pseudogene], *CSH-1* [CS gene], *GH-2* and *CSH-2*). Expression of *GH1* is regulated by the highly polymorphic proximal promoter and a locus control region (LCR) 15–32 kb upstream of the gene that confers the pituitary-specific and high-level expression of GH. Normally, the vast majority of GH (75%) produced by the pituitary is of the mature 22-kDa form. Alternative splicing results in deletion of amino acids 32 through 46, yielding a 20-kDa form that normally accounts for less than 10% of pituitary GH. The remainder of pituitary GH includes desamidated and N-acetylated forms, as well as various GH oligomers. A 17.5-kDa variant that results from complete skipping of exon 3 and lacks amino acids 32–71 is much less abundant (1%–5%).¹¹

Growth Hormone Secretion. GH can be identified in fetal serum by the end of the first trimester. The pulsatile pattern characteristic of GH secretion largely reflects the interplay of multiple regulators, including two hypothalamic regulatory peptides: GH-releasing hormone (GHRH) and somatostatin (somatotropin release-inhibiting factor [SRIF]). *GHRHR* encodes a G-protein-coupled receptor comprising seven transmembrane domains. The expression of *GHRHR* is upregulated by pituitary-specific transcription factor 1 (*POU1F1*) and is required for the proliferation of somatotrophs.

Regulation of GH production by GHRH is largely transcriptionally mediated and is dependent on stimulation of adenylyl cyclase and increases in intracellular cyclic adenosine monophosphate (cAMP) concentrations. Solid tumors secreting GHRH are a rare cause of GH excess. GHRH is used diagnostically, especially for the identification of adult GH deficiency, when it is frequently used in combination with arginine. However, it is not conventionally used for therapeutic purposes in patients with GH deficiency.

The actions of the 14-amino-acid peptide somatostatin appear to regulate the timing and amplitude of pulsatile GH secretion, rather than GH synthesis. The binding of somatostatin to its specific receptor results in an inhibition of adenylyl cyclase activity and a reduction in intracellular calcium concentrations. The pulsatile secretion of GH observed *in vivo* is believed to result from a simultaneous reduction in hypothalamic somatostatin release and increase in GHRH activity. Conversely, a trough of GH secretion occurs when somatostatin release is increased in the presence of diminished GHRH activity. The net effects of these two hypothalamic hormones is modulation of GH secretion, as well as the timing and amplitude of peaks, resulting in pulsatile GH secretion.

Multiple neurotransmitters and neuropeptides are involved in regulating the release of these hypothalamic factors, including serotonin, histamine, norepinephrine, dopamine, acetylcholine, gamma-aminobutyric acid (GABA), thyroid-releasing hormone, vasoactive intestinal peptide, gastrin, neurotensin, substance P, calcitonin, neuropeptide Y, vasopressin, corticotrophin-releasing hormone, and galanin. These factors are implicated in the alterations of GH secretion observed in a wide variety of physiological states (such as stress, sleep, hemorrhage, fasting, hypoglycemia, and exercise) and form the basis for a number of GH-stimulatory tests used in the evaluation of GH secretory capacity/reserve. GH secretion is also impacted by a variety of nonpeptide hormones, including androgens, estrogens, thyroxine, and glucocorticoids. The precise mechanisms by which these hormones regulate GH secretion are complex, potentially involving actions at the hypothalamic and pituitary levels. Practically speaking, hypothyroidism and glucocorticoid excess may each blunt spontaneous and provocative GH secretion (and therefore should be corrected before GH testing). Sex steroids, at the onset of puberty or administered pharmacologically, appear to be responsible for the rise in GH secretion characteristic of puberty. Synthetic hexapeptides capable of stimulating GH secretion have been developed and termed *GH-releasing peptides* (GHRPs). These peptides, later recognized as analogues of the gastric hormone ghrelin, are capable of directly stimulating GH release and enhancing the GH response to GHRH. These agents have the potential advantage of oral administration, and, in the patient with an intact pituitary, may be capable of greatly enhancing GH secretion. When these agents were administered chronically to elderly patients and to some GH-deficient children, the amplitudes of GH pulses were significantly increased. Ghrelin-mimetic ligands were used to characterize a common receptor termed the *GH secretagogue receptor* (GHS-R) for the GH-releasing substances. The GHS-R is a G-protein-coupled receptor, which is distinct from the GHRH receptor. The receptor is strongly expressed in the hypothalamus, but specific binding sites for GHRPs have also been identified in other regions of the CNS and peripheral endocrine and nonendocrine tissues in both humans and other organisms. Ghrelin is a 28-amino-acid peptide that has been identified as the endogenous ligand for GHS-R.¹² It is expressed predominantly in the stomach, but smaller amounts are also produced within the bowel, pancreas, kidney, the immune system, placenta, pituitary, testis, ovary, and hypothalamus. Ghrelin is a unique gene product that requires octanoylation for normal function. Intravenous, intracerebroventricular, and intraperitoneal administration of ghrelin in animal models stimulates food intake and obesity and raises plasma GH concentrations, and, to a lesser extent, prolactin (PRL) and adrenocorticotrophic hormone (ACTH) concentrations. In addition, it influences endocrine pancreatic function and glucose metabolism, gonadal function, and behavior. It also controls gastric motility and acid secretion and has cardiovascular and antiproliferative effects. Both ghrelin and GHRPs release GH synergistically with GHRH but the efficacy of these compounds as growth-promoting agents is poor. Variants in the ghrelin receptor have been identified as a possible cause of idiopathic short stature (ISS) and GH deficiency.^{13,14} However, note that mouse models with targeted deletion of the receptor (*ghsr*^{-/-}) have a near normal phenotype.¹⁵ A second peptide encoded by the same gene as ghrelin has been identified and termed *obestatin*. This gene appears to regulate weight but not GH secretion.

In addition to the complex regulatory processes described previously, the synthesis and secretion of GH are also regulated by feedback by the insulin-like growth factor (IGF) polypeptides. IGF receptors have been identified in the pituitary. Inhibition of GH secretion by IGF-1 has been demonstrated

in multiple systems. In addition, inhibition of spontaneous GH secretion has been demonstrated in humans treated with subcutaneous injections of recombinant IGF-1.¹⁶ GH also regulates its own secretion by acting directly on hypothalamic GH receptors (GHRs), via a short loop negative feedback.¹⁶

During puberty, sex steroids increase GH pulse amplitude contributing to the very high serum concentrations of IGF-1 characteristic of puberty. GH secretion begins to decline by late adolescence and continues to fall throughout adult life. Indeed, puberty may be considered with some justification a period of “acromegaly,” whereas aging (with its characteristic decrease in GH secretion) has been termed the *somatopause*.

In addition to aging, a wide variety of physiological conditions affect GH secretion. These include stage of sleep, nutritional status, acute fasting, exercise, stress, and sex steroids. Ho and associates³⁹⁴ have reported that neither age nor sex influenced the integrated serum concentrations of GH when the effects of estradiol were removed from analysis. The effects of testosterone on serum IGF-1 concentrations may be at least in part independent of GH because individuals with mutations of the GHR still experience a rise in serum IGF-1 during puberty.

The pulsatile nature of GH secretion is readily demonstrable by frequent serum sampling, especially when coupled with sensitive assays for GH. Such assays demonstrate that, under normal conditions, serum GH concentrations are less than 0.2 ng/mL between bursts of GH secretion. It is consequently impractical to assess GH secretion by a single, random serum sample. Maximal GH secretion occurs during the night, especially at the onset of the first slow-wave sleep (stages III and IV). Rapid-eye-movement (REM) sleep is, on the other hand, associated with low GH secretion.

Normal young men generally experience, on average, 12 GH secretory bursts per 24 hours. Obesity is characterized by decreased GH secretion, reflected by a decreased number of GH secretory bursts. Fasting increases the number and amplitude of GH secretory bursts, presumably reflecting decreased somatostatin secretion. The impact of the pulsatile secretory nature of GH secretion on its biological actions remains uncertain.

Growth Hormone Receptor/Growth Hormone-Binding Protein. The GHR comprises an extracellular, hormone-binding domain, followed by a single membrane-spanning domain, and a cytoplasmic domain. Two genomic *GHR* isoforms that exist only in humans have arisen from ancestral homologous recombination. They differ in the retention or deletion of exon 3. Exon 3 of the GHR has been shown to be deleted in a number of normal individuals. This delta-3 GHR polymorphism has been shown by some, but not all, investigators to affect responsiveness to GH and to be associated with birth size and postnatal growth.¹⁷ There are also short isoforms of the GHR because of alternative splicing, resulting in a truncated receptor with loss of a large portion of the cytoplasmic domain.

The GHR is a member of the class 1 hematopoietic cytokine family and is highly homologous with the prolactin receptor and shares sequence homology with many of the receptors for interleukins (ILs), as well as receptors for erythropoietin (EPO), leptin, granulocyte-macrophage colony-stimulating factor, and interferon.

Examination of the crystal structure of the GH-GHR complex revealed that the complex consists of one molecule of GH bound to two GHR molecules, indicating a GH-induced receptor dimerization—which is necessary for GH action. Interestingly, a genetically engineered fusion complex of GH and the GHR has been shown to have a significantly improved efficacy and a dramatically longer half-life compared with GH alone when tested in rodent models.

The GHR, like its family group member EPO-R, is preformed as a dimer and is transported in a nonligand bound state to the cell surface.¹⁸ GH then binds in a sequential manner to the GHR dimer where the first GHR binds to the stronger site 1 of the GH molecule followed by the second GHR binding to the weaker site 2.¹⁹ Binding of GH results in a conformational change whereby rotation of the GHRs results in repositioning of the intracellular domains and of Box11-1-associated Janus Kinase 2 (JAK2), a major GHR-associated tyrosine kinase. As a result, JAK2 is autophosphorylated and activated, which in turn leads to cross-phosphorylation of distal tyrosine residues of GHR. This enables SH2 (*Src* homology 2) domain molecules to dock to these sites. The GHR itself appears to have no intrinsic kinase activity. It is likely that colocalization of two JAK2 molecules by the dimerized GHR results in transphosphorylation of one JAK2 by the other, leading to JAK2 activation. Signal transducer and activator of transcription (Stat)5a and 5b molecules contain SH2 domains and bind to these phosphorylated tyrosine sites, and then they in turn become phosphorylated. Phosphorylated Stat5 molecules (homo- and hetero-) dimerize and translocate to the nucleus where they bind deoxyribonucleic acid (DNA), as dimers or as tetramers, and activate target genes. Importantly, the dimerization of the GHR by GH is exploited by the use of Pegvisomant, a genetically modified form of GH, which binds to one receptor only and therefore cannot dimerize the receptor. It therefore acts as a GH antagonist and can be used to treat pituitary gigantism and acromegaly.²⁰

Both Stat5a and Stat5b can be activated by GH, and they have both overlapping and distinct functions. Gene inactivation mouse models have shown that Stat5b is of greater importance for stimulation of growth than Stat5a.²¹

Negative Regulation of Growth Hormone Signaling. Activation of JAK-STAT signaling occurs rapidly, within minutes after GH stimulation, but is transient because of the tight control of the termination of signaling. This negative regulation of signaling occurs at several levels: GHR internalization, suppressors of cytokine signaling (SOCS), protein tyrosine phosphatases (PTPs), and protein inhibitors of activated Stats (PIAS).

In humans, the circulating GH-binding protein (GHBP) appears to derive from proteolytic cleavage of the extracellular domain of the GHR. GHBP has an identical affinity for GH as GHR. It binds to GH with high specificity and affinity, but with relatively low capacity. It increases GH half-life in the circulation and may serve a function in the transportation of GH to target tissues and subsequent binding to the receptor. GHBP is, like GHR, present in many tissues, but GHBP in the circulation is mostly derived from the liver. Although GHR and GHBP are regulated by and are very sensitive to GH, and GHR and GHBP often change in parallel, measurement of plasma GHBP has not been shown to reflect GHR and GH responsiveness. Measurement of serum GHBP concentrations may, however, aid in identifying patients with GH insensitivity (GHI) caused by genetic abnormalities of the GHR. Patients with GHI from nonreceptor abnormalities, abnormalities of the intracellular portion of the GHR, or inability of the receptor to dimerize may have normal serum concentrations of GHBP. Recently, a complex of the GH and the GHBP molecule has been shown to be more effective than GH alone—indicating a physiological and possible therapeutic role for GHBP.

Growth Hormone Actions. According to the somatomedin hypothesis, the anabolic actions of GH are mediated through the IGF polypeptides.²² Although this hypothesis is at least in part true, it appears that GH is capable of stimulating a variety of effects that are independent of IGF activity. Indeed, the effects of GH and IGF are on occasion contradictory, as for example, the “diabetogenic” actions of GH and the

glucose-lowering activity of IGFs. Green and colleagues³⁹⁶ attempted to resolve some of these differences in a “dual-effector” model in which GH stimulates precursor cells, such as prechondrocytes, to differentiate. When differentiated cells or neighboring cells then secrete IGFs, these peptides act as mitogens and stimulate clonal expansion. This hypothesis is based on the ability of IGF peptides to work not only as classic endocrine factors that are transported through the blood but as paracrine or autocrine growth factors. GH also stimulates a variety of metabolic effects, some of which appear to occur independently of IGF production, such as lipolysis, amino acid transport in diaphragm and heart, and production of specific hepatic proteins. Thus there are multiple sites of GH action, and it is not entirely clear which of these actions are mediated through the IGF system and which might represent IGF-1–independent effects of GH.

Insulin-Like Growth Factor-1.

Insulin-Like Growth Factor-1 Historical Background. The IGFs (or somatomedins) constitute a family of peptides that are at least in part GH-dependent and that are believed to mediate many of the anabolic and mitogenic actions of GH. Although they were originally identified in 1957 by their ability to stimulate [^{35S}]sulfate incorporation into rat cartilage, it has been established over the ensuing 45 years that they are involved in diverse metabolic activities.

Insulin-Like Growth Factor Structure and Molecular Biology. IGF-1, previously termed *somatomedin-C*, is a basic polypeptide of 70 amino acids, whereas IGF-2 is a slightly acidic polypeptide of 67 amino acids. The two peptides are structurally related, sharing 45 of 73 possible amino acid positions. They have approximately 50% amino acid homology to insulin. Like insulin, both IGFs have A and B chains connected by disulfide bonds and an intervening connecting (C-peptide) region. This structural homology explains the ability of both IGFs to bind to the insulin receptor and for insulin to bind to the type 1 IGF receptor. On the other hand, structural differences explain the failure of insulin to bind to the IGF-binding proteins.

Serum Concentrations of Insulin-Like Growth Factors. In human fetal serum, IGF-1 concentrations are relatively low and are positively correlated with gestational age. A correlation between fetal cord serum IGF-1 concentrations with birth weight has been reported by some groups, although others have reported no correlation. IGF-1 concentrations in human newborn serum are generally 30% to 50% of adult concentrations. There is a slow, gradual rise in serum concentrations during childhood, with attainment of adult concentrations at the onset of sexual maturation.²³ During puberty, IGF-1 concentrations increase to 2 to 3 times the concentrations seen in adults. Thus concentrations during adolescence correlate better with Tanner stage (bone age) than with chronological age. Girls with gonadal dysgenesis show no adolescent increase in serum IGF-1, clearly establishing the association of the pubertal rise in IGF-1 with the production of sex steroids. Estrogen stimulates GH secretion, which increases hepatic IGF-1 production. It is of note, however, that patients with GHI because of *GHR* mutations show a pubertal rise in serum IGF-1, which may be mediated by direct effects of androgen on IGF-1.

After adolescence, or at least after 20 to 30 years of age, serum IGF-1 concentrations demonstrate a gradual and progressive age-associated decline. It has been suggested that this decline may be responsible for the negative nitrogen balance, decrease in body musculature, and osteoporosis characteristic of aging. Although this provocative hypothesis remains unproven at this time, it has generated considerable interest in the potential use of GH and/or IGF-1 therapy in normal aging.

Human newborn concentrations of IGF-2 are generally 50% of adult concentrations. By 1 year of age, however, adult concentrations are attained with little, if any, subsequent decline even out to the seventh or eighth decade of life. This is in contrast to rodents, whose IGF-2 expression declines early following birth. Lack of rodent models has impeded our understanding of the physiological role of IGF-2 persistence in humans.

Insulin-Like Growth Factor Receptors. IGFs bind (although generally with low affinity) to insulin receptors, thus providing an explanation for their insulin-like activity. In addition, IGFs bind to at least two classes of IGF receptors.

The type 1 IGF receptor is closely related to the insulin receptor. Both are heterotetramers composed of two identical membrane-spanning alpha subunits and two identical intracellular beta subunits. The alpha subunits contain the binding sites for IGF-1 and are linked by disulfide bonds. The beta subunits contain a transmembrane domain, an adenosine triphosphate (ATP)-binding site, and a tyrosine kinase domain, which constitutes the presumed signal transduction mechanism for the receptor.

Although the type 1 IGF receptor has been commonly referred to as the *IGF-1 receptor*, the receptor is capable of binding both IGF-1 and IGF-2 with high affinity—and both IGF polypeptides appear capable of activating tyrosine kinase by binding to this receptor. Affinity of the type 1 receptor for insulin is generally 100-fold less, thereby providing one of the mechanisms for the mitogenic effects of insulin. IGF-1 acts primarily through IGF1R but can bind with lower affinity to the highly homologous insulin receptor (IR), and to IGF1R/IR heterodimers. Vice versa, insulin is able to signal through the IGF1R. Signs of such alternative signaling can become apparent in pathological IGF-1 or insulin signaling.

The type 1 IGF receptor mediates IGF actions on multiple cell types, and these actions are diverse and tissue specific. In general, it is believed that all of the effects of IGF receptor activation are mediated by tyrosine kinase activation and phosphorylation of substrates, which activate specific cellular pathways, leading to various biological actions. Among these effects is induction of cell growth through activation of the cell cycle machinery, maintenance of cell survival (prevention of apoptosis) mediated by effects on the Bcl family members, and induction of cellular differentiation, which occurs by as yet incompletely characterized mechanisms.

The substrates phosphorylated by the IGF receptor include members of the insulin receptor substrate family (particularly IRS-1 and IRS-2); knockout of these genes results in poor growth in mice (as well as insulin resistance). In addition, several other signaling molecules respond to IGF receptor activation. Blockade of the type 1 receptor has been proposed as a cancer therapy.

Mutations that decrease IGF signaling lead to an extension of life expectancy in nematodes, flies, and mice.²⁴ It is unclear, however, what relevance the IGF-1/IR has for human longevity. Recent data have suggested that loss-of-function variants in IGF1R are overrepresented among female centenarians, suggesting a role of this pathway in modulation of human life span.²⁵

The type 2 IGF receptor, however, bears no structural homology with either the insulin or the type 1 IGF receptor. The type 2 receptor does not contain an intrinsic tyrosine kinase domain or any other recognizable signal transduction mechanism and has been found to be identical to the cation-independent mannose-6-phosphate (CIM6P) receptor, a protein involved in the intracellular lysosomal targeting of a variety of acid hydrolases and other mannosylated proteins. Unlike the type 1 IGF receptor, which binds both IGF polypeptides with high affinity and insulin with 100-fold

lower affinity, the type 2 receptor only binds IGF-2 with high affinity. IGF-1 binds with substantially lower affinity, and insulin not at all. Most studies have indicated that the classic mitogenic and metabolic actions of IGF-1 and IGF-2 are mediated through the type 1 IGF receptor, with its tyrosine kinase signal transduction mechanism.²⁶

Insulin-Like Growth Factor-Binding Protein Superfamily. Although insulin and the IGFs share significant structural homology, and despite the structural-functional similarity of the insulin and type 1 IGF receptors, the IGFs differ from insulin in that the IGFs circulate in plasma complexed to a family of binding proteins.²⁷ These carrier proteins extend the serum half-life of the IGF peptides, transport the IGFs to target cells, and modulate the interaction of the IGFs with their surface membrane receptors. Six distinct IGF-BPs have been identified. Additional lower affinity IGF binding proteins (named *IGFBP related proteins, IGFBPrPs*) were found by in silico searches for homology to the known IGF-BPs; many of these molecules were previously known in other contexts, serving roles in normal or neoplastic growth.²⁷

Under most conditions, the IGF-BPs appear to inhibit IGF action—presumably by competing with IGF receptors for IGF polypeptides. This concept is supported by the observation that IGF analogues with decreased affinity for IGF-BPs generally appear to have increased biological potency. In addition, IGFBP-3 appears to inhibit cell growth even in the absence of added IGF—suggesting a direct inhibitory role of the binding protein. Under specific conditions, however, several of the IGF-BPs apparently are capable of enhancing IGF action—perhaps by facilitating IGF delivery to target receptors.

Evidence indicates that IGF-BPs are essentially bioactive molecules that, in addition to binding IGFs, have a variety of IGF-1-independent functions. These include growth inhibition in some cell types, growth stimulation in other tissues, direct induction of apoptosis, and modulation of the effects of other non-IGF growth factors. These effects of IGF-BPs are mediated by binding to their own receptors. Because IGFBP-3 is regulated by GH, it is intriguing that in vivo, IGFBP-3 enhances IGF-1 action when given to hypophysectomized rats (rather than inhibiting it). The mechanisms involved in this effect have not been elucidated but may explain the limited effects of IGF-1 therapy on the growth of Laron patients.

The relative amounts of each of the IGF-BPs vary among biological fluids. IGFBP-1 is the major IGF-BP in human amniotic fluid. IGFBP-2 is prominent in cerebrospinal fluid and seminal plasma. IGFBP-3 is the major IGF-BP in normal human serum and demonstrates clear GH dependence. Among the IGF-BPs, IGFBP-3 and IGFBP-5 are unique in that they normally circulate in adult serum as part of a ternary complex consisting of IGFBP-3 or IGFBP-5, an IGF polypeptide, and an acid-labile subunit (ALS).

Analysis of IGF-BPs is further complicated by the presence of IGF-BP proteases, capable of various levels of IGF-BP degradation. Initially reported in the serum of pregnant women, proteases for IGFBP-3, -4, and -5 have already been demonstrated in a variety of biological fluids. Proteolysis of IGF-BPs complicates their assay by both Western ligand blotting and radioimmunoassay methodologies and must be taken into consideration when concentrations of the various IGF-BPs in biological fluids are reported. The physiological significance of limited proteolysis of IGF-BPs remains to be determined, although evidence suggests that protease activity results in decreased affinity of the IGF-BP for IGF peptides.²⁸ Recently, recessive mutations in the metalloproteinase pregnancy-associated plasma protein A2 (*PAPP-A2*) were associated with short stature. The mutations lead to increased binding of IGF-1 within the ternary complex and reduced free IGF-1.²⁸

Targeted Disruption of Components of the Insulin-Like Growth Factor System. The critical role of the IGF system in fetal and postnatal growth was demonstrated in a series of elegant gene knockout studies in mice.²⁹ Unlike GH and GHR knockouts, which are near normal size at birth, Igf1 null mice have a birth weight 60% of normal. Postnatal growth is also abnormal. A similar prenatal and postnatal growth phenotype has been observed in a reported human case of an *Igf1* gene deletion.³⁰ Igf2 null mice also show diminished pre- and postnatal growth. The *Igf2* gene is imprinted in humans, such that only the paternal gene is expressed. Therefore loss-of-function mutations on the paternal allele cause growth impairment whereas mutations on the maternal allele do not.³¹ When the gene for the type 1 IGF receptor is knocked out (*Igf1r* null mice), the mice are severely growth retarded. In humans, dominant and recessive *IGF1R* mutations are associated with intrauterine growth retardation (IUGR), postnatal growth failure, and learning difficulties³² (see section on Disorders of Childhood Growth for details). The relationship between GH and IGF-1 in controlling postnatal growth was analyzed in mouse mutants lacking GHR, IGF-1, or both. This demonstrated that GH and IGF-1 promote postnatal growth by independent and common functions.

Thyroid Hormone. Thyroid hormone is required for normal linear growth. Newborns with hypothyroidism are of normal birth length, suggesting that fetal growth is not greatly affected by fetal thyroid hormone production. In contrast, severe, long-standing postnatal hypothyroidism can impair linear growth and delay skeletal maturation.³³ Mutations in either thyroid hormone receptor-alpha or -beta cause some impairment in linear growth, suggesting that both of these receptors contribute to linear growth regulation.^{34,35} Thyroid hormone has both a direct effect on growth plate chondrocytes, particularly supporting chondrocyte hypertrophy, and an indirect effect, mediated by a stimulatory effect on growth hormone secretion.³⁶

Glucocorticoids. Glucocorticoids, when present in concentrations that exceed physiological levels, impair linear growth. This linear growth impairment arises in part from a direct effect of glucocorticoids on growth plate chondrocyte proliferation.³⁶ Glucocorticoids may also indirectly affect growth plate chondrogenesis by altering GH secretion. However, not all studies show an effect, and any effects may be caused by the glucocorticoid-induced obesity. Circulating concentrations of IGF-1, a marker and mediator of GH action, do not appear to be reduced by glucocorticoid excess, which would be consistent with the idea that the decreased GH concentrations are primarily caused by obesity. The inability of GH treatment to fully compensate for the linear growth impairment caused by glucocorticoid excess³⁷ further suggests that the growth impairment is primarily caused by a direct action of glucocorticoids on growth plate chondrocytes.

Estrogens. In adolescents, both male and female, estrogens stimulate linear growth, contributing to the pubertal growth spurt.³⁶ In boys, the estrogen that stimulates the adolescent growth spurt is produced by aromatization of testicular and adrenal androgens. The growth acceleration is mediated in part by the stimulatory effect of estrogens on GH secretion. In addition, estrogen appears to have direct actions on growth plate chondrocytes.³⁶ Estrogen stimulates growth plate senescence, the developmental program in the growth plate that is responsible for the progressive slowing of linear growth with age. Consequently, estrogen exposure leads to more rapid “aging” of the growth plate, earlier growth cessation, and earlier epiphyseal fusion. This effect of estrogen accounts for the early epiphyseal

fusion in children with precocious puberty and the late epiphyseal fusion in individuals with hypogonadism, aromatase deficiency, and estrogen resistance.

Thus the effect of estrogen on linear growth is a “two-edged sword” in that it has two opposing effects on adult height. Estrogen stimulates the linear growth rate, which would be expected to increase adult height, but also accelerates growth plate senescence, which would be expected in decreased adult height. In general, the latter effect predominates. As a result, untreated precocious puberty can cause initial childhood tall stature but eventual adult short stature, whereas untreated hypogonadism or delayed puberty can cause adolescent short stature but eventual adult tall stature. These concepts also suggest that gonadotropin-releasing hormone (GnRH) analogues and aromatase inhibitors would increase adult height (see section on Treatment of Short Stature, later in this chapter).

Androgens. Androgens also can accelerate linear growth and thus contribute to the pubertal growth spurt. Androgens, secreted by the gonads or adrenal glands can be aromatized to estrogens in various peripheral tissues, including adipose tissue and thereby affect linear growth. Aromatase is also expressed in growth plate cartilage³⁸; thus local conversion into estrogen may occur. In addition to androgen’s role as a precursor for estrogen, androgen per se appears also to stimulate linear growth. For example, dihydrotestosterone, which is not aromatizable, appears to accelerate linear growth in adolescent boys.³⁹ Animal and in vitro studies suggest that these effects are mediated, at least in part, through a direct effect on the growth plate.³⁶

Insulin. Insulin positively regulates human fetal growth. Consequently, fetal growth retardation occurs in individuals with decreased fetal insulin production because of permanent neonatal diabetes mellitus⁴⁰ and those with decreased insulin sensitivity because of severe biallelic insulin receptor defects.⁴¹ Conversely, increased fetal growth occurs in pregnancies complicated by gestational diabetes. This macrosomia, which primarily involves weight rather than length,⁴² is thought to be caused by the high glucose concentrations stimulating high fetal insulin concentrations.

Nutritional Regulation of Linear Growth

Inadequate nutritional intake causes functional GH insensitivity, with decreased circulating IGF-1 concentrations and increased GH concentrations. Proposed mechanisms include decreased insulin concentrations, causing downregulation of GHR expression^{43,44} and increased FGF-21 concentrations, causing a decrease in hepatic GHR and phosphorylated STAT5 (which is involved in GH signal transduction).^{44,45} The increased FGF-21 concentrations in malnutrition may impair GH sensitivity not only in the liver but also in the growth plate.⁴⁵ In addition, undernutrition can decrease thyroid hormone concentrations, as part of the nonthyroidal illness syndrome,⁴⁶ increase cortisol concentrations,⁴³ and decrease sex steroids (mediated by decreased leptin and hence gonadotropins),^{43,44} all of which may contribute to the decrease in linear growth.

Conversely, overnutrition can stimulate linear growth. Obese children tend to be tall with an increased bone age.^{45,47,48} Because of the accelerated skeletal maturation and, in girls, the earlier puberty, there is little effect on adult height.⁴⁹ Proposed mechanisms by which obesity affects linear growth include increased levels of estrogens because of peripheral aromatization and increased free IGF-1, leptin, prolactin, and adrenal androgens.⁴⁵

Cytokine Regulation of Linear Growth

Impaired linear growth often occurs in children with systemic inflammatory disorders, including juvenile idiopathic arthritis (JIA), IBD, and cystic fibrosis. The underlying mechanisms are likely complex and involve multiple mediators, including malnutrition and glucocorticoid excess. In addition, there is evidence that elevated levels of proinflammatory cytokines contribute to the poor growth. Various proinflammatory cytokines, including tumor necrosis factor- α (TNF- α), IL-1 β , and IL-6, act directly on growth plate chondrocytes to suppress bone growth.^{50,51} Proinflammatory cytokines may also act indirectly on the growth plate by decreasing circulating IGF-1, sex steroid, and thyroid hormone concentrations.^{50,52} The effects of these cytokines may be mediated in part by upregulation of an intracellular protein called SOCS, which decreases GHR signaling.

Autocrine/Paracrine Regulation of Linear Growth

Many different autocrine/paracrine factors are secreted by growth plate chondrocytes and act locally on other chondrocytes. These factors serve to orchestrate the complex processes of proliferation and differentiation in the growth plate. Consequently, genetic defects in these local growth factors, their receptors, or other genes involved in growth factor signaling can impair growth plate chondrogenesis and therefore linear growth of the child. Depending on the specific paracrine system involved and the severity of the genetic abnormality, the bones might be both short and malformed, presenting clinically as a chondrodysplasia, or short but not malformed, presenting clinically as isolated short stature.⁵³ Following are some examples of autocrine/paracrine growth factors that regulate growth plate chondrocytes and are clinically important.

C-Type Natriuretic Peptide. C-type natriuretic peptide (CNP) was named based on its structural similarity to atrial and brain natriuretic peptides. However, CNP serves different functions. It acts locally in the growth plate to stimulate chondrocyte proliferation and hypertrophy. Consequently, loss-of-function mutations in NPR2, the receptor for CNP, cause short stature whereas gain-of-function mutations cause tall stature (see section on Disorders of Childhood Growth for details).⁵⁴ CNP analogues are in clinical trials to augment bone growth in achondroplasia (ACH).

Fibroblast Growth Factors. FGFs, acting through FGF receptor-3 (FGFR3), negatively regulate growth plate chondrogenesis. As a result, gain-of-function mutations in FGFR3 impair linear growth. Depending on the severity of the mutation, the clinical presentation can include several skeletal dysplasias with severe short stature. Recent evidence suggests that milder gain-of-function mutations can present as isolated short stature without an evident skeletal dysplasia.⁵⁵ Conversely, loss-of-function mutations cause tall stature.⁵⁶

Insulin-like Growth Factors. IGF-1 and -2 act through the receptor IGF1R to stimulate growth of many tissues. In the growth plate, they act on chondrocytes to stimulate proliferation and hypertrophy. IGF-1, produced primarily in the liver, acts in an endocrine fashion on the growth plate (see section Regulation of Linear Growth-Endocrine Regulation of Linear Growth), but IGF-1 is also thought to be produced locally in the growth plate, by cells in the perichondrium and/or chondrocytes, and act locally on chondrocytes as a paracrine factor.⁵⁷ In rodents, both endocrine and paracrine effects are important, but the relative importance in humans is unclear. IGF-2 acts primarily as a paracrine factor and is expressed at high levels in fetal tissues. The *IGF2* gene is

imprinted and consequently is expressed only by the paternal allele. In humans, mutations in IGF1, IGF2, and IGFR1 can all impair both fetal and postnatal growth (see section on Disorders of Childhood Growth for details)^{31,58} indicating that both IGF-1 and IGF-2 are important for growth before and after birth.

Parathyroid Hormone-Related Protein and Indian Hedgehog. Parathyroid hormone-related protein (PTHrP) is expressed in the chondrocytes near the ends of the long bones in the embryo and in the resting zone of the growth plate postnatally. It diffuses down through the growth plate. PTHrP acts through PTH1R (the same receptor used by PTH) and, in part, through Gs-alpha, to prevent proliferative zone chondrocytes from undergoing hypertrophic differentiation until they reach a sufficient distance from the source of PTHrP. Indian hedgehog (IHH) is produced by chondrocytes that have just begun hypertrophic differentiation. IHH stimulates production of PTHrP, forming a negative feedback loop.⁵⁹ Mutations in genes that encode components of this system impair bone growth. For example, loss-of-function mutations in PTH1R cause Blomstrand lethal chondrodysplasia, and gain-of-function mutations in PTH1R cause Jansen metaphyseal chondrodysplasia. Similarly, loss-of-function mutations in IHH cause brachydactyly type A1⁶⁰ or short stature with nonspecific skeletal abnormalities,⁶¹ and loss-of-function mutations in Gs-alpha cause Albright hereditary osteodystrophy. Mutations in genes affecting subsequent steps in the PTHrP signal transduction pathway cause acrodyostosis.

Cartilage Matrix Regulation of Linear Growth

Growth plate chondrocytes secrete a cartilage matrix that serves a structural function, allowing the growth plate cartilage to bear the considerable mechanical forces required of the skeletal system. The cartilage matrix also provides the milieu through which endocrine and paracrine factors must travel to reach growth plate chondrocytes. This matrix is a complex mixture of molecules, including multiple types of collagen, for example, collagen types II and X, and proteoglycans, such as aggrecan. Mutations in many of the encoding genes, for example, *COL2A1*, *COL10A1*, and *ACAN* (aggrecan), cause chondrodysplasias. Heterozygous mutations in *ACAN* can also present as short stature with advanced bone age (see section on Disorders of Childhood Growth for details). Mutations in the collagen 1 genes, *COL1A1* and *COL1A2*, cause osteogenesis imperfecta. Affected patients have bone fragility, reflecting the important role of collagen type I in bone matrix, but also can have short stature.

Intracellular Regulation of Linear Growth

Proliferation and hypertrophic differentiation of growth plate chondrocytes is also under complex control by intracellular factors. For example, the short stature homeobox-containing gene (*SHOX*) encodes a transcription factor that is required for normal growth plate function and consequently mutations in *SHOX* cause short stature. Another example of an intracellular system that regulates growth plate chondrocyte function is the RAS-mitogen-activated protein kinase (MAPK) pathway. It is a signal transduction system that regulates cell proliferation and differentiation in many tissues. Ligand binding to tyrosine kinase receptors causes signal transduction involving phosphorylation of a series of proteins. Mutations that augment RAS-MAPK signaling lead to Noonan syndrome (NS), which includes short stature.⁶²

Growth Plate Senescence

Linear growth is extremely rapid in the human fetus and progressively slows during infancy and childhood. This deceleration is briefly interrupted by the pubertal growth spurt but then the deceleration resumes, causing growth to eventually cease. The decline in linear growth is caused by a developmental program intrinsic to the growth plates termed *growth plate senescence*. This developmental program includes a functional decline in chondrocyte proliferation and also a gradual involution of the growth plate with a decrease in the number of chondrocytes and a decrease in the height of the growth plate. Growth plate senescence advances until chondrocyte proliferation essentially ceases. At that point, the growth plate is no longer causing bone elongation, and the now-inert cartilage is remodeled into bone, an event termed *epiphyseal fusion*. Thus epiphyseal fusion is not the cause, but rather the effect, of growth cessation.⁶³ The bone age (usually assessed by a radiograph of the nondominant hand and wrist) serves as a radiological marker for growth plate senescence. As a consequence, the bone age provides an estimate of how far senescence has proceeded in a child and therefore how much of the child's growth potential has been expended and how much remains. For this reason, the bone age is useful for prediction of adult height.

Growth-inhibiting conditions, such as malnutrition, hypothyroidism, and GH deficiency, generally slow not only the growth rate, but also the rate of growth plate senescence. This delay in growth plate senescence is reflected by the delay in the bone age. From an evolutionary standpoint, this delay in growth plate senescence likely serves an important function in the malnourished child, allowing growth to slow to conserve nutrients, while conserving much of the growth potential for better times.

In contrast, estrogen accelerates growth plate senescence, explaining the advanced bone age and loss of adult height in children with precocious puberty and explaining the delayed bone age and increase in adult height of adolescents with hypogonadism, aromatase deficiency, and estrogen resistance. For example, in a man with biallelic mutations in estrogen receptor-alpha, linear growth continued at a slow rate well into adulthood, resulting in tall stature, and epiphyseal fusion occurred at 35 years of age.⁶⁴ This effect of estrogen on growth plate senescence also explains the potential therapeutic use of GnRH analogues⁶⁵ and aromatase inhibitors⁶⁶ to increase adult height.

Catch-Up Growth

Catch-up growth occurs in children following a period of growth inhibition.⁶⁷ Linear growth can be inhibited by many different conditions, including malnutrition, hypothyroidism, growth hormone deficiency, and glucocorticoid excess. If the condition persists long enough, the child's height standard deviation score (SDS) for age will decline (decreasing percentile on height curve). Often the growth-inhibiting condition will eventually resolve, for example, if food becomes more available, thyroid hormone or growth hormone replacement is initiated, or pharmacological glucocorticoids can be stopped. In this situation, the child's linear growth rate usually does not just increase to equal the normal growth rate for age. Instead, the child's growth rate exceeds normal, causing the height SDS to improve. This catch-up growth is often not complete in that the child's height SDS does not return all the way back to the value before the growth inhibition, and the adult height may still be somewhat compromised.

For some time, it was thought that catch-up growth results from a mechanism within the CNS that assesses the child's actual body size, compares this actual body size to

age-appropriate set point, and then adjusts the growth rate accordingly.⁶⁸ After a period of growth inhibition, this hypothesized mechanism would sense the height deficit and increase the growth rate to cause catch-up growth. However, more recent evidence suggests that the primary mechanism responsible for catch-up growth resides not in the CNS but rather in the growth plates and involves delayed growth plate senescence. Growth-inhibiting conditions slow growth plate senescence. When the growth-inhibiting condition resolves, the growth plates are less senescent than normal and therefore grow more rapidly than normal and for a longer period of time, causing catch-up growth.⁶⁹ In some conditions, the rate of human catch-up growth fits this hypothesis, but in others conditions the high initial rate of catch-up growth suggests the possibility of other contributing mechanisms.^{70,71}

Normal Variation in Stature
