Williams Textbook of Endocrinology

14TH EDITION

Shlomo Melmed, MB ChB, MACP

Executive Vice President and Dean of the Medical Faculty
Cedars-Sinai Medical Center
Los Angeles, California

Richard J. Auchus, MD, PhD

Professor
Departments of Pharmacology and Internal Medicine
Division of Metabolism, Endocrinology, and Diabetes
University of Michigan
Endocrinology Service Chief
Ann Arbor VA Healthcare System
Ann Arbor, Michigan

Allison B. Goldfine, MD

Associate Physician, Division of Endocrinology, Diabetes, and Hypertension
Brigham and Women's Hospital
Lecturer, Part-Time
Harvard Medical School
Boston, Massachusetts
Director, Translational Medicine Cardiometabolic Disease
Novartis Institute of Biomedical Research
Cambridge, Massachusetts

Ronald J. Koenig, MD, PhD

Professor
Department of Internal Medicine
Division of Metabolism, Endocrinology, and Diabetes
University of Michigan
Ann Arbor, Michigan

Clifford J. Rosen, MD

Professor of Medicine
Tufts University School of Medicine
Boston, Massachusetts

Preface

The Editors are delighted to welcome you to the 69th anniversary 14th edition of *Williams Textbook of Endocrinology.* In this new edition, we have strived to maintain Robert Williams' original 1950 mandate to publish "a condensed and authoritative discussion of the management of clinical endocrinopathies based upon the application of fundamental information obtained from chemical and physiological investigation." With the passing of the decades, our scholarly goal has been enriched by the addition of genetic, molecular, cellular, and population sciences, together forming the basis of multiple new insights into both the pathogenesis and management of endocrine disorders. Editors of this textbook aim to provide a cogent navigation through the wealth of information emanating from novel medical discoveries that advance the field and bring new therapeutic approaches to patients with endocrine diseases. Our challenge remains to be both concise and didactic, while comprehensively covering relevant translational and clinical endocrine science in an accessible fashion.

With these goals in mind, we have once again assembled a team of outstanding authorities who each contribute their unique expertise to synthesize current knowledge in their respective topic area. For this edition, we have added new chapters on the global burden of endocrine disease and the navigation of the prolific expert endocrine guidelines, as well as chapters devoted to transgender endocrinology, and osteomalacia. The section on diabetes mellitus has been expanded with dedicated chapters on the physiology of insulin secretion, as well as a comprehensive update on therapeutics of type 2 diabetes mellitus. These new contributions reflect the changing emphasis of endocrine practice today and the availability of a wealth of new knowledge and therapeutic options that together affect clinical care. Each section has undergone significant revision and updating to bring the most current information to our readers.

We are deeply appreciative of the valued co-workers in our respective offices, including Shira Berman, and Grace Labrado for their dedicated efforts. We also thank our colleagues at Elsevier—Rae Robertson and Nancy Duffy—for shepherding the production process so professionally. The final product of this exemplary text is due to their skilled navigation of the medical publishing world. We are confident that our combined efforts have succeeded in achieving the high standards set by previous editions that have made Williams the classic "go to" book for all those interested in endocrinology.

1

Principles of Endocrinology

SHLOMO MELMED, RICHARD J. AUCHUS, ALLISON B. GOLDFINE, RONALD J. KOENIG, CLIFFORD J. ROSEN, P. REED LARSEN, KENNETH S. POLONSKY, AND HENRY M. KRONENBERG

CHAPTER OUTLINE

KEY POINTS

- Endocrinology is a scientific and medical discipline with a unique focus on hormones that features a multidisciplinary approach to understanding normal and pathologic hormone production and action, as well as diseases related to abnormal hormone signaling.
- Endocrine and paracrine systems differ in important respects that illustrate the evolutionary pressures on these distinct cell-signaling strategies.
- Differentiated hormone-secreting cells are designed to efficiently synthesize hormones and secrete them in a regulated way.
- Hormones in the bloodstream often are associated with binding proteins to enhance their solubility, protect them from degradation and renal excretion, and regulate their stability in the extracellular space.
- Hormones either act on receptors on the plasma membranes of target cells or move into cells to bind to intracellular receptors; in either case, the target cell is not a passive recipient of signals but rather has key roles in regulating hormonal responses.
- Control of hormone secretion involves integrated inputs from multiple distant targets, nervous system inputs, and local paracrine and autocrine factors, all leading to complex patterns of circadian secretion, pulsatile secretion, secretion driven by homeostatic stimuli, or stimuli that lead to secular changes over the lifespan.
- Endocrine diseases fall into broad categories of hormone overproduction or underproduction, altered tissue response to hormones, or tumors arising from endocrine tissue.
- Hormones and synthetic molecules designed to interact with hormone receptors are administered to diagnose and treat diseases.

About a hundred years ago, Starling coined the term *hormone* to describe secretin, a substance secreted by the small intestine into the bloodstream to stimulate pancreatic secretion. In his Croonian Lectures, Starling considered the endocrine and nervous systems as two distinct mechanisms for coordination and control of organ function. Thus, endocrinology found its first home in the discipline of mammalian physiology.

Over the next several decades, biochemists, physiologists, and clinical investigators characterized peptide and steroid hormones secreted into the bloodstream from discrete endocrine glands or other organs. Diseases such as hypothyroidism and diabetes could be treated successfully for the first time by replacing specific hormones. These initial triumphs of discovery formed the foundation of the clinical specialty of endocrinology.

Advances in cell biology, molecular biology, and genetics over the ensuing years began to reveal mechanisms underlying endocrine disease pathogenesis, hormone secretion, and action. Even though these advances have embedded endocrinology in the framework of molecular cell biology, they have not changed the essential subject of endocrinology—the signaling that coordinates

and controls functions of multiple organs and processes. Herein we survey general themes and principles that underpin diverse approaches used by clinicians, physiologists, biochemists, cell biologists, and geneticists to understand the endocrine system.

The Evolutionary Perspective

Hormones are broadly defined as chemical signals secreted into the bloodstream that act on distant tissues, usually in a regulatory fashion. Hormonal signaling represents a special case of the more general process of signaling between cells. Even unicellular organisms such as baker's yeast, *Saccharomyces cerevisiae,* secrete short peptide mating factors that act on receptors of other yeast cells to trigger mating between the two cells. These receptors resemble the ubiquitous family of seven membrane-spanning mammalian receptors that respond to diverse ligands such as photons and glycoprotein hormones. Because these yeast receptors trigger activation of heterotrimeric G proteins just as mammalian receptors do, this conserved signaling pathway was likely to have been present in the common ancestor of yeast and humans.

Signals from one cell to adjacent cells, termed *paracrine signals,* often use the same molecular pathways used by hormonal signals. For example, the sevenless receptor controls the differentiation of retinal cells in the *Drosophila* eye by responding to a membrane-anchored signal from an adjacent cell. Sevenless is a membrane-spanning receptor with an intracellular tyrosine kinase domain that closely resembles signaling by hormone receptors such as the insulin receptor tyrosine kinase. As paracrine factors and hormones can share signaling machinery, it is not surprising that hormones can, in some settings, act as paracrine factors. Testosterone, for example, is secreted into the bloodstream but also acts locally in the testes to control spermatogenesis. Insulin-like growth factor 1 (IGF1) is a polypeptide hormone secreted into the bloodstream from the liver and other tissues but is also a paracrine factor produced locally in most tissues to control cell proliferation. Furthermore, one receptor can mediate actions of a hormone, such as parathyroid hormone (PTH), and of a paracrine factor, such as parathyroid hormone–related protein. In some cases, the paracrine actions of "hormones" exhibit functions quite unrelated to the hormonal functions. For example, macrophages synthesize the active form of vitamin D, 1,25-dihydroxyvitamin D_3 ($1,25[OH]_2D_3$), which can then bind to vitamin D receptors in the same cells and stimulate production of antimicrobial peptides.[1] This example illustrates that the vitamin D 1α-hydroxylase (P450 27B1) responsible for activating 25-hydroxyvitamin D is synthesized in tissues in which its function is unrelated to the calcium homeostatic actions of the $1,25(OH)_2D_3$ hormone.

Target cells respond similarly to signals that reach them from the bloodstream (hormones) or from adjacent cells (paracrine factors); the cellular response machinery does not distinguish between sites of origin of hormone signals. The shared final common pathways used by hormonal and paracrine signals should not, however, obscure important differences between hormonal and paracrine signaling systems (Fig. 1.1). Hormone synthesis occurs in specialized cells designed specifically for their production, and the hormone then travels in the bloodstream and diffuses in effective concentrations into tissues. Therefore, hormones must be produced in much larger amounts to act as hormones relative to the amounts needed to act as paracrine factors, which act at specific local locations. Hormones must be able to travel to and be protected from degradation in transit from the site of production to the distant site of action. Therefore, for example, lipophilic hormones bind to soluble proteins that allow them to travel in the aqueous media of blood at relatively high concentrations. The ability of hormones to diffuse through the extracellular space implies local hormone concentrations at target sites will rapidly decrease when glandular secretion of the hormone ceases. As hormones quickly diffuse throughout extracellular fluid, hormonal metabolism can occur in specialized organs, including liver and kidney, in a manner that determines the effective hormone concentration in other tissues.

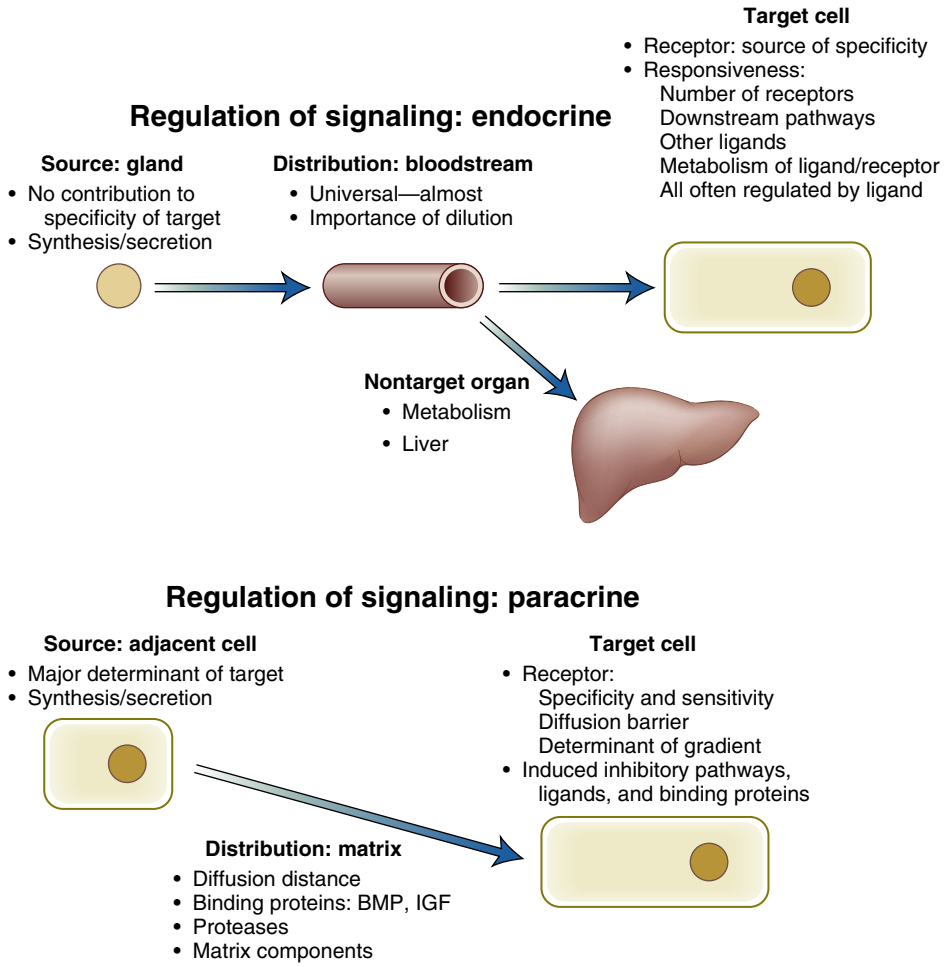
Paracrine factors have rather different constraints. Paracrine signals do not travel very far; consequently, the specific site of origin of a paracrine factor determines where it will act and provides specificity to that action. When the paracrine factor bone morphogenetic protein 4 (BMP4) is secreted by cells in the developing kidney, BMP4 regulates differentiation of renal cells; when the same factor is secreted by cells in bone, it regulates bone formation. Thus the site of origin of BMP4 determines its physiologic role. In contrast, because hormones are secreted into the bloodstream, their sites of origin are often divorced from their functions. Like BMP4, thyroid hormone, for example, acts in many tissues but the site of origin of thyroid hormone in a gland in the neck is not functionally relevant to the sites of action of the hormone.

Because specificity of paracrine factor action is so dependent on its precise site of origin, elaborate mechanisms have evolved to regulate and constrain the diffusion of paracrine factors. Paracrine factors of the hedgehog family, for example, are covalently bound to cholesterol to constrain diffusion of these molecules in the extracellular milieu. Most paracrine factors interact with binding proteins that block their action and control their diffusion. For example, chordin, noggin, and many other distinct proteins bind to various members of the BMP family to regulate their action. Proteases such as tolloid then destroy the binding proteins at specific sites to liberate BMPs so that they can act on appropriate target cells.

Thus, hormones and paracrine factors have several distinct strategies regulating biosynthesis, sites of action, transport, and metabolism. These differing strategies may partly explain why a hormone such as IGF1, unlike its close relative insulin, has multiple binding proteins to control its action in tissues. IGF1 exhibits a double life as both a hormone and a paracrine factor. Presumably the IGF1 actions mandate an elaborate binding protein apparatus to enable appropriate hormone signaling.

All the major hormonal signaling programs—G protein–coupled receptors, tyrosine kinase receptors, serine/threonine kinase receptors, ion channels, cytokine receptors, nuclear receptors—are also used by paracrine factors. In contrast, several paracrine signaling programs are used only by paracrine factors and not by hormones. For example, Notch receptors respond to membrane-based ligands to control cell fate, but no known blood-borne ligands use Notch-type signaling. Perhaps the complex intracellular strategy used by Notch, which involves cleavage of the receptor and subsequent nuclear actions of the receptor's cytoplasmic portion, is too inflexible to serve the purposes of hormones.

Analyses of the complete genomes of multiple bacterial species, the yeast *Saccharomyces cerevisiae,* the fruit fly *Drosophila melanogaster,* the worm *Caenorhabditis elegans,* the plant *Arabidopsis thaliana,* humans, and many other species have allowed a comprehensive view of the signaling machinery used by various forms of life. *S. cerevisiae* uses G protein–coupled receptors; this organism,



• **Fig. 1.1** Comparison of determinants of endocrine and paracrine signaling. *BMP,* bone morphogenetic protein; *IGF,* insulin-like growth factor.

however, lacks tyrosine kinases, used in the insulin signaling pathway, and nuclear receptors that resemble the estrogen/thyroid receptor family. In contrast, the worm and fly share with humans the use of each of these signaling pathways, although with substantial variation in numbers of genes committed to each pathway. For example, the *Drosophila* genome encodes 21 nuclear receptors, the *C. elegans* genome encodes about 284, and the human genome encodes 48 such receptors. These patterns suggest ancient multicellular animals must already have established the signaling systems that are the foundation of the endocrine system as we know it in mammals.

Our understanding of endocrine systems and novel physiologic biology continues to expand. Even before the sequencing of the human genome, sequence analyses had made clear that many receptor genes are found in mammalian genomes for which no clear ligand or function was known. Analyses of these "orphan" receptors broadened current understanding of hormonal signaling. For example, the liver X receptor (LXR) was one such orphan receptor found when searching for unknown putative nuclear receptors. Subsequent experiments found oxygenated derivatives of cholesterol are the ligands for LXR, which regulates genes involved in cholesterol and fatty acid metabolism.[2] The examples of LXR and many others raise the question of what constitutes a hormone. The classic view of hormones is that they are synthesized in discrete glands and have no function other than activating receptors on cell membranes or in the nucleus. Cholesterol, which is converted in cells to oxygenated derivatives that activate the LXR receptor, in contrast, uses a hormonal strategy to regulate its own metabolism. Other orphan nuclear receptors similarly respond to ligands such as bile acids and fatty acids. These "hormones" have important metabolic roles quite separate from their signaling properties, although hormone-like signaling permits regulation of the metabolic function. The calcium-sensing receptor is an example from the G protein–coupled receptor family that responds to a nonclassic ligand, ionic calcium. Calcium is released into the bloodstream from bone, kidney, and intestine and acts on the calcium-sensing receptor on parathyroid cells, renal tubular cells, and other cells to coordinate cellular responses to calcium. Thus, many important metabolic factors have hormonal properties as part of a regulatory strategy within complex organisms. Broadened understanding of these new metabolic factors is leading to new therapeutic approaches to treat or prevent human diseases.

Endocrine Glands

Hormone formation may occur either in the endocrine glands, which are localized collections of specific cells, or in cells that have additional roles. Many protein hormones, such as growth hormone (GH), PTH, prolactin (PRL), insulin, and glucagon, are

produced in dedicated cells by standard protein synthetic mechanisms common to all cells. These secretory cells contain specialized secretory granules designed to store large amounts of hormone and to release the hormones in response to specific signals. Hormones made in these glands and specialized cells are considered to be classic endocrine systems. Formation of small hormone molecules initiates with commonly found precursors, usually in specific glands such as the adrenals, gonads, or thyroid. In the case of the steroid hormones, the precursor is cholesterol, which is modified by various cytochrome P450–based hydroxylations and carbon-carbon bond cleavages and by specific oxidoreductases to form the glucocorticoids, androgens, estrogens, and their biologically active derivatives.

However, not all hormones are formed in dedicated and specialized endocrine glands; the adipose, enteroendocrine, and other systems are now also recognized to be complex endocrine systems. Thus with the discovery of novel peptides and amino acid or steroid-based molecules and their regulatory functions, the field of endocrinology and metabolism has recently been greatly expanded. For example, the protein hormone leptin, which regulates appetite and energy expenditure, is formed in adipocytes, providing a specific signal reflecting the nutritional state of the organism to the central nervous system. The enteroendocrine system comprises a unique hormonal system in which peptide hormones that regulate metabolic and other responses to oral nutrients are produced and secreted by specialized endocrine cells scattered throughout the intestinal epithelium. The cholesterol derivative, 7-dehydrocholesterol, the precursor of vitamin D_3, is converted in skin keratinocytes to previtamin D_3 by a photochemical reaction.

Thyroid hormone synthesis occurs via a unique pathway. The thyroid cell synthesizes a 660,000-kDa homodimer, thyroglobulin, which is then iodinated at specific tyrosines. Some iodotyrosines combine enzymatically to form the iodothyronine molecule within thyroglobulin, which is then stored in the lumen of the thyroid follicle. For tyrosine iodination to occur, the thyroid cell must concentrate trace quantities of iodide from the blood and oxidize it via a specific peroxidase. Release of thyroxine (T_4) from thyroglobulin requires phagocytosis and cathepsin-catalyzed digestion by the same cells.

Hormones are synthesized in response to biochemical signals generated by various modulating systems. Many of these systems are specific to the effects of the hormone product; for example, PTH synthesis is regulated by the concentration of ionized calcium, and insulin synthesis is regulated by the concentration of glucose. For others, such as gonadal, adrenal, and thyroid hormones, control of hormone synthesis is achieved by the homeostatic function of the hypothalamic-pituitary axis. Cells in the hypothalamus and pituitary monitor circulating hormone concentrations and secrete trophic hormones, which activate specific pathways for hormone synthesis and release. Typical examples are GH, luteinizing hormone (LH), follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and adrenocorticotropic hormone (ACTH).

These trophic hormones increase rates of hormone synthesis and secretion, and they may induce target cell division, thus causing enlargement of the various target glands. For example, in hypothyroid individuals living in iodine-deficient areas of the world, TSH secretion causes a marked hyperplasia of thyroid cells. In such regions, the thyroid gland may be 20 to 50 times its normal size. Adrenal hyperplasia occurs in patients with genetic deficiencies in cortisol formation. Hypertrophy and hyperplasia of parathyroid cells, initiated by an intrinsic response to the stress of hypocalcemia, occur in patients with renal insufficiency or calcium malabsorption.

Hormones may be fully active when released into the bloodstream (e.g., GH or insulin), or they may require activation in specific cells to produce biologic effects. These activation steps are often highly regulated. For example, T_4 released from the thyroid cell is a prohormone that must undergo specific deiodination to form the active 3,5,3'-triiodothyronine (T_3). This deiodination reaction can occur in target tissues, such as in the central nervous system; in thyrotrophs, where T_3 provides feedback regulation of TSH production; or in hepatic and renal cells, from which it is released into the circulation for uptake by all tissues. A similar postsecretory activation step catalyzed by a 5α-reductase causes tissue-specific activation of testosterone to dihydrotestosterone in target tissues, including the male urogenital tract, prostate, genital skin, and liver. Vitamin D undergoes hydroxylation at the 25 position in the liver and in the 1 position in the kidney. Both hydroxylations must occur to produce the active hormone, 1,25-dihydroxyvitamin D. Activity of 1α-hydroxylase, but not 25-hydroxylase, is stimulated by PTH and hypophosphatemia but is inhibited by calcium, 1,25-dihydroxyvitamin D, and fibroblast growth factor 23 (FGF23).

Most hormones are synthesized as required on a daily, hourly, or minute-to-minute basis with minimal storage, but there are significant exceptions. One is the thyroid gland, which contains enough stored hormone to last for about 2 months. This storage permits a constant supply of thyroid hormone despite significant variations in the availability of iodine. However, if iodine deficiency is prolonged, normal T_4 reservoirs can be depleted.

Feedback signaling systems exemplified earlier enable the hormonal *homeostasis* characteristic of virtually all endocrine systems. Regulation may include the central nervous system or local signal recogniton mechanisms in the glandular cells, such as the calcium-sensing receptor of the parathyroid cell. Disruption of hormonal homeostasis due to glandular or central regulatory system dysfunction has both clinical and laboratory consequences. Recognition and correction of disorders of these systems are the essence of clinical endocrinology.

Transport of Hormones in Blood

Protein hormones and some small molecules, such as catecholamines, are water soluble and readily transported via the circulatory system. Others are nearly insoluble in water (e.g., steroid and thyroid hormones), and their distribution presents special problems. Such molecules are tightly bound to 50-kDa to 60-kDa carrier plasma glycoproteins such as thyroxine-binding globulin (TBG), sex hormone–binding globulin (SHBG), and corticosteroid-binding globulin (CBG) or weakly bound to abundant albumin. Ligand-protein complexes serve as hormone reservoirs, ensure ubiquitous distribution of water-insoluble ligands, and protect small molecules from rapid inactivation or excretion in urine or bile. Protein-bound hormones exist in equilibria with the often-minute quantities of hormone in the aqueous plasma, with the "free" fraction of the circulating hormone taken up by the target cell. For example, if tracer thyroid hormone is injected into the portal vein in a protein-free solution, it binds to hepatocytes at the periphery of the hepatic sinusoid. When the same experiment is repeated with a protein-containing solution, uniform distribution of the tracer hormone occurs throughout the hepatic lobule.[3] Despite the very high affinity of some binding proteins for their

respective ligands, one specific protein may not be essential for hormone distribution. For example, in humans with congenital TBG deficiency, other proteins—transthyretin (TTR) and albumin—subsume its role. As the affinity of these secondary thyroid hormone transport proteins is several orders of magnitude lower than that of TBG, it is possible for the hypothalamic-pituitary feedback system to maintain free thyroid hormone in the normal range at a much lower total hormone concentration. The fact that the free hormone concentration is normal in individuals with TBG deficiency indicates that the hypothalamic-pituitary axis defends the free, active hormone.[4]

Availability of gene-targeting techniques allows specific assessments of the physiologic roles of hormone-binding proteins. For example, mice with targeted inactivation of the vitamin D–binding protein (DBP) have been generated.[5] Although the absence of DBP markedly reduces circulating concentrations of vitamin D, the mice are otherwise normal. However, they have enhanced susceptibility to a vitamin D–deficient diet due to the reduced reservoir of this sterol. In addition, the absence of DBP markedly reduces the half-life of 25-hydroxyvitamin D by accelerating its hepatic uptake, making the mice less susceptible to vitamin D intoxication.

Protein hormones and some small ligands (e.g., catecholamines) produce their effects by interacting with cell surface receptors. Others, such as steroid and thyroid hormones, must enter the cell to bind to cytosolic or nuclear receptors. In the past, it has been thought that much of the transmembrane transport of hormones was passive. Evidence now demonstrates specific transporters involved in cellular uptake of thyroid and some steroid hormones,[7] providing yet another mechanism for regulating the distribution of a hormone to its site of action. Studies in mice devoid of megalin, a large, cell surface protein in the low-density lipoprotein (LDL) receptor family, suggest estrogen and testosterone bound to SHBG use megalin to enter peripheral tissues while still bound to SHBG.[8] In this scenario, the hormone bound to SHBG, rather than "free" hormone, is the active moiety that enters cells. It is unclear how frequently this apparent exception to the "free hormone" hypothesis occurs.

MicroRNAs (miRNAs) have recently also been shown to elicit remote metabolic actions. For example, exosomal miRNA derived from adipose tissue regulates distant tissue gene expression, glucose tolerance, and circulating fibroblast growth factor 21 (FGF21) levels. MiRNAs may thus function as circulating adipokines.[9] Other small lipid signaling molecules are being discovered, especially for their role in activating or suppressing what were previously designated as orphan receptors.

Target Cells as Active Participants

Hormones determine cellular target actions by binding with high specificity to receptor proteins. Whether a peripheral cell is hormonally responsive depends to a large extent on the presence and function of specific and selective hormone receptors and the downstream signaling pathway molecules. Thus receptor expression and intracellular effector pathways activated by the hormone signal are key determinants for which cells will respond, and how. Receptor proteins may be localized to the cell membrane, cytoplasm, or nucleus. Broadly, polypeptide hormone receptors are cell membrane associated, but steroid hormones selectively bind soluble intracellular proteins (Fig. 1.2).

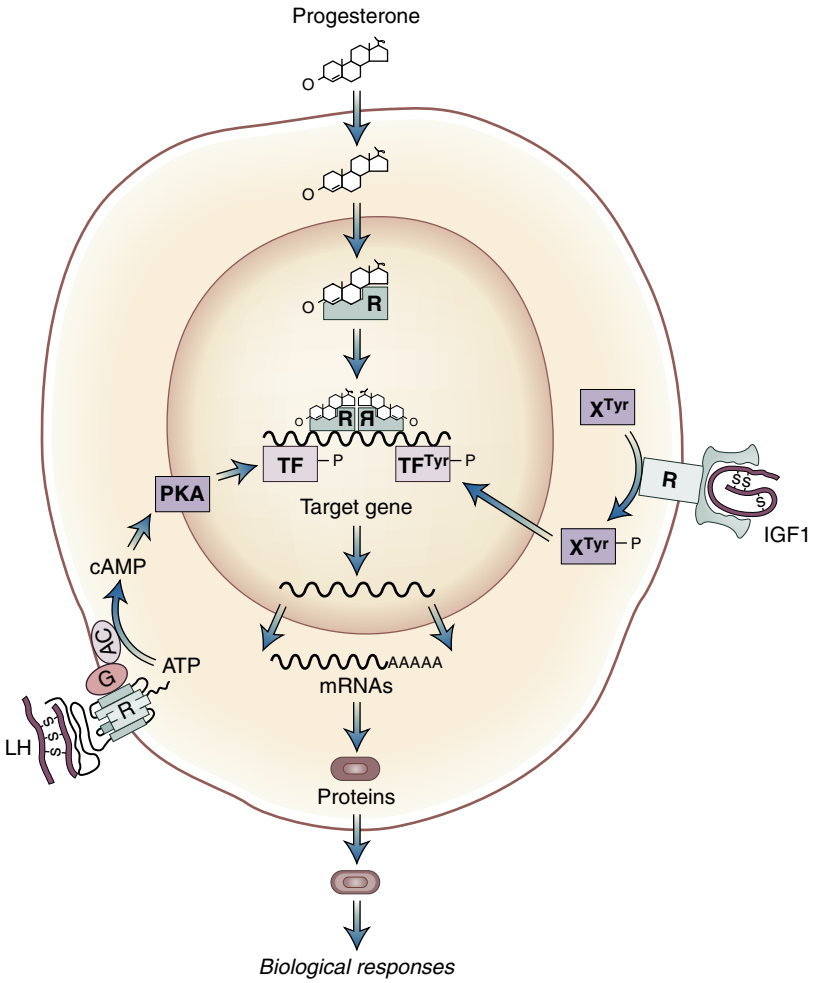
Membrane-associated receptor proteins usually consist of extracellular sequences that recognize and bind ligand, transmembrane-anchoring hydrophobic sequences, and intracellular sequences, which initiate intracellular signaling. Intracellular signaling is mediated by covalent modification and activation of intracellular signaling molecules (e.g., signal transducers and activators of transcription [STAT] proteins) or by generation of small molecule second messengers (e.g., cyclic adenosine monophosphate) through activation of heterotrimeric G proteins. Subunits of these G proteins (α-subunits, β-subunits, and γ-subunits) activate or suppress effector enzymes and ion channels that generate the second messengers. Some of these receptors (e.g., those for somatostatin) may in fact exhibit low constitutive activity and have been shown to signal in the absence of added ligand.

Several growth factors and hormone receptors (e.g., for insulin) behave as intrinsic tyrosine kinases or activate intracellular protein tyrosine kinases. Ligand activation may cause receptor dimerization (e.g., GH) or heterodimerization (e.g., interleukin 6), followed by activation of intracellular phosphorylation cascades. These activated proteins ultimately determine specific nuclear gene expression.

Both the number of receptors expressed per cell and their responses are regulated, thus providing a further level of control for hormone action. Several mechanisms account for altered receptor function. Receptor endocytosis causes internalization of cell surface receptors; the hormone-receptor complex is subsequently dissociated, resulting in abrogation of the hormone signal. Receptor trafficking may then result in recycling back to the cell surface (e.g., as for the insulin receptor) or the internalized receptor may undergo lysosomal degradation. Both these mechanisms triggered by activation of receptors effectively lead to impaired hormone signaling downregulation of the receptors. The hormone signaling pathway may also be downregulated by receptor desensitization (e.g., as for epinephrine); ligand-mediated receptor phosphorylation leads to a reversible deactivation of the receptor. Desensitization mechanisms can be activated by a receptor's ligand (homologous desensitization) or by another signal (heterologous desensitization), thereby attenuating receptor signaling in the continued presence of ligand. Receptor function may also be limited by action of specific phosphatases (e.g., Src homology phosphatase [SHP]) or by intracellular negative regulation of the signaling cascade (e.g., suppressor of cytokine signaling [SOCS] proteins inhibiting Janus kinase/signal transducers and activators of transcription [JAK-STAT] signaling). Certain ligand-receptor complexes may also translocate to the nucleus.

Mutational changes in receptor structure can also determine hormone action. Constitutive receptor activation may be induced by activating mutations (e.g., TSH receptor) leading to endocrine organ hyperfunction, even in the absence of ligand. Conversely, inactivating receptor mutations may lead to endocrine hypofunction (e.g., testosterone or vasopressin receptors). These syndromes are well characterized (Table 1.1) and are well described in subsequent chapters.

The functional diversity of receptor signaling results in overlapping or redundant intracellular pathways. For example, GH, PRL, and cytokines each activate JAK-STAT signaling, whereas the distal effects of these stimuli clearly differ. Thus, despite common upstream signaling pathways, hormones can elicit highly specific cellular effects. Tissue-type or cell-type genetic programs or receptor-receptor interactions at the cell surface (e.g., hetero-oligomerization of dopamine D2 with somatostatin receptor, or insulin with IGF1 receptor) may also confer a specific cellular response to a hormone and provide an additive cellular effect.[10] In addition, effector protein expression may differ in select cells to modulate



• **Fig. 1.2** Hormonal signaling by cell surface and intracellular receptors. The receptors for the water-soluble polypeptide hormones, luteinizing hormone (LH), and insulin-like growth factor 1 (IGF1) are integral membrane proteins located at the cell surface. They bind the hormone-utilizing extracellular sequences and transduce a signal by the generation of second messengers: cyclic adenosine monophosphate (cAMP) for the LH receptor and tyrosine-phosphorylated substrates for the IGF1 receptor. Although effects on gene expression are indicated, direct effects on cellular proteins (e.g., ion channels) are also observed. In contrast, the receptor for the lipophilic steroid hormone progesterone resides in the cell nucleus. It binds the hormone and becomes activated and capable of directly modulating target gene transcription. *AC,* adenylyl cyclase; *ATP,* adenosine triphosphate; *G,* heterotrimeric G protein; *mRNAs,* messenger RNAs; *PKA,* protein kinase A; *R,* receptor molecule; *TF,* transcription factor; *Tyr,* tyrosine found in protein X; *X,* unknown protein substrate. hormonal response. For example, the glucose transporter-4 protein, which leads to insulin-mediated glucose uptake, is most abundantly expressed in muscle, hepatic and adipose tissues, causing these tissues to be the most sensitive tissues for insulin-mediated glucose disposal.

A final mechanism of nuclear receptor modulation is prereceptor regulation via intracellular enzymes that convert the circulating molecules to more or less potent hormones. In addition to the activation of T_4 and testosterone described earlier, selective hormone inactivation occurs in some cells. In the distal nephron, the enzyme 11β-hydroxysteroid dehydrogenase type 2 converts the mineralocorticoid-receptor ligand cortisol to inactive cortisone, thus preventing receptor activation. This mechanism allows aldosterone, which is not a substrate for the enzyme, to regulate mineralocorticoid activity in the kidney despite circulating aldosterone concentrations 1000 times lower than those of cortisol.

Control of Hormone Secretion

Anatomically distinct endocrine glands are composed of highly differentiated cells that synthesize, store, and secrete hormones. Circulating hormone concentrations are a function of glandular secretory patterns and hormone clearance rates. Hormone secretion is tightly regulated to attain circulating levels that are most conducive to elicit the appropriate target tissue response. For example, longitudinal bone growth is initiated and maintained by exquisitely regulated levels of circulating GH, yet mild GH hypersecretion results in gigantism, and GH deficiency causes growth retardation. Ambient circulating hormone concentrations are not uniform, and secretion patterns determine appropriate physiologic function. Thus, insulin secretion occurs in short pulses elicited by nutrient and other signals; gonadotropin secretion is episodic, determined by a hypothalamic pulse generator; and PRL

TABLE 1.1 Diseases Caused by Mutations in G Protein–Coupled Receptors.

Condition[a]	Receptor	Inheritance	ΔFunction[b]
Retinitis pigmentosa	Rhodopsin	AD/AR	Loss
Nephrogenic diabetes insipidus	Vasopressin V2	X-linked	Loss
Familial glucocorticoid deficiency	ACTH	AR	Loss
Color blindness	Red/green opsins	X-linked	Loss
Familial precocious puberty	LH	AD (male)	Gain
Familial hypercalcemia	Ca^{2+} sensing	AD	Loss
Neonatal severe parathyroidism	Ca^{2+} sensing	AR	Loss
Dominant form hypocalcemia	Ca^{2+} sensing	AD	Gain
Congenital hyperthyroidism	TSH	AD	Gain
Hyperfunctioning thyroid adenoma	TSH	Somatic	Gain
Metaphyseal chondrodysplasia	PTH-PTHrP	Somatic	Gain
Hirschsprung disease	Endothelin-B	Multigenic	Loss
Coat color alteration (*E* locus, mice)	MSH	AD/AR	Loss and gain
Dwarfism (*little* locus, mice)	GHRH	AR	Loss

[a]All are human conditions with the exception of the final two entries, which refer to the mouse.

[b]Loss of function refers to inactivating mutations of the receptor, and gain of function to activating mutations.

ACTH, Adrenocorticotropic hormone; *AD,* autosomal dominant inheritance; *AR,* autosomal recessive inheritance; *FSH,* follicle-stimulating hormone; *GHRH,* growth hormone–releasing hormone; *LH,* luteinizing hormone; *MSH,* melanocyte-stimulating hormone; *PTH-PTHrP,* parathyroid hormone and parathyroid hormone–related peptide; *TSH,* thyroid-stimulating hormone.

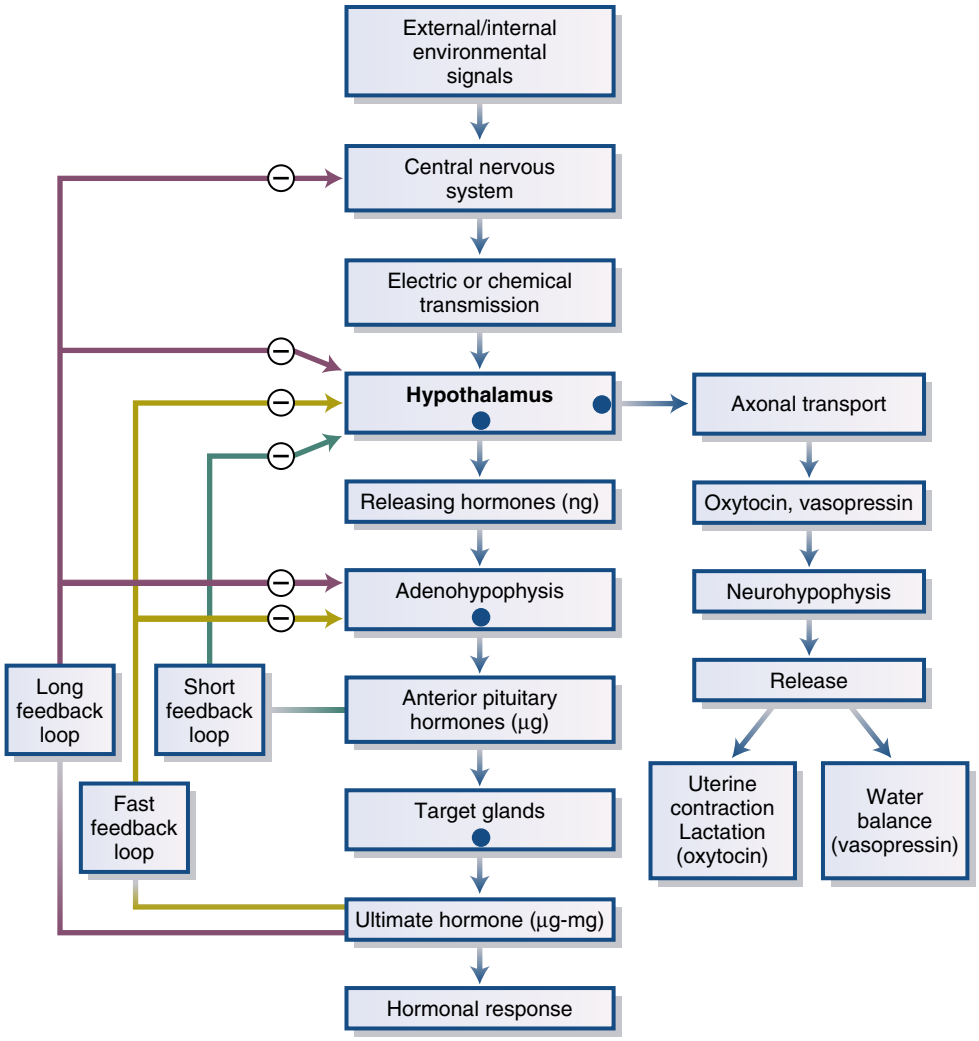
secretion appears to be relatively continuous, with secretory peaks elicited during suckling.

Hormone secretion also adheres to rhythmic patterns. Circadian rhythms serve as adaptive responses to environmental signals and are controlled by a circadian timing mechanism.[11] Light is the major environmental cue adjusting the endogenous clock. The retinohypothalamic tract entrains circadian pulse generators situated within hypothalamic suprachiasmatic nuclei. These signals subserve timing mechanisms for the sleep-wake cycle and determine patterns of hormone secretion and action. Disturbed circadian timing results in hormonal dysfunction and may also be reflective of entrainment or pulse generator lesions. For example, adult GH deficiency due to a damaged hypothalamus or pituitary is associated with elevations in integrated 24-hour leptin concentrations and decreased leptin pulsatility, yet preserved circadian rhythm of leptin. GH replacement restores leptin pulsatility, promoting loss of body fat mass.[12] Sleep is an important cue regulating hormone pulsatility. About 70% of overall GH secretion occurs during slow-wave sleep, and increasing age is associated with declining slow-wave sleep and concomitant decline in GH and elevation of cortisol secretion.[13] Most pituitary hormones are secreted in a circadian (day-night) rhythm, best exemplified by ACTH peaks before 9 AM, whereas ovarian steroids follow a 28-day menstrual rhythm. Disrupted episodic rhythms are often a hallmark of endocrine dysfunction. For example, loss of circadian ACTH secretion with high midnight cortisol levels is a feature of Cushing disease.

Hormone secretion is induced by multiple specific biochemical and neural signals. Integration of these stimuli results in the net temporal and quantitative secretion of the hormone (Fig. 1.3). Signals elicited by hypothalamic hormones (growth hormone–releasing hormone [GHRH], somatostatin), peripheral hormones (IGF1, sex steroids, thyroid hormone), nutrients, adrenergic pathways, stress, and other neuropeptides all converge on the somatotroph cell, resulting in the ultimate pattern and quantity of GH secretion. Networks of reciprocal interactions allow for dynamic adaptation and shifts in environmental signals. These regulatory systems involve the hypothalamic, pituitary, and target endocrine glands, as well as the adipocytes and lymphocytes. Peripheral inflammation and stress elicit cytokine signals that interface with the neuroendocrine system, resulting in hypothalamic-pituitary axis activation. Parathyroid and pancreatic secreting cells are less tightly controlled by the hypothalamus, but their functions are tightly regulated by the distal effects they elicit. For example, PTH secretion is induced when serum calcium levels fall and the signal for sustained PTH secretion is abrogated by rising calcium levels, whereas insulin secretion is induced when blood glucose rises but suppressed when glucose concentrations fall.

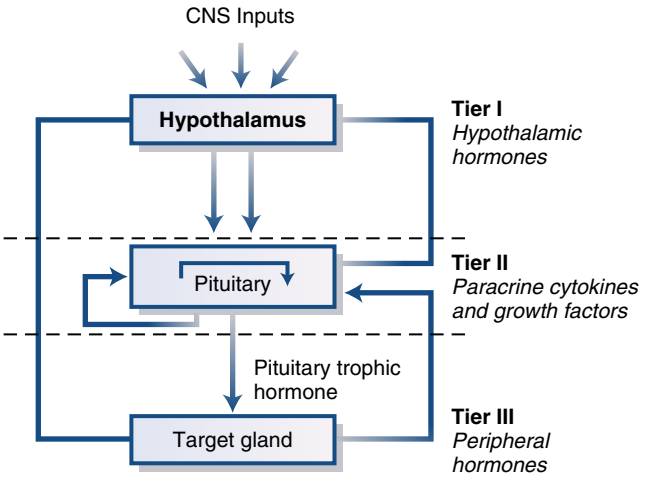
Several tiers of control subserve the ultimate net glandular secretion. First, central nervous system signals, including afferent stimuli, neuropeptides, and stress, signal the synthesis and secretion of hypothalamic hormones and neuropeptides (Fig. 1.4). Four hypothalamic-releasing hormones (GHRH, corticotropin-releasing hormone [CRH], thyrotropin-releasing hormone [TRH], and gonadotropin-releasing hormone [GnRH]) traverse the hypothalamic portal vessels and impinge upon their respective transmembrane trophic hormone-secreting cell receptors. These distinct cells express GH, ACTH, TSH, and gonadotropins, respectively. In contrast, hypothalamic somatostatin and dopamine suppress GH or PRL and TSH secretion, respectively. Trophic hormones



• **Fig. 1.3** Peripheral feedback mechanism and a millionfold amplifying cascade of hormonal signals. Environmental signals are transmitted to the central nervous system, which innervates the hypothalamus, which responds by secreting nanogram amounts of a specific releasing hormone. These are transported down a closed portal system, pass the blood-brain barrier at either end through fenestrations, and bind to specific anterior pituitary cell membrane receptors to elicit secretion of micrograms of specific anterior pituitary hormones. These hormones enter the venous circulation through fenestrated local capillaries, bind to specific target gland receptors, trigger release of micrograms to milligrams of daily hormone amounts, and elicit responses by binding to receptors in distal target tissues. Peripheral hormone receptors enable widespread cell signaling by a single initiating environmental signal, thus facilitating intimate homeostatic association with the external environment. Arrows with a large dot at their origin indicate a secretory process. (From Normal AW, Litwack G. *Hormones.* 2nd ed. New York: Academic Press; 1997:14.)

maintain the structural and functional integrity of endocrine organs, including the thyroid and adrenal glands and the gonads. Target hormones, in turn, serve as powerful negative feedback regulators of their respective trophic hormone, often also suppressing secretion of hypothalamic-releasing hormones. In certain circumstances (e.g., during puberty), peripheral sex steroids may positively induce the hypothalamic-pituitary-target gland axis. For example, LH induces ovarian estrogen secretion, which feeds back positively to induce further LH release. Pituitary hormones themselves, in a short feedback loop, also regulate their own respective hypothalamic-controlling hormone. Hypothalamic-releasing hormones are secreted in nanogram amounts and have short half-lives of a few minutes. Anterior pituitary hormones are produced in microgram amounts and have longer half-lives, but peripheral hormones can be produced in up to milligram amounts daily, with much longer half-lives.

A further level of secretion control occurs within the gland itself. Intraglandular paracrine or autocrine growth peptides serve to autoregulate pituitary hormone secretion, as exemplified by epidermal growth factor (EGF) control of PRL or IGF1 control of GH secretion. Molecules within the endocrine cell may also subserve an intracellular feedback loop. For example, corticotrope SOCS-3 induction by gp130-linked cytokines serves to abrogate the ligand-induced JAK-STAT cascade and block proopiomelanocortin (POMC) transcription and ACTH secretion. This rapid on-off regulation of ACTH secretion provides a plasticity for the endocrine response to changes in environmental signaling and serves to maintain homeostatic integrity.[14]



• **Fig. 1.4** Model for regulation of anterior pituitary hormone secretion by three tiers of control. Hypothalamic hormones impinge directly on their respective target cells. Intrapituitary cytokines and growth factors regulate trophic cell function by paracrine (and autocrine) control. Peripheral hormones exert negative feedback inhibition of respective pituitary trophic hormone synthesis and secretion. *CNS,* central nervous system. (From Ray D, Melmed S. Pituitary cytokine and growth factor expression and action. *Endocr Rev.* 1997;18:206–228.)

In addition to the central nervous system–neuroendocrine interface mediated by hypothalamic chemical signal transduction, the central nervous system directly controls several hormonal secretory processes. Posterior pituitary hormone secretion occurs as direct efferent neural extensions. Postganglionic sympathetic nerves also regulate rapid changes in renin, insulin, and glucagon secretion, while preganglionic sympathetic nerves signal to adrenal medullary cells eliciting epinephrine release.

Hormone Measurement

Endocrine function can be assessed by measuring levels of basal circulating hormone, evoked or suppressed hormone, or hormone-binding proteins. Alternatively, hormone function can be assessed. When a feedback loop exists between the hypothalamic-pituitary axis and a target gland, the circulating level of the pituitary trophic hormone, such as TSH or ACTH, is typically an exquisitely sensitive index of deficient or excessive function of the thyroid or the adrenal cortex, respectively. Meaningful strategies for timing hormonal measurements vary from system to system. In some cases, circulating hormone concentrations can be measured in randomly collected serum samples. This measurement, when standardized for fasting, environmental stress, age, and gender, is reflective of true hormone concentrations only when levels do not fluctuate appreciably. For example, thyroid hormone, PRL, and IGF1 levels can be accurately assessed in fasting morning serum samples. On the other hand, when hormone secretion is clearly episodic, timed samples may be required over a defined time course to reflect hormone bioavailability. Thus, early morning and late evening cortisol measurements are most appropriate. A 24-hour sampling for GH measurements, with samples collected every 2, 10, or 20 minutes, is expensive and cumbersome, yet may yield valuable diagnostic information. Random sampling may also reflect secretion peaks or nadirs, thus confounding adequate interpretation of results.

In general, confirmation of failed glandular function is made by attempting to evoke hormone secretion by recognized stimuli. Testing of pituitary hormone reserve may be accomplished by injecting appropriate hypothalamic-releasing hormones. Injection of trophic hormones, including TSH and ACTH, evokes specific target gland hormone secretion. Pharmacologic stimuli (e.g., metoclopramide for induction of PRL secretion) may also be useful tests of hormone reserve. In contrast, hormone hypersecretion can best be diagnosed by suppressing glandular function. Failure to appropriately suppress GH levels after a standardized glucose load implies inappropriate GH hypersecretion. Failure to suppress insulin secretion during hypoglycemia indicates inappropriate hypersecretion of insulin and should prompt a search for the cause, such as an insulin-secreting tumor.

Radioimmunoassays use highly specific antibodies that uniquely recognize the hormone, or a hormone fragment, to quantify hormone levels. Enzyme-linked immunosorbent assays (ELISAs) use enzyme-conjugated antibodies, and enzyme activity is reflective of hormone concentration. Immunometric assays use two antibodies directed to different epitopes of a polypeptide hormone: one "capture" antibody that isolates the hormone to a solid support and one "signal" antibody coupled to a signal-generating molecule such as acridinium ester or an enzyme. These sensitive techniques have allowed ultrasensitive measurements of physiologic hormone concentrations. Hormone-specific receptors may be used in place of the antibody in a radioreceptor assay. However, all antibody-based assays may be subject to artifacts, which should be kept in mind especially when the assay results are discordant with the clinical picture.

Endocrine Diseases

Endocrine diseases fall into four broad categories: (1) hormone overproduction, (2) hormone underproduction, (3) altered tissue responses to hormones, and (4) tumors of endocrine glands. An additional albeit atypical fifth category is exemplified by one kind of hypothyroidism in which overexpression of a hormone-inactivating enzyme in a tumor leads to thyroid hormone deficiency. Other disorders of inadequate hormone inactivation include apparent mineralocorticoid excess, vitamin D 24-hydroxylase deficiency, and X-linked hypophosphatemic rickets (PHEX deficiency).

Hormone Overproduction

Occasionally, hormones are secreted in increased amounts because of genetic abnormalities that cause abnormal regulation of hormone synthesis or release. For example, in glucocorticoid-remediable hyperaldosteronism, an abnormal chromosomal crossover event creates a fusion gene that encodes a protein with aldosterone synthase activity under the control of the ACTH-regulated 11β-hydroxylase promoter. More often, diseases of hormone overproduction are associated with an increase in the total number of hormone-producing cells. For example, hyperthyroidism associated with Graves disease, in which antibodies mimic TSH and activate the TSH receptors on thyroid cells, is accompanied by dramatic increase in thyroid cell proliferation and increased synthesis and release of thyroid hormone from each thyroid cell. In this example, the increase in thyroid cell number represents a polyclonal expansion of thyroid cells, in which large numbers of thyroid cells proliferate in response to an abnormal stimulus. However, most endocrine tumors are not polyclonal expansions but instead represent monoclonal expansions of a single mutated cell. Pituitary and parathyroid tumors, for example, are usually monoclonal expansions in which somatic mutations in multiple

tumor suppressor genes and proto-oncogenes occur. These mutations lead to an increase in proliferation or survival of the mutant cells. Sometimes this proliferation is associated with abnormal secretion of hormone from each tumor cell. For example, mutant $G_s\alpha$ proteins in somatotrophs can lead to both increased cellular proliferation and increased secretion of GH from each tumor cell.

Hormone Underproduction

Underproduction of hormone can result from a wide variety of processes, ranging from surgical removal of parathyroid glands during neck surgery, to tuberculous destruction of adrenal glands, to iron deposition in pancreatic beta cells of islets in hemochromatosis. A frequent cause of destruction of hormone-producing cells is autoimmunity. Autoimmune destruction of beta cells in type 1 diabetes mellitus or of thyroid cells in chronic lymphocytic (Hashimoto) thyroiditis are two of the most common disorders treated by endocrinologists. Recently a direct passage of insulin fragments by exocytosis from pancreatic islets to lymphoid tissue has been shown to trigger autoimmune diabetes in mice.[15] Multiple genetic abnormalities can also lead to decreased hormone production. These disorders can result from abnormal development of hormone-producing cells (e.g., hypogonadotropic hypogonadism caused by *KAL* gene mutations), from abnormal synthesis of hormones (e.g., deletion of the GH gene), or from abnormal regulation of hormone secretion (e.g., the hypoparathyroidism associated with activating mutations of the parathyroid cell's calcium-sensing receptor). Drugs are important causes of endocrine gland dysfunction as exemplified by immune checkpoint inhibitors leading to multiple endocrinopathies.

Altered Tissue Responses to Hormones

Resistance to hormones can be caused by a variety of genetic disorders. Examples include mutations in the GH receptor in Laron dwarfism and mutations in the $G_s\alpha$ gene in the hypocalcemia of pseudohypoparathyroidism type 1A. Insulin resistance in muscle and liver central to the cause of type 2 diabetes mellitus is complex in origin, resulting from inherited variations in many genes, as well as from theoretically reversible physiologic stresses. Type 2 diabetes is also an example of a disease in which end-organ insensitivity is worsened by signals from other organs, in this case by signals originating in fat cells. In other cases, the target organ of hormone action is more directly abnormal, as in PTH resistance occurring with renal failure.

Increased end-organ function can be caused by mutations in signal reception and propagation. For example, activating mutations in TSH, LH, and PTH receptors can cause increased activity of thyroid cells, Leydig cells, and osteoblasts, even in the absence of ligand. Similarly, activating mutations in the $G_s\alpha$ protein can cause precocious puberty, hyperthyroidism, and acromegaly in McCune-Albright syndrome.

Tumors of Endocrine Glands

Tumors of endocrine glands often result in hormone overproduction. Some endocrine gland tumors produce little if any hormone but cause disease by local, compressive symptoms or by metastatic spread. Examples include so-called nonfunctioning pituitary tumors, which are usually benign but can cause a variety of symptoms due to compression of adjacent structures, and thyroid cancer, which can metastasize without causing hyperthyroidism.

Excessive Hormone Inactivation or Destruction

Although most enzymes important for endocrine systems activate a prohormone or precursor protein, there are also those whose function is to inactivate the hormone in a physiologically regulated fashion. An example is the type 3 iodothyronine deiodinase (D3), which inactivates T_3 and T_4 by removing an inner ring iodine atom from the iodothyronine, blocking its nuclear receptor binding. Large infantile hepatic hemangiomas express high D3 levels, causing "consumptive hypothyroidism," because thyroid hormone is inactivated at a more rapid rate than it can be produced.[16,17] Furthermore, D3 may also be induced in other tumors by tyrosine kinase inhibitors. In theory, accelerated destruction of other hormones could occur from similar processes as yet to be determined.

Diagnostic and Therapeutic Uses of Hormones

In general, hormones are used pharmacologically for their replacement or suppressive effects. Hormones may also be used for diagnostic stimulatory effects (e.g., hypothalamic hormones) to evoke target organ responses or to diagnose endocrine hyperfunction by suppressing hormone hypersecretion (e.g., T_3). Ablation of endocrine gland function due to genetic or acquired causes can be restored by hormone replacement therapy. Thyroid hormones and some steroids can be replaced orally, whereas peptide hormones and analogues (e.g., insulin, PTH, GH) are administered parenterally or absorbed through mucous membranes (inhaled insulin, intranasal desmopressin). Gastrointestinal absorption and first-pass kinetics determine oral hormone dosage and availability. Physiologic replacement can achieve both appropriate hormone levels (e.g., thyroid) and approximate hormone secretory patterns (e.g., GnRH delivered intermittently via a pump). Hormones can also be used to treat diseases associated with glandular hyperfunction. Long-acting depot preparations of somatostatin receptor ligands suppress GH hypersecretion in acromegaly and hypersecretion of diarrhea-causing mediators from neuroendocrine tumors of the pancreas and small intestine. Estrogen receptor antagonists (e.g., tamoxifen) are useful for some patients with breast cancer, and GnRH analogues may downregulate the gonadotropin axis and benefit patients with prostate cancer.

Novel formulations of receptor-specific hormone ligands are now being clinically developed (e.g., estrogen agonists/antagonists, somatostatin receptor subtype-specific ligands, or peroxisome proliferator-activated receptor alpha [PPARα] ligands), resulting in more selective therapeutic targeting. Modes of hormone injection (e.g., for PTH) may also determine therapeutic specificity and efficacy. Improved hormone delivery systems, including computerized minipumps, intranasal sprays (e.g., for desmopressin), pulmonary inhalers, depot intramuscular injections, and orally bioavailable peptide formulations, will also enhance patient compliance and improve ease of administration. Cell-based therapies using the reprogramming of human cells to perform differentiated functions, either through differentiation of induced pluripotent stem cells or directed differentiation of one somatic cell type into another, are under active investigation.[18] Novel technologies offer promise of marked prolongation in the half-life of peptide hormones, thereby requiring infrequent administration. For example, a once weekly preparation of glucagon-like peptide-1 (GLP-1) analogues is used in the treatment of type 2 diabetes.

Important progress has been made in the therapeutic use of hormones. Although delivery of insulin usually still relies on frequent administration by injection and close monitoring by the patient, purity of the insulin preparations, as well as novel delivery devices, has enhanced patient compliance and quality of life. Preparations with differing pharmacokinetics allow the normal physiology of insulin secretion to be more closely mimicked. Continuous administration via subcutaneous pump infusion enhances therapeutic effectiveness in carefully selected patients. These include closed-loop systems, in which the dose of insulin is automatically adjusted depending on continuously monitored interstitial glucose concentrations. Implementation of such systems has the potential to substantially reduce the burden of this disease. However, hormones are biologically powerful molecules that exert therapeutic benefit and effectively replace pathologic deficits. They should not be prescribed without clear-cut indications and should not be administered without careful evaluation by an appropriately qualified medical practitioner.

Future Perspectives

An introduction to the principles underlying endocrinology should end by emphasizing the rapidly changing dynamics of discovery in this field and attempting to foresee what remains to be discovered. New hormones are continually being discovered, from the recent focus on major regulators of metabolism and phosphate homeostasis (FGF19, FGF21, and FGF23) to the continued quest to identify ligands for orphan nuclear and G protein–coupled receptors.[19] Presumably other equally important hormones remain to be discovered. The observation that nuclear receptors, like most transcription factors, bind to thousands of specific sites within the cell's nucleus stresses how little we understand about hormone action. Even the name "nuclear receptors" may be viewed in the future as misleading, since there is an increasing appreciation of extranuclear, rapid actions of nuclear receptors. Many of our diagnostic tests are severely limited by both technology and our inability to foresee novel diagnostic targets. For example, the "disappearance" of isolated GH deficiency when many children with that diagnosis achieve adulthood means either that we have little understanding of the etiology/pathogenesis of that childhood deficiency or that our diagnostic tools today yield many false-positive results. Although endocrinologists pride themselves with having logical treatments for many diseases, these treatments seldom address their underlying causes. We have no satisfactory tools for preventing autoimmune endocrine deficiencies or for preventing the benign tumors that underlie many diseases characterized by hormone excess. Treatments for diseases such as type 1 diabetes, although highly effective, are still very obtrusive in the lives of patients with this disease.

This new edition communicates major advances that have been made in our field over the past 5 years, yet gaps in our knowledge about endocrinology remain. Importantly, debilitating chronic endocrine illnesses with significant morbidity (e.g., diabetes and Cushing disease) still pose significant diagnostic and therapeutic challenges.

Principles of Hormone Action

EVAN D. ROSEN AND CHRISTIN CARTER-SU

CHAPTER OUTLINE

KEY POINTS

- Hormones signal to target cells via receptors on the cell surface or in the cell nucleus.
- Polypeptide hormones act at the cell surface and trigger a cascade of events in the cytoplasm as well as in the nucleus that alter the function of their target cells.
- In addition to polypeptide hormones, many nonpolypeptide hormones such as catecholamines signal via cell surface receptors.
- There are multiple classes of cell surface receptors, including ligand-gated ion channel receptors, G protein–coupled receptors, receptors with intrinsic enzymatic activity, and receptors that associate with enzymes.
- Some of the cell surface receptors have intrinsic catalytic activity, whereas others depend on interaction with other signaling proteins to exert their actions.
- Ligand binding to the extracellular domain of cell surface receptors causes conformational changes in the receptors that activate enzymatic activity and recruitment of cytoplasmic signaling proteins.
- Steroid and thyroid hormones signal via nuclear receptors.
- Some nuclear receptors transduce signals from vitamins, metabolites, and drugs acting as ligands to regulate reproduction, growth, and metabolism.
- Nuclear receptors work directly in the cell nucleus to regulate gene transcription, acting at the genome and recruiting coregulator proteins called corepressors and coactivators.
- Hormone binding to nuclear receptors causes a conformational change in the receptor that favors the recruitment of coactivators to the specific genes that are regulated.
- Some nuclear receptors may work through additional pathways that involve nongenomic mechanisms.

Introduction to Hormone Signaling

The evolution of multicellularity enabled specialization of organs and tissues. As organs took on distinct functions, mechanisms were required to allow communication between tissues; this is the fundamental purpose of hormones. Hormones encode information about environmental or developmental conditions in one location and transmit that information to a separate location. This process ultimately requires that information move from outside of the target cell to its interior, so that cellular function can be altered to meet the needs of the organism. Specifically, the concentration of the substance must be detected by the target cell and converted into a change in cellular activity, a process known as *signal transduction*. The strategies used by hormones to affect cellular function are analogous and, in many cases, identical to those used by other extracellular agents such as neurotransmitters, drugs, and metabolites. However, classic endocrinology defines itself as the process by which extracellular signaling molecules use the bloodstream to travel from the organ of origin to the target tissue. By its nature, this process invariably results in dilution of the secreted molecule in the intravascular space, and thus, with rare exception, the target cell must be capable of detecting and responding to very low concentrations of hormone.

In spite of the vanishingly small concentrations of hormones present in the circulation, classic endocrine organs are usually uniquely equipped to secrete substantial amounts of hormone. Much of the history of endocrinology is defined by purification of hormones from these specialized secretory tissues. In the earliest days, the discovery of a hormone usually followed a stereotypical

course of events: (1) A syndrome, often resembling some human disease, was associated with removal of an endocrine gland; (2) the abnormal phenotype would be corrected by the reimplantation of the absent organ; (3) the same cure would be accomplished by administration of an extract from the organ of interest; and (4) the active agent would be purified from the organ. The discovery of insulin represents the prototype for this series of observations, but the same process led to the identification of other hormones such as thyroid hormone and cortisol.

Hormones can be divided into two groups on the basis of where they function in a target cell. The first group includes hormones that interact with receptors at the cell surface. All polypeptide hormones (e.g., growth hormone [GH], insulin), monoamines (e.g., serotonin), and prostaglandins (e.g., prostaglandin E_2) use cell surface receptors. The second group includes hormones that can enter cells. These hormones bind to intracellular receptors that function in the nucleus of the target cell to regulate gene expression. Classic hormones that use intracellular receptors include thyroid and steroid hormones.

It is worth noting that many molecules behave both as classical hormones that use the bloodstream to travel from their site of production to their site of action and as signaling molecules that do not meet that strict definition. For example, insulin-like growth factor 1 (IGF1) is produced and secreted by the liver under the positive influence of GH and circulates to target tissues like bone, but it is also produced locally by some tissues (e.g., chondrocytes at bone growth plates) to exert effects on neighboring cells. Similarly, norepinephrine is a neurotransmitter that is released at nerve endings and binds to cell surface receptors at postsynaptic membranes, but it is also secreted into the blood by the adrenal medulla, allowing it to act as a classic endocrine hormone. Testosterone is a nuclear receptor ligand that is produced by the Leydig cells of the testis; it can circulate as a hormone and act on muscle, bone, and other tissues, but it also acts as a paracrine agent on neighboring seminiferous tubules. Finally, many secreted molecules that are not regarded as classic hormones meet virtually all of the criteria used to define such agents. For example, cytokines are released by immune cells at the site of inflammation, but they also circulate in plasma and bind to cell surface receptors in the brain, evoking fever. In this sense, many circulating molecules, including those produced exogenously (i.e., obtained from the diet or synthesized by commensal bacteria), could be regarded as having hormonal properties. The key point is that a complete understanding of cell surface and nuclear receptor biology requires a more inclusive perspective than is typically achieved by adhering to a strict set of definitional criteria established decades ago. Having said that, in the interest of brevity, this chapter focuses primarily on receptors that bind classic hormonal ligands, with examples drawn from other systems as needed to provide a more comprehensive picture that reflects our current understanding of receptor biology.

Ligands That Act Through Cell Surface Receptors

The impermeability of the plasma membrane to peptides and small, water-soluble, charged molecules requires that receptors that recognize such substances be located on the outer surface of the cell. The limiting membrane of a typical eukaryotic cell is a 5-nm to 8-nm structure composed of proteins embedded in a bilayer of phospholipids and cholesterol, forming the fluid-mosaic membrane. The phospholipid polar head groups face outward from the membrane, interacting with the hydrophilic milieu that comprises the extracellular fluid and the cytoplasm. Buried between these two charged surfaces are the hydrophobic lipid tails of the phospholipids made up of acyl groups, which are long chains of hydrocarbons derived from fatty acids. The strongly nonpolar environment prevents the diffusion of water-soluble molecules, including many hormones, across the membrane. Thus surface proteins are needed to detect the presence of extracellular ligands that cannot diffuse and are not transported into the cell. Information from this hormone-binding process must then be transmitted across the plasma membrane so that intracellular signaling can commence.

TABLE 2.1 Hormones That Work on the Cell Surface

Peptides and Proteins

Adrenocorticotropic hormone (ACTH)
Antidiuretic hormone (ADH)
Atrial natriuretic peptide (ANP)
Calcitonin
Cholecystokinin
Corticotropin-releasing hormone (CRH)
Follicle-stimulating hormone (FSH)
Gastrin
Glucagon
Gonadotropin-releasing hormone (GnRH)
Growth hormone (GH)
Growth hormone–releasing hormone (GHRH)
Insulin
Insulin-like growth factor 1 (IGF1)
Luteinizing hormone (LH)
Oxytocin
Parathyroid hormone (PTH)
Prolactin (PRL)
Secretin
Somatostatin (SS)
Thyrotropin-releasing hormone (TRH)
Thyrotropin or thyroid-stimulating hormone (TSH)

Molecules Derived From Amino Acids

Dopamine (inhibits prolactin)
Epinephrine (also called adrenaline)
Norepinephrine (also called noradrenaline)
Serotonin

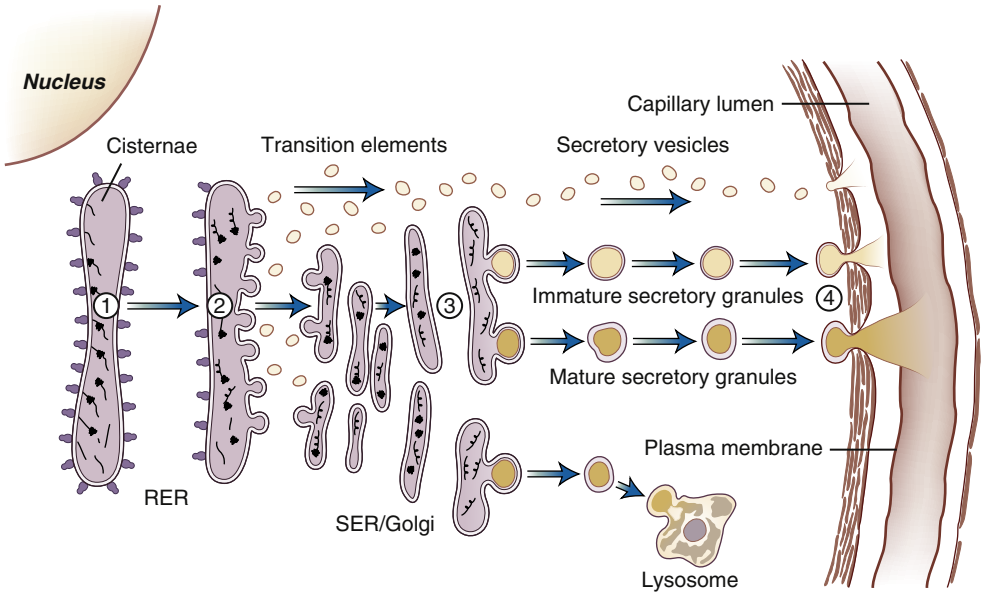
Eicosanoids

Prostaglandins: PGA_1, PGA_2, PGE_2

Classic Peptide Hormones

Most notable among the hormones that bind to cell surface receptors are the peptide hormones, which vary in size from a handful to hundreds of amino acids. Examples of peptide hormones include the glycoproteins and the GH family of proteins secreted by the pituitary, the pancreatic hormones glucagon and insulin, and numerous peptides secreted from nonglandular organs, such as leptin from adipocytes and atrial natriuretic peptide from the heart (Table 2.1).

A hormone's rate of secretion is closely tailored to its lifetime in the circulation and to its time course of action. In general, peptide hormones are released from endocrine glands quickly, as they are preformed and stored in secretory vesicles or granules. In the



• **Fig. 2.1** Subcellular organelles involved in transport and secretion of polypeptide hormones or other secreted proteins within a protein-secreting cell. (1) Synthesis of proteins on polyribosomes attached to rough endoplasmic reticulum (RER) and vectorial discharge of proteins through the membrane into the cisterna. (2) Formation of shuttling vesicles (transition elements) from endoplasmic reticulum followed by their transport to and incorporation by the Golgi complex. (3) Formation of secretory granules in the Golgi complex. (4) Transport of secretory granules to the plasma membrane, fusion with the plasma membrane, and exocytosis resulting in the release of granule contents into the extracellular space. Notice that secretion may occur by transport of secretory vesicles and immature granules or by transport of mature granules. Some granules are taken up and hydrolyzed by lysosomes (crinophagy). *Golgi,* Golgi complex; *SER,* smooth endoplasmic reticulum. (From Habener JF. Hormone biosynthesis and secretion. In: Felig P, Baxter JD, Broadus AE, et al, eds. *Endocrinology and Metabolism*. New York: McGraw-Hill; 1981:29–59.)

course of synthesis, peptide hormones are diverted to secretory vesicles via a regulated secretory pathway (Fig. 2.1). The cytoplasm of endocrine glands containing such secretory vesicles, such as the endocrine pancreas, the anterior pituitary, and the parathyroid glands, is filled with 200-nm electron-dense granules that represent the packaged hormone awaiting secretion. Just as secretion of hormones stored within vesicles can be evoked quickly, often within milliseconds, release can usually be terminated abruptly with great efficiency. Peptide hormones tend to have very short half-lives within the circulation, which allows blood levels to change rapidly in response to changes in secretion. Like the rapid changes in secretion and blood concentrations, initiation of signaling tends to be rapid, which is facilitated by high *on rates* for hormone binding to receptors. In contrast, the *off rate* is often slow, which results in a high equilibrium binding constant that enables the receptors to detect the relatively low levels of hormone in blood. However, a slow off rate is not compatible with the relatively rapid transient nature of peptide hormone–initiated signaling, suggesting mechanisms must exist for turning off the hormonal signal other than simple diffusion of the hormone off of the receptor.

A notable exception to the general rule that peptide hormones turn over quickly and have short durations of action is provided by IGF1. Unlike most peptide hormones, IGF1 circulates in the bloodstream bound to one or more binding proteins, which has two important consequences. First, the concentration of total IGF1 in blood is much greater than that of the unbound, biologically active hormone. Second, the lifetime of IGF1 is greatly extended, such that circulating levels of the hormone change slowly over the course of hours or days. As predicted by these properties, IGF1 primarily influences phenotypes that are modified over extended periods, such as growth and differentiation, and in marked contrast to its cousin insulin, most of the cellular targets of IGF1 are transcriptional.

Nonpeptide Hormones That Act at Cell Surface Receptors

In addition to peptide hormones, there are small, hydrophilic hormones related to monoamine neurotransmitters that bind cell surface receptors. These include adrenergic agents such as norepinephrine as well as other amino acid–derived water-soluble molecules such as melatonin, serotonin, and histamine. Like peptide hormones, these hormones can be stored in dense secretory vesicles, but they are more typically packaged into small, approximately 50-nm electron-lucent vesicles that are similar morphologically to vesicles in neural and neuroendocrine cells. The major difference is that in the presynaptic cleft, the vesicles are arranged in a tightly packed array at the membrane.

Interestingly, while most lipophilic molecules have intracellular receptors, there is at least one class of lipid that breaks this rule. The eicosanoids are a group of extracellular signaling molecules derived from 20-carbon fatty acids that includes the leukotrienes and prostaglandins. Many biologically active eicosanoids bind to cell surface receptors, which initiate their functions.[1]

The recent expansion of messenger types and the novel modes of interorgan communication have dramatically changed the traditional view of endocrinology such that all cell types can potentially both send and receive messages. One of the more interesting recent additions to the assortment of hormone-like molecules has

TABLE 2.2 Receptors for Metabolites and Ions

Metabolite	Receptor
Lactate	GPR81
Ketone bodies	GPR109A
3-Hydroxyoctanoate	GPR109B
Succinate	GPR91
α-Ketoglutarate	GPR80/99
Long-chain fatty acids	GPR40, GPR120
Medium-chain fatty acids	GPR84
Short-chain fatty acids	GPR41, GPR43
Calcium	CASR

been circulating metabolites such as lactate, ketone bodies, and succinate, as well as ions such as calcium[2] (Table 2.2). An even more distant modification of the original definition of *hormone* is the idea that metabolites produced by microbes in the gut, such as short-chain fatty acids, can signal by binding to cell surface receptors.[3]

Binding Properties of Cell Surface Receptors

When a hormone or hormone-like molecule arrives at a target cell, at least three critical components are required to induce the appropriate biologic response. First, there has to be recognition of the hormone as different from all other components of the extracellular milieu. This is an issue of specificity (the ability to distinguish the hormone from other structurally related molecules). Second, the receptor must be able to recognize the low concentration of hormone found in the blood, which is an issue of sufficient affinity of the receptor for the hormone. Third, the initial recognition step mediated by the receptor must be converted into a single action or a defined set of cellular events. Studies of the binding properties of hormones and neurotransmitters crystallized into a fundamental rule governing the action of extracellular agents: A biologic effect is directly proportional to the ligand occupancy of the receptor. A subtle but important modification to occupancy theory is the notion of *spare receptors,* which describes the situation in which a maximal biologic response is achieved by occupancy of only a portion of the available receptors. One consequence of the existence of spare receptors is that a decrease in the number of cellular receptors results in a change in the ED_{50} (effective dose for eliciting a 50% response) for a hormone but does not necessarily alter the maximal biologic response, as detailed later for insulin.[4,5]

As noted, a fundamental characteristic of a cell surface receptor is the ability to bind hormone with high specificity and high affinity. In addition, because there is a limited number of receptors, binding is saturable, such that adding additional ligand above a certain level results in no additional binding and no further increment in downstream biologic activity. Specificity, affinity, and saturability can be established experimentally by assessing the binding of ligands to receptors, using radioactive ligands in a variety of in vitro binding assays.[6] Authentic physiologic receptors for a given hormone will display a greater affinity for the cognate hormone than other potentially competing circulating molecules. In addition, the half maximal binding for a hormone to its real receptor will always be in the range of the circulating free concentration of that hormone.

Cell Surface Hormone Receptors

Cell surface receptors can be grouped conveniently into four classes: ligand-gated ion channel receptors, G protein–coupled receptors, receptors with intrinsic enzymatic activity, and receptors that associate with enzymes.

Ligand-Gated Ion Channels

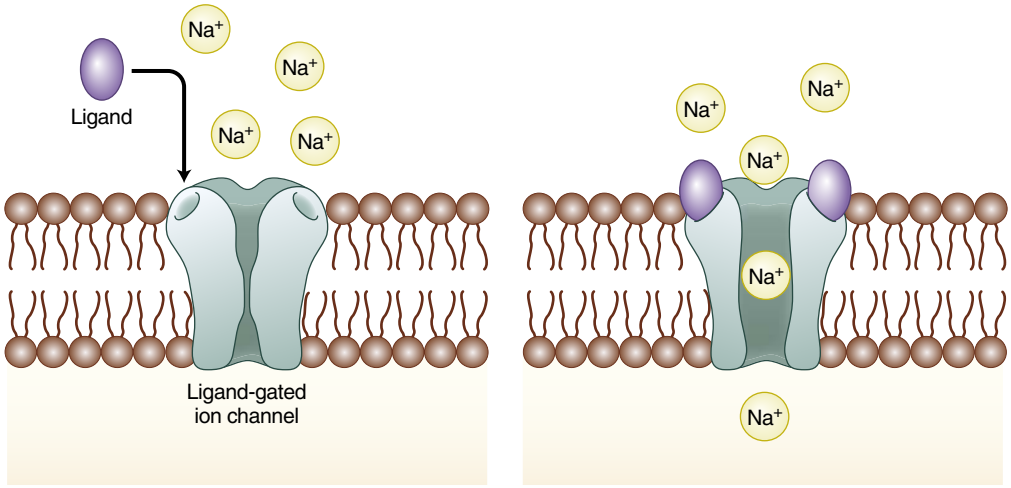
The simplest form of a cell surface signaling system is one in which both hormone-binding and signal-generating functions are provided by a single protein or complex of proteins. Ligand-gated ion channels fall into this category. They are made up of two key components: a ligand-binding domain accessible from the surface of the cell and a transmembrane domain containing a channel. Binding of ligand to the exofacial surface of the receptor generates a conformational change that results in the opening of a pore, allowing specific ions to travel through the channel across the plasma membrane (Fig. 2.2).

The prototype and founding member of the family of ligand-gated ion channels is the nicotinic acetylcholine receptor, which is present on some neurons and on the postsynaptic membrane of the neuromuscular junction.[7] When a nerve impulse arrives at the presynaptic terminal, depolarization leads to an increase in cytosolic calcium and secretion of acetylcholine. The secreted acetylcholine binds to its receptor on the muscle, which elicits a conformational change that opens the pore and allows sodium and potassium ions to pass in and out of the cell, respectively. This leads to depolarization and muscle contraction. The structure of the acetylcholine receptor, which is made up of four different peptides that constitute five subunits, defines a family of receptors that also includes the 5-hydroxytryptamine type 3 ($5HT_3R$), glycine, and inhibitory GABA type A receptors. Another shared characteristic of pentameric receptors is a conserved 15-amino acid dicysteine loop in the extracellular ligand-binding domain (LBD), giving this family its alternative name, the *cys-loop receptors*.[8]

Most ligand-gated ion channels, which when activated can elicit microsecond changes in signal transduction, serve as neurotransmitter receptors rather than receptors for classic hormones. A notable exception involves the receptors for some hypothalamic releasing factors, which are discharged from hypothalamic neurons into the portal circulation to regulate the secretion of hormones from the anterior pituitary. For example, it is thought that serotonin regulates release of prolactin by binding to the $5HT_3R$ receptor in lactotrophs of the anterior pituitary.[9] Glycine and GABA receptors are present in the pituitary gland, but their physiologic functions appear complex and remain imperfectly understood. Another class of ligand-gated ion channels, the purinergic cation receptors, are also expressed in the pituitary and most likely function in an autocrine/paracrine fashion in response to extracellular adenosine triphosphate (ATP).

G Protein–Coupled Receptors

The largest family of cell surface receptors is defined by their use of heterotrimeric G proteins for signaling, leading to their designation *G protein–coupled receptors* (GPCRs). These receptors



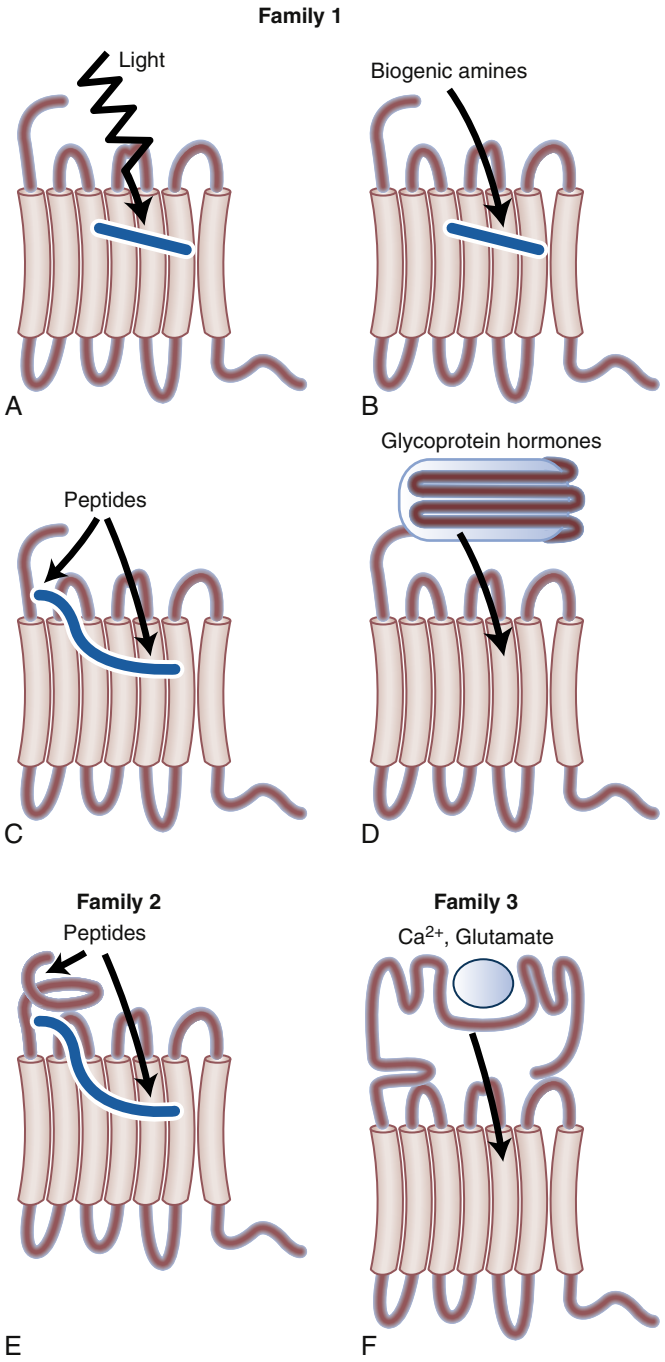
• **Fig. 2.2** Ligand-gated ion channels are transmembrane proteins that comprise at least two domains, a ligand-binding domain and a membrane-spanning domain capable of functioning as a pore. When a ligand binds, it induces a conformational change in the receptor such that the pore opens to the passage of ions, in this case sodium ions, down their electrochemical gradient.

have seven 25–amino acid α-helical segments that pass through the plasma membrane, with the amino (N)-terminus and carboxy (C)-terminus outside the cell and in the cytoplasm, respectively, leading to the name *seven transmembrane* (7TM) proteins.[10] There are more than 800 GPCR family members, with the vast majority being olfactory receptors. The diversity of ligands capable of binding to GPCRs is remarkable, ranging from a single photon to large proteins and including ions, odorants, amines, peptides, lipids, nucleotides, and metabolic intermediates. The smaller hormones, including catecholamines, bind to their GPCRs within the transmembrane-spanning region, oriented parallel to the cell surface; larger hormones bind to the extracellular N-terminus, which itself can range in size from 10 to 600 amino acids,[11] in addition to interacting with the transmembrane-spanning region (Fig. 2.3). The GPCR family has been divided into five subfamilies based on primary sequence and phylogeny, named the glutamate, rhodopsin, adhesion, frizzled/taste2, and secretin families.[12] Many hormones, including some hypothalamic releasing factors, the glycoprotein hormones secreted by the pituitary, and the amines, bind to members of the rhodopsin-like family. On the other hand, glucagon, parathyroid hormone (PTH), calcitonin, and some hypothalamic hormones, such as GH-releasing factor and corticotropin-releasing factor, bind to members of the secretin-like family. For many GPCRs, the endogenous ligand and its function are not known; these GPCRs are known as *orphan receptors*.

Signaling by Heterotrimeric G Proteins

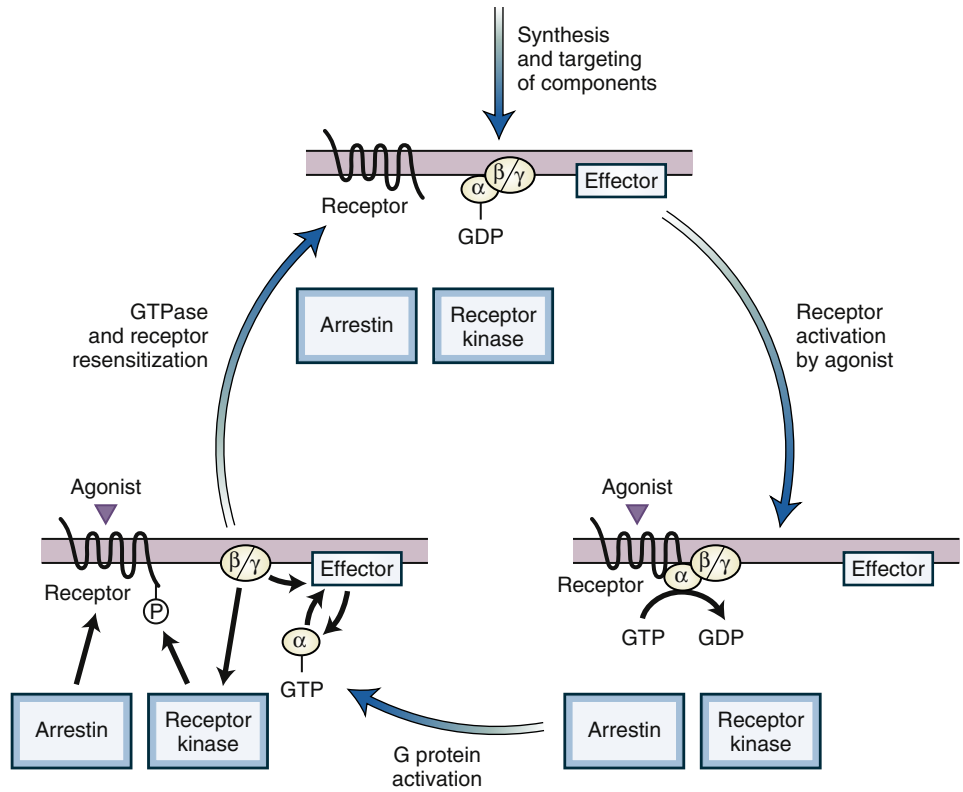
An important advance in the understanding of GPCRs occurred when Bourne and associates took advantage of the lethality of cyclic adenosine monophosphate (cAMP) toward lymphoma cells to select mutant lines resistant to the actions of the β-adrenergic agent isoproterenol.[13] Because the mutant cell lines lost responsiveness to a number of nonadrenergic agonists, it was clear that the genetic lesion did not reside in the β-adrenergic receptor but in a downstream component. When the signaling module that restored hormone responsiveness to the deficient membranes was purified, it turned out to be a heterotrimeric G protein complex, now known as G_s.[14] G_s binds a single guanosine triphosphate (GTP) to its α-subunit, which causes the α-subunit to dissociate from its other two (β, γ) subunits. The GTP-bound α-subunit of G_s is necessary and sufficient for activation of its downstream target, adenylyl cyclase. Like G_s, all G protein complexes are composed of one member each of the α-subunit, β-subunit, and γ-subunit families. Which exact subunit family member determines the downstream effector(s). Sixteen distinct genes encode about 20 different G protein α-subunits, which can be divided into four groups based on both structure and function: $G\alpha_s$, $G\alpha_i$, $G\alpha_{q/11}$, and $G\alpha_{12}$.[10] The $G\alpha_s$ family has only two members, $G\alpha_s$ and the G protein for the olfactory receptor, $G\alpha_{olf}$; both couple to activation of adenylyl cyclase. The $G\alpha_i$ group of eight includes three $G\alpha_i$ proteins, all of which inhibit adenylyl cyclase; two $G\alpha_0$ proteins that are abundant brain proteins whose multiple targets are still not completely defined; two $G\alpha_t$ proteins that couple photoreceptors to cAMP phosphodiesterase (PDE); and $G\alpha_z$, which inhibits potassium channels. The $G\alpha_{q/11}$ subfamily consists of six members, all of which activate the enzyme phospholipase C beta (PLCβ), generating the second messengers diacylglycerol (DAG) and inositol trisphosphate (IP_3). $G\alpha_{12}$ and $G\alpha_{13}$, which inhibit and activate the guanine nucleotide exchange factor, RhoGEF, respectively, form the final group. The combinational possibilities are complex, with 5 β-subunit isoforms and over 12 γ-subunit isoforms.

The key operational feature of G protein signaling is that the system behaves like a timed switch. Engagement of hormone with its cognate receptor promotes its association with a heterotrimeric G protein comprised of subunits Gα, Gβ, and Gγ (Fig. 2.4). This stimulates dissociation of guanosine diphosphate (GDP) from the α-subunit, allowing GTP to bind to the unoccupied site as a result of its greater intracellular concentration compared to GDP. The occupied receptor then detaches from the G protein. GTP loading of the G protein also induces the trimeric G protein complex to dissociate into the α-subunit and a dimeric β/γ-subunit, at least in vitro; it is not clear that dissociation actually occurs in an intact cell. In most cases, the α-subunit modulates an associated amplifier, which in the case of G_s is adenylyl cyclase, but other targets of α-subunits include those referred to previously. The β/γ-dimer can also interact with and regulate downstream signaling molecules. For example, the β/γ-dimer activates potassium channels following ligand binding to the muscarinic acetylcholine receptor.



• **Fig. 2.3** The G protein–coupled receptor (GPCR) superfamily: diversity in ligand binding and structure. Each panel depicts members of the GPCR superfamily. The seven-membrane-spanning α-helices are shown as cylinders, with the extracellular amino (N)-terminus and three extracellular loops above them and the intracellular carboxy (C)-terminus and three intracellular loops below. The superfamily can be divided into three subfamilies on the basis of amino acid sequence conservation within the transmembrane helices. Family 1 includes the opsins (A), in which light *(arrow)* causes isomerization of retinal covalently bound within the pocket created by the transmembrane helices *(bar)*; monoamine receptors (B), in which agonists *(arrow)* bind noncovalently within the pocket created by the transmembrane helices *(bar)*; receptors for peptides such as vasopressin (C), in which agonist binding *(arrow)* may involve parts of the extracellular N-terminus and loops and the transmembrane helices *(bar)*; and glycoprotein hormone receptors (D), in which agonists *(oval)* bind to the large extracellular N-terminus, activating the receptor through undefined interactions with the extracellular loops or transmembrane helices *(arrow)*. (E) Family 2 includes receptors for peptide hormones such as parathyroid hormone and secretin. Agonists *(arrow)* may bind to residues in the extracellular N-terminus and loops and to transmembrane helices *(bar)*. (F) Family 3 includes the extracellular Ca^{2+}-sensing receptor and metabotropic glutamate receptors. Agonists *(circle)* bind in a cleft of the Venus flytrap–like domain in the large extracellular N-terminus, activating the receptor through undefined interactions with the extracellular loops or transmembrane helices *(arrow)*.

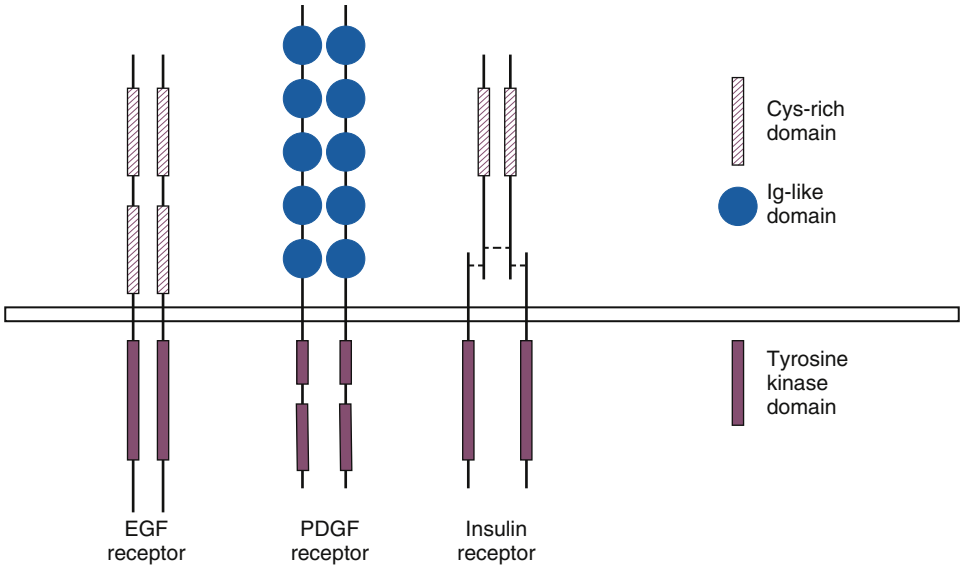
Critical to signal transduction by G proteins is that they remain active as long as GTP is bound. The rate of conversion of nucleotide GTP to GDP determines both the timing for inactivation of signaling and reassembly of subunits. Thus the G protein can exist in two distinct states: bound to GTP and active or bound to GDP and inactive; the time spent in each condition defines the strength of signaling. G protein α-subunits have low levels of intrinsic GTPase activity, but this can be enhanced by association with the regulators of G protein signaling (RGS) proteins.[15] Thus RGS proteins, which function as GTPase accelerating proteins



• **Fig. 2.4** The G protein guanosine triphosphatase (GTPase) and G protein–coupled receptor (GPCR) desensitization-resensitization cycle. In each panel, the *shaded area* denotes the plasma membrane, with the extracellular region above and the intracellular region below. In the basal state, the G protein is a heterotrimer with guanosine diphosphate (GDP) tightly bound to the α-subunit. The agonist-activated GPCR catalyzes release of GDP, which permits guanosine triphosphate (GTP) to bind. The GTP-bound α-subunit dissociates from the βγ-dimer. *Arrows* from the α-subunit to the effector and from the βγ-dimer to the effector indicate regulation of effector activity by the respective subunits. The *arrow* from effector to the α-subunit indicates regulation of its GTPase activity by effector interaction. Under physiologic conditions, effector regulation by G protein subunits is transient and is terminated by the GTPase activity of the α-subunit. The latter converts bound GTP to GDP, thereby returning the α-subunit to its inactivated state with high affinity for the βγ dimer, which reassociates to form the heterotrimer in the basal state. In the basal state, the receptor kinase and arrestin are shown as cytosolic proteins. Dissociation of the GTP-bound α-subunit from the βγ-dimer permits the dimer to facilitate binding of receptor kinase to the plasma membrane (*arrow* from βγ-dimer to receptor kinase). Plasma membrane binding permits the receptor kinase to phosphorylate the agonist-bound GPCR (*P,* depicted here as occurring on the carboxy-terminal tail of the GPCR, although sites on intracellular loops are also possible). GPCR phosphorylation facilitates arrestin binding to the GPCR, resulting in desensitization. Endocytic trafficking of arrestin-bound GPCR and recycling to the plasma membrane during resensitization are not shown.

(GAPs), serve to shorten the duration of signaling by G proteins, providing another important site of regulation. Many members of the large family of RGS proteins contain within their primary sequences canonical domains indicative of other functions and undergo complex post-translational modification. Modulation of the levels of RGS proteins affords a mechanism for signaling pathways to communicate with each other. For example, both thyroid-stimulating hormone (TSH, thyrotropin) and PTH signal through a G_s-cAMP pathway to increase expression of RGS2, which feeds back to inhibit G_s and to antagonize other pathways that depend on G_q.

Another GPCR regulatory system involves a family of proteins called arrestins (see Fig. 2.4). Two of the four arrestins (1 and 4) have been designated visual arrestins because they are expressed only in photoreceptor cells, while two arrestins (2 and 3) are expressed ubiquitously; the latter two are also called β-arrestins 1 and 2. Ligand binding to a GPCR not only signals the dissociation of the G protein complex as described earlier, but also promotes a conformational change in the GPCR that often leads to phosphorylation of the receptor by a G protein receptor kinase (GRK).[16] GRKs are represented by a family of seven related kinases. Phosphorylation of the GPCR at serine and threonine residues by GRKs allows the binding of an arrestin, which sterically uncouples the GPCR from the G protein, terminating the signal. Binding to the receptor also alters the conformation of the arrestin such that it interacts with components of the endocytosis system such as clathrin.[17] The GPCR is escorted to the sorting endosome where it either recycles back to the cell surface or is targeted to the lysosome for degradation. This system provides an efficient mechanism for homologous desensitization, in which there is receptor-specific downregulation of signaling pathways. This mechanism stands in contrast to negative regulation by second messenger–dependent protein kinases, which phosphorylate and inhibit all susceptible GPCRs regardless if occupied by ligand. In addition to its role in the modulation of G protein signaling, β-arrestin has a well-defined function as a signaling intermediate.



• **Fig. 2.5** Receptor tyrosine kinases. Three of the 16 families of receptor tyrosine kinases are represented. All receptor tyrosine kinases possess an extracellular domain containing the ligand-binding site, a single transmembrane domain, and an intracellular portion containing the tyrosine kinase domain. Several structural motifs (i.e., cysteine-rich domain, immunoglobulin-like domain, tyrosine kinase domain) in these receptor tyrosine kinases are indicated on the right side of the figure. *Dotted lines* indicate disulfide bonds. *Cys,* cysteine; *EGF,* epidermal growth factor; *Ig,* immunoglobulin; *PDGF,* platelet-derived growth factor.

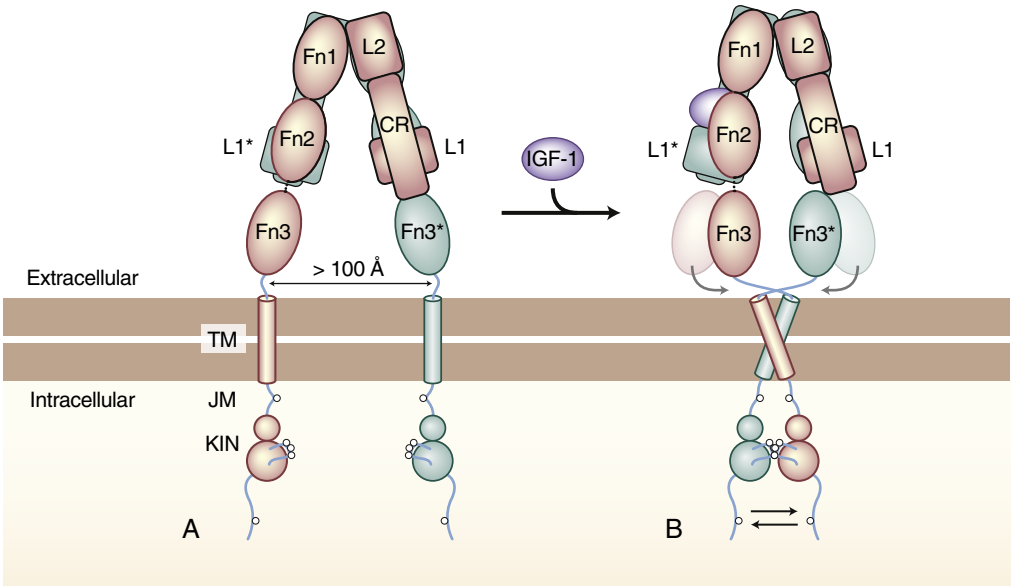
β-arrestin is now known to bind multiple members of the Src family of tyrosine kinases as well as other proteins, such as mitogen-activated protein kinases (MAPKs, also known as extracellular regulated kinases [ERKs]), phosphoinositide 3-kinase (PI3K), Akt, PDE4, and c-Jun N-terminal kinase-3.[18,19]

One of the most interesting aspects of GPCR signaling is the ability of GPCRs to undergo functional selectivity (also known as biased signaling), defined as the ability of ligands to stimulate distinct downstream signaling pathways, presumably due to stabilization of distinct conformational states of the receptor.[20] For GPCR receptors that can activate multiple G proteins, biased signaling refers to the ability to preferentially activate pathways downstream of a subset of the G proteins. For GPCR receptors that can activate arrestins, biased signaling usually refers to the ability of the receptor to favor the G protein response and minimize the arrestin response. Most of the research activity around biased signaling has taken place in the pharmaceutical industry, where the principle has been used in attempts to develop more specific therapeutics. For example, attempts have been made to develop opioid agonists that activate the analgesic effects mediated by G protein signaling but are devoid of arrestin-dependent desensitization and tolerance.[21,22] A similar strategy is being attempted to dissociate G protein–mediated opioid analgesia from arrestin-mediated constipation and respiratory depression.[21,22] Which downstream pathways are initiated by activation of a given GPCR is affected by the type and concentration of the ligand itself, and also the recruitment of specific GRKs, the subcellular location of the GPCR, and the time after ligand exposure.[23]

Receptor Tyrosine Protein Kinases as Cell Surface Receptors

The receptors that make up the receptor tyrosine protein kinase (RTK) family use a number of strategies to accomplish the same goal: to convert the binding of ligand to the exofacial portion of the receptor to a change in the activity of a tyrosine protein kinase domain residing in the interior of the cell. All of these receptors are type I transmembrane proteins with an N-terminal hormone-binding domain on the outside, a 25–amino acid hydrophobic segment that spans the membrane (the transmembrane domain), and a carboxy portion of the protein containing a kinase domain extending into the cytoplasm[24] (Fig. 2.5). The intracellular catalytic domain transfers phosphate from ATP to tyrosine residues in proteins, including the receptor itself. The 58 RTKs expressed in humans can be divided into about 20 subfamilies based on structural features. One of these groups is exemplified by the insulin receptor, which, unlike other RTKs, exists as a disulfide-linked tetramer in the basal state. Receptors in all other subgroups of RTKs, including receptors for fibroblast growth factor, platelet-derived growth factors (PDGFs), and epidermal growth factor (EGF), exist as monomers, though there is evidence that many associate noncovalently into larger structures in the basal state.

Biochemical experiments involving affinity cross-linking and biosynthetic labeling identified the structure of the insulin receptor and that of the highly related IGF1 receptor as a heterotetramer, composed of two 125-kDa α-subunits and two 90-kDa β-subunits linked by disulfide bonds[25,26] (Figs. 2.5 and 2.6). The receptor is synthesized as a single peptide with a cleavable signal sequence directing insertion cotranslationally into the membrane, and it is glycosylated and cleaved into the α and β chains in the Golgi complex.[27] Even though they exist as two separate peptides in the mature protein, each pair of α and β chains behaves much like a receptor monomer found in other growth factor receptors. Affinity labeling by insulin shows cross-linking to both the α-subunit and β-subunit, indicating that both are accessible to substances at the surface of the cell. Insulin binding has been long recognized to exhibit *negative cooperativity,* which means that the affinity for additional hormone decreases as the population of receptors binds more ligands.[28] In structural terms, this is explained by the presence of four binding sites on



• **Fig. 2.6** How insulin-like growth factor 1 (IGF1) activates its receptor. Each IGF1 receptor is made up of two half-receptors, which are linked by disulfide bonds (not shown). The six domains in the extracellular region of the first half-receptor (orange) are L1, CR, L2, Fn1, Fn2, and Fn3; the domains in the second half-receptor (green) are the same and labeled with an asterisk. The L1, CR, L2, and Fn1 are in the α-chain, and the Fn3 and the transmembrane and intracellular domains make up the β-chain of each half-receptor; the Fn2 domain is made up of contributions from both chains. The intracellular region comprises the juxtamembrane region (JM) and the tyrosine kinase domain (KIN). Sites of transphosphorylation are shown as circles. (A) When IGF-1 is not bound to the receptor, an interaction between L1* of the second half-receptor and Fn2 and Fn3 of the first half-receptor (and vice versa) is thought to maintain a large separation between the transmembrane (TM) helices *(double arrow)*. (B) When IGF1 binds to L1* (or to L1), it disrupts the L1*-Fn2 (or L1-Fn2*) interaction. This allows Fn2 and Fn3 of each half-receptor to pivot *(curved arrows)* toward each other (the previous positions of Fn2 and Fn3 are shown semitransparently). This in turn facilitates the dimerization of the TM helices in the membrane, which juxtaposes the kinase domains for efficient transphosphorylation *(black arrows)*. Binding of a single IGF1 molecule (shown as binding to the left side) is sufficient to activate the receptor, but exactly how this asymmetry affects the conformational changes in the receptor is unclear. It is believed that the same mechanism also applies to activation of the insulin receptor. (Modified from Hubbard SR, Miller WT. Closing in on a mechanism for activation. *eLife.* 2014;3:e04909.)

each holoreceptor—two of low affinity and two of high affinity. Insulin initially binds to a low-affinity site before binding to a high-affinity site on the contralateral α/β-dimer, thus effectively cross-linking the two halves of the receptor such that the stoichiometry of this high-affinity complex is one insulin molecule per insulin receptor. This stable structure prevents binding of hormone to the second high-affinity site. This structural organization for binding is largely conserved in the association of IGF1 with its receptor.[29] Other classes of RTKs use alternative strategies for ligand binding. For example, activation of the EGF receptor appears to require binding of one EGF molecule to the outer surface of one of two noncovalently associated EGF receptors,[30,31] while PDGF binds as a dimer to two noncovalently associated PDGF receptors.[32]

In general, activation of RTKs requires the formation of a receptor dimer. In some cases, such as the insulin, IGF1, FGF, and EGF receptors, the unbound receptors appear to consist of preformed dimers. In other cases, bivalent ligand binding to two receptor monomers is thought to promote dimer formation. Examples of receptors thought to act this way include the receptors for PDGF, vascular endothelial growth factor, and nerve growth factor.

Because some of the RTK receptors exist as a dimer in the basal state, it is clear that dimerization alone is not sufficient to activate RTKs; there must also be some fundamental change in the interaction between the two halves of the receptor. In the case of the insulin and IGF1 receptors, the extracellular portions of the unbound receptor exist in an inverted V conformation formed by the α-subunits and part of the β-subunits.[33] The base is continuous with and anchored by the transmembrane domains of the β-subunits. Insulin or IGF1 binding to its low-affinity site removes a brake on a molecular hinge, allowing the V to close and bring the transmembrane domains closer to each other[34,35] (see Fig. 2.6). This conformational change is transmitted to the cytoplasmic domains, where it has the effect of bringing the two kinase domains into closer proximity. In the unbound state, each kinase domain is inactive due to an intramolecular peptide, the *activation loop,* which is buried in the catalytic cleft and sterically hinders entry of substrates.[36] When the two cytoplasmic portions of the receptor domains are brought sufficiently close together, the kinase domain of one β-subunit phosphorylates the other on a cluster of tyrosine residues in the activation loop, forcing the loop out of the catalytic cleft, thus activating the kinase domain.[37] This is possible because of the kinetic nature of the receptor's inactive state, in which the catalytic site is always alternating between open and closed conformations, though in the basal state the activation loop is inaccessible most of the time. However, when the contralateral kinase domain is brought sufficiently close, it can phosphorylate the activation loop during the brief period it is in the extended

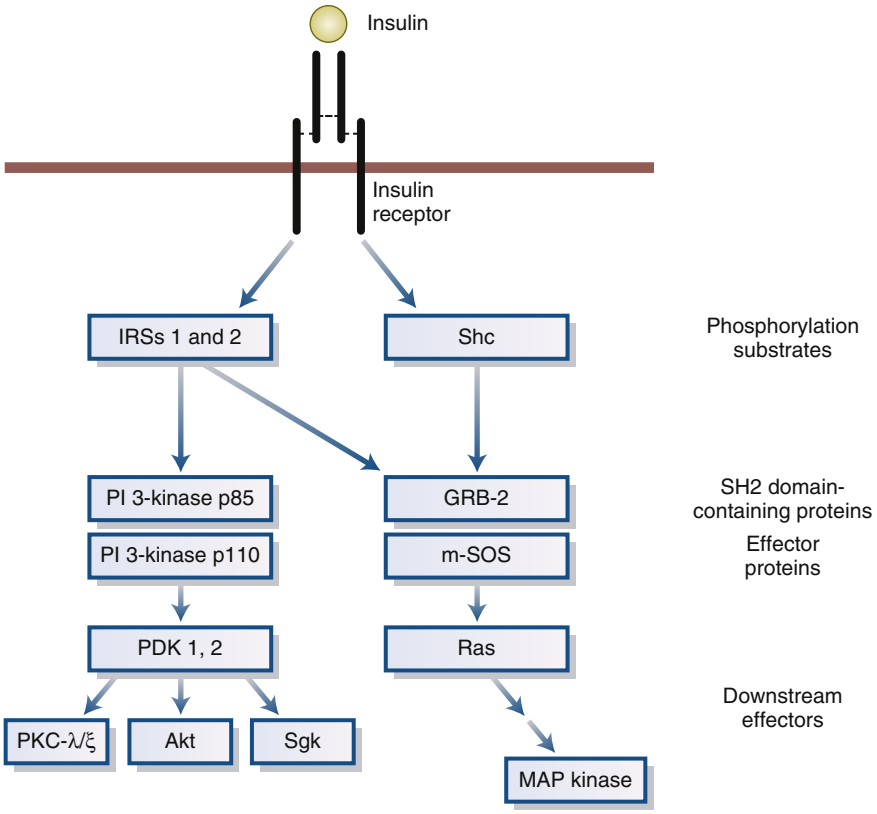
position, converting this to the more stable conformation. In this way, phosphorylation of one-half of the receptor increases its kinase activity, allowing the kinase in that half of the receptor to phosphorylate the activation loop in the other half and, ultimately, exogenous substrates.[38] Proximity-driven phosphorylation and activation of one monomer by the other are common features of RTK activation, but the precise strategies utilized to achieve this vary. Thus, although the active conformations of all tyrosine protein kinases are similar, the configurations of the inactive states differ enormously. An exception to the rule of activation by transphosphorylation is provided by the EGF receptor, in which activation depends on allosteric regulation of the kinase domain of one monomer by the other monomer, once again brought about by a conformational change bringing the two domains into adjacency. The critical interaction is between the C lobe of the activator kinase and the N lobe of the receiver kinase, which disrupts an autoinhibitory interaction present in the inactive monomer.[39]

Signaling by Receptor Tyrosine Protein Kinases

Because the insulin receptor is an enzyme with catalytic activity residing on the cytoplasmic surface of the plasma membrane, it stands to reason that it would transmit its signal by phosphorylating protein substrates within the cell. Nonetheless, though autophosphorylation sites within and outside the cytoplasmic kinase domain of the β-subunit have been long recognized, it proved difficult to identify robust, physiologically significant phosphorylation of tyrosine residues in other proteins. This seeming paradox is partially explained by the underlying mechanism of activation of signaling pathways by RTKs, which signal by recruiting a variety of signaling proteins to the different phosphorylated tyrosines in the receptor. These signaling proteins contain motifs such as the Src homology 2 (SH2) domain and the phosphotyrosine binding (PTB) domain that bind to phosphorylated tyrosines in specific contexts. In the case of the SH2 domain, a phosphorylated tyrosine residue in concert with some amino acids C-terminal to the phosphotyrosine serves as the binding interface for SH2 domains and therefore provides much of the specificity of the interaction.[40] For example, after PDGF binds to its receptor, autophosphorylation of tyrosines within the PDGF receptor in a context defined by the sequence tyrosine–methionine–any amino acid–methionine (YMXM) generates a binding site for the SH2 domains of the regulatory subunit of PI3K.[41] PI3K comprises a regulatory subunit that contains two SH2 domains in tandem and a catalytic subunit. Recruitment of PI3K to a phosphorylated receptor present in the plasma membrane both activates PI3K and brings the PI3K into proximity to its major physiologic substrate, the lipid phosphatidylinositol 4,5-bisphosphate ($PI4,5P_2$), which resides on the inner surface of the plasma membrane. PI3K phosphorylates $PI4,5P_2$ on the 3′-position of its inositol ring, generating phosphatidylinositol 3,4,5-trisphosphate (PIP_3), a potent signaling molecule by virtue of its ability to recruit protein kinases and other signaling molecules to the membrane. This illustrates an important principle governing RTK signaling: The initiation of intracellular events is often driven primarily by the spatial relationship of proteins and lipids rather than changes in the specific activity of assembled components. Although in some cases the hormone-bound receptor will modulate the activity of target protein by phosphorylation, the more important event is often the establishment of adjacency between two or more critical signaling molecules, such as PI3K and its substrate, $PI4,5P_2$. An additional example of this signaling mechanism is provided by activation of another proto-oncogene, c-Ras. In this case, signaling is initiated by recruitment of the adapter protein SH2 domain-containing protein (SHC) or growth factor receptor-bound protein 2 (GRB2) via their SH2 and/or PTB domain. When SHC is recruited, it is in turn tyrosyl phosphorylated by the RTK, enabling it to recruit GRB2 via its SH2 domain. GRB2 contains two Src homology 3 (SH3) domains that remain constitutively bound to a polyproline sequence in the son of sevenless (SOS) protein, which is thus, in turn, carried to the plasma membrane.[42,43] Association of SOS with the plasma membrane is necessary and sufficient for activation of the small G protein Ras.[44] SOS is a guanine nucleotide exchange factor (GEF) protein that activates Ras by catalyzing the removal of GDP from inactive Ras to allow binding of GTP. As noted earlier, the critical event that determines the activity of Ras is the positioning of SOS in proximity to Ras.[45,46]

The insulin and IGF1 receptors signal using a variation of the strategy described previously for the PDGF receptor (Fig. 2.7). Rather than assembling a signaling complex on the cytoplasmic domain of the receptor, they assemble the complex on members of a family of scaffolds called insulin receptor substrate (IRS) proteins.[47] There are at least three members of this family in humans, but IRS1 and IRS2 are thought to be the most important to physiologic signaling by insulin and IGF1. Like other members of the group, IRS1 and IRS2 lack intrinsic enzymatic activity; they serve solely as docking proteins to bring signaling molecules together into a multimeric complex. IRS1 and IRS2 are heavily tyrosine phosphorylated by activated insulin receptor, generating binding sites for the SH2 domains of PI3K, GRB2, and the phosphotyrosine phosphatase SHP2. A pleckstrin homology (PH) domain and PTB domain located at the N-terminus of IRS1/2 are instrumental in bringing the protein to the receptor.[48] Upon ligand engagement of the insulin or IGF1 receptor, IRS1/2 is rapidly phosphorylated on tyrosine residues and more slowly on serine/threonine residues, the latter by a number of cytoplasmic kinases, including protein kinase C (PKC), c-Jun N-terminal kinase (JNK), and pp70 S6 protein kinase. Serine/threonine phosphorylation of IRS proteins provides a strong negative feedback signal as it is thought to block further tyrosine phosphorylation and in some cases induces degradation of the protein.

There is some evidence that the insulin receptor is capable of signaling through scaffolds other than the IRS proteins, though the physiologic significance of these pathways remains unclear. The insulin receptor recruits SHC to a phosphotyrosine motif via SHC's PTB domain and phosphorylates SHC to generate a docking site for the SH2 domain of GRB2; this leads to activation of Ras as described earlier.[49] GRB10, and most likely its close relative GRB14, is an SH2 domain–containing protein that binds to the insulin receptor with high affinity.[50] However, unlike the IRS proteins, GRB10 binds to the three phosphorylated tyrosine residues in the activation loop and blocks the activity of the insulin receptor, inhibiting the insulin-dependent production of PIP_3.[51] GRB10 is stabilized via phosphorylation by mammalian (mechanistic) target of rapamycin complex 1 (mTORC1), itself activated downstream of insulin, providing another form of negative feedback.[52,53] Disruption of GRB10 in mice yields embryonic overgrowth, consistent with its role as a negative regulator of IGF1 signaling.[54] Both SH2B1 and SH2B2 (formerly known as APS) bind directly to the phosphorylated insulin receptor and both enhance the actions of insulin in vivo. However, while insulin sensitivity is decreased in SH2B1-deficient mice, consistent

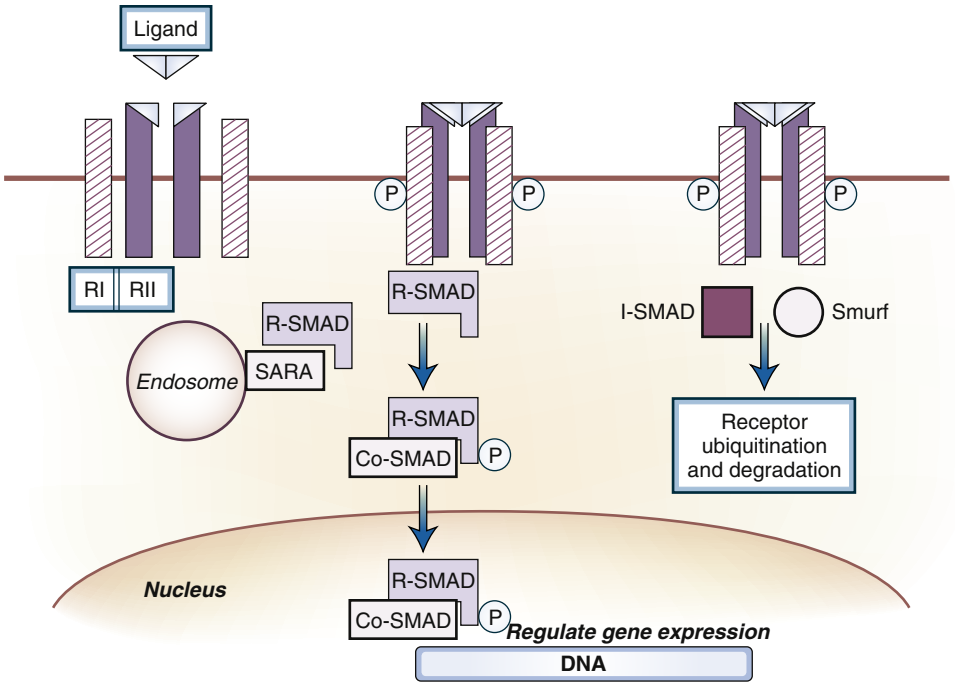


• **Fig. 2.7** Simplified model of signaling pathways downstream from the insulin receptor. Insulin binds to the insulin receptor, activating the receptor tyrosine kinase to phosphorylate tyrosine residues on insulin receptor substrates (IRSs), including IRS1 and IRS2. The phosphotyrosine residues in the IRS molecules bind to Src homology 2 (SH2) domains in molecules such as growth factor receptor–binding protein 2 (GRB2) and the p85 regulatory subunit of phosphoinositide (PI) 3-kinase (PI3K). These SH2 domain–containing proteins initiate two distinct branches of the signaling pathway. Activation of PI3K leads to activation of phosphoinositide-dependent kinases (PDKs) 1 and 2, which activate multiple protein kinases, including Akt/protein kinase B, atypical protein kinase C (PKC) isoforms, and serum-induced and glucocorticoid-induced protein kinases (Sgk). GRB2 interacts with m-SOS, a guanine nucleotide exchange factor that activates Ras. Activation of Ras triggers a cascade of protein kinases, leading to activation of mitogen-activated protein (MAP) kinase. *Shc,* Src, homology domain–containing protein.

with SH2B1 enhancing the actions of insulin, insulin sensitivity is modestly increased in SH2B2-deficient mice, suggesting that the SH2B2 gene product(s) may negatively regulate insulin sensitivity in animals.[51]

Receptor Serine/Threonine Protein Kinases

One of the more interesting variants on signaling by intracellular protein kinases is provided by a class of integral membrane receptors possessing intrinsic serine/threonine protein kinase activity. Ligands for these receptors are members of the transforming growth factor-β (TGFβ) family of first messengers. These 42 agonists encoded in the human genome can be classified into distinct groups typified by TGFβ itself, activin, inhibin, bone morphogenetic protein (BMP)/growth and differentiation factor (GDF), nodal, myostatin, and antimüllerian hormone. Each ligand is composed of a dimer of two peptides joined by hydrophobic interactions and often disulfide bonds. The hormone inhibin was isolated as an activity produced by gonadal tissue that blocks the secretion of follicle-stimulating hormone (FSH) from the pituitary.[55] Like other members of the TGFβ family, it is composed of two chains, an α-subunit and one of two related β-subunits. The hormone activin, which promotes the release of FSH, is formed by the assembly of homodimers of the β-subunit.[56] Like inhibin, activin was originally identified as a product of the gonads but is now known to be secreted by many tissues and to function in an autocrine or paracrine manner as well. The first indication that the TGFβ family of ligands exerts its actions via membrane protein kinases arose from the cloning of a complementary DNA encoding the activin receptor and recognition of a canonical kinase domain.[57] Like all receptors for ligands in the TGFβ superfamily, the activin receptor is composed of four transmembrane glycoproteins, two type 1 receptors and two type 2 receptors. Type 1 and 2 receptors have a similar primary structure, the major difference being an insertion of a conserved 30–amino acid sequence rich in glycine and serine (the GS domain) in the type 1 cytoplasmic domain preceding the kinase domain, which binds the immunophilin FKBP12. Activin interacts initially with type 2 receptors, which brings the type 1 and type 2 receptors into proximity so that the type 2 receptors can phosphorylate the GS domain of the partner type 1 receptors. This alleviates steric hindrance of the type 1 receptor kinase catalytic site and releases FKBP12, the two changes working in concert to activate the type 1 receptors, which allows the receptors to phosphorylate target substrates.[58] Inhibin exerts its inhibitory action by recruiting the transmembrane glycoprotein betaglycan (also called the type III receptor) to form a



• **Fig. 2.8** Mechanism of action for receptor serine kinases. Binding of dimeric ligand to the type II receptor (RII) subunit triggers assembly of the receptor into the heterotetrameric $[(RI)_2(RII)_2]$ state. RII transphosphorylates the type I receptor (RI), thereby activating phosphorylation of the receptor-regulated SMAD (R-SMAD) protein that is bound to the SMAD anchor for receptor activation (SARA) in endosomes. The phosphorylated R-SMAD associates with a comediator SMAD (Co-SMAD). Eventually, the R-SMAD is translocated into the nucleus, where it binds to DNA, enabling it to regulate gene transcription. The inhibitory SMAD (I-SMAD) can also bind to the activated receptor, promoting ubiquitination and degradation of the receptor. *P,* phosphorylation; *Smurf,* SMAD ubiquitination regulatory factor.

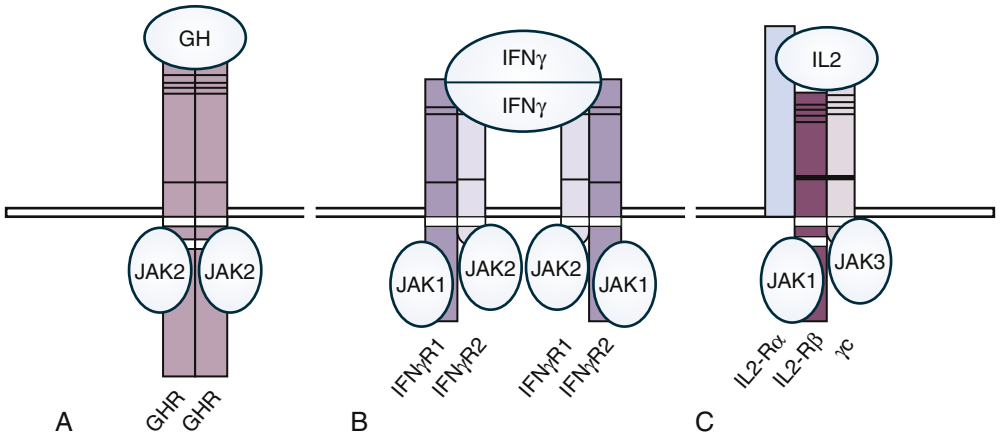
stable complex with type 2 receptors, thus sequestering them and preventing activation of the partner type 1 receptors.[59]

The major intracellular signaling mechanism utilized by all members of the TGFβ family involves SMAD proteins, which function as the major substrates for type I receptors (Fig. 2.8). There are eight human genes coding for SMAD proteins. Five of the human SMAD proteins, termed the receptor regulated SMADs or R-SMADs (SMADs 1, 2, 3, 5, and 8/9), contain a Ser-X-Ser phosphorylation site at their C-terminal tail and serve as substrates for the type I receptors. The activin receptor phosphorylates SMAD3 (and possibly SMAD2). Two R-SMADs then form a trimer with the common partner SMAD or co-SMAD (SMAD4) and are transported to the nucleus.[60] It is likely that other SMAD isoforms contribute to activin regulation of gene expression in vivo in a tissue-specific manner. Upon import into the nucleus, SMAD proteins are modified at their so-called linker domains by a complex set of phosphorylation events that serve both to enhance binding of SMAD proteins to transcriptional regulatory proteins and to target SMAD proteins for ubiquitin-dependent proteasomal degradation. SMAD proteins bind directly to DNA through a conserved N-terminal domain and interact with other transcription factors, which, in concert with the SMAD proteins, exert control over a transcriptional network defined by the cell type and activating ligand. A third class of SMADs, the inhibitory or I-SMADs (SMADs 6 and 7), can bind to the activated receptor and promote ubiquitination and degradation of the receptor.

One particularly interesting member of the TGFβ family is the hormone myostatin, formerly known as GDF8. Myostatin is secreted by skeletal muscle and negatively regulates muscle growth through binding to a type II (ActR-IIB) receptor and type 1 receptors (ALK4 and ALK5), which phosphorylate SMAD2 and SMAD3.[61] A deficiency of myostatin is responsible for the "double-muscled" phenotype of Belgian Blue and Piedmontese cattle, and deletion of its gene in mice and humans leads to massive muscle hypertrophy and hyperplasia.[62]

Signaling by Receptors That Associate With Enzymes

Another mode of signal transduction across the plasma membrane is provided by receptors that possess no intrinsic catalytic activity but that associate with a cytoplasmic, non–membrane-spanning tyrosine kinase. The best example of this is the family of class I and class II cytokine receptors, which are type 1 transmembrane proteins with the N-terminus on the outside of the cell and a cytoplasmic C-terminus (Fig. 2.9). As for RTKs, dimerization or higher order oligomerization appears important for activation of the receptor. In many cases, including the GH receptor, a single ligand molecule contains two distinct recognition sequences. The initial binding is to a high-affinity site, which is followed by a second lower affinity association with a site located on a second, associated monomer. The two monomers that compose the activated receptor make significant contact with each other, again in the exofacial domain close to where the receptor inserts in the membrane. For GH, prolactin, leptin, thrombopoietin, and erythropoietin (EPO), the receptor is a homodimer with two identical subunits. However, for some cytokines, the receptors consist of a ligand-specific monomer and one or more transmembrane chains shared with other cytokine receptors (see Fig. 2.9). For example, the interleukin 2 (IL2) receptor consists of an IL2 receptor–specific

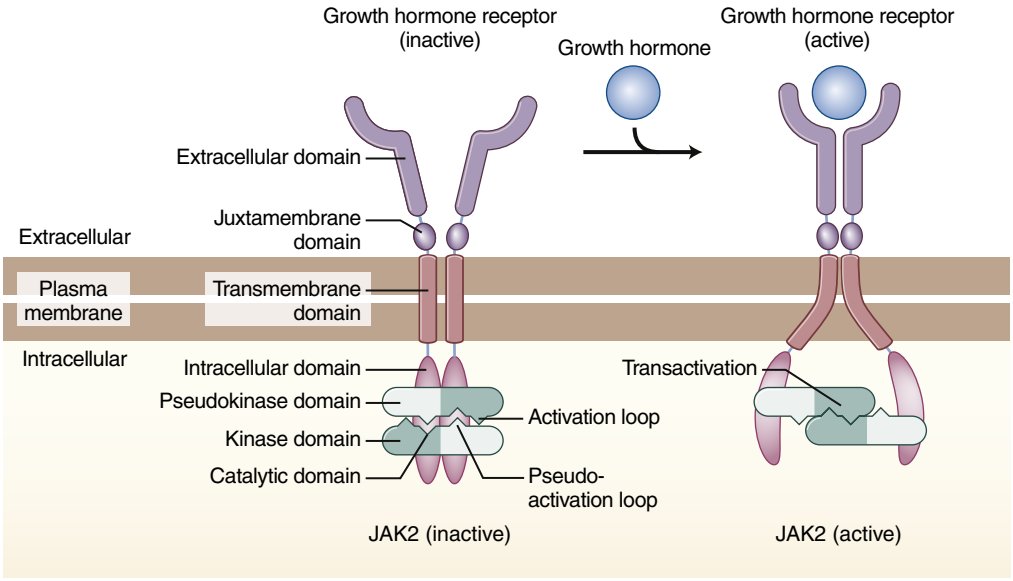


• **Fig. 2.9** Cytokine receptors are composed of multiple subunits and bind to one or more members of the Janus kinase (JAK) family of tyrosine kinases. (A) Growth hormone (GH), such as prolactin and leptin, binds to growth hormone receptor (GHR) homodimers and activates JAK2. (B) Interferon-γ (IFNγ) homodimers bind to their ligand-binding γR1 subunits. The γR2 subunits are then recruited, leading to activation of JAK1, which binds to the γR1 subunit, and JAK2, which binds to the γR2 subunit. Both subunits and both JAKs are necessary for responses to IFNγ. (C) Interleukin 2 (IL2) binds with high affinity to receptors composed of three subunits: a γc subunit shared with receptors for IL4, IL7, IL9, IL15, and IL21; an IL2Rβ subunit shared with the IL15 receptor; and a noncytokine receptor subunit, IL2Rα. IL2 activates JAK3, bound to the γc subunit, and JAK1, bound to IL2Rβ. Extracellular regions of homology are indicated by the *black lines* and *colored patterns*. Intracellular regions of homology are indicated by the *small white boxes*. Identical subunits are indicated by *identical colors*.

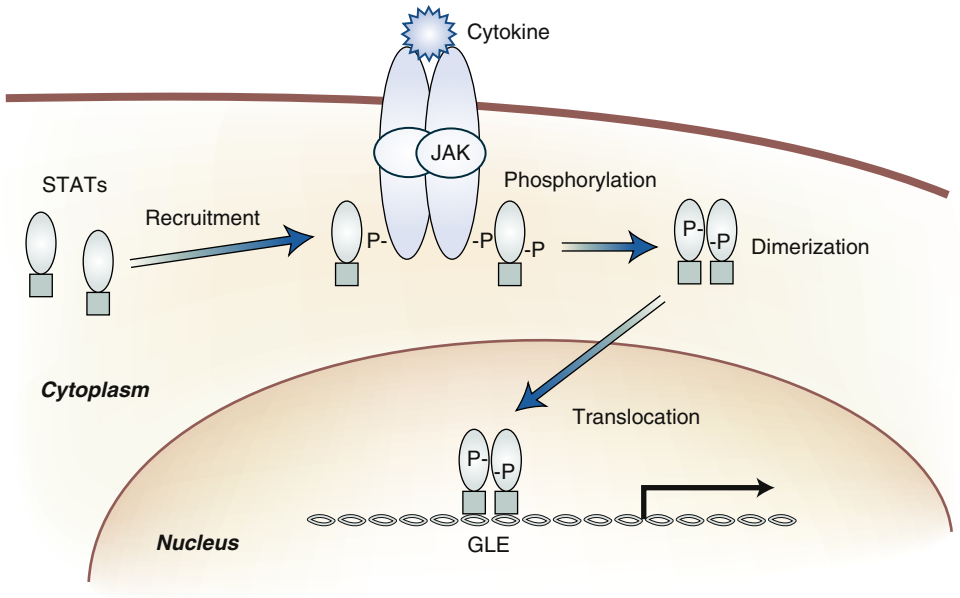
subunit (IR2Rα), a second subunit shared with the IL15 receptor (IL2Rβ), and a γc subunit that is shared with the receptors for IL4, IL7, IL9, and IL15. The IL6 receptor has a unique subunit but shares a glycoprotein 130 (GP130) subunit with at least five other receptors. As with RTKs, oligomerization appears important for activation of these receptors, as indicated by the observation that bivalent, but not monovalent, antibodies are capable of activating the receptors. However, also like RTKs, dimerization alone is insufficient to activate this class of receptors. This was recognized when the EPO receptor and subsequently the GH and prolactin receptors were examined in situ and found to exist as preformed dimers even in the unbound state.[63] The importance of dimerization of the GH receptor is illustrated by the effectiveness of the GH antagonist pegvisomant in treating acromegaly, a disease of excess GH secretion. Pegvisomant competes with native GH for its receptor and prevents functional dimerization.[64]

Proximal to the membrane on the inside of the cell, the class I and class II cytokine receptors have a conserved sequence that is critical to binding a protein tyrosine kinase of the JAK family. There are four members of this family: JAK1, JAK2, JAK3, and tyrosine kinase 2 (TYK2), with JAK3 largely restricted to cells of the hematopoietic lineage.[65] For those receptors that function as homodimers, JAK2 is the predominant isoform involved in signaling. Cytokine receptors that function as heterodimers or higher order oligomers tend to bind more than one JAK family member. For example, the IFNγR1 subunit of the IFNγ receptor binds JAK1 and the IFNγR2 subunit binds JAK2, while the IL2 receptor recruits JAK1 to the IL2Rβ subunit and JAK3 to the γc subunit (see Fig. 2.9). The JAK proteins associate with a cytoplasmic, juxtamembrane portion of the cytokine receptors via a conserved, N-terminal domain structure called the FERM domain (named for its presence in Band 4.1 protein, ezrin, radixin, and moesin).[66] The carboxy half of JAK consists of two homologous regions in tandem, a pseudokinase domain followed by a kinase domain. The former has many of the conserved sequences that define a protein kinase, but it also has mutations of amino acids that are essential for catalytic activity. It is believed that in the non–ligand-bound receptor, the intracellular portions of two monomers are arranged in a way such that each pseudokinase domain binds to and suppresses the catalytic activity of the kinase on the other subunit, and vice versa. Binding of GH to its receptor results in a conformational change in the extracellular domain of the receptor, which induces a motion intracellularly like the opening of scissors, causing sliding of the two subunits of JAK in opposite directions. This relieves the allosteric inhibition of the kinases[67,68] (Fig. 2.10).

The major consequence of releasing the block to GH receptor-associated JAK2 activity is the JAK2-catalyzed transphosphorylation of the contralateral receptor subunit and its associated JAK2.[65] This allows binding of the SH2 and/or PTB domains of a number of signaling molecules, including IRS1/2 and PLCγ, thus recruiting them to the receptor and plasma membrane.[69] However, more important than these to the actions of GH on growth are members of the signal transducers and activators of the transcription (STAT) family (Fig. 2.11). The GH receptor binds a number of STAT family members, but STAT5b is most critical to its growth-promoting actions. There are seven STAT proteins with a shared domain structure. The N-termini are composed of four helical coils that function in binding to other proteins, followed by a DNA-binding domain (DBD).[70] The carboxy half of the proteins consists of a linker region, an SH2 domain, and a transcriptional transactivation domain. Several of the tyrosine residues in the GH receptor that undergo phosphorylation by JAK2 in response to ligand binding serve as docking sites for STAT5b. Once recruited to the receptor, STAT5b is itself phosphorylated, resulting in dimerization, with each STAT5b protein binding via its phosphorylated tyrosine to its partner's SH2 domain. At the same time, STAT5b dissociates from the receptor and translocates into the nucleus where it can regulate gene transcription. In addition to this basic pathway, there are numerous other layers of regulation. Serine/threonine protein kinases such as members of the MAPK and PKC families also phosphorylate STAT proteins; in some cases, this latter phosphorylation is required for maximal



• **Fig. 2.10** Scissor model for activation of the human growth hormone (hGH) receptor. In the basal state, the hGH receptor exists as an inactive dimer in which the two subunits are held together through weak interactions in the transmembrane membrane domain (TMD) and poised in the inactive state through electrostatic repulsion in the extracellular juxtamembrane domain (JMD) and pseudokinase inhibition in the associated JAK2 dimer *(left)*. Binding of hGH to the receptor *(right)* clamps the JMD such that it avoids the electrostatic repulsion and mechanically alters the TMD such that the intracellular domain is splayed outward. Splaying pulls on the JAK2 molecules to align their kinase domains. This triggers a wave of phosphorylation events, including the STAT proteins critical to receptor signaling. (Modified from Wells JA, Kossiakoff AA. New tricks for an old dimer. *Science*. 2014;344:703.)



• **Fig. 2.11** Cytokines activate signal transducers and activators of transcription (STATs). STAT proteins are latent cytoplasmic transcription factors. STATs bind through Src homology 2 (SH2) domains to one or more phosphorylated tyrosines (P) in activated receptor–Janus kinase (JAK) complexes. Once bound, STATs themselves are tyrosyl phosphorylated, presumably by the receptor-associated JAKs. STATs then dissociate from the receptor-JAK complex, homodimerize or heterodimerize with other STAT proteins, move to the nucleus, and bind to gamma-activated sequence-like elements (GLEs) in the promoters of cytokine-responsive genes. *P,* phosphorylation. (Modified from J. Herrington, used with permission.)

transcriptional activation. Using a different mechanism, SH2B1 binds to and enhances JAK2 activity.[69,71] STAT proteins can also heterodimerize with other STAT proteins or other transcription factors. For example, STAT5b has been shown to dimerize with the glucocorticoid receptor, with the latter acting as a coactivator for STAT5b to promote expression of GH-regulated genes (e.g., *IGF1*) implicated in body growth.[72]

Another important hormone that uses the JAK/STAT signaling pathway is leptin. Leptin is secreted by adipocytes; it acts on the arcuate nucleus of the hypothalamus as well as other regions in the brain to suppress appetite and, in rodents, increase metabolic rate. Humans deficient in leptin display massive obesity early in life.[73] Like GH, leptin binds to homodimers of a class I cytokine receptor and activates JAK2.[74] However, in contrast to the GH receptor, the leptin receptor recruits STAT3 as its primary signaling molecule, which binds to phosphotyrosines in a YXXQ motif. The phosphorylated leptin receptor also binds STAT5 and the SH2-containing protein tyrosine phosphatase 2 (SHP2; PTPN11). The latter is thought to act as a positive signaling module by mediating the first step in the activation of the ERK cascade.[75] On the other hand, the tyrosine phosphatase PTP1B dephosphorylates the leptin receptor and inhibits leptin action, and thus its deletion in mouse brain leads to obesity and insulin resistance.[76] JAK2 also phosphorylates IRS proteins, thereby engaging the PI3K pathway. The roles of the different signaling pathways activated downstream of leptin and JAK2 have been investigated using mice in which specific tyrosine residues in the receptor have been mutated. Replacement of tyrosine 1138 by serine completely blocks recruitment of STAT3, generating mice similar in their degree of obesity to those lacking leptin receptors, showing that STAT3 signaling is critical to the regulation of appetite and energy metabolism.[77]

Termination of class I cytokine signaling occurs in response to dephosphorylation of key phosphotyrosines; it is also promoted by the transcriptional induction of the suppressors of cytokine signaling, or SOCS proteins. The eight members of the SOCS family are direct targets of the STAT transcription factors and provide a potent negative feedback signal by binding to phosphorylated tyrosines in the receptors via the SOCS SH2 domain. Upon interacting with the receptors, SOCS proteins inhibit their action by reducing JAK activity, by competing for binding of other signaling molecules, and/or by inducing the degradation of receptor via the ubiquitin pathway due to the conserved SOCS box located at the C-terminus of the protein.[78] Mice deficient for SOCS2 appear normal when young but after weaning grow substantially larger than their wild-type littermates, consistent with enhanced GH signaling.[79] Cytokine signaling via STAT proteins can also be downregulated by members of the protein inhibitor of activated STAT (PIAS) family, which have been shown to regulate transcription through several mechanisms, including blocking the DNA-binding activity of transcription factors, recruiting transcriptional corepressors, and promoting protein sumoylation.

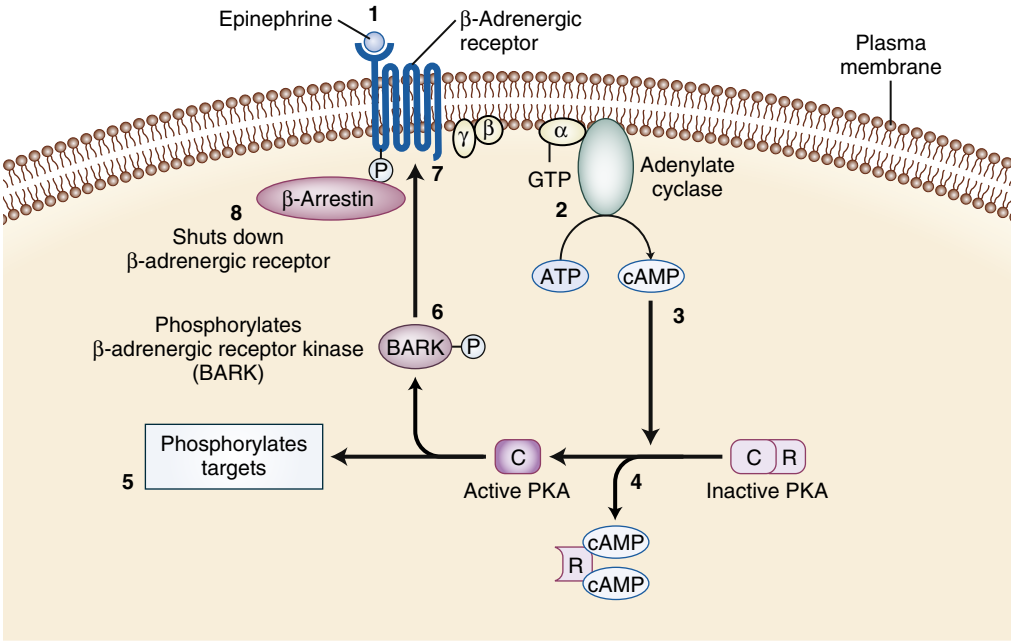
Coupling of Cell Surface Receptors to Intracellular Signaling

Downstream Signaling by Cyclic Adenosine Monophosphate

For the many hormones that bind exclusively to the outer surface of cells to carry out their actions, there must be some means of translating the extracellular signal into an intracellular response. The first example of a transduction system that was understood in some detail derived from investigating one of the key features of the fight-or-flight response, the mobilization of stored carbohydrate in the liver. The physiologic response to stress requires a supply of readily consumable energy, best provided in the form of blood glucose, which is stored as polysaccharide glycogen primarily in the liver. β-Adrenergic stimulation of hepatocytes by epinephrine leads rapidly to the hydrolysis of glycogen and the release of free sugar; glucagon also stimulates the breakdown of hepatic glycogen. The mechanism used to transmit this response is the prototypical example of a second messenger system, in which the agonist that interacts with the outside of the cell, in this case glucagon or epinephrine, is considered a *first messenger,* and a soluble, intracellular signaling molecule generated by hormone-receptor association is called a *second messenger*.[80] For hepatic glycogen breakdown in response to glucagon or β-adrenergic agents, the second messenger is cAMP, which is produced by a plasma membrane enzyme, adenylyl cyclase, from ATP (Fig. 2.12). Adenylyl cyclase is a direct target of $G\alpha_S$, which becomes GTP loaded and active in response to receptor occupancy.

The scope and diversity of hormones and other extracellular signals that activate adenylyl cyclase and increase the level of intracellular cAMP are remarkably extensive. Included in the long list of hormones that signal through this mechanism are β-adrenergic agents, glycoprotein hormones such as TSH, glucagon, adrenocorticotropic hormone (ACTH), hypothalamic hormones, and antidiuretic hormone. Moreover, the range of physiologic and biochemical events modulated by cAMP is equally vast. Thus, although the second messenger cAMP defines a commonly used mechanism for transducing signals from extracellular hormones, it also presents another problem in signaling: How do cells maintain selectivity in the way they respond to a given hormone? Much of this is accomplished by the subcellular compartmentalization of signaling complexes. A-kinase anchoring proteins (AKAPs), which are scaffolds localized to distinct intracellular sites, bind a number of proteins that modulate the actions of cAMP, including degrading enzymes and target kinases.[81] The regulated assembly of higher order structures confers a spatiotemporal resolution to cAMP signaling that can allow multiple biologic responses to exist within the same cell. For example, β-adrenergic agents and prostaglandin E_1 both act on the heart through elevations in cAMP, but each regulates a different cardiac function. This is accomplished through stimulation of distinct populations of cAMP target kinases, such that β-adrenergic agents are more potent than prostaglandins in their effects on the particulate fractions of the heart cell.[82] It is likely that AKAPs confer this specificity to the cardiomyocyte.

cAMP is degraded to AMP and phosphate by a specific PDE, and the balance between synthesis and degradation of cAMP determines the levels of the cyclic nucleotide. Although hormones generally use adenylyl cyclase as the means for modulating cAMP levels within the cell, the PDEs provide an additional site of regulation.[83] The cyclic nucleotide PDEs are a large and complex family of enzymes, whose diversity in both tissue and subcellular localization has made them favorite targets for the development of therapeutics. Caffeine and theophylline were two of the first drugs recognized to be inhibitors of PDE, but more recently, selective inhibitors of PDE5, an enzyme that degrades cyclic guanosine monophosphate (cGMP), have been widely used for the treatment of erectile dysfunction. In addition, PDE inhibitors are either currently being used or are in development for the treatment of a wide variety of diseases, including asthma, neurologic diseases, and pulmonary hypertension.



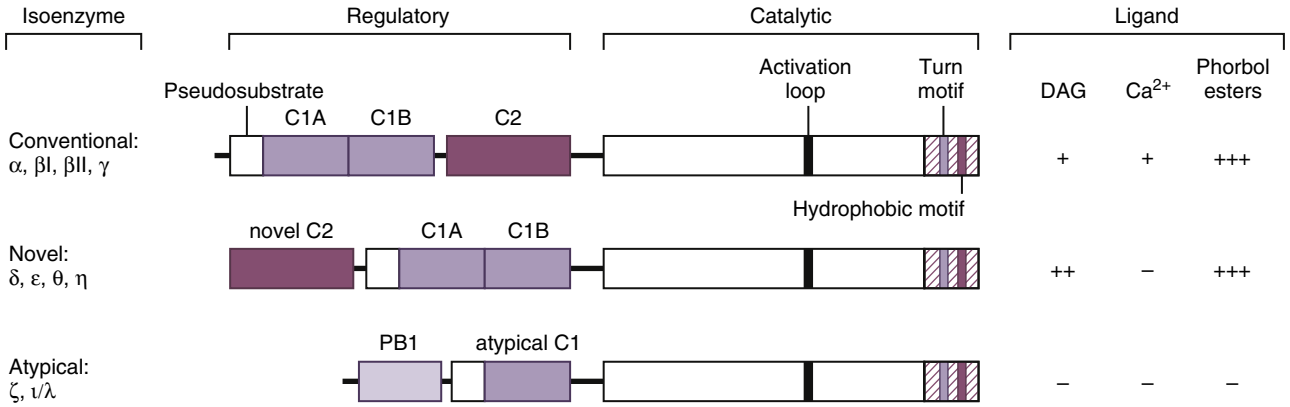
• **Fig. 2.12** Adenylate cyclase, protein kinase A (PKA), and β-adrenergic receptor kinase (BARK) activation by epinephrine. Step 1: Upon binding of epinephrine to the β-adrenergic receptor, G_s is activated. Step 2: $G_s\alpha$ binds to and stimulates adenylate cyclase. Step 3: Adenylate cyclase catalyzes the conversion of ATP to cAMP. Step 4: cAMP binds to the regulatory subunit (R) of PKA, releasing free catalytic subunit (C), which is active. Step 5: C phosphorylates a number of intracellular substrates in a manner determined by its location in the cell. Step 6: C phosphorylates serine and threonine residues on BARK. Step 7: BARK, itself a serine/threonine kinase, phosphorylates serine and threonine residues on the β-adrenergic receptor. Step 8: β-Arrestin binds to the phosphorylated receptor, which blocks further activation of G_s. β-Arrestin also initiates signaling cascades, which are not shown.

Glycogen metabolism in liver and muscle provided the initial example of a common mode of signaling initiated by second messengers—activation of a cascade of intracellular protein kinases. Signal transduction by protein phosphorylation stands as one of the most critical regulatory mechanisms in biology. The state of a phosphoprotein is regulated dynamically, determined by the relative rates of phosphorylation and dephosphorylation by protein kinases and phosphatases, respectively. In most cases, the turnover of the phosphate is rapid, allowing regulation by either the kinase or phosphatase, or in many instances both coordinately. Numerous endocrine signals exert control over intracellular metabolism, growth, and other functions via modulation of protein kinase activity. Originally, protein kinases were found to phosphorylate proteins on serine and threonine residues, but, as described earlier, tyrosine phosphorylation has emerged as another mode of signaling.

One advantage of such series of kinases is signal amplification. Amplification occurs because each individual kinase molecule can modify many downstream target proteins. When these downstream targets are also kinases that become activated upon phosphorylation, each one of them can in turn modify and activate many more proteins. In the case of cAMP-initiated signaling, one receptor:ligand pair creates multiple cAMP molecules. The multiple cAMP molecules activate the serine/threonine kinase protein kinase A (PKA), which in turn phosphorylates multiple downstream effector proteins. In the case of glycogen metabolism, PKA phosphorylates and activates glycogen phosphorylase kinase, which in turn phosphorylates and activates glycogen phosphorylase, which releases glucose-1-P from glycogen. In muscle, phosphorylase kinase is also stimulated by calcium, which is released from the sarcoplasmic reticulum during electrical stimulation and contraction. The mechanism by which cAMP activates PKA illustrates another theme in signal transduction: displacement or dissociation of intramolecular pseudosubstrates or substrates as a means to activate protein kinases, a mechanism also used by such protein kinases as PKC and myosin light chain kinase. cAMP binds to the two regulatory subunits of the heterotetrameric PKA, which causes them to dissociate from two catalytic subunits. A domain in the regulatory subunit resembles a PKA phosphorylation sequence but with the critical serine replaced by an alanine, which lacks the hydroxyl group required for transfer of the phosphate from ATP. When PKA is assembled into a heterotetramer of two regulatory subunits and two catalytic subunits, this pseudosubstrate interacts with the catalytic subunit, preventing it from phosphorylating target proteins.[84]

In addition to enhancing glycogen breakdown, PKA mediates the effects of a number of hormones in various tissues, including the positive inotropic and chronotropic effects of epinephrine on the heart, the trophic effects of the anterior pituitary hormones TSH and ACTH, and the effects of antidiuretic hormone on the permeability of the renal collecting duct to water. PKA also translocates into the nucleus to regulate gene transcription.[85] The best studied nuclear target of PKA is the cAMP-response element–binding protein (CREB), though it is still not clear how many of the physiologic actions of cAMP require this transcription factor to be phosphorylated. PKA also phosphorylates a number of coregulatory proteins, which also contribute to transcriptional outputs.

Importantly, cAMP also has actions that are independent of PKA. One of these is the direct regulation of ion channels;



• **Fig. 2.13** Domain structure and ligands of protein kinase C (PKC). The PKC family can be divided into three classes: the conventional, or classic, PKCs (cPKCs); the novel PKCs (nPKCs); and the atypical PKCs (aPKCs). The C1 domains bind diacylglycerol (DAG) or phorbol ester; the C2 domain binds calcium. A novel C2 domain in nPKCs does not bind calcium but mediates protein-protein interactions. Similarly, a PB1 domain in aPKCs is involved in protein-protein interactions. The aPKCs possess only one C1 domain and thus do not bind diacylglycerol. The conserved pseudosubstrate motif is represented by the *white boxes* in the regulatory domain. The activation loop and the turn and hydrophobic motifs are sites of regulatory phosphorylation.

another involves the exchange protein activated by cAMP (EPAC), which functions as a guanine nucleotide exchange factor (GEF) for the small GTP-binding protein Rap1.[86] Regulation of insulin secretion from pancreatic beta cells by glucagon-like peptide-1 (GLP1) and stabilization of the endothelial barrier by β-adrenergic agents are two processes thought to be mediated by EPAC.

Regulation by the Second Messengers Calcium and PKC

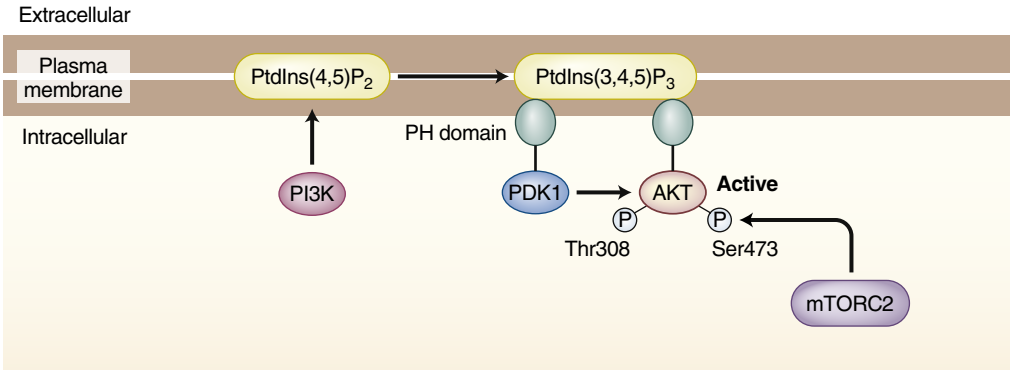
Many additional second messengers have been identified since the discovery of cAMP. These include calcium, cGMP, inositol polyphosphates, DAG, and nitric oxide. The calcium ion (Ca^{2+}) is one of the most common second messengers utilized by diverse cell types, and one that plays a particularly important role in the regulated secretion of hormones.[87] Ca^{2+} is maintained at low micromolar concentrations in the cytoplasm such that opening channels that lead to the outside of the cell or intracellular storage organelles results in a rapid increase in cytosolic Ca^{2+}. The heterotrimeric G proteins containing $G\alpha_q$ or $G\alpha_{11}$ cause increases in intracellular calcium by targeting the membrane-associated enzyme PLC. PLC catalyzes the hydrolysis of phosphatidylinositol 4',5'-bisphosphate into DAG and IP_3. Hormones that signal through G protein–dependent activation of PLC include angiotensin II, α-adrenergic catecholamines, growth hormone–releasing hormone (GHRH), and vasopressin. IP_3 binds to a receptor located on the cytoplasmic face of the endoplasmic reticulum, leading to the release of stored Ca^{2+} from that organelle. Ca^{2+} also interacts with the IP_3 receptor, further stimulating calcium discharge from the endoplasmic reticulum and providing a strong positive feedback loop. Another source of cytoplasmic Ca^{2+} is entry through receptor-operated channels in the plasma membrane, such as those activated by noradrenaline, endothelin, or histamine via heterotrimeric G proteins.

Ca^{2+} transmits its signal via a number of effectors, including protein kinases, in most cases through the intermediary binding protein, calmodulin, or its relative, troponin C. Calmodulin is a small, acidic protein that contains four copies of a canonical calcium-binding motif.[88] Calmodulin associates with and regulates in a Ca^{2+}-dependent manner glycogen phosphorylase kinase, myosin light chain kinase, and members of the family of calcium/calmodulin-dependent kinases. In addition to protein kinases, other calcium/calmodulin-dependent enzymes include the serine/threonine protein phosphatase, calcineurin, some adenylate cyclase and PDE isoforms, and nitric oxide synthase. Calcium interacts directly and independently of calmodulin with targets such as the protease calpain, synaptotagmin (a regulator of neurotransmitter and hormone exocytosis), and cytoskeletal proteins.

An important group of protein kinases directly activated by calcium is the PKC family. PKC, originally identified as the target of the tumor promoter phorbol ester, is a cyclic nucleotide-independent protein kinase regulated by the direct binding of DAG and calcium, two second messengers produced by the activation of PLC. The PKC family has been divided into three groups: classic (regulated by DAG, phosphatidylserine, and calcium), novel (regulated by DAG and phosphatidylserine), and atypical. All PKC proteins have a conserved kinase domain in their C-terminal portion and regulatory sequences in their N-terminal domain. For classic PKCs, the latter consist of a C1 domain, which binds DAG or phorbol ester, followed by a C2 domain, which associates with anionic lipids in a Ca^{2+}-dependent manner[89] (Fig. 2.13). Novel isoforms have a modified form of the C1 domain that confers a higher affinity for DAG than in the classic isoforms but lack the C2 domain, explaining the absence of Ca^{2+} regulation. Atypical PKCs have alterations in the C1 domain that eliminate DAG binding and also lack a site for Ca^{2+} binding. The regulation of PKC isoforms is complex, involving such covalent modifications as phosphorylation and proteolysis, as well as interaction with lipids and hydrophilic molecules other than those traditionally associated with activation of classic PKCs.[90]

Regulation of Protein Kinases by PI3K

Another important signaling pathway involves a family of related proteins that catalyzes phosphorylation of phosphoinositides on



• **Fig. 2.14** Mechanism of AKT activation. When phosphatidylinositol-3,4,5-trisphosphate (PtdIns(3,4,5)P_3) levels are low in the plasma membrane, AKT is in an inactive conformation in the cytoplasm and cannot be phosphorylated by the upstream activating 3-phosphoinositide-dependent protein kinase 1 (PDK1) (not shown). PtdIns(3,4,5)P_3 levels increase in the plasma membrane following the insulin-dependent recruitment to IRS1 and IRS2 of phosphoinositide 3-kinase (PI3K), which phosphorylates phosphatidylinositol-4,5-bisphosphate (PtdIns(4,5)P_2). AKT binds PIP_3 through its pleckstrin homology (PH) domain and induces a conformational change within the AKT kinase domain, allowing PDK1 to phosphorylate the critical residue in the activation loop required for AKT kinase activity, threonine 308 (Thr308). Mammalian target of rapamycin complex 2 (mTORC2) also phosphorylates AKT at the carboxy-terminal serine 473 (Ser473) site to fully activate its kinase activity. PDK1 has a PH domain that can bind PtdIns(3,4,5)P_3, but this interaction is not essential for PDK1 catalytic activity. (Redrawn from Finlay D, Cantrell DA. Metabolism, migration and memory in cytotoxic T cells. *Nat Rev Immunol.* 2011;11:109.)

the 3′ position of the inositol ring.[91] All class I PI3Ks are comprised of a catalytic protein associated with a regulatory subunit and use PI4,5P_2 as a preferred substrate; these isoforms are most important to signaling by RTK, GPCRs, and tyrosine kinase oncogenes. Class II PI3Ks phosphorylate PI and PI4P in vivo and lack stable regulatory subunits but probably associate with other proteins as modulating factors. They have been implicated in a diverse set of physiologic responses, but the downstream targets are largely unknown. Class III PI3K, which has one catalytic member also known as vacuolar protein sorting 34 (Vps34), binds tightly to the regulatory protein Vps15, uses exclusively PI as a substrate, and is involved primarily in membrane protein trafficking related to endocytosis, phagocytosis, and autophagy.

Class IA PI3Ks are defined by regulatory subunits containing SH2 domains, which target them to activated RTKs. The heterotrimeric G protein subunit pair Gβγ, when free, activates those class I PI3Ks containing regulatory subunits not bearing SH2 domains.

Class IA PI3Ks are thought to be the most important PI3Ks for the actions of hormones, particularly insulin and IGF1.[92] Activation of the receptors for either hormone leads to phosphorylation of IRS1 or IRS2 at sites specialized for docking with SH2 domains in the p85 regulatory subunit associated with the p110α catalytic subunit of PI3K. The bound PI3K catalyzes the production of PIP_3 and possibly PI3,4P_2, which serve to recruit additional proteins (including protein kinases) to the membrane by binding their PH domains.[93] PH domains are best known for their ability to bind phosphoinositides with high affinity and specificity, although only a small portion have been proven to do so. The serine/threonine protein kinase Akt, also named *protein kinase B* because of its structural similarities to PKA and PKC, contains an N-terminal PH domain that preferentially binds to PIP_3 and PI3,4P_2.[94] When insulin acts upon a target cell, the PH domain of Akt associates with the PIP_3 generated on the cytoplasmic face of the plasma membrane. The binding of the PH domain to PIP_3 serves two purposes: to recruit Akt to the membrane and to relieve steric hindrance of Akt's phosphorylation sites and catalytic domain by the PH domain. Also at the plasma membrane via its own PH domain is the enzyme 3-phosphoinositide-dependent protein kinase (PDK1), which phosphorylates Akt on a threonine in its activation loop (Fig. 2.14). mTORC2 also phosphorylates Akt on a serine in its C-terminus. Together, the PDK1 and mTORC2 phosphorylation events confer full activity to Akt. mTORC2 appears to be regulated by insulin, but the mechanism is unknown.

Akt is essential to many of the metabolic actions of insulin and growth effects of IGF1.[95,96] There are three Akt isoforms, each encoded by separate genes. Akt1 is the most widely expressed isoform and seems to be critical to the regulation of growth; Akt2 is enriched in insulin target tissues and is more important to the control of metabolism; and Akt3 is expressed primarily in the brain, where it controls growth of that tissue.[97] Indirect activation of mTORC1 by Akt and suppression of forkhead box (FOX)O–driven transcription are two of the critical targets for promoting organ growth, the Akt/mTORC1 pathway being particularly engaged in the regulation of cell size.[98] Members of the Rab GTPase-activating protein family, TBCD4 (also known as AS160) in fat cells and TBC1D1 in both muscle and fat, are phosphorylated and inhibited by Akt, contributing to the activation of glucose transport.[99]

Regulation of Protein Kinases by Ras

Routes to activation of Ras by GRB-SOS include both RTKs and GPCRs acting through β-arrestin.[100] GTP-bound Ras recruits several receptors to the plasma membrane, including the serine/threonine kinase Raf, which is activated by dimerization and a series of phosphorylation/dephosphorylation events.[101] Raf then phosphorylates MAPK/ERK kinase (MEK1), a tyrosine and serine/threonine–dual specificity protein kinase, initiating a protein kinase cascade centered on extracellular signal-regulated kinases 1 and 2 (ERK1/2). This represents one of four MAPK cascades,

the others involving c-Jun N-terminal kinase (JNK), the 38-kDa stress-activated kinases (p38), and ERK5. Specificity for MAPKs is conferred by scaffold proteins that bind most or all members of a given pathway, ensuring that each member phosphorylates only its appropriate target kinase.[102] Gonadotropin-releasing hormone, PTH, GH, angiotensin, and gastrin are just a few of the many hormones believed to signal at least in part through regulation of MAPKs.

Disease Caused by Defective Cell Surface Receptors

Numerous diseases develop as a result of dysfunctional binding to or signaling by hormone receptors. These *hormone resistance syndromes* invariably mimic the phenotype of the hormone-deficient state but present with high levels of biologically active hormones in the circulation.

Insulin Resistance Syndromes

The best studied inherited disease of hormone resistance is that caused by mutations in the insulin receptor. In addition to hyperinsulinism and the expected abnormalities in metabolism, patients with severe insulin resistance also display acanthosis nigricans (hyperpigmentation primarily in the skin folds) and often hyperandrogenism.[103] Beyond that, there is a range of syndromes that correlate with the degree of insulin signaling impairment. The strongest loss-of-function mutations result in leprechaunism, in which there are severe developmental defects presenting at birth. Some mutations of the insulin receptor gene cause a decrease in the number of receptors in the plasma membrane, in some cases accompanied by a decrease in the mRNA. Other mutations adversely affect hormone binding or the function of the kinase domain.[103] In contrast to insulin resistance caused by mutations in the receptor gene, sometimes referred to as type A insulin resistance, type B resistance presents at middle age, often with signs of autoimmunity such as vitiligo, alopecia, and arthritis. This syndrome is defined by the presence of antibodies directed against the insulin receptor; the levels of antibody correlate with the severity of the disease.

In many ways, the use of insulin resistance to describe the common syndrome associated with obesity or polycystic ovary syndrome (PCOS) is a misnomer. The term *resistance* was originally coined to describe the situation of hyperglycemia in the face of elevated concentrations of insulin in the blood.[105,106] However, the recognition that insulin has numerous physiologic actions in addition to those on carbohydrate metabolism has led to ambiguity in nomenclature. On the one hand, the term *insulin resistance* is often applied to abnormalities in insulin signaling to all outputs from the receptor; this typically occurs with mutations of the insulin receptor. However, in the insulin resistance of obesity or PCOS, some actions of insulin are preserved. This is demonstrated by a comparison of the phenotype of individuals with type 2 diabetes mellitus to those with genetically encoded partial defects in insulin receptor function.[107] Both groups share hyperglycemia, but only those with type A insulin resistance display defects in the regulation of hepatic lipid metabolism by insulin. Thus the metabolic phenotype associated with type A inherited insulin resistance is not faithfully phenocopied by the insulin resistance of obesity. Consistent with this, numerous pathologic mechanisms have been proposed to account for the insulin resistance associated with obesity, almost all of which involve a "post-receptor defect."

Defects in Cell Surface Receptors That Control Growth

One of the most clinically recognizable syndromes is resistance to the actions of GH, which results in shortness of stature. An inability to respond to GH results in Laron syndrome, characterized by high levels of circulating GH, very low levels of IGF1, and short stature.[108] Diverse molecular causes have been reported, including large deletions as well as missense, frameshift, and splicing mutations in the GH receptor. Similar syndromes of decreased growth can also result from mutations in STAT5b and deficiency in IGF-1 or defects in IGF-1 signaling. Recently, a syndrome has been described in which mutations in the *PIK3R1* gene, which encodes the p85α regulatory subunit of class I PI3K, lead to SHORT syndrome, which includes dysmorphic facial features and defects in growth (short stature, hyperextensibility, ocular depression, Rieger anomaly, and teething delay).[109] As might be expected by the similarities in IGF-1 and insulin signaling, individuals with SHORT syndrome also display lipodystrophy and insulin resistance.[110]

Diseases Caused by Mutations in GPCRs and G Proteins

A number of endocrine diseases can be attributed to mutations in the GPCR–G protein signaling system.[111,112] For GPCRs, many mutations are associated with some degree of loss of function and are inherited in a recessive manner (Table 2.3). Some examples include hypothyroidism from mutations in the thyrotropin-releasing hormone or TSH receptor, glucocorticoid deficiency from mutations in the melanocortin 2 receptor, extreme obesity from dysfunction of melanocortin 4 receptor, and infertility due to mutations in the receptor for luteinizing hormone or FSH. Gain-of-function mutations include those in the TSH receptor causing hyperthyroidism, in the α_2-adrenergic receptor, leading to diabetes mellitus, and in the calcium-sensing receptor resulting in hypoparathyroidism. Somatic activating mutations have been reported in the luteinizing hormone and TSH receptors.[111] A limited number of heterotrimeric G proteins are known to have mutations that cause human disease, and in all cases they affect the α-subunit. Mutation of the gene encoding the $G\alpha_t$ subunit of transducin is associated with night blindness. Dominant, activating mutations of $G\alpha_s$ cause pituitary adenomas, most often secreting GH, and more rarely, tumors of the thyroid, parathyroid, and adrenal glands.[112] Patients who inherit a loss of a functional allele in $G\alpha_s$ develop Albright hereditary osteodystrophy (AHO); those who inherit the mutant allele from their mothers also have pseudohypoparathyroidism type 1a in addition to AHO. This is due to imprinting of the $G\alpha_s$ gene, such that it is expressed preferentially from the maternal allele in a number of hormone target tissues, but biallelically in most other cell types.

Ligands That Act Through Nuclear Receptors

Many signaling molecules share with thyroid and steroid hormones the ability to function in the nucleus to convey intercellular and environmental signals. Lipophilic signaling molecules that use nuclear receptors include derivatives of vitamins A and D, endogenous metabolites such as oxysterols and bile acids, and

TABLE 2.3 Diseases Caused by G Protein–Coupled Receptor Loss-of-Function Mutations

Receptor	Disease	Inheritance
V_2 vasopressin	Nephrogenic diabetes insipidus	X-linked
ACTH	Familial ACTH resistance	AR

TABLE 2.4 Nuclear Receptor Ligands and Their Receptors

Ligand	Receptor
Classic Hormones	
Thyroid hormone	Thyroid hormone receptor (TR), subtypes α, β
Estrogen	Estrogen receptor (ER), subtypes α, β
Testosterone	Androgen receptor (AR)
Progesterone	Progesterone receptor (PR)
Aldosterone	Mineralocorticoid receptor (MR)
Cortisol	Glucocorticoid receptor (GR)
Vitamins	
$1,25\text{-}(OH)_2$-vitamin D_3	Vitamin D receptor (VDR)
All-*trans*-retinoic acid	Retinoic acid receptor, subtypes α, β, γ
9-*cis*-retinoic acid	Retinoid X receptor (RXR), subtypes α, β, γ
Metabolic Intermediates and Products	
Fatty acids	Peroxisome proliferator-activated receptor (PPAR), subtypes α, δ, γ
Oxysterols	Liver X receptor (LXR), subtypes α, β
Bile acids	Bile acid receptor (BAR, also called FXR)
Heme	Rev-Erb subtypes α, β
Phospholipids	Liver receptor homologue-1 (LRH1) Steroidogenic factor-1 (SF1)
Xenobiotics	Pregnane X receptor (PXR) Constitutive androstane receptor (CAR)

chemicals not naturally encountered in the environment (i.e., xenobiotics). These molecules are referred to as *nuclear receptor ligands*. The nuclear receptors for all of these signaling molecules are structurally related and are collectively referred to as the *nuclear receptor superfamily.* They are all transcription factors, serving to activate or repress specific gene sets that mediate their physiologic effects. The study of these receptors is a rapidly evolving field, and more detailed information can be obtained by visiting the Nuclear Receptor Signaling Atlas website.[113,114]

General Features of Nuclear Receptor Ligands

Unlike polypeptide hormones that function through cell surface receptors, no ligands for nuclear receptors are directly encoded in the genome. All nuclear receptor ligands are small (molecular mass <1000 Da) and lipophilic, enabling them to enter cells by passive diffusion, although in some cases a membrane transport protein is involved. For example, several active and specific thyroid hormone transporters have been identified, including monocarboxylate transporter 8 (MCT8), MCT10, and organic anion transporting polypeptide 1C1 (OATP1C1).[115]

All naturally occurring nuclear receptor ligands are derived from dietary, environmental, or metabolic precursors. In this sense, the function of these ligands and their receptors is to translate cues from the external and internal environments into changes in gene expression. Their critical role in maintaining homeostasis in multicellular organisms is highlighted by the fact that nuclear receptors are found in all vertebrates and insects but not in single-cell organisms such as yeast.[116]

Because nuclear receptor ligands are lipophilic, most are readily absorbed from the gastrointestinal tract. This makes nuclear receptors excellent targets for pharmaceutical interventions. In addition to natural ligands, many drugs in clinical use target nuclear receptors, ranging from drugs used to treat specific hormone deficiencies to those used to treat common multigenic conditions such as inflammation, cancer, and type 2 diabetes.

Subclasses of Nuclear Receptor Ligands

One classification of nuclear receptor ligands is outlined in Table 2.4 and is described in the following paragraphs.

Classic Hormones

The classic hormones that use nuclear receptors for signaling are thyroid hormone and steroids. Endogenous steroid hormones include cortisol, aldosterone, estradiol, progesterone, and testosterone. In some cases (e.g., thyroid hormone receptor α and β genes [*THRA* and *THRB*], estrogen receptor α and β genes [*ESR1* and *ESR2*]), more than one gene exists for a given type of hormone receptor. Each receptor gene may in turn encode additional receptors for the same hormone by alternative promoter usage or by alternative splicing (e.g., *THRB1* and *THRB2*).

Some receptors mediate the signals of multiple hormones. For example, the mineralocorticoid receptor, also known as the

aldosterone receptor, has equal affinity for aldosterone and cortisol and probably functions as a glucocorticoid receptor in some tissues, such as the brain.[117] Likewise, the androgen receptor binds and responds to both testosterone and dihydrotestosterone (DHT).[118]

Vitamins

Vitamins are essential constituents of a healthful diet. Two fat-soluble vitamins, A and D, are precursors of important signaling molecules that function as ligands for nuclear receptors.

Precursors of vitamin D are synthesized and stored in skin and activated by ultraviolet light; vitamin D can also be derived from dietary sources. Vitamin D is then converted in the liver to 25(OH)D (25-hydroxyvitamin D, calcidiol), which is subsequently converted by the kidney to $1,25(OH)_2D_3$ (1,25-dihydroxyvitamin D_3, calcitriol), the most potent natural ligand of the vitamin D receptor (VDR).[119] The 1-hydroxylation of calcidiol is tightly regulated, and calcitriol acts as a circulating hormone, arising in the kidney and circulating through the bloodstream to act on target tissues such as intestine and bone.

Vitamin A is stored in the liver and is activated by metabolism to all-*trans*-retinoic acid, which is a high-affinity ligand for retinoic acid receptors (RARs).[120] Retinoic acid functions as a signaling molecule in both a paracrine and an endocrine manner. Retinoic acid is also converted to its 9-*cis*-isomer, which is a ligand for another nuclear receptor, the retinoid X receptor (RXR).[121] These retinoids and their receptors are essential for normal development of multiple organs and tissues, and they have pharmaceutical utility for conditions ranging from skin diseases to leukemia.[122]

Metabolic Intermediates and Products

Certain nuclear receptors respond to naturally occurring endogenous metabolic products. The peroxisome proliferator-activated receptors (PPARs) constitute the best-defined subfamily of metabolite-sensing nuclear receptors.[123] All three PPAR subtypes are activated by polyunsaturated fatty acids, and although specific lipid species may act as selective PPAR ligands, the PPARs may also function as integrators of the concentration of a number of fatty acids.[124]

The natural ligand for PPARα has not been clearly identified, but may be a fatty acid derived from lipolysis.[125,126] The fibrate class of lipid-lowering pharmaceuticals are potent ligands for PPARα, and the very name of this receptor is derived from its ability to induce the proliferation of peroxisomes in the liver, organelles that break down very long-chain fatty acids through β-oxidation.[127] Indeed, stimulation of fatty acid oxidation is an important physiologic role of PPARα.

The other PPARs (δ and γ) are structurally related to PPARα but do not induce proliferation of peroxisomes when activated by their respective ligands. PPARδ, also known as PPARβ, is ubiquitous, and its ligands—other than fatty acids—are not well characterized. Activation of PPARδ increases oxidative metabolism in fat and skeletal muscle.[128] PPARγ is expressed primarily in adipocytes and is necessary for differentiation along the adipocyte lineage.[129] PPARγ is also expressed in other cell types, including colonic epithelial cells, macrophages, and vascular endothelial cells, where it may play physiologic and pathologic roles. The natural ligand for PPARγ is not known, but PPARγ is a major tissue target of thiazolidinedione (TZD) antidiabetic drugs that improve insulin sensitivity.[130,131] These pharmaceutical agents bind to PPARγ with nanomolar affinities. Non-TZD PPARγ ligands are also insulin sensitizers, further implicating PPARγ in this physiologic role.

Another metabolite-responsive nuclear receptor, the liver X receptor (LXR), is activated by oxysterol intermediates in cholesterol biosynthesis. Mice lacking LXRα have a dramatically impaired ability to metabolize cholesterol.[132] A related receptor known as farnesyl X receptor (FXR) binds and is activated by bile acids, and it plays a role in the regulation of bile synthesis and circulation in normal conditions and in disease states.[132]

Endobiotics and Xenobiotics

Other nuclear receptors appear to function as integrators of exogenous environmental signals, including natural endobiotics (medicinal agents and toxins found in plants) and xenobiotics (compounds that are not naturally occurring). In these cases, the role of the activated nuclear receptor is to induce cytochrome P450 enzymes that facilitate detoxification of potentially dangerous compounds in the liver. Receptors in this class include sterol and xenobiotic receptor (SXR), also known as *pregnane X receptor* (PXR), and constitutive androstane receptor (CAR).[133] Unlike other nuclear receptors that have high affinity for specific ligands, xenobiotic receptors have low affinity for a large number of ligands, reflecting their function in defense against a varied and challenging environment. Although these xenobiotic compounds are not hormones in the classic sense, the function of these nuclear receptors is consistent with the general theme of helping the organism to cope with environmental challenges.

Orphan Receptors

The nuclear receptor superfamily is one of the largest families of transcription factors, with 48 members in humans. The hormones and vitamins just described account for the functions of only a fraction of the nuclear receptors. The remaining receptors have been designated as *orphan receptors* because their putative ligands are not known.[134]

From analyses of mice and humans with mutations in various orphan receptors, it is clear that many of them are required for life or for the development of specific organs, ranging from brain nuclei to endocrine glands. Some orphan receptors appear to be active in the absence of any ligand (i.e., constitutively active) and may not respond to a natural ligand. Nevertheless, all of the receptors known to respond to metabolites and environmental compounds were originally discovered as orphans. Therefore future research will likely find that additional orphan receptors function as receptors for physiologic, pharmacologic, or environmental ligands. For example, the nuclear receptor NR1D1 (also known as Rev-Erbα), which is a regulator of circadian rhythms,[17] has been shown to be a receptor for heme,[135,136] although the physiologic significance of this remains to be determined.

Variant Receptors

The C-terminal domain of the nuclear receptors is responsible for hormone binding. In a few nuclear receptors, including THRA and the glucocorticoid receptor, alternative splicing produces variant receptors with unique C-termini that do not bind ligands.[137,138] These variant receptors are normally expressed, but their biologic relevance is uncertain. They may modulate the action of the classic receptor to which they are related by inhibiting its function.

Other normally occurring variant nuclear receptors lack a classic DBD (discussed later). These types include NR0B1 (also known as DAX1), which is mutated in human disease,[139] and PTPN6 (also known as SHP1).[140] Their ligands have not been identified, and it is likely that NR0B1 and PTPN6 bind to and repress the actions of other receptors.

TABLE 2.5 Mechanisms Regulating Ligand Levels

Precursor availability
Synthesis
Secretion
Activation (prohormone → active hormone)
Transport
Deactivation (active hormone → inactive hormone)
Elimination (hepatic, renal clearance)

Rare, naturally occurring mutations of hormone receptors can cause hormone resistance in affected patients. Inheritance of the hormone resistance phenotype is dominant if the mutant receptor inhibits the action of the normal receptor, as occurs with resistance to thyroid hormone or PPARγ ligands.[141] Inheritance is recessive if the mutation results in a complete loss of receptor function, as with the syndrome of hereditary calcitriol-resistant rickets, which is caused by mutations in the VDR.[142] Inheritance can also be X-linked, as with the mutated androgen receptor in androgen insensitivity syndromes.[143]

Regulation of Ligand Levels

Ligand levels can be regulated in several ways (Table 2.5). A dietary precursor may not be available in required amounts (e.g., hypothyroidism due to iodine deficiency). Pituitary hormones (e.g., TSH) regulate the synthesis and secretion of classic thyroid and steroid hormones. If the glands that synthesize these hormones fail, hormone deficiency can occur.

Many nuclear receptor ligands are enzymatically converted from inactive prohormones to biologically active hormones; examples include the 5′ deiodination of thyroxine (T_4) to triiodothyronine (T_3) (see Chapter 11). This can occur in the target cell itself or within other tissues that subsequently release T_3 to the circulation for action elsewhere in the body. In other cases, one hormone is a precursor for another, as illustrated by the aromatization of testosterone to estradiol. Biotransformation may occur in a specific tissue that is not the main target of the hormone, as with renal 1-hydroxylation of vitamin D (see Chapter 29), or it may occur primarily in target tissues (e.g., 5α-reduction of testosterone to DHT; see Chapter 19). Deficiency or pharmacologic inhibition of the enzymes responsible for these reactions can reduce hormone levels.

Transport into the target cell can also be a regulated process. T_3 and T_4, for example, do not penetrate the hydrophobic membrane by themselves; they require a transporter such as MCT8 or OATP1. Mutations in MCT8, for example, lead to neurologic issues, including severe intellectual disability and movement disorders with elevated serum T_3.[144] In this condition, it seems likely that the pathology is secondary to the inability of T_3 to enter neurons. Steroid hormones, by contrast, are believed to traverse the membrane by passive diffusion, although it remains possible that undiscovered binding proteins play a role.

Nuclear receptor ligands can be inactivated by hepatic or renal clearance or by more specific enzymatic processes. Mutations in genes encoding inactivating enzymes, or pharmacologic agents that inhibit these enzymes, can result in symptoms of hormone excess such as renal deactivation of cortisol by 11β-hydroxysteroid dehydrogenase (11βHSD). Because cortisol can activate the mineralocorticoid receptor, insufficient 11βHSD activity due to licorice ingestion, gene mutation, or extremely high cortisol levels causes syndromes of apparent mineralocorticoid excess.[145]

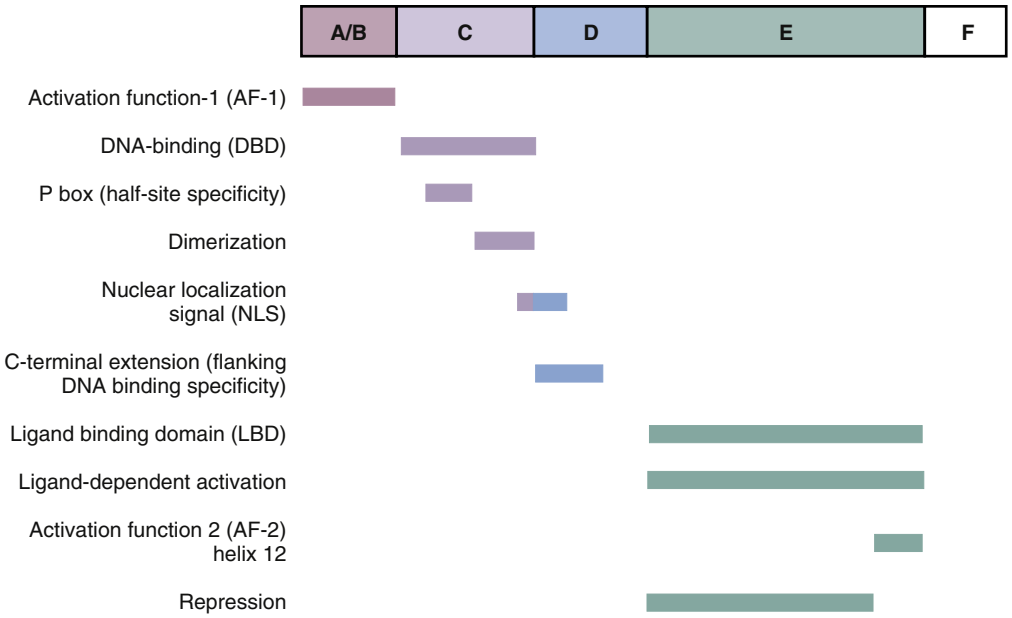
Nuclear Receptor Signaling Mechanisms

Nuclear receptors are multifunctional proteins that transduce the signals of their cognate ligands. General features of nuclear receptor signaling are illustrated in Fig. 2.15.

For hormone action, the ligand and the nuclear receptor must both get into the nucleus. The nuclear receptor also must bind its ligand with high affinity. Because a major function of the receptor is to selectively regulate target gene transcription, it must recognize and bind to promoter and enhancer elements in appropriate target genes. One discriminatory mechanism is dimerization of a receptor with a second copy of itself or with another nuclear receptor. The DNA-bound receptor must work in the context of chromatin to signal the basal transcription machinery to increase or decrease transcription of the target gene. In the regulation of signaling by nuclear receptors, some basic mechanisms are used by many or all members of the nuclear receptor superfamily, whereas other mechanisms impart the specificity that is crucial to the vastly different biologic effects of the many hormones and ligands that use these related receptors.

Domain Structure of Nuclear Receptors

Nuclear receptors are proteins with molecular masses between 50,000 and 100,000 Da. They share a common series of domains, referred to as domains A through F (Fig. 2.16). This linear depiction is useful for describing and comparing receptors, but it does not capture the roles of protein folding and tertiary structure in mediating various receptor functions. The structures of individual domains have now been solved for many receptors, as has the full-length structure of a more limited number of nuclear receptors.



• **Fig. 2.16** Domain structures of nuclear receptors.

Nuclear Localization

The nuclear receptors, like all cellular proteins, are synthesized on ribosomes that reside outside the nucleus. Import of the nuclear receptors into the nucleus requires the nuclear localization signal (NLS), which is located near the border of the C and D domains (see Fig. 2.16). As a result of their NLSs, most of the nuclear receptors reside in the nucleus, with or without their ligands. A major exception is the glucocorticoid receptor; in the absence of hormone, it is tethered in the cytoplasm to a complex of chaperone molecules, including heat shock proteins (HSPs). Hormone binding to the glucocorticoid receptor induces a conformational change that results in dissociation of the chaperone complex, allowing the hormone-activated glucocorticoid receptor to translocate to the nucleus by means of its NLS.

Hormone Binding

High-affinity binding of a lipophilic ligand is mediated by the C-terminal ligand-binding domain (LBD), domains D and E in Fig. 2.16. This region of the receptor has many other functions, including induction of dimerization and transcriptional regulation (see later discussions).

The structure of the LBD has been solved for a number of receptors. All share a similar overall structure consisting of 12 α-helical segments in a highly folded tertiary structure (Fig. 2.17A). The ligand binds within a hydrophobic pocket composed of amino acids in helices 3, 4, and 5 (H3, H4, and H5, respectively). The major structural change induced by ligand binding is an internal folding of the most C-terminal helix (H12), which forms a cap on the ligand-binding pocket (see Fig. 2.17B). Although the overall mechanism of ligand binding is similar for all receptors, the molecular details are essential for determining ligand specificity.[146,147] Ligand binding is the most critical determinant of receptor specificity.

Target Gene Recognition by Receptors

Another crucial specificity factor for nuclear receptors is their ability to recognize and bind to the subset of genes that is to be regulated by their cognate ligand. Target genes contain specific DNA sequences that are called *hormone response elements* (HREs). Binding to the HRE is mediated by the central C domain of the nuclear receptors (see Fig. 2.16). This region is typically composed of 66 to 68 amino acids, including two subdomains that are called *zinc fingers* because the structure of each subdomain is maintained by four cysteine residues coordinated with a zinc atom.

The first of these zinc-ordered modules contains basic amino acids that contact DNA; as with the LBD, the overall structure of the DBD is similar for all members of the nuclear receptor superfamily. The specificity of DNA binding is determined by multiple factors (Table 2.6). All steroid hormone receptors, except for the estrogen receptor, bind to the double-stranded DNA sequence AGAACA (Fig. 2.18).

By convention, the double-stranded sequence is described by the sequence of one of its complementary strands, with the bases ordered from the 5′ to the 3′ end. Other nuclear receptors recognize the sequence AGGTCA. The primary determinant of this specificity is a group of amino acid residues in the *P box* of the DBD (see Fig. 2.18). These hexamer DNA sequences are referred to as *half-sites*. The only difference between these hexameric half-sites is the central two base pairs (underlined in Fig. 2.18). For some nuclear receptors, the C-terminal extension of the DBD contributes specificity for extended half-sites containing additional, highly specific DNA sequences 5′ to the hexamer. Another source of specificity for target genes is the spacing and orientation of these half-sites, which in most cases are bound by receptor dimers.

Receptor Dimerization

The nuclear receptor DBD has affinity for the hexameric half-site or for extended half-sites; however, many HREs are composed of repeats of the half-site sequence, and most nuclear receptors bind these HREs as dimers.[148] Steroid receptors, including estrogen receptors, function primarily as homodimers, which preferentially bind to two half-sites oriented toward each other (i.e., inverted repeats [IRs]) with three base pairs in between (IR3) (see Fig. 2.18A). The major dimerization domain in steroid receptors is within the C domain, although the LBD contributes. Ligand

binding facilitates dimerization and DNA binding of steroid hormone receptors. Most other receptors, including THR, RAR, PPAR, LXR, and VDR, bind to DNA as heterodimers with RXR (see Fig. 2.18B).

Heterodimerization with RXR is mediated by two distinct interactions, one involving LBDs and the other involving DBDs. The receptor LBD mediates the strongest interaction, which occurs even in the absence of DNA. These receptor heterodimers bind to two half-sites arranged as direct repeats (DRs) with a variable number of base pairs in between.

The spacing of the half-sites is a major determinant of target gene specificity; it results from the second receptor-receptor interaction, which involves the DBDs and is highly sensitive to the spacing of the half-sites. For example, VDR/RXR heterodimers bind preferentially to DRs separated by three bases (DR3 sites), TR/RXR binds DR4, and RAR/RXR binds DR5 with highest affinity.[149]

Studies of isolated DBD binding to DNA have shown that these spacing requirements are related to the fact that the RXR binds to the upstream half-site (i.e., farthest from the start of transcription). As a result of the periodicity of the DNA helix, each base pair separating the half-sites leads to a rotation of about 36 degrees of one half-site relative to the other. Subtle differences in the structure of the receptor DBDs make the interactions more or less favorable at different degrees of rotation.[150] Solution of the crystal structures of full-length nuclear receptor heterodimers bound to DNA has demonstrated remarkable diversity in the precise relationship between heterodimeric partners. For example, the PPARγ-RXR heterodimer forms a nonsymmetric complex, allowing the LBD of PPARγ to cooperate with both DBDs to enhance response element binding,[151] whereas the LXR-RXR heterodimer binds symmetrically to its target sequence.[152] Additional structures will be required to better understand the spectrum of RXR heterodimer binding to DNA.

The discovery of nuclear receptor binding sites has been largely empiric, based on the finding of binding sites in small numbers of known target genes. Unbiased analysis of thousands of

nuclear receptor binding locations in living cells using chromatin immunoprecipitation followed by next generation sequencing has confirmed the canonical binding sequences for many nuclear receptors, including those of the estrogen receptor,[153] the androgen receptor,[154,155] the glucocorticoid receptor,[156] and PPARγ-RXR heterodimers.[157, 158] The complete set of cellular binding sites is referred to as the *cistrome*.[159] Although the sequence of the genome is the same in nearly all cells of the body, cistromes are context dependent, owing to cooperation with factors that open chromatin in a cell type or developmentally specific way, allowing the receptors to bind.

Receptor Regulation of Gene Transcription

Nuclear receptors mediate a variety of effects on gene transcription. The most common modes of regulation are ligand-dependent gene activation, ligand-independent repression of transcription, and ligand-dependent negative regulation of transcription (Table 2.7). Much of this regulation is mediated by interactions of nuclear receptors with proteins called *coregulators,* which include coactivators and corepressors.[160]

Ligand-Dependent Activation

Ligand-dependent activation is the best understood function of nuclear receptors and their ligands. The ligand-bound receptor increases transcription of a target gene to which it is bound. The DBD brings the receptor domains that mediate transcriptional activation to a specific gene. Transcriptional activation itself is mediated primarily by the LBD, which can function as an independent unit even when it is transferred to a DNA-binding protein that is not related to nuclear receptors. The activation function (AF) of the LBD is referred to as *AF2* (see Fig. 2.12).

Gene transcription is mediated by a large complex of factors that ultimately regulate the activity of ribonucleic acid (RNA) polymerase, the enzyme that uses the chromosomal DNA template to direct the synthesis of messenger RNA. Most mammalian genes are transcribed by RNA polymerase II using a large set of cofactor proteins that include basal transcription factors and

associated factors collectively referred to as *general transcription factors* (GTFs). Details about GTFs are of fundamental importance and are available elsewhere.

The ligand-bound nuclear receptor communicates stimulatory signals to GTFs on the gene to which it is bound. Ligands specifically recruit a subset of the coregulators to the nuclear receptor LBD. Positively acting coregulators, called *coactivators*,

specifically recognize the ligand-bound conformation of the LBD and bind to the nuclear receptor on DNA only when an activating (agonist) hormone or ligand is bound. A number of coactivator proteins that bind to liganded nuclear receptors have been described (Table 2.8).[161]

The most important determinant of coactivator binding is the position of H12, which changes dramatically when activating ligands bind receptors (see Fig. 2.17B). Along with H3, H4, and H5, H12 forms a hydrophobic cleft that is bound by short polypeptide regions of the coactivator molecules.[162–164] These polypeptides, called *NR boxes* (see Fig. 2.17D), have characteristic sequences of LxxLL, in which L is leucine and xx can be any two amino acids.[165]

Coactivators increase the rate of gene transcription. This is accomplished by enzymatic functions, including histone acetyltransferase (HAT) activity; some coactivators possess intrinsic HAT activity, while others act as scaffolds to recruit HAT proteins.[166] HAT activity is critically important for activation because chromosomal DNA is tightly wrapped in nucleosomal units composed of core histone proteins. Acetylation, as well as some other histone modifications, opens up this chromatin structure.

The best understood class of coactivator proteins is the p160 family, whose name is based on their protein size (approximately 160 kDa). The family contains at least three molecules, each with many names (see Table 2.8).[167] These factors possess HAT activity and recruit other coactivators, such as CREB-binding protein (CBP) and p300, which are also HATs. A third HAT, p300/CBP-associated factor (PCAF), is also recruited by liganded receptors. These HATs, along with a complex of SMARC molecules (SWI/SNF-related, matrix-associated, actin-dependent regulators of chromatin) that direct ATP-dependent DNA unwinding, create a chromatin structure that favors transcription (Fig. 2.19).[168]

Recruitment of multiple HATs may reflect different specificities for core histones and, potentially, for some nonhistone proteins. Some HATs also interact directly with GTFs and further enhance their activities. The mediator complex, which has also been called the thyroid hormone receptor–associated protein (TRAP) complex, and the vitamin D receptor–interacting protein (DRIP) complex link nuclear receptors to GTFs.[169] The HATs and TRAP factors are recruited to the liganded, target gene–bound receptor in an ordered manner that also involves cycling on and off the target receptor with a time scale of minutes.[170] Nuclear receptor interactions with the genome are even more complex, with on-off rates that have been measured to be on the order of milliseconds.[171]

Repression of Gene Expression by Unliganded Receptor

Although DNA binding is ligand dependent for steroid hormone receptors, other nuclear receptors are bound to DNA even in the absence of their cognate ligand. In many cases, the unliganded, DNA-bound receptor actively represses transcription of the target gene. By reducing the expression of the target gene, this repressive function of the receptor amplifies the magnitude of the subsequent activation by hormone or ligand. For instance, if the level of gene transcription in the repressed state is 10% of the basal level in the absence of a receptor, hormone activation to 10-fold above that basal level represents a 100-fold difference of transcription rate between hormone-deficient (repressed) genes and hormone-activated genes (Fig. 2.20).[172] This phenomenon helps to explain why loss of hormone production can result in a much more profound phenotype than loss of the receptor. For example, hypothyroidism due to thyroid gland dysfunction or ablation or iodine

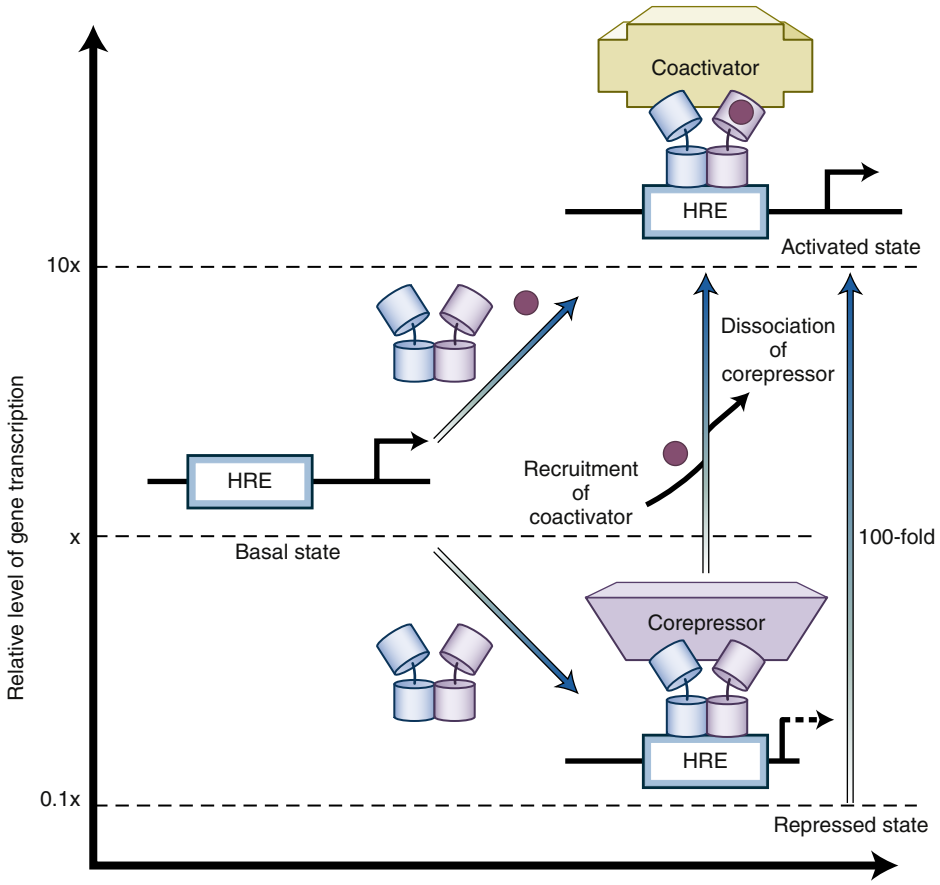
deficiency leads to severe consequences, up to and including cretinism, coma, and death. This is true in mice as well as people. On the other hand, mice lacking all thyroid hormone receptors are relatively mildly affected, with only moderate growth and fertility issues.[173,174] This discrepancy can be attributed to the fact that an unliganded receptor in the hormone deficient state exerts unchecked repressive activity, which has more severe consequences than loss of both repressive and activating functions of THR.

In many ways, the molecular mechanism of repression is the mirror image of ligand-dependent activation. The unliganded nuclear receptor recruits negatively acting coregulators, called *corepressors*, to the target gene. The two major corepressors are large (approximately 270 kDa) proteins: nuclear receptor corepressor (NCoR) and silencing mediator for retinoid and thyroid receptors (SMRT, also known as NCoR2).[175] NCoR and SMRT specifically recognize the unliganded conformation of nuclear receptors and use an amphipathic helical sequence similar to the NR box of coactivators to bind to a hydrophobic pocket in the receptor.

For corepressors, the peptide responsible for receptor binding is called the *CoRNR box* (see Fig. 2.17C), and it contains the sequence (I or L)xx(I or V)I, in which I is isoleucine, L is leucine, V is valine, and xx represents any two amino acids.[176] The receptor uses helices 3 to 5 to form the hydrophobic pocket, as in coactivator binding, but H12 does not promote and even hinders corepressor binding. This highlights the role of the ligand-dependent change in the position of H12 as the switch that determines repression versus activation by nuclear receptors (see Fig. 2.19).[177]

The transcriptional functions of NCoR and SMRT are the opposite of those of the coactivators. The corepressors themselves do not possess enzyme activity, but they recruit histone deacetylases (HDACs) to the target gene, thereby reversing the effects of histone acetylation described earlier and leading to a compact, repressed state of chromatin. Although the mammalian genome contains multiple HDACs, several of which may play a role in nuclear receptor function, the main one involved in repression is HDAC3, whose enzyme activity depends on interaction with NCoR or SMRT.[178] The ability of NCoR to bind and activate HDAC3 is required for normal metabolic and circadian physiology.[179] The corepressors interact directly with GTFs to inhibit their transcriptional activities, and they also exist in large, multiprotein complexes whose range of functions is not fully understood. Biology is complex, however, and recent studies suggest that in brown adipose tissue, HDAC3 foregoes its corepressor role and acts as a coactivator in concert with the nuclear receptor ERRα. In this case, the effect of HDAC3 is mediated at least in part by deacetylation of the key coactivator protein PGC-1, rather than a histone.[180]



• **Fig. 2.20** Repression and activation functions augment the dynamic range of transcriptional regulation by nuclear receptors. The magnitudes of activation and repression were arbitrarily set at 10-fold for this theoretical example. In cells, these magnitudes vary as a function of coactivator and corepressor concentration and in a target gene–specific manner. *HRE,* hormone response element.

Ligand-Dependent Negative Regulation of Gene Expression: Transrepression

The ligand-dependent switch between repressed and activated receptor conformations explains how nuclear receptor ligands activate gene expression. However, many important gene targets of such hormones are turned off in the presence of the ligand. This is referred to as *ligand-dependent negative regulation of transcription,* or *transrepression,* to distinguish it from the repression of basal transcription by unliganded receptors.

The mechanism of negative regulation is less well understood than ligand-dependent activation, and there may in fact be several mechanisms. One mechanism involves nuclear receptor binding to DNA-binding sites that reverse the paradigm of ligand-dependent activation (i.e., negative response elements). For example, when the unliganded thyroid receptor binds to the negative response element of the genes for the β-subunit of TSH or TSH-releasing hormone, transcription is activated,[181] although more recent studies suggest that the role and recruitment of coregulators in this process are complex.[182] In other cases, negative regulation may result from nuclear receptors that bind to, and inhibit, other transcription factors without binding DNA. This interaction leads to redistribution of coactivators from the other transcription factors that positively regulate the gene. Recent evidence supports this model, whereby inhibition of the activity of the positively acting factors results in the observed negative regulation.[183,184] Nuclear receptors can also lead to inhibition of gene expression indirectly by activating a gene that encodes a transcriptional repressor.

Roles of Other Nuclear Receptor Domains

The N-terminal A/B domain of the nuclear receptors is the most variable region among all members of the superfamily in terms of length and amino acid sequence. Subtypes of the same receptor often have completely different A/B domains, and the function of this domain is the least defined. It is not required for unliganded repression or for ligand-dependent activation. In many receptors, the A/B domain contains positive transcriptional activity, often referred to as activation function 1 (AF1) (see Fig. 2.16). Its activity is ligand independent, but it probably interacts with coactivators and may influence the magnitude of activation by agonists or partial agonists. This AF is tissue specific and tends to be more important for steroid hormone receptors, whose A/B domains are notably longer than those of other members of the superfamily.[185] The F domain of the nuclear receptors is hypervariable in length and sequence, and its function is not known.

Cross-Talk With Other Signaling Pathways

Hormones and cytokines that signal through cell surface receptors also regulate gene transcription, often by activating protein kinases that phosphorylate transcription factors such as CREB. Such signals can also lead to phosphorylation of nuclear receptors. Multiple signal-dependent kinases can phosphorylate nuclear receptors, leading to conformational changes that regulate function.[186] Phosphorylation can lead to changes in DNA binding, ligand binding, or coactivator binding, depending upon the specific kinase, receptor, and domain of the receptor that is phosphorylated. The properties of coactivators and corepressors are also regulated by phosphorylation.[187]

Receptor Antagonists

Certain ligands function as receptor antagonists by competing with agonists for the ligand-binding site. In the case of steroid hormone receptors, the position of H12 in the antagonist-bound receptor is not identical to that in the unliganded receptor or in the agonist-bound receptor. In antagonist-bound steroid receptors, H12, which has a sequence that resembles the NR box, binds to the coactivator-binding pocket of the receptor and thereby prevents coactivator binding.[188] This antagonist-bound conformation of the receptor also favors corepressor binding to steroid hormone receptors.

Tissue Selectivity of Ligands Interacting With Nuclear Receptors

Many endogenous hormones that act through nuclear receptors do so in a tissue-specific manner. The most obvious mechanism is differential expression of the receptors, both in space (e.g., cell type specificity)[189] and time (e.g., circadian variation).[190] Ligand levels may be regulated intracellularly (see earlier discussion and Table 2.5), and post-translational modification (e.g., phosphorylation) influences cell-specific receptor function. Although nuclear receptors bind at thousands of sites on genomic DNA, the specific binding sites are regulated in a cell type–specific manner. For example, the estrogen receptor binds to overlapping but clearly different sets of genomic sites in the uterus and in the breast, probably because of the differential actions of so-called pioneer transcription factors, which open tightly compacted chromatin in a tissue-specific manner and enable nuclear receptor and other transcription factors to bind.[191]

Some ligands function as antagonists in certain tissues but as full or partial agonists in others. These selective receptor modulators include compounds such as tamoxifen, a selective estrogen receptor modulator (SERM). SERMs are estrogen receptor antagonists with respect to the functions of AF2, including coregulator binding, and they require the AF1 for their agonist activity.[192] This agonism, like AF1 activity, tends to be tissue specific and therefore has great therapeutic utility.[193] Table 2.9 summarizes factors contributing to the tissue specificity of receptor activity.

Nongenomic Actions of Nuclear Receptor Ligands

Some actions of steroids and other nuclear receptor ligands occur within seconds or minutes, far quicker than should be possible

using the transcriptional mechanisms described in the chapter. This suggests that some traditional nuclear receptor ligands may have a discrete set of nongenomic actions. There is now reasonable evidence that thyroid hormone, estrogen, androgen, and possibly other ligands can bind and activate receptors outside of the nucleus. In most cases, these extranuclear receptors are splice variants of the same genes that encode the traditional nuclear receptor, often with loss of the DNA binding domain and NLS. Binding of ligands to these receptors causes activation of many classic signaling pathways, such as Src, ERK, and Akt pathways.[194] In some cases there may be binding of ligands to receptors that are completely unrelated to the nuclear receptors, though this is less clear. The nongenomic and genomic actions of ligands may act cooperatively (e.g., by causing phosphorylation of the nuclear form of the receptor).[195]

Genetics of Endocrinology

ROBERT L. THOMAS, JOEL N. HIRSCHHORN, AND AMIT R. MAJITHIA

CHAPTER OUTLINE

KEY POINTS

- The genetic basis of each heritable endocrine disease/trait is quantified by its genetic architecture (1) the number of genetic variants/genes, (2) their frequency in the population, and (3) their respective contributions to disease risk/phenotypic variation.
- Mendelian endocrine disorders are caused by variants found rarely in the population, usually from a relatively small number of genes, and each variant has a large individual effect on disease risk so that in any one individual, most of the disease risk is explained by variants in a single gene. Mendelian variants can be highly penetrant, but this is not always the case.
- Common endocrine diseases/traits such as stature, type 2 diabetes, and serum lipids are polygenic—the result of combined, simultaneous effects of many variants in many genes, often found frequently in the general population, and with each variant contributing a small individual effect so that the phenotype in any one individual results from variants in many different genes.
- Genetic information enables endocrinologists to personalize therapy for patients.
- Comprehensive genetic testing (i.e., genome sequencing) can be standardized and automated, but drawing valid and clinically useful conclusions requires integration with patient history, physical examination, and other laboratory examinations.
- Genetic information is most likely to be of direct clinical use in patients with suspected mendelian syndromes.

The Role of Genetics in Endocrinology

The sequencing of the human genome has ushered in an era of genomic medicine. The catalog of protein-coding genes in humans is essentially complete, and the number of associations between genes and specific diseases is growing rapidly. Moreover, it is now feasible to identify nearly every genetic variant in an individual's protein-coding genes (whole-exome sequencing [WES]) or in his or her entire genome (whole-genome sequencing) due to revolutionary advances in sequencing technologies (collectively referred to as next generation sequencing [NGS]). The ability to interpret this variation is less advanced but is improving, as databases of variants and their clinical associations increase in both size and accuracy. Founded in 1982, the National Center for Biotechnology Information's GenBank now contains more than 200 million sequences and includes worldwide contributions from the DNA Data Bank of Japan and the European Nucleotide Archive.[1] Ongoing projects include the Genome Aggregation Database, Exome Aggregation Consortium (ExAC), United Kingdom 100,000 Genomes Project, and the National Center for Biotechnology Information's Single Nucleotide Polymorphism Database. Available sequencing data are growing exponentially, and the volume of information places increasing the demand for methods to distinguish pathologic variants from benign ones.

With the expanding reach of *precision medicine*—individualized diagnosis and therapy informed by genetics—we anticipate that increasing numbers of patients will have clinical indications for exome or genome sequencing, and others will come to clinical encounters with their sequences already in hand. Clinicians will be asked to interpret these genetic data to shed light on an individual's risk of developing disease, on diagnosis and prognosis for those already affected, on implications to family members, and on individualization of therapy. As such, it is critical that clinicians are able to draw valid and clinically useful connections between DNA sequence variation and human traits and diseases. Perhaps even more important, it is critical that clinicians understand the limits of such information.

In this chapter, we present a guide to help clinicians appreciate and critically interpret the relationship between a DNA sequence (genotype) and an individual's clinical presentation (phenotype). We first discuss principles of genetics to provide the framework for understanding and interpreting DNA variation in patients. We then focus on endocrine disorders, providing an overview of the genetics of endocrine diseases, with illustrative examples from both mendelian disorders (caused by mutations in single genes) and polygenic disorders (in which variation in many genes influences disease risk). Finally, we examine scenarios for clinical uses of genetic information in endocrinology and provide recommendations.

Most diseases, including endocrine disorders, are heritable, meaning that genetic variation contributes to disease risk in a population. These diseases range across the spectrum of rare, single-gene disorders, such as multiple endocrine neoplasia (see Chapter 42), Carney complex (see Chapter 15), and congenital adrenal hyperplasia (CAH) (see Chapter 24) to polygenic diseases, such as type 2 diabetes (see Chapter 34 and 35), Graves disease (see Chapter 12), and osteoporosis (see Chapter 29). The detailed discussions of the genetics of these and other disorders can be found throughout this textbook; this chapter provides illustrative examples that illuminate key concepts and refers the reader to the appropriate chapters for additional detail.

Principles of Genetics

A Brief Historical Perspective

In Western conception, the relationship between inheritance and physical characteristics (disease and nonpathologic) has been recognized since the time of Aristotle (323 BC). But it was not until 1865 that the Austrian abbot Gregor Mendel, after decades of careful experimentation in pea plants, posited and provided evidence for the modern genetic concept of *genes* (as coined by the botanist Wilhelm Johannsen in 1909).[2] Mendel deduced certain rules governing the passage of genotype (the collective versions of multiple genes in an individual) from parent to offspring, enabling the prediction of the resulting physical characteristics (phenotype) of the offspring. It was recognized in the early 20th century that certain human phenotypes, including diseases, were inherited according to the same rules that Mendel had described; these diseases are called *mendelian*.

Over the course of the next century, numerous breakthroughs established that genes were composed of DNA, physically connected on chromosomes, and encoded proteins. The first description of the molecular basis of a mendelian disease was made for sickle cell anemia, which involved a mutation in a single gene. In the 1970s, the ability to sequence DNA revealed natural and heritable sequence variation (genetic polymorphisms) in any given gene among different individuals. It was appreciated that the molecular basis of variation in the genotypes of individuals resulted from DNA sequence polymorphisms, which in turn effected alterations in phenotype. By tracing the transmission of these polymorphisms in families, it became possible to identify genes causing mendelian human disorders (those caused by altered function in a single gene and that consequently show distinctive patterns of inheritance in families).[3]

However, most human diseases and phenotypes are not mendelian. Biometricians had appreciated in the early 1900s that most continuous and commonly varying traits (e.g., height and blood pressure) did not follow mendelian patterns of inheritance. In 1919, R.A. Fisher[4] provided a general framework explaining continually varying traits as the consequence of polygenic inheritance—that is, polygenic phenotypes are a result of combined, small, and additive effects of variation in many genes simultaneously. In this framework, monogenic/mendelian traits were a special case. Despite this recognition, only a few genetic variants were convincingly connected with polygenic diseases/traits over the next 80 years. It would take a series of technological advances, including the sequencing of the human genome (Human Genome Project 1990–2003) and the systematic cataloging of DNA sequence polymorphisms across diverse human populations (International HapMap Project 2002–2005 Phase I), to systematically identify the genetic causes for common polygenic diseases.[5]

Heritability: An Estimate of the Importance of Genetic Factors to Disease Causation

Relatives resemble each other in many ways. Resemblance with respect to traits such as height or to diseases such as multiple endocrine neoplasia type 1 (MEN1) could be explained by shared genotypes passed down through generations, shared environments, and nonlinear interactions between genes and environment. Heritability quantifies, as a proportion, how much of this familial resemblance is due to genetic factors. A trait that has no genetic influence would have a heritability of 0%; a trait that is completely determined by inherited factors would have a heritability of 100%. Most clinically important traits have heritabilities ranging from 20% to 80% (Table 3.1). Appreciating the heritability of a trait is important when interpreting the contribution of genetic risk factors in disease: genetic factors are less influential for traits with low heritability and are likely to have more predictive or explanatory power for traits with high heritability.

In the past, the gold standard for heritability estimation was the comparison of monozygotic and dizygotic twin concordance rates for diseases/traits. Such studies relied on the rationale that an excess of disease correlation between genetically identical individuals (monozygotic twin pairs) compared with those who share only 50% of their genes (dizygotic twin pairs) pointed to the role of genetic factors. However, the validity of comparing twin concordance rates across different families relied on the assumption that the effect of environment was the same for the twin pairs, regardless of whether they were monozygotic or dizygotic twins. More recent methods for heritability estimation can overcome some of these limitations by leveraging subtle fluctuations in genetic similarities between sibling pairs.[6]

Regardless of the methodology employed, it is critical to appreciate that heritability is not a fixed property of a disease/trait. The heritability estimate from any study must be interpreted in the context of the population in which it is being measured, including the historical period, and variability in environmental factors such as socioeconomic status and nutrition. These factors likely explain the wide range of heritability estimates for type 2 diabetes, ranging from 40% in Finland[7] to 80% in Japan.[8] An illustrative example of the importance of history can be drawn by examining type 1 diabetes rates across the Scandinavian region of Karelia. In 1940, this region was divided between Finland and the former Soviet Union with little contact between the two sections over the next 60 years. Finnish Karelians have a sixfold increased rate of type 1 diabetes compared with Russian Karelians.[9] As a result, heritability for type 1 diabetes will be different when estimated in the combined Karelian populations than when estimated in Finnish or Russian Karelians alone. The difference in diabetes rate is likely due to environmental factors, because both Karelian populations recently originated from a common ancestry and therefore likely have similar genetic risk factors for type 1 diabetes.[10]

Human DNA Sequence Variation: Molecular Forms and Biologic Effects

Each human has two versions of his or her genome (one from each parent); each version consists of a sequence of approximately 3 billion DNA bases. When comparing two versions of a human genome, either within the same person or between two different people, about 1/1000 of these bases vary (i.e., 99.9% of them are the same) (Table 3.2). There are many possible ways in which DNA sequences can vary; several specific types of DNA sequence variants are frequently observed (Fig. 3.1).

TABLE 3.1 Heritable Endocrine Traits and Diseases

Common Form	Heritability	Reference[a]	Selected Mendelian Forms
Type 1 diabetes	80%	132	*KCNJ11, ABCC8* (permanent neonatal diabetes)
Type 2 diabetes	40–80%	23, 28, 133	*AGPAT2* (congenital generalized lipodystrophy), *LMNA* (familial partial lipodystrophy 1) *HNF4A, GCK, HNF1A* (MODY1-3)
Obesity	40–70%	134, 135	*MC4R, POMC*
Hypertension	30–70%	136	*MEN1, RET* (MEN2A/B), *VHL, SCNN1A* (Liddle syndrome), *CYP17A1* (17OHD), *HSD11B2* (AME)
Height	80%	24, 72	*GH1, FGFR3* (achondroplasia), *SHOX1* (Ullrich-Turner syndrome), *FBN1* (Marfan syndrome)
Pubertal timing	50–80%	137	*KAL1, KISS1R, FGFR1* (hypogonadotropic hypogonadism)
Hyperthyroidism	80%	138	*TSHR* (familial nonautoimmune hyperthyroidism)
Hypothyroidism	67%	139	*TSHR, SLC5A5, TG, TPO,* and *TSHB* (congenital hypothyroidism)
Osteoporosis	50–85%	140, 141	*COL1A1, COL1A2, IFITM5* (osteogenesis imperfecta)
Serum calcium	40%	142, 143	*CASR* (familial hypocalciuric hypercalcemia), *HRPT2* (hyperparathyroid jaw-tumor syndrome)
Lipids	40–60%	85, 86	*Low-density lipoprotein:* LDLR (familial hypercholesterolemia)
			High-density lipoprotein: CETP
			Triglycerides: APOE (familial dysbetalipoproteinemia)
Kidney stones	56%	144, 145	*CLCN5* (X-linked recessive nephrolithiasis), *NKCC2* (Bartter syndrome)

[a]Numbers in this column indicate references listed at the end of the chapter.

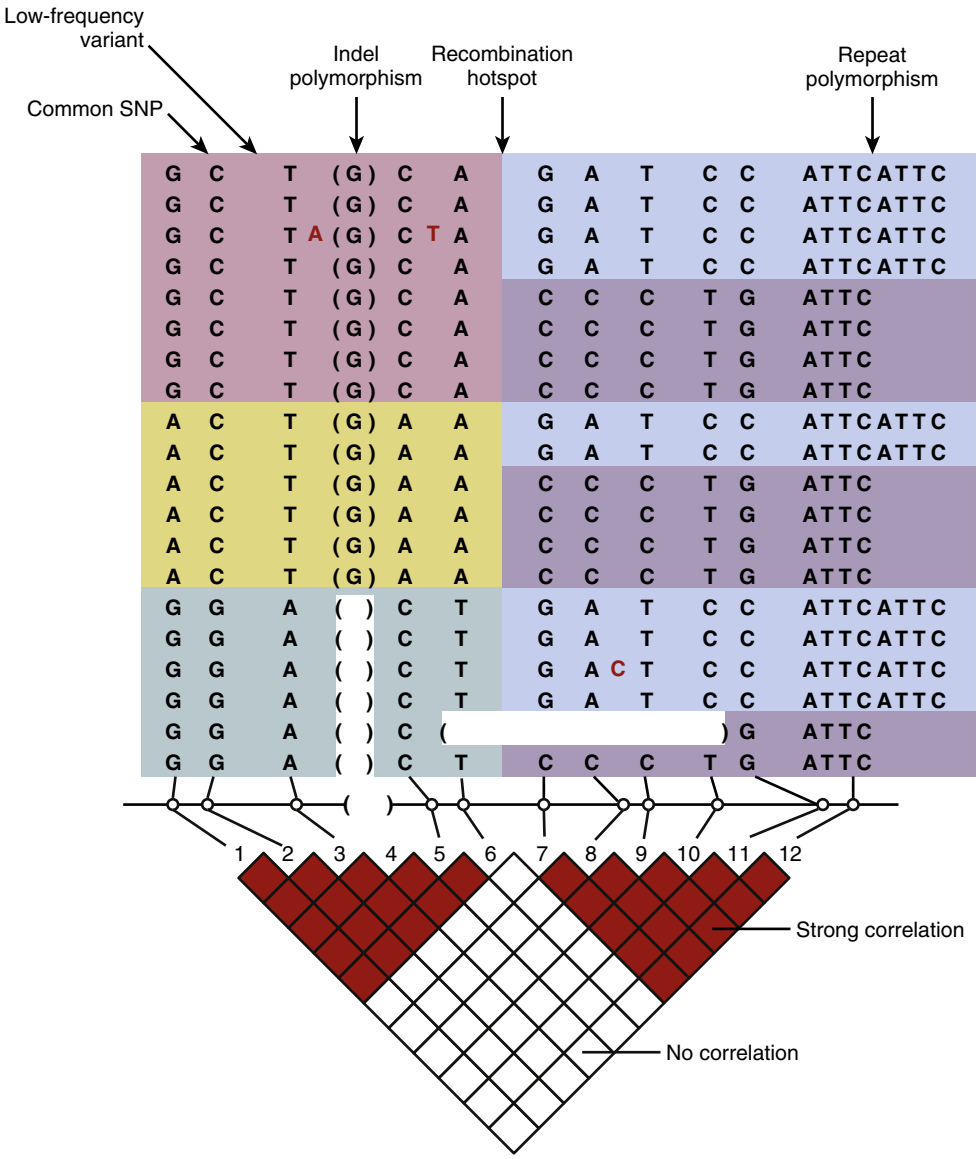
TABLE 3.2 Characteristics of Human Genome Sequence Variation

Characteristic	Frequency
Length of the human genome sequence (base pairs)	3 billion
Number of human genes (estimated)	20,000
Fraction of base pairs that differ between the genome sequence of a human and a chimpanzee	1.3% (1:80)
Fraction of base pairs that vary between the genome sequence of any two humans	0.1% (1:1000)
Fraction of coding region base pairs that vary in a manner that substantially alters the sequence of the encoded protein	0.02% (1:5000)
Number of sequence variants present in each individual as heterozygous sites	3 million
Number of amino acid–altering variants present in each individual as heterozygous sites	12,000
Number of sequence variants in any given human population with frequency >1%	10 million
Number of amino acid polymorphisms present in the human genome with a population frequency >1%	75,000
Fraction of all human heterozygosity attributable to variants with a frequency >1%	98%

Adapted from Altshuler D. The inherited basis of common diseases. In Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*, 24th ed. Philadelphia, PA: WB Saunders; 2012.

The most frequent form of variation, the single nucleotide polymorphism (SNP), refers to the situation in which a single base in the sequence of one individual is different from the base seen at the same position in the sequence of another individual. SNPs can exert a wide range of biologic effects, depending on where the variant occurs and whether it alters the function of the DNA sequence. Some SNPs occur within the portions of genes that are transcribed into RNA and then translated into proteins (protein-coding regions). Synonymous SNPs occur in the protein-coding portion of DNA but both versions (alleles) of the SNP encode the same amino acid, and so this sort of variation usually does not affect function. SNPs can be missense changes (alteration of a single amino acid in a protein-coding gene), as is the case of the C282Y mutation in the *HFE* gene responsible for autosomal recessive hereditary hemochromatosis (see Chapter 19). Some missense SNPs greatly alter function, whereas others appear to have no consequences. SNPs can also alter splice sites, disrupting the structure of the mRNA that is transcribed from the DNA during gene expression. For example, the most common cause of autosomal dominant isolated growth hormone (GH) deficiency is single-base mutations that inactivate a splice donor site of intron 3 in the *GH1* gene, causing skipping of exon 3 in *GH1* (see Chapter 25). SNPs can also introduce stop codons, leading to premature termination of translation and a truncated protein product. These nonsense variants typically dramatically impair or eliminate the function of the protein.

Changing the protein sequence is not the only way that SNPs (and other types of genetic variations) can alter gene function. Most of the human genome does not code for proteins (see Table 3.2), and most genetic variation occurs in this noncoding portion of the genome. For example, noncoding variants can alter the level, timing, or location of gene expression, without changing the sequence of the encoded protein. Noncoding variants often result in more



• **Fig. 3.1** DNA sequence variation in the human genome. Common and rare genetic variation in 10 individuals, carrying 20 distinct copies of the human genome. The amount of variation shown here is typical for a 5-kb stretch of genome and is centered on a strong recombination hotspot. The 12 common variations include 10 single-nucleotide polymorphisms (*SNP*s), an insertion-deletion polymorphism (indel), and a tetranucleotide repeat polymorphism. The six common polymorphisms on the left side are strongly correlated. Although these six polymorphisms could theoretically occur in 26 possible patterns, only 3 patterns are observed (indicated by pink, orange, and green). These patterns are called *haplotypes*. Similarly, the six common polymorphisms on the right side are strongly correlated and reside on only two haplotypes (indicated by blue and purple). The haplotypes occur because there has not been much genetic recombination between the sites. By contrast, there is little correlation between the two groups of polymorphisms because a hotspot of genetic recombination lies between them. In addition to the common polymorphisms, lower-frequency polymorphisms occur in the human genome. Five rare single-nucleotide polymorphisms are shown, with the variant nucleotide marked in red and the reference nucleotide not shown. In addition, on the second to last chromosome, a larger deletion variant is observed that removes several kilobases of DNA. Such larger deletion or duplication events (i.e., copy number variants) may be common and segregate as other DNA variants. (Redrawn from Altshuler D, Daly MJ, Lander ES. Genetic mapping in human disease. *Science.* 2008;322[5903]:881-888.)

subtle biologic effects, and the mechanisms are still being uncovered. For example, some SNPs subtly influence type 1 diabetes risk and lie in enhancers (noncoding DNA segments that activate gene transcription at a distance) that appear to affect gene expression only in lymphoid cells.[11]

Insertions and deletions (collectively called *indels*) respectively refer to the addition or removal of one or more bases in the DNA sequence. Indels in protein-coding sequences are called *frameshift mutations*, as long as the number of bases inserted or deleted is not a multiple of three. Because the genetic code is composed of

triplets (every three bases encode one amino acid), a frameshift mutation alters how every subsequent base in the sequence is translated into a protein, resulting in profound molecular and clinical consequences. For example, classic salt-wasting CAH is often caused by frameshift deletions in the *CYP21A2* gene that ablate its function (see Chapter 15 and 24). Repeat polymorphisms (often referred to as copy number variants [CNVs] if the repeats are large) are a special case of indels in which DNA sequences are repeated in tandem, and the number of copies of the repeated sequence varies. For example, the *AR* gene (encoding the androgen receptor [*AR*]) contains a repeat polymorphism in which a CAG codon, encoding glutamine, is repeated 11 to 31 times (see Chapter 24). Structural variation can include both insertions and deletions, as well as rearrangement of large chunks of DNA sequence (translocations and other complex forms of genomic variation). Structural variation causes familial hyperaldosteronism type 1; the adrenocorticotropic hormone (ACTH, corticotropin)-responsive promoter of the *CYP11B1* gene is incorrectly located adjacent to the aldosterone synthase gene (*CYP11B2*), causing aldosterone to be produced by ACTH stimulation (see Chapter 16).

Factors Influencing the Biologic Impact of Genetic Variants in a Particular Gene

As discussed previously, the impact of a genetic variant on gene function will depend on the type of variant and its location with respect to the gene. For example, frameshift deletions in the *CYP21A2* gene eliminate 21-hydroxylase activity, whereas missense variants in *CYP21A2* often retain partial 21-hydroxylase activity (see Chapter 24). However, even a single, specific variant may have different effects in different individuals. The effect of any given genetic variant (genotype) on the phenotype can be modified by variants in other genes (gene-gene interactions) or by environmental factors (gene-environment interactions) or by random chance. It is usually not possible to measure or quantify these factors in any one person, but their combined effect can be quantified on a population level as *penetrance*, the proportion of individuals carrying a genetic variant who exhibit the phenotype. The penetrance of a genetic variant is highly context dependent with respect to phenotypic definition. For example, the hemochromatosis-associated C282Y allele in the *HFE* gene exhibits high penetrance for the biochemical phenotype of high ferritin (>60% of homozygous carriers manifest increased ferritin levels) but only 2% penetrance for the clinical phenotype of liver cirrhosis. Temporal context is also an important consideration, as disease incidence often increases with age. Carriers of mutations causing MEN1 have nearly 100% penetrance for parathyroid adenomas by age 40 but only 20% penetrance at age 20.

A common observation in members of a family carrying the same disease-causing genetic variant is that not all members of the family are equally affected. This range of phenotypic expression resulting from a particular genotype is referred to as variable *expressivity* and, as with penetrance, arises from the range of impacts of specific variants, as well as modifying influences of genetic background (gene-gene interactions), environment (gene-environment interactions), and random chance. For example, the same mutation in the *AR* (encoding an S703G substitution) resulted in a spectrum of clinical androgen insensitivity such that some individuals were raised as 46,XY females and others as males; other mutations in *AR* have different ranges of phenotypic effects (see Chapter 24).

TABLE 3.3 Origins of DNA Sequence Variation in Human Populations: Common Versus Rare Variants

The type of genetic variant (missense, frameshift, noncoding, etc.) provides clues to its possible consequences. In addition, the population frequency of a variant, whether it is common or rare, can also provide information about its likely impact on phenotype. The relative balance between common and rare genetic variation is strongly influenced by evolution and human demographic history. Modern humans likely originated from a small population residing in Africa that had been evolving over millions of years. Within the past 50,000 years, members of this ancestral population migrated "out of Africa," settled the globe, and only recently, over the past 5000 to 10,000 years, multiplied exponentially.[127] As a consequence of this demographic history, most of the 3 million genetic variants an individual inherits from his or her parents are common (typically >1% frequency in the population), can be traced back to the ancient African population, and are shared in many unrelated individuals in the population. Individuals also inherit thousands of genetic variants unique to themselves and their relatives. These rare genetic variants arose more recently from spontaneous mutation in the past 10 millennia, after the migration of many humans out of Africa, and are typically observed infrequently (<0.1% of all chromosomes) in the population.

Mosaicism, whereby cells within a single individual have different genotypes, is another mechanism that leads to variable expressivity. Most mutations known to influence disease are *germline* mutations—inherited from the sperm or egg and present in every cell—but some diseases can be caused by somatic mutations that occur after fertilization and are present in only some cells, leading to mosaicism. In these cases, which tissues or organs carry the mutation will influence the clinical outcome. The most familiar class of disease caused in large part by somatic mutations is neoplasia, including endocrine tumor syndromes such as Conn syndrome and Cushing disease. Another classic example from endocrinology is the McCune-Albright syndrome, in which the same activating mutation in *GNAS1* exhibits variable expressivity because of postzygotic mosaicism. The phenotype of patients with McCune-Albright syndrome depends on which tissues and what fraction of cells carry the *GNAS1* mutation. A minority of affected individuals (24%) display the classic triad of café au lait spots, polyostotic fibrous dysplasia, and gonadotropin-releasing hormone (GnRH)-independent precocious puberty; the majority express two or fewer features of the classic triad (see Chapter 26). The mechanism of variable expressivity likely maps to the zygotic stage in which the mutation arose: a mutation earlier in embryogenesis is present in more tissue lineages. Because mutations in a mosaic individual are not present in every cell, they can be hard to detect in DNA isolated from a blood sample if the cell in which the mutation occurred does not give rise to blood leukocytes. The *GNAS1* mutation responsible for the McCune-Albright syndrome is detected in only 8% to 46% of blood samples from affected individuals but is found in 90% of affected tissue sampled irrespective of clinical presentation (see Chapter 26). Conversely, blood cells can contain somatic variation that is absent in other tissues or the germline.[12]

It is important to remember that the base pair composition of a DNA sequence is not the only molecular determinant of phenotypic expression (Table 3.3). DNA is subject to other forms of modification besides sequence variation (termed *epigenetic variation*), such as cytosine methylation or packaging into nucleosomes

with various biochemically modified histones. Thus, the same molecular form of DNA sequence variation can vary in its cellular and phenotypic effect through epigenetic modifications. Indeed, epigenetic modification is a normal part of development and is the reason different cells have different properties even though they share the identical DNA sequence. A striking example of the effect of epigenetics is imprinting, the expression of a genetic variant in a parent-of-origin specific manner. For paternally imprinted genes, the copy that is inherited from the father is silenced, and only the mother's copy is expressed in the offspring. Imprinting can affect the impact of disease-causing mutations. Inactivating mutations in *SDHD* cause familial paraganglioma type 1. *SDHD* is maternally imprinted, so the mutation does not cause disease when inherited from the mother but is highly penetrant when inherited from the father. Imprinting can also be tissue specific. A paternally inherited inactivating mutation in *GNAS1* causes Albright hereditary osteodystrophy (pseudopseudohypoparathyroidism; see Chapter 29). The same mutation, when maternally inherited, manifests not only with Albright hereditary osteodystrophy but also with hypocalcemia secondary to parathyroid hormone resistance (pseudohypoparathyroidism type 1a [PHP1a]), because only the maternal copy of *GNAS1* is expressed in renal proximal tubules.

Evolution influences the frequency of variants that affect human phenotypes (e.g., endocrine diseases) through the process of natural selection. Variants that greatly increase the risk of a disease that is deleterious from a reproductive standpoint are less likely to be passed on to offspring and will be rare in the population (unless they have a compensatory benefit like malaria resistance in carriers of sickle cell disease). If a disease is at least mildly evolutionarily deleterious, then most common variants associated with that disease will only modestly increase disease risk. This is because those common variants, if they had strongly increased disease risk, would have then been subject to strong negative evolutionary selection and never would have risen in frequency to become common in the first place. By contrast, it is more plausible for rare/recent variants to exert strong effects on phenotype and greatly increase disease risk.

Finally, the number of genes that contribute to disease in a single individual (mendelian or polygenic disease) will be related to the strength of effect of any one variant on disease risk. By definition, variants that cause mendelian disorders have strong effects, whereas variants contributing to risk of polygenic diseases will typically have more modest effects. Thus, most variants with strong effects on disease will be rare, especially for those diseases that are clearly deleterious from an evolutionary standpoint (lethal before reproductive age). By contrast, common polygenic diseases and traits will have a much more substantial contribution from common genetic variants, although these considerations do not rule out an important role for rarer variants in polygenic phenotypes. As we will see later in this chapter, these patterns of genetic variation have important implications for identifying genetic variants that underlie disease and for interpreting the impact of genetic variation on disease.

Summary

To summarize this introductory section, we have briefly described several basic principles of genetics. Heritability describes the proportion of a disease/trait that can be explained by genetic factors; the heritability of most endocrine diseases ranges between 20% and 80% (see Table 3.1). Genetic variants can take many forms ranging from single-base changes (SNPs) to translocations of entire chromosomes (see Fig. 3.1). The biologic effect of these variants depends on the type of variant; where in the DNA they are located (e.g., within coding sequence, splice sites, enhancers); how severely the variant affects function; and for somatic mutations, the cells and tissues that carry the mutation. Biologic impact can also be modified by the presence of genetic variants in other genes (gene-gene interactions), the individual organism's environment (gene-environment interactions), and random chance. The demographic history of modern human populations explains the presence of common and rare genetic variants in the human genome (see Table 3.2). Common variants are mostly ancient and typically have relatively modest clinical effects, whereas rare variants tend to have arisen more recently and can exert larger clinical effects (Table 3.4).

Genetics of Endocrine Diseases

As described earlier, heritable diseases and traits, including endocrine phenotypes, span a range of genetic architectures ranging from single-gene mendelian disorders to common, polygenic diseases and traits. Mendelian and polygenic disorders represent two ends of a spectrum (Fig. 3.2) of genetic architectures. Although we distinguish between these two extremes of genetic architecture, it is important to appreciate that many disorders lie between these two extremes: rare variants of moderate effect can affect the common form of the disease, and genetic and nongenetic modifiers can strongly influence the outcome of mendelian disorders. Furthermore, many polygenic endocrine disorders also have rare mendelian forms (see Table 3.1).

The genes for a wide range of mendelian endocrine diseases have been mapped, revealing great mechanistic insight. Although mendelian diseases have offered valuable insights into pathophysiology, not all insights gained from mendelian forms of disease translate directly to the common forms of disease. For example, mendelian obesity caused by recessive inactivating mutations in the leptin receptor could be well treated by exogenous leptin, but this clinical insight did not apply to most obese individuals who actually demonstrate elevated leptin levels and do not respond to exogenous therapy with leptin (see Chapter 40). Obesity as a common trait is highly heritable (heritability 40–80%), and genome-wide association studies (GWASs) analysis has begun to identify risk variants for the common form.[13] Although some of the risk variants overlap with those causing mendelian syndromes (as is also true for other diseases), GWASs have pointed to additional genetic contributions outside the mendelian genes. And, of course, the variants that have strong effects on quite rare genetic syndromes do not explain much, if any, of the risk of the common forms of disease. Thus, genetics of both mendelian forms and common polygenic forms will have important and often complementary impacts on our understanding of disease and on patient care.

The sections that follow discuss representative examples of mendelian and polygenic endocrine disorders that illustrate important concepts in gene discovery, understanding of the impact of genetic variation on disease, and implications for clinical care and insights into new biology. We discuss several classes of mendelian diseases and highlight three polygenic endocrine diseases/traits: (1) type 2 diabetes, (2) stature, and (3) serum lipids. In each section, we discuss what is known about the underlying genetic contributors, the impact of genetics on our understanding of disease biology, and the translation into clinical care in the short and long term.

TABLE 3.4 Performing and Interpreting Genetic Studies

For any heritable disease, the success of genetic mapping efforts, the strategy employed, and the clinical utility of any resulting genotype-phenotype map depend on its genetic architecture: (1) the number of genetic variants/genes, (2) their frequency in the population, and (3) their respective contributions to risk (i.e., penetrance). On one end of the spectrum lie mendelian diseases, such as multiple endocrine neoplasia type 1, characterized by (1) few variants often in a single gene, (2) extremely rare frequency in the population (<1:1000), and (3) potentially high penetrance (>50-fold risk). On the other end of the spectrum lie the so-called common diseases, such as type 2 diabetes, characterized by (1) many variants in many genes (polygenic), (2) high frequency in the population (>1:20), and (3) often low penetrance (<1.5-fold risk) (see Fig. 3-2).

Because of their simple genetic architectures, mendelian endocrine disorders were ideally suited for genetic mapping using the techniques of familial linkage mapping developed in the 1980s.[3] Because they are rare and have strong effects on phenotype, mendelian variants were typically identified in families. As a result, the genotype-phenotype correlations for these variants could not be generalized to the population at large. For example, penetrance of mendelian variants could be accurately estimated only if these variants were ascertained in the general population rather than in selected families with a specific genetic background. Large-scale sequencing studies in the general population, which can identify all variants, rare and common, are now enabling such estimates. Such studies have found that, when ascertained in the general population, the so-called mendelian variants are less penetrant than was estimated from family-based studies.[146]

By contrast, the variants for common polygenic disorders have been identified through genetic association studies in the general population. Genetic association studies do not require the identification of rare families segregating disease, because they simply compare the frequency of a given genetic variant in disease cases and controls. Thus, they can be applied to identify genetic factors underlying diseases occurring in a population of unrelated individuals (i.e., common diseases). Unlike clinical risk factors/biomarkers association studies, correlation in genetic association studies implies causation, because genotype always precedes phenotype. Through the 1980s, genetic association studies were performed using single-nucleotide polymorphisms at candidate genes selected by educated guessing. Such studies yielded several common disease associations but were poorly reproducible and confounded by false-positive results arising from population stratification. The development of modern sequencing and genotyping technologies along with the cataloging of more than 10 million common variants (the International HapMap project[147]) enabled genome-wide association studies (GWASs), a systematic approach to simultaneously test all genes for associations that could account for population-based confounding.[5] GWASs have yielded a large number of reproducible genetic associations for diverse common/polygenic diseases/traits,[148] yielding insight into disease biology and genetic architecture.

When interpreting a result from any genetic study, it is important to bear in mind that the actual variant (usually a single-nucleotide polymorphism) tested in the study marks a haplotype (a combination of genetic variants inherited together) that can span millions of bases. The causal variant, in the sense that it is molecularly responsible for alteration in gene function leading to cellular and disease phenotype, may lie anywhere on this haplotype. As with the chromosomal linkage studies of the past, identifying the causal variants/genes on a haplotype necessitates a combination of further association analysis (fine-mapping)[149,150] and functional experimentation in model systems.[151]

Mendelian Endocrine Diseases

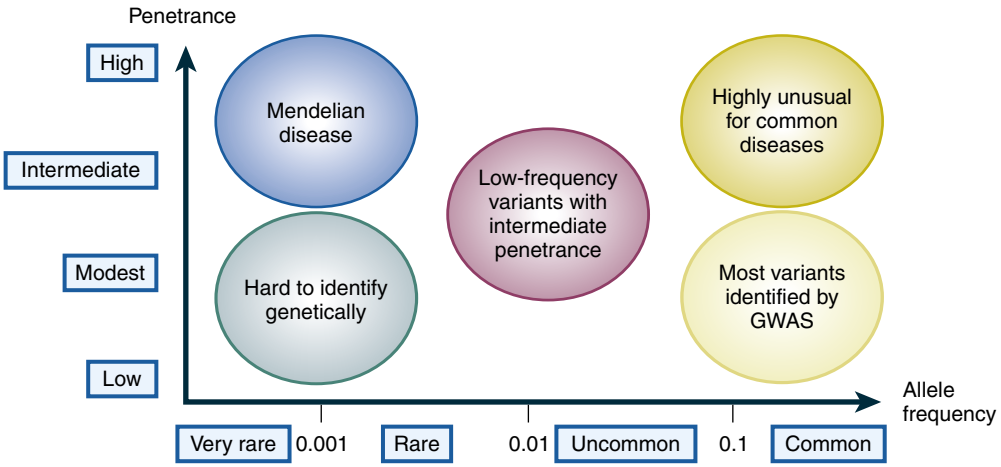
Genetic Architecture

Mendelian diseases represent one extreme of a spectrum of possible genetic architectures (see Fig. 3.2). The alleles causing mendelian diseases are found in a *small number of genes*, are typically *rare* (<1:1000), can be (although not always) *highly penetrant*, and follow simple patterns of dominant and recessive inheritance. They are considered monogenic in that a mutation in a single gene causes disease in an individual or family. But as different families segregating the same mendelian disease are identified and the causal genetic variants mapped, *genetic heterogeneity* is often observed: different alleles in different genes can cause the same disease. Some mendelian disorders (e.g., MEN2) demonstrate recurrent mutations in the same gene but of different molecular forms and locations, a phenomenon termed *allelic heterogeneity*. For other disorders (e.g., familial paraganglioma), multiple genes across different chromosomes are implicated, each causing the same/similar disease in different individuals. This phenomenon, variants in different genes causing the same disease, is termed *locus heterogeneity*. It is important to bear in mind that locus heterogeneity is intrinsically tied to the precision of disease definition. For example, CAH can be caused by defects in multiple genes encoding steroid biosynthetic enzymes (*CYP21A2*, *CYP11B1*, *CYP17A1*, *HSD3B2*, *POR*, *StAR*; see Chapter 15). However, if the CAH phenotype is refined to include biochemical measurements (mineralocorticoid, sex hormone, and electrolyte levels), individual subtypes emerge, each of which possesses a simpler genetic architecture (i.e., decreased locus heterogeneity).

When contrasted with common polygenic diseases, mendelian disorders exhibit relatively less locus heterogeneity. In other words, an appreciable fraction of mendelian disease cases can be largely explained by mutations in one or a few genes. For example, recurrent mutations in a single gene (the eponymous *MEN1*) account for 70% of families segregating the MEN1 clinical syndrome. Even in this classic mendelian case, however, the genetic architecture remains incompletely defined, as 30% of cases have no mutation in *MEN1*. Thus, much of the genetic architecture of mendelian diseases remains uncharted territory for genetic mapping. Modern sequencing technologies have facilitated a renaissance in mendelian disease gene mapping and will help improve our understanding of the genetic basis of mendelian disorders. By exome sequencing two individuals in a kindred with familial combined hypolipidemia (see Chapter 41), investigators identified two nonsense mutations in *ANGPTL3* that segregated with low serum lipoproteins when genotyped in other family members.[14] These mutations and the *ANGPTL3* gene were contained in the region identified by traditional linkage mapping[14] and could be quickly identified because the sequence of all exons in that region had been determined.

Disease Biology

Every endocrine organ ranging from the pituitary to adrenal is affected by well-described and less-described mendelian disorders. Mechanistic insight into disease biology has been gained from discovering the identities of the genes that lead to disease. When mutations in several different genes can all cause a disease (locus heterogeneity), additional mechanistic insight into molecular pathophysiology becomes possible. This makes intuitive sense in the context of a molecular understanding of genes as encoding proteins that act in concert to accomplish cellular functions. For example, Noonan syndrome (characterized endocrinologically by variable short stature, delayed puberty, and cryptorchidism in the



• **Fig. 3.2** Genetic architecture of common and mendelian diseases. On one end of the spectrum are mendelian diseases caused by few variants in few genes, each with a large individual effect on disease risk. On the other end of the spectrum are common diseases and traits caused by the combined effects of many variants, observed frequently in the population, each with a modest individual effect. *GWAS*, genome-wide association. (Redrawn from McCarthy MI, Abecasis GR, Cardon LR, et al. Genome-wide association studies for complex traits: consensus, uncertainty and challenges. *Nat Rev Genet.* 2008;9[5]:356-369.)

setting of dysmorphic features and variable cardiac defects [see Chapter 24]) is typically caused by activating the RAS-MAPK (mitogen-activated protein kinase) signaling pathway. Dominant gain-of-function mutations in multiple pathway members (*PTPN11*, *SOS1*, *KRAS*, *RAF1*, *BRAF*, *NRAS*) have all been shown to cause Noonan syndrome. For other disorders, a more complex picture emerges in which multiple molecular pathways are implicated. For example, Kallmann syndrome (see Chapter 26), which arises from failure of migration of GnRH neurons during fetal development, demonstrates X-linked (*KAL1*), autosomal dominant (*FGFR1*), and autosomal recessive (*PROK2*) inheritance. The gene product of *KAL1*, a secreted protein called *anosmin*, is thought to interact with the fibroblast growth factor (FGF) receptor, whereas the gene product of *PROK2*, the secreted protein prokineticin 2, interacts with a different receptor. Both signaling pathways are required for GnRH neuronal migration.

At the level of a single gene/locus, genotype-phenotype correlations mapping allelic heterogeneity to phenotypic heterogeneity can provide detailed insight into how alterations in gene function affect disease severity. CAH caused by *CYP21A2* deficiency is a classic case. Several genetic variants including frameshifting deletions, splice site alterations, and missense mutations have been identified (see Chapter 24) in *CYP21A2*. This spectrum of alleles has been mapped to a biochemical spectrum of 21-hydroxylase enzyme activity, which in turn maps to a spectrum of clinical features along the axes of mineralocorticoid sufficiency, androgen excess, and ACTH elevation (see Chapter 24). In this disorder, it is possible to make predictions about clinical phenotype (categorized as salt wasting, simple virilizing, and nonclassic) based on genotype. Notably, the positive predictive value (PPV, the strength of the genotype-phenotype correlation) is strongest for variants that severely affect *CYP21A2* gene function and are predicted to cause severe disease (salt wasting, PPV ~100%). Predictive power is weaker for genetic variants that are expected to have more moderate effects on gene function and therefore result in milder disease (nonclassic, PPV ~60%). Some of this complexity is due to the potentially compensatory 21-hydroxylase enzyme activity of *CYP2C19* and *CYP3A4*, a form of gene-gene interaction. Genotype-phenotype correlations must be established empirically and are not possible in many cases. Even when mutations of varying molecular severity are identified, they may not predictably affect phenotype. For example, many individuals with genetic variants in the *SRD5A2* gene (encoding 5α-reductase type 2) of differing molecular severity and location have been identified (see Chapter 24), but no correlation between the genotype and the clinical degree of virilization is apparent.

A second example of synergy between NGS and classical genetic study design revealed gain-of-function mutations in the *KCNJ5* and *CACNA1D* genes as causes of hyperaldosteronism.[15,16] By sequencing exomes in a series of aldosterone-producing adenomas from individuals with primary hyperaldosteronism (Conn syndrome), investigators identified missense mutations in the *KCNJ5* gene in about one-third of tumors from unrelated individuals. They also identified a separate *KCNJ5* missense mutation in a mendelian family with hypertension, primary hyperaldosteronism, and massive adrenal hyperplasia (familial hyperaldosteronism type 3; see Chapter 16). Follow-up biochemical and electrophysiologic studies showed that this series of somatic and inherited missense mutations eliminated ion selectivity in the *KCNJ5* gene product, a potassium channel. The increased sodium conductance through these mutant channels caused membrane depolarization of adrenal cortical cells in the zona glomerulosa, stimulating aldosterone release and cell proliferation.

As demonstrated previously, modern genome sequencing technologies facilitates the identification of pathogenic mutations. Translation of mutations into a disease mechanism, however, requires relevant experimental model systems and close correlation with human phenotype. PHP1a (see Chapter 29) with gonadotropin-independent sexual precocity provides a classic example of the iterative relationship between mutations, human phenotypes, and laboratory experiments. Some individuals with PHP1a harbor the Ala366Ser missense mutation in a stimulatory G protein (G_s). This mutation destabilizes the protein, causing loss of function in most body tissues and thus hormone resistance. But these mutation carriers also exhibited paradoxical testotoxicosis consistent with gain of function in G_s. The paradox of the same mutation causing both loss and gain of function was

resolved with a series of experiments showing that the Ala366Ser mutation caused a temperature-sensitive effect physiologically relevant to the normal temperature for Leydig cells. In most body tissues maintained at 37° C, the mutant G_s protein was destabilized, whereas in Leydig cells (within the testes, maintained at a 3–5° C lower temperature), the mutant G_s demonstrated increased activity. Elucidating this mechanism required an appreciation of the discordant phenotype (testotoxicosis) and biochemical characterization in the relevant physiologic system (Leydig cells at a lower temperature).

Clinical Translation

Target discovery, risk prediction, and the tailoring of pharmacotherapy based on genotype are potential clinical applications of genotype-phenotype correlation. The existence of loss-of-function and gain-of-function variants in an allelic series and their concordance with opposing phenotypes can provide a rationale for therapeutically modulating gene function.[17] For example, inactivating mutations in the KISS1R receptor cause hypogonadotropic hypogonadism, whereas an Arg386Pro missense variant in *KISS1R* is associated with central precocious puberty. Kisspeptin, the agonist ligand of the KISS1R receptor, has shown promise as a fertility treatment.[18]

Genotype-phenotype correlation can be used to predict risk of disease in asymptomatic carriers. Prior to the identification and cloning of the *RET* proto-oncogene, MEN2 kindreds were monitored for evidence of medullary thyroid cancer (MTC) by calcitonin stimulation tests. Once mutations in *RET* were established as causing MEN2A/B and familial MTC, it became apparent that specific mutations could be mapped to the different syndromes. The *RET* gene product encodes a cell surface receptor tyrosine kinase. Mutations in the extracellular domain predispose to MEN2A (characterized by MTC, pheochromocytomas, and hyperparathyroidism), whereas mutations in the intracellular tyrosine kinase domain predispose to MEN2B (characterized by MTC, pheochromocytomas, and mucosal neuromas) (see Chapter 42). The clinical aggressiveness of MTC, the sine qua non of all three syndromes, is greatest in MEN2B, then less in MEN2A, with familial MTC demonstrating the least propensity to grow and metastasize. A well-defined genotype-phenotype correlation between specific *RET* mutations and clinical aggressiveness of MTC now dictates the timing of lifesaving prophylactic thyroidectomy in carriers of *RET* mutations.[19] The key to establishing clinically robust risk prediction based on genotype-phenotype correlations is a well-differentiated allelic series derived from multiple individuals/families. The consensus genotype-phenotype correlation for prophylactic thyroidectomy in *RET* mutation carriers was derived from analysis of more than 200 individuals from more than 100 families (see Chapter 42).

A genetic diagnosis in several mendelian disorders can also directly inform pharmacotherapies. A classic example includes obesity caused by leptin deficiency (see Chapter 40), which can be treated by exogenous leptin injections. Other examples include *HNF1A* MODY (maturity-onset diabetes of the young) and neonatal diabetes (discussed in detail later) caused by genes whose properties predict excellent response to sulfonylureas. In the case of congenital hyperinsulinism, autosomal recessive mutations in *ABCC8* or *KCNJ11* correlate with diffuse disease on spectroscopic imaging and lack of responsiveness to medical therapy (diazoxide); such individuals require near-total pancreatectomy for control of hypoglycemia.[20]

Type 2 Diabetes

Genetic Architecture

Type 2 diabetes (T2D) is a multifactorial, polygenic disorder for which manifestation depends on multiple interacting genetic and environmental risk factors. Heritability estimates show strong evidence of familial clustering, ranging from 40%[7] to 80%.[8] Approximately 5% of diabetes cases that may be classified as nonautoimmune arise from a single-gene disorder, follow mendelian patterns of inheritance, and cluster into clinically defined syndromes. These mendelian diabetes syndromes include neonatal diabetes, MODY, and congenital lipodystrophies.[21] To date, familial linkage studies have successfully implicated approximately 30 genes as monogenic causes of diabetes.[22]

The genetic factors underlying the majority of T2D cases (95% of cases) fit a polygenic model; genetic variants in multiple genes independently contribute to disease risk, each with a modest effect. The partial elucidation of these genetic risk factors required the advent of genetic association studies/GWASs and the assembly of cohorts of thousands of cases and control subjects.[23] As of 2014, about 70 loci have been identified from aggregated analysis on about 150,000 case controls. Taken together, these loci account for about 6% of heritability for T2D.[23] Of these loci, an SNP at *TCF7L2* (with the risk-increasing allele present at a frequency of ~30%) has the largest overall effect on risk, conferring a 1.4-fold increase in risk per allele.[23]

By contrast, type 1 diabetes shows a somewhat different genetic architecture, with common loci of large effect (a variant at the *HLA* locus found in 61% of the population confers a fivefold increase in risk,[24] and a common variant at the insulin gene confers a threefold increase in risk). This finding was consistent with prior studies from the 1980s estimating that 50% of the heritability of type 1 diabetes was explained by common haplotypes at the *HLA* locus.[25,26] Notably, the genes implicated in monogenic causes of diabetes also contribute to polygenic forms but through distinct genetic variants. Genes associated with mendelian diabetes syndromes, such as *KCNJ11* (neonatal diabetes), *HNF1A* (MODY2), and *PPARG* (familial partial lipodystrophy 3),[27] were found to harbor common variants that conferred risk for common T2D.[21,28] Conversely, genes first found associated with diabetes through GWASs have subsequently been identified as having rare, highly penetrant alleles. For example, noncoding common variants pointed to the *MTNR1B* gene (encoding the melatonin receptor) as a T2D-associated locus (1.15-fold risk).[29] Subsequently, large-scale resequencing studies identified multiple, rare coding variants of the same gene (present in <1:1000 individuals) that conferred a greater than fivefold increased risk of T2D.[30]

Mapping studies performed across various populations reveal both similarities and differences in the genetic risk factors contributing to diabetes among different ancestral groups. T2D GWASs performed in multiple populations/ancestries (European, South Asian, East Asian, Latino, African American)[31] reveal that many common variants are shared across populations with equivalent effects on disease risk, regardless of ancestry. This pattern is consistent with the origin of most common variants in an ancestral African population (see Table 3.3), but remarkable ancestry-specific effects have also been identified. A T2D GWAS performed in individuals of Latino and Mexican ancestry identified a common SNP at a locus containing the genes *SLC16A11/13* that confers a 1.25-fold increased risk of diabetes.[32] The same locus was identified by

another T2D GWAS performed in Japanese individuals.[33] Because the associated SNPs were rare in Europeans, the locus had not been detected in GWASs in European-ancestry populations. Similarly, a common variant in *TBC1D4* in individuals from Greenland (present in 17% of Greenland's population) strongly increases risk of T2D (10-fold increased risk).[34] This variant, which causes a premature truncation and is associated with elevated muscle insulin resistance, is extremely rare in continental Europe and likely became common in Greenland because it was present in the founding ancestors of Greenland's current population.

In summary, genetic mapping studies over the past three decades have revealed a genetic architecture for T2D with widespread locus and allelic heterogeneity. With regard to effect size and allele frequency, T2D genetic architecture so far consists of some very rare variants of large effect, some common variants with small to moderate effects (1.2- to 1.5-fold increased risk), and a larger number of common variants with even more modest effects on disease risk, with rare and common genetic variants spread out across multiple loci in the genome. This genetic architecture has proved to be typical for other common diseases[24] (see Fig. 3.2) and reflects both the underlying genetic architecture of the disease and the ability of large GWAS to more readily detect common variants of modest effect.

Disease Biology

The past three decades of genetic discoveries in T2D have nucleated a molecular understanding of disease mechanisms, highlighted differences between glycemia and T2D, and implicated previously unknown physiology in disease pathogenesis.

Supporting the current physiologic conception of T2D as a disorder of decreased insulin production, as well as decreased insulin sensitivity, genetic mapping has pointed to a molecular basis for both axes. Prediabetic individuals harboring T2D-associated variants in beta-cell genes (*SLC30A8*, *HNF1A*) and cell survival genes (*CDKAL1*) manifest with decreased insulin secretion (homeostatic model assessment B; see Chapter 34).[28] However, prediabetic individuals harboring T2D-associated variants in adipocyte genes (*PPARG*, *KLF14*) tend toward increases in homeostatic model assessment insulin resistance (see Chapter 34).[28] About 30% of T2D-associated SNPs point to insulin secretion/beta-cell function, and 15% point to insulin resistance.[22] Interestingly, the SNPs associated with insulin secretion in prediabetic individuals predict incident T2D, but the SNPs associated with insulin resistance do not.[35] These findings from genetic epidemiology are consistent with beta-cell failure being a final common pathway for manifestation of hyperglycemia and diagnosis of T2D. Importantly, more than half of the associated SNPs and the genes they point to cannot be connected with either insulin secretion or sensitivity. Their pathogenic mechanisms remain to be elucidated by physiologic and functional investigation.

Even without a full understanding of their molecular/cellular mechanism of causation, the large number of T2D-associated loci (~70 as of 2014) have been deployed to refine disease classification. By examining quantitative glycemic traits (insulin production, sensitivity, processing, and fasting glucose) in nondiabetic individuals genotyped for 37 T2D-associated common genetic variants, investigators were able cluster genes with glycemic traits to define unique diabetes subtypes.[36] For example, individuals harboring variants in *MNTR1B* and *GCK* manifested a combination of fasting hyperglycemia and decreased insulin secretion, whereas those harboring variants in *SLC30A8*, *CDKN2A/B*, *TCF7L2*, and other genes manifested primarily with decreased insulin secretion. Notably, many genes did not cluster with predefined glycemic traits, again suggesting that the current physiologic description of T2D remains incomplete.

Genetic mapping has also corroborated the epidemiologically identified intersection between T2D and obesity. An SNP in the second intron of the *FTO* gene was identified in parallel in GWASs for T2D [37] and obesity.[38-40] The association signal for T2D entirely disappeared with correction for body mass index (BMI), indicating that this SNP increased T2D risk by increasing BMI. Interestingly, this locus illustrates some of the difficulties in proceeding from GWAS signal to function. Although this SNP was initially thought to exert its effect on BMI by affecting *FTO* gene function, detailed mechanistic studies have revealed that it may function by altering expression levels of *IRX3*, a gene over a million bases away.[41] Although initial studies in mice showed that increasing *Fto* gene dosage increased food intake leading to increased fat mass,[42] no connection has been found between the disease-associated SNPs and *Fto* expression level or function.[43]

Even more recently, splice acceptor variants that generate premature stop codons and loss of function in *ADCY3* (a gene highly expressed in visceral adipose tissue) has been identified as causal for increased BMI and T2D risk. Concordant functional studies in mice with loss of function causing obesity, hyperphagia, and insulin resistance suggest that ADCY3 may be a new therapeutic target.[44]

Whereas T2D is diagnosed on the basis of hyperglycemia, genetic mapping has revealed that the genes that determine fasting glucose are partly distinct from those that are associated with T2D. Comparison of GWASs performed for blood glucose levels in nondiabetics versus T2D case-control studies revealed that glycemia and T2D have distinct genetic associations.[45] Some genes harbor variants that increase blood glucose levels and T2D risk, whereas others alter blood glucose levels but do not confer T2D risk. Thus, the two phenotypes have both common and distinct biology. Additionally, it is important to bear in mind that the genetic basis for surrogate measures of glycemia do not always point to genes specifically altering glycemic physiology. A particularly salient example is the association of hexokinase 1 (*HK1*) with hemoglobin A_{1c} levels but not with fasting or dynamic glycemia.[46] It is thought that the genetic variant in *HK1* alters hemoglobin A_{1c} levels as a result of the alteration of the red blood cell life span and anemia.[46]

Clinical Translation

The principle of genetics pointing to important therapeutic targets in T2D is well validated. Both rare and common genetic variants link *PPARG*, the drug target of thiazolidines, to syndromic and common T2D.[27] Similarly, rare variants in the sulfonylurea receptor (encoded by *ABCC8*) cause neonatal diabetes.[47] Although these oral hypoglycemics were identified in a pregenetic era, they point to an optimistic future of genetically guided drug discovery, one that will require detailed mechanistic understanding of the genes mapped by studies to date. A particularly attractive target nominated by genetics is *SLC30A8*, a gene that encodes a zinc transporter expressed almost exclusively in the endocrine pancreas (ZnT8). The common R325W missense variant in the protein encoded by the *SLC30A8* gene (present in ~1:3 individuals in most continental populations) was found to associate with protection from T2D (1.18-fold decreased risk).[48] Rare, protein-truncating variants in *SLC30A8* (present in ~2:1000 individuals) have also been associated with protection from T2D with a larger effect size (2.6-fold decreased risk).[49] The finding of human

heterozygous knockouts for *SLC30A8* who are protected from T2D and have no other deleterious phenotype offers a tantalizing therapeutic hypothesis that a chemical or antibody inhibitor of *SLC30A8* could treat diabetes and minimize side effects.

In the arena of risk prediction, genetics has not yet made a major impact on T2D because existing clinical risk factors already predict disease well. Common genetic variants, by virtue of their relatively high frequency, can explain a large part of heritability for a trait/disease but have small effects on the individual. For example, the common P12A variant in PPARG is associated with 1.25-fold risk of T2D.[50] Based on the high population frequency of the risk variant (85% P), if one were to theoretically substitute every P to A in the population, 20% of diabetes would be eliminated. Despite this incredible population-attributable risk, any given individual carrying the P variant only has a 25% increased risk of diabetes when compared with someone carrying the A variant. Given the high population frequency of common variants, many disease susceptibility variants are found in the same individual, each of which confers modest increases in risk. The progressive accessibility of genome sequencing makes it feasible to ascertain all known risk-conferring variants in an individual at once and combine these for potentially more clinically meaningful risk prediction. Investigators have attempted to combine common variants into a genetic risk score with modest success. For T2D, a risk score combining 18 common variants (including *PPARG* P12A) demonstrated 2.6-fold elevated risk in the high-risk versus low-risk group.[51] By contrast, simply reporting a family history of diabetes increases risk by threefold to sevenfold.[52]

Tailoring pharmacotherapy based on genotype has been successful in monogenic diabetes; the genome-sequencing era promises to bring this benefit to a wider group of individuals. The classic example of genotype guiding pharmacotherapy is that of individuals with MODY2 caused by autosomal dominant mutations in the *GCK* gene. Such individuals meet diagnostic criteria for diabetes but are able to regulate glycemia at a higher set-point, thus avoiding all secondary complications (see Chapter 35). Thus, a genetic diagnosis of *GCK*-related diabetes can allow such individuals to avoid pharmacotherapy. Individuals with permanent neonatal diabetes caused by *ABCC8* or *KCNJ11* mutations can be safely treated with high-dose sulfonylureas in place of insulin.[53,54] It is likely that individuals with functional mutations in *ABCC8* or *KCNJ11* will be found who do not present with the classic neonatal syndrome and are classified as common T2D but who may still respond preferentially to sulfonylureas. Proving this prediction will require identifying such individuals and performing prospective clinical trials. Prospective genotype-based intervention trials have been performed in individuals with MODY3 caused by *HNF1A* mutations and have shown the superiority of sulfonylureas over metformin.[55] Interestingly, exome sequencing of Latin American T2D case-control groups revealed the *HNF1A* E508K variant, previously annotated as MODY3, as conferring a fivefold risk of T2D in approximately 1:1000 individuals. These data demonstrate that the E508K is not fully penetrant; nevertheless, the individuals who carry it may still benefit preferentially from sulfonylurea treatment, as do their counterparts with clinically defined MODY3.

Large-scale sequencing of the known monogenic diabetes genes has uncovered many novel protein-coding variants; these present both an opportunity for pharmacogenetics and a challenge. As a case in point, sequencing of *PPARG* in approximately 20,000 T2D case controls identified 49 rare protein-coding variants. Three of the 49 had ever been identified before, were known to cause loss of function, and had been associated with mendelian lipodystrophy[56]; 46 variants were novel and of unknown function. Functional testing of each of the variants with respect to their ability to rescue adipocyte differentiation revealed nine of the novel variants causing loss of PPARG function, with the rest being indistinguishable from wild type.[56] The variants causing loss of function conferred a sevenfold increased risk of T2D, whereas the wild-type–like variants conferred no additional risk of T2D. To address the challenge of interpreting novel protein-coding variants at the scale they are being discovered (1:500 individuals in the general populations carry a rare protein-coding variant in *PPARG*) and which ones might be amenable to pharmacotherapy, investigators applied synthetic biology and high throughput sequencing to synthesize and functionally test all possible (~10,000) protein-coding variants in *PPARG*.[57] Using the resulting "lookup table" for PPARG function, clinical investigators identified two PPARG mutations (R308P and A261E) in patients affected by diabetes and partial lipodystrophy and demonstrated in vivo responsiveness to thiazolidinediones.[58] These studies demonstrate a proof of concept for the use of genetic information and high throughput functional characterization to guide pharmacotherapy in other monogenic disease genes.

Short Stature

Genetic Architecture

Adult height is a polygenic quantitative trait with a heritability of 80%.[6] Many mendelian syndromes manifest (see Chapter 25) large phenotypic variations in stature, and more than 150 genes are associated with monogenic short stature or overgrowth. The effect sizes for these rare, highly penetrant alleles are typically large, up to 300 mm (with 1 standard deviation [SD] for height equal to 55–60 mm). The genetic factors underlying most of human height variation are polygenic. GWASs aggregating more than 690,000 European samples have identified more than 3290 independent loci associated with height[59] through common variant association. Common variants account for about 60% of heritability.[59,60] The effect sizes for these common alleles are in the range of <1 to 15 mm (<0.02–0.20 SD). Taken together, these genetic mapping studies show that the genetics of height consists of the additive effects of common alleles with modest individual effects except in very short individuals (>2 SD below the mean).[61] In extremely short individuals, it is likely that rare alleles of large effect play a larger role.[61] Many of the genes (more than expected by chance) in height-associated loci identified by GWASs contain rare monogenic alleles. These height-associated genes frequently also harbor common alleles that contribute to polygenic stature variations.[59] A classic example is *GH1* (isolated GH deficiency 1a; see Chapter 25). This substantial overlap suggests that the genes in associated loci that have yet to demonstrate rare, large-effect alleles may be prime candidates for resequencing studies to discover new monogenic causes of alterations in stature.[62]

Genetic causes of short stature include Turner syndrome, mutations of the GH/insulin-like growth factor (IGF) pathway, and SHOX mutations. Previous GWASs have identified 700 common variants that explain approximately 20% of height variation in the population, with an additional 1.7% caused by rare coding variants. After excluding environmental factors such as nutrition, the cause of 60% to 80% of height variation remains unknown, but much of it likely is attributable to common variants that have not yet been identified as associated with height.[62] Short stature, but not tall stature, has been associated with deletions in the genome.

By systematically comparing CNVs across the genomes of more than 4000 individuals with developmental delay and congenital abnormalities with 7000 population-based control subjects, investigators observed that individuals with short stature harbored an excess number of low-frequency (found in <5% of the population) deletions.[63] Individuals in the cohort clinically diagnosed with short stature demonstrated an average loss of 900,000 bp from their genomes.[63]

In summary, the genetic architecture of height is consistent with classical theory and animal models[64] for a polygenic, quantitative trait: thousands of genetic variants in hundreds of genes contribute to the genetic variability in height. Most of the genetic variation in height (97%) occurs from the additive effects of common variants, each contributing a modest effect. Rare variants of large effect often causing mendelian syndromes cluster at the short extreme of height variation.

Disease Biology

Genetic mapping of genes influencing both normal variation and the extremes of stature have revealed diverse molecular pathways operating in multiple tissue types that work through both endocrine and cell-autonomous mechanisms.

Genetic mapping in individuals with low GH levels and short stature have delineated multiple components of the GH/IGF1 axis as a key endocrine pathway in human height regulation (see Chapter 25). These components include hormones, their receptors, binding proteins, and intracellular signaling proteins, such as GH1, GH receptor (GHR), GH-releasing hormone receptor (GHRHR), STAT5B, IGF acid-labile subunit (IGFALS), IGF1, and IGF1 receptor (IGF1R). IGF bioavailability varies according to its association with IGF binding proteins including IGFBP3. Recent WES in two families with short stature and microcephaly revealed the critical role of PAPP-A regulation in IGF signaling. PAPP-A is a metalloproteinase that cleaves IGF binding proteins to release the active hormone near IGF receptors. Inherited homozygous loss-of-function mutations in PAPP-A resulted in progressive growth failure in several family members despite elevated total circulating IGF.[65] A subsequent meta-analysis of exome array association data for height identified low-frequency coding variants in *STC2* (Stanniocalcin-2) with profound effects on height. STC2 covalently binds and inhibits PAPP-A.[66] Rare missense mutations in *STC2* decrease PAPP-A binding, resulting in increased PAPP-A activity, increased IGF availability, and an associated average 2 cm height increase. The same study identified rare *AR*, *CRISPLD2*, and *IHH* gene mutations, all of which decreased average height by approximately 2 cm. Remarkably, these rare IGF pathway gene variants have effect sizes that are often greater than 10 times the magnitude of common height variants.[67]

Genetics has also pointed to the importance of the pituitary gland as a key endocrine organ regulating height, as mutations in genes that encode transcriptional regulators of pituitary development, such as *HESX1*, *PITX1*, *PITX2*, *PROP1*, *POU1F1*, and *LHX3*, also lead to short stature when mutated in humans.[68] At the paracrine and cell-autonomous levels, genetic mapping has highlighted the importance of cellular proliferation, extracellular matrix deposition, and cartilage/bone development. These cellular processes were first implicated by monogenic short stature syndromes caused by mutations in genes such as *FGFR3* (achondroplasia) and *SHOX* (Langer mesomelic dysplasia) or tall stature syndromes, such as *FBN1* (Marfan syndrome) and *EZH2* (Weaver syndrome).

GWASs for height as a polygenic trait, combined with systematic clustering of genes in associated loci, have refined and expanded insights gained from mendelian genetics. Common variants associated with multiple members of the GH/IGF1 axis demonstrate the importance of this pathway in height regulation within the normal range.[69] The association of TGF-β itself and of its binding proteins, LTBP1 through LTBP3, complements the finding of *FBN1* mutations in Marfan syndrome in highlighting TGF-β signaling.[70] Similarly, the FGF signaling pathways are also highlighted, as common variants near *FGF4* are associated with height, complementing the finding of monogenic mutations in *FGFR3* causing achondroplasia. Clustering of GWAS-associated genes has also implicated hedgehog signaling (*GLI2*, *LAMA5*), Wnt signaling (*CTNNB1*, *FBXW11*, *WNT4*, *WNT5A*), and mammalian target of rapamycin (mTOR) signaling (*SMAD3*, *MTOR*) cascades in genetic control of height. Many associated loci do not cluster with the pathways above or other known tissue/cellular processes such as bone/cartilage formation, implicating previously unknown biology in height regulation. A notable example is the microRNA cluster *MIR17HG*, which was also identified as a syndromic cause of short stature.[71] By cross referencing GWAS-associated genes with gene-expression microarrays from thousands of human tissue samples, investigators have found that height-associated genes are predominantly expressed in the growth plate and to a lesser extent in cartilage, bone, and endocrine organs.[59,72]

Clinical Translation

Gene mapping and functional characterization in monogenic stature disorders have motivated therapeutic advances for diseases of overgrowth and short stature. A classic example is that of Marfan syndrome, in which excess TGF-β signaling resulting from the effects of disruptive mutations in *FBN1* has led to the development of TGF-β antagonist therapies.[73] Human trials of the angiotensin receptor blocker losartan, which exhibits TGF-β antagonist properties in in vivo preclinical models, were begun in cohorts of Marfan syndrome patients.[74] Results 3 years after treatment showed a decrease in aortic root diameter but not more so than conventional therapy with β-blockers.[75] The identification of the activating G380N mutation in *FGFR3* that causes 95% of achondroplasia has motivated the development of inhibitors of the tyrosine kinase activity of *FGFR3* through small molecules,[76] as well as through analogues of C-type natriuretic peptide.[77]

Due to the magnitude of its effect on height, *STC2* represents an intriguing novel therapeutic target for short stature and IGF-associated disease. Transgenic STC2 overexpression in mice causes severe postnatal growth retardation that is abolished when STC2 is replaced with a mutant protein lacking the ability to bind PAPP-A. STC2 overexpression may treat IGF excess in conditions including acromegaly and malignancies while knocking down STC2 with siRNA may help promote growth to treat short stature.[66,78] The diagnosis of short stature is an important application of genetic testing, particularly in pediatric populations. For example, the genotype-phenotype correlation of *SHOX* deficiency shows a clinical spectrum ranging from homozygous loss-of-function mutations causing the severe syndrome Langer mesomelic dysplasia to heterozygous defects found in patients with milder syndromic disease (Léri-Weill dyschondrosteosis, Ullrich-Turner syndrome) or idiopathic short stature.[79] Genetic diagnosis qualifies these patients for GH therapy. Genetic diagnosis also enables directed screening for comorbid conditions. For example, males with the likely underdiagnosed 3-M syndrome

(caused by mutations in *CUL7*, *OBSL1*, or *CCDC8*), clinically defined by severe postnatal growth retardation, characteristic facies, and radiographic findings of skeletal abnormalities, are at high risk of primary hypogonadism and need to be monitored.[79] Similarly, individuals with short stature secondary to Noonan syndrome are also often underdiagnosed and are at higher risk for cardiac disease.[80] Recent work added WES to targeted genetic testing to test whether sequencing would substantially improve genetic diagnosis. Of 565 patients with short stature referred for genetic evaluation, targeted genetic testing revealed the underlying genetic etiology in 13.6% of patients. Of the remaining 491 patients without a known diagnosis, 200 underwent WES, and a variant in a gene known to cause short stature was found in an additional 16.5% of patients in this population, suggesting that adding WES can increase diagnostic yield.[62] Genetic diagnosis could improve care for short stature by facilitating early identification and intervention prior to puberty and growth plate closure, screening for known comorbidities associated with the diagnosis, and potentially predicting the efficacy of interventions such as GH therapy.

Tailoring pharmacotherapy based on genotype can be a useful adjunct to biochemical testing in monogenic stature disorders. Physiologic stimulation and serum biochemistry are the gold standards for assessing GH sensitivity and resistance guiding its pharmacologic use. But genetic information plays an important role in solidifying diagnoses suggested by biochemical testing and suggesting alternative pharmacologic therapy. For example, children with defects in the GH receptor or post-GH receptor signaling (STAT5B) will be candidates for treatment with recombinant IGF1 (mecasermin).[81] Children with defects in IGFALS, a serum protein that stabilizes IGFs, respond poorly to both medications.[82] GH therapy is used to treat short stature arising from certain genetic defects outside the GH/IGF1 axis but is costly and not indicated in many others. Given the variable expressivity in many syndromic stature disorders, clinically distinguishing among syndromes presenting with short stature can be challenging and imprecise. Genetic diagnosis can resolve ambiguity, particularly in children before all the features of a syndrome are present. For example, GH is contraindicated in chromosomal breakage disorders. Bloom syndrome (caused by loss-of-function mutations in *BLM*, which encodes a DNA helicase) is one such disorder presenting with short stature. In the absence of genetic diagnosis with only clinical and biochemical testing, there are case examples of children being treated for years with GH until their clinical presentation evolved and Bloom syndrome was diagnosed.[83]

Lipids and Coronary Artery Disease

Genetic Architecture

Serum lipid levels are a complex polygenic trait significantly influenced by environmental factors such as diet. Heritability estimates suggest a large role for genetic factors: approximately 40% to 60% for high-density lipoprotein cholesterol (HDL-C), about 40% to 50% for low-density lipoprotein cholesterol (LDL-C), and about 35% to 48% for triglycerides (TG).[84] Monogenic disorders causing extremes of dyslipidemia have been associated with around 20 genes. Mendelian dyslipidemia syndromes can present with single or combined lipoprotein abnormalities (see Chapter 41). On the hyperlipidemic side, these abnormalities include syndromes of elevated LDL (familial hypercholesterolemia, sitosterolemia), elevated TG (lipoprotein lipase deficiency, APOCII deficiency), elevated HDL (CETP deficiency), and combined LDL/TG elevation (familial combined hyperlipidemia, dysbetalipoproteinemia). Monogenic disorders manifesting with extremely low lipid levels have also been identified and include low LDL (familial hypobetalipoproteinemia, *PCSK9* mutations), low HDL (familial hypoalphalipoproteinemia, lecithin cholesterol acyltransferase deficiency, Tangier disease), and combined low cholesterol/TG (abetalipoproteinemia, chylomicron retention syndrome).

The genetic factors underlying most serum lipid variations are polygenic. GWASs aggregating approximately 200,000 multiethnic samples have identified more than 150 independent loci associated with serum lipids through common variant association accounting for about 15% of heritability.[85] The effect sizes of common variants on lipid levels range from less than 1 mg/dL to about 15 mg/dL (SNP rs964184 at *APOA1* and TG).[86]

Among the loci identified, many alter one of the lipoproteins identified, a few (*CETP*, *TRIB1*, *FADS1-2-3*, *APOA1*) alter all lipoprotein levels, and a subset alters various combinations of lipoproteins.[85] These overlaps are consistent with observations in mendelian disorders and corroborate the shared metabolism and lipoprotein constituents of LDL, HDL, and TG.

Many of the genes identified as monogenic causes of dyslipidemia also alter lipid levels in the general population through both common and rare variants. *LDLR*, encoding the LDL receptor, provides a case in point of how the allelic spectrum of genetic variation ranges from rare mendelian alleles to common small-effect alleles with effect sizes inversely proportional to variant frequency. Disruptive mutations (those that frameshift or prematurely terminate the protein) in *LDLR* like the ones found in familial hypercholesterolemia are found in 2:1000 to 7:1000 individuals and increase LDL levels by 150 to 200 mg/dL.[87] Missense variants that decrease function of LDLR in cell models are found in about 1:100 individuals and increase LDL levels by about 100 mg/dL.[88] A common intronic SNP in *LDLR* found in 1:10 individuals decreases LDL levels by 7 mg/dL.[86]

In summary, the genetic architecture of serum lipids consists of a full spectrum of rare and common alleles in hundreds of genes throughout the genome acting in a polygenic fashion. Different variants at the same locus, based on varying impact on gene function, can alter lipid levels in a broad range. Variant frequency in the population is inversely correlated with the magnitude of effect on serum lipid levels. Many loci have an impact on multiple lipoprotein levels simultaneously.

Disease Biology

Genetic mapping for lipid traits has a rich history of synergy with biochemical and physiologic investigation to reveal the molecular mechanisms of lipoprotein metabolism and its relationship to cardiovascular disease in humans.

Mendelian hyperlipidemia syndromes were the first to yield pathophysiologic insight, starting with Brown and Goldstein's classic studies showing that LDL failed to suppress HMG-CoA (3-hydroxy-3-methyl-glutaryl coenzyme A) reductase activity in fibroblasts from subjects with familial hypercholesterolemia.[89] Subsequent studies of families with severe hypercholesterolemia (*LDLR*, *APOB*, *ABCG5*, *ABCG8*, *ARH*, *PCSK9*) yielded insights into basic mechanisms of cholesterol absorption and biliary excretion and contributed to basic biologic understanding of receptor-mediated endocytosis, recycling, and feedback regulation.[90,91] The association between high LDL-C and increased rates of myocardial infarction (MI) was also noticed in these families and complemented by observations of low rates of coronary disease in families segregating unusually low LDL-C levels (familial

hypobetalipoproteinemia: *APOB*, *PCSK9*, *ANGPTL3*).[91] Epidemiologic association and the success of statin therapy in preventing coronary heart disease (CHD) extended the relationship of LDL-C and CHD to the general population,[92] as have common LDL-C–associated SNPs identified by GWASs.[86]

The large number of associated loci for LDL-C, HDL-C, and TG combined with clinical outcome data on population-size cohorts of genotyped individuals has enabled causality testing for epidemiologic associations with important public health consequences. Elevated HDL-C levels have been associated with protection from MI, but the causality of this association is controversial. Should public health efforts be made to raise HDL levels in the population? Should drugs that increase HDL-C levels continue to be developed after early clinical failures?[93] By leveraging common variants associated with HDL-C levels, the causality of HDL-C in heart disease can be tested using an approach called *mendelian randomization*.[94] As described earlier, genetic associations imply causality because genotype precedes phenotype, mitigating epidemiologic issues of confounding, bias, and reverse causation. Mendelian randomization can be conceived of as a clinical trial performed by nature in which the subjects are randomized at conception to genetic variants associated with a risk factor (e.g., SNPs increasing levels of HDL-C). The subjects randomized to genotype are assessed for the outcome (e.g., MI), and their relative risk for the outcome is compared in patient groups with and without the genetic variants in question.

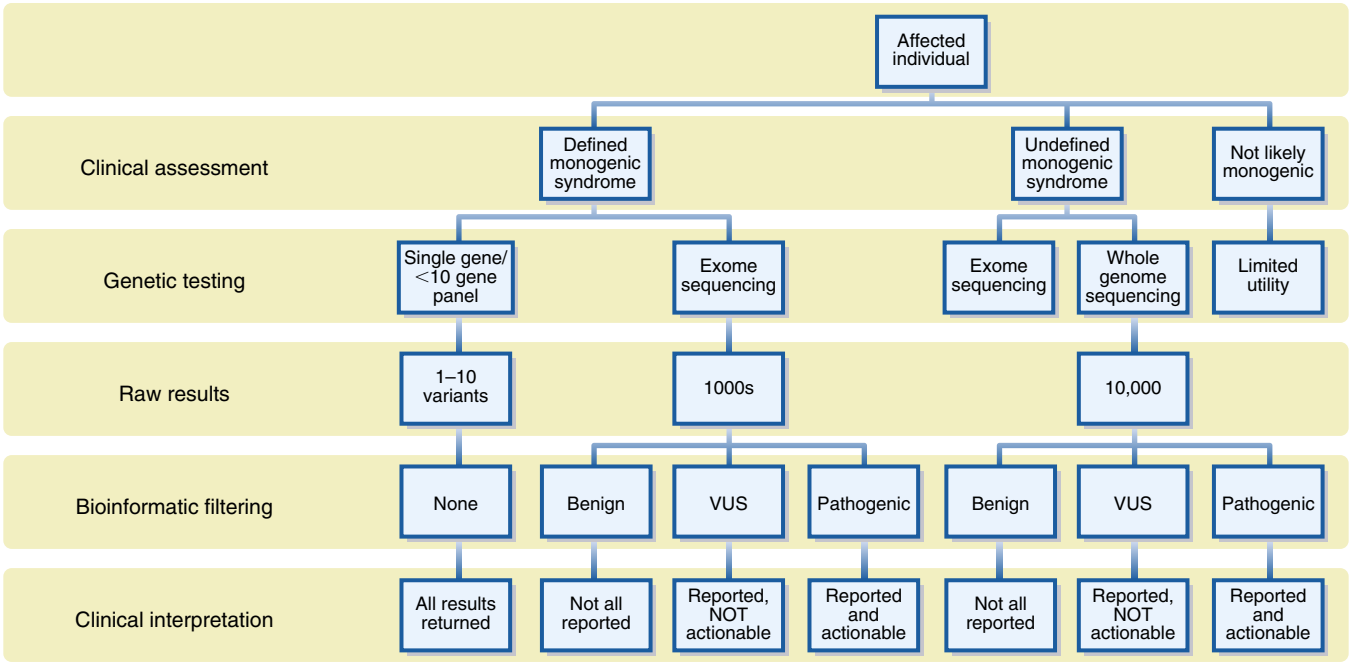
Although earlier observational studies showed a strong correlation between elevated HDL-C and CHD,[95] investigators tested the causality of this association using a mendelian randomization approach with SNPs quantitatively associated with lipid levels. They found that genetic variants increasing HDL-C were not protective for MI, whereas genetic variants decreasing LDL-C were protective of MI.[96,97] These findings are consistent with drug trials showing that LDL-C–lowering agents protect from MI, whereas multiple agents aimed at increasing HDL-C do not.[98] These results indicate that targets with support from human genetics are more likely to be clinically effective in humans.[99,100]

For TG, however, multiple lines of genetic evidence have supported a causal connection with CHD. First, rare, loss-of-function mutations in *APOC3* are associated with low levels of TG and are also protective for ischemic cardiovascular disease in European[101] and American cohorts.[102] Second, a mendelian randomization study showed that SNPs that raised serum TG levels also increased rates of CHD.[103] Finally, because of the interrelatedness of TG, LDL-C, and HDL-C, investigators have systematically examined all lipid-associated loci in cohorts phenotyped for CHD to dissect the contribution of TG to CHD risk apart from LDL-C and HDL-C.[85] By constructing a statistical framework to account for the pleiotropic effects of SNPs on all three lipoprotein levels, they demonstrated that (1) SNPs that alter LDL-C and TG in the same direction of effect are associated with CHD risk, (2) SNPs that exclusively alter TG levels are also associated with CHD, and (3) the strength of an SNP's effect on TG levels independently are correlated with the magnitude of effect on CHD risk.[85]

Clinical Translation

In the area of therapeutics, mapping of genes that affect lipid levels has exemplified a promising approach to drug target identification: genes that protect from disease when inactivated by nature might be useful pharmacologic targets. Statins, which inhibit HMG-CoA reductase (encoded by *HMGCR*), are among the most therapeutically successful drugs in lowering LDL-C levels and decreasing risk for CHD in both primary and secondary prevention settings. GWAS did identify *HMGCR* as a locus altering LDL-C levels (with an effect size of about 3 mg/dL),[86] but how would this particular locus be prioritized as a therapeutic candidate among more than 100 other associated loci? In some cases, experiments of nature (i.e., an allelic series) can be used to infer a dose-response curve of gene function that indicates how enhancement or suppression of the encoded protein's activity raises or lowers disease risk. In the well-known case of *PCSK9*, for instance, loss-of-function mutations decrease LDL-C and cardiovascular disease risk, whereas gain-of-function mutations increase LDL-C and cardiovascular disease risk.[104] Early clinical trials suggest that inhibiting the protein encoded by *PCSK9* is a promising strategy for lowering LDL-C and preventing cardiovascular disease.[105] Identifying genes that, when inactivated by nature, protect from disease offers several advantages for therapeutic targeting: (1) the target is already validated in humans, (2) designing inhibitors of gene/protein function is more tractable than increasing gene/protein function, and (3) nature has performed a lifelong clinical trial of inhibiting gene function, and the side effects of doing so are known. In the case of *PCSK9*, individuals with loss-of-function mutations demonstrated no phenotypic abnormalities other than low LDL-C levels and decreased risk of heart attack. In a similar example, naturally occurring mutations that disrupt *NPC1L1* function, the inhibitory target of ezetimibe, were found to be associated with reduced plasma LDL-C levels and a reduced risk of CHD.[106]

Genetic risk predictors of CHD based on lipid-associated loci alone have historically added little to the excellent risk prediction already provided by clinical risk factors, but recent work has shown significant promise in using combinations of SNPs to identify individuals at high risk. Working in the UK Biobank, investigators validated a polygenic risk score that contained SNP combinations conferring threefold risk in CHD, equivalent to the risk conferred by familial hypercholesterolemia. These high-risk polygenic combinations were identified in 8% of the study population, making them 20 times more prevalent than familial hypercholesterolemia. Given the broad indications for statins in primary and secondary CHD prevention,[107] genetics can help predict treatment efficacy and elucidate side effects. GWASs have identified a few reproducible loci (*APOE*, *LPA*, *SLCO1B1*, and *SORT1/CELSR2/PSRC1*) for the trait of LDL-C response following statin therapy.[108] *SLCO1B1* encodes the organic anion transporter, OATP1B1, which has been shown to regulate the hepatic uptake of statins.[109] When exposed to a single dose of simvastatin, individuals carrying a missense variant in *SLCO1B1* (V174A), which causes loss of function, have up to a 2.5-fold increase in plasma levels of statin.[109] A GWAS for statin-induced myopathy performed in a secondary prevention cohort receiving high-dose simvastatin identified the same genetic signal (via a noncoding SNP within the same haplotype) at *SLCO1B1*, which conferred a 4.5-fold risk of myopathy for one allele and a 16.9-fold risk of myopathy in homozygous individuals.[110] The investigators estimated that 60% of the myopathy cases in their cohort were due to this variant at *SLCO1B1*.[110] They performed a GWAS on only 200 case controls for myopathy, and it is likely that additional pharmacogenetically relevant loci like *SLCO1B1* will be identified in future studies with larger sample sizes. Several observational and intervention studies have also associated statin therapy with increased T2D risk. An important question is whether this risk is mediated by an off-target effect of statins or an on-target effect via HMG-CoA reductase. An off-target effect suggests that new,



• **Fig. 3.3** The suggested use of targeted and genome-wide genetic testing is shown in individuals suspected of harboring a monogenic/mendelian disease. *VUS*, variants of uncertain significance (see text).

more specific statins could be developed without this side effect, whereas an on-target effect implies that the development of more potent and specific statins would increase the risk of T2D. Genetics has begun to shed light on this question. Taking a mendelian randomization approach, investigators have found that SNPs at *HMGCR* that decrease LDL-C levels also increase BMI, insulin resistance, and risk for T2D, suggesting an on-target mechanism for statin-mediated T2D risk.

Considerations for Clinical Use of Genetic Information and Sequencing in Endocrinology

Generally speaking, medical application of laboratory testing requires three components. First, a validated test must be established with sufficient accuracy and precision for consistent measurement across testing centers and over time (clinical grade assay). Second, representative control populations of sufficient size must undergo testing to establish a normal clinical reference range. Third, mapping between test values and phenotypic outcome must be established using robust clinical studies. Ideally, these take the form of prospective randomized controlled trials. Expensive in their own right, these studies were prohibitive given early sequencing technology. NGS has provided the first requirement, furnishing high throughput, high-fidelity sequencing at an increasingly reasonable cost. The second requirement is currently under way. Genomics databases are growing around the world, providing a "reference range" for common gene sequences in healthy individuals.

As detailed previously, the clinical applications of genetic information include diagnosis, prognosis, risk prediction, and personalized therapy (e.g., pharmacogenetics). With the barriers of cost and feasibility diminishing every year, we believe that the use of genetic information will become commonplace in clinical practice. To maximize benefits to patients while minimizing the burden of false-positive and false-negative results, clinicians will have to select the right patients, deploy the appropriate genetic testing technology, and properly interpret the results. Specific clinical algorithms for patient/genetic test selection are being proposed for various endocrine diseases (e.g., short stature),[79] but they will take time to validate. With this in mind, we present a series of broad patient scenarios ranging from those with no clinically apparent disease to affected individuals with clinically identifiable genetic syndromes, summarizing benefits and caveats of genetic testing in each scenario. We subsequently review issues related to targeted and genome-wide testing and provide some guidance for patient and test selection. Finally, we provide an overview of disease-relevant classification of genetic findings, examine the interpretation of genetic information as presented in a clinical laboratory report, and make suggestions for clinical decision making (Fig. 3.3).

Genome Screening in the General Population

Population-based screening for mendelian mutations known to cause disease would seem to be an advantageous application of genome sequencing. As mentioned earlier, certain mutations in the *RET* gene predispose to aggressive MTC with such high penetrance that the American Thyroid Association recommends prophylactic thyroidectomy in infants under 1 year of age.[19] As genome sequencing becomes commonplace, it seems reasonable that genomes from the general population (e.g., as part of newborn screening) might be examined for *RET* mutations causing this rare but potentially fatal disease. Cases of cancer might be prevented and lives saved. However, one must consider that the clinical data on *RET* gene mutations have been obtained from kindreds affected by MEN2A/B and familial MTC (see Chapter 42). Are genotype-phenotype correlations between *RET* mutations and MTC, or between other gene mutations and the risk of other diseases, applicable to someone from the general population with no family history of disease?

An investigation of mendelian diabetes mutations ascertained in the general population suggests that genotype-phenotype correlations identified in mendelian disease families may not generally hold for the population at large. As a case in point, genome sequencing of a population-based US cohort phenotyped longitudinally for diabetes identified 25 individuals with mutations previously known to cause autosomal dominant diabetes (MODY). Despite harboring mutations from a curated catalogue of disease genes (Human Gene Mutation Database Professional[111]), only one of these individuals met the clinical criteria for MODY, and overall this group of MODY mutation carriers developed diabetes at a rate no different from that in the general population. As population-based sequencing becomes prevalent, it will become necessary to re-examine estimates of penetrance and genotype-phenotype correlations in the context of differing genetic backgrounds (e.g., ancestry) and environment. The current evidence and state of knowledge do not support genome sequencing for population-based screening.

Genetic Information and Sequencing in Individual Patients

Asymptomatic Individuals

Endocrinologists may be referred individuals with no apparent symptoms in whom risk of disease may be increased: (1) those with a family history of known genetic disease who have not yet been tested, and (2) those without family history who were tested and found with an apparently pathogenic mutation (i.e., a "genetic incidentaloma"). At present, this family history serves as a proxy for genetic predisposition or risk used to calculate pretest probability for screening. As with any medical test, the implication of genetic testing with regard to the likelihood of developing disease in the individual depends on a combination of inherent test characteristics (quantified by sensitivity/specificity) and the pretest likelihood of disease. For individuals with a family history of genetic disease, the pretest probability of disease can be as high as 1 in 2 for a highly penetrant autosomal dominant disorder or 1 in 4 for a sibling of an individual with a recessive disorder. Thus, for individuals with a family history of mendelian endocrine disease, genetic testing is often warranted (depending on the risks and benefits for the individual patient at hand, including psychosocial factors); this fits well with current clinical practice for asymptomatic individuals from families with mendelian disorders.

However, for individuals with no family history presenting with a mendelian-like "genetic incidentaloma," the pretest likelihood of disease is that of the population (1:10,000 to 1:100,000). Even with a mutation conferring 50-fold increased risk, the individual is far more likely to remain free of disease. So what reassurance can be offered to such individuals who carry mendelian mutations? Population-based sequencing surveys reveal that, on average, the genome of an apparently healthy individual contains approximately 100 mendelian-like disruptive mutations (i.e., frameshifting indels and SNPs resulting in premature stop codons), up to 20 of which are homozygously inactivated.[112] Thus, even the protein-coding portion of the human genome (comprising only 1–2% of the total genome) contains unexpected redundancy that protects from disease. Depending on the severity of clinical consequences and the estimate of penetrance in the general population, watchful waiting can be a prudent course of action.

Symptomatic Individuals

Individuals with symptomatic disease can present with clinically defined or unknown syndromes. In both cases, a genetic diagnosis can be of psychological benefit, inform family planning, and sometimes can direct therapeutic screening/intervention. NGS has the potential to improve diagnostic efficiency in these symptomatic individuals. Techniques including GWASs and WES shift the diagnostic workflow from a sequential search for candidate genes to parallel sequencing panels. By simultaneous testing a host of target genes, NGS avoids a lengthy process of diagnosis by exclusion. In addition, NGS panels can be designed to simultaneously ascertain second-order disease modifying mutations that are missed by classic sequential analysis.

The genotype-phenotype correlation of endocrine tumor syndromes (MEN1, MEN2; see previous discussion) are a classic example of the benefits of genetic diagnosis for directed screening and prophylactic interventions in both affected individuals and close relatives. For example, the genotype-phenotype correlation of *RET* oncogene mutations dictates the urgency of prophylactic thyroidectomy (ranging from <1 year old to >5 years old) in children.[19] Thus, even with a clinical diagnosis, genetic testing can have great prognostic value. Another example is the 3-M syndrome (clinically defined by short stature, facial dysmorphism, and skeletal abnormalities) caused by mutations in the *CUL7* gene (among others). Males with this syndrome are at high risk for hypogonadism and should be screened more vigilantly as a result of the genetic diagnosis to prepare for future infertility. Sometimes a genetic diagnosis can allow a patient to avoid lifelong treatment and testing. Individuals with diabetes from *GCK* mutations (MODY2) manifest hyperglycemia but are still able to regulate their blood sugar levels such that they neither require hypoglycemic therapy nor are at elevated risk for secondary complications of diabetes. More generally, and especially for heterogeneous endocrine diseases such as diabetes, genetic classification has the potential to guide pharmacotherapy. An existing example of genetically guided pharmacotherapy can be found in individuals with diabetes caused by *HNF1A* mutations. In clinical trials, these *HNF1A* mutation carriers were much more sensitive to sulfonylureas than noncarriers and maintained more durable glycemic control without additional agents.[55]

As in the cases described previously, genetic testing of affected patients is most likely to be informative when a high penetrance genetic variant is identified (i.e., for rare mendelian-type diseases). We offer the following criteria and mnemonic (SSSS), which should raise clinical suspicion for a mendelian disorder: (1) severe—more severe than usual for the disease; (2) segregating—multiple affected family members or family history of consanguinity; (3) syndromic—features such as dysmorphism, developmental abnormalities, and unusual biochemical phenotypes; and (4) too soon—early age of onset. The diagnostic yield of genetic testing is highly variable both due to technological reasons and underlying genetic (locus) heterogeneity. Even for well-described mendelian syndromes such as MEN1, 30% of kindreds have no identifiable mutations identified by *MEN1* gene sequencing. For affected individuals with unknown syndromes, or for whom targeted sequencing has failed to make a diagnosis, systematic gene sequencing using NGS methods would be required, and diagnostic yields are typically lower. A National Institutes of Health study of exome sequencing for rare disorders found a diagnosis in 20% of cases.[113]

Avoiding Invasive Diagnostics

As ultrasound, computed tomography, and magnetic resonance imaging continue to improve, the number of incidental endocrine findings also increases. NGS provides a tool to evaluate these

findings without resorting to invasive resections. Thyroid nodules present a classic diagnostic dilemma for the endocrinologist. Although most nodules are benign, fine-needle aspiration identifies 100,000 nodules with indeterminate cytology in the United States each year.[114] Several endocrine societies recommend surgical diagnosis via lobectomy or total thyroidectomy for indeterminate cases, although only 5% to 30% of these nodules prove to be malignant.[115] In these cases, genetic diagnosis may help reduce the need for surgery and lifelong thyroid replacement. A recent study applied genetic testing to 176 thyroid biopsies with indeterminate cytology. For these nodules, typical workup includes lobectomy, total thyroidectomy, or close observation. Instead, fine-needle aspiration biopsies were analyzed using NGS to check for mutations associated with thyroid malignancy. The resulting analysis demonstrated a specificity of 91% and prevented diagnostic hemithyroidectomy in 49 patients. Of 46 patients who presented for subsequent ultrasound follow-up, 45 had nodules that remained stable in size, and the exception was benign on repeat biopsy. Successful clinical application of genetic screening tools may thus save patients from the morbidity and cost of invasive surgical diagnosis.[116]

NGS can also help distinguish papillary thyroid carcinoma (PTC) from benign adenomatoid nodules. By analyzing patients with coincident benign nodules and PTC, Ye and colleagues were able to identify *BRAF* somatic mutations (22/32) that are only found in PTC, whereas mutations in *SPOP* (4/38), *ZNF148* (6/38), and *EZH1* (3/38) were enriched in adenomatoid nodules.[117] Several of the adenomatoid markers were found to be mutually exclusive, and phylogenetic tree analysis demonstrated that PTCs develop independently rather than progressing from adenomatoid nodules. This model reveals a distinct genetic origin for invasive thyroid neoplasms that differs from the progressive dysplasia evident in tissues such as colon. The data suggest that thyroid sequencing studies may rule out malignant potential in adenomatous nodules and reduce the need for further surveillance. In the future, specific genetic signatures may increase the specificity of aspiration biopsies and reduce the cost, care burden, and lifelong morbidity associated with thyroidectomy.[117]

Selection of Genetic Tests: Targeted Versus Genome-wide Approaches

If cost were no object, one might consider deploying whole-genome sequencing to maximize sensitivity and find the "smoking gun" mutation in every case. Using genome sequencing in this way is tantamount to performing thousands of genetic tests at once and clinically analogous to ordering every possible hormone level for every endocrine patient. Intuitively, this approach is not pursued because every test carries with it the possibility of false-positive results. The more tests one orders, the more likely at least one result will be false. The same logic applies to genetic tests and genome sequencing. Even if genetic variants are identified with 100% analytical sensitivity and specificity, their clinical sensitivity and specificity for disease risk are much less, due to incomplete penetrance, variable expressivity, and our incomplete knowledge of genotype-phenotype correlations.

Limitations of Genomic Testing

The molecular type of genetic variation (single-base changes or more complex variation, e.g., insertions/deletions/duplications) strongly affects the analytic sensitivity and specificity. The most commonly used gene-panel and genome-wide tests rely on NGS technology, which is currently well suited for detecting single or multiple base variations but poorly optimized for the detection of structural variants (chromosomal rearrangements), large indels, triplet repeat expansions, poly T and A sequences, novel breakpoints, and copy number variation.[118] For example, all false-positive genetic variants identified in a pilot clinical-grade genome sequencing study were indels or were near repetitive DNA stretches.[119] As NGS technology and genome reconstruction algorithms improve, so will the ability to accurately detect these more complex genetic variants, reducing both false-negative and false-positive results. Currently, alternative modes of testing, such as chromosomal microarrays (array CGH), are used to identify large (>50 kb) structural and CNVs.[120]

Even as technology addresses sequencing limitations, proper classification of gene variants limits deployment of sequencing in clinical practice. Recent data from the ExAC database focused on analysis of rare germline coding region, nonsynonymous, single-nucleotide variants (SNVs) in 38 endocrine disease genes. The study concluded that current variant prediction tools suffer from ascertainment bias and dependence on in silico pathogenicity prediction. Ascertainment bias results from dependence on studies that identified rare SNVs in disease cohorts. As genetic screening expands to the general population, the baseline prevalence of "pathogenic" SNVs must be validated in large healthy control populations. Again, a truly pathogenic variant should be enriched in affected individuals and absent in controls. At this stage, too many variants have been called *pathogenic* using disease cohorts without being appropriately excluded due to their presence in healthy controls. Meanwhile, in silico prediction for functional effects of mutations is much less robust for missense mutations than more dramatic frameshift and nonsense mutations. As a result of these two factors, genetic prediction models frequently misclassify benign variants as pathogenic, and the number of identified pathogenic gene variants far exceed reported disease prevalence. Several such examples emerge from the ExAC study in which individuals with mendelian disease are not included. For MEN1, apparently "pathogenic" missense mutations occur in 1:2000 individuals sequenced, whereas disease prevalence is 1:30,000.[121] Ultimately, healthy individuals carry a large number of misclassified "pathogenic alleles" initially identified as rare variants in individuals with disease. As genetic testing becomes more widespread, our definition of pathogenic variations and clinically actionable mutations will require increasing rigor.[121]

Targeted testing (either measuring variation in a requested set of genes or masking/only reporting back variation in the requested set of genes) is one solution to decrease false-positive results. In addition, clinical laboratories that focus on testing specific sets of genes may be particularly well versed in interpretation of variation in these genes, potentially improving sensitivity and specificity. Of course, when targeted testing is negative, then more comprehensive testing may be required to make a diagnosis. However, even beyond the issue of false-positive findings, targeted testing may offer superior analytic performance. Detection of variants can be highly variable in current versions of genome-wide sequencing, in which millions of genetic variants are identified simultaneously.[122] There is often a trade-off between the number of variants identified and the sensitivity/specificity for detecting and calling any individual variant. This analytic sensitivity/specificity relates to coverage, which is the depth of sequencing performed, or the number of independent times a particular nucleotide has been sequenced in a single test. Depth can vary greatly across the genome. For example, a clinical trial of whole-genome sequencing reported clinical-grade genome sequencing at "30× coverage on

average and at least 8× coverage for more than 95% of bases."[119] This means that of the 3 billion bases in the human genome, each base was sequenced independently 30 times on average, and more than 95% of bases were observed at least 8 times. However, 5% of the human genome was still poorly observed or missing. Thus, if clinical suspicion motivated examination of certain genes or genomic regions, a targeted approach might well have higher analytic sensitivity and specificity. The clinical-grade genome described previously is sufficient for detecting variants at a frequency found with germline heterozygosity (on average 50% of the molecules sequenced would contain the variant base), but for disorders requiring detection below germline heterozygosity, such as somatic mutation testing in tumors, higher coverage would be required.

Interpretation of Identified Genetic Variants

Once genetic variants are identified (from sequencing or otherwise), they must be interpreted for their impact on health and disease. This interpretation requires the integration of population data (to know whether a variant is seen at higher frequency than expected for a pathogenic variant), computational predictions, experimental evidence, and familial comparisons. Curated databases are being established to begin to accurately catalogue this information and assist in interpretation. The ClinVar archive aggregates information about genomic variation and its relationship to human health.[123]

Identified variants can be classified into three broad clinical categories: benign variants, pathogenic variants, and variants of uncertain significance (VUS), but intermediate categories have also been proposed.[124] In single-gene or disease-targeted testing, the number of identified variants is small enough to allow for the individual assessment of all variants in each patient, once common benign variations are curated. However, exome sequencing identifies tens of thousands of variants, and genome sequencing identifies several million in each individual.[125] Thus, automated filtering is necessary to point out a few pathogenic variants in a haystack of benign ones. Based on the assumption that the testing was done for a mendelian variant with high penetrance, most genetic variants can be filtered as benign based on having been observed at a frequency greater than 1% (or even lower thresholds for rare disorders) in suitable reference populations. Computational analysis can support a benign classification by showing a variant is *silent* (e.g., encodes the same amino acid as the reference base). This assumption, however, misses rare exceptions such as the *LMNA* Gly608Gly mutation in Hutchinson-Gilford progeria syndrome. Although mutating cytosine to thymine at position 1824 still codes for glycine, this variant introduces a new splice site in exon 11 that eliminates 50 amino acids from the final progerin protein.[126] Conversely, experimental data can provide evidence that a missense variant does not actually alter protein function in disease-relevant bioassays. In addition, family-based data can be extremely powerful for interpretation; for example, most variants for dominant diseases can be classified as benign if they are also observed in healthy relatives. Typically, the filtering of benign variants results in a 100- to 1000-fold reduction in the number of variants, requiring further analysis for 30 to 300 variants.[119,127]

Among these, a similar hierarchy of evidence can support a *pathogenic* designation, or the evidence can remain inconclusive, resulting in a VUS designation. Computational analysis showing predicted gene disruption (premature stop or frameshift variants) in a gene known to cause disease when inactivated provides strong evidence of pathogenicity. Experiments in disease-relevant bioassays can demonstrate deleteriousness of a variant, and family-based data can increase the conclusiveness of findings by showing that a proposed pathogenic variant segregates with disease or that it is absent from both parents in de novo cases of disease. Presence of the variant in databases such as the Human Gene Mutation Database can also provide supportive evidence, but the quality of evidence can vary widely among variants. Before final reporting, variants classified as pathogenic are typically validated by resequencing using traditional methods (i.e., Sanger sequencing),[124] although this practice may shift depending on the state of sequencing technology. In a recent pilot case-control study of 20 cardiomyopathy patients and controls subjected to genome sequencing, two to four variants per individual (in both cases and controls) were classified as pathogenic,[125] illustrating the challenges in interpreting genetic variation in isolation.

Using a Genetics Laboratory Report to Make Clinical Decisions

In the clinic, genetic testing is used to identify or confirm the cause of disease and to help the physicians make individualized treatment decisions (Table 3.5). Given the complexity of genetic testing, especially at the genomic (exome or genome) scale, physicians and clinical laboratories will have to work collaboratively to achieve useful results. For example, when a laboratory finds a rare or novel variant in the course of genomic sequencing, the director cannot assume it is relevant to a patient just because it is rare, or novel. The context of the patient's history, physical examinations, and previous laboratory examinations are key to distinguishing among causal variants for the patient's disorder, incidental findings, and benign variants.

How should identified variants be used in clinical decision making? Variant analysis contains uncertainties that are implicitly defined in the three-part classification described earlier: benign, pathogenic, and VUS. American College of Medical Genetics guidelines[124] recommend that variants classified as pathogenic can be used in clinical decision making. However, genetic evidence should not be the only evidence of disease and should be used in conjunction with complementary clinical information when possible, especially as some pathogenic variants may be misclassified. Examples of corroborative clinical data include enzyme assays, physical findings, and imaging studies. VUS should generally not be used in clinical decision making. Efforts to resolve the classification of the variant as pathogenic or benign should be undertaken, and interpretation in the context of the patient's clinical scenario is critical. Variants classified as benign can usually be assumed not to cause the patient's disorder. Detection of pathogenic variants incidental to the diagnostic motivation for sequencing, but of potential clinical relevance, will be an inevitable consequence of genomic testing. This scenario is analogous to the inevitable detection of adrenal masses in computed tomography scans or thyroid nodules on physical examination.

A clinician ordering genomic testing should be aware of laboratory policies and current ethical guidelines regarding such incidental or secondary findings. Current recommendations are to offer the patient the option not to receive such incidental findings, and laboratories may vary in their reporting of such incidental findings. From both the clinician and patient perspectives, incidental findings can also be specifically requested or declined. The laboratory should provide clear information about what constitutes a reportable incidental finding and how a finding may be requested

TABLE 3.5 Examining a Clinical Genetics Laboratory Report

A clinician considers several issues when examining a clinical genetics laboratory report.

Technical Summary of Genetic Testing

For targeted tests, the list of genes tested and coverage for each gene can be found at the Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/sites/GeneTests). For genomic tests, average coverage (e.g., >30×) and minimum coverage (e.g., >8× for 95% of bases) should be considered in evaluating test quality. Genes with poor coverage or no coverage should be listed. For both targeted and genomic testing, the specific limitations of detection for different molecular classes of genetic variants given the technology utilized (e.g., copy number variants are not well captured by next generation sequencing) should be described.

Clinical Interpretation

With regard to the clinical indication for testing, was the test positive (an explanatory variant identified for the patient's condition), negative (no explanatory variants identified), or inconclusive (only variants of uncertain significance identified)? Does the potential explanatory variant fit with the clinical scenario or at least explain some of the patient's phenotypes? With regard to incidental findings, is there a carrier risk to future progeny or future risk of monogenic disease to the patient? A compendium of monogenic diseases and their patterns of inheritance can be found at the Online Mendelian Inheritance in Man website (https://www.omim.org/).

Variant Reporting and Classification

When applicable, the gene name, transcript, molecular form of variant (single-nucleotide polymorphism, indel, etc.), base changes, amino acid change, zygosity, population frequency, and classification (benign, pathogenic, variants of uncertain significance) should be provided. Naming conventions are determined by the HUGO Gene Nomenclature Committee (http://www.genenames.org). Variant frequencies in the population can be found at the 1000 Genomes Project (http://www.1000genomes.org) and for exomes at the Exome Aggregation Consortium (http://exac.broadinstitute.org/). The justification for variant classifications should be provided, taking into account family-based data if available and information from clinical databases. Previously reported relationships among variants and phenotypes can be found at ClinVar (http://www.ncbi.nlm.nih.gov/clinvar).[123] The analytic accuracy of each reported variant in terms of coverage and validation (e.g., Sanger resequencing) should be reported.

or declined. Guidelines have been set forth in the American College of Medical Genetics recommendations for reporting of incidental findings in clinical exome and genome sequencing.[128]

Future Perspectives and Summary

In the future, we anticipate that a genome sequence will become a standard accompaniment to the medical chart; thus, the question "Should we sequence?" will transmute to "What part of the sequence should we look at?" A rational clinical approach will require the discipline to not look at all of it, or at least to rigorously interpret sequence data in the clinical context. As detailed previously, every human genome is littered with thousands of VUS and multiple variants classified as pathogenic; clinical suspicion is essential to help direct where to look and how to interpret genetic variation. This approach recapitulates current clinical algorithms for genetic testing. For example, familial paraganglioma shows locus heterogeneity as a mendelian disorder with cases attributable to mutations in multiple genes encoding proteins for the succinate dehydrogenase complex. The current genetic testing algorithm is hierarchical, starting with the gene that best fits the clinical presentation of the index case (e.g., sequencing of the *SDHB* gene if the neoplasm is abdominal or malignant vs. *SDHD* if located in the head or neck). If no mutations are found in the most likely candidate gene, other complex members are tested (e.g., *SDHC*). In a genome-sequencing era, a clinical algorithm might hierarchically look up mutations in the succinate dehydrogenase complex members from a sequenced individual with familial paraganglioma syndrome. No additional sequencing costs would be incurred as each gene is subsequently tested, but honing in on the appropriate and interpretable areas of the genome will reduce the clinical burden of false-positive results.

As mentioned earlier, changes in DNA sequence are not the only means of passing on inherited information. Looking beyond primary sequencing data, epigenetic changes including DNA base methylation and histone modification are likely to become essential for accurate genetic diagnosis. Epigenetic changes can permanently and heritably alter the expression of genes and thus clinical phenotypes. Methylation of cytosine residues in CpG dinucleotides of DNA is so ubiquitous in the genome that it has been referred to as the "5th base."[129] Hypermethylation at promoters reduces gene expression by decreasing affinity for transcription factors and increasing recruitment of methylated DNA-binding gene repressors. DNA methyltransferases reproduce these methylation patterns in daughter cells and generate new methylation patterns according to environmental influences and extracellular signaling.

The clinical impact of inherited methylation on genetic disease is just beginning to be understood. Recent work assessed the genome-wide methylation state in more than 5000 individuals with respect to T2D and obesity in a process analytically similar to GWASs. Of the 187 methylation sites associated with increased adiposity and T2D, 38 were found in loci harboring genes such as *ABCG1*, a known regulator of lipid homeostasis and insulin resistance. These methylation loci predicted obesity and T2D independently of SNP variation and outperformed inflammatory markers such as C-reactive protein.[130]

In summary, genetic information is most likely to be of clinical use in individuals with suspected mendelian syndromes (see the SSSS criteria enumerated earlier). For individuals with a clinically defined syndrome, for which targeted panels exist and are well validated, a targeted approach (single-gene or gene panel testing) is currently recommended as an initial approach. For example, genome-wide sequencing is likely not needed when MEN2B is suspected on clinical grounds; sequencing *RET* will usually make a diagnosis. If results from targeted genetic testing are uninformative, and the suspicion of a genetic disorder is high, exome or genome sequencing will make additional diagnoses in some patients (see Fig. 3-3). We recommend primary genome-wide approaches that assess both structural variation and sequence variation for individuals with clinically unclassifiable genetic syndromes or when targeted panels are not available or well validated. Depending on technological progress, this may simply be an unmasking of data that had not been reported back in a targeted test or may require new sequencing. The exome comprises 1% to 2% of the genome yet contains nearly 85% of known disease-causing mutations.[131] Thus, given current technologies, exome sequencing supplemented with or following array CGH is a reasonable initial genome-wide approach.

Many other best practices will improve the outcome of genetic diagnosis through sequencing. Ideally, DNA from both parents should be obtained, if possible, and DNA from additional relatives may also aid in interpretation. If unaffected and affected tissues are identified, paired affected tissue-blood samples should be obtained when possible. Identified variants can be classified as benign, pathogenic, or VUS, based on cross referencing with databases of diseased and undiseased individuals, as well as family members; computational analysis; and experimental evidence. Indeed, to maximize interpretability of any genomic approach, it will be vital to interpret variation in the context of massive numbers of genome sequences obtained in healthy individuals and in patients with disease. Finally, accurate classification will require physicians and clinical laboratories to work collaboratively, and the resulting genetic information should always be used in conjunction with complementary data (chemistries, imaging, etc.) for clinical decision making.

Laboratory Techniques for Recognition of Endocrine Disorders

PATRICK M. SLUSS AND FRANCES J. HAYES

CHAPTER OUTLINE

KEY POINTS

- The practice of endocrinology relies heavily on accurate laboratory measurements. Small changes in hormone levels, biomarkers, or molecular markers are often more specific and earlier indicators of disease than the appearance of physical symptoms.
- Analytic methods for assessing endocrine problems are continually expanding. Traditional measurement of endocrine factors, protein, and steroid hormones and related factors has been supplemented by a wide array of disease biomarkers, particularly with respect to endocrine cancers.
- Newer systems are often manufactured outside the laboratory. Although the configurations are generally more user friendly, they also become more of a "black box," concealing most of the details of the system. Numeric values, especially when reported to several decimal places, can falsely suggest levels of accuracy and reproducibility beyond the technical limits of the technology used.
- Understanding the basic principles of method validation and quality control is essential if endocrinologists are to assess the reliability and robustness of numeric values reported and to work effectively with the laboratory to reconcile test values that do not match clinical presentations.
- Laboratory testing as practiced today contributes significantly, both directly and indirectly, to the cost of care, which over the past decade or so has increased faster than improvements in clinical outcomes. Clinicians and pathologists are increasingly required to understand the inner workings of laboratory medicine and work as a team in determining optimal management strategies to contain the costs of care without compromising quality.

Endocrinology is a practice of medicine that is highly dependent on accurate laboratory measurements. Small changes in hormone levels, biomarkers, or molecular markers often may be more specific and more sensitive for early disease detection (or risk) than the classic physical signs and symptoms. Most endocrinologists no longer have facilities to develop and validate laboratory assays. They must rely on centralized hospital or commercial reference laboratories. Understanding the nuances of laboratory testing can greatly aid the clinician in working with the laboratory, particularly when faced with disparate clinical observations and laboratory results.

Laboratory testing as practiced today contributes significantly, both directly and indirectly, to the cost of care, which, over the past decade or so, has increased faster than improvements in clinical outcomes.[1] Current treatment guidelines, especially in endocrine practice, rely heavily on early laboratory testing. Thus clinicians and pathologists are increasingly required to understand the inner workings of laboratory medicine and work as a team in determining optimal management strategies to contain the costs of care without compromising quality.

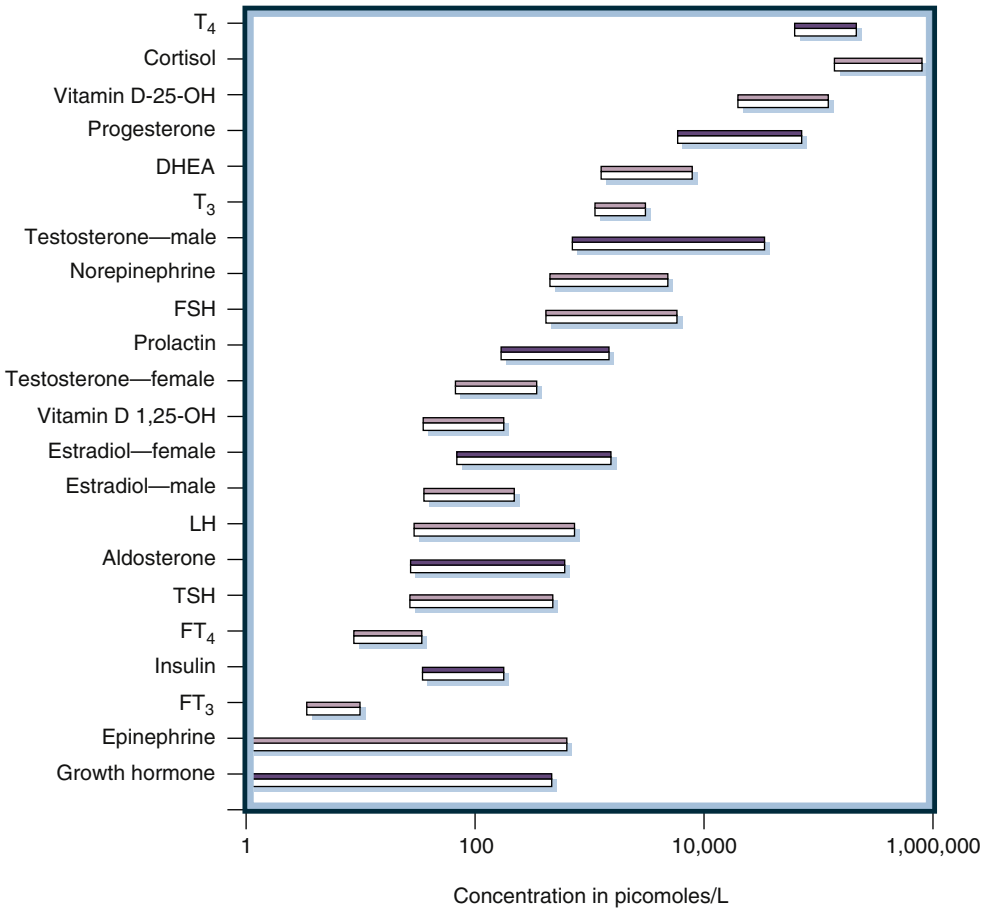
This chapter provides an overview of the analytic techniques typically used for diagnosing and monitoring the progress of endocrine disorders. Historically the quantitative measurement of endocrine factors, protein, and steroid hormones and related factors, such as steroid binding proteins, in blood and urine has been the primary goal. More recently, wide arrays of disease biomarkers, particularly with respect to endocrine cancers, have become valuable targets for measurement in the clinical laboratory. Analytic validation is then discussed. The parameters of analytic validation are not method specific. Principles are presented to help endocrinologists better assess the performance of the analytic systems that they are using. Techniques used by clinical laboratories to control

and assure quality testing results and services follow to provide guidance in appreciating the reliability and robustness of numeric values reported and in working with the laboratory to reconcile test values that do not match clinical presentations. Finally, especially for the academic practitioner, the classes of assays are discussed to provide some clarity on the regulatory requirements laboratories are required to meet in providing test results for patient care, federally supported human studies, and federally regulated clinical trials.

Laboratory Methods

Historically laboratory methods unique to the clinical practice of endocrinology were directed at the measurement of peripheral levels of hormones or hormone metabolites in serum, plasma, and/or urine. This measurement is analytically challenging because concentrations of most hormones are much lower than those of general chemistry analytes. Specialized techniques are necessary to measure these low concentrations that can be reported in molar units, mass units, or standardized units, such as the World Health Organization (WHO) international unit (IU). Fig. 4.1 illustrates the concentrations of representative hormones in plasma from healthy individuals. Expressed in molar units to allow direct comparisons, peripheral hormone levels range from 10^{-6} to 10^{-12} mol/L (i.e., micromolar to picomolar concentrations). Thus clinically useful analytic methods must have exquisite sensitivity. Furthermore, as also illustrated in Fig. 4.1, the range of concentrations is very broad (often several orders of magnitude), necessitating methods with a very wide dynamic range of measurement. Antibody-based methods are ideally suited to achieve sensitivity and wide dynamic ranges and were the first methods successfully used both to define endocrine systems and to be applied clinically in patient care. Because of their cost effectiveness, suitability for high throughput implementation, and potential for automation, antibody methods replaced earlier chromatographic/mass spectrometric methods that were used in the discovery and characterization of hormones, particularly steroid hormones. Initially, competitive binding assays using polyclonal antibodies were utilized; then with the development of monoclonal antibody technology in the 1980s immunometric, or double antibody, methods were utilized. Both of these analytic designs are automated and are in widespread use today: Competitive binding assays are used for measuring small molecules and immunometric assay is used for measuring antigens containing multiple antibody-binding epitopes (i.e., protein hormones and biomarkers).

As discussed in detail later, antibody-based assays are subject to interference and lack of specificity that can result in inaccurate measurements. Even when a given assay has been well validated and reference intervals are known (see discussion under "Analytic Validation"), this limitation is manifest as producing measurements that are method specific, vitiating the ability of clinicians to compare measurements reported using different assays (e.g., assays



• **Fig. 4.1** Six-logarithm range of normal plasma concentrations in endocrine tests. *DHEA,* dehydroepiandrosterone; *FSH,* follicle-stimulating hormone; *FT_4,* free thyroxine; *FT_3,* free triiodothyronine; *LH,* luteinizing hormone; *T_3,* triiodothyronine; *T_4,* thyroxine; *TSH,* thyrotropin.

from different laboratories) for the same hormone or biomarker. Although preanalytic methods such as extraction and chromatography have been tried to improve the accuracy of immunoassays used in research settings, these methods are seldom utilized in clinical laboratories today because of their high cost, complexity, and lack of commercial availability; all are by definition laboratory-developed tests (see "Classes of Assays").

Since the early 2000s, technologic advances in mass spectrometry–based assay systems have led to the rapid and ongoing replacement of antibody-based methods for the clinical measurement of hormones and biomarkers relevant to the endocrine practice. Currently these more complex and expensive methods are utilized primarily by commercial reference and large academic hospital laboratories, but as the technology becomes more cost effective and user friendly, its use will clearly increase. Thus it is important for clinicians to appreciate the principles of these assays as well as those of the older, albeit still widely used, antibody-based methods.

The final technologies considered in this section are molecular-based assays. These methods are not specifically designed for endocrine practice but are generic for identifying and in some cases quantifying genetic variance. Subsequent to the sequencing of the human genome and the continuing evolution of molecular methods and knowledge, these methods are rapidly penetrating endocrine practice. Although these methods are still in the early stages of clinical use and generally require specialized informatics and interpretative support, laboratories are increasingly providing molecular-based testing with respect to determining endocrine cancers, inherited disease, and individualized therapeutics.

Antibody-Based Methods

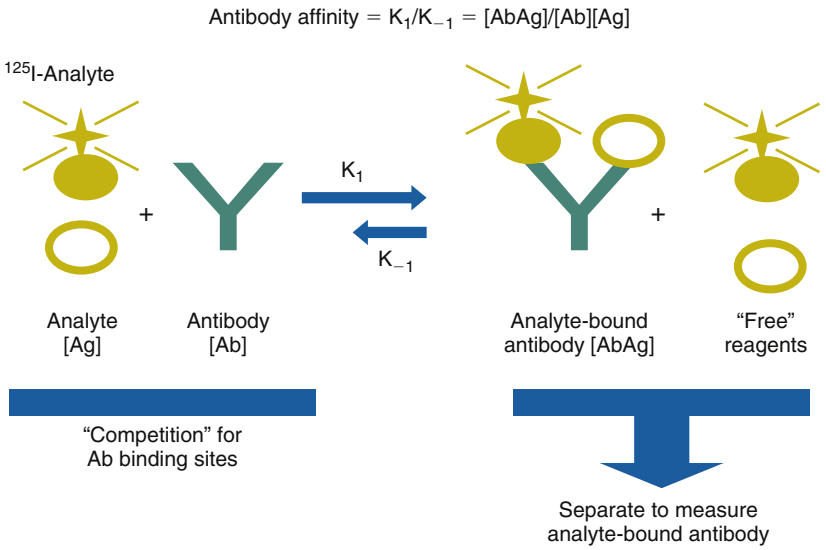
Classic Competitive Binding Immunoassays

The term *competitive binding assay* refers to a measurement method in which an analyte (e.g., a hormone or biomarker) in a specimen competes with a labeled reagent analyte for a limited number of binding sites on a binding protein. The earliest clinical assays used for the measurement of circulating concentrations of endocrine hormones utilized radioisotope-labeled analytes and antibodies in the classic radioimmunoassay format illustrated in Fig. 4.2. The three basic components of a competitive immunoassay are antibody, labeled analyte, and unlabeled analyte.[2,3] The basic principle of this methodology is to allow an equilibrium or steady-state condition (e.g., competition) to be established between a labeled analyte and the unlabeled analyte in calibrators or specimens binding to the antibody. The reaction obeys the law of mass action and is driven by the affinity of the antibody (Ab) for the target analyte, or antigen (Ag), as shown in Fig. 4.2. If the concentrations of antibody and labeled analyte are held constant, the amount of labeled analyte bound is inversely proportional to the concentration of the competing unlabeled analyte, as illustrated in Fig. 4.3. By comparing the percentage of bound antigen (% [bound/total]) generated by an unknown specimen to the dose-response curve generated by known concentrations of analyte (see Fig. 4.3B), the amount of analyte in a specimen can be quantified.

Competitive antibody-based assays are referred to generically as immunoassays. The analytic sensitivity of a competitive immunoassay is approximately inversely related to the affinity of the antiserum, such that an antiserum with an affinity constant of 10^9 L/M can be used to measure analytes in the nanomolar concentration range. This methodology has evolved significantly since the development of the prototypical radioimmunoassay in the late 1950s. Currently, although radioimmunoassays still have a role in the research laboratory, the immunoassays most widely utilized in clinical endocrine testing are fully automated, nonisotopic instrument systems whose manufacture and reagents are regulated by the Food and Drug Administration (FDA). Each of the component parts of the competitive immunoassay is discussed in detail next.

Antibody

Antibodies are ideal as the binding component in a competitive binding assay that is highly specific and can measure very low concentrations of analyte in complex mixtures such as serum or plasma. Antibodies are inherently specific, and both their specificity and affinity can be manipulated in developing immunoassays. Immunoassays developed prior to the mid-1980s relied upon polyclonal antiserum produced in animals. Limited quantities of high-affinity antisera that react primarily with the specific target antigen are obtained and can be used either as diluted antiserum or, most often, as purified immunoglobulins.



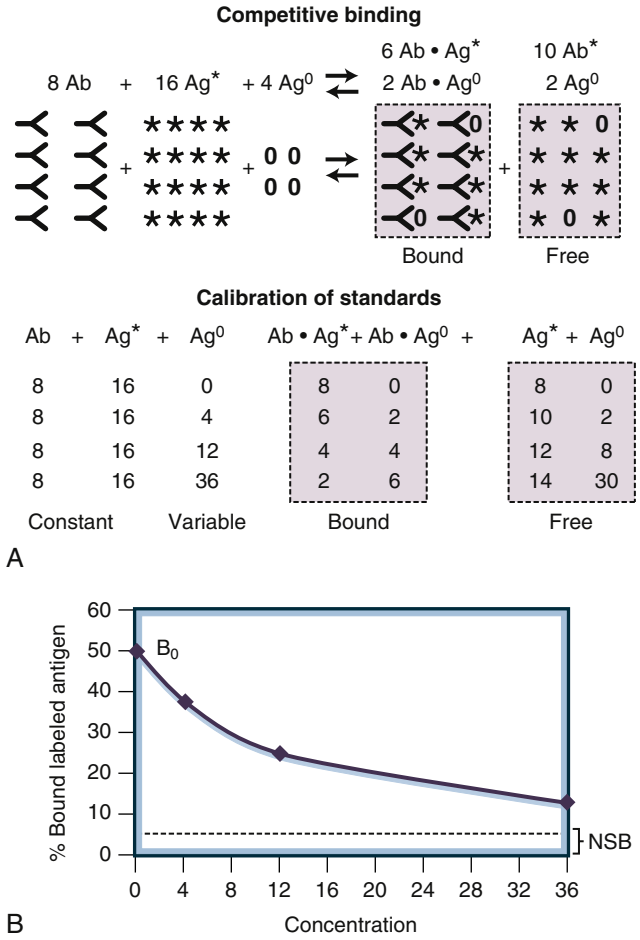
• **Fig. 4.2** Components of a radioimmunoassay; a prototype competitive binding methodology.

A polyclonal antiserum represents a composite of many immunologic clones, with each clone having a different affinity and different antigenic epitope specificity. Most clones have affinities in the range of 10^7 to 10^9 L/M. The affinity of the antiserum or purified immunoglobulins for the analyte (i.e., the immunogen) is the sum of the affinities of all the various clones. Antisera used in immunoassays typically have affinity constants above the 10^{12}-L/M range and can easily measure picomolar concentrations of analytes in biologic fluids. Various techniques are used to develop a specific antiserum. For example, the antigen may be altered chemically to block cross-reacting epitopes either before or after immunization. Historically immunoaffinity purification of antiserum to obtain epitope-specific immunoglobulins has been effectively used. This technology can also be applied to preanalytic assay steps to enhance the specificity of immunoassays as well as enrich specimens for chromatographic or mass spectrometric assays by selecting or eliminating cross-reacting factors.[4–6] The major disadvantage of a polyclonal antiserum is the limited quantity produced. Commercial manufacturers require large quantities of immunoassay reagents to support high-volume clinical testing performed by a large number of laboratories, and these reagents require rigorous validation. Thus the majority of commercial immunoassay systems available today are based on monoclonal antibodies that can be produced in virtually limitless quantities.

Monoclonal antibodies are used in most current immunoassays and are required for immunometric assays because they are epitope, as opposed to antigen, specific and can be produced virtually without limit. These antibodies are obtained by immunizing animals using techniques similar to those used for polyclonal antisera. Instead of harvesting the antisera from the blood, lymphocytes from the spleen are fused with myeloma cells to make cells (hybridomas) that will grow in culture continuously and produce monospecific antibodies.[7–10] These fused cells are separated into clones by means of dilution plating techniques similar to those used in subculturing bacteria. The supernatant of pure monoclonal cell lines (or ascites fluid if the cells are transplanted into carrier mice) contains monoclonal antibodies. The selection processes used to separate the initial clones can be targeted to identify specific clones, producing antibodies with high affinities and low cross-reactivity to related compounds.[11]

The epitope specificity of monoclonal antibodies allows assays to be designed for large analytes (containing multiple nonoverlapping epitopes), which do not depend on competition; these immunometric assays are often referred to as *two-site* or *sandwich assays* (see later). However, the high specificity of monoclonal-based assays can cause problems for some endocrine assays. Many hormones circulate in the blood as heterogeneous mixtures of multiple biologically active forms. Some of these forms are caused by genetic differences in patients; others are related to metabolic precursors and degradation products of the hormone. Genetic differences cause some patients to produce variant forms of a hormone, such as luteinizing hormone (LH). These genetic differences can cause marked variations in measurements made using assays with specific monoclonal antibodies, compared with more uniform measurements made using assays with polyclonal antisera that tend to cross-react with the multiple forms.[12] Well-characterized monoclonal antibodies can be mixed together to produce engineered polyclonal antibodies with improved sensitivity and specificity.[13]

Cross-reactivity with precursor forms of the analyte and with metabolic degradation products can cause major differences in assays. For example, the degree of cross-reactivity among six molecular forms of human chorionic gonadotropin (hCG) causes differences in hCG assays. Similarly, cross-reactivity among various circulating metabolic fragments causes method-specific differences in parathyroid hormone (PTH) assays.[14,15] Cortisol is an example of an analyte for which major cross-reactivity with other steroids, such as corticosterone, 11-deoxycortisol, cortisone, and numerous synthetic steroids, causes significant immunoassay interferences.[16] Matrix effects with albumin also can cause major differences in cortisol immunoassays (see "Mass Spectrometry" for a more robust method for measuring steroids).[17]



• **Fig. 4.3** Quantitation using competitive binding assays. (A) Principles of competitive binding assays. *Ab,* antibody; *Ag*,* labeled antigen; Ag^0, native antigen. See text for details. (B) Typical dose-response curve. The point on the curve labeled B_0 represents the percentage binding of the radiolabeled antigen when zero native antigen is present. The nonspecific binding (NSB) level is the minimal binding level of radiolabeled antigen at high concentrations of native antigen.

Labeled Antigen

In radioimmunoassays, radioactive iodine (^{125}I or ^{131}I) was originally used to label the antigen. Subsequently a large variety of methods have been developed to label the analytes.[18–23] Today most commercial kits and all automated immunoassays use nonisotopic signaling systems to measure hormone concentrations. These assays use colorimetric, fluorometric, or chemiluminescent signals rather than radioactivity to quantify the relative amount of antigen bound to the antibody used in the assay. The advantages of these nonisotopic labeling technologies include biosafety,

longer reagent shelf life, ease of automation, and reduced cost. On the other hand, they can be more subject to matrix interferences than radioactive detection systems. Radioactivity is not affected by changes in protein concentration, hemolysis, color, or drugs (except for other radioactive compounds), whereas many of the current signal systems can yield spurious results when such interferences are present. Later in this chapter, potential troubleshooting steps are outlined to help clinicians evaluate the integrity of test measurements when spurious results are suspected.

The specificity and accuracy of labeled antigen assays (e.g., competitive assays) depend on the purity of the labeled antigen. Especially with respect to labeling small molecules, such as steroid hormones, purification of the labeled antigen can be challenging and certainly contributes to lot-to-lot variance in assay performance. Additionally, sensitivity in this assay design is influenced by the specific activity of the labeled product (i.e., the amount of label incorporated into the antigen on a molar basis). An alternative design for competitive assays is to attach the antigen to a solid phase and label the antibody. A competitive binding assay is then achieved by allowing unlabeled antigen to compete with solid-phase antigen for labeled antibody binding. Although this addresses issues associated with antigen labeling, this format is subject to similar issues associated with modification of antibody binding characteristics as the antigen is chemically attached to a solid phase or due to restricting its conformation once the antigen is attached.

Unlabeled Antigen

Labeled and unlabeled antigens must compete for a limited number of binding sites. The competition is not always equal because the labeled antigen (tracer) and the native antigen may react differently with the antibody. This disparity in reactivity may be caused by alteration of the antigen due to labeling, as discussed earlier, or by differences in the endogenous antigen compared with the form of the antigen labeled for use as an assay reagent. The latter is a problem often encountered with protein hormones or biomarkers that often exhibit a wide range of isoforms and degradation products in peripheral circulation. For this reason, immunometric assay designs are preferable for proteins with multiple antibody-binding epitopes.

Because an assay can be calibrated with certified reference materials having known concentrations, differences in reactivity of labeled compared to unlabeled antigens do not prevent obtaining useful clinical measurements as long as the reactions are reproducible and appropriate reference intervals are established. Such differences do, however, result in method-specific measurements, and in this case assay results cannot be extrapolated across assays using different reagents.

Separation of Reactants/Automation

As illustrated in Figs. 4.2 and 4.3, immunoassays depend on detecting only the labeled antigen bound by the antibody. Thus the entire antibody-bound antigen component of the assay must be recovered and separated from any unbound reactants (i.e., labeled or unlabeled antigens not bound to antibody). Over the years since the introduction of radioimmunoassays, vast arrays of technologies have been developed to accomplish this separation. Approaches vary from methods to precipitate immunoglobulins and recover them by centrifugation or filtration to innovative ways to create solid-phase antibodies (i.e., antibodies attached to solid surfaces that can be washed to remove unreacted reagents after the binding process is completed).

Separation of immune complexes by precipitation and centrifugation is labor intensive and, like the use of radioactivity itself, not amenable to full automation. This approach is still widely used in research applications but seldom utilized in clinical testing. In contrast, solid-phase approaches are widely used and can be batch or fully automated. Three frequently used solid-phase materials are microtiter plates, polystyrene or latex beads, and paramagnetic particles. Most recently the use of immunoassay systems at the point of care and miniaturized assay systems are driving the development of novel solid-phase antibody systems.[21,23–25] Separation of solid-phase immune complexes from the unbound moieties is accomplished by plate washers, bead washers, magnetic wash stations, or microfluidics.

Antibodies can be attached to solid-phase materials directly or indirectly. Antibodies can be passively attached directly to plastic surfaces by hydrophobic interactions, and this method is often used in the manufacture of enzyme-linked immunosorbent assays (ELISA). Automated assays, requiring inline capture and washing systems, typically involve chemical procedures in which amino acid groups or carbohydrate groups on the Fc portion of immunoglobulins are covalently coupled to solid phases such as beads or magnetic particles. This can be achieved directly by coupling the antibody used in the assay to the solid phase or indirectly by covalently coupling a universal capture to the solid phase. Examples of universal capture systems are solid-phase particles with covalently attached streptavidin to capture biotinylated assay antibodies or solid-phase particles covalently coated with goat antimouse IgG as attachment moiety for mouse monoclonal-based assays. Another novel way of accomplishing this separation is to attach high-affinity linkers to antiserum, which then can be coupled to a complementary linker on the solid phase.

Quantitation

Fig. 4.3 illustrates the principles of quantitative measurement using competitive immunoassay techniques. In the schematic diagram, 8 units of antibody react with 16 units of labeled antigen and 4 units of native antigen. At equilibrium (assuming equal reactivity), 6 units of labeled antigen and 2 units of native antigen are bound to the limited supply of antibody. The antigen bound to the antibody is separated from the liquid antigen by any of several methods, and the amount of labeled antigen in the bound portion is quantified (see Fig. 4.3A). The assay is calibrated by measuring standards with known concentrations and cross-plotting the signal (i.e., counts of the gamma rays emitted from the radioactive label) versus the concentration of the standard to generate a dose-response curve. As the concentration increases, the signal decreases exponentially (see Fig. 4.3B).

Statistical data-processing techniques are needed to translate the assay signals into concentrations. These dose-response curves typically are not linear, and numerous curve-fitting algorithms have been developed. Before the introduction of microprocessors, tedious, error-prone manual calculations were required to mathematically transform the data into linear models. Today, curve fitting usually is accomplished electronically with the use of programs that test the robustness-of-fit of multiparameter curves after statistically eliminating discordant data points.[26,27] However, users of these systems must understand their limitations and should pay attention to any warnings presented by the programs during processing of the data. Commercial immunoanalyzers, used by the majority of clinical laboratories currently, are closed systems. The manufacturer validates not only the method (see "Analytic Validation") but

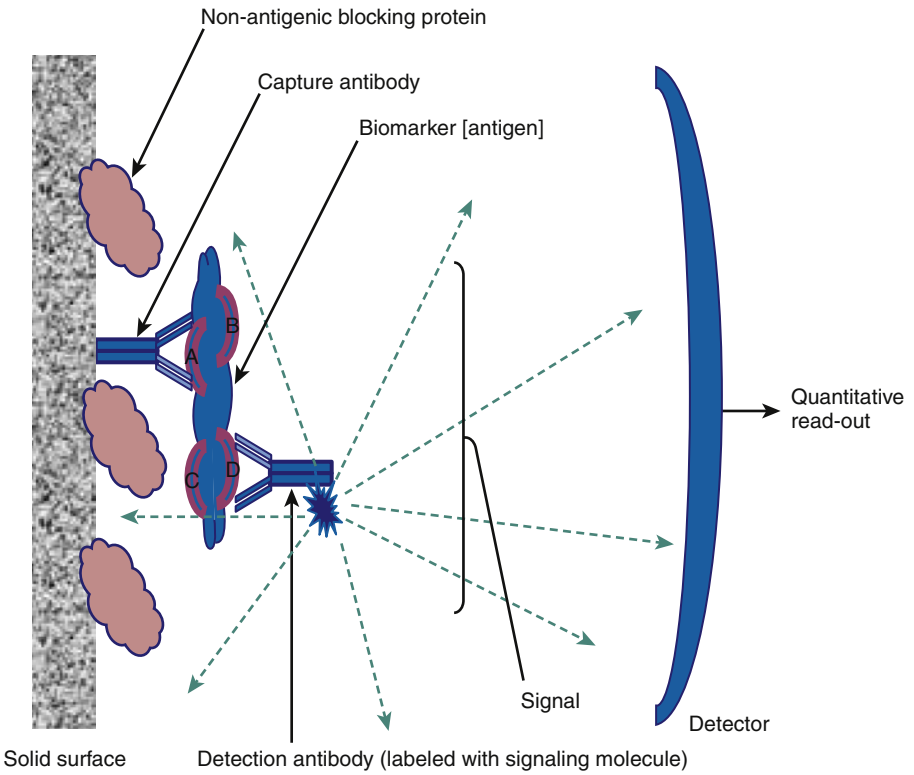
also the curve-fitting software, which cannot be altered by the user. Thus clinical laboratories and clinicians see only the final values for the signal generated and calculated analyte concentration for a given specimen.

In clinical practice today, competitive assays are used primarily for the measurement of small molecules, such as steroid hormones or bioactive peptides, which present only one antigenic epitope. For molecules in which multiple epitopes are present, allowing more than one antibody to bind each molecule, two-site or immunometric assays are used. Immunometric assays, discussed in detail in the following section, are advantageous because they do not require the time-consuming establishment of a binding steady-state condition and thus can be performed much faster. Speed of test performance is an important factor in the clinical laboratory supporting acute care. Speed is also directly related to high testing throughput, which is an important cost factor to optimize in modern clinical laboratories.

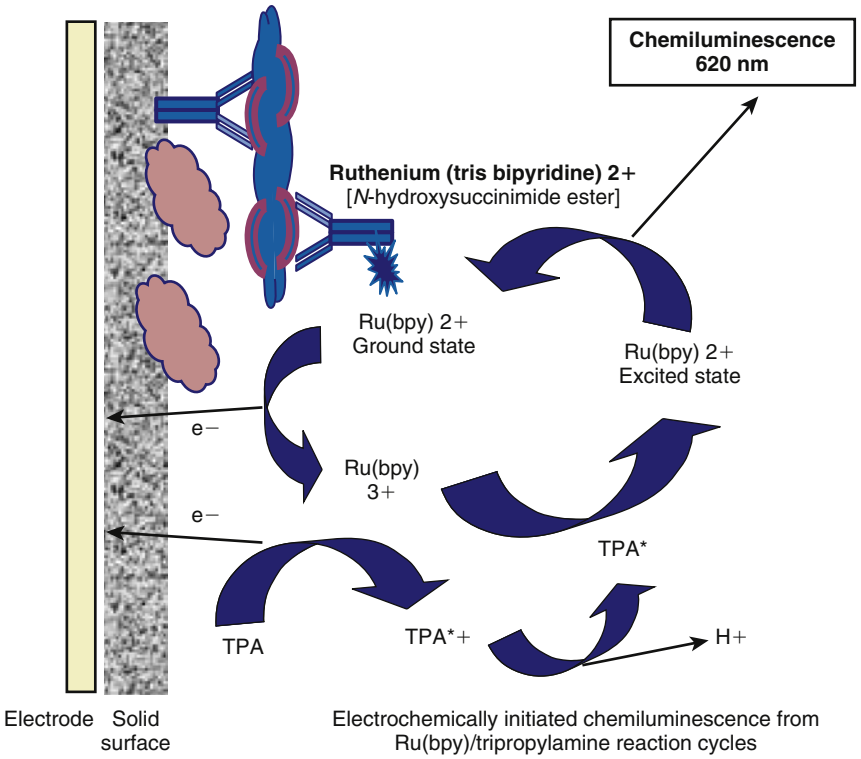
Immunoassays measure antigen concentrations rather than biologic activity. The reactive site for most antibodies is relatively small, about 5 to 10 amino acids for linear peptides. Some antibody reactions are specific for the tertiary structure that corresponds to unique molecular configurations. In either case, linear or conformational antigenic epitopes, the structural elements of the hormone involved in receptor activation and biologic signaling, are not necessarily identical to antigenic epitopes recognized in the assay. Clinicians must keep this in mind when interpreting the results of antibody-based assays. When measurements are ordered to identify abnormal secretion of hormones, the possible disparity between antigenic and biologic epitopes is not as relevant as when measurements are ordered to assess the endocrine stimulus received by the target glands.

Epitope-Specific Immunometric Assays

As briefly mentioned earlier, for larger analytes that contain more than one nonoverlapping antigenic epitope, the development of methods to produce monoclonal antibodies facilitates a unique assay design in which two antibodies are used. This format is illustrated in Fig. 4.4. The analyte in this example has four nonoverlapping epitopes: A, B, C, and D. A solid-phase monoclonal antibody (referred to as the capture antibody) that is specific to one site (in this example, A) can be used to bind the antigen in calibrators or specimens. Using a second, labeled monoclonal antibody (referred to as the detection antibody) that is specific to one of the other epitopes (in the example, D), the captured antigen can be quantified after washing away the unreacted reagents. Because there are four distinct antibody-binding sites on the analyte, 12 different assays can be configured using nonoverlapping epitope-specific monoclonal antibodies to each of these epitopes. It is important to realize that each of these 12 formats is a distinct assay with unique performance characteristics, each requiring validation. The detection systems used include all the options discussed earlier for labeling protein antigens in immunoassay formats. Fig. 4.5 illustrates one of the most common signaling systems used today in either fully automated clinical immunoanalyzers or as multiwell plate assays. The detection antibody is covalently labeled with ruthenium (tris bipyridine), which can be excited by an electric circuit that draws an electron from the molecule, leading ultimately to a high-energy state that will emit light when it decays; this is an electrochemiluminescent signaling system.[28] The assay buffer contains an excess of the electron donor tripropylamine (TPA). The Ru^{2+} (tris bipyridine ruthenium metal cation) complex is used as the chemical luminescent label. Ru^{2+} undergoes an electrochemical



• **Fig. 4.4** Components and design of an immunometric assay. See discussion in text. (From Sluss PM. Methodologies for measurement of cardiac markers. *Clin Lab Med.* 2014;34:167–185.)



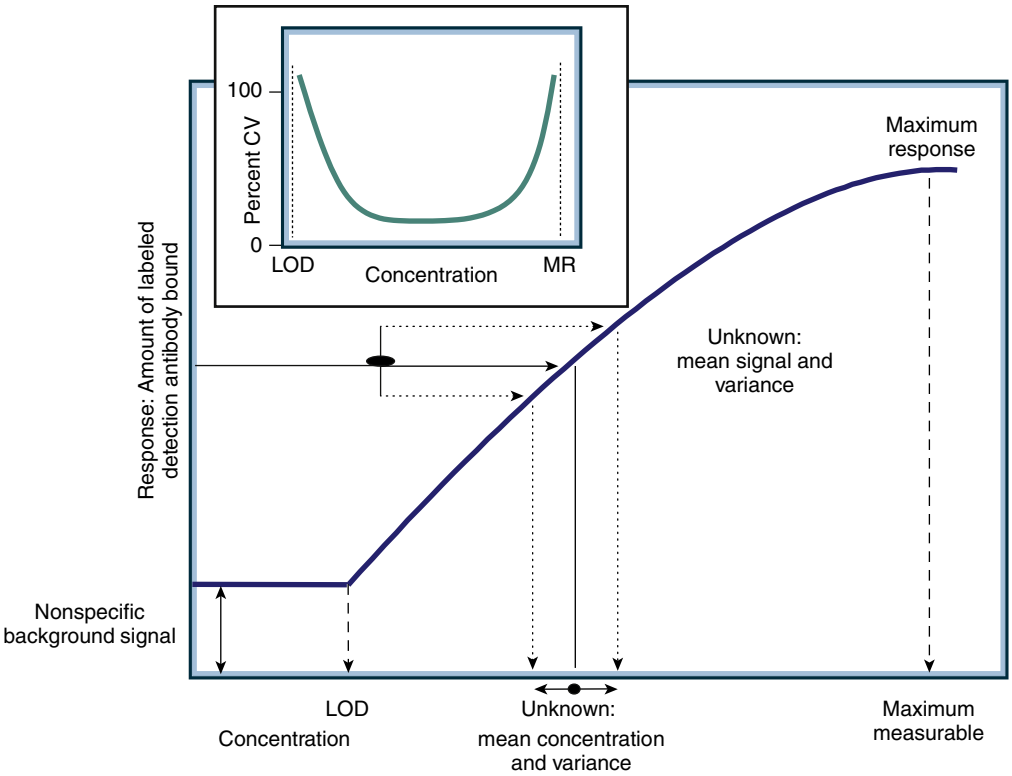
• **Fig. 4.5** Electrochemiluminescence detection system as employed in an immunometric assay. See text for details. *byp,* bipyridine; *TPA,* tripropylamine. (From Sluss PM. Methodologies for measurement of cardiac markers. *Clin Lab Med.* 2014;34:167–185.)

oxidation reaction on the electrode surface and transitions to an excited state to become Ru^{3+}. When the excited state returns to the ground state, light is emitted. The magnetic particles that are captured on the electrode are immunocomplexes that consist of sample and Ru metal complex (Ru^{2+}) and emit light at a specified voltage. The amount of light emitted is proportional to the amount of the immunocomplex and thus the analyte concentration in the sample. It can therefore be used for quantitative measurement. This design is typical of modern detection systems in that the signal generated is controlled in the analyzer (in this case, light production initiated by activating the electrode), and a regenerating system (in this case, TPA in the assay buffer) is used to enhance the signal generated, hence achieving high sensitivity detection.

In contrast to competitive immunoassays, immunometric (e.g., two-site, double antibody) assays use a large excess of antibody-binding sites relative to the concentration of antigen. The capture antibody immunoextracts the antigen from the sample, and the signal antibody binds to the capture antibody-antigen complex to form a tertiary complex. These assays are referred to as *immunometric* because the binding reaction is very fast (first-order kinetics due to excess antibody) and because it is not necessary to establish a binding steady state (a requirement for competitive assays) in the assay before quantifying the amount of label associated with the immune complex. Immunometric assays can be performed very quickly (5–20 minutes compared to 30 minutes to days for competitive assays) and typically have very broad measuring ranges (several log orders).

In contrast to competitive assays, the dose-response curve generated in an immunometric assay is directly proportional to the analyte concentration (Fig. 4.6). The signal increases progressively with the analyte concentration because the amount of labeled antibody bound increases proportionally to the amount of analyte present. Quantitative measurements are achieved in the same manner as those used in competitive assays. The signal generated by the specimen (the "unknown" in Fig. 4.6) is compared to a calibration curve generated by known concentrations of the analyte (plotted on the x-axis in Fig. 4.6).

As with any assay, there is a minimum detection limit (referred to as the limit of detection [LOD]) at which the signal generated by the analyte is not statistically different from that generated in the absence of analyte (referred to as nonspecific signal). Note that for an immunometric assay the LOD is associated with a small signal, but in a competitive assay the LOD is associated with a large signal (compare the dose-response curve in Fig. 4.6 to that illustrated in Fig. 4.3B). All antibody-based assays also have an upper limit of measurement associated with the maximum signal that can be generated by the assay. The working or dynamic range of the assay encompasses only analyte concentrations between the LOD and the maximum response. Analyte concentrations above the maximum response or below the LOD level do not generate signal changes (e.g., there is no dose-response relationship). Thus the measurement variance across the dynamic range of an antibody-based assay is heteroscedastic. The insert in Fig. 4.6 shows the measurement variance expressed as the percent coefficient of variance (CV) of repeated measurements of the same specimen. The CV is calculated as the standard deviation (SD) of the repeated measures divided by the mean value of the measurements. The highest percent CV (e.g., CV × 100) will occur at the extremes of the measurement where the analyte dose response is lost. This point



• **Fig. 4.6** Characteristics of the signal generated by an immunometric assay. Signal generated by the amount of detection antibody bound to the capture-analyte complex is directly proportional to the concentration of analyte in an immunometric assay. The concentration can be extrapolated from response (signal measured) by measuring known concentrations of "calibrators." As shown in the *inset,* the variance associated with measurement is heteroscedastic and increases significantly as the upper or lower limits of the assay are approached. *CV,* coefficient of variance; *LOD,* limit of detection; *MR,* maximum response. (From Sluss PM. Methodologies for measurement of cardiac markers. *Clin Lab Med.* 2014;34:167–185.)

is critical when interpreting assay results or monitoring quality control performance. Variance determined in the middle of the dynamic range of an assay will always underestimate the variance at the extremes.

Although the laboratory can control variance associated with high analyte concentrations by determining at what level of analyte to dilute and retest the specimen, variance associated with relatively low concentrations cannot be altered for a given assay without changing the kinetics of the system (i.e., the concentrations of reagents and/or incubation conditions). Changing the kinetics of a commercial clinical assay is not possible by the performing laboratory because the systems are "locked" to comply with FDA Good Manufacturing Practice regulations.

The combined specificity of two antibodies can produce exquisitely sensitive and specific immunoassays. In the past, a common problem with early competitive immunoassays was cross-reactivity among the structurally similar glycoprotein hormones: LH, follicle-stimulating hormone (FSH), thyrotropin (thyroid-stimulating hormone [TSH]), and human chorionic gonadotropin. The α-subunits of each of these hormones are identical, and the β-subunits, though unique, share considerable structural homology. The polyclonal antisera used for measuring one of these hormones in many of the earlier immunoassays had significant cross-reactivity for the other gonadotropins. The cross-reactivity of a pair of antibodies is less than the cross-reactivity of each of the individual antibodies because any cross-reacting substance must contain both of the binding epitopes to simultaneously bind to both antibodies. For example, consider two antibodies for LH, each having 1% cross-reactivity with hCG. The cross-reactivity of the pair is less than the product of the two cross-reactivities or, in this case, less than 0.01%. Most current immunoassays for LH have a cross-reactivity of less than 0.01%. This low cross-reactivity is important because pregnant patients or patients with choriocarcinoma can have very high hCG concentrations that could interfere with measurements of the other gonadotropin hormones. Most hormones circulate in the blood in multiple forms. Some hormones (e.g., prolactin, growth hormone) circulate with macro forms, which can cause difficulty in their analysis if specimens are not pretreated.[29,30] For hormones composed of subunits (e.g., the gonadotropins), both the intact and the free subunits circulate in blood. Immunometric assays can be made specific for intact molecules by pairing an antibody specific for the α-β bridge site of the subunits with a second antibody specific for the β-subunit. Assays using these antibody pairs retain the two-antibody low cross-reactivity needed for measuring gonadotropins and do not react with the free subunit forms of the hormones.

The heterogeneous forms of circulating hormones, and differences in specificity characteristics of immunoassays for these forms, make calibration and harmonization difficult. Two immunoassays calibrated with the same reference preparation still can give widely varying measurements on patient specimens. Consider the example of hCG in Table 4.1. The three assays are calibrated with a pure preparation of intact hCG,

such as the WHO Third International Reference Preparation. The three assays differ in their cross-reactivity with free β-hCG (0%, 100%, and 200%, respectively). These assays give identical measurements for a specimen containing only intact hCG but progressively disparate values as the percentage of free β-hCG in the specimen increases. In reality, the standardization issue is much more complex because multiple forms of hormones (i.e., intact hormone, free subunits, nicked forms, glycosylated forms, degradation products) circulate in patients, and each assay has different cross-reactivity characteristics with respect to these forms.[31–34]

Because of their speed, specificity, and sensitivity, immunometric assay designs have also been applied successfully to point-of-care testing devices. A typical design is shown in Fig. 4.7. In this example, a lateral flow assay system is shown with two solid-phase monoclonal antibodies affixed to the flow device. One antibody is specific for the analyte, and the other, located on a different section of the analytic strip, is directed at the capture antibody itself. This strip contains a reservoir of detection antibody covalently coupled to gold microparticles. A drop of specimen (e.g., blood, serum, plasma, urine) is placed on one end of the strip and carried across the analytic strip by lateral flow, passing first through the detection antibody reservoir and then over the capture antibodies in sequence. The final state, as illustrated in Fig. 4.7, results in a band of gold particles over the capture antibody region that is proportional to the amount of analyte in the specimen and a positive control band of gold particles over the antidetection antibody region. Such tests are generally qualitative but with the use of a standardized meter for measuring the gold bands and calibrator can be quantitative. Increasingly, these systems are being miniaturized and the detection methods optimized to enable accurate quantitative measurement at the point of care and in other nonlaboratory settings (e.g., field testing and low-resource settings). Although still primarily research tools, similar technologies are utilized in developing multiarray assays (e.g., "lab on a chip" assays) that will likely become part of the clinical laboratory's repertoire of tools in the future.[19,24,25,35,36]

TABLE 4.1 Effect of Immunoassay Specificity on Calibration of Human Chorionic Gonadotropin Assays

hCG Sample	Assay 1	Assay 2	Assay 3
Specificity for intact hCG standard (%)	100	100	100
Cross-reactivity with free β-hCG (%)	0	100	200
Measured values (IU/L)

hCG, Human chorionic gonadotropin.

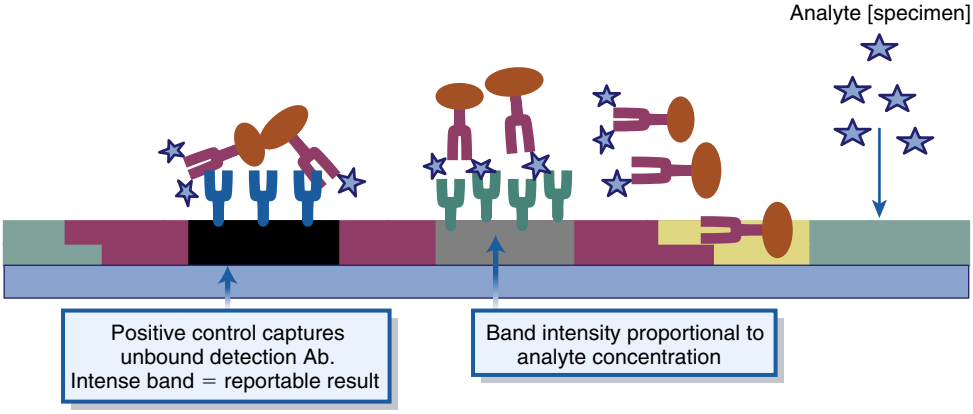
Molecular Structure–Based Methods

Extraction Methods

Extraction of hormones from serum and urine specimens before measurement is a technique used to enhance both the sensitivity and the specificity of immunoassays or mass spectrometry–based assays. Mass spectrometry–based assays are generally of limited sensitivity compared with immunoassay. Their application in endocrine testing relies on relatively large specimen volumes from which analyte can be concentrated by extraction. Extraction, especially in combination with chromatography, also results in the removal of interfering substances, which can produce inaccurate measurements in either immunoassays or mass spectrometry–based assays.

Generally, extraction procedures required for the measurement of serum steroids are based on the polarity or water solubility of the analytes. Extraction methods for proteins/peptides can be based on molecular size as well as polarity. It is essential in any extraction method that recovery (i.e., the amount of analyte extracted) is consistent across all specimens or adjusted quantitatively for each specimen tested. If the extraction recovery is less than 100% but consistent, the method will produce biased yet usable, albeit method-specific, results. If the recovery is different among specimens and cannot be corrected by monitoring, the assay is not valid.

Numerous extraction systems have been developed, including organic-aqueous partitioning to remove water-soluble interferences seen with steroids, solid-phase extraction with absorption, and selective elution from resins such as silica gels and immunoaffinity chromatography. Early immunoassays for steroids relied heavily on extraction prior to assay and provided a basis for assessing interference in subsequent direct assays.[37,38] However, extraction before immunoassay is seldom used in clinical assays today. Extraction techniques are difficult to automate, require



• **Fig. 4.7** Laminar flow immunometric assay design. See discussion in text. *Ab,* antibody. (From Sluss PM. Methodologies for measurement of cardiac markers. *Clin Lab Med.* 2014;34:167–185.)

skills and equipment not available in many clinical laboratories, and generally require correction based on measuring recovery. Monitoring recovery in automated immunoassays is very difficult and creates issues with regulatory compliance (i.e., modification of manufacturer methods). In contrast, extraction methods are a key element in preanalytic processing for mass spectrometry–based assays in which it is possible to measure recovery using an internal standard added to every specimen being tested. Extraction can also be applied to the measurement of proteins/peptides. Most current mass spectrometry assays for steroids involve deproteinization of the specimen (extraction of the steroids) prior to further extraction/purification preanalytically. Similarly, mass spectrometry–based assay of proteins/peptides generally utilizes a batch extraction based on molecular size or polarity. A good deal of progress has been made in developing preanalytic extraction methods prior to assay.[39–50]

Chromatographic Systems

The second major method of measuring hormone concentrations involves chromatographic separation of the various biochemical forms and quantitation of specific characteristics of the molecules. High-performance liquid chromatography (HPLC) systems use multiple forms of detection, including light absorption, fluorescence, and electrochemical properties.[51–53] Chromatography also is frequently combined with mass spectrometry. There are two major advantages of these techniques: They can be used to simultaneously measure multiple forms of an analyte, and they are not dependent on unique immunologic reagents. Therefore harmonization of measurements made with different assays is more feasible. The major disadvantages of these methods are their complexity and their limited availability.

Many chemical separation techniques are based on chromatography, but the two most commonly used for liquid chromatography are normal-phase HPLC and reverse-phase HPLC. In both systems, a bonded solid-phase column is made that interacts with the analytes as they flow through in a liquid solvent. In normal-phase HPLC, the functional groups of the stationary phase are polar (e.g., amino or nitrile ions) relative to the nonpolar mobile phase (e.g., hexane); in reverse-phase HPLC, a nonpolar stationary phase (e.g., C18 octadecylsilane molecules bonded to silica) is used. Polymeric packings made of mixed copolymers have been made with C4, C8, and C18 functional groups directly incorporated so that they are more stable over a wide pH range. The mobile and stationary phases are selected to optimize adherence of the analytes to the stationary phase. The adhered molecules can be eluted differentially from the solid phase, after washing to separate specific forms of the analyte from interfering substances. The elution is called an isocratic elution if the composition of the mobile phase remains constant throughout the run. If the mobile-phase composition is abruptly changed, then it is a step elution. If the composition is gradually changed throughout the run, then a gradient elution occurs.

The efficiency of separation in a chromatography system is a function of the flow rates of the different substances. The resolution of the system is a measure of the separation of the two solute bands in terms of their relative retention volumes (V_f) and their bandwidths (ω). Resolution (R_s) of solutes A and B is calculated as follows:

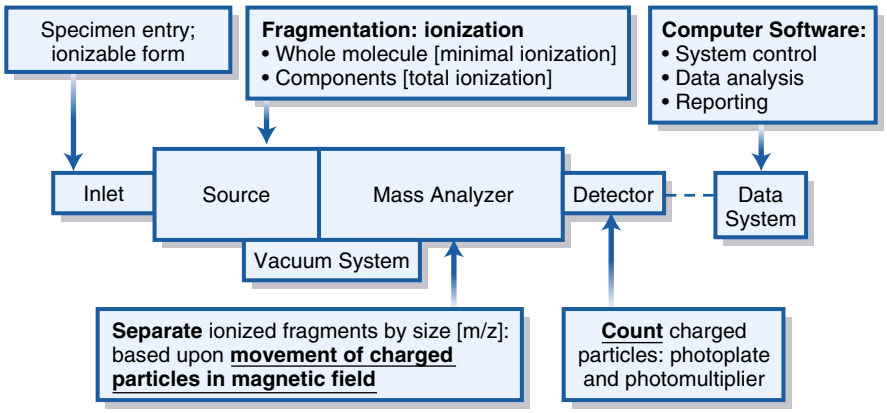
$$R_S = \frac{2\left[V_f(B) - V_f(A)\right]}{\omega(A) + \omega(B)}$$

Values of Rs less than 0.8 result in inadequate separation, and values greater than 1.25 correspond to baseline separation. The resolution of a chromatography column is a function of flow rates and thermodynamic factors.

HPLC remains the method of choice for clinical measurements of catecholamines in biologic fluids.[54,55] Simultaneous measurement of the three catecholamines (epinephrine, norepinephrine, and dopamine) can be obtained. Prior extraction by absorption on activated alumina and acid elution helps to improve specificity. Dihydroxybenzylamine, a molecule similar to endogenous catecholamines, can be used as an internal standard.

Mass Spectrometry

Mass spectrometry depends on the movement of charged particles through a magnetic field to separate and quantify them on the basis of their mass, or more rigorously their mass-to-charge ratio (m/z).[56] A mass spectrometer is an instrument designed to ionize analytes, accelerate them into a device (mass analyzer) that separates them based on their m/z, and quantifies their relative abundance. Fig. 4.8 illustrates the components and principles of a generic mass spectrometer. The heart of the system is the mass analyzer, which utilizes adjustable magnetic fields to accelerate or deflect volatile (e.g., in gaseous form) ions, typically in a vacuum so that the ion's flight path is determined only by the magnetic field. A source is used to ionize and, if necessary, volatilize and fragment analytes to introduce them into the mass analyzer. Analytes are introduced into the source via an inlet that can be as



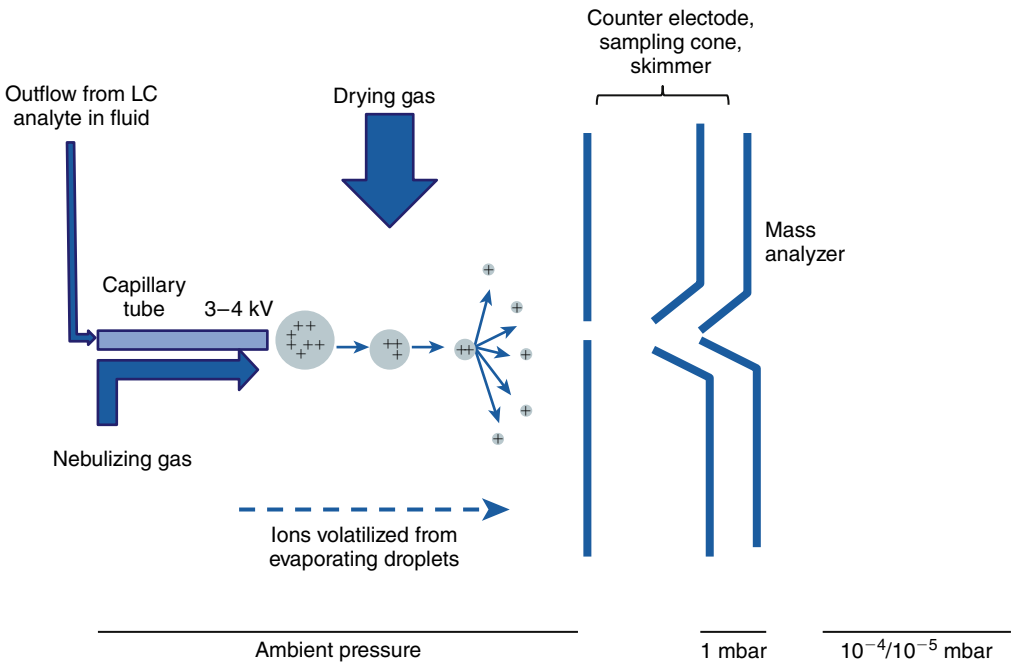
• **Fig. 4.8** Components and principles of a generic mass spectrometer. See discussion in text. *m/z*, mass-to-charge ratio.

simple as an injection port or as sophisticated as a laser-driven matrix desorption system or photoionization chamber. Charged particles passing through the mass analyzer are counted by a simple Faraday plate detector, which generates an electric current proportional in intensity to the frequency (abundance) of ions striking the detector. Mass spectrometers used in endocrine clinical testing are quite complex, with analytes being delivered to the inlet via a chromatography system, subtle selection of ions with *m*/*z* characteristics unique to the analyte, and measurement based on system calibration and recovery of internal standards. All of these aspects are controlled by the data system (computer software), which also generates data outputs that comply with clinical reporting requirements and increasingly can be integrated into fully electronic laboratory and medical record systems. These components are discussed in more detail later.

Analytic mass spectrometry was developed in tandem with the discovery and characterization of endocrine steroids during the 1930s, 1940s, and 1950s.[57] The source for these instruments ionized the analyte by electron impact (i.e., by bombarding gas molecules from the sample with electrons emitted from a heated filament), creating a full fragmentation of the analyte and multiple charged particles of each of the composite atoms. By determining the relative abundance and mass of each ionized particle, the molecular structure of the steroid could be constructed. However, the methodology requires that the steroids, indeed any analyte, be purified and volatilized prior to fragmentation and ionization in the source. Most steroid hormones are easily heat damaged and must be derivatized with molecules that can be volatilized and ionized before mass analysis. This methodology was used in strictly research applications in which it was invaluable in delineating the physiology of reproductive steroids. The development of gas chromatography, in conjunction with electron impact mass analyzers (GC/MS), led to the clinical use of mass spectrometry, which was applied first to endocrine steroids and subsequently to other small biologically important molecules. GC/MS, using quadrupole analyzers in scanning mode (see later), remains a key technology in the research laboratory today and arguably is the method of choice for the study of steroid hormone metabolites.[58] GC/MS was replaced for clinical endocrine steroid testing by the cheaper, higher throughput antibody-based assays, which remain the primary method in all but a few very large academic hospital or reference laboratories. However, dramatic advances in mass spectrometry design have led to the availability of instruments that are rapidly replacing many antibody-based assays, especially competitive immunoassays, in clinical laboratories.

The technologic advances leading up to modern mass spectrometers involve primarily the source and the mass analyzer components. The most dramatic advance in sources, with respect to clinical applications of mass spectrometry in endocrine testing, was the development of electrospray ionization (ESI).[59,60] This technology underlies the direct connection of liquid chromatography systems to mass spectrometry and is currently the method of choice for measuring analytes relevant to endocrinology, such as steroid hormones, in biologic fluids. The principle of ESI is illustrated in Fig. 4.9. The specimen to be measured in the effluent from a chromatography system is pushed at low speed through a capillary column into the source region of the spectrometer to create an aerosol when high voltage (positive or negative) is applied to the tube in the presence of a nebulizing gas. As the droplets in the aerosol dry, often with the aid of a drying gas, the molecules in the specimen become charged and volatilized. In gaseous form, these molecules then enter the mass analyzer.

ESI has directly resulted in the development of systems that are rapidly replacing the antibody-based assays in the clinical laboratory. The most obvious advantage is that liquid chromatography systems can be coupled directly to the mass spectrometer. This system allows the extensive knowledge of steroid and peptide purification by liquid chromatography to be directly applied in mass spectrometry systems that for the first time can be automated and support high throughput testing. Because the



• **Fig. 4.9** Principle of electrospray ionization for introducing analytes isolated by liquid chromatography (LC) directly into the mass spectrometer.

analysis time (seconds) in a mass analyzer is much shorter than the time required for chromatographic separations (minutes), several independent liquid chromatography systems can be supported by one mass spectrometer. Thus the technical advantages of the mass spectrometer (measurements based directly on the molecular composition of the analyte rather than indirect competition of the analyte for antibody binding) can be realized in the practical setting of clinical testing services.

The ionization achieved by ESI is also an important technologic advance. Although the exact mechanisms are still unclear, ESI is characterized by ionization at low temperatures and pressures and results in relatively little fragmentation of the analyte so that a molecular ion is always generated. This procedure has allowed the development of exquisitely specific methods. Most significant with respect to current clinical testing is tandem mass spectrometry, especially triple quadrupole mass analyzers linked together.

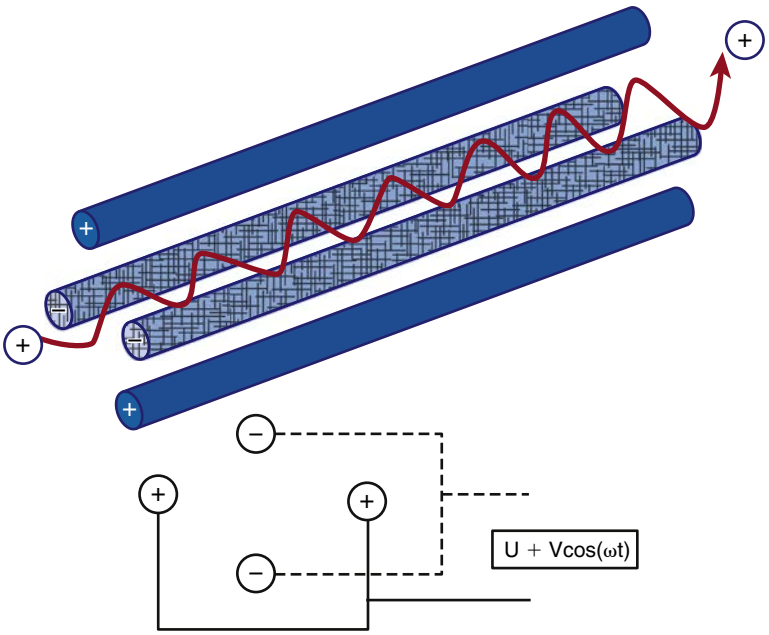
The design of a quadrupole mass analyzer is illustrated in Fig. 4.10. The analyzer is composed of four round electrodes. Voltage of the same polarity is applied to directly opposite electrodes, and opposite voltage polarity is applied to adjacent ones. An oscillating electric field is generated within the quadrupole when an alternating current (voltage V, frequency ω, and time t) is applied with a superimposed direct current (voltage U). Thus charged particles (ions) moving through the quadrupole follow oscillating paths and only ions with a specific *m*/*z* can pass through to the downstream detector. Ions with greater or lesser *m*/*z* collide with the electrodes and are not detected. By controlling the applied voltages, the analyzer can be operated to select ions of specific *m*/*z* for detection (or transit). Because ions are moving rapidly, and voltage can be controlled rapidly, the analysis time is very short. The analyzer thus can be operated in three distinct modes to (1) filter ions for the quantitation of only one *m*/*z*, (2) scan to sequentially quantify all ions by *m*/*z*, or (3) trap ions within the quadrupole.

Combining three quadrupole analyzers results in a very powerful system (Fig. 4.11), often referred to as the *triple quad mass spectrometer* and often in the clinical literature as simply LC/MS-MS or LC/tandem MS. The molecular ions generated by ESI can be filtered by the first mass analyzer (quadrupole) to capture, in a second mass analyzer, a molecular ion whose *m*/*z* is consistent with that of the target analyte. The captured molecular ion is fragmented and ionized in the second analyzer, which becomes the source for the third analyzer that either analyzes all the fragments or selects one that is unique to the parent ion. By operating the first and second quadrupoles in various modes, different analytic goals can be achieved. The primary approaches used for endocrine testing are multiple reaction monitoring and product ion scanning.

Multiple reaction monitoring mode allows both analytic analyzers (quadrupoles 1 and 3) to be fixed, selecting for a specific *m*/*z*. This adjustment increases specificity and sensitivity. This mode is used to monitor specific analytes and to confirm unambiguously the presence of a compound in a matrix. For example, two unique ions (first/second analyzer) for testosterone are 289.221/97.140 and 289.222/109.130. Because steroid hormones have well-known and unique elution times from LC systems, this mode is also widely used for steroid profiling, as illustrated in Fig. 4.12.

Product ion scanning allows a parent or precursor ion to be selected in quadrupole 1, and the scan in quadrupole 3 measures all the product ions resulting from fragmentation of that ion. This is a particularly useful method of operation for providing structural information concerning small organic molecules or for generating peptide sequence information.

Mass analyzer design continues to evolve rapidly. Another system that deserves consideration with respect to endocrine clinical testing is time-of-flight mass spectrometers (TOFMSs). As illustrated in Fig. 4.13, TOFMSs are simple, albeit more highly engineered, instruments designed to determine *m*/*z* based on the time required to traverse a vacuum tube. The source is designed to align and accelerate ions after ionization so that they all enter the vacuum tube at the same time. The time required to traverse the vacuum tube is proportional to *m*/*z* (more precisely, the square root of the *m*/*z*); smaller or more highly charged ions will move faster to the detector. Most modern TOFMSs have electronic reflectors to effectively increase path length



• **Fig. 4.10** Design of the quadrupole mass analyzer. See discussion in text.

and thus resolution; this design is often referred as a TOF-TOFMS. Time-of-flight spectrometers are especially well suited for the measurement of large molecules, including proteins larger than the range of quadrupole analyzers. The range of TOFMS includes DNA fragments and even whole microorganisms. Another particular advantage of TOFMSs is their compatibility with pulse ionization sources such as matric-assisted laser desorption/ionization (MALDI) or surface-enhanced laser desorption/ionization (SELDI) systems. Since the introduction of TOF spectrometry in the mid-1980s, a wide range of combination analyzers such as MALDI-TOF or SELDI-TOF

instruments have been developed and used in genomic, proteomic, and metabolomics studies as well as applied to biomarker discovery and microorganism identification.[61–66]

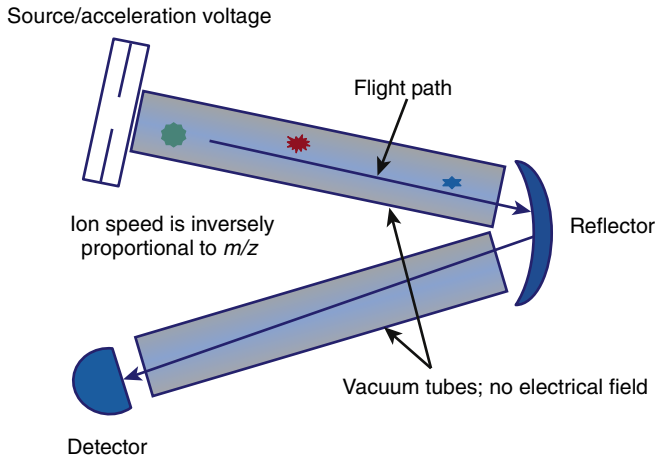
Translating the progress achieved by research applications of TOFMS into clinical diagnostics is still limited to the identification of microorganisms, mostly bacteria and fungi based on spectral libraries. Improved preanalytic, analytic, and postanalytic processes, including standardization, improved clinical sensitivity without loss of specificity for microorganism identification, and qualitative measurement of antibiotic sensitivity remain challenges to wider clinical applications.[67–71] In the near future, TOFMS is likely to find increasing applications in endocrine clinical laboratories. For example, current antibody-based methods for proteins such as TSH, prolactin, and thyroglobulin are often inaccurate in the presence of endogenous antibody. Mass spectrometry, particularly the MALDI-TOF given its ability to measure large proteins, is an attractive approach to addressing this issue.

Free Hormone Methods

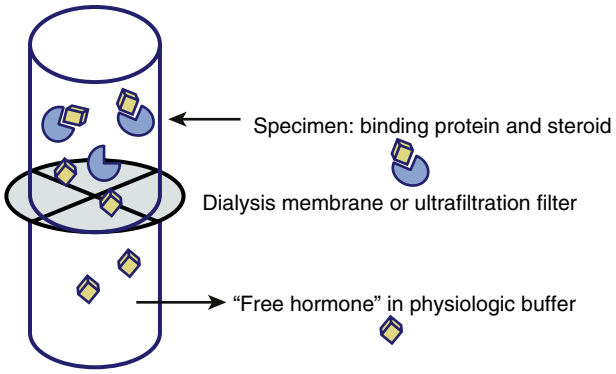
The design of assays, either antibody or mass spectrometry based, to measure steroid hormones and sterols (such as vitamin D) present special issues that warrant discussion. These analytes, which for the sake of simplicity are discussed as steroid hormones, are extremely hydrophobic. In aqueous environments, particularly blood and blood-derived specimens in which measurement is intended, steroid hormones are associated with hydrophobic regions of proteins or bound tightly to high-affinity, specific transport proteins. The former includes albumin, prealbumin, transthyretin, and apolipoproteins, among others, and the latter includes specific transport proteins listed in Table 4.2. Less than 5% to 10% of most steroid hormones circulate as free (unbound) analytes, and assay design requires that the protein-bound analyte be released or does not interfere in the assay in order to have an accurate measure of the total hormone present. Although not universally applicable, in many cases the physiologic effects of steroid hormones depend on the free hormone concentration rather than the total hormone concentration. Of course, under normal conditions the free and total hormone concentrations are directly related. This concept, known as the free hormone hypothesis, is the basis for the design of methods specifically intended to measure only the free hormone levels.[72–77] The free hormone hypothesis itself is controversial, and a critical discussion of it is beyond the scope of this chapter; however, the reader is directed to specific applications in the clinical chapters of this text. Here it is hoped that a technology-based discussion will give the reader an appreciation of the various methods that have been and are currently used to measure free hormones.

There are two basic types of assay designs for measuring free hormones: (1) assays based on the physical separation of bound and free hormones prior to measurement and (2) antibody-based binding assays designed to measure only the free hormones.

Fig. 4.14 illustrates the design of assays based on physically separating bound from free steroid hormones. Classically, a dialysis



• **Fig. 4.13** Design of a time-of-flight mass spectrometer. *m/z*, mass-to-charge ratio.



• **Fig. 4.14** Free hormone assay design: Physical separation of free hormone. Dialysis membranes or ultrafiltration allow the separation of free hormone from protein-bound hormone prior to measurement of free hormone directly or by determining the percent distribution of labeled hormone added to the specimen before processing.

TABLE 4.2 Circulating High-Affinity Protein Carriers of Steroid Hormones

Protein Carrier	Primary Ligand(s)	Note
Corticosteroid-binding globulin (CBG)	Glucocorticoids, mineralocorticoids	Also binds cell membranes
Sex hormone–binding globulin	Dihydrotestosterone, testosterone, estradiol	Also binds cell membranes
Thyroxine-binding globulin (TBG)	Thyroxine (T_4), triiodothyronine (T_3)	
Vitamin A–binding protein(s)	Vitamin A (retinol)	
Vitamin D–binding protein	25(OH) vitamin D_2, 25(OH) vitamin D_3, 1,25(OH) vitamin D_2, 1,25 vitamin D_3	Also binds cell membranes

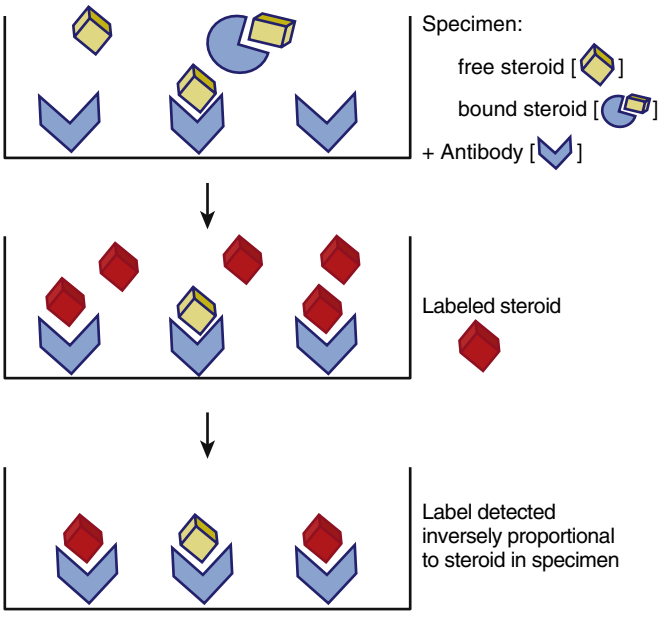
membrane was used to separate two fluid-filled chambers (e.g., tubes). The pore size of the dialysis membrane is specific to the analyte/binding proteins but in principle allows free movement of free steroid hormones while retaining the higher molecular-weight binding proteins and conjugated binding protein-steroid hormone complexes. Thus by placing the specimen in one chamber (top in Fig. 4.14) and matrix-appropriate buffer in the other and allowing the diffusion of free hormone to equilibrate, the free hormone can be measured directly by this equilibrium dialysis approach. Subsequent variations on the method include using an ultrafiltration membrane to allow faster (e.g., no need to wait for an equilibrium to be established) separation of bound from free steroid hormone (as illustrated in Fig. 4.14) or to chemically separate the high-molecular-weight bound hormone from the free hormone (e.g., precipitation of sex hormone–binding globulin–bound steroid using ammonium sulfate). The biggest challenge associated with this approach, regardless of how separating bound from free steroid hormone was achieved, is the measurement of the very low concentrations of free steroid hormone after separation (e.g., in the dialysate or lower chamber in Fig. 4.14). Thus a variation on the equilibrium dialysis design is to add labeled steroid hormone to the specimen prior to dialysis. High specific activity labels, such as radioisotopes, allow the detection of trace amounts of free hormone after dialysis. It is then possible to use the percentage of free hormone based on the distribution of labeled hormone to calculate the mass of free hormone from a direct measurement of total hormone by traditional methods.

One might easily get the misimpression, especially now that LC/MS-MS systems with sufficiently high sensitivity have been combined with it, that equilibrium dialysis is the method of choice or a gold standard method for measuring free hormones.[57,78,79] However, it must be emphasized that currently there is no established reference method for the measurement of free steroid hormones and that most separation methods, including equilibrium dialysis, have not been applied in a fashion that is necessarily valid or directly applicable to in vivo conditions.[73,77,80,81]

Antibody-based binding assays designed to measure only the free hormone can be divided into two classes: (1) two-step assays and (2) one-step assays.

The two-step immunoassay relies on labeled steroid and is illustrated in Fig. 4.15. Solid-phase antibody is used to capture the free hormone present in the specimen. The amount, if any, of bound hormone capture will depend on the relative affinity of the steroid for the antibody versus the binding protein. If the antibody affinity is much higher, the bound steroid will be stripped from the binding protein. If the antibody affinity is relatively low compared to the binding protein, only free hormone will be bound. In either case, after washing the solid-phase antibody, unoccupied antibody-binding sites are titrated using labeled steroid, which after a second wash step can be quantified. The signal generated by the captured labeled steroid is inversely proportional to the amount of free hormone in the specimens. It is important to note that free in this assay format is defined by the relative affinity of the antibody used and the endogenous steroid binding proteins.

One-step immunoassays are designed using either labeled steroid or labeled antibody. The basic formats are illustrated in Fig. 4.16. These assays are fast and easy to perform given their relatively simple format, which is also quite amenable to automation. The use of a labeled steroid analogue is summarized in Fig. 4.16A. The labeled analogue is not recognized by the binding protein but is able to compete with free hormone for antibody-binding sites on the solid phase. This type of assay depends on the validity of



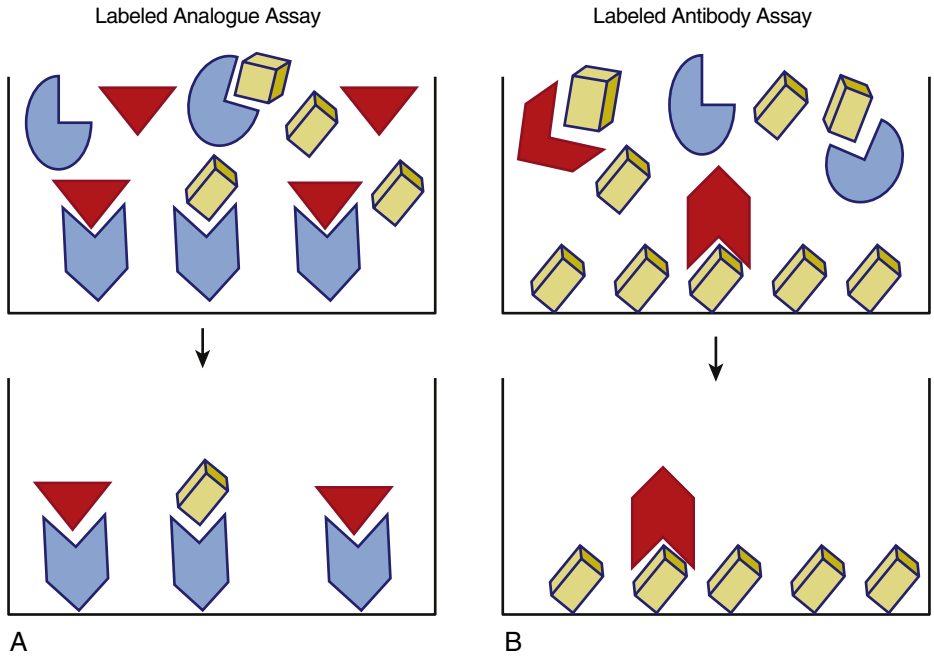
• **Fig. 4.15** Free hormone assay design: Solid-phase, indirect immunoassay. Excess solid-phase antibody binds the free steroid hormone during step 1 of this method. After washing, incubation with labeled steroid hormone (step 2) allows unbound antibody sites to be titrated. After a second wash, the amount of labeled steroid bound to the solid-phase antibody is inversely proportional to the amount of free hormone in the specimen.

the assumption that the signal generated, which is inversely proportional to the concentration of free steroid in the specimen, is solely due to the competition with free hormone. This has been shown not to be true for free testosterone assays and is likely valid only over a limited range for binding protein concentrations for free thyroxine assays.[77,82–87] An alternative approach is shown in Fig. 4.16B in which a labeled antibody is employed in an assay based upon its binding to solid-phase antigen (e.g., the analyte of interest). In this design, the signal generated reflects the amount of labeled antibody bound to the solid phase which, after reaching a steady state, is inversely proportional to the concentration of free steroid hormone in the specimen. The advantage of this newer approach is that a relatively higher signal is measured (e.g., improved sensitivity and precision), and it is not necessary to alter the structure of the steroid (other than that which may be associated with attachment to the solid phase).

It is important to recognize that for free steroid assay designs, the kinetics of competition and binding are very complex given the variety of proteins interacting with steroid hormones over a wide range of affinities. Specimens with low concentrations of binding proteins, including low-affinity but high-capacity binders such as albumin, are particularly challenging. As is true for any assay, all of these free hormone measurement methods require careful validation and method-specific reference intervals to be clinically useful.[73,74,80,81,88,89]

Nucleic Acid–Based Methods

Nucleic acid–based assays are designed to identify variations in an individual's DNA or RNA sequence that reflect molecular variance (e.g., mutations, rearrangements) that alters gene expression, regulatory pathways, and bioactive molecules in a fashion relevant to human disease (i.e., early diagnosis or increased disease



• **Fig. 4.16** Free hormone assay design: One-step immunoassays. (A) A labeled analogue steroid hormone that binds to antibody but not to binding proteins is used in a classic competitive binding format to measure only the free hormone in the specimen. (B) Labeled antibody is used in a single-step competitive assay in which free steroid hormone in the specimen competes with solid-phase steroid hormone for antibody binding. The amount of labeled antibody bound to the solid phase after washing is inversely proportional to the amount of free steroid hormone in the specimen. Red indicates labeled analogue steroid hormone in (A) and labeled antibody in (B).

susceptibility). Genetic variance results in a range of alterations from whole chromosome effects visible by karyotyping/cytogenetics to point mutations leading ultimately to changes in protein expression or functionality. As small molecules such as steroid hormones depend on protein enzymes, genetic alterations may affect all aspects of endocrine function and hence are important analytic targets. A plethora of analytic methods exist for the analysis of nucleic acids.

Discussion of the full range of methods is beyond the scope of this review, but these methods can be grouped into three major categories: (1) chromosome visualization methods, with or without application of sequence-selective enzymatic fragmentation; (2) assays based on binding of labeled nucleic acid probes, which obey Watson and Crick base-pairing rules and thus are sequence specific; and (3) direct sequencing of DNA or RNA. Methods in categories 2 and 3 are generally combined with methods for the amplification or selective enrichment of target sequences, but methods in category 1 generally depend on microscopy (whole chromosome analysis), fragmentation, gel electrophoresis, and blotting techniques (e.g., Southern blotting for DNA or Northern blotting for RNA). Thus the key elements to appreciate are hybridization, restriction enzyme fragmentation, electrophoretic separation, amplification, and nucleic acid sequencing. Methods composed of various combinations of these principles are available for scanning DNA sequences for new variants, scoring DNA sequences for known variants, and expression analysis of DNA or RNA target sequences. Direct sequencing effectively scores known variants as well as identifies new variants.

Currently, molecular methods being utilized by clinical laboratories are primarily for well-known inherited diseases, cancer diagnostics and management, and increasingly in infectious disease applications. Based on developments in research laboratories, particularly with respect to next generation sequencing (NGS), these methods are likely to affect clinical endocrine testing in the very near future.[90–92] The majority of nucleic acid–based assays are laboratory-developed methods applied in research settings or highly specialized clinical reference laboratories. However, this picture is rapidly changing as devices suitable for use in hospital clinical laboratories are increasingly becoming available.

Hybridization Assays (Mutation Assays, Genotyping)

Nucleic acid molecules have a unique ability to bind with high affinity to complementary base-pair sequences. When a fragment of a known sequence (probe) is mixed under specific conditions with a specimen containing a complementary sequence, hybridization occurs. This feature is analogous to the antibody-antigen binding used in immunoassays. Many of the formats used for immunoassay have been adapted to nucleic acid assays, including some of the same signal systems (e.g., radioactivity, fluorescence, chemiluminescence) and the same solid-phase capture systems (e.g., magnetic beads, biotin-streptavidin binding). In situ hybridization, which involves the binding of probes to intact tissue and cells, provides information about morphologic localization analogous to that provided by immunohistochemistry. Combining hybridization methods with enzymatic procedures to amplify, extend, and ligate DNA targets or probes greatly enhances the analytic sensitivity and specificity of hybridization-based methods. Hybridization methods, like other binding assays, are quite amenable to automation and incorporation into relatively simple devices suitable for clinical laboratory utilization.

Restriction Fragmentation

DNA restriction enzymes break DNA strands at specific sites based on the nucleic acid sequence. Thus digestion with a given restriction enzyme or combination of restriction enzymes will produce fragments of different lengths that are directly related to the DNA sequence. Mutations that alter the sequence of the enzyme cleavage site(s) will result in altered fragment size patterns, referred to as restriction fragment length polymorphisms (RFLPs), which can be visualized after fragment separation by gel electrophoresis or other separation methods. For known mutations the affected DNA sequence can be amplified (see later) prior to RFLP analysis (or by single-nucleotide extension if the mutation does not alter a restriction enzyme cleavage site). A large number of online tools are available to support researchers designing methods involving the use of restriction enzymes.[93,94] These tools can be useful in designing validation studies of commercially available assays for molecular variance.

Electrophoretic Separation

E.M. Southern invented an electrophoretic separation technique known as Southern blotting.[77] Restriction enzymes are used to digest a sample of DNA into fragments, and the product is subjected to electrophoresis. The separated bands of DNA are then transferred to a solid support and hybridized. Northern blotting is a similar technique in which RNA is used as the starting material. Western blotting refers to electrophoresis and transfer of proteins. Currently a wide range of methods for electrophoretic separation and blotting of DNA, RNA, and proteins is available and incorporated into clinically relevant methods. All are relatively complex laboratory-developed methods.

Amplification

Nucleic acid assays have an advantage in that low concentrations can be amplified in vitro before quantitation. The best-known amplification procedure is the polymerase chain reaction (PCR). The three steps in the process (denaturation, annealing, and elongation) occur rapidly at different temperatures. Each cycle of amplification can occur in less than 90 seconds by cycling the temperature. The target double-stranded DNA is denatured at high temperature to make two single-stranded DNA fragments. Oligonucleotide primers, which are specific for the target region, are annealed to the DNA when the temperature is lowered. Addition of DNA polymerase allows the primer DNA to extend across the amplification region, thus doubling the number of DNA copies.

At 85% to 90% efficiency, this process can amplify the DNA by about 250,000-fold in 20 cycles. This huge amplification is subject to major problems with contamination if special precautions are not taken.

Sequencing Methods

Traditionally, sequencing was performed using DNA polymerase to selectively incorporate dideoxynucleotides (causing chain termination) during in vitro DNA replication. This method, which was developed by Sanger and is now referred to as Sanger sequencing, remains the gold standard.[95,96] Although this method, which was used in the first sequencing of the human genome, is straightforward and reliable, it is primarily used in directed sequencing of relatively small lengths of DNA.

Next generation sequencing is a very different approach to sequencing and refers to a wide array of applications, including whole genome sequencing, exon sequencing, DNA-protein interaction assays, and RNA sequencing.[90,97–99] NGS methods, also referred to as high-throughput sequencing, all involve simultaneous identification (i.e., parallel sequencing) of nucleic acids released from DNA or RNA fragments rather than identification of nucleic acids released/identified in a serial fashion as is done in the earlier procedures (e.g., Sanger sequencing). NGS approaches hold tremendous clinical diagnostic potential because parallel sequencing is faster and orders of magnitude cheaper than serial sequencing.[100,101]

Methods encompassed in NGS are evolving very rapidly but currently include massively parallel signature sequencing, polony sequencing, pyrosequencing, dye sequencing (Illumina), and sequencing by ligation (Applied Biosystems) as well as a plethora of newer methods.[102–107] Currently the focus of new sequencing approaches is to develop methods capable of sequencing larger, more complex (e.g., high redundancy sequence) fragments of DNA. In particular, complex, repetitive, megabase DNA regions are subject to technical and computational limitations to accurately assessing sequence variance.[102,108,109]

NGS is still primarily a research tool providing unique information concerning the mechanisms of disease. NGS has already provided valuable insight into endocrine diseases by identifying sequence variants associated with (1) endocrine tumors, (2) disorders of bone and mineral metabolism, (3) adrenal disorders, (4) gonadal disorders, (5) pituitary and hypothalamic diseases, (6) thyroid disorders, (7) sex development disorders, and (8) multiple endocrinopathy syndromes.[109–119] The clinical value of NGS is clear, and its clinical use is a potential game-changer as it allows diagnosis of disease at a personal rather than a population level and can contribute to prognosis and/or suggest the most effective interventions for individual patients.[104,120,121] However, to truly achieve clinical value, NGS-based diagnostics must be fully validated, standardized, cost effective, provide for secure data storage, produce actionable results, and be compliant with ethical standards of patient care.[101,122–130]

Analytic Validation

In this section, the basic elements of method validation are outlined and are applicable to any quantitative assay method discussed in the methods sections earlier. It is only the degree to which the parameters are determined and the frequency with which they are verified that vary from method to method or as a function of assay class. Clearly, to be clinically valuable an analytic method must be valid; that is, the results or measurements generated are accurate and reproducible within the context of use (i.e., specified concentration limits, specimen types, clinical settings). This is often expressed as demonstrating that the method is "fit for use." In more straightforward terms, any given method is valid only within specifications of use. In practical terms, methods are validated, or more accurately, their validity is verified, by clinical laboratories to the extent required by appropriate regulatory guidelines (see "Classes of Assays").

The validation process begins with the design and development of the method, regardless of the technical processes involved. Clinical laboratories approach validation differently depending on the technologies and reagents used. Commercial systems (instruments and reagents) are validated by the manufacturer, who is also responsible for quality control of subsequent reagent lots and instrument change. Clinical laboratories conduct limited studies to verify the validation. When using instruments and reagents made or modified by the clinical laboratory, full validation is necessary. In both settings, the clinical laboratory relies on professional guidelines specific to the technology.

Failure to fully appreciate these subtleties can lead to very erroneous perspectives of the results reported by a given laboratory or obtained by a given method. For example, the majority of assays used to diagnose endocrine diseases are accurate only over specific ranges of analytes, only with reference to specific and generally nonstandardized calibration materials, and only when applied to specific specimen types. In many cases, results that are essential to patient care are method specific and cannot be extrapolated between methods and laboratories.

The basic elements of method validation are listed in Table 4.3 along with the typical studies conducted to characterize each parameter. The parameters that define an assay's analytic performance are dependent on the technology and reagents employed and are often referred to as intrinsic characteristics. These characteristics include sensitivity, specificity, precision, and accuracy. Validation must also include specification of the assay's utility and provide data to support the clinical interpretation of results generated by the assay; these are listed in Table 4.3 as utility and interpretation parameters. As illustrated in Fig. 4.17, intrinsic parameters are interrelated. For example, as illustrated in Fig. 4.18, accuracy and precision are related parameters and must be optimized and validated in conjunction with each other. In the context of method development, assay validation is typically an iterative process, as shown in Fig. 4.19. It is only after an assay is optimized analytically for specificity, sensitivity, and precision, and accuracy is applied to clinical testing, that these parameters can be fully evaluated and interpretive specifications can be established.

Intrinsic Performance Parameters

Analytic Specificity

Analytic specificity can be simply defined as the ability of the assay to measure only the intended analyte. In other words, the value obtained from a measurement reflects only the concentration of the target analyte. Clearly, then, specificity is closely related to accuracy; an assay cannot be accurate if it is not specific. On the other hand, an assay may be specific but not accurate if, for example, the assay measures only the target analyte but produces a value that overestimates or underestimates its concentration due to calibration, recovery, or other technical issues. From a more practical perspective, specificity is often defined based on the signal generated in the assay; that is, the signal produced in a specific assay is generated only by the target analyte. Few assays, regardless of the technology used, are truly specific in this sense; typically, the signal measured can be generated by components of the specimen or assay systems in addition to the target analyte. Thus practical validation of specificity encompasses not only specificity per se but also interferences, such as matrix effects or ion suppression that can alter the derived concentration resulting in an inaccurate measurement. It is important to emphasize that interference can be specimen specific and is a challenge to assay validation as well as quality control and quality assurance.

TABLE 4.3 Parameters and Studies for Method Validation

Parameter of Performance	Validation Study
Specificity	Cross-reactivity Interference
Sensitivity	Analytic sensitivity Limits
Precision	Intra-assay variance Inter-assay variance
Accuracy	Recovery Bias Linearity Carryover
Utility (robustness)	Specimen stability Reagent stability Assay stability
Interpretation	Reportable range Reference intervals Diagnostic power

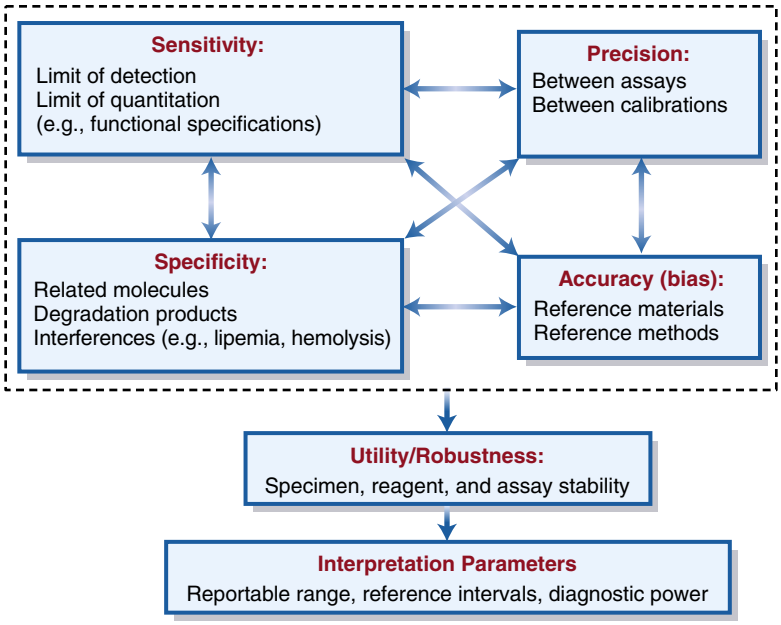
Cross-Reactivity

Assay cross-reactivity can be generically defined as signal generation by similar analytes. It is typically a definable and predictable assay characteristic (e.g., any specimen containing cross-reacting analytes will not be accurately measured).

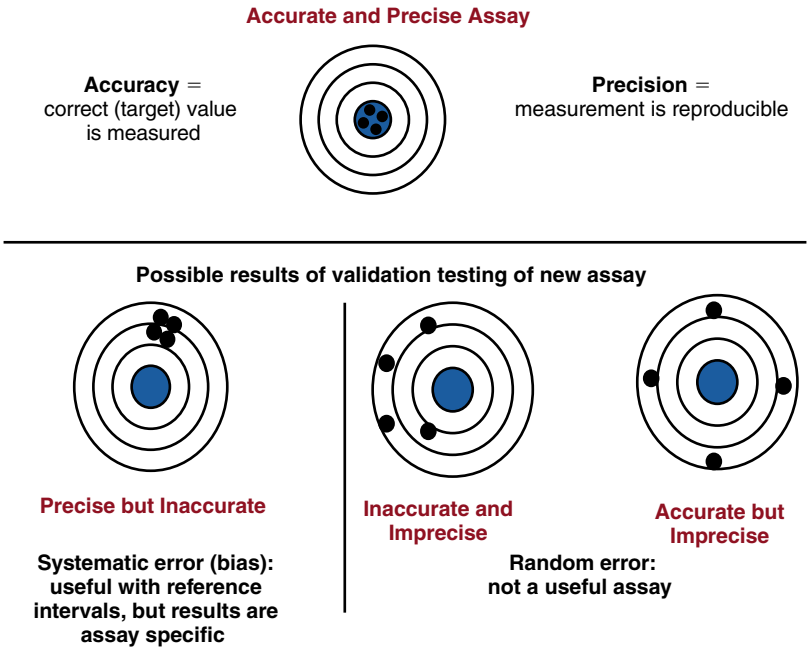
Cross-reactivity in antibody-based assays is due primarily to the specificity of the antibody-binding sites used in the assay. For example, steroids with a similar structure may bind to the antibody and compete with the labeled analyte to produce the same signal (decrease in labeled analyte binding) as the target analyte. Similarly, proteins containing a binding epitope similar to the ones targeted in an immunometric assay can generate signal (i.e., increased binding of the detection antibody). Cross-reactivity is not a term typically used with respect to structural or nucleic acid–based assays, but the concept is applicable. For example, if the fragment used for quantification can be generated by more than one analyte, the signal generated is not specific. Similarly, if the sequence target for a nucleic acid–binding assay is large, the detection probe may bind to more than one analyte. In all cases, the cross-reactivity is not necessarily complete in that the cross-reacting analyte may generate the same, more, or less signal than the target analyte. Thus the degree to which cross-reactivity vitiates assay measurements will be dependent on the concentration of cross-reacting analyte and the degree to which it cross-reacts.

Assays are validated with respect to cross-reactivity primarily by two approaches: (1) response curve comparison and (2) spiked specimen measurement.

Response curve comparisons are done by adding known amounts of analytes expected to cross-react (based on the design of the assay) to the appropriate matrix to generate a dose-response curve for each analyte to be tested. These response curves are compared to those used to quantify the target analyte (e.g., the calibration curve). When possible, the curves are compared at the half-maximal response point where precision and sensitivity (see later) are highest. The degree of cross-reactivity can then be expressed as a percentage. An example of the procedure is shown in Fig. 4.20. The half-maximal response (50% B_{max}/total labeled antibody bound) is generated by a concentration of 200 mass/mL of the target analyte. In contrast, 2000 mass/mL of the cross-reacting analyte is required to generate a half-maximal response. Thus the cross-reactivity of this cross-reacting analyte is 10% (i.e., % cross-reactivity = [200/2000] × 100). It is important to appreciate that this approach is valid only if the response curves are parallel.



• **Fig. 4.17** Relationships and sequencing of method validation parameters.

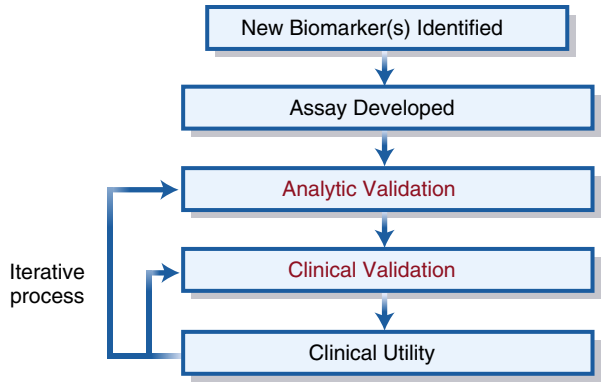


• **Fig. 4.18** Assay accuracy and precision are closely related parameters that must be optimized and validated together.

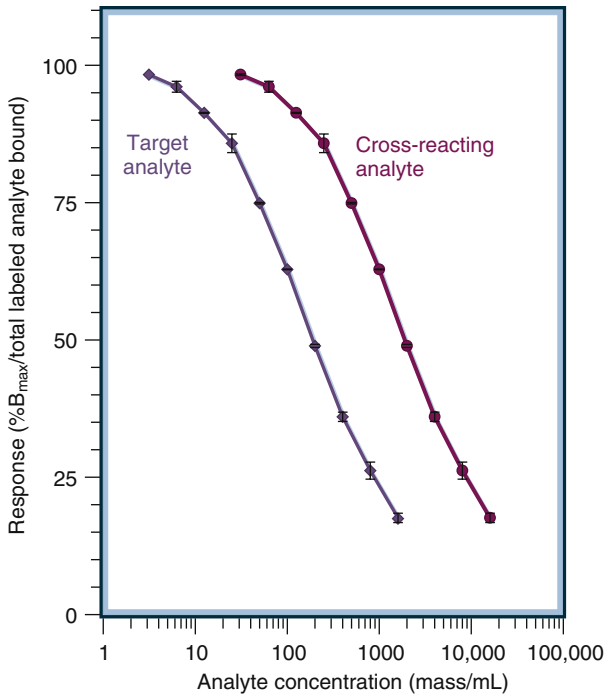
Spiked specimen measurement is often used to determine analyte cross-reactivity. This approach involves adding the cross-reacting analyte to a specimen that has been measured and then performing re-assay to determine if the added analyte cross-reacted. This approach is often seen in the package inserts of commercial assays. An example is shown in Table 4.4 for a commercial assay for the measurement of cortisol in human serum or plasma. The concentration achieved by spiking human serum is indicated for each potential cross-reactant listed. The unspiked human serum contained 12 µg/dL of endogenous cortisol as measured in the assay. Thus a cross-reactivity of 36.6% for fludrocortisone means that a cortisol value of 16.4 µg/dL was measured after the addition of 100 µg/dL of fludrocortisone to the specimen. Spiked specimen cross-reactivity data must be interpreted carefully as it assumes that the percent of cross-reactivity will be the same at all levels of cross-reactant and that the concentrations of cross-reactant tested are clinically relevant.

Interference

As alluded to previously, interference can be due to the influence of a specimen component on the signal generated by the target analyte or to the generation of signal by the interfering substance. In the latter case, what distinguishes interference



• **Fig. 4.19** Iterative nature of the assay development and validation process.



• **Fig. 4.20** Method for determining analyte cross-reactivity. See discussion of cross-reactivity in text.

from cross-reactivity is the lack of parallelism in the signal generation by interfering substances. Often the interfering substance or the mechanism of interference is something known; frequently encountered examples are given in the following paragraphs. In other cases, neither the mechanism nor interfering substance is known; in this case, interference is referred to as a matrix effect. Matrix effects are typically identified only during the validation of accuracy (see later). They can be specimen specific, in which case they are identified only during the investigation of results that are inconsistent with the clinical setting or other analytic results. It is critical that the clinical laboratory keep in mind that any analytic method can be subject to specimen-specific interferences unknown to the laboratory or indicated by routine quality control monitoring. Thus, despite a numeric value often to several decimal places and reported from a validated method, an analytic result from any single specimen must be interpreted in the overall clinical context.

TABLE 4.4 Example of Spiked Specimen Cross-Reactivity Data From a Commercial Immunoassay for the Measurement of Cortisol

Compound	Concentration (µg/dL)	Cross-Reactivity (%)
Aldosterone	1000	0
Beclomethasone	1000	0
Budesonide	1000	0
Canrenone	1000	0.1
Corticosterone	1000	0.9
Cortisol 21-glucuronide	1000	0.2
Cortisone	1000	2.7
β-Cortol	1000	0
β-Cortolone	1000	0
11-Deoxycorticosterone	100	0
11-Deoxycortisol	100	1.9
Dexamethasone	1000	0
DHEA	1000	0
DHEAS	1000	0
β-Estradiol	1000	0
Estriol	1000	0
Estrone	1000	0
Fludrocortisone	100	36.6
Fluticasone propionate	1000	0

DHEA, Dehydroepiandrosterone; *DHEAS*, dehydroepiandrosterone 3-sulfate.

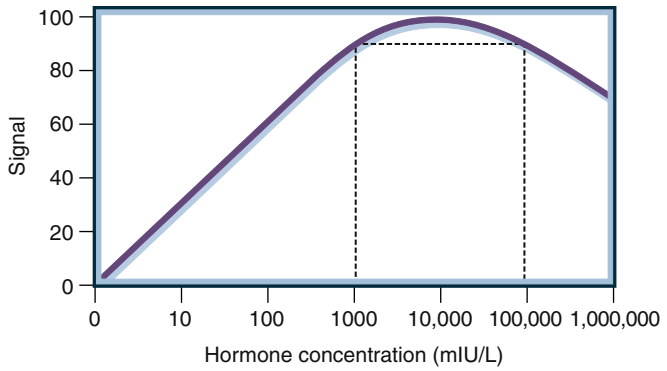
Well-known interference with assays that depend on light or fluorescence signaling can be due to hemolyzed, lipemic, and icteric specimens. Interference can also be a function of physically influencing the system. For example, a severe degree of lipemia can result in inaccurate measurement of water-soluble analytes. Interference can also be analyte specific. Some proteins are inaccurately measured in hemolyzed specimens due to digestion by proteases released during hemolysis (rather than due to a nonspecific color interference with light detection).

Two interferences that are well known to affect immunometric assays (but an issue to some extent for all antibody-based assays) are hook effects and heterophile antibody interferences.

The mechanism of the hook effect is illustrated in Fig. 4.21. As the antigen concentration approaches the effective binding capacity of the capture antibody system, the signal no longer increases. At this point, laboratory specifications for maximum reportable signal are exceeded and the specimen is diluted to obtain an accurate measurement. However, analyte concentrations vastly exceeding the binding capacity of the capture antibody result in also blocking the detection antibody, resulting in a decrease in signal back into the reportable range. Extending the principle to the extreme, it is theoretically possible to have so much analyte present that all the binding sites on both the capture and detection

antibodies are occupied; in this case, no detection antibody can be bound to the solid phase and the signal is baseline, which would be interpreted as no analyte present! Hook effects occur and are extremely important to recognize in the context of measuring hormones in patients with tumors that secrete large quantities of the hormone. Hook effects have been extensively reported for prolactin, hCG, thyroglobulin, calcitonin, and α-fetoprotein.[29,30,131–139]

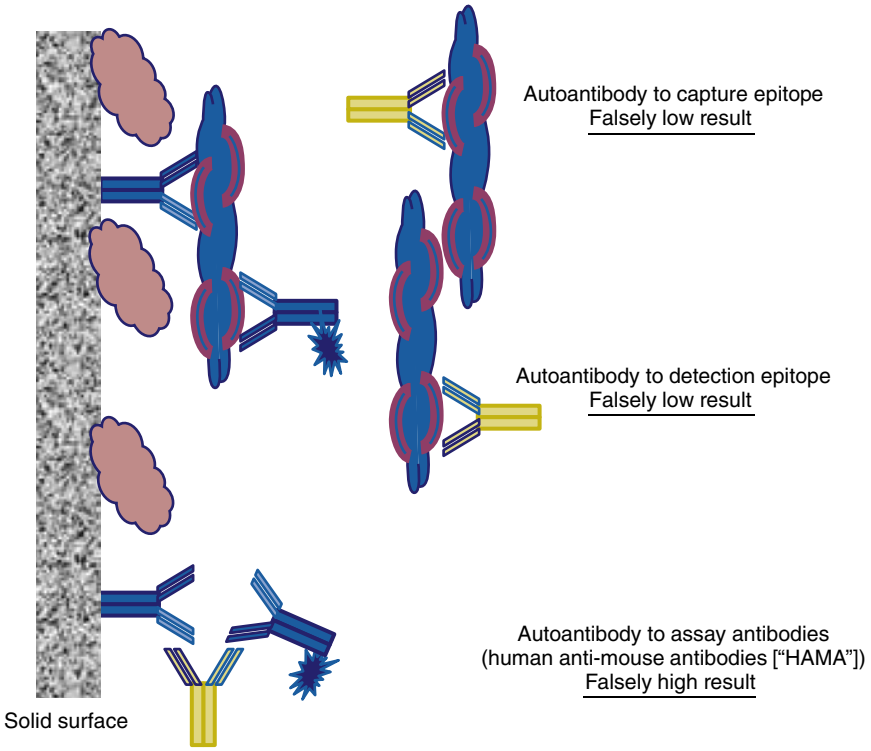
Heterophile antibody interference is, if not a misnomer, certainly a process that encompasses more than just the ability of endogenous antibodies to animal immunoglobulins to interfere in immunometric assays. The mechanism is simple and is illustrated in Fig. 4.22. Any analyte-independent process that alters the amount of detection antibody bound to the solid will result in inaccurate assay values. As shown in Fig. 4.22, endogenous antibodies (called heterophile antibodies) to animal immunoglobulins



• **Fig. 4.21** Immunometric high-dose hook effect. The response signal reaches a maximum and then decreases when the antigen concentration exceeds the limit of the assay.

can, because antibodies are bivalent, link the detection antibody to the solid-phase capture antibody in the absence of analyte, resulting in a falsely high value reported. Animal immunoglobulins are foreign proteins, and thus most humans are expected to have low titers of animal immunoglobulin antibodies. Immunometric assays are designed with blockers to eliminate heterophile antibody interference. However, some individuals have high titers of heterophile antibodies, which overcome the assay blockers and result in inaccurate measurements. In some cases, such as patients treated with drugs containing animal immunoglobulins (e.g., monoclonal-based therapeutics), it is clear why the patient has high titers; in others it is difficult to identify a priori individuals whose specimens might be subject to this artifact.[140–150] Heterophiles are not the only form of endogenous antibody that can interfere with immunometric assays by this mechanism (e.g., antibody-based analyte-independent interference). Fig. 4.22 shows that endogenous antibodies to epitopes on the target analyte can also result in inaccurate measurements—in this case, falsely low results—because the endogenous antibodies block the quantitative detection of analyte. Although the protein hormones and biomarkers relevant to endocrine practice do not elicit the formation of endogenous antibodies in healthy individuals, patients with various autoimmune conditions or other disease processes may have endogenous antibodies that interfere with specific immunometric assays. A classic example of nonheterophile endogenous antibody interference is the interference in thyroglobulin assays by thyroglobulin antibodies in cancer patients.[151–153]

Endogenous antibodies and binding proteins can also interfere with the interpretation of values obtained from antibody-based assays. For example, endogenous antibodies bound to prolactin create what is referred to as *macroprolactin*. Macroprolactin is not biologically active but is measured in many immunometric assays. This results in prolactin levels being reported that are discordant



• **Fig. 4.22** Heterophile antibody interference. See text for details. (From Sluss PM. Methodologies for measurement of cardiac markers. *Clin Lab Med.* 2014;34:167–185.)

with clinical manifestations of hyperprolactinemia.[135,154] Another example is the ability of competitive assays to measure small molecules, such as thyroid or sex hormones, that are inactive when bound to high-affinity carrier proteins, such as thyroxine-binding globulin or sex hormone–binding globulin. In this case, values reported by immunoassay can grossly overestimate the biologic signal represented by the hormone measurement.

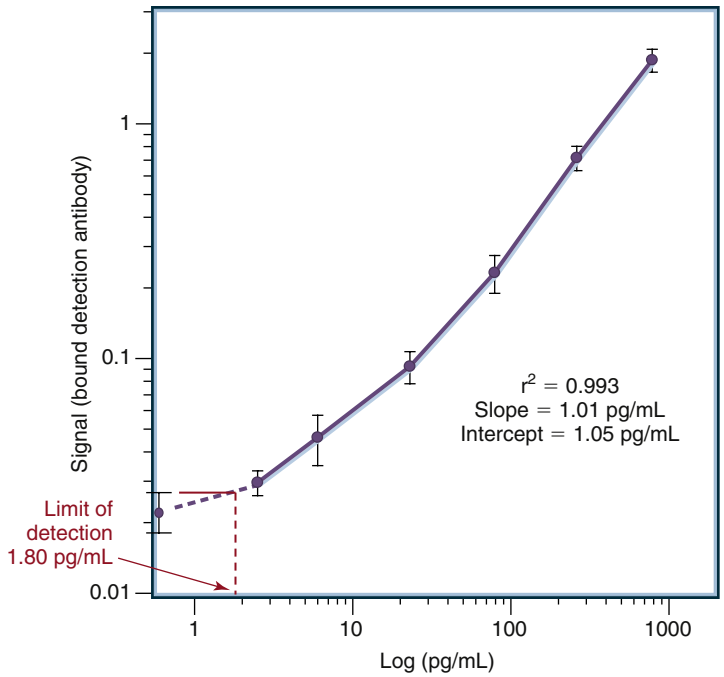
Antibody-based assays that utilize biotinylated antibodies or analytes are susceptible to interference from high levels of biotin in the assay sample, which can occur if the patient is taking very large doses of biotin as a health supplement. This can result in falsely elevated sample values in competitive binding immunoassays and falsely low sample values in immunometric assays. If, for example, free thyroxine and TSH assays both use biotin, the reported free thyroxine can be falsely high and the reported TSH can be falsely low, a situation that could be mistakenly interpreted as indicative of thyrotoxicosis. Biotin interference can be especially difficult to suspect where the artifact causes both a high free thyroxine (FT_4) and a low TSH.[155] There is an increasing awareness that oral biotin can interfere with the accuracy of results from not only thyroid assays but also a wide range of analytes measured by methods involving biotin-streptavidin binding.[156–158] As information regarding oral biotin use is typically not available to the laboratory, it is important for ordering physicians to be aware of this issue.

Analytic Sensitivity

Strictly, analytic sensitivity is the slope of the response curve. It is determined simply as the change in signal as a function of the change in analyte concentration and represents the smallest change in analyte concentration that can be measured. An example calibration curve is shown in Fig. 4.23. The slope of this calibration curve determined by least squares linear regression analysis was 1.01 pg/mL with a goodness of fit of $r^2 = 0.993$ and an intercept of 1.05. Thus the smallest difference that can be measured overall is 1.01 pg/mL with an LOD (intercept) of 1.08 pg/mL. This approach is useful only when the calibration curve is linear (or linearized by log transformation of the analyte concentrations) and the zero calibrator is accurately determined (i.e., there is no matrix effect on the blank measurement). Dose-response curves for clinical assays, regardless of technology employed, are seldom linear, and detector imprecision can be high. Thus limits of detection and direct estimates of variance at clinically meaningful analyte concentrations are typically more meaningful in describing assay performance.

The analytic LOD, often less rigorously referred to as sensitivity, is a statistical definition of the lowest concentration that can be measured (i.e., distinguished for zero analyte in the assay system). This concentration is mathematically determined as the upper 95% limit of replicate measurements of the zero standard, calculated from the average signal plus 2.0 SD. The LOD for the curve in Fig. 4.23 is 1.80 pg/mL. This minimal detection limit is valid only for the average of multiple replicate measurements. When individual determinations are performed on a specimen having a true concentration exactly at the minimal detection limit, the probability that the measurement is above the noise level of the assay is only about 50%.

A second parameter for the lowest level of reliable measurement for an assay is the functional detection limit, or the limit of quantitation. For this value to be determined, multiple pools with low concentrations are made and analyzed in replicate testing. A cross-plot of the coefficient of variation of the measurements versus concentration allows one to generate a precision profile. The analyte concentration corresponding to a coefficient of variation of 20% is the functional detection limit. This term typically applies to across-assay variation, but it also can be calculated for within-assay variation if one uses the tests to evaluate results measured within one run (e.g., provocative and suppression tests).



• **Fig. 4.23** Determination of analytic sensitivity and limit of detection. See text for details.

Precision

Precision is a measure of the replication of repeated measurements of the same specimen; it is a function of the time between repeats and the concentration of the analyte. Both short-term precision (within a run or within a day) and long-term precision (across calibrations and across batches of reagents) should be documented at clinically appropriate concentration levels.[159] In general, normal range, abnormally low range, and abnormally high range targets are chosen for precision studies; however, targets focused on critical medical decision limits may be more appropriate for some analytes.

Twenty measurements are generally considered minimal at each level for both short-term and long-term precision validations. Precision usually is expressed as the coefficient of variation, calculated as 100 times the SD divided by the average of the replicate measurements.[160] There is no universal agreement on the performance criteria for analytic precision, although numerous recommendations have been put forth. Two major approaches to defining these criteria have been (1) comparison with biologic variation and (2) expert opinion of clinicians based on their perceived impact of laboratory variation on clinical decisions.

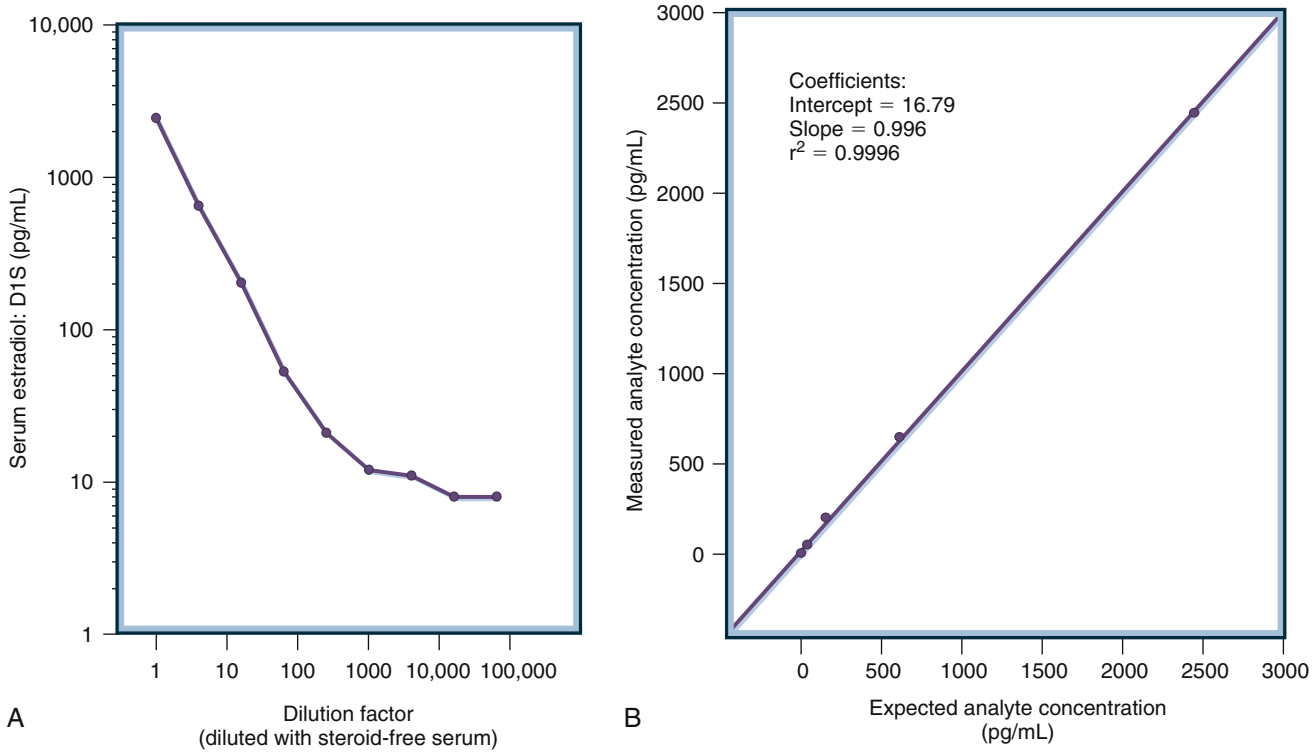
The total variation clinically observed in test measurements is a combination of the analytic and biologic variations. For instance, if the analytic SD is less than one-fourth of the biologic SD, the analytic component increases the SD of the total error by less than 3%. If the analytic precision is less than one-half of the biologic SD, the total error increases by only 12%. These observations have led to recommendations for maintaining precision of less than one-fourth or one-half of the biologic variation.

The expert opinion precision recommendations are based on estimates of the magnitude of change of a test value that would cause clinicians to alter their clinical decisions.

Accuracy

Two methods of assessing the recovery of assays are (1) measuring the proportional changes caused by mixing high-concentration and low-concentration specimens and (2) measuring the increase in test values after the reference analyte is added. Some analytes circulate in the blood in multiple forms, and some of these forms may be bound to carrier proteins. The recovery rate of pure substances added to a specimen may be low if the assay does not measure some of the bound forms. Mixtures of patient specimens may not be measured correctly if one of the specimens contains cross-reacting substances such as autoantibodies. A thorough understanding of the chemical forms of the analyte and their cross-reactivities in the assay is important during assessment of recovery data.

Measuring the proportional changes caused by mixing high-concentration and low-concentration specimens is referred to as a *linearity validation*. An example is shown in Fig. 4.24. A specimen containing a relatively high analyte concentration is diluted with a specimen containing "no" analyte. Practically, "no" analyte means analyte levels less than the detection limit of the assay as specimens with no analyte are typically not available. Fig. 4.24A shows the measurement of diluted specimens as a function of dilution. The point at which concentration no longer changes with increasing dilution is called the *limit of blank* (in this example, 10 pg/mL). The limit of blank can be significantly higher than the LOD or the limit of quantitation in some assays. Dilution linearity data (as in Fig. 4.24A) can be replotted (as in Fig. 4.24B) to evaluate the accuracy of an assay in terms of the analytic recovery of added analyte. Usually data are fitted by a linear regression. Assuming that the x-axes and y-axes have identical scaling, the slope*100 is the percent analytic recovery. Analytic recoveries less than or more than 100 reflect the bias of measurement for a given assay.



• **Fig. 4.24** Determination of assay accuracy. (A) Linear dilution recovery. (B) Spike analyte recovery.

Measuring the increase in test values after a reference analyte is added is referred to as a *spiked recovery validation*. The analytic approach is identical to that illustrated in Fig. 4.24B except that the expected analytic concentration is based on the addition of analyte to specimens rather than calculated based on the dilution of specimens. The most appropriate analytes for use in analytic recovery studies are certified reference materials, such as those from the WHO or the National Institute of Standards and Technology (NIST), although such well-characterized materials are not available for all analytes. Ideally, a rigorous method validation would also include comparison to a reference method (i.e., a method that has been carefully validated previously). These are generally performed by highly specialized laboratories, and reference methods do not yet exist for many analytes of interest in endocrine testing or for novel biomarkers.[161–169]

At a minimum, the evaluation of accuracy by any of the methods described previously should be conducted using specimens from healthy subjects and specimens from patients with the diseases being investigated.[170] When possible, the assay should be traceable to established reference standards or methods. Between 100 and 200 different specimens distributed over the assay range are recommended for method comparisons.[171–175] Although acceptable performance criteria for method comparisons are not well established, some important characteristics to examine are as follows:

- Any grossly discordant test values
- The degree of scatter about the regression curve
- The size of the regression offset on the vertical axis
- The number of points crossing between the low, normal, and high reference intervals for the two methods

The European Union has enacted the In Vitro Diagnostics Directive, which requires manufacturers marketing in the European Union to establish that their products are "traceable to reference standards and reference procedures of a higher order" when such references exist.[176] Hopefully, medically relevant performance characteristics that define the allowable ranges for differences between a specific assay's test values and the traceable standards will be linked with this traceability requirement. This combination of traceability and allowable error requirements could serve to harmonize many test methods worldwide because most diagnostic companies market internationally. Standardization and harmonization of hormone assays have become priorities for quality health care.[164,169,176,177]

Carryover

Many diagnostic systems use automated sample-handling devices. If a specimen to be tested is preceded by a specimen with a very high concentration, a trace amount remaining from the first specimen may significantly increase the reported concentration in the second specimen. The choice of the concentration that should be tested for carryover depends on the pathophysiology of the disease, but high values may need to be tested because some endocrine disorders can produce extremely high values. Validations also typically include assessing possible carryover from the sampling probe and for plate-based assays assessing detector carryover from nearby wells.

Utilization Parameters

Once an assay has been analytically validated, it is necessary to validate its utilization. The key aspects of utilization involve defining limits associated with specimen and reagent stability and ensuring that the assay is stable over time.

Specimen Stability

Validating specimen stability typically involves testing a series of aliquots exposed to different handling conditions to determine if the analyte measurement changes over time. This evaluation typically includes specimens representing the full range of specimen types to be tested (see later) and encompasses processing times and temperatures expected with respect to specimen collection and transport to the laboratory as well as stability during laboratory processing and on instrument time and during the assay itself. This is a critical aspect of method validation that can be very costly and labor intensive.

Reagent Stability

The stability of reagents used in the assay must also be defined. This includes both on-board stability and shelf-life stability for commercial, automated systems that are widely used in modern clinical laboratories. Although reagent expiration dates are determined and provided by commercial manufacturers, they must be verified under the actual working conditions of the laboratory and take into account workflow processes such as reconstituting lyophilized calibrators or refreezing calibrator/control aliquots. For laboratory-developed methods such as LC/MS-MS, the laboratory must also determine expiration dates for all reagent components and stock materials.

Robustness (Assay Stability)

Robustness is typically defined as the stability of measurement over time, which includes variance associated with reagent lot changes, equipment changes, and technologist performance.[178] Robustness validation provides the specifications for the reliability of the method during extended normal usage. These specifications become the basis for setting limits on variance, and it is critical that laboratories inform clinicians of changes that exceed these practice-relevant limits. For example, changes in antisera can cause significant changes in immunoassay performance, which in turn require revising reference interval and clinical decision points.

Interpretation Parameters

Reportable Range

The measuring range of an assay usually spans from the limit of quantitation to the concentration of the highest calibrator. Signal measured above the highest standard requires specimen dilution and retesting. This is typically done automatically in instrument systems but must be done manually in plate assay systems. In either case, an important aspect of method validation is to assess accuracy when a specimen must be diluted. Dilution is often associated with alternation of matrix effects and other interferences in an assay. Thus an assay that is accurate over the calibration range may not be accurate over the full reportable range when dilutions are utilized to obtain quantitative measurements. The validity of the analytic range is documented by the linearity and recovery studies. Most clinical laboratories confirm the reportable range of each assay at least twice a year.

Reference Intervals

Reference intervals, also commonly referred to as normal ranges, describe the analyte values expected from a given assay when healthy individuals are tested.[179–181] This is in contrast to clinical decision points, or cutoff values, determined for identifying patients with specific disease conditions (see "Diagnostic Power"). The development and validation of reference intervals

for endocrine tests can be very complex tasks as they require defining the healthy population by clinical evaluation[182,183] and testing large numbers of healthy individuals,[179,181] which often involves obtaining informed consent and related costly activities. Manufacturers of commercially available assays are required to provide reference intervals, but these do not necessarily represent the subpopulation served by a given laboratory.

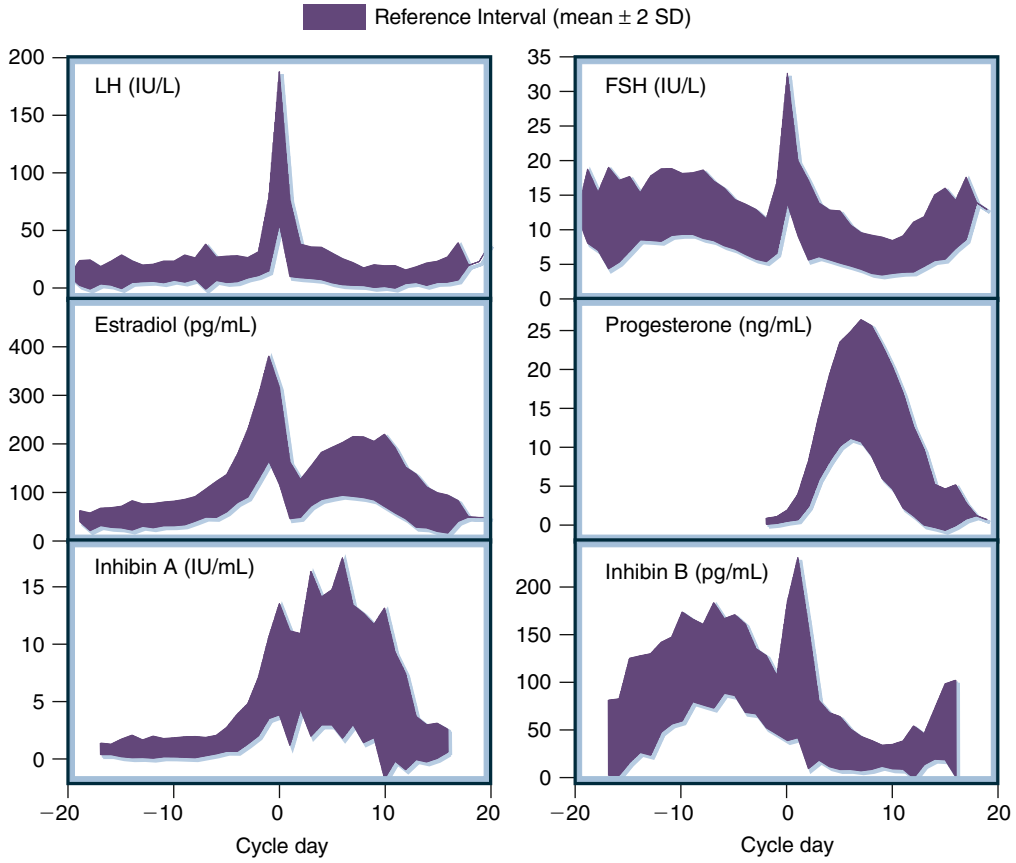
The normal reference interval for most laboratory tests is based on estimates of the central 95 percentile limits of measurements in healthy subjects. A minimum of 120 subjects is needed to reliably define the 2.5 and 97.5 percentiles. Formal statistic consultation is usually required to determine the appropriate number of subjects to test and to develop statistical models for defining multivariate reference ranges.[184–186]

The reference intervals for many endocrine tests depend on gender, age, developmental status, and other test values. Fig. 4.25 illustrates this complexity. Shown are the ranges of values (shaded areas) expected on a daily basis for hormone measurements in healthy young women across the menstrual cycle.

Diagnostic Power

Determining the clinical usefulness of the assay is typically the last step in validation. For commercially available assays the manufacturer is required to do this. The degree to which the assay is validated in this regard depends on specific FDA regulatory requirements (see "Classes of Assays"). Clinical laboratories using these assays are required to verify clinical utility claims depending on the specific requirements of the relevant accrediting organization, but generally the approach is to verify the clinical sensitivity and specificity of the assay using specimens from patients known to have or not have a specific clinical condition that the assay is designed to address. In contrast, for laboratory-developed methods, which include mass spectrometry and many molecular-based assays, the clinical laboratory is required to determine clinical decision points (cutoff values). In either case, good laboratory practice includes verification of clinical utility periodically as part of the laboratory's quality control (QC) and quality assurance (QA) programs. The details of clinical utility validation are beyond the scope of this chapter, but a high-level understanding of the processes is important because clinical sensitivity and specificity and cutoff parameters can help clinicians determine the relative weight to give assay results in the context of the entire clinical picture. Many excellent discussions have been published to provide in-depth details for interested readers.[186–191]

Clinical sensitivity and specificity are not to be confused with analytic sensitivity and specificity, which are assay characteristics. In contrast, clinical sensitivity and specificity quantify the ability of the assay, or any clinical diagnostic procedure, to correctly identify disease states, and these parameters are expressed as percentages. Clinical sensitivity is the percentage of patients with positive test results who actually have the target condition (i.e., they have the disease the assay is intended to identify); it is the true rate of accurate diagnosis. Subtraction of the clinical sensitivity from 100 provides the rate of false-positive results for an assay (i.e., the percentage of patients with positive test results who do not have the disease).



• **Fig. 4.25** High-resolution reference intervals required for the interpretation of reproductive hormone measurements across the menstrual cycle. *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *SD,* standard deviation.

Clinical specificity deals with patients with negative assay results. It is the percentage who actually do not have the disease (i.e., who are correctly identified as negative by the assay). Subtracting the clinical specificity from 100 gives the false-negative rate of the assay.

Clearly, to determine clinical sensitivity and specificity the laboratory must have two key things: (1) specimens from patients known to have or not have the disease and (2) either reference intervals or clinical cutoff points to provide a positive or negative interpretation to quantitative test results. Obtaining specimens from patients with known conditions for the purpose of assay validation/verification is challenging as the process requires accurate clinical information, Health Insurance Portability and Accountability Act (HIPAA) compliance, and specimens collected and handled in a fashion consistent with normal workflow. All these steps can be expensive and challenging and are best accomplished with the close collaboration of physicians who utilize the laboratory services.

Clinicians must appreciate that laboratory-derived clinical sensitivities and specificities are subject to many potential biases. First, in many cases laboratories rely on already established assays to provide the disease status information; in other words, they are comparing to predicate device results rather than clinical information. Even when using clinically characterized individuals to provide the disease-positive specimens, bias can be incorporated if the healthy group is not age or gender matched. Finally, using either clinical cutoffs or reference intervals to define a positive versus negative assay result is subject to statistical biases, such as normal versus nonnormal distribution of measurement.

Operational Parameters (Preanalytic Considerations)

Specimen Types

Many types of specimens are routinely used for the measurement of analytes in bodily fluids. The most common are whole blood, serum, plasma, urine, and saliva. Less frequently, fluids or cells derived from fine-needle aspirates are sent to the clinical laboratory for analysis. It is critical to understand that each type of specimen must be subjected to rigorous validation to ensure accurate measurements. Simply because an assay is valid for a given specimen type does not mean that it is valid for any specimen type. Even if an assay is capable of reproducible and specific measurement of an analyte in different specimen types, there may be clinically significant bias depending on the specimen type tested. Reference intervals and clinical cutoff values must be verified for each specimen type utilized.

Whole Blood

Whole blood specimens have both the limitation and the advantage of time dependency. The ability to detect rapid changes to a provocative stimulus is a strong advantage, whereas the unsuspected changes resulting from pulsatile secretions may be a major limitation. Whole blood is advantageous when the analyte is very labile as the specimen can be collected and tested quickly. The ability to test whole blood without processing at the point of care can be cost effective and enhance patient management as well as effectively address problems of specimen stability with respect to very labile analytes.

Blood drops collected on filter paper from punctures of a finger or heel are a convenient system for collecting, transporting, and measuring hormones.[192,193]

If standardized collection conditions and extraction techniques are used, these measurements correlate well with serum measurements. Integration of immunochemistry with computer chip technology has also led to immunochips that can measure multiple analytes using a single drop of blood.[194]

The use of whole blood is severely limited by several factors, most importantly: (1) Whole blood must be prevented from clotting during analysis, necessitating the use of anticoagulants, which often interfere in assays, and (2) whole blood is a very complex mixture of components that can directly interfere with analytic methods. Solutions to these problems include (1) dilution of the whole blood specimen in the assay, which in turn requires that the analyte being measured is in relatively high concentration or that the assay is extremely sensitive, and (2) preanalytic processing to remove the cellular fraction or reduce the complexity of the specimen. Traditionally specimen types most often used for endocrine testing are serum or plasma for these reasons.

Serum

Serum is obtained from whole blood specimens simply by allowing the blood to clot. Allowing whole blood to clot in glass tubes allows the serum to be completely and easily separated from the clot by centrifugation. The resultant serum specimen is free of cells, and many of the proteins involved in the clotting process are also removed. This has been the method of choice for large protein analytes such as immunoglobulins or for very stable analytes such as steroid hormones. In most laboratories glass phlebotomy tubes have been replaced with safer plastic ones that will not break during handling, especially in fully automated laboratories. Unfortunately, whole blood does not clot cleanly or quickly in plastic tubes, so clot activators or enhancers are added to the tubes. These factors can interfere with many analytic methods and must be carefully validated.

Plasma

Plasma is obtained by chemically preventing the clotting process and then centrifuging to remove the cellular components of whole blood. There are many approaches to preventing clotting; most commonly, ethylenediaminetetraacetic acid (EDTA), citrate, or heparin is added to prevent clotting. These chemicals, especially EDTA, have the additional advantage of inhibiting proteolysis and are thus advantageous when testing labile analytes such as adrenocorticotropic hormone (ACTH) or PTH. Other additives are added to stable plasma for specific tests; for example, sodium fluoride is added to EDTA tubes to inhibit glycolysis when glucose measurements are desired. Of course, all these additives have the potential to interfere with specific assay methods.

Separation of the cellular elements in anticoagulated whole blood can be enhanced by the use of gel separators. This type of tube is often preferred in automated aliquoting systems. Unfortunately, the gel used can interfere directly or indirectly (e.g., by trapping analytes) in some analytic methods.

Phlebotomy tubes with additives also create special considerations when collecting blood in multiple tube types. Tubes must be drawn in a specific order to avoid contamination with additives that are known to interfere in standard laboratory tests. Failure to collect additive tubes in the proper order is not identifiable once the tubes are received in the laboratory and can lead to serious inaccuracies in test results. The correct order for drawing the most commonly used phlebotomy tubes is shown in Fig. 4.26.[195] The stopper color is standardized to indicate what additives each tube contains. For example, the tube with a red stopper (3) contains

only clot activators; the yellow stopper tube (2) contains both clot activators and a separation gel. The lavender-topped tube (6) contains EDTA and must be drawn after a clot tube for serum (2 or 3) or tubes containing heparin (4 and 5).

Urine

Urine often contains not only the original hormone but also key metabolites that may or may not have biologic activity. The 24-hour urine specimen is used for many endocrine tests. Such urine specimens represent a time average that integrates over the multiple pulsatile spikes of hormone secretion occurring throughout the day. The 24-hour urine specimen also has the advantage of better analytic sensitivity for some hormones and metabolites.[55,196–203]

Drawbacks include the inconvenience of collecting the 24-hour specimen and delays in collection. Another limitation of urine specimens is uncertainty regarding the completeness of the collection. Measurement of urinary creatinine concentrations helps in monitoring collection completeness, especially when this value is compared with the patient's muscle mass. Many urinary hormones are conjugated to carrier proteins before excretion. Therefore, both hepatic function and, to a lesser degree, renal function may alter urinary hormone values.

Saliva

Saliva is an attractive alternative specimen for measuring non–protein-bound hormones and small molecules.[204–207] Small analytes in blood pass into oral fluid by crossing capillary walls and basement membranes and by passing through lipophilic membranes of epithelial cells.[208] This transport involves passive diffusion, ultrafiltration, active transport, or some combination of these processes. The concentration in saliva depends on the concentration of the non–protein-bound analyte in blood, the salivary pH, the acid dissociation constant (pKa) of the analyte, and the size of the analyte. Analytes entering saliva by passive diffusion usually are less than 500 Da in size, non–protein bound, and nonionized. As with any specimen type, it is essential to fully validate the use of saliva in each analytic method and to establish the data needed for interpretation of test results, such as reference intervals.

• **Fig. 4.26** The order in which blood tubes containing no or various additives must be filled to avoid contamination and possible interference with accurate laboratory measurements. Tube types: 1, citrate; 2, clot tube (serum) with separator gel; 3, clot tube without separator gel; 4, heparin; 5, heparin with separator gel; 6 and 7, EDTA; 8, sodium fluoride/EDTA. (Courtesy Michael Purugganan.)

Saliva measurements reportedly correlate with blood measurements for some hormones such as cortisol, progesterone, estradiol, and testosterone, but they do not correlate well for others (e.g., thyroid and pituitary hormones).[209–217] Multiple preanalytic variables can affect the salivary measurement. Stimulation of oral fluid production by chewing or by sucking candy or drops that contain stimulants such as citric acid can increase oral fluid volume and stabilize pH but may alter some analyte concentrations. Several commercial devices are available for collection of oral fluid; however, these devices need to be validated for each analyte and each assay system to ensure they adequately recover each of the analytes.

Saliva is also an effective specimen type for obtaining genomic DNA and other nucleic acid assay applications. Its use in this regard is now well established and rapidly advancing.[218–220]

Fluids and Tissue From Fine-Needle Aspiration

Fine-needle aspiration (FNA) involves the insertion of a hollow needle into tissue, typically a suspicious lump or inflamed tissue, to withdraw fluid or cells for diagnostic evaluation. The procedure is usually performed manually by the surgeon or a cytopathologist when a palpable lump is present or the tissue target can be seen (e.g., during a surgical procedure). Deep sampling can be achieved using, for example, ultrasound guidance. Analysis of the cellular components of the FNA is done in the cytopathology laboratory and involves the examination of cells by histologic and immunohistologic procedures.

Thus FNA fluids represent a unique specimen type for analysis of biomarkers by traditional immunoassays or by LC/MS-MS methods. However, FNA fluids present special considerations with respect to handling, stability, validation, and interpretation. Aspirated fluids are typically obtained in volumes too small to directly assay and often will clot due to contamination with whole blood. Analyte stability as well as assay parameter validation must be determined using aspirated fluid and diluents required to provide the necessary volume and anticoagulation prior to testing. Interpretation is often difficult because reference intervals applicable to blood levels are seldom available and often analytes, such as thyroglobulin in neck mass aspirates, are high enough to cause artifacts in assays (such as hook effects in antibody-based assays).

Aspirated cells can provide sufficient DNA and RNA for genetic analysis. Currently this is an area of intensive investigation that has only just begun to be applied by clinical laboratories. Typical methods being applied include expression arrays, real-time PCR, and DNA methylation assays as well as the widespread and traditional application of immunohistochemical assays for specific biomarkers.[221] For example, expression arrays can provide clinically valuable information for the 15% to 30% of thyroid nodules subjected to FNA and characterized as indeterminate by cytologic tests.[222]

Other current clinical applications of FNA in conjunction with diagnostic assays include chorionic villus sampling[223,224] and measurement of biomarkers in aspirates from pancreatic tumors.[225–227]

Quality Control

Laboratory quality control procedures are intended to ensure that the tests are being performed within defined limits established during the validation of the assay.[228–232] The goal of these procedures is to identify circumstances when results obtained may not be accurate. They rely heavily on the testing of materials with known analyte concentrations. Quality control failures are meant

to detect instrument problems (hardware or instrument failures), reagent or calibration failures, and human mistakes (improper handling of reagents or specimens, training problems, or shift change communication failures).

Statistically there are two major forms of analytic errors: random and systematic. Random error relates to reproducibility; systematic error relates to the offset or bias of the test values from the target or reference value. Performance criteria can be defined for each of these parameters, and quality control systems can be programmed to monitor compliance with these criteria. Control systems must have low false-positive rates as well as high statistical power to detect assay deviations. The multirule algorithms developed by Westgard and colleagues use combinations of control rules—such as two consecutive controls outside warning limits, one control outside action limits, or moving average trend analyzers outside limits—to achieve good statistical error detection characteristics.[229–232] Traditionally, quality control programs have focused primarily on precision; however, analytic bias also can cause major clinical problems. If fixed decision levels are used to trigger clinical actions (e.g., therapy, additional investigations), changes in the analytic set-point of an assay can cause major changes in the number of follow-up cases. More modern quality control systems include using moving averages of patient test values to help monitor changes in analytic bias. Increasing numbers of web-based systems are available for laboratories to share quality performance data, allowing better statistical evaluations (larger numbers of values to identify shifts and drifts in quality control measurements).

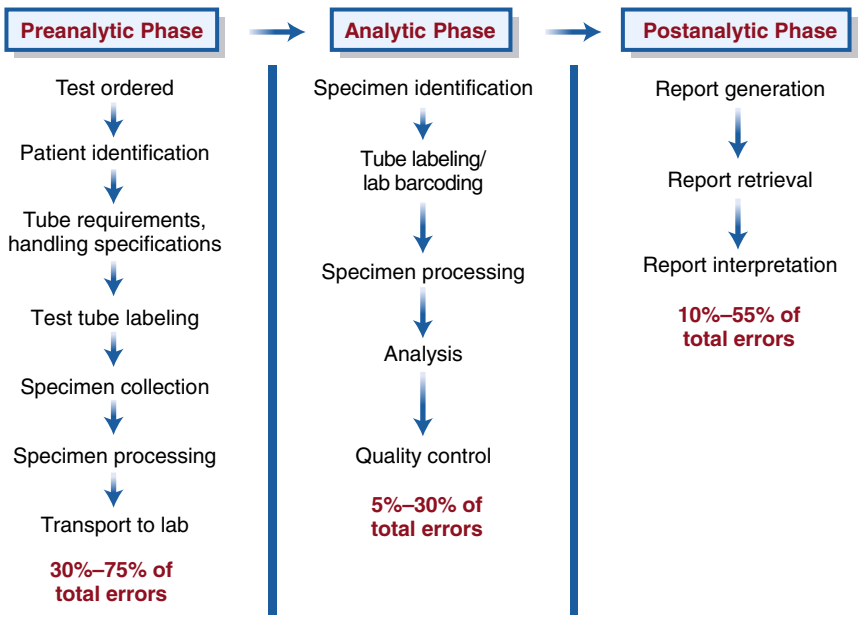
Quality Assurance

Quality assurance procedures go beyond monitoring test values for control materials. Testing of quality control materials only identifies errors that occur during testing per se (i.e., the analytic phase of the overall process from ordering a test until the results are reported back to the physician). A look at when errors typically occur provides important insight into the issues. As illustrated in Fig. 4.27, errors that occur during the analytic process represent less than a third of all errors associated with laboratory testing.

Quality assurance procedures are part of the regulatory requirements of a clinical laboratory. All laboratories have procedures to monitor things such as specimen transport times and report accuracy, which are processes that can be established solely within the laboratory. A key element of quality assurance, and one that should be emphasized for clinicians who are critical to its success, is the identification and investigation of test values that are discordant. Some of these discordant test values may be analytically correct, but others may be erroneous. Clinicians must help identify and investigate these suspicious test values by requesting laboratories to perform a few simple validation procedures.

Repeated testing of the same specimen is a valuable first step. The laboratory assumes that the specimen has been stored under stable conditions and allows for the propagation or error during repeated measurements. Typically, a result is considered to be confirmed if the absolute value of the difference between the initial and the repeated measurements is less than 3 SDs of the analytic error associated with the initial measurement.

Linearity and recovery are valuable techniques for evaluating test validity in individual specimens. If the initial test value is elevated, serial dilution of the specimen in the assay diluent and re-assay should be considered. If the initial value is low, one may consider adding known quantities of the analyte to part of the specimen. Analyzing these spiked or diluted specimens with the original specimen allows one to evaluate both reproducibility and recovery. It may be helpful to analyze the linearity or recovery of the assay standards at the same time, to provide internal controls of the dilution or spiking procedures and the appropriateness of the diluent and spiking material. If the replication, dilution, or recovery experiment appears successful, further analytic troubleshooting will vary according to the method used. For example, immunoassays may be affected by interference caused by heterophile antibodies or hook effects as described earlier. Addition of nonimmune mouse serum or heterophile antibody-blocking solutions may neutralize these effects. Chromatographic assays are usually more robust than immunoassays but often lack the specificity. Specimens with suspected interference on one type of assay can be reanalyzed by means of an alternative methodology. Interferences with cross-reacting drugs and metabolic products can be



• **Fig. 4.27** Distribution of errors during the entire process of clinical laboratory testing.

minimized with selective extraction or identified by adding a drug to nondiscordant specimens.

Classes of Assays

In the United States the regulations governing clinical laboratories fall into several categories based on the manufacture of assay components, the intended use of the assay, and how the assay service is billed. To be reimbursed by Medicare and other health insurance organizations, laboratories must comply with federal legislation known as the Clinical Laboratory Improvement Amendments (CLIA). This legislation requires that laboratories be certified by specified organizations (e.g., the College of American Pathologists or the Joint Commission for the Accreditation of Hospital Organizations) and is administered by the Centers for Medicare & Medicaid Services (CMS) within the US Department of Health and Human Services (DHHS). CMS also administers the HIPAA of 1996 and other quality standards that laboratories must comply with under federal law. CMS/CLIA certification requires quality inspections every 2 years to ensure that laboratories are meeting the standards outlined in the federal CLIA guidelines and the performance standards specified by the laboratory's inspecting agency. Inspecting agency standards are based on the CLIA guidelines.

In contrast, the manufacture and sale of assay reagents and instruments are regulated by guidelines called Current Good Manufacturing Practices (cGMPs), which cover very specific topics and are periodically amended.[233–238] Compliance with cGMPs is enforced by the FDA under federal law.[239] Besides the manufacture and sale of instruments and reagents, laboratory-developed methods used in patient care are encompassed within the jurisdiction of the FDA. The FDA does not certify compliance and conducts its own quality inspections. Failure to comply with cGMPs is a violation of federal law (as opposed to reimbursement requirements under CLIA) and can result in laboratory closure as well as potential fines and legal actions. Sale of assay instruments and reagents requires premarket approval by the FDA or FDA clearance under Section 510(k), depending on the clinical use of the product and its potential impact on patient care.

Common elements of clinical laboratory standards, CLIA guidelines, and cGMP regulations include laboratory evaluation and documentation of validation verification for commercially available reagents and instruments, which have been cleared or approved by the FDA and whose continued manufacture is overseen by the FDA. Requirements for laboratory-developed methods, which include any modifications of FDA-approved/cleared commercial procedures, are more extensive, and validation per se is expected.

Conclusion

The analytic methods of assessing endocrine problems in patients are continually expanding. The newer systems are often based on analytic techniques similar to those outlined in this chapter, but the configurations are generally more user friendly. These advances make the systems more convenient, but they also become more of a "black box" that conceals most of the details of the system. The methods, their descriptions, and approach to their validation, as outlined in this chapter, are intended to provide the clinician with insights into the inner workings of these systems and to encourage a more detailed level of interaction with the clinical laboratory in its ever more challenging endeavors to provide cost-effective yet high-quality support for patient care.

The Global Burden of Endocrine Diseases

MARIA INÊS SCHMIDT, LAERCIO J. FRANCO, EWERTON COUSIN, AND BRUCE B. DUNCAN

CHAPTER OUTLINE

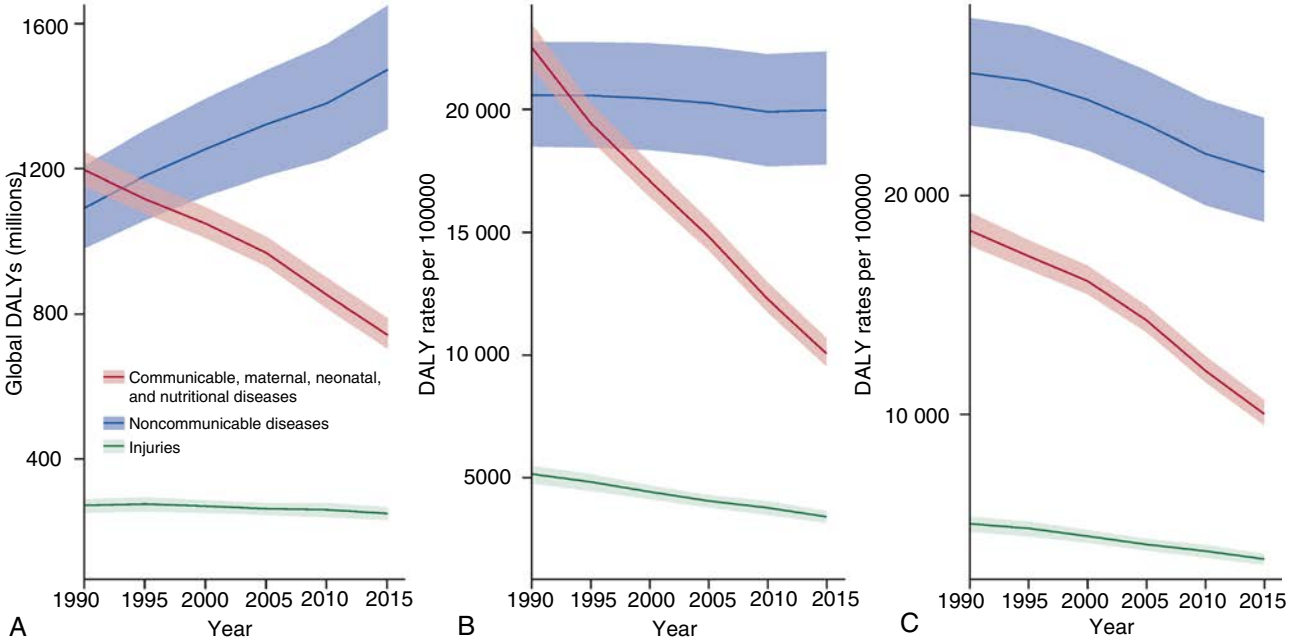
KEY POINTS

- High body mass index, including obesity, is now one of the world's top five risk factors causing disease burden.
- With the inexorable rise in the prevalence of excess weight, this burden is growing in all regions of the world.
- Diabetes incidence, prevalence, and burden have all increased in recent decades, with the aging of the population being a main driver of these trends. The scenario for burden, while stabilizing in countries with the highest degree of development, is most worrisome for those in the midrange of development.
- Given this scenario, diabetes, when joined with states of intermediate hyperglycemia, is now also one of the top five risk factors in the world.
- Thyroid diseases are among the most prevalent endocrinopathies across the world.
- Iodine deficiency is a highly prevalent public health problem in several countries.
- Incidence of thyroid cancer has increased globally over the last three decades, although a recent decline has been noted in countries with the highest level of development.
- The burden of thyroid cancer is higher in low-income and low-middle-income countries.

Introduction

The 20th and early 21st centuries have witnessed important social changes that have produced major demographic, nutritional, and epidemiologic transitions. As seen in Fig. 5.1A, from 1990 to 2015, the burden of disease (expressed as disability-adjusted life years [DALYs]) caused by communicable, maternal, neonatal, and nutritional disorders decreased remarkably, while that due to noncommunicable diseases (NCDs) increased.[1] The increase in NCD burden results, in part, from population growth and population aging. Fig. 5.1B shows that DALYs, when expressed as rates per 100,000, which account for population growth, are stable, and Fig. 5.1C shows that age-standardized DALYs, which also account for population aging over the period, are decreasing. Social progress and advances in scientific knowledge translated into clinical and population interventions were the main drivers of the declines seen in Fig. 5.1C. However, since the crude measures (see Fig. 5.1A and B) are the true indicators of population burden, the NCDs, many of which are caused by metabolic risk factors and include the principal endocrinopathies, have become, at the global level, the major cause of disease burden.

The 21st century is now faced with new and complex demands for action at both the population and clinical levels. Of major concern, progress in alleviating disease burden has not resolved longstanding inequities, leaving the less developed countries often with a double load of disease burden, the unresolved old ones and the new ones, thus posing difficult challenges to policymakers and to global health. We will address in this chapter the burden of endocrine diseases, namely obesity and excess weight, diabetes, iodine deficiency/thyroid goiter, and thyroid cancer, selected on the basis of their importance and the availability of reliable data. To facilitate the interpretation of burden presented, Table 5.1 summarizes the metrics utilized in its quantification throughout the chapter.



• **Fig. 5.1** Trends from 1990 to 2015, by GBD Level 1 disease groups, in (A) global DALYs, (B) crude DALY rates, and (C) age-standardized DALY rates. The difference in trends between (A) and (B) is caused by population growth, and the difference between (B) and (C) is caused by changes in the age distribution of the population. Shaded areas show 95% uncertainty intervals. *DALYs,* Disability-adjusted life years. (From GBD 2015 DALYs and HALE Collaborators. Global, regional, and national disability-adjusted life-years [DALYs] for 315 diseases and injuries and healthy life expectancy [HALE], 1990-2015: a systematic analysis for the Global Burden of Disease Study 2015. *Lancet.* 2016;388:1603–1658.)

TABLE 5.1 Epidemiologic Indicators of Disease Presence and Burden

Indicator (Metric)	Abbreviation	Definition
Incidence	—	The number of new cases of a given disease during a given period in a specified population.
Prevalence	—	The total number of cases of a given disease in a specified population at a designated time.
Years lived with disability	YLDs	Morbidity burden: YLDs consider any short-term or long-term health loss. It is calculated by multiplying the prevalence of the condition causing health loss (e.g., blindness due to diabetes) by the disability weight (0.19) estimated for that condition (i.e., a year lived with blindness is worth 81% of a year lived in full health).
Years of life lost due to premature mortality	YLLs	Mortality burden: YLLs are calculated by subtracting the age at death from the longest possible life expectancy for a person at that age.
Disability-adjusted life years	DALYs	Overall disease burden: The sum of years lost due to premature death (YLLs) and years lived with disability (YLDs).

Data from Institute for Health Metrics and Evaluation.[11,12] More detailed information on calculations can be found in the methodology supplements to GBD Capstone papers published in the *Lancet* in 2017[13]; and the Institute for Health Metrics and Evaluation (IHME). Obesity and Excess Weight

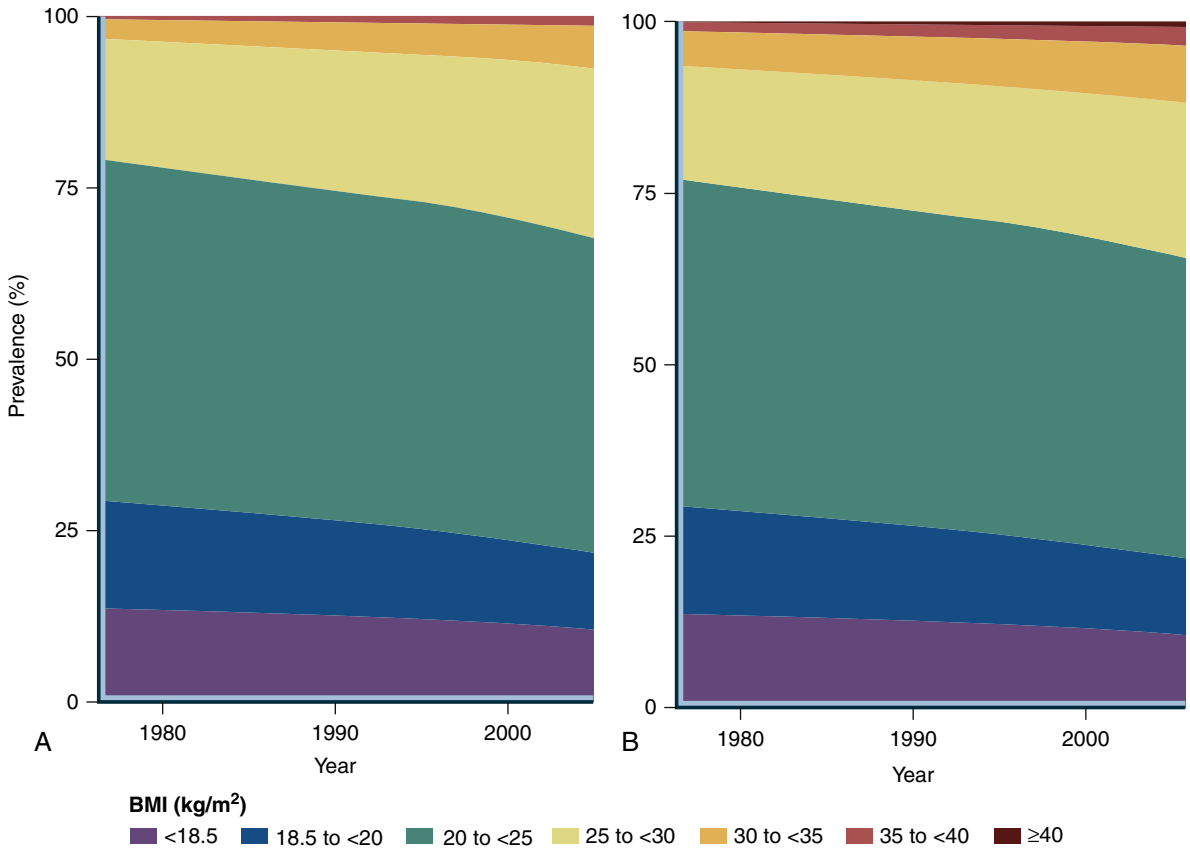
Prevalence and Trends

As extensively documented, the prevalence of obesity (body mass index [BMI] ≥30 kg/m^2) has increased dramatically over the past several decades throughout the world. From 1975 to 2014, as estimated by the NCD Risk Factor Collaboration,[2] global age-standardized mean BMI has increased 3.5 kg/m^2 for men, from 21.7 kg/m^2 (95% CI 21.3–22.1 kg/m^2) to 24.2 kg/m^2 (24–24.4 kg/m^2), and 2.3 kg/m^2 for women, from 22.1 kg/m^2 (21.7–22.5 kg/m^2) to 24.4 kg/m^2 (24.2–24.6 kg/m^2). These changes, expressed in the usual nutritional status categories, are visualized in Fig. 5.2. Similarly, from 1990 to 2017, as estimated by the Global Burden of Disease Study (GBD), the sum of risk across high levels of BMI increased 70%, and over the past decade increased 39%, the increase occurring at a constant rate of approximately 2% per year.[3]



• **Fig. 5.2** Worldwide trend in nutritional status categories. (A) Men and (B) women, 1975 to 2015. *BMI,* Body mass index. (From NCD Risk Factor Collaboration [NCD-RisC]. Trends in adult body-mass index in 200 countries from 1975 to 2014: a pooled analysis of 1698 population-based measurement studies with 19·2 million participants. *Lancet.* 2016;387:1377–1396.)

Currently, GBD estimates that 15.2% of all adults—766 (758–774) million adults—are obese, prevalence being greater in women than in men. Additionally, 5.3% of the world's children and adolescents—130 (125–134) million—are obese. Over the lifespan, rates of obesity decrease slightly from age 2 to the beginning of adolescence, then increase steadily from age 15 and peak between the fourth and seventh decades. This peak comes earlier and at a lower level in men than in women and in countries of lesser versus greater sociodemographic development. At the end of life, prevalence declines,[4] in large part due to greater premature mortality among the obese.

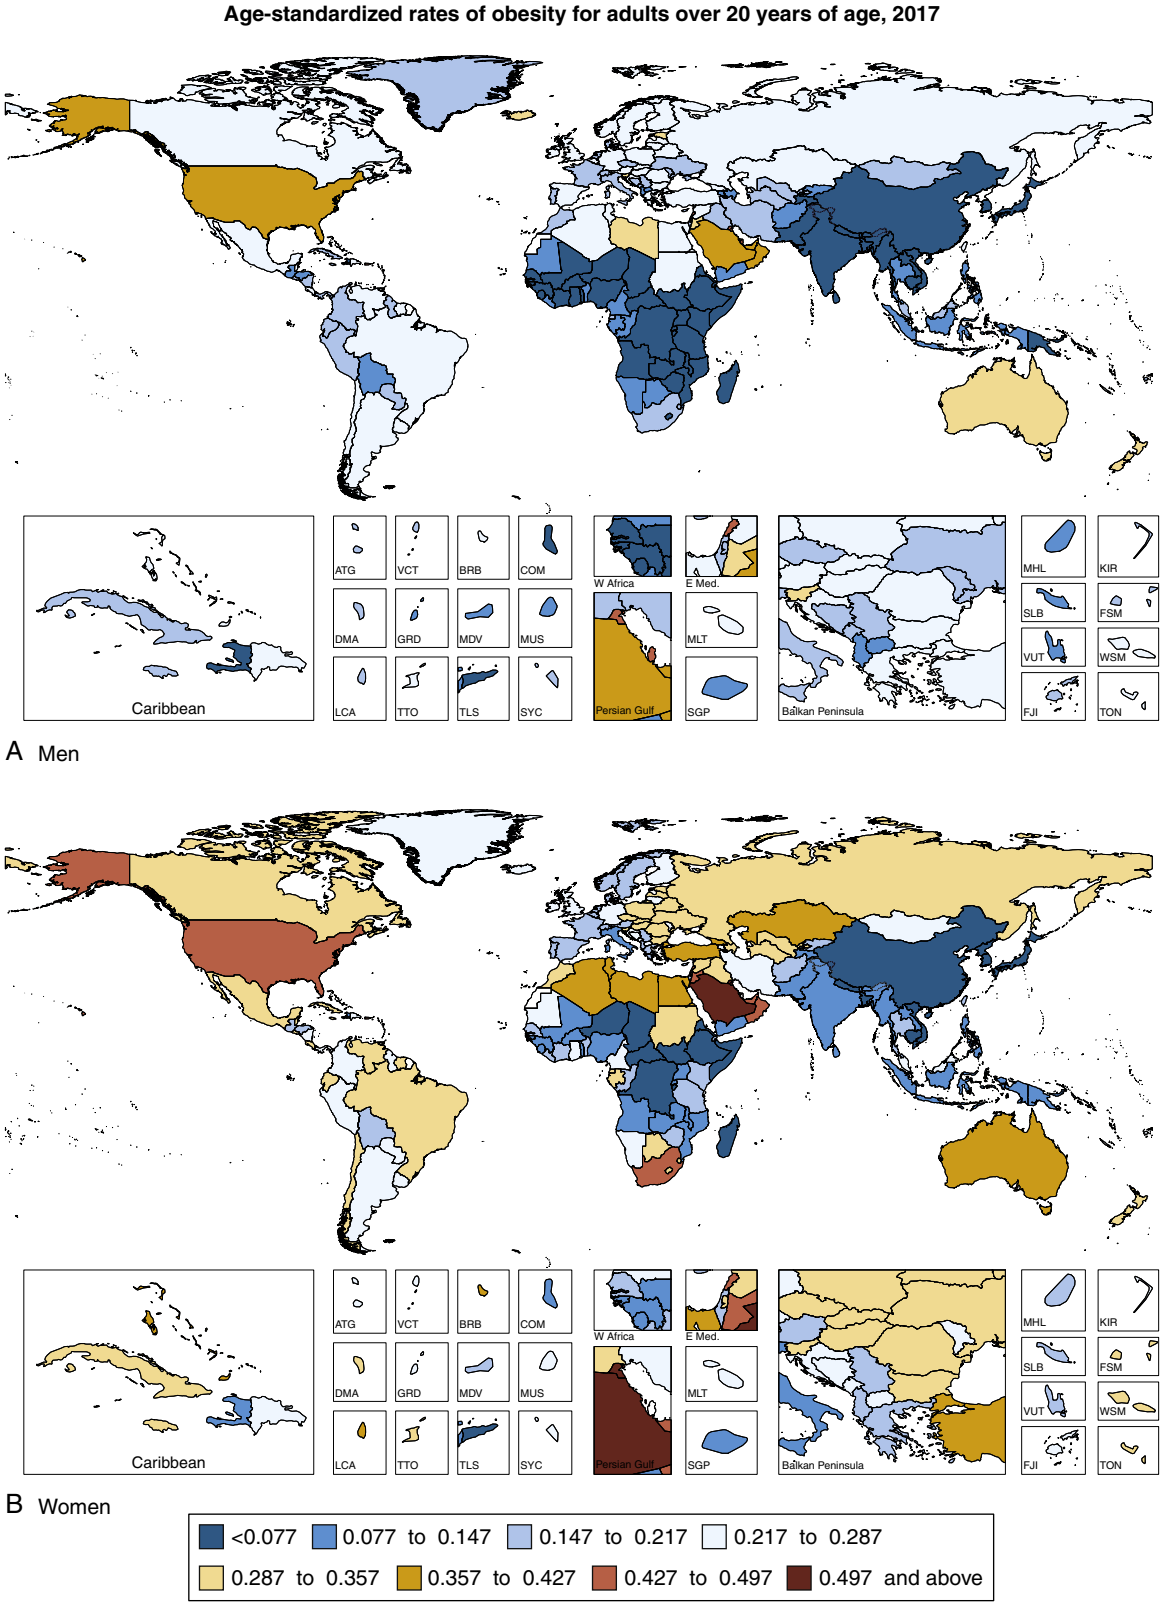
Although obesity rates are increasing in all geographic regions, both baseline values and rates of increase vary tremendously. As a result, obesity prevalence in countries extends across a broad range of values, as seen by the color coding in world maps (Fig. 5.3). In 2016, Pacific Islanders, followed by nations of the Middle East and then several higher income countries of Anglo-Saxon origin, had the greatest frequency of obesity. Lowest frequencies were seen in Asian countries. Examples of extreme country differences in obesity rates for women are seen comparing American Samoa (65.3%), Kuwait (47.1%), and the United States (36.5%) with Vietnam (2.7%) and Japan (3.9%).[5]

Part of this variability across nations can be explained by differences in socioeconomic development, as described by GBD sociodemographic index (SDI) categories, which are based on educational attainment, income, and fertility. As seen in Fig. 5.4, obesity rates among boys and men in low SDI locations have remained relatively stable over time, whereas rates in all other groups have risen steadily, for both children and adolescents, and for adults.

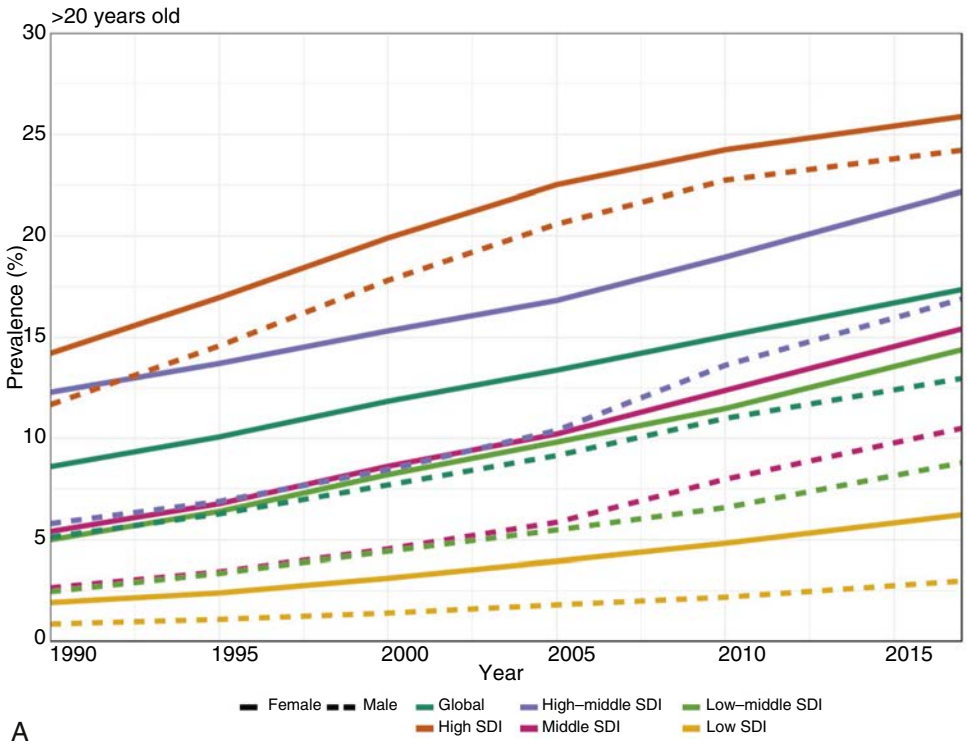
The Burden of Excess Weight

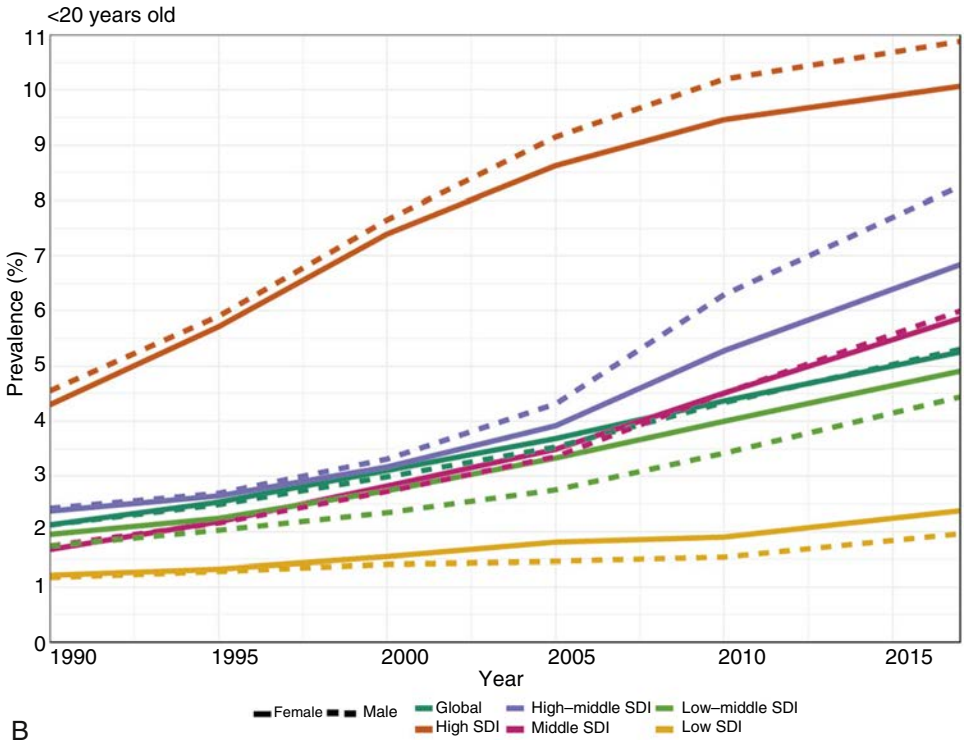
Fig. 5.5 shows the burden due to high BMI relative to that caused by other major cardiometabolic risk factors in 1990 and 2017. Within this comparison, the burden due to high BMI showed the greatest increase over this period. Currently, considering risk factors for all diseases, high BMI ranks 5th in terms of disease burden in the world, having risen from the 13th position in 1990.

High BMI causes both premature loss of life (72% of its burden) and disability among those living (the remaining 28%). The fraction due to disability has risen from 22% to 28% over recent decades and is anticipated to continue to rise in importance. In relative terms, considering unstandardized rates for the entire world population, high BMI is estimated to have caused 8.4% of deaths, 6.5% of premature mortality (years of life lost [YLLs]), 4.8% of morbidity (years lived with disability [YLDs]), and 5.9% of overall disease burden (DALYs). In relation to 1990, the burden it caused had increased 82% for deaths, 155% for YLLs, 90% for YLDs, and 133% for DALYs by 2017.



• **Fig. 5.3** Age-standardized fraction of the population presenting obesity by country, 2017. (A) Men and (B) women. (From Institute for Health Metrics and Evaluation; Global Burden of Disease [GBP] Group. www.healthdata.org/gbd.)

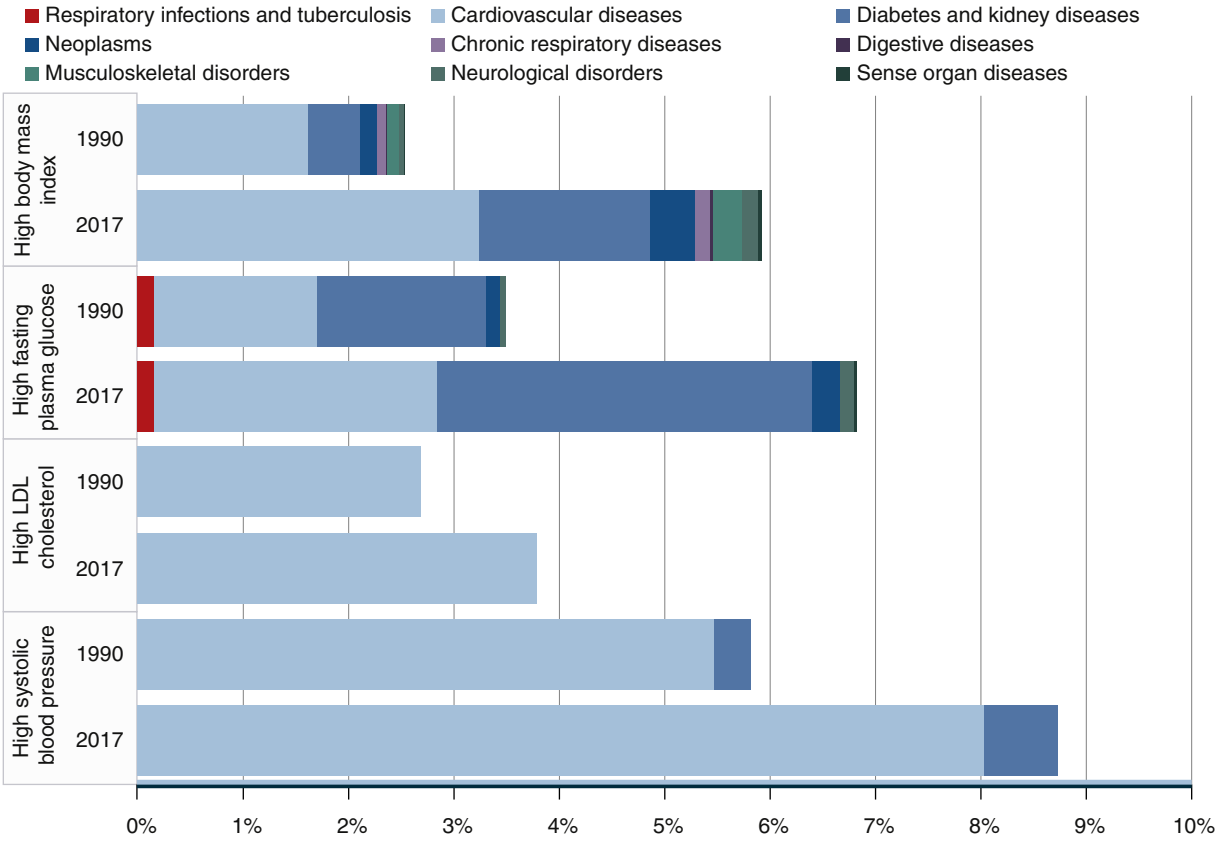




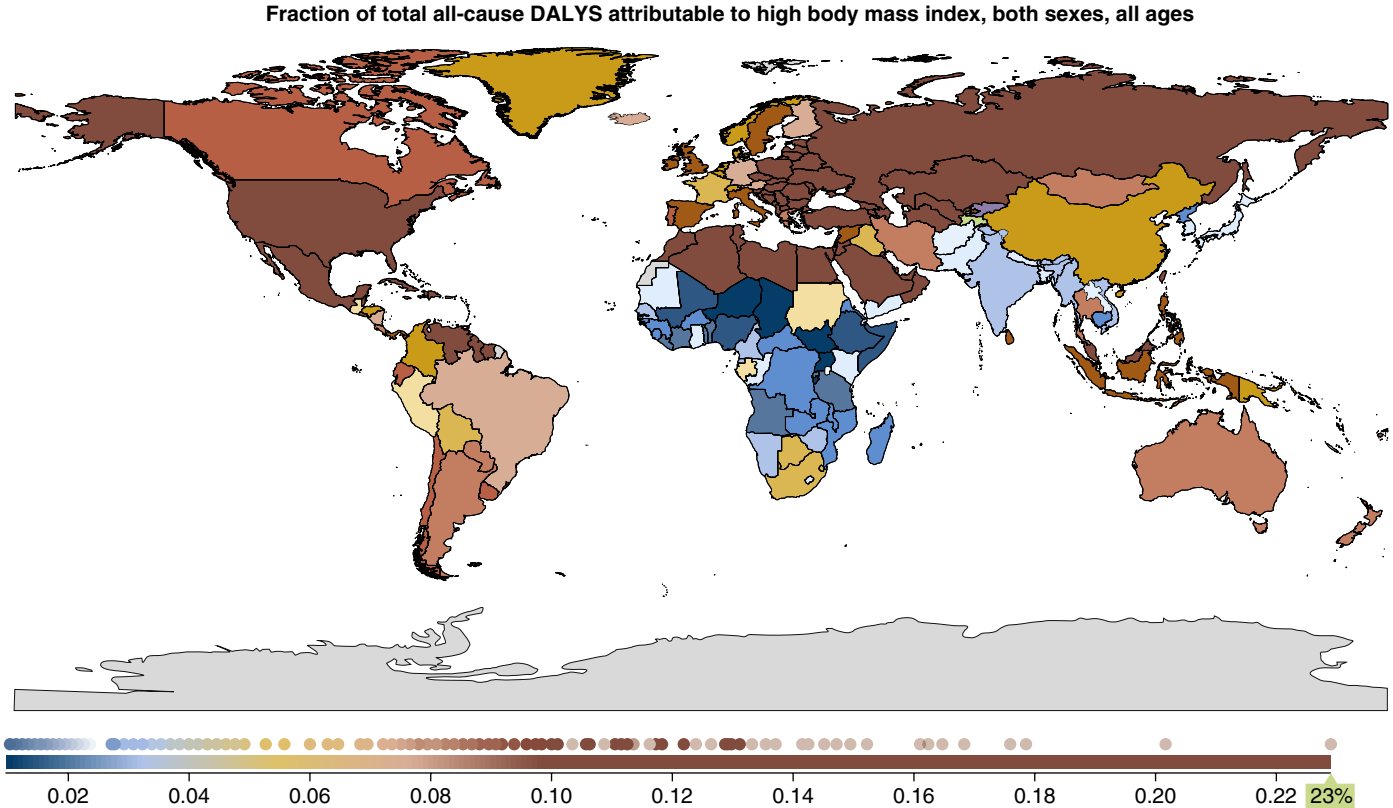
• **Fig. 5.4** Trends in the prevalence of obesity among children (A, aged >20) and adults (B, aged <20) from 1990 to 2017 overall and by level of sociodemographic development (SDI), separately for men and women. (From Institute for Health Metrics and Evaluation; Global Burden of Disease [GBP] Group. www.healthdata.org/gbd.)

As also seen in Fig. 5.5, the colors of the 2017 high BMI bar indicate that 55% of its burden resulted from cardiovascular diseases, 2% from chronic respiratory diseases, 28% from diabetes and renal diseases, 5% from musculoskeletal disorders, 7% from cancer, 3% from neurologic disorders (dementia), and 1% from remaining conditions.

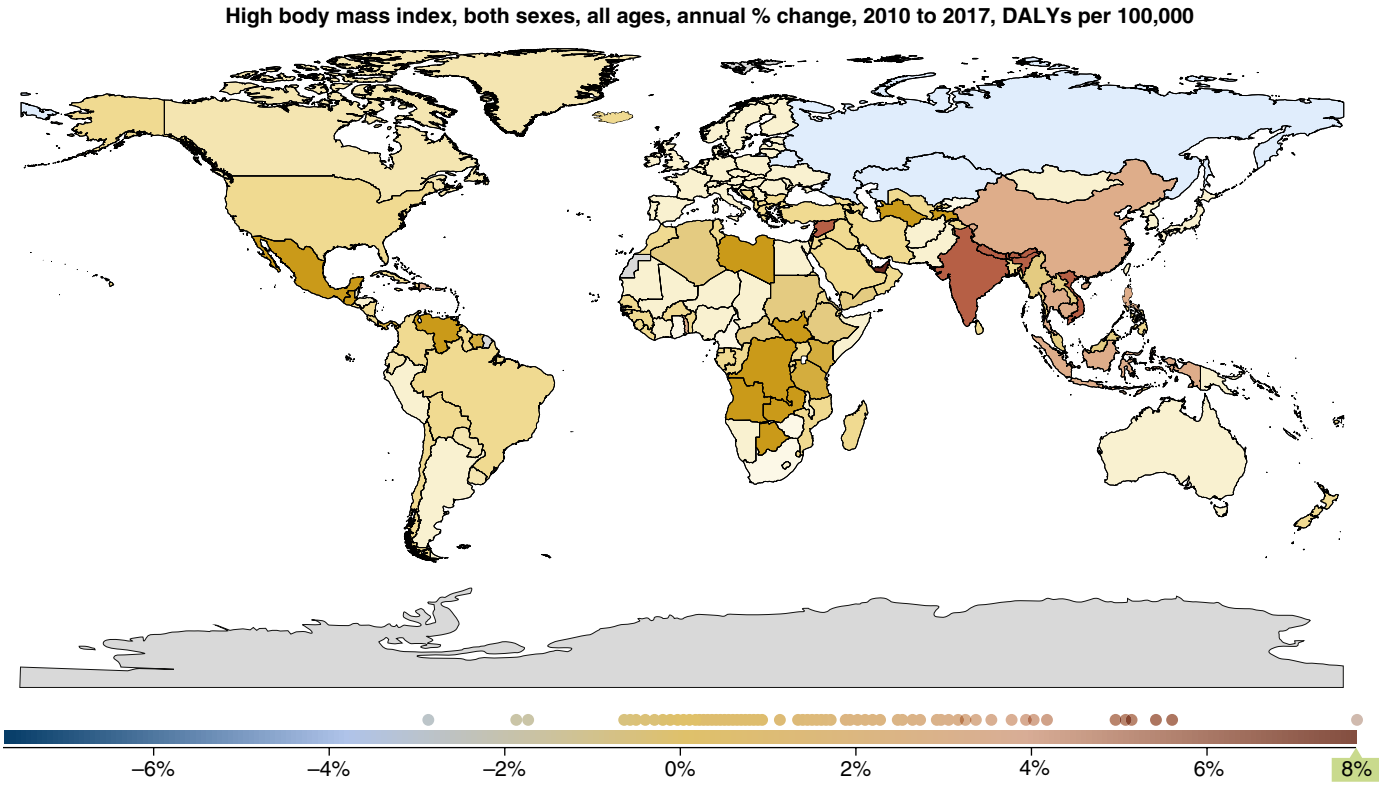
Like its prevalence, the burden of excess weight, though rising in all regions, is not evenly distributed among nations. Fig. 5.6



• **Fig. 5.5** Percent of total risk-factor–attributable disease burden due to the major risk factors for noncommunicable diseases, 1990 and 2017. The diseases causing this burden are shown by color codes. *LDL*, Low-density lipoprotein. (From Institute for Health Metrics and Evaluation [IHME]. GBD compare data visualization. 2017. https://vizhub.healthdata.org/gbd-compare/.)



• **Fig. 5.6** Crude fraction of all DALYs due to high BMI, men and women, 2017. (From Institute for Health Metrics and Evaluation [IHME]. GBD compare data visualization. 2017. https://vizhub.healthdata.org/gbd-compare/.)



• **Fig. 5.7** Relative annual percent change in the crude rate of DALYs attributable to high BMI, men and women, 2010 to 2017. (From Institute for Health Metrics and Evaluation [IHME]. GBD compare data visualization. 2017. https://vizhub.healthdata.org/gbd-compare/.)

shows the burden of high BMI, expressed as a fraction of disease burden, for the world's countries in 2017. For countries in dark brown greater than 10% of total disease burden was due to high BMI. For those in light brown, approximately 8% was due to high BMI; in dark yellow, approximately 6%; and in blue, less than 4%.

Fig. 5.7 shows the varying rates of growth of this burden, in terms of DALYs, from 2010 to 2017. The few countries shown in blue had a decrease in burden over this period and the small fraction of countries in yellow, a stable one. For those in tan, brown, light chocolate brown, and dark brown, burden has increased at annual rates of approximately 1%, 3%, 4% and 6%, respectively. The greatest increases are seen across the southern countries of Asia and much of Africa, both above and below the Sahara. Most of the Americas and much of Africa have experienced annual increases ranging from 1.5% to 3%. Europe and northern Asia, in general, have experienced the lowest increases.

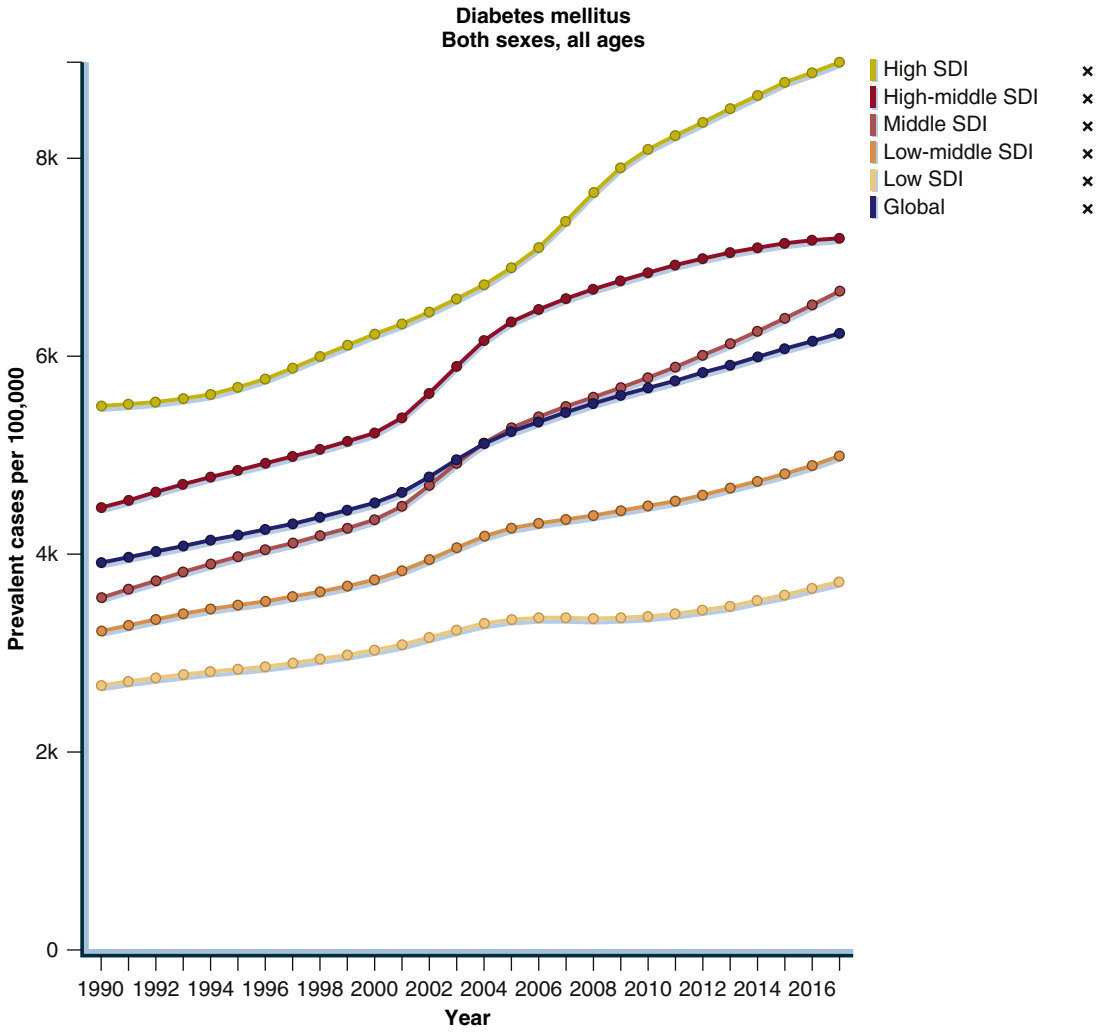
The Burden of Diabetes

Prevalence, Incidence, and Mortality Trends

From 1980 to 2014, as estimated by the NCD Risk Factor Collaboration,[6] the global age–standardized diabetes prevalence in adults aged 20 years and older more than doubled in men, from 4.3% (2.4–7%) to 9% (7.2–11.1%), and increased almost 60% in women, from 5% (2.9–7.9%) to 7.9% (6.4–9.7%). Given their large population size, China, India, the United States, Brazil, and Indonesia accounted for half of all adults with diabetes in 2014.

As seen in Fig. 5.8, from 1990 to 2017, the prevalence of diabetes has increased globally across all levels of development.[3] In large part this is due to the aging of the world's populations. As seen in Fig. 5.9, the crude incidence rates of diabetes generally increased over this period as well, driven by the aging of the population and the increase in certain risk factors, notably obesity. Also apparent from Fig. 5.9 is the stabilization of incidence in the high-SDI group and the decrease in incidence in high-middle SDI populations. It is noteworthy that the stabilization/decrease in incidence in higher SDI groups has not been sufficient to halt their rising prevalence of diabetes. The accentuated recent rise in prevalence in the high-SDI group is fueled in large part by the notable decline in diabetes mortality observed in this group since 2003, as seen in Fig. 5.10. Of note in this figure, all other SDI groups continue to show rising mortality due to diabetes.

An issue that has generated great concern in recent years is the rising prevalence/incidence of diabetes among the young populations. While incidence of type 1 diabetes has risen worldwide, the increase also results from the rising incidence of type 2 diabetes in the young.[7] Due to the early disease onset of type 2 diabetes, those affected will be exposed to metabolic and vascular disturbances for longer periods, resulting in an ominous prognosis, estimated to be worse than that predicted for type 1 diabetes manifesting in a similar period.[8] This new burden of young-onset diabetes coupled with the aging of the population heralds the emergence of growing populations of people with diabetes of extremely long duration manifesting premature complications, including renal failure, multiple morbidities, and frailty, and thus imposing new pressures on individuals, families, health care systems, and societies.



• **Fig. 5.8** Trends in the crude prevalence of diabetes globally and across sociodemographic index (SDI) quintiles, 1990 to 2017. (From Institute for Health Metrics and Evaluation [IHME]. GBD compare data visualization. 2017. https://vizhub.healthdata.org/gbd-compare/.)

Burden

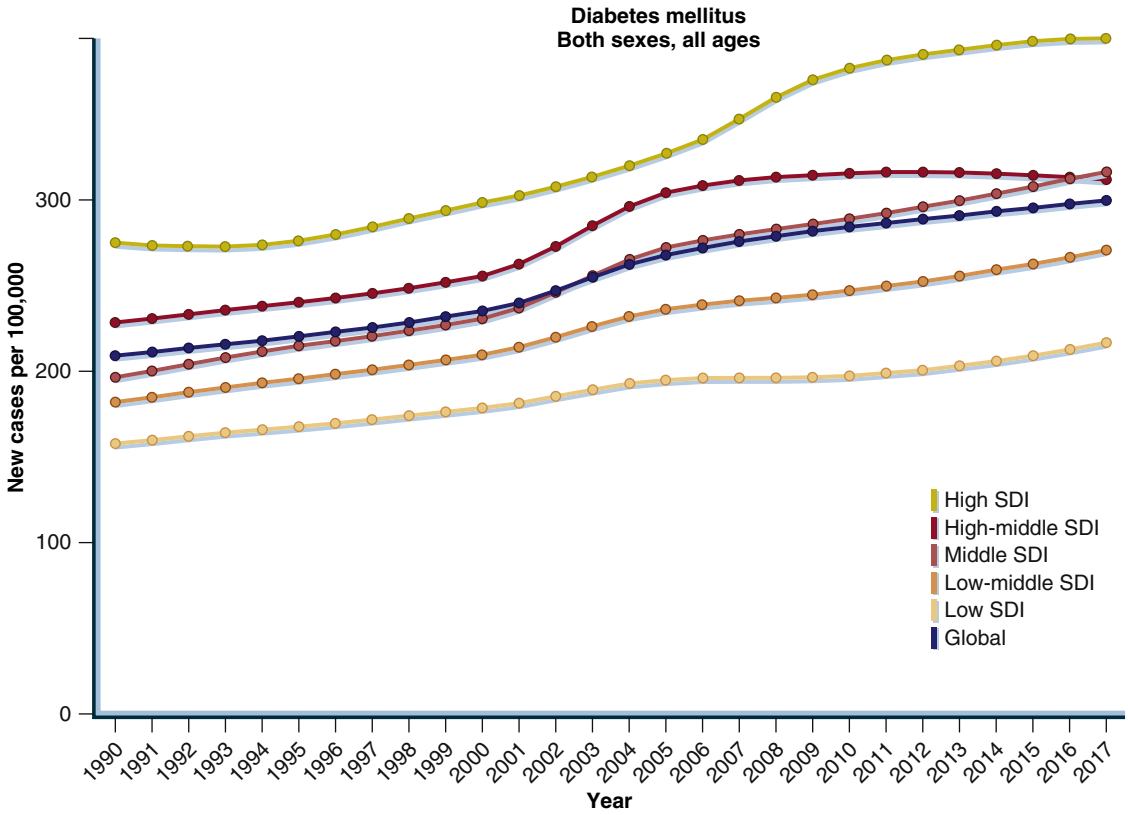
To characterize the burden of hyperglycemia along its continuous spectrum, GBD joins the burden of diabetes together with that of intermediate states of hyperglycemia, labeling it as burden due to "high fasting plasma glucose," defined as values above 4.5 to 5.4 mmol/L, their established range of minimal risk. High fasting plasma glucose in 2017 was the fourth leading risk factor for all-cause disease burden (crude DALYs) in the world, having risen from the ninth position in 1990.

Considering unstandardized rates for the world's population, high fasting plasma glucose is estimated to have caused 11.7% of deaths, 7.4% of YLLs, 5.8% of YLDs, and 6.8% of DALYs in 2017. In relation to 1990, this burden has increased 57% for deaths, 116% for YLL, 50% for YLDs, and 95% for DALYs. Fig. 5.5 shows that acute or microvascular complications (including renal disease) and living with diabetes in general produced 52% of the burden; cardiovascular diseases, 39%; cancer, 4%; tuberculosis, 2.5%; neurologic disorders (dementia), 2%; and cataract and glaucoma, <1%.

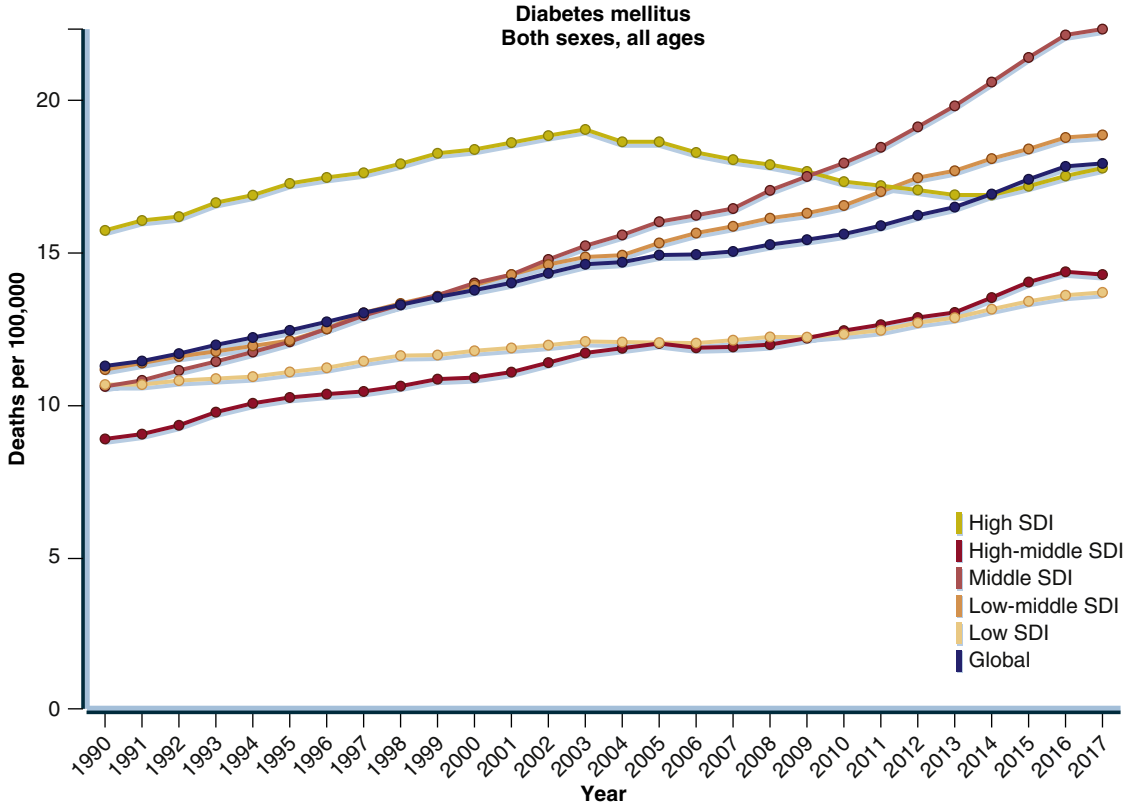
The Burden of Thyroid Diseases

GBD 2017 data provide information regarding the two clinically important subgroups of thyroid diseases: iodine deficiency/thyroid goiter and thyroid cancer.[3]

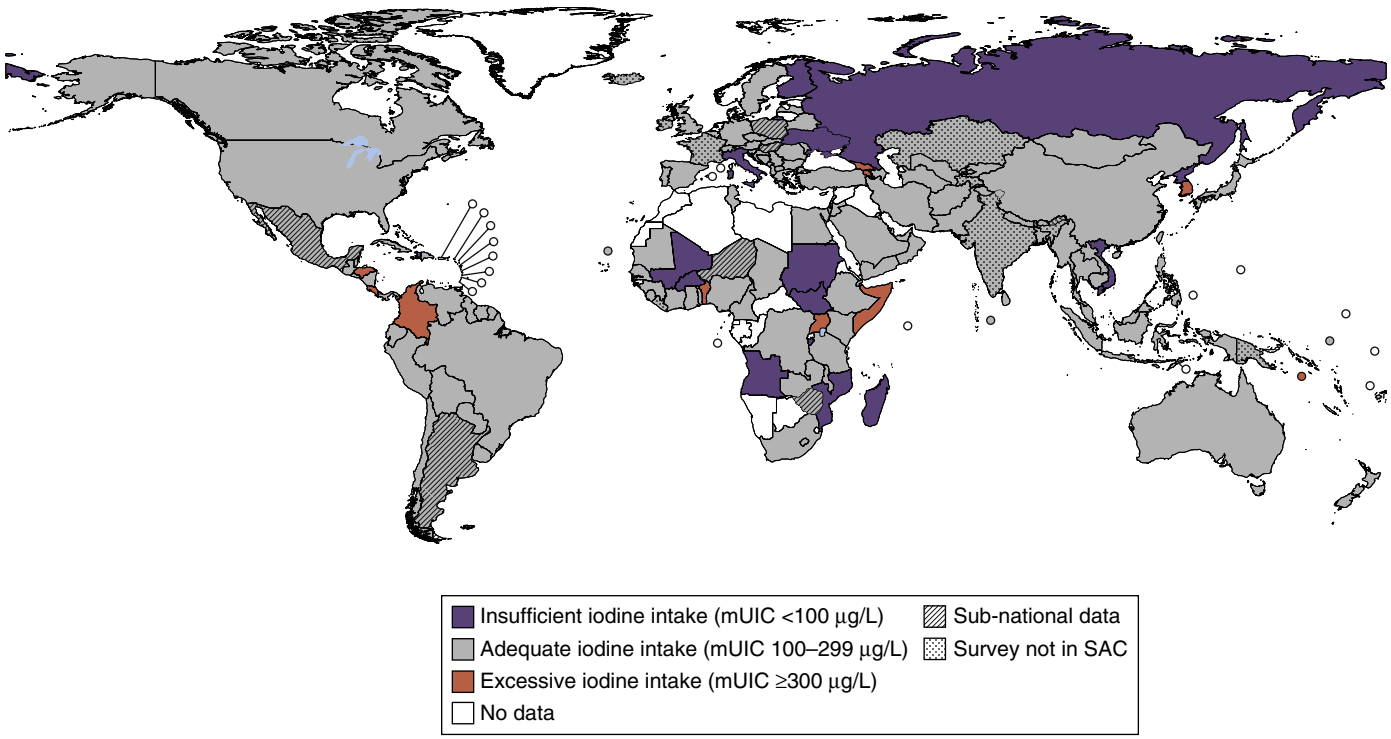
Deficiency of iodine, an essential component of the thyroid hormones, leads to inadequate thyroid hormone production. Thyroid hormones and thus iodine are necessary for many activities in the body. Iodine deficiency produces several consequences in humans, collectively called *iodine deficiency disorders*. It is one of the most prevalent preventable nutrient deficiencies in the world. Although the number of countries in which iodine intake is adequate has increased in recent decades, many nations still have a clinically relevant prevalence of deficiency. Most of them are low-income and middle-income countries, such as Angola, Burkina Faso, Burundi, Haiti, Mozambique, Sudan, and South Sudan. However, even countries in transition, such as Russia and the Ukraine, and some high-income countries (Finland, Israel, and Italy), present problematic levels.[9] Fig. 5.11 presents a global scorecard of iodine nutrition based on median urinary iodine concentration in school-age children and adults, in 2017.



• **Fig. 5.9** Trends in the crude incidence of diabetes globally and across sociodemographic index (SDI) quintiles, 1990 to 2017. (From Institute for Health Metrics and Evaluation [IHME]. GBD compare data visualization. 2017. https://vizhub.healthdata.org/gbd-compare/.)



• **Fig. 5.10** Trends in crude diabetes mortality globally and across sociodemographic index (SDI) quintiles, 1990 to 2017. (From Institute for Health Metrics and Evaluation [IHME]. GBD compare data visualization. 2017. https://vizhub.healthdata.org/gbd-compare/.)



• **Fig. 5.11** Global scorecard of iodine nutrition based on median urinary iodine concentration in school-age children (SAC) and adults, 2017. (From Iodine Global Network [IGN]. http://www.ign.org/index.cfm.)

The definition of iodine deficiency in GBD 2017 includes estimates of the subset of iodine deficiency associated with visible goiter (grade 2) and its associated sequelae because of the greater reliability and consistency of the clinical diagnosis of grade 2 goiter worldwide. It does not include estimates of subclinical iodine deficiency or nonvisible goiter (grade 1) induced by iodine deficiency. The global burden of iodine deficiency disorders, expressed in all-age DALYs, has shown improvement over the 1990–2017 period, declining 43.6%, from 61.7/100,000 (37.7–98.7/100,000) to 26.9/100,000 (16.3–42.6/100,000).[3]

Thyroid cancer incidence has increased in all continents, except in Africa. In fact, incidence rates are more than twofold higher in high-income countries compared with low-middle-income countries.[10] Fig. 5.12 illustrates the differences in age-standardized incidence rates for thyroid cancer in the 1990–2017 period, in countries categorized by the SDI. In spite of the overall increase in incidence in the last three decades, a recent decline has been noted in countries with high and high-middle SDI. Fig. 5.12 also highlights the discrepancy across the developmental continuum in incidence of thyroid cancer. This socioeconomic discrepancy is probably due to differences in access to diagnosis, which is more available in high-income countries.

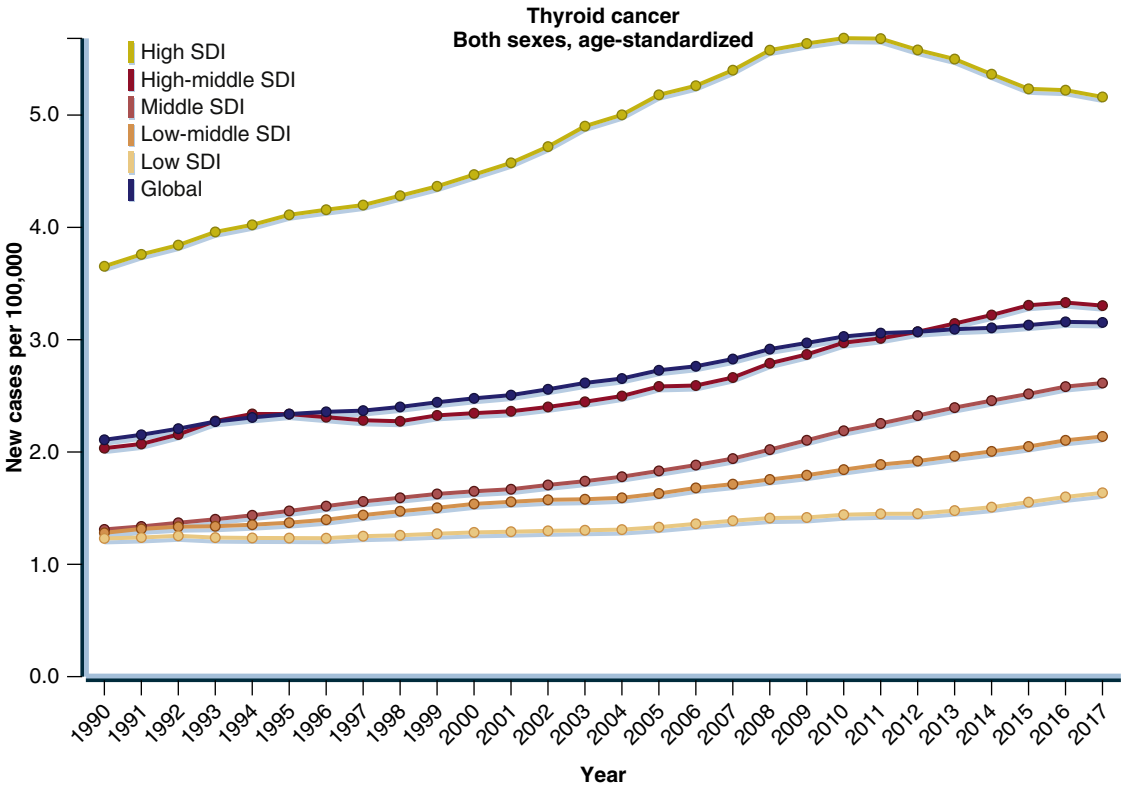
Despite this overall increase in incidence, age-standardized mortality rates of thyroid cancer have declined in countries with high, high-middle, and low SDI (by 18%, 11%, and 5%, respectively), while slightly increasing in countries with middle and low-middle SDI (by 6% and 8%, respectively), as shown in Fig. 5.13. As the decline is more evident in countries with high and high-middle SDI, it is likely due to earlier diagnosis with quick therapeutic intervention.

According to 2017 GDB data,[4] the crude global burden of thyroid cancer evaluated by DALYs in the 1990–2017 period increased from 12/100,000 (11–13.2) to 14.8/100,000 (14–16.1). Fig. 5.14 shows age-standardized DALYs due to thyroid cancer in countries categorized by SDI in this period. The global age–standardized DALY declined from 14.4/100,000 (13.4–15.8/100,00) to 14.1/100,00 (13.3–15.3/100,000). Despite the relatively accentuated decline in low-SDI countries, the burden of thyroid cancer (DALY) continues to be greater in countries with low or low-middle SDI. This socioeconomic discrepancy is reflecting differences in access to diagnosis and adequate treatment.

These data highlight the necessity to improve iodination programs and access to care for patients with thyroid diseases through the development of infrastructure and appropriate patient management in the developing world. These actions could save costs, improve quality of life, and produce a healthier workforce. These GDB results call attention to the need to include thyroid diseases in the public health agenda.

Perspectives for the Next Decade

Recent trends in the prevalence of high BMI and hyperglycemia suggest that unless major public health or clinical breakthroughs occur, the burden of obesity and diabetes will continue to grow and demand commitment of ever-greater resources in the foreseeable future. The continuous aging of the world's population will be a major driver in these trends. On the other hand, extension of policies involving iodine supplementation will likely continue to decrease the burden of iodine-related thyroid disease and complications. Access to early diagnosis and treatment of thyroid cancer, especially in countries at low and middle levels of development, will hopefully lead to a continuing decrease in disease burden.



• **Fig. 5.12** Trends in age-standardized incidence rates (per 100,000) of thyroid cancer, for both sexes, in countries categorized in quintiles by the sociodemographic index (SDI), 1990 to 2017. Navigating Through Clinical Practice Guidelines in Endocrinology

NAYKKY SINGH OSPINA, SPYRIDOULA MARAKA, RENE RODRIGUEZ-GUTIERREZ, JUAN P. BRITO, AND VICTOR MONTORI

CHAPTER OUTLINE

KEY POINTS

- Clinical practice guidelines provide actionable recommendations for clinicians to provide care.
- The GRADE system provides a systematic framework for an in-depth assessment of the quality of the evidence and considers important factors used in clinical decision making to determine the strength of clinical practice recommendations.
- A systematic evaluation of the available literature (body of evidence) and a multidisciplinary panel are important features of trustworthy guidelines.
- Recommendations have a direction (in favor of or against an intervention), a strength (strong or weak), and a judgment of the quality of the evidence supporting the recommendation (very low, low, moderate, high).
- To provide care supported by clinical guidelines, clinicians should engage in meaningful conversations with their patients to understand their situation because evidence alone is not sufficient to provide care.

Introduction

Clinical decision making is a complex process in which, ideally, clinicians and patients create plans of care that reflect the best available research evidence while also considering the patients' values, preferences, and context.[1–3] The increasing number of published trials and studies, unclear sources of evidence, increasing number of interventions, patients with more and complex comorbidities, and time constraints make clinical decision making and caring for patients even more challenging.[4–7] Clinical practice guidelines are statements that provide actionable recommendations intended to support clinicians in the decision-making process and improve patient care.[8,9] Because of their potential benefits, the production of clinical practice guidelines has increased during the last few years. In fact, the National Guideline Clearinghouse website had ~1500 available guidelines with more than 100 guidelines related to endocrine diseases.[10] The availability of this large number of clinical guidelines makes it imperative for clinicians to understand the process associated with their development, their applicability, and their downsides in clinical practice; at the same time, clinicians must recognize which guidelines can be trusted and are likely to result in improved patient care when implemented.

Development of Trustworthy Clinical Practice Guidelines

To be trustworthy, clinical practice guidelines should be based on one or usually multiple systematic reviews of the available evidence and include a multidisciplinary guideline panel (free or

transparent regarding financial relationships).[8] This panel should include members with methodologic and clinical expertise that can systematically evaluate the factors that may influence a clinical decision and provide recommendations that are clear and actionable. In addition, patient representatives can be included.[8,11–14] Although the best way to involve patients in the development of clinical practice guidelines has not been defined, their integration into these panels is feasible. Moreover, patient panels formulate similar recommendations when compared to physician panels when presented with evidence warranting moderate to high confidence.[14] The Institute of Medicine has suggested a series of criteria that can help different stakeholders evaluate the quality of the process used to develop clinical practice guidelines and their trustworthiness (Table 6.1).

Many systems have been developed to provide a framework to analyze clinical evidence and provide practice recommendations. Initially, many clinical practice guidelines were developed based on expert opinion without a systematic evaluation of the available literature, making them prone to bias and inclusion of untrustworthy recommendations.[9] Moreover, many of these approaches provided recommendations based on study design alone and did not include explicit judgments about the strength of recommendations (i.e., how trade-offs between the expected benefits, harms, and costs weigh in during development of the recommendation). Furthermore, most systems were found to have low reproducibility of judgments (suggesting evaluation of different factors when making recommendations) and did not fit the needs of stakeholders.[15] To overcome the shortcomings of these systems, the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) system was developed.[11] The GRADE system provides a systematic framework for an in-depth assessment of the quality of the evidence that is based on more than study design (randomized control trial vs. observational studies).[11–13,16,17] This approach also includes additional factors affecting the quality of evidence (Table 6.2) as well as other factors to consider when making a recommendation, such as the balance between benefits and harms, integration of the patient's values, preference and context, resources, and effects on health equity (Table 6.3).[12,17] This framework was first adopted by the Endocrine Society (Table 6.4) and is now used by more than 100 other organizations for the development of trustworthy guidelines.[9,18,19]

The GRADE system suggests several steps to develop trustworthy clinical practice guideline recommendations.[11–13,16,17,20–27]

Identification of the Clinical Question

Guideline panelists should select important clinical questions and identify the population to which the recommendations will apply, the intervention and comparator to be studied, and the health outcomes to be evaluated. The selected outcomes should be classified according to their clinical significance. When possible, patient-important outcomes should receive more value in decision making than surrogate markers (e.g., fracture rate compared to bone mineral density changes).[11,20,21]

Systematic Review of the Literature

Once the clinical question is identified, a systematic search of the literature is performed to identify all the available clinical studies (i.e., the body of evidence). This systematic and reproducible

TABLE 6.1 Suggested Criteria for Developing Trustworthy Guidelines

Criteria	Comment
Include a systematic evaluation of the clinical evidence	Allows identification of all the available evidence and prevents recommendations based on a single study or solely expert opinion. Allows comparison of effect estimates across different studies (likely including different populations and settings).
Include a multidisciplinary panel with clinical and methodologic expertise and other important stakeholders	A collaborative and multidisciplinary panel creates a space for evaluation of the evidence and of recommendations from different perspectives. Inclusion of patients is recommended. This can help clarify expected values and preferences of patients.
Consider the importance of patients' values and preferences	Clinical evidence is not sufficient to provide patient-centered care. As such, consideration of how the values and preferences of patients can affect clinical decision making is required. This is extremely important when there is expected variability in the values and preferences of patients.
Follow a transparent process	Guidelines can have significant impact on patient care and policy. Following a transparent and systematic approach increases our confidence that the recommendations are made to improve patient care and are free of conflict of interest. Guidelines should clearly report their funding source and potential conflict of interest of panel members.
Explain the logical relationship between alternative care options and health outcomes	Clear explanations of the reasoning behind recommendations, including harms/benefits, rating of the quality of the evidence, the value of patients' preferences, and the strength of the recommendation, are required. Differences in opinion between panel members can also be included. This transparency allows understanding of how recommendations were derived.
Provide explicit ratings of the quality of the supporting evidence and the strength of the recommendations	A systematic approach should be followed when assessing the quality of the evidence supporting different strengths of recommendations and clearly presented with each recommendation.
Be revised as new evidence warrants modification of the recommendations	Clinical practice guidelines should be updated to reflect the best available evidence.

TABLE 6.2 Domains Used to Assess the Quality of the Evidence

Domain	Comment
Rate Down the Quality of the Evidence	
1. Risk of bias	Randomized clinical trials and observational studies might be at higher risk of bias depending on features of their design or conduct that can lead to a systematic deviation of their results from the truth (bias). The presence of multiple sources of bias decreases the quality of the evidence.
2. Inconsistency	Refers to the difference in the magnitude of the effect across studies. Inconsistency is present when point estimates vary widely across studies or if there is no or only minimal overlap between confidence intervals. In addition, statistical tests such as the test for heterogeneity and the I^2 can help identify inconsistency.
3. Indirectness	This is present when there are significant differences between the populations, interventions, and outcomes evaluated in a study compared to the ones we want to study. In addition, the lack of head-to-head comparison between two alternative management strategies is a cause for indirectness.
4. Imprecision	The confidence intervals of an estimate are used to judge for imprecision. If the 95% confidence interval is wide, this suggests that the range in which the truth possibly lies is also wide. In addition, if the number of events and the sample size are small or if the confidence interval crosses the line of no effect, the quality of the evidence can also be rated down for imprecision.
5. Publication bias	Studies with statistically significant results are more likely to be published than those with negative results; as such, evaluation of the published literature can lead to an inaccurate estimate of the effect of an intervention. Publication bias can be considered when only a small number of studies is available and if most are sponsored by industry. The funnel plot is a commonly used method to assess for publication bias.
Rate Up the Quality of the Evidence	
1. Large effect	A magnitude of effect is considered large when the relative risk is between 2 and 5 or 0.5 and 0.2 without possible confounders or very large if the relative risk is above 5 or below 0.2 without problems of serious risk of bias or precision.
2. Dose-response gradient	This gradient is considered when evaluating cause-effect relationships. This is present when the effect increases with the dose/exposure.
3. Evaluation of plausible residual confounding	Rigorous observational studies will perform an adjusted analysis based on important prognostic factors. If a positive or negative effect is found after this adjustment, careful clinical analysis might help identify large effects, despite the presence of uneven groups that are expected to result in no effect.

evaluation of the literature will allow panelists to inform their recommendations based on the complete spectrum of the available literature and not only on the most recent clinical study. In addition, systematic reviews help generate a best estimate of the effect of the clinical intervention based on the body of evidence (and not on a single study) and allow the comparison of this estimate across different studies, which together often encompass a broad range of populations and settings. Moreover, having a summary of the body of evidence allows assessment for the possibility of publication bias.[11,20,21,23]

Evaluation of the Quality of the Evidence

A pivotal step in the development of clinical practice guidelines is the evaluation of the quality of the evidence. The quality of the evidence reflects the extent of our confidence that the estimates of an effect are adequate to support a recommendation. When high-quality clinical evidence is available across outcomes of most importance, there is good certainty of the potential effects of an intervention, allowing panelists and clinicians to feel confident in the expected outcomes of recommendations. When the quality of evidence is poor, panelists have less confidence in effect estimates and expected outcomes of recommendations.[12,13,16,21–26]

This evaluation starts by identifying the study design. In general, randomized controlled trials (RCTs) provide a high quality of evidence. However, for this to be true, these studies should be conducted following the accepted standards for RCTs that aim to protect them against bias such as adequate allocation concealment, blinding, follow-up, analysis, and complete outcome reporting. On the other hand, observational studies are considered to provide low-quality evidence because the groups are not balanced in terms of known and unknown prognostic factors at the start of the study (i.e., confounders). However, similar to the RCTs, specific details about how these studies were conducted can improve this initial rating (e.g., adequate selection of patients, adjustment of unbalanced factors and confounders, and follow-up).[12,13,16,21–26]

After this initial evaluation of the studies based on their design, the body of evidence is systematically evaluated in eight domains (see Table 6.2) that will allow panel members to categorize the quality of evidence associated with a specific recommendation as high quality, moderate quality, low quality, or very low quality across each outcome of interest. It is possible that the quality of the evidence varies among outcomes. In such cases, the quality of the evidence associated with the most important outcome should guide the quality of the evidence for a particular recommendation.[12,13,16,21–26]

TABLE 6.3 Factors Contributing to the Grading of Recommendations

Factors	Effect
Balance between desirable and undesirable outcomes	When the gradient between desirable and undesirable effects is large, panels are more likely to make a strong recommendation. When the gradient between desirable and undesirable effects is narrow, panels are more likely to make a weak recommendation.
Quality of the evidence (on patient-important outcomes)	When high-quality evidence for patient-important outcomes is available, panels are more likely to make a strong recommendation. When only very-low-quality evidence for surrogate markers or less important outcomes is available, panels are more likely to make a weak recommendation.
Confidence in the expected values and preferences of patients	Values and preferences refer to the processes that patients use when considering between alternative treatment options (benefits, harms, cost, and impact on daily life). It can be argued that there is always a degree of uncertainty in terms of the values and preferences of each individual patient. When the patients' values and preferences are unknown or great variability is expected, panels are more likely to make a weak recommendation. When the variability in patients' values and preferences is expected to be low, panels are more likely to make a strong recommendation.
Resources	Reliable evidence regarding resource use should be identified and important differences in resource use between alternative management strategies should be considered when grading recommendations.
Acceptability and feasibility of implementation	Panelists should consider if the proposed recommendations will be accepted and implemented in clinical practice. For example, they might consider the burden of treatment of a particular treatment agent compared to the alternative (e.g., multiple injections per day, need to be taken at a specific time of the day).
Health inequity (differences in health care that are avoidable and unfair or unjust)	Panelists should consider the impact of recommendations on health inequity and groups that are considered disadvantaged.

These levels of the quality of evidence refer to the panel's level of confidence that the true effect of an intervention lies within a particular range or on one side of an important clinical threshold.[28]

From Quality of the Evidence to Strength of Recommendation

In contrast to the construct of quality of the evidence, the strength of a recommendation refers to the panel's confidence that the desirable effects of an intervention outweigh the undesirable effects. In making this assessment, panel members take into consideration the quality of the evidence regarding expected benefits and harms of an intervention in addition to other factors that are important in medical decision making such as the values and preferences of patients, the setting where the intervention will take place, and available resources[12,13,17] (Fig. 6.1; also see Table 6.3).

Clinical Practice Guidelines Recommendations

Recommendations have a direction (in favor of or against an intervention), a strength (strong or weak), and a judgment of the quality of the evidence supporting the recommendation (very low, low, moderate, high)[12,13,21] (see case study later in the chapter).

Strong Recommendations

Strong recommendations are those in which the panel is confident that the desirable effects of following a recommendation clearly outweigh the undesirable effects. In general, these recommendations are based on high-quality or moderate-quality evidence. Panel members usually frame these recommendations as "We recommend…"[12,13,21] (see case study later in the chapter).

Strong recommendations assume that most patients faced with this health care decision will choose the proposed intervention given the certainty of potential benefits in important outcomes.[12,13,21] Clinicians are encouraged to follow these recommendations, policy makers can consider them as part of the standard of care, and they usually serve as the basis for quality or performance measures.

In some circumstances, strong recommendation can be based on low-quality evidence.[12,13,21] For example[29]:

- When low-quality evidence suggests benefit in a life-threatening situation (e.g., increasing the glucocorticoid dose in patients with congenital adrenal hyperplasia during severe illness)
- When low-quality evidence suggests benefit or equivalence of two alternatives and high-quality evidence suggests harm for one of the alternatives (e.g., recommendation for unilateral laparoscopic adrenalectomy for patients with documented primary hyperaldosteronism, instead of open adrenalectomy)
- When high-quality evidence suggests equivalence and low-quality evidence suggests harm in one treatment alternative (e.g., using propylthiouracil instead of methimazole during the first trimester of pregnancy)

Weak Recommendations (Also Called Conditional or Discretionary)

Weak recommendations are those in which the panel concludes that the desirable effect of following these recommendations probably outweighs the undesirable effects, but they are not confident about this conclusion. Weak recommendations are usually based on low-quality or very-low-quality evidence. Panel members usually frame these recommendations as "We suggest…"[12,13,21] (see case study later in the chapter).

In addition, in cases when the systematic evaluation of the evidence provides high-quality evidence that the benefits and risks of

alternative treatment are balanced, a weak recommendation can be made (see upcoming case study, question 2).[12,13,21] In general, the values and preferences of patients will significantly affect the medical decision when weak recommendations are made. Clinicians are encouraged to explore these values and preferences by engaging in shared decision making to reach the optimal medical decision based on the best available evidence and the values of patients.[3,12,13,30,31] In shared decision making, clinicians and patients work together to determine the best way to address the patient's situation.[3,30,31] Decision aids are tools that have shown to increase patients' knowledge and level of satisfaction with their medical decision and to enable patient-centered care; they can also help clinicians explore the values and preferences of patients.[30,32] These tools usually present a summary of the best available evidence about medical options for a particular clinical scenario and should help support the conversation between patients and clinicians.[30,32]

Good Practice Statements

This is a special category of clinical practice statements in which a formal evaluation of the literature is not necessary, as there is a large body of indirect evidence to support the benefit of the recommendation and where the evaluation of alternatives in clinical trials would be unproductive and unnecessary. These recommendations should be clear, necessary, and justified by panel members. In addition, guideline panelists should seldom use this type of recommendation, as there is the risk of using it to support strong recommendations in the absence of clinical evidence.[33] The following is an example of a Good Practice Statement from the Endocrine Society, titled "Endocrine Treatment of Gender-Dysphoric/Gender-Incongruent Persons"[34]:

> We advise that the clinician responsible for endocrine treatment and the primary care provider ensure appropriate medical clearance of transgender individuals for genital gender-affirming surgery and collaborate with the surgeon regarding hormone use during and after surgery.

In this case, it would be unreasonable to conduct a trial in which the endocrine team, the primary care provider, and the surgeon would not collaborate to achieve adequate surgical outcomes; in addition, there is indirect evidence that clinical collaboration is beneficial for patient care.

Clinical Practice Guidelines in Endocrinology

An analysis of the Endocrine Society clinical practice guidelines from 2008 to 2014, including 25 guidelines, found that up to 20% of the recommendations were based on very-low-quality evidence.[35] A similar study, including 17 Endocrine Society clinical practice guidelines published between 2005 and 2011, found that 58% of the recommendations were graded as strong (59% based on low-quality or very-low-quality evidence) and 42% were considered weak (92% based on low-quality or very-low-quality evidence).[29] These findings should highlight the importance of exploring patient values and preferences and engaging in shared decision making in endocrinology, given that a large number of recommendations are weak (conditional) and based on low-quality or very-low-quality evidence.[1,29,35] In addition, there is an urgent need of clinical research aimed at improving the quality of evidence supporting clinical practice guidelines in endocrinology. In fact, an assessment of current clinical trials in endocrinology found that only one in five recommendations that are based on

very-low-quality evidence has a clinical protocol in place trying to address this knowledge gap.[35]

Using Clinical Practice Guidelines in Patient Care

In clinical practice, guidelines can help physicians provide care that is based on the best available evidence and ideally supports patient-centered care.[9,12,13,36] Strong recommendations based on high-quality evidence can inform clinicians regarding the most effective and ineffective interventions, allowing them to adequately discuss the risks/benefits with their patients.[9] Weak recommendations based on low-quality evidence should lead to collaboration between patients and clinicians when deciding the next step in management.[3,30,31] The integration of decision aids and other tools to support shared decision making can help with the adequate implementation of clinical practice guidelines.[37,38]

Case Study: Management of Gestational Diabetes Using Clinical Practice Guidelines in Patient Care

An otherwise healthy 28-year-old gravida 1, para 0 at 25 weeks' gestation had an initial abnormal 50-g oral glucose challenge test (160 mg/dL, 8.8 mmol/L) followed by an abnormal 100-g 3-hour glucose tolerance test confirming the diagnosis of gestational diabetes. After 1 week of following medical nutrition therapy and daily moderate exercise for more than 30 minutes, she continues to have abnormal fasting glucose (95–109 mg/dL, 5.3–6.0 mmol/L) and postprandial hyperglycemia (140–160 mg/dL, 7.8–8.8 mmol/L).

Clinical Question 1: What should we do to improve pregnancy and offspring outcomes in this pregnant woman with gestational diabetes?

Answer: As per the Endocrine Society guidelines, "Diabetes and Pregnancy,"[39] using blood glucose-lowering pharmacologic therapy *is recommended* if lifestyle therapy is insufficient to maintain normoglycemia in women with gestational diabetes. (Strong recommendation, high-quality evidence)

The body of evidence is clear that maternal hyperglycemia has a deleterious effect on fetal, neonatal, and maternal outcomes.[40,41] Correction of maternal hyperglycemia, however, reduces or prevents adverse outcomes.[42] If this is not possible with nonpharmacologic management, well-conducted randomized clinical trials have shown that blood glucose–lowering pharmacologic therapy is effective at improving patient-important outcomes in this population (e.g., death, shoulder dystocia, large-for-gestational-age offspring).[42–45] Therefore, as the patient's clinician, you can strongly recommend initiation of a blood glucose–lowering medication, as it is expected that most otherwise healthy pregnant patients faced with this clinical recommendation would like to start a blood glucose–lowering medication.

Clinical Question 2: Of the available treatment options, which glucose-lowering medication would you recommend?

Answer: Providing evidence-based care for patients with gestational diabetes remains challenging because of the lack of well-conducted clinical trials in this population. Even among the major medical professional societies, including the Endocrine Society, the American Diabetes Association, and the American College of Obstetricians and Gynecologists (ACOG), consensus on management is often lacking.

As per the Endocrine Society guidelines, "Diabetes and Pregnancy,"[39] long-acting insulin analog detemir may be initiated during pregnancy for those women who require basal insulin and for whom neutral protamine Hagedorn (NPH) insulin, in appropriate doses, has previously resulted in, or for whom it is thought NPH insulin may result in, problematic hypoglycemia. (Weak recommendation, high-quality evidence)

It is also suggested that the rapid-acting insulin analogs lispro and aspart may be used over regular insulin. (Weak recommendation, moderate-quality evidence)

In addition, the Endocrine Society guidelines suggest that glyburide, an oral agent, is a suitable alternative to insulin therapy for glycemic control in women with gestational diabetes who fail to achieve sufficient glycemic control after a 1-week trial of medical nutrition therapy and exercise, except for women with a diagnosis of gestational diabetes before 25 weeks' gestation and for women with fasting plasma glucose levels above 110 mg/dL (6.1 mmol/L), in which case insulin therapy is preferred. (Weak recommendation, low-quality evidence.)

They also suggest that metformin therapy be used for glycemic control only for those women with gestational diabetes who do not have satisfactory glycemic control despite medical nutrition therapy and who prefer not to use insulin or glyburide and are not in the first trimester. (Weak recommendation, low-quality evidence.)

Therefore, in contrast to the confidence in recommending a blood glucose–lowering therapy for women with gestational diabetes based on the high-quality evidence supporting the medical guidelines, the decision about which agent to choose requires further discussion of the clinical evidence and the patient's situation. Health care professionals should fully and frankly discuss with women diagnosed with gestational diabetes the advantages and possible disadvantages of the available blood glucose–lowering pharmacologic therapy options and together reach a decision that makes intellectual, practical, and emotional sense to them.

Shortcomings of Clinical Practice Guidelines

Although clinical practice guidelines aim to help patients and clinicians collaborate in making better health decisions, there are still limitations in the development and implementation of clinical guidelines to improve care.

Guidelines as Tools That Support (Not Dictate) Care

There is high-quality evidence that statin therapy in patients with type 2 diabetes reduces the risk of adverse cardiovascular (CV) outcomes, including mortality.[46,47] Consequently, clinical practice diabetes guidelines unanimously advocate, as a strong recommendation, to use statins in this patient population.[48] However, not every patient will value the use of statins the same way as the panelists do. For instance, consider the case of Mr. Jones, a 54-year-old white man with a history of type 2 diabetes, obesity, controlled hypertension, depression, low back pain, sleep apnea, and new-onset dyslipidemia. His 10-year American College of Cardiology/American Heart Association CV risk is 10.0%.[49] If 100 patients

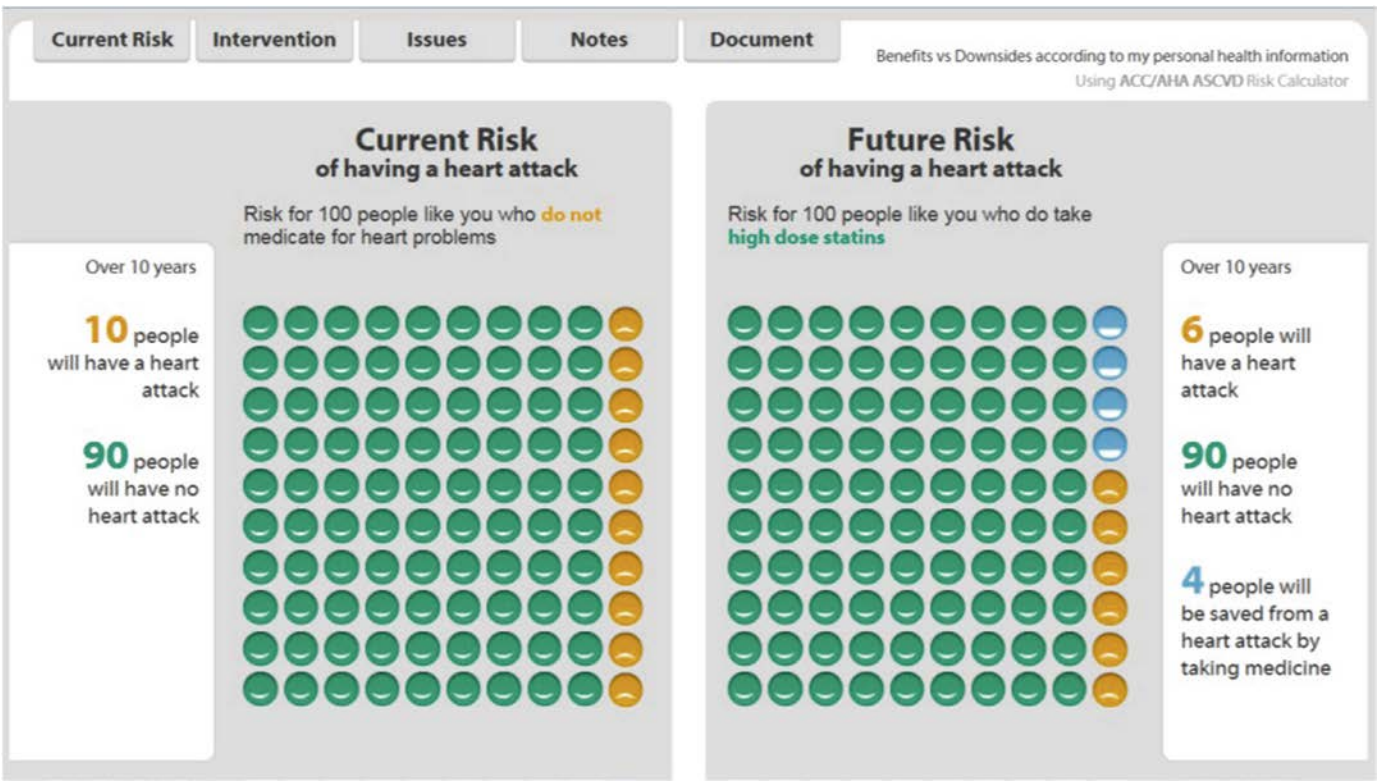
like Mr. Jones (Fig. 6.2) were actually *not to take* a statin for 10 years, 10 of them would have an adverse CV outcome while 90, despite not following the recommendation, would not have an adverse CV outcome. Alternatively, if all 100 patients *took* a statin for a decade, 6 patients would still have a fatal or nonfatal myocardial infarction and 4 patients would avoid a major CV event. This event would happen despite taking the statin every day for 10 straight years, with the risk of harm (i.e., muscle pain), out-of-pocket cost, and the required monitoring with lipid profile and consultation at least once or twice a year.[50] While for Mr. Jones there is little doubt that using a statin might have some CV benefit, at the moment taking statins does not fit his life. He has a high burden of illness (comorbidities), he takes more than 15 medications with many potential side effects, he has social and financial difficulties, and for Mr. Jones a 10-year risk of 10% versus 6% is simply not enough to start taking statins. Although guidelines recommend prescribing a statin for people *like* Mr. Jones, statin therapy may not be right *for* Mr. Jones.

Disease-Specific and Context-Blind Guidelines

Although almost a quarter of Americans have multiple chronic conditions, clinical guidelines are often disease specific and do not consider all aspects of care such as multimorbidity, socio-personal context, and patient preferences. A systematic search of clinical practice guidelines for patients with type 2 diabetes mellitus published between 2006 and 2012 demonstrated that there was a complete absence of incorporating the impact of comorbidities, socio-personal context, and patient preferences in 8 (29%), 11 (39%), and 16 (57%) of the 28 guidelines, respectively.[51] In other words, many guidelines recommendations are contextually blind. This limitation might be secondary to clinical evidence obtained from studies excluding patients with comorbidities. Guideline panelists should therefore be aware of this limitation and favor creating weak or conditional recommendations that promote a patient-centered approach such as shared decision making.[1] This approach allows clinicians to see how a particular recommendation fits into the life of the patient in front of them.[1]

Guideline Focus on Surrogate Outcomes (Not Patient-Important Outcomes)

Benefits ideally should be felt, improve quality of life, or reduce the risk of an undesired patient-important outcome (i.e., hard outcome); if not, they should at least provide the certainty that by treating a risk factor (i.e., surrogate outcome)—for instance, hemoglobin A1c or bone mineral density—the risk of the patient-important outcome (e.g., mortality and fracture, respectively) will be reduced.[8] Although there is no doubt that surrogate outcomes may help clinicians and researchers elucidate how and to what extent an intervention can affect health, there are a handful of RCTs that have demonstrated a nonlinear relationship between a surrogate marker (that physiologically sounds reasonable) and patient-important outcomes.[8,52,53] Patient-important outcomes have become more significant for patients with multiple chronic conditions in which the improvement of a surrogate marker may not always translate to the improvement of another surrogate marker from another disease and may be even harmful for the patient.[54] However, this problem has been systematically



• **Fig. 6.2** Decision aid for patients considering statin therapy. (From Mayo Foundation for Medical Education and Research. Statin choice decision aid [website]. Available at https://statindecisionaid.mayoclinic.org/index.php/statin/index.)

overlooked. While there is no data on guidelines, in ~200 diabetes trials in high-impact journals only 1 of 5 trials was focused on a patient-important outcome as the primary objective.[55]

Quality and Trustworthiness of Clinical Practice Guidelines

Ideally, clinical practice guidelines offer clinicians an easy and accessible way to be up to date with the best available evidence regarding a particular disease. However, it is important to acknowledge that delivering care drawn from "the best available evidence" is not an easy and straightforward task, as to do so means every recommendation should be linked to the best available evidence, preferably based on a systematic review. In addition, as mentioned in the previous discussion about how clinical guidelines are developed, there are strict steps that should be followed and guidelines should be systematically developed by authors with no conflicts of interest for them to be trustworthy.

The Appraisal of Guidelines and Research Evaluation II (AGREE II) instrument (by the AGREE Collaboration) can help clinicians assess the quality of clinical practice guidelines; it correlates with the principles described by the Institute of Medicine regarding trustworthy guidelines.[56] In addition, other tools that can help appraise clinical guidelines are available.[57]

When assessing the quality of clinical practice guidelines, the following domains are important to consider[56,58]:

1. Scope and purpose of the guideline: in which it is important to evaluate if the overall objectives, the clinical questions, and the patients to whom the guideline will apply are specifically described.
2. Stakeholder involvement: assess if the guideline development group or task force includes individuals from all pertinent professional groups and patients to provide the views and preferences of the targeted population.
3. Rigor in development: observe if systematic methods were used to search for the evidence, if methods for formulating recommendations are valid and adequately described, if there is an explicit link between recommendations and supporting evidence, and if a clear procedure for guideline updates has been provided.
4. Clarity of presentation: assess if the recommendations are specific or unambiguous, that when applicable, different options for management of the condition are clearly presented and that key recommendations are easily identifiable.
5. Applicability: assess if the guideline provides advice or tools that facilitate the clinical practice of the recommendation and the potential barriers and costs in applying the recommendations.
6. Editorial independence: it is critical to recognize the funding source and conflicts of interest of the guideline developers.

Conclusions

Clinical practice guidelines that are developed following rigorous and systematic methods by a multidisciplinary panel can provide recommendations that can support patient-centered care. In addition to being able to assess the trustworthiness of clinical practice guidelines, clinicians should understand how these recommendations can support care and collaborate with their patients to overcome their limitations.

Neuroendocrinology

RONALD M. LECHAN

CHAPTER OUTLINE

KEY POINTS

- An underlying principle of neuroendocrinology is that peptide and monoamine signaling molecules are secreted from specialized neurons directly into the circulation.
- Secretion of anterior pituitary hormones and expression of genes encoding these hormones are primarily regulated by releasing and inhibitory factors produced in hypophysiotropic hypothalamic neurons and secreted into the portal vessel system located in the median eminence.
- Homeostasis of each respective hypothalamic-pituitary axis is maintained by complex integration of positive and negative feedback loops involving the pituitary hormones themselves, downstream signals (including steroid hormones), and synaptic input from other brain areas onto the hypophysiotropic neurons.
- Hypothalamic neuropeptides are expressed in neurons throughout the brain to modulate activity of neural circuits and to coordinate a range of behavioral outputs that complement hormonal actions of the hypothalamic-pituitary axes.
- In addition to regulation of the pituitary gland, the hypothalamus subserves other important homeostatic functions, including thermoregulation and the sleep-wake cycle.
- Gene mutations, epigenetic alterations, tumors, inflammatory states, infections, vascular abnormalities, trauma, and psychogenic states can produce neuroendocrine disease involving the hypothalamus.
- Hypothalamic disease can present with nonendocrine manifestations in addition to alterations in hypothalamic-pituitary function.

Historic Perspective

The field of neuroendocrinology has expanded from its original focus on the control of pituitary hormone secretion by the hypothalamus to encompass multiple reciprocal interactions between the central nervous system (CNS) and endocrine systems in the control of homeostasis and physiologic responses to environmental stimuli. Although many of these concepts are relatively recent, the relationship between the hypothalamus and the pituitary gland was recognized as early as the 2nd century AD by Galen of Pergamon in *De Usu Partium*, the major treatise of Galenic physiology, and *Anatomicae Administrationes*, in which he described a physical connection between the infundibulum of the hypothalamic third ventricle and the pituitary gland and its association with a surrounding vascular network that he called the *rete mirabilis*. However, Galen thought the pituitary gland was a receptacle for brain "waste" in the form of mucus or phlegm (*pituita* in Latin) that is delivered to and "filtered" by the pituitary gland before exiting through the nasal cavities. These concepts dominated scientific thought about the hypothalamus and pituitary for more than a thousand years until the work of Andreas Vesalius in *De Humani Corporis Fabrica* (1543), in which he detailed the anatomic relationships between the hypothalamic infundibulum and the pituitary gland, and during the 17th century, by Thomas Willis in *Cerebri Anatome*, proposing that "humors" from blood perfusing the ventral surface of the brain are carried to the pituitary gland. The term *pituitary stalk* was not introduced into the literature until 1742 by Joseph Lieutaud, and the term *hypothalamus* was introduced in 1893 by the Swiss anatomist Wilhelm His. A series of major discoveries in the late 19th and early 20th centuries set the groundwork for rapid advancement in the understanding of the hypothalamus in the regulation of hormone secretion and energy homeostasis and continued to unravel throughout the 20th century and into the 21st century (see Anderson and Haymaker[1]

and Toni[2] for expanded historic perspective). Included were the discovery of the connection between the hypothalamus and the posterior pituitary (supraoptic-hypophysial tract) by Ramón Cajal in 1894 and subsequent work on neurosecretion in fish hypothalamus by Scharrer[3] in 1928, firmly establishing that neurons in the hypothalamus were the source of the axons that constitute the posterior pituitary; evidence by Popa and Fielding[4] in 1930 of an interconnection between the pituitary and hypothalamus through the "hypophyseo-portal vessels"; evidence by Wislocki and King[5] and Harris[6] that the blood flow in portal vessels is directed to the pituitary gland from the hypothalamic median eminence and electric stimulation of the hypothalamus is ineffective in eliciting a pituitary response if the pituitary stalk is severed; and the seminal studies by Hetherington and Ranson[7] in 1940 that destruction of the medial basal hypothalamus sparing the pituitary gland results in morbid obesity and neuroendocrine derangements recapitulating the syndrome of obesity, hypogonadotropic hypogonadism, and growth retardation described by Alfred Fröhlich[8] in 1901.

Subsequently, several important studies, especially those from Schally and colleagues and the Guillemin group, established that the anterior pituitary is tightly controlled by the hypothalamus.[9,10] Both groups identified several putative peptide hormone–releasing factors (see later sections). These fundamental studies resulted in the awarding of the Nobel Prize in Medicine in 1977 to Andrew Schally and Roger Guillemin. We now know that these releasing factors are the fundamental link between the CNS and the control of endocrine function. Furthermore, these neuropeptides are highly conserved across species and are essential for reproduction, growth, and metabolism. The anatomy, physiology, and genetics of these factors constitute a major portion of this chapter.

Over the past several decades, work in the field of neuroendocrinology has continued to advance across several fronts. Cloning and characterization of the specific G protein–coupled receptors (GPCRs) used by the hypothalamic-releasing factors have helped define signaling mechanisms utilized by the releasing factors. Characterization of the distribution of these receptors has universally demonstrated receptor expression in the brain and in peripheral tissues other than the pituitary, arguing for multiple physiologic roles for the neuropeptide-releasing factors. Finally, there have been tremendous advances in our understanding of both regulatory neuronal and humoral inputs to the hypophysiotropic neurons.

The adipostatic hormone, leptin, discovered in 1994,[11] is an example of a humoral factor that has profound effects on multiple neuroendocrine circuits.[12] Reduction in circulating leptin is responsible for suppression of the thyroid[13] and reproductive axes[14] during the starvation response. The subsequent discovery of ghrelin,[15] a stomach peptide that regulates appetite and also acts on multiple neuroendocrine axes, demonstrates that much remains to be learned regarding the regulation of the hypothalamic-releasing hormones. Traditionally, it has been extremely difficult to study releasing-factor gene expression or the specific regulation of the releasing-factor neurons because of their small quantities and, in some cases, diffuse distribution. Transformative technologies, including the development of transgenic mice in which expression of fluorescent marker proteins is specifically targeted to hormone-producing neurons such as gonadotropin-releasing hormone (GnRH) neurons[16] or arcuate pro-opiomelanocortin (POMC) neurons[17] (among many others), or the introduction of viral vectors into selective populations of hormone-producing neurons to modulate cellular activity and projection profiles, has provided new and powerful techniques to study properties of hypothalamic neurons both in vitro in the more native context of slice preparations or organotypic cultures and in vivo.

Although much of the field of neuroendocrinology has focused on hypothalamic-releasing factors and their control of reproduction, growth, development, fluid balance, and the stress response through their control of pituitary hormone production, the term *neuroendocrinology* has come to mean the study of interaction of the endocrine and nervous systems in the regulation of homeostasis. The field of neuroendocrinology has been further expanded by diverse areas of basic research, fundamental to understanding the neuroendocrine system including studies of neuropeptide structure, function, and mechanism of action; neural secretion; hypothalamic neuroanatomy; GPCR structure, function, and signaling; transport of substances into the brain; and the action of hormones on the brain. Moreover, homeostatic systems often involve integrated endocrine, autonomic, and behavioral responses. In many of these systems (e.g., energy homeostasis, immune function), the classic neuroendocrine axes are important but not autonomous pathways, and these subjects are also often studied in the context of neuroendocrinology.

In this chapter, the concepts of neural secretion, the neuroanatomy of the hypothalamic-pituitary unit, including CNS structures particularly relevant to the control of the neurohypophysis and adenohypophysis, and other homeostatic mechanisms regulated by the hypothalamus are presented. Each classic hypothalamic-pituitary axis is described, including a consideration of the immune system and its integration with neuroendocrine function. Then, modern concepts in the mechanisms involved in thermoregulation and the sleep-wake cycle are discussed. Finally, the pathophysiology of disorders of neural regulation of endocrine function are reviewed. The neuroendocrinology of energy homeostasis is fully considered in Chapter 39.

Neural Control of Endocrine Secretion

A fundamental principle of neuroendocrinology encompasses the regulated secretion of hormones, neurotransmitters, or neuromodulators by specialized cells.[3] Endocrine cells and neurons are prototypic secretory cells. Both have electrically excitable plasma membranes and specific ion conductances that regulate exocytosis of their signaling molecules from storage vesicles. Secretory cells are broadly classified by their topographic mechanisms of secretion. For example, *endocrine* cells secrete their contents directly into the bloodstream, allowing these substances to act globally as hormones. Cells classified as *paracrine* secrete their contents into the extracellular space and predominantly affect the function of closely neighboring cells. *Autocrine* secretory cells affect their own function by the local actions of their secretions. In contrast, secretory cells within *exocrine* glands secrete proteinaceous substances, including enzymes, and lipids into the lumen of ductal systems.

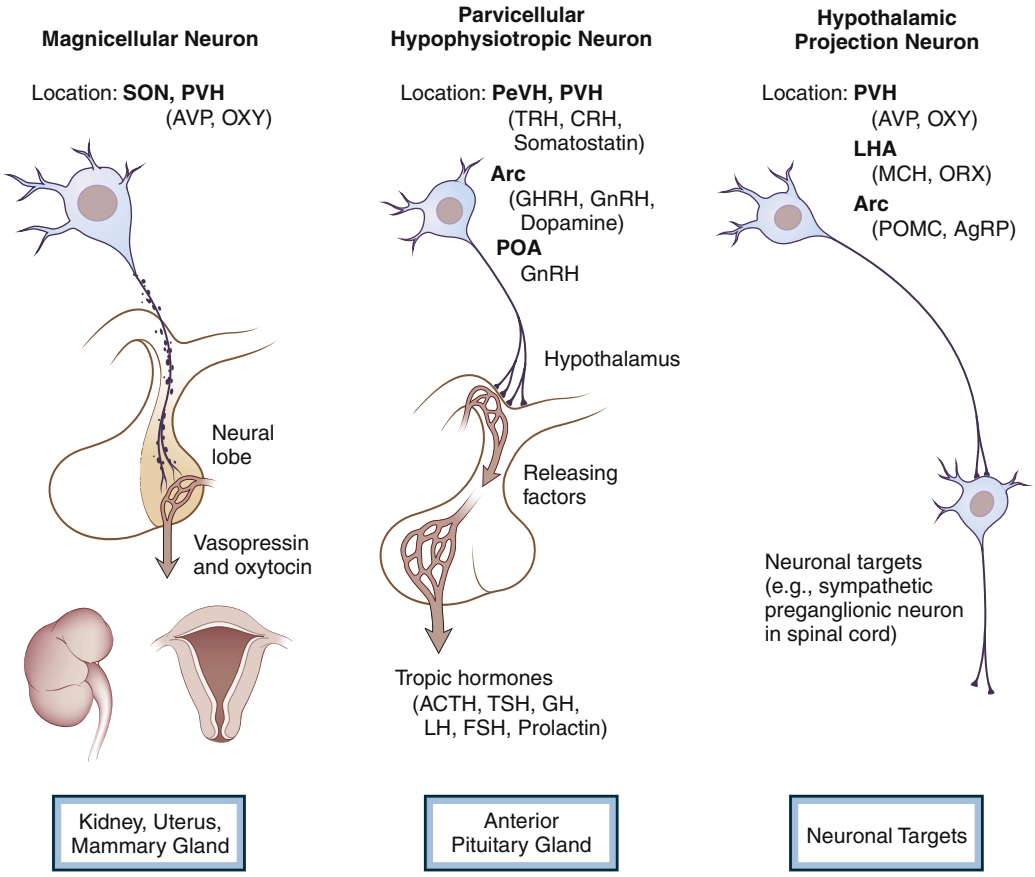
Neurosecretion

Neurons are excitable cells that send their axons throughout the nervous system to release their neurotransmitters and neuromodulators predominantly at specialized chemical synapses. Neurohumoral or neurosecretory cells constitute a unique subset of neurons whose axon terminals are not associated with classic synapses. Two examples of neurosecretory cells in the hypothalamus are neurohypophysial and hypophysiotropic cells. The prototypic

neurohypophysial cells are the magnicellular neurons of the paraventricular hypothalamic nucleus (PVH) and supraoptic nucleus (SON). *Hypophysiotropic cells* encompass all neurons that secrete their products into the pituitary portal vessels at the median eminence (Fig. 7.1).

In the most basic sense, neurosecretory cells are neurons that secrete substances directly into the bloodstream to act as hormones. The theory of neurosecretion evolved from the seminal work of Scharrer,[3] who used morphologic techniques to identify stained secretory granules in the SON and PVH neurons. They found that cutting the pituitary stalk led to an accumulation of these granules in the hypothalamus, which led them to hypothesize that hypothalamic neurons were the source of substances secreted by the neural lobe (posterior pituitary). It is now well established that the axon terminals in the neural lobe arise from the SON and PVH magnicellular neurons that contain oxytocin and the antidiuretic hormone, arginine vasopressin (AVP).

The modern definition of *neurosecretion* has evolved to include the release of any neuronal secretory product from a neuron. Indeed, a fundamental tenet of neuroscience is that all neurons in the CNS, including neurons that secrete AVP and oxytocin in the neural lobe, receive multiple synaptic inputs largely onto their dendrites and cell bodies. In addition, neurons have the basic ability to detect and integrate input from multiple neurons through specific receptors. They in turn fire action potentials that result in the release of neurotransmitters and neuromodulators into synapses formed with postsynaptic neurons. The vast majority of communications between neurons is accomplished by classic fast-acting neurotransmitters (e.g., glutamate, γ-aminobutyric acid [GABA], acetylcholine) and neuromodulators (e.g., dopamine, epinephrine, norepinephrine, neuropeptides) acting at chemical synapses.[18,19] Neurosecretion represents a fundamental concept in understanding the mechanisms used by the nervous system to control behavior and maintain homeostasis.



• **Fig. 7.1** Three types of hypothalamic neurosecretory cells. *Left*, A magnicellular neuron that secretes arginine vasopressin (AVP) or oxytocin (OXY). The cell body, which is located in the supraoptic nucleus (SON) or paraventricular hypothalamic nucleus (PVH), projects its neuronal process into the neural lobe, and neurohormone is released from nerve endings. *Center*, Parvicellular peptidergic neurons are located in the medial basal and dorsal hypothalamus in nuclear groups, including the periventricular hypothalamic nucleus (PeVH), the PVH, infundibular or arcuate nucleus of the hypothalamus (Arc), and preoptic area (POA). The neuropeptides in this case are released into the specialized blood supply to the pituitary to regulate its secretion. *Right*, A third category of hypothalamic peptidergic neurons terminates at chemical synapses on other neurons. These projection neurons are found in sites that include the PVH, Arc, and lateral hypothalamic area (LHA) that innervate multiple central nervous system nuclei, including autonomic preganglionic neurons in the brainstem and spinal cord. Such substances act as neurotransmitters or neuromodulators. *ACTH,* adrenocorticotropin hormone; *AgRP,* agouti-related peptide; *CRH,* corticotropin-releasing hormone; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GHRH,* growth hormone–releasing hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone; *MCH,* melanin-concentrating hormone; *ORX,* orexin/hypocretin; *POMC,* pro-opiomelanocortin; *TRH,* thyrotropin-releasing hormone; *TSH,* thyrotropin.

In the era of optogenetics, multidimensional "omics," and personalized medicine, the importance of these early observations is often not fully appreciated. However, accounts of these early studies are illuminating, and it is not an overstatement that the confirmation of the neurosecretion hypothesis represented one of the major advances in the field of neuroscience and neuroendocrinology. Indeed, this and other early experiments, including the pioneering work of Geoffrey Harris,[6] led to the fundamental concept that the hypothalamus releases hormones directly into the bloodstream (neurohypophysial cells). These observations provided the principles on which the modern discipline of neuroendocrinology is built.

Contribution of the Autonomic Nervous System to Endocrine Control

Another major precept of neuroendocrinology is that the nervous system controls or modifies the function of both endocrine and exocrine glands. The exquisite control of the anterior pituitary gland is accomplished by the action of releasing-factor hormones (see "Hypophysiotropic Hormones and Neuroendocrine Axes"). Other endocrine and exocrine organs (e.g., pancreas and adrenal, pineal, and salivary glands) are also regulated through direct innervation from the cholinergic and noradrenergic inputs from the autonomic nervous system. An appreciation of the functional anatomy and pharmacology of the parasympathetic and sympathetic nervous systems is fundamental in understanding the neural control of endocrine function.[20]

The efferent arms of the autonomic nervous system comprise the sympathetic and parasympathetic systems. They have similar wiring diagrams characterized by a preganglionic neuron that innervates a postganglionic neuron that, in turn, targets an end organ.[21] Preganglionic and postganglionic parasympathetic neurons are cholinergic. In contrast, preganglionic sympathetic neurons are cholinergic, and postganglionic neurons are noradrenergic (except for those innervating sweat glands, which are cholinergic). Another basic concept is that autonomic neurons coexpress several neuropeptides. This coexpression is a common feature of neurons in the central and peripheral nervous systems.[18] For example, postganglionic noradrenergic neurons can coexpress somatostatin and neuropeptide Y (NPY), whereas postganglionic cholinergic neurons can coexpress vasoactive intestinal polypeptide (VIP) and calcitonin gene–related peptide (CGRP).

Most sympathetic preganglionic neurons lie in the intermediolateral cell column in the thoracolumbar regions of the spinal cord.[21] Most postganglionic neurons are located in sympathetic ganglia lying near the vertebral column (e.g., sympathetic chain and superior cervical ganglia). Postganglionic fibers innervate target organs. As a rule, sympathetic preganglionic fibers are relatively short and the postganglionic fibers are long. In contrast, the parasympathetic preganglionic neurons lie in the midbrain (perioculomotor area, long misidentified as the Edinger-Westphal nucleus[22]), the medulla oblongata (e.g., dorsal motor nucleus of the vagus and nucleus ambiguus), and the sacral spinal cord. Postganglionic neurons that innervate the eye and salivary glands arise from the ciliary, pterygopalatine, submandibular, and otic ganglia. Postganglionic parasympathetic neurons in the thorax and abdomen typically lie within the target organs, including the gut wall and pancreas.[21] Consequently, the parasympathetic preganglionic fibers are relatively long and the postganglionic fibers are short.

The dual autonomic innervation of the pancreas illustrates the importance of coordinated neural control of endocrine organs. The endocrine pancreas receives sympathetic (noradrenergic) and parasympathetic (cholinergic) innervation.[21,23] The latter activity is provided by the vagus nerve (dorsal motor nucleus of the vagus) and is an excellent example of neural modulation because the cholinergic tone of the beta cells affects their secretion of insulin. For example, vagal input is thought to modulate insulin secretion before (cephalic phase), during, and after ingestion of food.[24] In addition, noradrenergic stimulation of the endocrine pancreas can alter the secretion of glucagon and inhibit insulin release.[23] Of course, a major regulator of insulin secretion is the extracellular concentration of glucose,[25] and glucose can induce insulin secretion in the absence of neural input. However, the exquisite control by the nervous system is illustrated by the fact that populations of neurons in the hypothalamus, including ventromedial and perifornical hypothalamic neurons, and catecholamine neurons in the rostral ventral lateral medulla of the brainstem, like the pancreatic beta cell, have the ability to sense glucose levels in the bloodstream.[26] This information is particularly important to initiate counterregulatory responses to prevent hypoglycemia by altering the activity of the autonomic nervous system innervating the pancreas and adrenal glands while simultaneously facilitating arousal through projections to histaminergic neurons in the tuberomammillary nucleus (TMN) and inducing feeding responses.[27,28]

Autonomic regulation of glucose homeostasis is also modulated by gut-hypothalamic interactions and adipose tissue–derived substances such as leptin (see later). Included is hypothalamic sensing of bile acids, which after release into the small intestine, stimulates FGF-19 secretion that acts on mediobasal hypothalamic neurons to induce autonomic responses that lower blood glucose via a multisynaptic pathway.[29] Certainly, an increased understanding of the complex interplay between peripheral signals, the CNS, and endocrine function is necessary to diagnose and clinically manage endocrine disorders and may have particularly important implications for the treatment of diabetes mellitus.

Hypothalamic-Pituitary Unit

The hypothalamus is one of the most evolutionarily conserved and essential regions of the mammalian brain. Indeed, the hypothalamus is the ultimate brain structure that allows mammals to maintain homeostasis, and its destruction is not compatible with life. Hypothalamic control of homeostasis stems from the ability of this collection of neurons to orchestrate coordinated endocrine, autonomic, and behavioral responses. A key principle is that the hypothalamus receives sensory inputs from the external environment (e.g., light, nociception, temperature, odorants) and information regarding the internal environment (e.g., blood pressure, blood osmolality, blood glucose levels). Of particular relevance to neuroendocrine control, hormones (e.g., glucocorticoids, gonadal steroids, thyroid hormone, leptin) exert both negative and positive feedback directly on the hypothalamus.

The hypothalamus integrates diverse sensory and hormonal inputs and provides coordinated responses through motor outputs to key regulatory sites. These sites include the anterior pituitary gland, posterior pituitary gland, cerebral cortex, premotor and motor neurons in the brainstem and spinal cord, limbic system structures (including the amygdala, septum, hippocampus, and thalamic nuclei), and parasympathetic and sympathetic preganglionic neurons. The patterned hypothalamic outputs to these effector sites ultimately result in coordinated endocrine, behavioral, and autonomic responses that maintain homeostasis. The

hypothalamic control of the pituitary gland is an elegant system that underlies the ability of mammals to coordinate endocrine functions that are necessary for survival.

Development and Differentiation of Hypothalamic Nuclei

Tremendous advances in knowledge of the molecular and genetic bases for embryonic development of the hypothalamic-pituitary unit have occurred in the past few decades as a result of the genome sequencing projects and use of transgenic model systems. Pituitary development is detailed in Chapter 8; only a few key points most relevant to the physiology and pathophysiology of the neuroendocrine hypothalamus are presented here.

There has been considerable debate concerning the extent to which developmental studies in the rodent hypothalamic-pituitary system are applicable to the human. However, accumulating data suggest that the similarities outweigh the differences. Ontogenic analyses of the organization of the human hypothalamus utilizing a battery of neurochemical markers have reinforced its homologies to the better-studied rat brain.[30] The cytoarchitectonic boundaries of hypothalamic nuclei are much more easily discerned in the fetal human brain than in the adult brain, and for the most part correspond to homologous structures in the rodent hypothalamus. This finding has important implications for the validity of interspecies comparative analyses. Two examples further illustrate this point. First, the ventromedial nucleus of the hypothalamic core (ventromedial hypothalamus [VMH]), which plays a role in energy balance and female sexual behavior, differentiates from neuroblasts in both humans and rodents at a time-point intermediate to the earlier differentiation of lateral hypothalamic nuclei and later differentiation of the midline nuclei, including the suprachiasmatic nucleus (SCN), the arcuate nucleus, and the PVH.[30,31] Expression of the transcription factor SF1 (steroidogenic factor 1) has been shown to be restricted both temporally and spatially to cells in the VMH, and knockout of the *Sf1* gene in mice alters VMH development by influencing the migration of cells and hence their ultimate location.[31] A second example of interspecies homologies in hypothalamic development is the migration of GnRH-secreting neurons from their origins in rostral neuroepithelium to the anterior hypothalamus.[32] As discussed later, spontaneous and inherited mutations in genes that affect the migration of these neurons are an important cause of Kallmann syndrome or hypogonadotropic hypogonadism associated with anosmia.

In addition to SF1 and the genes associated with Kallmann syndrome, there is a growing list of genes primarily encoding transcription factors that have been implicated in human neuroendocrine disorders and characterized experimentally in rodent models (see Chapter 3).[33,34] This list includes the homeobox transcription factor OTP and the heterodimeric complex formed by the basic helix-loop-helix (bHLH) transcription factors SIM1 and ARNT2 mediating the expression of the POU III–related homeobox genes that include Brn2. These factors are required for the proper development of the PVH and SON and for expression of many key hypophysiotropic neuropeptide genes. The physiologic importance of SIM1 is illustrated by the development of an obesity phenotype in both mice and humans with a haploinsufficiency of SIM1 expression.[33] A major breakthrough in the understanding of factors controlling the development and terminal differentiation of human hypothalamic neurons is the ability to generate these neurons in vitro from induced pluripotential stem cells.[35,36]

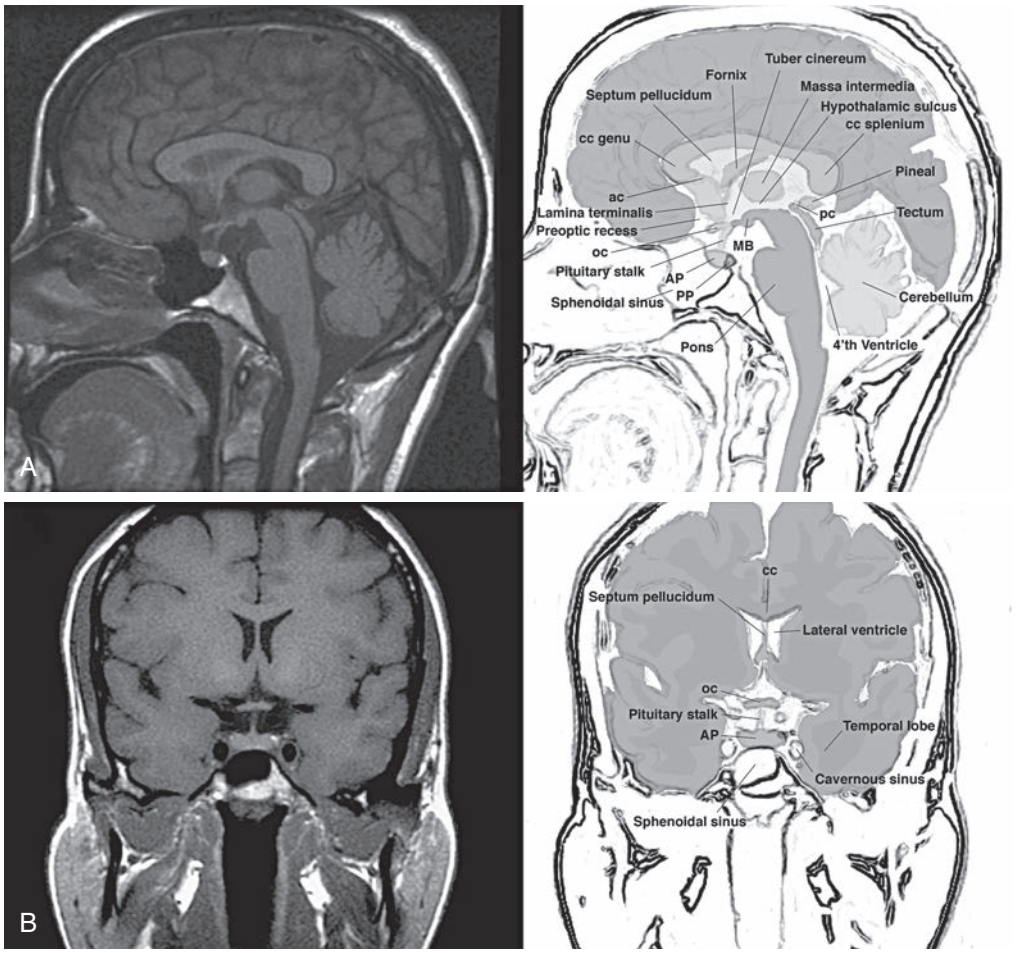
Two key concepts involved in CNS development, which also apply to the hypothalamus, are the balance between neurogenesis and cell death in the establishment of nuclei and the role of circulating hormones in providing organizational signals that regulate cell number and synaptic remodeling. The most thoroughly characterized examples are the effects of sex steroid hormones on the developing brain that result in key sexual dimorphisms of functional importance in later reproductive behaviors.[37] This principle has been extended recently to include organizational effects of other classes of hormones. For example, leptin plays an important role in the development of medial-basal hypothalamic circuits important for energy homeostasis.[38]

Anatomy of the Hypothalamic-Pituitary Unit

The pituitary gland is regulated by three interacting elements: hypothalamic inputs (releasing factors or hypophysiotropic hormones), feedback effects of circulating hormones, and paracrine and autocrine secretions of the pituitary itself. In humans, the pituitary gland (hypophysis) can be divided into two major parts, an anterior, epithelial lobe or adenohypophysis, and a posterior neural lobe or neurohypophysis, which are easily distinguishable from each other by T1-weighted magnetic resonance imaging (MRI) due to the hyperintense signal denoting the neurohypophysis (Fig. 7.2).[39] Women generally have a pituitary that is ~20% larger than men and increase the size and weight of the adenohypophysis during pregnancy due to lactotroph hyperplasia.[40,41] The adenohypophysis can be subdivided into three distinct lobes, the pars distalis (anterior lobe), pars intermedia (intermediate lobe), and pars tuberalis, with the pars distalis making up the bulk of the anterior pituitary and containing all of the hormone-secreting cells of the adenohypophysis. Whereas a well-developed intermediate lobe is found in most mammals, only rudimentary vestiges of the intermediate lobe are detectable in adult humans, with the bulk of intermediate lobe cells being dispersed in the anterior lobe.

The neurohypophysis is composed of the pars nervosa (also known as the neural or posterior lobe), the infundibular stalk, and the median eminence, the latter forming the central region of a mound, or tuber cinereum, at the base of the hypothalamus (see Fig 7.2). The infundibular stalk is surrounded by the pars tuberalis, and together they constitute the *hypophysial stalk*. The pituitary gland lies in the sella turcica (Turkish saddle) of the sphenoid bone and underlies the base of the hypothalamus. Pituitary tissue can also be present in the nasopharynx, commonly referred to as a pharyngeal pituitary, and is a residual of Rathke pouch during its migration from the oral cavity to the middle cranial fossa (see next).

The anterior and intermediate lobes of the pituitary derive from a dorsal invagination of the pharyngeal epithelium, called Rathke pouch. During development, Rathke pouch forms three diverticula, a single medial and two lateral. Precursor cells within the pouch undergo steps of organ determination, cell fate commitment to a pituitary phenotype, proliferation, and migration with cells in the medial diverticula differentiating into corticotrophs and thyrotrophs, lower portions of the lateral diverticulum into somatotrophs and gonadotrophs, and all three diverticula into lactotrophs. The upper part of the lateral diverticula gives rise to the pars tuberalis that differentiates into thyrotrophs and gonadotrophs. The intermediate lobe is in direct contact with the neural lobe and is the least prominent of the three lobes. With age, the human intermediate lobe decreases in size to leave a small, residual collection of POMC cells. In nonprimate species, these

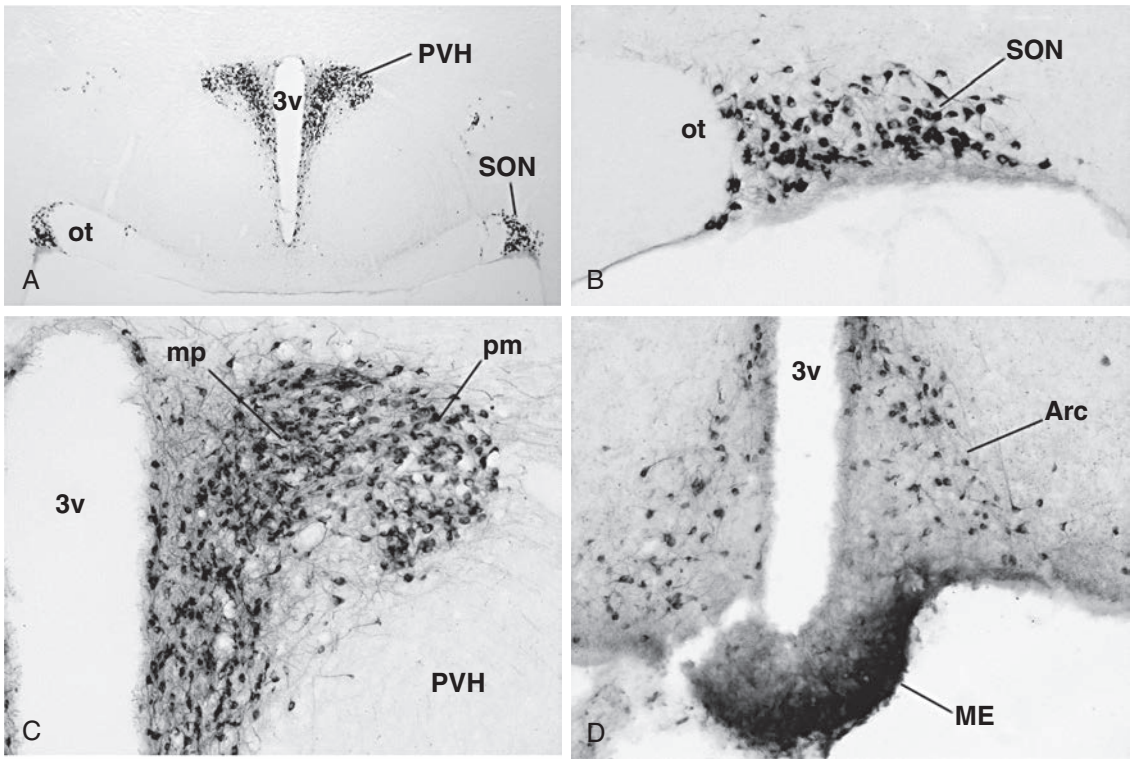


• **Fig. 7.2** Normal anatomy of the human hypothalamic-pituitary unit in (A) sagittal and (B) coronal planes. Structures that are visible in the T1-weighted magnetic resonance images *(left panels)* are identified in the corresponding diagrams *(right panels)*. The hypothalamus is bounded anteriorly by the optic chiasm, laterally by the sulci formed with the temporal lobes, and posteriorly by the mammillary bodies (in which the mammillary nuclei are located). Dorsally, the hypothalamus is delineated from the thalamus by the hypothalamic sulcus. The smooth, rounded base of the hypothalamus is the tuber cinereum; the pituitary stalk descends from its central region, which is termed the *median eminence*. The median eminence stands out from the rest of the tuber cinereum because of its dense vascularity, which is formed by the primary plexus of the hypothalamic-hypophysial portal system. The long portal veins run along the ventral surface of the pituitary stalk. Note the location of the pituitary stalk, the hyperintense signal *(white)* from the posterior pituitary (PP) (A, *left*), and the anatomic relationships of the pituitary gland to the optic chiasm (oc) and the sphenoidal and cavernous sinuses. *ac,* anterior commissure; *AP,* anterior pituitary; *cc,* corpus callosum; *MB,* mammillary body; *pc,* posterior commissure. (Magnetic resonance images courtesy Dr. D.M. Cook.)

cells are responsible for secreting the POMC-derived product, α-melanocyte-stimulating hormone (α-MSH).[42] Early contact of Rathke pouch with the primordial neurohypophysial tissue has a key role for histodifferentiation of anterior pituitary cell types as indicated by the lack of corticotrophs and gonadotrophs in anencephalic fetuses.[43] An expanding list of transcription factors involved in the development of the anterior pituitary gland and associated with genetic causes for human disorders of pituitary development and secretion has been recognized, with mutations of PROP1 being the most common genetic cause for combined pituitary hormone deficiency.[44]

The major component of the neural lobe is a collection of axon terminals arising from magnicellular secretory neurons located in the PVH and SON of the hypothalamus (Fig. 7.3; also see Fig. 7.1).[45] These axon terminals are in close association with a capillary plexus, and they secrete substances, including AVP and oxytocin, into the hypophysial veins and into the general circulation (Table 7.1). The blood supply to the neurohypophysis arises from the inferior hypophysial artery (a branch of the internal carotid artery). Glial-like cells called pituicytes comprise ~25% of the posterior pituitary and have an important role in regulating vasopressin and oxytocin secretion by at least two major mechanisms. These include structural modifications by engulfing or retracting from neurosecretory axon endings and the release of hormone modulators such as galanin-like peptide (GALP) and taurine that stimulate or inhibit the release of vasopressin, respectively.[46] As the source of AVP to the general circulation, the PVH and SON and their axon terminals in the neural lobe are the main effector arms for the central regulation of blood osmolality, fluid balance, and blood pressure (see Chapter 10).

The secretion of oxytocin by magnicellular neurons is critical at parturition, resulting in uterine myometrial contraction. In



• **Fig. 7.3** The tuberoinfundibular system is revealed by retrograde transport of cholera toxin subunit B (CtB). The location of hypothalamic cell bodies of neurons projecting to the median eminence (ME) and the posterior pituitary can be identified by microinjecting a small volume of the retrograde tracer CtB into the median eminence of the rat. (A) Retrogradely labeled cells can be seen in the paraventricular (PVH) and supraoptic nuclei of the hypothalamus (SON). (B) Magnicellular neurons are observed in the SON. (C) Labeled neurons are found in the posterior magnicellular group (pm) as well as the medial parvicellular subdivision (mp). The labeled cells in the PVH include those that contain corticotropin-releasing hormone (CRH) and thyrotropin-releasing hormone (TRH). (D) Retrogradely labeled cells are also found in the arcuate nucleus of the hypothalamus (Arc). These include neurons that release growth hormone–releasing hormone (GHRH) and dopamine. *ot,* optic tract; *3v,* third ventricle.

addition, the secretion of oxytocin is regulated by the classic milk let-down reflex. Mechanosensory information from the nipple reaches the magnicellular neurons, directly or indirectly, from the dorsal horn of the spinal cord, resulting in a synchronized burst of action potentials in the whole population of oxytocin neurons, followed by the release of oxytocin into the general circulation.[47] Oxytocin acts on receptors on myoepithelial cells in the mammary gland acini leading to the release of milk into the ductal system and, ultimately, the release of milk from the mammary gland. Oxytocin also acts on other regions of the brain, such as the medial preoptic area, ventral tegmental area, nucleus accumbens, and amygdala, to affect social behavior (particularly parental behavior) by reducing the stress response and increasing empathy, among others, whereas vasopressin may mediate various forms of aggression.[48] Vasopressin also synergizes with the corticotropin-releasing hormone (CRH) to release adrenocorticotropin hormone (ACTH) secretion (see upcoming discussion). A potential therapeutic role for oxytocin in the treatment of autism has been proposed.[49]

The Median Eminence and Hypophysiotropic Neuronal System

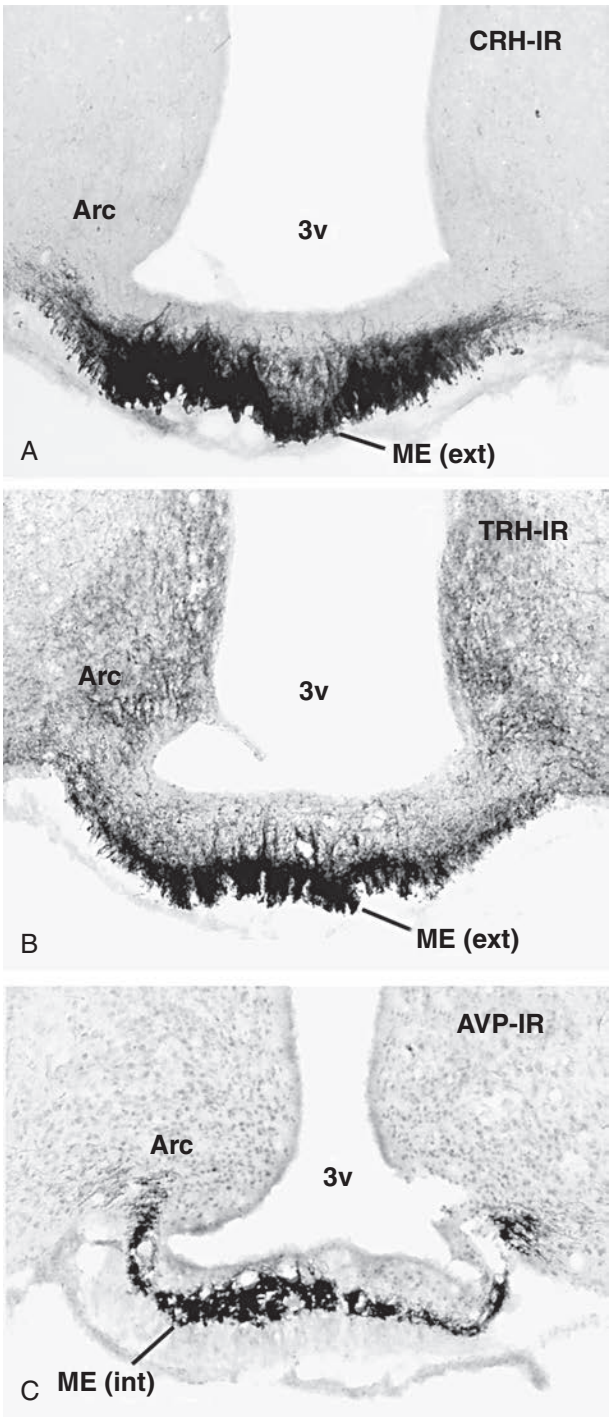
The median eminence is the functional link between the hypothalamus and the anterior pituitary gland. It lies in the center of the tuber cinereum and is composed of an extensive array of blood vessels and nerve endings (Fig. 7.4; also see Fig. 7.2).[50] Its extremely rich blood supply arises from the superior hypophysial artery (a branch of the internal carotid artery), which sends off many small branches that form capillary loops. The small capillary loops extend into the internal and external zones of the median eminence, form anastomoses, and drain into sinusoids that become the pituitary portal veins that enter the vascular pool of the pituitary gland. The flow of blood in these short loops is thought to be predominantly (if not exclusively) in a hypothalamic-to-pituitary direction. This well-developed plexus results in a tremendous increase in the vascular surface area. In addition, the vessels are fenestrated, allowing diffusion of the peptide-releasing factors to their site of action in the anterior pituitary gland. Because this vascular complex in the base of the hypothalamus and its "arteriolized" venous drainage to the pituitary compose a circulatory system analogous to the portal vein system of the liver, it has been termed the *hypothalamic-hypophysial–portal circulation*.

Three distinct compartments of the median eminence are recognized: the innermost ependymal layer, the internal zone, and the external zone (see Fig. 7.4).[50] Ependymal cells form the floor of the third ventricle and are unique in that they have microvilli rather than cilia. Tight junctions at the ventricular pole of the ependymal cells prevent the diffusion of high-molecular-weight substances between the cerebrospinal fluid (CSF) and the extracellular space within the median eminence. The ependymal layer also

TABLE 7.1 Neurotransmitters and Neuromodulators in the Paraventricular Nucleus and the Arcuate Nucleus of the Hypothalamus

Paraventricular Nucleus	Arcuate Nucleus
Magnicellular Division	Acetylcholine
Angiotensin II	γ-Aminobutyric acid (GABA)
Cholecystokinin (CCK)	Agouti-related peptide (AgRP)
Corticotropin-releasing hormone (CRH)	Cocaine-regulated and amphetamine-regulated transcript (CART)
Dynorphins	Dopamine
Glutamate	Dynorphin
Nitric oxide (NO)	Endocannabinoids
Oxytocin	Enkephalins
Phoenixin	Galanin
Spexin	Galanin-like peptide (GALP)
Urocortin 1	Ghrelin
Vasopressin (AVP)	Glutamate
Parvicellular Divisions	Gonadotropin-releasing hormone (GnRH)
γ-Aminobutyric acid (GABA)	Growth hormone–releasing hormone (GHRH)
Angiotensin II	Kisspeptins
Atrial natriuretic factor (ANF)	Melanocortins (ACTH, α-MSH, β-MSH, γ-MSH)
Bombesin-like peptides	Nesfatin-1
Cholecystokinin (CCK)	Neurokinin B (NKB)
Corticotropin-releasing hormone (CRH)	Neuromedin U
Dopamine	Neuropeptide Y (NPY)
Endocannabinoids	Neurotensin
Enkephalins	Nociceptin/orphanin FQ (OFQ)
Galanin	Opioids (β-endorphin) peptides
Glutamate	Pancreatic polypeptide
Interleukin 1 (IL-1)	Phoenixin
Nesfatin-1	Prolactin (PRL)
Neuropeptide Y (NPY)	Pro-opiomelanocortin (POMC)
Neurotensin	Pyro-glutamyl-RFamide peptide (QRFP)
Nitric oxide (NO)	Somatostatin (SST)
Peptide histidine isoleucine (PHI)	Substance P
Pituitary adenylate cyclase activating polypeptide (PACAP)	VGF
RFamide-related peptides (RFRP)	
Somatostatin (SST)	
Thyrotropin-releasing hormone (TRH)	
Vasopressin (AVP)	
Vasoactive intestinal peptide (VIP)	

contains specialized cells, called *tanycytes*,[51] that send processes into the other layers of the median eminence and into the mediobasal hypothalamus. Functionally, tanycytes comprise part of the blood-brain and blood-CSF barriers as they express tight junction proteins, including occludins, ZO1, and claudins,[52] regulating access of circulating substances and/or substances secreted into the median eminence from entering the hypothalamus or CSF.[53] However, it is becoming increasingly recognized that tanycytes have a number of important neuroendocrine functions. Included are hormone transport, regulation of hypophysiotropic hormone release, thyroid hormone homeostasis, regulation of reproduction, nutrient sensing, changes in energy homeostasis, and to function as stem/progenitor cells for neurogenesis and gliogenesis, even in adult animals.[54–57] Some of these functions are discussed in greater detail later in the chapter.



• **Fig. 7.4** The median eminence is the functional connection between the hypothalamus and the pituitary gland. (A and B) Distribution of corticotropin-releasing hormone and thyrotropin-releasing hormone immunoreactivity (CRH-IR and TRH-IR) in the external layer of the median eminence (ME ext) of the rat. CRH and TRH cell bodies reside in the medial division of the paraventricular hypothalamic nucleus. (C) Arginine vasopressin immunoreactivity (AVP-IR) in nerve endings in the internal layer of the median eminence (ME int). *Arc,* arcuate nucleus; *3v,* third ventricle.

The internal zone of the median eminence is composed of axons of the SON and PVH magnicellular neurons that contain characteristic, large neurosecretory granules or Herring bodies passing en route to the posterior pituitary (see Fig. 7.4C). In addition, axons of the hypophysiotropic neurons and processes of

tanycytes destined for the external layer of the median eminence are seen (see Fig. 7.4A and B).

Finally, the external zone of the median eminence represents the exchange point of the hypothalamic releasing factors and the pituitary portal vessels.[50] In addition to the fenestrated portal capillaries and cytoplasmic extensions and end-feet processes of tanycytes, it contains numerous fine-caliber, unmyelinated axons and axon terminals of hypophysiotropic neurons that contain all of the hypothalamic releasing and inhibiting substances. Two general types of neurons project to the external zone and comprise the so-called hypothalamic tuberoinfundibular system: (1) peptide-secreting (peptidergic) neurons, including thyrotropin-releasing hormone (TRH), CRH, growth hormone–releasing hormone (GHRH), somatostatin, and GnRH (see Fig. 7.1), and (2) neurons containing monoamines (e.g., dopamine, serotonin). Although the secretion of these substances into the portal circulation is an important control mechanism, some peptides and neurotransmitters in nerve endings are not released into the hypothalamic-hypophysial–portal circulation but instead function to regulate the secretion of other nerve terminals. In addition, some nerve terminals, such as GnRH nerve endings, are enveloped by tanycytes, which cover or uncover axonal endings in response to changes in functional status.[58,59] Thus supporting elements, with their own sets of receptors, can change the neuroregulatory milieu within the hypothalamus, median eminence, and pituitary (for further details, see "Physiologic Roles of Melatonin" and "Gonadotropin-Releasing Hormone and Control of the Reproductive Axis" [specifically "Regulatory Systems"]). As in the case of neurohormone secretion from the neurohypophysis, depolarization of hypothalamic neurons leads to the release of neuropeptides and monoamines at the median eminence.

The site of production, the genetics, and the regulation of synthesis and release of individual peptide-releasing factors are discussed in detail in later sections. Briefly, there are several cell groups in the medial hypothalamus that contain releasing factors that are secreted into the pituitary portal circulation (Table 7.2). These cell groups include the infundibular nucleus (called the *arcuate nucleus* in rodents) (see Fig. 7.3D), PVH (see Fig. 7.3A and C), periventricular nucleus, and a group of cells in the medial preoptic area near the organum vasculosum of the lamina terminalis (OVLT) (Fig. 7.5). As discussed earlier, magnicellular neurons in the SON and PVH send axons that predominantly traverse the internal zone of the median eminence to terminate in the neural lobe of the pituitary. However, a smaller number of magnicellular axons project directly to the external zone of the median eminence and may facilitate ACTH secretion.

In addition to axon terminals in the external zone of the median eminence, densely packed fibers derived from the sphenopalatine ganglion that contain vasoactive intestinal peptide (VIP) and the nitric oxide (NO)–synthesizing enzyme, nitric oxide synthase, are present on the ventral surface of the median eminence, surrounding portal vessels and innervating smooth muscle of precapillary arterioles that supply the portal capillary plexus.[60] Because both VIP and NO are potent vasodilators, these substances may have an important role in regulating the rate of blood flow to the median eminence and hence to the anterior pituitary.

The third structure often grouped as a component of the median eminence is a subdivision of the adenohypophysis called the *pars tuberalis*. It is a thin sheet of glandular tissue that lies around the infundibulum and pituitary stalk. In some animals, the epithelial component may make up as much as 10% of the total glandular tissue of the anterior pituitary. The pars tuberalis contains cells that produce luteinizing hormone (LH) and thyrotropin (thyroid-stimulating hormone [TSH]). As opposed to thyrotrophs in the pars distalis, however, TSH-producing cells in the pars tuberalis are smaller and lack receptors for TRH.[61] The physiologic role of the pars tuberalis in humans remains somewhat enigmatic, but it is clearly part of the photosensing pathway in the CNS as it expresses high concentrations of the melanocortin 1 receptor. Furthermore, in some mammals and birds, the pars tuberalis has an established role in the regulation of seasonal reproduction, energy balance, and body weight orchestrated through the release of melatonin.[62–65] The pars tuberalis also secretes a number of other substances, including neurokinin A, substance P, and endocannabinoids that are involved in the seasonal release of prolactin in some animal species through direct effects on the pars distalis.[66]

TABLE 7.2 Structural Formulas of Principal Human Hypothalamic Peptides Directly Related to Pituitary Hormone Secretion[a]

Vasopressin

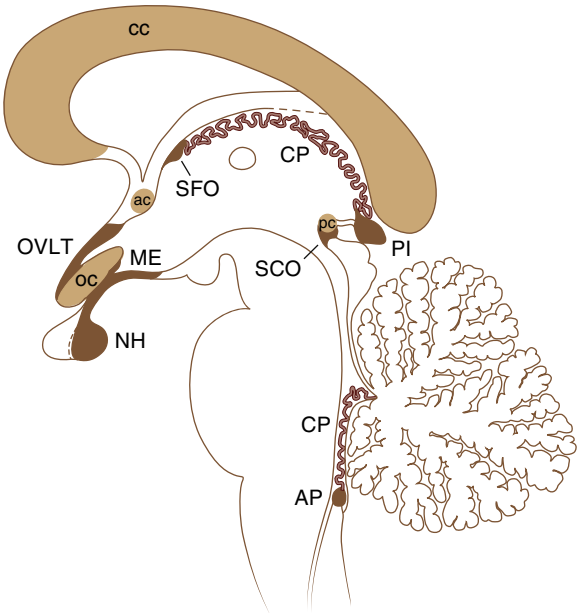
Circumventricular Organs

A guiding principle of neurophysiology and neuropharmacology is that the brain, including the hypothalamus, resides in an environment that is protected from humoral signals.[58,67] The exclusion of macromolecules is due to the structural vascular specializations that make up the blood-brain barrier.[68] These specializations include tight and adherens junctions of brain vascular endothelial



• **Fig. 7.5** Median sagittal section through the human brain to show the circumventricular organs *(dark brown)*. cells that preclude the free passage of polarized macromolecules, including peptides and hormones. In addition, astrocytic foot processes and perivascular microglial cells contribute to the integrity of the blood-brain barrier. However, to exert homeostatic control, the brain must assess key sensory information from the bloodstream, including hormone levels, metabolites, and potential toxins. For example, to monitor key signals the brain has "windows on the circulation," or circumventricular organs (CVOs), that serve as a conduit of peripheral cues into key neuronal cell groups that maintain homeostasis.[67]

As the name implies, CVOs are specialized structures that lie on the midline of the brain along the third and fourth ventricles. These structures include the OVLT, subfornical organ (SFO), median eminence, neurohypophysis (posterior pituitary), subcommissural organ (SCO), and area postrema (see Fig. 7.5). Unlike the vasculature in the rest of the brain, the blood vessels in CVOs have fenestrated capillaries that allow relatively free passage of molecules such as proteins and peptide hormones. Thus neurons and glial cells that reside within the CVOs have access to these macromolecules. In addition to the distinct nature of the vessels themselves, the CVOs have an unusually rich blood supply, allowing them to act as integrators at the interface of the blood-brain barrier. Several of the CVOs have major projections to hypothalamic nuclear groups that regulate homeostasis. Therefore the CVOs serve as a critical link between peripheral metabolic cues, hormones, and potential toxins and cell groups within the brain that regulate coordinated endocrine, autonomic, and behavioral responses. Detailed discussion of the physiologic roles of individual CVOs is beyond the scope of this chapter, but several in-depth reviews have assessed the function of each.[67,69–71]

Median Eminence

The median eminence (described earlier) has an essential role in the regulation of the pars distalis. The anatomic location of the median eminence places it in a position to serve as an afferent sensory organ as well as a functional link between the hypothalamus and the pituitary gland. Specifically, the median eminence is located adjacent to several neuroendocrine and autonomic regulatory nuclei at the tuberal level of the hypothalamus (see Fig. 7.3). These nuclear groups include the infundibular or arcuate, ventromedial, dorsomedial, and paraventricular nuclei.

The role of hypothalamic nuclei surrounding the median eminence as afferent sensory centers is supported by the observation that it is a portal of entry for hormones circulating in the bloodstream such as leptin and several gut-derived circulating hormones, including ghrelin. Both leptin and ghrelin are established mediators of body weight and neuroendocrine function that act on POMC and/or agouti-related protein (AgRP)/neuropeptide Y (NPY) neurons residing in the arcuate nucleus.[17,72–74] Thus it is likely that the median eminence is involved in conveying information from humoral factors to key hypothalamic regulatory neurons in the medial basal hypothalamus.[58]

Organum Vasculosum of the Lamina Terminalis and the Subfornical Organ

The OVLT and the SFO are located at the anterior wall of the third ventricle, the lamina terminalis. The OVLT and SFO lie, respectively, at the ventral and dorsal boundaries of the third ventricle (see Fig. 7.5). Because it lies at the rostral and ventral tip of the third ventricle, the OVLT is surrounded by cell groups of the preoptic region of the hypothalamus. Like other CVOs, the OVLT is composed of neurons, glial cells, and tanycytes. Axon terminals containing several neuropeptides and neurotransmitters, including somatostatin, angiotensin, dopamine, norepinephrine, serotonin, acetylcholine, oxytocin, AVP, and TRH, innervate the OVLT. Unlike the median eminence, however, blood from the OVLT does not drain into a portal plexus, but rather primarily to the medial preoptic region. However, in the rodent, neurons that contain GnRH and surround the OVLT possess unique projections with combined properties of dendrites and axons, termed *dendrons*, that bridge the distance between the OVLT and the median eminence.[75] In addition, the OVLT in the rat brain contains estrogen receptors, and the application of estrogen or electric stimulation at this site is capable of stimulating ovulation through GnRH-containing neurons that project to the median eminence.

Neurons in the OVLT project to many regions of the brain, including the preoptic nucleus, subfornical organ, arcuate nucleus, supraoptic nucleus, medial thalamus, and parts of the limbic system. Thus the OVLT is strategically placed to receive blood-borne information and then transmit this information to specific regions of the brain. Therefore, it is not surprising that the OVLT is involved in a diverse array of processes. For example, lesions of the OVLT and the surrounding preoptic area led to altered febrile responses after immunologic stimulation and disruptions in fluid and electrolyte balance, blood pressure, reproduction, and thermoregulation. Large lesions of the OVLT attenuate lipopolysaccharide-induced fever.[76] Consistent with this finding, it has been demonstrated that receptors for prostaglandin E_2 are located within and immediately surrounding the OVLT.[77] Because prostaglandin E_2 is thought to be an obligate endogenous pyrogen, the OVLT may be a critical regulator of febrile responses.

The OVLT is also likely to be involved in sensing serum osmolality through osmoreceptor cells that express the transient receptor potential vanilloid (TRPV) subfamilies 1 and 4 genes[78] and respond to circulating levels of angiotensin II and relaxin.[79,80] In addition, lesions of the OVLT attenuate AVP and oxytocin secretion in response to osmotic stimuli, whereas hypertonic saline administration induces activation in OVLT neurons.[81]

The SFO is located in the roof of the third ventricle below the fornix. This CVO critically regulates fluid homeostasis and contributes to blood pressure regulation.[67] Consistent with these functions, the SFO has receptors for angiotensin II and atrial natriuretic peptide.[82,83] Through direct projections to the paraventricular and supraoptic nuclei, SFO neurons induce the release of vasopressin from the posterior pituitary and activate paraventricular nucleus neurons that descend to sympathetic centers of the spinal cord that regulate vasoconstriction as well as other neuronal sites involved in fluid and blood pressure balance, including the median preoptic nucleus and OVLT.[84]

The critical importance of the SFO in maintaining fluid balance was demonstrated by Simpson and Routtenberg, showing that substances such as angiotensin II elicited drinking behavior when microinjected at low doses directly into the SFO.[85] Later studies demonstrated that SFO neurons have electrophysiologic responses to angiotensin II and that stimulation of the SFO elicits AVP secretion.[82] Like the OVLT, the SFO is activated by hypertonic saline administration.[81] Importantly, the use of Cre recombinase technology combined with optogenetics has enabled researchers to demonstrate that excitation of SFO neurons that express neuronal nitric oxide synthase (nNOS) and/or calmodulin kinase II (CaMKII) stimulates thirst, whereas excitation of vesicular GABA transporter–expressing neurons suppress thirst.[86] Subsequent studies have also established that chemogenetically activated CaMKII neurons in the SFO stimulate NaCl intake, indicating that the SFO is also the principal site for monitoring sodium levels.[87] Sodium sensing is mediated by NaX, the brain sodium-level sensor, which is expressed by glial cells in the SFO and by the release of lactate, activate GABAergic SFO neurons.[88] While most of the experimental work to establish the role of the SFO in salt and water balance has been done in rodents, clear evidence that the SFO mediates similar functions in humans is established by the demonstration in a pediatric patient with adipsic hypernatremia due to autoantibodies that target NaX.[89]

Area Postrema

The area postrema lies at the caudal end of the fourth ventricle adjacent to the nucleus of the tractus solitarius (NTS) (see Fig. 7.5). In rodents, it is a midline structure lying above the NTS.[67,90] However, in humans the area postrema is a bilateral structure. Because the area postrema overlies the NTS, it also receives direct visceral afferent input from the glossopharyngeal nerve and the vagus nerves. In addition, the area postrema receives direct input from several hypothalamic nuclei. The efferent projections of the area postrema include projections to the NTS, ventral lateral medulla, and parabrachial nucleus. Consistent with its role as a sensory organ, the area postrema is enriched with receptors for several neuropeptides, including glucagon-like peptide-1 and amylin.[91] It also contains chemosensory neurons that include osmoreceptors. The area postrema is thought to be critical in the detection of potential toxins and in the induction of vomiting in response to foreign substances. In fact, the area postrema is often referred to as the chemoreceptor trigger zone.[91]

The best described physiologic role of the area postrema is the coordinated control of blood pressure.[67] The area postrema contains binding sites for angiotensin II, AVP, and atrial natriuretic peptide. Lesions of the area postrema in rats blunt the rise in blood pressure induced by angiotensin II.[92] Finally, administration of angiotensin II induces the expression of c-Fos in neurons of the area postrema, an indication of its activation. The area postrema has also been hypothesized to play a role in responding to inflammatory cytokines during the acute febrile response, CNS glucose sensing, and the satiating effects of amylin.[92]

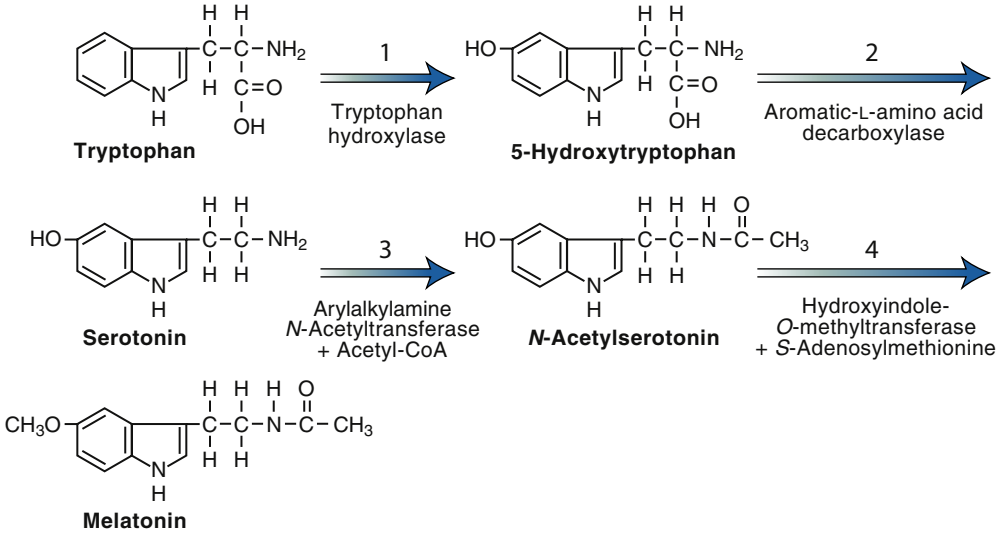
Subcommissural Organ

The SCO is located near the junction of the third ventricle and cerebral aqueduct below the posterior commissure and the pineal gland (see Fig. 7.5). It is composed of specialized ependymal cells that secrete a highly glycosylated protein of unknown function. The secretion of this protein leads to aggregation and formation of the so-called Reissner fibers.[93] The glycoproteins are extruded through the aqueduct, the fourth ventricle, and the spinal cord lumen to terminate in the caudal spinal canal. In humans, intracellular secretory granules are identifiable in the SCO, but Reissner fibers are absent. The SCO secretion in humans is therefore presumed to be more soluble and to be absorbed directly from the CSF. Compared with other CVOs, the physiologic role of the SCO is largely unknown. Hypothesized roles for the SCO include clearance of substances, including monoamines from the CSF.[93]

Pineal Gland

Descartes called the pineal gland the "seat of the soul." A more contemporary, although less colorful, viewpoint is that the pineal integrates information encoded by light into coordinated secretions that underlie biologic rhythmicity.[94] The pineal is both an endocrine gland and a CVO; it is derived from cells located in the roof of the third ventricle and lies above the posterior commissure near the level of the habenular complex and the sylvian aqueduct. The gland is composed of two cell types, pinealocytes and interstitial (glial-like) cells. Histologic studies suggest that the pineal gland cells are secretory in nature, and indeed the pineal is the principal source of melatonin in mammals.

The pineal gland is an epithalamic structure and consists of primordial photoreceptive cells. The gland retains its light sensitivity in lower vertebrates such as fish and amphibians but lacks direct photosensitivity in mammals and has evolved as a strictly secretory organ in higher vertebrates. However, neuroanatomic studies have established that light-encoded information is relayed to the pineal by a polysynaptic pathway.[95] This series of synapses ultimately results in innervation of the gland by noradrenergic sympathetic nerve terminals that are critical regulators of melatonin production and release. Specifically, retinal ganglion cells directly innervate the SCN of the hypothalamus through the retinohypothalamic tract. In turn, the SCN provides input to the dorsal parvicellular PVH, a key cell group in neuroendocrine and autonomic control. This pathway consists of direct and indirect intrahypothalamic projections. The PVH then provides direct innervation to sympathetic preganglionic neurons in the intermediolateral cell column of the thoracic regions of the spinal cord. Sympathetic preganglionic neurons innervate postganglionic neurons in the superior cervical ganglion and ultimately supply the noradrenergic innervation to the pineal gland (see "Hypothalamic-Pituitary Unit"). This circuitous pathway represents the anatomic substrate



• **Fig. 7.6** Biosynthesis of melatonin from tryptophan in the pineal gland. Step 1 is catalyzed by tryptophan hydroxylase, step 2 by aromatic-L-amino acid decarboxylase, step 3 by arylalkylamine *N*-acetyltransferase, and step 4 by hydroxyindole-*O*-methyltransferase. (From Wurtman RJ, Axelrod J, Kelly DE. Biochemistry of the pineal gland. In: Wurtman RJ, Axelrod J, Kelly DE, eds. *The Pineal*. New York: Academic Press; 1968:47–75.)

for light to regulate the secretion of melatonin through the release of norepinephrine. In the presence of light, whether morning light or a light impulse, norepinephrine release is inhibited, resulting in the shutdown of melatonin synthesis. In the absence of light input, the pineal gland rhythms persist but are not entrained to the external light-dark cycle.

The Pineal Is the Source of Melatonin

The predominant hormone secreted by the pineal gland is melatonin. However, the pineal contains other biogenic amines, peptides, and GABA. Pineal-derived melatonin is synthesized from tryptophan, which is first converted into 5-hydroxytrophan by tryptophan hydroxylase and then decarboxylated into serotonin (5-HT). Two additional steps transform 5-HT into melatonin, including the rate-limiting step catalyzed by the enzyme aralkylamine *N*-acetyltransferase (AANAT) to yield *N*-acetylserotonin, followed by the transfer of a methyl group from S-adenosyl methionine to the 5-hydroxy group of *N*-acetylserotonin by hydroxyindole-*O*-methyltransferase (HIOMT) (Fig. 7.6).[96] Melatonin plays a key role in regulating a myriad of circadian rhythms, and a fundamental principle of circadian biology is that the synthesis of melatonin is exquisitely controlled.[97] AANAT-mRNA levels, AANAT activity, and melatonin synthesis and release are regulated in a circadian fashion and are entrained by the light-dark cycle, with darkness thought to be the most important signal.[94,96] Melatonin and AANAT levels are highest during the dark and decrease sharply with the onset of light. Melatonin is not stored to any significant degree; it is released into the blood or CSF directly after its biosynthesis in proportion to AANAT activity but has a very rapid half-life (minutes) due to 6-hydroxylation in the liver.

Lack of light ultimately results in the release of norepinephrine from postganglionic sympathetic nerve terminals that act on β-adrenergic receptors in pinealocytes, resulting in an increase in adenylyl cyclase activity and synthesis of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate. Increased levels of intracellular cAMP activate downstream signal transduction cascades, including the catalytic subunits of protein kinase A and phosphorylation of cAMP response element (CRE) binding protein. CREs have been identified in the promoter of AANAT.[98] Therefore light (or lack of it) acting through the sympathetic nervous system induces an increase in cAMP, representing a fundamental regulator of AANAT transcription and melatonin synthesis that ultimately results in a dramatic change of melatonin levels across the day.[95] Interspecies comparative studies of melatonin's physiologic function must be tempered by knowledge of the key differences between rodent and human melatonin regulation, however. For example, significantly more light, as much as 4 log units, is required in humans to produce an equivalent nocturnal suppression of melatonin,[99] and the control of AANAT is largely post-transcriptional in humans rather than transcriptional.[96]

Physiologic Roles of Melatonin

One of the best-characterized roles of melatonin is the regulation of the reproductive axis, including gonadotropin secretion[100] and the timing and onset of puberty (see "Gonadotropin-Releasing Hormone and Control of the Reproductive Axis"). The potent regulation of the reproductive axis by melatonin is established in rodents and domestic animals such as sheep. It was observed experimentally with the demonstration that removal of the pineal leads to precocious puberty. In addition, male rats exposed to constant darkness or blinded by enucleation display testicular atrophy and decreased levels of testosterone. These profound effects of gonadal involution are normalized by removal of the pineal gland.[95] The physiologic significance of melatonin is probably most important in species referred to as seasonal breeders. Indeed, the role of melatonin in regulating reproductive capacity in species such as the sheep and the horse is now established. This type of reproductive strategy probably evolved to synchronize the length of day with the gestational period of the species to ensure that the offspring are born at favorable times of the year and maximize the viability of the young. Interestingly, although there is a strong and consistent correlation between altered melatonin secretion, day

length, and seasonal breeding in diverse species, the valence of the signal can be either positive or negative dependent on the ecologic niche for each species.

The signaling pathway by which melatonin regulates reproduction and puberty in seasonal species is becoming increasingly understood. Changes in the nocturnal duration of melatonin convey photoperiodic information to cells in the pars tuberalis via the MT1 receptor, which is expressed in high density on these cells to regulate clockwork proteins such as Cry 1 that are linked to the regulation of TSHβ synthesis.[101,102] TSHβ acting as a paracrine signal from the pars tuberalis binds to TSH receptors on tanycytes whose end-feet processes reside immediately dorsal to the pars tuberalis. TSHβ regulates the expression of type 2 (D2) and type 3 (D3) iodothyronine deiodinase in tanycytes, enzymes that either activate or inactivate the thyroid hormone, respectively, thus governing the bioavailabilty of the thyroid hormone in the mediobasal hypothalamus.[103–105] Under long day conditions (or short melatonin duration), D2 is upregulated, thereby increasing T3 availability, whereas under short day conditions (or long melatonin duration), D3 is upregulated, resulting in decreased T3 availability in the mediobasal hypothalamus. An increase in T3 bioavailabilty results in reproductive activation and can be replicated by implanting a T3 pellet into the hypothalamus of seasonal breeders maintained in short days that otherwise show reproductive inactivation.[106] The mechanism by which the thyroid hormone affects GnRH secretion involves regulation of the encasement of GnRH axon terminals in the external zone of the median eminence by tanycyte end-feet processes. When thyroid hormone is administered into the hypothalamus, it promotes retraction of these processes to allow direct access of secreted GnRH to the fenestrated portal vessels for conveyance to the pars distalis.[107,108] Thyroid hormone receptors are also plentiful throughout the hypothalamus and may be involved in the regulation of kisspeptin,[109] a hormone that has a critical role in the pulsatile release of GnRH (see "Gonadotropin-Releasing Hormone and Control of the Reproductive Axis").

Melatonin Receptors

Melatonin mediates some of its effects by acting on a family of GPCRs, which have been characterized by pharmacologic, neuroanatomic, and molecular approaches.[94,96,97] The first member of the family, MT1 (Mel_{1a}), is a high-affinity receptor that was isolated originally from *Xenopus* melanophores. The second, MT2 (Mel_{1b}), has approximately 60% homology with MT1. A third receptor in mammals, MT3, is not a GPCR but instead a high-affinity binding site on the cytosolic enzyme quinone reductase 2 that is involved in cellular detoxification and might explain some of melatonin's effects as an antioxidant.[94,96] Melatonin also acts directly as a free radical scavenger to detoxify reactive oxygen and nitrogen species.[95]

The mechanisms for melatonin's effects on regulating and entraining circadian rhythms are becoming increasingly understood. For example, melatonin inhibits the activity of neurons in the SCN of the hypothalamus, the master circadian pacemaker in the mammalian brain.[97,110,111] Melatonin can entrain several mammalian circadian rhythms, probably by the inhibition of neurons in the SCN. Neuroanatomic evidence suggests that many of the effects of melatonin on circadian rhythms involve actions on MT1 receptors in that the distribution of MT1 mRNA overlaps with radiolabeled melatonin binding sites in the relevant brain regions. These sites include the SCN, the retina, and the pars tuberalis of the adenohypophysis. The MT2 receptor is also expressed in the retina and brain, particularly the SCN, but evidently at much lower levels and more involved with phase-shifting effects of melatonin.[96,97,110]

Genetic studies in mice have also helped to illuminate the relative roles of each melatonin receptor in mediating the effects of this hormone. Targeted deletion (knockout) of the MT1, but not the MT2 receptor, abolished the ability of melatonin to inhibit the activity of SCN neurons.[111,112] Several studies have suggested that the inhibition of SCN neurons by melatonin is of great physiologic significance. Melatonin may underlie the mechanism by which light induces phase shifts. However, it should be noted that lack of the MT1 gene does not block the ability of melatonin to induce phase shifts. These unexpected and somewhat confusing results have resulted in the hypothesis that MT2 is involved in melatonin-induced phase shifts, as this receptor may be expressed in the SCN in the human brain.[96]

Melatonin Therapy in Humans

Melatonin is purported to exert multiple beneficial functions that include slowing or reversing the progression of aging, blood pressure and autonomic cardiovascular regulation, protecting against ischemic damage after vascular reperfusion, and enhancing immune function.[94–96,113,114] However, the most-studied and established role of melatonin in humans is that of phase shifting and resetting circadian rhythms. In this context, melatonin has been used to treat jet lag and may be effective in treating circadian-based sleep disorders.[115] In addition, melatonin administration has been shown to regulate sleep in humans, although two meta-analyses of the published reports on melatonin for the treatment of either primary or secondary sleep disorders concluded that there is limited evidence for significant clinical efficacy, but it is safe to use in the short term (≤3 months).[116,117] Melatonin therapy has also been suggested to have oncostatic effects on several tumors by acting as an antioxidant and to reduce blood pressure in patients with hypertension, improve major depressive disorder and anxiety, exert anti-inflammatory actions in rheumatoid arthritis and osteoarthritis, and because of its protective role against oxidative stress, potentially be efficacious for the treatment of Alzheimer disease, Parkinson disease, Huntington disease, and amyotrophic sclerosis.[118,119]

Hypophysiotropic Hormones and Neuroendocrine Axes

With the demonstration by the first half of the 1900s that pituitary secretion is controlled by hypothalamic hormones released into the portal circulation, the race was on to identify hypothalamic releasing factors. The search for hypothalamic neurohormones with anterior pituitary regulating properties focused on extracts of the stalk median eminence, neural lobe, and hypothalamus from sheep and pigs. To give some idea of the herculean nature of this effort, approximately 250,000 hypothalamic fragments were required to purify and characterize the first such factor, TRH.[10] Such hypophysiotropic substances were initially called *releasing factors* but are now more commonly called *releasing hormones*.

All of the principal hypothalamic-pituitary regulating hormones are peptides with the notable exception of dopamine, which is a biogenic amine and the major prolactin-inhibiting factor (PIF) (see later discussion and Table 7.2). All are available for clinical investigations or diagnostic tests, and therapeutic analogues for dopamine, GnRH, and somatostatin are widely prescribed.

In addition to regulating hormone release, some hypophysiotropic factors control pituitary cell differentiation, proliferation, and hormone synthesis. Some act on more than one pituitary hormone. For example, TRH is a potent releaser of prolactin (PRL) in addition to TSH, and under some circumstances, releases corticotropin (ACTH) and growth hormone (GH). GnRH releases both LH and follicle-stimulating hormone (FSH). Somatostatin inhibits the secretion of GH, TSH, and a wide variety of nonpituitary hormones. The principal inhibitor of PRL secretion, dopamine, also inhibits secretion of TSH, gonadotropin, and under certain conditions, GH. Dual control is exerted by the interaction of inhibitory and stimulatory hypothalamic hormones. For example, somatostatin interacts with growth hormone–releasing hormone and TRH to control secretion of GH and TSH, respectively, and dopamine interacts with prolactin-releasing factors (PRFs) to regulate PRL secretion. Some hypothalamic hormones act synergistically; for example, CRH and AVP cooperatively regulate the release of pituitary ACTH.

Secretion of the releasing hormones in turn is regulated by neurotransmitters and neuropeptides released by a complex array of neurons synapsing with hypophysiotropic neurons. Control of secretion is also exerted through feedback control by hormones such as glucocorticoids, gonadal steroids, thyroid hormone, anterior pituitary hormones (short-loop feedback control), and hypophysiotropic factors themselves (ultrashort-loop feedback control).

The distribution of the hypophysiotropic hormones is not limited to the hypothalamus and can be found in many different regions of the brain and its periphery, produced by nonhypophysiotropic cells where they mediate functions unrelated to pituitary regulation. Most of the peptides, hormones, and neurotransmitters involved in the regulation of hypothalamic-pituitary control transduce their signals through members of the extensive GPCR family.

Feedback Concepts in Neuroendocrinology

To understand the regulation of each hypothalamic-pituitary-target organ axis, it is important to understand some basic concepts of homeostatic systems. A simplified account of feedback control in relation to neuroendocrine regulation is presented here. Hormonal systems form part of a feedback loop in which the controlled variable (generally the blood hormone level or some biochemical surrogate of the hormone) determines the rate of secretion of the hormone. In negative feedback systems the controlled variable inhibits hormone output, and in positive feedback control systems it increases hormone secretion. Both negative and positive endocrine feedback control systems can be part of a closed loop, in which regulation is entirely restricted to the interacting regulatory glands, or an open loop, in which the nervous system influences the feedback loop. All pituitary feedback systems have nervous system inputs that either alter the set-point of the feedback control system or introduce open-loop elements that can influence or override the closed-loop control elements.

In engineering formulations of feedback, three controlled variables can be identified: a sensing element that detects the concentration of the controlled variable, a reference input that defines the proper control levels, and an error signal that determines the output of the system. The reference input is the set-point of the system.

Hormonal feedback control systems resemble engineering systems in that the concentration of the hormone in the blood (or some function of the hormone) regulates the output of the controlling gland. However, hormonal feedback differs from engineering systems in that the sensor element and the reference input element are not readily distinguishable. The set-point of the controlled variable is determined by a complex cascade beginning with the kinetics of binding to a receptor and the activities of successive intermediate messengers. Sophisticated models incorporating control elements, compartmental analysis, and hormone production and clearance rates exist for many systems. In fact, this sort of modeling applied to developmental programming, intracellular signaling cascades, and neural circuits in addition to endocrine feedback systems is commonly referred to as *systems biology*.[120]

Endocrine Rhythms

Virtually all functions of living animals (regardless of their position on the evolutionary scale) are subject to periodic or cyclic changes, many of which are influenced primarily by the nervous system (Table 7.3).[121,122] Most periodic changes are free running; that is, they are intrinsic to the organism, independent of the environment, and driven by a biologic clock.

Most free-running rhythms are coordinated (entrained) by external signals (cues), such as light-dark changes, meal patterns, cycles of the lunar periods, or the ratio of day length to night

TABLE 7.3 Terms Used to Describe Cyclic Endocrine Phenomena

Term	Definition
Period	Length of the cycle
Circadian	About a day (24 hours)
Diurnal	Exactly a day
Ultradian	Less than a day (i.e., minutes or hours)
Infradian	Longer than a day (i.e., month or year)
Mean	Arithmetic mean of all values within a cycle
Range	Difference between the highest and lowest values
Nadir	Minimal level (inferred from mathematical curve-fitting calculations)
Acrophase	Time of maximal levels (inferred from curve fitting)
Zeitgeber	Time giver (German); the external cue, usually the light-dark cycle that synchronizes endogenous rhythms
Entrainment	The process by which an endogenous rhythm is regulated by a zeitgeber
Phase shift	Induced change in an endogenous rhythm
Intrinsic clock	Neural structures that possess intrinsic capacity for spontaneous rhythms; for circadian rhythms, these are located in the suprachiasmatic nucleus

Modified from Van Cauter E, Turek FW. Endocrine and other biological rhythms. In: DeGroot LJ, ed. *Endocrinology*. 3rd ed. Philadelphia: Saunders; 1995:2497–2548.

length. External signals of this type (*zeitgeber*, or time giver) do not bring about the rhythm but provide the synchronizing time cue. Many endogenous rhythms have a period of ~24 hours (circadian [around a day] or diurnal rhythms). Circadian changes follow an intrinsic program that is ~24 hours long, whereas diurnal rhythms can be either circadian or dependent on shifts in light and dark. Rhythms that occur more frequently than once a day are ultradian. Infradian rhythms have a period longer than 1 day, as in the ~27-day human menstrual cycle and the yearly breeding patterns of some animals.

Most endocrine rhythms are circadian (Fig. 7.7). The secretion of GH and PRL in humans is maximal shortly after the onset of sleep, and that of cortisol is maximal between 2 AM and 4 AM. TSH secretion is lowest between 4 PM and 7 PM and maximal between 9 PM and 5 AM. Gonadotropin secretion in adolescents is increased at night. Superimposed on the circadian cycle are ultradian bursts of hormone secretion. LH secretion during adolescence is characterized by rapid, high-amplitude pulsations at night, whereas in sexually mature individuals secretory episodes are lower in amplitude and occur throughout the 24 hours. GH, ACTH, and PRL are also secreted in brief, fairly regular pulses. The short-term fluctuations in hormonal secretion have important functional significance. In the case of LH, the normal endogenous rhythm of pituitary secretion reflects the pulsatile release

of GnRH. The period of ~90 minutes between LH peaks corresponds to the optimal timing of GnRH pulses to induce maximal pituitary stimulation. Episodic secretion of GH also enhances its biopotency, but for many rhythms the function is not clear. Most homeostatic activities are also rhythmic, including body temperature, water balance, blood volume, sleep, and activity.[123,124]

Assessment of endocrine function must take into account the variability of hormone levels in the blood. Thus appropriately obtained samples at different times of the day or night may provide useful dynamic indicators of hypothalamic-pituitary function. For example, the loss of diurnal rhythm of GH and ACTH secretion may be an early sign of hypothalamic dysfunction. Furthermore, the optimal timing for the administration of glucocorticoids to suppress ACTH secretion (as in therapy for congenital adrenal hyperplasia) must take into account the varying suppressibility of the axis at different times of the day.

The best-understood neural structures responsible for circadian rhythms are the SCNs, paired structures in the anterior hypothalamus above the optic chiasm.[121,124] Individual cells of the SCN have an intrinsic capacity to oscillate in a circadian pattern due to the existence of a cell-autonomous transcription-translation feedback loop involving the transcription factors CLOCK and BMAL1 that interact with the promoters of the *period* (*PER*) and *cryptochrome* (*CRY*) genes.[125] If lesioned bilaterally, free-running circadian rhythmicity is produced, characterized by disruption of the sleep-wake cycle and loss of predictable daily oscillations in feeding, drinking, melatonin secretion, and the secretion of some anterior pituitary hormones.[126,127] Normal rhythmicity can be restored if the SCN is transplanted back into the lesioned animals.[128]

In addition to the massive retinohypothalamic projection from the retina described earlier carrying pituitary adenyl cyclase-activating peptide (PACAP) and nitric oxide, the SCN receives neuronal input from many nuclei, including GABA-containing and NPY-containing axonal projections from the intergeniculate leaflet of the thalamus and serotonin neurons from the midbrain raphe, the limbic system (hippocampus, bed nucleus of the stria terminalis [BNST], septum), and the hypothalamus itself. These inputs have an important role in modulating the endogenous rhythms of the individual SCN pacemaker cells and contribute to phase-shifting effects on SCN pacemaker activity.[129] The SCN is also organized to permit many reciprocal neuron-neuron interactions mediated by GABA at direct synaptic contacts. It is especially rich in neuropeptides, including AVP, VIP, gastrin-releasing peptide (GRP), and calretinin. The SCN also responds to melatonin through melatonin receptors.[94,96] Studies have indicated that intrinsic pacemaker function is not unique to neurons of the SCN; circadian oscillators are also found in many peripheral tissues.[124]

Metabolic changes in the SCN, such as increased uptake of 2-deoxyglucose and an increased level of VIP, accompany circadian rhythms. This nucleus projects to the pineal gland indirectly via the PVH and the autonomic nervous system (see earlier discussion) and regulates its activity and to the medial preoptic hypothalamus indirectly via the dorsal subparaventricular zone to regulate body temperature set-point and food-dependent energy intake.[129,121] However, the bulk of SCN outflow occurs in a trunk coursing dorsolaterally through the ventral subparaventricular zone and terminating in the dorsal medial hypothalamic nucleus. Polysynaptic pathways involving these latter structures are responsible for the actions of the SCN to produce the circadian rhythms in thermoregulation, glucocorticoid secretion, sleep, arousal, and feeding.[121,125]

Circadian rhythms during fetal life are regulated by maternal circadian rhythms.[130] Circadian changes can be detected 2 to 3 days before birth, and SCN from fetuses of this age display spontaneous rhythmicity in vitro. Maternal regulation of fetal circadian rhythms may be mediated by circulating melatonin or by cyclic changes in the food intake of the mother. The timing of the circadian pacemaker can be shifted in humans by the administration of triazolam, a short-acting benzodiazepine, melatonin (described earlier), or by altered patterns of intense illumination.[99]

Thyrotropin-Releasing Hormone

Chemistry and Evolution

TRH, the short peptide hypophysiotropic hormone, is the tripeptide pyroGlu-His-Pro-NH_2. Six copies of the TRH peptide sequence are encoded within the human TRH pre-prohormone gene (Fig. 7.8).[131] The rat pro-TRH precursor contains five TRH peptide repeats flanked by dibasic residues (Lys-Arg or Arg-Arg), along with seven or more non-TRH peptides.[132] Two prohormone convertases, PC1 and PC2, cleave the carboxy-terminal (COOH-terminal) side of these dibasic residues as the prohormone molecule transits the regulated secretory pathway. Carboxypeptidase E then removes the dibasic residues, leaving the sequence Gln-His-Pro-Gly. This peptide is then amidated at the COOH-terminus by peptidylglycine α-amidating monooxygenase (PAM), with Gly acting as the amide donor. The amino-terminal (NH_2-terminal) pyroglutamate residue results from cyclization of the Gln.

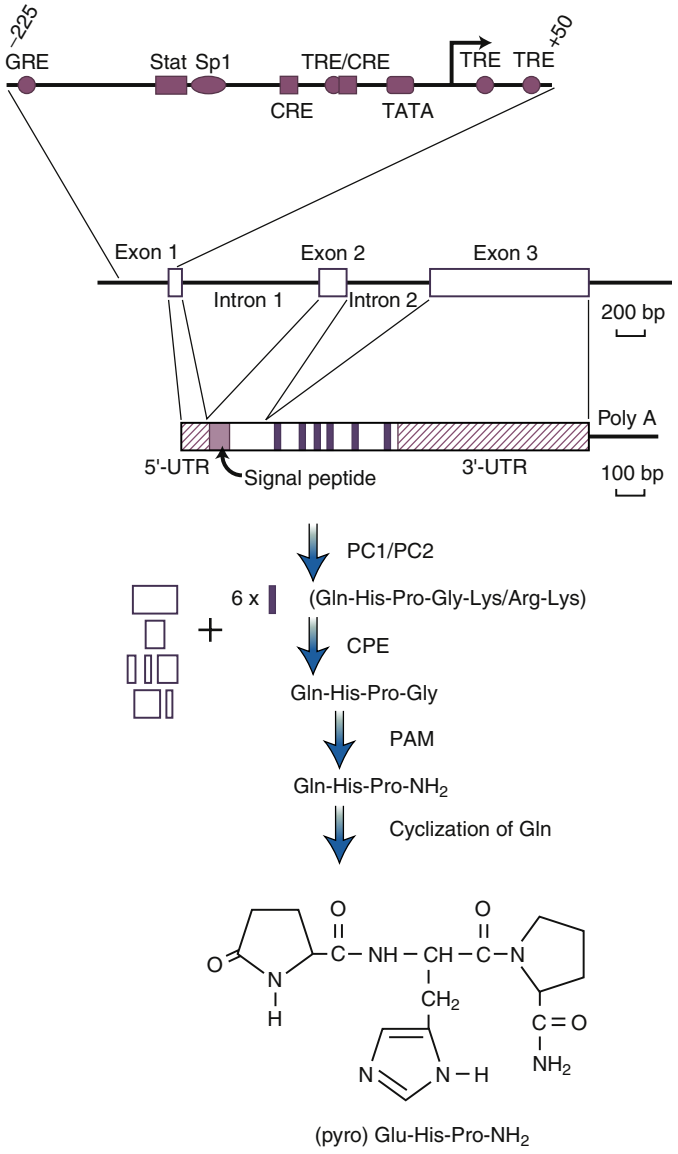
TRH is a phylogenetically ancient peptide; it has been isolated from primitive vertebrates such as the lamprey and even invertebrates such as the snail. TRH is widely expressed in both the CNS and its periphery in amphibians, reptiles, and fishes but does not stimulate TSH release in these poikilothermic vertebrates. Therefore TRH has multiple peripheral and central activities and was co-opted as a hypophysiotropic factor midway during the evolution of vertebrates, perhaps specifically as a factor needed for coordinated regulation of temperature homeostasis.

Although the TRH tripeptide is the only established hormone encoded within its large prohormone, rat pro-TRH yields seven additional peptides that have unique tissue distributions. Several biologic activities of these peptides have been observed: pro-TRH(160-169) may be a hypophysiotropic factor because it is released from hypothalamic slices and potentiates the TSH-releasing effects of TRH.[133] Pro-TRH(178-199) is also released from the median eminence and has been reported to stimulate PRL release or possibly function as a corticotropin release-inhibiting factor.[134]

Effects on the Pituitary Gland and Mechanism of Action

After intravenous injection of TRH in humans, serum TSH levels rise within a few minutes,[135] followed by a rise in serum triiodothyronine (T_3) levels; there is an increase in thyroxine (T_4) release as well, but a change in blood levels of T_4 is usually not demonstrable because the pool of circulating T_4 (most of which is bound to carrier proteins) is so large. TRH action on the pituitary is blocked by previous treatment with thyroid hormone, which is a crucial element in the negative feedback control of pituitary TSH secretion.

TRH is also a potent prolactin-releasing factor.[135] The time course of response of blood PRL levels to TRH, the dose-response characteristics, and the suppression by thyroid hormone pretreatment (all of which parallel changes in TSH secretion) suggest that



• **Fig. 7.8** Structure of the human thyrotropin-releasing hormone (TRH) gene, messenger RNA, and prohormone, showing six repeats of the TRH peptide sequence encoded within exon 3. *CPE,* carboxypeptidase E; *CRE,* cyclic AMP response element; *GRE,* glucocorticoid response element; *PAM,* peptidylglycine α-amidating monooxygenase; *PC1/PC2,* prohormone convertases 1 and 2; *Sp1,* specificity protein 1 binding sequence; *Stat,* signal transducer and activator of transcription binding sequence; *TATA,* Goldstein-Hogness box involved in binding RNA polymerase; *TRE,* thyroid hormone response element; *UTR,* untranslated. (Adapted from data in Yamada M, Radovick S, Wondisford FE, et al. Cloning and structure of human genomic DNA and hypothalamic cDNA encoding human preprothyrotropin-releasing hormone. *Mol Endocrinol.* 1990;4:551–556.)

TRH may be involved in the regulation of PRL secretion. Moreover, TRH is present in the hypothalamic-hypophysial–portal blood of lactating rats. However, it is unlikely to be a physiologic regulator of PRL secretion because the PRL response to nursing in humans is unaccompanied by changes in plasma TSH levels, and mice lacking TRH have normal lactotrophs and basal PRL secretion.[136] Nevertheless, elevated levels of TRH associated with hypothyroidism may occasionally cause hyperprolactinemia (with or without galactorrhea).

In normal individuals, TRH has no influence on the secretion of pituitary hormones other than TSH and PRL, but it enhances the release of GH in acromegaly and of ACTH in some patients with Cushing disease. Furthermore, prolonged stimulation of the normal pituitary with GHRH can sensitize it to the GH-releasing effects of TRH. TRH also causes the release of GH in some patients with uremia, hepatic disease, anorexia nervosa, and psychotic depression and in children with hypothyroidism.[135] TRH inhibits sleep-induced GH release through its actions in the CNS (see later discussion).

Stimulatory effects of TRH are initiated by binding of the peptide to its GPCR on the plasma membrane of the thyrotroph.[137] Thyroid hormone and somatostatin antagonize the effects of TRH but do not interfere with its binding. TRH action is mediated mainly through $G_{q/11}$ and hydrolysis of phosphatidylinositol, with phosphorylation of key protein kinases and an increase in intracellular free calcium (Ca^{2+}) as the crucial steps in postreceptor activation (see Chapter 2).[138] TRH effects can be mimicked by exposure to a Ca^{2+} ionophore and are partially abolished by a Ca^{2+}-free medium. TRH stimulates the formation of mRNAs coding for TSH and PRL in addition to regulating their secretion and stimulates the mitogenesis of thyrotrophs.

TRH is degraded to the dipeptide histidylprolineamide (His-Pro-NH_2) by pyroglutamyl aminopeptidase, following which the dipeptide is deaminated to yield His-Pro or cyclizes nonenzymatically to histidylproline diketopiperazine (cyclic His-Pro). Cyclic His-Pro is reported to act as a PRF and to have other neural effects, including reversal of ethanol-induced sleep (TRH is also effective in this system), elevation of brain cyclic guanosine monophosphate (cGMP) levels, an increase in stereotypical behavior, modification of body temperature, and inhibition of eating behavior. Some of the effects of TRH may be mediated through cyclic His-Pro, but the fact that cyclic His-Pro is abundant in some areas and is not proportional to the amount of TRH suggests that the peptide may not be derived solely from TRH. This latter assertion appears to be confirmed by the detection of substantial amounts of the dipeptide in brains of TRH knockout mice.[136]

Extrapituitary Function

In addition to the hypophysiotropic TRH neurons, TRH is also synthesized by nonhypophysiotropic neurons, including many neuronal groups in the hypothalamus and throughout the brain (amygdala, hippocampus, thalamus, brainstem, spinal cord).[139] The extensive distribution of TRH, its localization in nerve endings, and the presence of TRH receptors in brain tissue suggest that TRH serves as a neurotransmitter or neuromodulator in addition to its well-known function to regulate TSH secretion.[140,141] Central administration of TRH reduces appetite; increases locomotor activity; reduces anxiety; has an antiepileptic effect; induces hyperthermia indicative of a role in central thermoregulation[139]; has broad effects on autonomic regulation, resulting in increased blood pressure and heart rate, increased gastrointestinal motility, increased gastric acid secretion, and increased insulin secretion; and acts as an excitatory modulator of lower motoneuron function by directly synapsing on alpha-motoneurons in the ventral spinal cord.[142] TRH is also found outside the brain, including in anterior pituitary somatotrophs, where it may contribute to regulation of TSH secretion by a paracrine mechanism, retina, parafollicular cells of the thyroid, adrenal medulla, epididymis, prostate, Leydig cells of the testis, pancreatic islet cells, gastrointestinal tract, heart, spleen, lung, ovary, and hair follicles.

Clinical Applications

The use of TRH for the diagnosis of hyperthyroidism or to discriminate between hypothalamic and pituitary causes of TSH deficiency is uncommon since the development of ultrasensitive assays for TSH (see Chapter 11). TRH testing is also not of value in the differential diagnosis of causes of hyperprolactinemia but is useful for the demonstration of residual abnormal somatotropin-secreting cells in acromegalic patients who release GH in response to TRH before treatment.

Studies of the effect of TRH on depression have shown inconsistent results, possibly because of poor blood-brain barrier penetration and a short half-life.[139,141] Although a role for TRH in depression has not established, many depressed patients have a blunted TSH response to TRH, and changes in TRH responsiveness correlate with the clinical course. The mechanism by which blunting occurs is unknown.

TRH has been evaluated for the treatment of diverse neurobiologic disorders (for review see Gary and colleagues[139]), including spinal muscle atrophy and amyotrophic lateral sclerosis; transient improvement in strength was reported in both disorders, but the combined experience at many centers using a variety of treatment protocols (including long-term intrathecal administration) failed to confirm efficacy. TRH administration also reduces the severity of experimentally induced spinal and ischemic shock and may improve recovery after spinal cord injury and head trauma. TRH has been used to treat children with neurologic disorders, including West syndrome, Lennox-Gastaut syndrome, early infantile epileptic encephalopathy, and intractable epilepsy.[143] TRH has been proposed to be an analeptic agent. Sleeping or drug-sedated animals are awakened by the administration of TRH, and TRH reportedly reversed the sedative effects of ethanol in humans and awakened a patient with a profound sleep disorder caused by a hypothalamic and midbrain eosinophilic granuloma.[139]

Regulation of Thyrotropin Release

The secretion of TSH is regulated by two major, interacting elements: negative feedback by thyroid hormone and open-loop neural control by hypothalamic hypophysiotropic factors (Fig. 7.9). TSH secretion is also modified by tanycyte regulation of TRH secretion in the median eminence and other hormones, including estrogens, glucocorticoids, and possibly GH, and is inhibited by cytokines in the pituitary and hypothalamus.[133,144] Aspects of the pituitary-thyroid axis are considered further in Chapter 11.

Feedback Control: Hypothalamic-Pituitary-Thyroid Axis

In the context of a feedback system, the level of thyroid hormone in blood or of its unbound fraction is the controlled variable, and the set-point is the normal resting level of plasma thyroid hormone. The levels of thyroid hormone inversely regulate TSH secretion so that deviations from the set-point lead to appropriate changes in the rate of TSH secretion (Fig. 7.10). Factors that determine the rate of TSH secretion required to maintain a given level of thyroid hormone include the rate at which TSH and thyroid hormone disappear from the blood (turnover rate) and the rate at which T_4 is converted to its more active form, T_3.

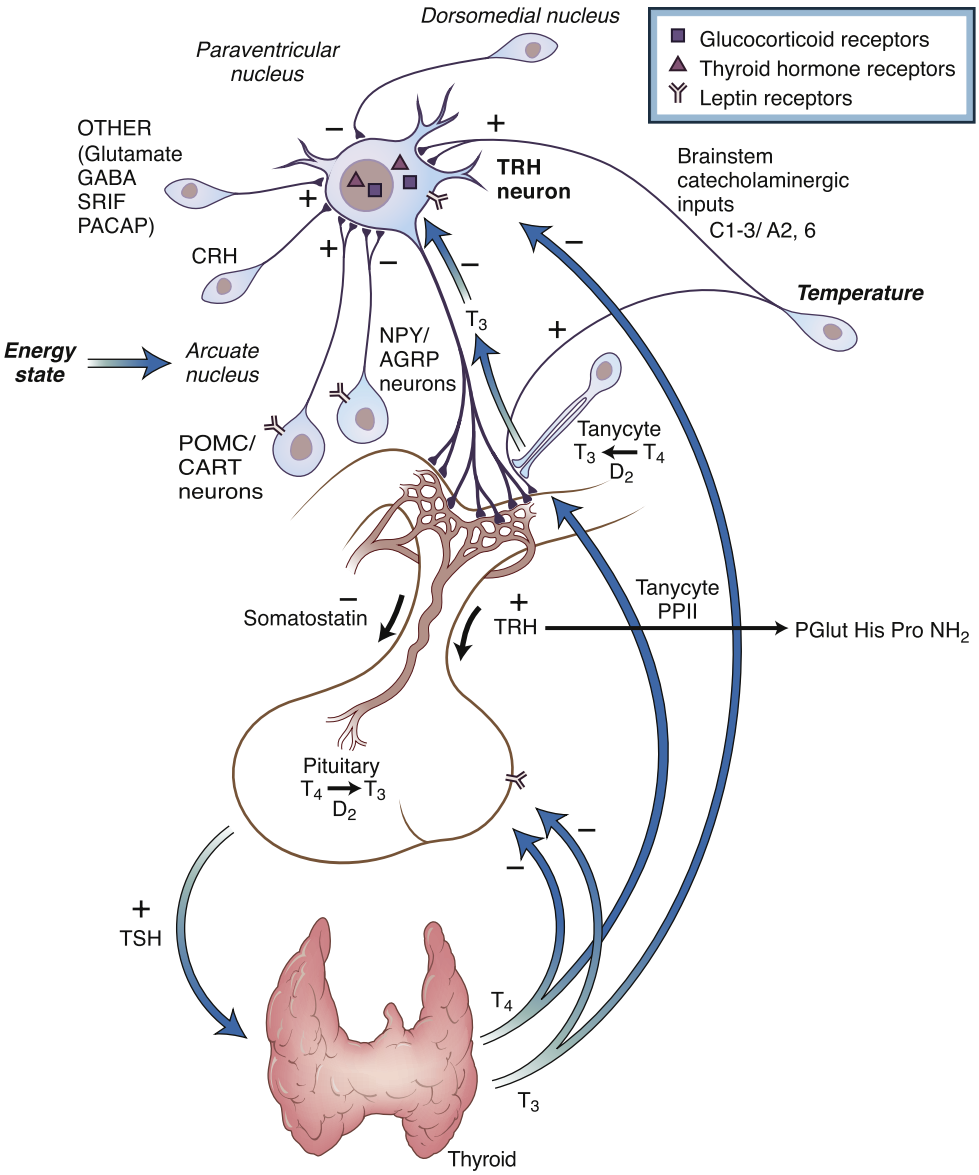
Thyroid hormones act on both the pituitary and the hypothalamus.[145] Feedback control of the pituitary by thyroid hormone is remarkably precise. Administration of small doses of T_3 and T_4 inhibit the TSH response to TRH, and barely detectable decreases in plasma thyroid hormone levels are sufficient to sensitize the pituitary to TRH. TRH stimulates TSH secretion within a few minutes through its action on a GPCR, whereas thyroid hormone actions, mediated by intranuclear receptors, require several hours to take effect.

The secretion of hypophysiotropic TRH is also regulated by thyroid hormone feedback. Systemic injections of T_3 or implantations of tiny T_3 pellets in the PVH of hypothyroid rats[146] (Fig. 7.11A and B) reduce the concentration of TRH mRNA and TRH prohormone in hypophysiotropic TRH-secreting cells that are located in the parvicellular subdivision of the PVH. The molecular mechanism governing negative regulation of TRH by thyroid hormone has not been firmly established but involves binding of the T_3-thyroid hormone receptor complex to a regulatory element in the TRH promoter called site 4 (see Fig. 7.8), the release of corepressors such as NCor and SMART, and recruitment of coactivators such as SRC-1.[145]

Thyroid hormone negative feedback regulation of hypophysiotropic TRH neurons is mediated by the beta 2 isoform of the thyroid hormone receptor ($TR\beta_2$),[147] which is expressed in hypophysiotropic, PVH TRH neurons. T_3 alone is not sufficient to normalize TRH expression in the PVH and requires the presence of T_4.[148] The mechanism is believed to involve the conversion of T_4 to T_3 by D_2 within tanycytes, following the uptake of T_4 circulating in the bloodstream or in the CSF by way of the thyroid hormone transporters OATP1 and MCT8 expressed on these cells.[133] T_3 released from tanycytes, can then be taken up by axon terminals of hypophysiotropic TRH neurons in the external zone of the median eminence that are in intimate contact with tanycyte end-foot processes and also express the thyroid hormone transporter MCT8, thereby inhibiting TRH following its retrograde axonal transport to cell bodies in the PVH.[133,148–150] Along these lines, it is of particular interest that D_3, the thyroid hormone degrading enzyme, is rarely expressed in hypophysiotropic TRH axons in the median eminence in contrast to axons originating from hypophysiotropic CRH, GnRH, and GHRH neurons.[151] Presumably this selectivity of D_3 expression allows hypophysiotropic TRH neurons to remain sensitive to changes in peripheral thyroid hormone levels while allowing other hypophysiotropic neuronal types to protect intracellular concentrations of T_3. Other central mechanisms contributing to feedback regulation of hypophysiotropic TRH by thyroid hormone include regulation of prohormone convertase enzymes in hypophysiotropic TRH neurons that are involved in the post-translational processing of proTRH, and the synthesis of the TRH degrading enzyme, pyroglutamyl peptidase II (PPII), by tanycytes that modulate the amount of TRH released into the portal circulation for conveyance to the anterior pituitary.[152,153]

Neural Control

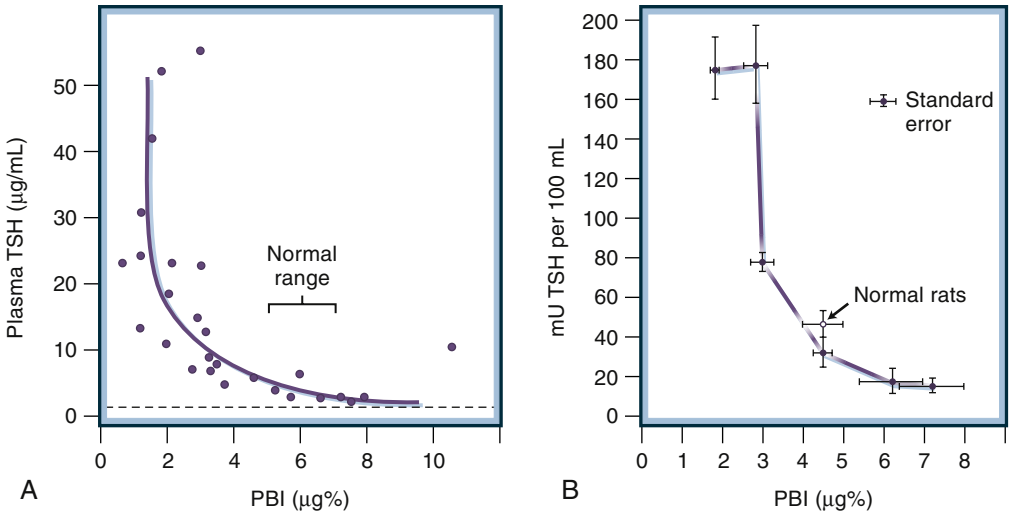
The hypothalamus determines the set-point of feedback control around which the usual feedback regulatory responses are elicited.[133] Lesions of the thyrotropic area lower basal thyroid hormone levels and make the pituitary more sensitive to inhibition by thyroid hormone, and high doses of TRH raise the levels of TSH and thyroid hormone. Synthesis of TRH in the paraventricular nuclei is regulated by feedback actions of thyroid hormone.[133,145] The hypothalamus can override normal feedback control through an open-loop mechanism involving neuronal inputs to the hypophysiotropic TRH neurons (see Fig. 7.9). Three main neuronal groups are known to project to hypophysiotropic TRH neurons, including two groups in the hypothalamus originating in the arcuate nucleus and dorsomedial nucleus and catecholamine-producing neurons in the brainstem.[133]



• **Fig. 7.9** Regulation of the hypothalamic-pituitary-thyroid axis. Central modulators of the hypothalamic tuberoinfundibular system include inputs from brainstem catecholamine neurons (C1–C3, A2, 6) that may also coproduce NPY and CART, NPY/AgRP, and α-MSH/CART neurons in the hypothalamic arcuate nucleus and the dorsomedial nucleus. Hypophysiotropic TRH neurons also receive a variety of other inputs, including CRH, glutamatergic, GABAergic, TRH, CRH, SRIF, and PACAP inputs. Feedback regulation by circulating thyroid hormone is mediated by the $TR\beta_2$ receptor expressed in hypophysiotropic TRH neurons. The conversion of T_4 to T_3 by type 2 iodothyronine 5′-monodeiodinase is required and proposed to take place in tanycytes lining the third ventricle. T_3 released from tanycytes can be taken up by TRH axon terminals in the median eminence that are in close contact with tanycyte end-feet processes and then transported retrogradely to the cell bodies in the hypothalamic PVH. *AGRP,* agouti-related peptide; *CART,* cocaine-regulated and amphetamine-regulated transcript; *CRH,* corticotropin-releasing hormone; *D_2,* type 2 iodothyronine deiodinase; *NPY,* neuropeptide Y; *POMC,* pro-opiomelanocortin; *PPII,* pyroglutamyl peptidase II; *T_3,* triiodothyronine; *T_4,* thyroxine; *TRH,* thyrotropin-releasing hormone; *TSH,* thyrotropin.

Neurons in the arcuate nucleus containing NPY, AgRP, α-MSH, and cocaine-regulated and amphetamine-regulated transcript (CART) have important roles in the regulation of energy homeostasis and respond to feeding-related signals in the bloodstream, including leptin, ghrelin, insulin, and glucose (see Chapter 39). These neurons establish numerous contacts with hypophysiotropic neurons and are involved in resetting the set-point for feedback regulation of thyroid hormone during nutritional insufficiency (see upcoming discussion about fasting and starvation). TRH neurons in the PVH of the human hypothalamus also receive inputs from NPY/AgRP neurons in the infundibular nucleus,[154] indicating evolutionary conservation of this important pathway.

The dorsomedial nucleus also has extensive projections to TRH neurons in the PVN[155] and, if ablated, results in an increase in circulating levels of T_3,[156] indicative of an inhibitory effect. Little is known about how the dorsomedial nucleus regulates hypophysiotropic TRH neurons, however, but it is hypothesized to be involved in circadian regulation of TSH (see "Circadian Rhythm").



• **Fig. 7.10** Relationship between plasma thyrotropin (TSH) levels and thyroid hormone as determined by plasma protein-bound iodine (PBI) measurements in humans and rats. These curves illustrate, in the human (A) and the rat (B), that plasma TSH levels are a curvilinear function of plasma thyroid hormone level. Human studies were carried out by giving myxedematous patients successive increments of thyroxine (T_4) at approximately 10-day intervals. Each point represents simultaneous measurements of plasma PBI and plasma TSH at various times in the six patients studied. The rat studies were performed by treating thyroidectomized animals with various doses of T_4 for 2 weeks before assay of plasma TSH and plasma PBI. These curves illustrate that the secretion of TSH is regulated over the entire range of thyroid hormone levels. At the normal set-point for T_4, the small changes above and below the control level are followed by appropriate increases or decreases in plasma TSH. (A, From Reichlin S, Utiger RD. Regulation of the pituitary thyroid axis in man: relationship of TSH concentration to concentration of free and total thyroxine in plasma. *J Clin Endocrinol Metab.* 1967;27:251–255, copyright by The Endocrine Society. B, From Reichlin S, Martin JB, Boshans RL, et al. Measurement of TSH in plasma and pituitary of the rat by a radioimmunoassay utilizing bovine TSH: effect of thyroidectomy or thyroxine administration on plasma TSH levels. *Endocrinology.* 1970;87:1022–1031, copyright by The Endocrine Society.)

Finally, hypophysiotropic TRH neurons receive a particularly dense innervation from catecholamine-producing neurons in the brainstem, including adrenergic neurons located in regions C1 to C3 in the rostroventrolateral medulla and within and adjacent to the nucleus tractus solitarius, and noradrenergic neurons located in A2 and A6 regions in the ventrolateral medulla and dorsal vagal complex.[157] Subpopulations of these catecholaminergic neurons coproduce peptides, contributing ~25% of the NPY innervation and ~60% of the CART innervation to TRH neurons in the PVN.[158,159] As will be described later, this projection pathway has a particularly important role in the regulation of TRH gene expression by cold.

Hypothalamic regulation of TSH secretion is also influenced by the inhibitory factor somatostatin. Antisomatostatin antibodies increase basal TSH levels and potentiate the response to stimuli that normally induce TSH release in the rat, such as cold exposure and TRH administration.[160] Thyroid hormone in turn inhibits the release of somatostatin, implying coordinated, reciprocal regulation of TRH and somatostatin by thyroid hormone. GH stimulates hypothalamic somatostatin synthesis and can inhibit TSH secretion. However, the physiologic role of somatostatin in the regulation of TSH secretion in humans is uncertain.

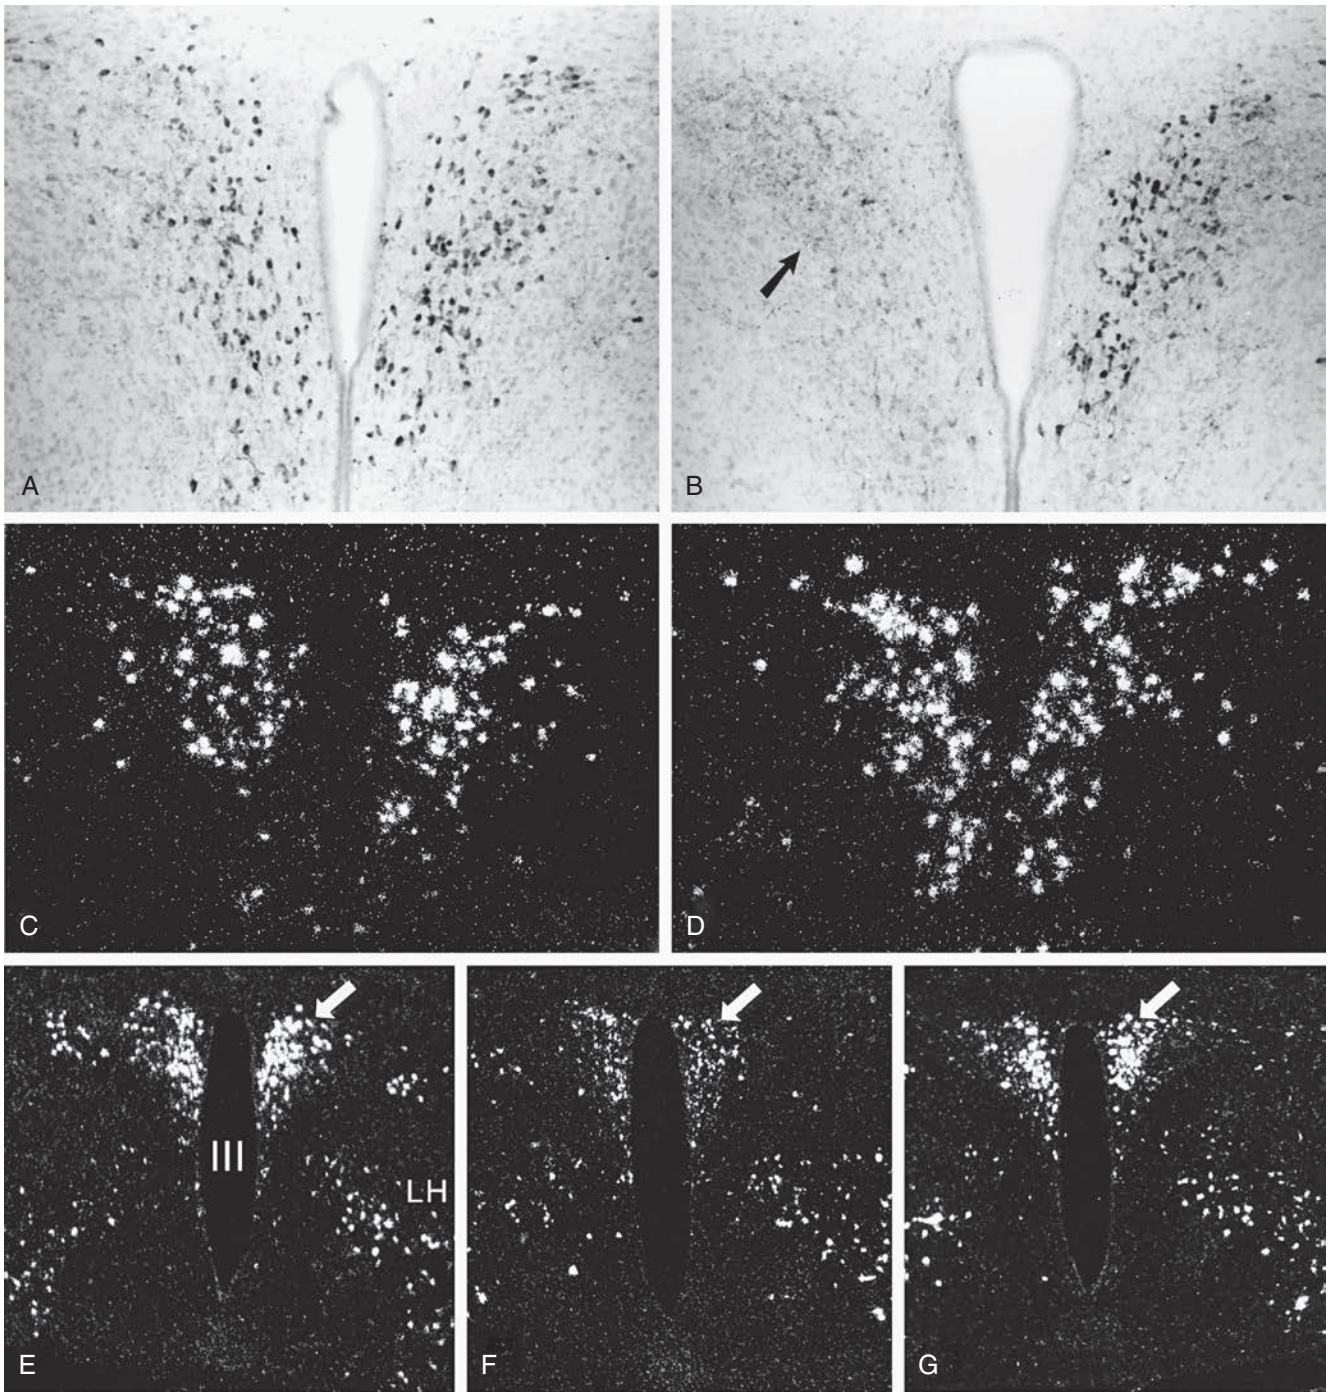
Circadian Rhythm

Plasma TSH in humans is characterized by a circadian periodicity, with a maximum between 9 PM and 5 AM and a minimum between 4 PM and 7 PM (see Fig. 7.7E).[161] Smaller ultradian TSH peaks occur every 90 to 180 minutes, probably because of bursts of TRH release from the hypothalamus, and are physiologically important in controlling the synthesis and glycosylation of TSH. Glycosylation is a determinant of TSH potency.[162]

Temperature

External cold exposure activates and high ambient temperature inhibits the pituitary-thyroid axis in animals, and analogous changes occur in humans under certain conditions.[163] Exposure of infants to cold at the time of delivery causes an increase in blood TSH levels, possibly because of alterations in the turnover and degradation of the thyroid hormones. Blood thyroid hormone levels are higher in the winter than in the summer among people living in cold climates but not in other climates. However, it is difficult to show that changes in environmental or body temperature in adults influence TSH secretion. For example, exposure to cold ambient temperature or central hypothalamic cooling does not modify TSH levels in young men. Behavioral changes, activation of the sympathetic nervous system, and shivering appear to be more important than the thyroid response for temperature regulation in adults.

The autonomic nervous system and the thyroid axis work together to maintain temperature homeostasis in mammals, and TRH plays a role in both pathways.[163] Hypothalamic TRH release is rapidly increased (30–45 minutes) in rats exposed to cold. Rapid inhibition of somatostatin release in the median eminence has also been documented, and both changes appear to play important roles in the rise in plasma TSH induced by cold exposure. TRH mRNA is elevated within an hour of cold exposure (see Fig. 7.11C and D). The regulation of hypophysiotropic



• **Fig. 7.11** (A and B) Direct effects of triiodothyronine (T_3) on thyrotropin-releasing hormone (TRH) synthesis in the rat hypothalamic paraventricular nucleus (parvicellular division) were shown in this experiment by immunohistochemical detection of pre-pro-TRH(25-50) after implantation of a pellet of either T_3 (B) or inactive diiodothyronine (T_2) as a control (A). The T_2 pellet had no effect on the concentration of pre-pro-TRH (A). In contrast, the TRH prohormone concentrations (B) were markedly reduced (*black arrow* indicates the unilateral pellet implantation). These studies indicate that thyroid hormone regulates the hypothalamic component of the pituitary-thyroid axis as well as the pituitary thyrotrope itself. (C and D) Effects of 1 hour at 4°C on TRH messenger ribonucleic acid (mRNA). (E to G) Effects on TRH mRNA levels of starvation (F) and leptin replacement during starvation (G). *White arrows* show the location of the paraventricular nucleus. *III,* 3rd ventricle; *LH,* lateral hypothalamus. Joseph-Bravo.)

TRH release and expression by cold is largely mediated by catecholamines, and a rapid rise in TRH release is observed after norepinephrine treatment of hypothalamic fragments. As mentioned previously, catecholamines arise from neurons originating in the brainstem and can affect TRH secretion both through contacts on TRH perikarya in the PVH and their axon terminals in the median eminence (see Fig. 7.9).[164]

Stress

Stress is another determinant of TSH secretion.[165] In humans, physial stress inhibits TSH release, as indicated by the finding that low levels of T_3 and T_4 in patients with the nonthyroidal illness syndrome do not cause compensatory increases in TSH secretion as would occur in normal individuals.[166]

A number of observations demonstrate interactions between the thyroid and adrenal axes.[165] Physiologically, the bulk of evidence suggests that glucocorticoids in humans and rodents act to blunt the thyroid axis through actions in the CNS.[167] Some actions may be direct because the TRH gene (see Fig. 7.8) contains a glucocorticoid response element consensus half-site,[132] and hypophysiotropic TRH neurons appear to contain glucocorticoid receptors.[168] The diurnal rhythm of cortisol is opposite that of TSH (see Fig. 7.7), and acute administration of glucocorticoids can block the nocturnal rise in TSH, but disruption of cortisol synthesis with metyrapone only modestly affects the TSH circadian rhythm.

Nevertheless, several lines of evidence identify conditions in which elevated glucocorticoids are associated with stimulation of the thyroid axis. Human depression is often associated with hypercortisolism and hyperthyroxinemia, and TRH mRNA levels are elevated by glucocorticoids in a number of cell lines as well as in cultured fetal hypothalamic TRH neurons from the rat. Thus, although glucocorticoids can stimulate TRH production in TRH neurons by binding to glucocorticoid receptor binding sites in the TRH promoter, their overall inhibitory effect on the thyroid axis results from indirect glucocorticoid negative feedback on structures such as the hippocampus. Disruption of hippocampal suppression of the hypothalamic-pituitary-adrenal (HPA) axis is proposed to be involved in the hypercortisolemia commonly seen in affective illness, and disruption of hippocampal inputs to the hypothalamus has been shown to produce a rise in hypophysiotropic TRH in the rat.[169]

Suckling

Suckling also increases TRH gene expression in hypophysiotropic neurons but primarily to increase prolactin secretion from the anterior pituitary. TSH and thyroid hormone levels do not increase in response to suckling, perhaps due to the simultaneous release of CART that is coexpressed with TRH in hypophysiotropic neurons that attenuate TRH-induced TSH secretion.[170]

Starvation

The thyroid axis is suppressed during starvation, presumably to help conserve energy by depressing metabolism (see Fig. 7.11E–G). In humans, reduced T_3, T_4, and TSH are seen during starvation or fasting.[133] There are also changes in the thyroid axis in anorexia nervosa, such as low blood levels of T_3 and low normal levels of T_4. Inappropriately low levels of TSH are found, suggesting defective activation of TRH production by low thyroid hormone levels. During starvation in rodents, reduced TRH release into hypothalamic-hypophysial portal blood and reduced pro-TRH mRNA levels are seen, despite lowered thyroid hormone levels.[171] Reduced basal TSH levels are also usually present.

The hypothyroidism seen in fasting or in the leptin-deficient *ob/ob* mouse can be reversed by administration of leptin,[14] and evidence suggests that the mechanism involves leptin's ability to upregulate TRH gene expression in the PVH (see Fig. 7.11E–G).[13] Leptin appears to act both directly through leptin receptors on hypophysiotropic TRH neurons and indirectly through its actions on other hypothalamic cell groups, such as arcuate nucleus POMC and NPY/AgRP neurons.[172,173] TRH neurons in the PVH receive dense NPY/AgRP and POMC projections from the arcuate and express NPY and melanocortin-4 receptors (MC4R),[174] and α-MSH administration partially prevents the fasting-induced drop in thyroid hormone levels.[172,173] Indeed, the TRH promoter contains a signal transducer and activator of transcription (STAT) response element and a CRE that have been demonstrated to mediate induction of TRH gene expression by leptin and α-MSH, respectively, in a heterologous cell system (see Fig. 7.8).[174] The regulation of TRH by metabolic state is likely to be under redundant control, however, because leptin-deficient children, unlike rodents, are euthyroid,[175] whereas both humans and rodents with MC4R deficiency are euthyroid.[176]

Dehydration-Induced Anorexia

The addition of 2.5% NaCl to drinking water markedly reduces food intake by 80%.[177] Despite the very low food intake, TRH gene expression in the PVH increases rather than the anticipated decrease as described previously. The mechanism for this response is uncertain but may involve activating effects of CRH from neurons in the lateral hypothalamus that project to hypophysiotropic TRH neurons. Dehydration-induced anorexia (DIA) also increases CRH gene expression in lateral hypothalamic neurons, and as noted previously, CRH induces TRH release in cell culture.[178]

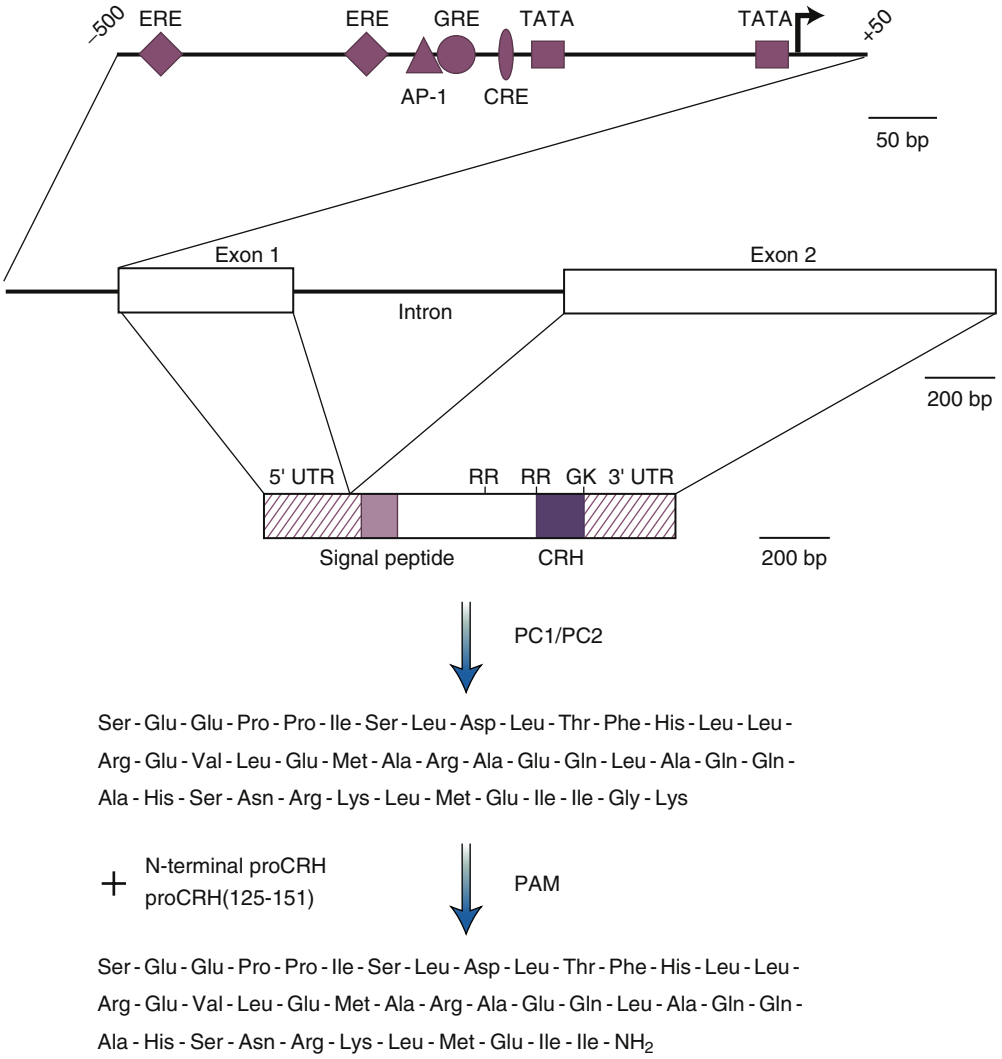
Infection and Inflammation

The molecular basis of infection-induced or inflammation-induced TSH suppression is partially established. TSH secretion is inhibited by sterile abscesses; by the injection of interleukin 1β (IL-1β), an endogenous pyrogen and secretory peptide of activated lymphocytes[179]; or by tumor necrosis factor-α (TNFα). IL-1β stimulates the secretion of somatostatin.[180] TNFα inhibits TSH secretion directly and induces functional changes in the rat characteristic of the sick euthyroid state.[181] It is likely that the TSH inhibition in animal models of the sick euthyroid syndrome is due to cytokine-induced changes in hypothalamic and pituitary function.[182] IL-6, IL-1, and TNFα contribute to the suppression of TSH in the nonthyroidal illness syndrome.[183] Other evidence suggests that bacterial lipopolysaccharide can directly stimulate tanycytes via their expression of toll-like receptor 4. The stimulated tanycytes express higher levels of type 2 deiodinase, perhaps directly induced by activation of nuclear factor-κB (NFκB), that in turn increases the levels of T_3 relative to T_4, causing feedback inhibition on TRH neurons by a mechanism described earlier.[133] Endotoxin also increases TSH production in the pars tuberalis, which, as described previously (see "Physiologic Roles of Melatonin"), can increase tanycyte D_2 expression.

Corticotropin-Releasing Hormone

Chemistry and Evolution

The HPA axis is the humoral component of an integrated neural and endocrine system that has an important role in the regulation of energy homeostasis through effects on hepatic glycogenolysis



• **Fig. 7.12** Structure of the human corticotropin-releasing hormone (CRH) gene, complementary DNA, and peptide. The sequence encoding CRH occurs at the carboxy-terminus of the prohormone. and lipolysis and functions in response to acute and chronic internal and external challenges to homeostasis (stressors). The system is comprised of neuronal pathways linked to the hypothalamic-pituitary control of ACTH release and hence the release of glucocorticoids from the adrenal cortex and can coordinate with activation of the autonomic nervous system to induce the release of catecholamines from the adrenal medulla (fight-or-flight response). Pituitary ACTH secretion is stimulated primarily by CRH, derived from neurons located in the parvicellular division of the PVH, and to a lesser extent by AVP, originating from magnicellular neurons in the SON and PVN but also cosecreted from hypophysiotropic CRH neurons (see Figs. 7.3 and 7.4). In a broader context, the CRH system in the CNS is also vitally important for the behavioral responses to stress. This complex system also includes nonhypophysiotropic CRH neurons, three additional CRH-like peptides, urocortin 1 to 3, at least two cognate GPCRs, CRH receptors (including CRH-R1 and CRH-R2), and a high-affinity CRH-binding protein, each with distinct and complex distributions in the CNS.

The Schally and Guillemin laboratories demonstrated in 1955 that extracts from the hypothalamus stimulated ACTH release from the pituitary. The primary active principle, CRH, was purified and characterized from sheep in 1981. Human CRH is an amidated 41–amino acid peptide that is cleaved from the COOH-terminus of a 196–amino acid pre-prohormone precursor by PC1 and PC2 (Fig. 7.12).[184] CRH is highly conserved phylogenetically; the human peptide is identical in sequence to the mouse and rat peptides but differs at seven residues from the ovine sequence. Mammalian CRH, the three urocortin peptides, fish urotensin, anuran sauvagine, and the insect diuretic peptides are

members of an ancient family of peptides that evolved from an ancestral precursor early in the evolution of metazoans, ~500 million years ago.[185] Comparison of peptide sequences in vertebrates suggests a grouping of the peptides into two subfamilies, CRH-urotensin-urocortin 1-sauvagine and urocortin 2-urocortin 3 (Fig. 7.13).[186] Urocortin 1 and sauvagine appear to represent tetrapod orthologues of fish urotensin. Sauvagine, isolated originally from *Phyllomedusa sauvagii*, is an osmoregulatory peptide produced in the skin of certain frogs; urotensin is an osmoregulatory peptide produced in the caudal neurosecretory system of fish. Whereas isolation of CRH required 250,000 ovine hypothalami, the virtual cloning of urocortin 2 and 3 was accomplished by computer search of the human genome database.[186]

The CRH peptides signal by binding to CRH-R1[187] and CRH-R2,[188] receptors that couple to the stimulatory G protein (G_s) and adenylyl cyclase. Two splice variants of the latter receptor that differ in the extracellular NH_2-terminal domain, CRH-R2α and CRH-R2β, have been found in both rodents and humans,[189] and a third NH_2-terminal splice variant, CRH-R2γ, has been reported in humans.[190] In mammals, CHR-R1 is the predominant receptor expressed in the brain and anterior pituitary, thereby being the primary receptor for CRH-mediated ACTH release,[191] whereas CRH-R2 has a more limited and selective distribution in the brain.[192] CRH, urotensin, urocortin 1, and sauvagine are potent agonists of CRH-R1; urocortin 1 is also a potent agonist of CRH-R2; urocortins 2 and 3 are specific agonists of CRH-R2.[193] Thus CRH activation of the HPA axis is mediated exclusively through CRH-R1, which is expressed in anterior pituitary corticotrophs.

While CRH neurons projecting to the median eminence are found mostly in the PVH (Fig. 7.14A), some CRH fibers originating from the PVH also project to the brainstem. In addition, nonhypophysiotropic CRH neurons are abundant elsewhere but primarily in limbic structures involved in processing sensory information and in regulating the autonomic nervous system. Sites include the prefrontal, insular, and cingulate cortices; amygdala; substantia nigra; periaqueductal gray; locus coeruleus; NTS; and parabrachial nucleus. In the periphery, CRH is found in human placenta, lymphocytes, autonomic nerves, heart, lung, skin, kidney, testes, ovaries, and the gastrointestinal tract. Urocortin 1 is expressed at the highest levels in the nonpreganglionic Edinger-Westphal nucleus, the lateral superior olive, and the SON of the rodent brain, with additional sites such as the substantia nigra, ventral tegmental area, and dorsal raphe (see Fig. 7.14B). In the human, urocortin 1 is widely distributed, with highest levels in the frontal cortex, temporal cortex, and hypothalamus,[194] and has also been reported in the nonpreganglionic Edinger-Westphal nucleus.[22] In the periphery, urocortin 1 is seen in placenta, mucosal inflammatory cells of the gastrointestinal tract, lymphocytes, and cardiomyocytes. Urocortin 2 is expressed in hypothalamic neuroendocrine and stress-related cell groups in the mouse, including the locus coeruleus, whereas urocortin 3 is expressed in the hypothalamus and amygdala and particularly in pancreatic islet beta cells.[195,196]

In addition to its expression in pituitary corticotrophs, CRH-R1 is found in the neocortex and cerebellar cortex, subcortical limbic structures, and amygdala, with little to no expression in the hypothalamus (see Fig. 7.14C). CRH-R1 is also found in a variety of peripheral sites in humans, including ovary, endometrium, and skin. CRH-R2α is found mainly in the brain in rodents, with high levels of expression seen in the ventromedial hypothalamic nucleus and lateral septum (see Fig. 7.14C)[197]; CRH-R2β is found centrally in cerebral arterioles and peripherally in the gastrointestinal tract, heart, and muscle.[188,198] In humans, CRH-R2α is expressed in the brain and periphery, whereas the β and γ subtypes are primarily central.[189,190] Little CRH-R2 message is seen in the pituitary. CRH-R1 and CRH-R2 are expressed in the rodent adrenal cortex, suggesting a potential intra-adrenal CRH-ACTH system involved in the fine-tuning of adrenocortical glucocorticoid release.

Regulation of signaling at CRH-R1 and CRH-R2 in both the brain and periphery also occurs by a 37-kDa high-affinity CRH-binding protein (CRH-BP), which also binds urocortin 1 with equal or greater affinity than to the CRH receptors.[199,200] This factor was initially postulated from the observation that CRH levels rise dramatically during the second and third trimesters of pregnancy without activating the pituitary-adrenal axis. Among hypophysiotropic factors, CRH is the only one for which a specific binding protein (in addition to the receptor) exists in tissue or blood.

The functional significance of the CRH-binding protein is not fully understood. The CRH-binding protein does not bind to the CRH receptor but does inhibit CRH action. For this reason, the CRH-binding protein probably acts to modulate CRH actions at the cellular level. Corticotroph cells in the anterior pituitary have membrane CRH receptors and intracellular CRH-binding protein.[201] Conceivably, the binding protein acts to sequester or terminate the action of membrane-bound CRH and has been shown to attenuate ACTH-releasing activity of CRH in anterior pituitary cells.[202] The CRH-binding protein is also present in regions of the CNS that synthesize CRH or receive innervation from CRH-containing neurons such as the bed nucleus of the stria terminalis and central nucleus of the amygdala.[203] Most importantly, however, CRH-BP may have a regulatory role within the CNS to modulate the stress response (reviewed by Ketchesin and colleagues[200]). For example, CRH-BP increases in the amygdala following restraint stress, predator stress, and food deprivation,[204–206] suggesting that it may function to reduce the anxiety-promoting (anxiogenic) effects of CRH by decreasing CRH-R1 activation. Indeed, transgenic mice with gene deletion of CRH-BP demonstrate increased anxiety-like behavior when subjected to the elevated plus maze test.[207]

Structure-activity relationship studies have demonstrated that COOH-terminal amidation and an α-helical secondary structure

Urocortin expression in rat brain: evidence against a pervasive relationship of urocortin-containing projections with targets bearing type 2 CRF receptors. *J Comp Neurol.* 1999;415:285–312, Fig. 17; and Steckler T, Holsboer F. Corticotropin-releasing hormone receptor subtypes and emotion. *Biol Psychol.* 1999;46:1480–1508, Fig. 1.)

are both important for biologic activity of CRH. The first CRH antagonist described was termed α-helical CRH(9-41).[208] A second, more potent antagonist, termed *astressin*, has the structure cyclo(30-33)(D-Phe^{12}, Nle^{21,38}, Glu^{30}, Lys^{33})hCRH(12-41).[209] Both peptides are somewhat nonspecific, antagonizing both CRH-R1 and CRH-R2. Because of the anxiogenic activity of CRH and urocortin 1, several pharmaceutic companies have developed small molecule CRH antagonists; many of these have been the subject of clinical trials for anxiety and depression (see later discussion). Thus far, this structurally diverse group of small molecule compounds, such as antalarmin, R121919, CP-154,526, NBI27914, NBI77860, BMS562086, and a novel series of thiazolol[4,5-*d*] pyrimidines-2-imine and 2-hydrazones, are potent antagonists of CRH-R1, with little activity at CRH-R2. The efficacy of these compounds across the entire behavioral, neuroendocrine, and autonomic repertoire of response to stress has been demonstrated in a number of laboratory animal studies. For example, oral administration of antalarmin in a social stress model in the primate (introduction of strange males) reduced behavioral measures of anxiety such as lack of exploratory behavior, decreased plasma ACTH and cortisol, and reduced plasma epinephrine and norepinephrine.[210] Activation of CRH-R2 by urocortin 2 or 3 in mice has also been shown to reduce anxiety and depression associated with the acute withdrawal of chronic nicotine treatment.[211,212] Thus selective CRH-2 agonists may also find clinical benefit.

Effects on the Pituitary and Mechanism of Action

Administration of CRH to humans causes prompt release of ACTH into the blood, followed by secretion of cortisol (Fig. 7.15) and other adrenal steroids, including aldosterone. Most studies have used ovine CRH, which is more potent and longer acting than human CRH, but human and porcine CRHs appear to have equal diagnostic value. The effect of CRH is specific to ACTH release and is inhibited by glucocorticoids.

As mentioned, CRH acts on the pituitary corticotroph to regulate both basal-induced and stress-induced ACTH release, primarily by binding to CRH-R1 and activating adenylyl cyclase. The concentration of cAMP in the tissue is increased in parallel with the biologic effects and is reduced by glucocorticoids. The rate of transcription of the mRNA that encodes the ACTH prohormone POMC is also enhanced by CRH.

Extrapituitary Functions

CRH and the urocortin peptides have a wide range of biologic activities in addition to the hypophysiotropic role of CRH in regulating ACTH synthesis and release. Centrally, these peptides have behavioral activities in anxiety, mood, arousal, locomotion, reward, and feeding[213,214] and increase sympathetic activation independent of any effects on the HPA axis.[215] Many of the nonhypophysiotropic behavioral and autonomic functions of these peptides, however, can be viewed as complementary to activation of the HPA axis in the maintenance of homeostasis under exposure to stress. In the periphery, activities have been reported in immunity, cardiac function, gastrointestinal function, and reproduction.[216]

Hyperactivity of the HPA axis is a common neuroendocrine finding in affective disorders (see Fig. 7.15),[213,217] and normalization of HPA regulation is highly predictive of successful treatment. Defective dexamethasone suppression of CRH release, implying defective corticosteroid receptor signaling, is seen not only in depressed patients but also in healthy subjects with a family history of depression.[218] Depressed patients also show elevated levels of CRH in the CSF.[219] Extensive behavioral testing in a variety of mutant mouse models with genetically altered expression of either the CRH ligands or receptors generally supports the hypothesis that activation of central CRH pathways is a critical neurobiologic substrate of anxiety and depressive states.[214,220] Signaling through CRH-R1 also participates in addictive behavior, particularly in the central nucleus of the amygdala and bed nucleus of the stria terminalis. Acute withdrawal from drugs of abuse or withdrawal from ethanol or nicotine results in increases in CRH in these regions.[221,222] In addition, injections of CRH receptor antagonists into the central nucleus of the amygdala reduce self-administration of addictive substances (reviewed by Roberto and colleagues[223]). Activation of dopaminergic neurons in the ventral tegmental area by CRH may also be involved in mediating addictive behaviors by signaling through both CRH-R1 and CRH-R2.

Responses to corticotropin-releasing hormone in the hypercortisolism of depression and Cushing's disease: pathophysiologic and diagnostic implications. *N Engl J Med.* 1986;314:1329–1335.)

Central administration of CRH or urocortin activates the neuronal cell groups involved in cardiovascular control and increases blood pressure, heart rate, and cardiac output.[224] However, urocortin is expressed in cardiac myocytes, and intravenous administration of CRH or urocortin decreases blood pressure and increases heart rate in most species, including humans.[224] This hypotensive effect is probably mediated peripherally because ganglionic blockade did not disrupt the hypotensive effects of intravenous urocortin. Furthermore, high levels of CRH-R2β have been seen in the cardiac atria and ventricles,[188,198] and knockout of the *Crhr2* gene in the mouse eliminated the hypotensive effects of intravenous urocortin administration.[225]

Cytokines have an important role in extinguishing inflammatory responses through activation of CRH and AVP neurons in the PVH and subsequent elevation of anti-inflammatory glucocorticoids. Interestingly, CRH is generally proinflammatory in the periphery, where it is found in sympathetic efferents, in sensory afferent nerves, in leukocytes, and in macrophages in some species.[216,226] CRH also functions as a paracrine factor in the endometrium, where it may play a role in decidualization and implantation and act as a uterine vasodilator.[216]

The relative contributions of each of the CRH-urocortin peptides and receptors to the different biologic functions reported have been the topic of considerable analysis, given the receptor-specific antagonists already described as well as the CRH, CRH-R1, and CRH-R2 knockout mice available for study (reviewed by Bale and Vale[220] and Keck and colleagues[214]). Examination of three potent stressors—restraint, ether, and fasting—demonstrated that other ACTH secretagogues, such as AVP, oxytocin, and catecholamines, could not replace CRH in its role in mounting the stress response. In contrast, augmentation of glucocorticoid secretion by a stressor after prolonged stress was not defective in CRH knockout mice, implicating CRH-independent mechanisms.

CRH and urocortin peptides also have potent anorexigenic activity, implicating the CRH system in stress-induced inhibition of feeding. However, studies utilizing CRH, CRH-R1, and CRH-R2 knockout mice have not fully unraveled the complex interactions of these peptides and receptor signaling pathways in the acute effects of stress on feeding behavior.

Additional gene knockout studies have suggested that urocortin 2 plays a physiologic role in female mice to dampen basal daily rhythms of the HPA axis and reduce behavioral coping mechanisms in response to chronic stress.[195] Urocortin 3 may have a primary action to augment insulin secretion in response to the metabolic stress of excessive calorie intake.[196]

Clinical Applications

No approved therapeutic application of CRH or CRH-like peptides exists, although the peptide has been demonstrated to have a number of activities in human and primate studies. For example, intravenous administration of CRH was found to stimulate energy expenditure but is an unlikely pharmaceutic target for inducing weight loss. The development of small molecule, orally available, CRH-R1 antagonists such as R121919 produced considerable interest in their potential for treatment of anxiety and depression[219,227] and even reached a Phase IIa trial.[228] However, while still of major interest in the treatment of psychiatric conditions, subsequent trials have proved disappointing, perhaps indicating that the neurobiology of signaling through the CRH-R1 is more complex than currently appreciated.[229] Recent studies, however, have suggested promising results for the use of the CRH-R1 antagonist pexacerfont (BMS562086) to reduce craving and stress-induced eating, and verucerfont (NBI77860) in the treatment of hyperandrogenism associated with congenital adrenal hyperplasia.[229,230]

Feedback Control

The administration of glucocorticoids inhibits ACTH secretion; conversely, removal of the adrenals (or administration of drugs that impair secretion of glucocorticoids) leads to increased ACTH release. The set-point of pituitary feedback is determined by the hypothalamus acting through hypothalamic-releasing hormones CRH and AVP (see Chapter 8).[231–234] Glucocorticoids act on both the pituitary corticotrophs and the hypothalamic neurons that secrete CRH and AVP. These regulatory actions are analogous to the control of the pituitary-thyroid axis. However, whereas TSH becomes completely unresponsive to TRH when thyroid hormone levels are sufficiently high, severe neurogenic stress and large amounts of CRH can break through the feedback inhibition due to modulation of hypophysiotropic CRH neurons by afferent input from other regions of the brain, including brainstem catecholaminergic neurons (primarily the NTS), BNST, hippocampus, and prefrontal cortex, among others. Comprehensive reviews of regulation of the HPA axis have emphasized the complexity of this control beyond that of a simple closed-loop feedback.[235,236]

Glucocorticoids are lipid soluble and freely enter the brain through the blood-brain barrier.[233] In brain and pituitary they can bind to two receptors: Type I (encoded by *NR3C1*) is called the *mineralocorticoid receptor* because it binds aldosterone and glucocorticoids with high affinity. Type II (*NR3C2*), the glucocorticoid receptor, has low affinity for mineralocorticoids.[232–234] Classic glucocorticoid action involves binding of the steroid-receptor complex to regulator sequences in the genome. Type I receptors are saturated by basal levels of glucocorticoids, whereas type II receptors are not saturated under basal conditions but approach saturation during peak phases of the circadian rhythm and during stress. These differences and differences in regional distribution within the brain suggest that type I receptors determine basal activity of the hypothalamic-pituitary axis and that type II receptors mediate stress responses.[237]

In the pituitary, glucocorticoids inhibit secretion of ACTH by inhibiting CRH binding to pituitary cells and reducing cAMP and the synthesis of POMC mRNA; in the hypothalamus they inhibit secretion of CRH and AVP and the synthesis of their respective mRNAs, although with distinct temporal patterns.[233,234,238] The latency of the inhibitory effect is so short (<30 minutes) that it is likely that gene regulation is not the sole basis of the response.[239] However, long-term suppression (>1 hour) clearly acts through genomic mechanisms. Glucocorticoids can also exert additional rapid signaling on hypophysiotropic CRH neurons via an endocannabinoid-mediated suppression of synaptic excitation.[240] These events involve the action of glucocorticoids on a membrane-associated receptor to mobilize endocannabinoids (2-arachidonoylglycerol [2-AG] and N-arachidonoylethanolamine [AEA]) from CRH neurons that act through a cannabinoid receptor (CB1R) to inhibit the release of glutamate from neurons synapsing on hypophysiotropic CRH neurons.[241] In addition, glucocorticoid-mediated inhibition of hypophysiotropic CRH activity can occur at other loci within the brain, such as the hippocampus, prefrontal cortex, and NTS, to inhibit CRH neurons directly or through multisynaptic pathways (see "Neural Control"), perhaps of greatest importance in regulation of the HPA stress response (reviewed in Keller-Wood[235] and Herman and colleagues[236]). Lesioning or selective deletion of glucocorticoid receptors in these regions is

associated with increased activity of hypophysiotropic CRH neurons and the HPA axis[242,243] (see "Neural Control").

Neural Control

Significant physiologic or psychologic stressors evoke an adaptive response that commonly includes activation of both the HPA axis and the sympathoadrenal axis. The end products of these pathways then help to mobilize resources to cope with the physiologic demands in emergency situations, acutely through the fight-or-flight response and over the long term through systemic effects of glucocorticoids on functions such as gluconeogenesis and energy mobilization. The HPA axis also has unique stress-specific homeostatic roles, the best example being the role of glucocorticoids in downregulating immune responses after infection and other events that stimulate cytokine production by the immune system.

The PVH is the primary hypothalamic nucleus responsible for providing the integrated whole-animal response to stress.[238,244,245] This nucleus contains within it three major types of effector neurons that are spatially distinct from one another: magnicellular oxytocin and AVP neurons that project to the posterior pituitary and participate in the regulation of blood pressure, fluid homeostasis, lactation, and parturition; neurons projecting to the brainstem and spinal cord that regulate a variety of autonomic responses, including sympathoadrenal activation; and parvicellular CRH neurons that project to the median eminence and regulate ACTH synthesis and release. However, approximately 50% of CRH neurons coexpress AVP, which acts synergistically with CRH by activating the V1b receptor subtype on corticotrophs. AVP is regulated quite differently in parvicellular versus magnicellular neurons but is also regulated somewhat differently from CRH by stressors in parvicellular cells that express both peptides.[238] Different stressors result in different patterns of activation of the three major visceromotor cell groups within the PVH, as measured by the general neuronal activation marker c-Fos and nerve growth factor 1B (NGF1B) (Fig. 7.16). For example, salt loading downregulates CRH mRNA in parvicellular CRH cells and upregulates CRH in a small number of magnicellular CRH cells, but consistently activates magnicellular cells. Hemorrhage activates every division of the PVH, whereas cytokine administration primarily activates parvicellular CRH cells with some minor activation of magnicellular and autonomic divisions.

The synthesis and release of AVP, which regulates renal water absorption and vascular smooth muscle, are controlled mainly by the volume and tonicity of the blood. This information is relayed to the magnicellular AVP cell through the NTS and A1 noradrenergic cell group of the ventrolateral medulla and projections from a triad of CVOs lining the third ventricle, the SFO, the medial preoptic nucleus (MePO), and OVLT. Oxytocin is primarily involved in reproductive functions, such as parturition, lactation, and milk ejection, although it is cosecreted with AVP in response to osmotic and volume challenges, and oxytocin cells receive direct projections from the NTS as well as from the SFO, MePO, and OVLT. In contrast to the neurosecretory neurons functionally defined by the three peptides, CRH, oxytocin, and AVP, PVH neurons projecting to the brainstem and spinal cord include neurons expressing each of these peptides.

In the rodent, a wide variety of stressors has been determined to activate parvicellular CRH neurons, including cytokine injection, salt loading, hemorrhage, adrenalectomy, restraint, foot shock, hypoglycemia, fasting, and ether exposure. In contrast to the relative simplicity of inputs to magnicellular cells (Fig. 7.17A), as noted previously, parvicellular CRH neurons receive a diverse and complex assortment of inputs (Fig. 7.18; also see Fig. 7.17B). These inputs are divided into three major categories: brainstem, limbic forebrain, and hypothalamus. Because the PVH is not known to receive any direct projections from the cerebral cortex or thalamus, stressors involving emotional or cognitive processing must involve indirect relay to the PVH.

Visceral sensory input to the PVH involves primarily two pathways. The NTS, the primary recipient of sensory information from the thoracic and abdominal viscera via the vagus and glossopharyngeal nerves, sends dense catecholaminergic projections to the PVH from A2 noradrenergic and C2 adrenergic cell groups, both directly and through relays in the ventrolateral medulla. These brainstem projections also account for about half of the NPY fibers present in the PVH and contain other peptides such as glucagon-like peptide 1 and activin.[246,247] In a similar fashion, increased secretion of glucocorticoids in response to infection or inflammation is due to activation of catecholaminergic nerves in the NTS and ventrolateral medulla mediated by endotoxin and proinflammatory cytokines.[245] If the ascending catecholamine pathway to the PVN is transected, the ability of IL-1 to increase CRH mRNA in PVH neurons is reduced.[248] It is proposed that IL-1 exerts its effect on endothelial cells and/or perivascular microglia at the blood-brain interface, resulting in activation of cyclooxygenase-2, the release of prostaglandin E_2 into surrounding tissue, and ultimately activation of catecholaminergic neurons through prostaglandin receptors.[249] In addition, cytokines may act directly on vascular endothelial cells in the PVH to promote prostaglandin synthesis and activation of CRH neurons via EP3 receptors.[250] A second major input responsible for transducing signals from blood-borne substances derives from three CVOs adjacent to the third ventricle, the SFO, OVLT, and ME. Collectively, these pathways account for activation of CRH neurons by what are referred to as *systemic* or *physiologic stressors* such as systemic inflammation, blood loss, hypoxia, or disorders of fluid and electrolyte balance.[245]

By contrast, what are termed *neurogenic*, *emotional*, or *psychologic* stressors involve, in addition, nociceptive or somatosensory pathways as well as cognitive and affective brain centers. Using elevation of c-Fos as an indicator of neuronal activation, detailed studies have compared PVH-projecting neurons activated by IL-1 treatment (systemic stressor) versus foot shock (neurogenic stressor).[245] Only catecholaminergic solitary tract nucleus and ventrolateral medulla neurons were activated by moderate doses of IL-1. In contrast, foot shock activated not only neurons of the NTS and ventrolateral medulla but also cell groups in the limbic forebrain and hypothalamus. Notably, pharmacologic or mechanical disruption of the ascending catecholaminergic fibers blocked IL-1–mediated activation but not foot shock–mediated activation of the HPA axis.[244,245] Thus, while the end result to increase circulating levels of glucocorticoids is similar in all stress paradigms, depending upon the type of stress, different regions of the brain are recruited to allow activation of the hypophysiotropic CRH neurons.

Except for the catecholaminergic neurons of the NTS and ventrolateral medulla, parts of the BNST, and the dorsomedial nucleus of the hypothalamus, many inputs to the PVH, such as those deriving from the prefrontal cortex and lateral septum, are thought to act indirectly through local hypothalamic glutamatergic[251] and GABAergic neurons[252] with direct synapses to the CRH neurons. The BNST is the only limbic region with prominent direct projections to the PVH. With substantial projections

from the amygdala, hippocampus, and septal nuclei, it may thus serve as a key integrative center for transmission of limbic information to the PVH.[244]

Inflammation and Cytokines

Stimulation of the immune system by foreign pathogens leads to a stereotyped set of responses orchestrated by the CNS. This constellation of stereotyped responses results from the complex interaction of the immune system and the CNS. They are mediated in large part by the hypothalamus and include coordinated autonomic, endocrine, and behavioral components with adaptive consequences to restore homeostasis. It is now clear that cytokines produced by peripheral circulating cells of the immune system and central glial cells mediate the CNS responses. Early evidence supporting this hypothesis was provided by the seminal observations that cytokines such as IL-1β can activate the HPA axis.[253–255] The resultant glucocorticoid secretion acts as a classic negative feedback to the immune system to dampen its response.

In general, glucocorticoids inhibit most limbs of the immune response, including lymphocyte proliferation, production of immunoglobulins, cytokines, and cytotoxicity. These inhibitory reactions form the basis of the anti-inflammatory actions of glucocorticoids.

Glucocorticoid feedback on immune responses is regulatory and beneficial because loss of this function makes animals with adrenal insufficiency vulnerable to inflammation. However, this feedback response can have pathophysiologic consequences, as chronic activation of the HPA axis can certainly be detrimental.[234,256] Indeed, prolonged exposure to elevated glucocorticoids is injurious to pyramidal neurons, and it is well established that chronic stress can lead to immunosuppression. The fact that products of inflammation such as IL-1β can activate the HPA axis suggests the operation of a negative feedback control loop to regulate the intensity of inflammation. The role of the hypothalamus in regulating pituitary-adrenal function is an excellent example of neuroimmunomodulation. Proposed models to explain how immune system signals might act upon the CNS to modulate homeostatic circuits by the integration of vagal input, peripheral cytokine interactions with receptors in the CVOs and cerebral blood vessels, and local production of cytokines within the CNS are explored in Chapter 39.

Other Factors Influencing Secretion of Corticotropin

Circadian Rhythms

In humans, levels of ACTH and cortisol peak in the early morning, drop during the day to reach a nadir at about midnight, and begin to rise between 1 AM and 4 AM (see Fig. 7.7). Within the circadian cycle approximately 15 to 18 pulses of ACTH can be discerned, their height varying with the time of day.[257] The set-point of feedback control by glucocorticoids also varies in a circadian pattern. Pituitary-adrenal rhythms are entrained to the light-dark cycle and can be changed over several days by exposure to an altered light schedule. It has long been assumed that the rhythm of ACTH secretion is driven by CRH rhythms, and CRH knockout mice were found to exhibit no circadian rhythm in corticosterone production. Remarkably, however, a diurnal rhythm in corticosterone was restored by a constant infusion of CRH to CRH knockout mice,[258] suggesting that CRH is necessary to permit pituitary or adrenal responsiveness to another diurnal rhythm generator.

Opiates

It has been long recognized that opiate analgesia can suppress the HPA axis, with approximately 10% of patients on chronic opiate therapy and 15% of patients receiving opiates intrathecally, developing abnormally low basal cortisol levels and flattened or reduced circadian rhythms of ACTH.[259,260] Profound adrenal insufficiency associated with hypotension and low ACTH and cortisol levels has also been reported.[261] The mechanisms for opioid-induced effects on the HPA axis are likely multifactorial but presumed to be mediated centrally through κ-receptors or δ-receptors, as there is relative insensitivity of the HPA axis to the potent μ-receptor agonist, naloxone.[262,263] Endomorphins injected directly into the hypothalamus acutely inhibit CRH gene expression,[264] but opiates may also act presynaptically on

noradrenergic terminals in the PVN to reduce CRH release.[265] Evidence that morphine inhibits the rise in ACTH to exogenous CRH further suggests an action of opiates on anterior pituitary corticotrophs.[266] It has been proposed that endogenous opiates may function to diminish the impact of the stress response, and during pregnancy, to protect the fetus from glucocorticoid excess.[267,268] Opiate-induced hyperprolactinemia may also contribute to suppression of the HPA axis given that chronic intracerebroventricular (ICV) infusion of antisense oligonucleotides against the prolactin receptor increase the stress-induced ACTH response, presumably by direct effects on CRH neurons or its noradrenergic input.[269]

Growth Hormone–Releasing Hormone

Chemistry and Evolution

Evidence for neural control of GH secretion originated from studies of its regulation in animals with lesions of the hypothalamus and from the demonstration that hypothalamic extracts stimulate the release of GH from the pituitary. When it was shown that GH is released episodically, follows a circadian rhythm, responds rapidly to stress, and is blocked by pituitary stalk section, the concept of neural control of GH secretion became a certainty. However, it was only with the discovery of the paraneoplastic syndrome of ectopic GHRH secretion by pancreatic adenomas in humans that sufficient starting material became available for peptide sequencing and subsequent cloning of a complementary deoxyribonucleic acid (cDNA).[270–272]

Two principal molecular forms of GHRH occur in the human hypothalamus: GHRH(1-44)-NH_2 and GHRH(1-40)-OH (Fig. 7.19).[273] As with other neuropeptides, the various forms of GHRH arise from post-translational modification of a larger prohormone.[270] The NH_2-terminal tyrosine of GHRH (or histidine in rodent GHRHs) is essential for bioactivity, but a COOH-terminal NH_2 group is not. A circulating type IV dipeptidyl peptidase potently inactivates GHRH to its principal and more stable metabolite, GHRH(3-44)-NH_2,[274] which accounts for most of the immunoreactive peptide detected in plasma. As in the case of GnRH, there are species differences among GHRHs; the peptides from seven species range in sequence homology with the human peptide from 93% in the pig to 67% in the rat.[273] The COOH-terminal end of GHRH exhibits the most sequence diversity among species, consistent with the exon arrangement of the gene and dispensability of these residues for GHRH receptor binding.

Despite its importance for the elucidation of GHRH structure, ectopic secretion of the peptide is a rare cause of acromegaly.[275] Fewer than 1% of acromegalic patients have elevated plasma levels of GHRH (see Chapters 8 and 9). Approximately 20% of pancreatic adenomas and 5% of carcinoid tumors contain immunoreactive GHRH, but most are clinically silent.[276]

In addition to expression in the hypothalamus, the *GHRH* gene is expressed eutopically in the human ovary, uterus, and placenta,[277] although its function in these tissues is not known. Studies in rat placenta indicate that an alternative transcriptional start site 10 kilobases upstream from the hypothalamic promoter is utilized together with an alternatively spliced exon 1a.[278]

Growth Hormone–Releasing Hormone Receptor

The GHRH receptor is a member of a subfamily of GPCRs that includes receptors for VIP, pituitary adenylyl cyclase–activating peptide, secretin, glucagon, glucagon-like peptide 1, calcitonin, parathyroid hormone or parathyroid hormone–related peptide, and gastric inhibitory polypeptide.[279] GHRH elevates intracellular cAMP by its receptor coupling to a G_s, which activates adenylyl cyclase, increases intracellular free Ca^{2+}, releases preformed GH, and stimulates GH mRNA transcription and new GH synthesis.[280] GHRH also increases pituitary phosphatidylinositol turnover. Nonsense mutations in the human GHRH receptor gene are the cause of rare familial forms of GH deficiency[281] and indicate that no other gene product can fully compensate for the specific receptor in the pituitary.

Effects on the Pituitary and Mechanism of Action

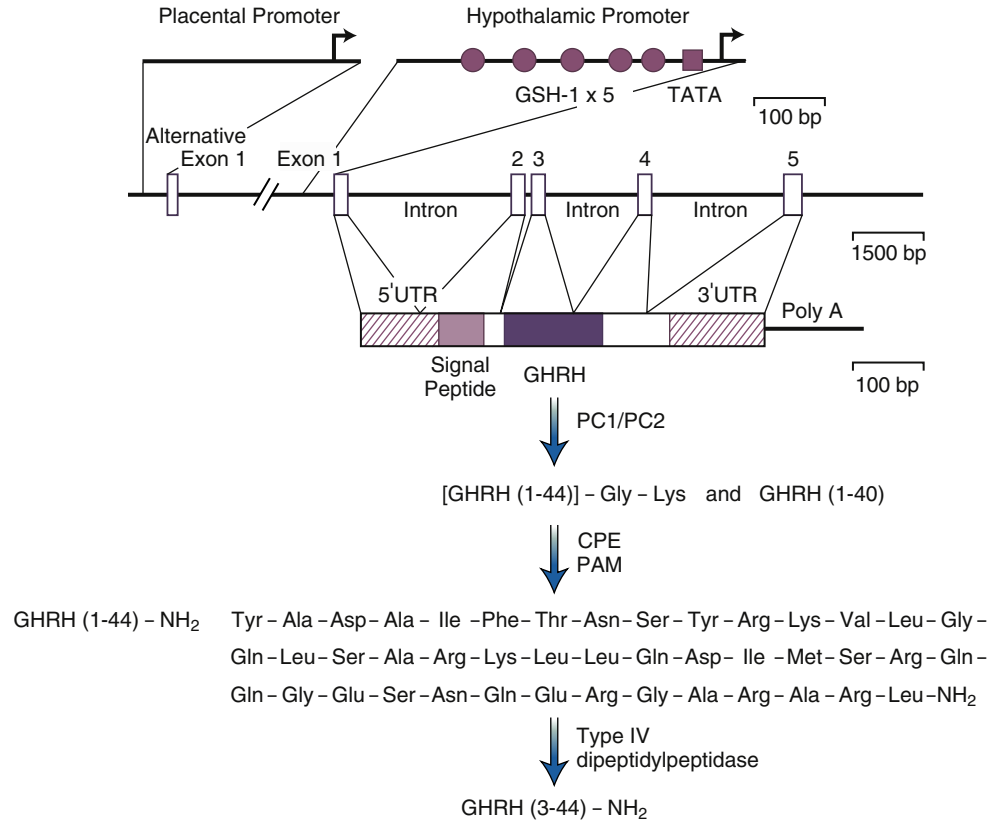
Intravenous administration of GHRH to individuals with normal pituitaries causes a prompt, dose-related increase in serum GH that peaks after 15 to 45 minutes, followed by a return to basal levels by 90 to 120 minutes (Fig. 7.20).[282] A maximally stimulating dose of GHRH is approximately 1 μg/kg, but the response differs considerably among individuals and within the same individual tested on different occasions, presumably because of endogenous cosecretagogue and somatostatin tone that exist at the time of GHRH injection. Repeated bolus administration or sustained infusions of GHRH over several hours cause a modest decrease in the subsequent GH secretory response to acute GHRH administration. However, unlike the marked desensitization of the GnRH receptor and decline in circulating gonadotropins that occur in response to continuous GnRH exposure, pulsatile GH secretion and insulin-like growth factor 1 (IGF-1) production are maintained by constant GHRH in the human.[282] This response suggests the involvement of additional factors that mediate the intrinsic diurnal rhythm of GH, and these factors are addressed in the following sections.

The pituitary effects of a single injection of GHRH are almost completely specific for GH secretion, and there is minimal evidence for any interaction between GHRH and the other classic hypophysiotropic-releasing hormones.[282] GHRH has no effect on gut peptide hormone secretion. The GH secretory response to GHRH is enhanced by estrogen administration, ghrelin, glucocorticoids, and starvation. Major factors known to blunt the response to GHRH are somatostatin, obesity, hyperinsulinemia, hyperglycemia, and advancing age. (For review see Steyn and colleagues[283].)

In addition to its role as a GH secretagogue, GHRH is a physiologically relevant growth factor for somatotrophs. Transgenic mice expressing a GHRH cDNA coupled to a suitable promoter developed diffuse somatotroph hyperplasia and eventually pituitary macroadenomas.[284] The intracellular signal transduction pathways mediating the mitogenic action of GHRH are not known with certainty but probably involve an elevation of adenylyl cyclase activity. Several lines of evidence support this conclusion, including the association of activating mutations of the $G_s\alpha$ polypeptide in many human somatotroph adenomas.[285]

Extrapituitary Functions

GHRH has few known extrapituitary functions. The most important may be its activity as a sleep regulator. The administration of nocturnal GHRH boluses to normal men significantly increases the density of slow-wave sleep and promotes nonrapid eye movement sleep,[286,287] mediated by GABAergic neurons in the preoptic nucleus and independent of GH.[286] Furthermore, there is a striking correlation between the age-related declines in slow-wave sleep and daily integrated GH secretion in healthy men.[288] These and other data suggest that central GHRH secretion is under circadian



• **Fig. 7.19** Diagram illustrating the genomic organization, messenger RNA structure, and post-translational processing of the human growth hormone–releasing hormone (GHRH) prohormone. Five GSH-1 homeodomain transcription factor–binding sites in the proximal promoter have been characterized in the rat gene. All of the amino acid residues required for bioactive GHRH peptides are encoded by exon 3. entrainment, and nocturnal elevations in GHRH pulse amplitude or frequency directly mediate sleep stage and sleep-induced increases in GH secretion.

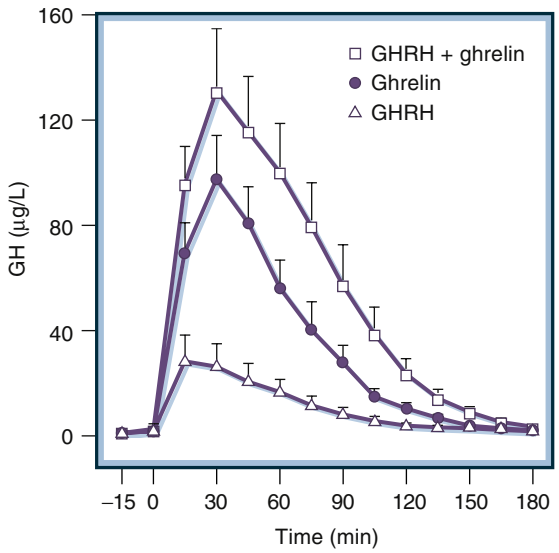
GHRH has been reported to stimulate food intake in rats and sheep, but the effect is dependent on route of administration, time of administration, and macronutrient composition of the diet.[279] The neuropeptide's physiologic relevance to feeding in humans is unknown. Evidence suggests that nonpituitary GHRH modulates cell proliferation and promotes the healing of skin wounds.[289]

Growth Hormone–Releasing Peptides

In studies of the opioid control of GH secretion, several peptide analogues of met-enkephalin were found to be potent GH secretagogues (GHS). These include the GH-releasing peptide GHRP-6 (Fig. 7.21), hexarelin (His-D2MeTrp-Ala-Trp-DPhe-Lys-NH_2), and other more potent analogues, including cyclic peptides and modified pentapeptides.[279,290] Subsequently, a series of nonpeptidyl GHRP mimetics were synthesized with greater oral bioavailability, including the spiropiperidine MK-0677 and the shorter acting benzylpiperidine L-163,540 (see Fig. 7.21). Common to all these compounds, and the basis of their differentiation from GHRH analogues in pharmacologic activity screens, is their activation of phospholipase C and inositol 1,4,5-trisphosphate. This property was exploited in a cloning strategy that led to the identification of a novel GPCR GHS receptor that is highly selective for the GHS class of ligands.[291] The GHS-R is unrelated to the GHRH receptor and is highly expressed in the anterior pituitary gland and multiple brain areas, including GHRH neurons in the medial basal hypothalamus, suggesting both direct and indirect effects on GH secretion.[292,293]

Peptidyl and nonpeptidyl GHSs are active when administered by intranasal and oral routes, are more potent on a weight basis than GHRH itself, are more effective in vivo than in vitro, synergize with coadministered GHRH, and are almost ineffective in the absence of GHRH.[279,282] Prolonged infusions of GHRP amplify pulsatile GH secretion in normal men. GHRP administration,



• **Fig. 7.20** Response of normal men to growth hormone–releasing hormone (GHRH)(1-29) (1 μg/kg), ghrelin (1 μg/kg), or the combination of GHRH(1-29) and ghrelin administered by intravenous injection. Note the prompt release of GH, followed by a rather prolonged fall in hormone level in response to both secretagogues. Ghrelin alone was more efficacious than GHRH(1-29), and there was an additive effect from the two peptides administered simultaneously. (From Arvat E, Macario M, Di Vito L, et al. Endocrine activities of ghrelin, a natural growth hormone secretagogue [GHS], in humans: comparison and interactions with hexarelin, a nonnatural peptidyl GHS, and GH-releasing hormone. *J Clin Endocrinol Metab.* 2001;86:1169–1174.)

like that of GHRH, facilitates slow-wave sleep. Patients with hypothalamic disease leading to GHRH deficiency have low or no response to hexarelin; similarly, pediatric patients with complete absence of the pituitary stalk have no GH secretory response to hexarelin.[294]

The potent biologic effects of GHRPs and the identification of the GHS-R suggested the existence of a natural ligand for the receptor that is involved in the physiologic regulation of GH secretion. The 28–amino acid peptide, ghrelin, produced and secreted into the circulation from the stomach, is this ligand (Fig. 7.22).[15] The effects of ghrelin on GH secretion in humans are identical to or more potent than those of the nonnatural GHRPs (see Fig. 7.20).[295] In addition, ghrelin acutely increases circulating PRL, ACTH, cortisol, and aldosterone levels.[295] There is debate concerning the extent and localization of ghrelin expression in the brain that must be resolved before the implications of gastric-derived ghrelin in the regulation of pituitary hormone secretion are fully understood. Furthermore, post-translational processing of pro-ghrelin gives rise to a second neuropeptide, obestatin, which may also have functional roles in activity of the GH/IGF-1 axis and metabolism.[296] A proposed role for ghrelin and obestatin peptides in appetite and the regulation of food intake is discussed in Chapter 39. It is of particular interest that although GH secretory bursts are smaller in ghrelin knockout mice, they show little differences in weight and body length compared to normal controls, raising the possibility that ghrelin's main function on GH secretion is to maintain blood glucose levels during caloric restriction.[283]

Clinical Applications

GHRH stimulates growth in children with intact pituitaries, but the optimal dosage, route, and frequency of administration, as well as possible usefulness by the nasal route, have not been determined. The availability of recombinant hGH (which requires less frequent injections than GHRH) and the development of the more potent GHSs with improved oral bioavailability have reduced enthusiasm for the clinical use of GHRH or its analogues. GHRH can be used to test for GH deficiency in adults, particularly when combined with arginine to improve diagnostic accuracy of the test; is not influenced by age, sex, or body mass index; and has a wider margin of safety than an insulin tolerance test.[297]

The potential clinical applications of GHSs are still being explored.[279,290] An area of intense interest is the normal, progressive decline in GH secretion with aging and its association with frailty, decreased muscle mass, central adiposity, cardiovascular morbidities, and increased fractures associated with somatopause. GH administration in healthy older individuals has been associated with increased lean body mass, increased muscle strength, and decreased fat mass, although there is a high incidence of adverse side effects, including edema, hypertension, carpal tunnel syndrome, and hyperglycemia. One must also take into consideration that animal models with growth hormone or IGF-1 deficiency tend to be associated with longevity and reduced cancer risk,[298–300] and this may also hold true for human longevity and slowing of the aging process.[301,302] Both GHRH and GHSs are also being investigated for the treatment of sleep disorders commonly associated with aging.

Neuroendocrine Regulation of Growth Hormone Secretion

GH secretion is regulated by two major hypothalamic peptides, GHRH that stimulates the release of GH and somatostatin that inhibits GH secretion, functioning in concert to give rise to the rhythmic 10 to 20 pulses of GH per 24 hours, depending upon the animal species. GHRH neurons are located in the arcuate nucleus or infundibular nucleus, whereas perikarya of the somatostatin neurons involved in GH regulation are located in the hypothalamic periventricular nucleus.[303] It is presumed that GH pulses are primarily driven by somatostatin, whereas the amplitude of the GH pulses is driven by GHRH.[304,305] However, other circulating hormones and additional modulatory peptides at the level of both the pituitary and the hypothalamus also contribute to the fine-tuning of GH secretion (see Fig. 7.22).[279,282,296,306–308] Additional background on somatostatin and its functions other than control of GH secretion are presented in "Somatostatin."

Feedback Control

Feedback control of GH secretion is regulated at both the pituitary and hypothalamus. GH release is mediated by negative feedback of GH, itself, and by IGF-1, the latter being synthesized in the liver and other tissues under the control of GH. Somatotrophs express GH receptors, and in cell culture their secretion is inhibited by the exogenous administration of GH.[309,310] IGF-1 also has a direct, major, inhibitory action on GH secretion as demonstrated by a rise in circulating GH levels when the IGF-1 receptor is selectively deleted from somatotrophs.[311] In addition, gene expression of both GH and the pituitary-specific transcription factor PIT1 is inhibited by IGF-1.[279]

GH also crosses the blood-brain barrier to feedback on the hypothalamus to regulate GH secretion, primarily by increasing somatostatin secretion into the portal capillary system. Indeed, the inhibitory effects of GH are abolished in knockout mice lacking somatostatin receptors (Fig. 7.23). As noted earlier, tuberoinfundibular somatostatin neurons are located in the hypothalamic periventricular nucleus and express GH receptors. GH receptors are also expressed by the majority of NPY neurons in the hypothalamic arcuate nucleus that show c-Fos expression in response to GH administration and are known to innervate somatostatin neurons in the periventricular nucleus.[312,313] In contrast to somatostatin neurons, however, only a small percentage of GHRH-producing neurons in the hypothalamus express GH receptors.[313] Thus, together with data from many other experiments, these results strongly support a model of GH negative feedback regulation that involves the activation of periventricular somatostatin neurons by GH using both direct and indirect (NPY) pathways. Similarly, in normal men, GH pretreatment blocks the subsequent GH secretory response to GHRH by a mechanism that is dependent on somatostatin.[314]

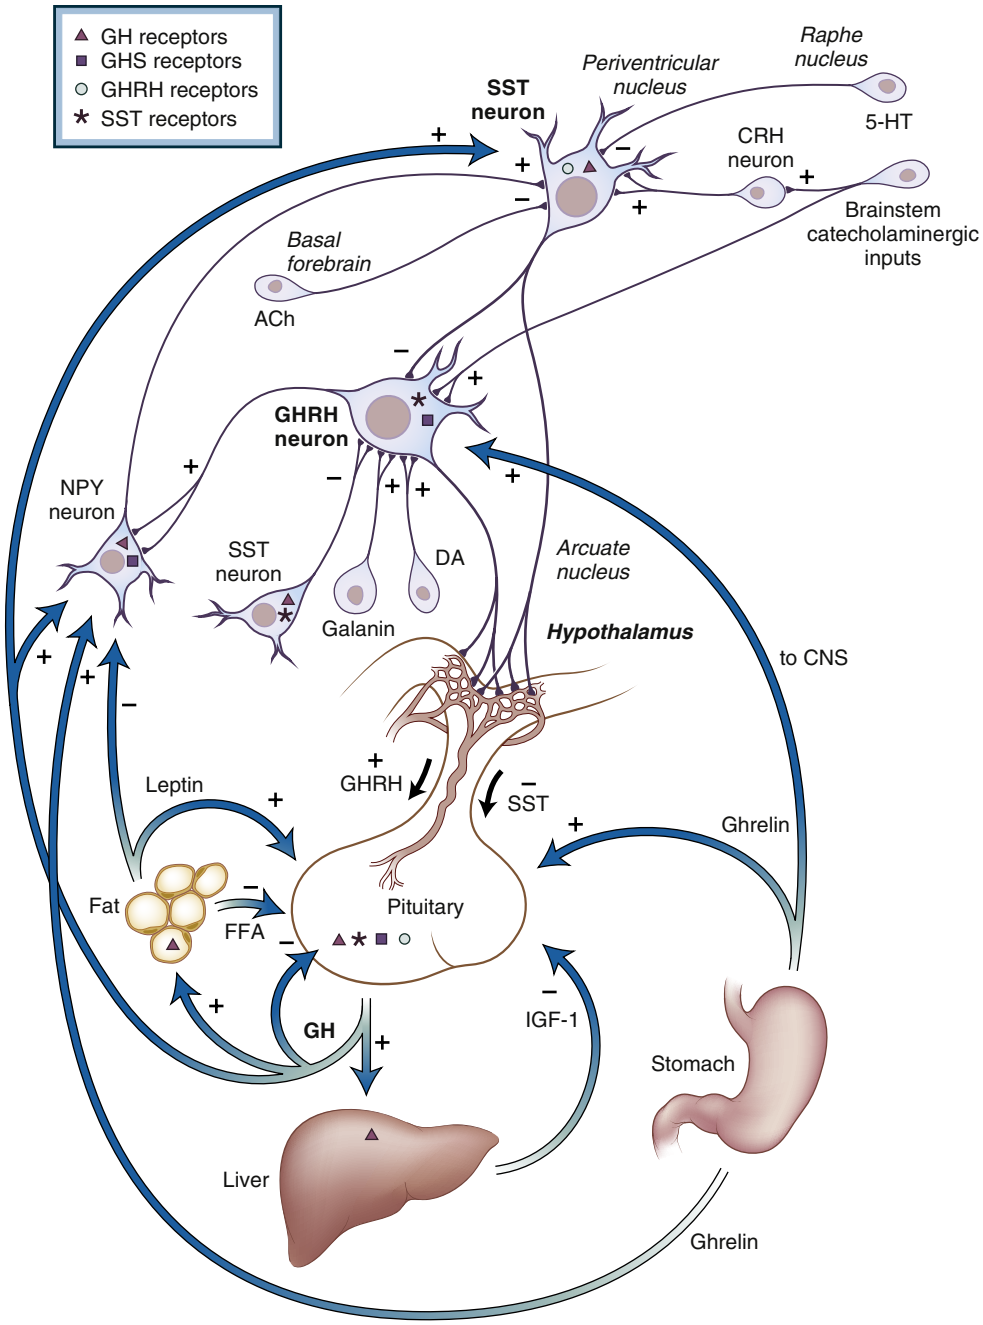
IGF-1 also has central effects to inhibit GH secretion that involves both an increase in somatostatin and a reduction in GHRH.[315] The feedback effects of IGF-1 account for the fact that serum GH levels are elevated in conditions in which circulating levels of IGF-1 are low, such as anorexia nervosa, protein-calorie starvation,[316] and Laron dwarfism (the result of a defect in the GH receptor).

GHRH and somatostatin also contribute to the pulsatile release of GH by exerting short-loop feedback effects on each other through bidirectional interactions.[317] Treatment of hypothalamic cultures with somatostatin inhibits GHRH, whereas treatment with GHRH induces somatostatin release.[318,319] In the human brain, however, there are very few GHRH contacts on somatostatin neurons, although the vast majority of GHRH neurons receive somatostatin contacts.[320] The feedback effects of GHRH on somatostatin neurons, however, may be indirect via arcuate nucleus NPY neurons (as described previously) that receive projections from GHRH neurons.[321] Evidence for extensive interactions among GHRH neurons in the human brain have also been observed and may be responsible for synchronizing their activity.[322]

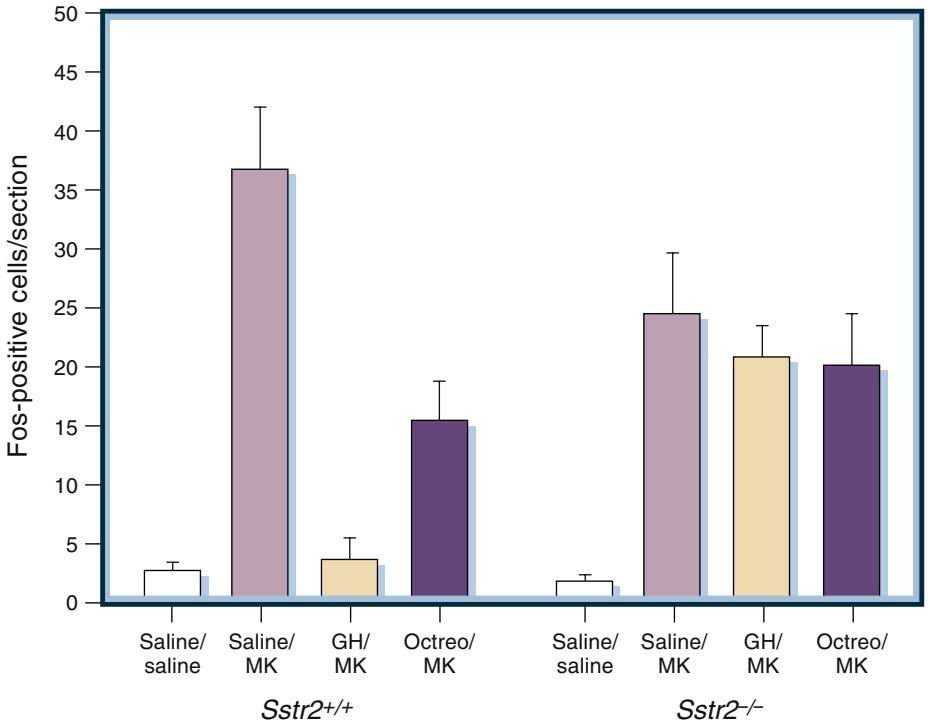
As mentioned previously, ghrelin receptors are highly expressed on somatotrophs in the anterior pituitary and in the hypothalamus, indicating both direct and indirect effects on GH secretion. When acylated with an eight-carbon fatty acid, ghrelin stimulates GHRH from hypothalamic explants, increases the firing rate of GHRH neurons, and when administered continuously, amplifies GH pulsatility.[323–325] The effect of ghrelin to increase GH secretion seems unaffected by the inhibitory effects of somatostatin, and in sheep, ghrelin also prevents the release of somatostatin into the portal capillary system, contributing to enhanced GH release.[326] Evidence for a gastro-hypophysial feedback loop has also been given as ghrelin levels fall in response to rising levels of GH.[327]

Neural Control

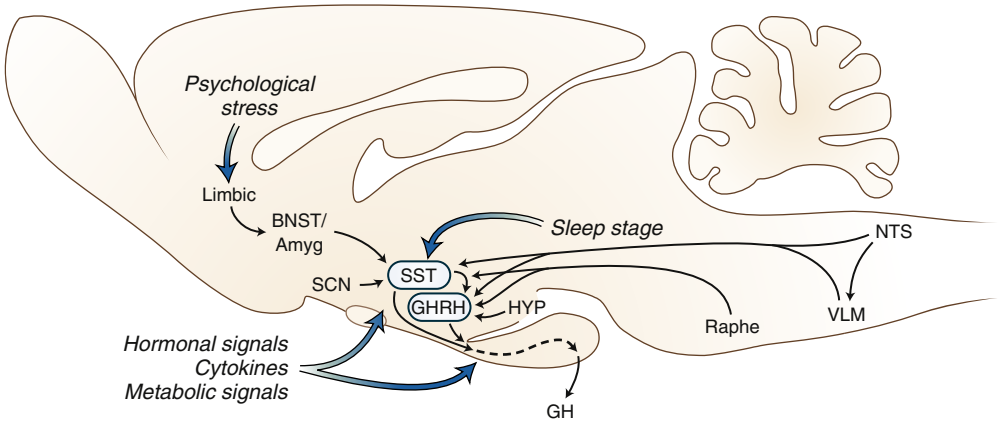
In addition to the regulatory mechanisms already described, multiple extrahypothalamic brain regions provide efferent connections to the hypothalamus and regulate GHRH and somatostatin neuronal activity (Fig. 7.24; also see Fig. 7.22). Somatosensory and affective information is integrated and filtered through the amygdaloid complex. The basolateral amygdala provides an excitatory input to the hypothalamus, and the central extended amygdala, which includes the central and medial nuclei of the amygdala together with the BNST, provides a GABAergic inhibitory input. Many intrinsic neurons of the hypothalamus also release GABA,



• **Fig. 7.22** Regulation of the hypothalamic-pituitary-growth hormone (GH) axis. GH secretion by the pituitary is stimulated by GH-releasing hormone (GHRH) and is inhibited by somatostatin (SST). Negative feedback control of GH secretion is exerted at the pituitary level by insulin-like growth factor 1 (IGF-1) and by free fatty acids (FFA). GH itself exerts a short-loop negative feedback through activation of SST neurons in the hypothalamic periventricular nucleus. These SST neurons directly synapse on arcuate GHRH neurons and project axon collaterals to the median eminence. Neuropeptide Y (NPY) neurons in the arcuate nucleus also indirectly modulate GH secretion by integrating peripheral GH, leptin, and ghrelin signals and projecting to periventricular SST neurons. Ghrelin is secreted from the stomach and is a natural ligand for the GH secretagogue (GHS) receptor that stimulates GH secretion at both the hypothalamic and pituitary levels. On the basis of indirect pharmacologic data, it appears that release of GHRH is stimulated by galanin, γ-aminobutyric acid (GABA), α_2-adrenergic, and dopaminergic inputs and inhibited by SST. Secretion of SST is inhibited by muscarinic acetylcholine (ACh) and 5-HT-1D receptor ligands, and increased by β_2-adrenergic stimuli and corticotropin-releasing hormone (CRH). *CNS,* central nervous system; *DA,* dopamine; *5-HT,* serotonin (5-hydroxytryptamine).



• **Fig. 7.23** Somatostatin and the somatostatin receptor 2 subtype are involved in the short-loop inhibitory feedback of growth hormone (GH) on arcuate neurons. Activation of neurons in the arcuate nucleus was determined by the quantification of immunoreactive Fos-positive cells after administration of the growth hormone secretagogue MK-0677 (MK). Preliminary treatment of wild-type mice *(Sstr2$^{+/+}$)* with either GH or the somatostatin analogue octreotide *(Octreo)* significantly attenuated the neuronal activation by MK-0677. In contrast, GH and octreotide had no effect on MK-0677 neuronal activation in somatostatin receptor 2–deficient mice *(Sstr2$^{-/-}$)*. (Adapted from Zheng H, Bailey A, Jian M-H, et al. Somatostatin receptor subtype 2 knockout mice are refractory to growth hormone-negative feedback on arcuate neurons. *Mol Endocrinol.* 1997;11:1709–1717.)



• **Fig. 7.24** Neural pathways involved in growth hormone (GH) regulation. This diagram illustrates the varied pathways by which impulses from the limbic system and brainstem ultimately impinge on the hypothalamic periventricular and arcuate nuclei to regulate GH release by opposing effects of somatostatin (SST) and growth hormone–releasing hormone (GHRH). Psychologic stress modulates hypothalamic function indirectly through the bed nucleus of the stria terminalis (BNST) and amygdalar complex (Amyg). Circadian rhythms are entrained in part by projections from the suprachiasmatic nucleus (SCN). Cortex and subcortical nuclei are involved in complex reciprocal interactions between sleep stage and GHRH release, but the detailed mechanisms are not known. Dopaminergic and histaminergic afferents originate from neurons located in the arcuate and mammillary nuclei, respectively, of the hypothalamus (HYP). Ascending catecholaminergic projections arise in both the nucleus of the tractus solitarius (NTS) and ventral lateral medulla (VLM). Serotoninergic (5-HT) afferents are from the raphe nuclei. In addition to these neural pathways, a variety of peripheral hormonal and metabolic signals and cytokines influence GH secretion by actions within the medial basal hypothalamus and pituitary gland.

often with a peptide cotransmitter. Excitatory cholinergic fibers arise to a small extent from forebrain projection nuclei but mostly from hypothalamic cholinergic interneurons, which densely innervate the external zone of the median eminence. Similarly, the origin of dopaminergic and histaminergic neurons is local with their cell bodies located in the hypothalamic arcuate and tuberomammillary bodies, respectively. Two important ascending pathways to the medial basal hypothalamus regulate GH secretion and originate from serotonergic neurons in the raphe nuclei and adrenergic neurons in the NTS and ventral lateral nucleus of the medulla.

Both GHRH and somatostatin neurons express presynaptic and postsynaptic receptors for multiple neurotransmitters and peptides (Table 7.4). The α_2-adrenoreceptor agonist clonidine reliably stimulates GH release; for this reason, a clonidine test was a standard diagnostic tool in pediatric endocrinology. The stimulatory effect is blocked by the specific α_2-antagonist yohimbine and appears to involve a dual mechanism of action: inhibition of somatostatin neurons and activation of GHRH neurons. In addition, partial attenuation of the effects of clonidine by mixed serotonin 5-HT1 and 5-HT2 antagonists suggests that some of the relevant α_2-receptors are located presynaptically on serotonergic nerve terminals and increase serotonin release. Both norepinephrine and epinephrine play physiologic roles in the adrenergic stimulation of GH secretion. The α_1-agonists have no effect on GH secretion in humans, but β_2-agonists such as salbutamol inhibit GH secretion by stimulating the release of somatostatin from nerve terminals in the median eminence. These effects are blocked by propranolol, a nonspecific β-receptor antagonist. Dopamine generally has a net effect to stimulate GH secretion and may be exerted directly on the pituitary gland[328] and/or GHRH neurons, as in the human brain. Dopamine-containing axonal varicosities heavily abut the majority of GHRH neurons.[329]

Serotonin's effect on GH release in humans is difficult to decipher because of the large number of receptor subtypes. However, clinical studies with the receptor-selective agonist sumatriptan clearly implicates the 5-HT1D receptor subtype in the stimulation of basal GH levels.[330] The drug also potentiates the effect of a maximal dose of GHRH, suggesting the recurring theme of GH disinhibition by inhibition of hypothalamic somatostatin neurons in its mechanism of action. Histaminergic pathways acting through H1 receptors play only a minor, conditional stimulatory role in GH secretion in humans.

Acetylcholine appears to be an important physiologic regulator of GH secretion and may contribute to the rise in GH during sleep.[331] Blockade of muscarinic acetylcholine receptors reduces or abolishes GH secretory responses to GHRH, glucagon and arginine, morphine, and exercise. In contrast, drugs that potentiate cholinergic transmission increase basal GH levels and enhance the GH response to GHRH. In vitro acetylcholine inhibits somatostatin release from hypothalamic fragments, and acetylcholine can act directly on the pituitary to inhibit GH release. There may even be a paracrine cholinergic control system within the pituitary. However, the sum of evidence suggests that the primary mechanism of action of M1 agonists is inhibition of somatostatin neuronal activity or the release of peptide from somatostatinergic terminals. Short-term cholinergic blockade with the M1 muscarinic receptor antagonist pirenzepine reduced the GH excess of patients with poorly controlled diabetes mellitus.[332]

Many neuropeptides in addition to GHRH and somatostatin are involved in the modulation of GH secretion in humans (see Table 7.4).[279,282] Among these, the evidence is most compelling for a stimulatory role of galanin acting in the human hypothalamus by a GHRH-dependent mechanism.[333] Many GHRH neurons are immunopositive for galanin as well as neurotensin and tyrosine hydroxylase. Galanin's actions may be explained, in part, by presynaptic facilitation of catecholamine release from nerve terminals and subsequent direct adrenergic

TABLE 7.4 Factors That Change Growth Hormone Secretion in Humans

Physiologic Factors	Hormones and Neurotransmitters	Pathologic Factors
Stimulatory Factors		
Episodic, spontaneous release	Insulin hypoglycemia	Acromegaly
Exercise	2-Deoxyglucose	TRH
Stress	Amino acid infusions	GnRH
Physical	Arginine, lysine	Glucose
Psychologic	Neuropeptides	Arginine
Slow-wave sleep	GHRH	Interleukins 1, 2, 6
Postprandial glucose decline	Ghrelin	Protein depletion
Fasting	Galanin	Starvation
	Opioids (μ-receptors)	Anorexia nervosa
	Melatonin	Renal failure
	Classic neurotransmitters	Liver cirrhosis
	α_2-Adrenergic agonists	Type 1 diabetes mellitus
	β-Adrenergic antagonists	
	M1 cholinergic agonists	
	5-HT1D receptor agonists	
	H1 histamine agonists	
	GABA (basal levels)	
	Dopamine (? D_2 receptor)	
	Estrogen	
	Testosterone	
	Glucocorticoids (acute)	
Inhibitory Factors[a]		
Postprandial hyperglycemia	Glucose infusion	Acromegaly L-Dopa
Elevated free fatty acids	Neuropeptides	D_2 receptor DA agonists
Elevated GH levels	Somatostatin	Phentolamine
Elevated IGF-1 (pituitary)	Calcitonin	Galanin
REM sleep	Neuropeptide Y (NPY[b])	Obesity
Senescence, aging	CRH[b]	Hypothyroidism
	Classic neurotransmitters	Hyperthyroidism
	$\alpha_{1/2}$-Adrenergic antagonists	
	β_2-Adrenergic agonists	
	H1 histamine antagonists	
	Serotonin antagonist	
	Nicotinic cholinergic agonists	
	Glucocorticoids (chronic)	

[a]In many instances, the inhibition can be demonstrated only as a suppression of GH release induced by a pharmacologic stimulus.

[b]The inhibitory actions of NPY and CRH on GH secretion are firmly established in the rodent and are secondary to increased somatostatin tone. Contradictory evidence exists in the human for both peptides, and further studies are required.

stimulation of GHRH release.[334] Opioid peptides also stimulate GH release, probably by disinhibition of GHRH neurons, but under normal circumstances, endogenous opioid tone in the hypothalamus is presumed to be low because opioid antagonists have little acute effect on GH secretion. Studies on the human hypothalamus have indicated that enkephalin, but not endorphin or dynorphin, is the endogenous mediator of opiate action on GHRH neurons.[335]

Other Factors Influencing Secretion of Growth Hormone

Human Growth Hormone Rhythms

The deciphering of rhythmic GH secretion has relied on a combination of technical innovations in sampling and GH assay, and sophisticated mathematical modeling, including deconvolution analysis and the calculation of approximate entropy as a measure of orderliness or regularity in minute-to-minute secretory patterns.[282] At least three distinct categories of GH rhythms, which differ markedly in their time scales, can be considered here.

The daily GH secretion rate varies over two orders of magnitude from a maximum of nearly 2.0 mg/day in late puberty to a minimum of 20 μg/day in older or obese adults. The neonatal period is characterized by markedly amplified GH secretory bursts followed by a prepubertal decade of stable, moderate GH secretion of 200 to 600 μg/day. There is a marked increase in daily GH secretion during puberty that is accompanied by a commensurate rise in plasma IGF-1 to levels that constitute a state of physiologic hypersomatotropism. This pubertal increase in GH secretion is due to increased GH pulse amplitude rather than increased pulse frequency. Although the changes are clearly related to the increases in gonadal steroid hormones and can be mimicked by administration of estrogen or testosterone to hypogonadal children, the underlying neuroendocrine mechanisms are not fully understood. One hypothesis is that decreased sensitivity of the hypothalamic-pituitary axis to negative feedback of GH and IGF-1 leads to increased GHRH release and action, particularly given that IGF-1 levels also increase during puberty.[336] However, young adults have a return of daily GH secretion to prepubertal levels despite continued gonadal steroid elevation, perhaps associated with increased weight gain. The so-called somatopause is defined by an exponential decline in GH secretory rate with a half-life of 7 years, starting in the third decade of life, although more pronounced in men than women until women go through menopause.

GH secretion in young adults exhibits a true circadian rhythm over a 24-hour period, characterized by a greater nocturnal secretory mass that is independent of sleep onset.[337] However, as discussed earlier, GH release is further facilitated when slow-wave sleep coincides with the normal circadian peak. Under basal conditions, GH levels are low most of the time, with an ultradian rhythm of about 10 secretory pulses per 24 hours in men (20 in women) as calculated by deconvolution analysis.[338] Both sexes have an increased pulse frequency during the nighttime hours, but the fraction of total daily GH secretion associated with the nocturnal pulses is much greater in men. Overall, women have more continuous GH secretion and more frequent GH pulses that are of more uniform size than men.[307,338] A complementary study using approximate entropy analysis concluded that the nonpulsatile regularity of GH secretion is also significantly different in men and women.[339] These sexually dimorphic patterns in the human are actually quite similar to those in the rat, although the sex differences are not as extreme in humans.[282,339]

The neuroendocrine basis for sex differences in the ultradian rhythm of GH secretion is not fully understood. Gonadal sex steroids play both an organizational role during development of the hypothalamus and an activational role in the adult, regulating expression of the genes for many of the peptides and receptors central to GH regulation.[279,282] In the human, unlike the rat, the hypothalamic actions of testosterone appear to result predominantly from its aromatization to 17β-estradiol and interaction with estrogen receptors. Hypothalamic somatostatin appears to play a more prominent role in men than in women in the regulation of pulsatile GH secretion, and this difference is postulated to be a key factor in producing the sexual dimorphism.[338,340]

External and Metabolic Signals

The various peripheral signals that modulate GH secretion in humans are summarized in Table 7.4 (also see Figs. 7.22 and 7.24). Of particular importance are factors related to energy intake and metabolism because they provide a common signal between the peripheral tissues and hypothalamic centers regulating nonendocrine homeostatic pathways in addition to the classic hypophysiotropic neurons. It is also in this complex arena that species-specific regulatory responses are particularly prominent, making extrapolations between rodent experimental models and human GH regulation less reliable.[279,282]

Important triggers of GH release include the normal decrease in blood glucose level after intake of a carbohydrate-rich meal, absolute hypoglycemia, exercise, physical and emotional stress, and high intake of protein (mediated by amino acids). Some of the pathologic causes of elevated GH represent extremes of these physiologic signals and include protein-calorie starvation, anorexia nervosa, liver failure, and type 1 diabetes mellitus.[283] A critical concept is that many of these GH triggers work through the same final common mechanism of somatostatin withdrawal and consequent disinhibition of GH secretion. In contrast, postprandial hyperglycemia, glucose infusion, elevated plasma-free fatty acids, type 2 diabetes mellitus (with obesity and insulin resistance), and obesity result in inhibition of GH secretion.[283] The majority of these stimuli are associated with increased insulin secretion, which can exert direct, inhibitory action on somatotrophs through their expression of insulin receptors.[341] The specific role of leptin in modulating GH release is complicated by its multiple sites of action, coexistent secretory environment, and the animal species. For example, while leptin prevents the fasting-induced fall in GH in rodents, it does not affect GH levels in fasting human subjects.[342,343] Similarly, other members of the cytokine family, including IL-1, IL-2, IL-6, and endotoxin, have been inconsistently shown to stimulate GH in humans.

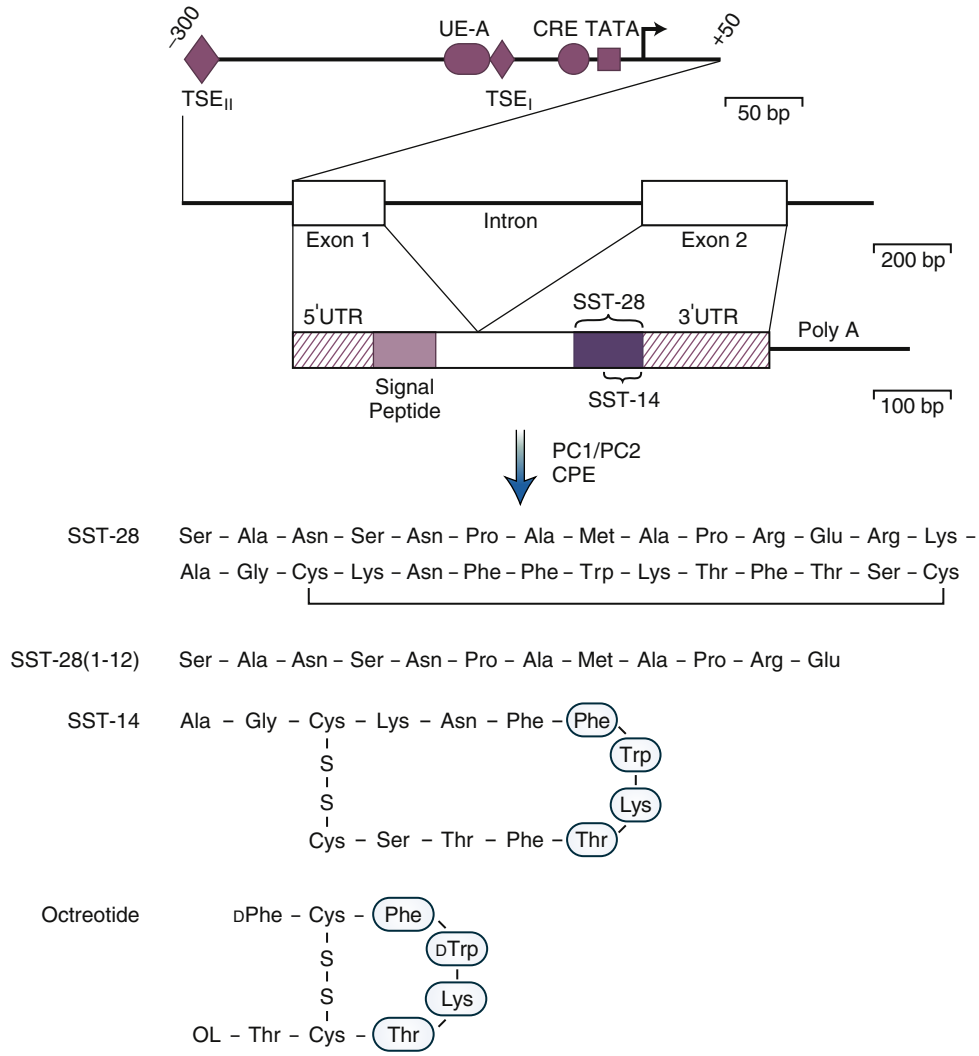
The actions of steroid hormones on GH secretion are complex because of their multiple loci of action within the proximal hypothalamic-pituitary components in addition to secondary effects on other neural and endocrine systems.[344] The acute administration of glucocorticoids results in an increase in GH through direct actions on somatotrophs and by increasing their sensitivity to GHRH.[345,346] High doses or long-term administration of glucocorticoids and individuals with Cushing disease have reduced GH secretion because of increased hypothalamic somatostatin tone and decreased GHRH.[347,348] CRH also has an inhibitory effect on GH secretion both by stimulating somatostatin release and through direct effects on GHRH neurons, contributing to impaired GH secretion associated with stress.[349,350] Similarly, physiologic levels of thyroid hormones are necessary to maintain GH secretion and promote GH gene expression. Excessive thyroid

hormone is also inhibitory to the GH axis, and the mechanism is speculated to be a combination of increased hypothalamic somatostatin tone, GHRH deficiency, and suppressed pituitary GH production.

Somatostatin

Chemistry and Evolution

A factor that potently inhibited GH release from pituitary in vitro was unexpectedly identified during early efforts to isolate GHRH from hypothalamic extracts. Somatostatin, the peptide responsible for this inhibition of GH secretion and the inhibition of insulin secretion by a pancreatic islet extract, was eventually isolated from the hypothalamus and sequenced by Brazeau and colleagues in 1973.[351] The term *somatostatin* was originally applied to a cyclic peptide containing 14 amino acids, also called *somatostatin-14* (SST-14) (Fig. 7.25). Subsequently, a second form, NH_2-terminal extended somatostatin-28 (SST-28), was identified as a secretory product. Both forms of somatostatin are derived by independent cleavage of a common prohormone by prohormone



• **Fig. 7.25** Diagram illustrating the genomic organization, messenger ribonucleic acid (mRNA) structure, and post-translational processing of the human somatostatin (SST) prohormone. Transcriptional regulation of the somatostatin gene, including the identification of tissue-specific elements (TSE), upstream elements (UE), and the cyclic adenosine monophosphate (cAMP) response element (CRE) that are binding sites for specific factors, has been studied extensively in pancreatic islet cell lines. It is not known whether all or some of these factors are also involved in the neural-specific expression of somatostatin. SST-28 and SST-14 are cyclic peptides containing a single covalent disulfide bond between a pair of cystine (Cys) residues. A β-turn containing the tetrapeptide Phe-Trp-Lys-Thr is stabilized by hydrogen bonds to produce the core receptor binding epitope. This minimal structure has been the model for conformationally restrained analogues of somatostatin, including octreotide. *CPE,* carboxypeptidase E; *PC1/PC2,* prohormone convertases 1 and 2; *TATA,* Goldstein-Hogness box involved in binding RNA polymerase; *UTR,* untranslated region. Predicting the biologically active conformations of short polypeptides. *Trends Pharmacol Sci.* 1989;10:70–74.)

convertases.[352] In addition, the isolation of SST-28(1-12) in some tissues suggests that SST-14 can be secondarily processed from SST-28. SST-14 is the predominant form in the brain, including the hypothalamus, whereas SST-28 is the major form in the gastrointestinal tract, especially the duodenum and jejunum.

The name *somatostatin* is descriptively inadequate because the molecule also inhibits TSH secretion from the pituitary and has nonpituitary roles, including activity as a neurotransmitter or neuromodulator in the central and peripheral nervous systems and as a regulatory peptide in gut and pancreas. As a pituitary regulator, somatostatin is a true neurohormone (i.e., a neuronal secretory product that enters the blood [hypothalamic-hypophysial–portal circulation] to affect cell function at remote sites). In the gut, somatostatin is present in the myenteric plexus, where it acts as a neurotransmitter, and in epithelial cells, where it influences the function of adjacent cells as a paracrine secretion. Somatostatin can influence its own secretion from delta cells (an autocrine function) in addition to acting as a paracrine factor in pancreatic islets. Gut exocrine secretion can be modulated by intraluminal action, so it is also a lumone. Because of its wide distribution, broad spectrum of regulatory effects, and evolutionary history, this peptide can be regarded as an archetypical pansystem modulator.

The genes that encode somatostatin in humans[353] (see Fig. 7.25) and a number of other species exhibit striking sequence homology, even in primitive fish such as the anglerfish. Furthermore, the amino acid sequence of SST-14 is identical in all vertebrates. Formerly, it was accepted that all tetrapods have a single gene encoding both SST-14 and SST-28, whereas teleost fish have two nonallelic preprosomatostatin genes (*PPSI* and *PPSII*), each of which encodes only one form of the mature somatostatin peptides. This situation implied that a common ancestral gene underwent a duplication event after the split of teleosts from the descendants of tetrapods.

However, both lampreys and amphibians, which predate and postdate the teleost evolutionary divergence, respectively, have now been shown to have at least two PPS genes.[354] A more distantly related gene has been identified in mammals that encodes cortistatin, a somatostatin-like peptide that is highly expressed in cortex and hippocampus.[355] Cortistatin-14 differs from SST-14 by three amino acid residues but has high affinity for all known subtypes of somatostatin receptors (see later discussion). The human gene sequence predicts a tripeptide-extended cortistatin-17 and a further NH_2-terminal extended cortistatin-29.[356] A revised evolutionary concept of the somatostatin gene family is that a primordial gene underwent duplication at or before the advent of chordates, and the two resulting genes underwent mutation at different rates to produce the distinct preprosomatostatin and preprocortistatin genes in mammals.[354] A second gene duplication probably occurred in teleosts to generate *PPSI* and *PPSII* from the ancestral somatostatin gene.

Apart from its expression in neurons of the periventricular and arcuate hypothalamic nuclei and involvement in GH secretion (discussed earlier), somatostatin is highly expressed in the cortex, lateral septum, extended amygdala, reticular nucleus of the thalamus, hippocampus, and many brainstem nuclei. Cortistatin is present in the brain at a small fraction of the levels of somatostatin and in a more limited distribution primarily confined to the cortex and hippocampus. The molecular mechanisms underlying the developmental and hormonal regulation of somatostatin gene transcription have been most extensively studied in pancreatic islet cells.[357,358] Less is known concerning the regulation of somatostatin gene expression in neurons except that activation is strongly controlled by binding of the phosphorylated transcription factor CRE-binding protein to its cognate CRE contained in the promoter sequence.[359,360] Enhancer elements in the somatostatin gene promoter that bind complexes of homeodomain-containing transcription factors (PAX6, PBX, PREP1) and upregulate gene expression in pancreatic islets may actually represent gene silencer elements in neurons (see Fig. 7.25, promoter elements TSE_{II} and UE-A). Conversely, another related *cis* element in the somatostatin gene (see Fig. 7.25, promoter element TSE_I) apparently binds a homeodomain transcription factor PDX1 (also called STF1/IDX1/IPF1) that is common to developing brain, pancreas, and foregut and regulates gene expression in both the CNS and gut.[361]

The function of somatostatin in GH and TSH regulation is considered earlier in this chapter. Its actions in the extrahypothalamic brain and diagnostic and therapeutic roles are considered in the remainder of this section and in Chapter 8. An additional function of somatostatin in pancreatic islet cell regulation is described in Chapter 33, and the manifestations of somatostatin excess as in somatostatinoma are described in Chapter 45.

Somatostatin Receptors

Five somatostatin receptor subtypes (SSTR1 to SSTR5) have been identified by gene cloning techniques, and one of these (SSTR2) is expressed in two alternatively spliced forms.[362] These subtypes are encoded by separate genes located on different chromosomes; they are expressed in unique or partially overlapping distributions in multiple target organs and differ in their coupling to second-messenger signaling molecules and in their range and mechanism of intracellular actions.[362] The subtypes also differ in their binding affinity to specific somatostatin analogues. Certain of these differences have important implications for the use of somatostatin analogues in therapy and in diagnostic imaging.

All SSTR subtypes are coupled to pertussis toxin–sensitive G proteins and bind SST-14 and SST-28 with high affinity in the low nanomolar range, although SST-28 has a uniquely high affinity for SSTR5. SSTR1 and SSTR2 are the two most abundant subtypes in the brain; they probably function as presynaptic autoreceptors in the hypothalamus and limbic forebrain, respectively, in addition to their postsynaptic actions. SSTR4 is most prominent in the hippocampus. All the subtypes are expressed in the pituitary, but SSTR2 and SSTR5 are the most abundant subtypes on somatotrophs. They are also the most physiologically important in pancreatic islets, with SSTR5 responsible for inhibition of insulin secretion from beta cells and SSTR2 responsible for inhibition of glucagon from alpha cells in mice.[363]

Binding of somatostatin to its receptor leads to activation of one or more plasma membrane–bound inhibitory G proteins ($G_{i/o}$), which in turn inhibit adenylyl cyclase activity and lower intracellular cAMP. Other G protein–mediated actions common to all SSTRs are activation of a vanadate-sensitive phosphotyrosine phosphatase and modulation of mitogen-activated protein kinase (MAPK). Different subsets of SSTRs are also coupled to inwardly rectifying K^+ channels, voltage-dependent Ca^{2+} channels, an Na^+/H^+ exchanger, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-kainate glutamate receptors, phospholipase C, and phospholipase A_2.[362] The lowering of intracellular cAMP and Ca^{2+} is the most important mechanism for inhibition of hormone secretion, and actions on phosphotyrosine phosphatase and MAPK are postulated to play a role in somatostatin's antiproliferative effect on tumor cells.

Effects on Target Tissues and Mechanism of Action

In the pituitary, somatostatin inhibits secretion of GH, TSH, and under certain conditions, PRL and ACTH. It exerts inhibitory effects on virtually all endocrine and exocrine secretions of the pancreas, gut, and gallbladder (Table 7.5). Somatostatin inhibits its secretion by the salivary glands and, under some conditions, the secretion of parathyroid hormone and calcitonin. Somatostatin blocks hormone release in many endocrine-secreting tumors, including insulinomas, glucagonomas, VIPomas, carcinoid tumors, and some gastrinomas.

The physiologic actions of somatostatin in the extrahypothalamic brain remain the subject of investigation.[364] In the striatum, somatostatin increases the release of dopamine from nerve terminals by a glutamate-dependent mechanism. It is widely expressed in GABAergic interneurons of the limbic cortex and hippocampus, where it modulates the excitability of pyramidal neurons. Temporal lobe epilepsy is associated with a marked reduction in somatostatin-expressing neurons in the hippocampus consistent with a putative inhibitory action on seizures.[365] In the amygdala, somatostatin has been associated with learning and expression of defensive responses.[366] A wealth of correlative data has linked reduced forebrain and CSF concentrations of somatostatin with Alzheimer disease, major depression, and other neuropsychiatric disorders, raising speculation about the role of somatostatin in modulating neural circuits underlying cognitive and affective behaviors.[367] A study using both genetic and pharmacologic methods to induce somatostatin deficiency in mice bolsters the hypothesis that the neuropeptide plays a physiologic role in the acquisition of contextual fear memory, possibly by altering long-term potentiation in hippocampal circuits.[368]

Clinical Applications of Somatostatin Analogues

An extensive pharmaceutic discovery program has produced somatostatin analogues with receptor subtype selectivity and improved pharmacokinetics and oral bioavailability compared with the native peptide. Initial efforts focused on the rational design of constrained cyclic peptides that incorporated D-amino acid residues and included the Trp^{9}-Lys^{10} dipeptide of somatostatin, which was shown by structure-function studies to be necessary for high-affinity binding to somatostatin receptors (see Fig. 7.25). Many such analogues have been studied in clinical trials, including octreotide, lanreotide, vapreotide, seglitide, and pasireotide.[362] These compounds are agonists with similarly high-affinity binding to SSTR2 and SSTR5, moderate binding to SSTR3, and no (or low) binding to SSTR1 (except for pasireotide) and SSTR4. A combinatorial chemistry approach has now led to a new generation of nonpeptidyl somatostatin agonists that bind selectively and with subnanomolar affinity to each of the five SSTR subtypes.[369] In contrast to the marked success in development of potent and selective somatostatin agonists, there is a relative paucity of useful antagonists.[370]

The somatostatin analogues have been effective in controlling excess secretion of GH in acromegaly in most patients and in shrinking the tumor size in about one-third of patients. They are also indicated for the treatment of recurrent TSH-secreting adenomas after surgery and a variety of functioning metastatic neuroendocrine tumors, including carcinoid, VIPoma, glucagonoma, and insulinoma, but they are seldom of use for the treatment of gastrinoma.[371] Somatostatin analogues are also useful in the management of many forms of diarrhea (acting on salt and water excretion mechanisms in the gut) and in reducing external secretions in pancreatic fistulas (thus permitting healing). A decrease in blood flow to the gastrointestinal tract is the basis for their use in bleeding esophageal varices, but they are not effective in the treatment of bleeding from a peptic ulcer.

TABLE 7.5 Biologic Actions of Somatostatin Outside the Central Nervous System

Hormone Secretion Inhibited (by Tissue)	Other Gastrointestinal Actions Inhibited
Pituitary gland	Gastric acid secretion
GH, thyrotropin, ACTH, prolactin	Gastric and jejunal fluid secretion
Gastrointestinal tract	Gastric emptying
Gastrin	Pancreatic bicarbonate secretion
Secretin	Pancreatic enzyme secretion
Motilin	Secretory diarrhea (stimulates intestinal absorption of water and electrolytes)
Glucagon-like peptide 1	Gastrointestinal blood flow
Glucose-dependent insulinotropic polypeptide	AVP-stimulated water transport
Vasoactive intestinal peptide	Bile flow
Pancreas	**Extragastrointestinal Actions Inhibited**
Insulin	Inhibits the function of activated immune cells
Glucagon	Inhibition of tumor growth
Somatostatin	
Genitourinary tract	
Renin	

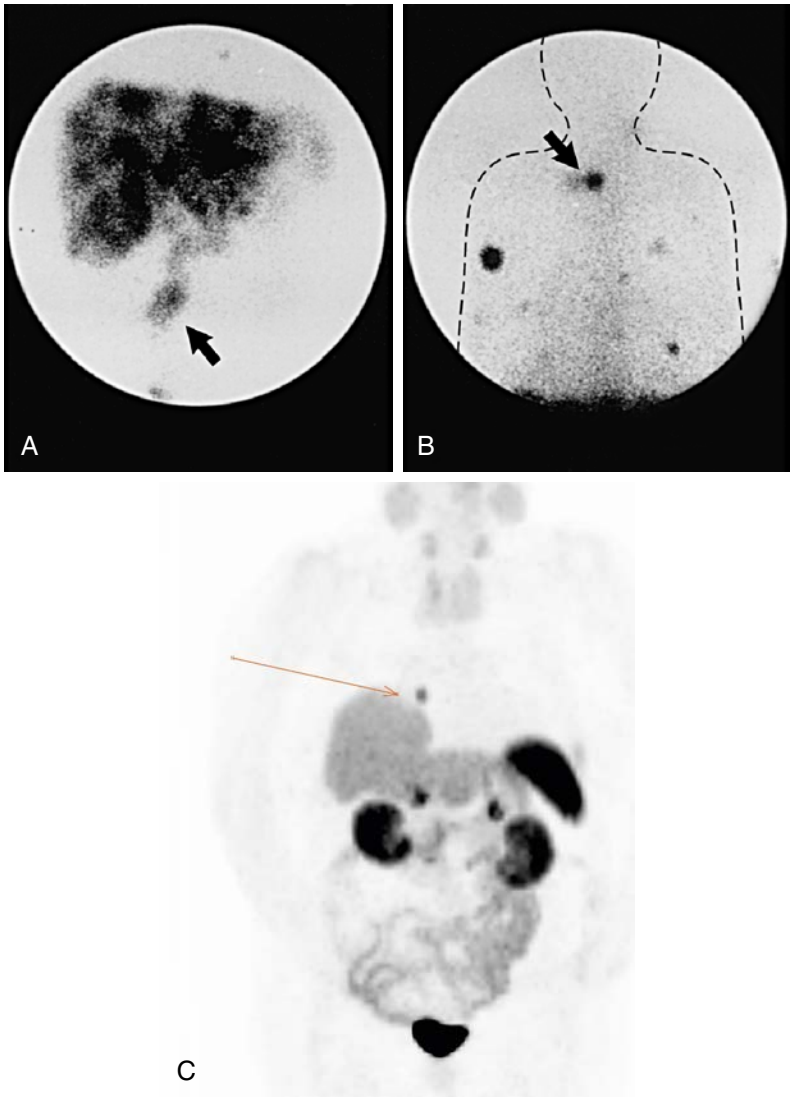
ACTH, Adrenocorticotropic hormone; *AVP,* arginine vasopressin; *GH,* growth hormone.

Somatostatin analogues labeled with a radioactive tracer have been used as external imaging agents for a wide range of disorders,[370,371] including indium-111 (^{111}In)-labeled and gallium-68 (^{68}Ga)-labeled somatostatin analogues, octreotate, DOTATATE, DOTATOC, and DOTANOC (Fig. 7.26). The majority of gastroenteropancreatic neuroendocrine tumors (GEP-NETs) and bronchopulmonary NETs, pheochromocytomas/paragangliomas, medullary thyroid carcinoma, many pituitary tumors, and a variety of nonendocrine tumors that express somatostatin receptors such as breast cancer, renal cell carcinoma, meningioma, and astrocytoma can be visualized by external imaging techniques, using these agents by either scintigraphy or positron emission tomography (PET). Because activated T cells of the immune system display somatostatin receptors, inflammatory lesions such as sarcoidosis, Wegener granulomatosis, and tuberculosis, and many cases of Hodgkin disease and non-Hodgkin lymphoma also take up these radionucleotides.[372]

The ability of somatostatin to inhibit the growth of normal and some neoplastic cell lines and to reduce the growth of experimentally induced tumors in animal models has stimulated interest in somatostatin analogues for the treatment of cancer. Somatostatin's tumoristatic effects may be a combination of direct actions on tumor cells related to inhibition of growth factor receptor expression, inhibition of MAPK, and stimulation of phosphotyrosine phosphatase. Activation of SSTR1, SSTR2, SSTR4, and SSTR5 can all promote cell cycle arrest associated with induction of the tumor suppressor retinoblastoma (Rb) and p21 (CDKN1A), and SSTR3 activation can trigger apoptosis accompanied by induction of the tumor suppressor p53 and the proapoptotic protein Bax.[362] In addition, somatostatin has indirect effects on tumor growth through its inhibition of circulating, paracrine, and autocrine tumor growth–promoting factors, and it can modulate the

activity of immune cells and influence tumor blood supply. Two major studies, PROMID and CLARINET trials, demonstrated that treated patients with neuroendocrine tumors have significantly longer progression-free survival than patients treated with placebo.[373,374] Pasireotide, a novel multireceptor-targeted somatostatin analogue with 40-fold increased binding efficacy to SSTR5, has been effective in approximately one-third of patients with neuroendocrine tumors resistant to octreotide or lanreotide.

A treatment approach using radiolabeled somatostatin analogues has also been used to achieve the arrest of cancer cells.[370,371] The first is receptor-targeted radionuclide therapy using octreotide chelated to a variety of γ-emitting or β-emitting radioisotopes, including [^{90}Y-DOTA^{0},Ty^{3}]octreotide or DOTATATE chelated to lutetium 177. Theoretic calculations and empiric data suggest that radiolabeled somatostatin analogues can deliver a tumoricidal radiotherapeutic dose to tumors expressing somatostatin receptors either by simply binding to the surface receptors or following receptor-mediated endocytosis. Improved progression-free survival with these radionuclides in patients with metastatic GEP-NETs compared to the use of somatostatin analogues alone has been established in the NETTER-1 trial and in a recent, large Dutch cohort.[375,376] A variation on this theme is the chelation of a cytotoxic chemotherapeutic agent, such as doxorubicin, to a somatostatin analogue. An alternative approach involves somatic cell gene therapy to transfect SSTR-negative pancreatic cancer cells with an SSTR gene.[377]

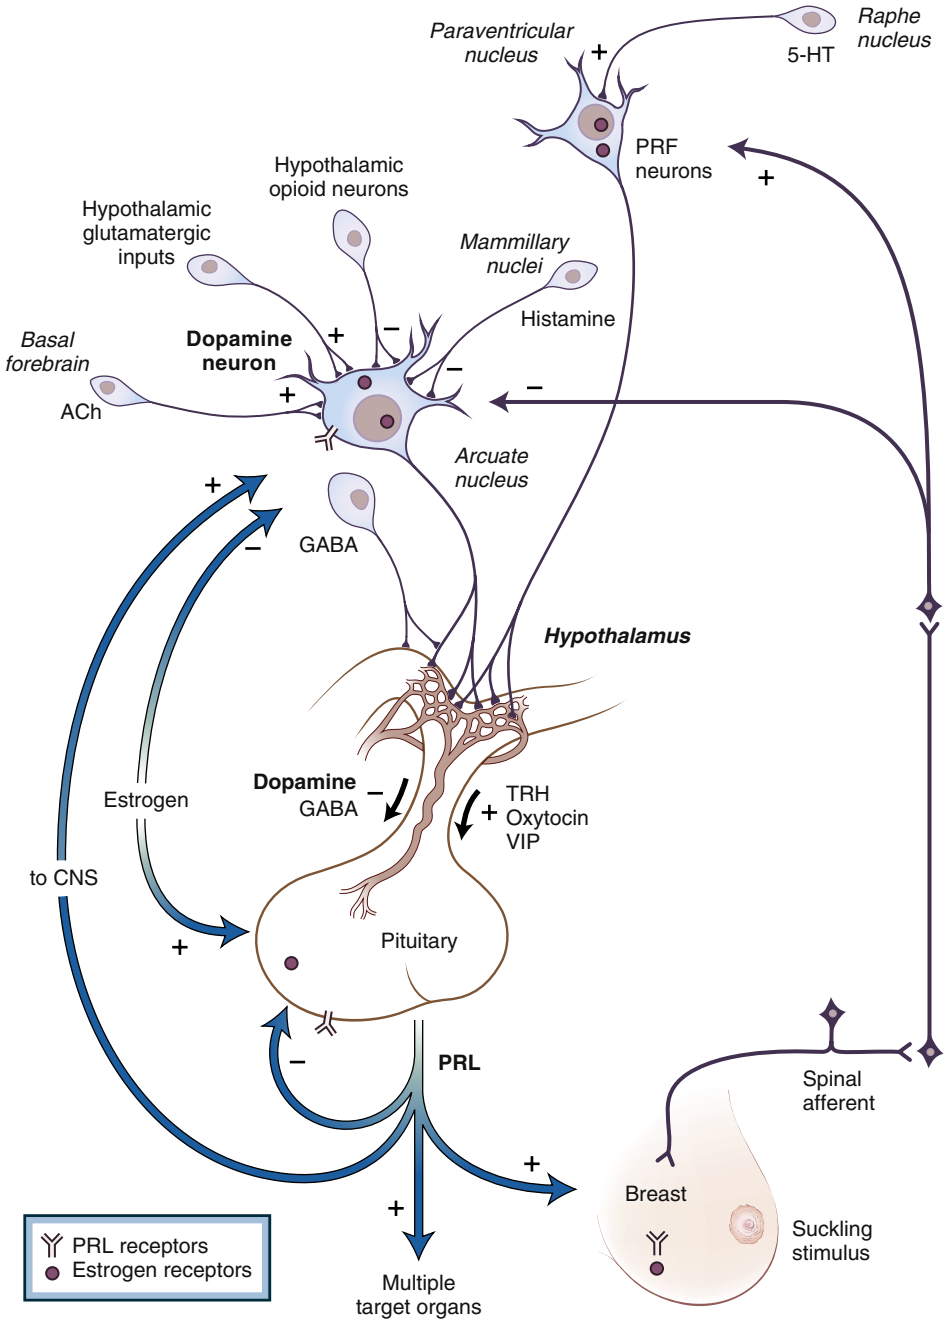


• **Fig. 7.26** The use of ^{111}In-labeled diethylenetriaminepenta-acetic acid (DTPA)-octreotide (A and B) and ^{68}Ga-DOTTATE (C) (radioactive somatostatin analogues) and external imaging techniques to localize a carcinoid tumor expressing somatostatin receptors. (A) Anterior view of the abdomen showing nodular metastases in an enlarged liver and the primary carcinoid tumor *(arrow)* in the wall of the jejunum of a patient with severe flushing and diarrhea. (B) Posterior view of the chest and neck showing a metastasis in a lymph node on the left side of the neck *(arrow)* and multiple metastases in the ribs and pleura. (C) Anterior view showing presence of a bronchopulmonary carcinoid tumor *(arrow)* causing ectopic ACTH syndrome and Cushing syndrome. (A and B, Modified from Lamberts SWJ, Krenning EP, Reubi J-C. The role of somatostatin and its analogs in the diagnosis and treatment of tumors. *Endocrine Rev.* 1991;12:450–482. Copyright 1991, The Endocrine Society.)

Prolactin-Regulating Factors

Dopamine

It is well known that PRL secretion, unlike the secretion of other pituitary hormones, is primarily under tonic inhibitory control by the hypothalamus (Fig. 7.27).[378] Destruction of the stalk median eminence or transplantation of the pituitary gland to ectopic sites causes a marked constitutive increase in PRL secretion, in contrast to a decrease in the release of GH, TSH, ACTH, and the gonadotropins. Many lines of evidence indicate that dopamine is the principal physiologic PIF released from the hypothalamus.[379] Dopamine is present in hypothalamic-hypophysial–portal vessel



• **Fig. 7.27** Regulation of the hypothalamic-pituitary-prolactin (PRL) axis. The predominant effect of the hypothalamus is inhibitory, mediated principally by the tuberohypophyseal dopaminergic neuron system and dopamine D_2 receptors on lactotrophs. The dopamine neurons are stimulated by acetylcholine (ACh) and glutamate and inhibited by histamine and opioid peptides. One or more prolactin-releasing factors (PRFs) mediate acute release of PRL (e.g., in suckling, during stress). There are several candidate PRFs, including thyrotropin-releasing hormone (TRH), vasoactive intestinal polypeptide (VIP), and oxytocin. PRF neurons are activated by serotonin (5-HT). Estrogen sensitizes the pituitary to release PRL, which feeds back on the pituitary to regulate its own secretion (ultrashort-loop feedback) and also influences gonadotropin secretion by suppressing the release of gonadotropin-releasing hormone (GnRH). Short-loop feedback is also mediated indirectly by prolactin receptor regulation of hypothalamic dopamine synthesis, secretion, and turnover. *CNS,* central nervous system; *GABA,* γ-aminobutyric acid.

blood in sufficient concentration to inhibit PRL release, dopamine inhibits PRL secretion from lactotrophs both in vivo and in vitro, and dopamine D_2 receptors are expressed on the plasma membrane of lactotrophs. Mutant mice with a targeted disruption of the D_2 receptor gene uniformly develop lactotroph hyperplasia, hyperprolactinemia, and eventually lactotroph adenomas, further emphasizing the importance of dopamine in the physiologic regulation of lactotroph proliferation in addition to hormone secretion.[380]

The intrinsic dopamine neurons of the medial basal hypothalamus constitute a dopaminergic population with regulatory properties that are distinct from those in other areas of the brain. Notably, they lack D_2 autoreceptors but express PRL receptors, which are essential for positive feedback control (discussed in detail later). In rats, these neurons are subdivided by location into the A12 group of Dahlstrom and Fuxe within the arcuate nucleus and the A14 group in the hypothalamic periventricular nucleus. The dorsomedially located A12 dopamine neurons are further classified as tuberoinfundibular dopamine neurons (TIDA) because they project to the external zone of the median eminence and the main group of dopamine neurons responsible for prolactin regulation. The more rostral A12 group is classified as tuberohypophysial dopamine neurons (THDA) and project to the neural lobe and intermediate lobe. Finally, the A14 periventricular hypophysial dopaminergic neurons (PHDA) send their axons only to the intermediate lobe of the pituitary gland where they are primarily involved in the release of α-melanocyte–stimulating hormone.

Although the TIDA neurons are generally considered to be the major source of dopamine to the anterior lobe through the long portal vessels originating in the median eminence, dopamine can also reach the anterior lobe from the neural and intermediate lobes by the interconnecting short portal veins.[381] In addition to direct actions of dopamine on lactotrophs, central dopamine can indirectly affect PRL secretion by altering the activity of inhibitory interneurons that in turn synapse on the TIDA neurons. These effects are complicated by opposing intracellular signaling pathways linked to D_1 and D_2 receptors located on different populations of interneurons.[382]

The binding of dopamine or selective agonists such as bromocriptine to the D_2 receptor has multiple effects on lactotroph function. The D_2 receptor is a member of the cytokine superfamily and couples to pertussis toxin–sensitive G proteins to inhibit adenylyl cyclase and decrease intracellular cAMP levels. Other effects include activation of an inwardly rectifying K^+ channel, increase of voltage-activated K^+ currents, decrease of voltage-activated Ca^{2+} currents, and inhibition of inositol phosphate production. Together, this spectrum of intracellular signaling events decreases free Ca^{2+} concentrations and inhibits exocytosis of PRL secretory granules.[383]

There is continuing debate concerning the mechanism by which D_2 receptor activation inhibits transcription of the PRL gene. Likely pathways involve the inhibition of MAPK or protein kinase C, with a resultant reduction in the phosphorylation of Ets family transcription factors. Ets factors are important for the stimulatory responses of TRH, insulin, and epidermal growth factor on PRL expression, and they interact cooperatively with the pituitary-specific POU protein Pit1, which is essential for cAMP-mediated PRL gene expression.[384]

The second-messenger pathways used by the D_2 receptor to inhibit lactotroph cell division are also unsettled.[385] A study using primary pituitary cultures from rats demonstrated that forskolin treatment, which activates protein kinase A and elevates intracellular cAMP, and insulin treatment, which activates a potent receptor tyrosine kinase, were both effective mitogenic stimuli for lactotrophs. Bromocriptine competitively antagonized the proliferative response caused by elevated cAMP. Furthermore, inhibition of MAPK signaling by PD98059 markedly suppressed the mitogenic action of both insulin and forskolin, suggesting an interaction of MAPK and protein kinase A signaling.[386]

Another line of study has implicated the stimulation of phospholipase D activity by a Rho A–dependent, pertussis toxin–insensitive pathway in the antiproliferative effects of D_2 receptor activation in both GH4C1 pituitary cells and NCI-H69 small cell lung cancer cells.[387] Activation of the extracellular signal-regulated kinase 1/2 pathway and inhibition of the AKT/protein kinase B pathway have also been implicated in the action of the D_2 receptor to reduce lactotroph mitogenesis.[388] Therefore it is clear that dopamine actions on lactotrophs involve multiple different intracellular signaling pathways linked to activation of the D_2 receptor, but different combinations of these pathways are relevant for the inhibitory effects on PRL secretion, PRL gene transcription, and lactotroph proliferation.

The other major action of dopamine in the pituitary is the inhibition of hormone secretion from the POMC-expressing cells of the intermediate lobe[389]—although, as noted earlier, the adult human differs from most other mammals in the rudimentary nature of this lobe. THDA and PHDA axon terminals provide a dense plexus of synaptic-like contacts on melanotrophs. Dopamine release from these terminals is inversely correlated with serum MSH levels and also regulates POMC gene expression and melanotroph proliferation.

Other hypothalamic factors likely play a role secondary to that of dopamine as additional PIFs.[378] The primary reason to conjecture the existence of these PIFs is the frequent inconsistency between portal dopamine levels and circulating PRL in different rat models. GABA is the strongest candidate and most likely acts through $GABA_A$ inotropic receptors in the anterior pituitary. Melanotrophs, like lactotrophs, are inhibited by both dopamine and GABA but with the principal involvement of G protein–coupled, metabotropic $GABA_B$ receptors.[390] Because basal dopamine tone is high, the measurable inhibitory effects of GABA on PRL release are generally small under normal circumstances. Other putative PIFs include somatostatin and calcitonin.

Prolactin-Releasing Factors

Although tonic suppression of dopamine by prolactin is the dominant effect of the hypothalamus on PRL secretion, other mechanisms may also contribute by either contributing to dopamine suppression or directly promoting PRL release from the anterior pituitary (see Fig. 7.27). The most important of the putative PRFs are TRH, oxytocin, and VIP, but vasopressin, angiotensin II, NPY, galanin, substance P, bombesin-like peptides, and neurotensin can also trigger PRL release under different physiologic circumstances.[378] TRH has already been discussed. In humans there is an imperfect correlation between pulsatile PRL and TSH release, suggesting that TRH cannot be the sole physiologic PRF under basal conditions.[391]

Like TRH, oxytocin, vasopressin, and VIP fulfill all the basic criteria for a PRF. They are produced in PVH neurons that project to the median eminence. Concentrations of the hormones in portal blood are much higher than in the peripheral circulation and are sufficient to stimulate PRL secretion in vitro. Moreover, there are functional receptors for each of the neurohormones in the anterior pituitary gland, and either pharmacologic antagonism or passive immunization against each hormone can decrease PRL secretion, at least under certain circumstances.[392]

AVP is released during stress and hypovolemic shock, as is PRL, suggesting a specific role for vasopressin as a PRF in these contexts. Similarly, another candidate PRF, peptide histidine isoleucine, may be specifically involved in the secretion of PRL in response to stress. Peptide histidine isoleucine and the human homologue, peptide histidine methionine, are structurally related to VIP and are synthesized from the same prohormone precursor in their respective species.[393] Both peptides are coexpressed with CRH in parvicellular PVH neurons, and presumably they are released by the same stimuli that cause release of CRH into the hypothalamic-hypophysial portal vessels.[394]

Serotonin arising from the brainstem dorsal raphe also appears to have a major role in prolactin secretion, particularly during lactation.[395,396] These neurons innervate TIDA neurons to inhibit their secretion of dopamine and hence increase prolactin secretion but may also have an activating effect on PRF through direct innervation of TRH in the PVH. Endogenous opiates also may have a role during lactation by inhibiting TIDA secretion mediated by dynorphin-producing or beta endorphin–producing neurons in the arcuate nucleus.

Intrapituitary Regulation of Prolactin Secretion

Probably more than that of any other pituitary hormone, the secretion of PRL is regulated by autocrine-paracrine factors within the anterior lobe and by neurointermediate lobe factors that gain access to venous sinusoids of the anterior lobe by way of the short portal vessels. The wealth of local regulatory mechanisms within the anterior lobe has been reviewed extensively[378,397] and is also discussed in Chapter 8. In brief, that some gonadotrophs are closely apposed to lactotrophs and secrete substances in response to GnRH that stimulate prolactin secretion is well known.[398,399] Candidate substances derived from gonadotrophs abound and include pituitary glycoprotein hormone alpha subunit (αGSU), an N-terminal fragment of POMC (POMC 1-74), neurotensin, angiotensin II, PACAP, calcitonin, and CART, among a number of other substances.[400] Galanin, VIP, endothelin-like peptides, epidermal growth factor, basic fibroblast growth factor, and the cytokine IL-6 are also potent local stimulators of PRL secretion. Locally produced inhibitors include PRL itself, acetylcholine, transforming growth factor β, and calcitonin. Although none of these stimulatory or inhibitory factors have a dominant role in the regulation of lactotroph function and much of the research in this area has not been directly confirmed in human pituitary, it seems apparent that the local milieu of autocrine and paracrine factors plays an essential, modulatory role in determining the responsiveness of lactotrophs to hypothalamic factors in different physiologic states.

Cell clustering has also been observed in the anterior pituitary during lactation,[401] in which there is proliferation and reorganization of lactotrophs into a honeycomb-like structure with increased contacts between the cells. Presumably these changes are a way to integrate or amplify signals from the hypothalamus and coordinate increased output of prolactin. Recent advances in two-photon imaging of the pituitary and three-dimensional analyses of pituitary cell networks reinforce the importance of these local connections.[402]

Neuroendocrine Regulation of Prolactin Secretion

Secretion of PRL, like that of other anterior pituitary hormones, is regulated by hormonal feedback and neural influences from the hypothalamus.[378,379,403] Feedback is exerted by PRL itself at the level of the hypothalamus. PRL secretion is regulated by many physiologic states, including the estrous and menstrual cycles, pregnancy, and lactation. Furthermore, PRL is stimulated by several exteroceptive stimuli, including light, ultrasonic vocalization of pups (in rodents), olfactory cues, and various modalities of stress. Expression and secretion of PRL are also influenced strongly by estrogens at the level of both the lactotrophs and TIDA neurons[404] (see Fig. 7.27) and by paracrine regulators within the pituitary such as galanin and VIP.

Feedback Control

Negative feedback control of PRL secretion is mediated by a unique short-loop mechanism within the hypothalamus. PRL activates PRL receptors, which are expressed on all three subpopulations of A12 and A14 dopamine neurons, leading to increased tyrosine hydroxylase expression and increased dopamine synthesis and release.[404,405] Ames dwarf mice that secrete virtually no PRL, GH, or TSH have decreased numbers of arcuate dopamine neurons, and this hypoplasia can be reversed by neonatal administration of PRL, suggesting a trophic action on these neurons.[406] However, another mouse model of isolated PRL deficiency generated by gene targeting appears to have normal numbers of hypofunctioning dopamine neurons.[407] Ultrashort feedback control via autocrine or paracrine regulation of prolactin at the level of the pituitary gland also occurs as indicated by an increased sensitivity of lactotrophs to dopamine inhibition in transgenic mice with conditional deletion of the prolactin receptor, selectively in lactotrophs.[408]

Neural Control

Lactotrophs have spontaneously high secretory activity; therefore the predominant effect of the hypothalamus on PRL secretion is tonic suppression, which is mediated by regulatory hormones synthesized by THDA neurons. Secretory bursts of PRL are caused by the acute withdrawal of dopamine inhibition, stimulation by PRFs, or combinations of both events. At any given moment, locally produced autocrine and paracrine regulators further modulate the responsiveness of individual lactotrophs to neurohormonal PIFs and PRFs.

Multiple neurotransmitter systems impinge on the hypothalamic dopamine and PRF neurons to regulate their neurosecretion[378] (see Fig. 7.27). Nicotinic cholinergic and glutamatergic afferents activate TIDA neurons, whereas histamine, acting predominantly through H_2 receptors, inhibits these neurons. An inhibitory peptidergic input to TIDA neurons of major physiologic significance is that associated with the endogenous opioid peptides enkephalin and dynorphin and their cognate μ-receptor and κ-receptor subtypes.[409] Opioid inhibition of dopamine release has been associated with increased PRL secretion under virtually all physiologic conditions, including the basal state, different phases of the estrous cycle, lactation, and stress. Ascending serotonergic inputs from the dorsal raphe nucleus are the major activator of PRF neurons in the PVH. There is still debate concerning the identity of the specific 5-HT receptors involved in this activation.

The PRL regulatory system and its monoaminergic control have been scrutinized in detail because of the frequent occurrence of syndromes of PRL hypersecretion (see Chapter 8). Both the pituitary and the hypothalamus have dopamine receptors, and the response to dopamine receptor stimulation and blockade does not distinguish between central and peripheral actions of the drug. Many commonly used neuroleptic drugs influence PRL secretion. Reserpine (a catecholamine depleter) and phenothiazines such as chlorpromazine and haloperidol enhance PRL release by disinhibition of dopamine action on the pituitary, and the PRL response is an excellent predictor of the antipsychotic effects of phenothiazines because of its correlation with D_2 receptor binding

and activation.[410] The major antipsychotic neuroleptic agents act on brain dopamine receptors in the mesolimbic system and in the pituitary-regulating TIDA system. Consequently, treatment of such patients with dopamine agonists such as bromocriptine can reverse the psychiatric benefits of such drugs. A report of three patients with psychosis and concomitant prolactinomas recommended the combination of clozapine and quinagolide as the treatment of choice to manage both diseases simultaneously.[411]

Factors Influencing Secretion

Circadian Rhythm

PRL is detectable in plasma at all times during the day but is secreted in discrete pulses superimposed on basal secretion and exhibits a diurnal rhythm with peak values in the early morning hours.[412] In humans, this is a true circadian rhythm because it is maintained in a constant environment independently of the sleep rhythm.[413] The combined body of data examining TIDA neuronal activity, dopamine concentrations in the median eminence, and manipulations of the SCN suggests that endogenous diurnal alterations in dopamine tone that are entrained by light constitute the major neuroendocrine mechanism underlying the circadian rhythm of PRL secretion. The nocturnal rise in PRL secretion in nursing and nonnursing women may have evolved as a mechanism of milk maintenance during prolonged nonsuckling periods at night.

External Stimuli

The suckling stimulus is the most important physiologic regulator of PRL secretion. PRL levels rise within 1 to 3 minutes of nipple stimulation and remain elevated for 10 to 20 minutes.[414] This reflex is distinct from the milk let-down, which occurs nearly simultaneously with prolactin secretion during suckling and involves oxytocin release from the neurohypophysis and contraction of mammary alveolar myoepithelial cells. These reflexes provide a mechanism by which the infant regulates both the production and the delivery of milk. Of interest, in nonlactating rats, prolactin secretion inhibits oxytocin neurons and stimulates dopamine release from TIDA neurons, whereas during lactation, prolactin enhances oxytocin release and does not increase dopamine release. Mechanisms involved may include prolactin-induced sensitization of TRPV1 channels that are upregulated in oxytocin neurons during lactation, an indirect effect mediated by GABA release from TIDA neurons,[415] and inhibition of the prolactin feedback loop by the dissociation of electric activity and dopamine release to allow for sustained elevations in prolactin during suckling.[416] Signaling of prolactin to TIDA neurons may also be diminished as a result of upregulation of SOCS proteins that inhibit JAK-STAT signaling, induced by the binding of prolactin to the prolactin receptor.[417]

After stimulation of mechanoreceptors, pathways involved in the suckling reflex are carried to the spinal cord by way of spinal afferent neurons, ascend the spinal cord through spinothalamic tracts to the midbrain, and enter the hypothalamus by way of the median forebrain bundle (see Fig. 7.27). Neurons regulating the oxytocin-dependent milk let-down response accompany those involved in PRL regulation throughout most of this pathway and then separate at the level of the PVH nuclei, although the intrahypothalamic pathways involved have not been precisely elucidated. Using c-Fos as a marker for neuronal activation, several potential relay centers in the brainstem have been identified, including the ventrolateral medulla (A1) and dorsal vagal complex (A2) catecholamine cell groups, locus coeruleus, lateral parabrachial nucleus, caudal portion of the paralemniscal nucleus, and lateral and ventrolateral portions of the caudal part of the periaqueductal gray through direct or indirect synaptic connections to oxytocin neurons.[418] Noradrenergic neurons arising in the A1 and A2 groups directly innervate oxytocin neurons.[419] Synchronization of oxytocin neurons, which contributes to the coordinated pattern of pulsatile oxytocin release, is regulated by afferent inputs from glutamatergic neurons, in the lateral septum and bed nucleus of the stria terminalis.[47] Retraction of astroglial processes that normally separate oxytocin neurons, allowing increased interactions through somatic appositions, also contributes to the pulsatile pattern of oxytocin secretion and may be regulated by "intranuclear release" of oxytocin, in which oxytocin is released locally from dendrites and soma.[420] The suckling reflex brings about an inhibition of PIF activity and a release of PRFs, although an undisputed suckling-induced PRF has not been identified.

Suckling-induced prolactin secretion not only has an important role in lactation but coordinates a number of other physiologic responses that complement lactation, including the development of maternal behavior, increased appetite, and inhibition of reproductive function. These effects are facilitated by upregulation of prolactin receptors in the choroid plexus during lactation, allowing increased entry of prolactin from the circulation into the brain through a carrier-mediated transport system.[421] Binding of prolactin to prolactin receptors in the MePO may be important for maternal behavior as antagonizing prolactin receptors with a specific prolactin receptor antagonist injected into the preoptic area delays the onset of maternal behavior.[422] Tuberoinfundibular peptide of 39 residues (TIP39) may also be an important component of the mechanism involved in maternal motivation by lactation.[423] This peptide, produced by neurons in the thalamus, has extensive projections to galanin neurons in the preoptic area, which are known to be activated by suckling.[424] Suckling also results in a marked increase in NPY and AgRP gene expression in the arcuate nucleus mediated by neuronal afferents from the brainstem and the fall in circulating levels of leptin, brought about by a negative energy balance secondary to the milk production.[425] As NPY and AgRP are powerful orexigenic peptides (see Chapter 39 for overview of neuroendocrine regulation of appetite and satiety), their increase during suckling may explain the hyperphagia associated with lactation to meet the energy demands imposed by milk production. Indeed, total ablation of NPY/AgRP neurons by diphtheria toxin administered to transgenic mice expressing the diphtheria toxin receptor exclusively in NPY/AGRP neurons leads to a significant reduction in food intake in lactating animals.[426] Activation of arcuate nucleus NPY neurons may also contribute to the inhibition of reproductive function associated with suckling through direct actions on GnRH neurons mediated by NPY Y5 receptors.[427]

Although their significance for PRL regulation in humans is not certain, environmental stimuli from seasonal changes in light duration and auditory and olfactory cues are clearly of great importance to many mammalian species.[378] Seasonal breeders such as sheep exhibit a reduction in PRL secretion in response to shortened days. Vocalization of rodent pups are also potent stimuli for PRL secretion in lactating and virgin female rats by activation of the inferior colliculus and lateral geniculate of the posterior thalamus.[418] Olfactory stimuli from pheromones also have potent actions in rodents. A prime example is the Bruce effect, or spontaneous abortion, induced by exposure of a pregnant female rat to an unfamiliar male. It is mediated by a well-studied neural circuitry involving the vomeronasal nerves, the corticomedial amygdala, and the medial preoptic area of the hypothalamus, which results in activation of TIDA neurons and a reduction in circulating PRL

that is essential for maintenance of luteal function in the first half of pregnancy.

Stress in many forms dramatically affects PRL secretion, although the teleologic significance is uncertain. It may be related to actions of PRL on cells of the immune system or some other aspect of homeostasis. Different stressors are associated with either a reduction or an increase in PRL secretion, depending on the local regulatory environment at the time of the stress. However, whereas well-documented changes in PRL are associated with relatively severe forms of stress in laboratory animal models, the relevance to human physiology is not well established.

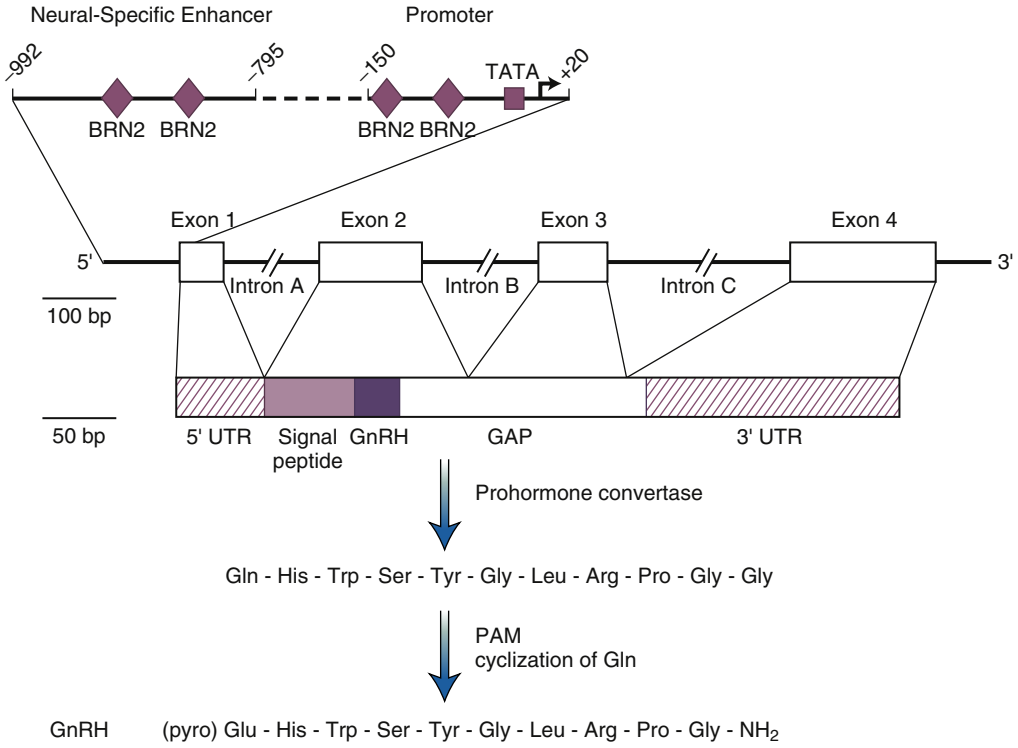
Gonadotropin-Releasing Hormone and Control of the Reproductive Axis

Chemistry and Evolution

GnRH is a 10–amino acid hypothalamic neuropeptide that controls the function of the reproductive axis. It is synthesized as part of a larger precursor molecule that is enzymatically cleaved to remove a signal peptide from the NH_2-terminus and GnRH-associated peptide (GAP) from the COOH-terminus (Fig. 7.28).[428] All forms of the decapeptide have a pyroGlu at the NH_2-terminus and Gly-amide at the COOH-terminus, indicating the functional importance of the terminal residues throughout evolution.

Two genes encoding GnRH have been identified within mammals.[429,430] The first, *GNRH1*, encodes a 92–amino acid precursor protein. This form of GnRH is found in hypothalamic neurons and serves as a releasing factor to regulate pituitary gonadotroph function.[431] The second GnRH gene, *GNRH2*, encodes a decapeptide that differs from the first by three amino acids.[432] This form of GnRH is found in the midbrain region and serves as a neurotransmitter rather than as a pituitary releasing factor. Both GnRH-I and GnRH-II are found in phylogenetically diverse species, from fish to mammals, suggesting that these multiple forms of GnRH diverged from one another early in vertebrate evolution.[431] A third form of GnRH, GnRH-III, has been identified in neurons of the telencephalon in teleost fish. GnRH is also found in cells outside the brain but is not well understood and is an area under current investigation.

All GnRH genes have the same basic structure, with the preprohormone mRNA encoded in four exons. Exon 1 contains the 5′ untranslated region of the gene; exon 2 contains the signal peptide, GnRH, and the NH_2-terminus of GAP; exon 3 contains



• **Fig. 7.28** Schematic diagram of the human gene for gonadotropin-releasing hormone-1 (*GNRH1*), the hypothalamic complementary deoxyribonucleic acid (cDNA), and post-translational processing of the GnRH prohormone. A cluster of binding sites for the homeodomain transcription factor BRN2 is present in both the proximal promoter and a distal enhancer region and is important for neuron-specific expression of the gene. Phylogenetically conserved homologous regions have been identified in the rat *Gnrh1* gene, but in that species the Oct1 transcription factor has been implicated in neuron-specific expression. The cDNA for GnRH-I isolated from human placenta has a longer 5′ untranslated region (UTR) because of differential splicing of the heterogeneous nuclear RNA (hnRNA) and inclusion of intron A sequences. *GAP,* GnRH-associated peptide; *PAM,* peptidylglycine α-amidating mono-oxygenase; *TATA,* Goldstein-Hogness box involved in binding RNA polymerase. the central portion of GAP; and exon 4 contains the COOH-terminus of GAP and the 3′ untranslated region (see Fig. 7.28).[431] Among species, the nucleotide sequences encoding the GnRH decapeptide are highly homologous. This section focuses on the hypothalamic GnRH that is derived from *GNRH1* mRNA and plays an important role in the regulation of the hypothalamic-pituitary-gonadal axis.

Two transcriptional start sites have been identified in the rat *GNRH1* gene, at the +1 and –579, with the +1 promoter being active in hypothalamic neurons and the other promoter active in placenta. The first 173 base pairs of the promoter are highly conserved among species. In the rat, this promoter region has been shown to contain two Oct1 binding sites, three regions that bind the POU domain family of transcription factors (SCIP, Oct-6, and Tst-1), and three regions that can bind the progesterone receptor.[433] In addition, a variety of hormones and second messengers have been shown to regulate GnRH gene expression, and a majority of the *cis*-acting elements, thus far characterized for hormonal control of GnRH transcription, are located in the proximal promoter region.[434,435] The 5′ flanking region of the rodent and human *GNRH1* genes also contains a distal 300–base pair enhancer region that is 1.8 or 0.9 kb, respectively, upstream of the transcription start site.[435,436] Studies have implicated the homeodomain transcription factors OCT1, MSX, and DLX in the specification of neuron expression and developmental activation.[436,437]

Anatomic Distribution

GnRH neurons are small, diffusely located cells that are not concentrated in a discrete nucleus. They are generally bipolar and fusiform in shape, with slender axons projecting predominantly to the median eminence and infundibular stalk. The location of hypothalamic GnRH neurons is species-dependent. In the rat, hypothalamic GnRH neurons are concentrated in rostral areas, including the medial preoptic area, the diagonal band of Broca, the septal areas, and the anterior hypothalamus. In humans and nonhuman primates, the majority of hypothalamic GnRH neurons are located more dorsally in the medial basal hypothalamus, the infundibulum, and the periventricular region. Throughout the hypothalamus, neurohypophysial GnRH neurons are interspersed with non-neuroendocrine GnRH neurons that extend their axons to other areas of the brain, including other hypothalamic regions and various regions of the cortex. GnRH secreted from non-neuroendocrine neurons has been implicated in the control of sexual behavior in rodents but not in higher primates.[438]

Embryonic Development

GnRH neuroendocrine neurons are an unusual neuronal population in that they originate outside the CNS, from the epithelial tissue of the nasal placode.[439] During embryonic development, GnRH neurons migrate across the surface of the brain and into the hypothalamus, with the final hypothalamic location differing somewhat among species. Migration is dependent on a scaffolding of neurons and glial cells along which the GnRH neurons move, with neural cell adhesion molecules playing a critical role in guiding the migration process.

Failure of GnRH neurons to migrate properly leads to the clinical condition Kallmann syndrome, in which GnRH neuroendocrine neurons do not reach their final destination and therefore do not stimulate pituitary gonadotropin secretion.[439,440] Patients with Kallmann syndrome do not enter puberty spontaneously. The X-linked form of Kallmann syndrome results from a deficiency of the *KAL1* gene, which encodes the extracellular glycoprotein termed *anosmin-1*. Mutations in the fibroblast growth factor receptor type 1 (*FGFR1*), *FGF8*, prokineticin 2 and its receptors (*PROK2* and *PROKR2*), and chromodomain helicase DNA-binding protein 7 (*CDH7*) genes produce an autosomal dominant form of Kallmann syndrome, and autosomal recessive forms of *PROK2* and *PROKR2* also occur. Other genes associated with Kallman syndrome include *CCDC141*, *DUSP6*, *FEZF1*, *FGF17*, *FLRT3*, *IL17RD*, *NELF*, *SEMA3A*, *SPRY4,* and *WDR11*.[441] These mutations, however, still account for only the minority of Kallmann cases, and other causes are yet to be characterized.[442] Administration of exogenous GnRH effectively treats this form of hypothalamic hypogonadism. Patients with Kallmann syndrome due to mutations in the *KAL1* gene often have other congenital midline defects, including anosmia, which results from hypoplasia of the olfactory bulb and tracts.

Action at the Pituitary

Receptors

GnRH binds to a membrane receptor on pituitary gonadotrophs and stimulates both LH and FSH synthesis and secretion. The GnRH receptor is a seven-transmembrane-domain GPCR, but it lacks a typical intracellular COOH-terminal cytoplasmic domain.[435] Under physiologic conditions, GnRH receptor number varies and is usually directly correlated with the gonadotropin secretory capacity of pituitary gonadotrophs. For example, across the rat estrous cycle, a rise in GnRH receptors is seen just before the surge of gonadotropins that occurs on the afternoon of proestrus. GnRH receptor message levels are regulated by a variety of hormones and second messengers, including steroid hormones (estradiol can both suppress and stimulate; progesterone suppresses), gonadotropins (which suppress), and calcium and protein kinase C (which stimulate).[433,435]

$G_{q/11}$ is the primary guanosine triphosphate–binding protein mediating GnRH responses; however, there is evidence that GnRH receptors can couple to other G proteins, including G_s and G_i.[435] With activation, the GnRH receptor couples to a phosphoinositide-specific phospholipase C, which leads to increases in calcium transport into gonadotrophs and calcium release from internal stores through a diacylglycerol-protein kinase C pathway. Increased calcium entry is a critical step in GnRH-stimulated release of gonadotropin secretion. However, GnRH also stimulates the MAPK cascade.

When there is a decline in GnRH stimulation to the pituitary, as occurs in a variety of physiologic conditions (including states of lactation, undernutrition, or seasonal periods of reproductive quiescence), the number of GnRH receptors on pituitary gonadotrophs declines dramatically. Subsequent exposure of the pituitary to pulses of GnRH restores receptor number by a Ca^{2+}-dependent mechanism that requires protein synthesis.[443] The effect of GnRH to induce its own receptor is termed *upregulation* or *self-priming*. Only certain physiologic frequencies of pulsatile GnRH can augment GnRH receptor production, and these frequencies appear to differ among species.[444] Upregulation of GnRH receptors after a period of low GnRH stimulation to the pituitary can take hours to days of exposure to pulsatile GnRH, depending on the duration and extent of the prior decrease in GnRH. The self-priming effect of GnRH to upregulate its own receptors also plays a crucial role in the production of the gonadotropin surge that occurs at midcycle in females of spontaneously ovulating species and triggers ovulation. Just before the gonadotropin surge, two factors—the

increased frequency of pulsatile GnRH release and a sensitization of the pituitary gonadotrophs by rising levels of estradiol—make the pituitary exquisitely sensitive to GnRH and allow an output of LH that is an order of magnitude greater than the release seen during the rest of the female reproductive cycle. This surge of LH triggers the ovulatory process at the ovary.

In contrast to upregulation of GnRH receptors by pulsatile regimens of GnRH, continuous exposure to GnRH leads to downregulation of GnRH receptors and an accompanying decrease in LH and FSH synthesis and secretion, termed *desensitization*.[445] Downregulation does not require calcium mobilization or gonadotropin secretion. It involves a rapid uncoupling of receptors from G proteins and sequestration of the receptors from the plasma membrane, followed by internalization and proteolytic degradation of the receptors.

The concept of downregulation has a number of clinical applications. For example, the most common current therapy for precocious puberty of hypothalamic origin (i.e., precocious GnRH secretion) is to treat it with a long-acting GnRH *superagonist* that downregulates pituitary GnRH receptors and effectively turns off the reproductive axis.[444,446] Children with precocious puberty can be maintained with long-acting GnRH agonists for years to suppress the premature activation of the reproductive axis, and at the normal age of puberty, agonist treatment can be withdrawn, allowing reactivation of pituitary gonadotrophs and a downstream increase in gonadal steroid hormone production (also see Chapter 17). Long-acting GnRH agonists are also used in the treatment of forms of breast cancer that are estrogen-dependent and of other gonadal steroid-dependent cancers.[444] Long-acting antagonists of GnRH have been developed that can also be used for these therapies.[447] Antagonists have the advantage of not having a flare effect (i.e., an acute stimulation of gonadotropin secretion that is seen during the initial treatment of individuals with superagonists).

Pulsatile Gonadotropin-Releasing Hormone Stimulation

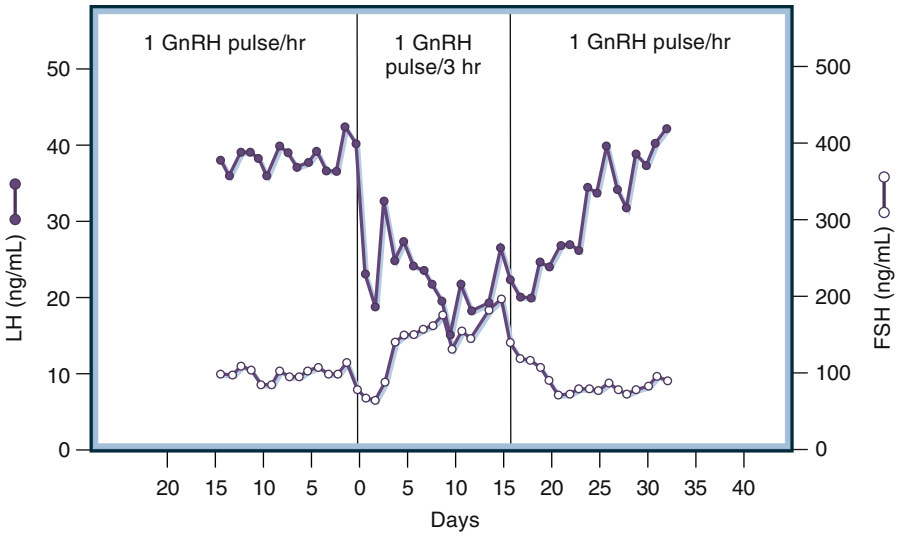
Because a single pulse of GnRH stimulates the release of both LH and FSH, and chronic exposure of the pituitary to pulsatile GnRH supports the synthesis of both LH and FSH, it is generally believed that there is only one releasing factor regulating the synthesis and secretion of LH and FSH. However, in a number of physiologic conditions, there are divergent patterns of LH and FSH secretion; thus a second FSH-releasing peptide has been proposed, but such a peptide has not been isolated to date. Other mechanisms, discussed in more detail later, are likely to account for the differential regulation of LH and FSH release.

The ensemble of GnRH neurons in the hypothalamus that send axons to the portal blood system in the median eminence fire in a coordinated, repetitive, episodic manner, producing distinct pulses of GnRH in the portal bloodstream. The pulsatile nature of GnRH stimulation to the pituitary leads to the release of distinct pulses of LH into the peripheral circulation. In experimental animals, in which it is possible to collect blood samples simultaneously from the portal and peripheral blood, GnRH and LH pulses have been found to correspond in about a 1:1 ratio at most physiologic rates of secretion.[448] Because the portal bloodstream is generally inaccessible in humans, the collection of frequent peripheral venous blood samples is used to define the pulsatile nature of LH secretion (i.e., frequency and amplitude of LH pulses), and pulsatile LH is used as an indirect measure of the activity of the GnRH secretory system. Indirect assessment of GnRH secretion by monitoring the rate of pulsatile LH secretion is also used in many animal studies examining the factors that govern the regulation of the pulsatile activity of the reproductive neuroendocrine axis. Unlike LH secretion, FSH secretion is not always pulsatile; even when it is pulsatile, there is only partial concordance between LH and FSH pulses.

It is possible to place multiple-unit recording electrodes in the medial basal hypothalamus of monkeys and other species and detect spikes of electrical activity that are concordant with the pulsatile secretion of LH secretion.[449] However, it is unknown whether these bursts of electrical activity reflect the activity of GnRH neurons themselves or the activity of neurons that impinge on GnRH neurons and govern their firing. With the development of mice in which the gene for green fluorescent protein has been put under the regulation of the GnRH promoter, it has been possible to identify GnRH neurons in hypothalamic tissue slices using fluorescence microscopy, to record from them intracellularly,[16] and to simultaneously measure GnRH release from the median eminence by fast-scan cyclic voltammetry.[450] These studies have shown that many, but not all, GnRH neurons show a bursting pattern of electrical activity. A central question in the field of reproductive neuroendocrinology is what causes GnRH neurons to pulse in a coordinated manner. Embryonic GnRH neurons from rhesus monkeys have shown intrinsic oscillatory changes in intracellular calcium concentration and synchronized calcium peaks among tens of neurons associated with GnRH release. A mathematical network model has been developed to further characterize this synchronization process.[451] The term *GnRH pulse generator* is often used to acknowledge the fact that GnRH secretion occurs in pulses and to refer to the central mechanisms responsible for pulsatile GnRH release.

A critical factor governing LH and FSH secretion is the rate of pulsatile GnRH stimulation of the gonadotrophs. Experimental studies in which the hypothalamus was lesioned and GnRH was replaced by pulsatile administration of exogenous GnRH showed that different frequencies of GnRH can lead to different ratios of LH to FSH secretion from the pituitary. Fig. 7.29 shows that in a monkey with a hypothalamic lesion, replacement of one pulse of GnRH per hour led to a relatively low ratio of FSH to LH secretion. Subsequent institution of a slower pulse frequency (one pulse of GnRH every 3 hours) led to a decrease in LH secretion but an increase in FSH secretion so that the ratio of FSH to LH secretion was greatly elevated. Thus, during the normal menstrual cycle, LH pulse frequency increases during the follicular phase as the midcycle ovulatory phase is approached, reflecting increased GnRH pulsatility, and then slows during the luteal phase. Abnormally low GnRH pulsatility is associated with delayed puberty, hypothalamic amenorrhea, opioid-induced hypogonadism, hyperprolactinemia, and obesity-related hypogonadism, whereas an inappropriately high GnRH pulsatility is associated with precocious puberty and polycystic ovarian syndrome (PCOS).[452] As discussed later, steroid hormones act at both the hypothalamus and pituitary to strongly influence the rate of pulsatile GnRH release and amount of LH and FSH secreted from the pituitary.

GnRH pulse frequency not only influences the rate of pulsatile gonadotropin release and the ratio of FSH to LH secretion, but also plays an important role in modulating the structural makeup of the gonadotropins. LH and FSH are structurally similar glycoprotein hormones. Each of these hormones is made up of an α-subunit and a β-subunit. LH, FSH, and TSH share a common α-subunit, and each has a unique β-subunit that conveys receptor specificity to the intact hormone. Before secretion of gonadotropins, terminal sugars are attached to each gonadotropin molecule.[162] The sugars include sialic acid, galactose, *N*-acetylglucosamine, and mannose,



• **Fig. 7.29** The influence of gonadotropin-releasing hormone (GnRH) pulse frequency on luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion in a female rhesus monkey with an arcuate nucleus lesion ablating endogenous GnRH support of the pituitary. Decreasing the GnRH pulse frequency from 1 pulse every hour to 1 pulse every 3 hours led to a decrease in plasma LH concentrations but an increase in plasma FSH concentrations. (Redrawn from Wildt L, Haulser A, Marshall G, et al. Frequency and amplitude of gonadotropin-releasing hormone stimulation and gonadotropin secretion in the rhesus monkey. *Endocrinology.* 1981;109:376–385.)

but the most important is sialic acid. The extent of glycosylation of LH and FSH is important for the physiologic function of these hormones.[162] Forms of gonadotropin with more sialic acid have a longer half-life because they are protected from degradation by the liver. Forms of gonadotropin with less sialic acid have more potent effects at their biologic receptors. Both the rate of GnRH stimulation and ovarian hormone feedback at the level of the pituitary regulate the degree of LH and FSH glycosylation. For example, slow frequencies of GnRH, seen during follicular development, are associated with greater degrees of FSH glycosylation, which would provide sustained FSH support to growing follicles. In contrast, faster frequencies of GnRH, seen just before the midcycle gonadotropin surge, are associated with lesser degrees of FSH glycosylation, providing a more potent but shorter lasting form of FSH at the time of ovulation.[453]

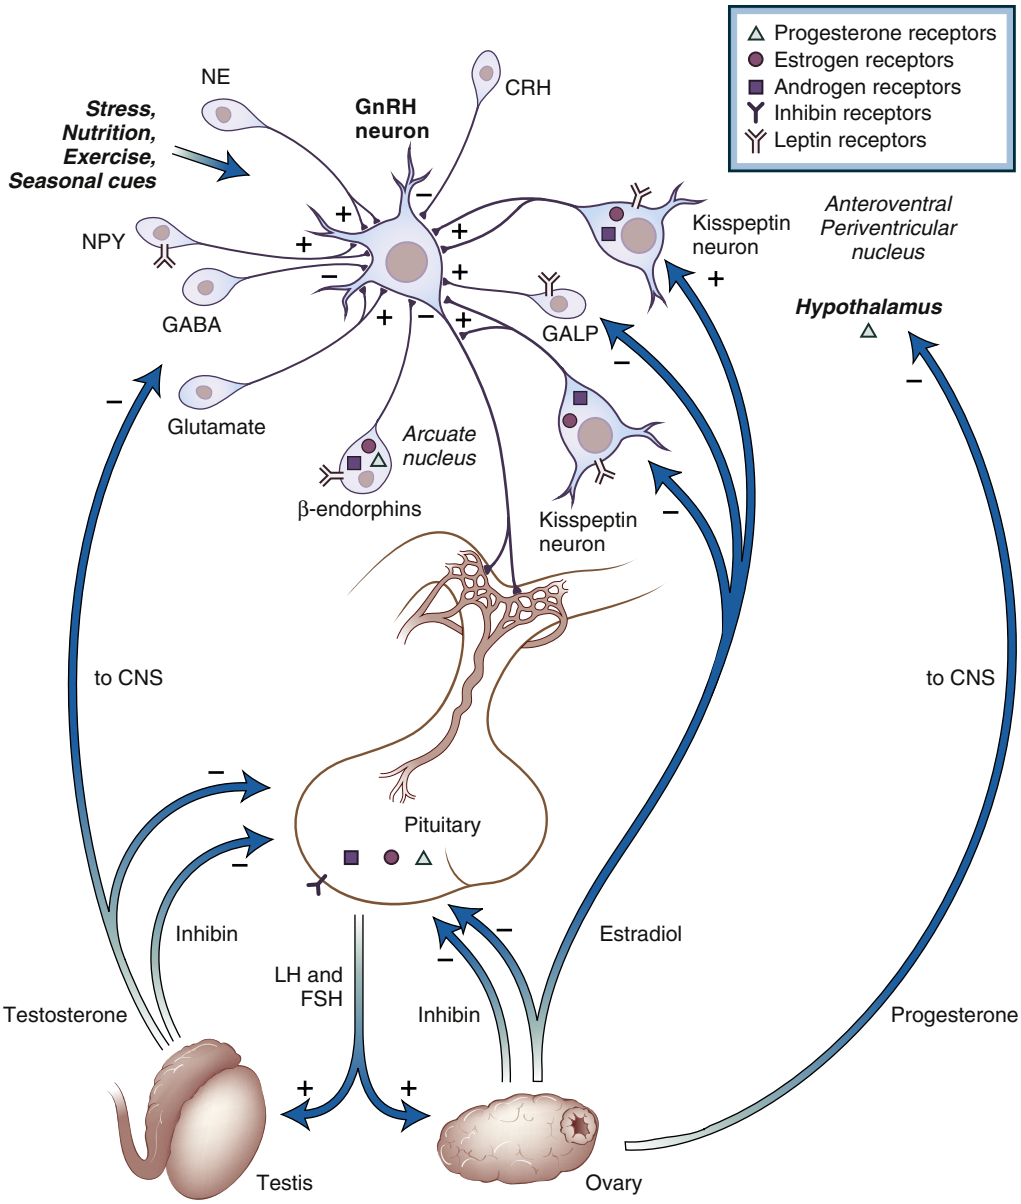
Regulatory Systems

Many neurotransmitter systems from the brainstem, limbic system, and other areas of the hypothalamus convey information to GnRH neurons (Fig. 7.30). These afferent systems include neurons that contain norepinephrine, dopamine, serotonin, GABA, glutamate, kisspeptin, endogenous opiate peptides, NPY, galanin, and a number of other peptide neurotransmitters. Glutamate and norepinephrine play important roles in providing stimulatory drive to the reproductive axis, whereas GABA and endogenous opioid peptides provide a substantial portion of the inhibitory drive to GnRH neurons. However, it is the kisspeptin neuronal network that is particularly essential for regulation of the GnRH neurons[454] and will be discussed in greater detail.

GnRH neuronal cell bodies are surrounded by astrocytes that may contribute to GnRH secretion through the release of prostaglandin E_2 (PGE_2) and/or transforming growth factor beta (TGFβ).[455] Changes in the steroid hormone milieu also influence the degree of glial sheathing of GnRH axon terminals in the external zone of the median eminence and have important roles in regulating delivery to the portal capillary plexus for conveyance to the anterior pituitary. Thus, during diestrus in the rat when GnRH output to the pituitary is very low, GnRH axon terminals in the median eminence are fully ensheathed by tanycyte end-feet processes, preventing GnRH from reaching the portal blood. The sprouting of tanycyte end-feet processes to engulf GnRH-containing axon terminals is mediated by transforming growth factor beta 1 (TGFβ1) and SEMA7A.[59] Conversely, during the preovulatory surge of proestrus when there is an increase in GnRH, estrogen binds to alpha-type estrogen receptors on tanycytes and induces retraction of tanycyte foot processes through PGE_2-dependent production of TGFβ1, allowing GnRH axon terminals to have direct contact with the fenestrated portal capillary system.[456] Estrogen may also affect the synthesis of adhesion molecules such as polysialylated neuronal cell adhesion molecule (PSA-N-CAM) and synaptic cell adhesion molecule (SynCAM) that facilitate glial-neuronal interactions and remodeling.[457] Endothelial cells of the portal capillary system may also contribute to tanycyte plasticity via estrogen-induced regulation of nitric oxide production that affects actin cytoskeleton remodeling.[458]

Feedback Regulation

Steroid hormone receptors are abundant in the hypothalamus and in many neural systems that impinge on GnRH neurons, including noradrenergic, serotonergic, kisspeptin, β-endorphin–containing, and NPY neurons. Early studies identifying regions of the brain that bound labeled estrogens showed that in rodents the preoptic area and VMH had the highest concentrations of estrogen receptors in the brain. Further localization studies, identifying estrogen receptors by immunocytochemistry or in situ hybridization, confirmed the strong presence of estrogen receptors in the hypothalamus and in brain areas with abundant connections to the hypothalamus, including the amygdala, septal nuclei, BNST, medial part of the NTS, and lateral portion of the parabrachial nucleus.[459] In 1986, a new member of the steroid hormone receptor superfamily with high-sequence homology to the classic estrogen receptor (now referred to as *estrogen receptor-α*) was isolated



• **Fig. 7.30** Regulation of the hypothalamic-pituitary-gonadal axis. Schematic diagram of the hypothalamic-pituitary-gonadal axis showing neural systems that regulate gonadotropin-releasing hormone (GnRH) secretion and feedback of gonadal steroid hormones at the level of the hypothalamus and pituitary. *CNS,* central nervous system; *CRH,* corticotropin-releasing hormone; *FSH,* follicle-stimulating hormone; *GABA,* γ-aminobutyric acid; *GALP,* galanin-like peptide; *LH,* luteinizing hormone; *NE,* norepinephrine; *NPY,* neuropeptide Y.

from rat prostate and named *estrogen receptor-β*. This novel estrogen receptor was shown to bind estradiol and to activate transcription by binding to estrogen response elements.[460]

In situ hybridization studies examining the localization of estrogen receptor-β mRNA have shown that these receptors are present throughout the rostral-caudal extent of the brain, with a high level of expression in the preoptic area, BNST, PVH and SON, amygdala, and laminae II to VI of the cerebral cortex.[461] Specific receptors for progesterone are induced by estrogen in hypothalamic regions of the brain, including the preoptic area, the ventromedial and ventrolateral nuclei, and the infundibular-arcuate nucleus, although there is also evidence for constitutive expression of progesterone receptors in some regions.[462] Androgen receptor mapping studies have shown considerable overlap in the distribution of androgen and estrogen receptors throughout the brain. The highest density of androgen receptors was found in hypothalamic nuclei known to participate in the control of reproduction and sexual behaviors, including the arcuate nucleus, PVH, MePO, ventromedial nucleus, and brain regions with strong connections to the hypothalamus (including the amygdala, nuclei of the septal region, BNST, NTS, and lateral division of the parabrachial nucleus).[459] The anterior pituitary also contains receptors for all of the gonadal steroid hormones.

Steroid hormones can dramatically alter the pattern of pulsatile release of GnRH and of the gonadotropins through actions at both the hypothalamus and the pituitary. At the hypothalamus, estradiol, progesterone, and testosterone can all act to slow the frequency of GnRH release into the portal bloodstream as part

of a closed negative feedback loop.[463] However, GnRH neurons lack estrogen receptors, indicating that the effects of estrogen on GnRH secretion is mediated by other neural systems that provide afferent input to GnRH neurons. Most important is the kisspeptin signaling pathway, which is now well established to be involved in the central regulation of puberty and reproduction by stimulating GnRH from the hypothalamus.

Kisspeptin, a RFamide-like peptide and the natural ligand for the former orphan GPCR, GPR54, is a 54–amino acid peptide that derives from the *KISS1* gene located on chromosome 1q33, although smaller forms that contain 10 to 14 amino acids have also been identified. Inactivating mutations of the *KISS1* gene result in hypogonadotropic hypogonadism or pubertal delay,[464] whereas activating mutations result in precocious puberty.[465] These neurons have been identified in two discrete areas in mammals: (1) the preoptic area and the infundibular nucleus in humans and primates and (2) the anteroventral periventricular nucleus (AVPV)/preoptic periventricular nucleus (defined together as the rostral periventricular area of the third ventricle [RP3V]) and arcuate nucleus in ruminants.[466–468]

Although GnRH neurons have an endogenous rhythmic activity in culture, they do not correlate well to the pulses of GnRH observed in vivo; therefore the pulse generator has largely been ascribed to the kisspeptin neurons. Kisspeptin neurons express estrogen (both α and β) and progesterone receptors and densely innervate GnRH neuronal cell bodies, particularly their axon terminals in the median eminence. In addition, GnRH neurons express the kisspeptin receptor (KISS1R).[469] Pulsatile secretion of GnRH is dependent upon pulsatile secretion of kisspeptin, as if kisspeptin is administered continuously, it results in suppression of LH secretion.[470] The mechanism by which pulsatile secretion of kisspeptin occurs is proposed to be mediated by at least two additional peptides coexpressed by kisspeptin neurons in the infundibular/arcuate nucleus with opposing actions, namely the tachykinin neurokinin B, which stimulates kisspeptin secretion, and dynorphin (or possibly enkephalin in humans[471]), which inhibits kisspeptin secretion.[454,472] For this reason, this population of kisspeptin neurons is commonly referred to as KNDy neurons.[472] This concept is supported by the presence of both tachykinin receptors and κ-opioid receptors on KNDy neurons and the extensive axosomatic and axodendritic interconnections among these neurons that coordinate their activity.[466] In addition, inactivating mutations of the genes encoding for neurokinin B or the neurokinin B receptor, NK3R, results in hypogonadotropic hypogonadism.[473,474] Substance P has also been shown to have an activating effect on KNDy neurons and is either synthesized within KNDy neurons themselves or by adjacent populations of neurons that innervate KNDy neurons, depending upon the animal species.[454,475] The action of kisspeptin on GnRH secretion, however, may occur primarily at axon terminals, as injection of a kisspeptin antagonist into the median eminence of monkeys can abolish GnRH pulses.[476]

Phoenixin-20 amide (PNX), a novel peptide that derives from the small, integral membrane protein 20 (SMIM20) and highly conserved among species, has also been found to have a role in regulation of the gonadal axis both by sensitizing gonadotrophs in the anterior pituitary to GnRH and through direct effects on GnRH neurons.[477] The observation that PNX is synthesized in kisspeptin neurons and increases KISS1 mRNA expression, and that kisspeptin neurons express GPR123 receptor for which PNX is a ligand, has raised the possibility that the peptide may activate kisspeptin neurons through an autocrine mechanism or through connections with other kisspeptin/PNS neurons.

Most of the time, the hypothalamic-pituitary axis is under the negative feedback influence of gonadal steroid hormones. If the gonads are removed surgically or their normal secretion of steroid hormones is suppressed pharmacologically, there is a dramatic increase (10-fold to 20-fold) in circulating levels of LH and FSH secretion in both males and females.[463] This type of *castration response* occurs normally at menopause in women, when ovarian follicular development and therefore ovarian production of large quantities of estradiol and progesterone decrease and eventually cease.

KNDy neurons in the infundibular nucleus are involved in mediating negative feedback regulation of GnRH release by steroid hormones, including estradiol (E_2), progesterone, and testosterone.[478–480] Estrogen suppresses kisspeptin and neurokinin B from infundibular KNDy neurons, and both kisspeptin and neurokinin B gene expression are upregulated in ovariectomized animals and postmenopausal women.[481] Negative feedback of steroid hormones can also occur directly at the level of the pituitary. For example, estradiol has been shown to be capable of binding to the pituitary, decreasing LH and FSH synthesis and release, and decreasing the sensitivity of pituitary gonadotrophs to the actions of GnRH so that less LH and FSH are released when a pulse of GnRH stimulates the pituitary. Evidence for such a direct pituitary action of estradiol came from studies with rhesus monkeys that had been rendered deficient in endogenous GnRH by a lesion in the arcuate nucleus and showed a decline in endogenous gonadotropin secretion. When these monkeys received a pulsatile regimen of GnRH treatments, subsequent estradiol infusions dramatically suppressed the responsiveness of the pituitary to GnRH and suppressed the gonadotropin secretion that was being driven by the pulsatile administration of GnRH.[482] Similarly, in a compound mutant mouse model on a GnRH-deficient (*Hpg*) genetic background, expression of a human FSH-β transgene was inhibited by testosterone directly at the pituitary level.[483] In primate species, including humans, there is considerable feedback of estradiol at the pituitary, but most of the progesterone and testosterone negative feedback occurs at the level of the hypothalamus.[463]

In addition to negative feedback, estradiol can have a positive feedback action at the level of the hypothalamus and pituitary to lead to a massive release of LH and FSH from the pituitary. This release of gonadotropins occurs once each menstrual cycle and is referred to as the *LH-FSH surge*. The positive feedback action of estradiol occurs as a response to the rising tide of estradiol that is produced during the process of dominant follicle development in the late follicular phase of the menstrual cycle. In women, elevated estradiol levels are generally maintained at about 300 to 500 pg/mL for about 36 hours before the stimulation of the gonadotropin surge.

Experiments have shown that both a critical concentration and duration of elevated estradiol are necessary to achieve positive feedback and a resulting gonadotropin surge. If supraphysiologic doses of estradiol are administered, the surge can occur as early as 18 hours after their administration. Because the ovary is responsible for the production of estradiol, and the time course and magnitude of estradiol release control the rate of positive feedback, the ovary has been referred to as the *zeitgeber* of the menstrual cycle. The dependence of the positive feedback system on the magnitude of estradiol production helps explain the fact that the portion of the menstrual cycle that varies most in length is the follicular phase. Production of higher levels of estradiol by

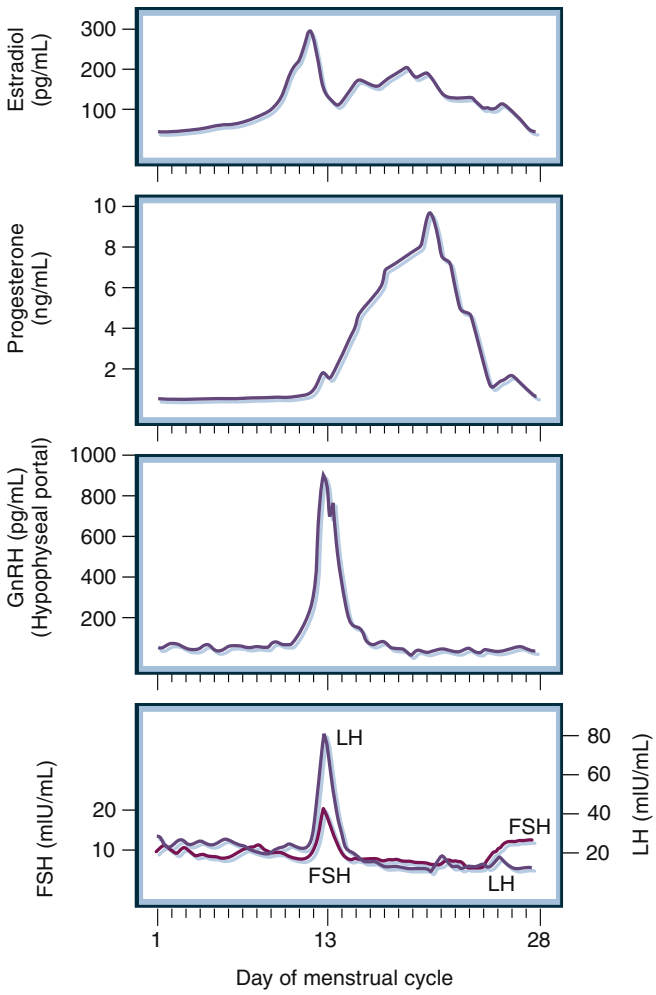
a dominant follicle in one cycle leads to a more rapid positive feedback action, with earlier ovulation and therefore a shorter follicular phase, compared to a cycle in which the dominant follicle produced lower levels of estradiol.

As with negative feedback in response to estradiol, the positive feedback actions of estradiol occur both at the hypothalamus to increase GnRH secretion and at the pituitary to enhance pituitary responsiveness to GnRH. Estradiol increases pituitary sensitivity to GnRH by increasing the synthesis of new GnRH receptors and by enhancing the responsiveness to GnRH at a postreceptor site of action. At the level of the hypothalamus, kisspeptin neurons in the preoptic and RPV3 nucleus are believed to function as the *surge center* to induce the ovulatory surge of GnRH. This particular subpopulation of kisspeptin neurons is activated in an estrogen-dependent manner immediately preceding the GnRH surge, as detected by Fos expression, and is postulated to play a key role in the positive feedback effects of estradiol on GnRH release.[484] In addition, lesions in areas adjacent to the medial preoptic area, near the anterior commissure and septal complex, block the ability of estrogen to induce a surge in these species without blocking its negative feedback effects.[485] It is also of note that kisspeptin expression in the RPV3 neurons is sexually diergic, with a much greater number of kisspeptin neurons in the female. The role of preoptic kisspeptin neurons in mediating the ovulatory surge in humans is controversial, however, as it is possible that KNDy neurons in the infundibular nucleus participate in the positive feedback effects of estrogen.[486] Cellular mechanisms that mediate the switch from negative to positive feedback of estrogen are not fully understood, but there is support for the concept that estrogen induction of various transcription factors and receptors may play an important role in mediating this switch.[487] Alternatively, KNDy neurons may not consist of a homogeneous population.

Regulation of the Ovarian Cycle

Cyclic activity in the ovary is controlled by an interplay between steroid hormones produced by the ovary and the hypothalamic-pituitary neuroendocrine components of the reproductive axis. The duration of each phase of the ovarian cycle is species dependent, but the general mechanisms controlling the cycle are similar in all species that have spontaneous ovarian cycles. In the human menstrual cycle, day 1 is designated as the first day of menstrual bleeding. At this time, small and medium-sized follicles are present in the ovaries, and only small amounts of estradiol are produced by the follicular cells. As a result, there is a low level of negative feedback to the hypothalamic-pituitary axis, LH pulse frequency is relatively fast (one pulse about every 60 minutes), and FSH concentrations are slightly elevated compared to much of the rest of the cycle (Fig. 7.31). FSH acts at the level of the ovarian follicles to stimulate development and causes an increase in follicular estradiol production, which in turn provides increased negative feedback to the hypothalamic-pituitary unit.

A result of the increased negative feedback is a slowing of pulsatile LH secretion over the course of the follicular phase to a rate of about one pulse every 90 minutes. However, as the growing follicle (or follicles, depending on the species) secretes more estradiol, the positive feedback action of estradiol is triggered, which leads to an increase in GnRH release and the LH-FSH surge. The surge of gonadotropins acts at the fully developed follicle to stimulate the dissolution of the follicular wall, leading to ovulation of the matured ovum into the nearby fallopian tube, where fertilization takes place if sperm are present. Ovulation results in a reorganization of the cells of the follicular wall; the cells undergo



• **Fig. 7.31** Diagrammatic representation of changes in plasma levels of estradiol, progesterone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) and portal levels of gonadotropin-releasing hormone (GnRH) over the human menstrual cycle.

hypertrophy and hyperplasia and start to secrete large amounts of progesterone and some estradiol. Progesterone and estradiol have a negative feedback effect at the level of the hypothalamus and pituitary, so the LH pulse frequency becomes very slow during the luteal phase of the menstrual cycle. The corpus luteum has a fixed life span; without additional stimulation in the form of human chorionic gonadotropin (hCG) from a developing embryo, the corpus luteum regresses spontaneously after ~14 days and progesterone and estradiol secretions diminish. This reduces the negative feedback signals to the hypothalamus and pituitary and allows an increase in FSH and LH secretion. The fall in progesterone is also a withdrawal of steroid hormone support to the endometrial lining of the uterus; as a result, the endometrium is shed as menses, and a new cycle begins.

In other species, the interplay between the neuroendocrine and ovarian hormones is similar, but the timing of events is different, and other factors, such as circadian and seasonal regulatory factors, play a role in regulating the cycle. The rat has an ovarian cycle without menses (the endometrial lining is absorbed rather than shed) of 4 to 5 days. The rat also shows strong circadian rhythmicity in the timing of the LH-FSH surge, with the surge always occurring in the afternoon of the day of proestrus. Sheep are an example of a species that has a strongly seasonal pattern of

ovarian cyclicity. During the breeding season, ewes have 15-day cycles, with a very short follicular phase and an extended luteal phase; during the nonbreeding season, signals relaying information about day length through the visual system, pineal, and SCN cause a dramatic suppression of GnRH neuronal activity, and cyclic ovarian function is prevented by a decrease in trophic hormonal support from the pituitary (see "Physiologic Roles of Melatonin").

Early Development and Puberty

Neuroendocrine stimulation of the reproductive axis is initiated during fetal development, and in primates in midgestation, circulating levels of LH and FSH reach values similar to those in castrated adults.[488] Later in gestational development, gonadotropin levels decline, restrained by rising levels of circulating gonadal steroids. The steroids that have this effect are probably placental in origin because after parturition there is a rise in circulating gonadotropin levels that is apparent for variable periods of the first year of life, depending on the species. The decline in reproductive hormone secretion in the postnatal period appears to be due to a decrease in GnRH stimulation of the reproductive axis because it occurs even in the castrated state and because gonadotropin and gonadal steroid secretion can be supported by the administration of pulses of GnRH.[489]

Pubertal reawakening of the reproductive axis occurs in late childhood and is marked initially by nighttime elevations in gonadotropin and gonadal steroid hormone levels.[489,490] The mechanisms controlling the pubertal reawakening of the GnRH pulse generator have been an area of intense investigation.[489,491] Although the mechanisms are still not fully understood, significant progress has been made in identifying central changes in the hypothalamus that appear to play a role in this process. At puberty, there is both a decrease in transsynaptic inhibition to the GnRH neuronal system and an increase in stimulatory input to GnRH neurons.[489] One of the major inhibitory inputs to the GnRH system is provided by GABAergic neurons. Studies in rhesus monkeys have shown that hypothalamic levels of GABA decrease during early puberty and that blocking GABAergic input before puberty, by intrahypothalamic administration of antisense oligodeoxynucleotides against the enzymes responsible for GABA synthesis, results in premature activation of the GnRH neuronal system.

It has been suggested on the basis of findings that a subset of glutamate receptors (i.e., kainate receptors) increase in the hypothalamus at puberty and that the pubertal decrease in GABA tone may be caused by an increase in glutamatergic transmission. Further evidence for a role for glutamate comes from studies showing that administration of *N*-methyl-DL-aspartic acid (NMDA) to prepubertal rhesus monkeys can drive the reawakening of the reproductive axis.[492] Increased stimulatory drive to the GnRH neuronal system also appears to come from increases in norepinephrine and NPY at the time of puberty.[489] Furthermore, as discussed earlier, there is evidence that growth factors act through release of prostaglandin from glial cells at puberty to play a role in stimulating GnRH neurons.[493]

Despite an increased understanding of the neural changes occurring at puberty, the question of what signals trigger the pubertal awakening of the reproductive axis is unanswered at this time.[491,494] However, the kisspeptin neuronal system described earlier in the section on feedback regulation has become a prime integrative candidate for this function, perhaps mediated by the activating effects of neurokinin B and substance P or increased tachykinin sensitivity.[484,454] Also relevant to pubertal onset is galanin-like peptide (GALP), which is expressed specifically in the arcuate nucleus and binds with high affinity to galanin receptors. GALP is a potent central stimulator of gonadotropin release and sexual behavior in the rat and can reverse the decreased reproductive function associated with diabetes mellitus and hypoinsulinemia.[495] Whereas GnRH neurons do not express leptin receptors, both kisspeptin and GALP neurons are targets of leptin and are hypothesized to be involved in the well-known modulation of puberty and reproductive function by food availability and nutritional status (see the following section). Epigenetic mechanisms have been proposed to coordinate the changes in the expression of multiple genes that accompany the initiation of puberty.[491]

Reproductive Function and Stress

Many forms of physical stresses, such as fasting, exercise, temperature stress, infection, pain, and injury, as well as psychologic stresses, such as being subordinate in a dominance hierarchy, can suppress the activity of the reproductive axis.[496] If the stress exposure is brief, there may be acute suppression of circulating gonadotropins and gonadal steroid hormones; in females disruption of normal menstrual cyclicity may occur, but fertility is unlikely to be impaired.[496] In contrast, prolonged periods of significant stress exposure can lead to complete impairment of reproductive function, also characterized by low circulating levels of gonadotropins and gonadal steroids. Stress appears to decrease the activity of the reproductive axis by decreasing GnRH drive to the pituitary because in all cases in which it has been examined, administration of exogenous GnRH can reverse the effects of the stress-induced decline in reproductive hormone secretion.

In the case of foot shock stress in rats[497] or immune stress (i.e., injection of IL-1α) in primates,[498] the suppression of gonadotropin secretion that occurs was shown to be reversible by administration of a CRH antagonist, implying that endogenous CRH secretion mediates the effects of these stresses on GnRH neurons. In other studies, naloxone, a μ-opioid receptor antagonist, was shown to be capable of reversing restraint stress–induced suppression of gonadotropin secretion in monkeys; however, naloxone is ineffective in reversing the suppression of gonadotropin secretion that occurs during insulin-induced hypoglycemia.[499,500] In the case of metabolic stresses, multiple regulators appear to mediate changes in the neural drive to the reproductive axis.

Various metabolic fuels, including glucose and fatty acids, can regulate the function of the reproductive axis, and blocking cellular utilization of these fuels can lead to suppression of gonadotropin secretion and decreased gonadal activity. Leptin, a hormone produced by fat cells, can also modulate the activity of the reproductive axis. Mutant *ob/ob* mice that are deficient in leptin are infertile, but fertility can be restored by administration of leptin.[501] Moreover, leptin administration has been shown to reverse the suppressive effects of undernutrition on the reproductive axis in some situations.[502] Leptin receptors are found in several populations that are known to have a strong influence on the reproductive axis, particularly kisspeptin neurons.[484] Furthermore, treatment with a neurokinin B agonist and dynorphin antagonist can recover suppressed GnRH and LH secretion.[503]

In summary, it appears that a number of neural circuits can mediate the effects of stress on the GnRH neuronal system and that the neural systems involved are at least somewhat specific to the type of stress that is experienced.

Thermoregulation and Sleep-Wake Cycle

In addition to regulation of the anterior and posterior pituitary, the hypothalamus orchestrates a number of functions that are critical for normal homeostasis, including the maintenance of normal body temperature and its resetting under certain physiologic conditions and the regulation of sleep and wakefulness. Appetite regulation is discussed in Chapter 39.

Preoptic Area Is the Primary Hypothalamic Thermoregulatory Center

It has been long recognized that the brain plays an important role in the regulation of body temperature mediated by neurons that respond to heat, commonly referred to as warm-sensitive neurons, and neurons that respond to cold, referred to as cold-sensitive neurons,[504] with the preoptic area (POA) being the most important thermoregulatory locus (see Siemens and Kamm[505] for comprehensive review). Neurons in this region serve as a major integrating center that functions to maintain a constant body temperature by receiving information from surface thermoreceptors in the skin, spinal cord, and deep structures in the abdominal cavity that are relayed to the POA through the lateral parabrachial nucleus by multisynaptic pathways via the dorsal horn of the spinal cord or splanchnic and vagal afferents.[504] In addition, some neurons in the POA have the intrinsic ability to sense changes in local brain temperature. Preoptic warming reduces heat production and increases heat-loss responses by vasodilation, sweating, increased respiration, inhibition of UCP-1 in brown adipose tissue (BAT), and specific behavioral responses such as moving to a cooler area; conversely, preoptic cooling increases heat production and reduces heat losses by inducing vasoconstriction, shivering, activation of UCP-1 in brown adipose tissue, increasing intermediary metabolism in muscle and other parenchymal organs, and by specific behavioral responses such as increasing locomotor activity and food intake.[506] As the number of warm-sensitive neurons is significantly greater than the number of cold-sensitive neurons in the POA, lesioning this region of the hypothalamus typically results in hyperthermia.[507]

Mechanisms for Thermoreception

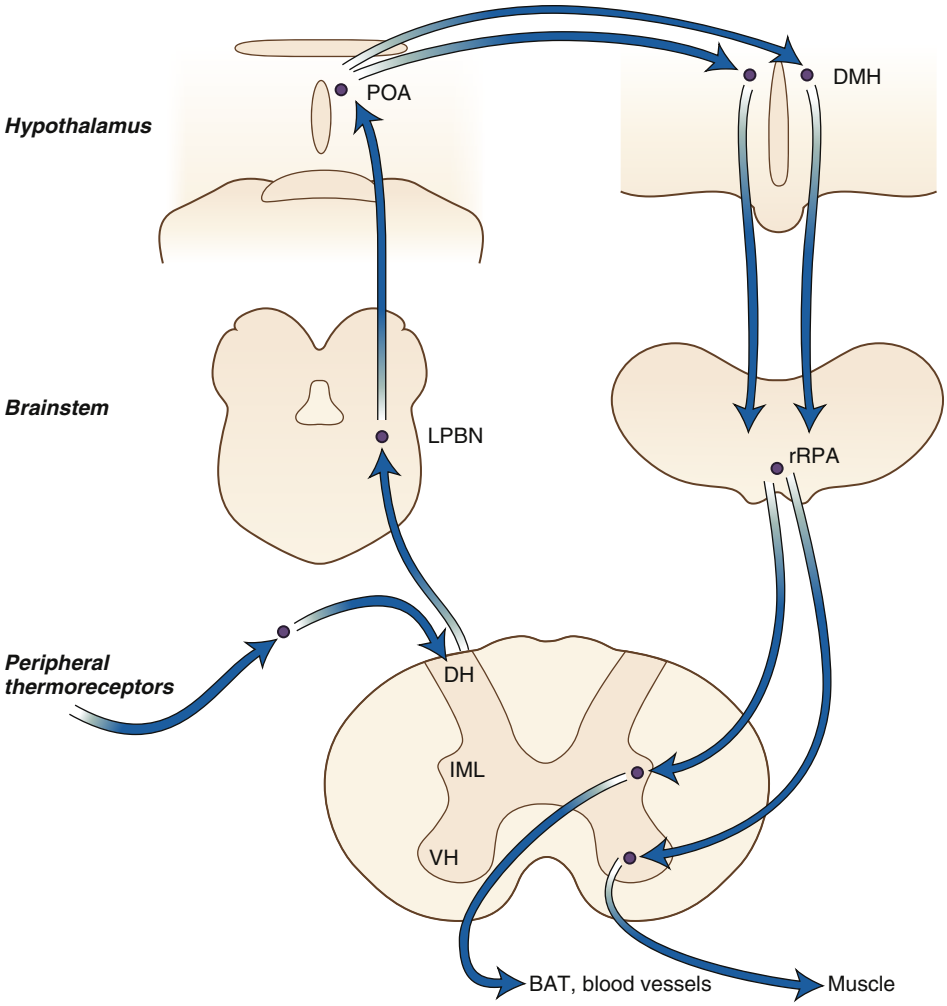
Within the periphery, primary sensory axon terminals express the TRP channel, transient receptor potential vanilloid 1 (TRPV1), which is activated by heat, and transient receptor potential cation channel subfamily M member 8 (TRPM8), which is activated by cold.[508] Animals with TRPM8 deficiency have impairment in maintaining normal body temperature when placed in a cold environment.[509] However, these animals can still thermoregulate when placed in extreme cold, indicating that other thermoreceptors and/or other mechanisms for temperature detection are also involved.

Within the POA, warm-sensitive neurons in the MePO and lateral preoptic nucleus (LPO) express transient receptor potential melastatin type 2 ion channels (TRPM2) that when selectively activated or inhibited results in profound hypothermia or hyperthermia, respectively.[510] In addition, transgenic animals deficient in TRPM2 have an exaggerated fever response. However, not all neurons in the POA involved in temperature regulation are intrinsically temperature sensitive. A subpopulation of neurons residing in the anterior ventromedial preoptic nucleus (VMPO), for example, respond to warming but do not express TRPM2 and therefore have been referred to as "warm-activated neurons."[511] These neurons receive inputs from skin receptors and are largely GABAergic but also coexpress the peptides BDNF and PACAP. When selectively activated using molecular techniques such as optogenetics, there is a decline in body temperature as a result of vasodilation and inhibition of heat generation from brown adipose tissue, as well as behavioral changes manifested by a preference for a colder environment.[511] Thus these warm-activated VMPO are capable of coupling three major heat-dissipating responses. Other subdivisions of the POA similarly trigger hypothermic responses when activated and receive thermal information from skin thermoreceptors, including the median preoptic nucleus (MnPO) and ventrolateral preoptic nucleus (VLPO).[512,513] Thus the POA is the primary locus for integrating a variety of thermoregulatory information, and through outputs to regions of the brain involved in regulation of the autonomic nervous system, behavior and other neuroendocrine responses orchestrate a series of responses to maintain normal core body temperature.

Central Circuitries Mediating Thermoregulation

Downstream targets of thermosensitive POA neurons are primarily components of the sympathetic nervous system, of which the dorsomedial hypothalamus (DMH) in the hypothalamus, sympathetic premotor neurons in the rostral ventromedial medulla that include the rostral raphe pallidus (rRPa), and preganglionic autonomic neurons of the intermediolateral cell column in the spinal cord, are particularly important (Fig. 7.32).[514]

On the basis of numerous anatomic and physiologic studies and more recent molecular approaches (see recent reviews by Siemens and Kamm[505] and Tan and Knight[515]), it is now believed that several regions in the POA are involved in relaying thermal information from peripheral thermoreceptors to the autonomic nervous system that may work in synchrony, and that no one discrete population of neurons in the POA mediates any single thermodefensive response (autonomic or behavioral). The downstream circuitry involved was initially recognized for the MnPO, which in response to skin cooling leads to a number of thermoregulatory responses that increase body temperature, such as shivering, heat generation from BAT, and vasoconstriction. It is proposed that the MnPO releases GABA to inhibit MePO neurons, as antagonizing $GABA_A$ receptors in the MePO block cooling-induced shivering.[516] These neurons have downstream projections to the DMH and rRPA, and the DMN also extensively innervates the rRPA. If either the DMN or rRPa is lesioned, the shivering response is blocked. In addition, selective activation of DMN thermosensitive neurons using DREADDS technology increases in temperature, along with an increase in energy expenditure and physical activity.[512] The rRPA then projects to α-motor neurons in the ventral horn of the spinal cord to mediate the shivering response but also to preganglionic neurons in the intermediolateral column of the spinal cord to regulate BAT thermogenesis, sweating, and vasomotor responses.[517] The MnPO also regulates cutaneous blood flow,[518] although it may do so by direct projections to the rRPa, bypassing the DMH, as cooling-induced cutaneous vasoconstriction is not affected by inhibiting DMH neurons.[519] The midbrain periaqueductal gray (PAG) may also be involved in the circuitry before proceeding to sympathetic preganglionic neurons in the spinal cord as PAG neurons show strong c-Fos induction following unilateral preoptic region heating[520] and induce cutaneous vasodilation when stimulated.[521]



• **Fig. 7.32** Simplified diagram of major loci and pathways involved in thermoregulatory responses. *BAT,* brown adipose tissue; *DH,* dorsal horn; *DMH,* dorsomedial hypothalamus; *IML,* intermediolateral cell column; *LPBN,* lateral parabrachial nucleus; *POA,* preoptic area; *rRPa,* rostral raphe pallidus; *VH,* ventral horn. (Redrawn and modified from Roth J, Blatteis CM. Mechanisms of fever production and lysis: lessons from experimental LPS fever. *Compr Physiol.* 2014;4:1563–1604.)

Using a technique of molecular profiling of neurons in the POA activated by heat, a population of GABAergic neurons in the VMPO that coproduce PACAP and BDNF was identified, and when activated by optogenetics leads to a rapid decline in core body temperature that persists as long as the stimulation continues.[511] Mechanisms for the heat loss included vasodilation and suppression of heat production from BAT, as well as behavioral responses because the animals move to colder temperatures. Mapping of these neurons not only demonstrated a direct projection to the DMH, but also the PVN, ventrolateral PAG, and structures associated with behavior (including BNST, paraventricular thalamus, and medial habenula), indicating that the VMPO mediates diverse autonomic and behavioral responses to heat.

Similarly, activation of GABAergic neurons in VLPO triggers a rapid reduction in temperature associated with a decrease in physical activity; conversely, inhibition raises core temperature.[512] These neurons also project to the DMH, and stimulating VLPO terminals locally in the DMN using optogenetics is similarly effective in reducing temperature by inhibiting DMH neuronal activity. Because the transsynaptic retrograde marker, pseudorabies virus, accumulates in the VLPO following injection into BAT,[522] the VLPO is also presumed to contribute to BAT thermogenesis.

Modulators of Thermoregulatory Responses

In addition to information relayed to the POA from thermosensory afferent pathways, body temperature can also be affected by peptide and hormonal mediators as well through circuitries within the CNS that serve to integrate thermoregulation with other homeostatic functions. Perhaps one of best-studied examples is the effect of thyroid hormone on temperature homeostasis.

Thyroid Hormone

Thyroid hormone is essential to sustain the effect of sympathetic activation of BAT, and in its absence, norepinephrine fails to increase BAT temperature, resulting in cold intolerance and hypothermia commonly observed in hypothyroid individuals.[523] Norepinephrine increases type 2 iodothyronine deiodinase (D_2) in BAT, which by converting T_4 to T_3 results in the upregulation of UCP-1 in mitochondria, allowing conversion of stored energy into heat. Thyroid hormone is similarly important for a maximal thermogenic response by skeletal muscle in which activation of the sympathetic nervous system increases D_2, leading to the activation of UCP-3.[524] T_3 also has a direct, central action on neurons in the hypothalamic ventromedial nucleus, which, by decreasing

the phosphorylation of AMP-activated kinase (AMPK), leads to increased sympathetic activity of nerves innervating BAT.[525] T_3 may also modulate feeding-related neurons in the hypothalamic arcuate nucleus that produce NPY and AgRP and contribute to the effect of these peptides on BAT activity.

Estrogen and Progesterone

The set-point for temperature regulation is sensitive to circulating levels of sex steroids, with core body temperature falling just prior to the midcycle surge in women and rising during the luteal phase.[526] Estrogen is responsible for the fall in temperature in the late follicular phase by activating warm-sensitive neurons in the POA,[527] whereas progesterone increases temperature in the luteal phase by decreasing the firing rate of these neurons and, perhaps, increasing the firing rate of cold-sensitive neurons.[528] Thermoregulatory effects of estrogen may also be mediated by KNDy neurons in the hypothalamic arcuate nucleus as further elaborated in "Neurokinin B." Estrogen and progesterone exert effects on peripheral blood vessels, with estrogen promoting vasodilation (and thereby heat dissipation) by activating nitric oxide synthetase (eNOS) in endothelial cells to produce nitric oxide,[529] and progesterone promoting vasoconstriction by enhancing adrenergic control through a prostaglandin-mediated mechanism.[530] It remains unclear as to the physiologic importance of these changes in body temperature over the menstrual cycle, although it has been proposed the increase in temperature during the luteal phase may facilitate implantation.[531]

Neurokinin B

Vasomotor symptoms, commonly referred to as hot flashes, are a frequent occurrence in menopausal women, can persist for many years, and disrupt sleep and daily activities. They are characterized by the sudden feeling of heat, leading to vasodilation and sweating as measures to increase heat loss. While the underlying etiology has long been known to be related to estrogen deficiency, the thermoregulatory mechanisms involved have only recently been elucidated with the discovery of kisspeptin and its role in regulation of GnRH (reviewed by Prague and Dhillo[532]). As mentioned previously (see "Gonadotropin-Releasing Hormone and Control of the Reproductive Axis"), kisspeptin neurons in the arcuate or infundibular nucleus coexpress neurokinin B and in some animal species, dynorphin, thereby coined KNDy neurons. During menopause, KNDy neurons hypertrophy and show increased neuronal excitability, presumably due to feedback effects of estrogen deficiency as these changes can be reversed by estrogen administration.[481,533] In addition, if KNDy neurons are selectively ablated, altered thermoregulatory responses are observed, suggesting that KNDY neurons are involved in the mechanism of heat dissipation.[534] Particularly noteworthy is that a population of thermosensitive neurons in the POA receive inputs from KNDy neurons[535] and also express the neurokinin 3 receptor (NK3R).[536] Thus, when a NK3R agonist is administered into the POA of experimental animals or neurokinin B is administered peripherally to human subjects, heat dissipation responses are observed.[537,538] Conversely, administration of an oral NK3R antagonist (MLE4901) to postmenopausal women reduces the frequency and severity of hot flashes.[539,540] As surmised by Prague and Dhillo,[532] the improvement in postmenopausal vasomotor symptoms observed with NK3R antagonists may provide an alternative to the use of estrogens, particularly in women with a history of or at risk of developing breast cancer, and for symptomatic men who are being treated for prostate cancer with androgen deprivation therapy.

Orexin-A

Orexin-A (sometimes referred to as hypocretin 1) derives exclusively from neurons in the lateral hypothalamic area, but it is contained in axons that are widely distributed throughout the central nervous system, including projections to thermoregulatory centers of the sympathetic nervous system such as the periaqueductal gray, rRPA, and intermediolateral cell column of the spinal cord.[541–543] While best known for its effects on arousal (see "Sleep-Wake Cycle") and its deficiency is etiologic for narcolepsy,[544] the peptide also regulates body temperature. Injection of orexin-A into the CSF increases sympathetic activity, including increased c-Fos in the rRPA,[545] and is associated with a rise in body temperature mediated by BAT thermogenesis.[546] The importance of this peptide (and/or associated co-neurotransmitters) in the maintenance of thermoregulatory homeostasis is indicated by a blunted hyperthermic response to cold exposure in mice with ablation of orexin neurons[547] and may explain dysregulation of thermogenesis in individuals with narcolepsy.[548]

Prostaglandins

Under certain circumstances, there is an adaptive advantage to elevate body temperature beyond the normal physiologic range that is highly conserved among animal species. Such is the situation during infection, when fever is a necessary response to facilitate recovery by improving the efficiency of immune cells and impairing replication of microorganisms.[549] A variety of cytokines, including IL-1, IL-6, and TNFα, are secreted in response to pathogens, resulting in the production of PGE_2 by the brain vasculature. GABAergic neurons in the MnPO and MePO express the prostaglandin EP_3 receptor, which when bound by PGE_2 alters the thermoregulatory set-point and induces fever.[550,551] EP_3 receptor POA neurons heavily project to DMN and rRPA,[552,553] disinhibiting these sympathoexcitatory neurons to provide excitatory drive for sympathetic outflow to BAT and to promote shivering through rRPa projections to ventral horn motor cells.[554]

In addition to inducing fever, endotoxin simultaneously activates an endogenous, counterregulatory, antipyretic response to prevent body temperature from rising too severely. This is largely achieved by stimulating the hypothalamic-pituitary-adrenal axis that exerts a dampening effect on the cytokine response, but more specifically by the direct antipyretic actions of α-MSH within the CNS.[555] As the VMPO is heavily innervated by axon terminals containing α-MSH, a direct effect on POA thermosensitive neurons is suggested.[556] Alpha-MSH is also contained in axons that heavily innervate autonomic regulatory neurons in the parvocellular PVN and the hypothalamic DMN, providing an alternative route for regulatory control over vasomotor responses and heat generation.

Opioids and Endocannabinoids

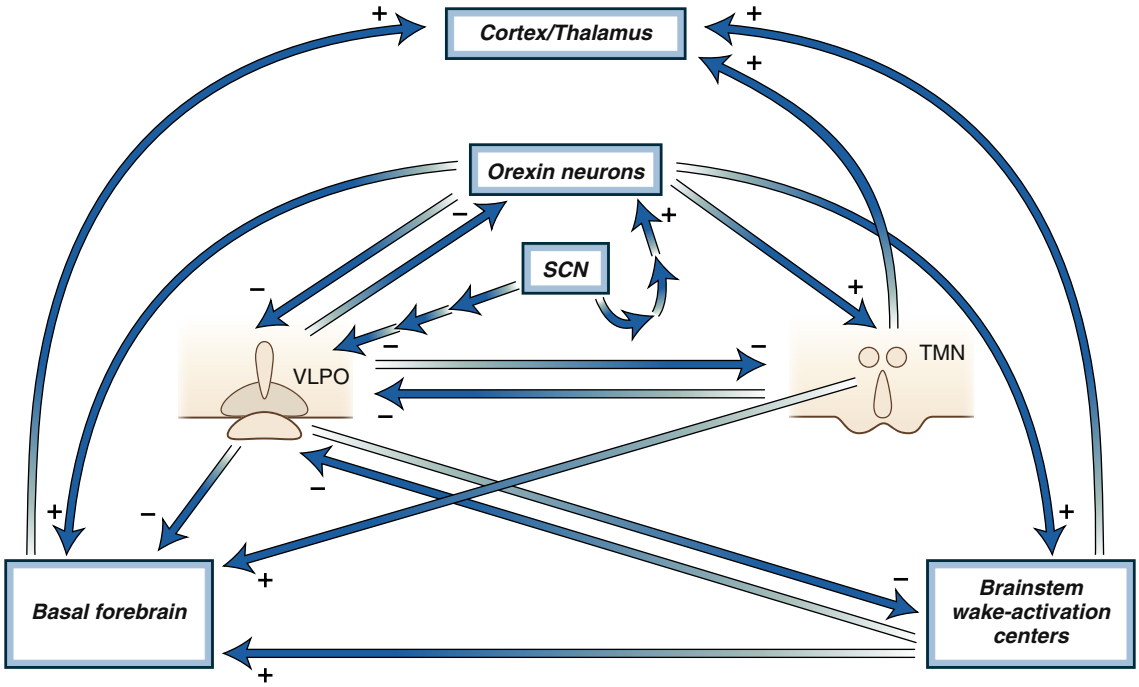
In addition to prostaglandins, there is evidence that opioids and endocannabinoids participate in febrile responses induced by pyrogens. Opioid receptors have been identified in the POA,[557] and activation of μ-opioid receptors causes hyperthermia.[558] In addition, fever induced by endotoxin administration of TNFα but not IL-1β can be reduced by a μ-opioid antagonist, indicating that the mechanism for the febrile response can differ among the various cytokines.[559] Similarly, endocannabinoids can also contribute to the febrile response as central administration of the CB1 receptor antagonist, AM251, reduces fever induced by TNFα, IL1β, and IL6.[560]

Sleep-Wake Cycle

Sleep is a natural state of altered consciousness that is divided into two distinct states: non–rapid eye movement (NREM) sleep characterized by the deepest sleep in stage 3 (slow-wave sleep) but with variable states of arousal, and rapid eye movement (REM) sleep, during which dreams are common and accompanied by autonomic activity. The neural organization of the sleep-wake cycle relies on multiple regions in the brain that produce either sleep or arousal and includes the hypothalamus. The primary sleep centers are located in the VLPO and MnPO of the hypothalamus and are composed of neurons that produce GABA and galanin.[561] Melanin-concentrating hormone (MCH) and GHRH neurons in the hypothalamus, somatostatin neurons in the basal forebrain, nNOS neurons in the cortex, and GABAergic neurons in the parafacial zone of the brainstem also contribute to sleep promotion.[562] Wakefulness centers are more numerous and include glutaminergic neurons in the parabrachial nucleus and pedunculopontine tegmental nucleus of the brainstem and GABAergic, cholinergic, and glutaminergic neurons in the basal forebrain.[562] Other nuclei involved in wakefulness include noradrenergic neurons in the locus coeruleus, serotonergic neurons in the dorsal raphe, dopaminergic neurons in the ventral periaqueductal gray, cholinergic cell groups in the pontine, and mesencephalic reticular formation, including the laterodorsal and pedunculopontine tegmentum, histaminergic neurons in the TMN, orexin (hypocretin)/glutamatergic and possibly GABAergic neurons in the lateral hypothalamic area, and neurons in the prefrontal cortex.[563] The reason for the need of such a large number of wake-promoting cell groups remains uncertain; perhaps they serve a redundant purpose, as with the exception of the parabrachial nucleus and pedunculopontine tegmentum, lesions of the other cell groups result in only partial loss of wake time (see Saper and colleagues[563] for review).

Central Circuitries Mediating the Sleep-Wake Cycle

The central pathways mediating the sleep-wake cycle are complex due to numerous interconnections among many regions of the brain, illustrated in Fig. 7.33 and reviewed in detail by Saper and colleagues,[563] Saper and Fuller,[562] Schwartz and Kilduff,[564] and Scammell and colleagues.[565] To briefly summarize salient points with particular reference to the hypothalamus, wake-promoting pathways ascend from the brainstem into two major divisions, a dorsal pathway that enters the thalamus and a ventral pathway that innervates the hypothalamus, basal forebrain, and cortex. Both pathways, however, are required for normal wakefulness.[566,567] Within the hypothalamus, TMN histaminergic neurons excite neurons in the cortex and thalamus and suppress VPLO activity. Orexin neurons excite the TMN but also project to the locus coeruleus and other arousal centers in the CNS.[568] NREM sleep is driven by the VLPO and MnPO, primarily by inhibiting wakefulness centers in the TMN, locus coeruleus, and dorsal raphe, and, if the VLPO is lesioned, there is profound reduction in NREM sleep.[569] Sleep-promoting neurons in the basal forebrain inhibit wake-promoting neurons in that same nucleus and directly inhibit cortical neurons.[565,570] The hypothalamic VLPO also contributes to REM sleep by innervating brainstem regions that promote REM sleep, such as the dorsal raphe and locus coeruleus. Hypothalamic neurons that synthesize MCH project to the subcoeruleus in the pons, producing muscle atonia that is characteristic of REM sleep,[571] and orexin neurons, although part of the wake-promoting system also appears to be involved in REM sleep as inhibiting these neurons increases REM sleep, presumably through brainstem projections.[572]



• **Fig. 7.33** Simplified diagram showing the connectivity of major regions of the brain involved in the sleep-wake cycle. *SCN,* suprachiasmatic nucleus; *TMN,* tuberomammillary nucleus; *VLPO,* ventrolateral preoptic nucleus.

Circadian Regulation of Sleep-Wake Cycle

Sleep is coupled to periods of wakefulness, giving rise to a circadian sleep-wake cycle whose timing is orchestrated to a 24-hour day-night cycle by photic stimuli transmitted to the hypothalamic SCN. As alluded to previously (see "Pineal Gland"), melatonin has an essential role in relaying this information to the SCN, ultimately attenuating the wake-promoting effects of the circadian clock. Thus sleep disorders are commonly observed in the blind due to the inability to synchronize with the day-night cycle (see Zisapel[573] for review), and ablation of the SCN or transgenic mice lacking various clock genes shows alterations in sleep time and sleep fragmentation.[574,575] The SCN is hardwired into the sleep-wake system, although indirectly. The main output of the SCN is to the subparaventricular zone of the hypothalamus that sends axons to the dorsomedial nucleus of the hypothalamus. The dorsomedial nucleus then projects to the VLPO to inhibit its activity and to orexin neurons in the lateral hypothalamus to activate its activity, hence promoting wakefulness.[576]

Somnogens

Somnogens are sleep-inducing substances and include adenosine, prostaglandin D_2, and cytokines, in particular IB-1β and TNF-α. Adenosine released from astrocytes is probably the most important somnogen and tends to increase during prolonged periods of wakefulness.[577,578] Prostaglandin D_2 is produced by the leptomeninges, and cytokines can either enter the CNS from the peripheral circulation or arise within the brain itself.[579] However, the somnogenic effect of cytokines may be mediated by prostaglandin D_2 as the effects of IL-1β on sleep can be suppressed by cyclooxygenase inhibitors, and the somnogenic effect of prostaglandin D_2 can be mediated by an increase in adenosine.[580] If adenosine A2A receptors are silenced, the somnogenic effect of prostaglandin D_2 is attenuated.[581] Adenosine A2A receptors promote NREM sleep by inhibiting histaminergic neurons in the TMN via activation of the VLPO.[582] This mechanism may also partly explain the arousing effects of caffeine, an adenosine antagonist that loses its wake-promoting effects in A2A knockout mice.[583]

As alluded to previously, GHRH has somnogenic effects (see "Growth Hormone–Releasing Hormone," then "Extrapituitary Functions"), and when administered ICV to experimental animals it stimulates NREM sleep that can be antagonized by somatostatin analogues.[584] The action of GHRH appears to be independent of GH and involves the actions of GHRH on the VLPO and MnPO as GABAergic neurons in these regions show increased c-Fos expression in response to GHRH. Evidence that GHRH also exerts somnogenic effects in humans is suggested by the well-recognized phenomenon of increased release of GH during sleep and individual reports demonstrating a reduction in sleep quality in individuals with GHRH resistance.[585]

Modifying Factors Influencing Sleep

The brain is also equipped to override the normal mechanisms involved in the sleep-wake cycle under situations when remaining awake is important for survival. Such a situation is food deprivation associated with increased wakefulness and locomotor activity. Orexin-producing neurons in the lateral hypothalamus have a major role in this response as transgenic animals in which orexin neurons have been ablated fail to respond to increased wakefulness with fasting.[586] Orexin neurons serve as an interface between wakefulness and energy homeostasis, maintaining arousal during periods of food unavailability. They are inhibited by glucose and leptin and activated by ghrelin, humeral signals that promote increased food intake and reduced energy expenditure (see Chapter 39). Orexin neurons project widely throughout the central nervous system and excite wakefulness centers (including histaminergic neurons in the TMN, monoaminergic neurons in the brainstem, and cholinergic neurons in the basal forebrain) and inhibit the VLPO.[587]

A variety of other factors can contribute to sleep disruption, including psychiatric disorders, psychosocial problems, alcoholism, pain, and chronic medical conditions such as diabetes mellitus, chronic renal failure, and Alzheimer disease, among many others (see Medic and colleagues[588] for review). However, the pathophysiology is likely multifactorial and not well established for most. Activation of the hypothalamic-pituitary-adrenal axis is likely involved for some conditions such as major depression[589] and due to elevations in cortisol, as similar sleep alterations are observed in individuals with Cushing syndrome.[590] However, CRH-induced activation of wakefulness centers, including orexin neurons in the lateral hypothalamus and norepinephrine neurons in the locus coeruleus, may also contribute to sleep disruption.[591] Stressed animals also show c-Fos activation in a variety of regions of the brain that may contribute to maintaining a waking state, including regions of the amygdala and infralimbic cortex.[592]

Neuroendocrine Disease

Disease of the hypothalamus can cause pituitary dysfunction, neuropsychiatric and behavioral disorders, and disturbances of autonomic and metabolic regulation. In the diagnosis and treatment of suspected hypothalamic or pituitary disease, four issues must be considered: the extent of the lesion, the physiologic impact, the specific cause, and the psychosocial setting. The cause of hypothalamic neuroendocrine disorders categorized by age and syndrome is summarized in Tables 7.6 and 7.7.

Manifestations of pituitary insufficiency secondary to hypothalamic or pituitary stalk damage are not identical to those of primary pituitary insufficiency. Hypothalamic injury causes decreased secretion of most pituitary hormones but can cause hypersecretion of hormones normally under inhibitory control by the hypothalamus, as in hypersecretion of PRL after damage to the pituitary stalk and precocious puberty caused by loss of the normal restraint over gonadotropin maturation. Impairment of inhibitory control of the neurohypophysis can lead to the syndrome of inappropriate vasopressin (antidiuretic hormone) secretion (SIADH) (see Chapter 10). More subtle abnormalities in secretion can result from impairment of the control system. For example, loss of the normal circadian rhythm of ACTH secretion may occur before loss of pituitary-adrenal secretory reserve, and responses to physiologic stimuli may be paradoxic. Because hypophysiotropic hormone levels cannot be measured directly and pituitary hormone secretion is regulated by complex, multilayered controls, assay of pituitary hormones in blood does not necessarily give a meaningful picture of events at hypothalamic and higher levels. Rarely, tumors secrete excessive amounts of releasing peptides and cause hypersecretion of hormones from the pituitary.

Disorders of the hypothalamic-pituitary unit can result from lesions at several levels. Defects can arise from destruction of the pituitary (as by tumor, infarct, inflammation, or autoimmune disease) or from a hereditary deficiency as with PROP1 mutations associated with GH, prolactin, and TSH deficiencies. Selective

TABLE 7.6 Etiology of Hypothalamic Disease by Age

Premature Infants and Neonates

Intraventricular hemorrhage
Meningitis: bacterial
Tumors: glioma, hemangioma
Trauma
Hydrocephalus, kernicterus

Age 1 Month to 2 Years

Tumors: optic glioma, histiocytosis X, hemangioma
Hydrocephalus
Meningitis
Congenital disorders: Kallmann syndrome, Laurence-Moon-Biedl syndrome, Prader-Willi syndrome

Age 2 to 10 Years

Tumors: craniopharyngioma, glioma, dysgerminoma, hamartoma, leukemia, histiocytosis X, ganglioneuroma, ependymoma, medulloblastoma
Meningitis: bacterial, tuberculous
Encephalitis: viral (exanthematous demyelinating)
Congenital diabetes insipidus
Radiation therapy
Diabetic ketoacidosis
Moyamoya disease, circle of Willis

Age 10 to 25 Years

Tumors: craniopharyngioma, glioma, hamartoma, dysgerminoma, histiocytosis X, leukemia, dermoid, lipoma, neuroblastoma
Trauma
Vascular: aneurysm, subarachnoid hemorrhage, arteriovenous malformation
Inflammatory disease: meningitis, encephalitis, sarcoidosis, tuberculosis
Structural brain defects: chronic hydrocephalus, increased intracranial pressure

Age 25 to 50 Years

Nutritional: Wernicke disease
Tumors: glioma, lymphoma, meningioma, craniopharyngioma, pituitary tumors, plasmacytoma, angioma, colloid cysts, sarcoma, ependymoma, histiocytosis X
Inflammatory diseases: sarcoidosis, tuberculosis, viral encephalitis
Vascular: aneurysm, subarachnoid hemorrhage, arteriovenous malformation
Damage from pituitary radiation therapy

Age 50 Years and Older

Nutritional: Wernicke disease
Tumors: pituitary tumors, sarcoma, glioblastoma, ependymoma, meningioma, colloid cysts, lymphoma
Vascular disease: infarct, subarachnoid hemorrhage, pituitary apoplexy
Inflammatory disease: encephalitis, sarcoidosis, meningitis
Damage from radiation therapy for ear-nose-throat carcinoma, pituitary tumors

TABLE 7.7 Etiology of Endocrine Syndromes of Hypothalamic Origin

Hypophysiotropic Hormone Deficiency

Surgical pituitary stalk section
Inflammatory disease: basilar meningitis and granuloma, sarcoidosis, tuberculosis, sphenoid osteomyelitis, eosinophilic granuloma
Craniopharyngioma
Hypothalamic tumor: infundibuloma, teratoma (ectopic pinealoma), astrocytoma
Maternal deprivation syndrome, psychosocial dwarfism
Isolated GHRH deficiency
Hypothalamic hypothyroidism
Panhypophysiotropic failure

Disorders of Regulation of GnRH Secretion

Female

Precocious puberty: GnRH-secreting hamartoma, hCG-secreting germinoma
Delayed puberty
Neurogenic amenorrhea
Pseudocyesis
Anorexia nervosa
Functional amenorrhea and oligomenorrhea
Drug-induced amenorrhea
Kallman syndrome
GPR54 (KISS1R) mutations

Male

Precocious puberty
Anorexia nervosa
Fröhlich syndrome
Drug-induced hypogonadism
Kallmann syndrome
GPR54 (KISSR1) mutations

Disorders of Regulation of Prolactin-Regulating Factors

Tumor
Sarcoidosis
Drug induced
Reflex
Herpes zoster of chest wall
Post-thoracotomy
Nipple manipulation
Spinal cord tumor
Psychogenic
Hypothyroidism
Carbon dioxide narcosis

Disorders of Regulation of CRH

Paroxysmal corticotropin discharge (Wolff syndrome)
Loss of circadian variation
Depression
CRH-secreting gangliocytoma

CRH, Corticotropin-releasing hormone; *hCG,* human chorionic gonadotropin; *GHRH,* growth hormone–releasing hormone; *GnRH,* gonadotropin-releasing hormone.

loss of thyroid hormone receptors or GnRH receptors in the pituitary can give rise to increased TSH secretion and thyrotoxicosis or hypogonadotropic hypogonadism, respectively. Furthermore, disorders can arise through disruption of the contact zone between the stalk and the median eminence, the stalk itself, or the nerve terminals of the tuberoinfundibular system; such disruption occurs after surgical stalk section, with tumors involving the stalk, including metastatic disease, and in some inflammatory disorders such as sarcoidosis or neurohypophysitis. At a higher level, tonic inhibitory and excitatory inputs can be lost as manifested by absence of circadian rhythms or the development of precocious puberty. Physical stress, cytokine products of inflammatory cells, toxins, and reflex inputs from peripheral homeostatic monitors also impinge on the tuberoinfundibular system. At the highest

level of control, emotional stress and psychologic disorders can activate the pituitary-adrenal stress response and suppress gonadotropin secretion (e.g., psychogenic amenorrhea) or inhibit GH secretion (e.g., psychosocial dwarfism) (see Chapter 25). Intrinsic disease of the anterior pituitary is reviewed in Chapters 8 and 9, and disturbances in posterior pituitary function are discussed in Chapter 10. This chapter primarily considers diseases of the hypothalamic-pituitary unit.

Pituitary Isolation Syndrome

Destructive lesions of the pituitary stalk, as occur with head injury, surgical transection, tumor, or granuloma, produce a characteristic pattern of pituitary dysfunction.[593,594] Central diabetes insipidus (DI) develops in a large percentage of patients, depending on the level at which the stalk has been sectioned. If the cut is close to the hypothalamus, DI is almost always produced, but if the section is low on the stalk, the incidence is lower. The extent to which nerve terminals in the upper stalk are preserved determines the clinical course. The classic triphasic syndrome of initial polyuria followed by normal water control and then by AVP deficiency over a period of 1 week to 10 days occurs in fewer than half of the patients. The sequence is attributed to an initial loss of neurogenic control of the neural lobe, followed by autolysis of the neural lobe with release of AVP into the circulation, and finally by complete loss of AVP. However, full expression of polyuria requires adequate cortisol levels; if cortisol is deficient, AVP deficiency may be present with only minimal polyuria. DI can also develop after stalk injury without an overt transitional phase. When DI occurs after head injury or operative trauma, varying degrees of recovery can be seen even after months or years. Sprouting of nerve terminals in the stump of the pituitary stalk may give rise to sufficient functioning tissue to maintain water balance. In contrast to the effects of stalk section, nondestructive injury to the neurohypophysis or stalk, as during surgical resection of sellar tumors, can sometimes give rise to transient or delayed SIADH.[595]

Although head injury, granulomas, and tumors are the most common causes of acquired DI, other cases develop in the absence of a clear-cut cause.[596] Autoimmune disease of the hypothalamus may be the cause in some instances, as was suggested by the finding of autoantibodies to neurohypophyseal cells in a third of cases of idiopathic DI in one series.[597] However, autoantibodies were also frequently found in association with histiocytosis X. Later reports suggested the importance of continued vigilance in cases of idiopathic DI. A definite cause is frequently uncovered in time, including a high proportion of occult germinomas, whose detection by MRI may be preceded by elevated levels of hCG in CSF.[598] Congenital DI can be part of a hereditary disease. DI in the Brattleboro rat is due to an autosomal recessive genetic defect that impairs production of AVP but not of oxytocin. In contrast, inherited forms of DI in humans have been attributed to mutations in the vasopressin V_2 receptor gene or less frequently in the aquaporin or the AVP genes.[599–601]

Menstrual cycles cease after stalk section, although gonadotropins may still be detectable, unlike the situation after hypophysectomy. Plasma glucocorticoid levels and urinary excretion of cortisol decline after hypophysectomy and stalk section, but the change is slower after stalk section. A transient increase in cortisol secretion after stalk section is believed to be due to release of ACTH from preformed stores. The ACTH response to the lowering of blood cortisol is markedly reduced, but ACTH release after stress may be normal, possibly because of CRH-independent mechanisms. Reduction in thyroid function after stalk section is similar to that seen with hypophysectomy. The fall in GH secretion is said to be the most sensitive indication of damage to the stalk, but the insidious nature of this endocrinologic change in adults who have suffered traumatic brain injuries may cause it to be overlooked and therefore contribute to delayed rehabilitation.[602]

Humans with stalk sections or with tumors of the stalk region have widely varying levels of hyperprolactinemia and may have galactorrhea.[603] PRL responses to hypoglycemia and to TRH are blunted, in part because of loss of neural connections with the hypothalamus. PRL responses to dopamine agonists and antagonists in patients with pituitary isolation syndrome are similar to those in patients with prolactinomas. Interestingly, PRL secretion continues to show a diurnal variation in patients with either hypothalamic-pituitary disconnection or microprolactinoma.[412] Both forms of hyperprolactinemia are characterized by a similarly increased frequency of PRL pulses and a marked rise in nonpulsatile or basal PRL secretion, although the disruption is greater in the tumoral hyperprolactinemia.

An incomplete pituitary isolation syndrome may occur with the empty sella syndrome, intrasellar cysts, or pituitary adenomas.[604,605] Anterior pituitary failure after stalk section is in part due to loss of specific neural and vascular links to the hypothalamus and in part due to pituitary infarction.

Hypophysiotropic Hormone Deficiency

Selective pituitary failure can be due to a deficiency of specific pituitary cell types or a deficiency of one or more hypothalamic hormones. Isolated GnRH deficiency is the most common hypophysiotropic hormone deficiency. In X-linked Kallmann syndrome (gonadotropin deficiency commonly associated with hyposmia),[440] hereditary agenesis of the olfactory lobe may be demonstrable by MRI.[606] Abnormal development of the GnRH system is a result of defective migration of the GnRH-containing neurons from the olfactory nasal epithelium in early embryologic life (see earlier discussion). Other malformations of the cranial midline structures, such as absence of the septum pellucidum in septo-optic dysplasia (De Morsier syndrome), can cause hypogonadotropic hypogonadism or, less commonly, precocious puberty. A surprisingly large percentage of children with septo-optic dysplasia who otherwise have multiple hypothalamic-pituitary abnormalities actually retain normal gonadotropin function and enter puberty spontaneously.[607] The genetic basis of hypogonadotropic hypogonadism include X-linked mutations in *KAL1*, the Kallmann syndrome gene, and in *NROB1* (formerly *AHC* or *DAX1*), the gene that causes adrenal hypoplasia congenital with hypogonadotropic hypogonadism.[442,608] Autosomal recessive hypogonadotropic hypogonadism has been associated with mutations in the genes encoding the GnRH receptor, KISS1 receptor, leptin, leptin receptor, FSH, LH, PROP1 (combined pituitary deficiency), and HESX (septo-optic dysplasia) genes, and deficient FGFR1 function causes an autosomal dominant form of hypogonadotropic hypogonadism. Mutations in *PROK2* and *PROKR2*, which encode prokinectin-2 and its receptor, have been associated with heterozygous, homozygous, compound heterozygous, and oligogenic patterns of genetic penetrance.

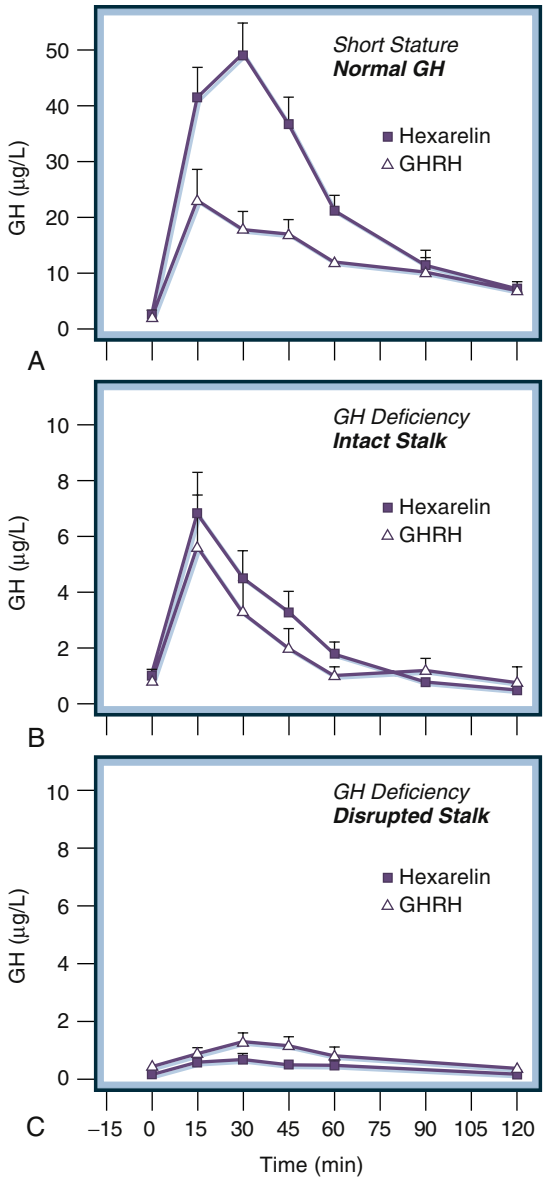
The GnRH stimulation test is of little value in the differential diagnosis of hypogonadotropic hypogonadism. Most patients with GnRH deficiency show little or no response to an initial test dose but normal responses after repeated injection. This slow response has been attributed to downregulation of GnRH

receptors in response to prolonged GnRH deficiency. In patients with intrinsic pituitary disease, the response to GnRH may be absent or normal. Consequently, it is not possible to distinguish between hypothalamic and pituitary disease with a single injection of GnRH. Prolonged infusions or repeated administration of GnRH agonists after hormone replacement therapy priming may aid in the diagnosis or provide therapeutic options for women with Kallmann syndrome who wish to become pregnant.[609,610]

Deficiency of TRH secretion gives rise to hypothalamic hypothyroidism, also called *tertiary hypothyroidism*, which can occur in hypothalamic disease or more rarely as an isolated defect.[611] Molecular genetic analyses have revealed infrequent autosomal recessive mutations in the TRH and TRH receptor genes in the cause of central hypothyroidism.[612] Hypothalamic and pituitary causes of TSH deficiency are most readily distinguished by imaging methods. Although it is theoretically reasonable to use the TRH stimulation test for the differentiation of hypothalamic disease from pituitary disease, the test is of limited value. The typical pituitary response to TRH administration in patients with TRH deficiency is an enhanced and somewhat delayed peak, whereas the response with pituitary failure is subnormal or absent. The hypothalamic type of response has been attributed to an associated GH deficiency that sensitizes the pituitary to TRH (possibly through suppression of somatostatin secretion), but GH also affects T_4 metabolism and may alter pituitary responses.[613] In practice, the responses to TRH in hypothalamic and pituitary disease overlap so much that they cannot be used reliably for a differential diagnosis. Persistent failure to demonstrate responses to TRH is good evidence for the presence of intrinsic pituitary disease, but the presence of a response does not mean that the pituitary is normal. Deficient TRH secretion leads to altered TSH biosynthesis by the pituitary, including impaired glycosylation. Poorly glycosylated TSH has low biologic activity, and dissociation of bioactive and immunoreactive TSH can lead to the paradox of normal or elevated levels of TSH in hypothalamic hypothyroidism.[611,614]

GHRH deficiency appears to be the principal cause of hGH deficiency in children with idiopathic dwarfism.[615] This condition is frequently associated with abnormal electroencephalograms (EEGs), a history of birth trauma, and breech delivery, although a cause-and-effect relationship has not been established. MRI scans show that most children with isolated, idiopathic hGH deficiency have a normal-sized or only slightly reduced anterior pituitary; less common findings are ectopic posterior pituitary, anterior pituitary hypoplasia, or empty sella.[616] In contrast, children with idiopathic combined pituitary hormone deficiency are significantly more likely to have evidence of moderate to severe anterior pituitary hypoplasia, ectopic posterior pituitary, complete agenesis of the pituitary stalk (both nervous and vascular components), and a variety of associated midline cerebral malformations.[616] Human GH is the most vulnerable of the anterior pituitary hormones when the pituitary stalk is damaged. It can be difficult to differentiate between primary pituitary disease and GHRH deficiency by standard tests of GH reserve. However, a substantial GH secretory response to a single administration of hexarelin occurs only in the presence of at least a partially intact vascular stalk (Fig. 7.34).[294]

In many children with dwarfism, the anatomic abnormalities of the intrasellar contents and pituitary stalk together with the frequent occurrence of other midline defects, such as those in septo-optic dysplasia, are consistent with the alternative hypothesis of a developmental defect occurring in embryogenesis.[616] There has been a remarkable advance in our understanding of the molecular ontogeny of the hypothalamic-pituitary unit, much of it based on mutant mouse models.[617] Parallel genetic analyses have been conducted in children with isolated GH deficiency or combined pituitary hormone deficiencies. These studies have identified autosomal recessive mutations in both structural and regulatory genes, including the genes encoding the GHRH receptor, PIT1, PROP1, HESX1, LHX3, and LHX4 that are responsible for a



• **Fig. 7.34** Effect of hypothalamic-pituitary disconnection on the growth hormone (GH) secretory responses to GH-releasing hormone (GHRH) (1 μg/kg) and the GH-secretagogue (GHS) receptor agonist, hexarelin (2 μg/kg), administered intravenously to children with GH deficiency. (A) Mean responses in a group of 24 prepubertal children with short stature secondary to familial short stature or constitutional growth delay are shown. (B) Children with GH deficiency and an intact vascular pituitary stalk as visualized by dynamic magnetic resonance imaging exhibited a clear, but blunted, GH response to both secretagogues. (C) In contrast, children with pituitary stalk agenesis (both vascular and neural components) had no response or a markedly attenuated response to both peptides. (From Maghnie M, Spica-Russotto V, Cappa M, et al. The growth hormone response to hexarelin in patients with different hypothalamic-pituitary abnormalities. *J Clin Endocrinol Metab.* 1998;83:3886–3889.)

sizable proportion of congenital hypothalamic-pituitary disorders once considered idiopathic.[281,615,616,618] Other mutations that are associated with variable GH deficiencies include ARNT2, GLI2, OTX2, PAX6, and SOX2.[44]

Adrenal insufficiency is another manifestation of hypothalamic disease and rarely is caused by CRH deficiency.[619] Isolated ACTH deficiency is uncommon, but there is suggestive evidence in at least one family of genetic linkage to the *CRH* gene locus.[620] More recent investigations have revealed mutations in *TBX19*, the gene encoding TPIT, a T-box transcription factor expressed only in pituitary corticotrophs and melanotrophs, which is associated with the majority of cases of isolated ACTH deficiency in neonates.[621] Mutations in ARNT2, a basic helix-loop-helix transcription factor and important in development of hypophysiotropic neurons in the PVH, can also result in ACTH and TSH deficiencies.[622] The CRH stimulation test does not reliably distinguish hypothalamic from pituitary failure as a cause of ACTH deficiency.[623]

Apart from intrinsic diseases of the hypothalamus such as tumors and granulomas, two environmental causes of central hypophysiotropic deficiencies are of increasing clinical importance: trauma to the brain,[594,602] particularly from motor vehicle accidents, and the sequelae of chemotherapy and radiation therapy for intracranial lesions in children and adults.[614,624,625] Improved short-term survival from head injuries associated with coma and CNS malignancies has greatly increased the prevalence of long-term neuroendocrine consequences.

Craniopharyngioma

Craniopharyngioma is the most common pediatric tumor occurring in the sellar and parasellar area (see Table 7.6) and accounts for 5% to 15% of all intracranial tumors in this age group.[626] Because of their location, these benign neoplasms frequently cause significant neuroendocrine dysfunction. Adamantinomatous tumors occur at all ages but are most common in children and usually contain both a cystic component filled with a turbid, cholesterol-rich fluid and a solid component characterized by organized epithelial cells.[627] Roughly 25% of craniopharyngiomas are diagnosed in patients over the age of 25 and include a papillary variety that is almost exclusively identified in adults. This subset of tumors tends to be solid and less likely to be calcified or cystic.[627] Both forms of craniopharyngiomas probably result from metaplastic changes in vestigial epithelial cell rests that originate in Rathke pouch and the craniopharyngeal duct during fetal development. The majority of adamantinomatous craniopharyngiomas have mutations of genes encoding β-catenin (*CTNNB1* and *APC*), whereas papillary craniopharyngiomas harbor BRAF V600E mutations.[628,629]

Common presenting symptoms are those due to a mass intracranial lesion and increased intracranial pressure. Visual field defects, papilledema, and optic atrophy can occur from compression of the optic chiasm or nerves. Between 80% and 90% of affected children have signs and symptoms of endocrine dysfunction, although these are not usually the chief complaint. The most frequent hormone deficiencies are GH and gonadotropins. The latter is almost universal in adolescents and adults and likely also present, but undetected, in prepubertal children with craniopharyngiomas. TSH and ACTH deficiency are also common, and approximately one-third of these patients develop diabetes insipidus. Even if not present at initial diagnosis, endocrine dysfunction often occurs subsequent to treatment that may also include obesity, imbalances in body temperature, autonomic dysfunction, sleep disturbances, and behavioral changes and necessitates long-term follow-up and retesting.[630,631]

MRI is the imaging modality of choice in cases of suspected craniopharyngioma.[632] A recommended examination includes T1-weighted thin sagittal and coronal sections through the sella and suprasellar regions, obtained before and after contrast administration. T2-weighted and fluid attenuation inversion recovery (FLAIR) images are useful to further delineate cysts and are hyperintense. Computed tomography scans can be useful to determine the presence of calcification.

Hypophysiotropic Hormone Hypersecretion

Pituitary hypersecretion is occasionally caused by tumors of the hypothalamus. GnRH-secreting hamartomas can cause precocious puberty.[633] CRH-secreting gangliocytomas can cause Cushing syndrome,[634] and GHRH-secreting gangliocytomas of the hypothalamus can cause acromegaly.[635] Although they do not arise from the hypothalamus, paraneoplastic syndromes can also cause pituitary hypersecretion, as with bronchial and pancreatic islet cell carcinoid tumors secreting CRH or GHRH.

Neuroendocrine Disorders of Gonadotropin Regulation

Precocious Puberty

The term *precocious puberty* is used when physiologically normal pituitary-gonadal function appears at an early age (see also Chapter 26).[636] By convention, it is defined as the onset of androgen secretion, and spermatogenesis must occur before the age of 9 or 10 years in boys and the onset of estrogen secretion and cyclic ovarian activity before age 7 or 8 in girls.[637,638] Central precocious puberty is due to disturbed CNS function, which may or may not have an identifiable structural basis. Pseudoprecocious puberty refers to premature sexual development resulting from excessive secretion of androgens, estrogens, or hCG; it is caused by tumors (both gonadal and extragonadal), administration of exogenous gonadal steroids, or genetically determined activation of gonadotropin receptors (see Chapter 25). Central precocious puberty with neurogenic causes and pineal gland disease are discussed in this chapter.

Idiopathic Sexual Precocity

Familial occurrence of idiopathic sexual precocity is uncommon, but there is a hereditary form of idiopathic sexual precocity that is largely confined to boys. Abnormal EEGs and behavioral disturbances, suggesting the presence of brain damage, have been reported occasionally in girls with idiopathic precocious puberty. The pathogenesis may be related to the rate of hypothalamic development or other as yet undetermined nutritional, environmental, or psychosocial factors. Many cases previously thought to be idiopathic are caused by small hypothalamic hamartomas (see later discussion). It has been argued that localized activation of discrete cellular subsets connected to GnRH neurons may be sufficient to initiate puberty.[639]

Neurogenic Precocious Puberty

Approximately two-thirds of hypothalamic lesions that influence the timing of human puberty are located in the posterior hypothalamus, but in the subset of patients who come to autopsy, damage is extensive. Specific lesions known to cause precocity include craniopharyngioma (although delayed puberty is far more common with these lesions), astrocytoma, pineal tumors, subarachnoid

cysts, encephalitis, miliary tuberculosis, tuberous sclerosis or neurofibromatosis type 1, the Sturge-Weber syndrome, porencephaly, craniosynostosis, microcephaly, hydrocephalus, empty sella syndrome, and Tay-Sachs disease.[640,641]

Hamartoma of the hypothalamus, a tumor-like collection of normal-appearing nerve tissue lodged in an abnormal location, can result in precocious puberty.[642,643] The parahypothalamic type consists of an encapsulated nodule of nerve tissue attached to the floor of the third ventricle or suspended from the floor by a peduncle, typically less than 1 cm in diameter. The intrahypothalamic or sessile type is enveloped by the posterior hypothalamus, which can distort the third ventricle. These hamartomas tend to be larger than the pedunculated variety, grow in the interpeduncular cistern, and are frequently accompanied by seizures, mental retardation, and developmental delays. Before the development of high-resolution scanning techniques, harmatoma was considered rare, but small ones can now be visualized. Miniature hamartomas of the tuber cinereum are common at autopsy. Precocious puberty occurs when the hamartoma makes connections with the median eminence and thus serves as an accessory hypothalamus. Peptidergic nerve terminals containing GnRH have been found in the tumors.[633] Early pubertal development is presumably due to unrestrained GnRH secretion, although the hamartomas almost certainly have an intrinsic pulse generator of GnRH secretion because pulsatility is required for stimulation of gonadotropin secretion (see earlier discussion).

Manifestations of premature puberty in patients with hamartomas are similar to those associated with other central causes of precocity. Hamartomas occur in both sexes and may be present as early as age 3 months. In the past, most cases were thought to be fatal by age 20 years, but many hamartomas cause no brain damage and need not be excised.[642] The interpeduncular fossa of the brain is difficult to approach, and surgical experience is somewhat limited. Early in the course of illness, epilepsy manifested as "brief, repetitive, stereotyped attacks of laughter"[644] may provide a clue to the disease. Late in the course, hypothalamic damage can cause severe neurologic defects and intractable seizures.

Hypothyroidism

Hypothyroidism can cause precocious puberty in girls that is reversible with thyroid therapy. Hyperprolactinemia and galactorrhea may be present. One possibility is that elevated TSH levels (in children with thyroid failure) cross-react with the FSH receptor.[645] Alternatively, low levels of thyroid hormone might simultaneously activate release of LH, FSH, and TSH. A third possibility is that hypothyroidism causes hypothalamic encephalopathy that impairs the normal tonic suppression of gonadotropin release by the hypothalamus. The high PRL levels that sometimes accompany this disorder may be due to a deficiency in PIF secretion, increased secretion of TRH, or increased sensitivity of the lactotrophs to TRH secretion.

Tumors of the Pineal Gland

Pineal gland tumors account for only a small percentage of intracranial neoplasms. They occur as a central midline mass with an enhancing lesion on MRI frequently accompanied by hydrocephalus. Pinealomas cause a variety of neurologic abnormalities. Parinaud syndrome, which consists of paralysis of upward gaze, pupillary areflexia (to light), paralysis of convergence, and a wide-based gait, occurs with about half of patients with pinealomas. Gait disturbances can also occur because of brainstem or cerebellar compression. Additional neurologic signs occurring with moderate frequency include spasticity, ataxia, nystagmus, syncope, vertigo, cranial nerve palsies other than VI and VIII, intention tremor, scotoma, and tinnitus.

Several discrete cytopathologic entities account for mass lesions in the pineal region (Table 7.8).[646] The most common nonneoplastic conditions are degenerative pineal cysts, arachnoid cysts, and cavernous hemangioma. Pinealocytes give rise to primitive neuroectodermal tumors, the so-called *small blue-cell tumors* that are immunopositive for the neuronal marker synaptophysin and negative for the lymphocyte marker CD45. True pinealomas can be relatively well-differentiated pineocytomas, intermediate mixed forms, or the less-differentiated pineoblastomas,[646,647] which are essentially identical to medulloblastomas, neuroblastomas, and oat cell carcinomas of the lung.

The most common tumors of the pineal gland are actually germinomas (a form of teratoma), so designated because of their presumed origin in germ cells. Germinomas may also occur in the anterior hypothalamus or the floor of the third ventricle, where they are often associated with the clinical triad of DI, pituitary insufficiency, and visual abnormalities.[641] Identical tumors can be found in the testis and anterior mediastinum. Intracranial

TABLE 7.8 Classification of Tumors of the Pineal Region

Germ Cell Tumors

- Germinoma
  - Posterior third ventricle and pineal lesions
  - Anterior third ventricle, suprasellar, or intrasellar lesions
  - Combined lesions in anterior and posterior third ventricle, apparently noncontiguous, with or without foci of cystic or solid teratoma
- Teratoma
  - Evidencing growth along two or three germ lines in varying degrees of differentiation
  - Dermoid and epidermoid cysts with or without solid foci of teratoma
  - Histologically malignant forms with or without differentiated foci of benign, solid, or cystic teratoma-teratocarcinoma, chorioepithelioma, embryonal carcinoma (endodermal–sinus tumor or yolk-sac carcinoma); combinations of these with or without foci of germinoma, chemodectoma

Pineal Parenchymal Tumors

- Pinealocytes
  - Pineocytoma
  - Pineoblastoma
  - Ganglioglioma and chemodectoma
  - Mixed forms exhibiting transitions among these types
- Glia
  - Astrocytoma
  - Ependymoma
  - Mixed forms and other less frequent gliomas (e.g., glioblastoma, oligodendroglioma)

Tumors of Supporting or Adjacent Structures

- Meningioma
- Hemangiopericytoma

Nonneoplastic Conditions of Neurosurgical Importance

- Degenerative cysts of pineal gland lined by fibrillary astrocytes
- Arachnoid cysts
- Cavernous hemangioma

From DeGirolami U. Pathology of tumors of the pineal region. In: Schmidek HH, ed. *Pineal Tumors*. New York: Masson; 1977:1–19.

germinomas have a tendency to spread locally, infiltrate the hypothalamus, and metastasize to the spinal cord and CSF. Extracranial metastases (to skin, lung, or liver) are rare. Teratomas derived from two or more germ cell layers also occur in the pineal region. Chorionic tissue in teratomas and germinomas may secrete hCG in sufficient amounts to cause gonadal maturation, and some of these tumors have the histologic and functional characteristics of choriocarcinomas. Diagnosis is confirmed by the combination of a mass lesion, cytologic analysis of CSF, and radioimmunoassay detection of hCG in the CSF.

Precocious puberty is a relatively unusual manifestation of pineal gland disease. When it occurs, neuroanatomic studies suggest that the cause is secondary to pressure or destructive effects of the pineal tumor on the function of the adjacent hypothalamus or to the secretion of hCG. Most patients have other evidence of hypothalamic involvement such as DI, polyphagia, somnolence, obesity, or behavioral disturbance. Choriocarcinoma of the pineal gland is associated with high plasma levels of hCG. The hCG can stimulate testosterone secretion from the testis but not estrogen secretion by the ovary; it therefore causes premature puberty almost exclusively in boys. The prevalence of elevated hCG levels in children with premature puberty related to tumors in the pineal region is unknown, but the fact that this phenomenon occurs further challenges the theory that nonparenchymal tumors cause precocious puberty by damaging the normal pineal gland. Rarely, pinealomas cause delayed puberty, raising speculation about the role of melatonin in inhibiting gonadotropin secretion in these cases.

Management of tumors in the pineal region is not straightforward.[646,648] Operative mortality rates can be high, but the rationale for an aggressive approach to the pineal region is based on the need to make a histologic diagnosis, the variety of lesions found in this region, the possibility of cure of an encapsulated lesion, and the effectiveness of chemotherapeutic agents for germinomas and choriocarcinoma. Stereotaxic biopsy of the pineal region provided diagnosis in 33 of 34 cases in one series, suggesting that this is a useful alternative to open surgical exploration for diagnostic purposes.[649] Long-term palliation or cure of many pineal region tumors is possible by combinations of surgery, radiation, gamma knife radiosurgery, or chemotherapy, depending on the nature of the lesion.[650]

Approach to the Patient with Precocious Puberty

Several groups have reviewed the diagnostic approach to suspected central precocious puberty (see Chapter 26).[651,652] Although guidelines differ, the index of suspicion is clearly inversely proportional to the age of the patient. A GnRH stimulation test to assess gonadotropin release and thereby differentiate between primed and inactive gonadotrophs is probably the single most important endocrinologic measure. If LH and FSH levels are not stimulated and there is no evidence of gonadal germ cell maturation, the cause of precocious puberty lies outside the hypothalamic-pituitary axis, and the diagnostic process should focus on the adrenal glands and gonads (see Chapters 15 and 17). MRI studies are central to the workup for exclusion or characterization of organic lesions in the areas of the sella, optic chiasm, suprasellar hypothalamus, and interpeduncular cistern.[653]

Management of Sexual Precocity

Structural lesions of the hypothalamus are treated by surgery, radiation, chemotherapy, or combinations of these as indicated by the pathologic diagnosis and extent of disease. Endocrinologic manifestations of precocious puberty are best treated by GnRH agonists with the therapeutic goals of delaying sexual maturation to a more appropriate age and achieving optimal linear growth and bone mass, possibly with the combined use of GH treatment.[654,655] Other approaches include the use of cyproterone acetate, testolactone, or spironolactone to antagonize or inhibit gonadal steroid biosynthesis.[656,657] Precocious puberty is stressful to both the child and the parents, and it is essential that psychologic support be provided.

Psychogenic Amenorrhea

Menstrual cycles can cease in young nonpregnant women with no demonstrable abnormalities of the brain, pituitary, or ovary in several situations,[658,659] including pseudocyesis (false pregnancy), anorexia nervosa, excessive exercise, psychogenic disorders, and hyperprolactinemic states (see Chapter 17). Psychogenic amenorrhea, the most common cause of secondary amenorrhea except for pregnancy, can occur with major psychopathology or minor psychic stress and is often temporary.

Exercise-induced amenorrhea may be a variant of psychogenic amenorrhea or may result from loss of body fat.[658,660] The syndrome is associated with intense and prolonged physical exertion such as running, swimming, or ballet dancing. Affected women are always below ideal body weight and have low stores of fat. If the activity is begun before puberty, normal sexual maturation can be delayed for many years. Fat mass may be a regulator of gonadotropin secretion with adipocyte-derived leptin as the principal mediator between peripheral energy stores and hypothalamic regulatory centers.[661] Studies in nonhuman primates showed a direct role of caloric intake in the pathogenesis of amenorrhea associated with long-distance running.[662] Exercise and psychogenic amenorrhea can have adverse effects because of the associated estrogen deficiency and accompanying infertility, osteopenia, and increased risk of stress fractures.[663,664] Nevertheless, because of a lack of clear benefit from oral estrogen administration on bone density, perhaps secondary to its suppression of IGF-1, short-term treatment with transdermal estrogen is recommended in women who have not had resumption in menses after a trial of nutritional, psychologic, and/or modified exercise interventions.[665]

Neurogenic Hypogonadism in Males

A discussion of neurogenic hypogonadism in males should begin with an account of Fröhlich syndrome (adiposogenital dystrophy), originally characterized as delayed puberty, hypogonadism, and obesity associated with a tumor that impinges on the hypothalamus.[8] It was subsequently recognized that either hypothalamic or pituitary dysfunction can induce hypogonadism and that the presence of obesity indicates that the appetite-regulating regions of the hypothalamus have been damaged. Several organic lesions of the hypothalamus can cause this syndrome, including tumors, encephalitis, microcephaly, Friedreich ataxia, and demyelinating diseases. Other important causes of hypogonadotropic hypogonadism are Kallmann syndrome and Prader-Willi syndrome.[666]

However, most males with delayed sexual development do not have serious neurologic conditions. Furthermore, most obese boys with delayed sexual development have no structural damage to the hypothalamus but have constitutional delayed puberty, which is commonly associated with obesity. It is not known whether there is a functional disorder of the hypothalamus in this condition. It is thought that psychosexual development of brain maturation depends on the presence of androgens within a critical developmental window corresponding to puberty; therefore hypogonadism in boys (regardless of cause) should be treated by the middle teen years (15 years of age at the latest).

In adult men, hypogonadism (including reduced spermatogenesis) can be induced by emotional stress or severe exercise,[667] but this abnormality is seldom diagnosed because the symptoms are more subtle than menstrual cycle changes in similarly stressed women. Prolonged physical stress and sleep and energy deficiency can also decrease testosterone and gonadotropin levels.[668] Chronic intrathecal administration of opiates for the control of intractable pain syndromes is strongly associated with hypogonadotropic hypogonadism and to a lesser extent with hypocorticism and GH deficiency in both men and women.[259] Finally, critical illness with multiple causes is well known to be associated with hypogonadism and ineffectual altered pulsation of GnRH.[669]

Neurogenic Disorders of Prolactin Regulation

Neurogenic causes of hyperprolactinemia include irritative lesions of the chest wall (e.g., herpes zoster, thoracotomy), excessive tactile stimulation of the nipple, and lesions within the spinal cord (e.g., ependymoma).[670] Prolonged mechanical stimulation of the nipples by suckling or the use of a breast pump can initiate lactation in some women who are not pregnant, and neurologic lesions that interrupt the hypothalamic-pituitary connection can cause hyperprolactinemia, as discussed earlier. Hyperprolactinemia also occurs after certain forms of epileptic seizures. In one series, six of eight patients with temporal lobe seizures had a marked increase in PRL, whereas only one of eight patients with frontal lobe seizures developed hyperprolactinemia.[671] Agents that block D_2-like dopamine receptors (e.g., phenothiazines, later generation atypical antipsychotics) or prevent dopamine release (e.g., reserpine, methyldopa, opiates) must be excluded in all cases.

Because the nervous system exerts such profound effects on PRL secretion, patients with hyperprolactinemia (including those with adenomas) may have a deficit of PIF or an excess of PRF activity. In studies of PRL secretion in patients apparently cured of hyperprolactinemia by removal of a pituitary microadenoma, regulatory abnormalities persisted in some but not all patients. Persistence of regulatory abnormalities may be due to incomplete removal of a tumor, abnormal function of the remaining part of the gland, or underlying hypothalamic abnormalities.[672]

Neurogenic Disorders of Growth Hormone Secretion

Hypothalamic Growth Failure

Loss of the normal nocturnal increase in GH secretion and loss of GH secretory responses to provocative stimuli occur early in the course of hypothalamic disease and may be the most sensitive endocrine indicator of hypothalamic dysfunction. As described earlier, anatomic malformations of midline cerebral structures are associated with abnormal GH secretion, presumably related to failure of the development of normal GH regulatory mechanisms. Such disorders include optic nerve dysplasia and midline prosencephalic malformations (absence of the septum pellucidum, abnormal third ventricle, and abnormal lamina terminalis). Certain complex genetic disorders, including Prader-Willi syndrome, also commonly involve reduced GH secretory capacity.[673] Idiopathic hypopituitarism with GH deficiency was considered earlier.

Maternal Deprivation Syndrome and Psychosocial Dwarfism

Infant neglect or abuse can impair growth and cause failure to thrive (the maternal deprivation syndrome). Malnutrition interacts with psychologic factors to cause growth failure in children with the maternal deprivation syndrome, and each case should be carefully evaluated from this point of view. Older children with growth failure in a setting of abuse or severe emotional disturbance (termed *psychosocial dwarfism*) may also have abnormal circadian rhythms and deficient hGH release after insulin-induced hypoglycemia or arginine infusion (see Chapter 25).[674] Deficient release of ACTH and gonadotropins may also be present. A variant termed *hyperphagic short stature* has been identified.[675] These disorders can be reversed by placing the child in a supportive milieu; growth and neuroendocrine hGH responses rapidly return to normal.[676] The pathogenesis of altered GH secretion in children in response to deprivation is unknown. Furthermore, in the adult human, physical or emotional stress usually causes an increase in hGH secretion (see earlier discussion).

Neuroregulatory Growth Hormone Deficiency

The availability of biosynthetic hGH for treatment of short stature has brought into focus a group of patients who grow at low rates (<3rd percentile) and have low levels of serum IGF-1 but a normal hGH secretory reserve. Studies of 24-hour hGH secretion profiles indicate that many of these children do not have normal spontaneous hGH secretion (i.e., abnormal ultradian and circadian rhythms or decreased number or amplitude of secretory bursts, or both). These children with idiopathic short stature may have a functional regulatory disturbance of the hypothalamus and appear to grow normally when given exogenous hGH.[677]

There is considerable uncertainty about the criteria for the diagnosis of neuroregulatory hGH deficiency. Many normally growing children have profiles of hGH secretion that are indistinguishable from those in children with the postulated syndrome.[678] Patterns of hGH secretion do not predict which child will benefit from therapy, and there is a poor correlation between hGH secretion and growth. Furthermore, the results of repeated tests in children show considerable variability. It has been suggested that specific genetic defects may underlie the pathogenesis of a subset of children with this heterogeneous syndrome of growth failure.[679] The prevalence of an hGH neuroregulatory deficiency syndrome is thus unclear, and the decision to treat short children with hGH should be made cautiously.[680,681]

Neurogenic Hypersecretion of Growth Hormone

Diencephalic Syndrome

Children and infants with tumors in and around the third ventricle frequently become cachectic, which is often associated with elevated hGH levels and paradoxical GH secretory responses to glucose and insulin.[682] GH hypersecretion may be due to a hypothalamic abnormality or to malnutrition. Deficits of pituitary-adrenal regulation are less common. A striking feature is an alert appearance and seeming euphoria despite the profound emaciation. A variety of associated neurologic abnormalities may be present, including nystagmus, irritability, hydrocephalus, optic atrophy, tremor, and excessive sweating. CSF abnormalities include increased protein and the presence of abnormal cells. Most cases are due to chiasmatic-hypothalamic gliomas, with the majority classified as astrocytomas.[682] Treatment options include surgical resection, radiation therapy, and chemotherapy.[683]

Growth Hormone Hypersecretion Associated With Metabolic Disturbances

Apparently inappropriate hGH hypersecretion occurs with uncontrolled diabetes mellitus, hepatic failure, uremia, anorexia nervosa, and protein-calorie malnutrition. Nutritional factors are probably

important in this response, because in normal persons obesity inhibits and fasting stimulates episodic GH hypersecretion.[684] In diabetes mellitus, cholinergic blockers reverse the abnormality,[332] possibly by inhibiting hypothalamic somatostatin secretion (see earlier discussion). Peripheral GH resistance leading to reduced IGF-1 synthesis and release may also contribute to increased levels of GH.

X-Linked Gigantism

Excess growth hormone secretion, resulting in acromegaly/gigantism, is most often associated with tumors of the anterior pituitary and, less commonly, ectopic secretion of GHRH from carcinoid tumors, pancreatic islet cell tumors, small cell lung carcinoma, adrenal adenomas, and pheochromocytomas (see Chapter 9). Genetic abnormalities resulting in gigantism have been associated with MEN1, MEN4, Carney complex, McCune-Albright syndrome, and *AIP* mutations. X-linked acrogigantism (XLAG) is a more recently identified disorder of early-onset GH excess associated with gigantism due to microduplications of the *GPR101* gene on the X chromosome. While the majority of affected individuals have pituitary adenomas, elevated circulating levels of GHRH, and the presence of diffuse hyperplasia of somatotrophs in some patients, expression of GPR101 in the arcuate nucleus has raised the possibility that increased hypothalamic secretion of GHRH underlies the pathogenesis for X-linked acrogigantism (see Trivellin and colleagues[685] for review). The presence of GPR101 in POMC neurons and increased food-seeking behavior in some affected individuals also raises the possibility of involvement of this gene in the regulation of energy homeostasis.

Neurogenic Disorders of Corticotropin Regulation

Hypothalamic CRH hypersecretion is the likely cause of sustained pituitary-adrenal hyperfunction in at least two situations: Cushing syndrome caused by the rare CRH-secreting gangliocytomas of the hypothalamus[686] and severe depression. Severe depression is associated with pituitary-adrenal abnormalities, including inappropriately elevated ACTH levels, abnormal cortisol circadian rhythms, and resistance to dexamethasone suppression.[213,218,219,687] The dexamethasone suppression test has in fact been used as an aid in the diagnosis of depressive illness. Another possible example of disordered neurogenic control of CRH associated with stress is the dysmetabolic syndrome.[688,689] This syndrome is characterized by mild hypercortisolism, blunted dexamethasone suppression of the HPA axis, visceral obesity, and hypertension and may be strongly associated with greater risks for cardiovascular disease and stroke.

A unique syndrome of ACTH hypersecretion termed *periodic hypothalamic discharge* (Wolff syndrome) has been described in one young man. The patient had a recurring cyclic disorder characterized by high fever, paroxysms of glucocorticoid hypersecretion, and electroencephalographic abnormalities.[690]

Nonendocrine Manifestations of Hypothalamic Disease

The hypothalamus is involved in the regulation of diverse functions and behaviors (Table 7.9). Psychologic abnormalities in hypothalamic disease include antisocial behavior; attacks of rage, laughing, and crying; disturbed sleep patterns; excessive sexuality; and hallucinations. Both somnolence (with posterior lesions) and pathologic wakefulness (with anterior lesions) occur, as do bulimia and profound anorexia. The abnormal eating patterns are analogous to the syndromes of hyperphagia produced in rats by destruction of the VMH or of connections to the PVH. Lateral hypothalamic damage causes profound anorexia. A more complete discussion of imbalance in energy homeostasis (both obesity and cachexia) associated with hypothalamic dysfunction and neuropeptides is presented in Chapter 39.

Patients with hypothalamic damage may experience hyperthermia, hypothermia, unexplained fluctuations in body temperature, and poikilothermy. Disturbances of sweating, acrocyanosis, loss of sphincter control, and diencephalic epilepsy are occasional manifestations. Hypothalamic damage also causes loss of recent memory, believed to be due to damage of the mammillothalamic pathways. Severe memory loss, obesity, and personality changes (e.g., apathy, loss of ability to concentrate, aggressive antisocial

TABLE 7.9 Neurologic Manifestations of Nonendocrine Hypothalamic Disease

Disorders of Temperature Regulation
Hyperthermia

Diencephalic syndrome of infancy
Cerebral gigantism

behavior, severe food craving, inability to work or attend school) may occur with suprasellar extension of pituitary tumors, hypothalamic radiation, or damage incurred from surgical removal of parasellar tumors. Hypothalamic tumors grow slowly and may reach a large size while producing minimal disturbance of behavior or visceral homeostasis, whereas surgery of limited extent can produce striking functional abnormalities. Presumably this is because slowly growing lesions permit compensatory responses to develop. These potential consequences should be weighed carefully with the neurosurgeon, patient, and patient's family in planning the therapeutic approach. Adverse effects of treatment have led to more conservative surgical guidelines for the treatment of craniopharyngioma. A review from the University of Pittsburgh summarizes their individualized treatment program that includes microsurgical tumor resection, intracavitary ^{32}P radiotherapy, and gamma knife stereotactic radiosurgery to produce maximal benefit with minimal morbidity.[691]

Paroxysmal Sympathetic Storms (Diencephalic Epilepsy)

Diencephalic epilepsy is characterized by episodic, autonomic discharge that can include tachycardia, bradycardia, diaphoresis, pupillary dilation, flushing, elevations in blood pressure, tachypnea, hypothermia and hyperthermia, and abnormal extensor posturing. Although thought due to seizures in the earlier literature, EEGs do not generally show evidence for epileptiform activity, and affected individuals do not respond well to anticonvulsants. Therefore it has been proposed to better describe these episodes as paroxysmal sympathetic storms.[692] The underlying etiology for this disorder is unknown, but most often it has been associated with acute increases in intracranial pressure and traumatic brain injury, although individual case reports have also reported an association with intracranial tumors and congenital malformations.

Narcolepsy

A convergence of functional genomics from two animal species, the dog and mouse, has dramatically refocused attention on neuropeptide circuits of the hypothalamus in the control of sleep and wakefulness. Positional cloning was used to identify mutations in the hypocretin-orexin receptor 2 as a cause of canine narcolepsy.[693] Subsequently, knockout of the gene encoding the orexin-hypocretin peptide precursor produced an equivalent narcoleptic syndrome in mice,[694] further establishing this neuropeptide system as a major component of sleep-modulating neural circuits. Targeted ablation of orexin neurons in the lateral hypothalamus of rats by means of a hypocretin receptor 2–saporin conjugate produced narcoleptic-like sleep behavior,[695] closely paralleling the clinical findings and profound reduction in numbers of orexin-hypocretin neurons in the lateral hypothalamus of humans with narcolepsy.[544] The additional role of orexin-hypocretin in coordinating arousal states and feeding behavior is discussed earlier in the chapter (see "Sleep-Wake Cycle" and "Modifying Factors Influencing Sleep") and in Chapter 39.

Most cases of spontaneous narcolepsy with cataplexy result from a degenerative hypothalamic disorder, most likely autoimmune in pathogenesis, that produces a selective destruction of neuropeptidergic neurons. The absence of immunoreactive orexin-hypocretin in CSF is a sensitive diagnostic test for the disease. Future development of bioavailable, orexin-hypocretin receptor-selective compounds may provide a specific treatment alternative or adjunct to the stimulant and antidepressant drugs currently used for management of symptoms. More generally, these recent discoveries suggest the possibility that other cryptic hypothalamic disorders could be caused by selective disturbances in other neuropeptidergic circuits.

Kleine-Levin Syndrome

Kleine-Levin syndrome is a periodic sleep disorder, generally of male adolescents, characterized by relapsing episodes of hypersomnia that can last hours to days associated with cognitive and behavioral abnormalities, including hyperphagia and hypersexuality, but normal behavior between episodes.[696] In contrast to narcolepsy, CSF orexin concentrations are usually normal, and the disorder is associated with a favorable prognosis as it tends to be self-limiting and tends to spontaneously resolve. The etiology is unknown, although several hypotheses have been put forward and reviewed by Al Shareef and colleagues[697] Evidence for abnormal perfusion by functional imaging studies in several brain regions, including the hypothalamus, thalamus, and cortex, has raised the possibility that Kleine-Levin syndrome may be an inflammatory disorder either due to viral or autoimmune encephalitis.[698] The latter possibility is of particular interest because of the tendency for the disorder to run in families and its higher prevalence in Ashkenazi Jews. Along these lines, linkage analysis and exome sequencing have identified chromosome 3 and a heterozygous missense variant in *LMOD3* in a large family with seven affected members with Kleine-Levin syndrome and in three other sporadic cases.[699] Lmod is a member of the tropomodulin gene family (Tmod), which has structural proteins involved in the sequestration of actin monomers and stimulation of ATP hydrolysis to accelerate actin nucleation and polymerization. While initially thought to be present exclusively in heart and skeletal muscle, Lmod proteins have been identified in several regions of the brain, including nuclear groups involved in the regulation of the sleep-wake cycle such as orexin neurons in the lateral hypothalamus, TMN, locus coeruleus, dorsal raphe, and ventral tegmental area.[699]

Hypothalamus and Neuropsychiatric Disorders

The role of the hypothalamus in the pathophysiology of eating disorders such as anorexia nervosa, Prader-Willi syndrome, and lesions destroying the base of the hypothalamus is well recognized and discussed in detail in Chapter 39. However, there is evidence to suggest that the hypothalamus is also involved in the pathophysiology of a number of common neuropsychiatric disorders. Genome-wide pathway and functional analysis of susceptibility genes associated with schizophrenia, for example, identify the hypothalamus as one of five major regions in the brain where these genes are predominantly expressed.[700] Included are glutaminergic, serotonergic, GABAergic and dopamine receptors, calcium and potassium ion channels, solute transporters, and neurodevelopment genes. Enlargement of the third ventricle is also known to be associated with schizophrenia and major depressive illness and thought secondary to loss of periventricular gray matter (see Bernstein and colleagues[701] for review). Along these lines, a decreased number of neurophysin-containing and nNOS-containing cells in the PVN and reduction in its innervation by beta-endorphin have been observed in schizophrenics.[702–704] A 50% reduction in total neuron number but increased numbers of oxytocin and vasopressin neurons in the PVN occur, and a similar reduction in enkephalin innervation has been observed in major depressive disorder.[704–706] Alterations in the SCN have also been described, including a reduced number of vasopressin neurons and vasopressin mRNA

in schizophrenics[707,708] and increased VIP in major depressive illness.[709] Furthermore, analysis of panels of susceptibility genes common to several psychiatric disorders identified genes involved in serotonin and dopamine homeostasis, including the serotonin receptor 2A (HTR2A), tryptophan hydroxylase 2 (TPH2), and the dopamine receptor D2 (DRD2), supporting the potential involvement of the SCN.[710]

Aberrant HPA activity and/or excessive CRHR-1 receptor stimulation are perhaps the best-recognized abnormalities associated with neuropsychiatric disorders, including schizophrenia, depression, anxiety disorders, autism, and obsessive-compulsive disorder.[711,712] Mechanisms proposed include impaired feedback inhibition of cortisol due to reduction in glucocorticoid and mineralocorticoid receptors, polymorphisms in glucocorticoid receptors and 11β-hydroxysteroid dehydrogenase type 1, increased CRH and elevated CRH mRNA expression in the hypothalamic PVH, and polymorphisms in the genes for CRH and the CRH receptor, CRH-R1. Nevertheless, with the exception of very few studies, trials employing a variety of CRH-R1 receptor antagonists have not been particularly successful,[229,712] perhaps signifying the complexities involved in the pathophysiology for these disorders and the need for more refined methods to establish adequate receptor occupancy and/or identify individuals who are most likely to respond.

Dysregulation of the oxytocin and orexin systems has also been implicated in the pathophysiology of neuropsychiatric disorders, although the data have been somewhat inconsistent.[713,714] Oxytocin receptor gene polymorphisms have been identified in schizophrenia and major depressive disorder, and some patients have shown improvement following administration of nasal oxytocin (including cognition in schizophrenic patients) and a decrease in depressive and anxiety symptoms in patients with major depressive disorder.[715–717] Similarly, oxytocin has been proposed to be involved in the pathophysiology of autism, as indicated by a reduction in plasma oxytocin levels and an increase in a biologically inactive extended form of oxytocin, as well as improved social interactions and reduced repetitive behaviors following intranasal oxytocin administration.[713] Orexin deficiency and downregulation of orexin receptors have been observed in depression and may contribute to the disrupted sleep pattern associated with this disorder.[714,718] In addition, the orexin receptor-2 (OxR2) knockout mouse demonstrates increased depressive-like behaviors, and in other studies, ICV administration of orexin improved some of the manifestations of depression.[719,720] Antidepressant actions of kisspetin,[721] the potential antidepressant action of somatostatin mediated through heterodimerization of somatostatin with dopamine D2 receptors[722] and elevated levels of nesfatin-1 in major depressive disorder,[723] further indicate that there is much yet to be learned about the role of peptides and the hypothalamus in neuropsychiatric disease.

Acknowledgments

The author greatly appreciates the important contributions made to previous versions of this chapter by Drs. Harry Friedgood, John D. Green, Monte Greer, Seymour Reichlin, Roger D. Cone, Joel Elmquist, Judy L. Cameron, and Malcolm Low. Special thanks to Dr. Seymour Reichlin for his teaching, guidance, and important work he has done to shape the direction of neuroendocrinology.

Pituitary Physiology and Diagnostic Evaluation

URSULA KAISER AND KEN HO

CHAPTER OUTLINE

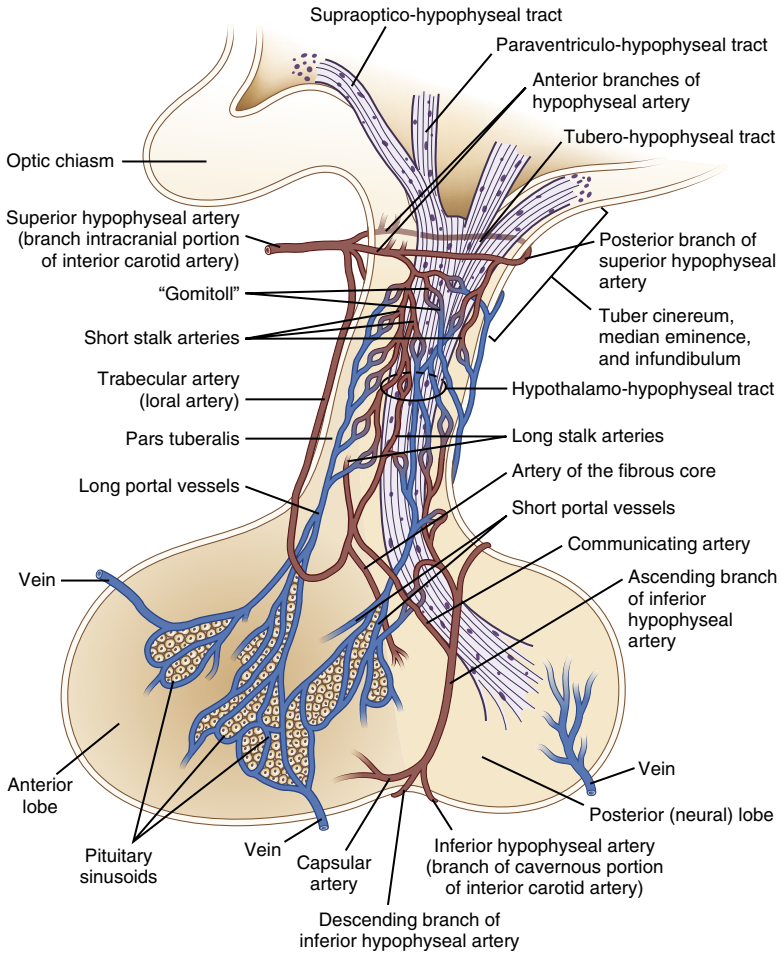
KEY POINTS

- The pituitary gland orchestrates endocrine system integrity through central hypothalamic and peripheral hormonal signals.
- Pituitary gland cells are organized into structural and functional networks formed during embryonic development but modified throughout life.
- Differentiated lactotrophs, somatotrophs, gonadotrophs, corticotrophs, and thyrotrophs are each regulated by system-specific factors.
- The growth hormone axis controls growth in childhood while regulating energy and substrate metabolism throughout life.
- Prolactin, responsible primarily for milk production during pregnancy and lactation, is uniquely under tonic inhibitory hypothalamic control by dopamine.
- The hypothalamic-pituitary-adrenal axis is the pivotal system subserving stress and survival, elaborated through effects on energy supply, fuel metabolism, immunity, and cardiovascular function.
- The hypothalamic-pituitary-gonadal axis plays a pivotal role in puberty, reproductive function, and fertility, controlling both gametogenesis and sex steroid hormone production.
- The hypothalamic-pituitary-thyroid axis plays a critical role in development, growth, and cellular metabolism, mediated by thyroid hormones.
- Pituitary gland failure can arise from developmental, heritable, and acquired disorders and is diagnosed by baseline and provocative pituitary and target gland hormone testing.

Anatomy, Development, and Overview of Control of Hormone Secretion

The pituitary gland, situated within the sella turcica, derives its name from the Greek *ptuo* and Latin *pituita*, meaning "phlegm," reflecting its nasopharyngeal origin. Galen hypothesized that nasal phlegm originated from the brain and drained via the pituitary gland. It is now clear that, together with the hypothalamus, the pituitary orchestrates the structural integrity and function of endocrine glands, including the thyroid, adrenal, and gonads, in addition to target tissues, including liver, cartilage, and breast. The pituitary stalk serves as an anatomic and functional connection to the hypothalamus. Preservation of the hypothalamo-pituitary unit is critical for integration of systemic and central nervous system (CNS) inputs for anterior pituitary control of sexual function and fertility, linear and organ growth, lactation, stress responses, energy, appetite, and temperature regulation, and secondarily for carbohydrate and mineral metabolism.

Integration of vital body functions by the brain was first proposed by Descartes in the 17th century. In 1733, Morgagni recorded the absence of adrenal glands in an anencephalic neonate, providing early evidence for a developmental and functional connection between the brain and the adrenal glands. In 1849, Claude Bernard set the stage for the subsequent advances in neuroendocrinology by demonstrating that central lesions to the area of the fourth ventricle resulted in polyuria.[1] Subsequent studies led to the identification and chemical isolation of pituitary hormones, and astute clinical observations led to the realization that pituitary tumors were associated with functional hypersecretory syndromes, including acromegaly and Cushing disease.[2–4] In 1948, Geoffrey Harris, the father of modern neuroendocrinology, reviewed the control of anterior pituitary gland hormones and proposed their hypothalamic regulation, predicting the subsequent discovery of specific hypothalamic regulating hormones.[5]



• **Fig. 8.1** Schematic representation of the blood supply of the hypothalamus and pituitary. (From Scheithauer BW. The hypothalamus and neurohypophysis. In: Kovacs K, Asa SL, eds. *Functional Endocrine Pathology.* Oxford, UK: Blackwell Scientific; 1991.)

Anatomy

The pituitary gland comprises the predominant anterior lobe, the posterior lobe, and a vestigial intermediate lobe (Fig. 8.1). The gland is situated within the bony sella turcica and is overlain by the dural diaphragma sellae through which the stalk connects to the median eminence of the hypothalamus. The adult pituitary weighs approximately 600 mg (range 400–900 mg) and measures approximately 13 mm in the longest transverse diameter, 6 to 9 mm in vertical height, and about 9 mm anteroposteriorly. Structural variation may occur in multiparous women, and gland volume also changes during the menstrual cycle. During pregnancy, these measurements may be increased in either dimension, with pituitary weight increasing up to 1 g. Pituitary hypertrophy without evidence for the presence of an adenoma was described in seven eugonadal women with pituitary height greater than 9 mm and a convex upper gland boundary observed on magnetic resonance imaging (MRI).[6]

The sella turcica, located at the base of the skull, forms the thin bony roof of the sphenoid sinus. The lateral walls comprise either bony or dural tissue about the cavernous sinuses, which are traversed by the third, fourth, and six cranial nerves and internal carotid arteries. Thus the cavernous sinus contents are vulnerable to intrasellar expansion. The dural roofing protects the gland from compression by fluctuant cerebrospinal fluid (CSF) pressure. The optic chiasm, located anterior to the pituitary stalk, is directly above the diaphragma sellae. The optic tracts and central structures are therefore vulnerable to pressure effects by an expanding pituitary mass, which typically follows the path of least tissue resistance. The posterior pituitary gland, in contrast to the anterior pituitary, is directly innervated by the supraopticohypophyseal and tuberohypophyseal nerve tracts of the posterior stalk. Hypothalamic neuronal lesions, stalk disruption, or systemically derived metastases to the hypothalamus are therefore often associated with attenuated vasopressin (diabetes insipidus) or oxytocin secretion.

The hypothalamus contains, among other neuronal populations, nerve cell bodies that synthesize hypophysiotropic releasing and inhibiting hormones, as well as the neurohypophyseal hormones of the posterior pituitary (arginine vasopressin [AVP] and oxytocin). Five distinct hormone-secreting cell types are present in the mature anterior pituitary gland:

1. Corticotroph cells express pro-opiomelanocortin (POMC) peptides, including adrenocorticotropic hormone (ACTH).
2. Somatotroph cells express growth hormone (GH).
3. Thyrotroph cells express the common glycoprotein α-subunit and the specific thyroid-stimulating hormone (TSH, thyrotropin) β-subunit.
4. Gonadotroph cells express the α-subunit and β-subunit for both follicle-stimulating hormone (FSH) and luteinizing hormone (LH).
5. Lactotroph cells express prolactin (PRL).

Each cell type is under highly specific signal controls that regulate their respective differentiated gene expression. The pituitary gland also contains support cells, known as pituicytes or folliculostellate cells.

Pituitary Blood Supply

The pituitary gland enjoys an abundant blood supply derived from several sources (see Fig. 8.1). The superior hypophyseal arteries branch from the internal carotid arteries to supply the hypothalamus, where they form a capillary network in the median eminence, which is external to the blood-brain barrier. Both long and short hypophyseal portal vessels originate from infundibular plexuses and the stalk, respectively. These vessels form the hypothalamic-portal circulation, the predominant blood supply to the anterior pituitary gland. They deliver hypothalamic releasing and inhibiting hormones to the trophic hormone-producing cells of the adenohypophysis, without significant systemic dilution, allowing the pituitary cells to be sensitively regulated by timed hypothalamic hormone secretion. Vascular transport of hypothalamic hormones is also locally regulated by a contractile internal capillary plexus (gomitoli), derived from stalk branches of the superior hypophyseal arteries.[7] Retrograde blood flow toward the median eminence also occurs, facilitating bidirectional functional hypothalamic-pituitary interactions.[8] Systemic arterial blood supply is maintained by inferior hypophyseal arterial branches, which predominantly supply the posterior pituitary. Disruption of stalk integrity may lead to compromised pituitary portal blood flow, depriving the anterior pituitary cells of hypothalamic hormone input.

Pituitary Development

The pituitary gland arises from within the rostral neural plate. Rathke pouch, a primitive ectodermal invagination anterior to the roof of the oral cavity, is formed by the fourth or fifth week of gestation[9] and gives rise to the anterior pituitary gland[10,11] (Fig. 8.2). The pouch is directly connected to the stalk and hypothalamic infundibulum and ultimately becomes distinct from the oral cavity and nasopharynx. Rathke pouch proliferates toward the third ventricle, where it fuses with the diverticulum and subsequently obliterates its lumen, which may persist as Rathke cleft. The anterior lobe is formed from Rathke pouch, and the diverticulum gives rise to the adjacent posterior lobe. Remnants of pituitary tissue may persist in the nasopharyngeal midline and rarely give rise to functional ectopic hormone-secreting tumors in the nasopharynx. The neurohypophysis arises from neural ectoderm associated with third ventricle development.[12]

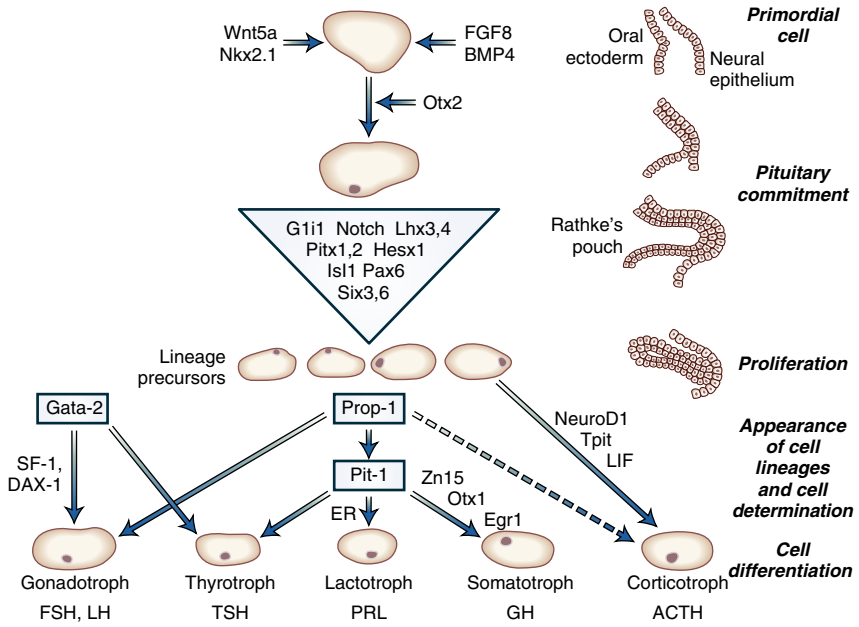
Functional development of the anterior pituitary cell types involves complex spatiotemporal regulation of cell lineage–specific transcription factors expressed in pluripotential pituitary stem cells, as well as dynamic gradients of locally acting soluble factors.[13–16] Critical neuroectodermal signals for organizing the dorsal gradient of pituitary morphogenesis include infundibular bone morphogenetic protein 4 (BMP4) required for the initial pouch invagination,[11] fibroblast growth factor 8 (FGF8), FGF10, Wnt5, and Wnt4.[17] Subsequent ventral developmental patterning and transcription factor expression are determined by spatial and graded expression of factors, including BMP2 and sonic hedgehog (SHH) protein, which appear critical for directing early patterns of cell proliferation.[18]

The human fetal Rathke pouch is evident at 3 weeks, and the pituitary grows rapidly in utero. By 7 weeks, the anterior pituitary vasculature begins to develop; by 20 weeks, the entire hypophyseal portal system is established. The anterior pituitary undergoes major cellular differentiation during the first 12 weeks, by which time all the major secretory cell compartments are structurally and functionally intact, except for lactotrophs. Totipotential pituitary stem cells give rise to acidophilic (mammosomatotroph, somatotroph, and lactotroph) and basophilic (corticotroph, thyrotroph, and gonadotroph) differentiated pituitary cell types, which appear at clearly demarcated developmental stages. At 6 weeks, corticotroph cells are morphologically identifiable, and immunoreactive ACTH is detectable by 7 weeks. At 8 weeks, somatotroph cells are evident with abundant immunoreactive cytoplasmic GH expression. Glycoprotein hormone–secreting cells express a common α-subunit, and at 12 weeks, differentiated thyrotrophs and gonadotrophs express immunoreactive β-subunits for TSH, LH, and FSH, respectively.[19] Fully differentiated PRL-expressing lactotrophs are only evident late in gestation (after 24 weeks). Prior to that time, immunoreactive PRL is only detectable in mixed mammosomatotrophs, also expressing GH, reflecting the common genetic origin of these two hormones.[20]

Pituitary Transcription Factors

Determination of anterior pituitary cell type lineages results from a temporally regulated cascade of homeodomain transcription factors.[13] Although most pituitary developmental information has been acquired from murine models,[21] histologic and pathogenetic observations in human subjects largely corroborate these developmental mechanisms (see Fig. 8.2; Tables 8.1 and 8.2). Early cell differentiation requires intracellular HESX1 and PITX expression. Rathke pouch expresses several transcription factors of the LIM homeodomain family, including LHX3, LHX4, and ISL1,[21] which are early determinants of functional pituitary development and are required for progenitor cell survival and proliferation. In contrast, activated Notch2 delays murine gonadotroph differentiation,[22] underscoring the role of NOTCH signaling pathways in the developmental cascade. Diversity of pituitary cell type determination is mediated by binary WNT/β-catenin signaling, leading to suppression of HESX1 and induction of Prophet of PIT 1 (PROP1).[23] These specific anterior pituitary transcription factors participate in a highly orchestrated cascade, ultimately leading to the commitment of the five differentiated cell types (see Fig. 8.2). The major proximal determinant of pituitary cell lineage is Prop1,[24] which determines subsequent development of POU1F1(PIT1)-dependent and gonadotroph cell lineages, while corticotroph cell commitment is directed by TBX19 protein.[25,26]

The bicoid homeodomain proteins, PITX1 and PITX2, behave as universal pituitary regulators and activate transcription of all the major anterior pituitary hormones.[27,28] PITX1 is expressed in the oral ectoderm and subsequently in all pituitary cell types, particularly those arising ventrally.[29] Rieger syndrome, characterized by defective eye, tooth, umbilical cord, and pituitary development, is caused by mutations in PITX2.[30] LHX3 determines GH, PRL, and TSH cell differentiation, and Prop1, a member of the paired-like family of homeodomain transcription factors, is expressed early in the development of Rathke pouch and behaves as a prerequisite for PIT1. PIT1 is a POU homeodomain transcription factor that determines development and appropriate temporal and spatial expression of GH, PRL, and TSH binding to specific DNA motifs to activate and regulate somatotroph, lactotroph,



Fetal appearance	12 weeks	12 weeks	12 weeks	8 weeks	8 weeks

and thyrotroph development and mature secretory function. Signal-dependent coactivating factors cooperate with PIT1 to determine specific hormone expression. Thus in POU1F1-containing cells, high estrogen receptor levels induce a commitment to express PRL, and thyrotroph embryonic factor (TEF) favors TSH expression. Selective pituitary cell type specificity is also perpetuated by binding of PIT1 to its own DNA regulatory elements as well as those contained within the GH, PRL, and TSH genes. Steroidogenic factor 1 (SF1) and DAX1 determine gonadotroph development.[31,32] TSH and gonadotropin-expressing cells share

a common α-subunit (αGSU) expression under developmental control of GATA2.[33] FOXL2, a forkhead transcription factor, regulates differentiation of cell types expressing αGSU, including gonadotrophs and thyrotrophs, and transcription of αGSU and FSHβ.[17,34–37] Corticotroph cell commitment, occurring earliest during fetal development, is independent of PROP1-determined lineages, and TBX19 protein is a prerequisite for POMC expression.[38] Hereditary mutations arising within these transcription factors may result in isolated or combined pituitary hormone failure syndromes (see later).[39]

Pituitary Stem Cells

The adult pituitary gland exhibits plastic and regenerative trophic properties, which allow maintenance of homeostatic functions.[40] This characteristic is exemplified by pituitary lactotroph expansion during pregnancy and pituitary trophic hormone cell hyperplasia occurring after target organ ablation. Mechanisms underlying adult pituitary cell renewal and expansion are as yet unclear and may include intrinsic pituitary transdifferentiation, differentiation of previously uncommitted "null" cells, or expansion of already differentiated cells.

Several lines of evidence support the existence of cells with stem or progenitor characteristics in the adult pituitary gland.[41–45] Pituitary progenitor cells exhibit several characteristics of a stem cell phenotype, including an undifferentiated gene profile, clonality, the ability to form colonies, and expression of known stem cell markers, including Scal and CD133. Other markers, including Notch, Wnt, and SHH, are essential transcription factors for cell type determination and expansion of pituitary cell lineages.[46,47] Evidence has emerged that SOX2, SOX9, and OCT4 are markers of pituitary progenitors with properties for multipotent pituitary cell differentiation,[48] and a population of nestin-expressing murine pituitary cells fulfill criteria consistent with organ-specific multipotent stem cells.[45] These cells form differentiated pituitary-expressing progeny and contribute to an adult pituitary stem cell population distinct from embryonic precursor cells. Expression of potential stem cell markers such as nestin in the marginal zone around Rathke cleft has suggested that the stem cell population may exist in this marginal zone.[49] Cell-lineage tracing analysis has demonstrated that SOX2-expressing and SOX9-expressing progenitors can self-renew and give rise to pituitary endocrine cells in vivo, supporting the model of these as tissue stem cells.[43,50,51] Moreover, these cells can become mobilized and differentiate toward a specific cell fate in response to physiologic stress.[50,51] Advances have also been made toward recapitulation of pituitary differentiation in vitro: Three-dimensional (3D) cultures of embryonic stem cells have been stimulated to differentiate into Rathke pouch–like 3D structures, and various endocrine cells, including functional corticotrophs and somatotrophs, were subsequently produced, opening new avenues for the application of pluripotent stem cells to treat hypopituitarism.[52,53] Interestingly, adamantinomatous craniopharyngiomas share expression of stem cell markers with pituitary progenitor/stem cells, suggesting a common origin.[54]

Pituitary Control

The endocrine and nonendocrine cells of the pituitary gland are organized into structural and functional networks formed during embryonic development but modified throughout life.[55] The various endocrine cell types form distinct networks in spatial relationships with the vasculature, which can explain the marked secretory capacity not evident from those observed from dispersed cells in culture.[56] The functional characterization of the network activity of GH, PRL, and gonadotropin has provided firm evidence for cell organization in gene regulation, in magnitude, and in temporal facets of hormone secretion. As such, the existence of these endocrine cell networks confers the pituitary as more than a gland that simply responds to external regulation; rather, it acts as an oscillator that can imprint memory and adapt to coordinated network responses to hypothalamic inputs.[56]

Three levels of control subserve the regulation of anterior pituitary hormone secretion (Fig. 8.3). Hypothalamic control is mediated by adenohypophysiotropic hormones secreted into the hypothalamic portal system to impinge directly upon anterior

TABLE 8.2 Hereditary Pituitary Deficiency Caused by Transcription Factor Mutations

Genes involved in pituitary development or in maintaining integrity of the hypothalamic-pituitary axis. Functional defects include missense or frameshifts leading to truncated or deleted protein, DNA binding abnormality.

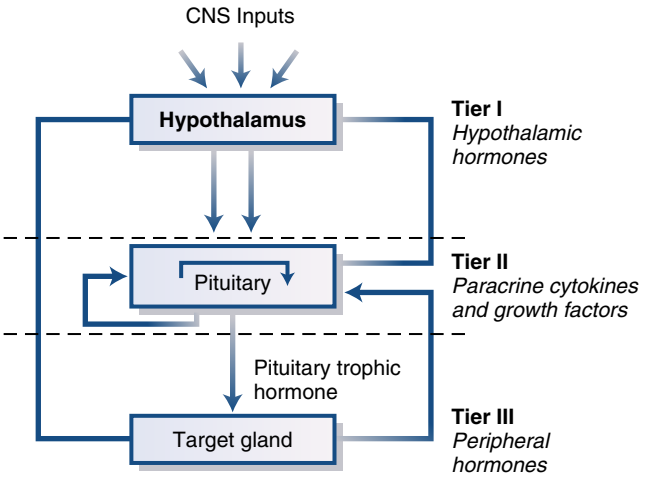
pituitary cell surface receptors. G protein–coupled cell surface membrane binding sites are highly selective and specific for each of the hypothalamic hormones and elicit positive or negative signals mediating pituitary hormone gene transcription and secretion. Peripheral hormones also participate in mediating pituitary cell function, predominantly by negative feedback regulation of trophic hormones by their respective target hormones. Intrapituitary paracrine and autocrine soluble growth factors and cytokines act to locally regulate neighboring cell development and function. The net result of these three tiers of complex intracellular signals is the controlled pulsatile secretion of the six pituitary trophic hormones—ACTH, GH, PRL, TSH, FSH, and LH (Fig. 8.4). Temporal and quantitative control of pituitary hormone secretion is critical for physiologic integration of peripheral hormonal systems, as exemplified by the menstrual cycle, which relies on complex and precisely regulated hormonal pulse control.

Physiology and Disorders of Pituitary Hormone Axes

Prolactin

Physiology

PRL is produced primarily by pituitary lactotrophs and is tonically inhibited by hypothalamic dopamine. The identification of PRL in humans was elusive until 1970 because human GH is highly lactogenic and active in bioassays used to isolate and measure PRL.[57]



• **Fig. 8.3** Model for regulation of anterior pituitary hormone secretion by three tiers of control. Hypothalamic hormones traverse the portal system and impinge directly upon their respective target cells. Intrapituitary cytokines and growth factors regulate tropic cell function by paracrine (and autocrine) control. Peripheral hormones exert negative feedback inhibition of respective pituitary trophic hormone synthesis and secretion. *CNS*, central nervous system. (From Ray D, Melmed S. Pituitary cytokine and growth factor expression and action. *Endocr Rev.* 1997;18:206–228.)

Furthermore, GH is present in human pituitary glands in much higher concentrations (5–10 mg) than PRL (~100 μg).[58] To distinguish human PRL from GH, lactogenic activity derived from GH effects was neutralized with GH antiserum; using this assay, sera from postpartum women and patients with galactorrhea still had high lactogenic activity in the presence of GH antibodies.[59,60] Purification and isolation of PRL by Friesen and development of a specific radioimmunoassay underscored the utility of PRL measurements in understanding human disease.[61,62]

Lactotroph Cells

About 15% to 25% of functioning anterior pituitary cells are lactotroph cells. Most PRL-expressing cells appear to arise from GH-producing cells. Ablation of somatotrophs by expression of GH-diphtheria toxin and GH-thymidine kinase fusion genes inserted into the germline of transgenic mice eliminates most lactotrophs, suggesting that the majority of PRL-producing cells arise from postmitotic somatotrophs in mice.[63] Two cell forms expressing the PRL gene include large polyhedral cells found throughout the gland and smaller angulated or elongated cells clustered in the lateral wings and median wedge. Large PRL secretory granules (250–800 nm) are present in the evenly distributed cells, while the laterally localized cells are sparsely populated by smaller (200–350 nm) granules. Occasional mammosomatotroph cells cosecrete both PRL and GH, often stored within the same granule. In animal models, lactotroph cell function is heterogeneous. Thus dopamine or thyrotropin-releasing hormone (TRH) responsiveness, and shifting proportions of PRL versus GH secreting cells, may depend on cell localization within the pituitary, as well as the surrounding hormonal milieu, especially that of estrogen.[64] Although their absolute number is similar in men and women and does not change with age, lactotroph hyperplasia does occur during pregnancy and lactation[65] and resolves within several months of delivery.

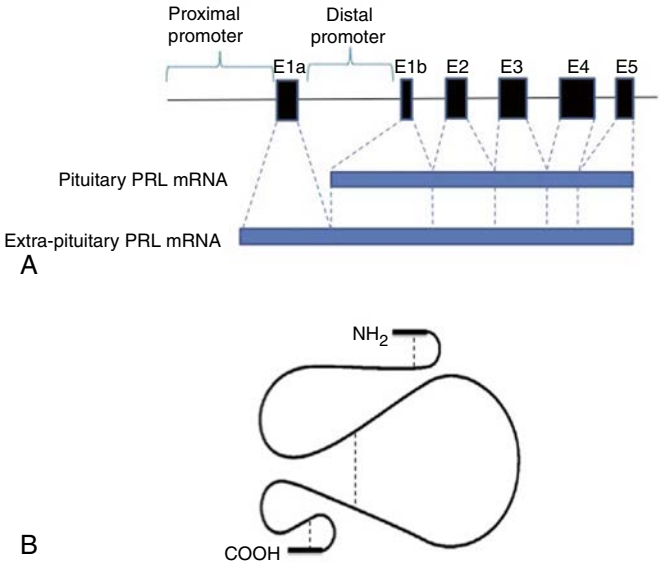
Prolactin Structure

The human PRL gene, located on chromosome 6,[66] arose from a single common ancestral gene, which gave rise to the relatively homologous PRL, GH, and placental lactogen-related proteins.[67] Several factors influence PRL gene expression, including estrogen, dopamine, and TRH.[68] The PRL gene is transcribed from two alternative promoter regions, with the more proximal directing pituitary-specific expression and the more upstream promoter region directing extrapituitary expression (Fig. 8.5; see also Fig. 8.2).[69] PRL is a 199–amino acid polypeptide containing three intramolecular disulfide bonds (see Fig. 8.5). It circulates in blood in various sizes—monomeric PRL ("little prolactin"; 23 kDa), dimeric PRL ("big prolactin"; 48–56 kDa), and macroprolactin ("big, big prolactin," comprised of prolactin bound to immunoglobulins; >100 kDa).[69a–72] The monomeric form is the most bioactive PRL. In response to TRH, the proportion of the monomeric form increases. A glycosylated form of PRL, identified in pituitary extracts, is less biologically active than the nonglycosylated form.[73] Monomeric PRL is cleaved into 8-kDa and 16-kDa forms,[74] and the 16-kDa variant is antiangiogenic.[75,76] Indeed, this 16-kDa PRL cleavage product has been implicated in peripartum cardiomyopathy.[77] The mechanism underlying this association was recently shown to result from actions of the 16-kDa PRL, also referred to as vasoinhibin,[78] on capillary endothelial cells, stimulating the production of miR-146a, which in turn acts through a paracrine mechanism on cardiomyocytes to inhibit metabolism by blocking the activity of ERBB4, a tyrosine kinase receptor, to impair cardiomyocyte function. Cardiac dysfunction could be improved by treatment with the dopamine agonist bromocriptine, which results in a fall in miR-146a levels in parallel with an improvement in cardiac function.[79–81]



• **Fig. 8.5** Schematic representation of the human PRL gene and protein. (A) The *PRL* gene consists of five exons (E1–E5). PRL gene transcription is regulated by two independent promoter regions, upstream of two alternative first exons (1a and 1b). The proximal promoter regions directs pituitary-specific expression, whereas the distal promoter region directs extrapituitary expression. Exons 1a and 1b both encode 5′-untranslated sequences, so the protein-coding sequences of both transcripts are identical. (B) PRL is a 23-kDa protein comprised of 199 amino acids with three disulfide bonds *(hatched lines)*.

Regulation

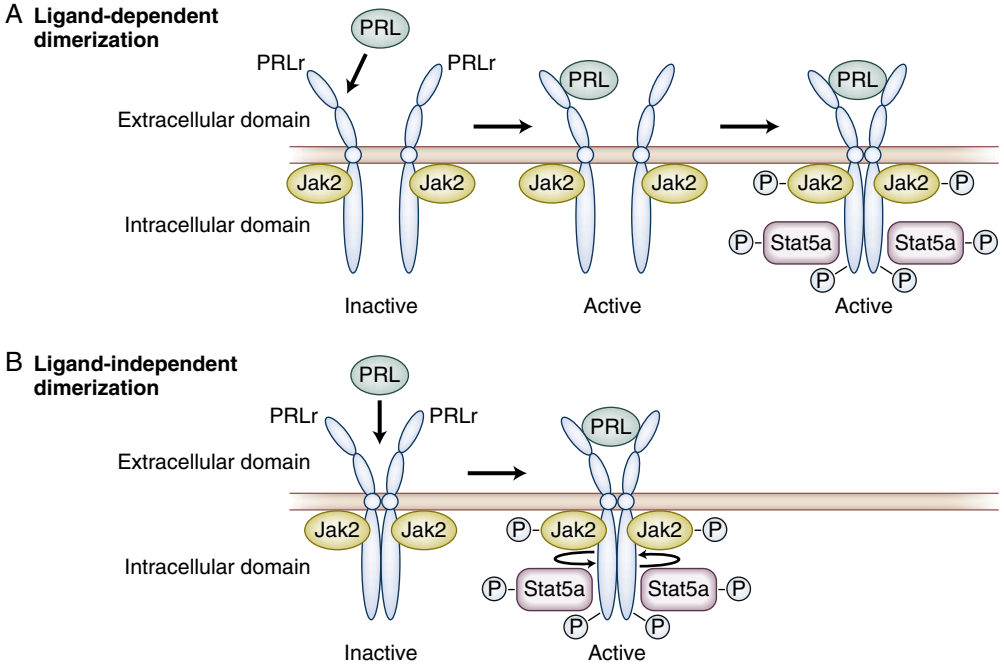
PRL secretion is under inhibitory control by dopamine, produced by the tuberoinfundibular (TIDA) cells and the hypothalamic tuberohypophyseal dopaminergic system.[82,83] Dopamine reaches the lactotrophs via the hypothalamic-pituitary portal system and binds to type 2 dopamine (D_2) receptors on pituitary lactotrophs to inhibit PRL secretion.[84] PRL, in turn, participates in negative feedback to control its release by increasing tyrosine hydroxylase activity, and thereby dopamine synthesis in the TIDA neurons.[83] In PRL-deficient mice, dopamine is decreased in the median eminence.[85] Mice lacking the D_2 receptor develop hyperprolactinemia and lactotroph proliferation.[84] Many other factors modulate PRL secretion, although their physiologic or clinical relevance remains unclear. Factors other than dopamine inhibit PRL secretion, including endothelin-1 and TGFβ1, which act as paracrine PRL inhibitors,[86,87] and calcitonin, which may be derived from the hypothalamus.[88] Several substances act as PRL-releasing factors. Growth factors such as basic FGF and epidermal growth factor (EGF) induce PRL synthesis and secretion. Neuropeptides acting through G protein-coupled receptors to stimulate PRL include vasoactive intestinal polypeptide (VIP), prolactin-releasing peptide (PrRP), opioid peptides, and TRH.[88a–88c,89] Estrogen stimulates PRL gene transcription and PRL secretion,[90] explaining why women have higher PRL levels, particularly during the periovulatory menstrual phase and in pregnancy.[91,92] The physiologic roles of other neuropeptides (e.g., neurotensin, substance P, bombesin, cholecystokinin, serotonin, and histamine) in regulating human PRL secretion are unresolved.[93] Evidence also suggests a short feedback loop with PRL negatively regulating its own secretion either via augmentation of hypothalamic TIDA turnover or through direct autocrine actions.[93–95]

Prolactin Secretion

The calculated production rate of PRL ranges from 200 to 536 μg/day/m^2, and the metabolic clearance rate ranges from 40 to 71 mL/minute per m^2.[96] PRL is cleared rapidly, with a calculated half-life in the circulation ranging from 26 to 47 minutes. PRL secretion occurs episodically, with 4 to 14 secretory pulses over 24 hours,[97,98] with the highest levels achieved during sleep and the lowest occurring between 10 AM and 12 noon.[99] The nocturnal elevation is sleep entrained, and a temporal relationship exists between rapid eye movement (REM) and non-REM sleep cycles.[100] PRL levels decline with age in both men and women. In older men, less PRL is produced with each secretory burst than in younger men.[101] Postmenopausal women have lower mean serum PRL levels and PRL pulse frequency than do premenopausal women, suggesting a stimulatory effect of estrogen on both of these parameters.[92]

Prolactin Action

The PRL receptor gene is a member of the cytokine receptor superfamily,[102] localized to chromosome 5p13, with an extracellular domain, a hydrophobic transmembrane domain, and an intracytoplasmic region homologous to the GH receptor[103] (Fig. 8.6). PRL receptor dimerization occurs in both ligand-dependent and ligand-independent manners, with a single PRL molecule binding to both components of the receptor dimer, with phosphorylation of intracellular Janus kinase/signal transducers and activators of transcription (JAK-STAT) molecules subsequent to PRL binding. Two ligand-receptor binding sites are critical for formation of the



• **Fig. 8.6** Ligand-dependent and ligand-independent dimerization of the prolactin (PRL) receptor (PRLr). (A) Ligand-dependent dimerization model. PRLr is in monomeric form at the cell membrane. One molecule of PRL first binds to one PRLr monomer via binding site 1, and this 1:1 complex then recruits the second PRLr via binding site 2. Dimerization of the two PRLrs leads to activating changes in the intracellular domain, leading to PRL signal transduction, such as phosphorylation (P) of Janus kinase 2 (Jak2), phosphorylation of the PRLr, and the recruitment and phosphorylation of the signal transducer and activator of transcription (Stat5). (B) Ligand-independent model. PRLr exists in dimeric form at the cell membrane in the absence of ligand. The receptors are held in an inactive form until binding of PRL to this preformed complex induces activating changes in the intracellular domain, leading to phosphorylation of Jak2, phosphorylation of the PRLr, and recruitment and phosphorylation of Stat5a. (From Clevenger C, Gadd SL, Zheng J. New mechanisms for PRLr action in breast cancer. *Trends Endocrinol Metab.* 2009;20:223–229.)

trimeric ligand-receptor complex and subsequent signaling.[104–106] PRL receptor induces protein tyrosine phosphorylation and activation of JAK2 and STAT1, STAT3, STAT5A, and STAT5B.[107,108] STAT5A phosphorylation is particularly important for mammary gland development and lactogenesis.[109]

PRL receptors are ubiquitously expressed in breast tissue as well as pituitary, liver, adrenal cortex, kidneys, prostate, ovary, testes, intestine, epidermis, pancreatic islets, lung, myocardium, brain, and lymphocytes. Regulation of milk production occurs via a cascade of intracellular events. Homozygous mice in which the PRL receptor has been inactivated are infertile.[104] A gain-of-function mutation conferring constitutive activity of the PRL receptor is present in a subset of patients with multiple breast fibroadenomas.[110] PRL receptor antagonists have been developed for targeting the receptor in PRL-sensitive disturbances, including resistant prolactinomas, breast tumors, and prostate tumors.[106,111]

PRL is essential for human species survival because it is responsible for milk production during pregnancy and lactation. Additional biologic functions ascribed to PRL include reproductive, metabolic, and immune effects.[69,93] Although PRL and its receptor are clearly crucial in lower animals,[112] the impact of PRL on maternal behavior in humans has not been fully delineated.

Mammary Gland Development

PRL is not essential for pubertal mammary development, which instead requires GH, the action of which is mediated by insulin-like growth factor 1 (IGF1).[113–115] At birth, the rodent mammary gland consists of a fat pad with small areas of ductal anlagen, which differentiate into pubertal mammary glandular elements under the influence of estrogen, GH, and IGF1. At puberty, a surge of estrogen begins the developmental process. Terminal end buds form and lead the process of mammary development by branching and extending into the substance of the mammary fat pad, leaving in its wake a network of ducts that virtually fill the mouse mammary fat pad.[116,117] GH acts on the mammary stoma compartment to produce IGF1, which in turn stimulates formation of terminal end buds and ducts in synergy with estrogen.[115,118] Parathyroid hormone–related protein is essential for fetal mammary development,[119] and epidermal growth is essential for pubertal mammary development.[120] Progesterone, possibly in association with GH and PRL, causes formation of lobular "decorations" along ducts, which are precursors to true glands.[121] In humans, pubertal mammary development begins in girls between the ages of 8 and 13 (see developmental scale of Tanner, Chapter 24). Once fully developed, the pubertal mammary gland remains quiescent until pregnancy, although cyclic changes occur during the menstrual cycle.

In human pregnancy, mammary gland alveolar elements proliferate and begin to produce milk proteins and colostrum. At 3 to 4 weeks of gestation, terminal ductal sprouting occurs, followed by lobular-alveolar formation, and true alveoli form at the end of the first trimester. Glandular elements proliferate further and secretory products appear in the alveolar lumina. During the third trimester, fat droplets are seen within alveolar cells, and the glands fill with colostrum.[122] A combination of estrogen, PRL, progesterone, and

possibly IGF1 and placental hormones are largely responsible for this phase of mammary development.[123] In mice with targeted disruption of the PRL gene, formation of alveolar structures is impaired.[84] Likewise, women with isolated PRL deficiency are unable to lactate.[124] Similarly, in mice lacking the progesterone receptor, lobular-alveolar formation does not occur.[125] Interestingly, only a minority of women have expressible milk during pregnancy, most likely due to the inhibitory effects of estradiol[126] and progesterone[127] on PRL-induced milk production.

Lactation

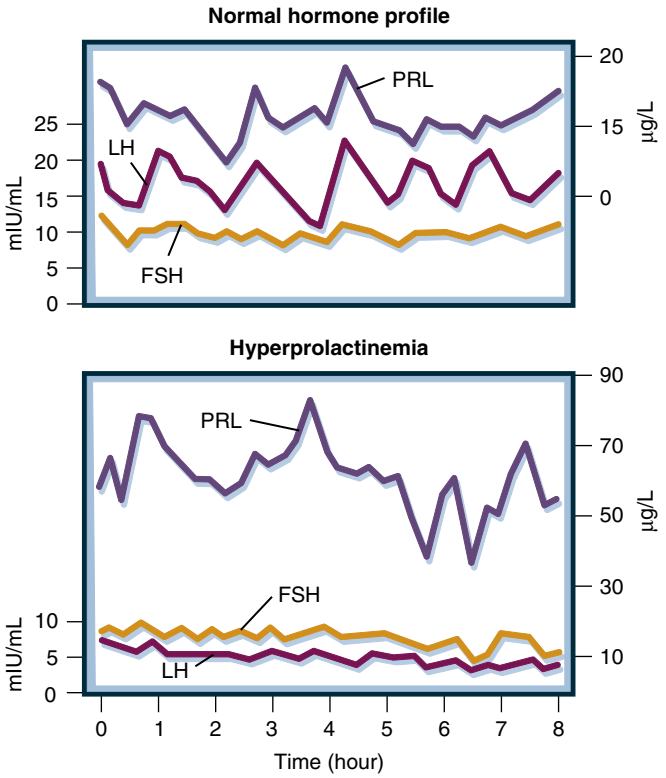
Active lactation is due in part to attenuation of estrogen and progesterone levels and elevation of PRL levels after delivery. Suckling also increases milk production after parturition and is essential for continued lactation because of its effect on pituitary hormone production and because it empties the mammary gland of milk.[128] Milk accumulation inhibits milk synthesis, explaining why a certain level of nursing activity is necessary for successful breastfeeding. In the absence of suckling, PRL concentrations, which rise throughout gestation, return to normal by 7 days postpartum.[129] Although PRL is essential for milk production, the milk yield does not correlate closely with serum PRL levels.[130] Suckling also stimulates posterior pituitary oxytocin release; unlike PRL, oxytocin responses to suckling do not decline for up to 6 months if nursing continues. Oxytocin induces myoepithelial cell contraction, thereby causing milk ejection.[131] Oxytocin also has important effects on alveolar proliferation.

Reproductive Function

Lactation results in amenorrhea and secondary infertility, and this natural form of contraception depends upon the frequency and duration of breastfeeding. The Kung hunter-gatherer women suckle their infants approximately four times an hour and at will during the night, and women bear a mean of 4.7 children during their reproductive years.[132] In contrast, the Hutterites of North America bear a mean of 10.6 children during their lifetimes, presumably because they nurse according to a rigid schedule, use supplemental feedings, and wean at 1 year. Amenorrhea and infertility result from PRL-mediated inhibitory effects on hypothalamic gonadotropin-releasing hormone (GnRH) and pituitary gonadotropin secretion of the gonadotropins, resulting in a reduction in both amplitude and frequency of LH pulses (Fig. 8.7).[133] In a hyperprolactinemic mouse model, hypothalamic kisspeptin immunoreactivity was reduced, and administration of kisspeptin restored estrous cyclicity, ovulation, and circulating LH and FSH levels. In addition, kisspeptin neurons have been shown to express PRL receptors.[134] Taken together, these data suggest that kisspeptin may be the missing link between hyperprolactinemia and the associated hypogonadotropic hypogonadism, anovulation, and infertility.[135,136] Indeed, kisspeptin administration to women with hyperprolactinemia-induced hypothalamic amenorrhea was shown to reactivate gonadotropin secretion.[136a] During lactation, additional metabolic factors induced by negative energy balance likely also contribute to disruption of pulsatile GnRH and LH secretion.

Other Actions

Early evidence indicated that PRL regulates immune function. However, some evidence indicates that PRL may not be important for immune function,[137] as innate immunity was not altered



• **Fig. 8.7** Effect of hyperprolactinemia on suppressing follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretory patterns leading to hypogonadotrophism in a female patient. *PRL,* prolactin. (Adapted from Tolis G. Prolactin: physiology and pathology. *Hosp Pract.* 1980;15:85–95.)

in transgenic mice devoid of either the PRL receptor ($PRLR^{-/-}$) or PRL ($PRL^{-/-}$).[84,138] Prolactin has been shown to have effects on maternal behavior in rodents, but its role in humans remains to be determined. Other roles that have been proposed for prolactin include effects on neurogenesis, metabolism and glucose homeostasis, appetite regulation, and bone and calcium homeostasis.[69,93]

Prolactin Measurements

Modern PRL measurements are based on immunoradiometric or chemiluminescent assays and are highly specific in distinguishing PRL from GH. The serum concentration of PRL can be given in mass concentration (μg/L or ng/mL), molar concentration (nmol/L or pmol/L), or international units (mIU/L). As these samples are usually assayed at a single dilution, extremely high PRL concentrations may saturate the capture and signal antibodies, preventing detection of very high PRL levels and resulting in a falsely low value being reported.[139] This "hook effect" may result in PRL-secreting macroadenomas diagnosed as clinically nonfunctioning adenomas. In patients harboring macroadenomas with clear-cut clinical features of hyperprolactinemia, serum samples should be subjected to at least 1:100 dilution prior to assay.

Conversely, macroprolactin, a physiologically inactive form of prolactin bound to IgG, can lead to a falsely elevated prolactin result, thus resulting in misdiagnosis of hyperprolactinemia. Misdiagnosis can be avoided by asking the laboratory to pretreat the serum with polyethylene glycol to precipitate macroprolactin before the immunoassay for prolactin in the supernatant.[140]

Prolactin Deficiency

Causes

Congenital PRL deficiency can occur in association with mutations in the transcription factors involved in lactotroph lineage development, including POU1F1, PROP1, LHX3, LHX4, and HESX1 (see Tables 8.1 and 8.2). In these cases, deficiencies in other anterior pituitary hormones occur in conjunction with PRL deficiency, with the spectrum of pituitary hormone deficiencies depending on the gene affected.[48] PRL deficiency has also been reported in conjunction with central hypothyroidism in a subset of patients with the immunoglobulin superfamily member 1 (IGSF1) deficiency syndrome.[167]

Manifestations

The only known clinical manifestation of PRL deficiency is the inability to lactate after delivery. Isolated PRL deficiency is rare but has been reported in association with autoantibodies directed specifically against PRL-secreting pituitary cells.[168] Most patients with acquired PRL deficiency have evidence of other pituitary hormone

deficiencies in association with pituitary injury.[169] Infarction of the pituitary gland after postpartum hemorrhage, known as Sheehan syndrome, has long been recognized as a cause of hypopituitarism.[170] In developed countries, postpartum hemorrhage now less often results in Sheehan syndrome than previously, largely due to improvements in obstetric care. No commercially available PRL preparation is available for these women, although studies with recombinant human PRL administration have been shown to increase milk volume in women with PRL deficiency or lactation insufficiency.[171]

Hyperprolactinemia

Causes

The causes of hyperprolactinemia may be physiologic, pathologic, or drug induced[141,142] (Table 8.3).

Physiologic Causes

Pregnancy. During pregnancy, the normal pituitary gland may double or more in size,[65] the result of a marked increase in the number of PRL-producing cells. Serum PRL concentrations rise to 10 times the normal concentration during pregnancy,[129] and amniotic fluid PRL concentrations are 100 times those of maternal or fetal blood.[129]

Suckling. Suckling increases serum PRL levels approximately 8.5-fold in actively nursing mothers.[143,144] As nursing continues, PRL concentrations fall, but each suckling episode continues to cause a subsequent episodic rise in serum PRL. Mean serum concentrations were 162 μg/L at 2 to 4 weeks postpartum, 130 μg/L at 5 to 14 weeks, and 77 μg/L at 15 to 24 weeks.[145] It is unclear why active milk production continues despite progressively lower PRL levels following parturition.

Idiopathic Hyperprolactinemia. An elevated circulating PRL level in patients in whom no cause is identified is considered idiopathic, and these patients are relatively resistant to dopamine agonist therapy. Mean serum PRL levels in patients with idiopathic hyperprolactinemia are usually less than 100 μg/L.[146]

Macroprolactinemia. PRL is a 23-kDa single-chain polypeptide but may also circulate in high-molecular-weight forms. High-molecular-weight PRL variants may, in some situations, represent 85% or more of total PRL, but under usual circumstances the 23-kDa variety predominates. Macroprolactinemia refers to these larger circulating PRL molecules, comprised of PRL bound to immunoglobulins, which exhibit markedly reduced bioactivity. Few of the expected clinical abnormalities usually associated with hyperprolactinemia (sexual dysfunction, hypogonadism, galactorrhea, osteoporosis) occur in patients with macroprolactinemia.[140,147] Screening for macroprolactinemia can be accomplished by polyethylene glycol precipitation of serum samples. In a 2005 survey, macroprolactinemia was detected in 22% of 2089 hyperprolactinemia samples.[148]

Pathologic Causes. Pathologic hyperprolactinemia may be caused by a prolactinoma, pituitary or sellar tumors that inhibit dopamine because of pressure on the pituitary stalk, or interruption of the vascular connections between the pituitary and hypothalamus. In a large series of histologically confirmed cases, a serum PRL level greater than 2000 mUL (~100 μg/L) was almost never encountered from stalk dysfunction.[149] However, prolactinomas can present with any level of PRL elevation.

Breast stimulation has only a minimal effect on serum PRL levels. In 18 normal women, serum PRL levels rose from a mean of 10 to 15 μg/L during breast pump stimulation.[143] Chest wall lesions (e.g., in association with herpes zoster [shingles]) can also be associated with mild hyperprolactinemia as a result of activation of neurogenic pathways that inhibit dopamine. Up to 20% of patients with hypothyroidism have elevated PRL levels.[150] Treatment of hypothyroidism with thyroid hormone normalizes serum PRL if the hyperprolactinemia is due to thyroid hormone deprivation.

PRL is moderately elevated (mean 28 μg/L) in patients with chronic renal failure and those on dialysis.[151] This increase is largely a result of an increase in PRL cleavage products, due in part to decreased glomerular filtration rate. Sexual dysfunction is common in men on dialysis, and reducing PRL with dopamine agonists improves sexual function[152] but does not normalize menses in women.[153] Side effects of dopamine agonists in patients with renal failure may be exacerbated because of fluid shifts and multiple medication interactions. PRL levels rise in response to stress, correlate with the degree of stress, and generally return to normal as stress abates. The mean peak serum PRL level in 19 women undergoing general anesthesia was 39 μg/L immediately prior to surgery, 173 μg/L at surgery, and still elevated at 47 μg/L 24 hours after surgery.[154] Traumatic brain injury can also result in hyperprolactinemia, often accompanied by diabetes insipidus or syndrome of inappropriate antidiuretic hormone (SIADH) secretion and other anterior pituitary hormone deficiencies. A meta-analysis found that 34% of patients develop hyperprolactinemia after cranial and hypothalamic irradiation, thought to be the result of decreased hypothalamic dopamine secretion.[154a]

Hyperprolactinemia was reported in association with an inactivating prolactin receptor mutation in three sisters with oligomenorrhea.[155] The mutation disrupted ligand binding and downstream signaling, demonstrated in vitro. The presence of hyperprolactinemia in these affected women suggested central negative feedback by prolactin on its secretion in humans, as previously demonstrated in animal studies.[84,85] Affected women were all heterozygous for the mutation; the presence of hyperprolactinemia suggests that the mutant receptor may interfere with signaling by the normal receptor, encoded by the wild-type allele, to result in PRL insensitivity. As the occurrence of oligomenorrhea and the ability to lactate is contrary to what might be predicted from a state of prolactin insensitivity, the function of PRL and its receptor in humans requires further study.[80]

Drug-Induced Causes. A variety of medications cause minimal or moderate prolactin elevations. Neuroleptic drugs elevate PRL because of their dopamine receptor antagonist properties, as do atypical antipsychotics that act by antagonizing both serotonin and dopamine receptors. Clozapine and olanzapine weakly induce PRL, and risperidone is a potent PRL stimulator.[156,157]

Unless patients exhibit hypogonadism, related osteoporosis, or troublesome galactorrhea, treatment of drug-induced hyperprolactinemia may not be necessary.[158] It should not always be assumed that hyperprolactinemia in patients on drugs known to elevate PRL is in fact due to those medications. Prolactinoma, other sellar lesions,[159] hypothyroidism, and renal failure should be considered as possible causes of hyperprolactinemia requiring active management. In patients taking neuroleptic medications, if the clinical situation permits, temporary drug withdrawal might be considered to determine if PRL levels normalize.[158] If PRL levels do not normalize or medication withdrawal is not possible, a pituitary MRI should be performed. When neuroleptics elevate PRL levels, switching to olanzapine may be attempted because the medication has minimal effects on PRL levels. In determining whether to discontinue a drug or whether to use alternative medication, the benefits should be weighed against the risks of drug replacement or cessation.[160] Although combined use of dopamine antagonists and dopamine agonists is not usually advised because of an increased risk of side effects, such as postural hypotension or

exacerbation of the underlying psychosis, some advocate the use of both formulations simultaneously.[161]

Clinical Features

Galactorrhea and reproductive dysfunction are the hallmarks of pathologic hyperprolactinemia. Women present with galactorrhea associated with a range of menstrual disturbances, including infertility, oligomenorrhea, and amenorrhea; men present with symptoms of hypogonadism and of tumor mass effects, with galactorrhea occurring infrequently.

Galactorrhea and amenorrhea were reported in the 19th century by Chiari and Frommel.[162] The Chiari-Frommel syndrome comprises postpartum galactorrhea, amenorrhea, and "uteroovarian atrophy" in patients not nursing. This disorder is usually self-limiting, and fertility eventually returns after normalization of PRL levels, sometimes without an intervening menstrual period. Patients with postpartum amenorrhea, hyperprolactinemia, and galactorrhea have sometimes subsequently been found to harbor prolactinomas. In the 1950s, Argonz and Del Castillo[163] and Forbes et al[164] associated galactorrhea and amenorrhea with pituitary tumors. In a report of 18 such patients, galactorrhea and amenorrhea were reported for up to 11 years after parturition with a mean PRL level of 45 µg/L.[150]

Inappropriate nipple secretion of milk-like substances may persist after childbirth or discontinuation of nursing for as long as 6 months. Thereafter, continued milk production is considered abnormal, and other causes for galactorrhea should be investigated. Galactorrhea can occur in either women or men and may be unilateral or bilateral, can be profuse or sparse, and can vary in color and thickness. If blood is present in the galactorrhea fluid, it could be the harbinger of an underlying pathologic process, such as a ductal papilloma or carcinoma, and mammography or sonography is indicated. Twenty-nine of 48 patients with pituitary tumors and galactorrhea had PRL concentrations of less than 200 µg/L, likely on the basis of stalk compression, suggesting that they harbored pituitary tumors other than prolactinomas.[150] It is likely that most patients with so-called idiopathic galactorrhea with amenorrhea harbor microprolactinomas. Fifty percent of patients with acromegaly also have galactorrhea, even in the absence of hyperprolactinemia, because human GH is a potent lactogen and can cause galactorrhea when elevated.[165] Normoprolactinemic galactorrhea with regular menses represents the most frequent cause of galactorrhea. In two-thirds of these patients, galactorrhea persists after parturition, despite the resumption of menses, and likely does not represent a pathologic entity. Normal PRL levels may still permit milk production because treatment of such patients with dopamine agonists alleviates galactorrhea. Galactorrhea may also develop transiently after surgical procedures to the chest wall, including mammoplasty, arising from neural reflexes due to intercostal nerve stimulation.[166] The optimal management of galactorrhea should be determined by identifying and treating the underlying cause. Regardless of the cause, galactorrhea associated with hyperprolactinemia responds to correction of hyperprolactinemia.

Growth Hormone

Physiology

Somatotroph Cells

Mammosomatotroph cells expressing both PRL and GH arise from the acidophilic stem cell and immunostain mainly for PRL. Somatotrophs are located predominantly in the lateral wings of the anterior pituitary gland and comprise 35% to 45% of pituitary cells (see Chapter 9, Fig. 9.1). These ovoid cells contain prominent secretory granules up to 700 µm in diameter. Juxtanuclear Golgi structures are particularly prominent with secretory granules in formation. The gland contains a total of 5 to 15 mg of GH.[172]

Structure

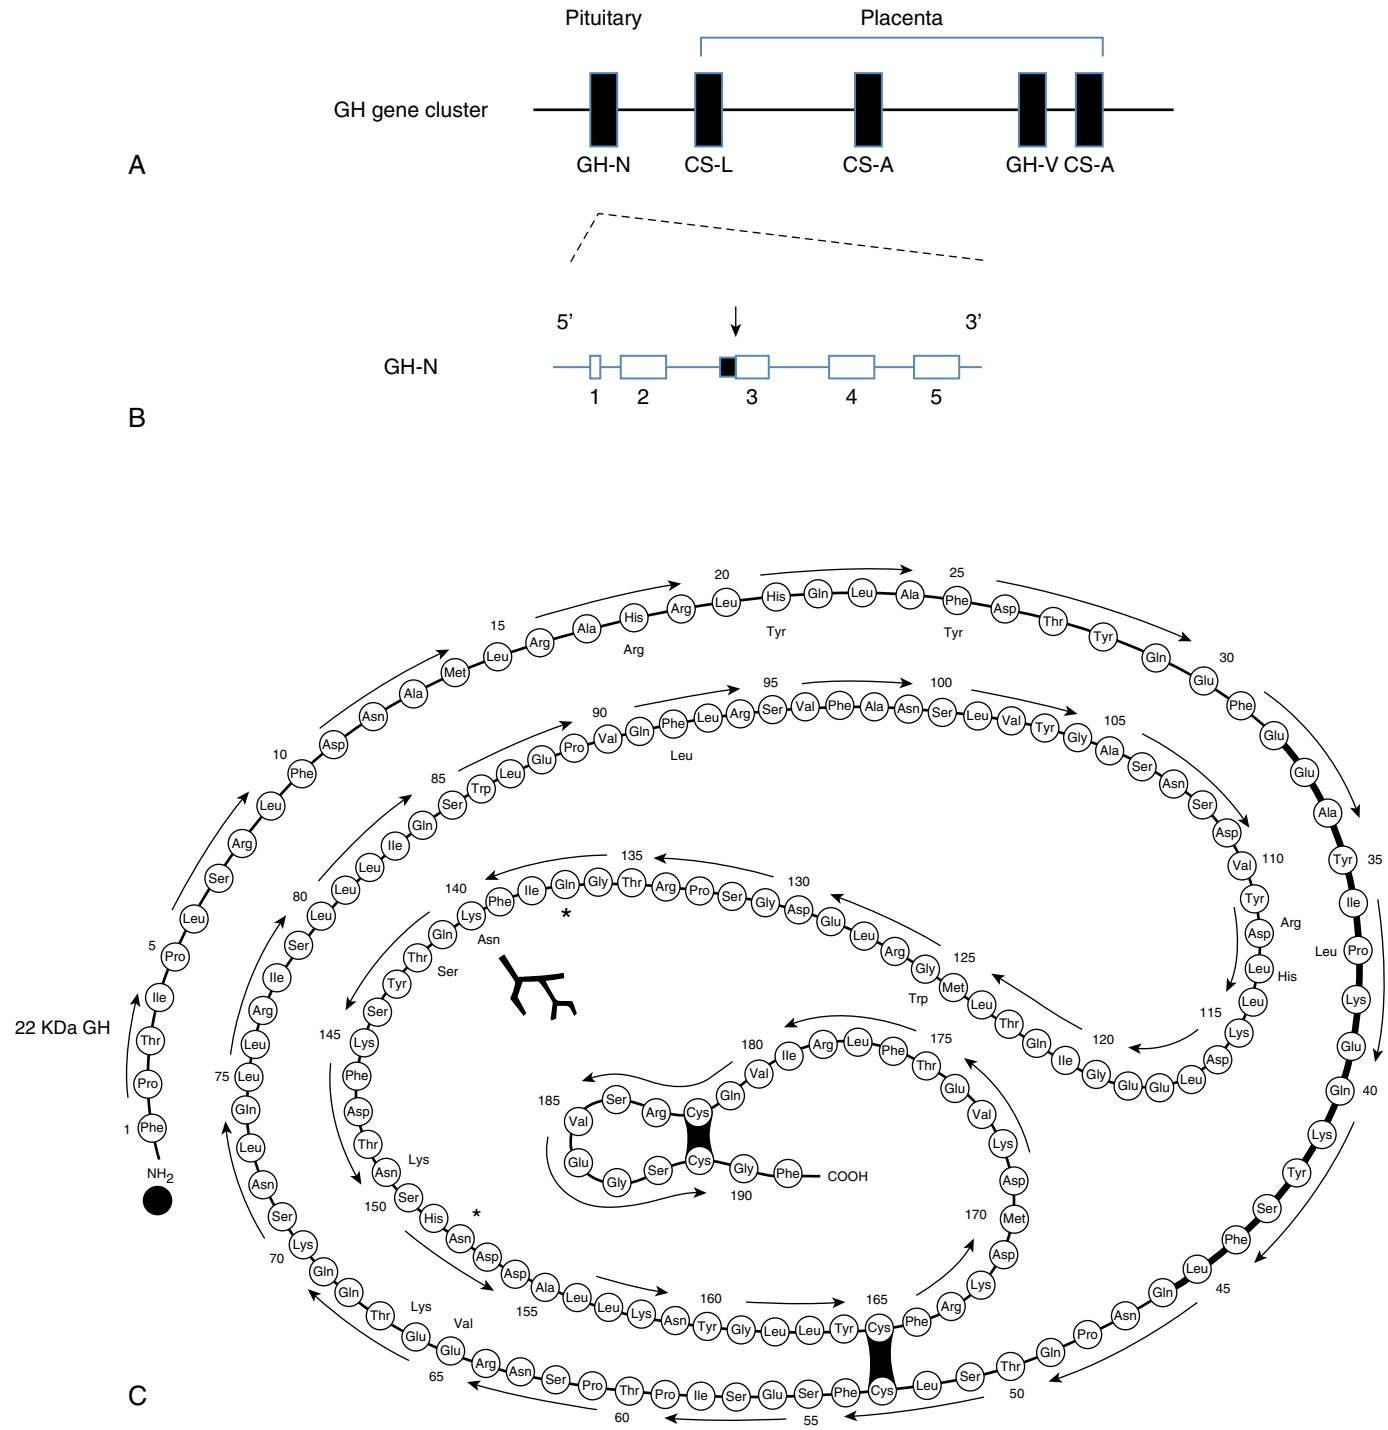
The human growth hormone (hGH) genome locus spans approximately 66 kb and contains a cluster of five highly conserved genes located on the long arm of human chromosome 17q22-24.[173] It encodes the following forms of hGH and human chorionic somatomammotropin (hCS): hGH-N, hCS-L, hCS-A, hGH-V, and hCS-B,[174] all of which consist of five exons separated by four introns (Fig. 8.8).

The GH-N gene is expressed in pituitary somatotrope cells and, to a minor extent, in lymphocytes, whereas GH-V and CS genes are expressed in the placenta. The level of GH gene expression in lymphocytes is sufficient to play a local paracrine/autocrine immunoregulatory role but is insufficient to fulfill a hormonal role at distant sites.

The hGH-N gene codes for a 22-kDa (191–amino acid) protein.[175] The hCS-A and hCS-B genes are expressed in placental trophoblasts.[176] hGH-V, expressed exclusively in placental syncytiotrophoblasts, encodes a 22-kDa protein that emerges from midgestation as hGH-V2. When hGH-V levels are elevated, hGH-N declines progressively, indicating feedback regulation of the maternal hypothalamic-pituitary axis. Postpartum circulating hGH-V levels drop rapidly and are undetectable 1 hour after delivery.[177] hCS-L is found in placental villi but has been considered a pseudogene.

The hGH promoter region contains *cis* elements that mediate both pituitary-specific and hormone-specific signaling. The POU1F1 transcription factor confers tissue-specific GH expression; a second, ubiquitous factor binds to a distal PIT1 site containing a consensus sequence for the Sp1 transcription factor. PIT1 and Sp1 both contribute to GH promoter activation, as mutation of the Sp1 binding site attenuates promoter activity.[178] DNase hypersensitive sites of a locus control region (LCR) located 14.5 kb upstream of the hGH-N promoter confers and restricts the expression of GH only to somatotrophs and mammosomatotrophs among the PIT1-positive cell population during development.[179] This distant locus also plays a major role in sustaining the level of hGH gene expression in somatotrophs. Growth hormone–releasing hormone (GHRH) stimulates GH synthesis and release mediated by cAMP. cAMP-response element binding (CREB) protein (CBP) is phosphorylated by protein kinase A and is a cofactor for PIT1-dependent human GH activation.

The GH molecule, a single-chain polypeptide hormone consisting of 191 amino acids, is synthesized, stored, and secreted by somatotroph cells. The crystal structure of hGH reveals four α-helixes.[180] Circulating GH molecules comprise several heterogeneous forms: 22-kDa and 20-kDa monomers, the latter lacking amino acids 32 through 46 deleted from alternative splicing of the GH gene (Fig. 8.8). The 22-kDa peptide is the major physiologic component, accounting for 75% of pituitary GH secretion, and the 20-kDa peptide accounting for about 10%. The 20-kDa GH has a slower metabolic clearance.[181] The pituitary gland also produces a number of other variants formed from post-translational modification, including two deamidated forms, acylated and glycosylated.[182]



• **Fig. 8.8** Schematic presentation of the human growth hormone gene cluster (A) on chromosome 17 containing GH-N, CS-L, CS-A, GH-V and CS-A genes. GH-N is expressed in the pituitary gland while the rest are expressed in the placenta. CS-L and GH-V are the predominant forms expressed during pregnancy. The GH-N gene (B) encoding human growth hormone contains five exons and four introns, and generates a full-length 22-kDa protein (C). Exon 3 contains a splice acceptor site *(arrow)* that generates a 20-kDa isoform that lacks amino acids 32 to 46, shown with *thickened lines* in the lower panel within the 22-kDa hormone. Regulation

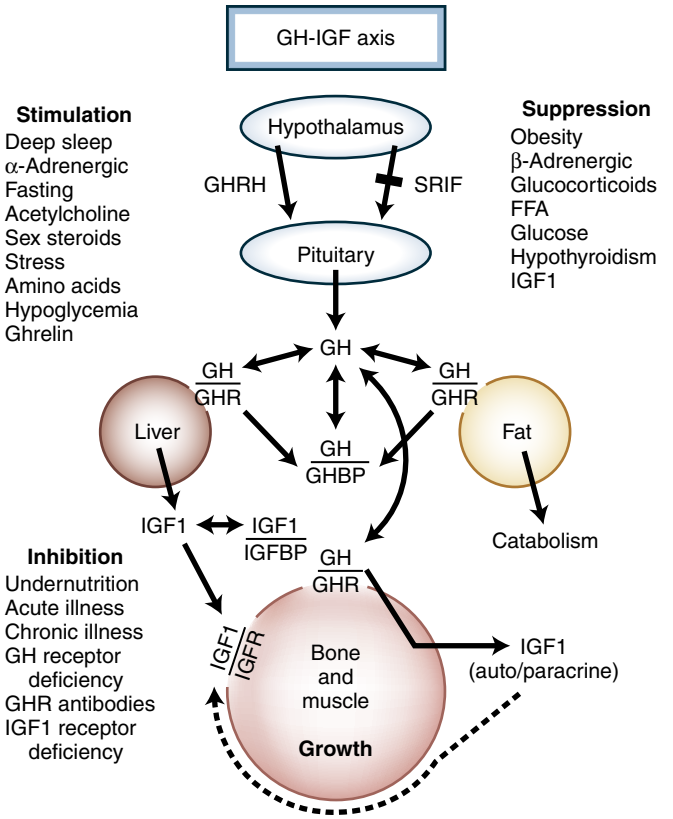
Neuropeptides, neurotransmitters, and opiates impinge on the hypothalamus and modulate release of GHRH and somatostatin (somatotropin release–inhibiting factor [SRIF]). Integrated effects of these complex neurogenic influences determine the final secretory pattern of GH (Fig. 8.9). Apomorphine, a central dopamine receptor agonist, stimulates GH secretion,[183] as does levodopa (L-dopa). Oral L-dopa administration evokes a brisk serum GH response within an hour in healthy young subjects. Norepinephrine increases GH secretion via α-adrenergic pathways and inhibits GH



• **Fig. 8.9** The growth hormone/insulin-like growth factor (GH-IGF) axis. Endocrine activities of ghrelin, a natural growth hormone secretagogue [GHS], in humans: comparison and interactions with hexarelin, a nonnatural peptidyl GHS, and GH-releasing hormone. *J Clin Endocrinol Metab.* 2001;86:1169–1174.)

release via β-adrenergic pathways. Insulin-induced hypoglycemia, clonidine, arginine administration, exercise, and L-dopa facilitate GH secretion by α-adrenergic effects.[184] β-Adrenergic blockade increases GHRH-induced GH release, possibly due to a direct pituitary action or by decreasing hypothalamic somatostatin release. Endorphins and enkephalins stimulate GH and may account for GH release during severe physical stress and extreme exercise[184] (see Fig. 8.9). Galanin, a 29–amino acid neuropeptide, induces GH release and enhances responses to GHRH. Cholinergic and serotonergic neurons and several neuropeptides stimulate GH, including neurotensin, VIP, motilin, cholecystokinin, and glucagon.

The somatotroph cell expresses specific receptors for GHRH,[185] GH secretagogues, and SRIF receptor subtypes 2 and 5, which mediate GH secretion.[186,187] GHRH selectively induces GH gene transcription and hormone release.[188] GHRH elicits a prompt rise in serum GH levels, with higher levels occurring in females.[189] SRIF suppresses secretion but not GH biosynthesis.

Ghrelin

The isolation of ghrelin from the stomach has revealed an additional control system for GH (see Chapter 39). Ghrelin is a 28–amino acid peptide that binds the growth hormone secretagogue (GHS) receptor to induce hypothalamic GHRH and pituitary GH release.[197] A unique *n*-octanoylated serine 3 residue confers GH-releasing activity to the molecule. Ghrelin is synthesized in peripheral tissues, especially gastric mucosal neuroendocrine cells, as well as in the hypothalamus. Control of GH secretion thus requires hypothalamic GHRH/SRIF as well as ghrelin.[198] Ghrelin dose-dependently evokes GH release. It requires the presence of GHRH to evoke GH release as evidence in patients with intact pituitary but disordered hypothalamic function, when GHS does not induce GH.[199] This is because GHRH acts as an allosteric coagonist for the ghrelin receptor.[200] GHS agonists also potentiate GH release in response to a maximal stimulating dose of exogenous GHRH. After a saturating dose of GHRH, subsequent GHRH administration is ineffective, although GHS agonists remain effective.[192] Hypothalamic ghrelin likely controls GH secretion interacting with GHRH and SRIF.[198,201,202] Ghrelin and synthetic hexapeptidergic analogues of the GHS receptor induce potent and reproducible GH release associated with modest increases in PRL and ACTH/cortisol that occur with some GHSs (Fig. 8.10). The GHS receptor uses intracellular

signaling pathways distinct from the GHRH receptor.[199,200] In addition to its GH-releasing action, there is strong evidence that ghrelin is a pleotropic hormone regulating appetite, energy balance, sleep-wake rhythm, gastric motility, glucose homeostasis, cell growth, and cardiac function.[203,204]

Extrapituitary GH

GH is expressed outside the pituitary gland in the brain, immune cells, reproductive tract (breast, ovary, testis, prostate), gastrointestinal system (liver, pancreas, gut), and lungs.[205] The regulation of GH in these tissues is poorly understood. Evidence suggests that GH subserves developmental and proliferative function, acting in an autocrine and paracrine manner. Autocrine GH binds GHRs that are translocated to the nucleus, inducing cell cycle proliferation.[206] Extrapituitary GH expression is strongly implicated in neoplastic transformation of breast, prostate, and colonic neoplasms.[207,208]

Secretion

GH secretion is episodic and exhibits a diurnal rhythm with approximately two-thirds of the total daily GH secretion produced at night triggered by the onset of slow-wave sleep. Major GH secretory pulses accounting for up to 70% of daily GH secretion occur with the first episode of slow-wave sleep.[209] Normal GH secretion is characterized by secretary episodes separated by troughs of minimal basal secretion, during which GH is undetectable for more than 50% of a 24-hour period. GH concentration is high in the fetal circulation, peaking at approximately 150 μg/L during midgestation. Neonatal levels are lower (~30 μg/L), possibly reflecting the negative feedback control by rising levels of circulating IGF1. GH output falls to a stable level during childhood, rising at the onset of puberty by a twofold to threefold level at late puberty. GH secretion starts to decline exponentially during the third decade of life, progressively declining with advancing age to about 50% of that observed in the third decade.[184] The decline in GH status occurs by a change in pulse amplitude rather than frequency. On average, the daily production of GH in the prepubertal state is 200 to 600 μg/day, rising to 1000 to 1800 μg/day at the peak of puberty.[184] In adulthood, production rates range from approximately 200 to 600 μg/day with rates higher in women than in men.[184,210] Adiposity accounts for a significant component of declining GH output with increasing age[211] (Table 8.4). Exercise and physical stress, including trauma with hypovolemic shock and sepsis, increase GH levels.[184] Emotional deprivation and endogenous depression suppress GH secretion.

The levels of IGF1 in childhood, adolescence, and adulthood reflect the status of GH output during the corresponding phases of life. IGF1 levels are stable postnatally and during childhood, rising at the start of puberty and peaking in late adolescence (Fig. 8.11).[583] This close correspondence throughout life renders age-stratified IGF1 level a valuable serum marker of GH status in both sexes.

Nutrition plays a major role in GH regulation, in part mediated by the inhibitory actions of insulin.[212] Malnutrition increases GH secretion, whereas obesity has the opposite effect. These nutritional effects occur acutely, as exemplified by fasting, which amplifies GH secretion within 12 hours[213] (Fig. 8.12), and glucose ingestion, which suppresses GH secretion. Central glucoreceptors appear to sense glucose fluctuations rather than absolute levels. Intravenous (IV) administration of single amino acids, such as arginine and leucine, stimulate GH secretion. Free fatty acids blunt the effects of arginine infusion, sleep, L-dopa, exercise, and GHRH on GH release.[214] Leptin plays a key role in regulation of food intake and energy expenditure[215] and may act as a metabolic signal in stimulating GH secretion[216] through interactions with somatostatin, GHRH, and the neuropeptide Y (NPY) system.

TABLE 8.4 Adult Growth Hormone Secretion[a]

Interval	Young Adult	Fasting	Obesity	Middle Age
24-h secretion (μg/24 h)	540 ± 44	2171 ± 333	77 ± 20	196 ± 65
Secretory bursts (number in 24 h)	12 ± 1	32 ± 2	3 ± 0.5	10 ± 1
GH burst (μg)	45 ± 4	64 ± 9	24 ± 5	10 ± 6

GHRH and SRIF Interaction

Hypothalamic SRIF and GHRH are secreted in independent waves and interact together to generate pulsatile GH release. The rat hypothalamus releases GHRH and SRIF 180 degrees out of phase every 3 to 4 hours, resulting in pulsatile GH levels. SRIF antibody administration elevates GH levels, with intact intervening GH pulses,[190] implying that hypothalamic SRIF secretion generates GH troughs. Similarly, GHRH antibodies eliminate spontaneous GH surges. In humans, GH pulsatility persists when GHRH is tonically elevated, as in ectopic tumor GHRH production or during GHRH infusion,[191] suggesting that hypothalamic SRIF is largely responsible for GH pulsatility. However, GHRH antagonists inhibit GH pulses, indicating an important role in the generation of pulsatile secretion in humans.[192] The periodic, pulsatile GH release is the result of coordinated SRIF and GHRH secretion and action.

Chronic GHRH stimulation, either by continuous infusion or repeated bolus administration, eventually desensitizes GH release in vitro and in vivo, possibly due to depletion of a GHRH-sensitive pool of GH. GHRH pretreatment also decreases somatotroph GHRH binding sites.[193] GH stimulates hypothalamic SRIF, GHRH and SRIF autoregulate their own respective secretion, and GHRH stimulates SRIF release.[194] GH secretion is further regulated by its target growth factor, IGF1, which participates in a hypothalamic-pituitary peripheral regulatory feedback system.[195,196] IGF1 stimulates hypothalamic SRIF release and inhibits pituitary GH gene transcription and secretion.

Interaction With Other Hormone Axes

Glucocorticoids acutely stimulate GH secretion, but chronic steroid treatment inhibits GH. Three hours after acute glucocorticoid administration, GH levels rise and remain elevated for 2 hours.[217] Glucocorticoids administered to normal subjects dose-dependently inhibit GHRH-simulated GH secretion.[217] Thyroid hormones are required for the function of the GH system. Gonadal steroids regulate GH secretion and GH action in men and women. Testosterone stimulates GH secretion, an effect that is mediated centrally and dependent on prior aromatization to estrogen.[218] In women,

• **Fig. 8.12** Effect of fasting on growth hormone (GH) secretion patterns in a healthy male subject. (From Hartman ML, Veldhuis JD, Johnson ML, et al. Augmented growth hormone [GH] secretory burst frequency and amplitude mediate enhanced GH secretion during a two-day fast in normal men. *J Clin Endocrinol Metab.* 1992;74:757–765.)

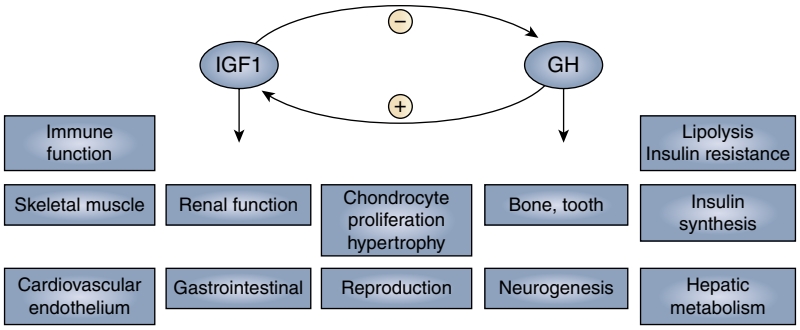
estrogen stimulates GH secretion, evident only with oral but not parenteral administration because of a first-pass effect hepatic, effect reducing IGF1 production[219] and enhancing GH secretion through reduced feedback inhibition.[219] In women, endogenous GH secretion is driven centrally by aromatization of androgens. Thus in women, estrogens act centrally in a paracrine manner in stimulating but act peripherally in an endocrine manner in enhancing GH secretion through reduced IGF1 feedback inhibition.[220]

Action

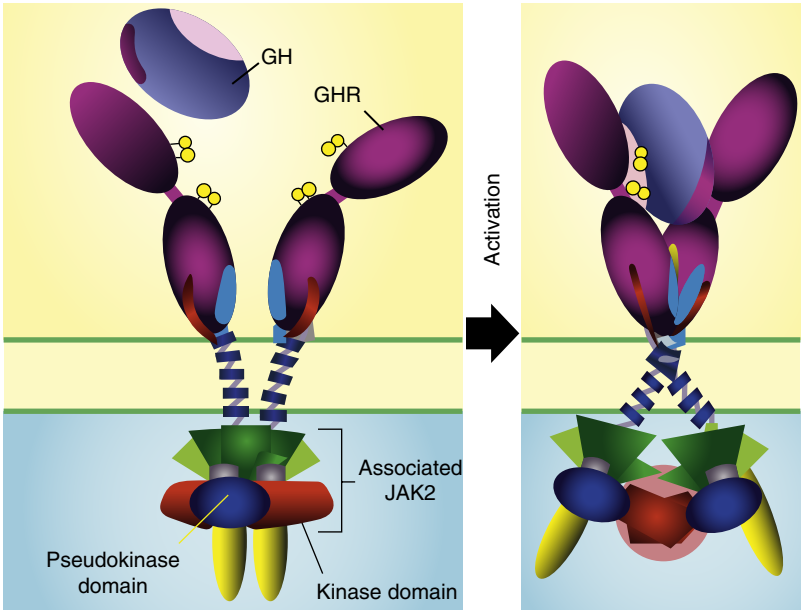
Growth hormone exerts its pleiotropic effects directly and indirectly through the actions of IGF1. These mediated actions stimulate growth and a host of functions in various tissues, organs, and systems (Fig. 8.13).

GHR Signaling

GH elicits intracellular signaling through a peripheral receptor, initiating a phosphorylation cascade involving the JAK-STAT pathway.[221] The GHR is a 620–amino acid 70-kDa protein of the class I cytokine/hematopoietin receptor superfamily that consists of an extracellular ligand-binding domain, a single membrane-spanning domain, and a cytoplasmic component.[222] The GHR superfamily is homologous with receptors for PRL, interleukin 2 (IL2) through IL7, erythropoietin, interferon, and colony-stimulating factor. These receptors exist as constitutive dimers. GHR activation is triggered by the binding of GH at two distinct sites to extracellular domains of each of the two receptor dimers (Fig. 8.14). The binding reorients and rotates the receptor separating the transmembrane domains, sliding the pseudokinase inhibitory domain of one JAK kinase away from the kinase domain of the other JAK within the receptor dimer-JAK complex (see Fig. 8.14).[223,224] This results in phosphorylation of intracellular signaling molecules,[223,224] including the signal transducing activators of transcription proteins (STAT1, STAT3, and STAT5).[225] Phosphorylated STAT proteins are directly translocated to the cell nucleus, where they elicit GH-specific target gene expression by binding to nuclear DNA. STAT1 and STAT5 may also interact directly with the GHR molecule.[225] GH also induces c-Fos induction, insulin receptor substrate 1 phosphorylation, and insulin synthesis. Additional intracellular signaling pathways induced by GH include mitogen-activated protein kinase (MAPK), protein kinase C, SH2β, SHP2, SIRPA, SHC, FAK, CrKll, C-SRC, paxillin, and tensin. Intracellular GH signaling is abrogated by suppression of cytokine signaling (SOCS) proteins, which disrupt the JAK-STAT pathway and thus disrupt GH action.[226] In transgenic mice with deletion of SOCS2, gigantism develops presumably due to unrestrained GH action. As SOCS proteins are also induced by proinflammatory cytokines, critically ill patients or those with renal failure may develop GH resistance due to cytokine-induced SOCS.[227] Unraveling STAT/SOCS regulation in syndromes associated with disordered GH signaling will likely yield mechanistic insights for dysregulated GH action. The GHR is expressed in virtually all tissues with liver, fat, muscle, and kidney showing highest levels of expression.[228] A polymorphism of the GHR, resulting in the deletion of exon 3, has attracted widespread interest since an observation in 2004 that signaling was 30% higher than that of the full-length receptor.[229] A recent meta-analysis found no



• **Fig. 8.13** Major physiologic actions of growth hormone and insulin-like growth factor 1 (IGF1) action. Given that growth hormone uses signal transducer and activator of transcription 5 (STAT5) to induce both IGF1 and for many of its direct actions, it is difficult to attribute specific roles to growth hormone or IGF1 for many biologic effects. However, those actions that involve more direct growth hormone action are placed to the right, whereas those involving induced IGF1 to the left, acknowledging that these assignments may change. Note that the growth hormone–IGF1 system is regulated by the tight negative feedback loop between hepatic IGF1 production and pituitary growth hormone secretion. *GH,* growth hormone; *IGF1,* insulin-like growth factor 1. (Redrawn from Brooks AJ, Waters MJ. The growth hormone receptor: mechanism of activation and clinical implications. *Nat Rev Endocrinol*. 2010;6:515–525.)



• **Fig. 8.14** Schematic representation of the GH receptor in the basal state *(left)* and the active state *(right)*. Binding of GH at two distinct sites to predimerized receptors leads to a crossover rotation and realignment, producing a separation of the lower transmembrane domains. This results in the separation of two associated JAK2s and the removal of the inhibitory pseudokinase domain from the kinase domain of the other JAK2, bringing the two kinase domains into position for transactivation, initiating tyrosine phosphorylation of the receptor cytoplasmic domain and signaling proteins such as STAT5. (Redrawn from Brooks AJ, Dai W, O'Mara ML, et al. Mechanism of activation of protein kinase JAK2 by the growth hormone receptor. *Science*. 2014;344:1249783.)

convincing influence of the exon 3–deleted GHR on stature, on GH-induced growth responsiveness in children, on metabolic benefits of GH replacement in adults with growth hormone deficiency (GHD), or on clinical manifestations and response to treatment in acromegaly.[230]

The pattern of GH secretion also determines tissue responses to GH in addition to the absolute amount secreted. Gender-specific patterns of GH secretion profiles determine sex-specific expression of cytochrome P450 enzymes. In turn, circulating steroids regulate neuroendocrine release of GH. SRIF, by suppressing interpulse GH levels, serves to masculinize the ultradian GH rhythm. In mice harboring a disrupted SRIF gene, plasma GH secretory patterns are elevated and liver enzyme induction loses its gender-specific dimorphism, but these animals retain sexually dimorphic growth patterns.[231] Linear growth patterns and liver enzyme induction are phenotypically gender specific, driven by higher GH pulse frequency rates involving STAT5B mediation. STAT5B is sensitive to repeated pulses of injected GH,[232] unlike other GH-induced responses, which are desensitized by repeated GH administration. Disruption of STAT5B in transgenic mice

impairs male pattern body growth[233] associated with female pattern IGF1 and testosterone levels. Appropriate GH pulsatility drives body growth mediated by STAT5B[234,235] but not metabolic GH effects. In humans, GH secretion is also sexually dimorphic and regulates the P450 liver enzymes.[235] A flatter pattern appears to evoke a higher IGF1 response and a lesser degree of lipolysis.[236]

IGF1 mediates growth-promoting activities of GH in an endocrine or paracrine manner.[237] In mice, paracrine IGF1 produced in extrahepatic tissues is critical for growth, which persists even when hepatic IGF1 is deleted.[238] GHR mutations are associated with partial or complete GH insensitivity and growth failure. These syndromes are associated with normal or high circulating GH levels, decreased circulating GHBP levels, and low levels of circulating IGF1. Multiple homozygous or heterozygous exonic and intronic GHR mutations have been described. These occur mostly in the extracellular ligand-binding receptor domain (see Chapter 25).

Growth Hormone–Binding Proteins

Two high-affinity and low-affinity circulating GH-binding proteins (GHBPs) include a 20-kDa low-affinity GHBP and a 60-kDa high-affinity GHBP, which corresponds to the extracellular domain of the GHR and binds half of the circulating 22-kDa GH form.[239,240] The high-affinity GHBP in humans is generated by proteolytic cleavage through the action of tumor necrosis factor-α–converting enzyme, a metalloprotease.[241] The 20-kDa GH binds preferentially to the low-affinity binding protein, which is unrelated to the GHR. It has been proposed that the circulating level of GHBP reflects global GHR expression in the body. The GHBPs dampen the acute oscillations in serum GH levels associated with pulsatile pituitary GH secretion, and plasma GH half-life is prolonged by decreased renal GH clearance of bound GH. The high-affinity binding protein also competes with GH for binding to surface GHRs and as such alters GH pharmacokinetics and distribution.

GHBP concentrations are unaffected by GH status such as in GHD or acromegaly.[242] Some patients with Laron dwarfism have absent or reduced levels of GHBP, reflecting mutations that result in absent translation of the GHR or of the extracellular domain.[243] Serum concentrations of GHBP are low in some children with idiopathic short stature[244] and in African pygmies, suggesting abnormalities in the gene for the GHR.[245] GHBP levels are increased in obesity, pregnancy, and in subjects undergoing refeeding[245] and by oral estrogen administration.[219] Levels are reduced in malnutrition, cirrhosis, and hypothyroidism and by glucocorticoids and androgens.[246]

Metabolic Action

GH functions as a major metabolic hormone in the adult, optimizing body composition and physical function as well as regulating energy and substrate metabolism. Metabolic actions of GH also closely interact with those of insulin in the control of fat, glucose, and protein metabolism during fasted and fed states.

GH promotes fat metabolism by enhancing lipolysis and fatty acid oxidation. This function is particularly important during the fasted state when GH secretion is enhanced, resulting in the partitioning of fuel utilization toward fat with the sparing of protein. Stimulation of lipolysis occurs indirectly through potentiating the activity of hormone-sensitive lipase by β-adrenergic stimulation. GH also regulates lipoprotein metabolism by enhancing low-density lipoprotein (LDL) clearance and by activating expression of hepatic LDL receptors.[247,248] The atherogenic profile of lipoproteins is increased in GHD and reduced by GH therapy.[249]

GH exerts profound effects on glucose metabolism either directly or by antagonizing insulin action. GH enhances glucose uptake and utilization in cells, referred to as its *insulin-like* effects.[250] At the whole-body level, GH suppresses glucose oxidation and utilization while enhancing hepatic glucose production subserving the nonoxidative[250] use of glucose. As GH is an important counterregulatory hormone, it is conceivable that this function protects against hypoglycemia.

Protein anabolism is a signature property of GH mediated by IGF1. However, GH directly stimulates amino acid uptake and incorporation into protein in vitro.[251] Arteriovenous measurements in the forearm report an acute increase in protein synthesis over a few hours of GH infusion, suggesting a direct non-IGF1 mediated effect.[252] Whole-body studies in humans using isotopes have consistently shown that GH reduces protein oxidation and stimulates protein synthesis.[148] The protein-sparing effect of GH is coupled to the availability and increased parallel utilization of free fatty acids, whereas pharmacologic reduction of free fatty acids during fasting augments the rate of protein breakdown.[250]

Growth Hormone Assays

Plasma GH is measured by radioimmunoassay (RIA; polyclonal or monoclonal) or by immunoradiometric assay (IRMA; dual monoclonal), but considerable differences exist in the results of GH measurements between assays by as much as threefold.[253,254] These differences are due mainly to heterogeneity in assay components and characteristics. An important contributor is the use of different calibrator materials[255] and international reference preparations, shifting from purified pituitary extracts to recombinant GH.[255] Not all assays are calibrated to the recombinant international GH reference preparation (98/574). Heterogeneity of secreted GH poses an additional problem as it consists of monomers, dimers, and other post-translational modified products. Their detection varies, with different antibodies having different specificity for the different molecular forms of GH. The reporting of assay results also varies. GH assay results are expressed in mass units but also in international units, which have been arbitrarily defined and do not have a clear relationship to mass.[255] Many factors interfere with GH measurements, including GHBP, which binds approximately 50% of circulating GH. Modern two-site monoclonal assays are engineered to detect solely 22-kDa GH and return lower values to polyclonal RIA, thus detecting various circulating forms. The inhomogeneity of GH immunoassay results poses a challenge in the definition of accepted standards for diagnosis of GHD where criteria are based on cutoffs. Clinicians should be aware of the nature of the GH assay and how values compare to those previously obtained by polyclonal RIA.

Similar issues apply to assays for IGF1. A significant issue arises from interference of IGF binding proteins, which bind over 95% of IGF1. This necessitates dissociating IGF1 from its binding proteins as a step before immunologic detection. Two-site assays have now overcome the need for prior dissociation. IGF1 measurements are particularly valuable in the management of GH-related disorders because GH status can only be estimated from repeated GH measurements over an extended period. Like GH, IGF1 status changes over the human lifespan, rising to a peak in late puberty and declining in early adulthood and gradually thereafter the fourth decade. A recent study employing a two-site chemiluminescent assay calibrated against a recombinant human

IGF1 standard (02/254) in over 15,000 subjects has provided timely age-stratified and gender-stratified reference ranges from childhood to senescence (see Fig. 8.11).

Growth Hormone Deficiency

GH is the most abundant hormone in the adult pituitary gland, and it plays an important role in maintaining the metabolic process and the integrity and function of many tissues and systems after the cessation of growth. Life expectancy is reduced in hypopituitary patients with GHD. In a meta-analysis of six studies totaling over 19,000 patients, the mortality is twice that of the control population (Fig. 8.15) with the risk greater in women than men and greater in those who received radiotherapy.[256–260]

Pathophysiology

Adult GHD may be acquired or congenital[261] (Table 8.5). Surgical or radiation treatment of pituitary, parasellar, and brain tumors is the most common cause of GHD, accounting for nearly two-thirds of cases. The frequency of causes differs between patients with childhood-onset and adult-onset GHD (Fig. 8.16).[262] Idiopathic causes, representing the most commonly encountered group in childhood-onset GHD, likely represent a heterogeneous collection of congenital developmental abnormalities, including mutations of *PROP1* or *POU1F1* genes, causing GHD with other pituitary hormone deficiencies.[263] Isolated GHD may be complete or partial, and up to 67% of children initially diagnosed with idiopathic GHD had normal GH responses when subsequently retested as adults for GHD following cessation of GH treatment.[264] Children with GHD should be retested before GH treatment is continued into adulthood unless they have clearly documented panhypopituitarism or a defined genetic or developmental abnormality that causes complete and irreversible GHD. Mutations in the GH[265] and GHRH receptor genes,[266] and GH insensitivity as a result of primary GHR dysfunction,[267] result in a selective lack of GH action.

Presentation

The clinical consequences of GHD in adults are shown in Table 8.6. Symptoms of GHD are nonspecific and include fatigue, lack of energy, social isolation, low mood, poor concentration, and reduced physical function, contributing to a poor quality of life.[268] The signs are also nonspecific and include general and central adiposity and reduced lean tissue and bone mineral density (BMD), along with unfavorable biochemical changes such as hyperlipidemia[269,270] and glucose intolerance.[268] Some patients have established evidence of macrovascular disease such as increased carotid intimal thickness.[271,272] GH deficiency impairs cardiac function.[273,274] Cardiovascular risk abnormalities are less pronounced in adults with childhood-onset GHD than in those acquiring the deficiency during adulthood who have more pronounced disordered quality of life, lipids, and body composition.[270]

Subjects with isolated GHD or inactivating mutation of the GHR manifest some features that contrast with those of GHD as a component of multiple pituitary hormone deficits. Patients with selective absence of GH action display enhanced insulin sensitivity, lower prevalence of diabetes, absence of premature atherosclerosis, and normal life expectancy.[275,276] These findings suggest that the observed increased mortality rate in hypopituitary adults with GHD arises in part from suboptimal replacement regimens and coexisting comorbid conditions.

Evaluation

GHD is diagnosed biochemically within an appropriate clinical context. Biochemical testing for GHD occurs with a high probability in patients with a history of organic hypothalamic-pituitary dysfunction, cranial irradiation, known childhood-onset GHD, and traumatic brain injury (TBI).[277,278] The features of adult GHD are not particularly distinct and mimic body compositional and biochemical changes of the aging process. Thus clinical suspicion must be confirmed by accurate biochemical diagnosis to ensure that GH-deficient patients are accurately identified and treated.

Provocative Testing. The diagnosis of adult GHD is established by provocative testing of GH secretion (Table 8.7). Other hormone deficits should be corrected before testing. Several provocative tests include insulin tolerance test (ITT), arginine, glucagon, clonidine, growth hormone–releasing peptides (GHRPs), and

GHRH, alone or in combination with arginine or pyridostigmine. GHRPs are synthetic analogues of ghrelin. Because provocative tests vary in the ability to evoke GH release, a single value cannot be applied as a diagnostic threshold across different tests.[279] ITT is a more potent stimulator of GH release than arginine, clonidine, or L-dopa, whereas combinations such as arginine plus GHRH, or GHRP plus GHRH, are more potent than ITT alone.[280–282]

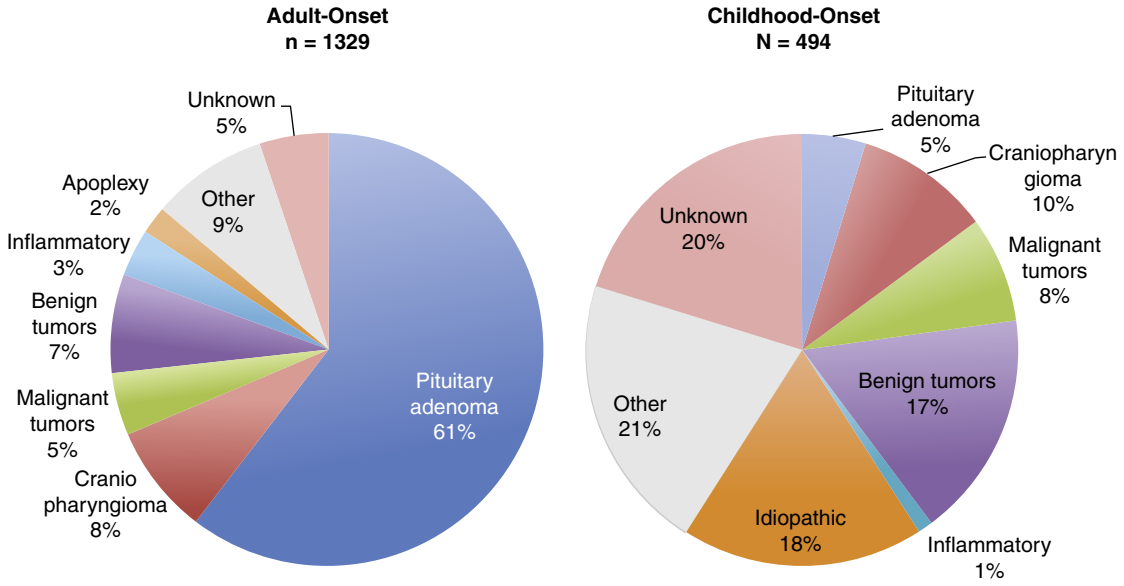
The ITT is the gold standard test for GHD. Normal subjects respond to insulin-induced hypoglycemia with peak GH concentrations of more than 5 μg/L[283] (Fig. 8.17). Severe GHD is defined by a peak GH response to hypoglycemia of less than 3 μg/L.[284] These cutoff values were defined using polyclonal GH RIAs.[284] The test is contraindicated in patients with electrocardiographic evidence or history of ischemic heart disease and in patients with seizure disorders.

Glucagon,[285] GHRH, and ghrelin mimetics (GHRP2, GHRP6, and macimorelin[286]), alone[287] or in combination,[282,288] are validated diagnostic tests.[281,282,288] The diagnostic thresholds for these tests are shown in Table 8.7. The unavailability of GHRH has brought glucagon greater attention as a simple diagnostic test for GHD when the ITT is not desirable.[289] The ITT evaluates the integrity of the hypothalamic-pituitary axis and has the added advantage of also stimulating ACTH secretion. Diagnostic tests employing GHRH or GHRPs, both of which directly stimulate GH release from the pituitary gland, may not identify GHD caused by hypothalamic disease.[290] This is exemplified by studies in patients treated with cranial irradiation, when the ITT shows the greatest sensitivity and specificity within the first 5 years after irradiation.[291] If peak GH levels are normal during a GHRH plus arginine test in patients who have received irradiation, then an ITT should also be performed. In irradiated patients as well as those with inflammatory and infiltrative parasellar lesions, GHD may develop many years after the initial insult. Therefore this group of patients should be followed in the long term with repeat testing. Obesity confounds the diagnostic testing of GHD as it blunts the peak GH response.[292] Except for the GHRH plus arginine test, body mass index (BMI)–stratified normal ranges have not yet been established for any of the provocative tests.

Growth Hormone–Responsive Markers. These markers include IGF1, IGF binding protein 3 (IGFBP3), and the acid-labile subunit of the IGFBP complex. IGF1 is useful for diagnosis only when age-adjusted normal ranges are used. Although IGF1 levels are reduced in adult GHD, a normal concentration does not exclude the diagnosis[283] (see Fig. 8.17). A subnormal IGF1 level in an adult patient with coexisting pituitary hormone deficits is strongly suggestive of GHD, particularly in the absence of conditions known to reduce IGF1 levels, such as malnutrition, liver disease, poorly controlled diabetes mellitus, and hypothyroidism. The separation of IGF1 values between GH-deficient and normal subjects is greatest in the young. As IGF1 levels decline with aging in normal subjects, IGF1 measurements become less reliable as a biochemical marker of GHD in patients older than 50 years when the values merge with those of normal age-matched subjects.[293] Measurement of IGFBP3 or the acid-labile subunit does not offer any diagnostic advantage over IGF1.[277,278]

In patients with organic hypothalamic-pituitary disease, the prevalence of GHD is strongly linked to the number of pituitary hormone deficits, ranging from approximately 25% to 40% in those with no other deficit to virtually 95% to 100% when more than three pituitary hormone deficiencies are present.[294] Patients with three or more pituitary hormone deficiencies and an IGF1 level below the reference range have a greater than 97% chance of being GH deficient (see Table 8.7)[295] and therefore do not require GH stimulation testing.[277,278]

Spontaneous GH Secretion. As pituitary GH secretion occurs episodically, accurate quantification of integrated GH secretion requires continuous measurement of secretion over 24 hours. This procedure requires insertion of a continuous withdrawal pump or patent indwelling catheter for frequent sampling. Continuous 24-hour GH measurement in the diagnosis of GHD is inferior to provocative testing[283] (see Fig. 8.17) and is cumbersome and expensive.



• **Fig. 8.16** Frequency of the causes of childhood-onset and adult-onset growth hormone deficiency in Denmark. "Other" includes cysts, hypophysitis, granulomas, trauma, and empty sella syndrome. (Data from Stochholm K, Gravholt CH, Laursen T, et al. Incidence of GH deficiency—a nationwide study. *Eur J Endocrinol*. 2006;155:61–71.)

Gene Expression Analysis

With the advent of high throughput and computational technology, there has been much interest in applying genomics and transcriptomics to identify dysfunction of the GH system and predict responsiveness to GH therapy. A recent study of well-characterized children with GH deficiency combining genotyping and gene expression analysis of peripheral blood mononuclear cells has identified a cluster of probe sets that strongly associate with the biochemical severity of GHD.[296] The results provide tantalizing evidence that gene expression analysis from a blood sample may aid in the diagnosis of GH deficiency. However, evidence that blood transcriptome changes are useful in predicting growth in children[297] or identifying GH abuse is poor.[298]

Growth Hormone Replacement Therapy

The effects of GH replacement were first reported in 1989. GH replacement induces profound effects on protein, fat, and energy metabolism, which result in increased lean body mass and decreased fat mass without a significant change in body weight within months[299] (Fig. 8.18). The greatest reduction of body fat occurs in abdominal and visceral adipose tissue[300] (Fig. 8.19). Significant increases in extracellular water occur as a consequence of the dose-dependent antinatriuretic properties of GH.[301] GH-induced reduction in abdominal and visceral fat is accompanied by a significant shift in lipoprotein metabolism to a less atherogenic profile with improvements in the cholesterol and in HDL-cholesterol ratio but little or no change in triglycerides.[249] Long-term experience of more than 10 years indicates that treatment provides sustained benefits in body composition and metabolic risk markers[302] (Fig. 8.20). GH treatment reduces intimal media thickness of the carotid arteries.[271] Proinflammatory factors such as C-reactive protein and IL6, strongly implicated in the pathogenesis of vascular disease, fall significantly with GH treatment.[269]

GH replacement activates bone formation and bone resorption, resulting in a transient decline before a net increase in bone mass by 12 months.[303–305] Markers of bone turnover increase over the first 12 months but return to baseline after 3 to 4 years.[306] The increase is greater in men and in younger subjects.[304] BMD may increase for up to 10 years in the lumbar spine, whereas a decline that occurs in the femoral neck may start sooner[307] (Fig. 8.21). In an observational study, the fracture incidence over a mean follow-up period of 4.9 years was 30% lower in patients replaced with GH compared to an unreplaced group providing evidence of long-term protective benefit.[308]

GH replacement improves physical function through gains in anaerobic[309] and aerobic capacity,[310,311] the latter mediated in part by an increase in red cell mass, plasma volume, and cardiac output.[312,313] Most studies assessing GH effects beyond 12 months have reported a significant improvement in muscle strength through gains in muscle mass,[314–316] without affecting contractile force or fiber composition.[317]

Most trials with GH replacement report improved quality of life.[318] Discrepant results likely arise from varying study tools, with some being generic health questionnaires and others being disease specific. Domains of energy and emotional reaction tend to show the greatest improvements. Disease-specific tools have reported unequivocal improvement in measures of life satisfaction after GH treatment.[319] A large survey of 304 patients showed improved quality of life and significant reduction in the numbers of sick leave days and doctor visits during 12 months of GH therapy.[320,321]

Growth Hormone Administration. GH secretion is greater in the young and greater in women than in men. It is recommended that the starting dose of GH in young men and women be 0.2 and 0.3 mg/day, respectively, and in older individuals 0.1 mg/day,[277,278] which is then titrated according to serum IGF1 concentrations and at a rate that minimizes side effects[322] (Fig. 8.22). If side effects occur, the dose should be reduced; if no side effects are reported, the therapeutic goal is to maintain IGF1 levels in the normal age-matched and gender-matched range while avoiding levels in the upper quintile or above. Dose determination based on body weight

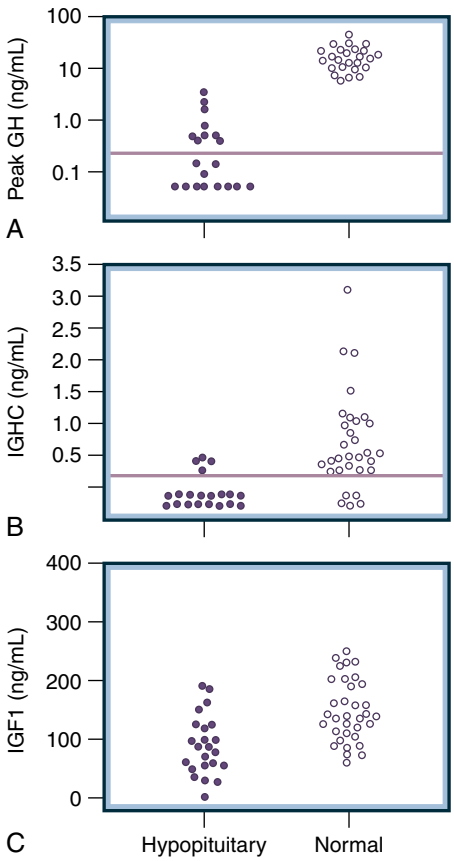
is not recommended because GH secretion is reduced in the obese.[277,278] GH is administered by nightly subcutaneous injection to mimic the greater secretion of GH at night. Side effects of GH in children are considerably fewer than those observed in adults.

Women with GHD require higher doses of hGH when also receiving oral rather than transdermal estrogen[323,324] because of a first-pass hepatic effect. Fifty percent more GH was required during oral estrogen treatment to maintain an IGF1 level equivalent to that achieved during transdermal administration; the waste is even greater when contraceptive instead of replacement estrogen doses are prescribed (Fig. 8.23).[325] In contrast, androgens enhance metabolic effects of GH.[148] The divergent effects of estrogens and androgens on GH action largely explain why women are less responsive than men to GH.[302]

Transition-Age Patients. GH treatment of the GH-deficient child normally is terminated when final height and epiphysis closure are reached.[326] These GHD patients who transition from the time of cessation of linear growth do not attain the somatic and structural skeletal maturity that continues to occur in the early years of normal adulthood. GH-deficient children should continue GH treatment after puberty to complete somatic maturation of muscle and bone.[326] A significant proportion of patients with childhood-onset GHD exhibit normal GH response when retested at the end of GH treatment as young adults. Therefore patients considered for continuation of GH replacement in the transition years must be retested. GH retesting is not required for those patients with a transcription factor mutation (e.g., POU1F1, PROP1) or those with more than three demonstrated pituitary hormone deficits.[277,278]

Precautions and Caveats of Treating With Human Growth Hormone. The most common side effects of hGH replacement include edema, arthralgias, and myalgias (Table 8.8). However, these symptoms are mild, dose related, and resolve in the majority of patients either spontaneously or with dosage reduction.[322] Although GH antagonizes insulin action, the risk of developing hyperglycemia is very low (see Fig. 8.20). A meta-analysis of 13 placebo-controlled trials involving 511 patients found a mean elevation of fasting blood glucose of 0.22 mmol/L compared to placebo levels.[249] However, the propensity for developing diabetes is increased up to eightfold in GHD adults who are obese.[327]

Patients with active malignancies should not be treated with GH. The possibility that hGH might initiate new cancers or stimulate growth of preexisting benign tumors is an important theoretic issue. The incidence of cancer is markedly reduced among subjects with inactivating mutations of the GHR.[275] A number of epidemiologic studies have reported association between higher, albeit normal, IGF1 levels and later risk of developing prostate cancer,[328] breast cancer in premenopausal women,[329] and colon and lung cancer.[330]



• **Fig. 8.17** Comparison of peak growth hormone (GH) concentration obtained during an insulin-tolerance test (A), integrated GH concentration (IGHC) obtained from blood samples withdrawn every 20 minutes over 24 hours (B), and insulin-like growth factor 1 (IGF1) concentrations (C) in patients with organic hypopituitarism and sex-matched normal subjects. *Horizontal lines* represent the limit of reading. In contrast, patients with acromegaly do not have an increased incidence of either breast or prostate cancer or cancer in general. The overall risk for cancer in acromegaly is lower than expected. However, these patients have a significantly increased mortality risk from colon cancer.[331,332] Pediatric experience shows no convincing evidence for a causal link between GH treatment and tumor recurrence or the development of neoplasia, including leukemia.[333,334] When comparing the relative risk of brain tumor recurrence in 180 children treated with hGH versus 891 who did not receive hGH, the risk of recurrence after a mean of 6.4 years was lower in the treated group than in those not receiving hGH.[335] GH treatment does, however, increase the risk of radiation-induced second tumor formation, especially meningiomas.[336]

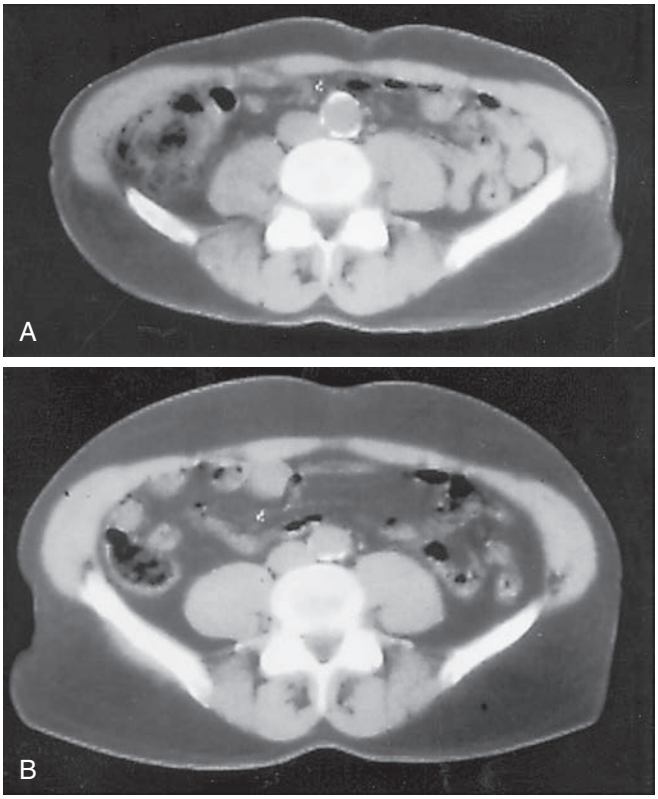
From observational studies, the incidence of malignancies in hypopituitary patients not receiving GH is higher than the general population but not in those replaced with GH.[337] The recurrence rate of craniopharyngiomas[338] and the recurrence rate and life expectancy in patients with nonfunctioning pituitary adenomas[339] were not different between patients replaced and unreplaced with GH over a follow-up period in excess of 10 years. Although observational studies are subject to selection bias, these findings provide some evidence supporting the long-term safety of GH replacement therapy. Nevertheless, long-term surveillance with adequate control groups in adults being treated for adult GHD is required to ensure that adult GH replacement does not increase the incidence of new cancers or growth of existing benign tumors.

Investigational Uses of Growth Hormone

Catabolic States. The anabolic actions of GH have prompted investigational use of GH in catabolic states, including surgery, trauma, burns, parenteral nutrition, and organ failure. The negative nitrogen balance in critically ill patients is partly attributable to GH resistance as well as to decreased IGF-1 production and action.[340] Beneficial effects of GH have been reported in patients with extensive burns, in those receiving high-dose glucocorticoid treatment, and in those with chronic obstructive pulmonary disease. There is some evidence that GH treatment in people with large burns results in more rapid healing of the burn wound and donor sites, and in reduced length of hospital stay, but there is an increased risk of hyperglycemia.[341] A study in which critically ill patients received very high doses of GH (up to 7 mg/day) approximating 15 to 20 times normal daily production rates was prematurely terminated due to increased fatality.[342] It has been suggested that GH may have had an adverse effect on acute-phase protein

in these patients.[343] Caution is advised for nonapproved uses of GH in adults.[344]

Osteoporosis. There is strong evidence that GH administered to otherwise healthy subjects with idiopathic osteoporosis improves bone mineral mass.[345] A double-blind, placebo-controlled treatment study for 18 months observed improvements in bone mineral content at the lumbar spine, in the femoral neck, and of the whole skeleton by up to 14%, which was sustained at 4 years.[346] Unclear long-term side effects, cost, and lack of comparative studies with other therapies for osteoporosis limit the potential use of GH in osteoporosis.



• **Fig. 8.19** Computed tomography scan through the abdomen before (A) and after treatment with human growth hormone (GH) (hGH) (B) in a GH-deficient patient. (Courtesy B.A. Bengtsson.)

Human Immunodeficiency Virus Infection. GH is Food and Drug Administration (FDA) approved for administration to adult patients with human immunodeficiency virus (HIV)–associated cachexia and results in positive nitrogen balance, increased lean body mass, decreased body fat, and improved work output.[347] One large study using supraphysiologic GH doses of 4 mg/day reported impairment in glucose tolerance.[348] A study using a physiologic dosing to maintain IGF1 in the high-normal range reported beneficial body compositional changes of lesser magnitude, reduced triglycerides, and lowered diastolic blood pressure but impaired glucose tolerance.[349] Treatment with a GH-releasing factor analogue for 26 weeks improved visceral fat and lipid profiles.[350] However, long-term beneficial effects of GH on survival and quality of life in those with HIV infection have not yet been reported.

Sports. The public policy issues of GH abuse in competitive sports have received much attention. GH has been widely abused by athletes to enhance performance.[351] A systematic review concluded that claims that GH enhances physical performance are not supported by the scientific literature evaluating effects on aerobic capacity, strength, and power[352] and that more research is needed to conclusively determine the effects of GH on athletic performance. A double-blind, placebo-controlled study reported that GH enhances anaerobic sprint capacity but not aerobic capacity, strength, or power in recreational athletes.[353] The benefit to sprinting provides the first evidence justifying the prohibition of GH as a performance-enhancing drug.

Aging. Disease mongering of declining GH status is rampant and spawned by unsubstantiated claims that GH is an antiaging

	Baseline	1 yr	3 yr	5 yr	7 yr	10 yr

The GH sensitivity index was calculated as change in insulin-like growth factor 1 *(IGF1)* level *(nmol/L)* by dose of GH *(mg)*. Created using data from several studies. (From Birznieve V, Ho KKY. Growth and development: patching up a better pill for GH-deficient women. *Nat Rev Endo*. 2012;8:197–198.)

hormone.[354] The claims are based on observations that body composition changes that accompany the physical decline of the aging process superficially recapitulate the features of adults with organic GHD for which beneficial effects of GH replacement are established. A systematic review of literature published on randomized controlled trials in the healthy elderly indicates that GH supplementation is associated with small changes in body composition, no functional or cognitive benefit, but increased rates of

adverse events.[355] GH cannot be recommended as an antiaging therapy.[354]

GH Excess

GH secretion is stimulated by fasting and by inadequate nutrition. This arises from the removal of substrates such as glucose and fatty acids, and of insulin, all of which suppress GH secretion.[213] The liver, being the major source of circulating IGF1, plays an important role in modulating feedback control of GH secretion. Thus liver disease and systemic illness affecting hepatic function and nutritional intake cause reversible hypersecretion of GH.[356,357] GH secretion is enhanced in type1 diabetes and falls when glycemic control improves.[358] Oral estrogen therapy enhances GH secretion by reducing blood IGF1 levels.[219] Under these circumstances episodic GH secretion is amplified, retaining a diurnal profile associated with subnormal IGF1 concentrations. This stands in contrast to the hypersecretion in acromegaly where secretion is autonomous and associated with elevated IGF1 concentration.

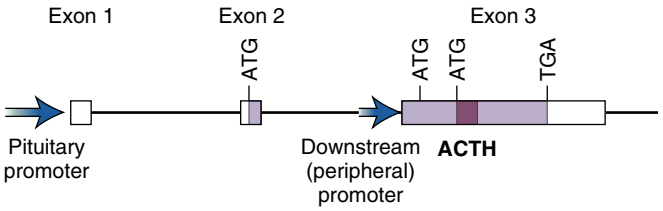
Adrenocorticotropic Hormone

Physiology

The hypothalamic-pituitary-adrenal (HPA) axis is the major system subserving stress and survival. Key components of the stress response are aimed at providing adequate amounts of glucocorticoids, which exert vital pleotrophic effects on energy supply, fuel metabolism, immunity, and cardiovascular function.

Corticotroph Cells

Corticotroph cells comprise about 20% of functional anterior pituitary cells and are the earliest detectable human fetal pituitary cell type, appearing by the eighth week of gestation. Corticotrophs are clustered mainly in the central median pituitary wedge. They are large, irregular cells, and their ultrastructural features include prominent neurosecretory granules (150–400 nm), endoplasmic reticulum, and Golgi bodies.[359] These cells produce the POMC gene products, including ACTH(1-39), β-lipotropin (βLPH), and endorphins. Because of the rich carbohydrate moiety of these molecules, the cells are strongly positive for periodic acid–Schiff (PAS). In the presence of excess glucocorticoid, characteristic hyaline deposits develop. In the normal human pituitary, POMC is expressed only in corticotroph cells. Most mammals possess an intermediate lobe comprising POMC-expressing melanotroph cells; however, this lobe is not developed in adult humans. Tpit, now referred to as Tbx19,[38] is a critical transcriptional factor for corticotroph cell differentiation during pituitary development and for transcription of the POMC gene.[38]



• **Fig. 8.24** Structure of POMC gene. Exon 1 encodes the RNA leader sequence, and exon 2 encodes the initiator methionine (ATG), the signal peptide, and several N-terminal residues of the precursor peptide, the remainder of which is encoded by exon 3. Corticotroph expression is determined by the upstream pituitary promoter *(longer arrowhead)*, whereas peripheral expression of the short POMC mRNA is determined by the downstream promoter *(shorter arrowhead)*. Translation of these shorter transcripts initiates from the initiator methionines *(ATG)* indicated in exon 3. The precursor peptide coding region is lightly shaded, and the ACTH coding region is darkly shaded. (From Adrian JL, Clark AJL, Swords FM. Molecular pathology of corticotroph function. In: Rappaport R, Amselem S, eds. *Hypothalamic-Pituitary Development*. Basel, Switzerland: Karger; 2001.)

Structure

The primary translation product of POMC is a 266–amino acid pre-prohormone molecule encoding corticotrophic, opioid, and melanotropic peptides. The peptide contains a leader sequence and multiple dibasic proteolytic cleavage sites for glycosylation, acetylation, and amidation. Products of this processing include ACTH(1-39) and βLPH, which in turn give rise to γLPH and β-endorphin, also containing metenkephalin. ACTH itself may also be cleaved to give rise to α-melanocyte–stimulating hormone (MSH)(1-13) and corticotropin-like intermediate lobe peptide (CLIP)(18-39).

The 8-kb human POMC gene, located on chromosome 2p23,[38,360] consists of three exons interspersed with two intervening introns (Fig. 8.24). The first exon encodes a leader sequence, the second encodes the signal initiation sequence and the amino-terminal (N-terminal) portion of the POMC peptide, and the third exon encodes most of the mature peptide sequences, including ACTH and βLPH.[361] The POMC gene is expressed in pituitary and nonpituitary tissues, including brain, skin, placenta, gonads, gastrointestinal tissues, liver, kidney, adrenal medulla, lung, and lymphocytes. The pattern of POMC processing differs between pituitary and extrapituitary issues and is determined by tissue-specific expression and activity of cleavage enzymes.

In corticotroph cells, a pituitary-selective promoter region for POMC generates a POMC messenger RNA (mRNA) transcript of approximately 1200 nucleotides. The 800 nucleotides of the coding region are translated into a pre-POMC molecule that includes a 26–amino acid signal peptide, which is rapidly cleaved. The parent POMC protein of 241 amino acids enters the secretory pathway for subsequent processing.

In extrapituitary tissues, POMC gene expression is regulated differently from that in the pituitary. An upstream promoter generates a longer transcript of approximately 1350 nucleotides. A downstream promoter generates short truncated transcripts of approximately 800 nucleotides arising from the 5′ end of exon 3. In the brain, however, neurons in the arcuate nucleus express

POMC mRNA that is identical to that of the pituitary.[362] In these neurons, POMC serves as a precursor to brain β-endorphin, αMSH, and other peptides, which have important functions on food intake and energy homeostasis.

Regulation

Pituitary POMC expression is primarily under the positive regulation of corticotropin-releasing factor (CRF) and negative regulation of glucocorticoids. However, multiple other signals regulate pituitary POMC gene expression: AVP, cytokines, catecholamines, and VIP activate while somatostatin and ANP inhibit.[363]

By contrast, POMC expression in the hypothalamus is stimulated by glucocorticoids, in turn enhancing the production of α-MSH, which mediates the suppression of appetite.[363] Leptin and insulin also enhance hypothalamic POMC gene expression.[364,365]

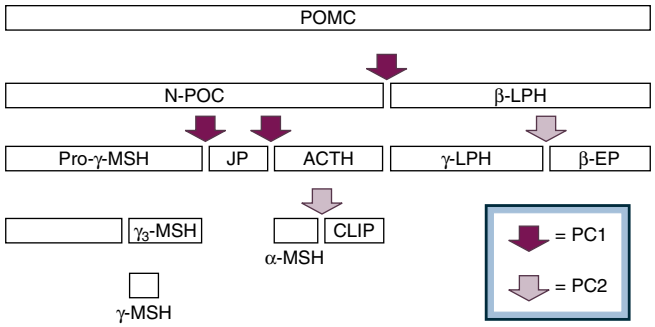
The corticotropin-releasing hormone (CRH) type 1 receptor is predominantly expressed on the corticotroph,[366] and receptor activation increases cAMP, protein kinase A, and CREB induction of CRH-binding protein (CRHBP) to the promoter, leading to POMC transcription.[367] CRH also activates an AP1 site within the first exon by a MAPK-mediated pathway. This receptor also appears critical for fear and anxiety responses, possibly by a related ligand, urocortin.[368] The type 2 CRH receptor predominantly regulates cardiovascular function.[369]

The corticotroph is regulated by inflammatory and nutritional signals that potentiate or inhibit CRF.[370] CRH action is potentiated by vasopressin and β-adrenergic catecholamines, enhancing POMC transcription and synthesis and increasing ACTH secretion.[363] Glucocorticoid inhibition of POMC transcription involves GR binding 5′-regulatory elements via two cooperative binding sites.[362] Normal pituitary corticotrophs express somatostatin receptors. Of the five subtypes, subtypes 2 and 5 are predominantly expressed. Somatostatin inhibits ACTH secretion, but the sensitivity is strongly regulated by glucocorticoids, which nullify the inhibition via downregulating somatostatin receptor expression.[371] Dopamine receptors have not been characterized in normal human corticotrophs, although they are highly expressed in the intermediate lobe of the rat pituitary.

POMC Processing

Several post-translational POMC modification steps are required for ultimate polypeptide hormone secretion (Fig. 8.25). First, the N-terminal signal sequence is removed, followed by glycosylation via an *O*-linkage to Thr45 and *N*-linkage to Asn65.[372] Serine-phosphorylation then occurs within the Golgi apparatus. After being transported to secretory vesicles, the constituent peptides are cleaved at dibasic amino acid residues, and ACTH-related peptides are stored in dense secretory granules for ultimate regulated release. Some POMC products also undergo carboxy-terminal (C-terminal) amidation mediated by peptidylglycine-amidating mono-oxygenase (PAM), peptidylhydroxyglycine-amidating lyase (PAL),[373] and N-terminal acetylation.

POMC proteolytic processing occurs at Lys-Arg or Arg-Arg residues by enzymes called prohormone convertases (PCs), mediated by either or two called PC1 or PC2. They are part of a superfamily of subtilisin/kexin proteinases. Tissue distribution of the two PCs are distinct and determine the function of the cleaved peptides at the tissue level. PC1 is most abundant in the anterior pituitary and in the hypothalamus. PC2 is present in the neurointermediate lobe, hypothalamus, various brain regions, skin, and pancreatic islets but is absent in the pituitary.



• **Fig. 8.25** Processing and cleavage of pro-opiomelanocortin (POMC). The mature POMC precursor peptide is sequentially cleaved by prohormone convertase 1 (PC1) in the anterior pituitary corticotroph. In the neurointermediate lobe and other cell types, cleavage by PC2 allows release of βMSH or β-endorphin, or both. Carboxypeptidase H *(not shown)* removes residual basic amino acids at cleavage sites. *ACTH,* adrenocorticotropic hormone; *CLIP,* corticotropin-like intermediate lobe peptide; *EP,* endorphin; *JP,* joining peptide; *LPH,* lipotropin; *MSH,* melanocyte-stimulating hormone; *N-POC,* N-terminal pro-POMC fragment. (From Clark AJL, Swords FM. Molecular pathology of corticotroph function. In: Rappaport R, Amselem S, eds. *Hypothalamic-Pituitary Development.* Basel, Switzerland: Karger; 2001.)

In corticotrophs, PC1 expression results in cleavage limited to four sites, with ACTH and ß-lipotrophin being major end products (see Fig. 8.25). In the hypothalamus and CNS, both PC1 and PC2 allow coordinated proteolysis, resulting in the generation of αMSH, CLIP, γLPH, and ß-endorphin. Heterozygous mutations of the PC1 gene are associated with childhood obesity, adrenal insufficiency, hyperproinsulinemia, and postprandial hypoglycemia[374] with elevated levels of plasma ACTH precursors.

Extrapituitary and CNS Expression of POMC

POMC is also expressed in the gonads, lung, skin, gastrointestinal and adrenal medullary neuroendocrine cells, and white blood cells. The biology of extrapituitary and extra-CNS POMC is poorly understood. There is little evidence that these tissues contain enzymes required for the production and secretion of the processed peptides.

Melanocortin Receptors

The major secreted POMC products from the pituitary are ACTH, ßLPH, and ß-endorphin. ACTH-derived and POMC-derived peptides bind to specific melanocortin receptors (MCR). MCRs are members of the rhodopsin-like receptors, a branch of the seven transmembrane-spanning domain G protein–coupled receptor (GPCR) superfamily. There are five MCRs, each showing different tissue distribution. All MCRs except for MC2R, the ACTH receptor, bind melanocortin peptides containing the conserved heptapeptide core MEHFRWG, found in αMSH, while the ACTH receptor further requires a peptide motif C-terminal to the 13 amino acids found in αMSH. Each MCR mediates diverse physiologic responses to αMSH, or ACTH, in the case of MC2R.[375] The distribution of MCR types is shown in Table 8.9.

The MC1Rs are found primarily in melanocytes that regulate pigmentation of skin and hair follicles. ACTH, βLPH, and γLPH produced from the corticotroph share a common heptapeptide sequence (Met-Glu-His-Phe-Arg-Trp-Gly) required to

TABLE 8.9 Tissue Distribution of Melanocortin Receptor (MCR) Types

MC Receptor Types	Tissue
MCR1	Skin, hair follicles
MCR2	Adrenal cortex
MCR3	Hypothalamus, limbic system
MCR4	Hypothalamus, various brain areas,[a] intestines
MCR5	Exocrine glands, skeletal muscle, adrenal cortex

[a]Cortex, thalamus, brainstem, and spinal cord.

activate MC1R. These peptides are responsible for inducing skin pigmentation in Addison disease because the other melanostimulating peptides, αMSH and βMSH, are not produced in the pituitary. Some MC1R variations show impaired signaling pathways strongly associated with red hair color, fair skin, and poor tanning ability.[376] POMC is also expressed in skin melanocytes, the expression of which is simulated by ultraviolet light, increasing local α-MSH and ß-endorphin production in parallel with PC1 and PC2 expression. ß-endorphin production alleviates pain and is thought to explain UV-seeking addictive behavior.[377]

MC3R and MCR4 are expressed almost exclusively in the CNS, especially the hypothalamus where they exert pivotal roles in satiety and energy homeostasis. Genetic and pharmacologic abrogation of the central melanocortin system causes profound obesity. POMC-deficient mice and humans are hyperphagic; MC4Rs are present in the L cells of the gut where they stimulate the production of anorexigenic peptides. The role of pituitary-secreted POMC peptides on gut MC4Rs is unknown.[378] MC5Rs play a major role in the regulation of exocrine gland function, especially of the sebaceous glands.[379] Recent findings provide evidence that MC5Rs in skeletal muscle enhance glucose uptake by αMSH independent of insulin.[380]

Adrenal Action

ACTH is a polypeptide of 39 amino acids with a molecular weight of 4.5 kDa. It is the only POMC-derived peptide with adrenocorticotrophic function, and it is the ligand of the MC2R. The function of MCR2 is dependent on a protein, melanocortin 2 receptor assessor protein (MRAP) required to traffic the receptor to the cell surface.[381] MRAP mutations cause familial glucocorticoid deficiency. MC2R activation results in production of adrenal glucocorticoids, androgenic steroids, and to a lesser extent, mineralocorticoids. The highly conserved 12 N-terminal amino acid residues are critical for adrenal gland steroid synthesis. N-terminal peptide POMC(1-28) exerts an independent mitogenic and growth-sustaining effect on the adrenal gland.[382]

ACTH signals via adenyl cyclase to regulate P450 enzyme transcription of cortisol, aldosterone, 17-hydroxyprogesterone, and to a lesser extent, adrenal androgens.[383] ACTH stimulates mitochondrial cholesterol transport and regulates the rate-limiting, side-chain cleavage of cholesterol to pregnenolone.[384] Adrenal cortisol response to ACTH is sensitive to the background ambient ACTH milieu. In states of chronic ACTH deficiency, adrenal reserve is compromised, although during ongoing ACTH hypersecretion the gland is primed such that a given ACTH bolus elicits a higher cortisol response. Both basal and stimulated (e.g., by CRH) ACTH secretion is blunted by glucocorticoids.

ACTH Secretion. The complex control of ACTH secretion reflects the integrated neuroendocrine control of the stress response. Similar to other anterior pituitary hormones, ACTH regulation is subserved by at least three tiers of control (see Fig. 8.3). First, the brain and hypothalamus release regulatory molecules (including CRH, vasopressin, and dopamine) that traverse the portal system and directly regulate corticotrophic function. Second, intrapituitary cytokines and growth factors act locally to regulate ACTH, either in concert with hypothalamic factors or independently. These paracrine controls often overlap and induce sensitive intracellular molecules that limit the ACTH response, preventing chronic ACTH hypersecretion. Third, glucocorticoids maintain regulatory feedback control of corticotroph secretion by rapidly inhibiting hypothalamic CRH and pituitary ACTH secretion. In a short feedback loop, pituitary ACTH inhibits hypothalamic CRH, and in an ultrashort loop, it may also suppress the corticotroph itself.

Stress Response

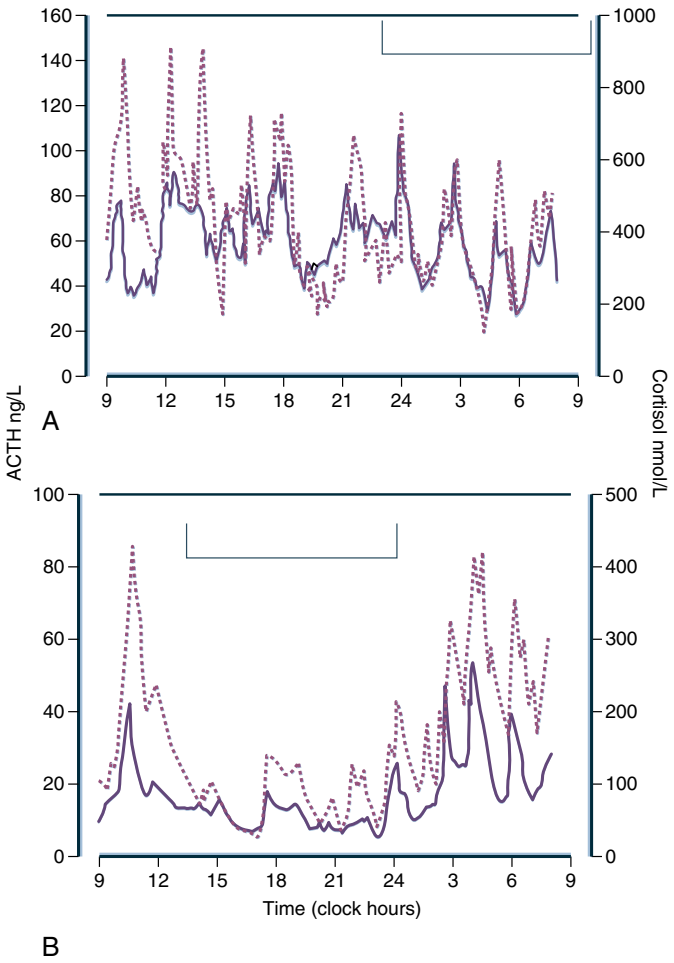
The HPA axes respond to a range of stressors, including pain, infection, inflammation, hemorrhage, hypovolemia, trauma, psychologic stress, hypoglycemia, and critical illness. The adaptation to stress involves vasovagal and catecholamine activation, cytokine secretion, and action. A tightly controlled immunoneuroendocrine interface regulates the ACTH response to peripheral stressors, which include pain, infection, inflammation, hemorrhage, hypovolemia, trauma, psychologic stress, and hypoglycemia. These signals vary in their ability to generate ACTH secretion and to sensitize the glucocorticoid response to ACTH. In addition to CRH, proinflammatory cytokines potently induce POMC transcription and ACTH secretion.[363] Sensitive intracellular signals within the corticotroph also serve to override the ACTH response to stress, thus preventing persistent and chronic hypercortisolemia.

Cytokines such as IL6 and leukemia inhibitory factor (LIF) activate the HPA axis and enhance glucocorticoid production, protecting the organism against lethality by constraining the inflammatory response.[370] Thus mice with inactivated CRH or LIF genes mount an inadequate neuroendocrine response to stress, inflammation, or endotoxins. During stress, glucocorticoid inhibition of ACTH is also prevented by nuclear factor κB activation, which interferes with pituitary glucocorticoid receptor function, thus further exaggerating enhanced ACTH secretion.[385]

Hypoglycemia evokes acute release of ACTH secretion. During the ITT, ACTH levels increase fivefold to sixfold, peaking by about 45 minutes, which is followed by peak cortisol at 60 to 90 minutes. Acute nutrient deprivation activates the secretion of ACTH. Exercise is a physiologic stimulus of ACTH release. Exercising to 90% of maximum oxygen capacity causes a significant elevation of ACTH, similar to levels observed during surgery or hypoglycemia.[386,387]

Circadian Periodicity

ACTH is secreted with both circadian periodicity and ultradian pulsatility under the control of the suprachiasmatic nucleus. The secretion of cortisol is tightly linked to and follows that of cortisol by 5 to 10 minutes (Fig. 8.26).[388] β-endorphin, coreleased with ACTH, also displays pulsatile, circadian, and ultradian rhythmicity with a close temporal coupling to cortisol.[389] The circadian pattern of ACTH secretion typically begins at about 4



• **Fig. 8.26** Plasma concentrations of ACTH *(dotted line)* and cortisol *(continuous line)* in a patient with Cushing disease (A) and a normal subject (B), showing the concordance between episodic ACTH and cortisol concentrations in blood. The ultradian pattern of ACTH and cortisol present in the normal subject is lost in the patient with Cushing disease. (Redrawn from Roelfsema F, Pincus SM, Veldhuis JD. Patients with Cushing's disease secrete adrenocorticotropin and cortisol jointly more asynchronously than healthy subjects. *J Clin Endocrinol Metab.* 1998;83:688–692.)

AM, peaking before 7 AM, with both ACTH and adrenal steroid levels reaching their nadir between 11 PM and 3 AM. Within this overall 24-hour diurnal cycle, periodic ACTH secretory bursts occur at a frequency of 40 pulses per 24 hours; amplitude rather than frequency modulation contributes to diurnal changes in ACTH profile.[390] ACTH circadian rhythm is entrained by visual cues, and the light-dark cycle is centrally controlled by CRH and other factors[391] and is lost in Cushing disease (see Fig. 8.26).[388]

The HPA axis is a critical component of a circadian system regulating substrate metabolism, immunity, cognition, and stress adaptation through the actions of glucocorticoids. This 24-hour rhythm partly reflects the activity of a master circadian pacemaker located in the suprachiasmatic nucleus, that is regulated by an oscillatory system governed by clock genes cued by light-dark and feeding cycles. The same molecular circuitry of core clock elements is present in multiple, if not all, peripheral tissues, including the heart, kidney, muscle, liver, pancreas, blood, fat, and adrenal gland.[392] The central clock also entrains peripheral clocks via neural and hormonal systems, the latter through the HPA axis. The physiologic effects of glucocorticoids are optimized when the central signal that controls the rhythm of glucocorticoid release and the peripheral rhythms in tissues expressing glucocorticoid receptors are aligned. There is strong evidence that a regular 24-hour temporal organization underpins good health. The early-morning peak subserves the metabolic and CNS preparation of physical activity and stressors at the start with declining levels favoring the optimization of insulin sensitivity for the rest of the day. The disruption of the circadian system brought by the lifestyles and social demands of modern civilization such as shift work and jet lag brings adverse health outcomes.[392] The 24-hour profile of cortisol concentrations does not adapt rapidly to acute shifts in light-dark, activity-rest, and/or feeding cycles. Under these circumstances the asynchrony between meal times and ultradian rhythm of cortisol secretion impairs substrate metabolism and worsens glucose tolerance (Fig. 8.27).[393] There is mounting evidence that the standard regimen of glucocorticoid replacement therapy does not restore physical, metabolic, and psychologic well-being among patients with adrenal insufficiency, from the failure to replicate the 24-hour rhythm of cortisol concentration.[394]

Measurement of ACTH

Measurements of plasma ACTH are extremely useful in the diagnosis of both Cushing syndrome and adrenal insufficiency. ACTH assays have evolved considerably since the first radioimmunoassay. Current commercially available two-site immunometric assays display high specificity and analytic sensitivity of less than 0.5 ng/L.[395] However, significant variability in precision and performance exists between commercial assays.[396] ACTH and other POMC-derived peptides such as αMSH, βLPH, or β-endorphin can also be measured with precision with current assays. Awareness of the assay peptide specificity may be especially critical when evaluating ectopic POMC products secreted by lung tumors. Ideally, nonstressed resting subjects should have venous blood withdrawn between 6 AM and 9 AM. As ACTH is relatively unstable at room temperature and has a propensity to adhere to glass, plasma samples should immediately be separated in iced siliconized glass tubes containing ethylenediaminetetra-acetic acid (EDTA) and stored below –20°C for transport. Morning (8 AM) plasma ACTH levels range from 8 to 25 ng/L. Episodic secretion and short plasma half-life result in wide and rapid fluctuation of plasma measurements. Cortisol values at 4 PM are about half those of morning levels, and 11 PM levels are usually less than 5 μg/dL. Plasma ACTH levels fluctuate broadly within the same individual and are highly sensitive to stress, time of collection, and gender. Pregnant females have higher ambient ACTH levels, possibly because of placental CRH secretion.[397]

ACTH Deficiency

Causes

Congenital ACTH deficiency may occur as an isolated pituitary defect or as a component of a wider spectrum of multiple pituitary hormone deficiencies. A mutation of *TBX19*, encoding Tpit, a transcription factor involved in corticotroph differentiation, is a cause of isolated ACTH deficiency (see Tables 8.1 and 8.2).[38] Mutations of transcription factors involved in early stages of pituitary cell differentiation or midline brain development may also give rise to ACTH deficiency as a component of multiple hormone deficiencies. These genes with mutations include *LHX4* and *HESX1* (see Table 8.2). Secondary causes include pituitary tumors, sellar mass lesions, trauma, irradiation, and lymphocytic

hypophysitis, which may be associated with other autoimmune manifestations (see Table 8.5).

Clinical Features

The manifestations of ACTH deficiency are clinically indistinguishable from glucocorticoid deficiency of any cause. The clinical features are dependent on severity, the time of onset, and clinical context. In the newborn, ACTH deficiency may present as hypoglycemia and failure to thrive. In the adult, there is slowly progressive weight and appetite loss, anorexia, and generalized fatigue, mimicking a wasting syndrome. As adrenal mineralocorticoid secretion is largely unimpaired, salt wasting, volume contraction, and hyperkalemia, commonly encountered features in Addison disease, are not manifest. Furthermore, hyperpigmentation, usually associated with exuberant ACTH-related peptide secretion in the face of adrenal damage, does not occur.

Evaluation

Diagnostic evaluation of adrenal insufficiency requires concurrent measurement of cortisol and ACTH levels. Morning serum cortisol levels lower than 3 µg/dL suggest ACTH deficiency, but basal morning cortisol levels higher than 18 µg/dL usually indicate normal ACTH reserve. Provocative tests are required to diagnose ACTH deficiency. As cortisol is highly bound to cortisol-binding globulin (CBG), the level of CBG may confound interpretation of cortisol values. Cirrhosis and hyperthyroidism lower CBG concentrations, whereas estrogens elevate them.

Dynamic Testing for ACTH Deficiency

Hypothalamic Testing. Insulin hypoglycemia is a potent endogenous stressor that evokes ACTH secretion as well as GH release. Insulin (0.1–0.15 U/kg) is injected intravenously after an overnight fast to achieve symptomatic hypoglycemia and a blood glucose level of less than 40 mg/dL. This test must be performed under supervision. Normal HPA response to this stressor evokes cortisol levels higher than 20 µg/dL. As hypoglycemia acts centrally, a normal response implies integrity of all three tiers of HPA axis control.[398] Venous samples are collected at –15, 0, 15, 30, 45, 60, 90, and 120 minutes for measurement of glucose, ACTH, and cortisol levels. After the test, oral glucose should be administered *to ensure euglycemia.* Both intraindividual variations in blood glucose levels attained by a given dose of insulin and fluctuations in central sensitivity to glucose and activation of catecholamines may lead to difficulties in reproducibility. Contraindications are similar to those for the diagnosis of GH deficiency described earlier. If pronounced adrenal insufficiency is likely, insulin injection may provoke an adrenal crisis as a result of inadequate adrenal reserve, and hydrocortisone (100 mg) should be available for urgent IV use, if required, and oral glucocorticoid replacement therapy should be initiated pending confirmation of the diagnosis.

The metyrapone test is an alternative to the ITT for hypothalamic evaluation of the HPA axis. In blocking cortisol synthesis by inhibiting adrenal 11β-hydroxylase, it releases the HPA axis from negative feedback by cortisol, normally resulting in an ACTH surge and elevated levels of 11-deoxycortisol. A single oral dose (2–3 g) is given at midnight and serum levels of ACTH, 11-deoxycortisol, and cortisol are measured at 8 AM the following day. The test is only valid when cortisol levels fall to less than 10 µg/dL. In normal subjects, peak ACTH values higher than 200 ng/L are achieved. Side effects include nausea, gastrointestinal upset, and insomnia.[399] False-positive results

may be obtained with phenytoin, which prevents adequate enzymatic blockade. This test should be performed under observation in a hospital because acute adrenal insufficiency may ensue.

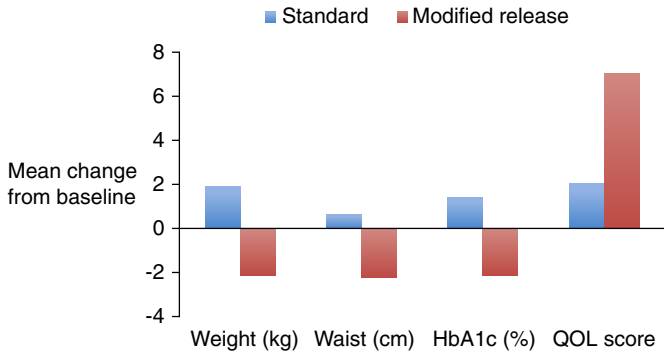
Pituitary Stimulation. Pituitary ACTH secretion is evoked by injecting either CRH or AVP. Ovine or human CRH (100 µg or 1 µg/kg) is administered intravenously, and cortisol and ACTH are measured at –5, –1, 0, 15, 30, 60, 90, and 120 minutes. Normally, maximal ACTH responses (twofold to fourfold above baseline) are evoked at 30 minutes,[400] and cortisol levels peak (>20 µg/dL) at 60 minutes or increase more than 10 µg/dL above baseline. Although CRH readily induces ACTH secretion and may demonstrate corticotrophic ACTH deficiency or ACTH excess, the wide variation of responses observed has limited the utility of this test. A useful application of the CRH test is in making the diagnosis of Cushing disease (see Chapter 15).

Adrenal Stimulation. The acute response of the adrenal gland to a bolus ACTH injection reflects ambient ACTH concentrations to which the gland has been exposed. Thus the cortisol response to an acute ACTH injection will be blunted if the subject has experienced chronic pituitary ACTH hyposecretion, with resultant adrenal atrophy and diminished cortisol reserve.[401] This time-honored test involves intramuscular or intravenous injection of 250 µg ACTH(1-24) (Cortrosyn or Synacthen) and cortisol levels measured before injection and then 30 minutes and 60 minutes after injection. Cortisol values greater than 20 µg/dL reflect a normal adrenal reserve response. The utility of this test in diagnosing diminished pituitary ACTH reserve has been challenged as a 250-µg dose may evoke a "normal" cortisol response in hypopituitary subjects. An unacceptably high false-negative rate (~65%) has been determined in a large series,[402] although peak cortisol levels at 30 minutes correlate well with peak responses to ITT.[403,404] Low-dose stimulation with 1 µg Synacthen evokes maximal serum cortisol levels at 30 minutes, and these correlate well with values observed after insulin or high-dose ACTH administration.[403] A cutoff value of more than 500 nmol/L provides almost 100% sensitivity and a specificity of 80% to 100%.[405] Failure to respond to low-dose ACTH should be corroborated by a standard dose of insulin or ACTH stimulation.

Adrenal Steroid Replacement

Hydrocortisone is widely used for glucocorticoid replacement. The normal secretory rate of cortisol is 15 to 20 mg/day, which is the recommended total daily dose. As plasma circulating half-life of cortisol is less than 2 hours, three times daily dosing of a total daily requirement of 10 to 20 mg (5–10 mg in the morning, 2.5–5 mg at noon, and 2.5–5 mg in the evening) is recommended.[406] Other synthetic glucocorticoids, including prednisolone (2.5–5 mg/day) and dexamethasone (0.25–0.5 mg/day), are suitable alternatives. Having longer half-lives, they can be administered once daily, but they are difficult to monitor biochemically. There is no consensus for monitoring treatment. Central diabetes insipidus may be unmasked after initial glucocorticoid replacement. Mineralocorticoid replacement is not required for treating secondary hypoadrenalism. Adrenal androgen replacement with dehydroepiandrosterone (DHEA) at doses of 25 mg/day may improve the sense of well-being, relieve fatigue, and improve sexual function in patients with primary and secondary adrenal insufficiency.[407,408]

However, conventional regimens do not recapitulate the physiologic pattern of cortisol release, and this may explain the high prevalence of poor quality of life and osteoporosis in these patients.[409] Two modified release formulations aimed at mimicking diurnal profiles have been evaluated in clinical trials.[410,411] One of these, a dual-release hydrocortisone tablet (DuoCort) containing an immediate-release coating and an extended-release core, was approved by the European Medicines Agency for once-daily therapy of adrenal insufficiency in 2012. In a 12-week randomized crossover study of 64 patients with adrenal insufficiency, DuoCort exhibited improved weight, glucose, and blood pressure control compared to conventional thrice-daily hydrocortisone dosing at the same total daily dose.[410] In a 26-week randomized controlled trial of 89 patients with adrenal insufficiency, significant benefits in weight, metabolic, immune, and quality-of-life measures were observed in the group randomized to once-daily, dual-release hydrocortisone (DuoCort) treatment compared to the group who continued with the conventional regimen of same daily dose administered thrice daily (Fig. 8.28).[394] Thus modified-release preparations mimicking cortisol diurnal profiles are a significant advance in the management of glucocorticoid insufficiency.



• **Fig. 8.28** Changes in body weight, waist circumference, HbA1c, and quality of life (QOL) in patients with hypoadrenalism randomized to standard treatment or modified-release hydrocortisone formulation for 26 weeks. Differences between treatments are all statistically significant ($p < 0.05$). (Data from Isidori AM, Venneri MA, Graziadio C, et al. Effect of once-daily, modified-release hydrocortisone versus standard glucocorticoid therapy on metabolism and innate immunity in patients with adrenal insufficiency [DREAM]: a single-blind, randomised controlled trial. *Lancet Diabetes Endocrinol.* 2018;6:173–185.)

ACTH Excess

Causes

Ectopic ACTH production occurs in tumors capable of generating high amounts of the pituitary-like 1072-nucleotide mRNA. However, the clinical manifestation depends on whether PC enzymes are appropriately expressed. Small cell lung cancers preferentially release intact POMC, but carcinoid tumors tend to process the precursor, releasing ACTH and smaller peptides.[412] Extrapituitary neuroendocrine tumors associated with ectopic ACTH secretion do not process the prohormone efficiently because of a general defect in PC expression. As ACTH is synthesized in nontumorous neuroendocrine cells, ectopic tumor hormone production may in fact reflect inappropriate ACTH processing. These patients also exhibit a higher ratio of circulating ACTH precursors, as well as smaller peptides, including CLIP. Where sufficient ACTH or ACTH precursors that are biologically active are secreted, these tumors can cause florid morbidity from excessive cortisol production.

Clinical Features

ACTH-induced adrenal hyperfunction causes a syndrome of hypercortisolism and of androgen excess in women. Manifestations arise from appetite stimulation (weight gain), altered fat distribution (moon facies, buffalo hump, central obesity), catabolism (skin thinning, muscle wasting), mood disturbance (depression, anxiety), sodium retention (hypertension), and androgen excess (menstrual irregularity, hirsutism, acne, oily skin). The evaluation and management of patients with Cushing disease is fully described in Chapter 15.

Gonadotropins

Physiology

The gonadotropins, LH and FSH, are produced by pituitary gonadotrophs. These hormones play an essential role in the reproductive process. LH and FSH act on the ovaries and testes to direct gametogenesis and sex steroid hormone synthesis. Reproduction is a tightly regulated function, influenced by genetic, nutritional, environmental, and socioeconomic factors. Befitting their important roles, the synthesis and secretion of LH and FSH are under complex regulation by hypothalamic input (e.g., GnRH), by positive and negative feedback from gonadal sex steroid and peptide hormones, and by paracrine modulation from local factors produced within the pituitary gland itself (e.g., activins, inhibins, follistatin).[34]

Gonadotroph Cells

Gonadotroph cells comprise about 10% to 15% of the functional anterior pituitary cells. They are a heterogeneous cell population, with large round cell bodies with prominent rough endoplasmic reticulum and Golgi apparatus. Immunocytochemical studies have demonstrated the presence of both bihormonal and monohormonal groups of gonadotrophs. Cells with LH secretory granules often accumulate peripherally, and their Golgi structures may be less prominent. Gonadotrophs are characterized also by GnRH receptor expression and by SF1 and DAX1 nuclear receptors, which contribute to gonadotroph-specific gene expression.

Gonadotropin Structure

FSH and LH function to regulate gonadal steroid hormone biosynthesis and initiate and maintain germ cell development in concert with peripheral hormones and paracrine soluble factors. The four heterodimeric glycoprotein hormones (LH, FSH, TSH, and human chorionic gonadotropin [hCG]) share structural homology, having evolved from a common ancestral gene. Although both the homologous LH and FSH molecules are cosecreted by gonadotrophs, their regulatory mechanisms are not uniformly concordant. The αGSU, LHβ, and FSHβ subunits are encoded by different genes, located on chromosomes 6, 11, and 19, respectively (Figs. 8.29 and 8.30; see also Fig. 8.2).[413] The heterodimeric structure of the common—and unique—subunits of LH and FSH is essential for biologic activity. Disulfide linkages within each subunit result in a tertiary structure that enables and maintains noncovalent heterodimerization, which also determines the ultrastructure of the mature folded molecule to facilitate specific ligand-receptor interaction.[414] Glycosylation of the subunits occurs by the transfer of oligosaccharide complexes to asparagine residues.[415] Post-translational processing of carbohydrate side chains is critical for hormone signaling, distinct for LH and FSH, and may even vary physiologically to influence

biologic activity and metabolic clearance rates.[415,416] The human LHβ/CGβ gene cluster comprises seven genes, arising from gene duplication, of which one gene encodes LHβ, one encodes CGβ, and the remainder are pseudogenes. Unlike LH, hCG is present only in primate and equine species and is expressed primarily in the placenta. The LHβ and CGβ genes have different promoters and transcriptional start sites, accounting for their different tissue distribution patterns of expression.[417] LHβ includes a 24–amino acid signal peptide followed by a 121–amino acid mature protein. In contrast, the mature hCGβ protein is 145 amino acids in length and does not include a leader peptide, but it contains a 24–amino acid C-terminal extension important for the longer biologic half-life of hCG.[413,418] The FSHβ gene, on chromosome 11, is organized similarly to the other glycoprotein hormone β genes, encoding a mature peptide of 111 amino acids, with two glycosylation sites, and like LHβ, it is expressed only in gonadotrophs.

Regulation

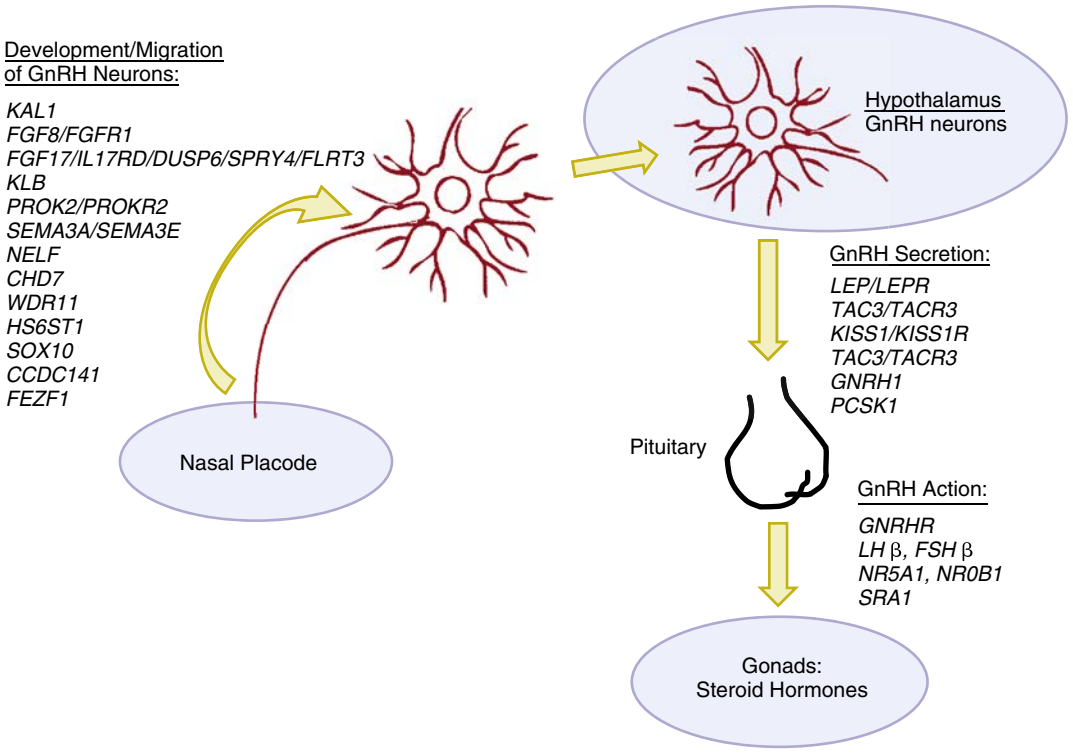
LH and FSH secretion patterns reflect the integration of sensitive complex hypothalamic signals (mediated primarily via GnRH), paracrine intrapituitary factors (primarily activin and follistatin), and peripheral feedback (both gonadal sex steroids and gonadal peptide hormones) (Fig. 8.31).

Gonadotropin-Releasing Hormone

Hypothalamic control of gonadotropin secretion occurs primarily through actions of GnRH. Hypothalamic GnRH neurons represent the pivotal integrators of peripheral signals in regulation of the pituitary-gonadal axis. Insights into the mechanisms that regulate GnRH secretion have been provided by the identification and study of genetic abnormalities in patients with pubertal disorders or infertility and by the use of animal models. Molecular defects that manifest as GnRH deficiency, or hypogonadotropic hypogonadism (HH), can be classified as defects in GnRH neuronal development, defects in control of GnRH secretion, and defects in GnRH action (Fig. 8.32; see Table 8.10). Conversely, genetic defects in *MKRN3* and *DLK1* were found to cause premature reactivation of GnRH secretion and central precocious puberty. *MKRN3* encodes a putative ubiquitin ligase and appears to act as a repressor or inhibitor of GnRH secretion during childhood.[419] *DLK1,* also known as preadipocyte factor 1, encodes a transmembrane noncanonical ligand in the Delta-Notch signaling pathway.[420]

Many neurotransmitters directly or indirectly modulate GnRH secretion, including norepinephrine, dopamine, serotonin, γ-aminobutyric acid (GABA), glutamate, opiates, NPY, and galanin, among others. Glutamate and norepinephrine provide stimulatory drive, whereas GABA and opioid peptides are inhibitory. Kisspeptins, encoded by the *KISS1* gene, and their cognate receptor, KISS1R, were identified as key GnRH secretagogues.[421,422] Administration of kisspeptin to normal men increases FSH, LH, and testosterone concentrations, and in normal women the peptide stimulates gonadotropin release most potently during the preovulatory surge.[423] Neurokinin B (NKB), a member of the substance P–related tachykinin family, is coexpressed with kisspeptin in the hypothalamus and appears to act through control of kisspeptin secretion to modulate GnRH release.[424,425] Substance P, another tachykinin family member, has also been shown to modulate GnRH secretion. Leptin, a product of peripheral adipose tissue, is a positive regulator of the hypothalamic-pituitary-gonadal (HPG) axis. This adipokine enables a pivotal link between body fat and reproduction, signaling energy availability centrally.[426] Nutritional, metabolic, stress, and circadian inputs all appear to act through these peptides to modulate GnRH, gonadotropin secretion, and activity of the HPG axis.[419]

The hallmark of hypothalamic GnRH secretion is the pulsatile rather than continuous release into the hypophyseal portal circulation, resulting in episodic stimulation of the gonadotroph.[427] In patients with GnRH deficiency, restoration of gonadotropin secretion can be achieved after exogenous pulsatile GnRH treatment, whereas continuous GnRH exposure suppresses gonadotropin secretion.[428] GnRH signaling initiates with recognition by its cognate receptor, GnRHR, which belongs to the rhodopsin G protein–coupled receptor family. GnRHR activation increases calcium mobilization and stimulates influx of extracellular calcium to induce pituitary LH and FSH secretion.[429] The pattern of GnRH signaling is important in determining the quantity and quality of gonadotropins secreted.[430,431] The amplitude, frequency, and contour of GnRH pulses can all vary, and each of these characteristics can influence gonadotroph responses, providing a mechanism for the differential synthesis and secretion of the two gonadotropins,



• **Fig. 8.32** Genetic and molecular basis of gonadotropin-releasing hormone (GnRH) neuronal development and migration, GnRH secretion, and GnRH action. (From Bianco SD, Kaiser UB. The genetic and molecular basis of idiopathic hypogonadotrophic hypogonadism. *Nat Rev Endocrinol.* 2009;5:569–576.)

LH and FSH. These alterations in GnRH pulse pattern are one mechanism by which two functionally distinct gonadotropins can be differentially regulated by a single hypothalamic-releasing hormone.

Inhibins and Activins

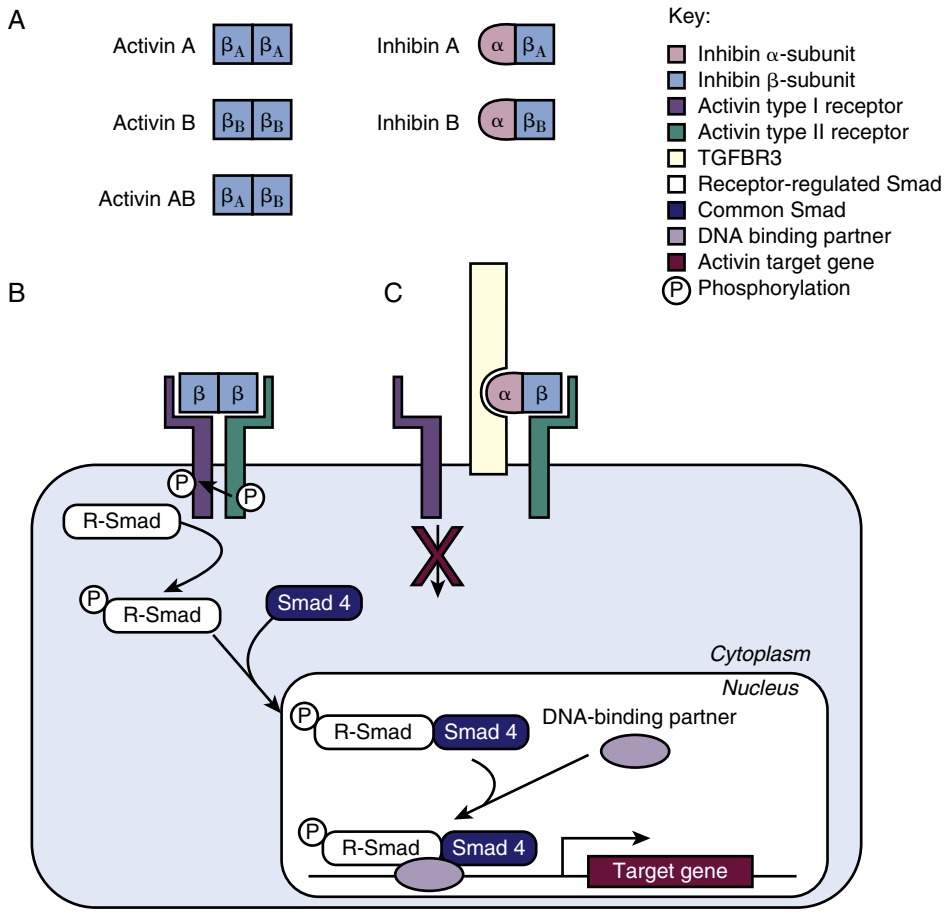
The hypothesis that a peptide of gonadal origin selectively regulates FSH secretion dates back to at least 1932.[432] It took over 50 years to isolate and characterize the structure of inhibin and its related peptides.[433] Inhibin-related peptides, members of the transforming growth factor-β family, are dimeric proteins covalently linked by a disulfide bridge and consisting of a common α-subunit and one of two highly homologous β-subunits, β_A or β_B (Fig. 8.33). In addition, the β-subunits can form dimers, called activins, to stimulate FSH synthesis and secretion.[434] A structurally unrelated, monomeric polypeptide, follistatin, was also identified, based on its ability to inhibit FSH.[434,435] These three peptides (inhibins, activins, and follistatin) are considered to be relatively selective for FSH in terms of their effects on gonadotropins and serve as an additional mechanism for the differential control of FSH and LH. Although inhibins act primarily as classic circulating endocrine hormones, originating in the gonads and acting on the pituitary to regulate FSH, activins play an important role as regulators of growth and differentiation in diverse tissues and are produced and act locally in the pituitary as autocrine/paracrine factors. In the human male, inhibin B is produced in the testes in response to FSH stimulation and circulates systemically to provide feedback inhibition of FSH. In women, inhibin A is secreted by dominant ovarian follicles and corpora lutea, contributing to the high circulating levels during the late follicular and luteal phases. Inhibin B is reciprocally elevated during the late luteal and early follicular phases of the menstrual cycle.

Activin receptors are heteromeric complexes comprising type I (ActRI) and type II (ActRII) serine-threonine kinase receptors. Activin binds to the type II receptors, thereby increasing association with the type I receptor and stimulating its phosphorylation, which in turn results in the activation by phosphorylation of intracellular signaling Smad proteins, resulting in translocation of the Smad complex to the nucleus, where it binds to gene regulatory elements and interacts with other transcription factors (such as FoxL2) to regulate gene transcription, thereby influencing cell fate and function.[34] Follistatin and inhibin act as extracellular modulators of activin through distinct mechanisms.[436] Follistatin, an activin-binding protein, inhibits activin action by interfering with activin binding to its receptor. Inhibins compete for binding to type II activin receptors, preventing recruitment of type I receptors and thereby blocking activin signaling. Additional extracellular and intracellular proteins and mechanisms also serve to modulate the local activin signal.

Sex Steroids

Gonadal steroid hormones include estrogens, progesterones, and androgens. Effects on gonadotropins occur both directly at the level of the gonadotroph and indirectly via effects at the hypothalamus that modulate GnRH secretion. Estrogen, androgen, and progesterone receptors have been identified in gonadotrophs, consistent with direct actions of these peripheral sex steroid hormones. Within the hypothalamus, these receptors have been identified in multiple neuronal cell types, suggesting that alterations in GnRH release largely occur indirectly through modulation of neuronal systems that impinge on GnRH neurons, particularly through kisspeptin neurons.[437,438]

In women, estrogens can exert dual feedback effects on gonadotropin secretion, depending on the reproductive state. The negative



• **Fig. 8.33** Activins and inhibins and their mechanism of action. (A) Inhibins and activins are dimeric proteins made up of two subunits. Inhibins are made up of an α-subunit linked to one of two β-subunits, whereas activins are made up by dimerization of two β-subunits. (B) Activin signaling pathway. Activins bind to specific sets of serine–threonine kinase type I and type II receptors on the cell surface. Upon ligand binding, the type II receptor phosphorylates and thereby activates the type I receptor, which in turn phosphorylates downstream signaling molecules, the receptor-regulated S-Smads (R-Smads). Once phosphorylated, the R-Smads associate with the common co-Smad (Smad 4) and translocate to the nucleus where, in combination with cell type–specific binding partners, they bind to the promoter sequences of target genes to regulate gene transcription and cellular function. (C) Inhibins bind to activin type II receptors and block the recruitment of type I receptors, thereby blocking R-Smad activation and activin signaling. The presence of TGFBR3, a TGFβ superfamily accessory receptor also known as betaglycan, enhances the binding of inhibins to type II receptors, thereby enhancing the antagonistic actions of inhibins. (From Stenvers KL, Findlay JK. Inhibins: from reproductive hormones to tumor suppressors. *Trends Endocrinol Metab.* 2010;21:174–180.)

feedback effects of estrogens are clearly demonstrated by the elevated LH and FSH levels that follow ovariectomy or menopause but reverse with estrogen replacement. Negative feedback effects of estrogens are observed at the level of α-subunit and at LHβ and FSHβ mRNA levels through effects on gene transcription in addition to effects on LH and FSH secretion, mediated in part directly at the level of the pituitary gland. Estrogen also has negative feedback effects at the levels of the hypothalamus, mediated in large part through effects on kisspeptin neurons.[439] On the other hand, during the late follicular phase of the menstrual cycle, the feedback effects of estrogens shift from negative to positive, triggering the midcycle ovulatory surge of LH and FSH secretion. Positive feedback effects of estrogen are mediated in large part through effects on sexually dimorphic kisspeptin neurons in the anteroventral periventricular region of the hypothalamus in female mice.[440,441] Estrogens may also elicit direct positive effects at the pituitary level.

The principal effect of progesterone is to decrease the frequency of gonadotropin pulses, mediated by effects on GnRH pulse frequency. During the luteal phase of the human menstrual cycle, when progesterone concentrations are the highest, LH pulse frequency is markedly slowed.

Testosterone and its aromatized derivative estradiol are the two steroid hormones that exert negative feedback effects on gonadotropin secretion in the male. The net in vivo effect of testosterone administration to normal men is inhibition of serum LH and FSH levels. The available evidence suggests that 5α-reduction of testosterone is not essential for the inhibitory effects of testosterone on LH. Administration of a potent 5α-reductase inhibitor, finasteride, to normal men did not result in elevated LH and FSH levels.[442] Much like the effects of estrogen, these inhibitory effects are felt to occur largely at the hypothalamic level, by kisspeptin neurons, mediated by both androgen and estrogen receptors (AR

and ERα). Mechanisms for testosterone feedback are complex, as testosterone also exerts a stimulatory effect on FSHβ mRNA levels.[443]

Secretion

In light of the episodic, pulsatile nature of LH and FSH secretion, there was a need to develop discrete pulse-detection algorithms. Santen and Bardin developed an algorithm that defined a peak as a 20% increase in the hormone concentration in a single sample over the preceding sample, which was subsequently modified to define the pulse based on a chosen multiple of the assay coefficient of variation. Because of its simplicity of use and apparent freedom from assumptions, this program is still widely used, although a number of refinements and alternative algorithms have also been developed. Application of deconvolution to pulse analysis made it possible to determine the instantaneous real-time secretory rates. The characteristic secretory episodes characterized for LH and FSH indicate daily production rates of 1000 IU and 200 IU, respectively, and a disappearance half-life of 90 minutes and 500 minutes for each respective β-subunit.[444,445] The longer circulating half-life of FSH makes the pulsatile secretory pattern of this gonadotropin less clear than that of LH, although differences in secretory pathways for FSH and LH also contribute.[446,446a]

Action

The primary targets of FSH and LH are the gonads, and thus targets and effects differ in the male and female (Fig. 8.34). The actions of FSH and LH in the male and female are presented briefly here but are discussed in greater detail in Chapters 17 and 19.

Female

FSH acts on FSH receptors in granulosa cells to facilitate follicular growth and estradiol biosynthesis (see Fig. 8.34).[447] The initiation of follicular growth can occur independently of gonadotropin stimulation, after which further maturation requires FSH. At these more advanced stages of development, follicles convert theca cell–derived androstenedione to estradiol (E_2) by the induction of aromatase activity in response to FSH.[448] FSH also controls granulosa cell production of inhibin during the follicular phase and induces LH receptor expression in granulosa cells of large preovulatory follicles. At the same time that FSH promotes the development of the dominant follicle, it also initiates the recruitment of the next generation of follicles that will enlarge during subsequent cycles.

LH, acting on LH receptors in ovarian theca cells, is a major regulator of ovarian steroid synthesis. LH stimulates estrogen production by promoting synthesis of androgen precursors in theca cells, which then diffuse into neighboring granulosa cells, where they are aromatized into estrogens under the control of FSH.[413] LH increases cholesterol availability for ovarian steroidogenesis by inducing the steroidogenic acute regulatory (StAR) protein,[449] which mediates cholesterol transfer from the outer to the inner membrane, where it becomes available for steroidogenesis. LH also enhances cytochrome P450–linked enzyme activity to synthesize pregnenolone and induces synthesis of 3β-hydroxysteroid dehydrogenase, 17α-hydroxylase, and 17,20-lyase. The midcycle LH surge stimulates resumption of oocyte meiosis and maturation in the preovulatory follicle, initiates the rupture of the ovulatory follicle and ovulation, and induces conversion of the follicle wall into the corpus luteum (luteinization).[447,448] LH stimulates the expression of progesterone receptors in the granulosa cells of the dominant follicle, which promotes luteinization. In addition, LH helps to sustain luteinization by stimulating progesterone synthesis.

Male

LH acts on LH receptors in Leydig cells to induce intratesticular testosterone synthesis, mediated by enhanced cAMP production. FSH in the male is involved in spermatogenesis (see Fig. 8.34), although the precise role in the spermatogenic process remains unclear.[450] FSH binds to FSH receptors on Sertoli cells and stimulates the production of inhibins, androgen-binding protein, androgen receptor, and other proteins. FSH mediates the maturation of spermatids into mature spermatozoa in concert with testosterone.[451]

Gonadotropin Measurements

Because of the high homology of the glycoprotein hormones, development of highly specific assays, especially those distinguishing free α-subunit from intact hormones, was necessary. Heterogeneity of circulating LH and FSH molecules, insufficient assay sensitivity to distinguish normal from low levels, and lack of rigorously pure reference preparations hampered assay development. Two-site–directed immunofluorometric and immunochemiluminescent LH and FSH assays have much improved sensitivity, are able to detect LH with a sensitivity of 0.1 mIU/mL, and have resolved prior challenges with cross-reactivity.[452] Differences in carbohydrate moieties result in isoelectric charge heterogeneity for LH, accounting for some observed disparities in biologic and immunoreactive LH ratios observed after GnRH agonist treatment, acute critical illness, or aging.

α-Subunit Assays

Both GnRH and TRH increase circulating levels of free α-subunit derived from either gonadotrophs or thyrotrophs, especially in patients with hypothyroidism, after castration, and during menopause. GnRH agonist treatment, TSH-secreting tumors, or nonfunctioning pituitary adenomas may result in discordant circulating ratios of free α-subunit from intact LH dimers.

GnRH Stimulation Test

A single bolus of GnRH (25–100 μg) dose-dependently evokes serum LH and FSH levels within 20 and 30 minutes. LH rises more abundantly than FSH, and peak values range from 8 to 34 mIU/mL. In contrast, patients with hypogonadotropic hypogonadism and no demonstrable hypothalamic-pituitary lesion have blunted LH responses and reversal of the LH:FSH ratio. The test, however, cannot adequately distinguish hypothalamic from pituitary lesions, and similar patterns are observed in patients with anorexia nervosa and hypothalamic amenorrhea. Repetitive GnRH pulses may in fact normalize responses, as would be expected from an intact hypothalamic-pituitary unit. GnRH responses may vary during the stages of puberty, reflecting altered pituitary sensitivity. This test is most frequently used in the assessment of pubertal status, for the diagnosis of hypogonadotropic hypogonadism or for evaluation of central precocious puberty.[453]

Clomiphene Stimulation Test

Clomiphene (100 mg), administered daily for up to 4 weeks, usually doubles LH levels, and FSH increases by about 50% over baseline. Because an abnormal or absent response does not distinguish hypothalamic from pituitary lesions, the utility of this test is limited.

Gonadotropin Deficiency

Causes

Gonadotropin deficiency may be congenital or acquired and may arise from hypothalamic or pituitary disorders. Congenital causes include gene mutations governing the processes of development and migration of GnRH neurons, the control of GnRH secretion, the development of the gonadotroph, or the regulation of LH and FSH secretion. Acquired HH may arise from functional or organic disorders. Functional causes are frequently encountered and include stress, malnutrition, chronic illness, depression, excessive exercise, and low body weight. Several centrally acting drugs, including opiates, glucocorticoids, sex steroids, GnRH agonists and antagonists, tranquilizers, antidepressants, and antipsychotic medications, suppress gonadotropin secretion either directly or indirectly via induction of hyperprolactinemia. Organic causes include malignant disease, developmental disorders, tumors, infiltrative disease, trauma, and hypothalamic or pituitary damage from surgery or radiotherapy. Congenital and acquired causes of central hypogonadism are considered more fully in Chapter 26.

Hypogonadotropic Hypogonadism. The genetic basis of HH was recognized over 60 years ago with the description by Kallmann of hypogonadism and anosmia in two families. It was not until 1991 that anosmin, a glycoprotein encoded by the *KAL1* gene, was identified as a cause of X-linked Kallmann syndrome.[454] The realization that *KAL1* gene defects only accounted for a small proportion of patients with classic Kallmann syndrome has led to genotype-phenotype studies that have provided important insights into the molecular genetics underlying HH. Gene mutations affecting the olfactory bulb and GnRH neuronal migration tend to give rise to the Kallmann phenotype. Multiple genetic defects have been associated with Kallmann syndrome, which in many cases can be distinguished clinically based on well-established nonreproductive phenotypes. On the other hand, defects in genes involved in regulating GnRH secretion or GnRH action are usually associated with normosmia, and in some cases the clinical phenotype is solely that of isolated HH (Table 8.10 provides details; see also Fig. 8.32).

Kallmann Syndrome. Kallmann syndrome consists of defective GnRH neuronal development, with olfactory nerve agenesis or hypoplasia and variable anosmia. Associated developmental disorders include optic atrophy, color blindness, sensorineural deafness, cleft palate, renal agenesis, cryptorchidism, and movement disorders.[455] This X-linked recessive disorder has been ascribed to a defective *KAL1* gene located on chromosome Xp22.3.[456] The encoded anosmin protein mediates hypothalamic migration of GnRH cells from the primitive olfactory placode, and its absence leads to defective GnRH synthesis and anosmia.[457,458] Both autosomal recessive and dominant forms of the disorder have since been described, with multiple additional genetic causes identified (see Table 8.10 and Fig. 8.32).

These patients are exposed to low or absent sex steroids from birth. Consequently, females are tall and present with primary amenorrhea and absent secondary sexual development, and males have delayed puberty and micropenis.[459] Absent GnRH secretory pulses result in characteristically low LH and FSH levels in the face of very low concentrations of estradiol or testosterone. Because the nonprimed normal pituitary may not respond initially to GnRH stimulation, this test is of little value in distinguishing a hypothalamic from a pituitary defect. In some patients, repetitive GnRH priming may elicit pituitary LH and FSH responses, indicating a hypothalamic defect in GnRH secretion.

Manifestations

Gonadotropin deficiency causes hypogonadism with decreased sex steroid production of varying degrees, depending upon the severity of the insult (Table 8.11). This disorder may occur at any stage of life. In its congenital form, primary amenorrhea and total absence of development of secondary sexual characteristics may occur. Onset later in life may present with a varying spectrum of reproductive dysfunction, ranging from luteal phase abnormalities with subfertility to oligomenorrhea or amenorrhea in women. Women exhibit secondary amenorrhea, infertility, decreased vaginal secretion, dyspareunia, hot flashes, decreased bone density, and breast tissue atrophy.

Males with congenital HH have small testes (<4 mL) and absence of secondary sexual characteristics. Tall stature with eunuchoid habitus may be present as a result of delayed or absent epiphyseal closure. Cryptorchidism and microphallus may be present, reflecting the absence of activity of the HPG axis during fetal development.[460] Men with gonadotropin deficiency later in life present with loss of libido, potency, and fertility. They may have impotence, testicular atrophy, decreased libido, low energy, infertility, loss of secondary sexual characteristics, decreased muscle strength and mass, decreased bone mass, decreased facial and body hair, and fine facial wrinkling.[461]

In both men and women, serum gonadotropin levels are inappropriately low in the face of decreased sex steroid levels. In women with amenorrhea or oligomenorrhea, serum LH, FSH, and estradiol levels should be measured. Endogenous estrogen sufficiency can also be assessed by the response to a progesterone challenge (100 mg intramuscularly or 10 mg medroxyprogesterone acetate orally daily for 5–10 days). Men should have serum LH, FSH, and testosterone levels measured in a morning sample.

Hypothalamic and pituitary disorders are the most common endocrine cause of male subfertility. Because normal secretion of both FSH and LH is required for quantitatively and qualitatively normal spermatogenesis, any disease that affects hypothalamic secretion of GnRH or pituitary secretion of FSH or LH will impair spermatogenesis.[462] As FSH is required for normal

spermatogenesis, isolated FSH deficiency is associated with oligospermia or azoospermia. Men with inactivating FSHβ mutations are azoospermic, but some have normal puberty associated with normal to low-normal testosterone levels and high LH levels, whereas another presented with a low testosterone concentration and absent puberty.[463–465] Inactivating FSHβ mutations have also been characterized in women and have resulted in a phenotype of delayed puberty, absent or incomplete breast development, primary amenorrhea, and infertility, with low levels of estradiol and progesterone, undetectable FSH, and high LH.[463,464]

Mutations that abolish the activity of LH, resulting in isolated LH deficiency, have also been reported.[466,467] Isolated LH deficiency in males may manifest with delayed or absent puberty, with eunuchoidal body proportions as a result of low testosterone levels. Low LH levels in these patients lead to low intratesticular testosterone concentrations with resultant decreased spermatogenesis. A female with isolated LH deficiency due to an LH mutation had normal pubertal development and menarche but secondary amenorrhea and infertility.

Management

The goals of therapy are to replace or restore sex steroid hormones and to induce and maintain normal reproductive function. If fertility is not an immediate objective, sex steroid hormone replacement is usually sufficient. For induction of gametogenesis in those desiring fertility, therapy with gonadotropins or GnRH is usually required.

Evaluation. In evaluating hypogonadal patients in the absence of an obvious pituitary or gonadal disorder, the primary diagnostic challenge is to distinguish constitutional pubertal delay from other causes of hypogonadotropism.[341,468] When puberty is delayed after 14 years of age, a primary developmental disorder, HH, should be considered in the absence of acquired causes. Cryptorchidism or micropenis is suggestive of congenital HH, whereas low patient height relative to the parents' height suggests constitutional delay of puberty (CDP) rather than congenital HH, in which height tends to be normal or even increased, possibly with eunuchoidal proportions. No single test clearly distinguishes constitutional delayed puberty and true HH, and expectant follow-up is often helpful as many patients enter puberty spontaneously. To enable androgenization, testosterone replacement should be provided intermittently until age 18, with periodic interruptions to unmask physiologic pubertal advance.

TABLE 8.11 Clinical Features of Hypogonadotropism

Prepubertal Onset

High-pitched voice
Absent terminal facial hair
Decreased or absent body hair
Eunuchoidal body proportions
Female escutcheon
Testicular volume <6 cm^3
Testicular length <2.5 cm
Cryptorchidism may be present
Penile length <5 cm
Hypopigmented scrotum with absent rugae
Small prostate
Decreased libido
Decreased muscle and bone mass

Postpubertal Onset

Decreased libido
Decreased spontaneous erections
Slow beard growth
Decreased body hair
Testicular atrophy if long standing
Decreased muscle and bone mass

Normal

Voice pitch
Skeletal proportions
Penis length
Scrotal rugae
Prostate size

Sex Steroid Replacement Therapy. Estrogen or testosterone replacement is required for inducing and maintaining primary and secondary sexual characteristics and to maintain normal body composition and integrity of BMD and muscle mass. For patients not seeking fertility, sex steroid therapy is warranted to correct central hypogonadism. However, monitoring of LH and FSH responses does not accurately reflect adequate steroid hormonal replacement, as basal gonadotropin levels are already low or undetectable.

Estrogens are available as a tablet, patch, gel, or implant. Initiation of puberty can begin with any type or route of exogenous estrogen, oral or transdermal. Initial therapy should consist of estrogen alone to maximize breast growth and to induce uterine and endometrial proliferation. A progestin eventually needs to be added to prevent endometrial hyperplasia but should be avoided before completion of breast development, because it is likely to reduce ultimate breast size. In premenopausal women, oral estrogens or transdermal estradiol delivering 50 to 100 mg daily can be used, with concomitant cyclic progesterone therapy for women with an intact uterus to prevent unopposed endometrial proliferation. Although early sex steroid replacement lessens the risk of developing osteoporosis, effects of estrogen replacement on cardiovascular function are unresolved. In patients with hypopituitarism, estrogen replacement should be maintained until the age of 50, after which continuation should be determined on an individual basis by assessing risks and benefits, especially in terms of bone mineral integrity, cardiovascular function, and cancer risk. Estrogen treatment may be associated with thromboembolic disease, breast tenderness, and possibly enhanced risk for breast cancer.

For men, androgen replacement is available as intramuscular, gel, patch, implants, nasal, or oral preparations. Intramuscular injection of testosterone enanthate or testosterone cypionate is usually administered at doses of 200 to 300 mg every 2 or 3 weeks.[461] Administration of lower doses on a more frequent basis (e.g., 100 mg weekly) may stabilize fluctuations of hormone levels. Elderly males require lower doses, as do boys with delayed puberty. Testosterone undecanoate provides long-term replacement for 3 to 4 months after each injection with improved pharmacokinetic profiles, but rare cases of pulmonary oil microembolism and anaphylaxis have been reported; it must be administered in an office or hospital setting by a trained health care provider, and the patient should be monitored for 30 minutes afterward for adverse reactions. Transdermal testosterone patch and gel systems deliver 4 to 6 mg and sustained testosterone profiles. Patch sites may develop skin irritation, blisters, and vesicles in approximately 25% of patients.[469] Oral androgen replacement therapy is generally not recommended because of nonuniform absorption and hepatotoxicity. Nasal testosterone is a recently approved alternative with a shorter half-life, administered three times daily[470]; at the other end of the spectrum, longer acting implantable testosterone pellets are available. Testosterone may cause acne, gynecomastia, prostatic hypertrophy, and polycythemia. Although there is no compelling evidence that testosterone replacement causes prostate cancer, benign prostatic hypertrophy can be exacerbated, especially in elderly patients. Testosterone replacement should not be administered to men with diagnosed prostate cancer. Target serum hormone levels, which benefit lean mass, muscle strength, and sexual function without inducing undesirable adverse consequences, vary, and in the future, individual targets may guide the treatment of hypogonadism in men.[471]

Fertility. In patients with HH, fertility may be achieved with gonadotropin or GnRH therapy. In males, even relatively low sperm counts may be adequate for impregnation when fertility is induced by gonadotropins or GnRH. As testosterone therapy may suppress spermatogenesis, the steroid should be discontinued prior to initiating treatment. Partial rather than complete hypogonadism predicts a more favorable response to treatment, whereas persistence of cryptorchidism beyond the age of 1 year reduces the likelihood of successful fertility induction. hCG is administered subcutaneously or intramuscularly (1000–2000 IU two to three times weekly) to induce spermatogenesis, with the dose titrated according to testosterone levels.[472] If necessary, after 6 months, human menopausal gonadotropin (hMG) or purified or recombinant FSH should be added to improve sperm quantity, and doses may be doubled after a further 6 months. An increase in testicular volume correlates well with induction of spermatogenesis. If testosterone levels are increased, subsequent conversion to estradiol may result. Therefore both testosterone and estradiol levels should be monitored.

Pulsatile GnRH therapy is an alternative treatment for patients with normal pituitary function (i.e., those with idiopathic HH or Kallmann syndrome). GnRH is infused subcutaneously by continuous minipump (5 mg every 2 hours), with the dose titrated to maintain normal gonadotropin and testosterone levels. This approach may be marginally more effective than treatment with gonadotropins and may cause less gynecomastia. These approaches require strong patient commitment, as adequate spermatogenesis may not be attained for 2 years or longer despite normalized testosterone levels. Aliquots of successfully generated sperm samples should be frozen for future impregnation.

Clomiphene citrate is a weak estrogen receptor antagonist that stimulates gonadotropin secretion in normal women and men. Clomiphene has been used to increase spermatogenesis in men with partial hypogonadotropism with oligospermia or azoospermia and normal to mildly low serum testosterone concentrations, particularly in men with functional hypogonadism, with variable results.

In women with HH, fertility may be effectively achieved by pulsatile GnRH administration or by gonadotropin therapy (fully discussed in Chapters 17 and 26). Although ovulation is often induced and pregnancy achieved by gonadotropin treatment, a high rate of multiple follicle development remains a concern.[473] If residual pituitary gonadotroph reserve is sufficiently robust, GnRH therapy is more likely to result in ovulation of a single rather than multiple follicles, thereby reducing the chances of multiple gestation.[474] Therapy with kisspeptin or kisspeptin analogues is an area of current investigation and holds promise for further reducing the chances of multiple gestation or the risks of ovarian hyperstimulation[475,475a–475c] (see Chapter 17).

Thyroid-Stimulating Hormone

Physiology

The hypothalamic-pituitary-thyroid system plays a critical role in development, growth, and cellular metabolism through the action of thyroid hormones.

Thyrotroph Cells

Thyrotroph cells comprise approximately 5% of the functional anterior pituitary cells and are situated predominantly in the anteromedial areas of the gland. They are smaller than the other cell types, irregularly shaped with flattened nuclei and relatively small secretory granules, ranging from 120 to 150 μm, and they contain TSH that is released under TRH stimulation. Immunoreactive TSH cells are present in the fetal pituitary by 12 weeks. The differentiation of thyrotrophs is critically dependent on the expression of transcription factors GATA2, POU1F1, and PROP1 during development.

Structure

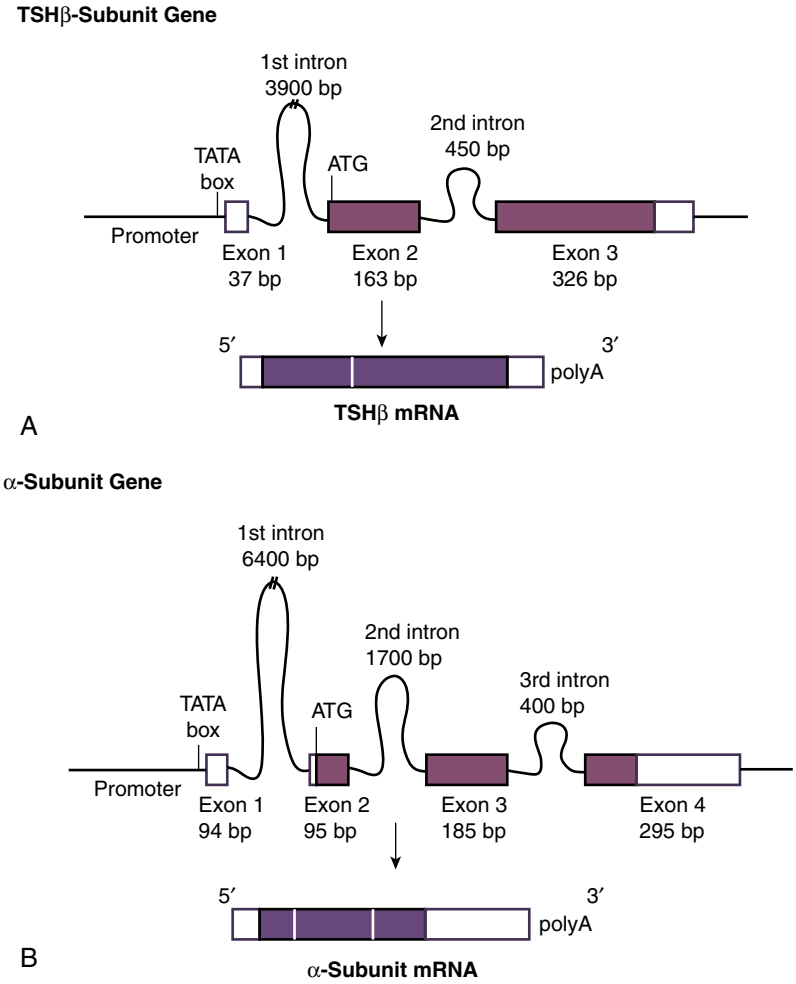
TSH is a glycoprotein hormone comprising a 28-kDa heterodimer of two noncovalently linked subunits (α and β).[476,477] The α-subunit and β-subunit are encoded by two separate genes located

on different chromosomes (Fig. 8.35). The tertiary TSH structure comprises three hairpin loops separated by central disulfide bonds, with the longer loop straddling one side.[477–479] The α-subunit is common to TSH, LH, FSH, and hCG, whereas the β-subunit is unique and confers specificity of action.[477] The α-subunit is the earliest hormone gene expressed embryonically, but activation of the β-subunit gene occurs later under the influence of GATA2 and POUF1F1.[480] The 13.5-kb α-subunit gene is located on chromosome 6 and comprises four exons and three introns (see Fig. 8.35).[481] Although the α-subunit gene is expressed in thyrotroph, gonadotroph, and placental cells, its regulation is uniquely cell specific. The downstream promoter region (−200 and below) is required for placental expression, intermediate sequences are required for gonadotroph expression, and upstream promoter elements are required for thyrotroph-specific expression.[482] The 4.9-kb TSH β-subunit gene located on chromosome 1 comprises three exons and two introns (see Fig. 8.35).[483] PIT1 binds directly to the gene promoter to confer tissue-specific expression.[484]

Production of the mature heterodimeric TSH molecule requires complex cotranslational glycosylation and folding of nascent α-subunit and β-subunit.[477] After subunit translation and signal peptide cleavage, glycosylation occurs at asparagine 23 on the β-subunit and at two asparagine residues, 52 and 78, on the α-subunit.[485] Appropriate glycosylation is required for accurate molecular folding and subsequent combination of α-subunit and β-subunit within the rough endoplasmic reticulum and Golgi apparatus.

Regulation

α-Subunit transcription is inhibited by the thyroid hormone receptor (TR) in concert with other nuclear corepressors.[486] TSHβ gene transcription is also suppressed by the TR acting directly on exon 1.[487] This potent suppression is evident within 30 minutes of T_3 exposure and is a critical determinant of ultimate TSH secretion. Both αTSH and βTSH subunit gene transcription are induced by TRH and suppressed by dopamine.[488] Both TRH and T_3 regulate TSH glycosylation, albeit in opposite directions.

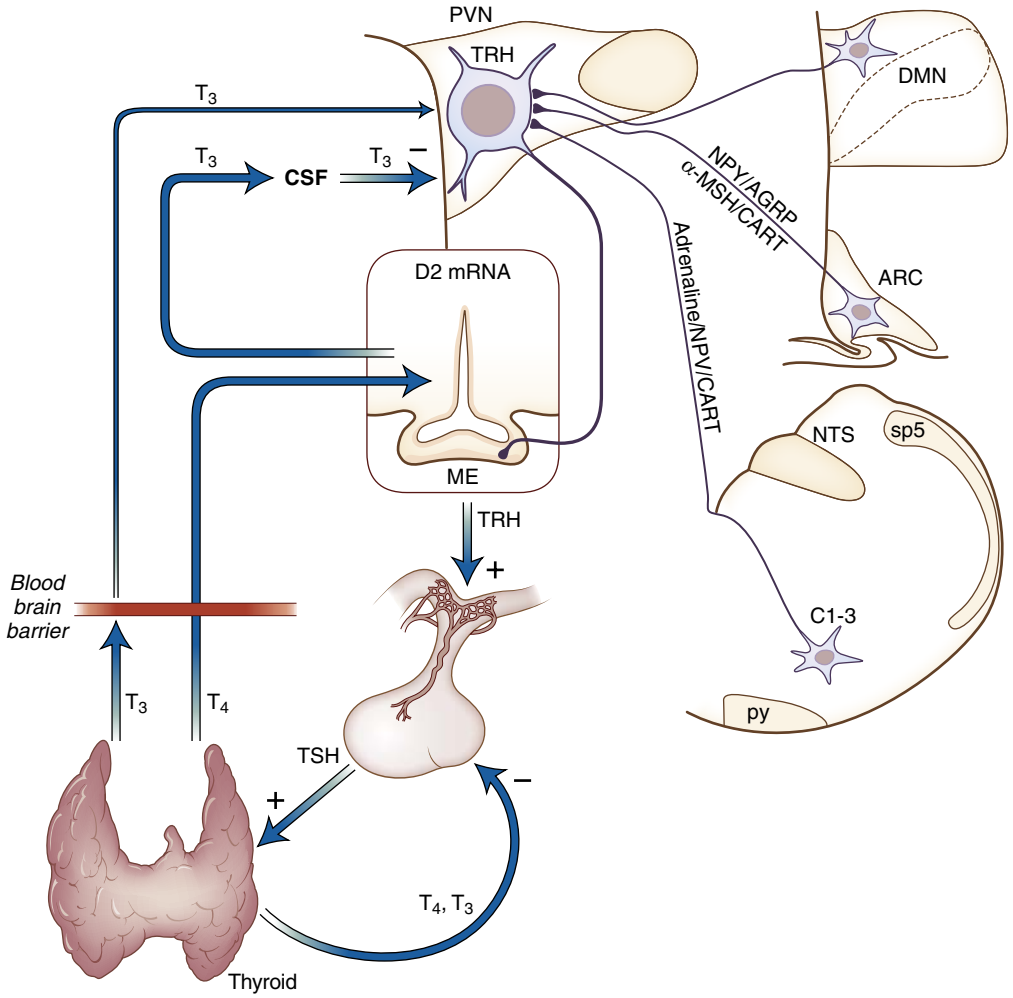


• **Fig. 8.35** Schematic representation of the TSHβ (A) and the α-subunit (B) genes. The relative locations and sizes of the exons and introns are shown within translated regions shown as *open boxes* and protein coding regions as *black boxes*. The TATA box position in the transcriptional start site is located in the promoter close to exon 1. The introns are spliced out during transcription and exons joined and a polyA tail added at the 3′ end. (From Gordon DF, Sarapura VD, Samuels MH, et al. Thyroid stimulating hormone: physiology and secretion. In Jameson JL, De Groot LJ, eds. *Endocrinology: Adult and Pediatric.* 6th ed. Philadelphia: Elsevier; 2010:1362–1383.)

TRH exposure or T_3 deprivation enhances oligosaccharide addition to the TSH molecule.[488,489]

The TRH neuron plays a central role in determining the set-point of the hypothalamic-pituitary-thyroid axis by regulating pituitary TSH release.[490] Hypothalamic TRH synthesis is in turn regulated by thyroid hormones. Three main neuronal groups mediate the effects of other physiologic stimuli on hypothalamic TRH neurons, which are located in the paraventricular nucleus. The first is adrenergic input from the medulla that mediates the stimulatory effects of cold exposure on the TRH neuron (Fig. 8.36). Second, TRH neurons receive projections from the arcuate nucleus that contain two leptin-responsive groups regulating energy homeostasis: The POMC system that promotes weight loss activates while the NPY/agouti-related protein (AGRP) system that promotes weight gain inhibits TRH neurons.[491] Fasting results in reduction of TRH expression, which is mediated by suppression of the POMC system and stimulation of the NPY/AGRP system. Third, the hypothalamic dorsomedial nucleus projects to the paraventricular nucleus and represents alternative pathways by which leptin acts to regulate TRH neurons.[491,492]

Feedback regulation by thyroid hormones on TRH and TSH are determined primarily by circulating thyroxine (T_4) entry into the blood-brain barrier elaborated through a complex system of paracrine control in the hypothalamus (see Fig. 8.36). The effects of thyroid hormones are mediated by thyroid hormone receptors, which are members of a superfamily of nuclear hormone receptors. TRs exist as two major isoforms, TRα and TRβ. TRα is the key TR isoform responsible for T_3-mediated negative-feedback



• **Fig. 8.36** Schematic illustration of the feedback system regulating the hypothalamic-pituitary-thyroid axis. Thyroid hormones exert negative feedback effect at the level of the pituitary and hypophysiotropic TRH neurons. The central feedback effect of thyroid hormones primarily depends on the circulating T_4 levels. In the hypothalamus, T_4 is converted to T_3 by deiodinase 2 (D2) in tanycytes. By volume transmission, T_3 secreted from tanycytes reaches the hypophysiotropic TRH neurons, where T_3 inhibits the proTRH gene expression via TRβ2 receptors. The set-point of the feedback regulation can be altered by two mechanisms: (1) regulation of D2 activity in tanycytes and (2) neuronal afferents altering CREB concentration in the hypophysiotropic TRH neurons. *ARC,* hypothalamic arcuate nucleus; *C1-3,* C1-3 adrenergic area of the brainstem; *CSF,* cerebrospinal fluid; *DMN,* hypothalamic dorsomedial nucleus; *ME,* median eminence; *NTS,* nucleus tractus solitarius; *PVN,* hypothalamic paraventricular nucleus; *py,* pyramidal tract; *sp5,* spinal trigeminal tract. (Redrawn from Fekete C, Lechan RM. Negative feedback regulation of hypophysiotropic thyrotropin-releasing hormone (TRH) synthesizing neurons: role of neuronal afferents and type 2 deiodinase. *Front Neuroendocrinol*. 2007;28:97–114.)

regulation by hypophysiotropic TRH neurons.[478] The local availability of T_3 is determined by deiodinase 2 and deiodinase 3, respectively, which provides and deactivates T_3.[490]

Deiodinase 2 is expressed in surrounding glial cells of the hypothalamus[491,493] and in tanycytes (lining the third ventricles), which generate T_3 from circulating T_4. Tanycytes appear to be the main contributor to the negative feedback regulation of the hypothalamic-pituitary-thyroid axis.[490] The expression by the TRH neuron of deiodinase 3, which inactivates T_3, points to the existence of an important local level of TRH regulation. T_3 suppresses hypothalamic TRH synthesis and decreases pituitary TRH receptor number.

In the anterior pituitary gland, deiodinase 2 is found in folliculostellate cells, whereas TRs and deiodinase 3 are expressed in thyrotrophs.[491,493] These findings indicate an important role for folliculostellate cells in processing and activating T_4. Production and action of local T_3 occur in separate cell types of the hypothalamus and anterior pituitary gland resulting in setting the level of TSH output.

Transporters of thyroid hormone play a key role in regulating the TRH neuron. The two most important transporter families that are involved in thyroid hormone transport in the brain are the organic anion transporting polypeptide (OATP) and the monocarboxylate transporter (MCT).[490] Among these, OATP14 is highly expressed in the paraventricular nucleus and OATP8 in brain neurons.[494] In humans, mutations in the MCT8 gene, located on the X chromosome, result in males with neurologic abnormalities with elevated T_3 levels and decreased T_4 levels in the presence of a normal TSH secretion.[495]

Secretion

Daily TSH production is approximately 100 to 400 mU[496] with a calculated circulating half-life of approximately 50 minutes. Secretion rates are enhanced up to 15-fold in hypothyroidism and are suppressed in hyperthyroidism. The degree of TSH glycosylation determines both metabolic clearance rate and bioactivity; in hypothyroidism, the molecule appears highly sialylated, enhancing bioactivity.[485] Immunoreactive fetal pituitary TSH is detectable by 12 weeks. Immediately after full-term birth, there is a brisk rise in TSH, which remains elevated for up to 5 days before stabilizing at adult levels.[497] TSH secretion is pulsatile; however, the low pulse amplitudes and long TSH half-life result in modest circulating variances that are amplified in hypothyroidism and abrogated in critical illness.[498] Secretory pulses every 2 to 3 hours are interspersed with periods of tonic, nonpulsatile TSH secretion.[499] Circadian TSH secretion peaks between 11 PM and 5 AM, mainly due to increased pulse amplitude that is not sleep entrained.[500] The 24-hour TSH secretion is stable and robust and not influenced by sex, body mass index, or age.[501] Thyroid hormones suppress tonic TSH secretion and pulse amplitude but not frequency. Free TSHα is secreted but not TSHβ.

Regulatory Factors

Several factors and drugs affect the secretion of TSH (Table 8.12). Somatostatin infusion inhibits TSH pulse amplitude and blocks the nocturnal TSH surge[502] directly at the pituitary level. Although SRIF analogues are used to treat TSH-secreting pituitary adenomas (see later), SRIF analogue treatment for acromegaly does not lead to hypothyroidism, although T_4 is lowered within the normal range. Dopamine infusions suppress TSH secretion and abrogate the nocturnal TSH surge.[502] Prolonged use of dopamine agonists, however, does not result in hypothyroidism. Glucocorticoids suppress TSH secretion; however, the effect does not result in hypothyroidism. Proinflammatory cytokines such as TNFα and IL1 inhibit TSH secretion.[503] Leptin increases TSH secretion from central stimulation of TRH. Acute opiate administration causes a mild transient increase of TSH levels.

A number of drugs such as nonsteroidal anti-inflammatory agents (e.g., meclofenamate, fenclofenac) displace thyroid hormone from thyroxine-binding globulin (TBG), increasing free hormone concentrations and thus causing transient decrease of TSH.[504]

TABLE 8.12 Factors Affecting the Secretion of TSH

Effect	Factors
Stimulatory	TRH Opioids Dopamine receptor antagonists Leptin
Inhibitory	Thyroid hormone Somatostatin analogues Dopamine agonists Proinflammatory cytokines Glucocorticoids

Action

TSH induces thyroid hormone synthesis and releases and maintains trophic thyroid cell integrity.[505] The TSH G protein–coupled receptor is located on the thyrocyte plasma membrane and is encoded by a gene on chromosome 11q31. Its regulation is comprehensively described in Chapters 11 and 12.

TSH Assays

The availability of ultrasensitive TSH measurements has revolutionized the biochemical and diagnostic evaluation of thyroid disorders. This is due to the widespread availability of immunoradiometric assays. The assay principle is based on TSH serving as a link between an immobilized antibody binding TSH at one epitope and a labeled (radioactive, chemiluminescent, or colorimetric) monoclonal directed against a second portion of the peptide. This technology substantially increases sensitivity and specificity with technical improvements leading to sequential generations of assays of higher sensitivity. Current commercial assays are mainly "third generation" with detection limits to 0.01 to 0.02 mU/L performed on automated platforms. They provide ready discrimination between hyperthyroid, euthyroid, and hyperthyroid states.[506,507] A major consequence of ultrasensitive TSH assay is the obsolescence of the TRH test for patients suspected of thyrotoxicosis. TSH measurement alone is not helpful in diagnosing central hypothyroidism, which is identified by concurrent measurement of thyroid hormone levels. Basal TSH levels are subnormal in only about one-third of patients with secondary hypothyroidism.[508] TSH deficiency is thus associated with low T_4 levels concomitant with low, normal, or even minimally elevated TSH levels. Importantly, this biochemical profile may also be encountered in critically ill patients with low TSH and T_4 levels without evidence of pituitary disease. The TRH test does not add to the diagnosis of central hypothyroidism or the sick-euthyroid state.[509] In a stimulation test, TRH (200–500 μg) is administered intravenously, and TSH levels are measured at –15, 0, 15, 30, 60, and 120 minutes. In euthyroid subjects,

peak TSH levels (up to 22-fold higher than basal) are observed after 30 minutes.[507] Because feedback suppression by elevated thyroid hormone levels on TSH overrides stimulation by the hypothalamus, basal TSH levels are undetectable and do rise to TRH in hyperthyroidism. The TRH test has a useful role in differentiating hyperthyroidism due to a TSH-secreting adenoma and elevated thyroid hormone levels due to thyroid hormone resistance. The TSH levels do not increase in response to TRH in most cases of TSH adenomas, but they do in thyroid hormone resistance.[509]

TSH Deficiency

Causes

Congenital isolated TSH deficiency may arise from mutational defects of the TSH and TRH receptor genes. Genetic disorders of pituitary gland development involved in cell differentiation give rise to TSH deficiency as a component of multiple pituitary hormone deficiencies. The developmental genes involved include *LHX3*, *PROP1*, and *POU1F1* (see Table 8.2). Pituitary damage may result in functional TSH deficiency.

Manifestations

The consequences of TSH deficiency are those of thyroid hormone deficiency, which causes childhood mental and growth retardation; in adults, it results in clinical features similar to primary hypothyroidism.

Treatment

L-Thyroxine is used for replacement therapy, in doses similar to those required for treating primary hypothyroidism ranging from 50 to 200 μg/day. Thyroxine is converted peripherally into the active T_3 and has a 7-day half-life with stable blood levels. There is strong evidence that patients with central hypothyroidism are frequently undertreated; it has been recommended that the dose be titrated to achieve midnormal free T_4 levels.[510] TSH cannot be used to guide dose titration in patients with secondary hypothyroidism because the damaged thyrotroph is unlikely to adequately reflect appropriate feedback suppression. As GH stimulates the conversion of T_4 to T_3, blood T_4 levels may fall into the subnormal range, unmasking central hypothyroidism during GH therapy for GH deficiency.[277,278] The principles of thyroid hormone replacement apply in this situation and T_4 supplementation is initiated. As many women with pituitary failure also likely receive estrogen replacement, free instead of total T_4 level is measured to avoid the confounding effects of increased TBG levels. Thyroid hormone replacement accelerates cortisol metabolism and requirements and may therefore exacerbate primary hypoadrenalism or precipitate adrenal crisis in patients with coexisting perturbed adrenal function. Therefore, in pituitary patients suspected of having ACTH deficiency, thyroid hormone replacement should only be initiated after adrenal status has been evaluated and treated.

TSH Excess

Other than primary hypothyroidism, TSH excess can rarely arise from TSH-secreting pituitary adenomas, thyroid hormone resistance, and TSH receptor resistance. The biochemical profiles of TSH adenoma and thyroid hormone resistance are similar, both conditions manifesting high TSH and thyroid hormone levels; however, the two are usually distinguished from familial history, imaging, clinical examination, and TRH testing.[508] Thyroid hormone resistance can arise from mutations of TRα and TRβ, with the latter being more common. TSH receptor mutations were first described in 1995 as a cause of congenital hypothyroidism.[511] However, mutations causing partial resistance may manifest as nonautoimmune subclinical hypothyroidism.[512]

Developmental, Genetic, and Acquired Causes of Pituitary Failure

Developmental Disorders

Congenital pituitary gland absence (aplasia), partial hypoplasia, or ectopic tissue rudiments are rarely encountered. Pituitary development follows midline cell migration from Rathke pouch, and impaired midline anomalies, including failed forebrain cleavage and anterior commissure and corpus collosum defects, lead to structural pituitary anomalies. Craniofacial developmental anomalies, including anencephaly, result in cleft lip and palate, basal encephalocele, hypertelorism, and optic nerve hypoplasia with varying degrees of pituitary dysplasia and aplasia. If these infants survive, lifelong appropriate pituitary hormone replacement is required. With sensitive MRI techniques for pituitary visualization, several anatomic features characteristic of hypopituitarism are now apparent. Evidence for acquired pituitary damage or destruction is often clearly visible on MRI, and patients presenting with hypopituitarism of undetermined cause may exhibit decreased gland volume, partial or complete empty sella, disturbed sella turcica architecture, absent or transected pituitary stalk, and an absent or ectopic posterior pituitary bright intensity signal.[513] Lesions of the pituitary stalk can arise from congenital maldevelopment causing stalk interruption (see later) or from acquired diseases involving the infundibulum. Among 92 patients with pituitary stalk lesions, 32% were found incidentally. About 15% were due to congenital causes (ectopic posterior pituitary, Rathke cyst), 33% to inflammatory causes (sarcoidosis, histiocytosis, hypophysitis), and over 50% to neoplastic causes (craniopharyngioma, pituitary adenoma, metastatic disease).[514] An absent infundibulum noted on MRI is associated with pituitary hormone deficits, and approximately 40% of patients with GHD of unclear cause show imaging evidence of mild stalk defects, reflecting a midline developmental anomaly.

Congenital basal encephalocele may result in the pituitary herniating through the sphenoid sinus roof, resulting in pituitary failure and diabetes insipidus.

Heritable Disorders

Mutations at each level of pituitary function, including hormones, receptors, and transcription factors that determine anterior pituitary development, may lead to pituitary deficiency syndromes[515] (see Table 8.1). Furthermore, mutations in specific pituitary genes, including those for GH, POMC, TSH, LH, and FSH, all lead to single hormone deficiencies. Patients heretofore diagnosed with idiopathic isolated or polyhormonal pituitary failure may in fact harbor a mutation, and as the transcriptional control of pituitary development is clarified, increasing numbers of mutant genes have become apparent (see Table 8.2).

HESX1, SOX2, SOX3, and OTX2

HESX1 (also known as RPX), one of the earliest transcriptional markers of the primitive pituitary, with expression restricted

to Rathke pouch, is a paired-like homeodomain transcription factor that acts as a transcriptional repressor.[516] Coincidentally, with appearance of specific pituitary cell types, HESX1 expression declines and is extinguished in the mature anterior pituitary,[517] leading to PROP1 activation. The heterogeneous syndrome of septo-optic dysplasia (hypoplastic optic nerves, absent corpus callosum and septum pellucidum, and hypopituitarism) is associated with mutations in HESX1.[518] Hypopituitarism ranges from panhypopituitarism to isolated GHD. Although the mutant molecule exhibits reduced DNA binding, panhypopituitarism may also occur secondary to profound anatomic defects in midline development. Mutations in HESX1 have also been associated with pituitary stalk interruption syndrome (PSIS), a congenital defect of the pituitary gland characterized by a very thin, interrupted pituitary stalk, an ectopic or absent posterior pituitary gland, and hypoplasia or aplasia of the anterior pituitary gland, visible on MRI.[519] Mutated SOX2, a member of the SRY-related high mobility group box (Sox) genes, is also associated with septo-optic dysplasia, anophthalmia, or microphthalmia, and anterior pituitary hypoplasia, frequently associated with HH and GHD, and other forebrain defects.[520] SOX3 mutations are associated with X-linked hypopituitarism and mental retardation. Affected males have GHD and may also have deficient gonadotropins, TSH, or ACTH. Both SOX3 duplications and loss of function mutations show similar phenotypes, suggesting that SOX3 dosage is critical for normal pituitary development.[521,522]

Mutations in OTX2 have also been implicated in anophthalmia/microphthalmia syndromes in humans. These mutations are associated with severe ocular and neurologic phenotypes, including developmental delay and seizures. Panhypopituitarism occurs, perhaps as a result of failure to activate transcription of HESX1 and POU1F1.[522]

LHX3 and LHX4

LHX3 is expressed early during anterior pituitary development, with strong uniform expression within Rathke pouch. Expression persists into adulthood. Missense and deletion mutations of LHX3, a LIM-type homeodomain transcription factor essential for pituitary development, are associated with failure of pituitary gland morphogenesis with reduced numbers of all cell types and multiple anterior pituitary hormone deficits, affecting all axes except for largely intact ACTH reserve.[436] Most missense mutations identified in patients have diminished capacity to activate transcription of the promoters of several potential LHX3 target genes, including those encoding αGSU, PRL, FSHβ, TSHβ, and POU1F1.[523] These patients also exhibit defective neck rotation ability due to a rigid cervical spine and variable sensorineural hearing loss.[524]

LHX4 is closely related to LHX3 and is also expressed throughout the invaginating Rathke pouch, but unlike LHX3, its expression is transient and not maintained in the adult pituitary. Patients with LHX4 mutations exhibit GHD and associated short stature, with variable additional endocrine deficits, particularly TSH and ACTH deficiency, and extrapituitary abnormalities. LHX4 mutations associated with anterior pituitary hypoplasia, an ectopic posterior pituitary, and with PSIS are unable to activate both PROP1 and POU1F1, and these result in pituitary failure.[522,525]

PITX1 and PITX2

PITX1 and PITX2, members of the class of bicoid homeodomain proteins, show a high degree of homology and are expressed in an overlapping pattern during pituitary development. PITX1 is expressed in all five anterior pituitary lineages in both the fetal and adult pituitary gland and is able to activate the expression of all six of the major anterior pituitary hormones, including LH and FSH, frequently acting in synergy with other pituitary transcription factors. Mutations in PITX2 cause Rieger syndrome, characterized by defects in the eyes and teeth and a protuberant umbilicus as well as pituitary hormone deficiencies.[27,28,526]

PROP1

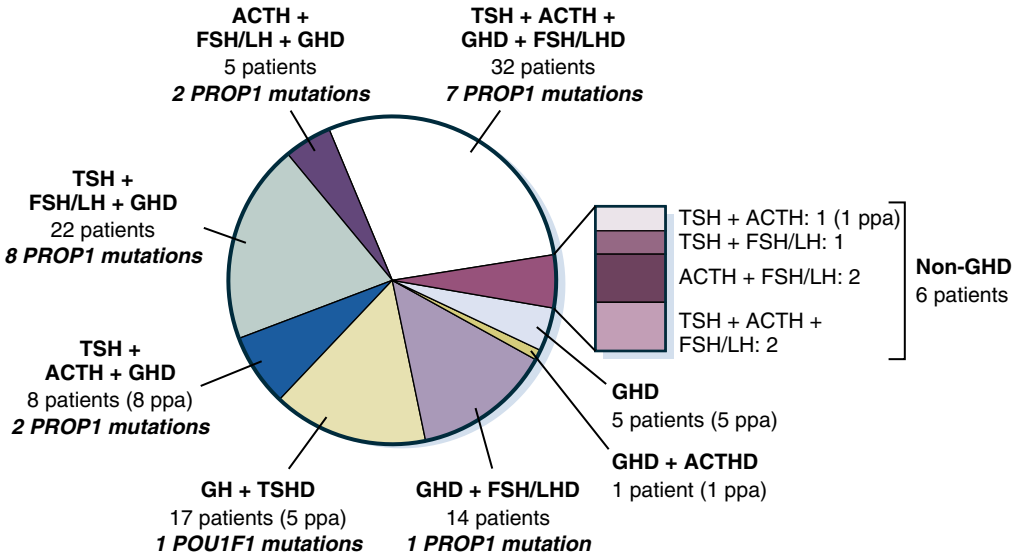
Mutations in PROP1 are the most common genetic cause of combined pituitary hormone deficiency (CPHD) (Fig. 8.37).[527] The role of this gene was first uncovered from studies of the Ames dwarf mouse, which harbors a missense PROP1 mutation and exhibits a hypoplastic pituitary gland with combined GH, PRL, and TSH deficiency. This mutation abrogates POU1F1 activation and results in failed development of POU1F1-dependent cell lineages.[528] Similarly, human PROP1 mutations are associated with deficiencies in POU1F1-dependent lineages (GH, PRL, and TSH). Impaired FSH and LH secretion, associated with delayed or absent puberty, HH, and infertility in females and in some males, is also frequently present.[529] ACTH deficiency can also occur, frequently with a later onset, suggesting a role in maintenance of corticotroph function and emphasizing the necessity for complete and continued clinical assessment of patients with PROP1 mutations.[263] Inheritance modes of PROP1 mutations usually reflect autosomal recessive patterns. Thus patients are usually homozygous for either deletion or missense frameshift mutations, leading to truncated PROP1 protein products devoid of functional activity.

The clinical spectra of CPHD associated with PROP1 mutations are variable and temporal. The phenotype varies with both the type of mutation and the age of the patient.[522] The onset of clinically evident pituitary failure is usually first manifest with slowing of linear growth (GHD, ~80%), then thyroid failure (TSH deficiency, ~20%), followed by hypogonadism, and later subclinical or overt adrenal insufficiency.[530] The pituitary gland size is usually small or normal. Combined hypothalamic hormone stimulation (GnRH, TRH, CRH, and GHRH) or insulin-evoked hypoglycemia reveals blunted responses consistent with varying degrees of pituitary hormone deficiencies. Serum IGF1 and IGFBP3 levels are usually low, but peripheral thyroid hormone levels are low or at the lower limits of normal ranges. In the face of low or absent TSH responses, these findings are consistent with secondary hypothyroidism. Most older patients also exhibit blunted cortisol responses to CRH and ACTH or insulin stimulation.[529]

POU1F1

The POU1F1 gene encodes a POU homeobox protein, PIT1, which activates transcription of the GH, PRL, TSHβ, and GHRH receptor genes.[531] PIT1 also partners with coactivators, including thyroid hormone, estrogen, and retinoic acid receptors, as well as other transcription factors, including CREB, LHX3, PITX1, HESX1, and ZN15. PIT1 autoregulates its own expression. Because of the absolute requirement of PIT1 for somatotroph, lactotroph, and thyrotroph development and specific gene expression, inactivating mutations of the gene result in a spectrum of pituitary hormone deficiencies.[532] The Snell and Jackson dwarf mouse strains both harbor POU1F1 gene mutations.[533] Both autosomal recessive (loss of function) and autosomal dominant (dominant negative action) POU1F1 mutations have been identified.

Some POU1F1 mutations exhibit characteristic clinical phenotypes, depending on the spectrum of loss of DNA binding,



• **Fig. 8.37** Pituitary hormone deficiencies repartition in 110 unrelated patients affected by congenital pituitary deficiency without stalk pituitary interruption or septo-optic dysplasia. Patients were studied for *PROP1*, *POUF1*, or *LHX3* according to hormonal deficit phenotype. Twenty mutations of *PROP1* and one mutation of *POU1F1* were found. Gonadotroph function was unavailable for prepubertal age *(ppa)* patients. *ACTH,* adrenocorticotropic hormone; *ACTHD,* ACTH deficiency; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GHD,* growth hormone deficiency; *LH,* luteinizing hormone; *LHD,* luteinizing hormone deficiency; *TSH,* thyroid-stimulating hormone; *TSHD,* thyroid-stimulating hormone deficiency. (From Reynaud R, Gueydan M, Saveanu A, et al. Genetic screening of combined pituitary hormone deficiency: experience in 195 patients. *J Clin Endocrinol Metab.* 2006;91:3326–3329.)

transcriptional activation, or interaction with partner proteins affected.[320,534] Both CBP/p300 protein recruitment as well as PIT1 dimerization are required for appropriate PIT1 activation of target hormone genes.[535] LHX4 appears to activate POU1F1, and mutations of LHX4 also lead to growth retardation.[525] Interestingly, adult-onset combined GH, PRL, and TSH deficiencies have also been reported in association with circulating autoantibodies directed against the PIT1 protein.[536]

IGSF1

Loss-of-function mutations have been identified in *IGSF1* in association with X-linked congenital central hypothyroidism, often in association with variable PRL deficiency and GHD and with testicular enlargement.[167] IGSF1 is a membrane glycoprotein highly expressed in the anterior pituitary gland, and the patients with mutations appear to have impaired pituitary TRH signaling.

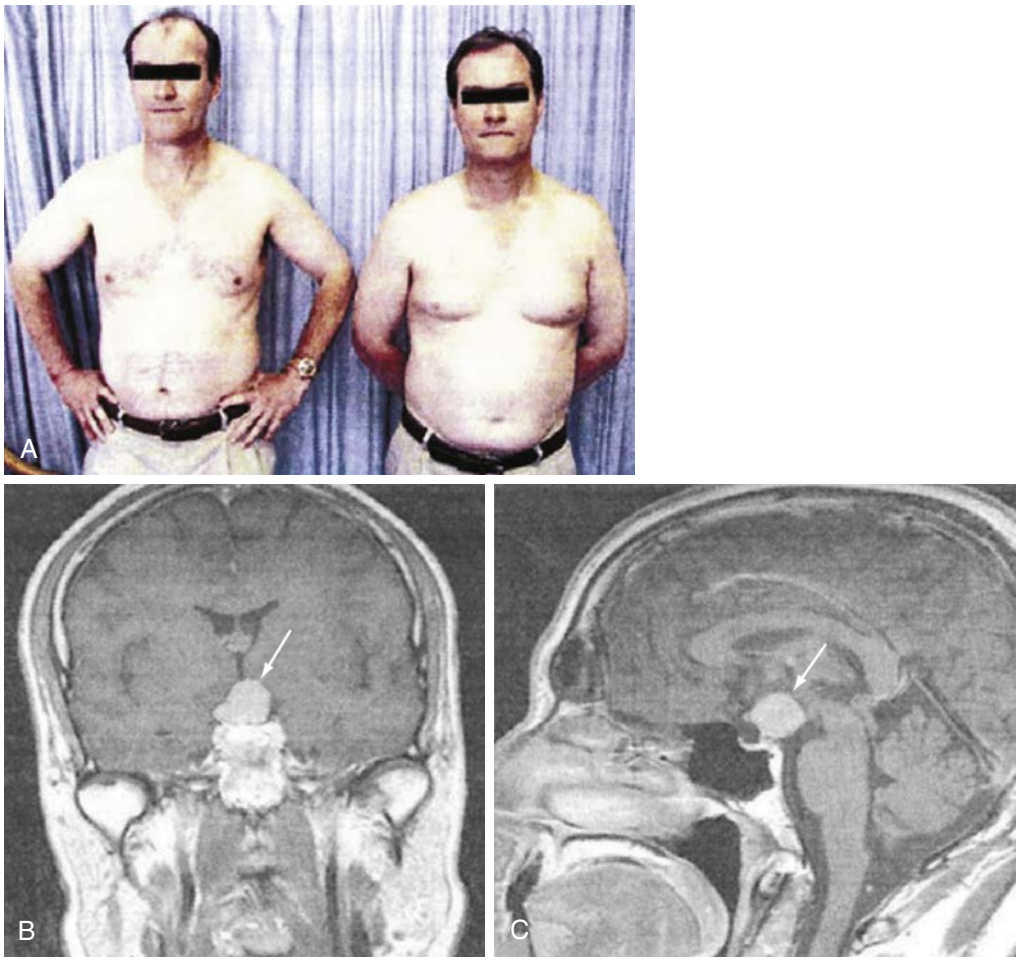
TBX19

TBX19 (also referred to as TPIT) mutations result in early-onset isolated ACTH deficiency and hypocortisolism[38] (see Table 8.2). Associated phenotypes, including those for POMC deficiency, may include obesity, red hair pigmentation, and other associated pituitary deficiencies. Patients are homozygous or compound heterozygous for TBX19 mutations, indicating an autosomal recessive mode of inheritance. Mutations in this gene appear to be the principal molecular cause of congenital neonatal isolated ACTH deficiency.[537] Interestingly, among 22 patients with isolated ACTH deficiency, diagnosed between ages 5 and 15 years, and no identified mutation of TBX19, three had common variable immunodeficiency (CVID), characterized by defective immunoglobulin production and recurrent infections, diagnosed at age 2 to 8 years. This has led to the proposal of a new syndrome linking these two rare disorders: deficient anterior pituitary function and variable immune deficiency (DAVID).[538] NFKB2, encoding a subunit of the transcription factor complex of nuclear factor-kappa-B, has recently been implicated as the transcription factor responsible for this syndrome.[539]

NR5A1 and NR0B1

NR5A1 encodes SF1, a member of the nuclear receptor family expressed throughout the reproductive axis (hypothalamus, pituitary, and gonads) and in the adrenal gland. It is a key transcriptional regulator of many genes involved in sexual differentiation, steroidogenesis, and reproduction, including the pituitary genes encoding αGSU, LHβ, FSHβ, and GnRHR. Patients with mutations in SF1 have been described with varying degrees of XY sex reversal, testicular dysgenesis, ovarian insufficiency, adrenal failure, and impaired pubertal maturation with HH.[61,540,541]

NR0B1 encodes DAX1 (*d*osage-sensitive sex-reversal *a*drenal hypoplasia critical region on the *X* chromosome protein *1*), a nuclear receptor transcription factor related to SF1, with a similar distribution pattern of expression. Mutations in NR0B1 are associated with X-linked HH and adrenal hypoplasia congenita,[31] with the majority of mutations causing truncations or frameshifts rendering the protein nonfunctional. HH is often mild, revealing itself as failure to undergo puberty or as incomplete puberty. The hypogonadism appears to be due to variable and combined hypothalamic and pituitary dysfunction. DAX1 is a transcriptional repressor and has been shown to inhibit SF1-mediated transcription of an array of target genes, including LHβ. How the loss of function in these two opposing genes, SF1 and DAX1, results in similar phenotypes is still not well understood. The HH is likely due to a developmental defect of the hypothalamus and pituitary, suggesting a role for DAX1 in proper development of these organs.[542]



• **Fig. 8.38** Features of hypopituitarism and hypogonadism, including central adiposity, proximal muscle wasting, loss of body hair, and gynecomastia. Note the contrast between the hypogonadal patient (A, *right side*) and his unaffected identical twin *(left side)*. Laboratory tests confirmed secondary hypogonadism, with testosterone level of 0.4 ng/mL (normal range, 2.9–8.0 ng/mL), follicle-stimulating hormone level of 2.8 IU/L (normal range, 1.5–12.4 IU/L), and luteinizing hormone level of 1.5 IU/L (normal range, 1.7–8.6 IU/L). Magnetic resonance imaging showed a lobulated, contrast-enhancing suprasellar mass (coronal view in B *[arrow]* and sagittal view in C *[arrow]*). Pathologic analysis confirmed the diagnosis of pituicytoma. (From Newnham HH, Rivera-Woll LM. Images in clinical medicine: hypogonadism due to pituicytoma in an identical twin. *N Engl J Med.* 2008;359:2824.)

Pituitary Stalk Interruption Syndrome

PSIS is a congenital defect of the pituitary gland characterized by a thin or interrupted pituitary stalk, anterior pituitary hypoplasia, and an ectopic posterior pituitary. Patients may present with an isolated pituitary hormone deficiency or with combined hypothalamic-pituitary hormone deficiencies. Accompanying midline defects and eye abnormalities suggest involvement of developmental processes. Mutations or single nucleotide variants in HESX1, LHX4, OTX2, SOX3, and PROKR2 have been associated with PSIS. A homozygous missense mutation was identified in a family with PSIS in GPR161, an orphan G protein–coupled receptor expressed in the hypothalamus and pituitary and implicated in the SHH signaling pathway.[543] A homozygous frameshift mutation in ARNT2, or aryl hydrocarbon receptor nuclear translocator 2, a helix-loop-helix transcription factor, has also been associated with anterior pituitary hypoplasia and pituitary stalk interruption, together with other CNS defects.[544] Mutations have been identified in less than 5% of patients with PSIS, suggesting that there is much more to be learned about the pathogenesis of this disorder.

Pituitary deficiencies have also been reported recently in patients with other syndromic disorders, including patients with CHARGE syndrome and CHD7 mutations; patients with PAX6 mutations, a well-known regulator of eye development; patients with septo-optic dysplasia or Kallmann syndrome and PROKR2, FGF8, and FGFR1 variants; and patients with holoprosencephaly and variants in SHH, GLI2, or TGIF.[539]

Acquired Disorders

In the absence of demonstrable hypothalamic-pituitary anatomic damage, and after excluding genetic and syndromic causes of pituitary insufficiencies, acquired, often transient, causes of pituitary failure should be considered (see Table 8.5). Causes of pituitary insufficiency, including pituitary tumors, parasellar masses, hypophysitis, aneurysms, and pituitary apoplexy, were discussed earlier. Hypothalamic damage reflected by the presence of a large parasellar mass, leading to decreased GnRH production, results in muscle wasting, obesity, and central hypogonadism with low levels of FSH and LH (Fig. 8.38). Marked caloric restriction, anorexia,[545] weight loss of other causes, and strenuous exercise may attenuate GnRH secretion and action. HH may occur in both men and women

TABLE 8.13 Hypopituitarism After Subarachnoid Hemorrhage

(see Chapters 17 and 19). Exogenous anabolic steroid therapy and glucocorticoid therapy suppress the reproductive and adrenal axes, respectively. Patients with severe critical illnesses or chronic debilitating disease (including cirrhosis) may have impaired GH/IGF1, adrenal, and gonadal axes. Hypothyroidism, hypoadrenalism, or hypogonadism cause hyperplasia of specific trophic cells due to lack of negative feedback and sometimes actual pituitary tumor formation.[546] Acquired immunodeficiency syndrome (AIDS) is associated with suppressed pituitary function that is independent of other associated infections.[547] Drugs such as estrogens, which suppress FSH and LH, and GnRH analogues used for treating prostate cancer inhibit gonadotropin action. In addition to pituitary apoplexy, other vascular accidents such as aneurysms, strokes, cavernous sinus thrombosis, and arteritis can cause pituitary hormone insufficiency. Isolated hormone pituitary hormone deficiencies may also occur as a manifestation of vascular abnormalities, including arteritis or subarachnoid hemorrhage (Table 8.13).

Head Trauma

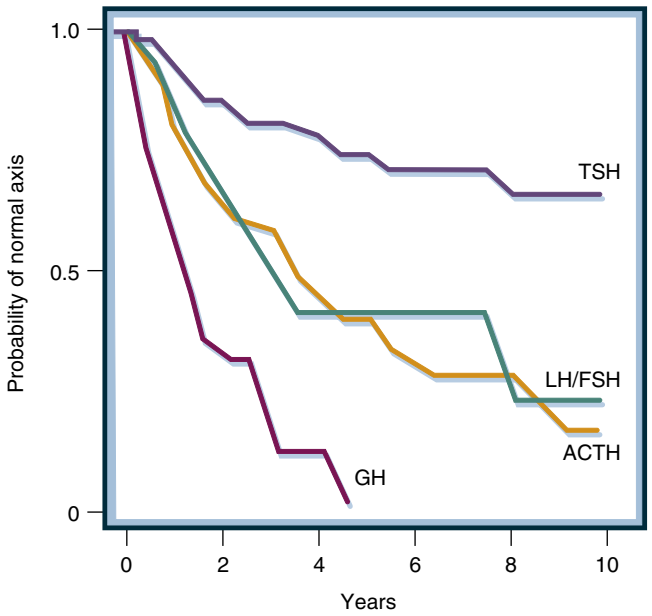
The pituitary may be partially or totally damaged by birth trauma, cranial hemorrhage, fetal asphyxia, or breech delivery. Head trauma may lead to direct pituitary damage by a sella turcica fracture, pituitary stalk section, trauma-induced vasospasm, or ischemic infarction following blunt trauma.[548] The most common traumatic cause of compromised pituitary function in the adult is iatrogenic neurosurgical trauma. Pituitary manipulation or damage during surgery leads to transient or permanent diabetes insipidus and varying degrees of anterior pituitary dysfunction. Hypopituitarism following head trauma usually manifests within a year after the insult. Seventy-five percent of patients with posttraumatic pituitary failure are young men under age 40 years involved in a motor vehicle accident. Virtually all patients with subsequent pituitary failure have a history of loss of consciousness following trauma, and half of all such patients have documented skull fracture.[548] One-third of these patients have demonstrable signs of hypothalamic or posterior pituitary hemorrhage or anterior lobe infarction on MRI. Diabetes insipidus is the most common endocrine disorder, encountered in about 30% of these patients.[549] As pituitary function can recover after trauma, the prevalence and extent of dysfunction vary and depend on the time of evaluation. A meta-analysis of more than 700 adult patients in 2007 reported that up to 35% of subjects acquired some impairment to pituitary function evaluated at least 5 months after major TBI.[550] GHD was found in 11%, gonadotropin deficiency in 13%, ACTH deficiency in 11%, TSH deficiency in 6%, and multiple deficits in 9%. There are sparse data of the pituitary consequences of TBI in children. A large prospective French study of 87 children, mean age of 6.7 years, reported a prevalence of 7% for GHD, 2% for thyroid, and 1% adrenal insufficiency evaluated 5 months after TBI.[551]

Klose and associates have questioned the accuracy of the frequency of adult GHD from previous studies because of methodologic issues arising from the use of different diagnostic tests, assays, and criteria based on published guidelines.[552] Using normative data drawn from over 100 healthy control subjects, the authors observed that the prevalence of GHD among 439 patients with TBI was highly dependent on choice of local or guideline-derived cutoffs, on diagnostic tests, and on the use of either single or confirmatory testing. They reported a prevalence of GHD of 4% with the ITT and 12% with the combined pyridostigmine-GHRH test and of isolated GHD in just 1% confirmed from these two tests. The nonspecific symptomology of hypopituitarism and the usually profound and variable CNS consequences of mixed brain and physical injuries pose a major challenge to the identification of pituitary dysfunction and its management. The level of evidence supporting who and when to investigate is low because endocrinopathy is one component of a much larger complex clinical problem. In the acute situation, assessment should focus on the HPA axis because of the vital role glucocorticoids play in the stress response. As pituitary impairment may recover, there is merit in deferring the assessment of the other axes to a time when the vital systems are stable.

Radiation

The progression and degree of hypopituitarism are dose and time dependent with pituitary exposure. Susceptibility is also

dependent on the age of irradiation.[553,554] The GH axis is the most radiosensitive, followed by the gonadotropin, adrenocorticotropic hormone (ACTH), and TSH axes[555,556] (Fig. 8.39). GH deficiency can develop with doses as low as 18 Gy with higher doses (30–50 Gy) that can reach 50% to 100% within 3 to 5 years. Gonadotrophin deficiency occurs with doses in excess of 30 Gy; however, lower doses in children cause precocious puberty. Pituitary irradiation induces hyperprolactinemia, a result of hypothalamic damage. This develops with exposure to 40 Gy or higher and occurs in both sexes in all age groups. Table 8.14 summarizes the conditions for which radiation is given, the exposure to the pituitary gland, and the impact on pituitary function.[557] Pituitary irradiation indicated for pituitary adenoma therapy will directly cause atrophy of the gland, in addition to damaging hypothalamic neurons.[554] Early anterior-pituitary dysfunction seems less likely after stereotactic radiosurgery for pituitary adenomas than after fractionated radiotherapy; however, the long-term, cumulative incidence of anterior-pituitary dysfunction is similar.[553] Previously irradiated patients should therefore undergo lifelong periodic anterior pituitary hormone testing to unmask incipient pituitary failure prior to onset of morbidity.[558]



• **Fig. 8.39** Life-table analysis indicating probabilities of initially normal hypothalamic-pituitary-target gland axes remaining normal after radiotherapy (3750–4250 cGy). Growth hormone (GH) secretion is the most sensitive of the anterior pituitary hormones to the effects of external radiotherapy, and thyroid-stimulating hormone (TSH) secretion is the most resistant. In two-thirds of patients, gonadotropin deficiency develops before adrenocorticotropic hormone (ACTH) deficiency. The reverse occurs in the remaining third. *FSH,* follicle-stimulating hormone, *LH,* lutenizing hormone. (From Littley MD, Shalet SM, Beardwell CG, et al. Hypopituitarism following external radiotherapy for pituitary tumors in adults. *Q J Med.* 1989;70:145–160.)

Empty Sella Syndrome

Damage to the sellar diaphragm may lead to arachnoid herniation into the sellar space. An empty sella may develop as a consequence of a primary congenital weakness of the diaphragm in those patients in whom no secondary cause is evident. Up to 50% of patients with primary empty sella have associated benign intracranial hypertension.[559] A secondary empty sella may develop subsequent to infarction of a pituitary adenoma or surgical or radiation-induced damage to the sellar diaphragm. These patients usually exhibit demonstrable pituitary tissue compressed against the sellar floor, with lateral stalk deviation visible on MRI. Although an empty sella is usually an incidental finding, if more than 90% of pituitary tissue is compressed or atrophied, pituitary failure usually occurs. About 10% of patients may develop small GH-secreting or PRL-secreting adenomas within the narrow rim of compressed pituitary tissue.

Clinical Features of Hypopituitarism

Patients with pituitary failure, regardless of cause, have excessive mortality rates, primarily due to vascular disease.[256] Age at diagnosis, female gender, and history of craniopharyngioma were the most striking determinants of increased fatality. The spectrum of clinical features of pituitary insufficiency depends on several factors. In acquired pituitary insufficiency the clinical spectrum depends upon the degree of hormone deficiency, the number of hormones impaired, and the rapidity of onset. In congenital forms, the earlier the age of onset, the greater the severity of thyroid, gonadal, adrenal, growth,

TABLE 8.14 Pituitary Dysfunction After Cranial Irradiation in Various Conditions

Condition Treated	Schedule	Dose (Gy)	Pituitary Dysfunction
Leukemia and lymphoma	Fractionated TBI Fractionated cranial	7–16 18–24	Isolated GHD, mostly pubertal children Isolated GHD, mostly pubertal children Precocious puberty girls only
Nonpituitary brain tumors	Conventional fractionated cranial	30–50	GHD (30–100%) Gonadotrophin, TSH, ACTH, Prl (3–20%) Precocious puberty both sexes
Nasopharyngeal carcinoma and skull-base tumors	Conventional fractionated cranial	50–70	GHD (100% within 5 yr) Gonadotrophin, TSH, ACTH, Prl (20–50%)
Pituitary tumors	Conventional fractionated cranial	30–50	GHD (100% within 5 yr) Gonadotrophin, TSH, ACTH, Prl (20–60%)

Prl, Prolactin; *TBI,* Total body irradiation.

TABLE 8.15 Assessment of Anterior Pituitary Function

Test	Dose	Normal Response	Side Effects
ACTH			
Insulin tolerance	0.1–0.15 U/kg IV	Peak cortisol response >18 μg/dL, or increase by 7 μg/dL	Sweating, palpitation, tremor
Metyrapone	Oral administration of 30 mg/kg at 11 PM	Peak 11-DOC ≥7 μg/dL Peak cortisol ≤7 μg/dL Peak ACTH >75 pg/mL	Nausea, insomnia, adrenal crisis
CRH stimulation	100 μg IV	Peak ACTH ≥ twofold to fourfold Peak cortisol ≥20 μg/dL or ↑ ≥7 μg/dL	Flushing
ACTH stimulation	250 μg IV or IM or 1 μg IV	Peak cortisol ≥20 μg/dL	Rare
TSH			
Serum T_4 (free T_4) Total T_3 TSH—third generation TRH stimulation	200–500 μg IV	Peak TSH ≥2.5-fold or ↑ ≥5–6 mU/L (females), ↑ ≥2–3 mU/L (males)	Flushing, nausea, urge to micturate
PRL			
Serum PRL TRH stimulation	200–500 μg IV	PRL ≥2.5-fold	Flushing, nausea, urge to micturate
LH/FSH			
Serum LH and FSH Serum testosterone GnRH stimulation	100 μg IV	Elevated in menopause and in men with primary testicular failure 300–900 ng/mL (age-adjusted normal ranges) LH ≥ twofold to threefold, or by 10 IU/L FSH 1.5–2-fold, or by 2 IU/L	Rare
GH			
Insulin tolerance	0.1–0.15 U/kg	GH peak >5 μg/L	Sweating, palpitation, tremor
Glucagon	1–1.5 mg IM	GH peak >3 μg/L	Nausea, headaches
L-Arginine plus GHRH L-Arginine	0.5 g/kg (max 30 g) IV over 30 min	Peak GH >9 μg/L	Nausea
GHRH	1 μg/kg		Flushing

ACTH, Adrenocorticotropic hormone; *CRH,* corticotropin-releasing hormone; *11-DOC,* 11-deoxycorticosterone; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GHRH,* growth hormone–releasing hormone; *GnRH,* gonadotropin-releasing hormone; *IM,* intramuscular; *IV,* intravenous; *LH,* luteinizing hormone; *PRL,* prolactin; T_3, triiodothyronine; T_4, thyroxine; *TSH,* thyroid-stimulating hormone; *TRH,* thyrotropin-releasing hormone.

or water disturbances. Heritable genetic disorders invariably exhibit the most severe phenotypic changes, although later changes may also occur in these disorders, as seen with PROP1 mutations. The resilience of the individual pituitary cell lineages to compressive, inflammatory, vascular, radiation, and invasive insults also differs. The lactotroph cell is often hyperfunctional as a result of decreased tonic inhibitory signals. PRL deficiency is thus exceedingly rare, except for complete pituitary destruction or genetic syndromes. The order of diminished trophic hormone reserve function by pituitary compression usually is as follows: GH > FSH > LH > TSH > ACTH. The corticotroph cell appears particularly resistant to hypothalamic or pituitary destruction and is usually the last cell to lose function. The qualitative phenotypic manifestations of pituitary failure are determined by which specific trophic hormones are lost (see earlier for description of individual hormone deficiencies).

Screening for Pituitary Failure

As the onset of hypopituitarism may be extremely slow, subclinical pituitary failure is often not apparent to the patient or physician. Screening for pituitary dysfunction should be undertaken in patients with hypothalamic or pituitary mass lesions, developmental craniofacial abnormalities, inflammatory disorders, brain granulomatous disease, prior head or neck irradiation, head trauma, prior skull base surgery, those with newly discovered empty sella, and those who have previously experienced pregnancy-associated hemorrhage or blood pressure changes.[560]

As hypopituitarism may develop insidiously and is often not readily clinically apparent, screening of appropriate patients is important to prevent long-term morbidity. Therefore all patients harboring hypothalamic or pituitary masses should be screened for hypopituitarism (Table 8.15). PRL should be measured because many patients with hypopituitarism may also present with secondary hyperprolactinemia. Up

TABLE 8.16 Replacement Therapy for Adult Hypopituitarism[a]

Deficient Hormone	Treatment
ACTH	Hydrocortisone, 10–20 mg daily in divided doses Cortisone acetate, 15–25 mg/day in divided doses
TSH	L-Thyroxine, 0.05–0.2 mg daily according to T_4 levels
FSH/LH	*Males:* Testosterone enanthate, 200 mg IM every 2–3 weeks Testosterone undecanoate 1000 mg IM every 3–6 months Testosterone skin patch, 2.5–5.0 mg/day—can increase dose up to 7.5 mg/day Testosterone gel, 5–10 gm/day (delivering 50–100 mg/day) For fertility: hCG three times weekly, or hCG + FSH or menopausal gonadotropin or GnRH *Females (nonoral route is recommended):* Estradiol skin patch, 4–8 mg, twice weekly Estradiol gel Conjugated estrogen, 0.65 mg daily Micronized estradiol, 1 mg daily Estradiol valerate, 1–2 mg Piperazine estrone sulfate, 1.25 mg All of the estrogens are administered with progesterone or progestin sequentially or in combination if uterus present For fertility: menopausal gonadotropin and hCG or GnRH
GH	*Adults:* Somatotropin, 0.2–1.0 mg SC daily *Children:* Somatotropin, 0.02–0.05 mg/kg/day
Vasopressin	Intranasal desmopressin, via rhinal tube, 5–20 μg twice daily Oral DDAVP, 300–600 μg daily, usually in divided doses

[a]Doses shown should be individualized and reassessed during stress, surgery, or pregnancy. Male and female fertility management is fully discussed in Chapter 26.

ACTH, Adrenocorticotropic hormone; *DDAVP,* desmopressin acetate; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GnRH,* gonadotropin-releasing hormone; *hCG,* human chorionic gonadotropin; *IM,* intramuscularly; *SC,* subcutaneously; T_4, thyroxine.

to two-thirds of patients harboring pituitary macroadenomas, craniopharyngiomas, and other parasellar lesions have compromised pituitary reserve function. Less commonly, patients with intrasellar aneurysms, pituitary metastases, parasellar meningiomas, optic gliomas, and hypothalamic astrocytomas may also have pituitary failure. Although about a third of patients with hypopituitarism undergoing pituitary surgery recover function after decompression, about 25% of patients experience further loss of pituitary function after surgery and therefore should be screened annually. Treatment regimens for pituitary failure are described in Table 8.16.

Pituitary Masses and Tumors

SHLOMO MELMED

CHAPTER OUTLINE

KEY POINTS

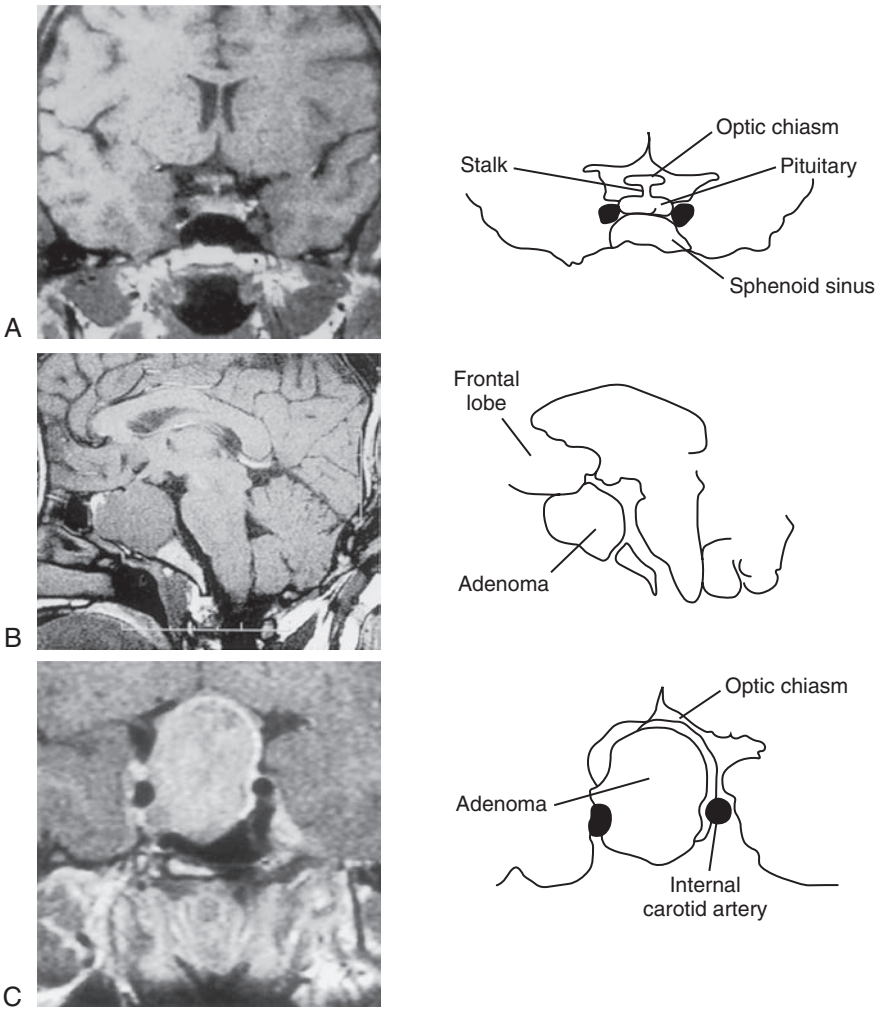
- Intrapituitary or parasellar masses are mostly benign pituitary adenomas.
- Nonpituitary sellar masses are rare and are usually inflammatory processes, infiltrations, or metastatic deposits, or may arise from adjacent structures, including aneurysms, meningiomas, or chordomas.
- Nonsecreting pituitary adenomas are usually of gonadotroph or null cell origin and usually present with compressive features or are diagnosed as incidentalomas.
- Secreting pituitary adenomas exhibit unique syndromes due to excess production of prolactin (prolactinomas), growth hormone (acromegaly/gigantism), adrenocorticotrophic hormone (Cushing disease), or very rarely, thyrotrophic hormone or gonadotrophins.
- Management of pituitary masses includes surgery, radiation, and specific targeted medical therapies.

Pituitary Masses

Pituitary Mass Effects

An expanding intrasellar mass may compress normal pituitary tissue and inexorably alter sellar size and shape by bony erosion and remodeling (Fig. 9.1). Although the time course for this process is unclear, it appears to be slowly progressive over years or decades. The tumor may invade soft tissue, and the dorsal sellar roof presents the least resistance to expansion from within the confines of the bony sella. Both suprasellar and parasellar compression and invasion may occur with an enlarging mass, with resultant clinical manifestations (Table 9.1). As sellar masses impinge upon the optic chiasm, they may interfere with vision. Because of the anatomy of the chiasm, pressure from below affects temporal visual fields, starting superiorly and ultimately extending to the entire temporal field. Continued growth and pressure on the optic apparatus can extend visual loss to the nasal field and may ultimately result in blindness. Long-standing optic chiasmal pressure results in optic disc atrophy. Extension of pituitary lesions laterally may also impinge on or invade the dural wall of the cavernous sinus. Despite invasion, these lesions only rarely compromise the third, fourth, and sixth cranial nerves, as well as the ophthalmic and maxillary branches of the fifth cranial nerve. Although tumors in the cavernous sinus often surround the internal carotid artery, clinical vascular sequelae are rarely encountered. Varying degrees of diplopia, ptosis, ophthalmoplegia, and decreased facial sensation may occur infrequently, depending on the extent of neural involvement by the cavernous sinus mass. In contrast to cavernous invasion by slow tumor progression, sudden insults to the cavernous sinus by hemorrhage or infarction of a pituitary tumor occur more frequently and may affect nerves coursing through the sinus. Downward extension into the sphenoid sinus indicates that the parasellar mass has eroded the bony sellar floor. Aggressive tumors may also invade the roof of the palate and cause nasopharyngeal obstruction, infection, and cerebrospinal fluid (CSF) leakage. Infrequently, temporal or frontal lobes may be invaded, causing uncinate seizures, personality disorders, and anosmia. In addition to the anatomic lesions caused by the expanding mass, direct hypothalamic involvement of the encroaching mass may lead to important metabolic sequelae discussed in Chapter 7.

Intrasellar tumors commonly present with headaches, even in the absence of demonstrable suprasellar extension. Small changes in intrasellar pressure caused by a microadenoma within the



• **Fig. 9.1** Magnetic resonance images of the pituitary. (A) Coronal section of a normal pituitary gland. (B) Sagittal view of a large pituitary adenoma lifting and distorting the optic chiasm and invading the sphenoid sinus and impinging the frontal lobe. (C) Coronal view of a large macroadenoma elevating the optic chiasm and invading the right cavernous sinus.

confined sella are sufficient to stretch the dural plate with resultant headache. Headache severity does not correlate with the size of the adenoma or the presence of suprasellar extension.[1] Relatively minor diaphragmatic distortions or dural impingement may be associated with persistent headache. Successful medical management of small functional pituitary tumors with dopamine agonists or somatostatin analogues is often accompanied by remarkable headache improvement. In a retrospective assessment of transsphenoidal surgery for microadenomas, headaches resolved or disappeared in 90% of patients with nonfunctioning tumors and in 56% of those with functioning tumors.[2] Regardless of cause or size, pituitary masses, including adenomas, may be associated with compression of surrounding healthy pituitary tissue and resultant hypopituitarism. In 49 patients undergoing transsphenoidal resection of pituitary adenomas, mean intrasellar pressure was elevated twofold to threefold in patients with associated pituitary failure. Furthermore, prevalence of headache and elevated prolactin (PRL) levels correlate positively with intrasellar pressure levels,[3] suggesting interrupted portal delivery of hypothalamic hormones. Thus, surgical decompression of a sellar mass may lead to recovery of compromised anterior pituitary function. In patients who do not recover pituitary function postoperatively, irreversible compromised pituitary reserve or ischemic necrosis of residual pituitary tissue is likely to have occurred. Stalk compression may result in pituitary failure caused by encroachment of the portal vessels that normally provide pituitary access to hypothalamic trophic hormones. Stalk compression also usually leads to hyperprolactinemia due to compromised dopamine access, with concomitant failure of other pituitary trophic hormones.

Evaluation of Pituitary Masses

Approach to the Patient Harboring a Pituitary Mass

Most pituitary masses are adenomas. Ninety-one percent of 1120 patients undergoing transsphenoidal surgery for sellar masses were diagnosed as harboring pituitary adenomas.[4] In a series of 2598 patients undergoing pituitary magnetic resonance imaging (MRI), pituitary adenomas accounted for 82% of visible lesions. Most commonly encountered nonadenomatous lesions include Rathke cleft cyst, craniopharyngioma, and meningioma,[5] with Rathke cysts accounting for up to 40% of all such masses.[6] Thus, the

TABLE 9.1 Local Effects of an Expanding Pituitary, Parasellar, or Hypothalamic Mass

Impacted Structure	Clinical Effect
Pituitary	Growth failure, adult hyposomatotropism, hypogonadism, hypothyroidism, hypoadrenalism
Optic tract	Loss of red perception, bitemporal hemianopia, superior or bitemporal field defect, scotoma, blindness
Hypothalamus	Temperature dysregulation, obesity, diabetes insipidus; thirst, sleep; appetite, behavioral, and autonomic nervous system dysfunctions
Cavernous sinus	Ptosis, diplopia, ophthalmoplegia, facial numbness
Temporal lobe	Uncinate seizures
Frontal lobe	Personality disorder, anosmia
Central	Headache, hydrocephalus, psychosis, dementia, laughing seizures
Neuro-ophthalmologic tract	*Field defects:*
	Bitemporal hemianopia (50%), amaurosis with hemianopia (12%), contralateral or monocular hemianopia (7%)
	Scotomas—junctional; monocular central, arcuate, altitudinal; hemianopic
	Homonymous hemianopia
	Acuity loss:
	Snellen
	Contrast sensitivity
	Color vision
	Visual evoked potential
	Pupillary abnormality:
	Impaired light reactivity
	Afferent defect
	Optic atrophy:
	Papilledema
	Cranial nerve palsy—oculomotor, trochlear, abducens, sensory trigeminal
	Nystagmus
	Visual hallucinations
	Postfixation blindness

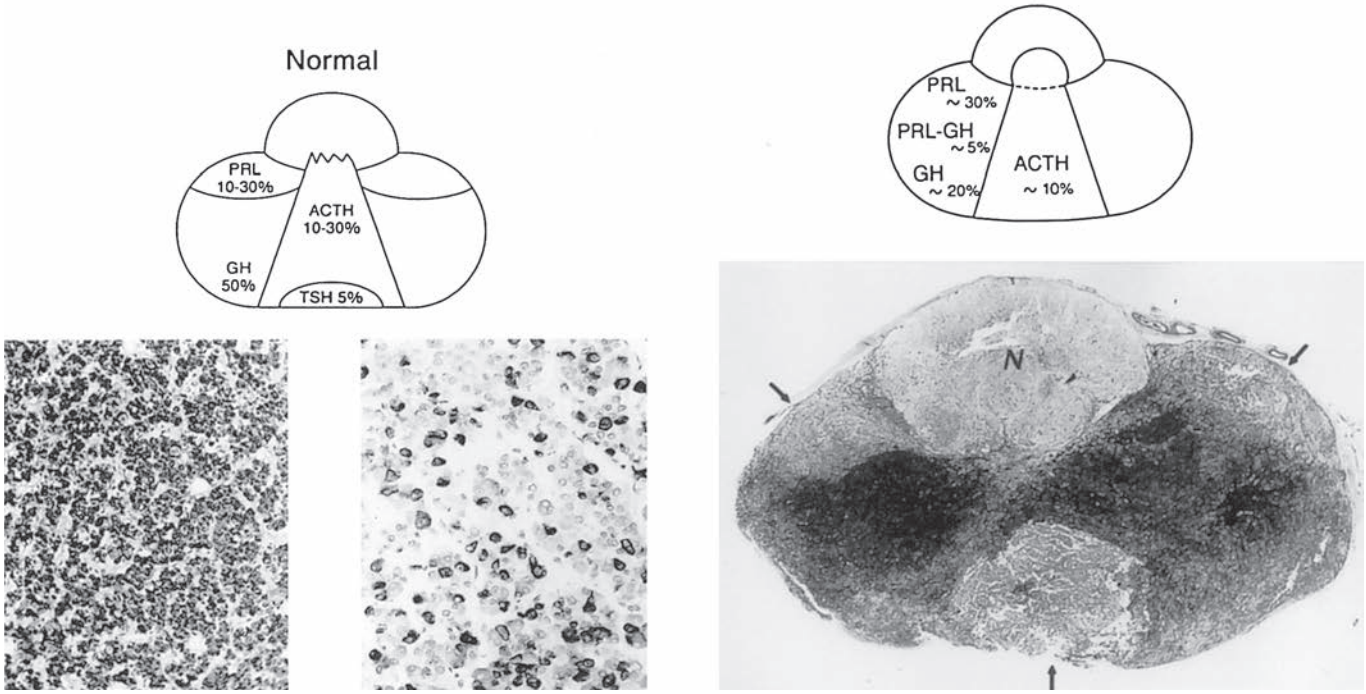
differential diagnosis of a pituitary mass should be aimed at excluding the diagnosis of a pituitary adenoma before considering the presence of other rare sellar lesions. Pituitary adenomas arise from differentiated cells secreting trophic hormones, including growth hormone (GH), PRL, adrenocorticotrophic hormone (ACTH), thyroid-stimulating hormone (TSH, thyrotrophic hormone), or gonadotrophins. These tumors may hypersecrete respective hormones or may be clinically nonsecreting (Fig. 9.2). The management and prognosis of anterior pituitary adenomas differ markedly from those for other nonpituitary masses, and an important diagnostic challenge is to effectively distinguish a pituitary adenoma from other parasellar masses. Several physiologic states are associated with pituitary enlargement. Lactotroph hyperplasia occurs during pregnancy, and thyrotroph, gonadotroph, or rarely corticotroph hyperplasias occur in the presence of long-standing primary thyroid, gonadal, or adrenal failure, respectively.[7] Pituitary enlargement may also occur as a result of ectopic GH-releasing hormone (GHRH) or corticotrophin-releasing hormone (CRH) secretion, from pulmonary and pancreatic neuroendocrine tumors or hypothalamic gangliocytomas, with resultant hyperplasia of somatotroph or corticotroph cells. Autopsy series show that up to 20% of subjects harbor an incidental clinically silent pituitary adenoma (incidentaloma). With the widespread use of sensitive imaging techniques for nonpituitary indications, including head trauma, chronic sinusitis, or headaches, previously inapparent pituitary lesions are being identified with increasing frequency. Incidental pituitary cysts, hemorrhages, and infarctions are also discovered at autopsy. Pituitary abnormalities compatible with the diagnosis of microadenoma are detectable in about 10% of the normal adult population undergoing MRI studies.[8] Recognizing that approximately 90% of observed pituitary lesions represent pituitary adenomas, initial assessment should determine whether the mass is hormonally functional and whether local mass effects are apparent at the time of diagnosis or likely to develop in the future.

As the onset of clinical features associated with disordered hormone secretion is insidious and may be unnoticed for years or decades, endocrine function should always be tested at presentation (Table 9.2). Clinical evaluation for changes compatible with hypersecretion or hyposecretion of GH, gonadotrophins, PRL, or ACTH may reveal unique long-term sequelae requiring distinct therapies. In the absence of clinical features of a humoral hypersecretory syndrome, cost-effective laboratory screening should be performed. Serum PRL levels greater than 200 ng/mL strongly suggest the presence of a microprolactinoma or macroprolactinoma. Any elevation in serum PRL from minimal to high can occur when a microadenoma is present. A minimal to moderate elevation can also indicate secondary stalk interruption by a pituitary mass (usually a nonfunctioning macroadenoma). A PRL level greater than 500 ng/mL in a nonpregnant individual is considered pathognomonic of a prolactinoma, as significant PRL elevations can be caused by drugs such as risperidone and other second-generation antipsychotics.[9] Elevated age-matched and gender-matched insulin-like growth factor 1 (IGF1) levels indicate the presence of GH-secreting adenoma, and a high 24-hour urinary free cortisol level or elevated nighttime salivary cortisol[10] is an effective screen for most patients with Cushing disease. Nevertheless, the overall incidence of functional hormone-secreting tumors in asymptomatic subjects with incidentally discovered pituitary masses is low. The presence of, or the potential for, local compressive effects must also be considered. Because the risk for microadenoma progression to a compressive macroadenoma is low, no direct intervention may be warranted. For parasellar masses of uncertain origin, histologic examination of surgically excised tissue may be the best approach to yield an accurate diagnosis. Clearly, the benefits versus risks of biopsy or surgery should be considered in such cases, especially for lesions that are not growing or not causing a functional deficit. Although imaging features may



• **Fig. 9.2** Distribution of normal adenohypophyseal cells is reflected in pituitary adenomas. Nonfunctioning tumors, on the other hand, are typically macroadenomas that efface pituitary landmarks. The localization and frequency of functioning microadenomas reflect the maximal concentration of their corresponding normal pituitary cells. TABLE 9.2 Screening Tests for Functional Pituitary Adenomas

Disorder	Test	Comments
Acromegaly	IGF1 OGTT with GH obtained at 0, 30, and 60 minutes	Interpret IGF1 relative to age-matched and gender-matched control subjects. Normal subjects should suppress GH to <1 μg/L.
Prolactinoma	Serum PRL level	A level >500 ng/mL is pathognomonic for macroprolactinoma. If >200 ng/mL, prolactinoma is likely.[a]
Cushing disease	24-hour UFC Nighttime salivary cortisol Dexamethasone (1 mg) at 11 PM and fasting plasma cortisol measured at 8 AM ACTH assay	Ensure that urine collection is total and accurate by measuring urinary creatinine. Free salivary cortisol reflects circadian rhythm, and elevated levels may indicate Cushing disease. Normal subjects suppress to <1.8 μg/dL. Distinguishes adrenal adenoma from ectopic ACTH secretion or Cushing disease.
TSH-secreting tumor	TSH measurement Free T_4 by dialysis Total T_3	If T_4 or T_3 is elevated and TSH is measurable or elevated, a TSH-secreting tumor may be present.

[a]Risperidol may result in prolactin levels >200 ng/mL.

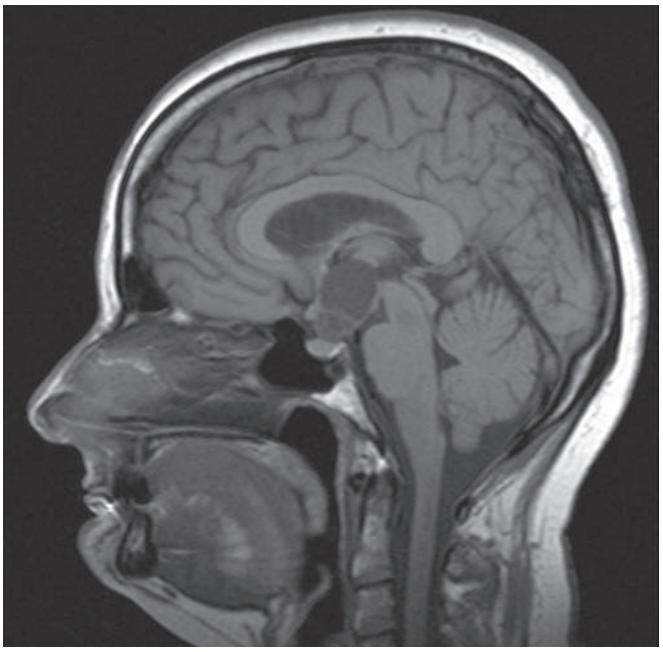
be helpful in diagnosing the cause of a nonpituitary sellar mass, the final diagnosis may remain elusive until pathologic confirmation is obtained.

Parasellar masses include neoplastic and nonneoplastic lesions and manifest clinically by local compression of surrounding vital structures or as a result of metabolic or hormonal derangements. Rarely, sellar masses or infiltrative processes may be the presenting feature of a previously undiagnosed systemic disorder such as lymphoma, tuberculosis,[11] sarcoidosis, or histiocytosis.[12] Fever with or without associated sterile or septic meningitis may rarely be caused by fluid leakage into the subarachnoid space from Rathke cleft, dermoid, and epidermoid cysts, craniopharyngioma, and apoplexy.[13] Pituitary masses may present with hemorrhage and infarction, especially during pregnancy (see earlier discussion), when there is a pituitary tumor or when elderly individuals with unsuspected pituitary tumors become hypotensive because of another illness. Rarely, these adenomas present with CSF leak, which may predispose to meningitis. Pituitary masses may also undergo silent infarction leading to development of a partial or totally empty pituitary sella, with normal pituitary reserve, implying that the surrounding rim of pituitary tissue is fully functional. Rarely, functional pituitary adenomas may arise within the remnant pituitary tissue, and these tumors may not be visible by sensitive MRI (i.e., <2 mm in diameter), despite their endocrine hyperactivity. More than one kind of tumor may be found coincidentally in the same patient, such as a pituitary tumor and a meningioma[14] or pituitary adenoma with a craniopharyngioma component.[15] Acute or chronic infection with abscess formation may rarely occur within the mass. Compromised pituitary hormone hyposecretion may be due to direct pressure effects of the expanding mass on hormone-secreting cells or parasellar pressure effects that attenuate synthesis or secretion of hypothalamic hormones, with resultant pituitary failure.

Imaging

Tumors of the pituitary gland are best diagnosed with MRI because the technique has better resolution than other radiologic modalities for identifying soft tissue changes (see Fig. 9.1). When a pituitary tumor or other parasellar mass is suspected, an MRI specifically focused on the pituitary should be performed, as more widely spaced cuts during a routine brain MRI are often inadequate to visualize relatively small pituitary tumors.[16] This technique permits high-contrast detailed visualization of tumor mass effects on neighboring soft tissue structures, including the cavernous sinus or optic chiasm. A pituitary MRI includes images of the optic chiasm, hypothalamus, pituitary stalk, and cavernous and sphenoid sinuses.[17] High-resolution T1-weighted sections in the coronal and sagittal plane both before and after gadolinium-based contrast administration will distinguish most pituitary masses. Slice thickness should be less than 3 mm to obtain a pixel of 1 mm. Contiguous sections are therefore required to diagnose lesions of 1 to 3 mm. If necessary, especially for diagnosing high-signaling hemorrhage, T2-weighted images will provide additional diagnostic information. MRI thus clearly delineates the pituitary gland, stalk, optic tracts, and surrounding soft tissues. The gland may be concave, convex, or flat. The posterior pituitary lobe exhibits a discrete bright spot of high signal intensity on T1-weighted images, which declines with age and is absent in diabetes insipidus and most posterior pituitary lesions. This T1 shortening may reflect the presence of antidiuretic hormone (ADH) localized within neurosecretory vesicles.[18] The pituitary gland may transiently enlarge during adolescence, pregnancy, and postpartum, with teenage girls exhibiting increasing gland convexity during the menstrual cycle. During pregnancy, the gland should normally not exceed 10 to 12 mm, and the stalk should not exceed 4 mm in diameter. Pregnant women may rarely develop visual field deficits due to an enlarging pituitary gland even in the absence of a pituitary tumor. A thickened stalk may indicate the presence of hypophysitis, granuloma, germinoma, or chordoma. After gadolinium injection, microadenomas usually appear hypodense compared to the normal gland, especially when multiple thin section echo sequences are examined in the first few minutes after contrast agent injection. It has been suggested that intrasellar hypointensity may reflect compromised microadenoma vasculature.[19] Microadenomas may also cause gland asymmetry or stalk deviation. In contrast, macroadenomas, which are significantly more vascular than microadenomas, have a higher uptake of gadolinium. They often enlarge the sella turcica by remodeling the bony fossa, suggesting a gradual long-term process. These tumors can grow upward toward the optic apparatus and cause draping of the nerves over the tumor, often accompanied by visual field abnormalities. Tumors can also extend into the sphenoid sinus and not infrequently invade connective tissue separating the pituitary from the cavernous sinus. Radiologically, visible tumor tissue surrounding the carotid artery confirms cavernous sinus invasion. Infrequently, these patients may develop palsies of the third, fourth, or sixth cranial nerves. MRI may readily distinguish pituitary adenomas from other masses, including hyperplasias, craniopharyngiomas, meningiomas, chordomas, cysts, and metastatic lesions. Visualization of a distinct pituitary gland adjacent to a parasellar mass (Fig. 9.3) suggests that the mass is not of pituitary origin. Secondary distinguishing features such as visualization of noninvolved pituitary tissue, mass consistency, calcification, hemorrhage, and suprasellar involvement usually allow an imaging diagnosis of these masses, which can often only be confirmed by direct tissue histologic diagnosis. Preoperative



• **Fig. 9.3** Sagittal magnetic resonance image of a craniopharyngioma, with cystic and solid components. The tumor is in the suprasellar area located above a normal pituitary gland. The presence of a separate pituitary gland indicates that the suprasellar tumor is not of pituitary origin. (Courtesy N. Karavitaki.)

localization of carotid artery aneurysms can also be confirmed by MRI or MR angiography. Administration of gadolinium may be contraindicated in patients with impaired renal function because it may cause acute renal failure or be associated with nephrogenic systemic fibrosis.[20]

Pituitary computed tomography (CT) allows visualization of bony structures, including the sellar floor and clinoid bones, and identifies bony invasion. CT also recognizes calcifications that characterize craniopharyngiomas, meningiomas, and rarely aneurysms that are not evident on MRI. Rarely, pituitary adenomas may calcify. Pituitary CT scan is indicated for discovery of hemorrhagic lesions, metastatic deposits, chordomas, and evidence of calcification.

Receptor Imaging

As prolactinomas express dopamine 2 (D_2) receptors, they can be imaged with a radiolabeled D_2 receptor antagonist by using ^{123}I-iodobenzamide single-photon emission scanning. Failure to visualize nonfunctioning tumors by this technique has led some to advocate its use to distinguish the two tumor types.[21] Radiolabeled indium-pentetreotide has been used for in vivo tumor imaging. Most pituitary adenomas express somatostatin receptor subtypes to a varying degree, thus limiting the specificity of the procedure. As the sensitivity of single-photon emission CT (SPECT) is about 1 cm, and also detects normal pituitary tissue receptor expression, its use is limited for pituitary tumor detection, but it may be helpful for imaging ectopic ACTH-secreting tumors.

Neuro-Ophthalmologic Assessment of Pituitary Masses

The optic tracts are particularly vulnerable to compression by expanding pituitary masses. Accurate neuro-ophthalmologic evaluation is helpful for tumor diagnosis, determining pretreatment baseline visual status for posttreatment monitoring, or detection of mass recurrence.[22] The relationship of the optic chiasm and the intracranial components of the optic nerves with the pituitary gland and surrounding vessels are depicted in Fig. 9.4. A 10-mm posteriorly angled gap separates the optic chiasm and diaphragma sellae (Fig. 9.5). Therefore extensive suprasellar mass extension is required before visual function is compromised. Decussation of neural fibers originating from the nasal half of each retina occurs at the chiasm, and those originating from the temporal retinal halves are situated ipsilaterally.[23] Fibers from the superior and inferior retinal aspect are segregated in the corresponding chiasmal regions. Local vascular compromise and chiasmal stretching contribute to the pathogenesis of selective visual compromise. Reversibility of visual effects may correlate inversely with acuteness of the compressive insult, and long-standing visual tract compression from larger tumors invariably leads to adverse outcomes.

Visual Symptoms

An abnormal visual examination may unmask the presence of a pituitary mass in an asymptomatic patient. Prior to the availability of sophisticated assay and imaging techniques, virtually all pituitary masses presented with visual loss. Currently, fewer than 10% of patients present with visual loss and most harbor clinically nonfunctioning pituitary adenomas often detected by incidental imaging. Unilateral or bilateral temporal or central visual loss is often asymmetric and may be quite insidious, remitting, or recurring. Rarely, sudden visual loss occurs in a previously asymptomatic patient. Other symptoms include diplopia, impaired depth perception, and very rarely visual hallucinations.[24] The retinal nerve fiber layer may be decreased as a reflection of optic atrophy.[25]

Clinical Signs and Approach

Impingement of the inferior crossing chiasmal fibers leads to bitemporal visual loss, especially in the superior field portions, accounting for most pituitary-related visual defects (Fig. 9.6). Rarely, tumors compress the optic chiasm from above and cause inferior temporal compromise. As damage to the optic chiasm becomes more extreme, field cuts can extend into the nasal field and also cause optic atrophy. Pituitary-related defects preferentially marginate at the vertical field midline in contrast to other causes of bitemporal defects, which tend to occur away from the midline. Despite prominent field defects, many of which can be directly correlated with defined tumor location by MRI, visual acuity in the remaining fields is invariably normal in most patients. Anterior tumor extension may damage central visual acuity.[26] Rarely, pupillary abnormalities, optic atrophy, papilledema, cranial nerve palsies, and nystagmus may be encountered. Preoperatively, asymptomatic visual field deficits should be identified by visual field and acuity testing by automated quantitative perimetry, assessment of visual evoked potentials, and afferent pupillary defects, as well as disc appearance. Employing optic coherence tomography to assess retinal fiber layer thickness or damaged ganglion cell layer may provide an indication of potential for postoperative vision recovery.[22]

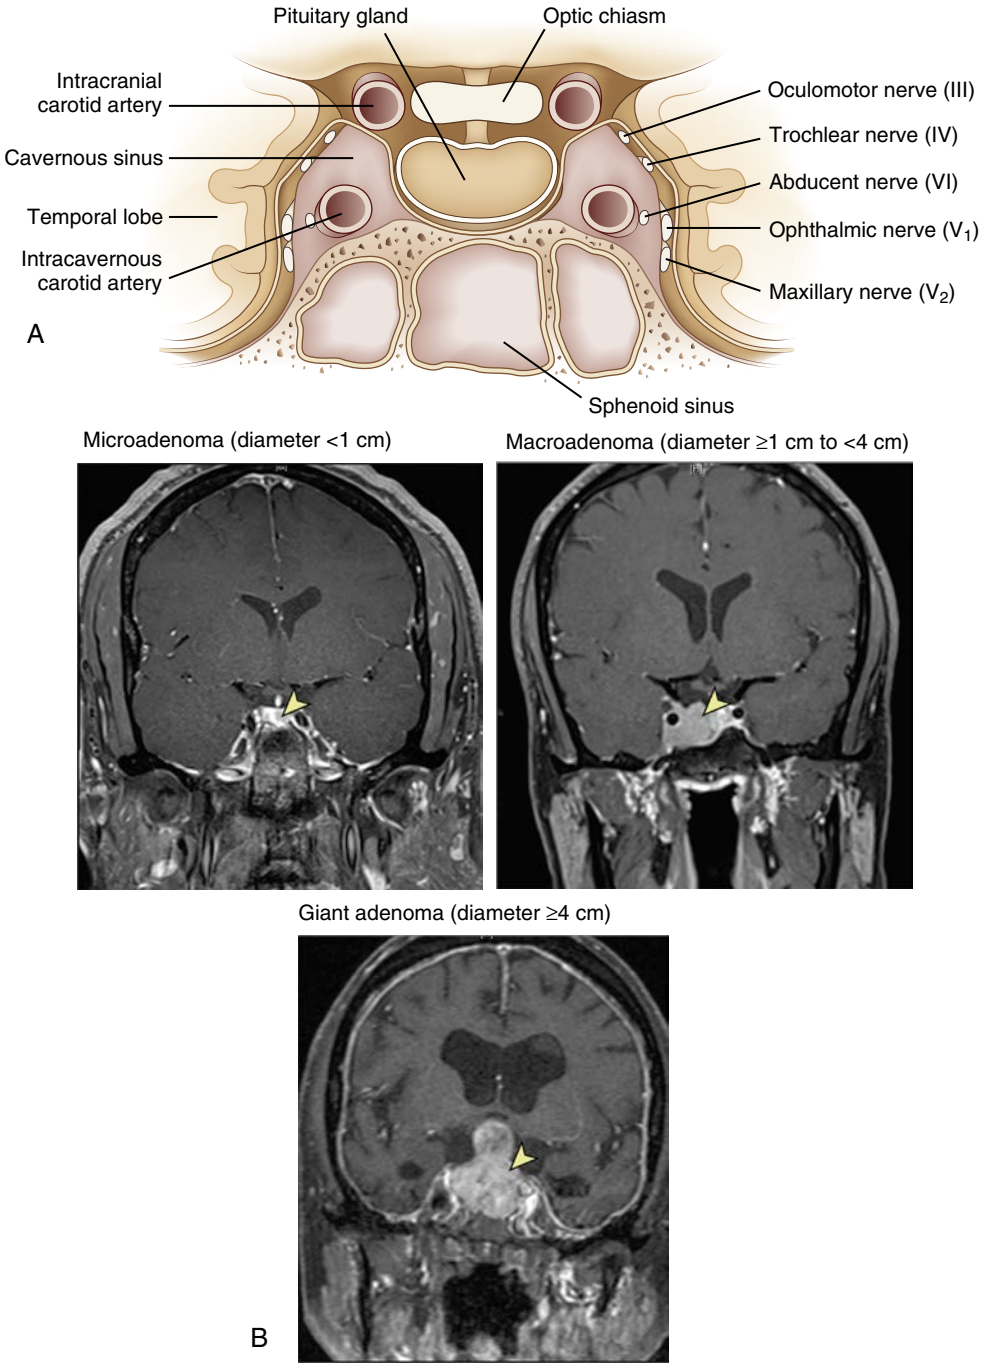
Management of Pituitary Masses

Although pituitary masses are usually benign, they may compress local structures or invade brain tissue (Fig. 9.7). The goals of therapy are to alleviate local compressive mass effects and to suppress hormone hypersecretion or relieve hormone hyposecretion, while maintaining intact pituitary trophic function. Three modes of available therapy include surgical, radiotherapeutic, and medical approaches. In general, the benefits of each type of therapy should be weighed against their respective risks, and comprehensive physician and patient awareness is required to individualize treatment approaches. Appropriate consolidated approaches from expert endocrinologists, neurosurgeons, radiologists, pathologists, and ophthalmologists have been advocated as ideal management teams in pituitary centers of excellence.[27]

Surgical Management of Pituitary Tumors and Sellar Masses

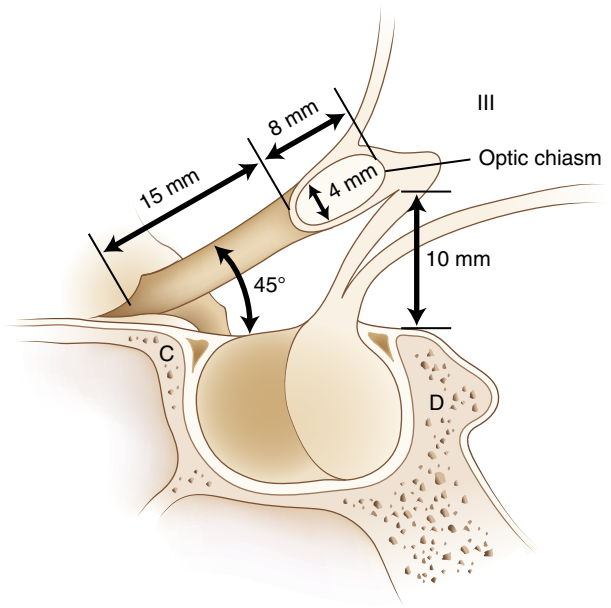
Pituitary surgery is indicated for excision of mass lesions causing central pressure effects, including visual compromise, primary correction of hormonal hypersecretion, or functional tumor resection in patients resistant or not immediately responsive to medical treatment. Unusual sellar lesions may require diagnostic tissue evaluation, and rarely, primary or secondary parasellar malignancies require wide excision.

In 1904, Horsley reported the surgical resection of a pituitary tumor by a lateral middle fossa approach.[28] The first successful transsphenoidal approach for pituitary tumor resection was reported by Schloffer in 1907[29] and subsequently refined by Cushing, who between 1910 and 1925 operated on 231 patients harboring pituitary tumors with a remarkably low 5.6% mortality rate.[28] Cushing used a sublabial incision to enable an endonasal approach for removing the septum and improved visualization using the Kanavel headlight. Hardy later improved the technique by using the operating microscope and intraoperative fluoroscopy, resulting in markedly reduced morbidity and mortality rates compared to those usually encountered with craniotomy, and his approach became the mainstay surgical technique for resecting these tumors.



• **Fig. 9.4** Coronal section of sellar structures and cavernous sinus. (A) Illustration showing the relationship of the oculomotor (III) and trochlear (IV) cranial nerves to the pituitary gland. (B) MRI of pituitary microadenoma *(left),* macroadenoma *(right),* and giant adenoma *(bottom). Arrows* indicate location of adenoma. (A, from Silver SI, Sharpe JA. Neuro-ophthalmologic evaluation of pituitary tumors. In: Thapar K, Kovacs K, Scheihauer BW, et al, eds. *Diagnosis and Management of Pituitary Tumors.* Totowa, NJ: Humana Press; 2001:173–200; B, from Molitch ME. Diagnosis and treatment of pituitary adenomas: a review. *JAMA.* 2017;317:516–524.)

The transsphenoidal approach avoids invasion of the cranial cavity and precludes the need for brain tissue manipulation required during a subfrontal surgical approach (Fig. 9.8). A ventral sphenoid approach for resection of pituitary masses likewise does not violate the cranial fossa. Thus, transsphenoidal surgery is associated with minimal morbidity and mortality rates, most patients are ambulatory within 6 to 9 hours, and the hospital stay is generally about 3 days. Furthermore, the transsphenoidal approach allows for a clearly visible operative field with high magnification and internal illumination. Normal pituitary can be clearly distinguished from tumor tissue, facilitating microdissection and small tumor resection (Fig. 9.9). The use of the transsphenoidal approach has been greatly enhanced by several technologic advances, including head immobilization techniques, microinstrumentation development,



• **Fig. 9.5** Relationship of the pituitary gland to the optic chiasm. The intracranial optic nerve/chiasmal complex lies up to 10 mm above the diaphragma sellae. *C,* anterior clinoid process; *D,* dorsum of the sella turcica. (From Miller NR. *Walsh and Hoyt's Clinical Neuro-Ophthalmology,* 4th ed, vol 1. Baltimore, MD: Williams & Wilkins; 1985:60–69.)

and novel angled endoscopes. Enhanced MRI sensitivity and precision, as well as intraoperative use of MRI, allow for clear delineation of tumor location, size, and invasiveness—all critical determinants of surgical success.

The endoscopic surgical technique has enabled an approach to both intrapituitary and some extrasellar masses.[30] Most approaches are endonasal[31] but some traverse the cranial base, and suprasellar lesions are reached by transposing the pituitary to access the lesion. In experienced hands, the endoscopic technique results in similar complication rates and outcomes, as compared to the traditional transsphenoidal approach.[32,33]

Craniotomy is indicated for the rare invasive suprasellar masses extending into the frontal or middle cranial fossa, optic nerves, or extensive posterior clival invasion. Suprasellar extension contained by a small diaphragmatic aperture ("hour-glass configuration") may also require a transcranial approach. Very rarely, tumors that are too solid to be removed transsphenoidally may require a combination of transsphenoidal and intracranial surgery.

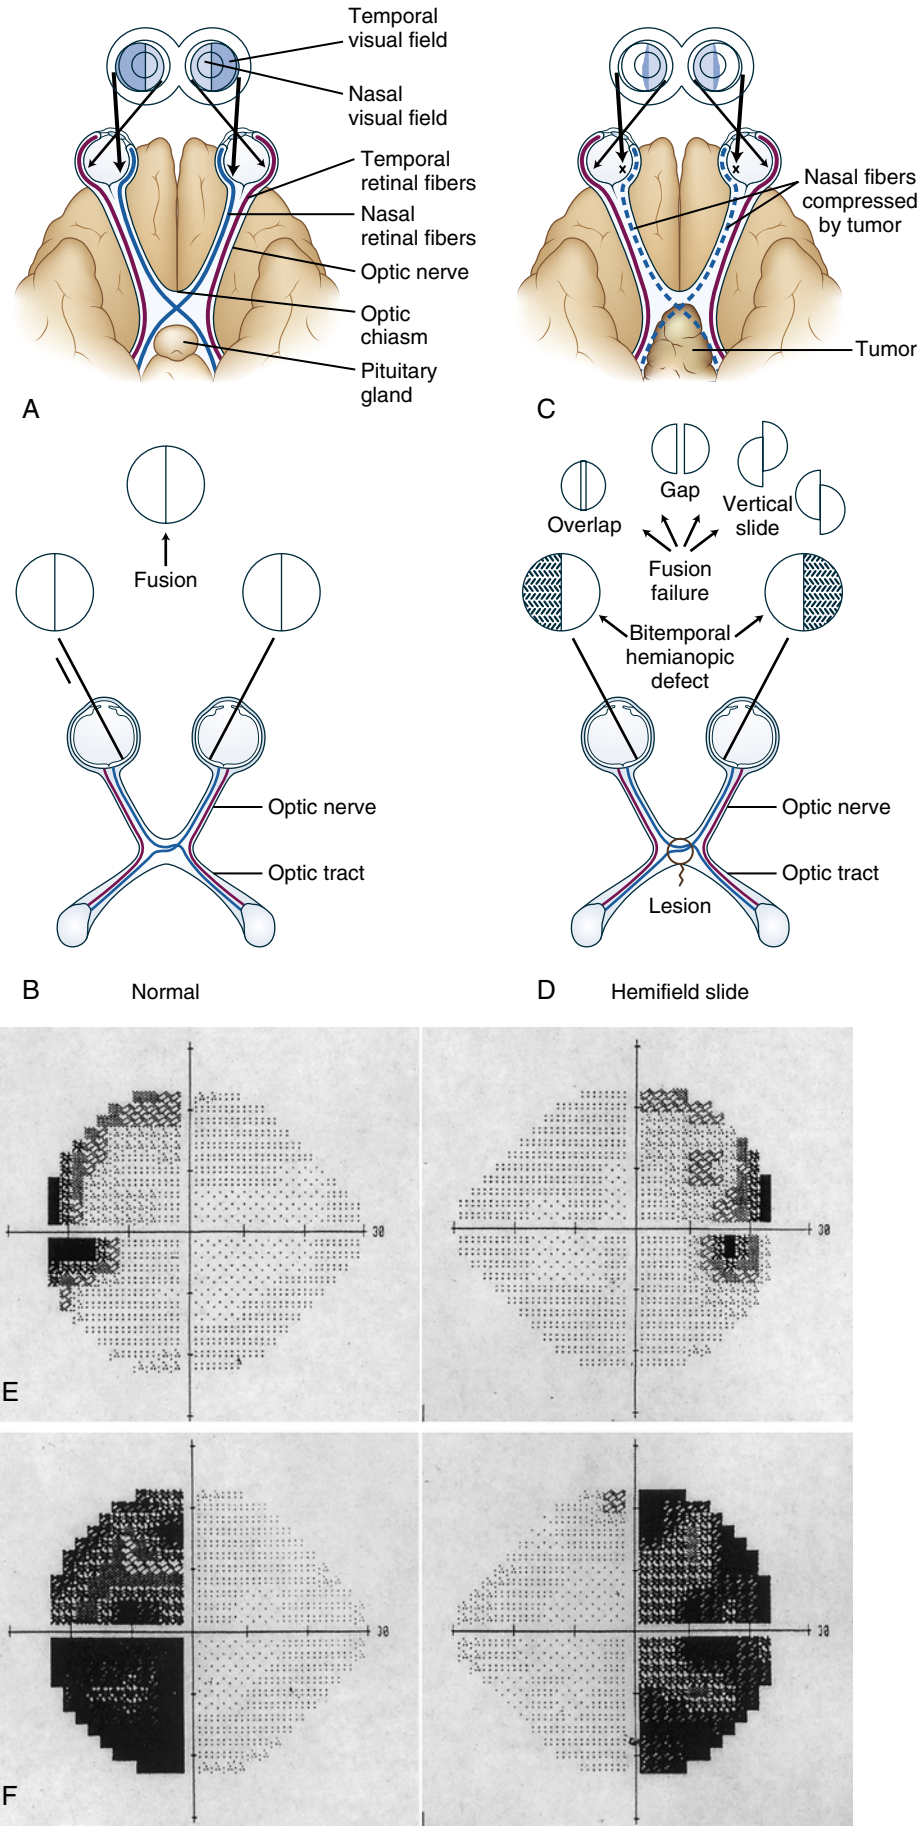
Goals of Surgery

The goal of pituitary surgery is for total resection limited to the lesion, without compromising postoperative endogenous pituitary function.[34] Careful selective mass resection may be difficult for poorly encapsulated lesions, those embedded deeply within the gland body, and those extending into the wall or the body of the cavernous sinuses or suprasellar lesions. However, suprasellar tumors (e.g., craniopharyngiomas) may also be successfully removed via a transnasal approach. Poor operative field visibility also limits precise resection. Excision of normal pituitary tissue and intraoperative gland manipulation should be avoided unless critical for effective tumor dissection. Occasionally, hemihypophysectomy or even nonselective total gland resection may be indicated for multifocal tumors if the surrounding normal gland is necrotic or if no mass lesion is discernible despite an accurate clinical and biochemical diagnosis (especially for ACTH-cell tumors). Successful surgery should decompress central visual defects and compromised trophic hormone secretion. For children and young adults, the consideration of adequate normal tissue for subsequent growth patterns and reproductive function is an important determinant for intraoperative decision making. Nevertheless, especially for functional tumors, small residual remnants attached to the dura are difficult to access but remain hypersecretory with persistent clinical progression. Thus the skilled neurosurgeon will carefully balance maximally effective tumor removal with the requirement to preserve nontumorous pituitary trophic function.

Recent advances have enabled improved surgical results, and long-term outcomes using new techniques have been rigorously compared to standard operations performed by skilled surgeons.[34,35] Image-guided approaches enable intraoperative surgical navigation by three-dimensional (3D) imaging. Intraoperative ultrasound and MRI technologies allow for real-time assessment of the dimensions and extent of the pituitary mass and the progress of surgery. Intraoperative MRI is performed while the surgical field is still open, thus allowing the surgeon to directly assess the need for further dissection, and provides an excellent baseline for postoperative follow-up. If there is suspicion of a vascular lesion, carotid and intracranial angiography is indicated prior to surgery. In contrast, postoperative image stabilization may not be evident for months after surgery, and MRI may be useful only after 1 year or longer, especially after resection of secretory tumors with measurable serum biomarkers.[36] Endonasal transsphenoidal endoscopy (Fig. 9.10) avoids use of a retractor or speculum, does not require nasal packing, and sometimes leads to a shorter operating time, allowing for reduced postoperative morbidity and a shorter hospital stay. The advantages of the technique include a clear panoramic view of bony landmarks and the ability to access suprasellar and parasellar tumor extensions into the cavernous sinuses.[32] Disadvantages of this approach include the management of perioperative intrasellar bleeding and CSF leaks. Combining both techniques may allow the advantages of both approaches.

Indications for Transsphenoidal Surgery

A pituitary mass that may or may not be compressing local vital structures should be evaluated for surgical resection (Table 9.3). Although surgical resection offers a rapid resolution of hormone hypersecretion and many of the resultant clinical features of functioning adenomas, indications for the procedure differ depending on tumor type (see upcoming discussion). In general, patients who are intolerant or resistant to medical therapy require surgery. Surgery is primarily indicated for patients with well-circumscribed GH-secreting adenomas, TSH-secreting adenomas, all ACTH-secreting tumors, and nonfunctioning macroadenomas that require surgery. Surgery may also be indicated when tissue histologic confirmation is required for diagnosing the nature of an enigmatic sellar mass. Progressive compressive features, including visual field loss, compromised pituitary function, or other central nervous system (CNS) functional change, are indications for surgical debulking and sellar decompression. Hemorrhage into the encased bony sella turcica, usually occurring within a known or previously unknown adenoma, may require immediate surgical decompression. Urgent surgical decompression is required for acute pituitary hemorrhage, especially in patients who have developed sudden visual field compromise. Hypopituitarism due to increased portal vessel pressure may recover shortly after



• **Fig. 9.6** (A–D) Local effects of an expanding pituitary tumor causing visual field defects. (A) Normal vision; (C) bitemporal hemianopia. (B–D) Hemifield slide phenomena arising in the setting of bitemporal hemianopia and from fusion instability. The nasal and temporal fields lose their linkage, resulting in overlap of the preserved visual fields. (E and F) Threshold field test showing superior bitemporal hemianopia in a patient with pituitary tumor compressing the optic chiasma (E) which later advanced to bitemporal hemianopia (F). TABLE 9.3 Transsphenoidal Pituitary Surgery

Primary Indications

General

Visual tract or central nervous compression arising from within sella
Relief of compressive hypopituitarism by presenting, residual, or recurrent tumor tissue
Tumor recurrence after surgery or irradiation
Pituitary hemorrhage
Cerebrospinal fluid leak
Resistance to medical therapy
Intolerance of medical therapy
Personal choice
Desire for immediate pregnancy with macroadenoma
Requirement for diagnostic tissue histology

Specific

Acromegaly
Cushing disease
Clinically nonfunctioning macroadenoma
Prolactinoma
Nelson syndrome
TSH-secreting adenoma

Side Effects

Transient

Diabetes insipidus
Cerebrospinal fluid leak and rhinorrhea
Inappropriate ADH secretion
Arachnoiditis
Meningitis
Postoperative psychosis
Local hematoma
Arterial wall damage
Epistaxis
Local abscess
Pulmonary embolism
Narcolepsy

Permanent (up to 10%)

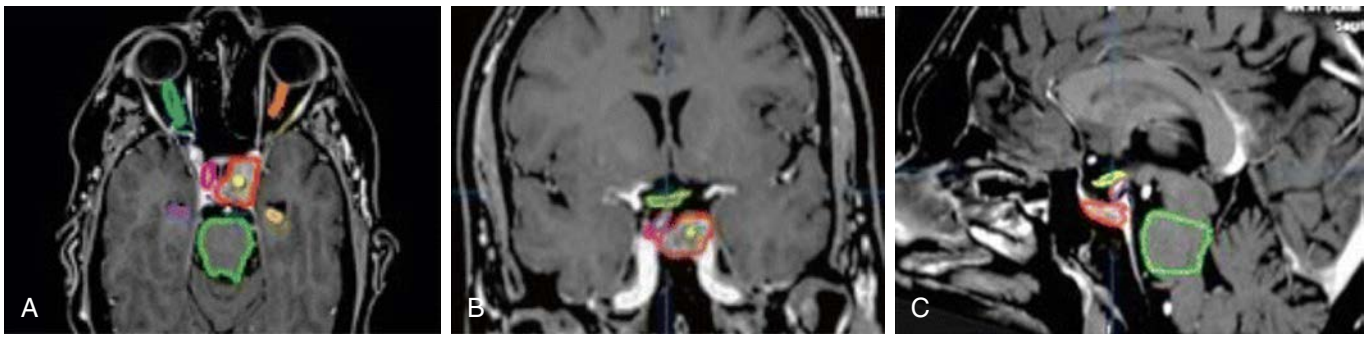
Diabetes insipidus
Total or partial hypopituitarism
Visual loss
Inappropriate ADH secretion
Vascular occlusion
CNS damage—oculomotor palsy, hemiparesis, encephalopathy
Nasal septum perforation

Surgery-Related Mortality (up to 1%)

Brain, hypothalamic injury
Vascular damage
Postoperative meningitis
Cerebrospinal fluid leak
Pneumocephalus
Acute cardiopulmonary disease
Anesthesia-related
Seizure

ADH, Antidiuretic hormone; *CNS,* central nervous system; *TSH,* thyroid-stimulating hormone.

decompressive surgery. When pituitary function after surgery was assessed in 234 patients, 52 patients developed new trophic hormone dysfunction, and 45 of 93 patients with preoperative evidence for hypopituitarism recovered between one and three previously suppressed axes. Significant factors determining restoration of postoperative pituitary function were no visible tumor remnants as assessed by MRI and no tumor invasion as determined both by the neurosurgeon and by pathologic examination of surrounding tissue.[37] Therefore, as some patients with preoperative pituitary failure recover function, depending on the clinical circumstance, patients should be considered for retesting of pituitary reserve prior to initiating postoperative substitution therapy, except for adrenal steroid replacement, which requires



• **Fig. 9.11** MR images showing radiation target delineation for a pituitary adenoma, axial (A), coronal (B), and sagittal (C). Gross tumor and planning target volumes are highlighted in *red*. Organs at risk include optic chiasm, left optic nerve *(orange),* right optic nerve *(cyan),* left optic lens *(light yellow),* right optic lens *(light blue),* brainstem *(green),* pituitary stalk *(pink),* right hippocampus *(purple),* and left hippocampus *(golden yellow).* (From Minniti G, Osti MF, Niyazi M. Target delineation and optimal radiosurgical dose for pituitary tumors. *Radiat Oncol*. 2016;11:135.)

greater caution. Indications for second surgery in the same patient include tumor recurrence, persistent hormonal hypersecretion by tumor remnants, and repair of a CSF leak.

After surgery, patients should be kept at bedrest at an angle of 30 to 45 degrees, and urine and serum osmolality and serum electrolytes are measured every 6 hours. Indications for postoperative vasopressin replacement include polyuria, especially with elevated serum sodium and osmolality and inappropriately low urine osmolality. Postoperative polyuria alone is not an indication for vasopressin replacement, unless it is a reflection of compromised posterior pituitary function. Excess fluid given intraoperatively may also result in postoperative polyuria. Requirements for fluid replacement should take into consideration both fluid intake and urine output.

Side Effects

The success of surgery is largely determined by the skill and experience of the neurosurgeon. Higher volume pituitary centers and experienced surgeons report superior postoperative outcomes and shorter hospital stays.[38,39] Pituitary surgery complications include sinus damage, disrupted nerve function, postoperative infections, vascular complications, or endocrine dysfunction. Importantly, tumor growth persistence or recurrence is a reflection of subsequent adverse outcome. Tumor size, degree of invasiveness, preoperative hormone levels, and previous pituitary surgery are determinants of surgical outcome.[40] Overall, the most significant predictors of postoperative recurrence of hormone-secreting tumors is the postoperative basal hormone level.[41,42] CSF leakage, transient diabetes insipidus, and inappropriate ADH secretion are the most commonly encountered transient side effects, occurring in up to 20% of patients (see Table 9.3). Local damage may result in arachnoiditis, vascular bleeding, hematoma formation, and epistaxis. Rarely, pulmonary embolism, narcolepsy, and local abscess have been reported. Iatrogenic hypopituitarism, diabetes insipidus, or syndrome of inappropriate antidiuretic hormone secretion (SIADH) is reported in up to 10% of patients. Rarely, the CNS may be permanently damaged with hemiparesis, cranial nerve palsies, or encephalopathy.

Three phases of postoperative diabetes insipidus have been described. The initial transient disorder is followed by an interphase on days 6 to 11 with no polydipsia or polyuria. During this second phase, hyponatremia with features of inappropriate ADH secretion have also been reported, even in patients with no signs and symptoms of diabetes insipidus after surgery.[43] The third phase is return of polyuria, polydipsia, and reduced ability to concentrate urine. Fatality has been reported in up to 1% of patients undergoing pituitary surgery and may be related to direct hypothalamic or cerebrovascular damage, meningitis, pneumocephalus formation, or anesthetic complications. Surgical failure may result from a non–pituitary-related event, including anesthesia-related complication or bleeding disorder. Incomplete tumor removal may also be due to inaccurate preoperative MRI localization or identification. Rarely, a previously undiagnosed functioning pituitary tumor or ectopic source of ACTH may be unmasked after initially unsuccessful pituitary surgery. Readmission rates following pituitary surgery are low. In a series of 466 consecutive cases, 29 were readmitted within 30 days, mainly for epistaxis, hyponatremia, or CSF leak.[44]

Pituitary Radiation

Principles

High-energy ionizing radiation can be delivered to deep tissues by megavoltage techniques.[45] The challenge is to provide maximal localized necrotizing radiation to the pituitary lesion while minimally exposing surrounding normal structures to radiation damage. Several advances have improved both efficacy and safety, including highly precise tumor localization and a high-voltage (6–15 MeV) linear accelerator. If required, accurate simulation models with isocentric rotational arcing allow repeat head positioning at the same exact points for recurrent patient visits. For fractionated approaches, up to a maximum of 5000 rads (= 50 Gy) are administered as 180-rad daily fractions for about 5 to 6 weeks. High-precision techniques such as stereotactic radiosurgery may be administered as either single or multiple fractions and may be delivered by cobalt-60 Gamma Knife or CyberKnife robotic surgery or linear accelerator. These allow delivery of high energy directly targeting the pituitary lesion, while minimizing radiation exposure to surrounding tissues[46] (Fig. 9.11). Radiosurgery is best suited for intrasellar and cavernous lesions distant from the optic nerves (Tables 9.4 and 9.5). In a long-term study with a mean 96-month follow-up of 76 patients, about half were in remission, 23% developed new-onset hypopituitarism, and 3 patients developed oculomotor palsies.[47] Whether or not stereotactic radiosurgery exhibits superior long-term efficacy or safety over fractionated treatments remains unresolved.[48]

TABLE 9.4 Pituitary Irradiation

INDICATIONS

Pituitary adenoma—adjuvant therapy for acromegaly, Cushing disease, nonfunctioning adenoma, prolactinoma
Craniopharyngioma
Nelson syndrome
Nonadenomatous invasive sellar mass
Tumor recurrence
Hormone hypersecretion recurrence
Resistance to surgery and medical treatments

SIDE EFFECTS

Hypopituitarism—deficient growth hormone, gonadotrophin, TSH, and ACTH reserve
Eye—visual loss, optic neuritis
Brain—brain necrosis, temporal lobe deficits, cognitive dysfunction

Stereotactic radiosurgery for acromegaly: an international multicenter retrospective cohort study. *Neurosurgery.* 2019;84:717–725.

Indications

The use of radiation for treating pituitary tumors is highly individualized and depends on the expertise of the treating center, the conviction of the treating physician in weighing the potential benefits and risks of the procedure, and patient preference based upon informed choice (see Tables 9.4 and 9.5).[49] In general, radiation techniques are indicated for persistent hormone hypersecretion or residual mass effects after surgery or when surgery of a compressive mass is contraindicated. Overall, fractionated radiotherapy (45–50 Gy) halts growth in over 90% of nonsecreting tumors by 10 years, while secretory tumors are usually more resistant.[50] As GH-secreting and PRL-secreting tumors are generally amenable to medical therapy, indications for irradiation are rare for these adenomas. Most indications for radiation are adjuvant to either surgical or medical treatment. Radiation may be indicated after resection of a potentially recurring or inadequately resected pituitary mass, such as nonfunctioning pituitary adenoma, craniopharyngioma, or chordoma. In acromegaly, use of radiation as primary treatment is generally not recommended and is usually reserved as adjuvant to surgery or medical treatments,[51] but for aggressively growing prolactinomas that are resistant to medical therapy, the procedure may prevent further local invasion. Recurrent pituitary-dependent Cushing disease appears to be particularly suited for radiation, especially in younger patients.

Side Effects

Hypopituitarism. Pituitary failure occurs commonly in patients who have received pituitary irradiation (Table 9.6). Within 10 years after radiation, up to 80% of patients may have gonadotroph, somatotroph, thyrotroph, or corticotroph deficits.[47] The median time to develop pituitary failure after pituitary radiosurgery is about 5 years.[52] The mechanism for hypopituitarism appears to involve damage to hypothalamic hormone–releasing cells as well as direct pituitary damage. These patients require lifelong endocrine follow-up for pituitary reserve testing and hormone replacement when appropriate.

Second Brain Tumors. Glioma has been reported after conventional pituitary radiation for adenomas and craniopharyngioma with a mean latency period of 11.5 years[53] (see Table 9.4). In patients irradiated for pituitary tumors, it appears that the standardized incidence ratio (SIR) for second brain tumors is approximately 6 (confidence interval, 3.16–10.69), with a latency of 6 to 24 years in separate cohorts.[54,55] During 53,786 patient-years of surveillance following both stereotactic and conventional radiotherapy, the risk of developing a brain tumor following pituitary-directed radiotherapy increased 2.4-fold and meningioma risk increased 1.6-fold with every decade of younger age at therapy.[56] As patients harboring pituitary tumors are more likely to undergo routine brain imaging during follow-up, it is not entirely clear whether observed meningiomas are coincidental findings. This very rare complication appears to be dose and age related, and fractionated doses should not exceed 50 Gy. Use of confocal radiation techniques to irradiate a smaller tissue volume may minimize this adverse effect, but long-term, prospective controlled surveillance studies are required to further evaluate this important question.

Cerebrovascular Disease. The incidence of cerebrovascular events, but not mortality, was increased threefold, mainly in men irradiated for nonfunctioning adenomas.[57] However, in another study, mortality rate from cerebrovascular disease appeared higher in previously irradiated pituitary-deficient patients.[58,59] The direct causality of this relationship is unclear, but direct effects on cerebral vasculature, including atherosclerotic occlusive lesions, have been reported.[60]

TABLE 9.6 Complications After Stereotactic Radiosurgery for Nonfunctioning Pituitary Adenomas.

From Sheehan JP, Starke RM, Mathieu D, et al. Gamma Knife radiosurgery for the management of nonfunctioning pituitary adenomas: a multicenter study. *J Neurosurg.* 2013;119(2):446–456.

Visual Damage. The risk of visual damage (and very rarely blindness) is minimized by fractionating dosages to less than 200 rads per treatment session for conventional radiotherapy. The incidence of reported new visual damage in patients undergoing radiosurgery is approximately 4%.[61]

Brain Necrosis. Dose-related radiation-induced brain necrosis was documented by MRI in 14 of 45 patients, with temporal lobe atrophy and cystic and diffuse cerebral atrophy reported. Cognitive dysfunction, especially memory loss, has also been reported.[62]

Medical Management

Pituitary tumors often express receptors mediating hypothalamic control of hormone secretion, and appropriate therapeutic ligands for dopamine D_2 receptor and the somatostatin receptor subtype 2 (SST2) are employed to effectively suppress PRL, GH, and TSH hypersecretion; to block tumor growth; and often to shrink tumor size. Medical ablation of target gland function, including thyroid and adrenal, may also be useful in mitigating the deleterious impact of pituitary tumor trophic hormone hypersecretion. Peripheral antagonists block GH or cortisol action without targeting the respective pituitary tumor source. These medical approaches are considered later in this chapter.

Parasellar Masses

Hypothalamic masses are described in Chapter 7, and causes of parasellar masses are depicted in Table 9.7.

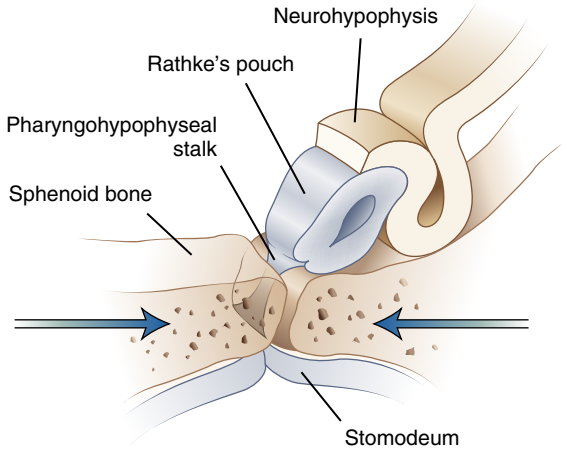
Modified from Famini P, Maya MM, Melmed S. Pituitary magnetic resonance imaging for sellar and parasellar masses: ten-year experience in 2598 patients. *J Clin Endocrinol Metab.* 2011;96:1633–1641.

Types of Parasellar Masses

Parasellar masses account for about 20% of all brain tumors, with a reported incidence of 13,340 new cases of pituitary tumors and craniopharyngiomas in the United States in 2016.[63]

Rathke Cysts

The anterior and intermediate lobes of the pituitary gland arise embryologically from Rathke pouch. Inadequate pouch obliteration results in cysts or cystic remnants at the interface between



• **Fig. 9.12** Pathogenesis of Rathke cysts. Schematic of the embryologic progenitors of sellar and parasellar structures. Rathke pouch arises from an outpocketing of stomodeum (ectoderm) and gives rise to the adenohypophysis. The pharyngohypophyseal stalk, which connects the stomodeum and Rathke pouch, is divided by the sphenoid bone as it grows together *(arrows),* isolating Rathke pouch and the neurohypophysis within the sella. (From Harrison MJ, Morgello S, Post KD. Epithelial cystic lesions of the sellular and parasellular region: a continuum of ectodermal derivates? *J Neurosurg.* 1994;80:1018–1025.)

the anterior and posterior pituitary lobes found in about 20% of pituitary glands at autopsy[64] (Fig. 9.12). Pituitary adenomas may also occasionally contain small cleft cysts. They are lined by cuboidal or columnar ciliated epithelium surrounding mucoid cyst fluid and arise from midline rudiments of failed Rathke cyst invagination and account for approximately 3% of pituitary mass lesions.[65] In contrast, pituitary epidermoid cysts are lined by squamous epithelium and rarely become malignant. Rathke cysts vary in size and may also extend to the suprasellar region. These lesions have heterogeneous MRI characteristics and may rarely present with panhypopituitarism with or without diabetes insipidus.[66] Most, however, are not symptomatic and in 43 of 75 patients followed for up to 126 months, cyst size did not change. Accordingly, most of these patients can be followed expectantly.[67] The extent of headache or visual disturbance is determined by the size and location of the cyst. Cyst formation is associated with sellar enlargement. MRI reveals hyperdense or hypodense masses on either T1-weighted or T2-weighted images, and CT scan shows homogeneous hypodense areas that may be distinguished from pituitary adenomas.[66] These patients should all be evaluated for hypopituitarism. After surgical resection or drainage, which may be required to alleviate severe headache,[68] MRI should be performed during long-term follow-up for signs of cyst recurrence.[64,65]

Arachnoid, epidermoid, and dermoid cysts develop mainly in the cerebellopontine angle but may also arise in the suprasellar region. Dermoid cysts containing greasy sebaceous products or hair follicles are rarely encountered in the pituitary, and the cyst lining may be calcified. Acquired pituitary cysts may arise secondarily to intrapituitary hemorrhage, usually associated with an underlying adenoma, and these rarely cause pituitary failure. Cyst compression causes internal hydrocephalus, visual disturbances, GH or ACTH deficiency, hyperprolactinemia, and diabetes insipidus. Rarely, squamous cell carcinoma may arise in the cyst.[69]

Granular Cell Tumors

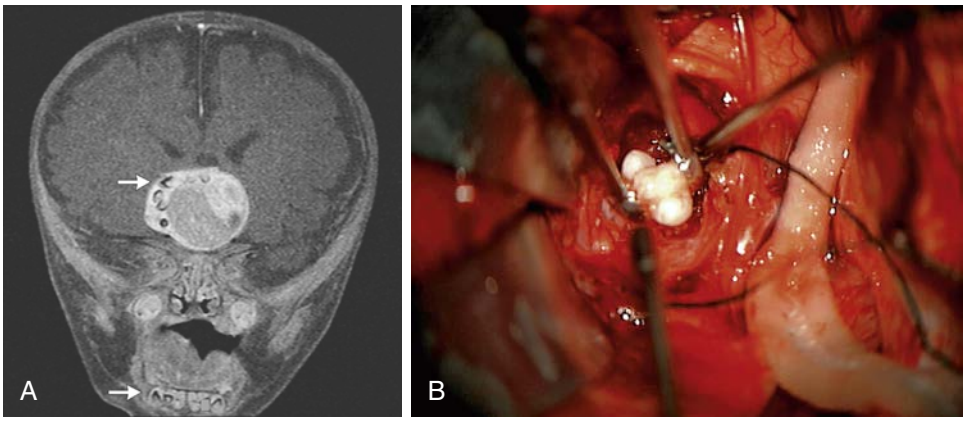
Pituitary choristomas, or schwannomas, usually present only after the age of 20. Their abundant cytoplasmic granules do not contain pituitary hormones, but these lesions may present with diabetes insipidus. Pituitary adenomas are occasionally coincidentally associated with these tumors.[70]

Chordomas

These slow-growing cartilaginous tumors arise from midline notochord remnants, are locally invasive, and may metastasize.[71] Most arise from the vertebrae and about one-third involve the clivus region. Chordomas contain a mucin-rich matrix that allows diagnosis by fine-needle aspiration. They present with headaches, asymmetric visual disturbances, hormone deficiency, and occasional nasopharyngeal obstruction. The tumor mass is associated with osteolytic bony erosion and calcification, and MRI may allow the normal pituitary gland to be distinguished from the very heterogeneous and often flocculent tumor mass. At surgery, the tumors are rough, heterogeneous, and lobular. Markers for epithelial cells, including cytokeratin and vimentin, are present. Recurrences commonly occur after surgical excision, with mean patient survival time of about 5 years. Rarely, chordomas undergo sarcomatous transformation with an aggressive natural history and require extensive surgical dissection.[72] Because of their anatomic location, the endoscopic endonasal approach may be preferable for chordoma surgical resection.[73]

Craniopharyngiomas

This parasellar tumor constitutes about 3% of all intracranial tumors and up to 10% of childhood brain tumors. The tumors are commonly diagnosed during childhood and adolescence.[74] However, they show a bimodal age distribution, occurring in children between 5 and 14 years and adults from 50 to 74 years of age.[75] Tumors arise from embryonic squamous remnants of Rathke pouch extending dorsally toward the diencephalon and may be large (>10 cm in diameter) and invade the third ventricle and associated brain structures. Over 60% arise from within the sella, and others arise from parasellar cell rests.[76,77] When intrasellar, they can often be distinguished from pituitary adenomas by separate visible rim of normal pituitary tissue seen on MRI (see Fig. 9.1A). The cystic mass is usually filled with cholesterol-rich viscous fluid, which may leak into the CSF, causing aseptic meningitis. These slow-growing tumors are composed of embryonic precursor cells and may also contain calcifications, teeth, and immunoreactive human chorionic gonadotropin (hCG) (Fig. 9.13).[78] Histologic appearance shows these tumors comprising two cell populations: Cysts are lined with a squamous epithelium containing islands characterized by columnar cells, and a mixed inflammatory reaction may also occur with calcification. Adamantinomatous craniopharyngiomas have a greater propensity to relapse than the less aggressive papillary variant.[79] Although large craniopharyngiomas may obstruct CSF flow, they rarely undergo malignant transformation. Increased intracranial pressure results in headache, projectile vomiting, papilledema, and somnolence, especially in children. Only about one-third of patients are over 40 years of age, and they commonly present with asymmetric visual disturbances, including papilledema, optic atrophy, and field deficits. If cavernous sinus invasion is present, other cranial nerves may also be involved. On CT imaging, most children and about half of all adults exhibit characteristic flocculent or convex calcifications. Rarely, however, pituitary adenomas, other parasellar tumors, and vascular lesions within the sella are also calcified.

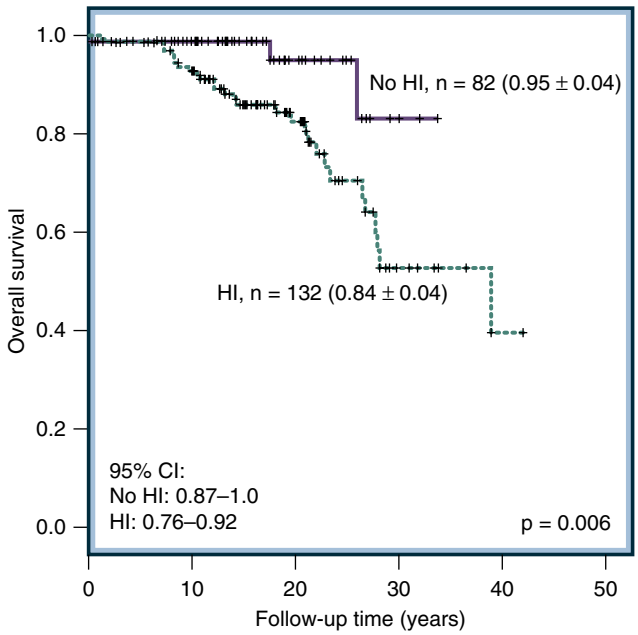


• **Fig. 9.13** Adamantinomatous craniopharyngioma containing teeth. (A) MRI showing tooth-like structures in the parasellar mass and mandible *(arrows).* (B) Fully formed teeth in the resected tumor. (From Beaty NB, Ahn E. Adamantinomatous craniopharyngioma containing teeth. *N Engl J Med*. 2014;370:860.)

In contrast to pituitary adenomas, where it is rarely encountered, diabetes insipidus is often the earliest feature of craniopharyngioma. These patients may also develop partial or complete pituitary deficiency. GH deficiency with short stature, diabetes insipidus, and gonadal failure are common. Pituitary stalk compression or damage to hypothalamic dopaminergic neurons results in hyperprolactinemia. Thus, craniopharyngioma may mimic a prolactinoma by intrapituitary imaging, presence of hyperprolactinemia, and favorable biochemical response to dopamine agonists.

Treatment of primary or recurrent craniopharyngiomas may involve radical surgery, radiotherapy, or a combination of these modalities.[75] A major side effect associated with such surgery is severe postoperative obesity, which can be mitigated by surgery that spares the hypothalamus.[80] The more complicated the surgical operation, the more visual problems are encountered. Patients with diabetes insipidus also have higher rates of anterior pituitary hormone deficits and subsequent obesity.[81] Treatment outcome appears to be related to hypothalamic involvement of the tumor, and careful hypothalamus-sparing surgery followed by local radiation therapy is recommended. Postoperative recurrences and tumor growth progressions are frequent.[74] Trans-sphenoidal microscopic surgery is successfully used for intrasellar craniopharyngiomas, and the expanded endoscopic transnasal approach has been successfully crafted to approach suprasellar tumors.[74] Adjuvant stereotactic irradiation is also used. Postoperative recurrence may occur in about 20% of patients undergoing radical surgical excision, and the degree of hypothalamic impairment is a major determinant of outcome (Fig. 9.14).[82] As several oncogenic mutations have been discovered in adamantinomatous (*CTNNB1*) and papillary (*BRAF* V600E) craniopharyngiomas, therapeutic approaches with BRAF/MEK targeting appear promising.[83]

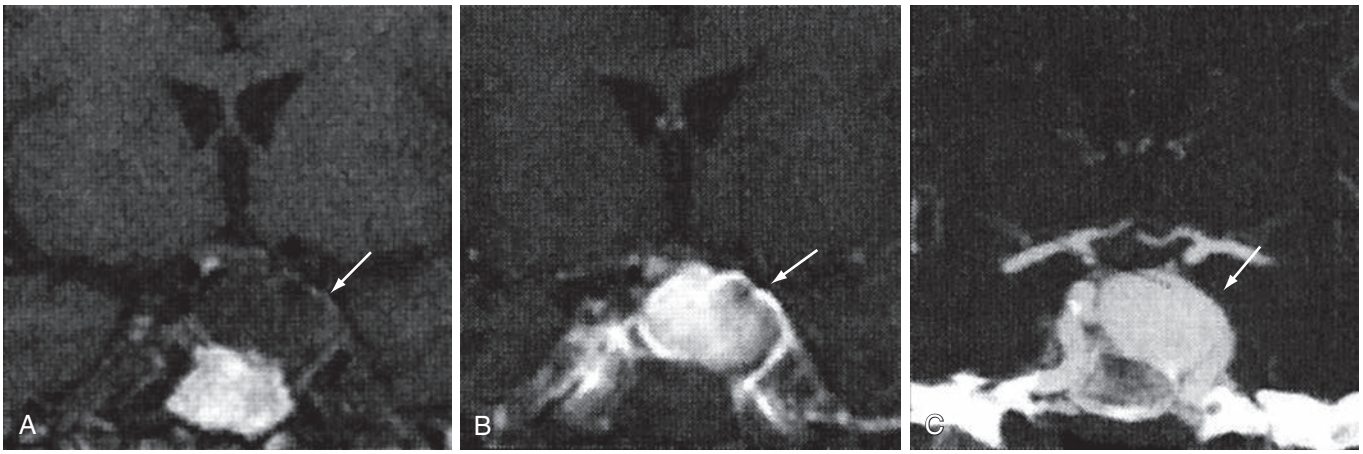
Life-complicating obesity that occurs after craniopharyngioma resection is associated with increased appetite (often insatiable), nonoptimal social development, as well as altered food intake–regulating hormones leptin and ghrelin.[82] Preoperative treatment with glucagon-like peptide-1 (GLP1) analogues led to weight loss.[84] These patients are at high risk for developing diabetes and cerebrovascular disease with increased mortality (standardized mortality ratio [SMR] 2.7; 95% confidence interval [CI]: 2.0–3.8) observed in 224 patients with 3153 years of follow-up.[85] Mortality from cerebrovascular disease is increased fivefold in those with childhood-onset craniopharyngiomas.[86]



• **Fig. 9.14** Overall survival for craniopharyngioma patients after surgical resection with and without hypothalamic involvement (HI). (Redrawn from Sterkenburg AS, Hoffmann A, Gebhardt U, et al. Survival, hypothalamic obesity, and neuropsychological/psychosocial status after childhood-onset craniopharyngioma: newly reported long-term outcomes. *Neuro Oncol*. 2015;17:1029–1038.)

Meningiomas

Meningiomas arise from arachnoid and meningioendothelial cells; those occurring in the sellar and parasellar region account for about one-fifth of all meningiomas.[87] Sellar meningiomas are usually well circumscribed and do not attain the size of craniopharyngiomas. Suprasellar meningiomas may invade the pituitary ventrally, and intrasellar tumor origins are rare.[88] Coexisting functional pituitary adenomas have been described in patients with parasellar meningiomas. Secondary hyperprolactinemia occurs in up to half of these patients, who usually present with local mass effects, including headache and progressive visual disturbances accompanied by optic atrophy. The differential distinction of a suprasellar meningioma with downward extension from an upwardly extending pituitary adenoma may be difficult. On MRI,



• **Fig. 9.15** Giant cavernous aneurysm of the left internal carotid artery. (A) Coronal T1-weighted MRI without intravenous contrast. A mildly hypointense mass is seen within the sella and left cavernous sinus. (B) Coronal T1-weighted MRI after gadolinium contrast. The mass enhances heterogeneously. (C) CT angiogram with maximum intensity reconstruction. *Arrows* indicate origin of the left internal carotid artery giant cavernous aneurysm. (From Lawson EA, Buchbinder BR, Daniels GH. Image in endocrinology: hypopituitarism associated with a giant aneurysm of the internal carotid artery. *J Clin Endocrinol Metab.* 2008;93:4616.)

meningiomas are isodense on both T1-weighted and T2-weighted imaging, in contrast to other parasellar lesions, which are usually hyperdense on T2-weighted imaging. Dural calcification may be evident on CT scanning. Because of their rich vascularization, these tumors pose an intraoperative risk for hemorrhage and a resultant higher surgical mortality rate than is usually encountered for pituitary adenoma resection.

Gliomas

Optic gliomas and low-grade astrocytomas arise from within the optic chiasm or optic tract, they often infiltrate the optic nerve, and less than one-third are intraorbital. Von Recklinghausen disease is the underlying cause in about one-third of these patients, and occasionally these tumors may be associated with growth retardation and delayed or precocious puberty and mass effects that include visual disturbances, diencephalic syndrome, diabetes insipidus, and hydrocephalus. Rarely, gliomas arise within the sella associated with hyperprolactinemia and should be considered in the uncommon differential diagnosis of a PRL-secreting pituitary adenoma.[89] Important distinguishing features include the young age of these patients (80% are <10 years old), relatively intact pituitary function, gross visual disturbances, and localization of the mass as visualized on MRI. Gliomas, unlike hamartomas, usually enhance after contrast injection.

Mucocele

Mucoceles are expanding accumulations of fluid within the sphenoid sinus and may compress parasellar structures. Headaches, visual disturbances (usually unilateral), and exophthalmos are characteristic features. On MRI, the homogeneous sphenoid mass may be quite prominent but may be distinguished from the pituitary gland dorsally.

Parasellar Aneurysms

A parasellar aneurysm may mimic a pituitary adenoma, and intraoperative rupture may be catastrophic, underlying the absolute need for preoperative diagnosis. Differentiating features of aneurysms from other pituitary masses may be subtle, including eye pain, very intense headaches, and relatively sudden onset of cranial nerve palsies (Fig. 9.15). Although imaging techniques usually distinguish blood and hemorrhage from solid tumor or tissue, a highly vascular meningioma may be confused with an aneurysm. Rarely encountered internal carotid artery aneurysms may cause hyperprolactinemia.[90]

Pituitary Infections

Acute pituitary abscesses and perisellar arachnoiditis are encountered with sinus infections, especially after transsphenoidal surgery. Pituitary abscess may develop from hematogenous or direct local spread of infectious agents or may arise within a preexisting pituitary adenoma and may be difficult to distinguish from an adenoma, as these patients may not have fever or signs of meningitis. They often present with diabetes insipidus and headache, and over 80% of a series of 66 patients presented with pituitary insufficiency.[91] On MRI, an isointense central cavity with surrounding ring enhancement is characteristic for an abscess.[4,91] In 33 consecutive patients with pituitary abscess, most presented with a mass associated with pituitary failure, and 5 had undergone previous surgery. Typical MRI features included a sellar cystic mass with an enhanced rim.[92] Gram-positive streptococci or staphylococci may originate from nasopharyngeal passages. Disseminated *Entamoeba histolytica*, *Pneumocystis jirovecii,* or *Klebsiella* may also seed to the pituitary.[93,94] Immunosuppressed patients may develop pituitary infections, including cytomegalovirus, toxoplasmosis, aspergillosis, histoplasmosis, and coccidiosis. Syphilitic gumma may also lead to pituitary damage, insufficiency, and painful hypophysitis.[95] Common viral infections, including influenza, measles, mumps, and herpes, are rarely associated with pituitary damage and insufficiency. Although tuberculosis is rarely confined to the pituitary gland, most of the fewer than 20 reported patients exhibited suprasellar extension of the pituitary mass, compromised pituitary function, and visual defects. Although systemic tuberculosis is usually present, isolated sellar tuberculomas have been described.[96]

Hematologic Malignancies

Primary CNS lymphomas are usually B-cell non-Hodgkin types, and to date, 33 such patients with pituitary lymphoma have been described.[97–99] The pituitary mass may be an isolated presentation of the underlying disease. The disorder is usually diagnosed by histologic finding of tissue obtained by excision biopsy. Presentation includes headache and cranial nerve abnormalities with varying degrees of hypopituitarism. MRI reveals cavernous sinus invasion and isotense T1-weighted and T2-weighted images, which enhance after gadolinium. About 38% of patients with solitary pituitary plasmacytomas may develop classic multiple myeloma.[100] Acute lymphoblastic leukemia may be associated with periglandular pituitary infiltrates with minimal pituitary dysfunction.

Pituicytoma

Pituicytoma is a rare benign central noninvasive suprasellar glial cell tumor that presents with mass effects or hypopituitarism.[101] The tumor, which is isointense or hypointense on T1-weighted MR and hyperintense on T2, arises from cells in the neurohypophysis and stains for vimentin, S100 protein, and glial fibrillar acidic protein.[102] The preferred effective resection is by an expanded endoscopic endonasal transsphenoidal and transplanum approach.[103]

Sarcoidosis

Hypothalamic granulomatous involvement is commonly encountered in patients with CNS sarcoidosis and may be the sole manifestation of the disease.[104] The hypothalamus, pituitary stalk, and posterior pituitary are diffusely invaded by noncaseating granulomas, consisting of giant cells, macrophages, and lymphocytes. These patients may present with varying degrees of anterior pituitary failure with or without diabetes insipidus.[105] Onset of diabetes insipidus with no obvious features of a pituitary disorder should alert the physician to exclude hypothalamic sarcoid deposits especially in the face of a thickened stalk on MRI.[106] In 24 patients with hypothalamic-pituitary sarcoid, all but 2 had anterior pituitary dysfunction (gonadotrophin deficiency 21/24, TSH deficiency 15/24, and hyperprolactinemia in 12/24 cases), and 12 had diabetes insipidus. Imaging studies showed pituitary stalk thickness and involvement of the infundibulum and pituitary gland, which improved or disappeared in 50% of patients. After glucocorticoid treatment, two patients experienced reversal of hypopituitarism.[107]

Langerhans Cell Histiocytosis

The disorder may be associated with granulomatous damage to the hypothalamus and/or posterior pituitary, with characteristic diabetes insipidus occurring in about 25% of children with this disorder.[108] Sleep disorders, adipsia, morbid obesity, axillary skin rash, history of recurrent pneumothorax, and classic bony lesions can occur.[109] Pituitary lesions comprise dendritic Langerhans cells, and pituitary MRI may reveal stalk thickening or a diminished posterior pituitary bright spot. Adults with the disorder should be carefully evaluated for anterior pituitary hormone deficits and appropriately replaced. Multisystem Langerhans cell histiocytosis causes long-term morbidity extending into adulthood.[110] Although surgery and radiation were, for many years, the mainstay treatments, a chemotherapeutic approach using cladribine has been successful in some patients.[111]

Hereditary Iron Storage Diseases

Hemochromatosis and hemosiderosis result in predominantly gonadotroph cell damage.

Idiopathic Retroperitoneal Fibrosis

Idiopathic retroperitoneal fibrosis may also be associated with a suprasellar mass and hypothalamic panhypopituitarism.[112]

Metastases to the Pituitary Region

Pituitary metastases are found in up to 3.5% of cancer patients,[113] especially in older patients with diffuse malignant disease. As the vascular supply to the posterior pituitary is derived directly from the systemic circulation via the internal carotid arteries, the posterior pituitary is the preferred site for bloodborne metastatic spread.[114] Over one-third of carcinomas that metastasize to the pituitary are breast metastases (37.2% of 425 reported cases), followed by lung (24.2%), prostate (5.2%), renal (4.9%), and 28 other sites.[115] Diabetes insipidus is a common presenting sign, and cranial nerve palsies and hypopituitarism may occur as well.[116] If extensive bony erosion is present and disease onset is rapid, the diagnosis is more readily apparent. However, pituitary imaging may not clearly distinguish metastatic deposits from a pituitary adenoma; these lesions may masquerade as an adenoma and the diagnosis only made by histologic study of the resected specimen.[117] When the diagnosis is clear cut in the presence of a primary cancer, relatively low-dose pituitary radiation may be sufficient to shrink the metastasis and improve morbidity.

Evaluation of Parasellar Lesions

Because the differential diagnosis of parasellar lesions covers a wide spectrum of neoplastic, vascular, inflammatory, and infectious processes, patient age and sex, relevant clinical history and symptoms, and other comorbid conditions can often help narrow down the differential diagnosis. MRI with gadolinium is essential in defining the exact location of the lesion, the gadolinium enhancement pattern, the presence of vascular voids or cystic regions, and associated vasogenic edema in surrounding brain tissue. Other imaging studies are often used in select cases: CT scan identifies calcification in craniopharyngiomas; CT angiogram, MR angiogram, or other angiography may be used when vascular lesions are suspected; and positron emission tomography may occasionally be used to identify metabolically active and rapidly growing lesions.

In a subset of lesions, serum molecular markers may be helpful in the diagnostic workup. For example, nongerminomatous germ cell tumors, which often localize to the suprasellar space, can be diagnosed by elevation of characteristic tumor markers, including β-hCG or α-fetoprotein. Furthermore, if the lesion is suspected to cause pituitary or hypothalamic dysfunction, pituitary function testing is useful in characterizing potential endocrine dysfunction. As parasellar lesions often impinge on the optic apparatus, due to their anatomic proximity, neuro-ophthalmologic evaluation, including Humphrey visual fields test, is required. The decision to resect a parasellar lesion depends on factors related to the patient (age, neurologic status, medical comorbid conditions) and the lesion itself (size, anatomic location, vascular pattern, benign or malignant growth pattern, sensitivity to radiotherapy or chemotherapy, sensitivity to medical therapy).

If resection is pursued, a number of surgical approaches can be used, including craniotomies (pterional, supraorbital, subfrontal), as well as endoscopic transnasal approaches. Minimally invasive transnasal endoscopy is useful for resection of select parasellar lesions, with excellent surgical outcomes and potentially fewer complications than those observed after conventional craniotomy.[30]

Primary Hypophysitis

Pituitary mass lesions composed of inflammatory cells may arise as primary disorders of the anterior and posterior pituitary glands or the neurohypophysis.[118,119] At least five clinicopathologic forms have been described, and the definitive diagnosis may require pituitary biopsy.

Lymphocytic Hypophysitis

This autoimmune inflammatory disorder may occur during or shortly after parturition[120] and has also been reported after menopause[119]; approximately 15% of reported cases occur in males. Of the 57% of patients developing the disorder in association with pregnancy, most often the disorder occurs during the last month of pregnancy or during the first 2 months postpartum.[119] It is characterized by a lymphocytic and plasma cell pituitary infiltrate, which may be isolated or associated with other recognized endocrinopathies. Circulating antipituitary antibodies have occasionally been reported, and the presence of isolated pituitary hormone deficiency may imply a selectively targeted autoimmune process to pituitary cell types. Although the natural history is often short lived, the few comprehensive pathologic evaluations suggest that secondary adenohypophyseal cell atrophy, with a resultant empty sella, is a frequent outcome. Pathologic criteria for diagnosis include islands of anterior pituitary cells surrounded by diffuse lymphocytic (T-cell and B-cell) infiltrates. The defining feature is lymphocytic infiltration comprising T and B lymphocytes; plasma cells were found in 53%, eosinophils in 12%, and macrophage histiocytes and neutrophils in 6% of cases,[119] and mast cells have also been identified.

Clinical Features

Over half of patients with lymphocytic hypophysitis present with headache, visual field impairment, and hyperprolactinemia,[119] and pituitary deficiency accounts for the remaining cases. Fifty-six percent of patients have secondary hypoadrenalism, followed in frequency by hypothyroidism, hypogonadism, and GH or PRL deficiency. Hypothyroidism may occur later, even after 9 months. In 76 patients reported by the German Pituitary Working Group, headache and obesity were prominent, and only 11% were associated with pregnancy. Hypogonadism was the most frequent feature of pituitary failure.[121] MRI reveals a pituitary mass, often indistinguishable from an adenoma. Both intrasellar and suprasellar pituitary enlargement occur, and the pituitary stalk may be thickened, especially when diabetes insipidus is present. The inflammatory process often resolves with time, and initially abnormal pituitary function may be restored as well or may remain chronically compromised. Diabetes insipidus, which is encountered in up to 20% of patients, has been attributed to posterior pituitary or stalk infiltration of the inflammatory process.[122] In a study of 95 patients with autoimmune hypopituitarism and positive antipituitary antibodies, those with central diabetes insipidus had antihypothalamic antibodies, suggesting autoimmune involvement of the hypothalamus rather than expansion of the pituitary inflammatory process.[123] In one-third of patients, other autoimmune conditions, including thyroiditis, hypoadrenalism, parathyroid failure, atrophic gastritis, systemic lupus erythematosus, or Sjögren syndrome, may also be present. The differential diagnosis includes prolactinoma and other sellar masses, and careful history and demonstrated loss of the posterior pituitary "bright spot" on MRI are useful for supporting the diagnosis.

Laboratory Findings

The erythrocyte sedimentation rate is often elevated; antibodies to a 49-kDa cytosolic protein were detected in 70% of patients with histologically confirmed lymphocytic hypophysitis and in 10% of control subjects.[124] PRL levels are usually elevated in both female and male patients. Hyperprolactinemia is expected during pregnancy and during the early postpartum period, and the mass effect may contribute to stalk compression and secondary hyperprolactinemia in the others. GH and ACTH responses to hypothalamic hormone challenges may be blunted. Rarely, the disorder may be associated with isolated ACTH or TSH deficiencies.

Treatment

If the diagnosis is convincingly supported, then in the absence of compressive visual field disturbances, surgical therapy should be withheld, pituitary hormone deficits appropriately replaced, and spontaneous resolution of the inflammatory mass expectantly followed. Treatment with high-dose glucocorticoids is the mainstay, often resolving the sellar mass and improving endocrine dysfunction, although recurrences are reported in over 40% of those responding to glucocorticoids.[125] Glucocorticoids are also indicated if adrenal reserve is compromised. Transsphenoidal or endoscopic surgical resection may be required to confirm a tissue diagnosis and may also relieve compression symptoms, but the degree of surgical resection should be constrained by the need to conserve viable pituitary tissue, particularly in view of frequent spontaneous resolution.[125]

Granulomatous Hypophysitis

Granulomatous hypophysitis is not usually associated with pregnancy, but in a systematic review comprising 82 patients, females predominated.[126] Rarely, the condition may coexist with lymphocytic hypophysitis in the same gland. Pituitary histologic appearance shows features of chronic inflammation and granuloma with histiocytes and multinucleated giant cells. Patients present with headache and may have aseptic meningitis. Fever, nausea, or vomiting at presentation and histologic evidence of necrosis correlate with reduced time to presentation. Panhypopituitarism at presentation is predictive of the requirement for long-term replacement therapy.[126] MRI shows pituitary enlargement. Suprasellar extension occurs in about 60% of patients, often with extension to or compression of the optic chiasm (25.7%). The condition may reflect an underlying systemic disorder such as sarcoidosis[127] or Takayasu disease.[128]

Xanthomatous Hypophysitis

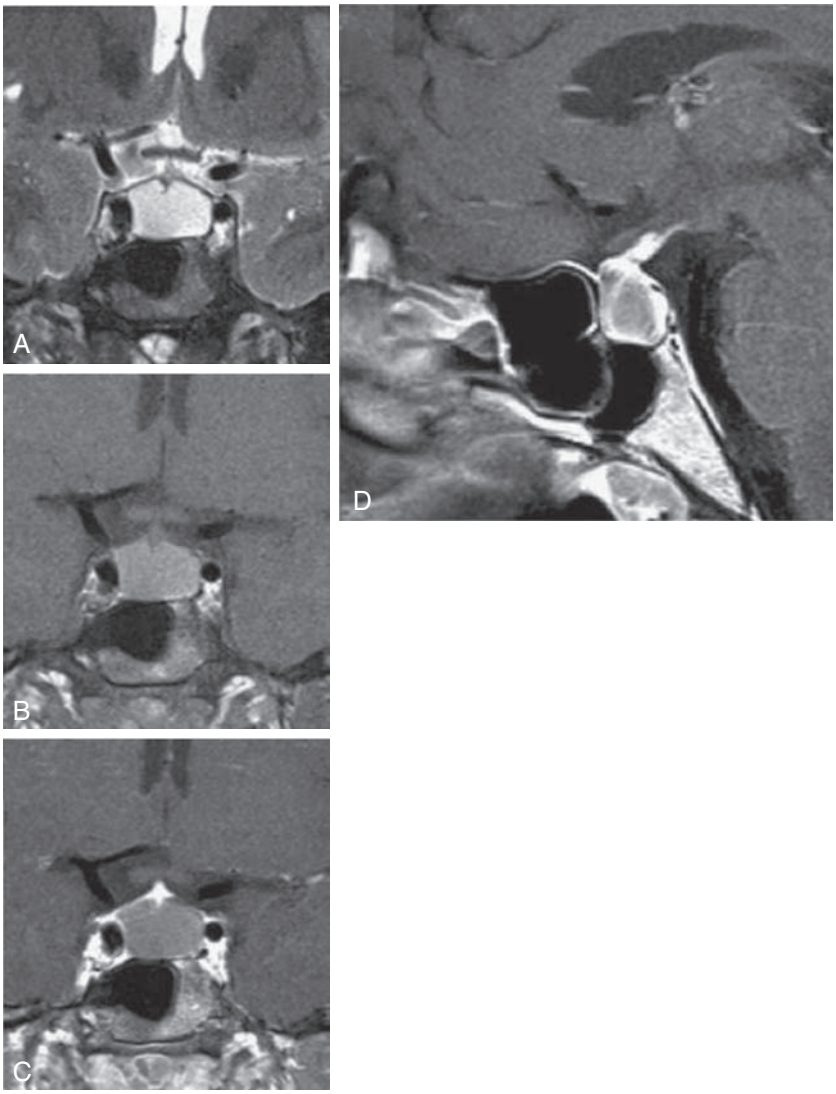
This rare primary pituitary inflammatory process occurs at equal frequency in both sexes and comprises lipid-laden macrophages. MRI often reveals a highly cystic lesion, possibly reflecting an inflammatory response to a ruptured pituitary cyst.

Necrotizing Infundibulo-Hypophysitis

This rare form of hypophysitis has been reported in patients with an enlarged sellar mass. Patients present with diabetes insipidus, hypopituitarism, and severe headache[129] (Fig. 9.16).

IgG4-Related Hypophysitis

Patients with these rarely encountered pituitary lesions may also have retroperitoneal fibrosis, pancreatitis, and thyroid, lung, and meningeal involvement.[130] Only 34 such patients have been reported,[131] and they may present with pituitary failure, diabetes insipidus, and elevated IgG4 levels.



• **Fig. 9.16** Infundibulo-hypophysitis depicted by MRI. The 22 × 20 × 16-mm pituitary mass is isointense to hyperintense on T2-weighted image with suprasellar extension (A) and hypointense in T1-weighted, non-enhanced image (B). After intravenous contrast (C), only slight to moderate and inhomogeneous enhancement occurs, most pronounced at the periphery of the mass. The pituitary stalk and infundibulum are slightly thickened, showing avid enhancement (D). (From Gutenberg A, Caturegli P, Metz I, et al. Necrotizing infundibulo-hypophysitis: an entity too rare to be true? *Pituitary.* 2012;15:202–208.)

Immune Checkpoint Inhibitor-Induced Hypophysitis

This form of hypophysitis is caused by exposure to an antibody, ipilimumab, used to treat metastatic cancer. The drug blocks the cytotoxic T-lymphocyte antigen 4 (CTLA4), which is also expressed on pituitary tissue, leading to local complement activation[132] (Table 9.8). In a single-center analysis of 211 patients with advanced melanoma, an 8% overall incidence of hypophysitis was reported. Presenting symptoms include headache, nausea, vomiting, extreme fatigue, diarrhea, arthralgias, and mental status changes.[133] The median time to onset following drug administration was 4 months, but a delay in up to 19 months after treatment was also observed. The most common endocrine deficit encountered was secondary adrenal insufficiency (84%). In contrast to other forms of hypophysitis, no patients receiving ipilimumab developed diabetes insipidus.[134] Many also had evidence of hypothyroidism/thyroiditis (6%). Eleven of 19 patients had biochemical evidence consistent with central hypothyroidism (low free T_4 [thyroxine] and normal or low TSH). Diabetes has also been observed in these patients. Pituitary MRIs were clearly abnormal in most patients with diffuse enlargement. Treatment with high-dose steroids initially, followed by replacement doses in those with sustained secondary adrenal insufficiency, is effective. However, few patients exhibit return of normal endocrine function.[135] Azathioprine has been found effective in some patients.[136] Less commonly, the antibodies pembrolizumab, nivolumab, and their respective combinations may also induce hypophysitis.

Hemorrhage and Infarction

Intrapituitary hemorrhage and infarction are usually caused by ischemic damage to the hypophyseal-portal system and may be catastrophic. These acute events cause significant damage to the

TABLE 9.8 Features of Ipilimumab-Induced Hypophysitis

Measurement	Result
Incidence	10%
Ipilimumab dose	3 or 10 mg/kg
M:F ratio	2:1
Time until hypophysitis diagnosis	7–16 weeks
Anterior hypopituitarism	All affected patients
Central hypothyroidism	60–100%
Adrenal insufficiency	50–84%
Thyroiditis	Up to 25%
Hyponatremia	Up to 50%
Prolactin	Usually low
Testosterone	Usually low

Data from retrospective analyses of 365 patients treated for melanoma in Faje AT, Sullivan R, Lawrence D, et al. Ipilimumab-induced hypophysitis: a detailed longitudinal analysis in a large cohort of patients with metastatic melanoma. *J Clin Endocrinol Metab*. 2014;99:4078–4085; Ryder M, Callahan M, Postow MA, et al. Endocrine-related adverse events following ipilimumab in patients with advanced melanoma: a comprehensive retrospective review from a single institution. *Endocr Relat Cancer*. 2014;21:371–381.

pituitary gland, and small clinically silent microinfarcts are found in up to 5% of unselected autopsies. Pituitary cells are relatively resilient to vascular insult, and pituitary insufficiency is only clinically apparent when approximately 75% of the gland is ischemically damaged. Ten percent residual functional pituitary cell mass appears sufficient to mask complete pituitary failure. Ischemic damage is limited to the anterior lobe, and posterior pituitary function usually remains intact, reflecting the predominant neural control of oxytocin and ADH secretion. Acute intrapituitary hemorrhage can cause significant life-threatening damage to the pituitary and its surrounding vital structures.[137]

Postpartum Pituitary Infarction

During pregnancy, the pituitary gland normally enlarges in response to estrogen stimulation. The hypervascular gland is thus particularly vulnerable to arterial pressure changes and prone to hemorrhage. Sheehan syndrome classically described after severe postpartum hemorrhage is now less commonly encountered with the advent of modern obstetric care,[138] but it occurs much more frequently in developing countries.[139,140] The presentation varies from development of hypovolemic shock resulting in adenohypophyseal vessel vasospasm and pituitary necrosis to the gradual onset of partial to complete pituitary insufficiency over months to years. Initial presentations also include hyponatremia, asthenia, and weight loss. Most prominent among symptoms are inability to nurse and postpartum amenorrhea.[139] Pituitary autoimmunity has been implicated in gland failure after postpartum hemorrhage.[141]

Pituitary Apoplexy

Pituitary apoplexy may result from spontaneous hemorrhage into a pituitary adenoma (pituitary tumor apoplexy) or may occur after head trauma, with skull base fracture, or in association with hypertension and diabetes mellitus, sickle cell anemia, or acute hypovolemic shock[142] (Table 9.9). Precipitating factors include major surgery, pregnancy, stereotactic irradiation, anticoagulant therapy,[143] coagulopathy secondary to liver failure,[144] and administration of thyrotrophin-releasing hormone (TRH), gonadotrophin-releasing hormone (GnRH) agonists, bromocriptine, and cabergoline.[145,146]

Clinical Features

Pituitary apoplexy is often an endocrine emergency.[147] The condition may evolve over 1 to 2 days, usually presenting with severe headache and ocular palsies or visual field defects. Cardiovascular collapse, change in consciousness, neck stiffness, and sometimes hypoglycemia may occur. Bilateral cerebral infarction may also occur.[148] Acute adrenal insufficiency is a frequent occurrence due to loss of ACTH. It may also be superimposed owing to disordered intravascular clotting disorders, heparin administration, or acute effects of CNS hemorrhage. Pituitary imaging without contrast (CT or MRI) usually reveals signs of intrapituitary or intra-adenoma hemorrhage, stalk deviation, compression of normal pituitary tissue, and in severe cases signs of parasellar hemorrhage[149] (Fig. 9.17). In a study of 13 consecutive patients with pituitary apoplexy, baseline serum cortisol was below 5 μg/dL in 7, between 5 and 15 μg/dL in 4, and above 15 μg/dL in 2 patients. Five patients also had low T_4 levels, and all 13 had evidence of gonadal dysfunction. Thus, these patients with underlying pituitary tumors likely had preexisting pituitary insufficiency.[150] Apoplexy, like Sheehan syndrome, is one of the few pituitary tumor presentations in which hyperprolactinemia is not a feature unless the infarction occurs within a prolactinoma. Patient characteristics, signs and symptoms, and outcomes in 207 patients in five series are portrayed in Table 9.9.[13]

Management

Patients with visual field compromise require emergency transsphenoidal surgery. Others may recover spontaneously but may develop long-term pituitary insufficiency. Patients who are fully alert and conscious with no visual symptoms may be observed. The decision to initiate therapy with high-dose glucocorticoids depends on the clinical status,[137] but the high incidence of adrenal dysfunction either before or after treatment indicates a need for replacement or stress doses of cortisone in most. Ophthalmoplegia, which is common, may resolve spontaneously over time.[137] Postoperative recovery of visual function correlates inversely with the time elapsed subsequent to the acute hemorrhage.[151] Cranial nerve palsies, however, often improve whether or not surgery is undertaken. Pituitary function does not commonly recover after resolution of the acute hemorrhage, and adrenal, thyroid, and gonadal steroid hormone replacement may be required. The subsequent atrophy of infarcted pituitary tissue often results in the development of a complete or partially empty sella evident on MRI.

Pituitary Adenomas

Pituitary Trophic Activity

Benign Adenomas

Transgenic animal models have been developed in which pituitary growth factors or genes have been overexpressed or deleted to recapitulate both functional and nonfunctional pituitary adenomas. For example, a transgenic zebrafish expressing corticotroph-targeted pituitary tumor-transforming gene (*PTTG*) recapitulates a Cushing phenotype with pituitary adenoma growth

and hypercortisolism.[152] In humans, benign monoclonal pituitary adenomas arise from differentiated pituitary cells (see Fig. 9.2). Pituitary trophic signals may enhance or restrain expansion of a monoclonal tumor cell population by regulating the intrapituitary milieu.[153,154]

Normal and hyperplastic pituitary tissues are polyclonal, whereas pituitary adenomas arise as the result of monoclonal pituitary cell proliferation. Using X-chromosomal inactivation analysis, the monoclonal origin of GH-secreting, PRL-secreting,[155] and ACTH-secreting adenomas[156,157] and nonfunctioning pituitary tumors was confirmed in female patients heterozygous for variant alleles of the X-linked genes hypoxanthine phosphoribosyltransferase (*HPRT*) and phosphoglycerate kinase (*PGK*). Thus an intrinsic somatic pituitary cell genetic alteration likely gives rise to clonal expansion of a single cell, resulting in adenoma formation (Table 9.10).

The pituitary gland responds to central and peripheral signals that regulate both hormone production and cell proliferation ranging from microadenoma to aggressive adenoma (Fig. 9.18). For example, during pregnancy hypothalamic and peripheral hormones act to regulate pituitary trophic activity resulting in increased pituitary volume, and prolonged target gland failure (e.g., hypothyroidism) can cause pituitary hyperplasia by releasing the gland from negative feedback inhibition. There is, however, no direct evidence in humans that pituitary hyperplasia is a prerequisite for tumor development. Thus lactotroph hyperplasia occurring with pregnancy and lactation does not lead to increased frequency of prolactinomas. Oral contraception use is also not associated with pituitary adenoma development, and somatotroph hyperplasia caused by ectopic GHRH production[158] is not commonly associated with true adenoma formation. Adenohypophyseal tissue surrounding pituitary tumors is usually not hyperplastic, supporting the notion that hypothalamic hormones, pituitary growth factors, and sex steroid hormones enable a permissive environment, which potentiates cell mutation and subsequent tumor growth.

Hormonal Factors

Hypothalamic factors may have a specific role in the pathogenesis of pituitary cell proliferation, in addition to regulating pituitary hormone gene expression and secretion (see Table 9.10). For example, ectopic GHRH-secreting tumors (bronchial neuroendocrine tumors, pancreatic islet cell tumors, or small cell lung carcinomas) result in GH hypersecretion and acromegaly with somatotroph hyperplasia.[158,159] In transgenic mice overexpressing a GHRH transgene, the pituitary size increases dramatically due to somatotroph hyperplasia, and older mice develop GH-secreting adenomas.[160] However, adenomatous hormonal secretion is usually independent of physiologic hypothalamic control, and the surgical resection of small well-defined adenomas usually results in definitive cure of hormonal hypersecretion. These observations imply that these tumors do not arise because of excessive polyclonal pituitary cell proliferation due to generalized hypothalamic stimulation. However, hypothalamic factors may promote and maintain growth of already transformed adenomatous pituitary cells (Fig. 9.19).

Genetic Factors

Activating mutations of the stimulatory G protein (G_s) are present in up to 40% of human GH-secreting adenomas (Table 9.11). These somatic heterozygous activating point mutations of the G protein α-subunit ($G\alpha_s$) gene involving either arginine 201 (replaced by cysteine or histidine) or glutamine 227 (replaced by arginine or leucine) constitutively activate the $G\alpha_s$ protein and convert it into an oncogene (*GSP*). This G protein activation increases cyclic adenosine monophosphate (cAMP) levels; activates protein kinase A, which in turn phosphorylates the cAMP response element-binding protein (CREB); and leads to sustained constitutive GH hypersecretion and cell proliferation. *GSP*-bearing adenomas are smaller, have mildly lower GH levels and enhanced intratumoral cAMP, do not respond briskly to GHRH, and are sensitive to the inhibitory effect of somatostatin.[161] *GSP*-activating mutations do not occur in PRL-secreting and in TSH-producing adenomas and are very rarely present in nonfunctioning pituitary tumors or ACTH-secreting tumors (<10%). Similar early postzygotic somatic mutations in codon 201 of the $G\alpha_s$ were identified in tissues derived from patients with McCune-Albright syndrome.[162] As transgenic mice overexpressing an inactive pituitary CREB mutant exhibit a dwarf phenotype and somatotroph hypoplasia,[163] cAMP likely stimulates

TABLE 9.10 Factors Involved in Pituitary Tumor Pathogenesis

Hereditary

MEN1
Carney complex
AIP mutations

Hypothalamic

Excess GHRH or CRH production
Receptor activation
Dopamine deprivation

Pituitary

Signal transduction mutations or constitutive activation (*GSP, USP8, GPR101, CREB,* McCune-Albright syndrome)
Disrupted paracrine growth factor or cytokine action (EGFR, FGF2, FGF4, LIF, BMP, STAT3)
Activated oncogene or cell cycle disruption (PTTG, RAS, P27, HMG)
Intrapituitary paracrine hypothalamic hormone action (GHRH, TRH)
Loss of tumor suppressor gene function with LOH (11q13, GADD45γ)

Environmental

Estrogens
Irradiation

Peripheral

Target failure (ovary, thyroid, adrenal)
Ectopic hypothalamic hormone secretion

Evidence for an Intrinsic Pituitary Defect in the Pathogenesis of Pituitary Tumors

Pituitary adenomas are monoclonal.
There is no hyperplasia surrounding the adenomas.
Surgical resection of well-circumscribed small adenomas leads to biochemical control in ~75% of patients.
Unrestrained pituitary hormonal hypersecretion persists independent of feedback suppression by elevated target hormones.
Hormonal pulsatility pattern is often restored after adenoma resection.

AIP, Aryl hydrocarbon receptor–interacting protein; *BMP,* bone morphogenetic protein; *CREB,* cyclic adenosine monophosphate response element–binding protein; *CRH,* corticotrophin-releasing hormone; *EGF,* epidermal growth factor; *FGF,* fibroblast growth factor; *GADD45γ,* growth arrest and DNA damage–inducible gamma gene; *GHRH,* growth hormone–releasing hormone; *GSP,* stimulatory G protein α-subunit oncogene; *HMG,* high mobility group; *LIF,* leukemia inhibitory factor; *LOH,* loss of heterozygosity; *MEN1,* multiple endocrine neoplasia type 1; *P27,* cyclin-dependent kinase inhibitor 1B; *PROP1,* prophet of Pit1 (paired-like homeodomain transcription factor); *PTTG,* pituitary tumor-transforming gene; *RAS,* RAS family of oncogenes; *TRH,* thyrotrophin-releasing hormone.

Data from Melmed S. Acromegaly pathogenesis and treatment. *J Clin Invest.* 2009;119:3189–3202; Melmed S. Pathogenesis of pituitary tumors. *Nat Rev Endocrinol.* 2011;7:257–266.

somatotroph proliferation mediated by CREB phosphorylation. This was borne out by the observation that 15 human GH-secreting pituitary adenomas were shown to express elevated levels of phosphorylated CREB.[164] However, only four of these tumors also contained the mutant *GSP* oncogene, and CREB phosphorylation was also demonstrated in adenomas overexpressing wild-type $G\alpha_s$ protein, suggesting a trophic role of CREB independent of G protein actions. Other signaling pathways overexpressed in pituitary tumors include those for AKT and mitogen-activated protein kinase (MAPK).[165]

Mice with heterozygous *Rb1* inactivation develop pituitary tumors with high penetrance, but mice with deregulated pituitary E2F activity develop tissue hyperplasia without progression to tumor formation, likely because sustained E2F activity ultimately triggers premature senescence in a pRB-dependent, p16-dependent, and p19-dependent fashion.[166] About 15% of spontaneous pituitary adenomas exhibit loss of heterozygosity (LOH) for chromosomes 11q13, 13, and 9, often correlating with tumor size and invasiveness. Although highly invasive pituitary tumors and pituitary metastases exhibit LOH of region 13q14 (*RB1* locus), no distinct tumor suppressor gene has yet been identified for sporadic pituitary tumors.[167] Nevertheless approximately 25% of GH-secreting adenomas do exhibit loss of pRB expression, likely associated with promoter hypermethylation.[168] *TP53* gene mutations (encoding the p53 protein) have not been detected in pituitary adenomas or in pituitary carcinomas and their metastases.[169]

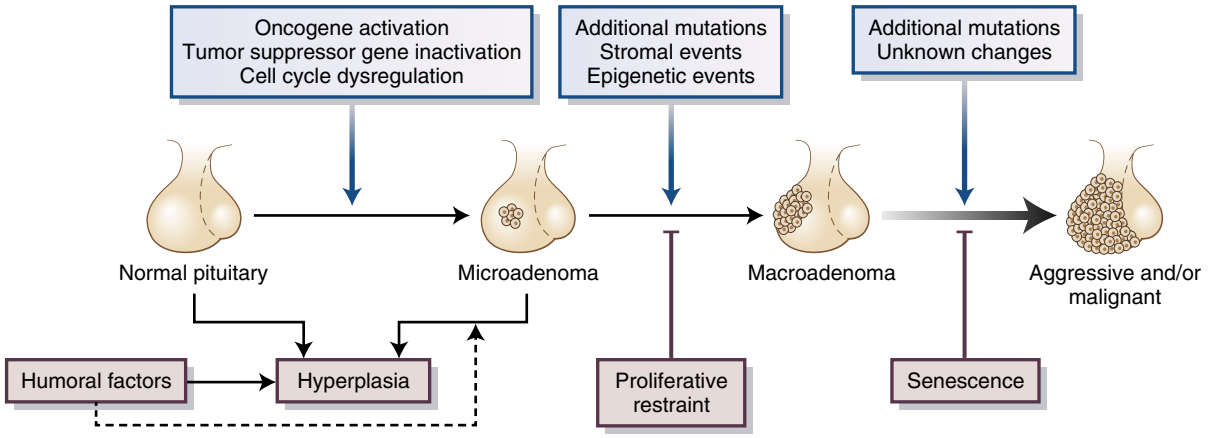
PTTG, isolated from experimental pituitary tumors, is abundant in all pituitary tumor types, especially prolactinomas.[170,171] *PTTG*, a mammalian securin homolog, also induces fibroblast growth factor (FGF) production and angiogenesis and is upregulated by estrogen.[172] *PTTG* overexpression may lead to dysregulated chromatid separation and cell aneuploidy,[173,174] and pituitary targeted *PTTG* transgene expression in mice leads to hormone-secreting adenomas.[175] *PTTG* mutations have not been identified in pituitary tumors, but tumor *PTTG* abundance is induced by the RWD-containing sumoylation enhancer (RSUME).[176] In a meta-analysis of 1464 adenomas in 24 studies, *PTTG* abundance was shown to correlate with pituitary tumor invasiveness.[177]

Cyclin D1, D2, and D3 are upregulated when quiescent cells enter the cell cycle and cyclin-dependent kinase (CDK) complexes lead to pRB phosphorylation, releasing E2F to promote cell cycle progression. Allelic imbalance at the *CCND1* locus encoding cyclin D1 is frequently observed in invasive, nonfunctioning pituitary adenomas.[178] The CDK4 and CDK6 inhibitor p16INK4a, encoded by the *CDKN2A* gene, maintains RB in the unphosphorylated state. In nonfunctioning pituitary tumors, the *CDKN2A* promoter is hypermethylated and consequently not expressed; less frequently the *CDKN2B* gene that encodes p15INK4b is also silenced. Mice deficient in p18INK4c develop features of gigantism with intermediate lobe pituitary hyperplasia and tumors.[179] When the CDK1 and CDK2 inhibitor p27Kip1 is knocked out, multiorgan hyperplasia occurs with development of intermediate lobe pro-opiomelanocortin (POMC) cell pituitary tumors.[180]

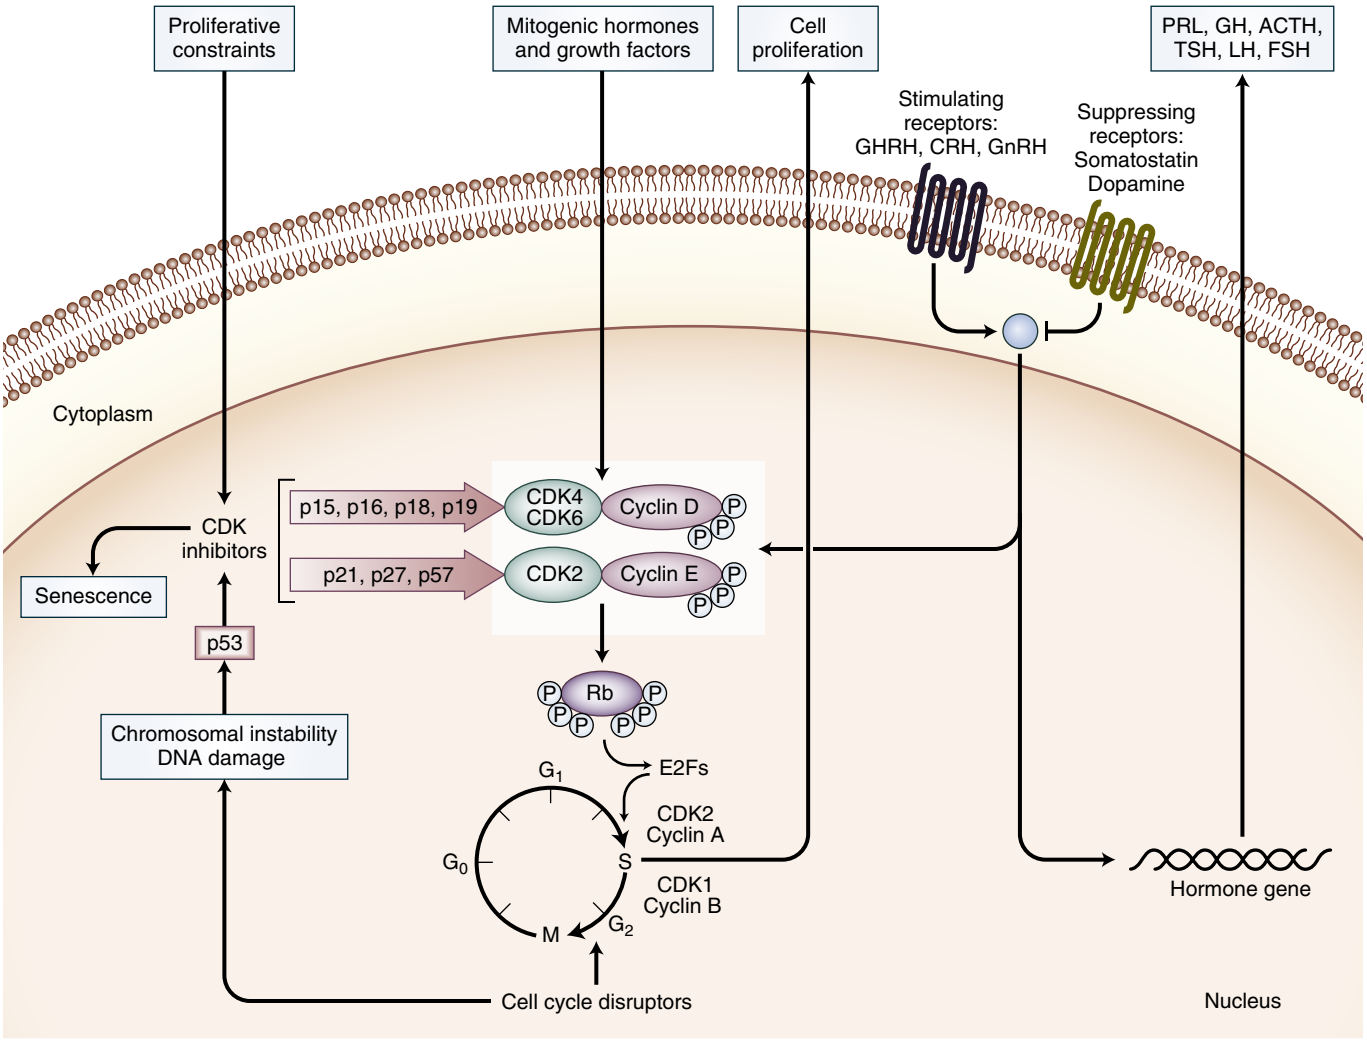
Basic FGF (FGF2) is abundantly expressed in the pituitary, and pituitary PTTG and FGF2 expression is increased in a time-dependent and dose-dependent manner in estrogen-treated rats.[172] Human prolactinomas express FGF4, and transfected FGF4 enhances PRL secretion and tumor vascularity.[181]

Epidermal growth factor (EGF) exhibits potent mitogenic activity in pituitary cells, and both EGF and its receptor EGFR are overexpressed in pituitary tumors, particularly in ACTH-secreting and nonfunctioning adenomas. EGFR abundance in a subset of ACTH-secreting tumors is induced by *USP8* mutations leading to deubiquitination.[182] Both ErbB2 and ErbB3 are expressed in aggressive, recurrent prolactinomas.[183] Gefitinib, the EGFR antagonist, decreases experimental prolactinoma cell proliferation and PRL secretion in vitro and in vivo, associated with abrogated EGFR/ERK signaling.[184] Two patients with dopamine-resistant aggressive prolactinomas showed attenuation of PRL levels and stabilization of tumor growth after treatment with lapatinib, a tyrosine kinase inhibitor.[185]

The growth arrest and DNA damage–inducible protein γ (GADD45γ), a tumor growth suppressor, is silenced in most pituitary adenomas, likely by methylation of CpG islands in



• **Fig. 9.18** Cascade of pituitary tumorigenesis. Pituitary hyperplasia is usually reversible, as exemplified by the situation that occurs during pregnancy. (Modified from Melmed S. Pathogenesis of pituitary tumors. *Nat Rev Endocrinol.* 2011;7:257–266; Di Ieva A, Rotondo F, Syro LV, et al. Aggressive pituitary adenomas: diagnosis and emerging treatments. *Nat Rev Endocrinol.* 2014;10:423–435, used with permission.)



• **Fig. 9.19** Pituitary tumorigenesis. Transcription of hormone genes in a differentiated cell and cell proliferation are mostly induced by pituitary mitogenic factors, including hypothalamic hormones and transcription factors, as well as endocrine hormones. Pituitary proliferative constraints include somatotrophin release-inhibiting factor and tumor suppressor genes. Cell cycle progression through G1 to S phase is mediated by CDK-cyclin complexes that phosphorylate Rb and cause it to release E2F, which drives cell proliferation. CDK inhibitors block kinase phosphorylation, thereby restraining the cell cycle. Chromosomal instability, DNA damage, and senescence may act to constrain malignant transformation of pituitary tumors. *ACTH,* adrenocorticotrophic hormone; *CDK,* cyclin-dependent kinase; *CRH,* corticotrophin-releasing hormone; *FSH,* follicle-stimulating hormone; *GHRH,* gonadotrophin-releasing hormone; *GH,* growth hormone; *GnRH,* growth hormone–releasing hormone; *LH,* luteinizing hormone; *PRL,* prolactin; *TSH,* thyroid-stimulating hormone. the gene promoter.[186] An isoform of *MEG3* containing an extra exon (*MEG3a*) is undetectable in both nonfunctioning and GH-secreting pituitary adenomas, conferring a tumor growth advantage, likely due to hypermethylation of the promoter region.[187]

Transgenic *HMGA1* and *HMGA2* overexpression results in murine GH-secreting adenomas and prolactinomas, and chromosome 12 trisomy, the locus for *HMGA2*, is frequently encountered in human PRL-secreting pituitary adenomas. *HMGA2* was overexpressed in 38 of 98 (39%) pituitary adenomas, being found in 15 of 22 FSH/LH-secreting adenomas (68%), 5 of 15 prolactinomas (31%), and 12 of 18 ACTH-secreting adenomas (18%).[188] *HMGA2* levels correlate with tumor size, invasiveness, and proliferation markers. *HMGA2* tumorigenic effects may also be mediated by inducing cyclin B2 expression[189] and activation of the E2F pathway. *HMGA2* is suppressed by *Let-7* microRNA, and *HMGA2* and *Let-7* expression correlates inversely in human pituitary adenoma samples.[188] Pituitary adenomas exhibit a high degree of aneuploidy, and when 127 adenomas were subjected to multiplexed next-generation sequencing, copy number variations were found to be more prominent in hormone-secreting adenomas.[190]

Frequent epigenetic changes are encountered in all pituitary tumor types, and novel targeted therapies to reverse disrupted epigenomic events have been proposed.[191]

Pituitary Senescence

Cellular senescence, or cell growth arrest, is induced by age-linked telomere shortening, DNA damage, oxidative stress, and oncogene activation. Oncogene-induced premature cell cycle arrest is protective of the cellular response to oncogenic events, is largely irreversible, and is mediated through upregulation of cell cycle inhibitors, including p16INK4A, p15INK4B, p21CIP1, and p53. p21CIP1 induction and senescence markers were elevated in all of the 38 GH-secreting adenomas tested.[192] In contrast, p21CIP1 was undetectable in pituitary carcinomas, nonsecreting pituitary oncocytomas, and null cell adenomas. Senescence-associated β-galactosidase activity, a marker of senescence, is also strongly positive in GH-secreting adenomas. As cellular senescence is protective for malignant transformation,[193] this process may underlie the invariably benign nature of pituitary adenomas.[166]

Familial Syndromes

These rare syndromes are summarized in Table 9.12 and include the following types.

Multiple Endocrine Neoplasia Type 1

Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominant hereditary disorder characterized by tumor formation or hyperfunction of parathyroid, pancreatic islets, anterior

TABLE 9.12 Genes Associated With Familial Pituitary Tumor Syndromes

Syndrome	Gene (Locus)	Most Frequent Mutation(s)	Pituitary Features	Other Features
MEN1	*MEN1* (11q13)	c.249-252delGTCT, an exon 2 predicted frameshift, in 4.5%	Pituitary adenoma in 30–40% (PRL 60%, NFA 15%, GH 10%, ACTH 5%, TSH rare)	Primary hyperparathyroidism, pancreatic tumors, foregut carcinoid tumors, adrenocortical tumors (usually nonfunctional), rarely pheochromocytomas, skin lesions (facial angiomas, collagenomas, and lipomas)
MEN1-like (MEN4)	*CDKN1B* (12p13)	Only two reported cases	Pituitary adenoma[a]	Primary hyperparathyroidism and single cases reported of renal angiomyolipoma, neuroendocrine cervical carcinoma
Carney complex	*PRKAR1A* (17q23-24)	c.491-492delTG in exon 5	Pituitary hyperplasia in most patients Adenoma in ~10% (GH and PRL)	Atrial myxomas, lentigines, Schwann cell tumors, adrenal hyperplasia
Familial, isolated pituitary adenomas	*AIP*[b] (11q13.3)	Gln14X nonsense mutation[c]	Pituitary adenoma (majority GH, PRL, or mixed GH and PRL)	Young patients, often macroadenomas with gigantism

[a]Only two reported cases to date: one GH-secreting adenoma and one ACTH-secreting adenoma.

[b]*AIP* mutations reported in 15% of individuals with familial isolated pituitary adenoma and 50% of those with isolated familial somatotropinomas.

[c]This is the most commonly identified mutation but is likely to be overrepresented secondary to a Finnish founder effect.

ACTH, Adrenocorticotrophic hormone; *GH,* growth hormone; *MEN1,* multiple endocrine neoplasia type 1; *NFA,* nonfunctioning adenoma; *NR,* not reported; *PRL,* prolactin.

From Elston MS, McDonald KL, Clifton-Bligh RJ, et al. Familial pituitary tumor syndromes. *Nat Rev Endocrinol.* 2009;5:453–461.

pituitary, and less commonly, other neuroendocrine, thyroid, and adrenal tumors.[194] Pituitary tumors are nonfunctioning or prolactin-secreting or GH-secreting microadenomas.[195] The MEN1 syndrome (fully described in Chapter 42), is associated with germ cell inactivation of the *MEN1* gene (encoding the menin protein) located on chromosome 11q13.[196] Unlike pituitary tumors in the MEN1 syndrome, *MEN1* gene mutations were not identified in non-MEN1 familial pituitary adenomas.[197] Mutations of other genes may also confer a MEN1 clinical syndrome. Approximately 20% of patients with a clinical diagnosis of MEN1 do not exhibit identifiable *MEN1* mutations, and rarely the gene for p27Kip1 (*CDKN1B*) is mutated in patients with clinical features of MEN1 but with no *MEN1* mutations.[198]

Familial Isolated Pituitary Adenomas

Less than 5% of prolactinomas and GH-secreting tumors are inherited on a familial basis.[199] In familial acromegaly, about 25% of afflicted individuals are diagnosed as teenagers or young adults, usually with gigantism. These patients have been linked to LOH at the 11q13.1-11q13.3 locus.[200] Germline mutations of the aryl hydrocarbon receptor–interacting protein (AIP) were found to predispose to familial pituitary tumors with autosomal dominant inheritance.[199,201] Eleven of 73 families with familial isolated pituitary adenomas were found to have 10 germline *AIP* gene mutations associated mainly with GH-secreting and PRL-secreting tumors.[202,203] *AIP* mutations are rarely encountered in patients with sporadic tumors and have been reported mainly in the youngest patients with acromegaly or gigantism.[204,205] When patients under the age of 30 with sporadic macroadenomas were tested, 11.7% were found to harbor germline *AIP* mutations. In young acromegaly patients, the frequency of *AIP* mutations ranged from 2.3% to 5.5% with no apparent differences in patients with or without mutations.[206]

Carney Complex

Carney complex is an autosomal dominant disorder comprising benign mesenchymal tumors, including cardiac myxomas, schwannomas, thyroid adenomas, and pituitary adenomas associated with spotty skin pigmentation.[207] The disorder has been mapped to chromosome 17q24 and results from a mutated type 1α regulatory subunit (R1α) of the cAMP-dependent protein kinase A (PRKAR1A).[208] These patients may have elevated levels of GH, IGF1, or PRL, and 10% exhibit clinical acromegaly with GH-secreting tumor formation associated with inactivating mutations of *PRKAR1A*, leading to constitutive protein kinase A catalytic subunit activation. Excess GH levels in those patients with concomitant acromegaly may, in fact, be a growth factor in development of cardiac myxomas.[209] In some patients, the wild-type *PRKAR1A* allele is retained in tumor tissue, and haploinsufficiency may be sufficient for tumorigenesis. A 17-miRNA signature for pituitary tumors was identified on the background of pituitary hyperplasia and *PRKARIA* mutations. In GH-secreting tumors, miR-26b and miR-128 appear to regulate the PTEN-AKT pathway.[210] These defects provide attractive potential subcellular therapeutic targets.

In summary, multifactorial mechanisms subserve the multistep pathogenetic process of pituitary adenoma formation, including early initiating chromosomal mutations that result in mutated pituitary stem or progenitor cells. The transformed pituitary cell is subjected to signals facilitating clonal expansion, and permissive factors, including hypothalamic hormone receptor signals, intrapituitary growth factors, and disordered cell

cycle regulation, may determine the ultimate biologic fate of the tumor. Autonomous anterior pituitary hormone production and secretion and cell proliferation, which are the hallmarks of pituitary adenomas, result. However, proximal subcellular events initiating the formation of most sporadic pituitary adenomas have yet to be elucidated.

Pathogenesis

Pituitary tumors account for about 15% of all intracranial neoplasms and are commonly encountered at autopsy[211] (Table 9.13). The Brain Tumor Registry of Japan reports that 15.8% of 28,424 cases were histologically confirmed pituitary adenomas.[212] The prevalence of pituitary tumors in Belgium is 1 in 1064 inhabitants,[213] and in Banbury, United Kingdom, 63 pituitary tumors were noted in 89,334 inhabitants, a population prevalence of approximately 77 cases per 100,000. Of these, 57% were prolactinomas, 28% were nonfunctioning adenomas, 11% were GH-secreting adenomas, and 2% were Cushing adenomas. The median age of onset was 37 years, but nonfunctioning tumors were most commonly encountered in patients older than 60 years.[214] A recent population-based study in Iceland showed a rising prevalence over time. The total prevalence of adenomas from 2003 to 2012 was 115 per 100,000, up from 72 per 100,000 in the period from 1993 to 2002. Prolactinomas accounted for 54/100,000 and nonfunctioning adenomas accounted for 43/100,000.[215] Using large and comprehensive population-based cancer registries, the annual pituitary tumor incidence rate in the United States was reported to increase from 2.52 per 100,000 population in 2004 to 3.13 in 2009 (Table 9.14).[216] An increase in incidence was similarly seen in a study in Sweden.[217] Whether or not this increase is due to an inherent actual tumor increase or to enhanced reporting, awareness, and diagnosis is yet unclear. These benign monoclonal adenomas may express and secrete hormones autonomously, leading to hyperprolactinemia, acromegaly, Cushing disease, and hyperthyroidism, or they may be functionally silent and initially diagnosed as a sellar mass. Although almost invariably benign, the neoplastic features of these adenomas represent a unique tumor biology, which is reflected in their important local and systemic manifestations. These neoplasms have a slow doubling time and rarely resolve spontaneously. Nevertheless, they can be aggressive and locally invasive or compressive to vital central structures. Two classifications, Hardy and Knosp, are used to characterize adenoma mass characteristics (Fig. 9.20). Although pituitary adenomas usually express a single differentiated gene product, polyhormonal expression may reflect a primitive stem cell or mature bimorphous cellular origin. In children, ACTH-secreting and PRL-secreting adenomas account for about 40% of surgical series, with a 65% surgical remission rate.[218] These tumors are particularly challenging to manage due to high recurrence rates and the need for rigorous pituitary hormone replacement.

Classification of Pituitary Tumors

Pituitary tumors arise from hormone-secreting adenohypophyseal cells, and their secretory products depend upon the cell of origin (Table 9.15). Pathologic classification enables accurate clinical correlates and identifies cell-type origin.[219–221] Previously, clinically inapparent pituitary adenomas were found in about 11% of autopsies. They localize to unique areas of the gland, reflecting relative cell-type abundance and intragland distribution (see Fig. 9.2). Although 46% of a subset of these immunostain for PRL,[222] expectant management may still be indicated.[223] In a study on 100 normal volunteers, 10 were found to have focal abnormalities on MRI consistent with microadenomas; they measured from 3 to 6 mm in diameter.[8] Such tumors have been termed *incidentalomas*. In a survey of 506 patients harboring incidentalomas, 20% were nonfunctioning; of these, 20% increased in size during a mean follow-up of 50 months.[222] When larger, particularly nonfunctioning tumors are encountered inadvertently, pituitary function should be assessed, including measuring PRL, IGF1, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and sex steroids. A 24-hour urinary free cortisol or salivary cortisol measurement may exclude Cushing disease. In a study of 52 patients with macroadenomas that were incidentally discovered by CT or MRI, 22 were gonadotroph cell adenomas, 21 were null cell adenomas, and 9 were clinically nonfunctioning but immunostained for various pituitary hormones.[224] Radiologic and surgical classifications are based upon tumor localization, size, and degree of invasiveness (see Fig. 9.20). Microadenomas are

TABLE 9.14 Pituitary Tumor Age-Adjusted Incidence and Annual Percent Change in Incidence in the United States

Year	No. of Cases	Age-Adjusted Incidence Rate (95% CI)	Annual Percent Change (95% CI)
2004–2009	51.125	2.87 (2.85–2.90)	4.25 (2.91–5.61)
2004	7243	2.52 (2.46–2.58)	
2005	7811	2.69 (2.63–2.75)	
2006	8485	2.88 (2.82–2.94)	
2007	8722	2.92 (2.86–2.98)	
2008	9266	3.07 (3.01–3.14)	
2009	9598	3.13 (3.07–3.20)

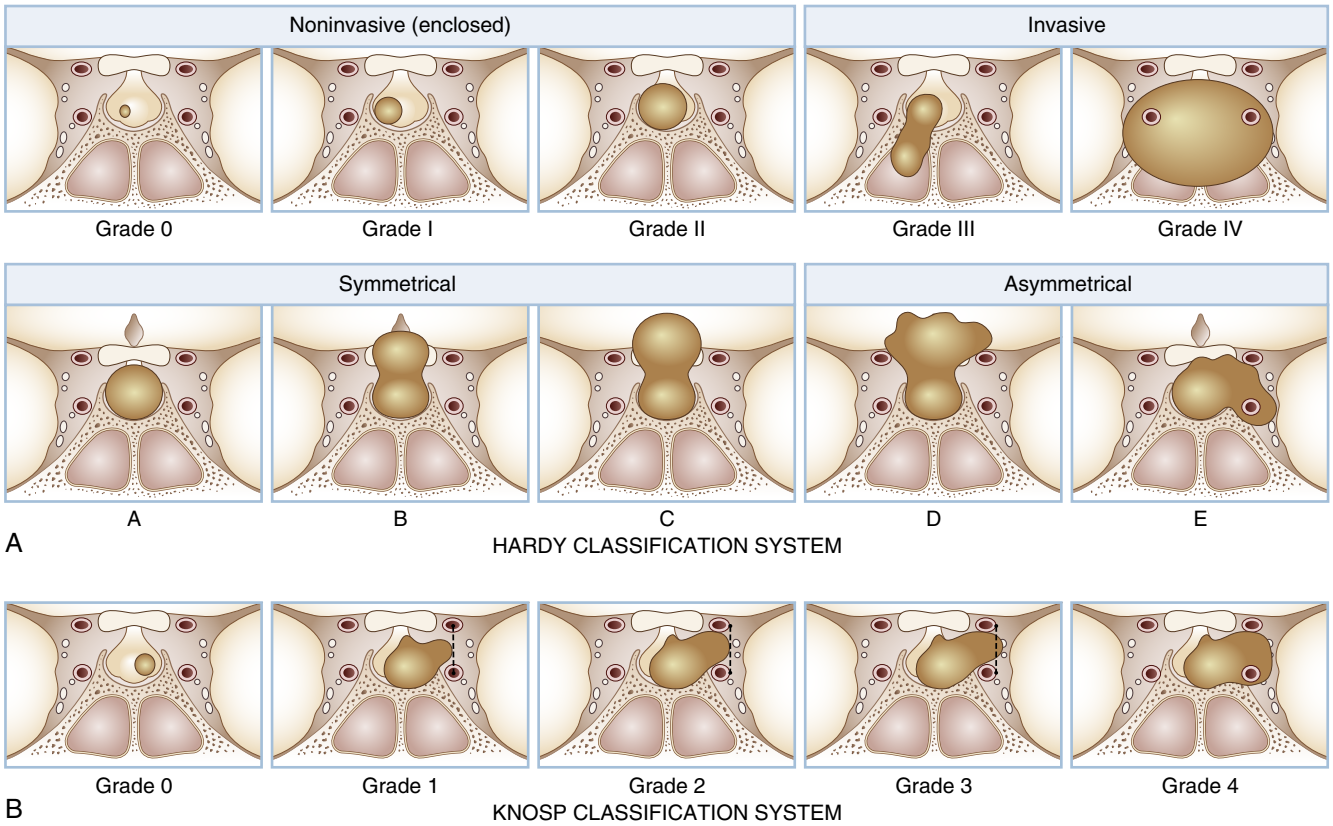
intrasellar and generally smaller than 10 mm in widest diameter. Macroadenomas are 10 mm or larger and usually impinge upon adjacent sellar structures. Specific tumor types are considered later for each respective cell type. Immunocytochemistry detects pituitary cell gene products at both the light and electron microscopic levels and allows classification of pituitary tumors based on their function. Unlike the corticotroph, somatotroph, lactotroph, and thyrotroph cell tumors, which hypersecrete their respective hormones, gonadotroph cell tumors are usually clinically silent and do not efficiently secrete their gene products. Double immunostaining identifies mixed tumors expressing combinations of hormones; they are often macroadenomas secreting GH concomitantly with PRL, TSH, or ACTH. Generally, immunohistochemical identification of pituitary hormones correlates with tumor-specific messenger RNA (mRNA) hormone transcription factor markers measured either in whole tissue extracts or at the single cell level.[225] With the exception of the glycoprotein α-subunit, immunohistochemical positivity of greater than 5% of cells composing the tumor is usually reflective of peripheral circulating hormone levels. Quantification of immunostaining intensity is subjective, and a scale of intensity



• **Fig. 9.20** Classification systems characterizing pituitary adenomas. (A) *Hardy classification system.* Sella turcica tumors can be noninvasive (grade 0, intact with normal contour; grade I, intact with bulging floor; or grade II, intact, enlarged fossa) or invasive (grade III, localized sellar destruction; or grade IV, diffuse destruction). Suprasellar tumors can be symmetrical (grade A, suprasellar cistern only; grade B, recess of the third ventricle; or grade C, whole anterior third ventricle) or asymmetrical (grade D, intracranial extradural; or grade E, extracranial extradural [cavernous sinus]). (B) *Knosp classification system* used to quantify invasion of the cavernous sinus, in which only grades 3 and 4 define true invasion of the tumor into the cavernous sinus. Grade 0, no cavernous sinus involvement; grades 1 and 2, the tumor pushes into the medial wall of the cavernous sinus but does not go beyond a hypothetical line extending between the centers of the two segments of the internal carotid artery (grade 1) or it goes beyond such a line but without passing a line tangent to the lateral margins of the artery itself (grade 2); grade 3, the tumor extends laterally to the internal carotid artery within the cavernous sinus; grade 4, total encasement of the intracavernous carotid artery. (Modified from Di Ieva A, Rotondo F, Syro LV, et al. Aggressive pituitary adenomas: diagnosis and emerging treatments. *Nat Rev Endocrinol.* 2014;10:423–435, used with permission.)

TABLE 9.15 The 2017 WHO Pathologic Classification of Pituitary Adenomas

Adenoma Type	Morphologic Variants	Pituitary Hormones by Immunohistochemistry	Transcription Factors and Other Cofactors	Clinical Syndrome
Somatotroph	Densely granulated	GH, α-subunit	Pit1	Acromegaly, gigantism
	Sparsely granulated	GH	Pit1	
	Mammosomatotroph	GH + PRL (in same cells) ± α-subunit	Pit1, ERα	
	Mixed somatotroph-lactotroph	GH + PRL (in different cells) ± α-subunit	Pit1, ERα	
Lactotroph	Sparsely granulated	PRL	Pit1, ERα	Hypogonadism, galactorrhea
	Densely granulated	PRL	Pit1, ERα	
	Acidophil stem cell	PRL, GH (focal and variable)	Pit1, ERα	
Thyrotroph		βTSH, α-subunit	Pit1, GATA2	Hyperthyroidism
Corticotroph	Densely granulated	ACTH	Tpit	Cushing disease
	Sparsely granulated	ACTH	Tpit	
	Silent[a]	ACTH	Tpit	
	Crooke cell	ACTH	Tpit	
Gonadotroph		βFSH, βLH, α-subunit (various combinations)	SF1, GATA2, ERα	Hypogonadism, local signs
Null cell[a]		None	None	None or pituitary failure
Plurihormonal	Pit1 positive[a]	GH, PRL, βTSH ± α-subunit	Pit1	Mixed, local signs
	Unusual immunohistochemical combinations	Various combinations		

[a]Usually nonsecreting and clinically silent.

Modified from Mete O, Lopes MB. Overview of the 2017 WHO classification of pituitary tumors. *Endocr Pathol.* 2017;28:228–243.

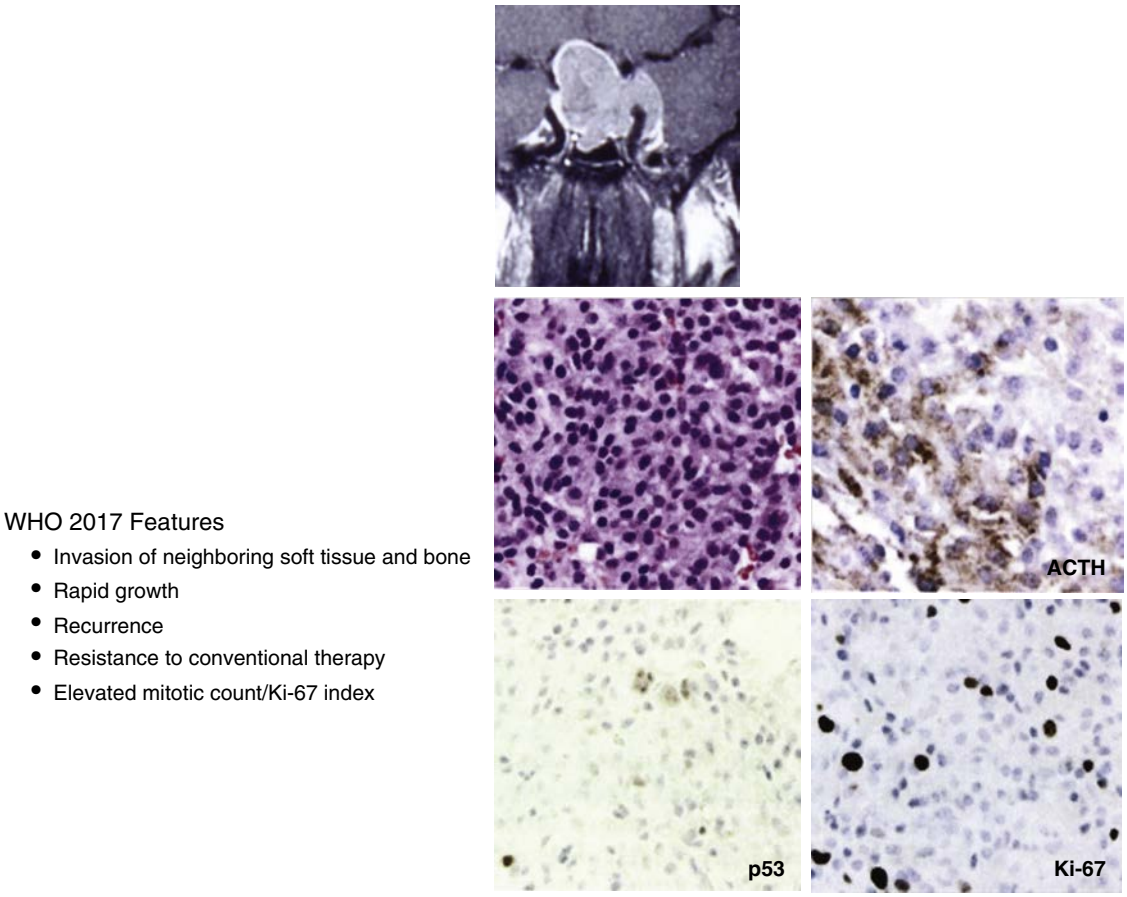
should also include a description of the extent of staining, such as whether occasional, scattered, or most tumor cells express the immunodetectable protein. Electron microscopy is useful for assessing the ultrastructure of hormone secretory granules, their size, and distribution. Other subcellular features important for diagnosis include visualizing large mitochondria in nonfunctioning oncocytomas and the secretory nature of Golgi and endoplasmic reticulum, especially for prolactinomas. Peroxidase or colloid gold particles of different diameters are also sensitive electron microscopic markers for identifying and localizing intracellular hormone signals. Because of the cost, other markers have superseded routine electron microscope usage. Invasive pituitary tumors are slow growing, and mitotic markers, including proliferating cell nuclear antigen (PCNA) and Ki-67, are useful.[226,227]

Aggressive Adenomas

True pituitary carcinoma with demonstrable extrapituitary metastases is exceedingly rare.[228,229] However, about 30% of patients undergoing adenoma resection exhibit persistent tumor growth or progressive growth for up to 37 years after surgery.[230] Tumors are regarded as aggressive if they are resistant to medical therapy and exhibit multiple recurrences despite rigorous surgical, medical, and radiation approaches.[231] Aggressive adenomas, previously referred to as atypical adenomas, are invasive, with elevated Ki-67 proliferative index and increased mitotic activity[231,232] (Fig. 9.21). In a series of 121 consecutive patients undergoing transsphenoidal pituitary tumor resection, 18 were classified as atypical.[233] These tumors grow aggressively and often persist or recur after surgery. In a study of 50 aggressive adenomas, more than 80% were macroadenomas and 42% had invaded the cavernous sinus.[234] They may arise from any of the pituitary cell types, and about 20% actively secrete GH or PRL; they rarely secrete ACTH. Several histologic types are particularly prone to aggressive growth, such as silent corticotroph adenomas.[186] No controlled prospective studies have rigorously assessed the postoperative recurrence rates of these tumors, and the utility of p53 as a prognostic marker has been questioned. There is yet no compelling evidence that these tumors undergo true malignant transformation. Nevertheless, frequently recurring or persistent invasive adenomas with high Ki-67 indices should raise awareness to consider the rare diagnosis of malignancy by excluding the presence of metastasis.[235]

Malignant Pituitary Tumors

Very rarely, pituitary tumors may metastasize either outside the central nervous system or as a separate focus within the brain; they account for 0.2% of pituitary adenomas.[236] Because no cell markers clearly distinguish aggressive invasiveness from malignancy, demonstration of extracranial metastasis is a prerequisite for diagnosis of pituitary malignancy.[237] When they occur, these cancers most often secrete either ACTH or PRL.



• **Fig. 9.21** Aggressive pituitary adenomas. Criteria for diagnosis as proposed by World Health Organization (WHO). Histologic panels depict atypical adrenocorticotrophic hormone (ACTH)–expressing adenoma. (From Zada G, Woodmansee WW, Ramkissoon S, et al. Atypical pituitary adenomas: incidence, clinical characteristics, and implications. *J Neurosurg.* 2011;114:336–344; Lopes MBS. The 2017 World Health Organization classification of tumors of the pituitary gland: a summary. *Acta Neuropathol.* 2017;134:521–535.)

As *HRAS* mutations are rarely encountered in distant metastatic pituitary carcinomas, but not in their respective primary pituitary tumors or in noninvasive adenomas,[169,238] these mutations may be important in the very rare progression to malignancy.

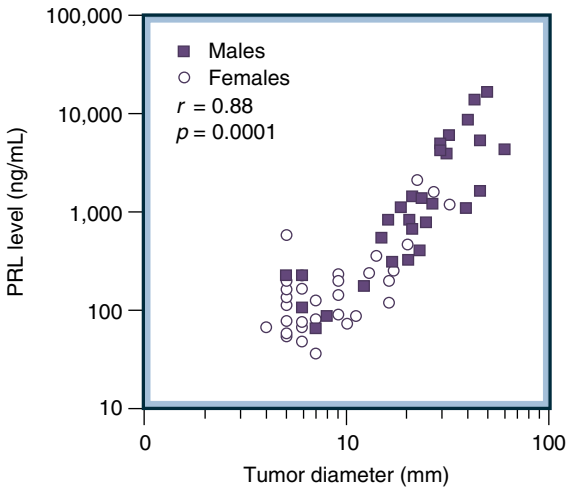
Temozolomide, an alkylating agent that induces DNA damage to disrupt gene transcription, has been used to treat aggressive pituitary tumors in patients who have failed to respond to other therapies or who have evidence of pituitary carcinoma. Results of tumor shrinkage or hormone suppression have been highly variable, with about half of patients showing initial responses.[239] It has been recommended that drug therapy be reevaluated after three treatment cycles. Although O^6-methylguanine-DNA methyltransferase (MGMT) may interfere with drug efficacy, assessing MGMT expression in pituitary tumor samples has been reported to have variable use.[240–243]

Prolactin-Secreting Adenomas

Prolactinomas are the most frequently encountered secretory pituitary tumors, occurring with an annual incidence of approximately 30 per 100,000 population.[214] This incidence would be much higher if the estimate included microadenomas discovered in approximately 11% of pituitaries at autopsy, 46% of which immunostain positively for PRL.[222] The female:male ratio for microprolactinomas is 20:1, and for macroadenomas the sex ratio is roughly equivalent. Both PRL levels and tumor size generally remain stable, although in some patients, PRL levels fall over time. Microadenomas may disappear after discontinuing dopamine agonist therapy, although 7% to 14% of microadenomas continue to grow.[244] Additionally, smaller prolactinomas may sometimes regress after pregnancy and lactation.[245]

Macroprolactinomas have a greater propensity to grow and tumor size correlates with serum PRL levels (Fig. 9.22), so a PRL level higher than 200 ng/mL is strongly indicative of a PRL-secreting pituitary tumor. Although prolactinomas account for more than 75% of all female pituitary adenomas,[214] men harbor larger tumors. In 45 men and 51 women with prolactinomas, mean serum PRL was 2789 ± 572 ng/mL versus 292 ± 74 ng/mL, respectively. Prolactinomas are larger in men than in women (26 ± 2 mm vs. 10 ± 1 mm), are more invasive, and show histologic evidence of more rapid growth.

PRL levels higher than 200 ng/mL may reflect use of a drug such as risperidone, but levels higher than 500 ng/mL are



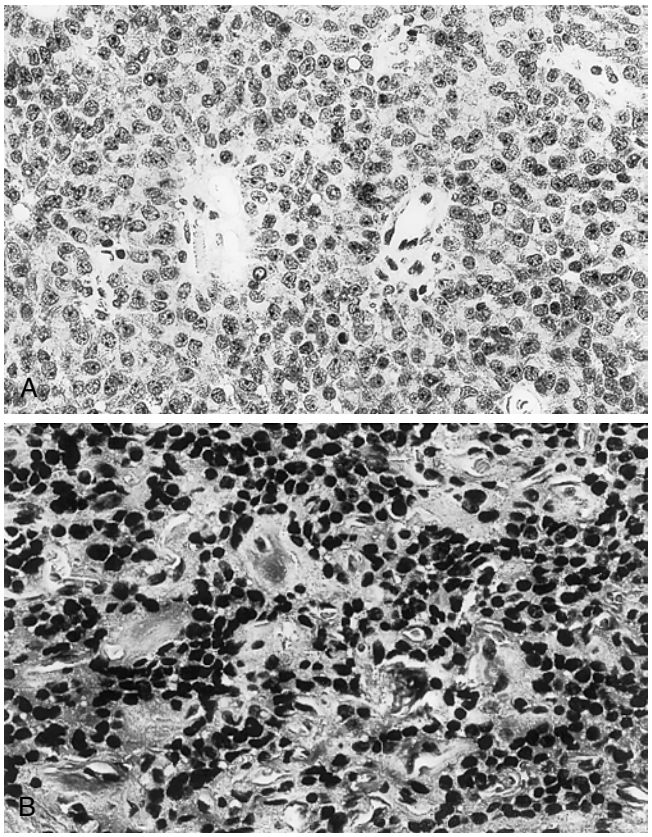
• **Fig. 9.22** Prolactin (PRL)–secreting tumors are more often macroadenomas in men (n = 31) versus women (n = 45). Serum prolactin levels highly correlate with tumor size. (Adapted from Danila DC, Klibanski A. Prolactin secreting pituitary tumors in men. *Endocrinologist.* 2001;11:105–111.)

exclusively observed in patients with prolactinomas.[246] In contrast, a lower PRL concentration of less than 200 ng/mL in a patient harboring a macroadenoma indicates that the tumor is likely not producing PRL, but hyperprolactinemia may occur as a result of mass pressure on the pituitary stalk or portal circulation, likely interrupting inhibitory control by dopamine.[247] Importantly, microprolactinomas can be associated with PRL levels ranging from minimal elevations to hundreds of nanograms per milliliter. However, when a patient with a small macroadenoma and a PRL level approximately 200 ng/mL is first encountered, it is prudent to first treat medically. If the tumor is indeed a prolactinoma, dopamine agonist treatment should lower PRL levels and shrink the tumor. If the tumor does not shrink, the mass is likely not secretory, and the hyperprolactinoma is caused by compressive stalk effect.

Pathology and Pathogenesis

Although more than 99% of prolactinomas are not malignant, and often sharply demarcated without evidence of invasion, about half may invade local structures[248] (Fig. 9.23). Invasive tumors may have higher mitotic activity and are more cellular and pleomorphic. Invasion into adjacent dura, bone, or venous structures may represent an intermediate form of prolactinoma between the sharply demarcated benign variety and the exceedingly rare malignant tumor. Invasive tumors that do not metastasize are considered benign. Immunostaining for PRL confirms the diagnosis of prolactinoma, which is usually distinct from the adjacent normal pituitary but is not truly encapsulated. These tumors have a "pseudocapsule" composed of compressed adenohypophyseal cells and a reticulin fiber network. About 20% of macroprolactinomas contain areas of hemorrhage not usually associated with features of apoplexy, and these areas may resolve.[249]

Prolactinomas are mostly slow growing, arise sporadically, usually occur singly, and are the most common pituitary tumors associated with MEN1, occurring in approximately 20% of a large kindred.[250,251] Familial prolactinomas have been described



• **Fig. 9.23** (A) Densely granulated prolactin-secreting adenoma. (B) Prolactin-producing pituitary adenoma removed by surgery from a patient treated with dopamine agonist in the preoperative period. The adenoma cells are small, possessing dark nuclei and a narrow rim of cytoplasm. Mild accumulation of interstitial connective tissue is apparent. (Hematoxylin-eosin stain; original magnification ×400.) (Photomicrograph kindly provided by Dr. Kalman Kovacs. University of Toronto, Toronto, Canada.)

with no other features of MEN1,[252] and rarely prolactinomas also occur in patients with germline *AIP* mutations.[253] Hyperprolactinemia derived from ectopic secretion from a perivascular epithelioid tumor resolved after resection of the abdominal mass.[254]

The entity of giant prolactinomas has been ascribed to those aggressive tumors representing <5% of prolactinomas that exhibit very high PRL levels (>1000 ng/mL) with a diameter greater than 40 mm, and with a high male preponderance (9:1).[255] Although these invasive tumors usually respond well to dopamine agonists, a subset is highly invasive and surgery is required, especially if mass effects do not resolve.[251,256] PRL levels may drop with cabergoline therapy or surgery, but recovery of gonadal function is only seen in about 30% of these patients. Recurrence rates are high and repeat surgery and/or radiation in addition to high-dose cabergoline are required for these aggressive tumors.

Clinical Features

Prolactinomas usually come to attention because of symptoms or signs associated with hyperprolactinemia or with tumor size or invasiveness (Table 9.16).

TABLE 9.16 Signs and Symptoms of Prolactinomas

Associated With Tumor Mass	Associated With Hyperprolactinemia
Visual field abnormalities	Amenorrhea, oligomenorrhea, infertility
Blurred vision or decreased visual acuity	Decreased libido, impotence, premature ejaculation, oligospermia
Symptoms of hypopituitarism	Galactorrhea
Headaches	Osteoporosis
Cranial nerve palsies	
Pituitary apoplexy	
Seizures (temporal lobe)	
Hydrocephalus (rare)	
Unilateral exophthalmos (rare)	

Hyperprolactinemia

Both large and small PRL-secreting tumors can present with signs and symptoms of hyperprolactinemia. Menstrual irregularities, sexual dysfunction, galactorrhea,[257] osteopenia,[258] and impaired quality of life[259] are attributable to elevated PRL levels and presence of a tumor. Elevated PRL causes sexual dysfunction via a short loop feedback effect on gonadotrophin pulsatility, presumably inhibiting GnRH[260] and LH pulse frequency and amplitude. High PRL also directly inhibits ovarian and testicular function. Women with prolactinomas may present with primary or secondary amenorrhea, oligomenorrhea, menorrhagia, delayed menarche, or regular menses with a short luteal phase that may cause infertility. Patients may also report changes in libido and vaginal dryness. Sexual dysfunction in men usually manifests as loss or decrease in libido, impotence, premature ejaculation or intracoital erection loss, oligospermia, or azospermia.[261]

Up to 50% of women and 35% of men with prolactinomas have galactorrhea; this difference may occur because male mammary tissue is less susceptible to lactogenic effects of hyperprolactinemia. Galactorrhea can be overlooked unless actively elicited. Bone density may decrease in both men and women as a result of hyperprolactinemia-induced sex steroid deficiency, and an increase in vertebral fractures detected radiologically has been reported in women.[262]

Tumor Mass Effects

Prolactinomas may present as a result of tumor size or invasiveness. Microadenomas range from entirely asymptomatic tumors found at autopsy as small as 2 to 3 mm in diameter to larger ones that are still less than 10 mm in diameter. These tumors can be invasive despite their small size. In contrast, macroadenomas range in size from noninvasive or diffuse tumors approximately 1 cm in diameter to huge tumors that may impinge upon parasellar structures. Signs and symptoms caused by large or invasive tumors are often related to compressive effects on visual structures. Objective findings are superior bitemporal defects, bitemporal hemianopsia, and decreased visual acuity. Headaches are common, but seizures (a result of extension into the temporal lobe) and hydrocephalus[263] are rarely encountered, as is unilateral exophthalmos. Tumors may invade the cavernous sinuses and yet cranial nerve palsies are rare. A sudden insult, such as pituitary apoplexy, is the more common cause of such palsies and may be a presenting symptom. Prolactinomas can also be discovered incidentally on an MRI or CT scan performed for another clinically unrelated purpose.

Evaluation

Patients with pituitary tumors should all have serum PRL levels measured. Conversely, patients with elevated serum PRL levels not fully explicable by an obvious cause (such as pregnancy or exposure to neuroleptic medications) should be evaluated for the presence of a pituitary tumor. Prolactinomas may also coexist with another cause of hyperprolactinemia, such as neuroleptic drug administration (see Chapter 8). Even minimal to moderate PRL elevations are important to investigate because they may indicate the presence of a large pituitary tumor that does not secrete PRL. PRL levels correlate with tumor size and are usually higher in male patients. Occasionally, a patient with a very high serum PRL level might have a "normal" result reported if serum dilutions are not assayed, a phenomenon called the "high-dose hook effect."[264] In contrast, serum PRL may be elevated by the presence of high-molecular-weight PRL, which is a weaker lactogen than the monomeric PRL molecule. Although usually clinically inactive, macroprolactinemia can also occur in patients with pituitary tumors. Pituitary adenomas are diagnosed in approximately 20% of patients with macroprolactinemia, some of which are associated with galactorrhea, oligomenorrhea or amenorrhea, or erectile dysfunction and decreased libido. Thus, assessment of macroprolactinemia by polyethylene glycol precipitation should be performed in patients with reported high levels of PRL and few or absent clinical features of hyperprolactinemia.[265]

A careful history will often unmask symptoms or signs of a space-related mass such as visual field abnormalities, impaired visual acuity, blurred or double vision, CSF rhinorrhea, headaches, diabetes insipidus, and hypopituitarism. Patients should also be questioned carefully about sexual history, including onset of menarche, regularity of menses, fertility, libido, potency, and ability to maintain an erection. A history of galactorrhea should also be ascertained. The coexistence of galactorrhea and amenorrhea suggests a diagnosis of pituitary adenoma until otherwise proven.

PRL is also elevated in up to 50% of patients with acromegaly.[266] Patients in the early stages of acromegaly or with mild disease or patients harboring acidophilic stem cell adenomas may have few obvious signs of GH excess. Because the human GH molecule has lactogenic properties similar to those of PRL,[267] signs and symptoms of a prolactinoma may be mimicked by a purely GH-secreting tumor, and serum IGF1 should be measured. Elevated PRL levels are occasionally encountered in patients with TSH-secreting tumors. Other pituitary hormone functions should be ascertained to determine the presence of hypopituitarism. An MRI is required to establish a definitive diagnosis of prolactinoma.

Treatment

Optimal treatment outcomes for a prolactinoma include normalization of PRL levels (and associated signs and symptoms) and complete tumor removal or shrinkage with a reversal of tumor mass effects. Specifically, previously abnormal sexual function and fertility should be restored, galactorrhea stopped, impaired bone density improved, tumor eliminated or reduced in size without impairing pituitary or hypothalamic function, and vision normalized, if impaired.

TABLE 9.17 Dopamine Agonist Treatment of Prolactinomas[a]

	Bromocriptine[b] (2.5–7.5 mg/day)	Cabergoline[b] (0.5–1 mg twice weekly)
PRL Normalized (range, 40–100%)		
Macroadenomas	70	80
Microadenomas	65	70
Menses Resumed (range, 40–100%)		
Macroadenomas	70	80
Microadenomas	85	80
Tumor Shrinkage (range, 20–100%)		
None	20	20
Up to 50%	40	55
50% or more	40	25
Visual Field Improvement (range, 33–100%)	90	70
Drug Intolerance	15	5

[a]Long-acting cabergoline has improved patient compliance and has fewer gastrointestinal side effects. For fertility, bromocriptine is preferred as it is short acting and can be discontinued immediately on pregnancy confirmation.

[b]Values = % of patients.

Medical Treatment

Medical management of prolactinomas with dopamine agonist drugs has been widely recommended as the treatment of choice[268] (Table 9.17).

Bromocriptine

Bromocriptine, a semisynthetic ergot alkaloid dopamine agonist, lowers elevated PRL levels, restores abnormal menstrual function in 80% to 90% of patients, shrinks prolactinomas, restores impaired sexual function, and resolves galactorrhea.[269] Improvement in visual field abnormalities occurs in approximately 90% of affected patients.[270] Drug withdrawal can result in rapid tumor expansion.[271] Occasionally, tumors that shrink during bromocriptine therapy do not enlarge following drug withdrawal. In a subset of patients, hyperprolactinemia disappears spontaneously after long-term observation. Very occasionally, bromocriptine lowers PRL levels despite continued tumor expansion, although when tumors grow during dopamine agonist therapy there is usually a simultaneous PRL elevation.

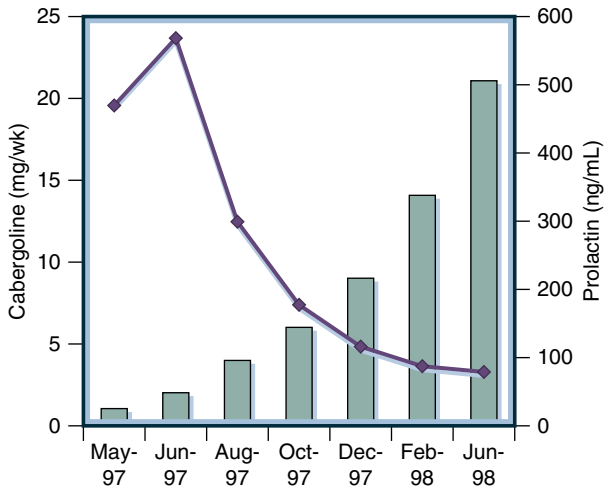
Despite high doses of bromocriptine, some patients are entirely or partially resistant to its effects and to those of cabergoline as well.[272] Not infrequently, it is difficult to completely normalize PRL levels in patients with initially very high levels, although these patients respond to treatment with impressive tumor shrinkage and sometimes improved sexual function. Although higher doses or a change in the form of dopamine agonist has been reported to further normalize PRL in some cases,[272] many such patients remain with elevated PRL levels regardless of treatment used. Resistance to dopamine agonists may reflect reduced D_2 receptor binding sites or receptor gene polymorphisms.[273]

Bromocriptine shrinks prolactinomas by shrinking tumor cell size, including cytoplasmic, nuclear, and nucleolar areas.[274] Histologic sections appear very dense as a result of small cell size and clumping of nuclei (see Fig. 9.23). PRL mRNA and PRL synthesis are inhibited, exocytoses are reduced, PRL secretory granules decrease, and rough endoplasmic reticulum and Golgi apparatus involute. The net effect is reduced cell volume. Tumor necrosis may also occur.[275]

Perivascular fibrosis observed in prolactinomas derived from patients treated with bromocriptine has been attributed to difficulty in tumor resection. However, there is no effect of prior treatment with bromocriptine on surgical success rates,[276] and bromocriptine was a helpful adjunct to transsphenoidal microsurgery for macroprolactinomas.[277] Even the largest tumors or those with the highest PRL levels respond well to treatment with up to 2.5 mg bromocriptine three times daily. Higher doses are often not more effective. Once positive effects on tumor size and amenorrhea and galactorrhea are established, some patients can be satisfactorily maintained with lower doses but rarely without medication.

Cabergoline

Because cabergoline has a longer duration of action than bromocriptine and is usually administered once or twice weekly, it has surpassed bromocriptine as the first-line therapeutic choice for most patients, unless pregnancy is desired.[270] The long half-life of cabergoline is a result of its high affinity for lactotroph D_2 receptors and a greater propensity of the drug to remain in pituitary tissue. In pharmacokinetic studies, cabergoline lowered PRL levels in a dose-related manner.[278] PRL levels were normalized in 83% of 459 women with hyperprolactinemia treated with cabergoline (0.5–1 mg twice weekly) and in 52% of women on bromocriptine (2.5–5 mg twice daily). Cabergoline was also more effective than bromocriptine in restoring ovulatory cycles and fertility (72% vs. 52%; $p < 0.001$), was better tolerated than bromocriptine, and caused fewer but similar side effects (Fig. 9.24). Tumor size decreased in 11 of 15 patients with macroadenomas, and menses resumed in 3 of 4 premenopausal women.[279] In 85 patients with



• **Fig. 9.25** Stepwise decrease in PRL levels *(diamonds)* concordant with stepwise increase in cabergoline doses in a patient with a prolactin-secreting macoadenoma *(bars)*. (Redrawn from Molitch ME. Pharmacologic resistance in prolactinoma patients. *Pituitary*. 2005;8:43–52.)

macroprolactinomas treated with cabergoline (0.25–10.5 mg/week), PRL concentrations were normalized in 61% of patients and decreased by at least 75% in an additional 24 patients, and tumor size decreased in 66% of patients. Nine patients were resistant to cabergoline despite doses of up to 7 mg per week.[272] Cabergoline also may result in dramatic improvement of prolactinoma-associated headache.[280]

Prolactinomas completely or substantially resistant to medication are infrequently encountered. Up to 15% of patients receiving optimal cabergoline doses fail to normalize PRL levels or exhibit less than 50% tumor mass shrinkage. Many of these patients respond to higher cabergoline doses (Fig. 9.25).[281] Most "resistant" patients may have partial resistance (i.e., tumors shrink and PRL levels are lowered but do not normalize). These patients may require surgery or radiation therapy. With tumor growth controlled on treatment, persistently elevated PRL levels should be addressed by evaluating and treating specific reproductive and bone disorders caused by hyperprolactinemia.

Administration

Attention to the mode of dopamine agonist administration may avoid or minimize potential adverse effects (Fig. 9.26). Usual starting doses are 1.25 mg bromocriptine (daily) or 0.25 mg cabergoline (weekly). Doses of medication are either increased gradually, as tolerated, or decreased depending on tolerability and should be initiated with a small dose with food before bedtime. Patients should initially avoid activities that cause peripheral vasodilatation (e.g., hot baths), thereby decreasing the risk of postural hypotension. If side effects are troublesome, the subsequent dose should be halved, then doses increased gradually thereafter to achieve effective levels. Switching from one medication to another may be beneficial. Application of intravaginal bromocriptine administration has been advocated to alleviate adverse gastrointestinal events.[282] Dopamine agonists are also effective in persistently shrinking cystic prolactinoma size.[283]

Remission of hyperprolactinemia may occur in about 20% of patients in whom dopamine agonists are tapered and then discontinued. Generally, withdrawal should only be attempted after at least 2 years of therapy and in those patients with no evidence of tumor invasion.[268,284] Tapering of cabergoline doses prior to complete therapy withdrawal has been recommended. Predictors of achieving normoprolactinemia after withdrawal include lower cabergoline doses required with evident tumor mass shrinkage and mass resolution.[285] Recurrences after withdrawal are more likely to occur for macroadenomas and are reported in about 30% of patients.[244,284,286,287]

In contrast to adults, about 75% of childhood prolactinomas are large macroadenomas.[288] In a cohort of 77 children and adolescents with macroprolactinomas, factors associated with dopamine agonist resistance encountered in 25% of patients included younger age of onset, higher PRL levels, and larger tumors.[289]

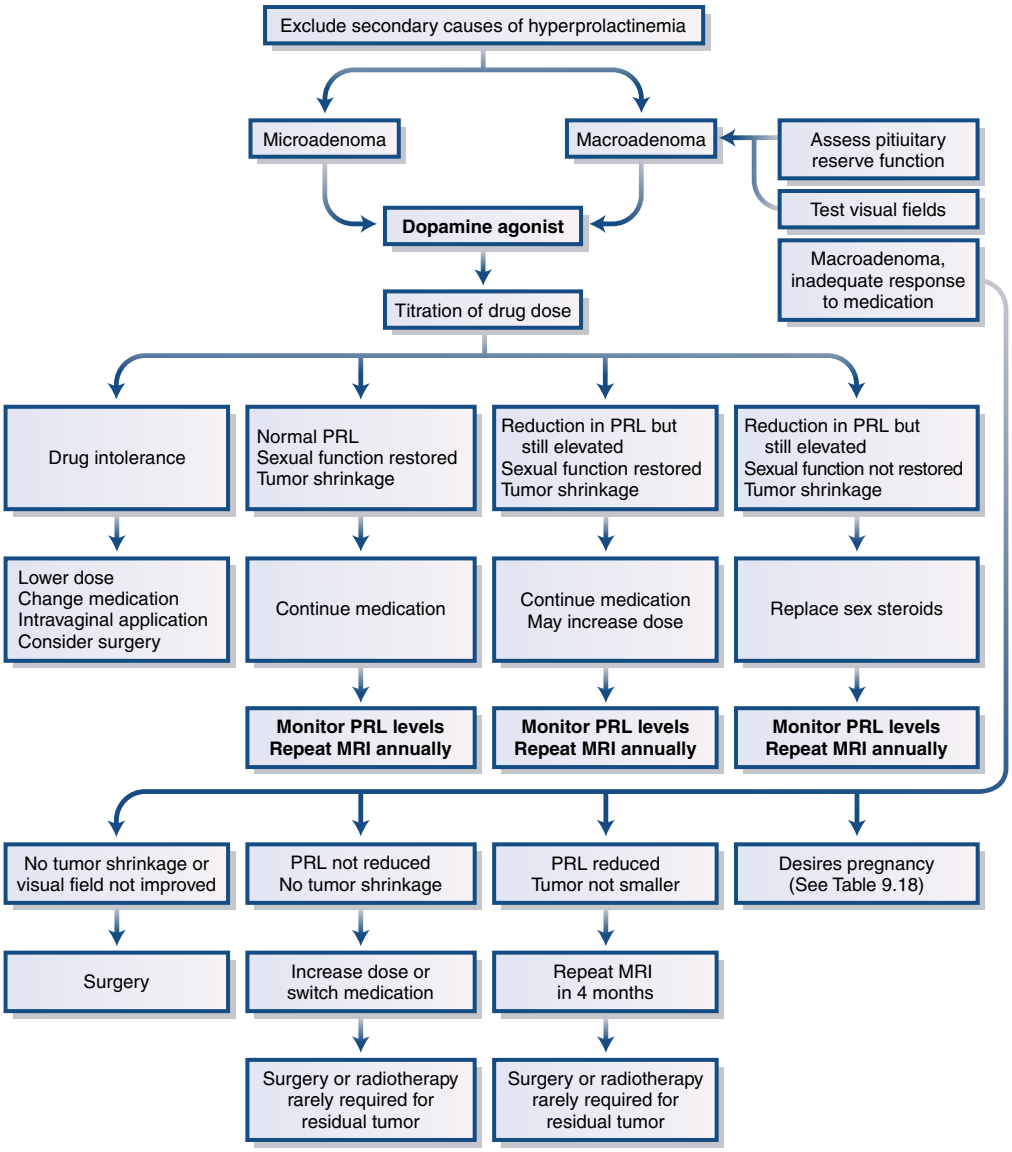
Adverse Effects of Dopamine Agonists

Side effects of dopamine agonists are common. Nausea occurs in up to 50% of patients; nasal stuffiness, depression, and digital vasospasm occur, the latter more frequently with higher doses, as seen in patients with Parkinson disease. Postural hypotension can cause loss of consciousness, occurs infrequently, and is usually avoided by careful dosing. Signs and symptoms of psychosis or exacerbation of preexisting psychosis can be encountered in up to 1.3% of patients receiving bromocriptine.[290] A history of psychotic symptoms should raise concerns about using these medications. If psychosis occurs in a patient in whom dopamine agonists are clearly the treatment of choice, the judicious combination of this agent and antipsychotic medication can be effective. A neuroleptic that is not a potent PRL stimulator, such as olanzapine, is preferred. CSF rhinorrhea occurs during dopamine agonist treatment in up to 6.1% of patients with macroadenomas, some of which are more resistant to dopamine agonists.[291] Other rarely reported serious side effects include hepatic dysfunction and cardiac arrhythmias. Retroperitoneal fibrosis, pleural effusions and thickening, and restrictive mitral regurgitation have been reported in patients taking high doses of bromocriptine.[292,293] Hypersexuality with disordered impulse control may occur with restoration of eugonadism or may be a direct dopamine effect.[294]

In patients with Parkinson disease high doses of ergot-derived dopamine agonists may lead to increase of moderate to severe regurgitation in at least one valve.[295] These observations with high ergot doses raise concern for patients with pituitary tumors who mostly require far lower drug doses. Several reports have shown no evidence that low doses of cabergoline place patients at risk for significant valve disease,[296] while some have raised the possibility that heart valve disease might be associated with standard endocrine doses of cabergoline used for patients with prolactinomas. One hundred prospectively studied patients with hyperprolactinemia who were exposed to dopamine agonists for a median of 124 months and received a median cumulative dose of 277 mg cabergoline showed no altered cardiac valve function or calcification.[297] In a cross-sectional study of 747 patients with hyperprolactinemia, there were no associations of cumulative doses of dopamine agonists and cardiac valvulopathy.[298] These results were affirmed in a follow-up of 192 of these patients.[299]

Radiation Therapy

Linear accelerator radiotherapy is effective in controlling or reducing the size of prolactinomas. However, this therapy takes years to achieve maximal effect. The usual recommended radiation dose is 4500 to 4600 cGy, and normalization of PRL was achieved in 18 of 36 patients at a mean of 7.3 years after treatment.[300] Hypopituitarism occurs as a side effect of radiation. In 36 patients with prolactinomas, of whom 83% had normal GH responses to insulin-induced hypoglycemia before therapy, 34 were GH deficient



• **Fig. 9.26** Prolactinoma management. After secondary causes of hyperprolactinemia have been excluded, subsequent management decisions are based on clinical imaging and biochemical criteria. *MRI,* magnetic resonance imaging; *PRL,* prolactin.

at 9 to 12 years after radiotherapy.[300] Stereotactic radiosurgery is often effective in treating prolactinomas resistant to or intolerant of dopamine agonists.[301]

Surgery

Endoscopic endonasal transsphenoidal surgery has been used to resect prolactinomas. Most patients with microprolactinomas experience normalization of PRL levels, and overall about 50% of patients with macroprolactinoma are in remission after surgery.[302] The success rate of pituitary surgery is determined by experience of the surgeon and correlates inversely with tumor size and serum PRL concentrations.[276] In a compilation of results in 31 published surgical series, serum PRL was normalized in 71% of 1224 patients with microprolactinomas. More recent studies report up to 100% cure rates for microprolactinomas achieved by high-volume surgeons.[302] Nevertheless, a high rate of hyperprolactinemia recurrence is commonly encountered postoperatively. Complete resection of macroprolactinomas, especially large invasive tumors, is difficult to achieve, and postoperative serum PRL levels were initially normalized in only 32% of patients, with a 19% to 45% recurrence rate.[303]

Although results of medical therapy are superior to those of surgery, there remains a role for surgery, especially in those resistant to dopamine agonist therapy who are particularly well suited for surgery. If tumor removal is only partial, adjunctive radiation therapy could be considered, as second surgery is usually associated with a higher complication rate. Prophylactic transsphenoidal surgery should be considered in women whose prolactinomas are large enough to potentially threaten vision during pregnancy. A subset of patients cannot tolerate dopamine agonists, and others prefer surgery and refuse medication.

Chemotherapy

For aggressive PRL-secreting tumors unresponsive to other therapies, temozolomide, an alkylating compound that readily crosses the blood-brain barrier, may control tumor growth.[304–306] The

TABLE 9.18 Management of Patients with Prolactinomas Planning Pregnancy

Microadenoma	Macroadenoma
Discontinue dopamine agonist when pregnancy test is positive	Consider surgery before pregnancy
Periodic visual field examinations during pregnancy	Ensure bromocriptine sensitivity before pregnancy
Postpartum magnetic resonance imaging (MRI) after 6 weeks[a]	Monitor visual fields expectantly and frequently
	Administer bromocriptine if vision becomes compromised
	Or continue bromocriptine throughout pregnancy if tumor previously affected vision
	Consider high-dose steroids or surgery during pregnancy if vision is threatened or adenoma hemorrhage occurs
	Postpartum MRI after 6 weeks

[a]Pituitary MRI may be performed during pregnancy if deemed necessary.

response to temozolomide may sometimes be predicted by low tumor staining for MGMT.[307,308]

Pregnancy

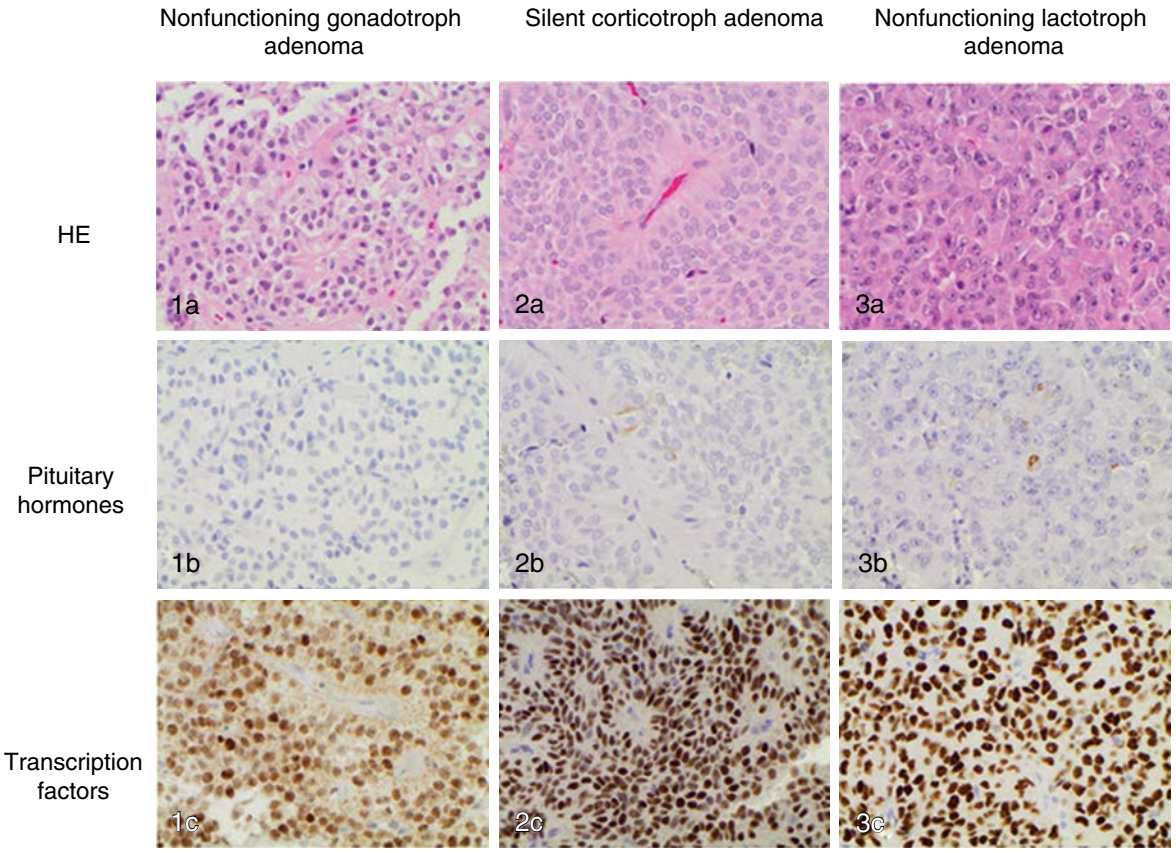
The normal pituitary enlarges during pregnancy and prolactinomas may also increase in size during pregnancy. The incidence of pregnancy-associated tumor enlargement, as determined by development of abnormal visual fields, has been estimated to occur in 1.4% of women with microadenomas and 16% of women with macroadenomas.[308] In other reports, the risk for macroadenoma enlargement has been estimated to be as high as 36%. In a prospective analysis in which 57 patients with microprolactinomas were followed by formal visual field examinations during pregnancy, none developed visual disturbances.[309]

Although dopamine agonists have been used during pregnancy to prevent tumor growth (Fig. 9.27),[310] it seems prudent to reduce fetal exposure to medication if possible.[311] It is recommended that menstrual periods be allowed to occur naturally for a sufficient period of time (3–4 months) to predict that a missed period might be a result of pregnancy (Table 9.18). Barrier contraception is recommended during this period. Within several days to a week of obtaining a positive hCG test, medication should be discontinued. Of 6239 pregnancies managed in this manner, bromocriptine therapy was not associated with increased abortions or terminations, prematurity, multiple births, or infant malformations above that expected in the control population. There is no compelling evidence that other dopamine agonists are less safe, but pregnancy exposure to the other agonist forms is less comprehensively documented. Treatment options for patients harboring prolactinomas whose vision becomes impaired during pregnancy include administering bromocriptine during pregnancy, high-dose steroids, and surgical resection.[308] Of 53 pregnant women receiving bromocriptine, mean offspring birth weight was normal, congenital abnormalities occurred in four babies, and physical and intellectual development of children was normal for up to 9 years. In an observational report on 380 pregnancies in women treated with cabergoline, early fetal exposure did not increase the risk of miscarriage or fetal malformation.[312] In 91 patients with hyperprolactinemia treated with cabergoline prior to pregnancy, the medication was discontinued at 6 weeks of gestation, and no increase in miscarriages or fetal malformations was observed when monitored for up to 60 months.[313]

To avoid neurologic complications of tumor enlargement during pregnancy, it is recommended that women with prolactinomas be tested for prolactin sensitivity to dopamine agonists, as well as tolerance of these drugs, before proceeding with a pregnancy. If tumors are insensitive to dopamine agonist–related tumor shrinkage, prophylactic surgery could be appropriate. If the tumor is a macroadenoma approximating the optic chiasm, the likelihood of visual difficulties is greater and therefore undertaking surgery prior to pregnancy could be prudent.[314]

Nonfunctioning Pituitary Tumors

Nonfunctioning pituitary tumors comprise approximately 25% to 35% of pituitary tumors.[315] These tumors are clinically silent (i.e., do not actively secrete hormones), but they arise from pituitary cells capable of expressing hormone genes, including LH and FSH, and more rarely, ACTH and TSH. Diagnostic markers useful for determining pituitary tumor classification and behavior include hormone immunohistochemistry and cell-specific transcription factors to define differentiated cell types, as well as



• **Fig. 9.28** Transcription factors determine cell-specific diagnosis of pituitary adenoma subtype when hormone expression is sparse or absent. proliferative indices (Fig. 9.28). Gonadotroph and corticotroph cell tumors predominate amongst the nonfunctioning tumors.[316]

Gonadotroph Cell Tumors

Most nonfunctioning or hormonally silent tumors arise from gonadotroph cells, and they most frequently present as clinically nonfunctioning masses not associated with elevated serum gonadotrophins. Yet, they usually express gonadotrophin subunits detectable by immunohistochemistry. In a series of nonfunctioning adenomas, 42% of tumors immunostained for TSH β-subunit, 83% for LH β-subunit, 75% for FSH β-subunit, and 92% for α-subunit.[317] Although LH, FSH, and α-subunit are released from these nonfunctioning tumors when maintained in culture, production is usually not sufficient to elevate blood levels. A small subset of gonadotroph tumors do secrete sufficient hormone to elevate serum gonadotrophin or α-subunit levels, which occasionally cause clinical syndromes.

Presentation

Clinically nonfunctioning tumors generally come to attention because of their large size, or they are detected incidentally (incidentaloma) (Table 9.19). Of 506 incidentally discovered pituitary masses, 324 were clinically nonfunctioning tumors, and the remainder were cystic or parasellar masses.[318] A gradual visual deficit arising from optic chiasmal compression is common, and patients are often unaware of the disturbance. Recognition of visual field deficits is often delayed because formal visual fields are not routinely evaluated unless a defect is suspected clinically. In the absence of associated space-occupying or hormonal disorders these large tumors may go unrecognized for many years and be inadvertently detected on MRI performed for other purposes. Sinusitis evaluation, pituitary apoplexy, or performance of a brain MRI for an unrelated indication (e.g., head trauma) may bring these tumors to clinical attention. Although not often the initial presenting complaint, these patients are commonly deficient in one or more pituitary hormones, as noted in two-thirds of 56 patients with nonfunctioning macroadenomas.[37] Although the most commonly encountered endocrine symptoms are related to gonadotrophin deficiency, quality of life may be decreased, and daytime somnolence has also been reported.[319]

A very small subset of gonadotroph adenomas producing elevated serum FSH, LH, and α-subunit concentrations are considered functioning gonadotroph adenomas and may be associated with specific endocrine syndromes. Most of these are macroadenomas, and imaging may also reveal ovarian cysts or increased testicular volumes.[320] High serum FSH level, usually with a low LH level, is usually the only sign that a pituitary

tumor secretes FSH. Female patients with such tumors may present with pelvic pain due to ovarian hyperstimulation.[321] High gonadotrophin levels associated with menopause or testicular failure may complicate interpretation of gonadotrophin levels, but both LH and FSH are high in primary gonadal failure (Table 9.20). LH-producing tumors are exceedingly rare and in males may cause elevations in serum testosterone with acne and skin oiliness. Very rarely, isosexual precocious puberty may be a presenting feature in children. Paradoxically, these patients may sometimes present with hypogonadism due to gonadal downregulation.

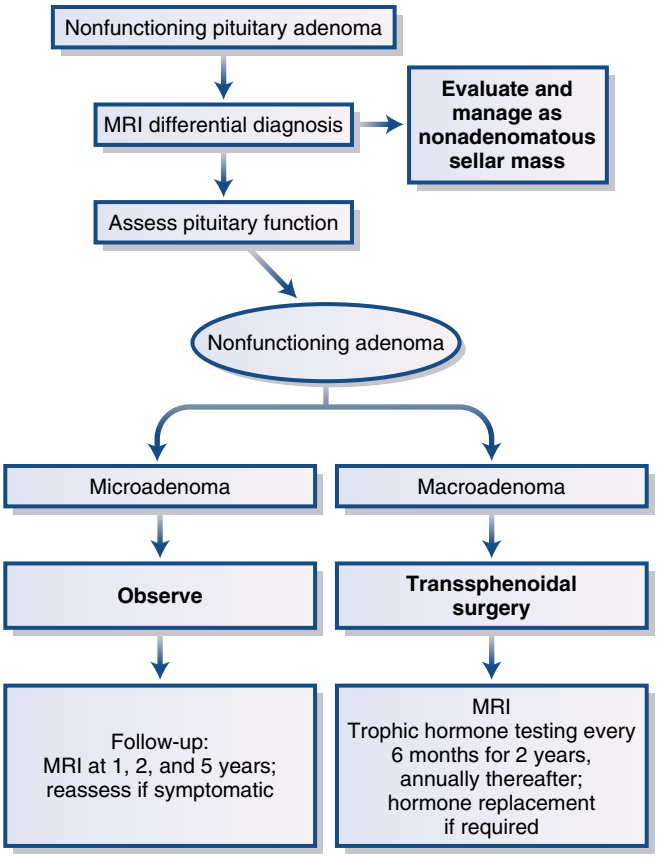
Evaluation

Patients with incidentally discovered adenomas (incidentalomas) should be comprehensively evaluated for hormone hypersecretion, pituitary failure, and local mass effects.[322] Subsequent decisions on whether to undertake surgery are determined by the size (>10 mm) of the mass, evidence of continued growth, visual effects, central compressive features, or signs of hemorrhage. If hormone hypersecretion is detected, specific therapeutic approaches are required.

MRI, visual field examination, and pituitary hormones should be evaluated, the latter not only to detect hypopituitarism but also to exclude hormone overproduction that may not be clinically apparent. This distinction of nonfunctioning versus secretory tumors is important for determining subsequent management.[323] LH, FSH, α-subunit, PRL, T_4, triiodothyronine (T_3), TSH, cortisol, and IGF1 levels should be measured. A serum cortisol at 8 AM, cortisol response to cosyntropin, or an insulin tolerance test is used to exclude secondary adrenal insufficiency. The extent of hormonal evaluation requires clinical judgment. Elevated LH or FSH levels should be interpreted in light of the patient's physiologic state. Elevated serum FSH in a woman with regular menstrual cycles would be interpreted differently from those detected in a menopausal patient; gonadotrophin elevations in patients with primary gonadal failure are not generally limited to one hormone, and circulating α-subunit elevation is consistent with a pituitary tumor but not gonadal failure. TRH stimulation may differentiate elevated gonadotrophin levels ascribed to end-organ failure or to independent tumor production. In patients harboring gonadotroph cell adenomas, increased FSH, LH, LH β-subunit, or α-subunit are evoked in response to TRH.[324]

Treatment

Clinical judgment should be used in determining appropriate therapy, including surgery, surgery followed by radiotherapy, radiotherapy alone, or expectant observation (Fig. 9.29). No reliable tumor marker is predictive of mass growth or recurrence.



• **Fig. 9.29** Management of nonfunctioning pituitary adenomas. Skilled magnetic resonance imaging *(MRI)* interpretation is crucial to diagnose nonadenomatous mass (e.g., meningioma, aneurysm, or other sellar lesion).

Surgery

Surgical resection of nonfunctioning adenomas is recommended for symptomatic patients, if vision is threatened, or for macroadenomas whose size threatens vital structures.[325] Transsphenoidal microscopic or endoscopic endonasal transsphenoidal surgery is the recommended approach[326] (Table 9.21). Gross total mass removal was reported after surgery in 137 of 173 patients with nonfunctioning pituitary adenomas,[326] and in another study gross total resection was achieved in 65.3% of 359 patients with improved vision or normalization of visual loss in 80% of affected patients.[327] In a large prospective study, visual function was restored in 75% to 90%, while hypopituitarism was rescued in up to 50% of patients.[328] Progression-free survival after surgery in 365 patients was strongly determined by extent of tumor invasion and grade.[329]

Postoperative Radiotherapy

To lower the postoperative risk of tumor growth progression, postoperative radiotherapy may be recommended.[330] An expectant follow-up of 65 patients after pituitary surgery for nonfunctioning adenomas showed that 32% of patients not receiving postoperative radiotherapy exhibited tumor regrowth during a mean follow-up period of 76 months.[331] Similar recurrence rates were observed in a retrospective follow-up of 212 patients.[332] In another study, tumor recurrence or regrowth occurred in 6% to 46% of patients not receiving radiotherapy after transsphenoidal surgery, and patients having received radiotherapy had a recurrence rate of 0% to 36%.[333] Nevertheless, despite the relatively high incidence of postoperative tumor regrowth, even after apparently complete resection, many neurosurgeons avoid routine postoperative radiation therapy. This approach requires advising careful follow-up, with periodic annual MRIs and visual evaluations, and encouraging patients to maintain medical follow-up.

Radiation can be offered if the tumor mass reexpands. In a retrospective study of 62 patients with nonfunctioning pituitary tumors treated with stereotactic radiosurgery, 60% experienced decreased tumor size and 37% of tumors remained unchanged. However, the risk of developing new anterior pituitary hormone deficits at 5 years was 32%.[334] In 140 consecutive patients undergoing stereotactic radiosurgery, the tumor mass was stabilized or decreased in 90% and median time to tumor progression was 14.5 years, with delayed hypopituitarism observed in 30% of patients.[335] In a large multicenter

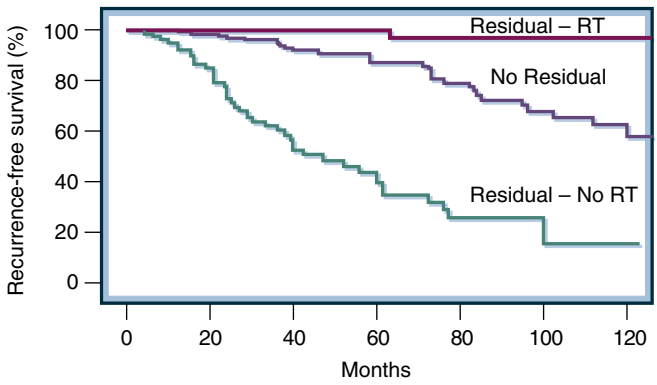
From Huang W, Molitch ME. Management of nonfunctioning pituitary adenomas (NFAs): observation. *Pituitary.* 2018;21:162–167.

outcomes analysis of 512 patients undergoing stereotactic radiosurgery for nonfunctioning pituitary adenomas, median follow-up was 36 months. Progression-free tumor survival was associated with smaller tumor size and absence of suprasellar extension. New or aggravated pituitary failure was encountered in 21% of patients.[336] Because patients may experience tumor regrowth even after radiation therapy, they too should undergo periodic posttreatment MRIs, albeit less frequently. In a retrospective study of 237 patients followed for a median of 5.9 years, the 5-year second regrowth rate was 36% after surgery, 12.5% after radiotherapy, and 12.7% after surgery with adjuvant radiotherapy.

Expectant Observation for Incidentalomas

Given the slow growth rate for nonfunctioning microadenomas or small macroadenomas, patients may be followed expectantly.[337] Some tumors do not grow over years or even decades. Overall, only 10% of incidentally discovered microadenomas will continue to enlarge. However, over 20% of incidental macroadenomas are reported to continue growing (Table 9.22). After 5 years, the rate of growth appears to increase.[337] Overall, about 10% of incidentalomas may decrease in size when followed for up to 8 years. Serial MRIs should be undertaken at 1, 2, and 5 years. Nonfunctioning adenomas may grow insidiously postoperatively and are usually asymptomatic until such time that they are large enough to affect vision (Fig. 9.30). As 20% of tumor regrowth occurs more than 10 years after surgery, performing serial MRIs, perhaps indefinitely, is suggested.[338] Periodic, but less frequent,



• **Fig. 9.30** Recurrence-free survival by Kaplan-Meier plots in 436 patients with silent (clinically nonfunctioning) pituitary adenomas according to the presence or absence of residual adenoma after surgery and with or without radiation therapy *(RT).* (Adapted from Losa M, Mortini P, Barzaghi R, et al. Early results of surgery in patients with nonfunctioning pituitary adenoma and analysis of the risk of tumor recurrence. *J Neurosurg.* 2008;108(3):525–532. As adapted in Mayson SE, Snyder PJ. Silent (clinically nonfunctioning) pituitary adenomas. *J Neurooncol.* 2014;117:429–436.)

endocrine evaluation is also suggested because hypopituitarism occurs frequently and may be challenging to detect. Over half of these patients exhibit pituitary hormone deficits (especially GH and gonadotrophins) prior to surgery, and postoperatively the condition may persist, recover, or become newly manifest. In

a nationwide follow-up of 2795 patients with nonfunctioning tumors in Sweden, overall excess mortality was reported, especially for patients younger than 40 years of age and women with hypopituitarism.[339] As ACTH and gonadotrophin deficiency are important determinants of mortality in patients with nonfunctioning adenomas (about a twofold to fivefold increase), careful hormone replacement regimens are required.[340]

Pregnancy

Microadenomas only very rarely lead to impaired vision during pregnancy, as opposed to macroadenomas, which do so with greater frequency.[341] Because macroadenomas do not usually shrink on medical therapy, the risks of visual impairment arising during pregnancy must be weighed carefully, and tumor resection may be indicated prior to pregnancy.

Medications

Medications are not usually effective in reducing tumor size and visual compromise. As most nonfunctioning adenomas express D_2 receptors, treatment with cabergoline has been advocated to shrink some nonfunctioning tumors or to prevent regrowth of postoperative remnants.[342] Treatment of 79 patients with cabergoline (mean weekly dose 1.5 mg) for a mean of 8.8 years resulted in overall control of tumor growth in 87%, with 38% experiencing tumor shrinkage. Overall, 13% of treated versus 42% of untreated patients required further surgery or radiotherapy.[343]

Silent Corticotroph Tumors

These tumors are usually resected with the clinical diagnosis of nonfunctioning macroadenomas and the diagnosis is subsequently made by pathologic assessment. They immunostain for ACTH and POMC but are clinically silent and more aggressive than nonsecreting tumors of pure gonadotroph cell origin.[344] ACTH secretion is unaltered, with no associated clinical or biochemical features of hypercortisolism, although these tumors are morphologically indistinguishable from adenomas associated with Cushing disease. A mixed corticotroph-gonadotroph cell origin may underlie the primitive tumor cell type, with associated aggressive growth.[345] Silent corticotroph tumors may represent up to 7% of all surgically removed adenomas and are usually hemorrhagic and invariably macroadenomas. Unlike Cushing disease, they have a 2:1 male preponderance, often present with mass effects, and about one-third have preoperative evidence for pituitary insufficiency. About half exhibit cavernous sinus or bony invasion, hemorrhage, necrosis, and cyst formation. They often recur and postoperative radiation and reoperation are required to eradicate tumor regrowth or residual mass.[346]

A review of 20 cases of silent ACTH-producing macroadenomas reported visual dysfunction as the most common presenting complaint (38%), and 13% presented with pituitary apoplexy.[346] In a study of 50 patients undergoing surgical resection and stereotactic radiosurgery for silent ACTH-secreting tumors and followed for a median of 40 months, 82% exhibited tumor growth control versus 91% control achieved for nonfunctioning adenomas.[347] Regular MRI follow-up is required because of the high risk for recurrence. Unless appropriate immunostaining is performed, many of these tumors remain undiagnosed and are inadvertently classified as recurrent nonfunctioning macroadenomas.

Silent Subtype 3 Tumors

This entity usually expresses GH, PRL, and/or TSH (i.e., cells of the Pit1 lineage). They are clinically aggressive, nonsecreting adenomas that exhibit cytologic features of nuclear atypia.[348]

Silent GH-Expressing Tumors

Silent GH-expressing tumors occur with a prevalence of about 2% of all pituitary adenomas. These patients should be followed prospectively for recurrences and for potential progression to acromegaly.[349]

Acromegaly

In 1886, Pierre Marie published the first clinical description of disordered somatic growth and proportion and proposed the name "acromegaly."[350] When relation of this syndrome to a pituitary tumor was later recognized, Benda showed in 1900 that these tumors comprise mainly adenohypophyseal eosinophilic cells, which he proposed to be hyperfunctioning.[351] Cushing, Davidoff, and Bailey documented the clinicopathologic features of acromegaly and demonstrated clinical remission of soft tissue signs after adenoma resection.[352] Evans and Long induced gigantism in rats injected with anterior pituitary extracts, confirming the association of a pituitary factor with somatic growth.[353] Establishment of the unequivocal pathophysiologic link between hyperfunctioning adenoma and acromegaly was the earliest example of a pituitary disorder to be clinically and pathologically recognized and appropriately managed by surgical excision of a hypersecreting source.

Incidence

The prevalence of acromegaly is estimated to range from 28 to 137 cases per million. Recent surveys indicate an increase in the annual incidence to about 10 cases per million[213,215,217,354–363] (Table 9.23). In the United States, over 3000 new cases of acromegaly are diagnosed annually, with an estimated population prevalence of 25,000 patients.[363]

Pathogenesis

GH and IGF1 act both independently and dependently to induce features of hypersomatotropism. Acromegaly is caused by pituitary tumors secreting GH or very rarely by extrapituitary disorders[364] (Fig. 9.31). Regardless of the cause, the disease is characterized by elevated levels of GH and IGF1 with resultant signs and symptoms of hypersomatotropism.

Pituitary Acromegaly

Over 95% of patients with acromegaly harbor a GH-secreting pituitary adenoma (Fig. 9.32 and Table 9.24). Pure GH-cell adenomas contain either densely or sparsely staining cytoplasmic GH granules, and these two variants are either slow (densely granulated) or rapidly growing (sparsely granulated).[365] The former type arises insidiously and presents during or after middle age, but the latter type arises in younger subjects with more aggressive tumor growth and florid disease. Mixed GH cell and PRL cell adenomas are composed of distinct somatotrophs expressing GH and lactotrophs expressing PRL. Monomorphous acidophilic stem cell adenomas arise from the common

Modified from Lavrentaki A, Paluzzi A, Wass JAH, et al. Epidemiology of acromegaly: review of population studies. *Pituitary.* 2017;20:4–9; Broder MS, Change E, Cherepanov D, et al. Incidence and prevalence of acromegaly in the United States: a claims-based analysis. *Endocr Pract.* 2016;22:1327–1335.

GH and PRL stem cell and often contain giant mitochondria and misplaced GH granule exocytosis. They grow rapidly, are invasive, and present with predominant features of hyperprolactinemia. Monomorphous mammosomatotroph cell adenomas express both GH and PRL from a single cell, but plurihormonal tumors may express GH with any combination of PRL, TSH, ACTH, and α-subunit. These patients present with clinical features of acromegaly as well as hyperprolactinemia, Cushing disease, or very rarely hyperthyroxinemia. Somatotroph hyperplasia is difficult to distinguish from a GH cell adenoma, and silver staining displays a well-preserved reticulin network without a surrounding pseudocapsule. The rigorous morphologic diagnosis of GH cell hyperplasia is usually associated with stimulation by ectopic GHRH derived from an extrapituitary tumor causing acromegaly.

Both pituitary and hypothalamic factors influence pituitary tumor pathogenesis. Even when exhibiting marked nuclear pleomorphism, mitotic activity, and invasiveness, these tumors are invariably benign.

Disordered GHRH Secretion or Action

Adenomas express receptors for GHRH, ghrelin,[366] and somatostatin, but functional mutations of either the GHRH or somatostatin receptor have not been reported. GHRH directly stimulates GH gene expression and also induces somatotroph mitotic activity. Clinically, GHRH production by hypothalamic, abdominal, or chest neuroendocrine tumors causes somatotroph hyperplasia, and rarely adenoma, with resultant unrestrained GH secretion and acromegaly.[159] However, histologic examination of most pituitary GH cell adenoma tissue specimens does not show hyperplastic somatotroph tissue surrounding the adenoma, implying no generalized hypothalamic overstimulation. Failure to downregulate GH secretion during prolonged GHRH stimulation also points to a role for GHRH in maintaining persistent GH hypersecretion. Furthermore, a GHRH antagonist reduced human growth hormone production in 50 patients with acromegaly, suggesting a role for endogenous GHRH.[367] Expression of intra-adenomatous GHRH abundance correlates with tumor size and activity, implying a paracrine role for GHRH in mediating adenoma growth.[368] However, complete surgical resection of well-defined GH-secreting microadenomas usually results in a definitive cure of excess hormone secretion with very low postoperative tumor recurrence rates, strongly suggestive of intact hypothalamic function in these patients.

Disordered Somatotroph Cell Function

The sequence of events leading to somatotroph clonal expansions appears multifactorial (see earlier discussion). An activated oncogene may be required for initiating tumorigenesis, and promotion of tumor growth may require GHRH and other growth factor stimulation. The cellular mutation may not be sufficient to provide a growth advantage for a GH-secreting adenoma without additional disordered hypothalamic or paracrine growth factor signaling.

Monoclonal origin of somatotroph adenomas was determined by X-chromosome inactivation analysis of somatotroph tumor DNA.[155] An altered $G\alpha_s$ protein identified in a subset of GH-secreting pituitary adenomas leads to high levels of intracellular cAMP and GH hypersecretion.[161] Point mutations in two critical sites, Arg201, the site for adenosine diphosphate ribosylation, and Gly227, the guanosine triphosphate (GTP)–binding domain of $G\alpha_s$ proteins, prevent GTPase activity and result in constitutive adenyl cyclase activation. This dominant *GSP* mutant mimics GHRH effects, results in elevated cAMP levels, and is present in about 30% of GH-secreting tumors. Germline inactivating mutations of *AIP* have been found in a subset of familial somatotropinomas,[203,253] especially in younger patients with acromegaly or gigantism.

McCune-Albright Syndrome

This rare hypersecretory syndrome consists of polyostotic fibrous dysplasia, cutaneous pigmentation, sexual precocity, hyperthyroidism, hypercortisolism, hyperprolactinemia, and acromegaly due to somatotroph hyperplasia. In a comprehensive review of 112 patients, acromegaly was reported in up to 30% of patients with the syndrome and was invariably associated with skull base fibrous dysplasia.[369] About half of these patients have definitive imaging evidence for a pituitary adenoma. $G\alpha_s$ mutations have been detected in both endocrine and nonendocrine tissues.[162] GH hypersecretion is rarely controlled by surgery, and these patients require somatostatin receptor ligands, GH receptor antagonist, or pituitary irradiation.

Extrapituitary Acromegaly

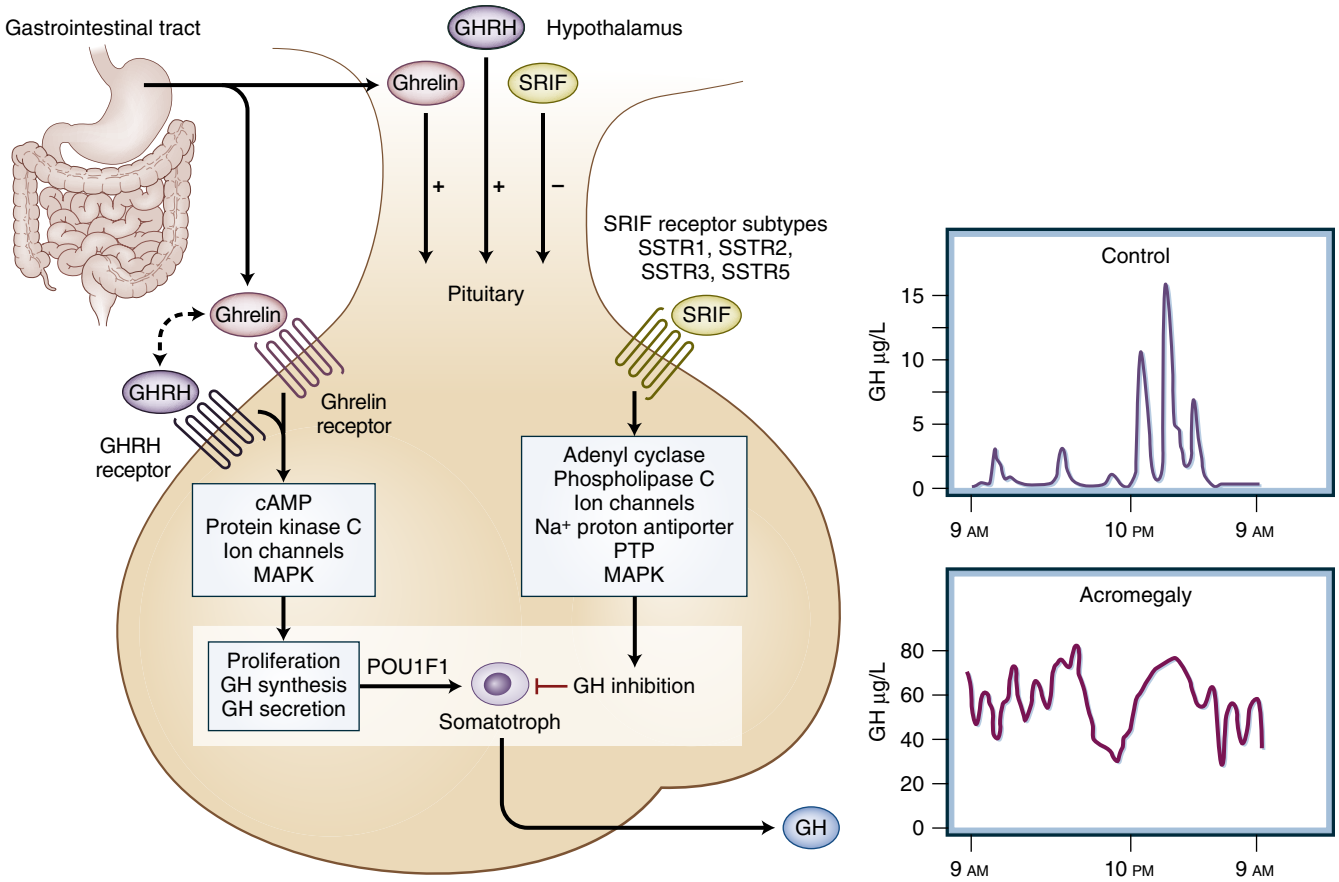
The source of excess GH secretion in acromegaly may not necessarily be of pituitary origin. Because management of ectopic acromegaly differs from that for pituitary-dependent GH hypersecretion, rigorous clinical and biochemical criteria should be fulfilled to confirm the diagnosis of ectopic acromegaly.[370] These include demonstration of elevated circulating GHRH or GH levels in the absence of a primary pituitary lesion, a significant arteriovenous hormone gradient across the ectopic tumor source, biochemical and clinical cure of acromegaly after resection of the ectopic hormone-producing tumor, as well as normalization of the GHRH/GH/IGF1 axis. Finally, GHRH or GH gene product expression should be shown. Patients with nonconclusive imaging or biochemical or clinical features of pituitary acromegaly may inadvertently be diagnosed as harboring a nonpituitary source of excess GH secretion and hence be inappropriately treated.

GHRH Hypersecretion

Hypothalamic tumors, including hamartomas, choristomas, gliomas, and gangliocytomas, may produce GHRH with subsequent somatotroph hyperplasia and resultant acromegaly[159] (see Fig. 9.31). Primary mammosomatotroph hyperplasia with no evidence for pituitary adenoma or an extrapituitary tumor source of GHRH has been described in gigantism.[371] The structure of hypothalamic GHRH was in fact elucidated from material extracted from pancreatic GHRH-secreting neuroendocrine tumors in patients with acromegaly.[158] GHRH immunoreactivity is detectable in about 25% of neuroendocrine tumor samples, and those of bronchial (foregut) origin comprise most tumors associated with ectopic GHRH secretion.[372] Acromegaly in neuroendocrine tumor patients, however, is uncommon. In a retrospective survey of 177 patients with acromegaly, only a single patient was identified with elevated plasma GHRH levels.[373] Rare pancreatic cell tumors, small cell lung cancers, adrenal adenoma, pheochromocytoma, and medullary thyroid, endometrial, and breast cancer express GHRH and may cause acromegaly.[374,375] Surgical resection of the tumor secreting ectopic GHRH should reverse GH hypersecretion, and pituitary surgery is not required in these patients. Carcinoid syndrome with ectopic GHRH secretion can also be managed with somatostatin receptor ligands (SRL), which lower GH and IGF1 levels and suppress ectopic tumor elaboration of GHRH.[376]

Ectopic Pituitary Adenomas

GH-secreting adenomas may arise from ectopic pituitary remnants in the sphenoid sinus, petrous temporal bone, or nasopharyngeal



• **Fig. 9.32** Normal and disrupted GHRH-GH-IGF1 axis and molecular targets for therapy. Normal and disrupted GHRH-GH-IGF1 axis in GH-secreting somatotroph adenomas, pituitary somatotroph cell development, and gene expression are determined by the POU1F1 transcription factor. Net GH secretion is determined by integration of hypothalamic, nutritional, hormonal, and intrapituitary signals. GH synthesis and secretion are induced by hypothalamic GHRH and gut-derived ghrelin. Hypothalamic somatostatin *(SRIF)* suppresses GH secretion mainly by high-affinity binding to SSTR2 and SSTR5 receptor subtypes expressed on somatotrophs. SRIF or analogs signal through SSTR2 and SSTR5 to control GH hypersecretion and shrink tumor mass. GH secretion patterns in a normal subject and in acromegaly are depicted in the insets showing secretory bursts (mainly at night) and daytime troughs. *cAMP,* cyclic adenosine monophosphate; *GH,* growth hormone; *GHRH,* growth hormone–releasing hormone; *IGF1,* insulin-like growth factor type 1; *MAPK,* mitogen-activated protein kinase; *PTP,* protein tyrosine phosphatase; *SRIF,* somatostatin (somatotropin release–inhibiting factor); *SSTR,* SRIF receptor subtypes. cavity.[377] Very rarely, pituitary carcinoma may spread to the meninges, CSF, or cervical lymph nodes, resulting in functional GH-secreting metastases, which may be diagnosed by radiolabeled octreotide imaging (Octreoscan).[378]

Peripheral Growth Hormone–Secreting Tumors

Lung adenocarcinoma, breast cancer, and ovarian tissues contain immunoreactive GH without clinical evidence of acromegaly. Rarely, GH-secreting intramesenteric pancreatic islet cell tumor[370] or a non-Hodgkin lymphoma[379] may cause acromegaly. These patients have a normal-sized or small pituitary gland on MRI, absent GH response to TRH injection, and normal levels of circulating plasma GHRH.

Acromegaloidism

Rarely, patients exhibit soft tissue and skin changes usually associated with acromegaly but normal baseline and dynamic GH and IGF1 with no demonstrable pituitary or extrapituitary tumor, termed *acromegaloid*. Pachydermoperiostosis should be considered in the differential diagnosis. Insulin resistance and defective IGF1 binding demonstrated in cells derived from some patients with acanthosis nigricans, and treatment is symptomatic.

Gigantism

Tall stature may be caused by a GH-secreting pituitary tumor or hyperplasia associated with several specific syndromes, including the McCune-Albright syndrome, with somatotroph hyperplasia or rarely pituitary adenomas.[380] *AIP* mutations have been traced in the lineage of some patients with gigantism.[381] Somatotroph hyperplasia and acidophilic stem cell adenomas (with hyperprolactinemia) may rarely cause gigantism during infancy or early childhood, suggesting early hypersecretion of GHRH or disordered pituitary cell differentiation.[371] Eighteen patients were reported with X-linked gigantism (X-LAG syndrome), with Xq26.3 chromosomal microduplications (Fig. 9.33). These patients exhibit features of very early accelerated gigantism. Tumors derived from these patients overexpress *GPR101*, a putative regulator of GH.[382] Pituitary gigantism

TABLE 9.24 Causes of Acromegaly

Cause	Prevalence (%)	Hormonal Products	Clinical Features	Pathologic Characteristics
Excess GH Secretion				
Pituitary	98			
Densely granulated GH cell adenoma	30	GH	Slow growing, clinically insidious	Resemble normal somatotrophs, numerous large secretory granules
Sparsely granulated adenoma	30	GH	Rapidly growing, often invasive	Cellular pleomorphism, characteristic ultrastructure
Mixed GH cell and PRL cell adenoma	25	GH and PRL	Variable	Densely granulated somatotrophs, sparsely granulated lactotrophs
Mammosomatotroph cell adenoma	10	GH and PRL	Common in children; gigantism, mild hyperprolactinemia	Both GH and PRL in same cell, often same secretory granule
Acidophil stem cell adenoma		PRL and GH	Rapidly growing, invasive, hyperprolactinemia dominant	Distinctive ultrastructure, giant mitochondria
Plurihormonal adenoma		GH (PRL with αGSU, FSH/LH, TSH, or ACTH)	Often secondary hormonal products are clinically silent	Variable; either monomorphous or plurimorphous
GH cell carcinoma or metastases		GH	Usually aggressive	Documented metastasis
MEN1 (adenoma)		GH or PRL	Pancreatic, parathyroid, or pituitary tumors	Adenoma
McCune-Albright syndrome		GH, PRL	Classic triad	Hyperplasia
Ectopic sphenoid or parapharyngeal sinus pituitary adenoma		GH	Ectopic mass	Adenoma
Familial acromegaly		GH	Young patients	Large adenomas
Carney syndrome		GH	Classic syndrome	Adenoma
Extrapituitary Tumor				
Pancreatic islet cell tumor	<1			Small pituitary
Excess GHRH Secretion				
Central—hypothalamic hamartoma, choristoma, ganglioneuroma	<1		Hypothalamic mass	Somatotroph hyperplasia
Peripheral—bronchial carcinoid, pancreatic islet cell tumor, small cell lung cancer, adrenal adenoma, medullary thyroid carcinoma, pheochromocytoma	1	GH, PRL	Systemic features	Somatotroph hyperplasia, rarely adenoma

ACTH, Adrenocorticotrophic hormone; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GHRH,* growth hormone–releasing hormone; *αGSU,* glycoprotein α-subunit; *LH,* luteinizing hormone; *MEN1,* multiple endocrine neoplasia type 1; *PRL,* prolactin; *TSH,* thyroid-stimulating hormone.

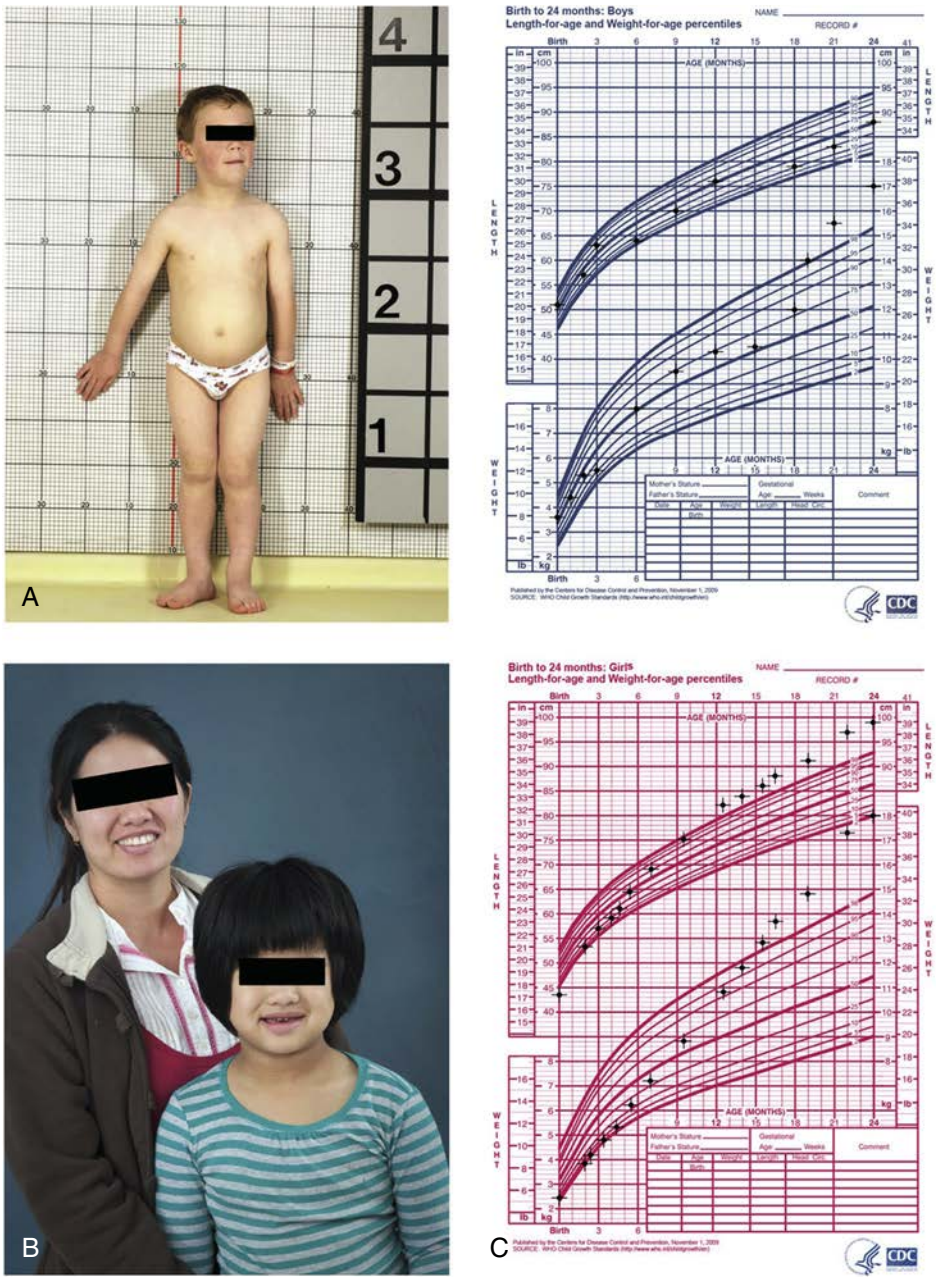
should be considered in children who are more than 3 standard deviations above normal mean height for age or more than 2 standard deviations over their adjusted mean parental height. The biochemical diagnosis is similar to that for acromegaly (i.e., GH levels >1 ng/mL after a glucose load, elevated concentrations of serum IGF1). In children undergoing pubertal growth spurts, GH responses to glucose may be paradoxical, and serum IGF1 concentrations are often physiologically elevated. Thus, the diagnosis requires clear-cut MRI evidence for a pituitary lesion. The differential diagnosis includes familial tall stature, redundancy of Y chromosomes, Marfan syndrome, and homocystinuria. Aggressive control of the tumor mass as well as hormone hypersecretion is important to mitigate long-term tissue damage from excess GH and IGF1. Surgery is recommended as primary therapy, and postoperative SRLs and the GH receptor antagonist have been used effectively.[383,384] Radiation therapy should be followed by lifelong serial evaluation of pituitary function.



• **Fig. 9.33** Growth patterns due to Xq26.3 microduplication. Clinical Features of Acromegaly

Manifestations of acromegaly are caused by either central pressure effects of the pituitary mass or peripheral actions of excess GH and IGF1. Headache is often severe and debilitating. Local signs are especially important presenting features because a higher preponderance of macroadenomas (>65%) is encountered in acromegaly as compared to mostly microadenomas for PRL-secreting tumors.[385]

Effects of hypersomatotropism on acral and soft tissue growth and metabolic function occur insidiously over several years[386](Table 9.25) (Figs. 9.34 and 9.35). As a result, acromegaly remains underrecognized; the slow onset and elusive symptomatology often result in delayed diagnosis, with a mean delay of almost 10 years, especially in females.[387] In a comparison of acromegaly features observed between 1981 and 1994, and between 1995 and 2006, the delay in diagnosis was quite similar (5.9 vs. 5.2 years). Although biochemical features were also remarkably similar, sleep apnea and colon polyps were more frequently encountered in the latter time frames, likely reflecting enhanced awareness.[388] Patients may seek care for dental, orthopedic, rheumatologic, or cardiac disorders. Only 13% of 256 patients diagnosed during a 20-year period

[a]Most soft tissue and metabolic changes are reversible by tight hormonal control. Bony changes, hypertension, and central sleep apnea are generally not reversible.

Modified from Bonert V, Melmed S. Acromegaly. In: Bar S, ed. *Contemporary Endocrinology*. Totowa, NJ: Humana Press; 2002:201–228.

presented with primary symptoms of altered facial appearance or enlarged extremities.[389] In a review of several hundred patients presenting with acromegaly worldwide, 98% had acral enlargement, and hyperhidrosis was prominent in 70%.[386] When presenting early, facial and peripheral features are usually not obvious, and serial review of old photographs often accentuates the progress of subtle physical changes. Characteristic features include large fleshy lips and nose, spade-like hands, frontal skull bossing, and cranial ridges. Enlarged tongue, bones, salivary glands, thyroid, heart, liver, and spleen are the effects of generalized visceromegaly. Increase in shoe, ring, or hat size is commonly reported. Progressive acral changes may lead to facial coarsening and skeletal disfigurement especially if excess GH secretion begins prior to epiphyseal closure.[390] These changes include mandibular overgrowth with prognathism, maxillary widening, teeth separation, jaw malocclusion overbite, large nose, and coarse oily skin. Sonorous voice deepening occurs in association with laryngeal hypertrophy and enlarged paranasal sinuses. Up to half of patients may experience joint symptoms severe enough to limit daily activities. Arthropathy occurs in about 70% of patients, most of whom exhibit joint swelling, hypermobility, and cartilaginous thickening.[391] Cartilage T2 relaxation times on MRI scans are high, reflecting increased water content.[392] These signs may often persist after complete remission.[393] Local periarticular fibrous tissue thickening may cause joint stiffening or deformities and nerve entrapment. Knees, hips, shoulders, lumbosacral joints, elbows, and ankles are affected as monoarticular or polyarticular arthritides, but joint effusions rarely develop. Spinal involvement includes osteophytosis, disk space widening, and increased anteroposterior vertebral length, which may result in dorsal kyphosis. Neural enlargement and wrist tissue swelling may lead to carpal tunnel syndrome in up to half of all patients.

• **Fig. 9.34** Harvey Cushing's first acromegaly patient. (A) Some years before presentation and (B) at admission. (From Jane JA, Laws ER. History of acromegaly. In: Wass J, ed. *Handbook of Acromegaly.* Bristol, UK: BioScientifica; 2001:3–15.)

Both median and ulnar nerve cross-sectional areas increase, and nerve conduction is abnormal.[394] Chondrocyte proliferation with increased joint space occurs early, and ulcerations and fissures of weight-bearing cartilage areas are often accompanied by new bone formation. Debilitating osteoarthritis may result in bone remodeling, osteophyte formation, subchondral cysts, narrowed joint spaces, and lax periarticular ligaments. Vertebral fractures occur with increasing frequency, and osteophytes commonly occur at the phalangeal tufts and over the anterior aspects of spinal vertebrae.[395–397] Synovial edema leads to hyperplastic wrist ligaments and tendons that contribute to painful median nerve compression. Peripheral acroparesthesias and symmetric peripheral neuropathy should be distinguished from diabetic neuropathy, which may occur secondarily to acromegaly.[398] Proximal myopathy may also be accompanied by myalgias and cramps. Ligaments may ossify, and periarticular calcium pyrophosphate deposition occurs. Hyperhidrosis and malodorous oily skin are common early signs, occurring in up to 70% of patients. Facial wrinkles, nasolabial folds, heel pad thickening, and body hair coarsening[399] are attributed to glycosaminoglycan deposition and increased connective tissue collagen production. Skin tags are common and may be markers for the adenomatous colonic polyps. Raynaud phenomenon is reported in up to one-third of patients.

Symptomatic cardiac disease is present in about 20% of patients at diagnosis and is a major cause of morbidity and mortality.[400] Hypertension is present in about 50% of patients with active acromegaly, and half of these patients have evidence of left ventricular (LV) dysfunction with or without regurgitant valve disease.[401] Asymmetric septal hypertrophy and cardiac failure with increased ventricular ejection fraction may occur, and subclinical LV diastolic dysfunction is due to myocardial hypertrophy, interstitial fibrosis, and lymphocytic myocardial infiltrates. Increased aortic root diameter and aortic ectasia were reported in 26% of patients.[402] Resting electrocardiograms are abnormal in about 50% of patients, with ST-segment depression, T-wave abnormalities, conduction defects, and arrhythmias. Plasma renin levels are suppressed, and renal sodium channel activity is induced by GH at the aldosterone-sensitive distal nephron.[403] In a prospective study of 30 patients, cardiovascular responses to SRL therapy were shown to be highly variable, despite attainment of biochemical control.[404] Despite increased cardiovascular risk factors,[405] there is no reported increased myocardial infarction in acromegaly.[406]

Prognathism, thick lips, macroglossia, and hypertrophied nasal structures may obstruct airways. Irregular laryngeal mucosa, cartilage hypertrophy, tracheal calcification, and cricoarytenoid joint arthropathy lead to unilateral or bilateral vocal cord fixation or laryngeal stenosis with voice changes. Tracheal intubation may be particularly difficult in patients undergoing anesthesia, and tracheostomy may be required. Both central respiratory depression and airway obstruction lead to paroxysmal daytime sleep (narcolepsy), sleep apnea, and habitual excessive snoring. Obstructive sleep apnea with daytime somnolence occurs especially in men with acromegaly, who also may have a ventilation-perfusion defect with hypoxemia. Sleep apnea may also be central in origin and associated with higher GH and IGF1 levels.[407]

Hypertrophied tissue surrounding the canal of Schlemm may impede aqueous filtration, leading to open-angle glaucoma. Progressive facial and bodily disfigurement often leads to lowered

• **Fig. 9.35** Clinical features of acromegaly. (A–C) Features of acromegaly/gigantism in identical twins. A 22-year-old man with gigantism due to excess growth hormone is shown to the left of his identical twin. The increased height and prognathism (A) and enlarged hand (B) and foot (C) of the affected twin are apparent. Their clinical features began to diverge at the age of approximately 13 years. self-esteem. Depression and mood swings may occur secondarily to physical deformity, with impaired quality of life.[408]

Growth Hormone and Tumor Formation

GH and IGF1 as well as insulin may exhibit direct or indirect mitogenic effects on mammalian cells and act as permissive cell growth stimulators.[409] In a meta-analysis, the risks of adenomatous and hyperplastic polyps and colorectal cancer were increased 2.5-fold, 3.6-fold, and 4.4-fold, respectively.[410] The prevalence of polyps was 32% in 165 patients in a case control study, with an estimated relative risk of 6.21 (95% CI, 4.08–9.48). Higher IGF1 levels at diagnosis were more likely associated with distal colon lesions.[411] Hypertrophic mucosal folds and colonic hypertrophy as well as diverticulae[412] are commonly present, and dolicomegacolon may be visualized by CT colonography.[413] Increased incidence of gallbladder polyps[414] and benign prostate hypertrophy[415] have been reported. Although the German Acromegaly Registry does not report higher cancer incidence,[416] a survey of 1512 patients in Italy revealed a moderately increased cancer incidence.[417] Similarly, a nationwide study in Denmark of 529 acromegaly patients revealed an overall cancer SIR of 1.5 (95% CI, 1.2–1.8). Incidence of colorectal, kidney, and thyroid cancers appear to be the most significantly elevated.[418–420] Thus, although disordered cell proliferation and increased risk for growth promotion of coexisting neoplasms as well as mortality could be anticipated from elevated GH and IGF1 levels, a significantly enhanced cancer incidence has not been consistently observed. Colon cancer appears to be of particular concern, and screening colonoscopy should be performed at diagnosis in all patients. Thereafter, screening should follow established guidelines. As acromegaly patients are now living longer as a result of improved biochemical and cardiac control, long-term prospective studies are required to resolve this question in an aging population.

Endocrine Complications

About 30% of patients exhibit elevated serum PRL levels (up to 100 ng/mL or more), with or without galactorrhea. Functional pituitary stalk compression by a pituitary mass prevents lactotroph access of hypothalamic dopamine, releasing the cell from tonic hypothalamic inhibition. GH-secreting adenoma

subtypes may also concomitantly secrete PRL. As GH behaves as an agonist for breast PRL-binding sites, the tumor may cause galactorrhea in the face of normal PRL levels. Tumor mass compressing surrounding normal pituitary tissue may also cause hypopituitarism. Over half of all patients have amenorrhea or impotence,[385–421] and secondary thyroid or adrenal failure is present in about 20% of patients. Gonadal dysfunction may exacerbate bone loss and vertebral fractures.[396,397] In a prospective controlled study of 22 patients, active acromegaly was associated with PTH-independent calcium-phosphate balance, with low PTH and high phosphorus levels associated with increased coupled bone formation and resorption.[422] Skeletal fragility may persist despite long-term biochemical control.[423,424]

GH suppresses beta cell function and antagonizes insulin action, and acromegaly is associated with increased insulin resistance, lipolysis, and gluconeogenesis,[425,426] despite increased lean body mass, decreased fat mass, and elevated IGF1 concentrations that would be expected to enhance insulin sensitivity. Accordingly, fasting glucose intolerance and diabetes mellitus occur in about 50% of patients.[426,427] Increased diabetes risk with a hazard ratio of 4.0 (95% CI: 2.7–5.8) was reported in a nationwide cohort study in Denmark.[361] Unique cardiomyopathy features are also associated with diabetes and acromegaly.[425] Carbohydrate intolerance and insulin requirements improve rapidly on lowering GH after surgery or somatostatin analogue therapy; however, diabetes may persist in some patients after biochemical remission.[428] Hypertriglyceridemia (type IV), hypercalciuria, and hypercalcemia also occur. Thyroid dysfunction may be associated with diffuse or nodular toxic or nontoxic goiter or Graves disease, especially as IGF1 is a major determinant of thyroid cell growth.[429] Associated MEN1 features may be present in affected individuals, including hypercalcemia with hyperparathyroidism or pancreatic tumors.

Morbidity and Mortality

In a meta-analysis of 16 studies, overall mortality rate was reported to be increased in acromegaly with a standardized mortality ratio of 1.72. Lower recent mortality rates reported likely reflect the positive impact of introduction of somatostatin analogues, improved surgical technique, and enhanced cardiac therapies[430] (Fig. 9.36). Cardiovascular disease is the leading cause of death followed by respiratory disease (18%) and cerebrovascular disease (14%). Diabetes mellitus, occurring in 20% of patients, is associated with 2.5 times the predicted mortality rate, and hypertension is present in about half of all patients.[431] The most significant mortality determinants are GH levels greater than 2.5 μg/L, elevated IGF1 levels, the presence of coexisting hypertension and cardiac disease, older age, a history of pituitary irradiation, and overreplaced ACTH-dependent adrenal insufficiency.[59] Overtreatment of adrenal insufficiency with doses of hydrocortisone more than 25 mg daily also is predictive of mortality.[59] In the large UK West Midlands acromegaly registry comprising 501 patients, a last available recorded GH level of 1 ng/mL or less versus 1 ng/mL or more was highly predictive of mortality rate. However, when summated over time in an unbiased fashion, the relative risk of fatality appeared to be associated with a GH cutoff level of 5 ng/mL.[432] Moreover, control of GH levels to less than 2.5 μg/L and normal IGF1 levels after surgery or medical treatments is associated with significant reductions of both morbidity and mortality.[431,433] However, in a 20-year follow-up controlled study, all-cause mortality rates remained elevated (odds ratio [OR] 1.6; 95% CI, 1.2–2.2) and was more evident in women (Table 9.26).

Causes of death shifted with time from predominantly cardiovascular to cancer diagnoses.[434]

Diagnosis

Measurement of Growth Hormone and IGF1 Levels

The diagnosis of acromegaly requires measurement of a GH nadir during a 75-g glucose load of less than 0.4 μg/L using ultrasensitive GH assays or GH less than 1.0 μg/L using standard assays with an accompanying elevated IGF1 level[435,436] (Fig. 9.37).

In healthy subjects, serum GH levels initially fall after oral glucose administration and subsequently increase as plasma glucose declines. In patients with acromegaly, oral glucose fails to suppress GH; GH levels may increase, remain unchanged, or fall modestly in approximately one-third of patients. Basal morning (AM) and random GH levels are usually elevated in acromegaly. Because of the episodic nature of GH secretion, however, serum concentrations may normally fluctuate from "undetectable" up to 30 μg/L. Unlike the largely undetectable nadir GH levels in normal subjects, those with acromegaly sampled over 24 hours have mean GH levels above 2 μg/L.[436] Evoked GH responses to GHRH administration are not of diagnostic use. Random GH levels measured with sensitive assays in acromegaly may be as low as 0.37 μg/L with persistently elevated postoperative IGF1 levels.[437] Serum IGF1 levels are high[438,439] and correlate with clinical features (Fig. 9.38). Basal GH levels determine ambient circulating IGF1 levels in a log-linear fashion.[440] Age-matched and gender-matched IGF1 elevations may persist for several months after GH levels are biochemically controlled after surgery. Although elevated IGF1 levels may be encountered during pregnancy and late puberty, an appropriately corrected high IGF1 level is highly specific for acromegaly and correlates with clinical indices of disease activity. IGF-binding protein 3 (IGFBP3) levels are also elevated but provide little added diagnostic value. GH-secreting adenomas exhibit discordant GH responses to TRH and GnRH administration in up to 50% of patients, but these adjunctive tests are rarely required to confirm the diagnosis.

Differential Diagnosis

The overwhelming majority of patients with acromegaly harbor a GH cell pituitary adenoma; rarely extrapituitary acromegaly should be considered. Regardless of the cause of unrestrained GH secretion, IGF1 levels are invariably elevated, and GH levels fail to suppress after an oral glucose load. When clinical features of acromegaly are associated with normal GH and IGF1 levels, "burned out" or "silent" acromegaly associated with an infarcted pituitary adenoma, often with a secondary empty sella, should be considered.[441] About 5% of consecutive patients with proven GH cell adenomas have "normal" GH and elevated IGF1 levels. Plasma GHRH levels are invariably elevated in patients with peripheral GHRH-secreting tumors but are normal or low in those with hypothalamic GHRH-secreting tumors.[373] Presumably, excess eutopic hypothalamic GHRH secretion into the hypophyseal portal system does not appreciably enter the systemic circulation.

MRI and CT scanning are used to localize pituitary or extrapituitary tumor. Routine abdominal or chest imaging of all acromegaly patients will yield a very low incidence of ectopic tumors and is not recommended. A normal-sized or small pituitary gland, or clinical and biochemical features of other tumors known to be associated with extrapituitary acromegaly and elevated circulating GHRH levels, are indications for extrapituitary imaging. An enlarged hyperplastic pituitary gland, however, is often present in patients with peripheral GHRH-secreting tumors, and the radiologic diagnosis of a pituitary adenoma may be difficult to exclude. The very rare McCune-Albright syndrome should be considered after definitive exclusion of pituitary and extrapituitary tumors.

Treatment

Aims

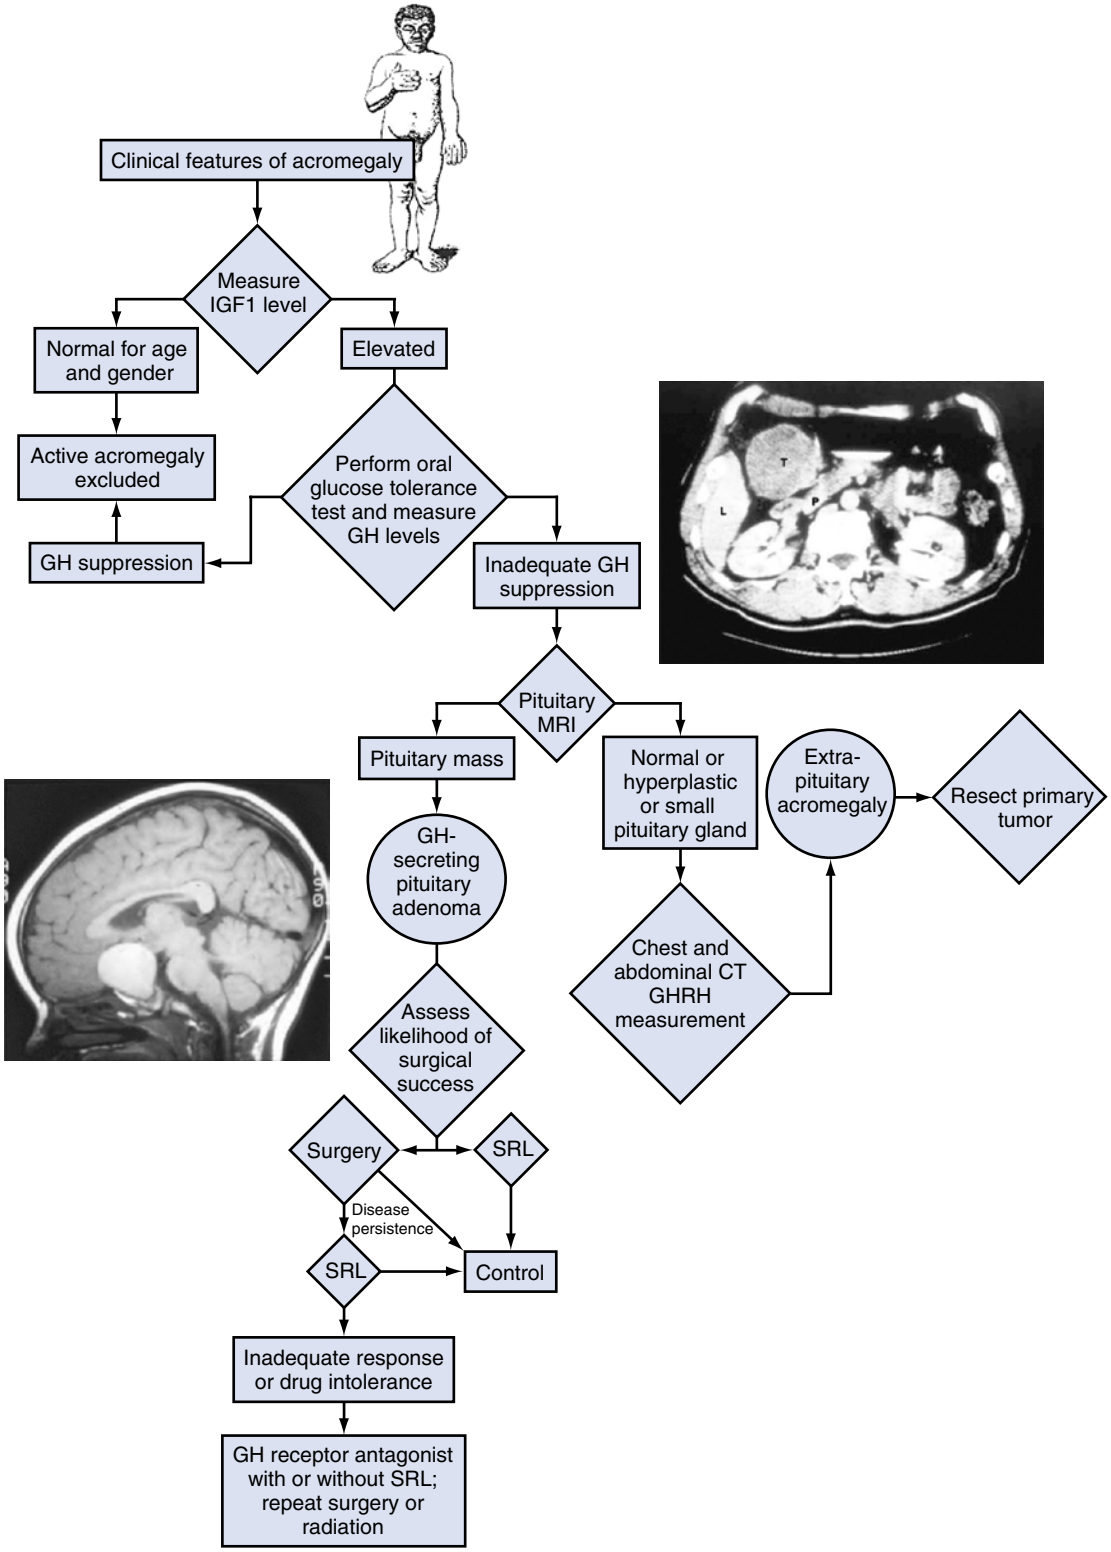
A comprehensive strategy for treating patients with acromegaly should aim to manage the pituitary mass, suppress GH and IGF1 hypersecretion, and prevent long-term clinical sequelae of hypersomatotropism while maintaining normal anterior pituitary function.[442,443] Serum GH levels should be suppressed to at least 1 μg/L or less after an oral glucose load, and age-matched and gender-matched serum IGF1 levels should be normalized. Ideally, a controlled patient should also have a "normal" 24-hour integrated secretion of GH (<2.5 μg/L), but these measurements are impractical. As current therapeutic modes for acromegaly management, including surgery, irradiation, and medical treatment, do not uniformly fulfill these goals,[444] personalized approaches have been proposed (discussion to come).

Surgical Management

Well-circumscribed somatotroph cell adenomas should preferably be resected by transsphenoidal surgery using either microscopic or laparoscopic techniques.[445–447] Successful resection alleviates preoperative compression effects and compromised trophic hormone secretion, and the skilled surgeon balances the extent of maximal tumor tissue removal while preserving anterior pituitary function. Within 2 hours of successful resection, metabolic dysfunction and soft tissue swelling start improving, and GH levels are sometimes controlled within an hour. Overall, 38% to 83% of patients achieve normalized IGF1 levels. Fewer patients with macroadenomas are controlled. Of 1018 patients reported in 13 studies, 73% with microadenomas and 61% harboring macroadenomas achieved GH levels lower than 1.0 μg/L during glucose loading and normal serum IGF1 levels (Table 9.27).[448–450] When remission was rigorously defined as a normal IGF1 and either a nadir glucose-suppressed GH level less than 0.4 μg/L or a random GH level less than 1 μg/L, all 14 of 14 patients with microadenomas and 28 of 46 patients with macroadenomas achieved remission.[445] As over one-third of premenopausal women exhibit cavernous sinus tumor invasion, remission rates are lower than in men under 50 years of age.[451] Experience of the neurosurgeon,[38] smaller tumor size, lower Knosp score, and lower preoperative IGF1 and GH levels are predictive of postsurgical remission (Table 9.28). Postoperative GH level measured within 24 hours of surgery is a significant outcome predictor (Fig. 9.39).[42] Difficulties in endotracheal intubation due to macroglossia or severe kyphosis may rarely necessitate tracheostomy for anesthesia.

Side Effects

Although often transient, surgical complications may require lifelong pituitary hormone replacement. New hypopituitarism develops in up to approximately 20% of patients, reflecting operative damage to the surrounding normal pituitary tissue. Permanent diabetes insipidus, CSF leaks, hemorrhage, and meningitis occur in up to 10% of patients (see Table 9.3). Postoperative pituitary deficits assessed in a meta-analysis occur in ~15% of patients overall. GH deficiency may require careful replacement if clinical features of GH deficiency become apparent.[452] Secondary adrenal insufficiency is an important determinant of mortality,[453] and the incidence of postoperative adrenal failure is 2/1000 person-years in acromegaly patients in remission.[454] The extent and prevalence of local complications depend upon tumor size and invasiveness. Experienced pituitary surgeons report more favorable postoperative complication rates.[38,39] Biochemical or anatomic acromegaly recurrence (~7% over 10 years) or postoperative tumor persistence may indicate incomplete resection of adenomatous tissue, surgically inaccessible cavernous sinus tissue, or nesting of functional tumor tissue within the dura.



• **Fig. 9.37** Diagnosis and treatment of acromegaly. Oral glucose tolerance test (OGTT) is performed with 75 g glucose and growth hormone (GH) measured during 2 hours. Disease control implies nadir GH level of less than 1 μg/L after OGTT using standard assays and less than 0.4 μg/L using ultrasensitive assays, and age-matched and gender-matched normal insulin-like growth factor type 1 (IGF1) level. *CT,* computed tomography; *GHRH,* growth hormone–releasing hormone; *MRI,* magnetic resonance imaging; *SRL,* somatostatin receptor ligand. Radiation Therapy

Primary or adjuvant radiation of GH-secreting tumors may be achieved by conventional external deep x-ray therapy as well as heavy-particle (proton-beam) or stereotactic radiosurgery. Maximal tumor radiation should ideally be attained with minimal soft tissue damage. Radiation is a highly individualized choice, depending on the expertise and experience of the treating radiotherapist, and includes careful physician and patient consideration of the benefits of therapy weighed against potential risks. For conventional therapy, up to 5000 rads are administered in split doses of 180-rad fractions divided over 6 weeks. Radiation arrests tumor growth, and most adenomas ultimately shrink. As GH levels fall gradually during the first year after treatment, most patients are still exposed to unacceptably high levels of circulating GH and

IGF1 during the initial years if not receiving concomitant medical therapy. Stereotactic radiosurgery effectively focuses on the adenoma, thereby sparing normal surrounding structures.[51,455–457] Of 136 patients followed for a median 61.5 months, 65% achieved normalized IGF1 levels or nadir GH level less than 1 ng/mL after an oral glucose load.[51] Higher radiation doses to the tumor margin as well as maximal doses and lower initial IGF1 levels portend a significantly more favorable outcome.[51] In a comprehensive meta-analysis, stereotactic radiosurgery was shown to be modestly more effective than conventional radiotherapy, with significantly lower IGF1 levels achieved.[458] In a multicenter study comprising 371 patients receiving stereotactic radiosurgery, endocrine remission was achieved in 59% of patients, with a mean time to remission of 38 months. Biochemical relapse was observed in 9%, with a mean time to recurrence of 17 months.[459]

Side Effects

After 10 years, about half of all patients receiving radiotherapy have signs of pituitary trophic hormone disruption, and this prevalence increases annually thereafter, requiring gonadal steroids, thyroid hormone, or corticosteroid replacement. Side effects of conventional radiation, including hair loss, cranial nerve palsies, tumor necrosis with hemorrhage, and rarely loss of vision or pituitary apoplexy, have been documented in up to 2% of patients. Lethargy, impaired memory, and personality changes may also occur. In a 10-year follow-up study of 35 patients treated with Gamma Knife radiosurgery, half the patients developed pituitary hormone deficiencies (40% hypoadrenalism, 11% hypothyroidism, 13% hypogonadism, and 6% GH deficiency).[458] In another study, new pituitary hormone deficits were reported in 31% of patients within 61.5 months; however, visual deterioration and new cranial nerve palsies were rarely observed.[51] Because of side effects and slow onset of efficacy, radiation therapy should be used as an adjuvant for patients not controlled by surgery or medical management or for those who do not consent to these therapies. Prior radiation has been associated with increased acromegaly mortality, especially with a 4.42 (95% CI, 2.71–7.22) standardized mortality ratio for cerebrovascular deaths.[453]

Medical Management

Dopamine Agonists

D_2 receptor agonists have been used as either primary or adjuvant therapy for acromegaly, especially in patients with mildly elevated GH and IGF1 levels.[460] In open nonrandomized studies, cabergoline is reported to suppress GH to less than 2 μg/L and normalize IGF1 in up to a third of patients with relatively mild IGF1 elevations.[460] In patients resistant to SRLs, the addition of cabergoline may normalize IGF1 levels in about 50% of patients.[461] Dopamine agonist efficacy appears to be

• **Fig. 9.39** Postoperative GH monitoring. The probability of surgical remission according to the nadir growth hormone (GH) level in a 1-week postoperative oral glucose tolerance test (OGTT). When the nadir GH level on the 1-week postoperative OGTT is around 1 μg/L, an 88.9% probability of surgical remission is expected. However, if it is greater than 4 μg/L, it is unlikely that the patients will achieve delayed surgical remission. (Derived from Kim, Oh MC, Lee EJ, et al. Predicting long-term remission by measuring immediate postoperative growth hormone levels and oral glucose tolerance test in acromegaly. *Neurosurgery.* 2012;70:1106–1113.)

independent of PRL concentrations.[462] Side effects of cabergoline include gastrointestinal symptoms, dizziness, headache, and mood disorders.

SRLs

Of the five somatostatin receptor subtypes, SST2 and SST5 are preferentially expressed on somatotroph and thyrotroph cell surfaces and mediate suppression of GH and TSH secretion.[463,464] Several SRLs have been safely used as approved or investigational drugs for acromegaly (Fig. 9.40). Octreotide (D-Phe-Cys-Phe-D-Trp-Lys-Thr-Cys-Thr-OH), an octapeptide somatostatin analogue, binds predominantly to SST2 and less avidly to SST5[465] and inhibits GH secretion with a potency 45 times greater than native somatostatin, but its potency for inhibiting insulin release is only 1.3-fold that of somatostatin. The in vivo half-life of the analogue is prolonged (up to 2 hours) because of its relative resistance to enzymatic degradation. These properties are highly advantageous for long-term use in acromegaly.[466] GH responsiveness directly correlates with the abundance of pituitary SST2 receptors.

Subcutaneous octreotide (50 or 100 μg) suppresses GH secretion for up to 5 hours. In patients harboring microadenomas, integrated GH and IGF1 levels are almost invariably normalized, but the response in larger tumors is less pronounced.

Long-acting SRL formulations are convenient and allow for enhanced compliance and sustained biochemical control. Serum levels of long-acting release (LAR) octreotide (20–30 mg/intramuscularly), a sustained-release octreotide depot preparation,[467] peak at 28 days, with integrated GH levels effectively suppressed for up to 49 days. Monthly injections for 9 years reduced integrated serum GH levels to less than 2 μg/L in over 75% of patients.[468]

A long-acting preparation of lanreotide (autogel) is administered by monthly deep subcutaneous injection. In a randomized, placebo-controlled, multicenter study with a 52-week open extension, serum GH levels decreased by more than 50% from baseline in 63% of patients receiving lanreotide autogel.[469] When administered (60, 90, or 120 mg) every 28 to 42 days, GH was suppressed to less than 2.5 μg/L in 130 patients at 1 year.[470]

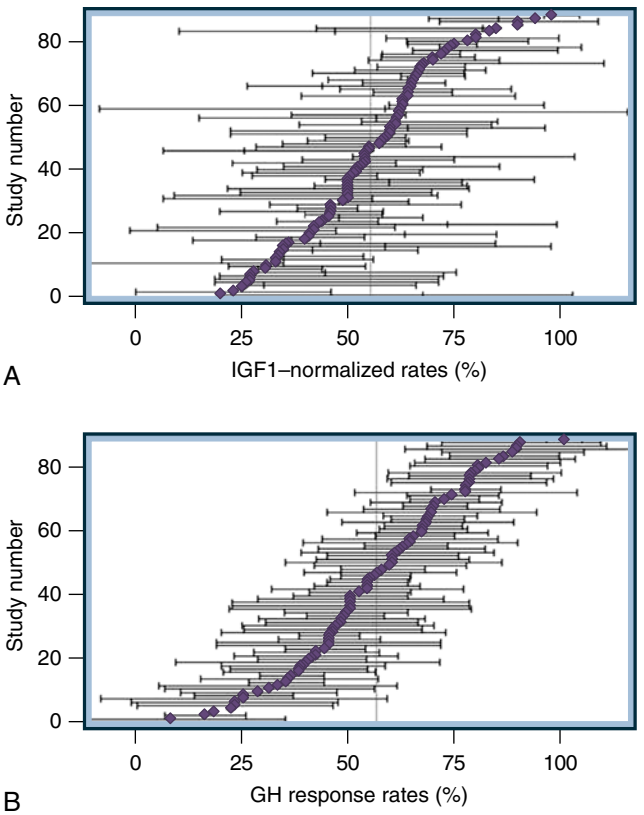
Pasireotide, a multireceptor-targeting SRL, exhibits highest affinity for SST5 more than SST2[471] and exhibits superior efficacy over octreotide.[472] In a randomized 12-month study in 358 patients, pasireotide LAR (40 mg) or octreotide (20 mg) resulted in biochemical control in 31% and 19% of patients, respectively.[472] Of those patients resistant to maximal doses of octreotide or lanreotide, 20% subsequently achieved control when placed on 60 mg pasireotide.[473] Reported side effects included those expected for SRLs as well as hyperglycemia noted in 57% of patients.

Oral octreotide formulated with a transient permeability enhancer attenuates basal and GHRH-elicited GH levels in healthy volunteers.[474] When administered to acromegaly patients, GH and IGF1 levels were controlled in 65% after being switched from injectable SRLs, and about 90% maintained responsiveness for up to 13 months. Although not yet approved, this formulation may offer an alternative future treatment option.[475]

Effects of SRLs on Pituitary Adenoma. Tumors rarely grow while patients receive depot SRL preparations, and a significant decrease in tumor size has been reported. In a comprehensive meta-analysis of 64 studies, 59% of patients were reported to experience a 50% reduction of tumor mass; this effect generally correlates with controlled GH and IGF1 levels[476] and may be observed within 6 months.[477] As the magnitude of shrinkage is variable, the use of preoperative SRL to improve subsequent surgical outcomes has been debated[478–480]; however, enthusiasm for this approach is dampened by the short prospective follow-up duration.

Effects on Clinical Features. Over 70% of patients experience improved general well-being, and soft tissue swelling dissipates within several days of treatment.[481] Headache, a common symptom, usually resolves within minutes of octreotide injection,[482] likely reflecting a specific central analgesic effect. Decreased heart rate and diminished LV wall thickness, reduced systemic arterial resistance and fluid volume, and restored functional activity are reported. Control of IGF1 and GH levels is associated with improved LV ejection function.[483] Joint function improves and crepitus is reduced, ultrasound shows evidence of bone or cartilage repair, and after several months sleep apnea resolves.[415] Although most soft tissue disease comorbidities are ameliorated once biochemical control has been achieved, low quality-of-life measures, including anxiety and depression, may persist.[484] Hypertension, joint space narrowing, and new-onset vertebral fractures do not appear to be ameliorated despite controlled GH and IGF1 levels.[424]

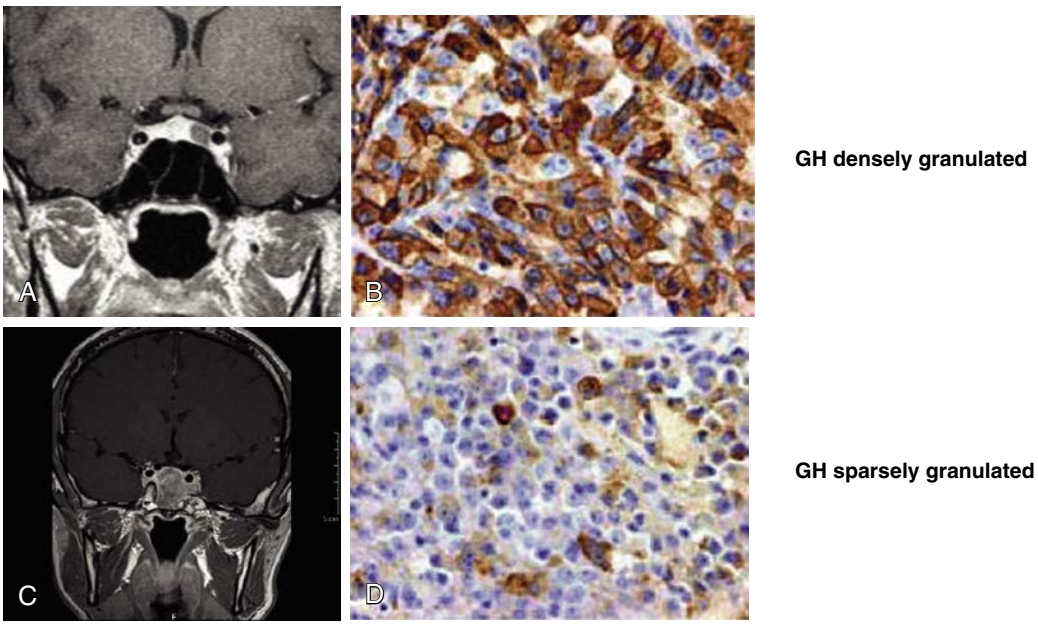
Determinants of SRL Responsiveness. In a meta-analysis of 4464 patients treated with an SRL, average GH control rates and IGF1 normalization rates were 56% and 55%, respectively (Fig. 9.41).[485] Lanreotide autogel and octreotide LAR exhibit similar clinical efficacy and side effect profiles, and they were shown equivalent in control of acromegaly symptoms and biochemical markers.[486] In 166 patients with acromegaly, results of oral glucose tolerance tests were concordant for appropriate diagnosis and establishing efficacy of surgery and radiotherapy but were not helpful in evaluating effectiveness of medical SRL therapy.



• **Fig. 9.41** Meta-analysis of somatostatin receptor ligand (*SRL*) responsiveness in acromegaly. (A) Insulin-like growth factor 1 (IGF1) response rates and 95% confidence intervals for 90 analyzed cohorts. Figures are sorted from least to greatest percent response rate. (From Carmichael J, Bonert VS, Nuno M, et al. Acromegaly clinical trial methodology impact on reported biochemical efficacy rates of somatostatin receptor ligand treatments: a meta-analysis. *J Clin Endocrinol Metab.* 2014;99:1825–1833.)

Measurement of serum IGF1 levels was the most rigorous marker to assess effectiveness of SRL therapy.[487] Results of controlled prospective studies show IGF1 levels normalized in up to 35% of patients.[469,472,488,489]

Understanding mechanisms driving SRL responsiveness and resistance, including both individual patient and tumor characteristics, has enabled a personalized approach to acromegaly classification and management.[365] Negative predictors of SRL therapeutic responses as well as markers of aggressive disease correlate with more adverse long-term outcomes. These determinants include patient age, treatment duration, frequency of drug administration, total daily dose, tumor size, degree of tumor GH granularity, and pretreatment GH and IGF1 levels. More favorable results reported in earlier studies may reflect clinical trial design, subject heterogeneity, and possibly selection of responsive patients. Increasing the monthly dose of octreotide LAR to 40 to 60 mg or the monthly lanreotide autogel dose to 180 mg, or, alternatively, increasing the dose frequency of lanreotide to 120 mg every 21 days, may improve efficacy.[490,491] Control rates also improve with time.[492] The most important determinant of therapeutic responsiveness is tumor SST2 expression.[493] Tumors immunopositive for SST2 expression are more likely to respond to octreotide and lanreotide,[494] and those with a higher SST2 to SST5 ratio show



• **Fig. 9.42** Growth hormone (GH) granulation pattern and clinical characteristics of GH-secreting adenomas. (A) Small noninvasive microadenomas usually contain (B) densely packed cytoplasmic GH granules (type 1 acromegaly).[369] (C) Larger and invasive macroadenomas are usually (D) very sparsely granulated, and these features portend a more adverse outcome (type 3 acromegaly). (A, from author's personal collection; B through D, courtesy Luis V. Syro, MD.)

improved therapeutic outcomes.[495] Tumors lacking SST5 immunoreactivity are resistant to pasireotide, while those immunoreactive for SST5 had superior biochemical responses.[496] Truncated SST5 variants may correlate inversely with GH responses to SRLs.[497]

Tumors containing large, dense intratumoral GH granules diffusely distributed throughout the cytosol are more responsive to SRLs than are those with sparse GH granules[498] (Fig. 9.42). Sparsely granulated adenomas express SST2 less abundantly and more SST5, and are more resistant to SRLs.[495,499–501] Sparse granules are also associated with larger and more invasive tumors, especially in younger patients,[502] which display MRI features of T2-weighted hyperintensity. Hypointense adenomas are smaller and less invasive than hyperintense and isointense adenomas and exhibit higher IGF1 levels. These MRI and histologic features are helpful in predicting both biochemical responses and tumor shrinkage in response to SRLs.[503,504]

Molecular tumor markers associated with SRL responsiveness include p21 expression, low AIP expression,[505–507] high β-arrestin,[508] and presence of the *gsp* oncogene mutation.[509]

Side Effects. SRLs are generally safe and well tolerated. Gastrointestinal side effects predominate, occur early, and include transient loose stools, nausea, cramps, mild malabsorption, and flatulence, reported in about one-third of patients. Hypoglycemia or hyperglycemia is not commonly encountered, and insulin requirements in diabetic patients with acromegaly are reduced within hours of receiving octreotide, concomitant with GH lowering. Overall, SRLs do not cause major effects on glucose homeostasis, and hyperglycemia may also be associated with uncontrolled underlying disease.[510] Pasireotide, however, is associated with hyperglycemia and new-onset diabetes in about 50% of patients.[511] The drugs attenuate gallbladder contractility, and delayed emptying leads to reversible sludge formation evidenced by ultrasonography in up to 25% of patients.[512] Cholecystitis is very rarely reported.[467] Octreotide may interact with cyclosporine, enhancing transplant rejection risk. SRL dose adjustments should be carefully titrated in patients requiring insulin or oral hypoglycemic agents, calcium channel blockers, and beta blockers. Asymptomatic sinus bradycardia has also been recognized.

Growth Hormone Receptor Antagonist

GH action through the surface membrane GH receptor is mediated by ligand-induced receptor signaling[513] (Fig. 9.43). The postreceptor GH signal is not elicited if the receptor is bound by pegvisomant, a GH-receptor antagonist, which blocks subsequent IGF1 generation.[514] The drug blocks peripheral GH action and does not target the pituitary tumor. IGF1 measurement is the appropriate marker of patient responsiveness, and measuring GH is therefore not an efficacy marker. Earlier studies showed that daily injections (up to 40 mg daily) normalize IGF1 levels in about 90% of patients, and they dose-dependently improve fatigue, decrease soft tissue swelling as assessed by ring size, and diminish perspiration.[515] In a subsequent drug surveillance report of 1288 patients, control of IGF1 was reported in 63% of patients,[516] likely reflecting submaximal dose titration as compared to controlled dosing of a clinical trial. Accordingly, in a 91-month follow-up (median 18 months), IGF1 levels were controlled in 95% of patients treated in two centers.[517] Similar results were obtained in a 9-year therapeutic follow-up.[518] The drug may be used as primary monotherapy[519] and is particularly useful in patients resistant to SRL therapy because it effectively normalizes IGF1 levels when added in these patients.[520,521] Significant drug response determinants include age, body mass index, and baseline IGF1 levels.[522] There is a concern that loss of negative IGF1 feedback control on somatotroph tumor proliferation may theoretically

• **Fig. 9.43** Action of growth hormone receptor (GHR) antagonist, somatostatin receptor ligands (SRLs), and dopamine (D_2) agonists. Normally a single molecule of GH binds two GH receptors through sites 1 and 2, and the GH signal transduction pathway is activated. Pegvisomant increases binding of GHR to site 1 and blocks binding at site 2 to prevent functional GHR dimerization, initiation of GH action, and induction of insulin-like growth factor type 1 (IGF1) synthesis and secretion. The peripheral effects of excess GH are antagonized at the cellular level, independent of the presence of somatostatin (SST) or dopamine receptors on the pituitary tumor. SRLs inhibit GH secretion and IGF1 synthesis and suppress pituitary tumor growth. GH-secreting adenomas express predominantly SST2 and SST5. Figure depicts affinities for SST receptor subtypes and for D_2 receptor. *a.a.,* amino acid; *ALS,* acid-labile subunit; *C,* carboxyl terminal; *GHRH,* gonadotrophin hormone–releasing hormone; *GHS,* gonadotrophin hormone secretagogue; *IC_{50},* 50% inhibitory concentration; *IGFBP3,* insulin-like growth factor–binding protein 3; *JAK2,* Janus kinase 2 tyrosine kinase; *LAR,* long-acting release; *MAPK,* mitogen-activated protein kinase; *N,* amino terminal; *ns,* not significant; *P,* elemental phosphorus; *PI3K,* phosphoinositide 3 kinase; *PL-C,* phospholipase C; *PTP,* protein tyrosine phosphatase; *SHC,* Src homology–containing protein; *SRIF,* somatostatin; *STAT,* signal transducer and activator or transcription. lead to rebound mass expansion. However, rebound tumor enlargement rarely occurs and may reflect discontinuing SRL, yet tumor growth while receiving pegvisomant should be monitored by MRI, especially if the residual tumor mass abuts visual tracts.[523–526] The GH receptor antagonist enhances insulin sensitivity and is therefore particularly suited for patients with coexisting diabetes.[517,527]

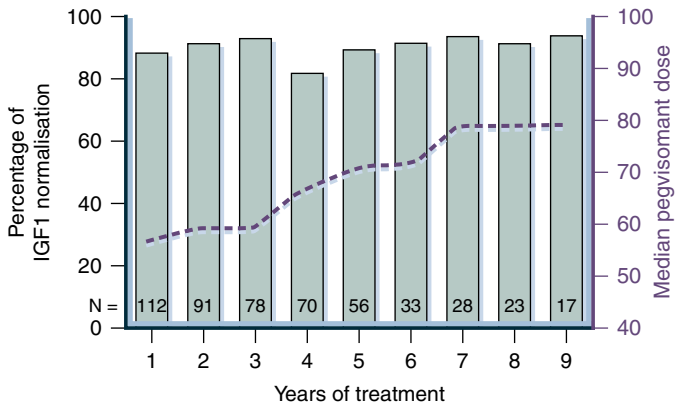
Side Effects. Because elevated (threefold or higher) hepatic transaminases have been reported,[528] liver enzymes should be



• **Fig. 9.44** Percentages of patients with insulin-like growth factor type 1 (IGF1) < 1.2 × ULN *(left axis)* and median pegvisomant doses *(dotted line, right axis)* each year during 9 years of combined somatostatin receptor ligand (SRL) and pegvisomant treatment. Long-term efficacy and safety of pegvisomant in combination with long-acting somatostatin analogs in acromegaly. *J Clin Endocrinol Metab*. 2014;99:3644–3652.)

measured every 6 months. Local injection site inflammation and lipodystrophy have been reported.[529] Levels of GH rise as IGF1 negative feedback on the pituitary is lost.

SRLs and GH Receptor Antagonist Combination

Combination treatment for acromegaly is most effective for patients in whom there has been tumor shrinkage on somatostatin analogue with reduction, albeit inadequate, in GH or IGF1 levels (Fig. 9.44). In 11 such uncontrolled patients, dual blockade of the GH axis with pegvisomant and SRLs has been shown to exhibit greater efficacy than either drug alone.[530] Monthly doses of long-acting somatostatin analogue have been successfully combined with weekly doses of pegvisomant.[531] A study in 63 patients showed that 4 years of combination treatment was safe, but 23 patients developed elevated liver enzymes, especially if they were diabetic.[532]

Management Approach

Employing an integrated classification base on clinical, biochemical, pathologic, and imaging features, acromegaly may be classified to enable evidence-based personalized management (Table 9.29).[365] Type I acromegaly accounts for over 50% of patients. These are usually older patients with smaller tumors containing dense GH granularity and abundant SST2 and p21 expression. IGF1 levels are lower and therapeutic outcomes are most favorable. In contrast, type 3 acromegaly is encountered in younger patients with smaller, sparsely granulated tumors and low p21 and SST2 expression. IGF1 levels are higher, and both surgical and medical outcomes are less favorable. Type 2 patients exhibit intermediate features.[365] Given the challenge of choosing the most appropriate therapy, use of classification systems, as well as clinical outcome instruments, may enable a rigorous personalized approach for evidence-based care.[365,533] Using these parameters prospectively will enable a personalized approach to determining optimal management for these patients.

Ideally, the goal of therapy should be tight control of GH secretion and normalization of IGF1 levels, as adverse comorbidities and mortality rates correlate with GH levels. Discordant GH and IGF1 results after treatment should necessitate repeating the respective assay(s) in a reputable laboratory using rigorous assay standardizations and appropriate sensitivity cutoffs.[439] Normal or low IGF1 levels may be encountered with systemic disease or malnutrition and GH elevations reflecting persistent disease activity. Each treatment modality has respective advantages and disadvantages that should be assessed to individualize patient care (Fig. 9.45 and Tables 9.30 and 9.31).[534] Counterintuitively, features of GH deficiency may be encountered after effective therapy, and judicious GH replacement may be required to reverse adverse quality of life and lipid disorders.[535]

Selective surgical excision of a well-defined pituitary mass is recommended for most patients with microadenomas.[536] As remission rates are lower for macroadenomas and locally invasive tumors, attempted medical debulking of the sellar mass prior to surgery would be intuitively desirable, and limited controlled prospective studies appear to confirm the validity of this approach to improve outcomes, especially for patients with surgically inaccessible tumor tissue and cavernous sinus invasion.[537] Surgical debulking may also improve subsequent responsiveness to SRL therapy.[538,539] For uncontrolled patients after surgery, a long-acting SRL should be administered.[443] Patients with mild GH

elevations can also be treated with cabergoline; although efficacy of this drug is low, it is relatively inexpensive and free of major side effects.

Primary therapy with SRLs may be offered to those patients in whom complete tumor removal is not likely or to those who refuse surgery or in whom the risks of surgery or anesthesia are unacceptable (Fig. 9.46). As invasive macroadenomas invariably hypersecrete GH postoperatively in patients whose pituitary lesion does not compress vital structures, primary medical management may be an appropriate therapeutic option.[489,540] Pegvisomant, either alone or in combination with an SRL, should be offered to resistant patients. Radiation should be administered to patients who are resistant to or cannot tolerate medications, who prefer not to receive long-term injections, or those who cannot afford medication. After irradiation, medications are required for several years until GH levels are effectively controlled. Tumors recurring despite medical therapy or irradiation may rarely require reoperation.

Acromegaly patients also require counseling for anxiety engendered by disfigurements and interpretation of laboratory test results. Patients should be followed until biochemical control is achieved; thereafter, hormone evaluation is performed semiannually. In those who are biochemically in remission and in whom no residual tumor tissue is present, MRI should be repeated every 1 to 2 years. Follow-up evaluation includes treating new soft tissue overgrowth, nerve entrapments, and jaw overbites; rheumatologic, dental, and cardiac evaluations; and metabolic assessment. Maximal and sustained long-term GH and IGF1 control should ameliorate most deleterious comorbidities by judicious use of available treatment modalities.

ACTH-Secreting Tumors (Cushing Disease)

The evaluation and management of patients with ACTH-secreting pituitary tumor (Cushing disease) is fully described in Chapter 15. Briefly, the diagnosis of an ACTH-secreting pituitary tumor is suggested by features of hypercortisolism, elevated 24-hour urinary free cortisol levels, and elevated late night salivary cortisol values, together with nonsuppressed serum ACTH levels. Failure to suppress morning cortisol levels to less than 1.8 μg/dL after 1 mg dexamethasone administered at 11 PM supports the diagnosis.[541] In healthy subjects, glucocorticoid feedback suppresses CRH and ACTH, attenuating cortisol secretion. Surgical resection of an ACTH-secreting adenoma is the treatment of choice. As these tumors are usually small, sometimes less than 2 mm diameter, they may not be visible by sensitive MRI and venous sampling for ACTH. Therefore these tumors pose a significant challenge even for the experienced surgeon. Bilateral petrosal venous sampling for ACTH levels and cavernous sinus venography should ideally be performed prior to surgery. However, if sellar venous sinus drainage is predominantly unilateral, left-right ACTH gradients may not reliably lateralize the lesion. If an ACTH gradient is indeed detected with normal venous drainage patterns, hemihypophysectomy may in fact be curative in most patients with clearly defined biochemical features of ACTH-dependent Cushing disease. Meticulous surgical exploration of both anterior and posterior lobes is required for these tiny tumors, which are often off-white and speckled by petechiae, and may be inadvertently suctioned. Even carefully performed preoperative lateralization is not infallible, and the "normal" side should also be carefully explored.

Assessment of Surgical Outcome

Transsphenoidal adenoma resection is the preferred treatment for these adenomas.[542] After selective adenomectomy of a clearly identifiable adenoma, remission was achieved in 75% of 295 patients. However, partial hypophysectomy performed in patients in whom an adenoma cannot be identified may result in biochemical remission in some patients.[543] On the third postoperative day, 1 mg dexamethasone can be given at 10 PM, and cortisol levels are measured the following morning prior to initiating hydrocortisone therapy. If the immediate postoperative cortisol level is less than 3 μg/dL, a 95% 5-year remission rate can be expected. In 21 of 27 patients tested prior to glucocorticoid administration, postoperative cortisol levels lower than those obtained from preoperative midnight sampling and values less than 10 μg/dL were predictive of remission.[544]

Medical Treatment

Pasireotide, an SRL, has been approved for treating ACTH hypersecretion associated with Cushing disease.[545] About 20% of patients exhibit normalized urinary free cortisol levels, associated with improved clinical features. Up to 50% of patients may develop hyperglycemia, and blood sugars should be aggressively monitored. Mifepristone, a glucocorticoid receptor antagonist, is

TABLE 9.30 Management of Acromegaly

Goals

Control GH and IGF1 secretion
Control tumor growth
Relieve central compressive effects, if present
Preserve or restore pituitary trophic hormone function
Treat comorbidities (hypertension, cardiac failure, hyperglycemia, sleep apnea, arthritis)
Normalize mortality rates
Prevent biochemical recurrence

TREATMENTS

Characteristic	Surgery	Radiotherapy	SRL	GHR Antagonist	Dopamine Agonist
Advantages					
mode	Transsphenoidal resection	Noninvasive	Monthly injection	Daily injection	Oral
Biochemical control					
GH <2.5 μg/L	Macroadenomas, <50% Microadenomas, >80%	~35% in 10 years	~55–65%	Increases	<15%
IGF1 normalized		<30%	~55–65%	>65%	<15%
Onset	Rapid	Slow (years)	Rapid	Rapid	Slow (weeks)
Patient compliance	One-time consent	Good	Must be sustained	Must be sustained	Good
Tumor mass	Debulked or resected	Ablated	Growth constrained or shrinks ~50%	Unknown	Unchanged
Disadvantages					
Cost	One time	One time	Ongoing	Ongoing	Ongoing
Hypopituitarism	~10%	>50%	None	Very low IGF1 if overtreated	None
Other	Tumor persistence or recurrence, 6% Diabetes insipidus, 3% Local complications, 5%	Local nerve damage Second brain tumor Visual and CNS disorders, ~2% Cerebrovascular risk	Gallstones, 20% Nausea, diarrhea	Elevated liver enzymes (rare)	Nausea, ~30% Sinusitis High dose required

OUTCOMES

Feature	Evaluation	Treatment
Safe Biochemical Activity		
Nadir GH <0.4 μg/L Age-matched normal IGF1 Asymptomatic No comorbidities	Assess GH/IGF1 axis Evaluate adrenal, thyroid, and gonadal axes Periodic but less frequent MRI	None or no change in current treatment
Unsafe Biochemical Activity		
Nadir GH >0.4 μg/L Elevated IGF1 Discordant GH and IGF1 Asymptomatic No comorbidities	Assess GH/IGF1 axis Evaluate pituitary function Periodic MRI	Weigh treatment benefit vs. risks Consider new treatment if being treated
Unsafe Biochemical and Clinical Activity		
Nadir GH >1 μg/L Elevated IGF1 Clinically active tumor growing	Assess GH/IGF1 axis Evaluate pituitary function Assess cardiovascular, metabolic, and tumoral comorbidity Periodic MRI	Actively treat or change treatment

approved to ameliorate hyperglycemia associated with Cushing disease.[546] Side effects include adrenal dysfunction due to cortisol withdrawal, hypokalemia, and excessive vaginal bleeding.

Thyrotrophic Hormone-Secreting Tumors

TSH-producing pituitary tumors are rare. During 1979 to 1992, Mindermann and Wilson analyzed tumor type by immunohistochemistry and found that the overall prevalence of TSH-secreting tumors was 19/2225 (0.85%). Between 1989 and 1991, the same group found a prevalence of 2.8% among pituitary adenomas.[547] More recent studies have confirmed a progressive increased prevalence, accounting for 4% of pituitary tumor resections.[548] It is not clear whether newer, more sensitive TSH assays account for this or whether the tumor type frequency is increasing. TSH-secreting tumors can also cosecrete other hormones, including GH, PRL, and rarely ACTH, and can cause elevated serum IGF1 or PRL levels.[549]

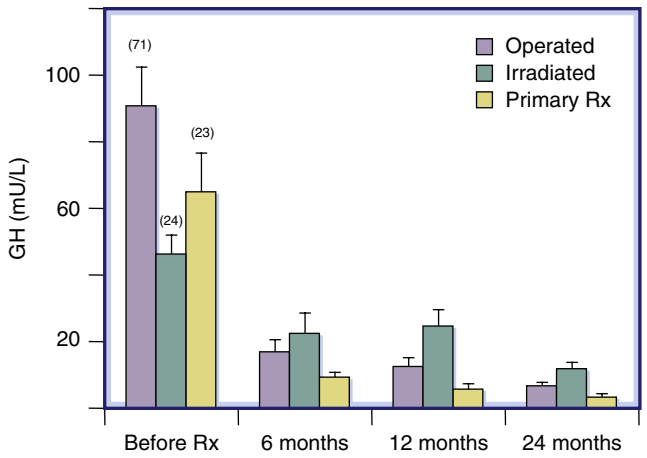
The hallmark of these rare tumors is an elevation of thyroid hormone levels in the face of inappropriately suppressed TSH levels. These biochemical features are reflective of autonomous tumor TSH production that is not suppressed by negative thyroid hormone feedback.

Pathology

These tumors are invasive but for the most part benign, and distant metastases are extremely rare. The expression pattern is often multihormonal, with immunoreactivity to TSHβ, α-subunit, GH, PRL, and sometimes ACTH.[550] Twenty-four-hour sampling indicates that pulse frequency of TSH is increased, yet diurnal rhythm was preserved at a higher mean hormone level.[551] TSH-secreting tumors exhibit positive immunostaining for α-subunit and TSHβ in up to 75% of cells and for the pituitary-specific transcription factor Pit1. These tumors express SST2 mRNA and, in some cases, SST3 and SST5 mRNA.[552]

Presentation

Patients may present with thyroid abnormalities, including goiter, nodules, and features of hyperthyroidism. As most TSH-secreting tumors are already macroadenomas at presentation,[553] they may present with symptoms due to tumor growth (including visual field abnormalities, cranial nerve palsies, or headache). Signs and symptoms of hyperthyroidism, including palpitations, arrhythmias, weight loss, tremor and nervousness, or goiter, are common. Very rarely, periodic paralysis and postoperative thyroid storm have been reported.[554,555] Serum TSH is often but not invariably elevated. In those cases, the combination of abnormally high thyroid hormone levels and a TSH value within the normal range points to a TSH-producing pituitary tumor. A relatively long period of hyperthyroidism, initially thought to be Graves disease and treated accordingly, often predates the realization that the hyperthyroidism is indeed a result of a TSH-secreting pituitary tumor. Alternatively, thyroid hormone insensitivity can also present with similar laboratory profiles.[556] TSH-secreting tumors are usually large, and 70% to 90% are macroadenomas, with most locally invasive.[557] From analysis of 10 reports on a total of 153 patients, it appears that TSH is frankly elevated in 58% of patients, with the remainder having normal albeit inappropriately elevated TSH levels. Patients previously treated with radioactive iodine for presumed Graves disease present with significantly higher TSH levels than patients not previously radioablated (mean: 56 mU/L vs. 9 mU/L, respectively). An



• **Fig. 9.46** Primary medical therapy in acromegaly patients. Control with medical therapy compared to surgery or radiation. Plasma growth hormone (GH) levels (mean ± SEM) in the group of patients (n = 118) before and during long-term treatment with lanreotide. *Rx,* treatment; *SEM,* standard error of the mean. (Data from Baldelli R, Colao A, Razzore P, et al. Two-year follow-up of acromegalic patients treated with slow release lanreotide [30 mg]. *J Clin Endocrinol Metab.* 2000;85[11]:4099–4103.)

ectopic TSH-producing tumor has also been reported.[558] Serum T_4 is high in most patients, as is the glycoprotein hormone α-subunit. Approximately two-thirds of patients with TSH-producing pituitary tumors have goiters with elevated radioactive iodine uptake. Rarely, patients with TSHomas have been reported with concurrent differentiated thyroid cancer.[559] About 30% of TSHomas cosecrete GH or PRL.[560] Consequently, features of acromegaly or hyperprolactinemia may also be present.

Evaluation

Serum T_4, T_3, TSH (by high sensitivity assay), and α-subunit should be measured. The combination of high T_4, T_3, and α-subunit; high or inappropriately normal TSH; and a pituitary tumor strongly confirms the diagnosis of a TSH-producing pituitary adenoma. TRH stimulation can differentiate between TSH overproduction by a TSH-secreting tumor and thyroid hormone insensitivity. In TSH-secreting tumors, the TSH response elicited by TRH is blunted. In contrast, TSH usually rises in response to TRH in patients with thyroid hormone insensitivity and in normal subjects. Concomitant measurement of α-subunit at each point during the TRH test is helpful because the molar ratio of α-subunit to TRH is high (>1) in almost 85% of patients with TSH-secreting tumors. A T_3 suppression test is helpful in that complete inhibition of TSH does not occur in patients with TSH-secreting tumors. This test can also differentiate subclinical hypothyroidism in patients previously treated with radioactive iodine for hyperthyroidism but found to have an incidental pituitary tumor. TSH elevation may also result from inadequate thyroid hormone replacement. A pituitary MRI should be performed, and IGF1 and PRL levels determined, to exclude acromegaly or hyperprolactinemia. Expression of other pituitary hormones in immunostained histologic sections does not necessarily imply elevated serum levels.

Importantly, the degree of hyperthyroidism should be assessed to determine whether control of these signs and symptoms should be undertaken prior to further evaluation or treatment of the pituitary tumor. Hyperthyroidism may be clinically severe and present in most patients for years before the diagnosis is made.

Management

Surgery

The European Thyroid Association guidelines suggest surgery as first-line therapy. Cures are achieved for most patients with microadenomas, but remission is achieved in about 60% of patients with macroadenomas.[560] After a mean follow-up of 64.4 months, 75% of 70 patients achieved biochemical control and 58% normalized both pituitary imaging and thyroid function, but complete surgical cures are achieved in fewer than 40% of patients[557] (Table 9.32 and Fig. 9.47). However, the rarity of this tumor type has precluded large controlled studies. Most patients have cavernous or sphenoid sinus invasion, and tumors are often fibrous and unusually hard. About one-third of patients require adjuvant radiotherapy to achieve biochemical normalization. Nevertheless, 9% developed pituitary hormone deficiencies, and 3% had recurrence of tumor or hyperthyroidism within the first 2 years of radiotherapy. After 18 to 96 months of follow-up, 32% of patients had developed new-onset pituitary deficits.[557]

Radiation Therapy

There are no large series reporting treatment of TSH-secreting tumors with radiotherapy alone. Radiation has mostly been used as adjunctive therapy to surgery, especially when the latter was not curative.

SRLs

Octreotide, used as either primary or adjunctive treatment, normalizes T_4 and T_3 and reduces TSH levels by half.[561] Overall, tumors shrink in about a third of patients. In 18 patients with TSH-secreting adenomas, lanreotide (30 mg every 10 or 14 days) significantly decreased TSH levels from 2.72 to 1.89 mU/L, decreased T_4 levels, but did not shrink tumors. Octreotide LAR (up to 30 mg monthly) responsiveness appeared similar to that observed for the subcutaneous preparation in seven patients.[562] In another report, octreotide suppressed TSH in 90% of patients with TSH-secreting tumors and reduced tumor size in 50% of these patients.[563] SRLs are effective in more than 90% of patients with TSHomas,[560] but tachyphylaxis may occasionally occur.

Preoperative Management

Unless vision is threatened, patients should be evaluated to determine whether clinical signs of hyperthyroidism warrant immediate treatment. Propranolol, radioactive iodine thyroid ablation, thyroidectomy, antithyroid medications (including methimazole), and SRLs are used. Both radioactive iodine and antithyroid medications are targeted to the thyroid gland rather than the pituitary seat of the disorder. This approach also inhibits the negative feedback of T_3 on TSH and leads to increased tumor TSH production. Surgery and SRLs simultaneously treat hyperthyroidism and tumor TSH hypersecretion. SRLs lower TSH, α-subunit, and T_4 and are recommended as first-line drugs in the initial control of hyperthyroidism due to TSH-secreting tumors because their onset of action is faster than other therapeutic approaches and tumor shrinkage occurs in up to 40% of patients. When invasive tumor tissue persists, patients continue to have abnormal TSH responses to TRH and require SRL therapy.

TABLE 9.32 TSH-Secreting Adenomas: Results of Surgical Treatment

Silent TSH-Secreting Tumors

A subset of TSH-secreting tumors immunostain positively for but do not hypersecrete TSH or cause thyrotoxicosis. Of 29 tumors that immunostained positively for TSH, 9 were not associated with hyperthyroidism.[564]

Posterior Pituitary

CHRISTOPHER J. THOMPSON AND JOSEPH G. VERBALIS

CHAPTER OUTLINE

KEY POINTS

- The posterior pituitary is composed of neural tissue and consists of distal axon terminals of the hypothalamic magnocellular vasopressin and oxytocin neurons that constitute the neurohypophysis.
- Regulation of neurohypophyseal hormone synthesis occurs at the level of transcription. Stimuli for the secretion of vasopressin or oxytocin also induce transcription and increase the hormone messenger ribonucleic acid (mRNA) content in the magnocellular neurons.
- Physiologic regulation of vasopressin synthesis and secretion involves two systems: osmotic and pressure/volume. Each are controlled by separate neural inputs to the neurohypophysis and have different thresholds for vasopressin secretion.
- Once released, vasopressin elicits end-organ effects via activation of vasopressin receptors. Renal vasopressin V_2 receptors induce antidiuresis via a signal transduction cascade that results in insertion of aquaporin 2 water channels into the apical membrane of principal cells in the renal collecting duct.
- Diabetes insipidus is a disorder of a large volume of urine (diabetes) that is hypotonic (dilute) and tasteless (insipid), leading to polyuria and polydipsia. It can be caused by deficient vasopressin section, increased vasopressin catabolism, or decreased vasopressin effect in the kidneys.
- The syndrome of inappropriate antidiuresis (SIAD) occurs when plasma levels of vasopressin are elevated at times when physiologic vasopressin secretion from the posterior pituitary would normally be osmotically suppressed, leading to water retention and hypoosmolality. It can be caused by several diseases and drugs.

Anatomy

Normal

The posterior pituitary is neural tissue and consists only of the distal axons of the hypothalamic magnocellular neurons that make up the neurohypophysis. The perikarya (cell bodies) of these axons are located in paired paraventricular and supraoptic nuclei of the hypothalamus. During embryogenesis neuroepithelial cells of the lining of the third ventricle mature into magnocellular neurons while migrating laterally to and above the optic chiasm to form the supraoptic nuclei and to the walls of the third ventricle to form the paraventricular nuclei.[1] In the posterior pituitary the axon terminals of the magnocellular neurons contain neurosecretory granules, membrane-bound packets of hormones stored for subsequent release. The blood supply for the anterior pituitary is via the hypothalamic/pituitary portal system, but the posterior pituitary is supplied directly from the inferior hypophyseal arteries, which are branches of the posterior communicating and internal carotid arteries. The drainage is into the cavernous sinus and internal jugular vein.

The hormones of the posterior pituitary, oxytocin and vasopressin, are for the most part synthesized in individual hormone-specific magnocellular neurons although a small number of neurons (~3%) express both peptides.[2] The supraoptic nucleus (SON) is relatively simple with 80% to 90% of the neurons producing vasopressin[3] and virtually all axons projecting to the posterior pituitary.[1] The organization of the paraventricular nucleus

(PVN), however, is much more complex and varies among species. In the human there are five subnuclei,[3] and parvocellular (smaller cell) divisions synthesize other peptides such as corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), and somatostatin[4] as well as opioids.[5] The parvocellular neurons project to the median eminence, brainstem, and spinal cord[6] where they play a role in a variety of neuroendocrine autonomic functions. The suprachiasmatic nucleus, which is located in the midline at the base of and anterior to the third ventricle, also synthesizes vasopressin and controls both circadian and seasonal rhythms.[3]

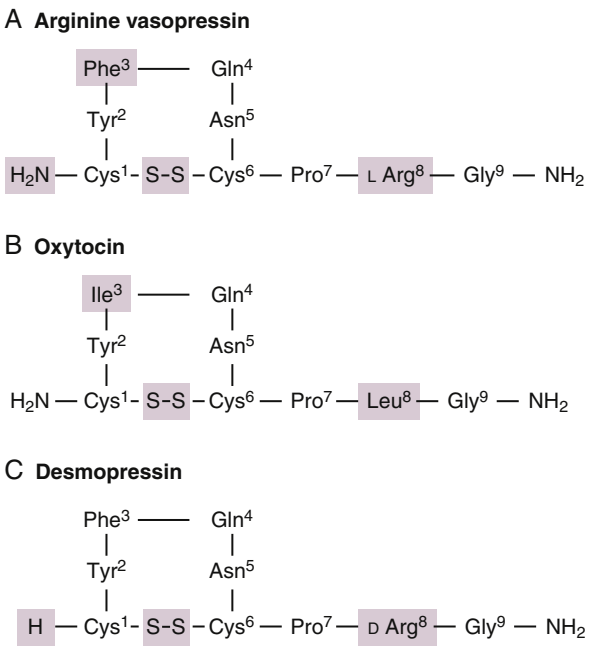
The major stimulatory neurotransmitter in the neurohypophysis is glutamate with noradrenergic stimulatory inputs acting by stimulation of glutamate.[7,8] Glutamate receptors account for 25% of synapses on magnocellular neurons.[7] The major inhibitory input is γ-aminobutyric acid (GABA), which accounts for 20% to 40% of the synaptic input to the magnocellular neurons.[9] Phasic firing of vasopressin neurons is the most efficient activity pattern for release of vasopressin from axon terminals. Phasic activity is controlled by glutamate stimulation and opioid inhibition. Dynorphin is synthesized in vasopressin neurons and co-released with vasopressin from dendrites at the somatic level where it acts in an autocrine fashion to inhibit the activity of the vasopressin neurons, contributing to the phasic firing pattern.[10,11] One of the most remarkable aspects of the magnocellular system is the plasticity of the system in response to prolonged stimulation. Plasticity is of most import in humans during parturition and lactation.[9]

Ectopic Posterior Pituitary

With the development of magnetic resonance imaging (MRI) scans of the brain it was discovered that T1-weighted images with MRI produced a bright signal in the posterior pituitary.[12] This allowed the identification of children in whom there was abnormal anatomy of the posterior pituitary when the "bright spot" was recognized in the base of the hypothalamus. These cases are referred to as *ectopic posterior pituitary* or *pituitary stalk interruption*. Etiologies include traumatic delivery (these patients have a higher incidence of breech delivery and perinatal injuries) and genetic abnormalities of the transcription factors that regulate pituitary embryogenesis.[13] The latter is supported in cases where abnormalities of the posterior pituitary and/or stalk are associated with extrapituitary malformations such as septal optic dysplasia. Cases with malformations are more likely to have diabetes insipidus or other osmotic dysfunction than simple ectopic posterior pituitary.[14,15] Cases are recognized in children with growth retardation and anterior pituitary deficiency rather than posterior pituitary deficiency. The degree of anterior pituitary deficit depends on the persistence of a pituitary stalk and a retained portal vasculature from the hypothalamus to the anterior pituitary.[16–18] Deficiency of adrenocorticotropic hormone (ACTH) is common and should be investigated as the patients may not respond appropriately to stress.[13]

Synthesis and Release of Neurohypophyseal Hormones

Vasopressin and oxytocin are nonapeptides consisting of a six–amino acid ring with a cysteine-to-cysteine bridge and a three–amino acid tail. All mammals have arginine vasopressin and oxytocin, as illustrated in Fig. 10.1, with the exception of the pig



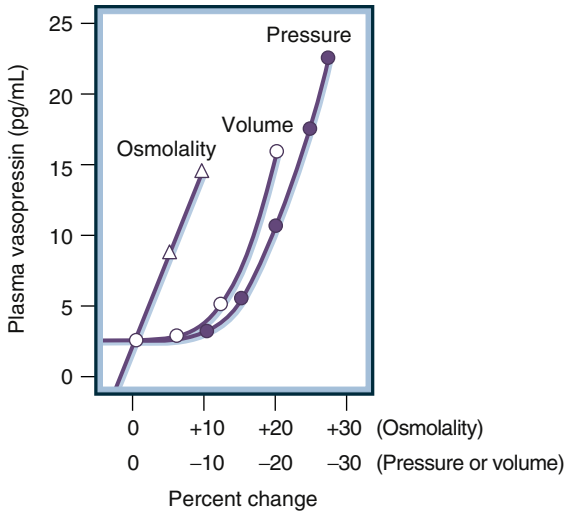
• **Fig. 10.1** Comparison of the chemical structures of arginine vasopressin (A), oxytocin (B), and desmopressin (C). The differences are illustrated by the shaded areas. Oxytocin differs from vasopressin in position 3 (Ile for Phe) and position 8 (Leu for Arg). Desmopressin differs from arginine vasopressin in that the terminal cystine is deaminated and the arginine in position 8 is a D-isomer rather than an L-isomer. (From A.G. Robinson, University of California at Los Angeles, used with permission.)

in which lysine is substituted for arginine in position 8 producing lysine vasopressin. Both genes are found on chromosome 20[19] although they are situated in a tail-to-tail position and transcribed in opposite directions.[20] The hormones are synthesized as part of a precursor molecule consisting of the nonapeptide and a hormone-specific neurophysin and, for vasopressin, a 39–amino acid peptide named copeptin.[21] The precursor is packaged in neurosecretory granules and cleaved to the products during transport to the posterior pituitary.

When a stimulus for secretion of vasopressin or oxytocin acts on the appropriate magnocellular cell body, an action potential is generated and propagates down the long axon to the posterior pituitary. The action potential causes an influx of calcium, which induces neurosecretory granules to fuse with the cell membrane and extrude the entire contents of the neurosecretory granule into the perivascular space and subsequently into the capillary system of the posterior pituitary. At physiologic pH of plasma there is no binding of hormone (vasopressin or oxytocin) to their respective neurophysins, so each peptide circulates independently in the bloodstream.

The control of hormone synthesis is at the level of transcription. Stimuli for secretion of vasopressin or oxytocin also stimulate transcription and increase the mRNA content in the magnocellular neurons. This has been studied in most detail in rats where dehydration[22] accelerates transcription and increases the levels of vasopressin (and oxytocin) mRNA[23–25] and where hypoosmolality produces a decrease in the content of vasopressin mRNA.[26]

The transport of neurosecretory vesicles from the site of synthesis to the posterior pituitary along microtubule tracks[27] is also regulated. When synthesis is turned off, transport stops; when synthesis is increased, transport is upregulated.[27] Thus



• **Fig. 10.2** Comparison in humans of the release of vasopressin in response to increased osmolality *(open triangles)* or to decreased blood pressure *(filled circles)* or blood volume *(open circles)*. Plasma vasopressin is much more sensitive to change in osmolality, responding to as little as a 1% increase, whereas a change of 10% to 15% or greater in volume or pressure is required to stimulate release of vasopressin. (Redrawn from Robertson GL, Berl T. Water metabolism. In: Brenner B, Rector F Jr, eds. *The Kidney*. 3rd ed, vol 1. Philadelphia, PA: Elsevier; 1986:385. Figure by A.G. Robinson, University of California at Los Angeles, used with permission.)

there is coordination of stimulated release of hormone, transport of hormone, and synthesis of new hormone. There is, however, asynchrony in the timing of these events. The asynchrony is demonstrated by changes in the content of vasopressin stored in the posterior pituitary. The absolute content varies considerably among species but is a remarkable store, generally equivalent to the amount of hormone required to sustain basal release for 30 to 50 days or maximum release for 5 to 10 days.[28] In animals, prolonged and intense stimulation of vasopressin release such as dehydration or salt loading produces a depletion of stored hormone in the posterior pituitary.[25,29,30] Then when animals are returned to normal water intake, there is in 7 to 14 days a gradual recovery of pituitary content back to baseline. Modeling of this phenomenon has provided experimental evidence that a long half-life of the vasopressin message, approximately 2 days, is (from a minimalist point of view) a plausible explanation.[31] When a strong and/or sustained stimulus releases vasopressin there is an immediate stimulus to transcription of new mRNA, but it requires several days for the peak level of mRNA to be reached; thus while release of hormone is rapid, translation increases slowly. When the stimulus is removed, the elevated mRNA slowly declines while continuing to synthesize hormone that repletes the store in the posterior pituitary.

Physiology of Secretion of Vasopressin and Thirst

The physiologic regulation of vasopressin synthesis and secretion involves two systems: osmotic and pressure/volume (Fig. 10.2). Functions of these two systems are so distinct that historically it was thought there were two hormones, an antidiuretic hormone and a vasopressor hormone. Hence the two names that are used interchangeably for (8-arginine) vasopressin. There are separate systems at the level of the receptors on the end organs of response. The V_{1a} receptors on blood vessels are distinct from V_2 receptors on renal collecting duct epithelia. These two vasopressin receptor subtypes are responsible for the main physiologic actions of vasopressin. A third receptor, V_{1b}, is responsible for the nontraditional biologic action of vasopressin to stimulate ACTH secretion from the anterior pituitary and has been found in numerous peripheral tissues and areas of the brain.[32] V_2 receptors also regulate the nontraditional action of vasopressin to stimulate factor VIII and von Willebrand factor production. Vasopressin is the main hormone involved in the regulation of water homeostasis and osmolality, while the renin-angiotensin-aldosterone system (RAAS) is mainly responsible for regulation of blood pressure and volume. Pathologic disorders of the neurohypophysis are primarily expressed as abnormalities of osmolality produced by abnormal excretion or retention of water. In the case of osmoregulation vasopressin secretion is relatively uncomplicated with small increases in osmolality producing a parallel increase in vasopressin secretion and small decreases in osmolality causing a parallel decrease in vasopressin secretion. The regulation of volume and blood pressure is significantly more complicated (see review by Thrasher[33]) and experimental models of vasopressin and baroreceptor regulation in animals often involve inhibiting and/or measuring other concurrent sympathetic inputs to the system to ascertain direct effects of any stimulus on secretion of vasopressin (see Fig. 10.2). Other influences on secretion of vasopressin such as the inhibiting influence of glucocorticoids and the potent stimulus of nausea and vomiting are less important as physiologic regulators of vasopressin but might contribute during pathologic situations.

Volume and Pressure Regulation

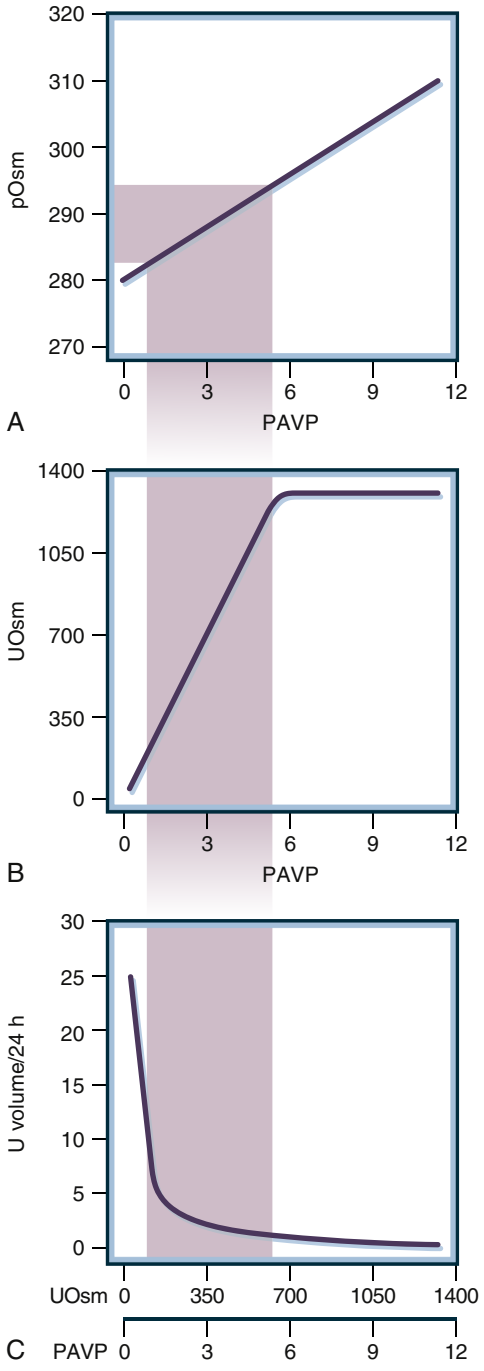
High-pressure arterial baroreceptors are located in the carotid sinus and aortic arch; low-pressure volume receptors are located in the atria and pulmonary venous system.[33] The afferent signals from these receptors are carried from the chest to the brainstem through cranial nerves 9 and 10. Interruption of the vagal input by vagal cold block in dogs[34,35] and destruction in rabbits of the A1 area of the medulla, which receives input from cranial nerves 9 and 10,[36–38] leads to an increase in vasopressin secretion. These and other data led to the concept that baroreceptors and volume receptors normally inhibit the magnocellular neurons and that decreases in this tonic inhibition result in release of vasopressin. Arterial and venous constriction induced by vasopressin action on V_{1a} receptors will contract the vessels around the existing plasma volume to effectively "increase" plasma volume and reestablish the inhibition of secretion of vasopressin. Vasopressin's action at the kidney to retain water will help replace volume but, in fact, the major hormonal regulation to control volume is the RAAS, which stimulates sodium reabsorption in the kidney (see Chapter 15). The concept of tonic inhibition of vasopressin secretion by baroreceptors has been questioned,[33,39] but there is agreement that the volume/baroreceptor responses are much less sensitive than are the osmoreceptors (see Fig. 10.2). The lesser response has been attributed to the fact that changes in blood volume and central venous pressure have little effect to increase vasopressin in humans as long as arterial pressure can be maintained by alternative regulatory mechanisms such as RAAS and sympathetic reflexes.[33] When the hypovolemia is sufficient to cause a decrease in blood pressure there is an exponential increase in the level of vasopressin in plasma[33,40] (see Fig. 10.2). There is also agreement that changes in

volume or pressure that are insufficient to cause direct increases in vasopressin can nonetheless modify the response of the vasopressin system to osmoregulatory inputs.[40,41] Increases in pressure and central volume will decrease the secretion of vasopressin,[42] but the response of the RAAS to cause sodium excretion is much more sensitive to increases of pressure and volume than is the response to decrease secretion of vasopressin.[33] Consequently, changes in blood pressure and volume involve both excitatory and inhibitory influences from the brainstem to magnocellular neurons, with the dominant effect depending on the physiologic circumstances.

Osmotic Regulation

The primary receptors for sensing changes in osmolality are located in the brain. Most of the brain is within the blood-brain barrier, which is generally impermeable to polar solutes. The osmostat is insensitive to urea and glucose, which readily cross cellular membranes but not the blood-brain barrier; this provides strong evidence that the osmoreceptors must be outside the blood-brain barrier. Experimental brain lesions in animals have implicated cells in the organum vasculosum of the lamina terminalis (OVLT) and in areas of the anterior hypothalamus near the anterior wall of the third cerebral ventricle as the primary osmoreceptors. Because these and other circumventricular organs are perfused by fenestrated capillaries, they are outside the blood-brain barrier. Surgical destruction of the OVLT abolishes vasopressin secretion and thirst responses to hyperosmolality but not their responses to hypovolemia.[43] Patients with brain damage that destroys the region around the OVLT cannot maintain normal plasma osmolalities even under basal conditions.[44] In contrast, destruction of the magnocellular neurons of the SON and PVN eliminates dehydration-induced secretion of vasopressin but does not alter thirst, clearly indicating that osmotically stimulated thirst must be generated at a site proximal to the magnocellular cells. Because the osmoreceptors are relatively solute specific, they are most sensitive to alterations in plasma sodium concentrations but respond less well to elevations in blood urea and seem insensitive to changes in plasma glucose concentration.[45]

Extracellular fluid osmolality (predominantly determined by sodium concentration) varies from 280 to 295 mOsm/kg H_2O in normal subjects, but in any individual it is maintained within a more narrow range. The ability to maintain this narrow range is dependent upon the sensitive response of plasma vasopressin to changes in plasma osmolality, the sensitive response of urine osmolality to changes in plasma vasopressin, and the gain in the system by the response of urine volume to change in plasma vasopressin (Fig. 10.3). Basal plasma vasopressin is in the range of 0.5 to 2 pg/mL. As little as a 1% increase or decrease in plasma osmolality will cause a rapid increase or decrease of vasopressin released from the store of hormone in the posterior pituitary.[40] Rapid metabolism of vasopressin is also characteristic of the hormone that circulates in plasma with a half-life of approximately 15 minutes, which allows rapid changes in levels of vasopressin in plasma. Thus small increases in plasma osmolality produce a concentrated urine and small decreases produce a water diuresis. Fig. 10.3A illustrates the linear relationship between plasma osmolality and plasma vasopressin that has been described in humans.[40] This linear relationship for osmolalities persists well above the normal excursion of osmolalities as demonstrated when the increase is induced by infusion of hypertonic saline or is observed during dehydration of patients with nephrogenic diabetes insipidus.[46] Similarly, Fig. 10.3B illustrates that there is a sensitive and linear relationship between the level of vasopressin in plasma and



• **Fig. 10.3** Effect of change in plasma osmolality (pOsm, in mOsm/kg of H_2O) on plasma arginine vasopressin (PAVP, in pg/mL) and consequent effects on urine osmolality (UOsm, in mOsm/kg of H_2O) and urine volume (L/day). The *shaded area* represents the normal range. (A) Small changes in pOsm induce changes in PAVP, typically between less than 0.5 and 5 to 6 pg/mL. (B) Changes in PVAP induce changes in UOsm through the full range, from maximally dilute to maximally concentrated urine. Although PAVP can rise to higher levels than 6 pg/mL, this does not translate into increased UOsm, which has a maximum determined by the osmolality of an inner medulla of the kidney. (C) The relationship of urine volume to UOsm is logarithmic, assuming a constant osmolar load and the urine volume that would excrete that osmolar load at the UOsm indicated. As a result, urine volume changes relatively little with small changes in the other parameters until there is almost complete absence of PAVP, after which the urine volume increases dramatically. (Calculated from a formula presented in Robertson G, Shelton R, Athar S. The osmoregulation of vasopressin. *Kidney Int*. 1976;10:25–37. Figure by A.G. Robinson, University of California at Los Angeles, used with permission of Macmillan Publishers, Ltd.)

the induced osmolality of the urine. Although plasma vasopressin might increase above the normal physiologic range, the urine osmolality plateaus at approximately 800 to 1200 mOsm/kg H_2O because the maximum concentration of fluid in the renal collecting duct is the osmolality of the inner medulla. Fig. 10.3C shows the relationship of plasma vasopressin to urine volume. This is a calculated relationship based on the urine volume necessary to excrete a fixed quantity of osmolytes (800 mOsm) at the urine osmolality produced by the change in plasma vasopressin. These graphs demonstrate the gain in the system when considering the changes in urine volume relative to plasma vasopressin. When vasopressin is absent, 18 to 20 L of urine are excreted daily; with an increase of vasopressin by as little as 0.5 to 1 pg/mL, however, urine volume is reduced to less than 4 L/day. This illustrates the important point that at low plasma levels of vasopressin small changes of vasopressin are much larger determinants of polyuria than are greater changes at higher plasma levels.

In the kidney, water is conserved by the combined functions of the loop of Henle and the collecting duct. The loop of Henle generates a high osmolality in the renal medulla via the countercurrent multiplier system. Vasopressin acts in the collecting duct to increase water (and urea) permeability, thereby allowing osmotic equilibration between the urine and the hypertonic medullary interstitium. The net effect of this process is to extract water from the urine (which is removed from the medulla by interstitial blood vessels, vasa recta), resulting in increased urine concentration and decreased urine volume (antidiuresis). Vasopressin produces antidiuresis by binding to V_2 receptors on the epithelial principal cells of the renal collecting tubule. Binding activates adenylate cyclase, increasing cyclic adenosine monophosphate (cAMP), which then stimulates protein kinase A. This leads to phosphorylation and activation of aquaporin 2 and movement of the water channels into the luminal membrane.[47] Aquaporin 2 is one of the widely expressed family of water channels that mediate rapid water transport across cell membranes.[48] In the kidney, water moves from the collecting duct into the hypertonic inner medulla producing concentrated urine.[49] In addition to moving constitutively synthesized aquaporin 2 from the cytoplasm to the luminal membrane, activation of the V_2 receptor also increases the synthesis of aquaporin 2 and the permeability of aquaporin 2 to water.[50] Aquaporin 3 and 4 are constitutively synthesized and are expressed at high levels in the basolateral plasma membranes of principal cells, where they are responsible for the high water permeability of the basolateral plasma membrane.[48,49] Dissociation of vasopressin from the V_2 receptor allows intracellular cAMP levels to decrease; the water channels are then reinternalized, terminating the increased water permeability. The aquaporin-containing vesicles remain just below the apical membrane and can be quickly "shuttled" into and out of the membrane in response to changes in intracellular cAMP levels. This mechanism allows minute-to-minute regulation of renal water excretion in response to changes in ambient levels of vasopressin in plasma. There is also long-term regulation of collecting duct water permeability in response to prolonged high levels of circulating vasopressin. Chronically high levels of vasopressin induce increased synthesis of aquaporin 2 and 3 water channels in the collecting duct principal cells and hence high levels of these proteins. This response requires at least 24 hours and is not rapidly reversible. Increased numbers of aquaporin 2 and 3 water channels combined with the effect of vasopressin to insert aquaporin 2 into the apical plasma membrane allows the collecting ducts to achieve extremely high water permeabilities and water conservation during prolonged dehydration.[48,49]

Thirst

Renal free water clearance can be reduced to a minimum by the antidiuretic actions of vasopressin, but water loss is not completely eliminated, and insensible water loss from respiration and sweating is a continuous process. To maintain water homeostasis, water must also be consumed to replace the obligate urinary and insensible fluid losses. This is regulated by thirst. The sensation of thirst can be stimulated by increases in plasma osmolality or by decreases in intravascular volume, in a manner identical to vasopressin. Furthermore, there is evidence that the receptors are similar (i.e., osmoreceptors in the anterior hypothalamus and low-pressure and/or high-pressure baroreceptors in the chest [with a likely contribution from circulating angiotensin II to stimulate thirst during more severe degrees of intravascular hypovolemia and hypotension]).[51] Careful physiologic studies in healthy humans, using quantitative estimates of subjective symptoms of thirst, have confirmed that the characteristics of osmotically stimulated thirst are similar to those of vasopressin secretion; the osmotic thresholds are similar, and there is a close linear relationship between thirst scores and plasma osmolality throughout a wide range of plasma tonicity.[52] The threshold for producing thirst by hypovolemia is significantly higher than that for osmotic stimulation.

Although osmotic changes clearly are effective stimulants of thirst, most humans consume the bulk of their ingested water as a result of the relatively unregulated components of fluid intake—that is, beverages are consumed with food for reasons of palatability, taken for desired secondary effects (e.g., caffeine), or taken for social or habitual reasons (e.g., sodas or alcoholic beverages). As a result, humans generally ingest volumes in excess of what can be considered an actual need for fluid. In humans, plasma osmolality does not vary by more than 1% to 2% of basal levels. However, in adipsic patients the absence of thirst is associated with profound alterations of plasma water homeostasis, which emphasizes that even in humans who mostly drink for pleasure, thirst still plays a fundamental role in physiologic osmoregulation.

Clinical Consequences of Osmotic and Volume Regulation

Under physiologic situations and during most pathophysiologic conditions, the integration of osmotic and baroregulated vasopressin release and thirst are closely integrated and maintain plasma osmolality and sodium concentrations within normal ranges. During dehydration, for example, plasma osmolality increases and blood volume decreases, and vasopressin secretion and thirst sensation occur as a composite result of the two separate stimuli. There is good evidence that a decrease in blood volume shifts the plasma vasopressin/plasma osmolality response curve to the left, resulting in a greater release of vasopressin per unit rise osmolality; in other words, hypovolemia enhances the vasopressin response to an osmotic stimulus.[33,53] Similarly, an excess of fluid produces a decrease in osmolality and an increase in volume, and both will cause a decrease in vasopressin secretion and thirst.

The clinical manifestations of osmoregulatory diseases are largely explainable on the basis of the physiology of vasopressin secretion and its antidiuretic actions. Fig. 10.3 shows that loss of vasopressin neurons sufficient to decrease the vasopressin secretory capacity from that able to produce plasma concentrations of 10 to 20 pg/mL down to a secretory capacity able to generate plasma concentrations of only 5 pg/mL would not compromise the ability to maximally concentrate urine. Further losses of vasopressin neurons such that maximal plasma vasopressin concentrations are

in the 1 to 5 pg/mL range are associated with a linear decrease in the ability to maximally concentrate the urine; however, from the urine volume curve it can be seen that this results in only modest increases in urine volume. But when loss of vasopressin neurons to produce maximal plasma vasopressin concentrations below 1 pg/mL occurs, there is a large increase in urine volume, as urine concentration is severely compromised. Water conservation is therefore protected despite minimal ability to secrete vasopressin. In addition, the phenomenon of recovery of diabetes insipidus after transsphenoidal surgery or traumatic brain injury, even after prolonged symptoms, might reflect a comparatively minor recovery of vasopressin neurons sufficient to abolish polyuric symptoms.

In contrast, in the syndrome of inappropriate antidiuresis, a patient who is unable to suppress plasma vasopressin levels to less than 1 pg/mL might be unable to excrete more than 2 to 4 L of urine a day at a standard osmolar load. However, because osmoregulated thirst is not suppressed despite hyponatremia in SIAD,[54] if fluid intake increases above these levels the antidiuretic effects of nonsuppressible vasopressin secretion lead to dilutional hyponatremia. Thus, although the regulation of vasopressin secretion and thirst demonstrates a simple but elegant human system to maintain water balance, abnormal functioning of these complex systems leads to the development of the pathophysiologic states that will be described in this chapter.

Reset Osmostat During Pregnancy

Major shifts of fluid during normal pregnancy produce a fall in plasma osmolality of about 10 mmol/kg and an increase in plasma volume[55]; this is the best physiologic example of a true resetting of the osmostat. The shift in osmotic threshold for vasopressin appears at about 5 to 8 weeks of gestation and persists throughout pregnancy, returning to normal by 2 weeks after delivery.[55] The physiology of the reset osmostat has been considered in relation to the expanded plasma volume. Total body water in pregnant women is increased by 7 to 8 L due to profound vasodilatation.[56] This volume is sensed as normal and vasopressin responds appropriately to decreases and increases of the expanded volume.[55,57] Both the changes in volume and the changes in osmolality have been reproduced by infusion of relaxin (a normal hormone of pregnancy that is a member of the insulin-like growth factor [IGF] family) into virgin female and normal rats,[58,59] and reversed in pregnant rats by immunoneutralization of relaxin.[60] Increased nitric oxide (NO) by relaxin is reported to increase vasodilatation, and estrogens also increase NO synthesis.[61]

In women the placenta produces an enzyme, cysteine aminopeptidase, which is released into the plasma and is known as oxytocinase.[55,62] This enzyme is equally potent in degrading oxytocin and vasopressin. The activity of oxytocinase (vasopressinase) increases markedly around 20 weeks of gestation and increases further to 40 weeks, returning slowly to normal over a few weeks after delivery.[63] The potential pathology produced by oxytocinase is described in "Diabetes Insipidus."

Osmotic Regulation in Aging

Numerous studies have reported that elderly humans are at risk for both hypernatremia and hyponatremia.[64,65] In older subjects there is a decrease in glomerular filtration rate,[64] and the collecting duct in the aged kidney is less responsive to vasopressin-stimulated increases in aquaporin 2 water channels, thus limiting the ability to excrete free water.[66] Elderly subjects are reported to have lower nocturnal plasma levels of arginine vasopressin (AVP) and a prolonged effect of administered desmopressin.[67] Many other abnormalities of fluid and electrolyte balance in the elderly are due to comorbid conditions and/or the numerous pharmacologic agents these patients are often taking.[68] Studies of responses to dehydration, osmolar stimulation, or volume stimulation in the elderly are complicated by the fact that by age 75 to 80 years total body water declines to 50% of the level of normal young adults.[69] The elderly have a decreased thirst with dehydration and a lesser fluid intake during recovery from dehydration.[70,71] At the other end of the spectrum, elderly patients have been found to excrete a water load less well than younger subjects, and at least part of this is due to decreased suppression of vasopressin.[72] In summary, there are age-related changes in body volumes and renal function that predispose the elderly to abnormalities in water and electrolyte balance.[73] Diseases that are more common in the elderly aggravate this; in addition, the therapy for these diseases affects water balance. Healthy elderly humans probably have at least a normal (or increased) ability to secrete vasopressin but a decreased appreciation for thirst and a decreased ability to achieve either a maximum concentration of urine to retain water or a maximum dilution of urine to excrete water. This demonstrates the necessity of paying attention to fluid balance problems in the elderly as undetected hypernatremia or hyponatremia can lead to increased morbidity and mortality.[74]

Diabetes Insipidus

Diabetes insipidus is a clinical disorder that is characterized by the excretion of large volumes of urine (diabetes) that is hypotonic, dilute, and tasteless (i.e., insipid). This is in contrast to the hypertonic and sweet urine of diabetes mellitus (i.e., honey). Diabetes insipidus can result from four abnormal pathophysiologic processes:

1. Primary polydipsia, caused by excess fluid intake
2. Hypothalamic or central diabetes insipidus, caused by diminished synthesis or secretion of vasopressin
3. Diabetes insipidus of pregnancy, caused by increased enzymatic metabolism of vasopressin
4. Nephrogenic diabetes insipidus, caused by renal resistance to vasopressin

Causes of Diabetes Insipidus

Diabetes Insipidus Due to Excess Fluid Intake (Primary Polydipsia)

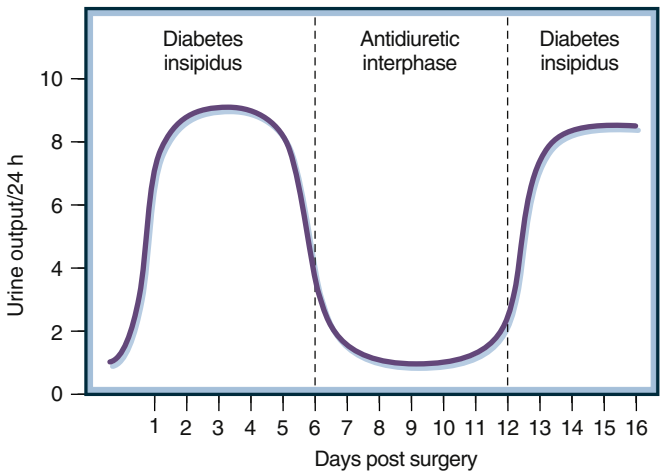
Primary polydipsia is associated with a wide variety of organic structural brain lesions, including sarcoidosis of the hypothalamus[75] and craniopharyngioma.[76] It can also be produced by drugs that cause a dry mouth or by any peripheral disorder causing an elevation of renin and/or angiotensin.[77] However, there is often no identifiable pathologic etiology; in this circumstance the disorder can be associated with psychiatric syndromes or be habitual throughout a lifetime. Series of patients in psychiatric hospitals have shown that as many as 42% have some form of polydipsia, and for over half of those there was no obvious explanation for the polydipsia.[78,79]

Hypothalamic/Central Diabetes Insipidus

Hypothalamic or central diabetes insipidus (CDI) can occur secondary to a large variety of genetic, immunologic, and structural conditions. The relative frequency of the causes of CDI depends on

the nature of the unit where the endocrinologist works. However, as most pituitary endocrinologists work in units where their work is integrated with that of a neurosurgical unit, neurosurgical conditions are usually the commonest encountered causes of CDI.[80]

Pituitary adenomas almost never cause CDI to such an extent that if a patient presents with a pituitary mass and polyuria and polydipsia, it is safe to assume that he or she does not have a pituitary adenoma. However, neurosurgical intervention with transsphenoidal or transcranial surgery causes CDI in as many as 50% to 60% of patients, most of whom will recover, with only a small number having permanent diabetes insipidus.[81] Permanent CDI is more common after craniotomy for large tumors. If there is complete stalk section, patients can exhibit a pattern known as triphasic diabetes insipidus (Fig. 10.4). The first phase is diabetes insipidus with onset within the first 24 hours of surgery and is thought to be due to axon shock and inability of action potentials to be propagated from the cell body to the neurons terminating in the posterior pituitary. The second phase is an antidiuretic phase, which is due to unregulated release of vasopressin from damaged neurohypophyseal neurons; this phase, which occurs typically 5 to 7 days following surgery, is often marked by hyponatremia, particularly if there is injudicious administration of intravenous hypotonic fluids. This phase terminates in permanent CDI, as the damaged neurons undergo gliosis, and loss of secretory function. An important observation is that the second phase of the triphasic response (i.e., uncontrolled release of vasopressin due to axon trauma) can occur without preceding or subsequent diabetes insipidus.[82,83] This has been reported clinically and has been produced experimentally in the rat by unilateral lesion of the supraopticohypophyseal track.[83] The interpretation is that if the trauma is to only some of the axons coursing to the posterior pituitary then the remaining intact axons will have sufficient vasopressin function to avoid clinically apparent diabetes insipidus characteristic of the first and third phases of the triphasic response. However, the store of hormone in the posterior pituitary is sufficiently large that necrosis of even a fraction of these vasopressin neurons will cause enough uncontrolled release of vasopressin to produce hyponatremia if excess fluid is administered. The hyponatremia



• **Fig. 10.4** Typical triphasic response of urine volume after sectioning of the pituitary stalk induced by surgery or head trauma. The first phase of diabetes insipidus occurs immediately postoperatively and continues to day 6. The second phase of antidiuresis occurs from day 7 and continues to day 12. The third stage is the recurrence of diabetes insipidus on day 13. Durations vary; see text for detailed discussion. (From A.G. Robinson, University of California at Los Angeles, used with permission.)

is often symptomatic and patients present with headache, nausea and emesis, or seizure.[84] When all the vasopressin from the damaged neurons has been secreted, the stimulus for water retention resolves and the retained water is excreted producing recovery from the hyponatremia. Thus the clinical picture is one of hyponatremia occurring around 7 to 10 days after pituitary surgery, persisting for a few days, and then returning to normal. This syndrome of transient hyponatremia has been referred to as "isolated second phase"[83] to emphasize the pathophysiologic etiology. Isolated hyponatremia has been reported in 10% to 25% of patients after pituitary surgery.[85–87]

A patient presenting with a sellar mass is more likely to have another tumor in the pituitary area or, alternatively, a granulomatous disorder. Craniopharyngioma is particularly associated with CDI, particularly after extensive suprasellar surgery; it is hoped that the new recommendations for a more limited surgical approach in conjunction with postoperative radiotherapy for craniopharyngioma will result in fewer hypothalamic complications such as CDI, but there is a paucity of randomized controlled data to address this possibility. Other tumors, such as germinoma, pinealoma, or a metastasis from a distant solid organ tumor, can also present with CDI. Metastatic disease involving the pituitary is usually found in association with widespread metastatic disease and may be asymptomatic and only reported at autopsy. Metastases are twice as likely to involve the posterior pituitary as the anterior pituitary,[88,89] which is thought to be due to a more direct arterial blood supply to the posterior pituitary.[90] Most primary tumors in the hypothalamic/pituitary area that cause diabetes insipidus are relatively slow growing, and any tumor in this area that shows rapid growth in a short period of time should be considered as a possible metastatic tumor.[91,92] Pituitary abscess is a rare cause of a pituitary mass and diabetes insipidus.[93,94] Diabetes insipidus has been reported with lymphomas and leukemia in the hypothalamic/pituitary area.[95–97] Diabetes insipidus is distinctly more common in nonlymphocytic leukemia.[98–100] MRI studies in leukemia can show infiltration or an infundibular mass[98] but often are normal even when leukemic cells are found in the cerebrospinal fluid (CSF).[100]

A variety of granulomatous diseases, such as sarcoidosis and histiocytosis, have been associated with CDI; usually there is evidence of characteristic disease elsewhere in the body.[101–103] The MRI often shows involvement of the hypothalamus and absence of the posterior pituitary bright spot on T1-weighted images with widening of the pituitary stalk (Table 10.1). Although there are occasional reports of resolution of the diabetes insipidus with

TABLE 10.1 Diseases Associated With Enlarged Infundibular Stalk

1. Germinoma
2. Craniopharyngioma
3. Metastases to the hypothalamus and long portal vessels (e.g., carcinoma of the breast or lung)
4. Granulomatosis diseases
   a. Langerhans cell histiocytosis
   b. Sarcoidosis
   c. Wegener granulomatosis
   d. Non–Langerhans cell histiocytosis (e.g., Erdheim-Chester disease)
5. Tuberculosis
6. Lymphocytic infundibulo-hypophysitis

appropriate therapy primary disease, in most cases once established, diabetes insipidus is permanent.[104–106] Lymphocytic infundibuloneurohypophysitis, associated with a thickened stalk and loss of the pituitary bright spot on T1-weighted MRI, also presents commonly with CDI. Lymphocytic adenohypophysitis presents classically in females around the time of a pregnancy, whereas infundibuloneurohypophysitis occurs in either sex. Infundibuloneurohypophysitis occurring in middle-aged to elderly males in association with IgG4-related systemic disease has recently been reported. IgG hypophysitis is often associated with other organ involvement, including the pancreas, and other endocrine glands. The diagnosis can be established by elevated serum IgG4 and characteristic histology of biopsies. Response to steroids or other immunosuppressive drugs is characteristic.[107,108]

CDI with no obvious underlying cause has traditionally been considered to be idiopathic, but evidence suggests that a significant proportion of idiopathic CDI cases are in fact autoimmune in origin.[109,110] Several groups have reported the presence of antibodies to vasopressin cells in the plasma of patients with "idiopathic" CDI, and one series reported an incidence of associated autoimmune endocrine disease in 30% of patients with idiopathic CDI,[111] which is higher than the rate reported in, for example, type 1 diabetes mellitus.

CDI has been reported in a number of vascular and traumatic brain disorders. Approximately 15% of patients who have sustained subarachnoid hemorrhage develop acute CDI,[112] which nearly always resolves if the patient survives the initial insult. Very few survivors of subarachnoid hemorrhage have permanent CDI; however, some patients who have surgical clipping of anterior communicating artery aneurysms can develop permanent adipsic CDI due to vascular damage to the perforating arteries of the anterior communicating artery, which provide vascular input to the anterior hypothalamus where the osmoreceptors are situated (see upcoming discussion). Patients who have moderate or severe traumatic brain injury (TBI) also develop CDI quite commonly in the immediate aftermath of injury: 15% to 20% develop CDI, and if close attention is not paid to fluid balance when the patient is obtunded or has cognitive decline, hypernatremia can develop. Hypernatremia and persistent CDI have been shown to be a poor prognostic indicator in acute TBI, often heralding a rise in intracerebral pressure as a preterminal event. Patients who develop CDI secondary to TBI also occasionally go through the triphasic response of early polyuria, followed by transient hyponatremia due to unregulated AVP release, before gliosis produces permanent CDI. There may be a risk in TBI patients during the second phase of SIAD, as hyponatremia will produce cerebral edema, which leads to raised intracranial pressure. It is important therefore to treat early CDI with intermittent dosing of parenteral desmopressin; the effect of one dose should be allowed to wane before administering another dose to ensure that the patient has not developed second phase SIAD. Patients with moderate/severe TBI can also develop anterior pituitary deficiency, including ACTH and cortisol deficiency, which can affect the ability to excrete water. Cortisol deficiency should therefore be considered if diabetes insipidus appears to resolve spontaneously with reversal of polyuria. Cortisol deficiency alone decreases the ability to excrete water even in the absence of vasopressin.[113] Lastly, in a long-term follow-up of these patients partial diabetes insipidus can occur,[114,115] but there may be return of sufficient vasopressin function that under basal conditions the patient is no longer symptomatic from polyuria.[113,114]
