Most patients with CDI have normal osmoregulated thirst; as a result, they do not develop hypernatremia unless they develop diminished consciousness or cognitive impairment or are in an environment where water supply is insufficient.[116] However, damage to the osmoreceptors in the anterior hypothalamus[117] may lead to the dangerous combination of CDI and adipsia. Adipsic DI can be seen where surgical damage is so severe that the damage is not only to the neurohypophysis but also to the central anteriorly placed osmostat,[117] such as following extensive surgery for large craniopharyngioma.[76] Adipsic DI can also be caused by isolated damage to the hypothalamic osmoreceptors, with intact baroreceptors, as seen after surgery to an anterior communicating artery aneurysm.[118] In the former case, there is no release of vasopressin in response to either osmotic or baroreceptor stimulation; in the latter case, however, there is adequate synthesis of vasopressin with normal baroregulated but attenuated osmotic release of AVP.[119] Adipsic DI is sometimes associated with widespread damage to other parts of the hypothalamus and can be associated with other manifestations of hypothalamic syndrome, such as hyperphagia, sleep apnea, thermoregulation, seizures, and high mortality.[117,120]

Although rare, genetic abnormalities of the vasopressin gene are a recognized cause of CDI in childhood. Familial CDI is characterized by the onset of classic diabetes insipidus with polydipsia and polyuria in childhood or as a young adult, but during infancy they may be asymptomatic.[121,122] This is in contrast to cases of familial nephrogenic diabetes insipidus in which the defect is expressed as a polyuric disease at birth (see later description). A rare type of familial CDI that can be present at birth is in infants with homozygotes mutation of the AVP hormone region of the pre-prohormone. This can produce excretion of an inactive vasopressin but no difficulty in folding of the pre-prohormone.[123] In the usual familial CDI, MRI findings are variable even within affected family members, but the most constant finding is the presence of a posterior pituitary bright spot in children, which progressively disappears with time.[124] The genetic defect is usually in the biologically inactive neurophysin or in the signal peptide of the pre-prohormone. Although genetically heterozygous with the defect expressed in only one allele, the clinical phenotype is autosomal dominant. Lack of normal cleavage of the signal peptide from the prohormone and abnormal folding of the vasopressin/neurophysin precursor are thought to produce fibrillar aggregations in the endoplasmic reticulum, which is cytotoxic to the neuron, explaining the dominant phenotype.[125,126] Autopsy studies have confirmed neuronal cell death.[127] Genetic testing of asymptomatic children in affected families will negate the need for repeated dehydration testing and allow early treatment.[128] Wolfram syndrome is a rare autosomal recessive disease with diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (DIDMOAD). The genetic defect is for the protein wolframin that is found in the endoplasmic reticulum and is important for folding proteins.[129] Wolframin is localized to chromosome 4. It is involved in beta-cell proliferation and intracellular protein processing and calcium homeostasis, producing a wide spectrum of endocrine and central nervous system (CNS) disorders. Diabetes insipidus is usually a late manifestation and is associated with decreased magnocellular neurons in the paraventricular and supraoptic nuclei.[124,130]

Diabetes insipidus is reported as a premorbid development in 50% to 90% of patients with brain death.[131,132] This is most likely to represent a reaction to rising intracranial pressure. Although some aspects of hormonal treatment of organ donors

are controversial, a consensus has emerged that treatment of diabetes insipidus should be standard in donors who develop CDI.[133]

Diabetes Insipidus Due to Accelerated Metabolism of Vasopressin (Diabetes Insipidus of Pregnancy)

The physiologic adaptations associated with normal pregnancy include expansion of blood volume and decreased plasma osmolality and serum sodium. Although thirst and increased fluid intake are commonly reported in pregnancy, in some patients the increased thirst is driven by marked polyuria, which could be indicative of diabetes insipidus. There are two types of transient diabetes insipidus in pregnancy, both caused by the placental enzyme cysteine aminopeptidase, named oxytocinase, which enzymatically degrades oxytocin, which protects the fetal unit from early labor.[134] Because of the close structural homology between AVP and oxytocin, this enzyme also metabolizes AVP. In the first type of pregnancy-associated DI, the activity of oxytocinase is abnormally elevated. This syndrome has been referred to as "vasopressin resistant diabetes insipidus of pregnancy,"[135] and has been reported with preeclampsia, acute fatty liver, and coagulopathies. Affected patients have decreased metabolism of vasopressinase by the liver.[56,136–138] Characteristically, subsequent pregnancies are not complicated by diabetes insipidus or acute fatty liver. In the second type of pregnancy-associated DI, the accelerated metabolic clearance of vasopressin produces diabetes insipidus in a patient with borderline vasopressin function from a specific disease (e.g., mild nephrogenic diabetes insipidus or partial hypothalamic/neurohypophyseal diabetes insipidus).[62,139,140] Vasopressin is rapidly destroyed and the neurohypophysis is unable to keep up with the increased demand. Labor and parturition usually proceed normally and patients have no trouble with lactation.[141] There is the threat of chronic and severe dehydration when diabetes insipidus is unrecognized, and this can pose a threat to a pregnant woman.[142] Patients with Sheehan syndrome have been reported to have asymptomatic partial diabetes insipidus[143] but rarely develop overt diabetes insipidus.[144]

Nephrogenic Diabetes Insipidus

Genetic variants of nephrogenic diabetes insipidus (NDI) usually present in infancy, with vomiting, failure to thrive, and polyuria.[145,146] NDI can occur as a result of mutations in the V_2 receptor and mutations of the aquaporin 2 water channels.[145–147] Over 90% of cases are X-linked recessive in males, and over 200 different mutations of the V_2 receptor have been reported.[148] Three general categories of V_2 receptor mutations have been described[148]:

1. Type 1, characterized by impaired AVP binding
2. Type 2, typified by defective transport
3. Type 3, where unstable receptors are rapidly degraded

Most of the reported cases are of type 2.[149] Ten percent of the V_2 receptor defects causing congenital nephrogenic diabetes insipidus occur de novo. The majority of female carriers of the X-linked V_2 receptor mutation are asymptomatic, though careful physiologic testing reveals that some might have attenuated maximum urine osmolality in response to vasopressin.[150] In rare cases where heterozygous females have a defect as severe as males, it is thought that there is coexisting inactivation of the function of the X chromosome.[151,152]

When the proband is a female it is likely the defect is a mutation of the aquaporin 2 water channel gene due to an autosomal recessive disease.[153] This should be especially considered where consanguinity is known in the family and the disease is expressed in males and females. The patients can be heterozygous for two different recessive mutations[154] or be homozygous for the same abnormality from both parents.[155] Mutations of the aquaporin 2 protein can produce an autosomal dominant nephrogenic diabetes insipidus when the mutant aquaporin 2 protein associates with the wild-type normal protein to inhibit normal intracellular routing and function of the wild type.[156]

The development of NDI in an adult is less likely to reflect a genetic cause. The commonest cause of acquired NDI in clinical practice is lithium therapy, with other causes (including hypokalemia, hypercalcemia, and release of bilateral urinary tract obstruction) associated with downregulation of aquaporin 2 and decreased function of vasopressin.[153,156] Lithium produces a decrease in urea transporters, reducing vasopressin-stimulated urea uptake and decreasing urea recycling, which reduces intermedullary osmolality.[153,157] Even more dramatic is the reduction in aquaporin 2 levels to decrease water transport in the collecting duct.[156] There is as much as a 95% decrease in aquaporin 2 content and even the 5% of aquaporin 2 that persists is not normally transported to the renal principal cell membrane.[158] The defect of aquaporins with lithium is slow to correct both in experimental animals and in humans and can be permanent.[156,159] Demeclocycline is another commonly recognized drug to cause nephrogenic diabetes insipidus and is sometimes used clinically to treat SIAD. A comprehensive review[160] has documented the large number of drugs that can cause NDI.

Approach to the Differential Diagnosis of Polyuric States

The first diagnostic step is to confirm polyuria, because up to 15% of patients referred for investigation of polyuria have urinary frequency due to bladder wall defects, infection, or prostate disease, with normal urine volume. A 24-hour urine volume greater than 50 mL/kg body weight is worthy of further investigation. Diabetes mellitus, hypercalcemia, hypokalemia, and chronic renal failure are excluded by biochemical tests. Urine osmolality should be low in all polyuric states; however, a random urine osmolality above 700 mOsm/kg excludes diabetes insipidus and makes the diagnosis of primary polydipsia certain. Presenting serum sodium concentration is almost always normal in diabetes insipidus, but results at the higher part of the reference range are more suggestive of DI than primary polydipsia. However, it is difficult to confidently distinguish between CDI, NDI, and thirst disorders solely on baseline laboratory measurements, so osmotic stimulation of the posterior pituitary is needed to secure a firm diagnosis.

The water deprivation test, which incorporates a dehydration step followed by a desmopressin challenge, is usually the first line of investigation. The interpretation of the initial period of water deprivation is based on the understanding that a functioning osmoregulatory system will respond to elevation of plasma osmolality with the secretion of vasopressin and subsequent concentration of the urine. As the test progresses, urine volume decreases and urine osmolality rises usually to over 750 mOsm/kg H_2O. Importantly, an adequate osmotic stimulus to AVP secretion is necessary; a plasma osmolality of over 295 mOsm/kg H_2O is needed to stimulate sufficient AVP to maximally concentrate the urine. In primary polydipsia urine should concentrate relatively normally, as AVP secretion is normal, whereas in patients with either CDI or NDI, urine remains dilute at the end of dehydration. The second part of the test, the administration of desmopressin, is designed to differentiate CDI from NDI. As patients with

CDI are deficient in AVP, exogenous desmopressin concentrates urine osmolality, whereas patients with NDI do not respond to the antidiuretic effects of desmopressin and do not concentrate urine appropriately. The water deprivation test is best performed in a specialized center. Careful patient supervision to monitor for surreptitious drinking is important, and body weight is checked as patients with severe CDI can develop hypernatremia when fluid is withheld due to excess urination. In addition, there are subtleties of interpretation of results that must be considered. Although the water deprivation test differentiates between primary polydipsia, CDI, and NDI in classic and complete cases, published data have shown that accurate diagnosis was made in only 70% of polyuric patients, and the correct diagnosis in primary polydipsia was concluded in only 41% of cases.[161] A number of confounding factors can produce misleading or uninterpretable results:

1. Patients with prolonged severe polyuria may not concentrate urine in response to endogenous or exogenous vasopressin. Chronic hypoosmolality suppresses AVP secretion, and in the absence of V_2 receptor stimulation intracellular aquaporin 2 is not generated. Patients with thirst disorders may therefore be classified as partial DI on the basis of a subnormal rise in urine osmolality during the water deprivation step, despite normal AVP responses. For the same reason, receptor stimulation with desmopressin in step 2 might not stimulate increased urine concentration in patients with CDI, leading to an erroneous diagnosis of NDI.
2. In patients with partial CDI, upregulation of V_2 receptors can result in urine concentration with relatively low plasma AVP concentrations.
3. High plasma AVP concentrations achieved by fluid deprivation in NDI can partially overcome renal resistance; urine osmolality can rise to over 300 mOsm/kg H_2O, leading to diagnostic confusion with partial CDI.[162]

Several studies have demonstrated that the diagnostic accuracy of the water deprivation test was enhanced by the inclusion of measurement of plasma AVP concentration using a sensitive radioimmunoassay.[163,164] However, AVP is unstable after venipuncture and requires careful sample handling, immediate centrifugation, and storage at -70°C. In addition, commercially available AVP antibodies for use in clinical radioimmunoassays are poorly sensitive and have lower limits of detection for the hormone that exceeds low physiologic plasma concentrations. Good-quality, sensitive and specific assays are available in a few specialized centers, but results are often only available weeks after testing has been performed. A recent analysis claimed a diagnostic accuracy of only 46% when direct AVP measurement was prospectively tested in 50 patients with polyuria,[161] but the results may have reflected suboptimal performance of the AVP assay that was used. Alternatively, measurement of the AVP responses during the intravenous infusion of hypertonic (3–5%) sodium chloride solution at the end of a water deprivation test enables more confident distinction between CDI and NDI or primary polydipsia.

Because the logistic difficulty of accurate and sensitive plasma AVP measurements make routine use of the assay impractical for most clinical laboratories, there has been much interest in the measurement of plasma copeptin, which offers a biologic surrogate for the measurement of plasma AVP. Copeptin is the C-terminal locus of the AVP precursor provasopressin, and it is co-secreted from the neurohypophysis in equimolar amounts with AVP in response to the same stimuli. It is much more stable ex vivo, so sample handling is straightforward. A sandwich immunoluminometric assay is used rather than a radioimmunoassay, which enables quick, reliable turnover of results. Careful studies have revealed that the copeptin responses to changes in plasma osmolality are similar to those seen with plasma AVP levels when measured during water deprivation.[165,166] In a prospective multicenter study, a postoperative copeptin concentration of less than 2.5 pmol/L had a post-transsphenoidal surgery predictive value of 81% for CDI, with a specificity of 97%. Conversely, high plasma copeptin concentrations effectively excluded the diagnosis of central DI; a plasma copeptin concentration over 30 pmol/L on day 1 following transsphenoidal surgery was associated with a negative predictive value of 95%, with a sensitivity of 94%.[167] In addition, a single copeptin concentration of over 21.4 pmol/L has been shown to differentiate NDI from other causes of polyuria, with a sensitivity and specificity of 100%, thus mitigating the need for water deprivation testing.[168] Conversely, a baseline copeptin less than 2.6 pmol/L diagnoses complete CDI with 95% sensitivity and 100% specificity. Copeptin is therefore a promising marker of plasma AVP secretion, which offers a convenient, rapid, and sensitive diagnostic tool for polyuric states. The assay should be manageable in most clinical laboratories, and it is likely to replace measurement of plasma AVP in routine diagnostic practice.

Measurement of thirst, using a simple visual analogue scale, in osmotic studies has demonstrated that thirst onset occurs at the same osmotic threshold as AVP secretion[52] and is rapidly switched off by drinking.[169] The characteristics of osmoregulated thirst are surprisingly reproducible.[170] When patients with CDI are studied during water deprivation testing or hypertonic saline infusion, they show a similar pattern of linear elevation during osmotic stimulation, and they show suppression after drinking.[116]

Measurement of thirst is valuable diagnostically in two clinical situations. In adipsic DI, absent osmoregulated thirst during water deprivation or hypertonic saline infusion is the gold standard for diagnosis of the condition.[116,117] Patients with primary polydipsia have three clearly defined abnormalities of thirst: (1) a low osmotic threshold for thirst, which is disconnected from that of AVP release; (2) exaggerated thirst responses to elevation of plasma osmolality; and (3) failure to suppress thirst during drinking after osmotic stimulation.[171] Failure to suppress thirst after drinking by more than 50% of stimulated levels is the most useful of these abnormalities, as it is a strong diagnostic indicator of primary polydipsia.

Further Investigations of Diabetes Insipidus

Once a diagnosis of CDI is established, MRI of the hypothalamo-neurohypophyseal region is indicated. T1-weighted MRI images show a classic bright spot in the posterior pituitary[12] caused by AVP stored in neurosecretory granules.[29,172–175] The bright spot is present in over 80% of normal subjects[176,177] and it is absent in most patients with central diabetes insipidus.[178] Some patients with familial hypothalamic/neurohypophyseal diabetes insipidus can have a posterior pituitary bright spot early in the disease, when diabetes insipidus is partial; however, the bright spot disappears as AVP-secreting neurons diminish in numbers and AVP deficiency gets worse.[179]

The posterior pituitary bright spot decreases with a prolonged stimulus to vasopressin secretion[180] and has been variably reported in other polyuric disorders. In primary polydipsia the bright spot usually is seen.[174,181] In nephrogenic diabetes insipidus the bright spot has been reported to be absent in some patients[174] but present in others.[174,182] Patients with nephrogenic diabetes insipidus have high levels of vasopressin in plasma and are chronically

dehydrated, so the posterior pituitary might be depleted of vasopressin stores. Similarly, with the osmotic stress of untreated diabetes mellitus or the transient diabetes insipidus of pregnancy the posterior pituitary can be depleted of vasopressin, and the bright spot is transiently lost only to reappear with resolution of the underlying condition.[180,183]

Imaging of the hypothalamus is also important to establish whether structural abnormalities of the neurohypophysis are responsible for CDI. Because 90% of the vasopressin neurons must be destroyed to produce symptomatic CDI,[113,184] a mass lesion must either destroy a large area of the hypothalamus or be located where the tracks of the supraoptic and paraventricular nuclei converge at the base of the hypothalamus, superior to the pituitary stalk. Pituitary adenomas confined within the sella do not cause diabetes insipidus.[113] Diseases of the pituitary stalk commonly cause CDI and are listed in Table 10.1. When there is a diagnosis of CDI, thickening of the stalk is usually associated with absence of the posterior pituitary bright spot, and a search for systemic diseases is indicated.[101] A thickened stalk with coexistent anterior pituitary deficiency is especially suggestive of etiologic systemic disease.[185,186] A recent retrospective study has suggested that T2 DRIVE sequence images of the pituitary stalk are so reliable that the need for gadolinium enhancement is unnecessary.[187]

In the absence of structural causes of CDI on MRI, it is important to recognize that in some cases of germinoma the tumor may not be detectable on the initial scans. Therefore, particularly in children and young adults who are more vulnerable to germ cell tumors, markers such as beta human chorionic gonadotropin (βhCG) and alpha-fetoprotein (AFP) should be measured in the blood and in the cerebrospinal fluid if the index of clinical suspicion is high enough. In addition, repeat MRI should be obtained every 3 to 6 months for the first 2 years of follow-up.[185,186,188,189] If follow-up imaging shows a decrease in size of the stalk, a likely diagnosis is infundibulo-neurohypophysitis.[190] Increases in size often occur initially with infundibuloneurohypophysitis, but sustained increases over a 2-year period necessitate biopsy of the pituitary stalk.

Other investigations are dictated by clinical circumstances; if histiocytosis X is suspected, a radiologic skeletal survey should be performed. Sarcoidosis can be revealed by classic radiographic or computed tomography (CT) thorax changes or elevation of serum angiotensin-converting enzyme activity. When MRI of the pituitary is normal, autoimmune variants of CDI should be considered; studies of patients classified as "idiopathic" CDI have revealed the presence of antibodies to AVP-neurons and a high incidence of related autoimmune conditions, most commonly thyroid disease.[111]

Treatment of Polyuric Conditions

Central Diabetes Insipidus in Ambulatory Patients

Treatment of CDI depends on regulation of water intake and excretion. Because thirst is normal in CDI, water intake self-regulates. Replacement of absent AVP is generally done with desmopressin,[191,192] a synthetic analog of vasopressin in which the substitution of D-arginine markedly reduces pressor activity and removing the terminal amine increases the half-life (see Fig. 10.1). These two changes produce an agent nearly 2000 times more specific for antidiuresis than naturally occurring L-arginine vasopressin.[193] Desmopressin is available as tablets for oral administration, a lyophilate for sublingual administration (oral melt), a solution for intranasal administration, and a solution for parenteral use.[194] Most patients prefer desmopressin tablets (0.1 and 0.2 mg); the oral preparations are effective, and unlike nasal sprays absorption is not impaired with nasal infections. However, intestinal peptidase activity can result in increased degradation before absorption, so the tablets should be taken 1 hour before or 2 hours after meals. Desmopressin melt (60, 120, and 240 μg) is reported to be more acceptable in some children.[195] As the degree of AVP deficiency is variable among patients, the dosage and frequency of desmopressin are also highly variable.[196–198] Some patients with partial CDI need a single dose before bed to prevent nocturia, whereas some patients with complete AVP deficiency need desmopressin two to four times daily. The total duration of action of desmopressin will usually be 6 to 18 hours depending on the route of administration.

When a dose of desmopressin is sufficient to elicit a stable therapeutic response, further increasing (e.g., doubling) the dose produces a moderate increase in duration of only a few hours,[196,197] consistent with the half-life of desmopressin in plasma.[196] The maximum dose rarely exceeds 0.2 mg orally or 20 μg intranasally (two sprays) given two or three times a day (usually three for tablets and two for intranasal).[197] For greater flexibility with intranasal administration, the patient can be taught to use the rhinal catheter.[192] Parenterally administered desmopressin (2-mL vials of 4 μg/mL) is only needed for ambulatory patients during an intercurrent illness.[197] Parenterally administered desmopressin gives virtually identical therapeutic response when given as an intravenous bolus, intramuscularly or subcutaneously,[197] and the parenteral administration is 5 to 20 times as potent as an intranasally administrated dose.[192,197] Published studies have reported an increased antidiuretic response to desmopressin in women and in the elderly.[199]

Hyponatremia is a common complication of desmopressin therapy. Mild hyponatremia (plasma sodium 131–134 mmol/L) occurs in 27% of ambulatory blood samples in patients with intact thirst, and in 15% of blood samples serum sodium is less than 130 mmol/L.[80] This reflects the tendency in humans to drink for pleasure or to drink socially; as desmopressin produces a continuous antidiuretic effect, the usual physiologic suppression of endogenous AVP that occurs during drinking does not occur, with consequent dilutional hyponatremia. The hyponatremia seen due to desmopressin is severe enough to precipitate hospital admission in 6% of patients.[80] Hyponatremia is particularly an issue in infants, who consume a large part of their calories as liquid formula or breast milk, and in whom treatment with desmopressin can cause erratic serum sodium consequences and the risk of symptomatic hyponatremia.[200] The risk of dilutional hyponatremia can be reduced by any one of three desmopressin dosing schedules:

1. Omitting a full dose once a week to allow an aquaresis to occur; this is effective, but unpleasant for the patient
2. Delaying a desmopressin dose once or twice weekly until the patient urinates two or three times
3. Delaying each dose of desmopressin until the patient begins to urinate

In practice, individual patients vary as to which of these methods they prefer.

Hypernatremia is much less common in ambulant patients, as the intact thirst mechanism ensures that fluid intake is sufficient to supply physiologic needs; only 1% of ambulant plasma sodium concentrations are above the normal reference range.[80] In patients with adipsic DI, ambulatory hypernatremia is much more common, occurring in up to 20% of blood samples.

Central Diabetes Insipidus in Hospitalized Patients

Although hypernatremia is rare in ambulatory patients with normal thirst, the incidence is much higher during intercurrent illness, particularly if the patient is vomiting, and unable to absorb oral desmopressin. As a result, close attention must be paid to fluid balance when patients are admitted as emergencies. If the patient develops severe hypernatremic dehydration, consideration should be given to anticoagulation to prevent thrombotic complications. Equally, if a patient is on intravenous fluids, regular electrolyte estimations are necessary to ensure that dilutional hyponatremia does not develop, particularly if hypotonic fluids such as dextrose solutions are used. In patients with abnormal thirst, hypernatremia and hyponatremia are both much more common, and the need for careful monitoring of electrolytes and fluid balance is more crucial.[80]

Central Diabetes Insipidus in Neurosurgical Patients

Transient polyuria due to CDI is not uncommon after pituitary surgery; it is more common after extensive surgery for larger pituitary adenomas or for craniopharyngioma. The diagnosis is made by the presence of the classic triad of polyuria, hypernatremia, and dilute urine after exclusion of other possibilities such as diabetes mellitus and mannitol therapy. Sometimes diuresis after surgery is the result of water retention during the procedure. Vasopressin is released during surgical procedures and administered fluid is retained. When the stress of surgery abates, the vasopressin level falls and retained fluid is excreted. If an attempt is made to match the urine output with further fluid infusion, persistent polyuria might be mistaken for diabetes insipidus. If in doubt, fluid should be withheld until there is a modest increase in serum sodium. If the urine output decreases and the serum sodium remains normal, the polyuria was due to excretion of physiologically retained fluid. If the serum sodium begins to rise while urine osmolality is low and there is a positive response to administered desmopressin, the diagnosis of diabetes insipidus can be established.[201] If the duration of diabetes insipidus is quite transient, it is acceptable to treat this simply with fluid replacement, parenterally or orally. However, most patients who develop diabetes insipidus require desmopressin 0.5 to 2 μg subcutaneously, intramuscularly, or intravenously. Urine output will be reduced in 1 to 2 hours and the duration of effect is 6 to 24 hours. Care should be taken that hypotonic intravenous fluids are not given excessively after administering desmopressin, as the combination can lead to profound hyponatremia.[202] Because there is always the possibility of developing the triphasic response due to pituitary stalk damage, it is recommended that polyuria should be recurrent before a decision to administer subsequent doses of desmopressin is made.[203]

Acute diabetes insipidus after traumatic brain injury can be treated similarly to that recommended for patients following pituitary surgery; as the patient with head injury is more likely to be comatose or cognitively impaired, and thus unable to depend on thirst, hypernatremia is more likely to develop. Because a comatose patient must be given fluids parenterally, it is important to monitor serum sodium concentration regularly to check for dilutional hyponatremia. Persistent diabetes insipidus has been demonstrated in prospective studies to be a predictor of fatal outcome after traumatic brain injury, perhaps because it is a manifestation of rising intracranial pressure and imminent herniation.[204]

Adipsic Diabetes Insipidus

The combination of attenuated thirst and diabetes insipidus confers high risk of severe hypernatremia. As well, when treated with desmopressin they are at risk for developing hyponatremia. A carefully monitored regimen of a fixed dose of desmopressin to maintain chronic antidiuresis and a prescribed volume of fluid intake is preferable.[205,206] Daily weight can be used to guide intake, and regular follow-up with measurement of serum sodium is essential to ensure that these patients do not develop water intoxication with hyponatremia or recurrent dehydration with hypernatremia. Patients with adipsic DI have been reported to develop thrombotic complications when severely dehydrated, and they should be prophylactically anticoagulated when admitted with severe intercurrent illness. Although management of water balance is the clinical priority for endocrinologists, it is important to holistically approach the hypothalamic complication associated with adipsic DI. Sleep apnea can respond to treatment with continuous positive airway pressure (CPAP) or modafinil, and treatment for associated hypothalamic obesity is also important.[117] This group of patients has high mortality rates and requires very careful management.

Treatment of Diabetes Insipidus in Pregnancy

Desmopressin is the only therapy recommended for treatment of diabetes insipidus during pregnancy. Desmopressin has 2% to 25% the oxytocic activity of lysine vasopressin or arginine vasopressin[193] and can be used with minimal stimulation of the oxytocin receptors in the uterus.[141,207] Desmopressin is not destroyed by the cysteine aminopeptidase (oxytocinase) of pregnancy[141,208] and is reported to be safe for both the mother and the child.[209,210] During delivery, patients can maintain adequate oral intake and are therefore safe to continue administration of desmopressin. Physicians should be cautious about overadministration of fluid parenterally during delivery because these patients will not be able to excrete the fluid and can develop water intoxication and hyponatremia. After delivery, plasma oxytocinase decreases and patients can recover completely or be asymptomatic with regard to fluid intake and urine excretion.

Treatment of Nephrogenic Diabetes Insipidus

Adequate water intake is the mainstay of treatment of NDI as pharmacologic reversal of the renal resistance to AVP is rarely possible. Nephrogenic diabetes insipidus does not respond to desmopressin therapy, although occasionally partial defects have limited response to high doses of desmopressin.[211,212] In congenital NDI, therapy aimed at reducing symptomatic polyuria is addressed primarily by inducing plasma volume contraction via a low sodium diet and a thiazide diuretic. It has been hypothesized that contraction of extracellular fluid volume, decreased glomerular filtration rate, proximal tubular sodium and water reabsorption, and decreased delivery of fluid to the collecting duct result in a decreased volume of urine.[213] Studies have also demonstrated that thiazide diuretics can increase aquaporin 2 independent of vasopressin.[214] All the thiazide diuretics appear to have similar effects. Potassium replacement and/or coadministration of a potassium-sparing antidiuretic may be necessary, as hypokalemia can worsen renal resistance to AVP. The effect of thiazides can be augmented by coadministration of nonsteroidal anti-inflammatory drugs (NSAIDs), but this combination is nephrotoxic, and careful monitoring of renal function is mandatory. Selective cyclooxygenase 2 (COX2) inhibitors with less gastrointestinal (GI) effect have been reported to decrease water loss, but long-term safety has not been documented.[156]

Drug-induced nephrogenic diabetes insipidus should be treated by stopping the offending agent if possible. Persistence

of nephrogenic diabetes insipidus can be treated by hydrochlorothiazide and amiloride. Plasma volume contraction produced by thiazide diuretics can decrease lithium excretion and predispose to lithium toxicity.[160,215] The diuretic amiloride blocks sodium channels in the luminal membrane of the collecting duct cells and inhibits lithium reabsorption, a unique advantage in treating lithium-induced nephrogenic diabetes insipidus.[216] In animal studies of lithium-induced nephrogenic diabetes insipidus, treatment with amiloride increased levels of both aquaporin 2 and urea transporters.[157]

Studies have reported the possibility of rescuing mutant receptors in NDI. In autosomal dominant type 2 NDI, the misfolded receptor protein is trapped in the quality control system of the endoplasmic reticulum, but in some cases the defect involves transport of the receptor, and were the receptor to reach the cell membrane it would respond to vasopressin. V_2 receptor antagonists (vaptans) have been reported to act as pharmacologic chaperones that combine with the misfolded receptor, changing the confirmation to allow maturation and transport to the plasma membrane where vasopressin (in excess of the vaptans) would cause the receptor to be activated.[217–219] Similar studies of rescue have recently been reported with nonpeptide V_2 receptor agonists. These agonists combine with the mutant receptor trapped in the endoplasmic reticulum and allow maturation of the mutant receptor. The rescued receptor is then inserted into the cell membrane and when stimulated by vasopressin or desmopressin generates sufficient cAMP to move aquaporin 2 from the cytoplasm to the cell membrane to enhance water transport.[218,219] Nonpeptide antagonists working as chaperones is a potential new treatment of nephrogenic diabetes insipidus, especially in patients with a partial disorder.[220] Sequencing of genes in all families with NDI is recommended because of the small size of the genes to be sequenced and because of the value of the information.[149] In X-linked disorders, carrier females can be distinguished from noncarrier females, so it will be known which sibling's children are at risk and require special observation at birth. Molecular testing of newborns will confirm the need for long-term treatment to avoid complications in the affected children and obviate the need for water deprivation or other testing in unaffected children.[152,221]

Treatment of Primary Polydipsia

Treatment of primary polydipsia entails reduction of excessive fluid intakes, best done in a graded fashion to allow patients to slowly achieve a level of intake that reduced urine volume below polyuric levels (50 mL/kg BW). Measures to reduce mouth dryness (e.g., ice chips, hard candy to stimulate salivary flow) are useful adjuncts to reduce thirst. Pharmacologic therapies have been tried but without consistent evidence of success.

Diabetes Insipidus in Association With Other Therapeutic Decisions

Routine Surgical Procedures

In all cases there should be preoperative consultation of the surgeon, the anesthesiologist, and the endocrinologist/nephrologist. For most routine surgical procedures the patient is not unconscious for a sufficiently long period of time to require anything more that administration of the usual dose of desmopressin and careful monitoring of fluids during the surgery to prevent overhydration. If the patient is taking desmopressin orally and is NPO, a parenteral dose can be administered before the procedure. Close monitoring of serum sodium is essential. In NDI there should be a greater emphasis on fluid replacement to avoid dehydration and hypernatremia.[222]

Panhypopituitarism

Patients with coexistent diabetes and anterior pituitary deficiency are at risk of developing hyponatremia, as cortisol deficiency is associated with impaired water excretion. Patients who miss their hydrocortisone doses are vulnerable to desmopressin-induced hyponatremia.

Hypertonic Encephalopathy

Hypertonic encephalopathy is uncommon in diabetes insipidus and is only seen when there is inadequate fluid intake in an adipsic patient or in a patient who is unconscious and not receiving adequate fluid supplementation. Conditions other than diabetes insipidus are more common causes of hypernatremic encephalopathy. The condition is associated with loss of hypotonic fluids by the kidney or the intestines, or from insensible losses; or, it might occur following administration of hypertonic sodium containing fluids or hyperalimentation.[223] Hypernatremia leads to osmotic movement of water out of cells and cellular dehydration. Studies indicate that in the brain idiogenic osmoles, mainly polyols, trimethylamines, and amino acids, are generated intracellularly so the degree of cell shrinkage is less than would occur based on the degree of hypernatremia.[224] Loss of water from the brain occurs in minutes and electrolytes enter the brain in a few hours, but the increase in organic osmoles occurs over several days.[225] When fluid is replaced, intracellular organic osmoles dissipate more slowly than the decrease in osmolality of extracellular fluid. This asynchrony increases the potential for cerebral edema and worsening of the neurologic condition with overzealous treatment of hypernatremia.[225] In most cases of diabetes insipidus seen following neurosurgery or head injury the diagnosis will be made within a few hours and therapy should be instituted promptly. In cases where the duration of the hypernatremia is not known, the degree of correction of hypernatremia should not exceed 0.5 mEq/L/hour to prevent cerebral edema and convulsions.[223,225]

The Syndrome of Inappropriate Antidiuresis

The SIAD is produced when plasma levels of vasopressin are elevated at times when the physiologic secretion of vasopressin from the posterior pituitary would normally be osmotically suppressed. The clinical abnormality is a decrease in the osmotic pressure of body fluids, so the hallmark of SIAD is hypoosmolality. This led to the identification of the first well-described cases of this disorder in 1957[226] and the subsequent clinical investigations that resulted in delineation of the essential characteristics of the syndrome.[227] Although initially called the syndrome of inappropriate antidiuretic hormone (SIADH) secretion, the term SIAD is more appropriate in view of the inability to measure elevated vasopressin levels in some patients with this disorder. It is necessary to first review hypoosmolality and hyponatremia before discussing details that are specific to SIAD.

Hypoosmolality and Hyponatremia

Incidence

Hypoosmolality is the most common disorder of fluid and electrolyte balance encountered in hospitalized patients. The incidence and prevalence of hypoosmolar disorders depend on the nature of the patient population studied as well as on the

laboratory methods and criteria used to diagnose hyponatremia. Most investigators have used the serum sodium concentration ($[Na^+]$) to determine the clinical incidence of hypoosmolality. When hyponatremia is defined as a serum $[Na^+]$ of less than 135 mEq/L, prevalences as high as 15% to 38% have been observed in studies of both acutely and chronically hospitalized patients.[228,229] However, incidences decrease to the range of 1% to 4% when only patients with serum $[Na^+]$ under 130 to 131 mEq/L are included, which represents a more appropriate level at which to define the occurrence of clinically significant cases of this disorder.[230] Even using these more stringent criteria, incidences from 7% to 53% have been reported in institutionalized geriatric patients.[231] Although hyponatremia and hypoosmolality are quite common, the majority of cases are relatively mild and most are acquired during the course of hospitalization. Nonetheless, hyponatremia is important clinically because (1) severe hypoosmolality (serum $[Na^+]$ levels <120 mEq/L) is associated with substantial morbidity and mortality,[232] (2) even relatively mild hypoosmolality can quickly progress to more dangerous levels during the course of therapeutic management of other disorders, (3) overly rapid correction of hyponatremia can itself cause severe neurologic morbidity and mortality,[233] and (4) it has been observed that mortality rates are from 3-fold to 60-fold higher in patients with even asymptomatic degrees of hypoosmolality compared to normonatremic patients.[234,235]

Osmolality, Tonicity, and Serum $[Na^+]$

As discussed, the osmolality of body fluid normally is maintained within narrow limits for each individual by osmotically regulated vasopressin secretion and thirst. Plasma osmolality can be determined directly by measuring the freezing-point depression or the vapor pressure of plasma. Alternatively, it can be calculated indirectly from the concentrations of the three major solutes in plasma:

$$\text{pOsm}\ (\text{mOsm/kg}\ H_2O) = 2 \times [Na^+]\ (\text{mEq/L}) + \text{glucose}\ (\text{mg/dL})\ /\ 18 + \text{blood urea nitrogen}\ (\text{mg/dL})\ /\ 2.8$$

Direct measure and calculation produce comparable results under most conditions. However, while either of these methods produce valid measures of *total* osmolality, this is not always equivalent to the *effective* osmolality, which is commonly referred to as the "tonicity" of the plasma. Only solutes such as Na^+ and Cl^- that are impermeable to the cell membrane and remain relatively compartmentalized within the extracellular fluid (ECF) space are effective solutes, because these solutes create osmotic gradients across cell membranes and regulate the osmotic movement of water between the intracellular fluid (ICF) compartment and the ECF compartment. Solutes that readily permeate cell membranes (e.g., urea, ethanol, and methanol) are not effective solutes. Therefore only the concentrations of effective solutes in plasma should be used to ascertain whether clinically significant hyperosmolality or hypoosmolality is present.

Sodium and its accompanying anions represent the major effective plasma solutes, so hyponatremia and hypoosmolality are usually synonymous. However, there are two situations in which hyponatremia will not reflect true hypoosmolality. The first is *pseudohyponatremia*, which is produced by marked elevations of either lipids or proteins in plasma. If serum $[Na^+]$ is measured by flame photometry, the concentration of sodium per liter of plasma is artifactually decreased because of the larger relative proportion of plasma volume that is occupied by the excess lipids or proteins.[236] However, the increased protein or lipid will not appreciably change the total number of solute particles in solution, so the directly measured plasma osmolality will not be significantly affected. Measurement of serum $[Na^+]$ by ion-specific electrodes, which is now commonly used by most clinical laboratories, is less influenced by high concentrations of lipids or proteins than is measurement of serum $[Na^+]$ by flame photometry. However, this can still occur if the electrode measurement is done using a diluted sample of the serum. The second situation in which hyponatremia does not reflect true plasma hypoosmolality occurs when high concentrations of effective solutes other than Na^+ are present in the plasma. The initial hyperosmolality produced by the additional solute causes an osmotic shift of water from the ICF to the ECF, which in turn produces a dilutional decrease in serum $[Na^+]$. Once equilibrium between both fluid compartments is achieved, the total effective osmolality remains relatively unchanged. This situation most commonly occurs with hyperglycemia and represents a frequent cause of hyponatremia in hospitalized patients, accounting for up to 10% to 20% of all cases.[234] Misdiagnosis of true hypoosmolality in such cases can be avoided by measuring plasma osmolality directly or, alternatively, by correcting the measured serum $[Na^+]$ for the glucose elevation. Traditionally this correction factor has been 1.6 mEq/L for each 100-mg/dL increase in serum glucose concentration above normal levels,[237] but some studies have shown a more complex relation between hyperglycemia and serum $[Na^+]$ and reported that a more accurate correction factor is closer to 2.4 mEq/L.[238] When the plasma contains significant amounts of unmeasured solutes, such as osmotic diuretics, radiographic contrast agents, and some toxins (ethanol, methanol, and ethylene glycol), plasma osmolality cannot be calculated accurately, and in these situations osmolality must be ascertained by direct measurement.

Pathogenesis of Hypoosmolality

Water moves freely between the ICF and ECF, consequently osmolality will always be equivalent in both of these fluid compartments. Since the bulk of body solute is comprised of electrolytes, namely the exchangeable Na^+ (Na^+_E) in the ECF and the exchangeable K^+ (K^+_E) in the ICF along with their associated anions, total body osmolality (OSM_T) will largely be a function of these parameters[239]:

$$OSM_T = OSM_{ECF} = OSM_{ICF}$$

$$OSM_T = (\text{ECF solute} + \text{ICF solute})\ /\ \text{body water}$$

$$OSM_T\ (2 \times Na^+_E + 2 \times K^+_E + \text{nonelectrolyte solute})\ /\ \text{body water}$$

According to this definition, the spresence of plasma hypoosmolality indicates a relative excess of water to solute in the ECF. This can be produced either by an excess of body water, resulting in a *dilution* of remaining body solute, or by a *depletion* of body solute, either Na^+ or K^+, relative to body water. This classification is an oversimplification, because most hypoosmolar states involve significant components of both solute depletion and water retention. Nonetheless, it is conceptually useful for understanding the mechanisms underlying the pathogenesis of hypoosmolality and as a framework for therapy of hypoosmolar disorders.

Solute Depletion

Depletion of body solute can result from any significant losses of ECF. Body fluid losses by themselves rarely cause hypoosmolality because excreted or secreted body fluids are usually isotonic or hypotonic relative to plasma and therefore tend to increase plasma osmolality. When hypoosmolality accompanies ECF losses, it is the result of replacement of body fluid losses by more hypotonic solutions either by drinking or by infusion, thereby diluting the remaining body solutes. If the solute losses are marked, these patients show signs of volume depletion (e.g., addisonian crisis). However, such patients often have a more deceptive clinical presentation because the volume deficits have been partially replaced. Moreover, they may not manifest signs or symptoms of cellular dehydration because osmotic gradients will draw water into the ICF, which is relatively hypertonic to the solute-depleted ECF. Therefore clinical evidence of hypovolemia strongly supports solute depletion as the cause of plasma hypoosmolality, but absence of clinically evident hypovolemia never completely eliminates this as a possibility. Although ECF solute losses are responsible for most cases of depletion-induced hypoosmolality, ICF solute loss can also cause hypoosmolality as a result of osmotic water shifts from the ICF into the ECF. This mechanism contributes to some cases of diuretic-induced hypoosmolality in which depletion of total body K^+ often occurs.[240]

Water Retention

Despite the importance of solute depletion in some patients, most cases of clinically significant hypoosmolality are caused by increases in total body water rather than by primary losses of extracellular solute. This can occur because of either impaired renal free water excretion or excessive free water intake. The former accounts for most hypoosmolar disorders because normal kidneys have sufficient diluting capacity to allow excretion of 18 to 24 L/day of free water. Intakes of this magnitude are occasionally seen in some psychiatric patients but not in most patients with SIAD in whom fluid intakes average 2 to 3 L/day.[241] Consequently, dilutional hypoosmolality usually is the result of an abnormality of renal free water excretion. The renal mechanisms responsible for impairments in free water excretion can be subgrouped according to whether the *major* impairment in free water excretion occurs in proximal or distal parts of the nephron, or both. Any disorder that leads to a decrease in glomerular filtration rate causes increased reabsorption of both Na^+ and water in the proximal tubule. As a result, the ability to excrete free water is limited because of decreased delivery of tubular fluid to the distal nephron. Disorders that cause a decreased glomerular filtration rate in the absence of significant ECF fluid losses are, for the most part, edema-forming states associated with decreased effective arterial blood volume (EABV) and secondary hyperaldosteronism.[242] Even though these conditions are characterized by increased proximal reabsorption of both Na^+ and fluid, water retention also results from increased distal reabsorption caused by nonosmotic baroreceptor-mediated stimulated increases in plasma vasopressin levels. Distal nephron impairments in free water excretion are characterized by an inability to dilute tubular fluid maximally. These disorders are usually associated with abnormalities in the secretion of vasopressin. Just as depletion-induced hypoosmolar disorders usually include an important component of secondary impairments of free water excretion, most dilution-induced hypoosmolar disorders also involve significant degrees of secondary solute depletion. This is described later with SIAD.

Some dilutional disorders do not fit well into either category, specifically the hyponatremia that sometimes occurs in patients who ingest large volumes of beer with little food intake for prolonged periods, called "beer potomania."[243] Even though the volume of fluid ingested may not seem sufficiently excessive to overwhelm renal diluting mechanisms, free water excretion is limited by very low urinary solute excretion, thereby causing water retention and dilutional hyponatremia.

Adaptation to Hyponatremia: ICF and ECF Volume Regulation

Many past studies have suggested that the combined effects of water retention plus urinary solute excretion cannot adequately explain the degree of plasma hypoosmolality observed in patients.[227,244] This observation led to the theory of *cellular inactivation of solute,* which suggested that as ECF osmolality falls, water moves into cells along osmotic gradients, thereby causing the cells to swell; at some point during this volume expansion, the cells theoretically osmotically "inactivate" some of their intracellular solutes as a defense mechanism to prevent continued cellular swelling with subsequent detrimental effects on cell function and survival. This effect would decrease the intracellular osmolality allowing water to shift back out of the ICF into the ECF, thereby further worsening the dilution-induced hypoosmolality. Despite the appeal of this theory, its validity has never been demonstrated conclusively in either human or animal studies. An alternative theory is that cell volume is maintained under hypoosmolar conditions by extrusion of intracellular solutes such as potassium.[245] Whole brain volume regulation via electrolyte losses was first described by Yannet[246] and has long been recognized as the mechanism by which the brain is able to adapt to hyponatremia and limit brain edema to sublethal levels.[247] Following the recognition that low molecular weight organic compounds, called *organic osmolytes,* also constituted a significant osmotic component of a wide variety of cells, studies demonstrated the accumulation of these compounds in response to hyperosmolality in both kidney[248] and brain[249] tissue and conversely that the brain also loses organic osmolytes in addition to electrolytes during volume regulation to hypoosmolar conditions in experimental animals[250,251] and human patients.[252] These losses occur relatively quickly (within 24–48 hours in rats) and can account for as much as one-third of the brain solute losses during hyponatremia.[253] Such coordinate losses of both electrolytes and organic osmolytes from brain cells allow effective regulation of brain volume during chronic hyponatremia.

Although recent studies of volume regulation during hyponatremia have focused on the brain, all cells regulate volume by cellular losses of both electrolyte and organic solutes to varying degrees. However, volume regulatory processes are not limited to cells. In most cases of hyponatremia induced by stimulated antidiuresis and water retention, natriuresis also regulates the volumes of the ECF and intravascular spaces. Both experimental and clinical observations are consistent with ECF volume regulation via secondary solute losses. First, the concentrations of most blood constituents other than Na^+ and Cl^- are not decreased in patients with SIAD,[254] suggesting that plasma volume is not nearly as expanded as would be predicted simply by the measured decreases in serum $[Na^+]$. Second, an increased incidence of hypertension has never been observed in patients with SIAD, again evidence against significant expansion of the arterial blood volume. Third, results of animal studies in both dogs[255] and rats[256] have indicated that a significant component of chronic hyponatremia is attributable to secondary Na^+ losses rather than water retention; the relative

contributions from water retention versus sodium loss vary with the duration and severity of the hyponatremia: Water retention was found to be the major cause of decreased serum [Na^+] in the first 24 hours of induced hyponatremia in rats, but Na^+ depletion then became the predominant etiologic factor after longer periods (7–14 days) of sustained hyponatremia, particularly at very low (<115 mEq/L) serum [Na^+] levels.[256] Finally, multiple studies of body fluid compartment volumes in hyponatremic patients have not demonstrated either plasma or ECF expansion. For example, a report of body fluid space measurements using isotope dilution techniques in hyponatremic and normonatremic patients with small cell lung carcinoma showed no differences between the two groups with regard to exchangeable sodium space, ECF volume by $^{35}SO_4$ distribution, or total body water.[257] Fig. 10.5 schematically illustrates the volume regulatory processes that occur in response to water retention induced by inappropriate antidiuresis.

Differential Diagnosis of Hyponatremia and Hypoosmolality

Because of the multiplicity of disorders causing hypoosmolality and the fact that many involve more than one pathologic mechanism, a definitive diagnosis is not always possible at the time of initial presentation. Nonetheless, an approach based on clinical parameters of ECF volume status and urine sodium concentration generally allows a sufficient categorization for appropriate decisions regarding initial therapy and further evaluation.

Decreased Extracellular Fluid Volume

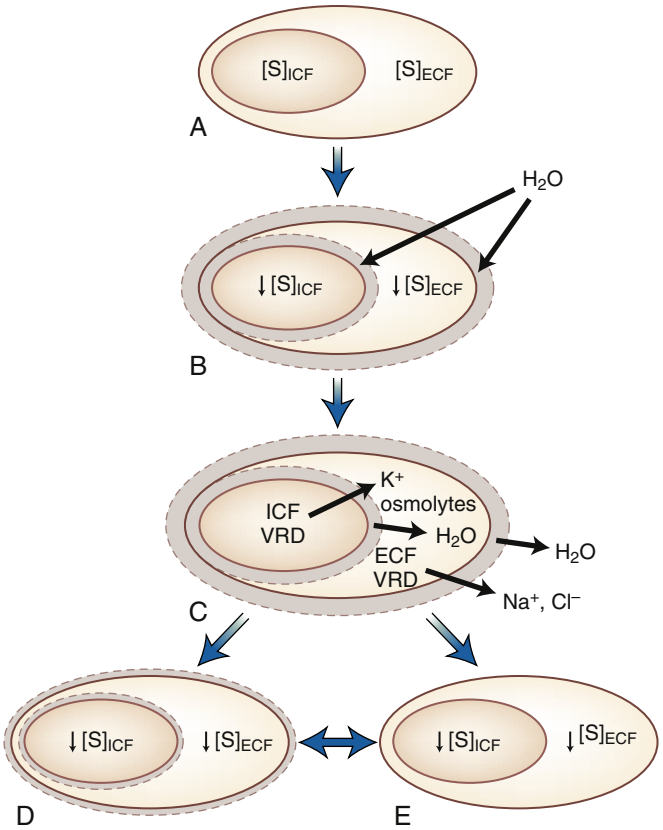
Clinically detectable hypovolemia always signifies total body solute depletion. A low urine [Na^+] indicates a nonrenal cause and an appropriate renal response. A high urine [Na^+] indicates renal causes of solute depletion are more likely. Therapy with thiazide diuretics is the most common cause of renal solute losses,[240] particularly in the elderly,[258] but mineralocorticoid deficiency as a result of adrenal insufficiency or mineralocorticoid resistance must be considered as well as (less commonly) renal solute losses due to salt-wasting nephropathy (e.g., polycystic kidney disease, interstitial nephritis, or chemotherapy).

Increased Extracellular Fluid Volume

Clinically detectable hypervolemia always signifies total body Na^+ excess. In these patients hypoosmolality results from an even greater expansion of total body water caused by a marked reduction in the rate of water excretion (and sometimes an increased rate of water ingestion). The impairment in water excretion is secondary to a decreased EABV,[242] which increases the reabsorption of glomerular filtrate not only in the proximal nephron but also in the distal and collecting tubules by stimulated secretion of vasopressin. These patients generally have a low urine [Na^+] because of secondary hyperaldosteronism. However, under certain conditions urine [Na^+] may be elevated if there is concurrent diuretic therapy, a solute diuresis (e.g., glucosuria in diabetics), or after successful treatment of the underlying disease (e.g., improved cardiac output in patients with congestive heart failure).

Normal Extracellular Fluid Volume

Many different hypoosmolar disorders present with euvolemia, and measure of urinary [Na^+] is an especially important first step.[259] A high urine [Na^+] usually implies a distally mediated, dilution-induced hypoosmolality such as SIAD. However, glucocorticoid deficiency can mimic SIAD so closely that these two disorders are often indistinguishable in terms of water balance.



• **Fig. 10.5** Schematic illustration of potential changes in whole-body fluid compartment volumes at various times during adaptation to hyponatremia. (A) Under basal conditions, the concentrations of effective solutes in the extracellular fluid ($[S]_{ECF}$) and in the intracellular fluid ($[S]_{ICF}$) are in osmotic balance. (B) During the first phase of water retention resulting from inappropriate antidiuresis, the excess water distributes across total body water, causing expansion of both ECF and ICF volumes *(dotted lines)*, with equivalent dilutional decreases in both $[S]_{ICF}$ and $[S]_{ECF}$. (C) In response to the volume expansion, compensatory volume regulatory decreases *(VRD)* occur to reduce the effective solute content of the ECF (via pressure diuresis and natriuretic factors) and the ICF (via increased electrolyte and osmolyte extrusion mediated by stretch-activated channels and downregulation of synthesis of osmolytes and osmolyte uptake transporters). (D and E) If both processes go to completion, such as under conditions of fluid restriction, a final steady state can be reached in which ICF and ECF volumes have returned to normal levels but $[S]_{ICF}$ and $[S]_{ECF}$ remain low. In most cases, this final steady state is not reached, and moderate degrees of ECF and ICF expansion persist, although they are significantly less than would be predicted from the decrease in body osmolality (D). Consequently, the degree to which hyponatremia is the result of dilution due to water retention versus solute depletion from volume regulatory processes can vary markedly, depending on which phase of adaptation the patient is in and the relative rates at which the different compensatory processes occur. For example, delayed ICF VRD can worsen hyponatremia because of shifts of intracellular water into the ECF as intracellular organic osmolytes are extruded and subsequently metabolized; this likely accounts for some component of the hyponatremia that was unexplained by the combination of water retention and sodium excretion in early clinical studies. (From Verbalis JG. Hyponatremia: epidemiology, pathophysiology, and therapy. *Curr Opin Nephrol Hypertens*. 1993;2:626–652.)

Hyponatremia from diuretic use also can present without clinically evident hypovolemia, and the urine [Na^+] will usually be elevated.[240] A low urine [Na^+] suggests a depletion-induced hypoosmolality from ECF losses with subsequent volume replacement by water or other hypotonic fluids. The solute loss often

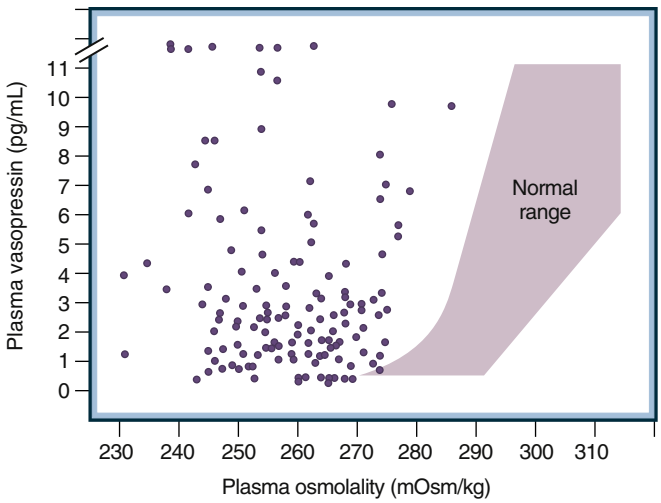
is nonrenal, but an important exception is recent cessation of diuretic therapy, because urine [Na^+] can decrease to low values within 12 to 24 hours after discontinuation of the drug. A low urine [Na^+] also can also be seen during the recovery phase from SIAD.

Syndrome of Inappropriate Antidiuresis

SIAD is the most common cause of euvolemic hypoosmolality and it is also the single most common cause of hypoosmolality of all etiologies encountered in clinical practice with prevalence rates from 20% to 40% among all hypoosmolar patients.[234,241] The clinical criteria necessary to diagnose SIAD remain basically as set forth by Schwartz and Bartter in 1967:[227]

1. Decreased effective osmolality of the extracellular fluid (P_{osm} <275 mOsm/kg H_2O). Pseudohyponatremia or hyperglycemia alone must be excluded.
2. Inappropriate urinary concentration at some level of hypoosmolality. This does not mean that urine osmolality is greater than plasma osmolality, only less than maximally dilute (i.e., urine osmolality >100 mOsm/kg H_2O). Also, urine osmolality need not be elevated inappropriately at all levels of plasma osmolality, because in the reset osmostat variant form of SIAD, vasopressin secretion can be suppressed with resultant maximal urinary dilution if plasma osmolality is decreased to sufficiently low levels.[260]
3. Clinical euvolemia, as defined by the absence of signs of hypovolemia (orthostasis, tachycardia, decreased skin turgor, dry mucous membranes) or hypervolemia (subcutaneous edema, ascites). Hypovolemia or hypervolemia strongly suggests different causes of hypoosmolality. Patients with SIAD can become hypovolemic or hypervolemic for other reasons, but in such cases it is impossible to diagnose the underlying inappropriate antidiuresis until the patient is rendered euvolemic and is found to have persistent hypoosmolality.
4. Elevated urinary sodium excretion while on a normal salt and water intake. This criterion is included because of its utility in differentiating between hypoosmolality caused by a decreased EABV, in which case renal Na^+ conservation occurs, and distal dilution-induced disorders, in which urine Na^+ excretion is normal or increased secondary to ECF volume expansion. Patients with SIAD can have low urine Na^+ excretion if they subsequently become hypovolemic or solute depleted, conditions that sometimes follow severe salt and water restriction. Consequently, a high urine Na^+ excretion is the rule in most patients with SIAD; its presence does not guarantee this diagnosis, and its absence does not rule out the diagnosis.
5. Absence of other potential causes of euvolemic hypoosmolality. Most notably are hypothyroidism, hypocortisolism (Addison disease or pituitary ACTH insufficiency), and diuretic use.

Several other criteria support but are not essential for a diagnosis of SIAD. Volume expansion and vasopressin acting on V_1 receptors in the kidney increase the clearance of uric acid, so hypouricemia is found with SIAD. When patients are hyponatremic, values of uric acid are generally <4 mg/dL (<0.24 mmol/L).[261] A water-loading test is of value when there is uncertainty regarding the etiology of modest degrees of hypoosmolality in euvolemic patients, but it does not add useful information if the plasma osmolality is already under 275 mOsm/kg H_2O. Inability to excrete a standard water load normally (with normal excretion defined as a cumulative urine output of at least 90% of the administered water load within 4 hours and suppression of urine osmolality to <100 mOsm/kg H_2O) confirms the presence of an underlying defect in free water excretion. However, water excretion is abnormal in almost all disorders that cause hypoosmolality, whether dilutional or depletion induced with secondary impairments in free water excretion. Two exceptions are primary polydipsia, in which hypoosmolality can rarely be secondary to excessive water intake alone, and the reset osmostat variant of SIAD, in which normal excretion of a water load can occur once plasma osmolality falls below the new set-point for vasopressin secretion.



• **Fig. 10.6** Plasma arginine vasopressin (AVP) levels in patients with the syndrome of inappropriate antidiuretic hormone (SIADH) secretion as a function of plasma osmolality. Each point depicts one patient at a single point in time. The *shaded area* represents AVP levels in normal subjects over physiologic ranges of plasma osmolality. The lowest measurable plasma AVP level that could be detected with this radioimmunoassay was 0.5 pg/mL. (From Robertson GL, Aycinena P, Zerbe RL. Neurogenic disorders of osmoregulation. *Am J Med.* 1982;2:339–353.)

Another supportive criterion is an inappropriately elevated plasma vasopressin level in relation to plasma osmolality. However, several factors limit the utility of vasopressin measurements to diagnose SIAD. First, although plasma vasopressin levels are elevated in most patients with this syndrome, the elevations generally remain within the normal physiologic range and are abnormal only in relation to plasma osmolality (Fig. 10.6). Second, 10% to 20% of patients with SIAD do not have measurably elevated plasma vasopressin levels and are at the limits of detection by radioimmunoassay (see Fig. 10.6).[262] Third, and perhaps most importantly, most disorders causing solute and volume depletion or decreased EABV are associated with elevations of plasma vasopressin levels secondary to nonosmotic hemodynamic stimuli.

Etiology

Although the list of disorders associated with SIAD is long (Table 10.2), they can be divided into several major etiologic groups.

Tumors

The most common association of SIAD is with tumors. Many different types of tumors have been associated with SIAD, but bronchogenic carcinoma of the lung has been uniquely associated with SIAD since the first description of this disorder in 1957.[226] In virtually all cases, the bronchogenic carcinomas causing this syndrome have been of the small cell variety. Incidence

TABLE 10.2 Common Causes of the Syndrome of Inappropriate Antidiuretic Hormone (SIADH) Secretion

Tumors

Pulmonary/mediastinal (bronchogenic carcinoma, mesothelioma, thymoma)
Nonchest (duodenal carcinoma, pancreatic carcinoma, ureteral/prostate carcinoma, uterine carcinoma, nasopharyngeal carcinoma, leukemia)

Central Nervous System Disorders

Mass lesions (tumors, brain abscesses, subdural hematoma)
Inflammatory diseases (encephalitis, meningitis, systemic lupus erythematosus, acute intermittent porphyria, multiple sclerosis)
Degenerative/demyelinative diseases (Guillain-Barré syndrome, spinal cord lesions)
Miscellaneous (subarachnoid hemorrhage, head trauma, acute psychosis, delirium tremens, pituitary stalk section, transsphenoidal adenomectomy, hydrocephalus)

Drug Related

Stimulated release of AVP (nicotine, phenothiazines, tricyclics)
Direct renal effects or potentiation of AVP antidiuretic effects (dDAVP, oxytocin, prostaglandin synthesis inhibitors)
Mixed or uncertain actions (ACE inhibitors, carbamazepine and oxcarbazepine, chlorpropamide, clofibrate, clozapine, cyclophosphamide, 3,4-methylenedioxymethamphetamine [ecstasy], omeprazole; serotonin reuptake inhibitors, vincristine)

Pulmonary

Infections (tuberculosis, acute bacterial and viral pneumonia, aspergillosis, empyema)
Mechanical/ventilatory causes (acute respiratory failure, COPD, positive-pressure ventilation)

Other Causes

Acquired immunodeficiency syndrome (AIDS) and AIDS-related complex
Prolonged strenuous exercise (marathon, triathlon, ultramarathon, hot-weather hiking)
Senile atrophy
Idiopathic

ACE, Angiotensin-converting enzyme; *AVP,* arginine vasopressin; *COPD,* chronic obstructive pulmonary disease; *dDAVP,* desmopressin.

of hyponatremia is as high as 11% of all patients with small cell carcinoma,[263] or 33% of cases with more extensive disease,[264] have been reported. The high incidence of small cell carcinoma of the lung makes it imperative that all adult patients presenting with an otherwise unexplained SIAD be investigated thoroughly and aggressively for a possible lung tumor. Head and neck cancers account for another group of malignancies associated with relatively higher incidences of SIAD,[265] and some of these tumors have clearly been shown to synthesize vasopressin.[266] A report from a large cancer hospital showed an incidence of hyponatremia for all malignancies of 3.7%, with approximately one-third of these due to SIAD.[267]

Central Nervous System Disorders

A large number of different CNS disorders are associated with SIAD, but without a common denominator linking them. This is not surprising when one considers the neuroanatomy described earlier. Magnocellular vasopressin neurons receive excitatory inputs from osmoreceptive cells located in the anterior hypothalamus, but also a major innervation from brainstem cardiovascular regulatory and emetic centers. Although various components of these pathways have yet to be elucidated fully, many of them appear to have inhibitory as well as excitatory components. Consequently, any CNS disorder can potentially cause vasopressin hypersecretion either by nonspecifically exciting these pathways via irritative foci or alternatively by disrupting them and thereby decreasing the level of inhibition.

Drugs

Drug-induced hyponatremia is a common cause of hypoosmolality.[268] Table 10.2 lists some of the agents that have been associated with SIAD, but new drugs are added continually. Pharmacologic agents may stimulate secretion of vasopressin, activate renal V_2 receptors, or potentiate the antidiuretic effect of vasopressin. Not all of the drug effects are fully understood, and many appear to work through a combination of mechanisms. A particularly interesting and clinically important class of agents is the selective serotonin reuptake inhibitors (SSRIs). Hyponatremia following SSRI administration has been reported almost exclusively in the elderly, with rates as high as 22% to 28%, although in larger series the incidence was closer to 1 in 200.[269] A similar effect is likely also responsible for the recent reports of severe fatal hyponatremia caused by use of the recreational drug 3,4-methylenedioxymethamphetamine, "ecstasy," which possesses substantial serotonergic activity.[270]

Pulmonary Disorders

A variety of pulmonary disorders have been associated with this syndrome, but other than tuberculosis, acute pneumonia, and advanced chronic obstructive lung disease, the occurrence of hypoosmolality has been noted only sporadically. Hypoxia stimulates secretion of vasopressin in animals,[271] but in humans hypercarbia is more associated with abnormal water retention. Elevated vasopressin may be limited to the initial days of hospitalization, when respiratory failure is most marked. Therefore, with SIAD in nontumor pulmonary disease, the pulmonary disease is obvious with severe dyspnea or extensive radiographically evident infiltrates, and the inappropriate antidiuresis will usually be limited to the period of respiratory failure. Mechanical ventilation can cause SIAD via inappropriate secretion of vasopressin via decreased venous return.

Other Causes

In acquired immunodeficiency syndrome (AIDS) or AIDS-related complex (ARC) and in patients with human immunodeficiency virus (HIV) infection, hyponatremia has been reported as high as 30% to 38% in adults and children.[272] Although there are many potential etiologies, including dehydration, adrenal insufficiency, and pneumonitis, from 12% to 68% of AIDS patients who develop hyponatremia appear to meet criteria for a diagnosis of SIAD.[272] Not unexpectedly, some of the medications used to treat these patients may cause the hyponatremia, either via direct renal tubular toxicity or induced SIAD.[273]

Elderly patients often develop SIAD without any apparent underlying etiology, and the high incidence of hyponatremia in geriatric patients[231,274] suggests that the normal aging process may be accompanied by abnormalities of regulation of water balance and of secretion of vasopressin as noted earlier. Such an effect could potentially account for the fact that drug-induced hyponatremia occurs much more frequently in elderly patients. In a

series of 50 consecutive elderly patients meeting criteria for SIAD, 60% remained idiopathic despite rigorous evaluation, leading the authors to conclude that extensive diagnostic procedures were not warranted in such elderly patients if routine history, physical examination, and laboratory evaluation failed to suggest an underlying etiology.[275]

Pathophysiology

Sources of Vasopressin Secretion

Elevated plasma levels of vasopressin can be broadly divided into those associated with paraneoplastic ("ectopic") secretion of vasopressin or pituitary hypersecretion of vasopressin. There is substantial cumulative evidence that tumor tissue can in fact synthesize vasopressin,[276] but it is not certain that all tumors associated with SIAD do so because only about half of small cell carcinomas have been found to contain vasopressin immunoreactivity, and many of the tumors listed in Table 10.2 have not been carefully studied.

Pituitary Vasopressin Secretion—Inappropriate Versus Appropriate

In the majority of cases of SIAD, the vasopressin secretion originates from the posterior pituitary. This is also true of over 90% of all cases of hyponatremia, including patients with hypovolemic and hypervolemic hyponatremia.[234] This raises the question of what constitutes "inappropriate" secretion of vasopressin. Secretion of vasopressin in response to a hypovolemic stimulus is clearly physiologically "appropriate," but when it leads to symptomatic hyponatremia it could be considered inappropriate for the ECF osmolality. Despite these semantic conundrums, the diagnosis of SIAD should be based upon the original Schwartz-Bartter criteria and specifically exclude other clinical conditions that cause known impairments in free water excretion *even when* these are mediated by a secondary nonosmotic physiologic stimulation of vasopressin secretion. Without maintaining these distinctions, arguable as some may be, the definition of SIAD becomes too broad to retain any practical clinical utility.

Patterns of Vasopressin Secretion

Studies of plasma vasopressin levels in patients with SIAD during graded increases in plasma osmolality produced by hypertonic saline administration have defined four patterns of secretion: (1) random hypersecretion of vasopressin; (2) inappropriate nonsuppressible basal vasopressin release, but normal secretion in response to osmolar changes above basal plasma osmolality; (3) a reset osmostat system, whereby vasopressin is secreted at an abnormally low threshold of plasma osmolality but otherwise displays a normal response to relative changes in osmolality; and (4) low or even undetectable plasma vasopressin levels despite classic clinical characteristics of SIAD.[262] The pattern of SIAD that occurs without measurable vasopressin secretion is not yet well understood, but the positive response of one such patient to a vasopressin V_2-receptor antagonist would suggest that this may represent increased renal sensitivity to low circulating levels of vasopressin.[277] It is surprising that no correlation has been found between any of these patterns of secretion of vasopressin and the various etiologies of SIAD.[262] Recent studies of pediatric patients with hyponatremia and unmeasurable plasma vasopressin levels led to the discovery of an activating mutation of the vasopressin V_2 receptor as the cause of their inappropriate antidiuresis.[278] It is more appropriate to call these cases the *nephrogenic syndrome of inappropriate antidiuresis*, reserving SIAD only for those cases where measured plasma vasopressin levels are really inappropriate. Although the incidence of nephrogenic syndrome of inappropriate antidiuresis in the general population is unknown, the description of Belgian kindred with this mutation suggests that it can present later in life as well as in childhood.

Contribution of Natriuresis to the Hyponatremia of SIAD

Since the original cases studied by Schwartz and Bartter, increased renal Na^+ excretion has been one of the cardinal manifestations of SIAD, indeed one which later became embedded in the requirements for its diagnosis.[227] Demonstration that the natriuresis accompanying administration of antidiuretic hormone is not due to vasopressin itself but to the volume expansion produced as a result of water retention was unequivocally shown by Leaf and associates even before the description of the disorder.[279] Although a negative Na^+ balance occurs during the development of hyponatremia in patients with SIAD, eventually urinary sodium excretion simply reflects daily sodium intake.[226] Thus the term *renal sodium wasting* is used to describe continued excretion of sodium despite being hyponatremic, but in reality there is a new steady state in which patients are in neutral sodium balance. Studies of long-term antidiuretic-induced hyponatremia in both dogs and rats have indicated that a large proportion of the hyponatremia was attributable to secondary Na^+ losses rather than to water retention,[255,256] but the natriuresis did not actually worsen the hyponatremia; rather, it allowed volume regulation of ECF.[280] Secondary natriuresis in patients with SIAD likely explains the failure to find expanded plasma or ECF volumes using tracer dilution techniques (see Fig. 10.5).[257]

Cerebral Salt Wasting

The degree to which hyponatremia might occur primarily as a result of primary natriuresis is controversial. Cerebral salt wasting syndrome (CSWS) was proposed by Peters and associates in 1950[281] as an explanation for the natriuresis and hyponatremia that sometimes accompanies intracranial disease, particularly subarachnoid hemorrhage in which up to one-third of patients often develop hyponatremia. After the description of SIAD in 1957, such patients were generally assumed to have hyponatremia secondary to vasopressin hypersecretion with a secondary natriuresis. However, over the last decade clinical and experimental data have been interpreted to indicate that some patients with subarachnoid hemorrhage and other intracranial diseases indeed have a primary natriuresis leading to volume contraction rather than SIAD,[282,283] and the elevated plasma vasopressin levels may be physiologically appropriate for the degree of volume contraction. With regard to the potential mechanisms of natriuresis, both plasma and CSF levels of atrial natriuretic peptide are elevated in many patients with subarachnoid hemorrhage and have been found to correlate variably with hyponatremia in patients with intracranial diseases.[284] However, clearly documented SIAD also is frequently associated with elevated plasma levels of atrial natriuretic peptide, so this finding does not prove causality. In other disorders of hyponatremia due to Na^+ wasting (e.g., Addison disease) and diuretic-induced hyponatremia, infusion of saline restores normal ECF volume and plasma tonicity by shutting off the secondary vasopressin secretion. In subarachnoid hemorrhage, however, large volumes of isotonic saline sufficient to maintain plasma volume did not change the incidence of hyponatremia.[285]

Those authors who have distinguished CSWS from SIAD have emphasized that in CSWS the primary disorder, salt

wasting, produces convincing evidence of decreased extracellular fluid volume.[286,287] There are only a few case reports of patients after traumatic brain injury or neurosurgery who while being observed in the hospital have acute onset of massive diuresis and natriuresis with clear evidence of volume contraction by weight loss, decreased central venous pressure, increased blood urea nitrogen (BUN), or increased hematocrit. Most of these cases have been in children[288,289] and have responded to replacement with normal or hypertonic saline, but concurrent treatment with fludrocortisone has also been advocated.[288,290] However, a recent study of 100 consecutive adult patients with acute nontraumatic aneurysmal subarachnoid hemorrhage found that the cause of the hyponatremia was attributable to SIAD in 71.4% and acute glucocorticoid deficiency in 8.2%, with the remaining cases caused by incorrect intravenous fluid administration or hypovolemia. Most significantly, no cases were found that met historically accepted criteria for a diagnosis of CSWS.[112] This suggests that CSWS is an exceedingly rare cause of the hyponatremia with intracranial disorders.

Renal Escape From Antidiuresis

In addition to excreting osmoles to bring volumes back toward normal, there are intrarenal adaptations that allow excretion of more water. Chronic stimulation by vasopressin in SIAD produces dramatic increases of aquaporin 2 content and insertion into the collecting duct principal cell membranes, which increases the efficiency of water retention and aggravates the pathology. However, the induced volume expansion and hypotonicity act on the tubular cells of the collecting duct to decrease the content and action of aquaporin 2 substantially, thus decreasing the amount of water resorbed in spite of high vasopressin levels. Experimental studies have suggested this may be due to downregulation of vasopressin V_2-receptor expression in the kidney.[291] This renal "escape" therefore represents another (in addition to natriuresis) adaptation that allows patients with persistent SIAD to come into a new steady state of Na^+ and water balance despite low serum sodium concentrations.[292]

Hypoosmolar Symptoms, Morbidity, and Mortality

Regardless of the etiology of hypoosmolality, most clinical manifestations are similar. Nonneurologic symptoms are relatively uncommon, although a number of cases of rhabdomyolysis have been reported presumably secondary to osmotically induced swelling of muscle fibers. Hypoosmolality is primarily associated with a broad spectrum of neurologic manifestations ranging from mild nonspecific symptoms (e.g., headache, nausea) to more significant disorders (e.g., disorientation, confusion, obtundation, focal neurologic deficits, and seizures).[293] This neurologic symptom complex has been termed "hyponatremic encephalopathy"[294] and primarily reflects brain edema resulting from osmotic water shifts into the brain because of decreased effective plasma osmolality. Significant neurologic symptoms generally do not occur until serum $[Na^+]$ falls below 125 mmol/L, and the severity of symptoms are roughly correlated with the degree of hypoosmolality.[293,295] However, individual variability is marked, and for any single patient the level of serum $[Na^+]$ at which symptoms appear cannot be predicted. The rate of fall of serum $[Na^+]$ is often more strongly correlated with morbidity and mortality than is the actual magnitude of the decrease.[293,295] This is due to the fact that the volume-adaptation process takes a finite period of time to complete, and the more rapid the fall in serum $[Na^+]$ the more brain edema will be accumulated before the brain is able to volume regulate. Thus there is a much higher incidence of neurologic symptoms as well as a higher mortality in patients with acute hyponatremia than in those with chronic hyponatremia.[293] For example, the most dramatic cases of death due to hyponatremic encephalopathy have generally been reported in postoperative patients in whom hyponatremia develops rapidly as a result of intravenous infusion of hypotonic fluids.[293,296] In such cases nausea and vomiting are frequently overlooked as potential early signs of increased intracranial pressure. Critically ill patients with unexplained seizures also should be immediately evaluated for possible hyponatremia, since as many as one-third of such patients have a serum $[Na^+]$ below 125 mEq/L as the cause of the seizure activity.[297] Underlying neurologic disease and nonneurologic metabolic disorders (e.g., hypoxia,[298] acidosis, hypercalcemia) can raise the level of plasma osmolality at which CNS symptoms occur.

In the most severe cases of hyponatremic encephalopathy, death results from respiratory failure after tentorial cerebral herniation and brainstem compression. One-quarter of patients with severe postoperative hyponatremic encephalopathy manifested hypercapneic respiratory failure, the expected result of brainstem compression, but three-quarters had pulmonary edema as the apparent cause of the hypoxia.[299] Studies of acute hyponatremia after marathon races have shown hypoxia and pulmonary edema in association with brain edema.[300] These results suggest the possibility that hypoxia from noncardiogenic pulmonary edema may represent an early sign of developing cerebral edema even before brainstem compression and tentorial herniation. Clinical studies have suggested that menstruating women[296] and young children[301] may be particularly susceptible to the development of neurologic morbidity and mortality during hyponatremia, especially in the acute postoperative setting.[294] However, other studies have failed to corroborate these findings.[302,303]

Although some studies have suggested that hyponatremia is an indicator of severe underlying disease and poor prognosis rather than a cause of the increased mortality in such patients, a meta-analysis of studies in which some patients had correction of their hyponatremia indicated that improvement in serum $[Na^+]$ was associated with a 50% reduction in mortality of the corrected groups compared to patients in whom the hyponatremia remained uncorrected, suggesting that hyponatremia may in fact be causally related to increased mortality.[304] Recent studies have further indicated that even mild hyponatremia is an independent predictor of higher mortality across a wide variety of disorders, including patients with acute ST-elevation myocardial infarction, heart failure, and liver disease.[228,235]A large study of over 55,000 electronic heath records from a single Boston hospital showed that the association of hyponatremia with inpatient mortality was significant across all levels of hyponatremia and even began at serum $[Na^+]$ levels in the lower part of the normal range.[229] These findings were corroborated in studies of 249,000 Danish patients hospitalized over a 5-year period that showed increased 30-day and 1-year mortality associated with all levels of hyponatremia, including the range of 130 to 134.9 mmol/L,[305] and analyses of 2.3 million hospitalized patients enrolled in the Cerner Health Facts database.[306] The mortality associated with chronic hyponatremia is much less well studied, but results of the Rotterdam Longitudinal Aging Study noted significantly decreased survival of elderly patients with hyponatremia over a 12-year period of observation.[307]

Once the brain has volume regulated via solute losses, thereby reducing brain edema, neurologic symptoms are not as prominent and may even be virtually absent. This accounts for the fairly common finding of relatively asymptomatic patients even with severe levels of hyponatremia.[295,308] Despite this powerful adaptation process, chronic hyponatremia is frequently associated with neurocognitive symptomatology, albeit milder and more subtle in nature, such as headaches, nausea, mood disturbances, depression, difficulty concentrating, slowed reaction times, unstable gait, increased falls, confusion, and disorientation.[309,310] Even in patients adjudged to be "asymptomatic" by virtue of a normal neurologic examination, accumulating evidence suggests that there may be previously unrecognized adverse effects as a result of chronic hyponatremia. In one study, 16 patients with hyponatremia secondary to SIAD, in the range of 124 to 130 mmol/L, demonstrated a significant gait instability that normalized after correction of the hyponatremia to a normal range.[309] The functional significance of the gait instability was illustrated in a study of 122 Belgian patients with a variety of levels of hyponatremia all judged to be asymptomatic at the time of visit to an emergency department (ED). These patients were compared with 244 age-matched, gender-matched, and disease-matched controls also presenting to the ED during the same time period. Researchers found that 21% of the hyponatremic patients came to the ED because of a recent fall, compared to only 5% of the controls; this difference was highly significant and remained so after multivariable adjustment.[309] Analogous results were found in a study of admissions to a US hospital geriatric trauma unit over a 3-year period; when patients admitted because of a fall (n = 1841) were analyzed for risk factors associated with fall, the odds ratio for serum [Na^+] below 135 mmol/L was 1.81 (p <0.001), which was greater than all other risk factors except age over 85 years.[311] Consequently, these studies clearly document an increased incidence of falls in so-called asymptomatic hyponatremic patients. Recent studies in both experimental animals[312] and humans[313] have demonstrated decreases in nerve conduction associated with hyponatremia as a potential cause of the gait disturbances.

The clinical significance of the gait instability and fall data have been indicated by multiple independent international studies that have demonstrated increased rates of bone fractures in patients with hyponatremia.[307,314–316] Other studies have shown that hyponatremia is associated with increased bone loss in experimental animals and a significantly increased odds ratio for osteoporosis of the femoral neck in those older than 50 years in the Third National Health and Nutrition Examination Survey (NHANES III) database.[317] These findings have been corroborated by multiple epidemiologic studies that have demonstrated decreased bone mineral density in human subjects.[318,319] In the largest epidemiologic analysis to date (2.9 million independent electronic health records), the odds ratios for osteoporosis and fractures were significantly greater for hyponatremia (3.99 and 3.05, respectively) than for any other diseases or medications associated with increased bone loss and fracture risk.[320] Of particular note, the odds ratios for both osteoporosis and fractures were the highest in patients with chronic persistent hyponatremia, indicating that duration of hyponatremia represents an important risk factor for bone disease and fractures.[320] These findings were supported by a subsequent clinical study of hip fractures in Argentina.[321]

Recent studies of a cohort of 5435 community dwelling men over the age of 65 in the United States have found that hyponatremia is independently associated with greater cognitive impairment and cognitive decline in this population,[322] and a retrospective study of 4900 hyponatremic patients in Taiwan found that the hyponatremic patients had a 2.36-fold higher hazard ratio of developing dementias compared to matched controls, which increased to a hazard ratio of 4.29 for patients with more severe hyponatremia. Thus the major clinical significance of chronic hyponatremia may lie in the increased morbidity and mortality associated with falls, fractures, neurocognitive impairments, and dementias in our older population as well as potential adverse effects not yet studied in humans.[323]

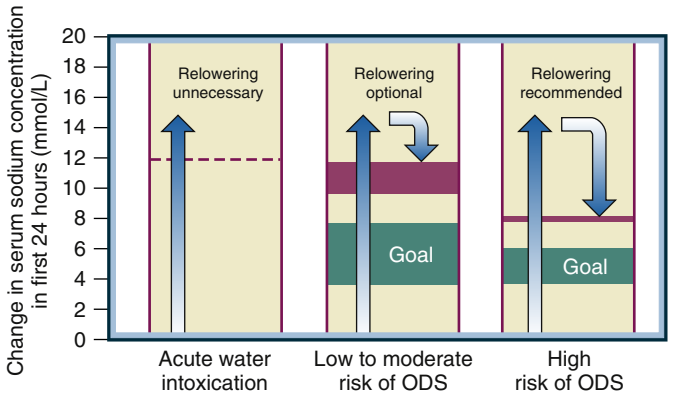
Therapy of SIAD and Other Hypoosmolar Disorders

General Principles

Correction of hyponatremia is associated with markedly improved neurologic outcomes in patients with severely symptomatic hyponatremia. In a retrospective review of patients who presented with severe neurologic symptoms and serum [Na^+] below 125 mmol/L, prompt therapy with isotonic or hypertonic saline resulted in a correction in the range of 20 mEq/L over several days and neurologic recovery in almost all cases; in contrast, in patients who were treated with fluid restriction alone, there was very little correction over the study period (<5 mmol/L over 72 hours), and the neurologic outcomes were much worse, with most of these patients either dying or entering a persistently vegetative state.[324] Based on this and similar retrospective analyses, prompt therapy to rapidly increase the serum [Na^+] represents the standard of care for treatment of patients presenting with severe symptoms of hyponatremia.

Brain herniation, the most dreaded complication of hyponatremia, is seen almost exclusively in patients with acute hyponatremia (usually <24 hours) or in patients with intracranial pathology.[325] In postoperative patients and in patients with self-induced water intoxication associated with marathon running, psychosis, or use of "ecstasy" (3,4-methylenedioxy-N-methamphetamine [MDMA]), nonspecific symptoms such as headache, nausea and vomiting, or confusion can rapidly progress to seizures, respiratory arrest, and ultimately death or a permanent vegetative state as a complication of cerebral edema.[232] Hypoxia from noncardiogenic pulmonary edema and/or hypoventilation can exacerbate brain swelling caused by the low serum [Na^+].[299,300] Although usually self-limited, hyponatremic seizures may be refractory to anticonvulsants.

As discussed earlier, chronic hyponatremia is much less symptomatic as a result of the process of brain volume regulation. Because of this adaptation process, chronic hyponatremia is arguably a condition that clinicians feel less concerned about, which has been reinforced by the common usage of the descriptor *asymptomatic hyponatremia* for many such patients. However, as discussed, it is clear that many such patients very often have neurologic symptoms, even if milder and more subtle in nature. Consequently, all patients with hyponatremia who manifest any neurologic symptoms that could possibly be related to the hyponatremia should be considered candidates for treatment of the hyponatremia, regardless of the chronicity of the hyponatremia or the level of serum [Na^+]. An additional reason to treat even asymptomatic hyponatremia effectively is to prevent a lowering of the serum [Na^+] to more symptomatic and dangerous levels during treatment of underlying conditions (e.g., increased fluid administration via parenteral nutrition, treatment of heart failure with diuretics).



• **Fig. 10.7** Recommended goals *(green)* and limits *(red)* for correction of hyponatremia based on risk of producing ODS and recommendations for relowering of serum sodium concentration ($[Na^+]$) to goals for patients presenting with serum $[Na^+]$ lower than 120 mmol/L who exceed the recommended limits of correction in the first 24 hours. *ODS,* osmotic demyelination syndrome. (From Verbalis JG, Goldsmith SR, Greenberg A, et al. Diagnosis, evaluation, and treatment of hyponatremia: expert panel recommendations. *Am J Med.* 2013;126:S1–S42.)

Therapies for Treatment of Hyponatremia

Conventional management strategies for hyponatremia range from saline infusion and fluid restriction to pharmacologic measures to adjust fluid balance. Although the number of available treatments for hyponatremia is large, some are not appropriate for correction of symptomatic hyponatremia because they work too slowly or inconsistently to be effective in hospitalized patients (e.g., demeclocycline, mineralocorticoids). Consideration of treatment options should always include an evaluation of the benefits as well as the potential toxicities of any therapy and must be individualized for each patient.[310,326] For all therapies, careful attention should be paid to recommendations for goals and limits of correction of the serum $[Na^+]$ to reduce the risk of the osmotic demyelination syndrome (ODS)[310] (Fig. 10.7). It should also be remembered that sometimes simply stopping treatment with an agent that is associated with causing hyponatremia is sufficient to correct a low serum $[Na^+]$.

Hypertonic Saline

Acute hyponatremia presenting with severe neurologic symptoms is life threatening and should be treated promptly with hypertonic solutions, typically 3% NaCl ($[Na^+]$ = 513 mmol/L), as this represents the most reliable method to quickly raise the serum $[Na^+]$. A continuous infusion of hypertonic NaCl is usually utilized in inpatient settings. Various formulae have been suggested for calculating the initial rate of infusion of hypertonic solutions,[325] but until now there has been no consensus regarding optimal infusion rates of 3% NaCl. One of the simplest methods to estimate an initial 3% NaCl infusion rate utilizes the following relationship[310]:

$$\text{Patient's weight (kg)} \times \text{desired correction rate (mEq/L/hr)} = \text{infusion rate of 3\% NaCl (mL/hr)}$$

This may not achieve the desired correction rate, but frequent monitoring of the serum $[Na^+]$ will inform the clinician whether the rate should be increased or decreased, similar to using measurement of serum glucose to guide the infusion rate of insulin drips. Depending on individual hospital policies, the administration of hypertonic solutions may require special considerations (e.g., placement in the intensive care unit [ICU], sign-off by a consultant), which each clinician needs to take into account to optimize patient care. One barrier to the use of hypertonic saline that appears to be overstated and unfounded is the frequent requirement for a central intravenous catheter for chronic infusion. A recent study demonstrated a low rate of complications using peripheral infusions of 3% NaCl (6% infiltration and 3% thrombophlebitis) and concluded that peripheral administration of 3% NaCl carries a low risk of minor nonlimb or life-threatening complications.[327]

An alternative option for more emergent situations is administration of a 100-mL bolus of 3% NaCl, repeated twice if there is no clinical improvement in 30 minutes, which has been recommended by a consensus conference organized to develop guidelines for the prevention and treatment of exercise-induced hyponatremia[328] and adopted as a general recommendation by several expert panels.[310,329] Injecting this amount of hypertonic saline intravenously raises the serum $[Na^+]$ by an average of 2 to 4 mmol/L, which is well below the recommended maximal daily rate of change of 10 to 12 mmol/L/24 hours or 8 mmol/L/24 hours for patients with increased risk factors for ODS (serum $[Na^+] \leq 105$ mmol/L, hypokalemia, advanced liver disease, malnutrition, or a history of alcoholism)[310,330] (see Fig. 10.7). Because the adult brain can only accommodate an average increase of approximately 8% in brain volume before herniation occurs, quickly increasing the serum $[Na^+]$ by as little as 2 to 4 mmol/L in acute hyponatremia can effectively reduce brain swelling and intracranial pressure.[331]

Isotonic Saline

The treatment of choice for depletional hyponatremia (i.e., hypovolemic hyponatremia) is isotonic saline ($[Na^+]$ = 154 mmol/L) to restore ECF volume and ensure adequate organ perfusion. This initial therapy is appropriate for patients who either have clinical signs of hypovolemia or in whom a spot urine $[Na^+]$ concentration is below 20 to 30 mEq/L.[310] Such patients often develop a free water diuresis (aquaresis) as their ECF volume is corrected, potentially leading to an overly rapid correction with increased risk of ODS, so the serum $[Na^+]$ and urine output should be followed carefully during the first 24 to 48 hours of therapy. However, isotonic saline is ineffective for dilutional hyponatremias such as SIAD,[226] and continued administration of isotonic saline to a euvolemic patient may worsen their hyponatremia[332] and/or cause fluid overload. Although saline may improve the serum $[Na^+]$ in some patients with hypervolemic hyponatremia, their volume status will generally worsen with this therapy, so unless the hyponatremia is profound both hypertonic and isotonic saline should be avoided.

Fluid Restriction

For patients with chronic hyponatremia, fluid restriction has been the most popular and most widely accepted treatment. When SIAD is present, fluids should generally be limited to 500 to 1000 mL/24 hours. Because fluid restriction increases the serum $[Na^+]$ by underreplacing the excretion of fluid by the kidneys, some have advocated an initial restriction to 500 mL less than the 24-hour urine output.[333] When instituting a fluid restriction, it is important for the nursing staff and the patient to understand that this includes all fluids that are consumed, not just water (Table 10.3). Generally the water content of ingested food is not included in the restriction because this is balanced by insensible water losses

TABLE 10.3 General Recommendations for Use of Fluid Restriction and Predictors of the Increased Likelihood of Failure of Fluid Restriction

General Recommendations

- Restrict *all* intake that is consumed by drinking, not just water.
- Aim for a fluid restriction that is 500 mL/day *below* the 24-hour urine volume.
- Do *not* restrict sodium or protein intake unless indicated.

Predictors of the Likely Failure of Fluid Restriction

- High urine osmolality (≥500 mOsm/kg H_2O).
- Sum of the urine [Na^+] and [K^+] concentrations exceeds the serum [Na^+] concentration.
- 24-hour urine volume <1500 mL/day.
- Increase in serum [Na^+] concentration <2 mmol/L/day in 24–48 hours on a fluid restriction of ≤1 L/day.

(perspiration, exhaled air, feces, etc.), but caution should be exercised with foods that have high fluid concentrations (such as fruits and soups). Restricting fluid intake can be effective when properly applied and managed in selected patients, but serum [Na^+] is generally increased only slowly (1–2 mmol/L/day) even with severe fluid restriction.[226] In addition, this therapy is often poorly tolerated because of an associated increase in thirst leading to poor compliance with long-term therapy.

Fluid restriction should not be used with hypovolemic patients and is particularly difficult to maintain in hospitalized patients with very elevated urine osmolalities secondary to high vasopressin levels; similarly, if the sum of urine [Na^+] and [K^+] exceeds the serum [Na^+], most patients will not respond to a fluid restriction since an electrolyte-free water clearance will be difficult to achieve.[334,335] These and other known predictors of failure of fluid restriction are summarized in Table 10.3; the presence of any of these factors in hospitalized patients with symptomatic hyponatremia make this therapy less than ideal. In addition, fluid restriction is not practical for some patients, particularly including patients in intensive care settings who often require administration of significant volumes of fluids as part of their therapies. Such patients are candidates for more effective pharmacologic or saline treatment strategies.

Arginine Vasopressin Receptor Antagonists

Conventional therapies for hyponatremia, although effective in specific circumstances, are suboptimal for many different reasons, including variable efficacy, slow responses, intolerable side effects, and serious toxicities. But perhaps the greatest deficiency of most conventional therapies is that they do not directly target the underlying cause of most dilutional hyponatremias, namely inappropriately elevated plasma vasopressin levels. A new class of pharmacologic agents (vasopressin receptor antagonists [vaptans]) that directly block vasopressin-mediated receptor activation have been approved for the treatment of euvolemic hyponatremia and hypervolemic hyponatremia in many countries.[326,336]

Conivaptan has been approved by the US Food and Drug Administration (FDA) for euvolemic and hypervolemic hyponatremia in hospitalized patients. It is available only as an intravenous preparation and is given as a 20-mg loading dose over 30 minutes, followed by a continuous infusion of 20 or 40 mg/day. Generally, the 20-mg continuous infusion is used for the first 24 hours to gauge the initial response. If the correction of serum [Na^+] is thought to be inadequate (e.g., <5 mmol/L), the infusion rate can be increased to 40 mg/day. Clinical studies have supported the efficacy of bolus infusions of conivaptan rather than continuous infusions.[337] Therapy is limited to a maximum duration of 4 days because of drug interaction effects with other agents metabolized by the CYP3A4 hepatic isoenzyme. Importantly, for conivaptan and all other vaptans, it is critical that the serum [Na^+] be measured frequently during the active phase of correction of the hyponatremia—a minimum of every 6 to 8 hours for conivaptan but more frequently in patients with risk factors for the ODS.[310] If the correction exceeds 10 to 12 mmol/L in the first 24 hours, the infusion should be stopped and the patient monitored closely. Consideration should be given to administering sufficient water, orally or as intravenous 5% dextrose in water, to avoid a correction of more than 12 mmol/L/day. The maximum correction limit should be reduced to 8 mmol/L over the first 24 hours in patients with risk factors for ODS[310] (see Fig. 10.7). The most common side effects of conivaptan include headache, thirst, and hypokalemia.[338]

Tolvaptan, an oral vasopressin receptor antagonist, is also FDA approved for the treatment of euvolemic and hypervolemic hyponatremia. In contrast to conivaptan, the availability of tolvaptan in tablet form allows short-term and long-term use.[339] Similar to conivaptan, tolvaptan treatment must be initiated in the hospital so that the rate of correction can be monitored carefully. In the United States, patients with a serum [Na^+] lower than 125 mmol/L are eligible for therapy with tolvaptan as primary therapy; if the serum [Na^+] is 125 mmol/L or higher, tolvaptan therapy is only indicated if the patient has symptoms that could be attributable to the hyponatremia and is resistant to attempts at fluid restriction.[340] In the European Union, tolvaptan is approved only for the treatment of euvolemic hyponatremia due to SIAD, but any symptomatic euvolemic patient is eligible for tolvaptan therapy regardless of the level of hyponatremia or response to previous fluid restriction. The starting dose of tolvaptan is 15 mg on the first day, although in clinical practice some clinicians recommend starting with a lower dose of 7.5 mg,[341] and the dose can be titrated to 30 and 60 mg at 24-hour intervals if the serum [Na^+] remains lower than 135 mmol/L or the increase in serum [Na^+] has been less than 5 mmol/L in the previous 24 hours. As with conivaptan, it is essential that the serum [Na^+] be measured frequently during the active phase of correction of the hyponatremia at a minimum of every 6 to 8 hours, particularly in patients with risk factors for ODS. Goals and limits for the safe correction of hyponatremia and methods to compensate for overly rapid corrections are the same as described previously for conivaptan (see Fig. 10.7). One additional factor that helps avoid overly rapid correction with tolvaptan is the recommendation that fluid restriction should not be used during the active phase of correction, thereby allowing the patient's thirst to compensate for an overly vigorous aquaresis. Common side effects of tolvaptan include dry mouth, thirst, increased urinary frequency, dizziness, nausea, and orthostatic hypotension.[340]

Vaptans are not needed in the treatment of hypovolemic hyponatremia because simple volume expansion would be expected to abolish the nonosmotic stimulus to AVP secretion and lead to a prompt aquaresis. Furthermore, inducing increased renal fluid excretion via diuresis or aquaresis can cause or worsen hypotension in such patients. This possibility has resulted in the labeling of these drugs as contraindicated for hypovolemic hyponatremia. Importantly, clinically significant hypotension was not observed in the conivaptan or tolvaptan clinical trials in euvolemic and

hypervolemic hyponatremic patients. Although vaptans are not contraindicated with decreased renal function, these agents generally will not be effective if the serum creatinine level is more than 3 mg/dL.

The FDA has issued a caution about hepatic injury that was noted in patients who received tolvaptan in a 3-year clinical trial examining the effect of tolvaptan on autosomal dominant polycystic kidney disease, the Tolvaptan Efficacy and Safety in Management of Autosomal Dominant Polycystic Kidney Disease and Its Outcomes (TEMPO) study.[342] Although the doses used in the TEMPO study were up to twice the maximum dose approved for hyponatremia (e.g., tolvaptan, 120 mg/day) and in clinical trials of tolvaptan at doses approved by the FDA for treatment of clinically significant euvolemic or hypervolemic hyponatremia liver damage was not reported, the FDA recommended that "Samsca treatment should be stopped if the patient develops signs of liver disease. Treatment duration should be limited to 30 days or less, and use should be avoided in patients with underlying liver disease, including cirrhosis." The European Medicines Agency (EMA) has approved the use of tolvaptan for SIAD but not for hyponatremia due to heart failure or cirrhosis. Based on the TEMPO trial results, the EMA also issued a warning about the possible occurrence of hepatic injury in patients treated with tolvaptan but did not recommend any restriction on the duration of treatment of SIAD patients with tolvaptan. Accordingly, appropriate caution should be exercised in patients treated with tolvaptan for hyponatremia for extended periods (e.g., >30 days), but this decision should be based on the clinical judgment of the treating physician. Patients who are refractory to or unable to tolerate or obtain other therapies for hyponatremia, and for whom the benefit of tolvaptan treatment outweighs the risks, remain candidates for long-term therapy with tolvaptan.

An additional barrier to the use of vasopressin antagonists for treatment of hyponatremia is the high cost of the drug. This is true in the United States and the European Union but interestingly not in Asian countries. Despite this pronounced geographic disparity, many economic analyses have confirmed the increased economic burden of hyponatremia, which is largely driven by longer hospital and intensive care stays.[343,344] An analysis of use of tolvaptan compared with fluid restriction showed a favorable cost savings that offset the high cost of tolvaptan, suggesting that selective use of these agents in appropriate inpatients may in fact be cost effective in hospitalized patients in the United States and the European Union.[345]

Urea

Urea has been described as an alternative oral treatment for SIAD and other hyponatremic disorders. The mode of action is to correct hypoosmolality not only by increasing solute-free water excretion but also by decreasing urinary sodium excretion. Doses of 15 to 60 g/day are generally effective; the dose can be titrated in increments of 15 g/day at weekly intervals as necessary to achieve normalization of the serum [Na^+]. It is advisable to dissolve the urea in orange juice or some other strongly flavored liquid to camouflage the bitter taste. Even if completely normal water balance is not achieved, it is often possible to allow the patient to maintain a less strict regimen of fluid restriction while receiving urea. The disadvantages associated with the use of urea include poor palatability, the development of azotemia at higher doses, and the unavailability of a convenient or FDA-approved form of the agent. Data suggest that blood urea concentrations may double during treatment,[346] but it is important to remember that this does not represent renal impairment.

Reports of retrospective, uncontrolled studies suggest that the use of urea has been effective in treating SIAD in patients with hyponatremia due to subarachnoid hemorrhage and in critical care patients,[347] and case reports have documented success in infants with chronic SIAD[348] and the nephrogenic syndrome of inappropriate antidiuresis.[349] More recent evidence from a short study in a small cohort of SIAD patients suggests that urea may have a comparable efficacy to vaptans in reversing hyponatremia due to chronic SIAD.[350] Although these reports suggest that urea might be an acceptable alternative for treatment of chronic hyponatremia, data regarding efficacy and safety of long-term urea treatment of hyponatremia are lacking.[351]

Furosemide and NaCl

The use of furosemide (20–40 mg/day) coupled with a high sodium intake (200 mEq/day) represents an extension of the treatment of acute symptomatic hyponatremia[352] in selected cases.[329,353] However, similar to urea, the efficacy of this approach to correct symptomatic hyponatremia promptly and within accepted goals limits is unknown.

Efficacy of Hyponatremia Treatment

There have been no adequately powered randomized controlled trials to compare the efficacy and safety of different treatments utilized to correct hyponatremia. However, results of a prospective observational study in a large number of hospitalized patients in the United States and the European Union provide useful data about the success rates of different therapies in euvolemic hyponatremic patients.[354,355] In this study, success was defined by three different criteria, from least to most stringent: (1) an increase in serum [Na^+] of at least 5 mmol/L, (2) correction to a serum [Na^+] of 130 mmol/L or above, and (3) correction to a normal serum [Na^+] of 135 mmol/L or above. Only 3% NaCl and tolvaptan had success rates significantly greater than 50% for the least stringent criterion, and only tolvaptan achieved this level for the next most stringent criteria and a significantly higher rate for the most stringent criteria of normalization of the serum [Na^+]. Of particular note, fluid restriction, the most frequently prescribed therapy in the Hyponatremia Registry patients, achieved a correction of serum [Na^+] in only 44% of patients treated with this therapy and isotonic saline in only 36% of patients. This is consistent with a prospective study of 183 hyponatremic patients that demonstrated that up to 60% of patients with SIAD had one or more criteria predicting nonresponse to fluid restriction (see Table 10.3).[356] These data underscore the importance of carefully selecting therapy for individual patients to meet predefined goals for correction of serum [Na^+].

Hyponatremia Treatment Guidelines Based on Symptom Severity

Although many authors have published recommendations on the treatment of hyponatremia,[310,329,357–361] no standardized treatment algorithms have yet been universally accepted, and some major differences between the various guidelines and expert recommendations exist.[326,362] For almost all treatment recommendations, the initial evaluation includes an assessment of the ECF volume status of the patient because treatment recommendations differ for hypovolemic, euvolemic, and hypervolemic hyponatremic patients.[310] Euvolemic patients, mainly including those with SIAD, represent a unique challenge because of the multiplicity

of causes and presentations of patients with SIAD. Recent expert opinion recommendations are based primarily on the neurologic symptomatology of hyponatremic patients rather than the serum [Na^+] or the chronicity of the hyponatremia, because the latter is often difficult to ascertain accurately.[310] A careful neurologic history and assessment should always be conducted to identify potential causes for the patient's symptoms other than hyponatremia, although it will not always be possible to exclude an additive contribution from the hyponatremia to an underlying neurologic condition. In this algorithm, patients are divided into three major groups based on their presenting symptoms.

Severe Symptoms. Coma, obtundation, seizures, respiratory distress or arrest, and unexplained vomiting usually imply a more acute onset or worsening of hyponatremia that requires immediate active treatment. Therapies that will quickly raise serum [Na^+] are necessary to reduce cerebral edema and decrease the risk of potentially fatal brain herniation.

Moderate Symptoms. Altered mental status, disorientation, confusion, unexplained nausea, gait instability, and falls generally indicate some degree of brain volume regulation and absence of clinically significant cerebral edema. These symptoms can be chronic or acute, but allow more time to elaborate a deliberate approach to the choice of therapies.

Mild or Absent Symptoms. Minimal symptoms, such as difficulty concentrating, irritability, altered mood, depression, or unexplained headache, or a virtual absence of discernible symptoms, indicate that the patient may have chronic or slowly evolving hyponatremia. These symptoms necessitate a cautious approach, especially when patients have underlying comorbidities, to prevent both worsening of the hyponatremia and overly rapid correction with production of ODS.

Patients with severe neurologic symptoms should be treated with hypertonic (3%) NaCl as first-line therapy, followed after 24 to 48 hours by fluid restriction and/or vaptan therapy. Because overly rapid correction of serum [Na^+] occurs in more than 10% of patients treated with hypertonic NaCl,[363] such patients are at risk for ODS unless carefully monitored. For this reason, some authors have proposed simultaneous treatment with desmopressin to reduce the rate of correction to only that produced by the hypertonic NaCl infusion itself.[364] Whether sufficient clinical data eventually prove that this approach is effective and safe in larger numbers of patients remains to be determined.[365,366] Only one case of ODS has been reported in a patient receiving vaptan monotherapy,[367] and two abstracts have reported ODS when vaptans were used directly following hypertonic saline administration within the same 24-hour period. Consequently, no additional active hyponatremia therapy should be administered until at least 24 hours following successful increases in serum [Na^+] using hypertonic NaCl.

The choice of treatment for patients with moderate symptoms will depend on their ECF volume status. Hypovolemic patients should be treated with solute repletion via isotonic NaCl infusion or oral sodium replacement. Euvolemic patients, typically with SIAD, will benefit from vaptan therapy, limited hypertonic saline administration, or in some cases urea (where available). This can be followed by fluid restriction or long-term vaptan therapy when the cause of the SIAD is expected to be chronic. In hypervolemic patients with heart failure, vaptans are usually the best choice because fluid restriction is rarely successful in this group,[368] saline administration can cause fluid retention with increased edema, and urea can lead to ammonia buildup in the GI tract if hepatic function is impaired. Although moderate neurologic symptoms can indicate that a patient is in an early stage of acute hyponatremia, they more often indicate a chronically hyponatremic state with sufficient brain volume adaptation to prevent marked symptomatology from cerebral edema. Most patients with moderate hyponatremic symptoms have a more chronic form of hyponatremia, so guidelines for goals and limits of correction should be followed closely (see Fig. 10.7), and close monitoring of these patients in a hospital setting is warranted until the symptoms improve or stabilize.

Patients with no or minimal symptoms should be managed initially with fluid restriction, although treatment with pharmacologic therapy, such as vaptans or urea, may be appropriate for a wide range of specific clinical conditions. Foremost of these is a failure to improve the serum [Na^+], despite reasonable attempts at fluid restriction, or the presence of clinical characteristics associated with poor responses to fluid restriction (see Table 10.3).

A special case is when spontaneous correction of hyponatremia occurs at an undesirably rapid rate because of the onset of water diuresis. This can occur following cessation of desmopressin therapy in a patient who has become hyponatremic, replacement of glucocorticoids in a patient with adrenal insufficiency, replacement of solutes in a patient with diuretic-induced hyponatremia, or spontaneous resolution of transient SIAD. Brain damage from ODS can clearly ensue in this setting if the preceding period of hyponatremia has been long enough (usually ≥48 hours) to allow brain volume regulation to occur. If the correction parameters discussed earlier have been exceeded and the correction is proceeding more rapidly than planned (usually because of continued excretion of hypotonic urine), the pathologic events leading to demyelination can be reversed by administration of hypotonic fluids, with or without desmopressin. The efficacy of this approach has been suggested from animal studies[369] and case reports in humans,[370] even when patients are overtly symptomatic.[371] However, relowering the serum [Na^+] after an initial, overly rapid correction is only strongly recommended for patients at high risk of ODS; it is considered optional for patients with a low-to-moderate risk of ODS, and unnecessary for patients with acute water intoxication (see Fig. 10.7).

Monitoring the Serum [Na^+] in Hyponatremic Patients

The frequency of serum [Na^+] monitoring is dependent on both the severity of the hyponatremia and the therapy chosen. All patients undergoing active treatment with hypertonic saline for symptomatic hyponatremia should have frequent monitoring of serum [Na^+], urine output, and ECF volume status (every 2–4 hours) to ensure that the serum [Na^+] does not exceed the limits of safe correction during the active phase of correction[310] since overly rapid correction of serum [Na^+] will increase the risk of ODS.[233] Patients treated with vaptans for moderate or mild symptoms should have serum [Na^+] monitored every 6 to 8 hours during the active phase of correction, which will generally be the first 24 to 48 hours of therapy. Active treatment with any therapy should be stopped when the patient's symptoms are no longer present, a safe serum [Na^+] (usually >125 mmol/L) has been achieved, or the rate of correction has reached maximum limits of 10 to 12 mmol/L within 24 hours, 18 mmol/L within 48 hours,[310,330] or 8 mmol/L over any 24-hour period in patients at high risk of ODS (see Fig. 10.7). In patients with a stable level of serum [Na^+] treated with fluid restriction or therapies other than hypertonic saline, measurement of serum [Na^+] daily is generally sufficient since levels will not change that quickly in the absence of active therapy or large changes in fluid intake or administration.

Long-Term Treatment of Chronic Hyponatremia

Some patients will benefit from continued treatment of hyponatremia following discharge from the hospital. In many cases, this will consist of a continued fluid restriction, but long-term compliance with this therapy is poor because of the increased thirst that occurs with more severe degrees of fluid restriction. Thus for select patients who have responded to tolvaptan in the hospital, consideration should be given to continuing the treatment as an outpatient after discharge. In patients with established chronic hyponatremia, tolvaptan has shown to be effective for maintaining a normal [Na^+] for as long as 3 years of continued daily therapy.[372] However, many patients with inpatient hyponatremia have a transient form of SIAD without the need for long-term therapy. Selection of which patients with inpatient hyponatremia are candidates for long-term therapy should be based on the cause of the SIAD. In all cases, consideration should be given to a trial of stopping the drug 2 to 4 weeks after discharge to determine if hyponatremia is still present. A reasonable period of tolvaptan cessation to evaluate the presence of continued SIAD is 7 days because this period was found to be sufficient for demonstration of a recurrence of hyponatremia in the tolvaptan SALT[339] and SALT-WATER trials.[372]

Findings of hepatotoxicity in a small number of patients on high doses of tolvaptan in a clinical trial of polycystic kidney disease led to a recent FDA recommendation that tolvaptan not be used for longer than 30 days. If tolvaptan is used for longer than 30 days, liver function should be assessed at regular intervals (e.g., every 3 months) at least for the first year of therapy. As is always the case, decisions about appropriate treatment of hyponatremia should be based on clinical judgment and risk/benefit analysis that is individualized for specific patients, because there is no single treatment that represents the "best" therapy for all patients with SIAD.[326]

Oxytocin

Study of the normal physiologic regulation of oxytocin secretion and action is complicated by the fact that secretion and function of oxytocin varies markedly among different experimental mammals. There are varying sites of synthesis in the ovary and in tissues of the uterus that are different among species. It is difficult to study pregnant women and human tissue, so physiologic regulation of oxytocin secretion and function is less well known in humans than other species. The classic roles of oxytocin are smooth muscle activation promoting milk letdown with nursing and uterine myometrial contraction at parturition.

Lactation

A characteristic of all mammals is lactation, and all mammals secrete oxytocin to stimulate milk letdown associated with nursing.[373] The other hormone critical to lactation is prolactin. Each of these pituitary/hypothalamic hormones is importantly influenced and regulated by gonadal steroid hormones. The milk-producing unit of the breast is the alveolar system with multiple clusters of milk-producing cells surrounded by specialized myoepithelial cells. The alveoli are directly connected to ductules, and then ducts converge and lead to the nipple. Milk is synthesized in the glandular cells of the alveoli.[374] Oxytocin receptors are localized on glandular cells, and oxytocin in the systemic circulation acts on these receptors to cause myoepithelial contraction. Oxytocin also acts on myoepithelial cells along the duct to shorten and widen the ducts to enhance milk flow through the ducts to the nipple.[375]

When an infant begins sucking at the breast, an afferent signal is transmitted from the mechanoreceptors or tactile receptors in the breast to the spinal cord and eventually ascend to the oxytocin magnocellular neurons in the supraoptic nucleus and the paraventricular nucleus.[375,376] Pulsatile release of oxytocin produces a pulsatile pumping action on the alveoli, which promotes maximum emptying of milk from the alveoli.[374] The importance of oxytocin in maintaining milk secretion is demonstrated by transgenic mice with a knockout that inhibits oxytocin synthesis. These animals deliver their young normally and have normal milk production, but there is no milk release in spite of normal suckling. The pups die of dehydration with no milk in the stomach.[377] Administration of oxytocin to these oxytocin-deficient mice rescues the ability to secrete milk and allows the pups to survive. Similarly oxytocin may promote successful lactation in women who have lactational insufficiency.[378]

As breastfeeding continues in humans, the basal levels of oxytocin decrease but pulses of oxytocin in response to suckling continue and may increase.[379] Humans with diabetes insipidus have been able to successfully breastfeed infants, and this has caused some to question the importance of oxytocin in humans.[380] However, oxytocin secretion may be preserved in the absence of vasopressin in patients with diabetes insipidus.

Parturition

The isolation of oxytocin was followed quickly by the description of oxytocin to stimulate uterine contractions, and this was followed shortly by clinical use of oxytocin as a uterotonic agent.[381] Parturition in humans is much more complex than just the role of oxytocin.[382] In all species the uterus must grow during pregnancy, and estrogen is a promoter of this growth. Levels of oxytocin in humans are not well defined in pregnancy but are not reported to increase until the expulsive stage at term.[382–384] The uterine myometrial cells have intrinsic contractile activity, but during pregnancy the uterus is maintained in a quiescent state by the actions of progesterone and relaxin (produced by the corpus luteum and decidual tissue).[385–387] The initiation of labor is accomplished by a relative increase in estrogen activation and a decrease in progesterone activation. Changes in oxytocin receptors and oxytocin produced by the placenta may be more important than levels of oxytocin in the circulation. During early labor there is an upregulation in the uterus of oxytocin receptor mRNA, and oxytocin receptor numbers increase.[384,388] Oxytocin receptors are prominent in the fundus of the uterus where they stimulate myometrial contraction and in decidual cells where they stimulate the production of prostaglandins. At parturition increased oxytocin activity in the fundus will push the fetus toward the cervix that is thinned and relaxed by the effects of prostaglandins.[383,389] Prostaglandins play a key role in an inflammatory process that is important in the uterus at parturition. Cytokines induce enzymes that digest extracellular matrix to soften and ripen the cervix.[383] The role of progesterone in maintaining uterine quiescence is not only the action on oxytocin receptors but also the antagonizing of the inflammatory response that softens the lower uterus and cervix.[384]

There are three situations in pregnancy where a pharmacologic role of oxytocin is of interest. The first situation and most widely used role of oxytocin is to induce and augment labor.[390] This has received increased interest in an effort to decrease the number of and morbidity of cesarean sections.[391] Oxytocin may be delivered alone or in combination with another pharmacologic agent such as propranolol or prostaglandins.[391,392] The second area of interest

is preterm labor with an effort toward prevention by decreasing contractile activity of the uterus and/or inhibiting the inflammatory response.[393] Peptide and nonpeptide oxytocin antagonists have been of special interest to inhibit myometrial contractions, but widespread clinical use awaits the development of antagonist with better risk/benefit activity.[394] The third pharmacologic interest in oxytocin is as a uterotonic to decrease postpartum hemorrhage associated with uterine atony.[395] Postpartum hemorrhage is the major cause of maternal deaths worldwide and ranks second to embolism as a cause of maternal death in the United States.[396] Mechanical options in the active management of the third stage of labor include cord traction to reduce the risk of retained placenta and uterine massage, which has been augmented by pharmacologic agents, most commonly oxytocin and/or ergotamine.[395] Maternal death by postpartum hemorrhage is most significant in developing countries. Oxytocin is heat labile and requires a trained staff for appropriate administration,[397] prompting a search for other agents. Promising results have been reported with prostaglandin analogues (e.g., misoprostol).[394,395,398]

Behavior

This chapter is about functions of vasopressin and oxytocin as traditional endocrine hormones secreted by the posterior pituitary. For further discussion related to these hormones in purported functions as neurotransmitters, especially with regard to influencing social and ingestive behaviors, the reader is referred to Chapters 9 and 20.

Thyroid Pathophysiology and Diagnostic Evaluation

DOMENICO SALVATORE, RONALD COHEN, PETER A. KOPP, AND P. REED LARSEN

CHAPTER OUTLINE

KEY POINTS

- This chapter illustrates the principal events involved in the ontogeny and development of the thyroid gland in many life forms, ranging from invertebrates to humans.
- The thyroid gland anatomy and function and the pivotal role played by iodine in thyroid economy are described.
- The key molecular elements and mechanisms involved in thyroid hormone action and metabolism in peripheral tissues are reviewed.
- This chapter also dissects the mechanisms responsible for thyroid hormone homeostasis and function under physiologic and pathologic conditions.
- In addition, this chapter provides the physiologic rationale and expected results for the various tests that can be used in the biochemical evaluation of patients with clinical thyroid dysfunction or disease.

Dysfunction and anatomic abnormalities of the thyroid are among the most common diseases of the endocrine glands. This chapter provides the physiologic and biochemical background and describes the various tests for evaluating patients with suspected thyroid dysfunction based on the pathophysiology of these conditions.

Phylogeny, Embryology, and Ontogeny

Phylogeny

The phylogeny, embryogenesis, and certain aspects of thyroid function are closely interlinked with the gastrointestinal tract. The capacity of the thyroid to metabolize iodine and incorporate it into a variety of organic compounds occurs widely throughout the animal and plant kingdoms. However, the anatomy of the thyroid gland differs considerably among the vertebrate classes. Monoiodotyrosine (3′-monoiodo-L-tyrosine [MIT]) and diiodotyrosine (3,5-diiodo-L-tyrosine [DIT]) are present in a variety of invertebrate species, including mollusks, crustaceans, coelenterates, annelids, insects, and certain marine algae. In these lower forms, however, no recognizable thyroid tissue is present. Thyroid tissue is confined to, and is present in, all vertebrates. A close link to the thyroid of higher vertebrates is evident in the ammocoete, the larval form of the lamprey, where the ventral part of the pharynx is the origin of a structure present only during larval life, the endostyle. The epithelium of the endostyle is capable of carrying out iodinations, and these cells are fated to become follicular cells only after metamorphosis, when they will form classic thyroid follicles.[1]

The phylogenetic association of the thyroid gland and the gastrointestinal tract is evident in several functions. The salivary and gastric glands, like the thyroid, are capable of concentrating iodide in their secretions, although iodide transport in these sites is not responsive to stimulation by thyrotropin (TSH, thyroid-stimulating hormone). The salivary gland contains enzymes that are capable of iodinating tyrosine in the presence of hydrogen peroxide, although it forms insignificant quantities of iodoproteins under normal circumstances.

Structural Embryology

The morphogenesis of the thyroid gland, the anterior-most organ that buds from the gut tube, begins with a thickening of the endodermal epithelium in the foregut, which is referred to as the *thyroid anlage*. The human thyroid anlage is first recognizable

at embryonic day 16 or 17. This median thickening deepens and forms first a small pit and then an outpouching of the endoderm adjacent to the developing myocardial cells. With continuing development, the median diverticulum is migrating caudally, following the myocardial cells in their descent. The primitive stalk connecting the primordium with the pharyngeal floor elongates into the thyroglossal duct. During its caudal migration, the primordium assumes a bilobate shape, coming into contact and fusing with the ventral aspect of the fourth pharyngeal pouch when it reaches its final position at about embryonic day 50. Normally the thyroglossal duct undergoes dissolution and fragmentation by about the second month after conception, leaving at its point of origin a small dimple at the junction of the middle and posterior thirds of the tongue, the *foramen caecum.* Cells of the lower portion of the duct differentiate into thyroid tissue, forming the pyramidal lobe of the gland. At this time, the lobes contact the ultimobranchial glands, leading to the incorporation of C cells into the thyroid. Concomitantly, histologic alterations occur throughout the gland. Complex interconnecting cordlike arrangements of cells interspersed with vascular connective tissue replace the solid epithelial mass and become tubule-like structures at about the third month of fetal life; shortly thereafter, follicular arrangements devoid of colloid appear, and by 13 to 14 weeks the follicles begin to fill with colloid. Investigations of thyroid gland development in mice using gene-targeting techniques are beginning to identify the critical factors that are required for normal thyroid gland development.[2,3] The role of these various proteins is currently being evaluated with respect to the potential for defects in the synthesis or formation of the thyroid gland (see Chapter 13).

Functional Ontogeny

The ontogeny of thyroid function and its regulation in the human fetus are fairly well defined.[4,5] Future follicular cells acquire the capacity to form thyroglobulin (Tg) as early as the 29th day of gestation, whereas the capacities to concentrate iodide and synthesize thyroxine (T_4) are delayed until about the 11th week. Radioactive iodine inadvertently given to the mother would be accumulated by the fetal thyroid soon thereafter. Early growth and development of the thyroid do not seem to be TSH dependent because the capacity of the pituitary to synthesize and secrete TSH is not apparent until the 14th week. Subsequently, rapid changes in pituitary and thyroid function take place. Probably as a consequence of hypothalamic maturation and increasing secretion of thyrotropin-releasing hormone (TRH), the serum TSH concentration increases between 18 and 26 weeks of gestation, after which levels remain higher than those in the mother.[4] The higher levels may reflect a higher set-point of the negative feedback control of TSH secretion during fetal life than at maturity. Thyroxine-binding globulin (TBG), the major thyroid hormone–binding protein in plasma, is detectable in the serum by the 10th gestational week and increases in concentration progressively to term. This increase in TBG concentration accounts in part for the progressive increase in the serum T_4 concentration during the second and third trimesters, but increased secretion of T_4 must also play a role because the concentration of free T_4 also rises.

Several aspects of thyroid development are of note from a clinical standpoint. Rarely, thyroid tissue may develop from remnants of the thyroglossal duct near the base of the tongue. Such lingual thyroid tissue may be the sole functioning thyroid present, and thus its surgical removal will lead to hypothyroidism. More commonly, elements of the thyroglossal duct may persist and later give rise to thyroglossal duct cysts, or ectopic thyroid tissue may be present at any location in the mediastinum or, rarely, even in the heart.

Anatomy and Histology

The thyroid is one of the largest of the endocrine organs, weighing approximately 15 to 20 g in North American adults. Moreover, the potential of the thyroid for growth is tremendous. The enlarged thyroid, commonly termed *goiter,* can weigh many hundreds of grams. The normal thyroid is made up of two lobes joined by a thin band of tissue, the isthmus, which is approximately 0.5 cm thick, 2 cm wide, and 1 to 2 cm high. The individual lobes normally have a pointed superior pole and a poorly defined blunt inferior pole that merges medially with the isthmus. Each lobe is approximately 2 to 2.5 cm in thickness and width at its largest diameter and is approximately 4 cm in length. Occasionally, especially when the remainder of the gland is enlarged, a pyramidal lobe is discernible as a finger-like projection directed upward from the isthmus, generally just lateral to the midline, usually on the left. The right lobe is normally more vascular than the left, is often the larger of the two, and tends to enlarge more in disorders associated with a diffuse increase in gland size. Two pairs of vessels constitute the major arterial blood supply: the superior thyroid artery, arising from the external carotid artery, and the inferior thyroid artery, arising from the subclavian artery. Estimates of thyroid blood flow range from 4 to 6 mL/minute/g, well in excess of the blood flow to the kidney (3 mL/minute/g). In a diffuse toxic goiter due to Graves disease, blood flow may exceed 1 L/minute and be associated with an audible bruit or even a palpable thrill.

The gland is composed of closely packed spherical units termed *follicles,* which are invested with a rich capillary network. The interior of the follicle is filled with the clear proteinaceous colloid that normally is the major constituent of the total thyroid mass. On cross section, thyroid tissue appears as closely packed, ring-shaped structures consisting of a single layer of thyroid cells surrounding a lumen. The diameter of the follicles varies considerably, even within a single gland, but averages about 200 nm. The follicular cells vary in height with the degree of glandular stimulation, becoming columnar when active and cuboidal when inactive. The epithelium rests on a basement membrane that is rich with glycoproteins separating the follicular cells from the surrounding capillaries. From 20 to 40 follicles are demarcated by connective tissue septa to form a lobule supplied by a single artery. The function of a given lobule may differ from that of its neighbors.

On electron microscopy, the thyroid follicular epithelium has many features in common with other secretory cells and some peculiar to the thyroid. From the apex of the follicular cell, numerous microvilli extend into the colloid. It is at or near this surface of the cell that iodination, exocytosis, and the initial phase of hormone secretion, *colloid resorption,* occur (Fig. 11.1). The nucleus has no distinctive features, and the cytoplasm contains an extensive endoplasmic reticulum (ER) laden with microsomes. The ER is composed of a network of wide irregular tubules that contain the precursor of Tg. The carbohydrate component of Tg is added to this precursor in the Golgi apparatus, which is located apically. Lysosomes and mitochondria are scattered throughout the cytoplasm. Stimulation by TSH results in enlargement of the Golgi apparatus, formation of pseudopodia at the apical surface, and the appearance in the apical portion of the cell of many droplets that contain colloid taken up from the follicular lumen (see Fig. 11.1).

The thyroid also contains parafollicular cells, or C cells, which are the source of calcitonin. The traditional view was that these

cells derive from the neural crest, but newer lineage tracing data suggest that they arise also in the endoderm.[6] Ultimately they come to rest either among the cells of the follicular epithelium or in the thyroid interstitium. They differ from the cells of the follicular epithelium in never bordering on the follicular lumen and in being rich in mitochondria. The C cells, detected also in human lingual thyroids,[7] undergo hyperplasia early in the syndrome of familial medullary carcinoma of the thyroid (multiple endocrine neoplasia type 2 [MEN2]) and give rise to this tumor in both its familial and its sporadic forms (see Chapter 42).

Iodine and the Synthesis and Secretion of Thyroid Hormones

The function of the thyroid is to generate the quantity of thyroid hormone necessary to meet the demands of the peripheral tissues. This action requires iodide uptake by the thyroidal sodium-iodide symporter (NIS), its transfer to the colloid, and its oxidation by thyroid peroxidase (TPO) to allow the synthesis of approximately 110 nmol/L (85 μg) of T_4, which is 65% iodine by weight. This requires the synthesis of an approximately 330-kDa glycoprotein, Tg. Specific tyrosine residues of Tg homodimers are then iodinated at the apical border of the thyroid cell to form MIT and DIT (see Fig. 11.1). This requires formation of hydrogen peroxide (H_2O_2) by dual oxidases (DUOX1 and 2) and TPO, which catalyzes the oxidation of iodide and its transfer to tyrosine. TPO also catalyzes the coupling of two molecules of DIT or one of DIT and one of MIT, leading to formation of T_4 and triiodothyronine (T_3), respectively, which are then stored within the colloid, still as part of the Tg molecule. Pinocytosis of stored colloid leads to the formation of phagolysosomes, the colloid droplets in which Tg is digested by specific proteases to release T_4, T_3, DIT, and MIT as the droplet is translocated toward the basal portion of the cell. T_4 and T_3 are transported out of the phagolysosomes and across the basolateral cell membrane, at least in part by MCT8, to exit the cell and enter circulation, whereas DIT and MIT are deiodinated by iodotyrosine dehalogenase (DEHAL1) to allow recycling of the iodide. The synthesis of thyroid hormones requires the expression of a number of thyroid cell–specific proteins. In addition to Tg and TPO, the TSH receptor (TSHR) is also required to transduce the effects of extracellular TSH for efficient hormone synthesis. A number of transcription factors, including thyroid transcription factors TTF1 (NKX2-1) and TTF2 (FOXE1), PAX8, and hepatocyte nuclear factor 3 (HNF3 [FOXE2]), as well as TSH, are necessary to achieve functional differentiation of the thyroid follicular cells and the onset of hormonogenesis.[1,3] Transient overexpression of the transcription factors NKX2-1 and PAX8 is sufficient to direct mouse embryonic stem cell (mESC) differentiation into thyroid follicular cells that organize into three-dimensional follicular structures when treated with TSH, and follicles show significant iodide organification activity.[8] Although the biochemical

details of these processes are beyond the scope of this discussion, those aspects with clinical relevance are reviewed in greater detail in the following section.

Dietary Iodine

Formation of normal quantities of thyroid hormone requires the availability of adequate quantities of exogenous iodine to allow thyroidal uptake of approximately 60 to 75 μg daily, taking into account the fecal losses of about 10 to 20 μg iodine of iodothyronines as glucuronides and about 100 to 150 μg as urinary iodine in iodine-sufficient populations.[9] Plasma iodide (I^-), the form of the element in biologic solutions, is completely filterable with about 60% to 70% of the filtered load reabsorbed. At least 100 μg of iodine per day is required to eliminate all signs of iodine deficiency (Table 11.1). In healthy adults, the absorption of iodide is greater than 90%. In North America, the daily dietary iodine intake is in the range of 150 to 300 μg, largely owing to the iodination of salt; in Japan, however, where large quantities of foods rich in iodine are consumed, intakes may be as high as several milligrams per day. Notably, iodine intake in the United States is decreasing due to a reduction in salt consumption, with median urinary iodine of 160 μg/L but a low urinary iodine (<5 μg/dL) in close to 10% of the population.[10] The daily dietary intake of iodine varies widely throughout the world, depending on the iodine content of soil and water and on dietary practice (see Table 11.1) (Iodine Global Network; http://www.ign.org/). Even in a single area, iodine intake varies among different individuals and in the same individual from day to day. Iodine may also enter the body via medications, diagnostic agents, dietary supplements, and food additives. As discussed more extensively under "Regulation of Thyroid Function," iodine deficiency is common, especially in mountainous and formerly glaciated regions of the earth.[11] An estimated 1 billion individuals live in iodine-deficient areas of the world, and these people often develop TSH-induced compensatory enlargement of the thyroid *(endemic goiter)*. If iodine deficiency is severe during pregnancy, fetal thyroid hormone production falls with irreparable damage to the developing central nervous system (CNS). This damage is manifested by varying degrees of mental retardation and is termed *endemic cretinism*. Thus iodine-deficiency disorders (IDDs), including endemic goiter and cretinism, are the most common thyroid-related human illnesses; indeed, they are the most common endocrine disorders worldwide. Iodine deficiency is also the most prevalent preventable cause of mental impairment.

Plasma iodide is partly replenished by that lost from the thyroid into the blood and by iodide liberated through deiodination of iodothyronines in peripheral tissues. Ultimately, however, the diet is its most important source. Iodine is ingested in both inorganic and organically bound forms. Iodide per se is rapidly and efficiently absorbed from the gastrointestinal tract (within 30 minutes), and little is lost in the stool. In the body, iodide is confined largely to the extracellular fluid. It is also found, however, in red blood cells and is concentrated in the intraluminal fluids of the gastrointestinal tract, notably the saliva and gastric juice, from which it is reabsorbed, thus reentering the extracellular fluid. Iodide is also concentrated in milk. Until oxidized and organified on tyrosyl residues in Tg, iodide entering the thyroid by active transport is in rapid equilibrium with the main iodide pool. The concentration of iodide in the extracellular fluid is normally 10 to 15 μg/L (~10^{-7} mol/L), and the content of the peripheral pool is approximately 250 μg. The thyroid contains the largest pool of body iodine, under normal circumstances approximately 8000 μg, most of which is in the form of DIT and MIT. Normally this pool of iodine turns over slowly (about 1% per day).

TABLE 11.1 Recommended and Typical Values for Dietary Iodine Intake

Recommended Daily Intake	
Adults	150 μg
During pregnancy[a]	220 μg
Children	90–120 μg
Median Urinary Iodine Concentrations[b]	
United States (2010)	213 μg
China (2017)	239 μg
Belgium (2011)	113 μg
Switzerland (2015)	137 μg
Russia (2004)	78 μg

[a]Recommendations by the Institute of Medicine, Food and Nutrition Board.

The World Health Organization (WHO), United Nations Children's Fund (UNICEF), and the International Council for the Control of Iodine Deficiency Disorders (ICCIDD) recommend a slightly higher iodine intake for pregnant women of 250 μg/day.

[b]Data from Iodine Global Network, http://www.ign.org/.

Iodide Metabolism by the Thyroid Cell

The spherical thyroid follicle, which is formed by a single layer epithelium of thyroid cells surrounding the lumen, is the functional unit of the thyroid and its integrity is essential for the synthesis of thyroid hormones. Because the concentration of iodide in plasma is so low, a mechanism is required for the thyroid cell to concentrate the required amounts of this element. This process, iodide trapping, is accomplished by a membrane protein, the sodium-iodide symporter NIS, encoded by the *SLC5A* gene. Human NIS is a 643–amino acid glycoprotein with 13 membrane-spanning domains. The transport of iodide is an active process dependent on the presence of a sodium gradient across the basal membrane of the thyroid cell such that downhill transport of two Na^+ ions results in the entry of one iodide atom against an electrochemical gradient (see Fig. 11.1). In addition to being expressed in the basolateral membrane of the thyroid cell, NIS has also been identified in other iodide-concentrating cells, including salivary and lactating mammary glands, choroid plexus, and gastric mucosa, and in the cytotrophoblast and syncytiotrophoblast.[12,13] NIS is also expressed in the ovary and testis and in ovarian cancer and the majority of seminomas and embryonal testicular carcinomas.[14] In the lactating mammary gland, NIS plays an important role by concentrating iodide in the milk, thereby supplying newborns with iodide for thyroid hormone synthesis. The iodide transport system generates an iodide gradient of 20 to 40 across the cell membrane, and NIS also transports pertechnetate (TcO_4^-), perchlorate (ClO_4^-), and thiocyanate (SCN^-), accounting for the utility of radioactive TcO_4^- as a thyroid scanning tool and the capacity of $KClO_4^-$ to block iodide uptake as a competitive inhibitor.[15,16] The affinity of NIS for iodide is much higher than it is for the other inorganic halide anions, such as bromide and chloride, accounting for the selectivity of the thyroid transport mechanism.[17]

Transcription of the *NIS* gene is increased by TSH, and TSH also prolongs NIS protein half-life and targets the protein to the cell membrane. Iodide uptake by NIS and the organification process are inversely regulated by high intracellular iodide concentrations (Wolff-Chaikoff effect; see later).[18]

That the iodide-concentrating mechanism is required for normal thyroid function has been known for decades in that its absence is associated with congenital hypothyroidism and goiter unless large quantities of inorganic iodide are provided.[19] A number of families have now been identified in which biallelic mutations in the *NIS* gene are associated with an iodide transport defect, resulting in congenital hypothyroidism. Importantly, several studies have documented decreases in NIS expression in human thyroid adenomas and carcinomas that contribute to the loss of iodine uptake in neoplastic thyroid cells, which therefore present as "cold" nodules on radioisotopic imaging.[19] However, changes in the subcellular location of NIS may also explain this phenomenon. At the apical membrane, iodide must enter the follicular lumen. This process is thought to involve pendrin, a highly hydrophobic membrane glycoprotein and multianion exchanger located at the apical membrane of thyrocytes.[20,21] In addition to the thyroid, pendrin is also expressed in the kidney and in the inner ear.[22] In the kidney, pendrin plays an important role in acid-base metabolism as a chloride/bicarbonate exchanger.[23] In the inner ear, pendrin is important for generation of the endocochlear potential.[19] Pendrin belongs to the SLC26A family and is encoded by the *SLC26A4* gene. Mutations in the *SLC26A4* gene lead to Pendred syndrome, an autosomal recessive disorder characterized by sensorineural deafness, goiter, and a partial defect in iodide organification.[24,25] Deafness or hearing impairment is the major phenotypic manifestation in Pendred syndrome. Goiter usually develops during childhood, and under conditions of scarce iodine intake, some individuals with biallelic mutations in pendrin present with congenital hypothyroidism. There is, however, a substantial variation within and between families and different geographic regions. This observation along with the absence of thyroid dysfunction in mice with targeted inactivation of the *Slc26A4* gene suggest that iodide efflux can also occur in the absence of pendrin.[21] Anoctamin 1 (ANO1/TMEM16A), a calcium-activated anion channel, which is also expressed at the apical membrane of thyrocytes, may also be involved in mediating apical efflux.[26,27]

Iodide Oxidation and Organification

After reaching the follicular lumen, iodide participates in a series of reactions that lead to the synthesis of the active thyroid hormones. The first of these involves oxidation of iodide and incorporation of the resulting intermediate into the hormonally inactive iodotyrosines MIT and DIT, a process termed *organification*. Iodide is normally oxidized rapidly, immediately appearing in organic combination with Tg. The iodinations that lead to formation of iodotyrosines occur within Tg, rather than on the free amino acids. Oxidation of thyroidal iodide is mediated by the heme-containing protein TPO and requires the H_2O_2 generated by the calcium-dependent DUOX1 and DUOX2 enzymes. The protein contains a membrane-spanning region near the carboxy-terminus, and it is oriented in the apical membrane of the thyroid cell with residues 1-844 in the follicular lumen in which iodination occurs (see Fig. 11.1). TPO is the major thyroid microsomal antigen, and recombinant human TPO is now used for the detection of antithyroid microsomal antibodies commonly present in the serum of patients with Hashimoto thyroiditis. The evanescent product of the peroxidation of iodide (i.e., the active iodinating form) remains unclear and hypoiodite (OI^-), hypoiodous acid (HOI), or iodonium (I^+) have been proposed.[28] The *DUOX1* and *DUOX2* genes encode glycoflavoproteins predominantly expressed at the apical thyrocyte membrane where they constitute the catalytic core of the H_2O_2 generator required for thyroid hormone synthesis (see Fig. 11.1).[29] They are Ca^{2+}, NADPH-dependent oxidases that catalyze the formation of the H_2O_2 required for TPO-catalyzed Tg iodination. The maturation factor DUOXA2, a resident ER protein, is required for the maturation, plasma membrane localization of DUOX2, and H_2O_2 generation.[30] Iodide excess inhibits DUOX2 glycosylation, which may be an additional mechanism contributing to the Wolff-Chaikoff effect.[31]

The rate of organic iodination is dependent on the degree of thyroid stimulation by TSH (see later). Congenital defects in the organification process cause goitrous congenital hypothyroidism or, if less severe, goiter without hypothyroidism (complete or partial iodide organification defect).[32] They can be caused by usually biallelic mutations in the *TG, SLC26A4, TPO, DUOX2,* and *DUOX2A* genes. Complete or partial TPO defects are among the most frequent causes of abnormal thyroid hormone biosynthesis.[33] Mutations in the *DUOX2* and *DUOXA2* genes have been identified in patients with permanent and transient congenital hypothyroidism, and digenic mutations in *DUOX1* and *DUOX2* have been found in a family with very severe congenital hypothyroidism (see Chapter 13).[34,35]

Iodothyronine Synthesis

The MIT and DIT are precursors of the hormonally active iodothyronines T_4 and T_3. Synthesis of T_4 from DIT requires the TPO-catalyzed fusion of two DIT molecules to yield a structure with two diiodinated rings linked by an ether bridge (the coupling reaction). Concomitantly, a residual dehydroalanine is formed at the site of the DIT residue contributing to the phenolic hydroxyl group.

Efficient synthesis of T_4 and T_3 in the thyroid requires Tg.[36] The Tg messenger RNA (mRNA) is approximately 8.5 kb in length and encodes a 330-kDa (12S) subunit that is 10% carbohydrate by weight. There are 134 tyrosyl residues in the 660-kDa homodimer. Only 25 to 30 of these are iodinated, but only residues 5, 1290, and 2553 form T_4 and residue 2746, T_3.[37] The T_4-forming, readily iodinated, and iodothyronine-forming acceptor residues of Tg from different species are in a Glu/AspTyr or a Thr/SerTyrSer sequence, suggesting an important role of primary sequence in these reactions. There are three to four T_4 molecules in each molecule of human Tg under conditions of normal iodination (25 atoms per Tg molecule, approximately 0.5% iodine by weight), but only about one in five molecules of human Tg contains a T_3 residue. In Tg from patients with untreated Graves disease, the content of T_4 residues remains approximately the same, but the number of T_3 residues doubles to an average of 0.4 per molecule. This difference is independent of the iodination state of the Tg and is a consequence of thyroidal stimulation. Because the coupling reaction is catalyzed by TPO, virtually all agents that inhibit organic binding (e.g., the thiourea drugs) also inhibit coupling.

Storage and Release of Thyroid Hormone

The thyroid is unique among the endocrine glands by virtue of the large store of hormone it contains and the low rate at which the

hormone turns over (1% per day). This aspect of thyroid hormone economy has homeostatic value in that the reservoir provides prolonged protection against depletion of circulating hormone in case synthesis ceases. In normal humans, the administration of antithyroid agents for as long as 2 weeks has little effect on serum T_4 concentrations. There are approximately 250 μg T_4 per gram of wet weight in normal human thyroid, or 5000 μg of T_4 in a 20-g gland.[38] This amount is sufficient to maintain a euthyroid state for at least 50 days. When released rapidly in an uncontrolled fashion during subacute or painless thyroiditis, this quantity of T_4 will cause significant transient thyrotoxicosis. Tg is present in the plasma of normal individuals at concentrations up to 50 ng/mL, probably leaving the thyroid through the lymphatics. However, peripheral hydrolysis of Tg does not contribute significantly to the thyroid hormones in the circulation, even during thyroiditis, when large quantities of this protein are present.

The first step in thyroid hormone release is the endocytosis of colloid from the follicular lumen by two processes: macropinocytosis by pseudopods formed at the apical membrane and micropinocytosis by small coated vesicles that form at the apical surface (see Fig. 11.1). Both processes are stimulated by TSH, but the relative importance of the two pathways varies among species, with micropinocytosis thought to predominate in humans. Following endocytosis, endocytotic vesicles fuse with lysosomes, and proteolysis is catalyzed by cathepsin D and D-like thiol proteases, all of which are active at the acidic pH of the lysosome. The iodotyrosines MIT and DIT released from Tg are rapidly deiodinated by the NADPH-dependent iodotyrosine deiodinase DEHAL1/IYD, and the released iodine is recycled.[39] Thyroid hormones are released from Tg in the lysosome, but it is not entirely clear how their transfer into the cytosol and subsequently the plasma is affected. Exit at the basolateral membrane involves, at least in part, the thyroid hormone transporter MCT8.[40] It has been shown that T_4 can be released from Tg within the thyroid cell with minimal disruption of its molecular weight. This presumably is a consequence of selective proteolysis, which is facilitated by the fact that the major hormonogenic peptides of the Tg molecule are located at the amino-terminus and the carboxy-terminus of the Tg monomer.

Presumably the T_4 becomes accessible to the thyroidal type 1 and 2 deiodinases (D1 and D2) because basal and TSH-stimulated conversion of T_4 to T_3 is readily demonstrated in the perfused dog thyroid. Because this conversion is inhibited by propylthiouracil (PTU), it is catalyzed by D1 (Table 11.2). The contribution of thyroidal T_4 deiodination to T_3 secretion in humans under physiologic conditions is not known. The fact that the ratio of T_4 to T_3 in human Tg is 15:1, although estimates of the molar ratio of T_4 to T_3 in thyroid secretion is approximately 10:1, suggests that this does occur. Stimulation of D1-catalyzed and D2-catalyzed 5′-deiodination of T_4 in the thyroid gland of patients with Graves disease may enhance that pathway and contribute to the marked increase of the ratio of T_3 to T_4 production in that condition.[41] An inhibition of the D1-catalyzed T_4 to T_3 conversion may contribute to the rapid effect of PTU to reduce circulating T_3 in patients with Graves disease (see Chapter 12).[41,42] That deiodinases in thyroid-derived cells can modulate the systemic conversion of T_4 to T_3 has been shown in several patients with metastatic thyroid carcinoma. The high expression of D2 in one large mediastinal tumor mass was associated with a high normal T_3 and reduced T_4 with a normal TSH. Removal of the tumor reversed these abnormalities.[43]

T_4 release from the thyroid cells is inhibited by several agents, the most important of which is iodide. Inhibition of hormone release is responsible for the rapid improvement that iodide causes in hyperthyroid patients. The mechanism by which this effect is mediated is uncertain, but iodide inhibits the stimulation of thyroid adenylate cyclase by TSH and by the stimulatory immunoglobulins of Graves disease. Increasing iodination of Tg also increases its resistance to hydrolysis by acid proteases in the lysosomes. Lithium inhibits thyroid hormone release, although its mechanism of action is poorly understood and may differ from that of iodide.[44]

Deiodination of Iodotyrosines

In addition to the active transport of iodide from the extracellular fluid, intracellular iodide is also generated by the action of the DEHAL1 or iodotyrosine deiodinase (IYD) enzyme. IYD catalyzes nicotinamide adenosine dinucleotide phosphate (NADPH)–dependent deiodination of MIT and DIT, with greater activity against MIT.[45] *Dhal1* transcription is stimulated by cyclic adenosine monophosphate (cAMP) and encodes a membrane protein concentrated at the apical cell surface, which catalyzes NADPH-dependent deiodination of MIT and DIT and recycles iodide. The iodide thereby released is immediately reconjugated to newly synthesized Tg after exiting the apical membrane of the cell. This process is interrupted by the thiourea class of antithyroid drugs that inhibit TPO, such as methimazole (MMI), carbimazole (CBZ), and PTU, thus causing intrathyroidal iodine deficiency in patients receiving these agents.[38] Biallelic mutations in the *IYD* gene have been identified in patients with hypothyroidism, goiter, and an elevated DIT level.[39] Functional studies revealed that the mutations abolished the capacity of IYD to deiodinate MIT and DIT.

Role and Mechanism of Thyrotropin Effects

All steps in the formation and release of thyroid hormones are stimulated by TSH secreted by the pituitary thyrotrophs (see Chapter 8). Thyroid cells express the TSHR, a member of the glycoprotein G protein–coupled receptor family. This protein contains a large extracellular amino-terminal domain, seven membrane-spanning domains, and an intracellular domain that transduces the signal by promoting exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on the α-subunit of G proteins.[46] In fact, the TSHR has been reported to couple to 11 different G protein α-subunits in vitro, and therefore much remains to be learned about signaling through it. Although the TSHR mainly couples to G_s, when activated by high concentrations of TSH (100 times physiologic levels), it couples also to G_q/G_{11}, activating the inositol-phosphate diacylglycerol cascade. The induction of signal via the phospholipase C (PLC) and intracellular Ca^{2+} pathways regulates iodide efflux, H_2O_2 production, and Tg iodination, whereas the signal via the protein kinase A (PKA) pathways mediated by cAMP stimulates growth and regulates iodine uptake and transcription of Tg, TPO, and the NIS mRNAs leading to thyroid hormone production (Table 11.3).[47] Although the discovery that different mutations in various regions of the TSHR molecule result in intrinsic activation and the identification of important domains for intramolecular TSHR signal transduction (see Chapter 12), the precise mechanisms of receptor activation and the early events of TSHR signal transduction are not fully understood.[46] Remarkably, the wild-type TSHR itself displays constitutive activity, a phenomenon that is not shared by the closely related

TABLE 11.2 Human Iodothyronine Selenodeiodinases

Parameter	Type 1 (Outer and Inner Ring)	Type 2 (Outer Ring)	Type 3 (Inner Ring)
Physiologic role	rT_3 and T_3S degradation, the source of plasma T_3 in thyrotoxic patients	Provide intracellular T_3 in specific tissues, a source of plasma T_3	Inactivate T_3 and T_4
Tissue location	Liver, kidney, thyroid, pituitary (?) (not CNS)	CNS, pituitary, BAT, placenta thyroid, skeletal muscle, heart	Placenta, CNS, fetal or adult liver, skeletal muscle
Subcellular location	Plasma membrane	Endoplasmic reticulum	Plasma membrane

Pathway	
Thyroid Hormone Secretion	
Pinocytosis of thyroglobulin	cAMP
Release of thyroglobulin into plasma via basolateral membrane	cAMP (?)
Thyrocyte Proliferation and Differentiation	
Mitogenesis, differentiation	cAMP, PLC, and $IGFI^-$ and FGF-mediated kinase activation

cAMP, Cyclic adenosine monophosphate; *FGF,* follicular growth factor; *IGF,* insulin-like growth factor; I^-, plasma iodide; *NADPH,* nicotinamide adenosine dinucleotide phosphate; *NIS,* sodium-iodide symporter; *PLC,* phospholipase C; *TPO,* thyroid peroxidase.

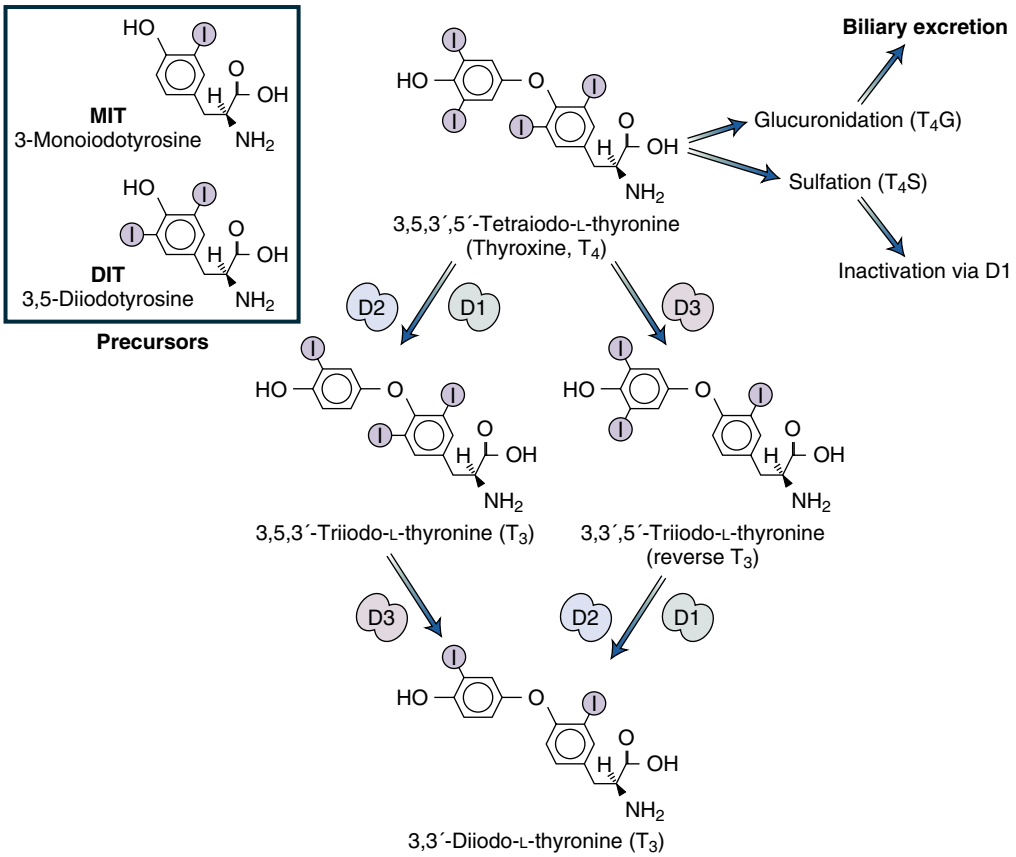
receptors for luteinizing hormone/chorionic gonadotropin (LH/CG) and follicle-stimulating hormone (FSH). This suggests that the unliganded TSHR might be less constrained than other G protein–coupled seven-transmembrane receptors.[46]

The TSHR, in addition to the TSH, also binds TSHR-stimulating antibody (TRAb), thyroid-blocking antibodies (TBAb), and neutral antibodies to the TSHR (see Chapter 12). The closely related luteinizing hormone and chorionic gonadotropin also bind to and activate TSHR signaling when present at high levels.[48] The latter accounts for the physiologic hyperthyroidism of early pregnancy. Besides the thyrocyte, the TSHR is also expressed in a variety of tissues such as osteoclasts, fibroblasts, and adipocytes, as well as retroorbital adipocytes and skin.[48,49] Activating mutations in the TSHR in the germline cause congenital nonautoimmune hyperthyroidism; somatic gain-of-function mutations result in toxic adenomas.[50] In contrast, biallelic inactivating mutations in the TSHR result in congenital hypothyroidism with thyroid hypoplasia or, in the case of partial inactivation, euthyroid hyperthyrotropinemia.[46]

Thyroid Hormones in Peripheral Tissues

Plasma Transport

The metabolic transformations of thyroid hormones in peripheral tissues determine their biologic potency and regulate their biologic effects. Consequently, an understanding of thyroid physiopathology requires knowledge of the pathways of thyroid hormone metabolism. A wide variety of iodothyronines and their metabolic derivatives exist in plasma. Of these, T_4 is highest in concentration and the only one that arises solely from direct secretion by the thyroid gland. In normal humans, T_3 is also released from the thyroid, but approximately 80% is derived from the peripheral tissues by the enzymatic removal of a single 5′ iodine atom (outer ring or 5′ monodeiodination) from T_4.[51] The remaining iodothyronines and their derivatives are generated in the peripheral tissues from T_4 and T_3. Principal among them are 3,3′,5′-triiodothyronine (reverse T_3, or rT_3) and 3,3′-diiodo-L-thyronine (3,3′-T_2) (Fig. 11.2). Trace concentrations of other diiodothyronines, monoiodothyronines, and conjugates thereof with glucuronic or sulfuric acid are also present.[52] Deaminated derivatives of T_4 and T_3 that bear an acetic acid rather than an alanine side chain (tetrac and triac) are also present in low concentrations. 3-Iodothyronamine (T1AM) is an endogenous thyroid hormone derivative with unknown biosynthetic origins.[53] Structural similarities have led to the hypothesis that T1AM is an extrathyroidal metabolite of T_4.



• **Fig. 11.2** Major deiodinative and nondeiodinative pathways of thyroid hormone metabolism. The iodothyronine deiodinases are abbreviated *D1, D2,* and *D3* for type 1, 2, and 3 deiodinases, respectively. *Arrows* refer to monodeiodination of the outer or inner ring of the iodothyronine nucleus, which are termed 5′ or 5 by convention. T_4 is activated by monodeiodination of the phenolic thyronine ring by D1 or D2 to form T_3. Deiodination of the tyrosyl ring by D1 or D3 inactivates T_4 and T_3. This inactivation pathway is markedly favored by sulfation of the phenolic hydroxyl to form T_4SO_4 (T_4S) or T_3SO_4 (T_3S). Glucuronidated T_4 and T_3 (T_4G and T_3G) are excreted into the bile but may be partially reabsorbed after deglucuronidation in the intestine.

The major iodothyronines are poorly soluble in water and thus bind reversibly to plasma proteins. The plasma proteins with which T_4 is mainly associated are TBG and transthyretin (TTR; formerly termed T_4-binding prealbumin [TBPA]) and albumin (Table 11.4). About 75% to 80% of T_3 is bound by TBG and the remainder by TTR and albumin.

Thyroxine-Binding Globulin

TBG is a glycoprotein with a molecular mass of about 54 kDa, about 20% of which is carbohydrate. It is encoded by a 3.8-kb transcript generated by the X chromosomal *TBG (SERPINA7)* gene.[54] The protein sequence of TBG resembles that of the serpin family of serine antiproteases. Because there is one iodothyronine binding site per TBG molecule, the T_4 or T_3 binding capacity of TBG in normal human serum is equivalent to its concentration, which is approximately 270 nmol/L (21 μg/dL). The half-life of the protein in plasma is about 5 days.

Congenital deficiency of TBG is common, occurring in 1 in 5000 newborns, and is associated with the complete absence of the protein in males. L-Asparaginase blocks the synthesis of TBG, which accounts for the low T_4 concentrations in patients receiving this agent.

The glycosylation of TBG influences its clearance from the plasma and its behavior during isoelectric focusing. In estrogen-treated patients, there is an increase in the prevalence of the more acidic bands of TBG. The more highly sialylated TBG is cleared more slowly from plasma than is the more positively charged TBG, because sialylation inhibits the hepatic uptake of glycoproteins. Sera from pregnant patients, women receiving oral contraceptives, and patients with acute hepatitis have increased fractions of acidic TBG. Patients with inherited TBG excess have normal amounts of highly sialylated TBG, as do men and nonpregnant women. Because TBG is the principal T_4-binding and T_3-binding protein, changes in TBG or its binding are paralleled by changes in total plasma T_4 and T_3 even though T_4 and T_3 production is little changed.

Another post-translational modification affecting TBG occurs in septic patients or following cardiopulmonary bypass surgery.[55] TBG is subjected to cleavage by a serine protease released from polymorphonuclear leukocytes, resulting in the release of a 5-kDa carboxy-terminal loop with a consequent decrease in affinity for T_4. An analogous reaction has been described for cortisol-binding globulin, which releases cortisol at the site of inflammation.[56] It has been postulated that the released T_4 might play a critical role

in the response to injury, perhaps by providing a supply of iodine for antibacterial purposes.[55] The cleaved TBG of approximately 49 kDa circulates, and because it binds T_4 with lower avidity, it may explain the increased ratio of free to bound T_4 in acute illness even when TBG saturation studies or immunoassays indicate TBG concentration is normal (see "Thyroid Function During Fasting or Illness").

Transthyretin

TTR is a transport protein for T_4 and retinol-binding protein bound to retinol (vitamin A), hence its name. It consists of four identical polypeptide chains with a total molecular mass of approximately 55 kDa and is not glycosylated. Its concentration in plasma is approximately 4 mmol/L (250 µg/mL). Each mole of TTR binds 1 mole of T_4 with high affinity, and a second T_4 molecule is bound with lower affinity at high concentrations of T_4. Its half-life in plasma is normally about 2 days, but this decreases during illness. TTR is expressed in the choroid plexus, and it is the major thyroid hormone–binding protein in the cerebrospinal fluid (CSF).[57] High levels of TTR have been detected in fetal serum, probably directly produced by placental cells.[58] Targeted TTR gene disruption in mice shows that there is no impairment of uptake of T_4 into the brain, leaving the role of TTR in CSF undefined in regard to thyroid physiology.[59,60]

Variant forms of TTR are associated with familial amyloidotic polyneuropathy.[61] In affected families, the TTR monomer has one of several different point mutations, and TTR accumulates in the amyloid tissue deposits. Neither thyroid dysfunction nor altered vitamin A metabolism has been reported, although there is altered affinity of some of the mutant proteins for T_4. Families with both high-affinity TTR and a few with increased TTR levels have been reported.

TABLE 11.4 Comparison of the Major Human Thyroid Hormone–Binding Proteins

Parameter	Thyroxine-Binding Globulin	Transthyretin	Albumin
Molecular weight of holoprotein (kDa)	54,000	54,000 (4 subunits)	66,000
Plasma concentrations (µmol/L)	0.27	4.6	640
T_4 binding capacity as µg T_4/dL	21	350	50,000
Association constants of the major binding site (L/mol)			
T_4	1×10^{10}	7×10^7	7×10^5
T_3	5×10^8	1.4×10^7	1×10^5
Fraction of sites occupied by T_4 in euthyroid plasma	0.31	0.02	<0.001
Distribution volume (L)	7	5.7	7.8
Turnover rate (% day)	13	59	5
Distribution of iodothyronines (% protein)			
T_4	68	11	20
T_3	80	9	11

T_3, Triiodothyronine; *T_4*, thyroxine.

Competition for T_4 and T_3 Binding to TBG and TTR by Therapeutic Agents

The TBG binding site has an affinity for T_3 that is about 20-fold less than that for T_4 (see Table 11.4). Binding of T_4 and T_3 by TBG is inhibited by phenytoin,[62] salicylate,[63] salsalate, furosemide, fenclofenac, and mitotane. The affinity of these compounds for TBG is much weaker than is that of the iodothyronines, but their concentration in plasma is sufficiently high to compete with T_4 and T_3 binding and reduce total hormone levels, although free T_4 remains normal. Because all methods used for estimating the free fractions of T_4 and T_3 in human serum except ultrafiltration dilute the serum, euthyroid patients receiving these drugs may appear to have low total and free T_4 or T_3, whereas in vivo the free fraction is normal.

Albumin

The affinity of albumin for T_4 and T_3 binding is much lower than that of either TBG or TTR, but the high concentration of this protein results in the binding of 10% of the plasma thyroid hormones (see Table 11.4). Changes in albumin concentration per se have little influence on total hormone levels, unless accompanied by alterations in TBG and TTR, all three of which are synthesized in the liver. Hepatic failure or nephrotic syndrome leads to decreases in the plasma concentration of all three, and the serum albumin concentration in patients with these illnesses may serve as a surrogate for estimating TBG concentrations.

The role of albumin in thyroid physiology becomes clinically important in patients with familial dysalbuminemic hyperthyroxinemia ($FDHT_4$) and hypertriiodothyroninemia ($FDHT_3$).[64,65] Both are dominantly inherited and characterized by a high concentration of total T_4 or T_3 (FDH). However, the free hormone concentrations remain normal and the patients are euthyroid. Recognition of these variants is important because affected individuals are at risk of erroneous treatment. Such patients may have a confusing pattern of test results, especially when analogue methods or labeled T_3 are used to estimate the free T_4 or T_3 (see Chapter 4).

Other Plasma Thyroid Hormone–Binding Proteins

Between 3% and 6% of plasma T_4 and T_3 are bound to lipoproteins. The T_4-binding lipoprotein is a 27-kDa homodimer with an affinity for T_4 that is lower than that of TBG. This binding is of uncertain physiologic significance but could play a role in targeting T_4 delivery to specific tissues.

Free Thyroid Hormones

Because most of the circulating T_4 and T_3 is bound to TBG, its concentration and degree of saturation are the major determinants of the free fraction of T_4. Binding of the thyroid hormones to the plasma proteins alters their metabolism. The negligible urinary excretion of T_3 and T_4 is due to the limited filterability of the hormone-binding protein complexes at the glomerulus. In vitro, the interaction between the thyroid hormones and their binding proteins conforms to a reversible binding equilibrium that can be expressed by conventional equilibrium equations. For the formulations that follow, T_4 is used as the prototype,

with the understanding that similar interactions apply in the case of T_3. The interaction between T_4 and TBG can be expressed as follows:

$$T_4 + TBG \overset{K_2}{\rightarrow} T_4 \bullet TBG$$

where TBG represents the *unoccupied* binding protein, k_a the equilibrium association constant for the interaction, and T_4 the concentration of *free* T_4; T_4 • TBG is T_4 bound to TBG (~68% of total T_4 is bound to TBG).

Rearranging, we can express this as:

$$\frac{T_4 \bullet TBG}{(T_4)\,(TBG)} = k_a$$

$$\frac{T_4}{T_4 \bullet TBG} = \frac{1}{(TBG)\,k_2}$$

Thus the free fraction of T_4 (T_4/T_4 • TBG) is inversely proportional to the concentration of *unoccupied* TBG binding sites. Estimates of the free T_4 concentration in serum can be generated by direct or indirect assays. In normal serum, the free T_4 is approximately 0.02% of the total (about 20 pmol/L, 1.5 ng/dL). The approximately 20-fold lower affinity of TBG for T_3 results in a higher proportion of unbound T_3 (0.30%) (Table 11.5; also see Table 11.4).

It is the free hormone that is available to the tissues for cellular uptake and feedback regulation that induces its metabolic effects and that undergoes deiodination or degradation. The bound hormone acts merely as a reservoir. It follows that the concentration of the free hormone is the determinant of the metabolic state, and it is this concentration that is defended by homeostatic mechanisms. If a change in TBG occurs, the free T_4 concentrations and T_3 concentrations can be maintained at normal levels only if the bound hormone changes in the same direction. For example, when TBG concentrations are increased by administration of estrogen, the free T_4 reduction reduces T_4 clearance, allowing an increase in the plasma total T_4 concentration. This is an iterative process that eventually would normalize the free T_4 at a new equilibrium without a change in T_4 secretion rate. The transient decrease in free thyroid hormones also slightly reduces the negative feedback on the hypothalamic-pituitary-thyroid axis, which causes an increase in thyroid hormone production as an additional compensation.[66]

The preceding formulation is termed the *free thyroid hormone hypothesis*.[67,68] If it is free hormone that is available for cellular entry, what is the role, if any, of the hormone-binding proteins? Protein binding facilitates the distribution of the hydrophobic thyroid hormones throughout the vascular system. For example, if a protein-free solution containing tracer T_3 is perfused through rat liver via the portal vein, there is a steep concentration gradient with a decreasing quantity of T_3 in the solution as the distance from the center of the portal lobule increases. In fact, virtually all of the T_3 is taken up by the first cells to be contacted by the bolus. In contrast, if albumin is added to the perfusate, the distribution of tracer is uniform throughout the lobule. Both influx and efflux of thyroid hormone from tissues are rapid. Thus intracellular free T_3 and T_4 are in equilibrium with the free hormone pool in plasma although transporter activity and metabolism will influence the magnitude of the ratio. In the steady state, the rate of T_3 and T_4 metabolism, not the dissociation rate from plasma proteins, is rate limiting in the exit of hormones from the plasma.

TABLE 11.5 Comparison of Triiodothyronine (T_3) and Thyroxine (T_4) in Humans

Parameter	T_3	T_4
Production rate (nmol/day)	50	110
Fraction from thyroid	0.2	1.0
Relative metabolic potency	1.0	0.3
Serum concentration		
Total (nmol/L)	1.8	100
Free (pmol/L)	5	20
Fraction of total hormone in free form ($\times 10^{-2}$)	0.3	0.02
Distribution volume (L)	40	10
Fraction intracellular	0.64	0.15
Half-life (days)	0.75	6.7

To convert T_4 from nmol/L to μg/dL (total) or pmol/L to ng/dL (free), divide by 12.87. To convert T_3 from nmol/L to ng/dL (total) or pmol/L to pg/dL (free), multiply by 65.1.

T_4 and T_3 Transport Across Cell Membranes and Intracellular T_3 Binding

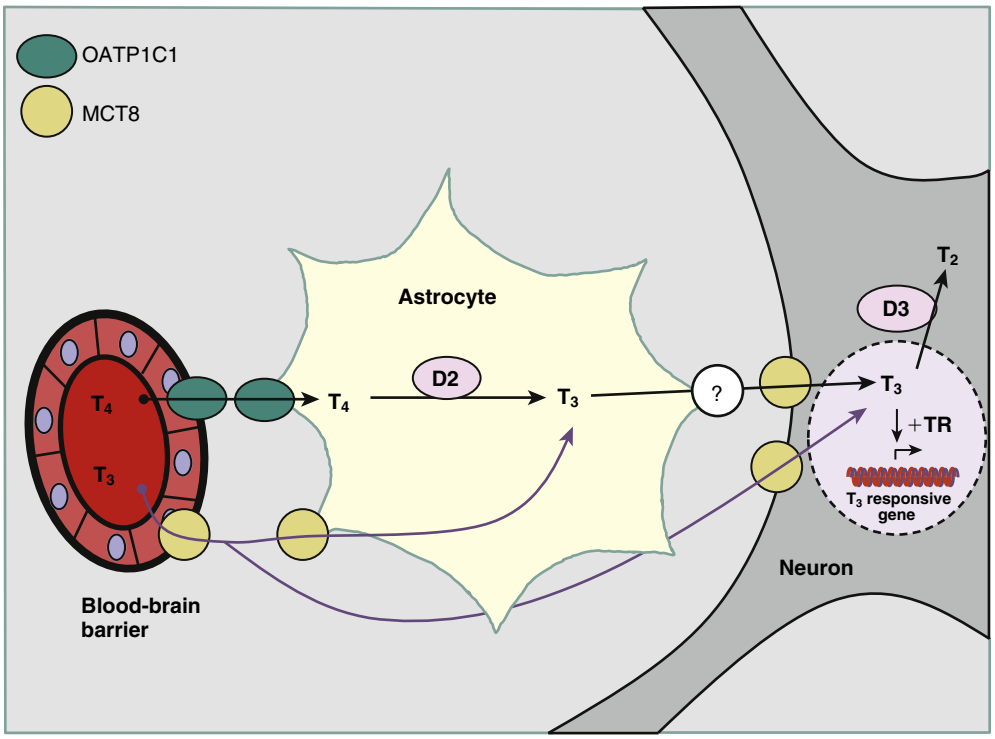
It has been assumed for a long time that transport of iodothyronines across the plasma membrane occurs by passive diffusion, but it has become increasingly clear that cellular uptake and efflux of thyroid hormone are mediated by transporter proteins.[69,70] Several specific thyroid hormone transporters have been identified, including monocarboxylate transporter 8 (MCT8), MCT10, organic anion transporting polypeptide 1C1 (OATP1C1), and L-type amino acid transporters LAT1 and LAT2. MCT8 and MCT10 are expressed in multiple tissues, where they facilitate transport of T_3, T_4, rT_3, and T_2 across cell membranes; OATP1C1 is expressed predominantly in the brain and transports preferentially T_4, wherein it may mediate the entry of T_4 into the astrocytes. A defect in a single thyroid hormone transporter molecule, MCT8, has been shown to cause a severe developmental neurologic phenotype.[71] The Allan-Herndon-Dudley syndrome (AHDS) is an X-linked condition characterized by severe mental retardation, dysarthria, athetoid movements, muscle hypoplasia, and spastic paraplegia associated with an elevated serum T_3.[72] All patients tested with this syndrome have mutations in the *MCT8* gene. More than 200 individuals belonging to some 100 families of all races and diverse ethnic origins harboring more than 70 different mutations have been identified.[73] Although most mutations result in a complete functional inactivation of the MCT8 protein, significant residual activity was observed with a number of *MCT8* mutations, some of which are associated with a milder clinical phenotype.[74] MCT8-null mice, despite the presence of marked increased T_3 levels, lack any overt neurologic abnormalities, a rather unexpected finding in light of the severe human phenotype.[75,76] The discrepancy with the human phenotype is now explained by the fact that mice express OATP1C1 at the blood-brain barrier, which compensates for the lack of transport by MCT8.[77] Coexistence of thyroid hormone excess and deprivation in different tissues is a distinct characteristic of this syndrome. Tissues expressing transporters other than

MCT8, such as liver and kidney, respond to the high circulating T_3 levels resulting in a local hyperthyroid state, whereas tissues depending on MCT8 for thyroid hormone entry into cells, such as the brain, are hypothyroid.[73,78] Two therapeutic options, PTU combined with levothyroxine T_4 (L-T_4)[73] and a thyromimetic compound, diiodothyropropionic acid (DITPA), which is not dependent on MCT8 for cellular entry, have been used to treat several patients harboring *MCT8* gene mutations.[79,80]

Another transporter specific for T_4, OATP1C1 (a member of the organic anion transporting polypeptide family), is expressed in capillaries throughout the brain, suggesting it may be involved in the transport of T_4 across the blood-brain barrier.[71] Taken together, these results suggest that the supply of T_3 to neurons may occur according to the schema shown in Fig. 11.3.[81] T_4 is transferred into the choroid plexus or into tanycytes via the action of OATP1C1, which is negatively regulated in brain capillaries by thyroid hormone. In the tanycyte or astrocyte, T_4 is converted to T_3 by the type 2 iodothyronine deiodinase (D2) and exits the cell, possibly via the MCT8/MCT10 transporters, where it becomes available for neuronal uptake, also via MCT8.[82,83] Neurons express the type 3 deiodinase (D3), which prevents activation of T_4 and catalyzes degradation of T_3 (see "Iodothyronine Deiodination"). This would provide a logical explanation of the association of the mutations in MCT8 with attention-deficit/hyperactivity disorder (ADHD), although it remains puzzling why the neurologic manifestations of this condition are so different from those seen in patients with untreated congenital hypothyroidism or severe iodine deficiency (see Chapter 13).

The transport field has become more complex as evidence accumulates of tissue-specific as well as generalized iodothyronine transporters belonging to a number of different transporter protein families. Each of these has many members with small variations in structure, which alter the specificity of the target substance. A thorough review of this topic is beyond the scope of this chapter, and the interested reader is referred to excellent reviews for further information.[69,70]

In most cells, about 90% of the intracellular T_3 is located in the cytosol. The known exception is in the pituitary, where approximately 50% of the intracellular T_3 is present in the nucleus. The mechanisms determining this distribution are still unknown, but it would not be surprising if there were active transport of thyroid hormones in and out of the nucleus and between other intracellular compartments. An intracellular T_3-binding protein (mu-crystallin) has been identified, which is expressed at high levels in the human brain, cochlea, and heart but is widely distributed. Disruption of the *Crym* gene encoding mu-crystallin leads to congenital deafness.[84] This or similar proteins may also play a role in the subcellular localization of the active hormone.



• **Fig. 11.3** Potential pathways for entry of T_3 into the central nervous system. Thyroid hormones are transported through the blood-brain barrier (organic anion transporting polypeptide [OATP]) or the blood-CSF barrier (OATP and MCT8). In the astrocytes and tanycytes, T_4 is converted to T_3, which then enters the neurons, possibly through MCT8. In the neurons, both T_4 and T_3 are degraded by D3. T_3 from the tanycytes may reach the portal vessels in the median eminence. Other transporters may be present on the astrocyte or tanycyte membranes. In most cases, the transport could be bidirectional, although only one direction is shown. The interaction of T_3 with the thyroid hormone receptor (TR) bound as a heterodimer with retinoid X receptor to the thyroid hormone–response element, often in the 5′ flanking region of a T_3-responsive gene, causes either an increase or a decrease in the transcription of that gene. This leads to parallel changes in the concentrations of critical proteins, thus producing the thyroid hormone response characteristic of a given cell. *D2* and *D3,* type 2 and type 3 iodothyronine deiodinases; *MCT8,* the monocarboxylate transporter 8; *T_2,* diiodothyronine; *T_3,* triiodothyronine; *T_4,* thyroxine.

Iodothyronine Deiodination

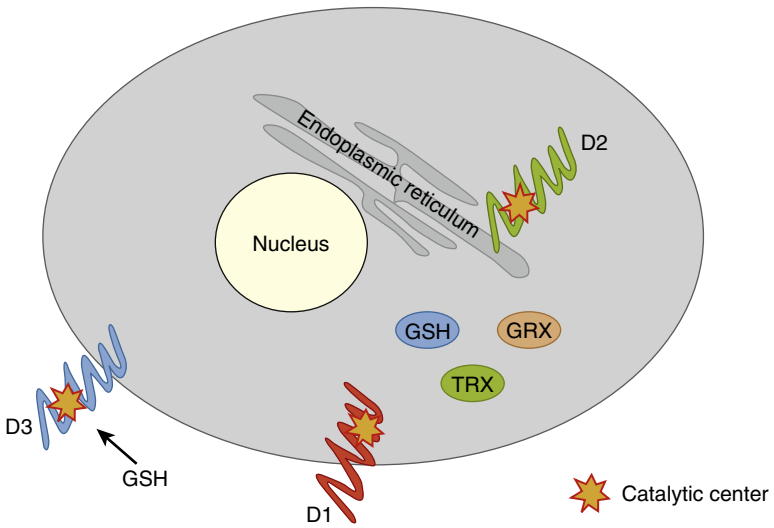
The most important pathway for T_4 metabolism is its outer ring (5′) monodeiodination to the active thyroid hormone, T_3. This reaction is catalyzed by the type 1 and 2 deiodinases (D1 and D2) and is the source of more than 80% of the circulating T_3 in humans (see Fig. 11.2). Inner ring deiodination, an inactivating step, is catalyzed primarily by D3, which inactivates T_3 and prevents activation of T_4 by converting it to rT_3 (see Fig. 11.2).[51,85] The structures of the three human deiodinases are similar, all being homodimers and integral membrane proteins and all requiring a thiol cofactor for successful catalysis (Fig. 11.4). They contain the rare amino acid selenocysteine in the active catalytic center (see Table 11.2). Selenocysteine has nucleophilic properties that make it ideal for catalysis of oxidoreductive reactions such as iodothyronine deiodination and the reduction of H_2O_2 by another family of selenoenzymes, the glutathione peroxidases.[86,87] The crystal structure of the catalytic domain of mouse deiodinase 3 (Dio3) revealed a close structural similarity to atypical 2-cysteine peroxiredoxin(s).[88] Selenium is thought to be the iodine acceptor during deiodination reactions. Mutagenesis of selenocysteine in D1 to cysteine, that is, replacing selenium with sulfur, reduces the enzyme velocity by approximately 200-fold. The presence of selenocysteine has implications beyond catalytic activity, considering that the cellular processes for synthesizing selenoproteins are complex and inefficient.[51] This is accomplished by a combination of a specific structural feature, the selenocysteine insertion sequence (SECIS) element, in the 3′ untranslated region of the mRNAs, encoding these proteins together with a specific group of selenocysteine incorporating gene products. All these elements are required for the complex cellular function by which the normal STOP codon UGA is recognized as the specific codon for the insertion of the selenocysteine residue during protein translation.[89,90]

Biallelic mutations in SECIS-binding protein 2 (SBP2) lead to abnormal thyroid function tests with elevated TSH, T_4, FT_4, and reverse T_3 but low total and free T_3 concentrations and can be associated with short stature and delayed bone age.[91]

Enzymology and Regulation of the Selenodeiodinases

Although both D1 and D2 activate T_4, they have several important differences (see Table 11.2). D1 catalyzes both 5′ and 5 deiodination of T_4 to form T_3 and rT_3, respectively, although the Michaelis-Menten constant (K_m) for these reactions is approximately 3 orders of magnitude greater than that of D2 and D3 for this substrate. The preferred substrates of D1 are rT_3 (5′ deiodination) and T_3SO_4 (5 deiodination). D1 is inhibited by PTU, unlike D2 or D3. D1 also differs from D2 in being markedly increased by excess thyroid hormone through increased gene transcription, whereas D2 mRNA and protein are reduced by thyroid hormones. D2 has a half-life of only 20 to 30 minutes but that of D1 and D3 is more than 12 hours. This is due to the rapid ubiquitination of D2, a process that is accelerated by interaction with its substrates T_4 or rT_3. D1 and D3 are not thought to be ubiquitinated.

The intracellular location of D2 close to the nucleus gives the T_3 formed by its catalytic action better access to the nucleus than that formed by D1.[92] The T_3 produced by D2 is especially effective in entering the nucleus and binding to thyroid hormone receptors (TRs), a property explained by its location in the endoplasmic reticulum (ER) (see Fig. 11.4). D1, on the other hand, is located in the plasma membrane, and the T_3 produced by this enzyme preferentially enters the plasma pool.[51] Studies with deiodinase inhibitors and cofactors differentially able to cross the cell membrane indicate that the D3 active center is outside the cell and that of D2 and D1 are intracellular (see Fig. 11.4).[93] This makes D2 especially important for regulating the hypothalamic-pituitary-thyroid axis, where its activity increases in response to a decrease in serum T_4 concentrations, such as occurs in iodine deficiency or early autoimmune thyroid disease, well before the serum T_3 falls. If the decrease in plasma T_4 is too great to be compensated for by the increase in D2 activity in the hypothalamus and thyrotrophs, an increase in TRH and TSH will occur to stimulate the thyroid. For this reason, D2 has principally been thought of as an enzyme that provides intracellular T_3, but there is increasing evidence that



• **Fig. 11.4** Predicted topologies of the three iodothyronine deiodinases. The deiodinases are integral membrane proteins that require a thiol cofactor for catalytic activity. The type 1 deiodinase (D1) is in the plasma membrane and type 2 (D2) is localized in the endoplasmic reticulum. The active centers of D1 and D2 are in the cytosol and depend on intracellular thiols such as reduced glutathione (GSH), thioredoxin (TRX), and glutaredoxin (GRX) for catalytic activity. The type 3 deiodinase (D3) is also anchored in the plasma membrane but has access to extracellular thiols.

D2 could also contribute to plasma T_3. Recent studies in rodents suggest that D2 ubiquitination in the hypothalamus is relatively less than in other D2-expressing tissues. As a result, the hypothalamus is wired to have increased sensitivity to T_4 and allows the physiologic TSH response to minimal variation in serum T_4.[94] On the other hand, in thyrotoxicosis, the threefold to fourfold increase in D1, particularly in the thyroid, and the reduced D2 make D1 the major extrathyroidal source of T_3. This explains why the D1-inhibitor PTU causes a much more rapid fall in circulating T_3 than does methimazole in the patient with Graves disease.[41,42]

A single-nucleotide polymorphism, A/G, in the *DIO2* gene, predicts a threonine (Thr) to alanine (Ala) substitution at codon 92 (D2 Thr92Ala).[95] This is present in about 20% of the Caucasian population. This polymorphism has been found, in some studies, to be associated with insulin resistance in obese patients, bipolar mood disorder, psychologic well-being, mental retardation, hypertension, and risk for osteoarthritis, although other studies failed to find such association. It is not yet clear whether this D2 polymorphism impairs its catalytic efficiency in vivo.[96,97] A recent study indicates that the D2 Thr92Ala polymorphism reduces D2 enzyme activity and serum T_3 levels in thyroid-deficient patients.[98]

In the opposite direction, D2 has been found overexpressed in a few follicular carcinomas. In these patients, a reduced T_4:T_3 ratio has been found and is likely due to the increased D2-mediated T_4 to T_3 conversion.[43]

D3 is the most important thyroid hormone–inactivating enzyme catalyzing deiodination of the inner ring of both T_3 and T_4.[99,100] D3 activity has been identified in only a limited number of postnatal tissues, including placenta and uterine endometrium, the CNS (in which it is primarily in neurons), and skin.

Much higher D3 expression has been demonstrated in various fetal tissues such as liver, brain, placenta, uterus, and umbilical arteries and veins. However, in adult tissues, D3 expression may be reinduced under conditions in which cellular proliferation is required.[101] In the adult, D3 has been identified in some malignant cell lines and in a number of human tumors, including astrocytomas, oligodendromas, gliosarcomas, glioblastomas, TSH-secreting pituitary adenomas, colon cancers,[102] and basal cell carcinomas.[103] Tumoral D3 activity can be robust, and the highest D3 activity reported in any human tissue to date has been in infantile hemangiomas. In infants with extensive hepatic hemangiomas, D3 may overwhelm the secretory capacity of the infant's thyroid, causing hypothyroidism, a syndrome termed *consumptive hypothyroidism*.[104] Although most patients with consumptive hypothyroidism have hemangiomas, it now has become evident that it can occur in other types of tumors, including gastrointestinal stromal tumors.[105] Patients with consumptive hypothyroidism may only represent the extreme of a clinical spectrum of hypothyroidism due to dysregulated thyroid hormone metabolism in malignant tissues. *DIO3* gene expression is increased by thyroid hormone at a transcriptional level.[106]

Gene-targeting studies have begun to provide further insights into the physiologic roles of the deiodinases in mammals.[107] Inactivation of the *Dio2* gene results in a phenotypically normal mouse with an elevated serum T_4, normal serum T_3, and elevated serum TSH.[85,108] These animals have hypothalamic-pituitary resistance to T_4, impaired auditory function, impaired thermogenesis in response to cold stress, impaired muscle regeneration,[109] and relatively subtle defects in neurologic function. These findings are all consistent with the expectations based on earlier studies indicating an important role for D2 in brown fat cell function, cochlear maturation, and neurologic development. The intracellular balance between D2 and D3 is dynamically regulated and plays a central role in controlling muscle homeostasis and regenerative potential.[110] Mice with targeted inactivation of *Dio1* are phenotypically normal but also have an elevated serum T_4 and a normal serum T_3, but TSH is normal.[111] The most striking finding in the D1-deficient mouse is a marked shift in the T_4 clearance pathway from deiodinative to biliary/fecal clearance. Interestingly, mice lacking both of the activating deiodinases D1 and D2 are still capable (by increasing TSH and thyroidal T_3 secretion) of maintaining normal T_3 concentrations in serum and do not suffer from systemic hypothyroidism, indicating that thyroidal T_3 production can guarantee T_3 homeostasis at least in rodents.[85,108] Mice with targeted inactivation of the *Dio3* gene show profound abnormalities. They have impaired fertility and develop central hypothyroidism in adult life, presumably due to hypothalamic thyrotoxicosis during developmental programming.[112]

Quantitative and Qualitative Aspects of Thyroid Hormone Metabolism

Thyroid Hormone Turnover

In the normal adult, T_4 has a distribution volume of approximately 10 L (see Table 11.5). Because the concentration of total T_4 in plasma is approximately 100 nmol/L (~8 μg/dL), the extrathyroidal T_4 pool is approximately 1 μmol (800 μg). In the adult, the fractional rate of turnover of T_4 in the periphery is about 10% per day (half-life, 6.7 days). Thus about 1.1 L of the peripheral T_4 distribution space is cleared of hormone daily, a volume containing approximately 110 nmol (85 μg) of T_4.

The kinetics of T_3 metabolism differ from those of T_4, partly because of its 10-fold to 15-fold lower affinity for TBG. The volume of distribution of T_3 in the normal adult is about 40 L, about four times that of T_4, and its fractional turnover rate is approximately 60% per day. At a mean normal serum T_3 concentration of 1.8 nmol/L (120 ng/dL), 50-fold lower than T_4, the daily production of T_3 is approximately 50 nmol (33 μg) or about 46% that of T_4 (see Table 11.5). The rapid metabolic clearance rate of the product of inner ring T_4 deiodination, rT_3, and the low concentration in plasma (0.25 nmol/L, 15 ng/dL) combine to yield daily production rates for rT_3 of about 45 nmol. Thus about 80% of T_3 and all of rT_3 production in humans can be accounted for by peripheral deiodination of T_4, findings consonant with the high ratio of T_4 to T_3 (15:1) and rT_3 (100:1) in human Tg. Of the T_3 generated via T_4 5′ deiodination in euthyroid humans, only about 70% is inhibited by PTU, consistent with a significant contribution of D2-dependent T_3 production.[113] Although much of the T_3 and rT_3 produced from T_4 in peripheral tissues exits those tissues and enters the blood, an uncertain fraction of both are degraded intracellularly before their exit. As discussed later, in some D2-containing tissues, such as the pituitary, a significant fraction of T_3 in the cell nucleus is derived from intracellular T_4 deiodination to T_3, rather than from the plasma. This is particularly true in the thyrotroph.[114]

Other pathways are also involved in T_4 and T_3 metabolism. In humans, T_4 undergoes glucuronidation of the phenolic hydroxyl by the uridine diphosphate glucuronyl transferases (UDPGTs), but only minimal amounts of T_3 undergo this process (see Fig. 11.2). This pathway is clinically significant because certain pharmacotherapeutic agents may enhance glucuronide conjugation through induction of UDPGT, leading to biliary excretion of T_4-glucuronide (T_4-G) into the intestine.[115] These agents include

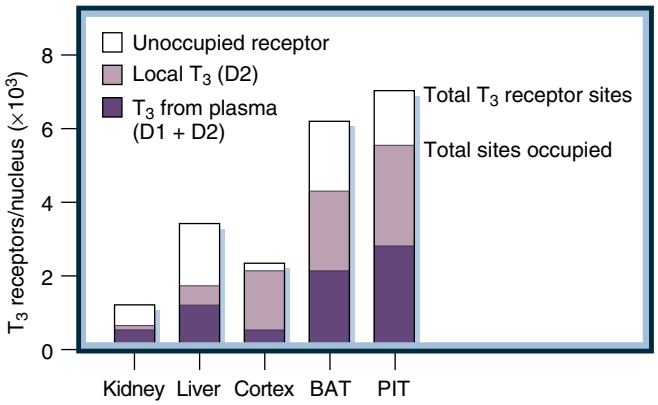
phenobarbital, phenytoin, rifampin, and possibly certain of the synaptosomal serotonin reuptake inhibitors, such as sertraline. Because T_4-glucuronide may not be easily reabsorbed from intestinal contents, the clinical significance of this pathway is that therapy with such agents will generally increase levothyroxine requirements. In patients with an intact thyroid, this will not be apparent because internal adjustments will increase the T_4 production rate to compensate for the accelerated biliary excretion. In patients with hypothyroidism, however, an increase in levothyroxine dosage will often be required.

Sources of Intracellular T_3

In view of the differential tissue distribution of the various deiodinases, their different K_m values, and differential regulation, it is not surprising that tissues may derive intracellular T_3 via different pathways (Fig. 11.5). In several rat tissues, including tissues expressing D1 such as kidney and liver, most of the nuclear T_3 is derived from plasma T_3. In D2-containing tissues, such as the rat cerebral cortex, pituitary, brown fat, and skeletal muscle, D2 functions as an additional intracellular source of T_3, such that the nuclear T_3 concentration will be higher given the combination of T_3 from the plasma and the T_3 that is locally converted from T_4. In these tissues, half or more of intracellular T_3 is generated locally from T_4 within the tissue. In the CNS, the D2-generated T_3 in neurons is likely to derive from paracrine sources in tanycytes and astrocytes (see Fig. 11.3). In the rat, the tissues that depend on D2 for nuclear T_3 are those in which a constant supply of thyroid hormone is critical for either normal development (cerebral cortex), thyroid gland regulation (pituitary), or survival during cold stress (brown adipose tissue). These tissues are also characterized by a high degree of saturation of the nuclear T_3 receptors in comparison to tissues such as the liver and kidney in which nuclear T_3 receptor sites are only about 50% occupied at normal serum T_3 concentrations (see Fig. 11.5).

Intracellular D2-catalyzed T_3 production has important implications for thyroid hormone physiology. First, because the T_3 produced from T_4 occupies a significant fraction of the receptors in those tissues, changes in either serum T_4 or serum T_3 can change receptor occupancy. However, because a fall in T_4 will also increase D2 protein half-life by decreasing the rate of ubiquitination and its proteasomal degradation, a rise in D2 activity mitigates the impact of a reduction of serum T_4 in D2-expressing tissues, helping to maintain T_3 homeostasis.[51] The requirement for both T_3 and T_4 for normal saturation of pituitary and CNS T_3 receptors permits a response of the hypothalamic-pituitary axis to a reduction in plasma T_4, which is the earliest manifestation of iodine deficiency or primary hypothyroidism (see "Regulation of Thyroid Function"). Because the *Dio2* gene is positively regulated by cAMP, D2 activity and T_3 production increase rapidly in brown adipose tissue under stimulation by the sympathetic nervous system. This response is critical to adaptive thermogenesis during cold exposure in the human neonate and lifelong in the rodent.[116]

At the same time, tissues expressing D3 have lower T_3 concentrations than would be expected from the plasma contribution (Fig. 11.6); thus D3-expressing tissues have a gene expression profile similar to hypothyroid cells. This is explained by the inactivation of T_3 and T_4 that takes place immediately after these hormones enter the cell. The D3-mediated reduction in T_3 levels likely occurs in several physiologic (development, regeneration) or pathologic settings (cancer cells, inflammation, myocardial infarction) in which D3 is upregulated.[117]



• **Fig. 11.5** Schematic diagram of the origin of the specifically bound nuclear T_3 in various rat tissues. Data are derived from studies in which the sources of specifically bound nuclear T_3 in rat tissues were estimated using double-isotope labeling techniques. In tissues in which the receptor saturation is significantly greater than 50%, the additional T_3 is provided by D2-catalyzed conversion of thyroxine (T_4) to T_3. T_3 in rat plasma is derived from thyroid secretion (~40%) with the remainder from D1-catalyzed and D2-catalyzed T_4 to T_3 conversion. *BAT,* brown adipose tissue; *D1* and *D2,* type 1 and 2 iodothyronine deiodinases; *PIT,* pituitary; *T_3,* triiodothyronine.

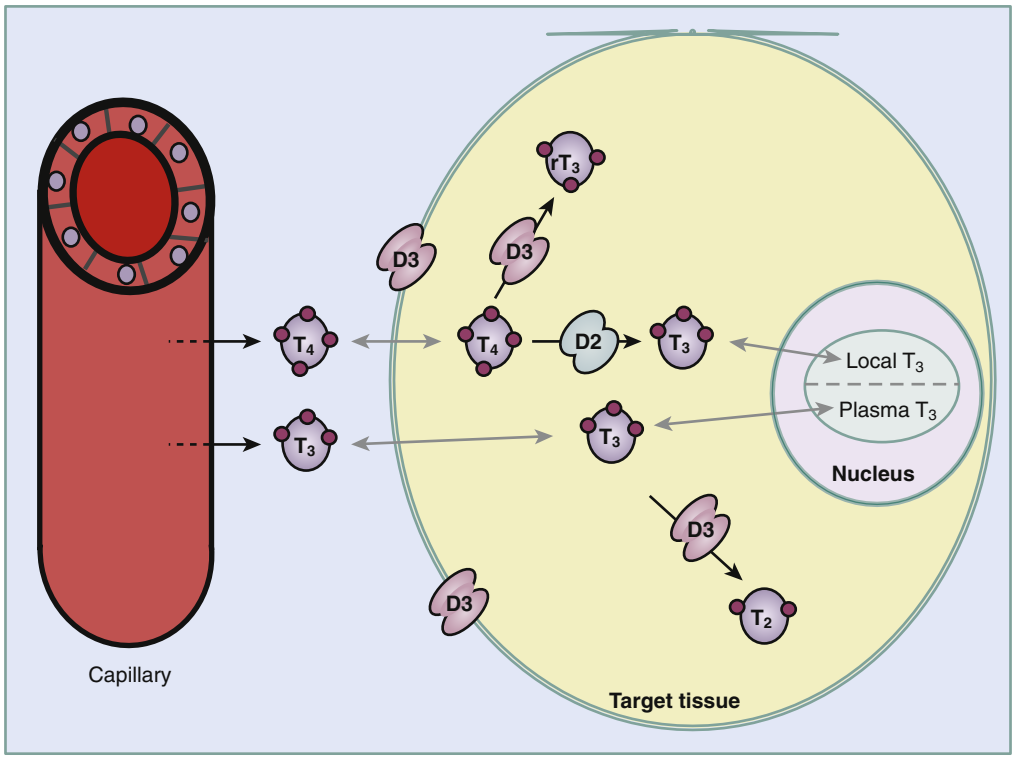
Pharmacologic Agents Inhibiting Thyroid Hormone Deiodination

A number of commonly used pharmacologic agents have significant effects on thyroid hormone deiodination. PTU inhibition of D1 has been mentioned earlier. The antiarrhythmic drug amiodarone shares sufficient structural similarity with T_4 that it can inhibit deiodination of T_4 and rT_3 by D1 and possibly by D2 (Fig. 11.7). This causes an increase in plasma T_4 to maintain serum T_3 in the normal range. Also, levels of TSH increase within the first weeks of therapy but gradually return to normal as the thyroid axis reequilibrates.[118] The T_4 and rT_3 metabolic clearance rates are reduced by 20% to 25%, with a reduction in the fractional T_4 to T_3 conversion rate of about 50%. Amiodarone also inhibits the active transport of T_4 and T_3 into hepatocytes, and the drug or one of its degradation products may interfere with T_3 binding to TRs.[119]

The effects of amiodarone resemble those observed with the iodoaniline derivatives formerly used for gallbladder visualization (see Fig. 11.7). Iopanoic and iopodipic acid inhibit the deiodinases by competing with the iodothyronine substrates.[51] These agents are useful in the acute treatment of patients with severe hyperthyroidism, but they are no longer available for clinical use in the United States.

High dosages of glucocorticoids (10 times replacement) will acutely reduce the ratio of T_3 to T_4 in plasma, suggesting that conversion of T_4 to T_3 is blocked. The ratio of rT_3 to T_4 increases, raising the possibility that D3 action is also increased.[120] These effects resolve during long-term therapy such that thyroid function is little affected and thyroid hormone requirements are not increased by chronic glucocorticoid therapy.

Recombinant growth hormone increases the circulating T_3:T_4 ratio. Growth hormone deficiency is associated with a decrease in the ratio of T_3 to T_4 in serum, possibly associated with a decrease in outer ring deiodination. As expected, dietary selenium deficiency also inhibits the synthesis of D1 in humans.[121]



• **Fig. 11.6** Schematic diagram of thyroid hormone activation and inactivation in a cell expressing the iodothyronine deiodinases D2 and D3. The triiodothyronine (T_3) that enters the cell can either be deiodinated to 3,3′-diiodothyronine (T_2) or enter the nucleus and bind to the thyroid hormone receptor. An additional source of T_3 is that generated by outer ring deiodination of thyroxine (T_4) within the cell. *rT_3*, reverse T_3.

Mechanism of Thyroid Hormone Action

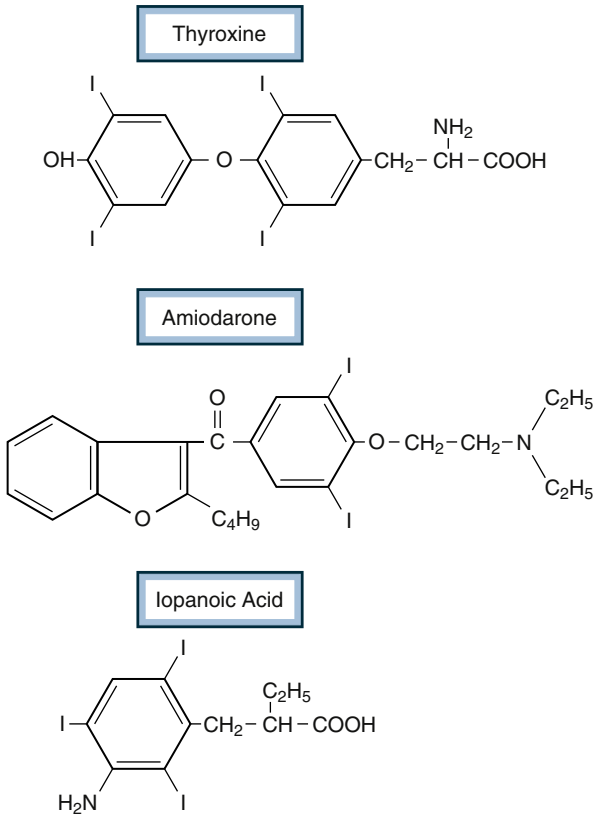
Thyroid hormone acts by binding to specific nuclear TRs, which in turn bind to DNA, usually as a heterodimer with retinoid X receptor (RXR) at specific sequences (thyroid hormone response elements [TREs]) dictated by the DNA binding-site preferences of the RXR-TR (or TR-TR) complex. In humans, there are two TR genes, α and β, found on different chromosomes (TRα, chromosome 17; TRβ, chromosome 3). Several alternatively spliced gene products from each of these genes form both active and inactive gene products. The active proteins are $TR\alpha_1$ and TRs β_1, β_2, and β_3.[122] The protein structure of TRs includes three major functional domains, one binding DNA, one binding ligand, and a major transcriptional activation domain in the carboxy-terminus.

The general mechanism by which nuclear receptor–activating ligands such as T_3 produce their effects is discussed in Chapter 2. T_3 has a 15-fold higher binding affinity for TRs than does T_4, explaining its function as the active thyroid hormone.

There are tissue-specific preferences in expression of the various TRs, suggesting that they subserve different functions in different tissues.[123] $TR\alpha_1$ mRNA is expressed in the brain and brown adipose tissue and also in skeletal muscle, the gastrointestinal tract, lungs, and heart. In general, TRβ, particularly $TR\beta_2$, is thought to be important in the hypothalamus and pituitary, in which regulation of thyroid function occurs.[124] $TR\beta_1$ is expressed in all tissues, although its mRNA is especially highly expressed in the kidney and liver. $TR\beta_2$ is also expressed in the cochlea and the retina. $TR\beta_3$ mRNA is expressed at very low levels but is more abundant in the liver, kidneys, and lungs in comparison with other tissues. In addition to differences in the amino-terminus between $TR\beta_1$ and $TR\alpha_1$, the two proteins are encoded by distinct genes and hence under the regulation of different promoters, which can function in tissue-specific patterns. $TR\beta_2$ is downregulated by T_3, whereas $TR\alpha_1$ mRNA expression is not affected.[125]

Experiments in which TRα and TRβ have been inactivated illuminate their different physiologic roles. Disruption of the *Thrb* gene (encoding both $TR\beta_1$ and $TR\beta_2$) in mice causes deafness, a marked reduction in feedback sensitivity of the hypothalamic-pituitary-thyroid axis, and a decrease in hepatic D1. Thus these mice have significant elevations in both TSH and thyroid hormones similar to those in families with resistance to thyroid hormone (RTH), in which TRβ mutations markedly reduce its binding affinity for T_3. RTH is dominantly inherited and characterized by resistance to thyroid hormone in tissues predominantly expressing TRβ (e.g., the liver and the pituitary) but signs of thyrotoxicosis in tissues with predominant expression of TRα (e.g., the heart).[126] Peripheral thyroid hormones are elevated and TSH remains inadequately normal or elevated. Clinical signs include goiter, tachycardia, and hyperactivity. The missense mutations in $TR\beta_1$ or $TR\beta_2$ disrupt binding of T3, and the mutated allele acts as a dominant negative inhibitor of the intact TRβ proteins encoded by the wild-type allele (see Chapters 2 and 13).

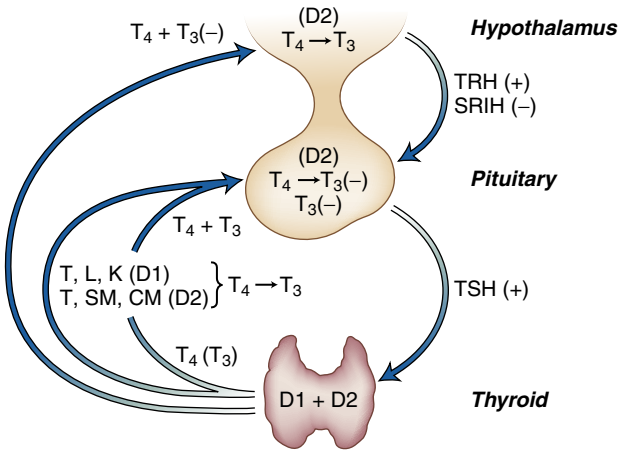
The effect of a $TR\alpha_1$ disruption in the mouse is quite different. The predominant phenotypic effects are modest bradycardia and hypothermia. Several patients with mutations in *THRA* have now been identified.[127,128] All patients are heterozygous, suggesting dominant negative effects of the mutant receptors on wild-type TRα. They presented with low serum T_4 and high serum T_3 levels, growth retardation, delayed mental and bone development, bradycardia, and decreased colonic motility with severe constipation.[127–129]



• **Fig. 11.7** Comparison of the chemical structure of thyroxine (T_4) with that of two agents that block the deiodination of the iodothyronines. The inhibition of T_4-to-T_3 conversion, which occurs in patients receiving amiodarone, may be due to the drug itself or to a metabolic product. Iopanoic acid and related iodoanilines are competitive inhibitors of all three iodothyronine deiodinases.

It is likely that small differences in the ligand-binding domains of TRα and TRβ will allow design of thyroid hormone analogues selective for one or the other of these receptors. This may result in agents that could, for example, suppress TSH in patients with thyroid cancer, without inducing tachycardia, such as GC1, a potential treatment for obesity via stimulation of metabolic rate and oxygen consumption.[130]

The ability of thyroid hormone to cause rapid effects, at least under certain experimental situations, has led to the investigation of other potential mechanisms for thyroid hormone action that are referred to as extranuclear, noncanonic, or nongenomic actions. Several examples are provided here. Studies of mice in which the endogenous thyroid hormone receptor genes have been mutated to prevent thyroid hormone receptor–DNA binding have provided strong evidence that heart rate, body temperature, blood glucose, and serum triglyceride levels can be regulated by nongenomic actions of TRs, whereas negative regulation of the hypothalamic-pituitary-thyroid axis requires DNA binding of TRβ.[131] T_3 has been shown to rapidly activate phosphatidylinositol 3-kinase at the cell membrane via interaction with TRβ, and this action enhances maturation of synapses in the mouse hippocampus in vivo.[132] In addition, integrin $\alpha_V\beta_3$ has been identified as a putative plasma membrane thyroid hormone–binding site and has been proposed as a mediator of rapid effects of T_4.[133] The effect of T_4 per se to initiate the ubiquitination of D2 is perhaps the most important nongenomic effect of physiologic concentrations of free T_4.[51]



• **Fig. 11.8** Roles of thyroxine (T_4) and triiodothyronine (T_3) in the feedback regulation of secretion of thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH). Secreted T_4 must be converted to T_3 to produce its effects. This conversion may take place in tissues such as the liver (L), kidney (K), and thyroid (T) catalyzed by the type 1 iodothyronine deiodinase, D1. Type 2 (D2) is present in human thyroid (T), skeletal muscle (SM), possibly cardiac muscle (CM), and the pituitary and hypothalamus. *SRIH,* somatotropin release-inhibiting factor (somatostatin hormone).

Regulation of Thyroid Function

The Hypothalamic-Pituitary-Thyroid Axis

The thyroid participates with the hypothalamus and pituitary in a classic feedback control loop (Fig. 11.8). In addition, there is an inverse relationship between the iodine level in the thyroid and the fractional rate of hormone formation. Such autoregulatory mechanisms stabilize the rate of hormone synthesis despite fluctuations in the availability of iodine. Stability in hormone production is achieved in part because the large intraglandular store of hormone buffers the effect of acute increases or decreases in hormone synthesis. Autoregulatory mechanisms within the gland in turn tend to maintain a constant thyroid hormone pool. Finally, the hypothalamic-pituitary feedback mechanism senses variations in the availability of free thyroid hormones, however small, and acts to correct them. Hypothalamic tanycytes play a role in the homeostatic regulation of the HPT axis to maintain circulating thyroid hormone levels in a narrow physiologic range.[134]

There is a close relationship between the hypothalamus, the anterior pituitary, the thyroid gland, and still higher centers in the brain, the function of the entire complex being modified in a typical negative-feedback manner by the availability of the thyroid hormones. In addition, other hormones and neuropeptides also influence this axis (see Chapters 7 and 8).

Thyrotropin-Releasing Hormone Synthesis and Secretion

TRH, a modified tripeptide (pyroglutamyl-histidyl-proline amide), is derived from a large prepro-TRH molecule of 29 kDa that contains five progenitor sequences. The TRH peptides are released from the prepro molecule by a peptidase that acts at flanking lysine/arginine residues. TRH is expressed in the hypothalamus, the brain, the C cells of the thyroid gland, the beta cells of the pancreas, the myocardium, the reproductive organs (including prostate and testis), and the spinal cord. The parvocellular region of the paraventricular nuclei (PVN) of the hypothalamus is the source of the TRH that regulates TSH secretion. The 5′ flanking region of the gene encoding TRH has sequences for mediating

responses to glucocorticoids and cAMP. In addition, at least two elements in this region are responsible for the negative regulation of this gene by thyroid hormone.[135] TRH travels in the axons of the peptidergic neurons through the median eminence and is released close to the hypothalamic-pituitary portal plexus. The neuron bodies producing TRH are innervated by catecholamine, leptin, neuropeptide Y (NPY), agouti-related protein (AgRP) or melanocyte-stimulating hormone (MSH), and somatostatin-containing axons, all of which potentially influence the rate of synthesis of the prepro-TRH molecule (see Chapter 7). T_3 suppresses the levels of prepro-TRH mRNA in the hypothalamus,[136,137] but normal feedback regulation of prepro-TRH mRNA synthesis by thyroid hormone requires a combination of T_3 and T_4 in the circulation, the latter giving rise to T_3 via T_4 5′ deiodination in the CNS in astrocytes and tanycytes (see Fig. 11.3). Another event in this feedback regulation may be the thyroid hormone–mediated induction of the TRH-inactivating pyroglutamyl peptidase II (PPII) in the hypothalamic tanycytes. This regulation is observed in vivo exclusively in the parvocellular division of the PVN, but in tissues outside the CNS expressing the *TRH* gene, negative regulation by thyroid hormone is absent. Thus part of the negative feedback induced by T_4 may be generated at the median eminence/arcuate nucleus at a point where neuropeptides and T_3 enter the pituitary portal system.[138] Although D2 is also present in astrocytes in the median eminence and arcuate nucleus region, selective ablation of D2 from astrocytes in transgenic mice has no significant effect on feedback regulation of the hypophysiotropic TRH neurons, indicating that astrocytes have little or no role in the regulation of this response.[139] In addition to inhibiting the synthesis of prepro-TRH mRNA, thyroid hormone also blocks the capacity of TRH to stimulate TSH release from the thyrotroph.

TRH is rapidly inactivated within the CNS by a cell-surface peptidase called TRH-degrading ectoenzyme (TRH-DE), also termed protein peptidase II. TRH-DE is very specific: There is no other ectopeptidase known capable of degrading TRH, and TRH is the only known substrate of this unique enzyme.[140]

Thyrotropin Synthesis and Secretion

TSH is the major regulator of the morphologic and functional states of the thyroid. It is a glycoprotein secreted by the thyrotrophs in the anteromedial portion of the adenohypophysis (see Chapter 8). TSH is composed of an α-subunit of 14 kDa (92 amino acids) that is common to luteinizing hormone, follicle-stimulating hormone, human chorionic gonadotropin (hCG), and a specific β-subunit synthesized only in thyrotrophs, which is a 112–amino acid protein. In normal thyrotrophs and in thyrotroph tumors, synthesis of α-subunit is in excess, indicating that the quantity of β-subunit is rate limiting for TSH secretion. Levels of the α-subunit in serum range from 0.5 to 5 μg/L but are increased in postmenopausal women and patients with pituitary tumors. TRH increases and thyroid hormone suppresses the transcription of both subunits; these are the two most important influences on TSH synthesis.

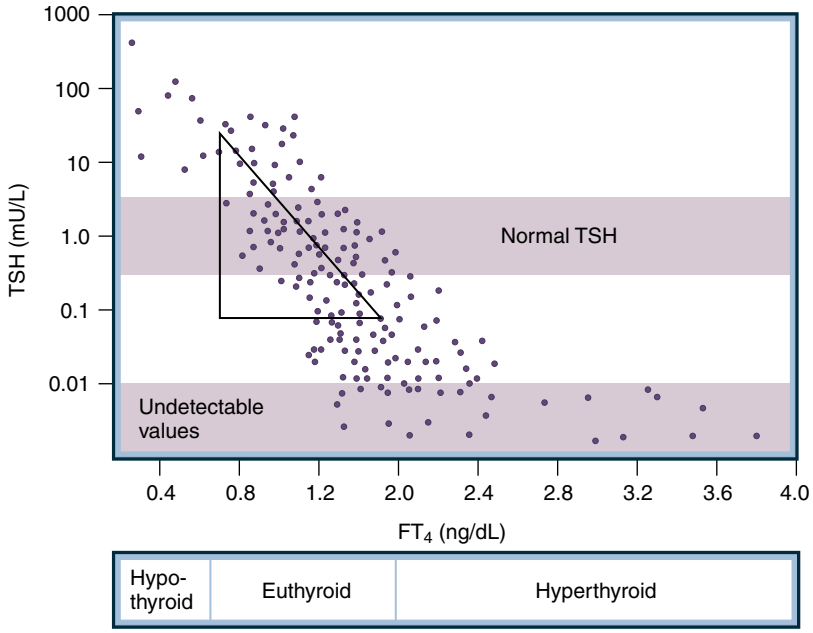
The pretranslational regulation of TSH synthesis and secretion is a complex process. The physiologic glycosylation of TSH involves several post-translational steps, including the excision of signal peptides from both subunits and cotranslational glycosylation with high mannose oligosaccharides.[141] The glycosylation of the subunits protects them from intracellular degradation and permits normal folding of the protein chains so that internal disulfide linkages are correctly formed. Glycosylation is required for full biologic activity.[142,143] TRH is required for this process as illustrated by the inappropriately low biologic activity of the TSH in the serum of patients with pituitary tumors or hypothalamic disorders. In animals that breed seasonally, alternatively glycosylated TSH secreted from the pars tuberalis (PT) of the anterior pituitary gland activates thyroid hormone within the hypothalamus, which in turn induces gonadotropin-releasing hormone (GnRH), leading to gonadal growth in a seasonal fashion.[144]

In normal serum, TSH is present at concentrations between 0.4 and 4.2 mU/L. The level is increased in primary hypothyroidism and reduced in thyrotoxicosis. The plasma TSH half-life is about 30 minutes, and production rates in humans are 40 to 150 mU/day. Circulating TSH displays both pulsatile and circadian variations. The former are characterized by fluctuations at intervals of 1 to 2 hours. The magnitude of TSH pulsations is decreased during fasting, during illness, or after surgery. There is an acute reduction of TSH in fasting humans, associated with a fall in leptin levels. This is due to a decrease in the amplitude of the TSH pulses.[145] The circadian variation is characterized by a nocturnal surge that precedes the onset of sleep and appears to be independent of the cortisol rhythm and fluctuations in the serum and T_4 and T_3 concentrations. The circadian rhythm shows parallelism with changes in T_3 levels.[146] When the onset of sleep is delayed, the nocturnal TSH surge is enhanced and prolonged, and the early onset of sleep results in a surge of lesser magnitude and shorter duration. TSH levels also show seasonal changes in humans with a decrease during the summer and an increase during winter, changes that correlate with daily temperatures.[147]

The degree of thyroid hypofunction after destruction of the hypothalamus is less severe than that which follows hypophysectomy, and residual thyroid function in the former circumstance can be altered by raising or lowering the concentration of thyroid hormones in the blood. Thus both T_4 and T_3 mediate the feedback regulation of TSH secretion, and TRH determines its set-point (see Fig. 11.8). There is a linear inverse relationship between the serum free T_4 concentration and the log of the TSH (Fig. 11.9), making the serum TSH concentration an exquisitely sensitive indicator of the thyroid state of patients with an intact hypothalamic-pituitary axis. Gene-targeting studies show that TRH secretion is likely to be the dominant factor mediating the thyroid hormone feedback regulation of TSH secretion because the markedly elevated TSH secretion of mice with inactivation of TRβ cannot be sustained in mice lacking the TRH gene.[148] This is somewhat surprising given the less severe hypothyroidism associated with hypothalamic (as opposed to primary) hypothyroidism but may be explained by the absolute nature of the TRH deficiency achieved by the genetic manipulation as opposed to the clinical situation in humans with central hypothyroidism, wherein the TRH deficiency is not likely to be complete.

Somatostatin (somatotropin release–inhibiting hormone [SRIH]), acting through inhibitory G protein (G_i), decreases TSH secretion in vitro and in vivo, but prolonged treatment with a somatostatin analogue does not cause hypothyroidism.[149,150] Similar acute effects occur during dopamine infusion and the administration of bromocriptine, a dopamine agonist. Both of these agents inhibit adenylate cyclase.

A number of drugs or hormones may suppress or stimulate TSH secretion (Table 11.6). Glucocorticoids given in high doses transiently suppress TSH secretion, although prolonged therapy is not associated with central hypothyroidism.[149] Patients with Cushing disease have subnormal TSH production but with minimal effects on T_4 production.[149] Bexarotene, a RXR agonist used for treatment of T-cell lymphoma, suppresses TSH sufficiently



• **Fig. 11.9** The log/linear relationship between thyroid-stimulating hormone (TSH) *(on the vertical axis)* and the free T_4 concentrations (FT_4). Typical free T_4 concentrations in hypothyroid, euthyroid, and hyperthyroid patients are shown.

TABLE 11.6 Endogenous and Exogenous Agents That May Stimulate or Inhibit Thyrotropin Secretion

Stimulatory Agents	Inhibitory Agents
Thyrotropin-releasing hormone (TRH)	Thyroid hormones and analogues
Prostaglandins (?)	Dopamine and dopamine agonists
α-Adrenergic agonist (? via TRH)	Biotin
Opioids (humans)	Opioids (rat)
Arginine vasopressin (AVP)	Glucocorticoids (in vivo, high dose)
Glucagon-like peptide 1 (GLP1)	Serotonin
Galanin	Cholecystokinin (CCK)
Leptin	Gastrin or gastrin-releasing peptide (GRP)
Glucocorticoids (in vitro)	Arginine vasopressin (AVP)
	Neuropeptide Y (NPY)
	Interleukin 1β and 6
	Tumor necrosis factor α (TNFα)
	Bexarotene (retinoid receptor agonist)
	Phenytoin
	Somatostatin and somatostatin analogues
	Mitotane

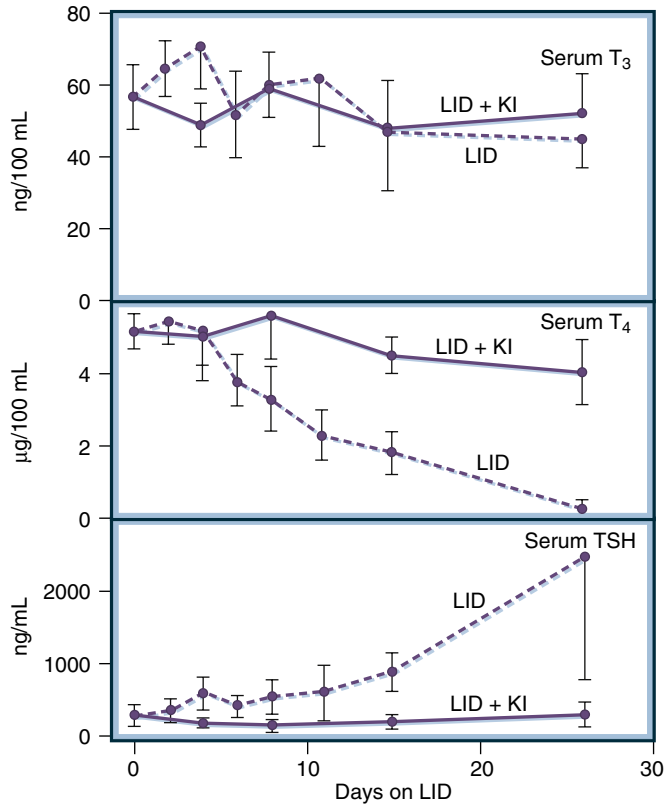
to cause central hypothyroidism, presumably by reducing TSHβ gene transcription.[151,152]

Neurotransmitters are important direct and indirect modulators in TSH synthesis and secretion. A complex network of neurotransmitter neurons terminates on cell bodies of hypophysiotropic neurons, and several neurotransmitters (such as dopamine) are directly released into hypophyseal portal blood, exerting direct effects on anterior pituitary cells. Furthermore, many dopaminergic, serotoninergic, histaminergic, catecholaminergic, opioidergic, and GABAergic systems project from other hypothalamic/brain regions to the hypophysiotropic neurons involved in TSH regulation. These projections are important for a normal TSH circadian rhythm and response to stress and cold exposure, but basal TSH secretion is mainly regulated by intrinsic hypothalamic activity.

Iodine Deficiency

The response of vertebrates to iodine deficiency is designed to conserve this limited resource and improve the efficiency of its utilization. These adjustments occur at the hypothalamic, pituitary, thyroid, and peripheral tissue levels. Removal of iodine from the diet causes a rapid decrease in serum T_4 concentrations and a simultaneous increase in serum TSH (Fig. 11.10).[153] Interestingly, no detectable decrease in T_3 occurs, suggesting that the signal to increase TSH must derive from a decrease in the T_3 generated intracellularly from T_4 in the pituitary, the hypothalamus, or both. TSH increases NIS, Tg, and TPO synthesis and iodine organification and Tg turnover (see Fig. 11.1). Because of the decrease in iodide supply and the ratio of DIT/MIT, the ratio of T_4 to T_3 in Tg decreases and the rate of thyroidal T_3 secretion may increase despite a fall in T_4 secretion. TSH also stimulates cell division, leading to goiter. In the rat model, the fall in plasma T_4 increases D2 from 5-fold to 20-fold in the CNS, hypothalamus, and pituitary, increasing the efficiency of T_4 conversion to T_3. With moderately severe iodine deficiency, D3 in the CNS is also reduced, prolonging the mean residence time of T_3 in that organ.[154] This permits serum T_3 to remain normal and the CNS T_3 to be only moderately reduced despite up to a 10-fold decrease in circulating T_4.

Despite the TSH elevation and nearly undetectable serum T_4 in acutely iodine-deficient rodents, growth, O_2 consumption, and thermal homeostasis can be maintained.[155] However, if iodine deficiency is prolonged and severe, hypothyroidism will supervene. In humans, these compensatory alterations in thyroid function come into operation when total iodine intake falls below



• **Fig. 11.10** Effects of acute depletion of dietary iodine on serum triiodothyronine (T_3), thyroxine (T_4), and thyroid-stimulating hormone (TSH) in rats. Animals received a low iodine diet (LID) without or with supplementation of potassium iodide (KI) in drinking water. (From Riesco G, Taurog A, Larsen PR, et al. Acute and chronic responses to iodine deficiency in rats. *Endocrinology* 1977;100:303–313.)

75 μg/day (see Table 11.1). This situation can occur even after the implementation of iodine supplementation programs in the absence of adequate longitudinal monitoring.[156]

Changes in serum hormones seen in experimental animals have been well documented in humans in areas of iodine deficiency and in patients with NIS mutations.[157] However, they may not be seen in older members of the population when thyroid autonomy often develops. The physiologic response to iodine deficiency is similar to that which occurs during the development of primary hypothyroidism in humans. It is also reproduced when the efficiency of iodide trapping and organification is reduced in Hashimoto disease or in the patient with Graves disease receiving thiourea drugs.[38] The physiologic effects of this series of events are clear. T_3 has approximately 10 times the potency of the prohormone T_4 and contains only three iodine atoms. This results in a more efficient use of the iodine atom. Maintenance of normal circulating T_3 independent of serum T_4 concentrations should provide hormone for those tissues in which the nuclear T_3 is completely derived from the plasma such as liver and kidney (see Fig. 11.5).

Iodine Excess

The thyroid is also protected against an excess of iodide that might otherwise lead to hyperthyroidism. As with the response to iodine deficiency, there are multiple levels of defense against this eventuality. The usual source of excess iodine is pharmaceutic,

TABLE 11.7 Iodine Content of Various Iodinated Pharmaceuticals [a]

Agent	Iodine Content
Saturated solution of potassium iodide	38 mg/drop
Lugol solution	6 mg/drop
Iodized salt (1 part KI/10,000 NaCl)	760 μg/10 g
Amiodarone (200-mg tablet)	75 mg organic iodine, 8–17% is released as iodide
Iopanoate, ipodate	350 mg/tablet
Angiographic and CT dyes	400–4000 mg/dose
Povidone-iodine	10 mg/mL
Kelp tablets	150 μg/tablet
Prenatal vitamins	150 μg/tablet
Iodinated glycerol	25 mg/mL
Quantity of iodine required to suppress radioactive iodine uptake to <2%	>30 mg/day

[a]Typical iodide intake in the United States is 100–400 μg/day.

CT, Computed tomography; *KI*, potassium iodide; *NaCl*, sodium chloride.

with radiographic dyes, amiodarone, and povidone-iodine being the most common sources (Table 11.7).

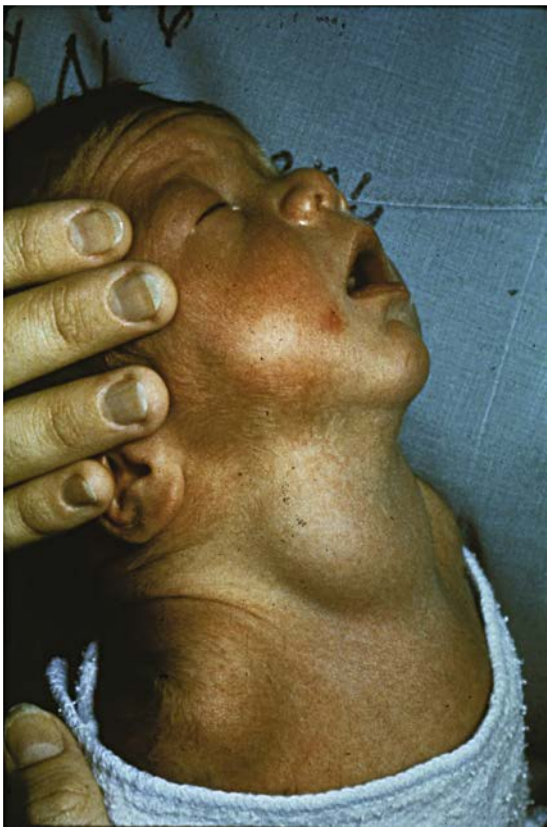
Effects of Increased Iodine Intake on Thyroid Hormone Synthesis

The quantity of iodine organified in Tg, which includes T_4 and T_3, displays a biphasic response to increasing doses of iodide, at first increasing and then decreasing as a result of a relative blockade of organic binding. This decreasing yield of organic iodine from increasing doses of iodide, the Wolff-Chaikoff effect, results from a high concentration of inorganic iodide within the thyroid cell.[18] The susceptibility to the Wolff-Chaikoff effect can be increased either by stimulation of iodide trapping, as occurs in patients with Graves disease, or during persistent TSH stimulation by impairment of iodine organification in the human fetus, in patients with Hashimoto disease, or in thyroids previously irradiated by either ^{131}I or external beam therapy. In such situations, goiter and hypothyroidism (iodide myxedema) can develop if excess iodide is given for long periods. The mechanism for organification inhibition may involve inhibitory effects of high iodide concentrations on TPO and DUOX2.

In normal subjects given iodide, the inhibition of iodothyronine formation is reversible over time. This escape or adaptation phenomenon occurs because iodide transport activity decreases probably through a decrease in NIS expression. Consequently, thyroidal iodide falls to levels insufficient to maintain the full Wolff-Chaikoff effect.[19,158] Importantly, it does *not* occur in the third-trimester fetus, so chronic high iodine intake during pregnancy must be avoided because it will cause fetal hypothyroidism and compensatory potentially obstructive goiter in the newborn (Fig. 11.11).

Effects on Thyroid Hormone Release

An important practical effect of pharmacologic doses of iodide is the prompt inhibition of thyroid hormone release. This occurs to



• **Fig. 11.11** Newborn infant with iodide-induced goiter due to Lugol solution treatment of the mother during the third trimester. This illustrates the danger of chronic excess iodide administration during pregnancy.

some extent normally but is especially apparent in patients with Graves disease or toxic nodules (see Chapter 12). The mechanism is unknown, but the effect is mediated at the thyroid cell level rather than through an action on TSH. Iodine also diminishes the hypervascularity and hyperplasia that characterize the diffuse toxic goiter of Graves disease. The pharmacologic use of iodide is therefore useful in patients with severe hyperthyroidsm *(thyroid storm)* or in the preparation of thyrotoxic patients for surgery.[159]

Thyroid Function in Pregnancy and in the Fetus and Newborn

Pregnancy affects virtually all aspects of thyroid hormone economy (Table 11.8).[160] The total serum T_4 and T_3 concentrations rise to levels about 1.5-fold those of nonpregnant women, owing to the increase in TBG concentration in the first trimester (Fig. 11.12). The markedly increased TBG extracellular pool must be filled steadily with increasing amounts of T_4 until a new equilibrium is reached. Human chorionic gonadotropin (hCG) cross-reacts with the TSHR, which results in a small and transient increase in free T_4 levels near the end of the first trimester (peak circulating hCG), resulting in a partial TSH suppression. In some women, hCG can induce transient gestational thyrotoxicosis, and trophoblast tumors (hydatidiform moles, choriocarcinomas) can rarely lead to severe hyperthyroidism. A mutation in the TSHR resulting in increased affinity for hCG has been found in familial gestational hyperthyroidism.[161] When tested in bioassays, normal hCG is only about 1/100 as potent as TSH. This weak thyrotropic activity explains why, in normal conditions, the effects of hCG remain largely unnoticed.[162] In addition to the increase in serum TBG, there is also an increased plasma volume as well as accelerated inactivation of T_3 and T_4 by D3 expression in the fetal-placental-uterine unit.[163] Based on the changes in requirements for levothyroxine during gestation in women with primary hypothyroidism, the estimated increase in T_4 production required during this period is 20% to 40%.

The requirement for increased T_4 secretion increases iodine requirements during pregnancy.[164] This need is compounded by the fact that the higher glomerular filtration rate during gestation enhances renal iodide clearance, leading to higher fractional

TABLE 11.8 Effects of Pregnancy on Thyroid Physiology

Physiologic Change	Thyroid-Related Consequences
↑ Serum thyroxine-binding globulin	↑ Total T_4 and T_3; ↑ T_4 production
↑ Plasma volume	↑ T_4 and T_3 pool size; ↑ T_4 production; ↑ cardiac output
D3 expression in placenta and (?) uterus	↑ T_4 production
First trimester ↑ in hCG	↑Free T_4; ↓ basal thyrotropin; ↑ T_4 production
↑ Renal I^- clearance	↑ Iodine requirements

• **Fig. 11.12** Changes in various critical components of the thyroid-pituitary axis during pregnancy. Note the early increase in free thyroxine (T_4), probably due to thyroidal stimulation by human chorionic gonadotropin (hCG), which causes a reciprocal modest suppression of serum thyrotropin (TSH) during the late first trimester. (From Burrow GN, Fisher DA, Larsen PR. Mechanisms of disease: maternal and fetal thyroid function. *N Engl J Med* 1994;331:1072–1078.)

urinary excretion of circulating iodide. In addition, maternal iodine intake must be increased to supply the requirements of the fetal thyroid during the second and third trimesters (see Table 11.8). If these increased requirements for iodide are not met, serum T_4 falls and TSH rises. This series of events is well documented in areas of endemic iodine deficiency or borderline iodine supply, such as Brussels, Belgium.[9] In that city, 70% of pregnant women carefully followed throughout pregnancy had a 20% or greater increase in thyroid volume during gestation due to increased TSH. After delivery, the changes in thyroid function gradually return to normal, and serum TBG values reach normal levels 6 to 8 weeks postpartum.

During pregnancy, autoimmunity is suppressed, affecting patients with Graves and Hashimoto diseases (see Chapters 12 and 13). In general, TSHR antibody (TRAb)–mediated thyroid stimulation in the Graves disease patient is exacerbated during the first trimester and is attenuated during the second and third trimesters only to exacerbate in the first several months postpartum. Thyroid autoantibody titers fall during gestation in patients with Hashimoto disease only to rise sharply postpartum in association with a phase of acute T-cell–mediated thyroid cell destruction—postpartum thyroid disease (PPTD)—which occurs in about 30% of patients with Hashimoto disease and significant residual thyroid tissue.[165]

The basal metabolic rate (BMR) increases during the second trimester owing to the increase in the total mass of body tissue consequent to the pregnancy. The changes of pregnancy, together with the decreased peripheral vascular resistance, vasodilatation, and modest tachycardia, may suggest thyrotoxicosis (see Table 11.8). It is important to appreciate that such changes are physiologic in pregnancy, especially when managing the hyperthyroid pregnant patient.

Fetal Thyroid Function

The peripheral metabolism of T_4 in the human fetus differs markedly from that in the adult, both quantitatively and qualitatively. Overall, rates of production and degradation of T_4 in terms of units per body mass exceed those in the adult by 10-fold. In addition, D1 catalysis is reduced and D3 is enhanced, favoring the formation of the inactive rT_3 at the expense of T_3. D3 is highly expressed in fetal tissues, including the liver, skin, tracheobronchial, urothelial, and gastrointestinal epithelia.[163] This condition results in a persistently low serum T_3 concentration and an elevated serum rT_3. This change permits the highly regulatable conversion of T_4 to T_3 by D2 to be the major pathway for generating tissue T_3.[166]

Fetal thyroid function begins at about the end of the first trimester.[5] Thereafter, there are steady increases in fetal TBG and total T_4 and T_3.[9,167] Throughout gestation, the serum TSH values are greater than are present in maternal circulation and higher than would be expected in adults with normal thyroid function. This indicates that there is increasing hypothalamic-pituitary resistance to T_4 during fetal development, which is speculated to be a consequence of increased TRH secretion.[168] Despite the low circulating T_3, the fetal free T_4 concentrations approximate those in the maternal circulation from the gestational age of 28 weeks and onward.

Maternal-Fetal Interactions

The fetal pituitary-thyroid axis functions as a unit that is essentially independent from the mother.[4,168] Transplacental passage of TSH from mother to fetus is negligible, but the same is not true of maternal T_4. In infants with congenital hypothyroidism caused by either genetic TPO deficiency or athyreosis, serum concentrations of T_4 in cord blood are usually one-third to one-half of normal.[169] Thus at least when the maternal-fetal concentration gradient is high, significant transfer of maternal T_4 to the fetal circulation can occur. This transfer may be significant, given the capacity of the fetal brain to increase the efficiency of T_4-to-T_3 conversion. Furthermore, T_4 can be found in coelomic and amniotic fluids before the onset of thyroid function.[170] The major factor limiting T_4 and T_3 transfer from mother to fetus is the D3 expressed in the uterus, placenta, and fetal epithelium.

Thyroid Function in the Newborn

Mean total T_4 level in cord sera is 150 nmol/L (12 μg/dL). Serum TBG concentrations are elevated, but are not as high as in the maternal serum. At term, free T_4 concentrations are slightly lower than those in the mother. Cord serum T_3 concentrations are low (0.8 nmol/L, 50 ng/dL), and rT_3 and T_3SO_4 are elevated.[4,171,172] After delivery, the serum TSH level in the neonate increases rapidly to a peak at about 2 to 4 hours after birth, returning to its initial value within 48 hours.[171] Levels above 60 mU/L are typical. This neonatal TSH surge is thought to occur in response to the rapid reduction in environmental temperature after delivery. In response, the serum T_4, T_3, and Tg concentrations increase rapidly during the first few hours after delivery and are in the hyperthyroid range by 24 hours of life.[173] The TSH surge doubtless contributes to the increase in serum T_3 concentration, but enhancement of extrathyroidal conversion of T_4 to T_3 by D1 or D2 is thought to be a major factor as well.[51] The adrenergic stimulation of the *Dio2* gene and the reactivation of D2 by its deubiquitination in brown adipose tissue are likely to be major contributors to this increase.[174]

Premature infants have an immature hypothalamic-pituitary-thyroid axis with low T_4, T_3, and TSH.[171,175] Serum T_4, TBG, and free T_4 all tend to correlate with gestational age. Preterm infants also have an attenuated TSH surge after delivery. In addition, when prematurity is accompanied by complications, such as respiratory distress syndrome or nutritional problems, serum T_4, and especially T_3, may fall to low levels as a result of a combination of reduced TBG production, immaturity of the thyroid gland, suppression of the hypothalamic-pituitary axis due to illness, impairment of T_4-to-T_3 conversion, and increases in D3 activity.[176,177] These changes are in many respects similar to those in adults with severe illness. All of these issues need to be taken into account when evaluating the thyroid status of the preterm infant, particularly given the increased prevalence of congenital hypothyroidism in this age group.[175]

Thyroid hormone production rates are higher per unit of body weight in neonatal infants and children than in adults. The daily levothyroxine requirement is about 10 μg/kg in the newborn, decreasing progressively to about 1.6 μg/kg in the adult.[175]

Aging and the Thyroid

The thyroid gland undergoes several anatomic changes with age. There is a reduction in weight of the gland, in the size of follicles, and in the content of colloid, and there is increased fibrosis, often with marked lymphocytic infiltration. However, these changes do not correlate with thyroid function.[176] In the healthy elderly patient, there is a normal level of free T_4, but serum T_3 levels appear to be lower, although studies of selected healthy people indicated that T_3 levels are unaffected by aging.[179] TSH may increase or decrease with age in relation to the iodine intake.[180] Population studies in

humans and animal models show negative correlations between thyroid hormone levels and longevity, a finding that led to the hypothesis that constraints on thyroid hormone signaling at certain life stages, notably during maturity, are advantageous for optimal aging.[181] However, some other studies have suggested that both subclinical hypothyroidism and subclinical hyperthyroidism might be associated with increased mortality in the elderly.[182]

Thyroid Function During Fasting or Illness

A number of changes take place in thyroid function during nutritional deprivation or illness. These changes consist of a central reduction in TSH secretion and a decrease in plasma T_3 levels and T_4 and T_3 binding in serum. This constellation of findings is termed the *low T_3 syndrome,* the *euthyroid sick syndrome,* or *nonthyroidal illness*.[183] The patterns of changes in circulating thyroid hormones and TSH during fasting and illness are quite similar. During fasting, there is a reduction of 50% or more in serum T_3 and an increase in serum rT_3 without initial changes in serum total or free T_4 (Table 11.9).[145,184] Although the role of specific deiodinases in causing these changes has not been documented at a tissue level in humans during fasting, several lines of evidence suggest that decreases in peripheral T_4-to-T_3 conversion by both D1 and D2 and a reduced clearance of rT_3 by D1 play a role in this process. The finding of normal T_3 plasma levels in mice with the genetic absence of both D1 and D2 enzymes suggests that, under normal conditions, the thyroid gland by itself is able to compensate for impaired peripheral conversion to normalize serum T_3. This observation suggests that very powerful mechanisms are in place to maintain serum T_3 levels within the normal range, with the notable exceptions of when it is not meant to be in that range (i.e., during fasting or illness). In these circumstances, by a mechanism probably regulated by the hypothalamus, all compensatory mechanisms are reduced and serum T_3 may drop to almost undetectable levels.[92] Deiodination by D3 increases the generation of rT_3 from T_4 and converts T_3 to 3,3′-diiodothyronine (see Fig. 11.2), which exaggerates the changes resulting from the decrease in D1 and D2. The finding that D3-null mice can still develop the low T_3 syndrome suggests that D3 upregulation is not the only event occurring in this clinical state. It is not yet known if such an increase in D3 also occurs during caloric restriction. The attenuation of TSH secretion despite a fall in serum T_3 levels during fasting is discussed earlier (see "The Hypothalamic-Pituitary-Thyroid Axis").

TABLE 11.9 Changes in Thyroid Hormone Levels During Illness

Severity of Illness	Free T_3	Free T_4	Reverse T_3	TSH	Probable Cause
Mild	↓	N	↑	N	↓ D2, D1
Moderate	↓↓	N, ↑↓	↑↑	N, ↓	↓↓ D2, D1, ? ↑ D3
Severe	↓↓↓	↓	↑	↓↓	↓↓ D2, D1, ↑ D3
Recovery	↓	↓	↑	↑	?

D1 through *D3,* Iodothyronine deiodinases; *N,* no change; *T_3,* triiodothyronine; *T_4,* thyroxine; *TSH,* thyroid-stimulating hormone (thyrotropin).

During fasting, basal oxygen consumption and heart rate decline, and nitrogen balance, initially negative, returns toward normal.[185] In some studies, these changes in overall metabolism are partially reversed by replacement of exogenous T_3 while fasting continues. Thus the decrease in T_3 during fasting (and presumably illness) can be viewed as a beneficial energy-sparing and nitrogen-sparing adaptation. Chronic malnutrition such as occurs in anorexia nervosa is also associated with a reduction in serum T_3 and rarely in free T_4.[186] TSH concentrations remain in the reference range, although again, they are inappropriately low in the context of the reductions in circulating T_3. In contrast, overfeeding, particularly with carbohydrates, increases T_3 production rates and the serum T_3 concentration, reduces serum rT_3, and increases basal thermogenesis.[187]

During illness, decreases in T_3 and pulsatile TSH release and increases in rT_3 also occur.[183] If illness progresses, the hypothalamic-pituitary-thyroid axis is even further suppressed, with a consequent reduction in the free T_4. Severe decreases in serum T_4 are associated with a high probability of death. This syndrome is associated with a decrease in TRH mRNA in the human PVN.[188] An increase in T_3 production by D2-catalyzed T_4-to-T_3 conversion in the tanycytes lining the third ventricle during illness may contribute to the blunted response of TSH to the reduced serum T_3, particularly during infections.[189] Cytokines, such as interleukin 6 (IL6), also increase during illness and are coincident with the decrease in circulating T_3, although it is not clear whether this is the cause of the hypothalamic changes.[190] An in vitro study indicated that IL6 causes an increase in intracellular and extracellular reactive oxygen species (ROS).[93] As mentioned, the active centers of both D1 and D2 are intracellular and that of D3 has access to extracellular thiols, which do not pass easily through the cell membrane (see Fig. 11.4). The increase in ROS reduces intracellular thiols such as GSH (glutathione) and presumably the GSH/NADPH-dependent thioredoxin and glutaredoxin. Thus T_4-to-T_3 conversion by D1 and D2 is reduced while D3-mediated T_3 and T_4 inactivation continues. In addition to these cofactor changes, the increase in ROS and the activation of MAPK-dependent pathways due to IL6 and ROS induce increases in the transcription of the deiodinases, especially D3.[93] In vitro, all these changes are reversed by addition of *N*-acetylcysteine (NAC) to the media, which rescues intracellular GSH synthesis. Interestingly, follow-up studies in patients with the low T_3 syndrome due to acute myocardial infarction show that the reduction in T_3 and the increase in rT_3 can be prevented by NAC infusions,[191] suggesting these in vitro results are relevant to sick patients. These endogenous changes may be further exaggerated by agents such as dopamine or glucocorticoids, which will also, at least transiently, suppress the TRH-TSH axis.[192] The changes in thyroid function are a continuum, with the abnormalities becoming progressively more severe in parallel with the patient's clinical condition (see Table 11.9). Postmortem studies show that hepatic D1 activity is reduced by about 50%, skeletal muscle D2 is absent, and D3 is present in liver and skeletal muscle.[193] No differences have been found in the T_3 transporter MCT8 in skeletal muscle or liver, and possible abnormalities in other thyroid hormone transporters have not been evaluated. Interestingly, the same global pattern of changes during acute medical illness has been described in patients with primary hypothyroidism receiving levothyroxine.[194] In such patients, serum T_4, T_3, and TSH concentrations all fell about 50% over the first 3 days, presumably due to a disruption of T_4 binding due to a decrease in TBG, TTR, and albumin, as well as a blockade of T_4-protein interactions due to circulating

interfering substances. Contributing to this may be the translational modification of TBG due to a serpin-catalyzed release of a carboxy-terminal fragment of TBG in inflamed tissues discussed earlier (see "Thyroxine-Binding Globulin").

Therapies have been introduced in an attempt to ameliorate certain of the illness-related central abnormalities in the hypothalamic-pituitary axis (including decreases in growth hormone and gonadotropins). One of these, infusions of growth hormone–releasing peptide 2 (GHRP2) combined with TRH, has resulted in increases in TSH, T_3, and T_4, as well as insulin-like growth factor 1 (IGF1), insulin, and the IGF-binding proteins 1, 3, and 5.[195] Although the biochemical improvements were significant, the clinical state did not change, suggesting that the thyroid dysfunction is a marker of the severity of the illness rather than its cause.

Although serum TSH concentrations in severely ill patients are reduced, an increase in TSH above the normal range may appear during recovery, with the elevation in TSH concentration persisting until circulating free T_4 and T_3 levels return to normal.[196] This pattern can be confusing if the elevated TSH concentration is associated with the still-reduced concentrations of free T_4. Such patients meet all laboratory criteria for primary hypothyroidism with the exception of the clinical context. Follow-up generally reveals a normalization of TSH and T_4 within 1 to 2 months (see Table 11.9).

Despite the severity of the abnormalities, particularly in serum T_3, there is still disagreement as to whether therapeutic intervention should be initiated even in the most severely ill patients because most controlled studies have not shown beneficial effects of T_4 or T_3 supplementation in such individuals.[183] The one exception is a possible beneficial effect of T_3 therapy in patients after coronary artery bypass grafting, with one study showing a positive effect but a second study showing none.[197,198] Therefore the cautious use of thyroid hormonal therapy in patients with low T_3 syndrome or a stunned myocardium was proposed.[199]

The Thyroid Axis and Neuropsychiatric Illness

Patients with neuropsychiatric disease can present with any of a number of abnormalities in thyroid function. Patients with bipolar disorders may show slight elevations in serum TSH and reductions in free T_4, whereas patients with severe depression have slight elevation in serum T_4 and reduced serum TSH. Other acutely psychotic patients may have either high or low serum TSH concentrations and tend to have elevations in free T_4.[200] The cause of these minor abnormalities is not clear, but such patients may have thyroid function test results resembling those of patients with primary thyroid disease from whom they must be differentiated.

Effects of Hormones on Thyroid Function

Glucocorticoids

The acute administration of pharmacologic doses of glucocorticoid eliminates pulsatile release of serum TSH concentrations in normal patients, presumably by reducing TRH release. With continued administration, there is an escape from this suppression (Table 11.10). Pharmacologic doses of glucocorticoid decrease the serum T_3 concentration in normal and hyperthyroid patients as well as in hypothyroid patients maintained on levothyroxine. The latter finding and the accompanying increase in rT_3 production suggest that glucocorticoids may increase D3 activity.[120]

Primary adrenal insufficiency may be associated with reduced serum T_4 and elevated serum TSH concentrations, suggesting the coexistence of primary hypothyroidism. However, treatment of the adrenal insufficiency can lead to complete resolution of these abnormalities, suggesting that in some patients they are a consequence of glucocorticoid deficiency rather than primary thyroid disease.[201] Nevertheless, the prevalence of primary hypothyroidism is increased in patients with autoimmune hypoadrenalism, so the two causes must be differentiated (see Chapter 15). Likewise, patients successfully treated for Cushing disease can develop thyroid autoimmunity.

Gonadal Steroids

Estrogen increases TBG by mechanisms already mentioned.[202] Presumably this increases T_4 secretion, in that total T_4 increases and free T_4 is unchanged. Estrogen also increases the levothyroxine requirement in patients with primary hypothyroidism.[66] In contrast, administration of androgens to women decreases TBG and decreases T_4 turnover and levothyroxine requirements in patients with primary hypothyroidism.[203]

Growth Hormone

Growth hormone increases the serum free T_3 and decreases free T_4 in both levothyroxine-treated and normal individuals, suggesting either suppression of D3 activity or increased T_4-to-T_3 conversion.

Physical Evaluation of the Thyroid Gland

Manifestations of thyroid disease are usually due to excessive or insufficient production of thyroid hormone, goitrous enlargement of the thyroid or nodules resulting in local symptoms in the neck through compression of adjacent structures, or, in the case of Graves disease, ophthalmopathy or dermopathy.

TABLE 11.10 Effects of Hormones on Thyroid Function

Glucocorticoids

Excess

Decrease TSH, TBG, TTR (high dose)
Decrease serum T_3/T_4 and increase rT_3/T_4 ratios
Increase rT_3 production (? ↑ D3)
Decrease T_4 and T_3 secretion in Graves disease

Deficiency

Increase TSH

Estrogen

Increase TBG sialylation and half-life in serum
Increase TSH in postmenopausal women
Increase T_4 requirement in hypothyroid patients

Androgen

Decrease TBG
Decrease T_4 turnover in women and reduce T_4 requirements in hypothyroid patients

Growth Hormone

Decrease D3 activity

D3, Type 3 deiodinase; *rT_3*, reverse T_3; *T_3*, triiodothyronine; *T_4*, thyroxine; *TBG*, thyroxine-binding globulin; *TSH*, thyrotropin; *TTR*, transthyretin.

A functional diagnosis of thyroid disease is based on a carefully taken history, a thorough search for the physical signs of hypothyroidism or thyrotoxicosis, and an appraisal of the results of laboratory tests. Although conditioned by the functional diagnosis, the anatomic diagnosis depends largely on the physical examination of the thyroid gland itself. The typical symptoms of an excess or a deficiency of thyroid hormone are discussed in Chapters 12 and 13.

Physical Examination

Examination of the neck is best accomplished with the patient seated in good light with the neck relaxed. The patient should be provided with a cup of water to facilitate swallowing. The physician should first inspect the neck, especially while the patient swallows, with the neck slightly extended. The presence of old surgical scars, distended veins, and redness or fixation of the overlying skin should be noted. The position of the trachea should be noted. If a mass is present, a determination should be made as to whether it moves with swallowing. A midline mass high in the neck, which rises further when the patient extends the tongue, is typical of a thyroglossal duct remnant or cyst. Movement on swallowing is a characteristic of the thyroid gland because it is ensheathed in the pretracheal fascia; this feature distinguishes a goiter from most other neck masses. However, if the thyroid is so large that it occupies all the available space in the neck, movement on swallowing may be lost. The physician should also inspect the posterior dorsum of the tongue, which is the origin of the thyroglossal duct and the location of lingual thyroid tissue.

Except when the thyroid enlargement is extreme, the thyroid examination can be readily performed with the physician facing the seated patient. The thyroid may also be examined with the physician standing behind the seated patient, palpating with the fingertips of both hands. The physician should use gentle thumb pressure to locate the thyroid isthmus just caudal to the cricoid cartilage. This provides a convenient starting point for the palpation of the lobes of the gland, but an increase in the thickness of the isthmus or a firm texture will already suggest the presence of some generalized thyroid enlargement. To examine the right lobe, the right thumb is then moved laterally, without release of gentle pressure, to locate the lobe of the thyroid by pressing it against the trachea as the patient swallows sips of water. This strategy allows the palpating thumb to laterally displace the medial border of the sternocleidomastoid muscle, allowing direct access to the entire thyroid lobe. As the patient swallows with the thumb pressing the lobe against the trachea with sufficient tension to displace it slightly over the midline, it will slide up and down under the ball of the thumb. This permits an appreciation of the size and texture of the gland as well as the presence or absence of nodules. A similar strategy with the left thumb is used for the left lobe.

The examiner should note the shape of the gland, its size in relation to normal, and its consistency, which is usually slightly greater than adipose tissue but less than muscle. The normal thyroid lobe has approximately the same size in frontal projection as the terminal phalanx of the patient's thumb. Whereas a diffuse goiter and the hyperplastic gland of the hyperthyroid patient with Graves disease may be softer than normal, the gland of Hashimoto disease is usually firm. Irregularities of the surface, variations in consistency, and tender areas should be noted. If nodules are palpated, their shape, size, position, translucency, and consistency in relation to the surrounding tissue should be determined. A firm mass may reflect a cyst, more rarely a malignancy. A search should be made for the pyramidal lobe, which is a thin band of tissue extending upward from the isthmus to the thyroid cartilage to the right or left of the midline. A hypertrophied pyramidal lobe may be mistaken for a pretracheal lymph node that sometimes accompanies thyroid carcinoma or thyroiditis. It is usually palpable in patients with generalized thyroid disease, such as Hashimoto or Graves disease. During palpation, a vascular thrill may be felt that, in the absence of cardiac disease, is suggestive of hyperthyroidism. Finally, palpation should always include examination of the regional lymph nodes along the jugular vein, posterior to the sternocleidomastoids and in the supraclavicular region.

Auscultation of the neck may confirm the increased vascularity of an enlarged, hyperactive gland, suggesting Graves disease. A systolic or continuous bruit is sometimes heard over a hyperplastic gland. Care should be taken to distinguish a thyroid bruit from a murmur transmitted from the base of the heart or from a venous hum that can be obliterated by gentle compression of the external jugular vein or by turning the head. A venous hum is generally found in younger patients with high cardiac output, such as occurs in Graves disease or with severe anemia.

An arm-raising test is useful when a retrosternal goiter is suspected. The basis for this maneuver is that if the size of the thoracic inlet is already reduced by such a goiter, raising both arms until they touch the sides of the head further narrows the thoracic inlet and causes congestion and venous engorgement of the face and sometimes respiratory distress *(Pemberton sign)* or even (rarely) syncope.

In addition to examination of the thyroid gland and regional lymph nodes, evidence of compression or displacement of adjacent structures should be sought. Hoarseness may indicate compression or infiltration of the recurrent laryngeal nerve, usually by a malignant thyroid neoplasm, and this should be confirmed by laryngoscopy. Displacement of the trachea may be evident, usually associated with a large nodule(s), and inspiratory stridor may indicate its compression.

Ultrasound is now widely available and has a superior sensitivity for the detection and characterization of thyroid nodules. Qualitative systems and Thyroid Imaging Reporting and Data Systems (TI-RADS) allow categorization of cystic and solid lesions and their relative risk for malignancy. It is also useful in the evaluation of patients with thyroiditis.[204,205] The use of ultrasound should enhance, not replace, the physical examination of the thyroid.

Laboratory Assessment of Thyroid Status

In considering the laboratory assessment of the patient with known or suspected thyroid disease, the physician should seek to arrive at both a functional and, when appropriate, an anatomic diagnosis. Laboratory determinations will confirm whether there is an excess, normal, or insufficient supply of thyroid hormone to verify the inferences from the clinical history and physical examination. Laboratory tests can be divided into five major categories: (1) those that assess the state of the hypothalamic-pituitary-thyroid axis, (2) estimates of the T_4 and T_3 concentrations in the serum, (3) tests that reflect the impact of thyroid hormone on tissues, (4) tests for the presence of autoimmune thyroid disease, and (5) tests that provide information about thyroidal iodine metabolism. The use of iodine and other isotopes for thyroid scanning is discussed in Chapter 14.

Tests of the Hypothalamic-Pituitary-Thyroid Axis

Thyroid-Stimulating Hormone

Although an inherently indirect reflection of thyroid hormone supply, tests that assess the state of the hypothalamic-pituitary-thyroid axis play a critical role in the diagnosis of thyroid disease.

This is because the rate of TSH secretion is exquisitely sensitive to the plasma concentrations of free thyroid hormones, thus providing a precise and specific indicator of the thyroid status of the patient (see Figs. 11.8 and 11.9). The rare exceptions to this rule are discussed later. Immunometric assay technology now makes it possible to define the normal range for serum TSH and hence to ascertain both when thyroid function is inadequate and when the hormone supply is excessive (see Chapter 4). This assay uses the TSH molecule to link a TSH antibody bound to an inert surface (e.g., particles, the side of a test tube) to a second antibody directed against a different TSH epitope that is labeled with a detectable marker (^{125}I, an enzyme, or a chemiluminescent reagent). Thus the signal generated is proportional to the concentration of TSH in the serum. This technique is more specific, sensitive, and rapid than radioimmunoassay.

Many of these assays take advantage of the biotin/streptavidin binding for high affinity for complex formation. This interaction can be affected by circulating biotin (vitamin B_7) in the serum of patients taking large amounts of this substance commonly available over the counter or prescribed for various skin conditions or even for type 2 diabetes. This is especially worrisome since high levels of serum biotin can both result in very low TSH levels and artifactually raise the free T_4 measured in robotic assays based on biotin/streptavidin chemistry (see Chapter 4).[206]

The reference range of the serum TSH concentration by immunometric assay is 0.4 to 4.2 mU/L. The lower limit of 0.4 is too high for pregnancy due to hCG-induced hyperthyroidism as discussed earlier.[162] It should be kept in mind that there is a diurnal variation of TSH secretion with peak values in the late evening and a nadir in the afternoon. A borderline abnormal value should always be repeated within a week or so to be certain that it is representative. A minimally suitable TSH assay should be able to quantitate concentrations of TSH of 0.1 mU/L with a coefficient of variation of less than 20%. Potential artifacts of these assays are discussed in Chapter 4.

The free α-subunit common to TSH, FSH, LH, and hCG is generally detectable in serum with a reference range of 1 to 5 μg/L, but the TSH β-subunit is not. When FSH and LH production are increased, as in postmenopausal women, or when TSH production is increased, as in primary hypothyroidism, the free α-subunit level is also increased. The α-subunit level may also be increased in patients with glycoprotein-producing tumors of the anterior pituitary (see Chapter 9). Its measurement may be useful in the rare patient with hyperthyroidism and a normal or elevated TSH to differentiate between neoplastic and nonneoplastic causes of TSH excess.[207,208]

TSH in Patients with Thyroid Dysfunction

Patients with primary hyperthyroidism (excess thyroid hormone secretion) or thyrotoxicosis (excess thyroid hormone from any cause) will virtually always have a subnormal TSH. The values fall into two general categories: (1) those between the lower limit of normal and 0.1 mU/L and (2) those less than 0.1 mU/L. Individuals in the former category may be asymptomatic *(subclinical hyperthyroidism),* whereas those in the latter group usually have symptomatic thyrotoxicosis and a significant elevation in free T_4. Patients with hypothalamic or pituitary hypothyroidism often have normal or possibly even slightly elevated serum TSH. The circulating TSH generally has reduced biologic activity due to abnormal glycosylation, reflecting the impaired access of TRH to the thyrotroph.[142,143] Patients with primary hypothyroidism have serum TSH concentrations that range from minimally elevated to 1000 mU/L. In general, the degree of TSH elevation correlates with the clinical severity of the hypothyroidism. Patients with serum TSH values in the range of 5 to 15 mU/L have few if any symptoms, and the serum free T_4 or free T_4 index (FT_4I) is typically low-normal, whereas the serum free T_3 concentration is often low-normal. Such individuals with modest TSH elevation are said to have *subclinical hypothyroidism* if the serum free T_4 is in the normal range. These findings may indicate early thyroidal failure with a compensatory increase in TSH secretion. A detailed discussion of the various conditions associated with abnormal serum TSH concentrations follows that describing the quantitation of serum thyroid hormones (see upcoming discussion).

An elevation in both serum TSH and free T_4 is unusual and indicates either autonomous TSH production (due to a TSH-secreting pituitary tumor, resistance to thyroid hormone) or hyperthyroidism with an artifactual elevation in TSH. Differentiating between these diagnoses may require magnetic resonance imaging (MRI) of the hypothalamic-pituitary region, markers of thyroid hormone action (e.g., ferritin or sex hormone–binding globulin), or consultation with the clinical chemistry laboratory to rule out an assay artifact (see Chapter 4).

Quantitation of Serum Thyroid Hormone Concentrations

Total T_4 and T_3

Quantitation of the circulating thyroid hormone concentrations is essential to confirm that the thyroid status abnormality suggested by an abnormal TSH result is accurate and to document its severity. Sensitive and specific radioimmunoassays are available for measuring the total concentrations of T_4 and T_3 and some of their metabolic byproducts (see Chapter 4). Because the thyroid status correlates with the free, rather than with the total, hormone concentration, the physician usually must also obtain an estimate of that (see following discussion). The degree of abnormality in the free T_4 generally correlates with the severity of the hormone excess or deficiency, whereas the serum TSH concentration is an indication of the impact of this abnormality in that specific patient. The reference range for total T_4 in healthy, euthyroid adults with a normal circulating TBG concentration is 64 to 142 nmol/L (5–11 μg/dL). Normal serum T_3 concentrations are 1.1 to 2.9 nmol/L (70–190 ng/dL). At birth (cord serum), T_3 concentrations are about 50% of those in normal adults, but within a few hours T_3 rises abruptly, peaking at about 24 hours at concentrations in the low thyrotoxic range for adults.

Radioimmunoassays for reverse T_3 (rT_3), T_3SO_4, triac, tetrac, and the diiodothyronines are of primary interest in the research setting because these iodothyronines are derived from the circulating T_4 or T_3, both of which can be easily quantitated.

Concentrations of Free T_4 and Free T_3

The most accurate and direct measurements of the concentrations of free T_4 and free T_3 in serum are performed by assay of these hormones in a dialysate or ultrafiltrate of serum. Such assays are not practical for clinical purposes, so alternative strategies have been developed to estimate free thyroid hormone concentrations. The absolute concentration of free hormone is the product of the total hormone concentration and the fraction that is dialyzable or ultrafiltrable. About 0.02% of T_4 and 0.3% of T_3 is free or

unbound (see Table 11.5). The reference range for free T_4 is 9 to 30 pmol/L (0.7–2.5 ng/dL), and for free T_3 the range is 3.5 to 6.5 pmol/L (0.22–0.43 ng/dL).

So-called direct measurements of free T4 are now available by robotic assays in virtually all laboratories. They have largely replaced the free T_4 index discussed in more detail in past editions of this textbook. These automated tests imply that they quantitate free T_4 directly, but they do not, and rarely results in sera with abnormal binding proteins or in very sick patients may not be accurate.[209] In most situations, especially in outpatients, this automated free T_4 estimate is all that is required to ascertain the state of thyroid secretion or supply.

These assays are subject to artifacts from endogenous antibodies to T_4, abnormal binding proteins, or severe illness.[208,210] Thus the clinician must be wary if the free hormone estimate by *any* method does not agree with the clinical state and the TSH. In such situations, the patient should be questioned as to potential excessive biotin (vitamin B_7) ingestion, and another method should be used to estimate the free T_4. A total T_4 and thyroid hormone–binding ratio (THBR) should be measured and the FT_4 I calculated or the result should be ignored. For pregnant or severely ill patients, the automated methods typically give falsely low results. A reasonable alternative for pregnancy is to use the normal range for the serum total T_4 concentration multiplied by 1.5 in lieu of an automated free T_4 assay.[211,212]

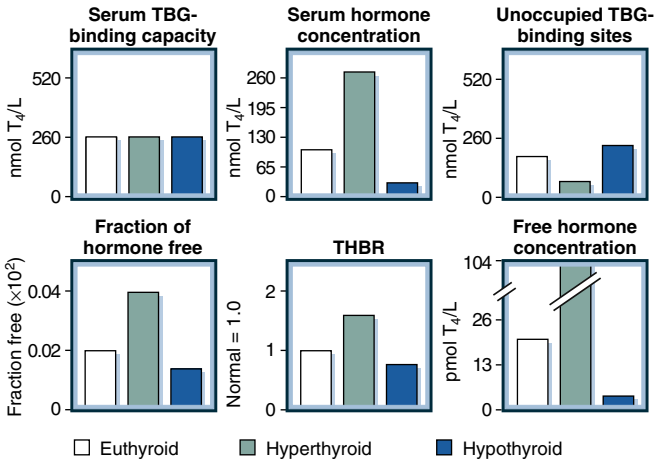
The Free T_4 Index

Although rarely necessary with the widespread availability of "direct" free T_4 assays, particularly useful in estimating the free T_4 in severely ill patients is the determination of the THBR, multiplying this result by the total T_4 (or T_3) to obtain a free hormone index (FT_4I or FT_3I). In this test, a tracer quantity of labeled T_4 (or T_3) is added to serum, which is then exposed to a solid phase matrix coated with T_4 or T_3 antibody or to an inert matrix that binds the iodothyronine irreversibly. The proportion of labeled T_4 or T_3 bound by the solid phase is then quantitated. This value varies inversely with the concentration of unoccupied TBG sites in the serum.

The results of such assays are normalized by comparing them with those obtained simultaneously for standard control sera with normal TBG and T_4 concentrations. This step can be performed by dividing the result for the unknown sample by that obtained for control sera in the same assay; in this case, the quotient is called the THBR (thyroid hormone–binding ratio), which typically has a normal range of 0.85 to 1.10. Because the THBR is proportional to the free fraction of the endogenous thyroid hormones in the serum, it can be multiplied by the total T_4 (or T_3) concentration to estimate the free thyroid hormone concentration (i.e., the free T_4 or T_3 index [FT_4I or FT_3I]). Because the midnormal THBR is 1.0, the FT_4I has a normal range in units that are identical to that of the total T_4 (or T_3)—for example, 64 to 142 nmol/L (SI units) and 5 to 11 µg/dL (gravimetric terms). A schematic demonstration of the relationships between total and free T_4, occupied and unoccupied TBG binding sites, and the THBR is shown in Fig. 11.13 for euthyroid individuals with variations in TBG concentrations and in Fig. 11.14 for subjects with a constant TBG and alterations in serum thyroid hormone production rates.

Estrogen, pregnancy, and severe illness are more common causes of changes in total T_4 concentrations than are hyperthyroidism and hypothyroidism (Table 11.11). In the euthyroid person, only about one-third of the available binding sites on TBG are occupied by T_4, and the free T_4 fraction is 2×10^{-4} of the total. During pregnancy, the TBG-binding capacity, the serum T_4, and the number of unoccupied TBG-binding sites approximately double, leading to an approximately 50% reduction of the free T_4 fraction. If the reduced THBR (or free fraction) is multiplied by an increased total T_4, the FT_4I estimate is normal, an accurate reflection of the free T_4 concentration. In patients in whom the serum T_4 concentration is reduced owing to a low TBG, the concentration of unoccupied binding sites is reduced to an even greater extent. This reduction leads to an increase in the free T_4 (and T_3) fractions and the THBR, and both the free T_4 and the FT_4I remain in the normal range. These concepts and expected results in patients with abnormalities in total T_4 or TBG are shown in Figs. 11.13 and 11.14. When concentrations of TBG are altered, the deviation of the total T_4 measurements from normal is in the opposite direction to that of the THBR (see central panels of Fig. 11.13). On the other hand, when the T_4 level is elevated due to increased T_4 secretion or overreplacement, the concentration of

To convert T_4 from nmol/L to µg/dL (total) or pmol/L (free), divide by 12.87.



• **Fig. 11.14** Pattern of changes in total serum thyroxine (T_4) concentration and thyroid hormone–binding ratio (THBR) in patients with hyperthyroidism or hypothyroidism with normal serum thyroxine-binding globulin (TBG) concentration.

TABLE 11.11 Circumstances Associated with Altered Binding of Thyroxine by Thyroxine-Binding Globulin

Increased Binding	Decreased Binding
Pregnancy	Androgens
Neonatal state	Large doses of glucocorticoids
Estrogens and hyperestrogenemic states	Active acromegaly
	Nephrotic syndrome
Tamoxifen	Major systemic illness
Oral contraceptives	Genetic factors
Acute intermittent porphyria	Asparaginase
Infectious and chronic active hepatitis	
Biliary cirrhosis	
Genetic factors	
Perphenazine	
Human immunodeficiency virus infection	

unoccupied TBG binding sites is reduced, and both the free fraction and the total T_4 are altered in the same direction (see Fig. 11.14).

Several caveats should be kept in mind in the interpretation of these results. The use of labeled T_3 in some assays can produce difficulties in three situations: (1) in cases of *familial dysalbuminemic hyperthyroxinemia* (FDH), (2) in the presence of endogenous antibodies directed against T_3, and (3) in sick patients, as already discussed. In FDH, the abnormal albumin binds T_4, but *not* T_3, with increased avidity. Therefore these patients have an elevated total T_4 and reduced free fraction of T_4 (when measured by the FT_4I) *but not* T_3.[213] It is also possible to measure TBG either by saturation analysis or radioimmunoassay. Normal concentrations of TBG by radioimmunoassay are about 270 nmol/L (1–1.5 mg/dL) and are only slightly higher in women than in men.

Causes of Abnormal TSH or Thyroid Hormone Concentrations

Several causes of an abnormal TSH should be considered by the clinician (Table 11.12). The clinical status and free T_4 results (and sometimes T_3 levels) allow evaluation of the cause for abnormal TSH levels.

Causes of a Suppressed TSH

The most common cause of a reduction in serum TSH is an excess supply of thyroid hormone due to either increased endogenous thyroid hormone production or excessive exogenous thyroid hormone. Because the concentration of TSH is inversely proportional to the degree of thyroid hormone excess, patients with clinical symptoms almost invariably have serum TSH concentrations below 0.1 mU/L. Such patients nearly always have an increase in the free T_4. When thyroid hormone supply is only slightly in excess of the requirement for that patient, serum TSH is suppressed, but clinical manifestations are subtle or absent, and the free T_4 is in the high-normal range. Such minimal changes can sometimes occur with mild Graves disease, autonomous thyroid hormone–producing adenomas, multinodular goiters, subacute or painless thyroiditis, and the ingestion of an amount of exogenous thyroid hormone slightly higher than that required for metabolic needs. This condition is termed *subclinical hyperthyroidism*.

The hypothalamic-pituitary axis may remain suppressed for several months after complete resolution of the thyrotoxic state.[214] The best test for assessing the physiologic state in such patients is the free T_4 (or FT_4I). A common scenario for this pattern is during follow-up of patients receiving antithyroid drugs or ^{131}I for Graves disease. With time, the TSH feedback regulatory loop will normalize, and TSH secretion will return and become appropriate for the circulating free thyroid hormone concentration. As mentioned, patients with few or no symptoms of thyrotoxicosis and subnormal TSH and high free T_4 values should be questioned regarding biotin ingestion.

In severe illnesses, with or without dopamine infusion or excess glucocorticoid, TSH is suppressed, making assessment of thyroid functional status difficult (see earlier discussion). Because the free T_4 may also be reduced in such patients, astute clinical judgment is required to assign the thyroid status.

Because hCG can activate the TSHR, conditions in which hCG is particularly high, such as in the first trimester of pregnancy, with twin pregnancies, and in patients with hydatidiform mole or choriocarcinoma, the TSH concentration is often suppressed.[162] Interestingly, there is a correlation with hCG levels and the occurrence of *hyperemesis gravidarum*. TSH returns to normal in the second and third trimesters in the euthyroid patient. A persistently suppressed TSH (<0.1 mU/L) in the pregnant patient after the first trimester suggests that the hyperthyroidism is due to autonomous thyroid function.

Changes in thyroid test results in patients with psychosis or depression, in the geriatric population, and with the use of long-term glucocorticoids have been discussed earlier. If the serum TSH is suppressed *and* the serum free T_4 is low, one should be suspicious that liothyronine (triiodothyronine) is being ingested before assuming pituitary or hypothalamic dysfunction. Desiccated thyroid also has a high T_3:T_4 ratio and if given in excess may cause a similar abnormality.[215]

Causes of an Elevated TSH

Elevations in TSH nearly always imply a reduction in the supply of T_4 or T_3, which may be permanent or transient. Primary hypothyroidism is far and away the usual explanation. Other causes include acutely ill patients, such as those with renal insufficiency,[216] or the asynchronous return of the hypothalamic-pituitary-thyroid axis to normal as critically ill patients recover.[217] Iodine deficiency is the most common cause of an elevation in TSH worldwide, but this does not occur in North America. The rare patient with RTH due to a mutation in the *THRB* gene (RTHβ) may have a complex phenotype with signs of hypothyroidism in some tissues and hyperthyroidism in others. The most common laboratory pattern is a serum TSH level that is normal or mildly elevated in absolute terms but inappropriately high for the elevated free T_4.[126] They must be differentiated from the patient with a thyrotroph tumor in whom the persistent secretion of TSH causes hyperthyroidism (see Chapters 9 and 12).[207] Patients with mutations in the *THRA* gene (RTHα) have a normal TSH, free T_3, but a low free and total T_4.[127]

Patients with hypothalamic-pituitary dysfunction may have clinical and chemical hypothyroidism but low, normal, or even elevated serum TSH concentrations. The explanation for this

TABLE 11.12 Thyroid Status and Free Thyroid Hormone Levels in Clinical States Associated With Abnormal Serum Thyrotropin (TSH) Concentrations[a]

	Expected TSH (mU/L)	Clinical Thyroid Status	Free T_4	Free T_3
Thyrotropin Reduced[a]

Artifact (endogenous antimouse γ-globulin antibodies)	10–500	N	N	N

[a]Arrows indicate the nature of the abnormality in free T_4 or T_3. Parentheses indicate that such a result is unusual but may occur. Excess serum biotin may suppress TSH and elevate free T_4.

N, No change; *T_3*, triiodothyronine; *T_4*, thyroxine.

paradox is that the biologic effectiveness of the circulating TSH is impaired as a result of abnormal glycosylation secondary to reduced TRH stimulation of the thyrotrophs. Nonetheless, the abnormal TSH is a suitable antigen in the immunometric assay. In adrenal insufficiency, TSH may be modestly elevated but returns to normal with glucocorticoid replacement.[201] This may reflect glucocorticoid-mediated amelioration of Hashimoto thyroiditis.

Despite the utility and general efficacy of the serum TSH measurement alone as a screening tool for identifying patients with thyroid dysfunction, a patient should not receive treatment solely on the basis of an abnormal TSH. The TSH assay is an *indirect reflection* of thyroid hormone supply and does not, by itself, permit a conclusive diagnosis of a specific disorder of thyroid hormone production. Accordingly, the TSH abnormality must be confirmed and the expected alteration in thyroid hormone concentrations documented before initiating treatment.

Tests That Assess the Metabolic Impact of Thyroid Hormones

Abnormalities in the supply of thyroid hormone to the peripheral tissues are associated with alterations in a number of metabolic

processes that can be quantitated. Some of these may be useful in the rare patient in whom serum TSH is not an accurate barometer of thyroid status, such as those with RTHβ. These tests may be the sole means of evaluating the metabolic response of the peripheral tissues to thyroid hormones in such patients but are rarely required otherwise.

Basal Metabolic Rate

Thyroid hormones increase energy expenditure and heat production, as manifested by weight loss, increased caloric requirement, and heat intolerance. Because it is impractical to measure heat production directly, the basal metabolic rate (BMR) measures oxygen consumption under specified conditions of fasting, rest, and tranquil surroundings. Under these conditions, the energy equivalent of 1 L of oxygen is 4.83 kcal.

Under basal conditions, approximately 25% of oxygen consumption is due to energy expenditure in visceral organs, including the liver, kidneys, and heart; 10% occurs in the brain, 10% in respiratory activity, and the remainder in skeletal muscle. Because energy expenditure is related to functioning tissue mass, oxygen consumption is related to some index thereof, most often body surface area. Calculated in this way, basal oxygen consumption (resting energy expenditure) is higher in men than in women and declines rapidly from infancy to the third decade and more slowly thereafter. Values in patients, calculated as a percentage of established normal means for sex and age, normally range from −15% to +5%. In severely hypothyroid patients, values may be as low as −40%, and in thyrotoxic patients, these values may reach +25% to +50%. Abnormal, usually elevated, values are seen during recovery in burn patients and in those with systemic disorders, such as febrile illnesses, pheochromocytoma, myeloproliferative disorders, anxiety, and disorders associated with involuntary muscular activity. Resting energy expenditure correlates very well with the free T_4 and TSH in hypothyroid patients given varying doses of exogenous levothyroxine.[218]

Biochemical Markers of Altered Thyroid Status

Occasionally a diagnosis of thyroid dysfunction is first suspected due to an abnormality in a laboratory result performed during an evaluation for an unrelated medical problem. Classic examples are a markedly elevated creatine kinase MM isoenzyme or low-density lipoprotein (LDL) cholesterol reading, leading to the recognition of hypothyroidism.[219] Other similar markers are listed in Table 11.13. These tests are not useful in the diagnosis of thyroid disease, but some, such as sex hormone–binding globulin (SHBG), ferritin, or LDL cholesterol, have been used as end points in clinical studies of the responsivity of the liver to thyroid hormone in patients with thyroid hormone resistance.

Serum Thyroglobulin

The functional sensitivity of most Tg assays is 1 ng/mL or less.[220] The results can be artifactually altered by serum anti-Tg antibodies, and serum should be screened for Tg antibodies with a sensitive Tg-antibody immunoassay. In immunoradiometric assays, interferences lead to underestimations of Tg or false-negative values, whereas values when measured by radioimmunoassay may be falsely elevated.

Tg is normally present in the serum, the concentration ranging up to 50 ng/mL; mean normal values vary with the assay used but are on the order of 20 ng/mL.[221] Concentrations are somewhat higher in women than in men and are elevated several fold in pregnant women and in the newborn. Levels are elevated in three types of thyroid disorders: goiter and thyroid hyperfunction, inflammatory or physical injury to the thyroid, and differentiated follicular cell–derived thyroid tumors and especially in consumptive hypothyroidism.[104] Values are elevated in both endemic and sporadic nontoxic goiter, and the degree of elevation correlates with the thyroid size. Transient elevations occur in patients with subacute thyroiditis and as a result of trauma to the gland during thyroid surgery or after ^{131}I therapy. Subnormal or undetectable concentrations are found in patients with thyrotoxicosis factitia and aid in differentiating this disorder from other causes of thyrotoxicosis with a low thyroid radioiodine uptake (RAIU).

A major clinical value of measuring the level of serum Tg is in the management, but not in the diagnosis, of differentiated thyroid carcinoma.[220,222] Serum Tg concentrations are increased in patients with both benign and differentiated malignant follicular cell–derived tumors of the thyroid and do not serve to distinguish between the two. After total thyroid ablation for papillary or follicular thyroid carcinoma, Tg should not be detectable, and its subsequent appearance typically signifies the presence of persistent or recurrent disease.[222] The serum Tg level is related to the mass of neoplastic tissue and may be undetectable in patients with small lymph node micrometastases (see Chapter 14). Secretion of Tg is TSH dependent. Therefore the serum Tg level may rise when suppressive therapy is withdrawn or after injections of recombinant human TSH (rhTSH), which will increase the sensitivity of the marker for the detection of persistent or recurrent thyroid carcinoma, even when ^{131}I scans are negative (see Chapter 14). Supersensitive assays of Tg with a functional sensitivity less than 0.1 ng/mL improve the sensitivity during thyroid hormone treatment, but at the expense of a decreased specificity.[223,224] This measurement is useful for the follow-up of patients treated with total thyroidectomy with or without radioactive iodine ablation.[225] Unfortunately there is a major potential artifact in some patients due to the presence of autoantibodies binding to Tg. In this situation,

TABLE 11.13 Biochemical Markers of Thyroid Status

Thyrotoxicosis
Increased

measurement of Tg by radioimmunoassay or liquid chromatography-tandem mass spectrometry (LC-MS/MS) may be more informative.[226]

In the hypothyroid newborn, serum Tg is undetectable in patients with thyroid agenesis and is usually elevated in those with ectopic thyroid tissue or goiter and in consumptive hypothyroidism due to infantile hemangioma.

Tests for Thyroid Autoantibodies

Graves disease and Hashimoto thyroiditis are well characterized and interrelated autoimmune thyroid disorders with a variety of clinical manifestations. The diagnostic hallmark of the autoimmune thyroid disorders is the presence, in most patients, of circulating autoantibodies and reactive T cells against one or more thyroid antigens.[227] Three varieties of thyroid autoantibodies are in common use and widely available in clinical diagnostic laboratories (Table 11.14). In this section, autoantibodies to Tg and TPO are discussed. Antibodies directed against the TSHR, the cause of hyperthyroidism in patients with Graves disease, are detailed in Chapter 12.

Autoantibodies to Thyroid Peroxidase and Thyroglobulin

Current automated assay techniques for thyroid autoantibodies have good precision because they depend on direct measurement of the interaction between autoantibody and autoantigen (i.e., the interaction between thyroid antigen and the patient's serum). In general, the more sensitive an assay, the more precise and antigen specific it is. However, many euthyroid individuals exhibit low levels of autoantibodies, and in this situation, the absolute concentration becomes important. The higher the concentration of autoantibody, the greater the clinical specificity (see Table 11.14).[228]

So that comparisons of thyroid antibody concentrations can be made from one office visit to the next, among different patients and among laboratories, assays for thyroid autoantibodies have been standardized with results expressed as standard units per milliliter. Of course, the actual standard serum preparation cannot be included in every assay. Instead, a serum pool is usually compared and normalized to the original standard. Autoantibodies differ considerably in their affinity and epitope recognition of antigen, and so the slopes of different standard curves may vary. As a result, despite this attempt at standardization, assay results from different commercial assays may still vary considerably. Hence when monitoring antibody titers (e.g., measuring Tg-Ab after the treatment of thyroid cancer), it is always best to consistently use the same autoantibody assay.

TABLE 11.14 Prevalence of Thyroid Autoantibodies

Group	TSHR-Ab (%)	hTg-Ab (%)	hTPO-Ab (%)
General population	0	5–20	8–27
Patients with Graves disease	80–95	50–70	50–80
Patients with autoimmune thyroiditis	10–20	80–90	90–100
Relatives of patients	0	40–50	40–50
Patients with IDDM	0	40	40
Pregnant women	0	14	14

IDDM, Insulin-dependent diabetes mellitus; *hTg-Ab,* human thyroglobulin antibody; *hTPO-Ab,* human thyroid peroxidase antibody; *TSHR-Ab,* thyroid-stimulating hormone receptor antibody.

Do Thyroglobulin and Thyroid Peroxidase Antibodies Have a Pathogenic Role?

Tg-Ab and TPO autoantibodies (TPO-Ab) appear to be a secondary response to thyroid injury and are not thought to cause disease themselves, although they may contribute to its development and chronicity. Both types of antibodies are polyclonal, and although they are of the immunoglobulin G class, they are not restricted to a particular immunoglobulin G subclass. These thyroid antibodies cannot transfer disease from mother to fetus or between animals even though they can pass across the placenta.[229] However, both antibodies may contribute to disease mechanisms. For example, TPO-Ab on the surface of B cells may be involved in antigen presentation, thus activating thyroid-specific T cells.[230] Such autoantibodies may have complement-fixing cytotoxic activity; TPO-Ab, in particular, correlates well with thyroid damage and lymphocytic infiltration.

Thyroid Autoantibodies in Hashimoto Thyroiditis and Graves Disease

The disease most widely associated with Tg-Ab and TPO-Ab is autoimmune thyroiditis, or Hashimoto disease (terms that embrace both goitrous thyroiditis, as first described by Hashimoto, and atrophic thyroid failure, previously referred to as primary myxedema). Both Tg-Ab and TPO-Ab are found in almost 100% of such patients, but TPO-Ab has a higher affinity and occurs in higher concentrations, so testing for TPO-Ab is more helpful.

Tg-Ab and TPO-Ab are also detectable in 50% to 90% of patients with Graves disease, indicative of the associated thyroiditis that is evident histologically as a heterogeneous lymphocytic infiltration. Hence Graves disease tends to develop on a background of autoimmune thyroiditis. Although the presence of such autoantibodies favors an autoimmune cause for hyperthyroidism over other causes, the tests are neither sensitive nor specific in this setting and are interpretable only as part of the clinical scenario. Testing for TSHR antibodies is important in the evaluation of hyperthyroid patients, along with consideration of a radioiodine uptake and scan.

Thyroid Autoantibodies in Nonautoimmune Thyroid Disorders

Tg-Ab and TPO-Ab are more common in patients with sporadic goiter, multinodular goiter, or isolated thyroid nodules and cancer than in the general population. This finding usually represents an associated thyroiditis on histologic examination. Low levels of thyroid autoantibodies may occur transiently in patients with subacute (de Quervain) thyroiditis but correlate poorly with disease course and are probably a nonspecific response to thyroid injury. There is also a higher prevalence of thyroid autoantibodies in many other autoimmune diseases, particularly insulin-dependent diabetes mellitus.

Thyroid Autoantibodies in Pregnancy

Euthyroid women with thyroid autoantibodies have been shown to suffer from increased early pregnancy loss. The miscarriage rate in the presence of TPO-Ab is almost doubled in many studies,[231–233] and the cause is uncertain. It is unclear if this is a reflection of an immune diathesis or due to subtle alterations in thyroid function.

The screening of pregnant women has been advocated by some groups but is controversial.[234]

The Normal Population

Although the prevalence of thyroid autoantibodies depends on the technique used for detection, Tg-Ab and TPO-Ab are common in the general population (see Table 11.14). At all ages, these antibodies are almost five times more common in women than in men. Selected groups at risk include younger women and relatives of patients with an autoimmune thyroid disorder, in whom the incidence is higher. The low levels of TPO-Ab and Tg-Ab found in many individuals are of uncertain significance in the presence of normal thyroid function; however, they remain a significant risk factor in families with autoimmune thyroid disorders.[235]

Radioiodine Uptake

A direct test of thyroid function uses a radioactive isotope of iodine as a marker for the body's stable form of iodine, ^{127}I. Most often the test involves the measurement of the fractional uptake by the thyroid of a tracer (chemically inconsequential) dose of radioiodine. However, several factors make this test less frequently used than in the past. The first is the improvement in indirect methods for assessing thyroid status. The second is the decrease in normal values for thyroid RAIU consequent to the widespread increase in daily dietary iodine intake, reducing the utility of the test in the diagnosis of thyroid disorders. However, the test is still useful in defining the etiology of thyrotoxicosis. It should not be performed in pregnant and breastfeeding women.

^{131}I (half-life 8.1 days) and ^{123}I (half-life 0.55 day) both emit gamma radiation, which permits their external detection and quantitation at sites of accumulation, such as the thyroid. These isotopes (abbreviated I* hereafter) are physiologically indistinguishable, not only from one another but also from the naturally occurring I, which permits their use as valid tracers. The shorter half-life of ^{123}I is preferable because the radiation delivered to the thyroid per amount of administered ^{123}I is only about 1% of that delivered by ^{131}I. ^{131}I also emits beta radiation, hence its utility in the therapy of patients with Graves disease, hyperfunctioning nodules, and well-differentiated thyroid cancer.

Physiologic Basis

When tracer quantities of inorganic radioiodine are administered orally or intravenously, the isotope quickly mixes with the endogenous stable iodide in the extracellular fluid and begins to be removed by the two major sites of clearance, the thyroid and the kidneys. As this process continues, the plasma level of tracer iodide I* decreases exponentially. Low levels are reached by 24 hours, and inorganic I* is virtually undetectable in the plasma 72 hours after its administration. The thyroid content of I* increases rapidly during the early hours and then at a decreasing rate until a plateau is approached. The proportion of administered I* ultimately accumulated by the thyroid is a function of the clearance of iodide by the thyroid and kidneys. The relationship is simply expressed by the following equation:

$$\text{RAIU at plateau} = \frac{C_T}{C_T + C_K}$$

where C_T represents the thyroid iodide clearance rate and C_K the renal iodide clearance rate. The normal thyroid iodide clearance rate is approximately 0.4 L/hour, and the renal iodide clearance rate is 2.0 L/hour, so the uptake of I* normally approximates 20% of the administered dose.

Measurements of RAIU are generally made at 24 hours, both as a matter of convenience and because the value at 24 hours is usually near the plateau, but RAIU can be measured at 6 hours with appropriate determination of a reference range.

Radioactive Iodine Uptake

Little difference will be noted if the uptake is measured at any time during the day following that on which the isotope was administered, and for the calculation of therapeutic radioiodine doses in treating thyrotoxic Graves disease an early uptake at 3 to 6 hours may produce results comparable to those found at 20 to 28 hours.[236] With the use of this modified early RAIU measurement, diagnosis and treatment of thyrotoxic Graves disease can be accomplished on the same day. In general, the reference range in North America is approximately 5% to 25%. Higher values are found in iodine-deficient regions or in patients with thyroid hyperfunction, but as with other procedures, patients with mild hyperthyroidism may display values at or just above the upper limit of the reference range (Table 11.15).

The Perchlorate Discharge Test

In normal individuals, more than 90% of thyroidal radioiodine is organified and present as iodotyrosine and iodothyronine within minutes of its entry into the thyroid. It is then no longer in the intracellular iodide pool. In patients with Pendred syndrome or with other disorders that inhibit the iodination of tyrosine, such as Hashimoto thyroiditis, or those receiving thiourea drugs, this process is delayed, as shown by the exit (discharge) of more than 10% of the thyroidal radioiodine within 2 hours of administration of 500 mg of $KClO_4$.[12] Perchlorate inhibits NIS function by competing with iodide for NIS, eliminating the iodide gradient that is required for maintaining the radioiodide in the gland. This illustrates that both iodide transport by NIS at the basal pole of the thyrocyte and its efflux across the apical membrane by pendrin are required for thyroid hormone synthesis.

States Associated With Increased RAIU

Hyperthyroidism

Hyperthyroidism (sustained excess endogenous thyroid hormone production) as distinct from *thyrotoxicosis*, which refers to the manifestations of excess thyroid hormone levels due to any cause, is accompanied by an elevated RAIU at 24 hours unless body iodide stores are increased. The increased uptake is always evident unless the release of labeled hormone is so rapid that the thyroidal content of I* has decreased to the normal range by the time the measurement is made. This condition is rare, is typically associated with severe thyrotoxicosis, and can be recognized by checking the thyroid uptake at 6 hours.

Aberrant Hormone Synthesis

RAIU can be increased in the absence of hyperthyroidism in disorders in which iodine accumulation is normal but the secretion of hormone is impaired, such as in patients with abnormal Tg synthesis.[237] The magnitude of the increase in uptake and the time at which the plateau is achieved vary with the nature and severity of the disorder. Differentiation of the foregoing states from hyperthyroidism is generally not difficult because in the former, clinical findings and laboratory evidence of hyperthyroidism are lacking, and indeed hypothyroidism may be present.

TABLE 11.15 Factors That Influence 24-Hour Thyroid Iodide Uptake

Factors That Increase Uptake

Increased Hormone Synthesis

- Hyperthyroidism
- Response to glandular hormone depletion
  - Recovery from thyroid suppression
  - Recovery from subacute thyroiditis
  - Antithyroid agents
- Excessive hormone losses
  - Nephrotic syndrome
  - Chronic diarrheal states
  - Soybean ingestion

Normal Hormone Synthesis

- Iodine deficiency
  - Dietary insufficiency
  - Excessive loss (dehalogenase defect, pregnancy)
- Hormone biosynthetic defects

Factors That Decrease Uptake

Decreased Hormone Synthesis

- Primary hypofunction
  - Primary hypothyroidism
  - Antithyroid agents
  - Hormone biosynthetic defects
  - Hashimoto disease
  - Subacute thyroiditis
- Secondary hypofunction
- Exogenous thyroid hormones

Not Reflecting Decreased Hormone Synthesis

- Increased availability of iodine
  - Diet or drugs
  - Cardiac or renal insufficiency
- Increased hormone release
  - Very severe hyperthyroidism (rare)

Iodine Deficiency

RAIU is increased in acute or chronic iodine deficiency, as demonstrated by measurement of urinary iodine excretion, with urinary iodine values lower than 100 μg/day, indicating deficiency. Chronic iodine deficiency is usually the result of an inadequate amount of iodine in food and water (endemic iodine deficiency). Patients with cardiac, renal, or hepatic disease may develop iodine deficiency if given diets severely restricted in salt, especially if diuretic agents are administered.

Response to Thyroid Hormone Depletion

Rebound increases in RAIU are seen after withdrawal of antithyroid therapy, after subsidence of transient or subacute thyroiditis, and after recovery from prolonged suppression of thyroid function by exogenous hormone. A striking increase in uptake occurs in patients with iodide-induced myxedema after cessation of iodide administration. The duration of the rebound depends on the time required to replenish thyroid hormone stores.

Excessive Hormone Losses

In nephrotic syndrome, excessive losses of hormone in the urine occurring in association with urinary loss of binding protein cause a compensatory increase in hormone synthesis and RAIU. A similar sequence may occur when losses of hormone via the gastrointestinal tract are abnormal, as in chronic diarrheal states or during ingestion of agents such as soybean protein and cholestyramine, which bind T_4 in the gut.

States Associated With Decreased RAIU

A general increase in iodine intake has made values of the RAIU in hypothyroidism indistinguishable from those at the lower end of the reference range. Therefore the major indication for measuring the RAIU is to establish whether thyrotoxicosis is due to hyperthyroidism (high RAIU) or thyroiditis (low RAIU).

Exogenous Thyroid Hormone: Thyrotoxicosis Factitia

Except in disorders in which homeostatic control is disrupted or overridden (e.g., Graves disease or autonomously functioning thyroid nodules), administration of exogenous thyroid hormone suppresses TSH secretion and reduces the RAIU, usually to values below 5%.

Low values of the RAIU in a patient who is clinically thyrotoxic may also indicate the presence of thyrotoxicosis factitia, the syndrome produced by the ingestion of excess thyroid hormone. The unmeasurably low level of Tg in serum differentiates thyrotoxicosis factitia from other causes of thyrotoxicosis with decreased RAIU.[238]

Disorders of Hormone Storage

The RAIU is usually low in the early phase of subacute thyroiditis and in chronic thyroiditis with transient hyperthyroidism. Here, inflammatory follicular disruption leads to loss of the normal storage function of the gland and leakage of hormone into the blood. In the early stage of subacute thyroiditis, leakage of hormone is usually sufficient to suppress TSH secretion and the RAIU. Transient hypothyroidism often occurs late in both diseases, when stores of preformed hormone are depleted; the RAIU may return to normal or increased values at that time.

Exposure to Excessive Iodine

Exposure to excessive iodine is a common cause of a subnormal RAIU. Such decreases are spurious in the clinical sense because they do not indicate decreased absolute iodine uptake or decreased hormone production but can be produced by the introduction of excessive iodine in any form: inorganic, organic, or elemental. Common offenders are organic iodinated dyes used as radiograph contrast media and amiodarone (see Table 11.7). The duration of suppression of the uptake varies among individuals and with the compound administered. In general, dyes used for pyelography or computed tomography scanning are cleared within a month, whereas amiodarone may influence the uptake for up to 12 months because of its storage in fat. A single large dose of inorganic iodide can decrease uptake for several days, and chronic ingestion of iodide may depress the uptake for many weeks. Excessive quantities of iodine may also be present in vitamin and mineral preparations, vaginal or rectal suppositories, and iodinated antiseptics such as povidone (see Table 11.7).

The measurement of urinary iodine excretion is an invaluable means of establishing or excluding the existence of excessive body iodide stores; the 24-hour iodine excretion can be roughly extrapolated from the iodide-to-creatinine ratio in a random urine sample. Values in excess of 2 mg/day can account for a low RAIU value, whereas values less than 1 mg/day suggest that a low RAIU is due to one of the other disorders discussed in this section.

Hyperthyroid Disorders

ANTHONY HOLLENBERG AND WILMAR M. WIERSINGA

CHAPTER OUTLINE

KEY POINTS

- Hyperthyroidism has a prevalence of 1% to 2% in women and 0.1% to 0.2% in men.
- The most common causes of an overactive thyroid are Graves disease and toxic multinodular goiter.
- Graves disease is caused by the development of unique human autoantibodies to the thyroid-stimulating hormone (thyrotropin, TSH) receptor; these autoantibodies act as TSH receptor agonists.
- Graves orbitopathy (GO) remains one of the most difficult endocrine diseases to treat and requires a multidisciplinary approach. It may occur before, during, or even long after resolution of the hyperthyroidism.
- Toxic thyroid nodules are caused by a constitutive activating mutation in the TSH receptor.
- Subacute thyroiditis secondary to infectious agents is usually painful, in marked contrast to the transient autoimmune thyroiditis seen in the postpartum period.
- The treatment of hyperthyroidism is best initiated with the antithyroid drug methimazole; propylthiouracil (PTU) is no longer recommended as first-line therapy because of its rare, but occasionally severe, hepatic toxicity. PTU may be useful in treating severe hyperthyroidism because of its capacity to block conversion of thyroxine (T_4) to triiodothyronine (T_3) by the type 1 deiodinase (D1) in liver, kidney, and Graves thyroid.
- Methimazole embryopathy is also rare. It may be avoided by the use of PTU in the first trimester as well as for women planning a pregnancy while under treatment for hyperthyroidism.
- Overtreatment of the pregnant hyperthyroid patient must be avoided because of the transplacental passage of both PTU and methimazole. Fetal hypothyroidism can impair cognitive development. Typically the TSH should remain suppressed and the free T_4 slightly above normal throughout pregnancy. If possible, the patient should be followed in concert with a high-risk obstetrician.

These days the terms *thyrotoxicosis* and *hyperthyroidism* are used interchangeably and refer to the classic or subtle physiologic manifestations of excessive quantities of the thyroid hormones, which are the characteristics of this condition (Table 12.1). In addition to overstimulation of the thyroid via the TSH receptor and true TSH receptor mutations, other common conditions causing hyperthyroidism include the passive release of thyroid hormones from damaged thyroid follicles; inflammation of the thyroid gland (called *thyroiditis*), which may be autoimmune, postviral, or drug induced; and extrathyroidal sources of thyroid hormone, most often iatrogenic or self-administered. For most patients with thyrotoxicosis, the symptoms and signs caused by an excess of thyroid hormone, whatever the source, lead to medical attention. Others may have surprisingly few symptoms and are referred because of a suppressed TSH. This chapter begins with a brief review of the symptoms and signs of thyrotoxicosis and their

TABLE 12.1 Causes of Hyperthyroidism

I. Excessive TSH-Receptor Stimulation

Graves disease (TRAb)
Pregnancy-associated transient hyperthyroidism (hCG)
Trophoblastic disease (hCG)
Familial gestational hyperthyroidism (mutant TSH receptor)
TSH-producing pituitary adenoma

II. Autonomous Thyroid Hormone Secretion

Multinodular toxic goiter (somatic mutations)
Solitary toxic thyroid adenoma (somatic mutation)
Congenital activating TSH-receptor mutation (genomic mutation)

III. Destruction of Follicles With Release of Hormone

Subacute de Quervain thyroiditis (virus infection)
Painless thyroiditis/postpartum thyroiditis (hashitoxicosis—autoimmune)
Acute thyroiditis (bacterial infection)
Drug-induced thyroiditis (amiodarone, interferon-γ)

IV. Extrathyroidal Sources of Thyroid Hormone

Iatrogenic overreplacement with thyroid hormone
Excessive self-administered thyroid medication
Food and supplements containing excessive thyroid hormone
Functional thyroid cancer metastases
Struma ovarii

hCG, Human chorionic gonadotropin; *TRAb,* thyrotropin receptor antibodies; *TSH,* thyroid-stimulating hormone (thyrotropin).

pathophysiologic basis. The appropriate use of the laboratory tests already described in Chapter 11 is then presented to show how these results can focus the search for a diagnosis.

Clinical Manifestations of Thyrotoxicosis

One very important clinical clue to the cause of the patient's thyrotoxicosis is the duration of symptoms. Patients with hyperthyroidism have generally had manifestations for months before presentation, but because the week-to-week increases in thyroid hormones are small, the effects of the disorder may become rather extreme, while going unnoticed by the patient. In addition, patients will often attribute the symptoms to other causes; for example, they may ascribe their fatigue to family or work responsibilities, heat intolerance to the weather, weight loss to an effective diet, and dyspnea and palpitations to a lack of regular exercise. On the other hand, patients with thyrotoxicosis due to thyroiditis can often date the onset of their symptoms precisely, usually to within a month or so of their seeking medical attention, as might be expected from the effects of the release of the equivalent of 30 to 60 days' supply of thyroid hormone into the circulation over a few days to weeks. Thus ascertaining the chronology as well as the spectrum of symptoms is a critical goal of the interview process.

Another general characteristic is that the symptoms and signs of thyrotoxicosis are more readily recognized in the younger than in the older patient. The term *masked* or *apathetic* thyrotoxicosis is used to describe the syndrome sometimes seen in the elderly, which may present as congestive heart failure with arrhythmia or as unexplained weight loss without the increased appetite and other typical symptoms and signs of the younger patient.

At present, the ready availability of sensitive serum TSH assays, a reliable indicator of excess thyroid hormone in the ambulatory patient (see Chapter 11), has made the more classic and severe manifestations of long-standing thyrotoxicosis less prevalent. In fact, a continued area of some controversy is how aggressively to treat the condition termed *subclinical* hyperthyroidism, a biochemical diagnosis in which a subnormal serum TSH level is accompanied by normal free thyroid hormone concentrations. Nonetheless, the classic presentation is still common, serves to illustrate the pleiotropic physiologic effects of excess thyroid hormones, and, if not recognized, can progress to life-threatening severity despite the fact that hyperthyroidism is a benign condition (accelerated hyperthyroidism). The next sections review the pathophysiology of the most important manifestations of excess thyroid hormone.

Cardiovascular System

Alterations in cardiovascular function in the thyrotoxic patient are in part due to increased circulatory demands that result from the hypermetabolism and the need to dissipate the excess heat produced.[1] At rest, peripheral vascular resistance is decreased, and cardiac output is increased as a result of an increase first in heart rate and, with more severe disease, in stroke volume. Thyroid hormones in excess also have a direct ionotropic effect on cardiac contraction mediated by an increase in the ratio of α-myosin to β-myosin heavy chain expression. Tachycardia is virtually always present and is due to a combination of increased sympathetic and decreased vagal tone.[2] Widening of the pulse pressure is due to the increase in systolic pressure and decrease in diastolic pressure caused by reduced resistance.[3] The decreased resistance is due to increased nitric oxide production via the PI3K/AKT signaling pathway.[4] The increased systolic force is often felt by the patient as a palpitation and is evident on inspection or palpation of the precordium. Because of the diffuse and forceful nature of the apex beat, the heart may seem enlarged, and echocardiography may show an increased ventricular mass. In addition, the preejection period is shortened and the ratio of preejection period to left ventricular ejection time is decreased.[3,5] The heart sounds are enhanced, particularly S_1, and a scratchy systolic sound along the left sternal border, resembling a pleuropericardial friction rub (Means-Lerman scratch), may also be heard. These manifestations abate when a normal metabolic state is restored. Mitral valve prolapse occurs more frequently in Graves or Hashimoto disease than in the normal population[6] and has been suggested as autoimmune in origin.[7] Cardiac arrhythmias are almost invariably supraventricular, especially in younger patients. Between 2% and 20% of patients with thyrotoxicosis have atrial fibrillation, and about 15% of patients with otherwise unexplained atrial fibrillation are thyrotoxic,[1] which may be caused directly by the thyroid hormone excess or by activating autoantibodies to the β_1-adrenergic receptors.[8,9] In the Framingham cohort, individuals over age 60 with a suppressed TSH level had a 2.8-fold increased risk of developing atrial fibrillation compared to those with normal serum TSH values,[10] and such a finding has been widely confirmed.[11]

The increased cardiovascular cost of a standard workload or metabolic challenge is adequately met if the thyrotoxic patient is not, or has not previously been, in heart failure. Thus in most patients without underlying heart disease, cardiac competence is maintained. Mild peripheral edema may occur in the absence of heart failure. Heart failure per se usually, but not always, occurs in patients with preexisting heart disease and therefore is more typically seen in the elderly, but it may not be possible to determine

whether underlying heart disease is present until after thyrotoxicosis is relieved. Atrial fibrillation decreases the efficiency of the cardiac response to any increased circulatory demand and may play a role in causing cardiac failure.[5] Attempts to convert or abate atrial fibrillation to sinus rhythm are not indicated while thyrotoxicosis is present, and about 60% of patients revert spontaneously to sinus rhythm after treatment, most within 4 months. While thromboembolism is not frequent in patients under 50 with thyrotoxicosis, the decision to anticoagulate should be potentially considered in such patients taking into account additional risks for embolic events and risks of therapy.[12] Medical or electrical cardioversion of patients with thyrotoxicosis-induced atrial fibrillation is often successful even after a year has passed.[13]

Protein, Carbohydrate, and Lipid Metabolism

The stimulation of metabolism and heat production is reflected in increased appetite and heat intolerance but only rarely by elevated basal body temperature.[14] Despite an increased food intake, a state of chronic caloric and nutritional inadequacy often ensues, depending on the degree of increased metabolism. Both synthesis and degradation rates of proteins are increased, the latter to a greater extent than the former, with the result that in severe thyrotoxicosis there is a net decrease in tissue protein as indicated by loss of weight, muscle wasting, proximal muscle weakness, and even mild hypoalbuminemia. Preexisting diabetes mellitus may be aggravated, one cause being accelerated turnover of insulin. Both lipogenesis and lipolysis are increased in thyrotoxicosis, but the net effect is lipolysis as reflected by an increase in the plasma concentration of free fatty acids and glycerol and a decrease in serum cholesterol level; triglyceride levels are usually slightly decreased. The enhanced mobilization and oxidation of free fatty acids in response to fasting or catecholamines are due to enhancement of lipolytic pathways by thyroid hormones, including their effects on mitochondrial beta oxidation in the liver.[14,15]

Sympathetic Nervous System and Catecholamines

Many of the manifestations of thyrotoxicosis and of sympathetic nervous system activation are similar. Nonetheless, the plasma concentrations of epinephrine and norepinephrine, as well as their urinary excretion and that of their metabolites, are not increased in patients with thyrotoxicosis, and thyroid hormones exert effects separate from, but similar and additive to, those of the catecholamines. The improvement in cardiac function in patients with hyperthyroidism by β-adrenergic blockade has led to the concept that there is increased sympathetic tone or increased cardiac sensitivity to the sympathetic nervous system.[16] Support for the latter are the results in the transgenic mouse in which overexpression of type 2 deiodinase in the heart increases myocardial T_3 and the cyclic adenosine monophosphate (cAMP) response to norepinephrine in the cardiac myocytes due to alterations in G proteins.[17,18] However, stimulation of the heart by thyroid hormones does not require β-adrenergic receptors in mouse models such that it is likely that β-adrenergic blockade in hyperthyroidism is only influencing part of the disorder. Still intact thyroid hormone signaling pathways are required for adrenergic signaling in white adipocytes leading to lipolysis and for the induction of UCP1 in brown adipocytes by adrenergic signaling pathways.[19,20]

Nervous System

Alterations in the function of the nervous system in thyrotoxicosis are manifested by nervousness, emotional lability, and hyperkinesia. Fatigue may be due both to muscle weakness and to the insomnia that is commonly present. Emotional lability is common, and in rare cases mental disturbance may be severe; manic depressive, schizoid, or paranoid reactions may emerge. The hyperkinesia of the thyrotoxic patient is characteristic and may manifest to such a point that the patient is almost levitating. During the interview the patient shifts positions frequently and movements are quick, jerky, exaggerated, and often purposeless. In children, in whom such manifestations tend to be more severe, inability to focus may lead to deterioration in school performance suggesting attention deficit hyperactivity disorder. There may be a fine tremor of the hands, tongue, or lightly closed eyelids. The electroencephalogram reveals an increase in fast wave activity, and in patients with convulsive disorders the frequency of seizures is increased.

Muscle

Weakness and fatigability are usually not accompanied by objective evidence of muscle disease save for the generalized wasting associated with weight loss. The weakness is most prominent in the proximal muscles of the limbs, causing difficulty in climbing stairs or fatigue from minimal exertion such as using a blow dryer or lifting an infant. Proximal muscle wasting may be out of proportion to the overall loss of weight (often referred to as *thyrotoxic myopathy*). In the most severe forms, the myopathy may involve the more distal muscles of the extremities and the muscles of the trunk and face. Although myopathy of ocular muscles is unusual, the disorder may mimic myasthenia gravis or ophthalmic myasthenia.[21–25] Muscular strength returns to normal when a normal metabolic state is restored, but muscle mass takes longer to recover.

Graves disease occurs in about 3% to 5% of patients with myasthenia gravis, and about 1% of the patients with Graves disease develop myasthenia gravis. Antibodies and T cells specific for the TSH and acetylcholine receptors are involved in the pathogenesis of the two diseases.[26] Unlike thyrotoxic myopathy, the association of myasthenia gravis with Graves disease has a distinct female preponderance. The effect of both thyrotoxicosis and its alleviation on the course of myasthenia gravis is variable, but in the majority of instances, myasthenia is accentuated during the thyrotoxic state and improves when a normal metabolic state is restored. A form of myasthenia affecting mainly the orbital muscles may also occur more commonly in patients with Graves disease and needs to be distinguished from GO by the prominence of bilateral ptosis of a variable degree.[22]

Periodic paralysis of the hypokalemic type may occur together with thyrotoxicosis, and its severity is accentuated by the latter disorder. The coincidence of the two disorders is particularly common in Asian and Latino males.[27,28]

Eyes

Some retraction of the upper or lower eyelids, or both, evident as the presence of a rim of sclera between either lid and the limbus, may be seen in all forms of thyrotoxicosis regardless of the underlying cause and is responsible for the typical stare of the patient. Also common is either lid lag, a phenomenon in which the upper lid lags behind the globe when the patient is asked to shift the gaze

slowly downward, or globe lag, which becomes evident when the eye lags behind the upper lid when the patient looks up. These ocular manifestations appear to be the result of increased adrenergic tone. It is important to differentiate these signs, which may occur in all forms of thyrotoxicosis, from those of infiltrative autoimmune orbitopathy, which are associated with Graves disease and are described later.

Skin and Hair

The most characteristic change in the patient with long-standing thyrotoxicosis is the warm, moist feel of the skin that results from cutaneous vasodilation and excessive sweating. The elbows may be smooth and pink, the complexion is rosy, and the patient blushes readily. Palmar erythema may resemble liver palms (palmar erythema), and telangiectasia may be present. The hair is fine and friable, and hair loss may increase. The nails are often soft and friable. A characteristic but uncommon finding is Plummer nails, onycholysis, typically involving the fourth and fifth fingers. Vitiligo, another autoimmune disease, is more common in patients with autoimmune thyroid disease.

Respiratory System

Dyspnea is common in severe thyrotoxicosis, and several factors may contribute to this condition. Vital capacity is commonly reduced, mainly from weakness of the respiratory muscles. During exercise, ventilation is increased out of proportion to the increase in oxygen uptake, but the diffusing capacity of the lung is normal. Because of the general increase in oxygen consumption associated with thyrotoxicosis, patients with chronic lung diseases may experience a rather severe worsening of the condition if they become thyrotoxic.

Alimentary System

An increase in appetite is common but is usually not seen in patients with mild disease. In more severe disease the increased intake of food is inadequate to meet the increased caloric requirements, and weight is lost at a variable rate. More often, the patient reports a gratifying success with a previously frustrated attempt at weight control. The frequency of bowel movements is increased; diarrhea, although rare, can also be a problem. The increased gastric emptying and intestinal motility in thyrotoxicosis appear to be responsible for slight malabsorption of fat, and these functions return to normal when a normal metabolic state has been restored. Celiac and Graves diseases coexist more commonly than once thought, and there is an increased prevalence of pernicious anemia.

Hepatic dysfunction occurs, particularly when thyrotoxicosis is severe; hypoproteinemia and increases in serum alanine aminotransferase (ALT) and bone or liver alkaline phosphatase levels may be elevated. Progressive hepatomegaly and jaundice was a cause of death prior to the development of successful treatment for Graves patients likely exacerbated by congestive heart failure.

Skeletal System: Calcium and Phosphorus Metabolism

Thyrotoxicosis is generally associated with increased excretion of calcium and phosphorus in urine and stool; with an increase in bone turnover and a net demineralization of bone, as demonstrated by routine bone densitometry; and occasionally with pathologic fractures, especially in elderly women.[21,23,29–32]

In such instances the pathologic changes are variable and may include osteitis fibrosa, osteomalacia, or osteoporosis, most likely varying with vitamin D status. Urinary excretion of collagen breakdown products (teleopeptides) is increased in thyrotoxicosis. Kinetic studies indicate an increase in the exchangeable calcium pool and acceleration of both bone resorption and accretion, particularly the former. Thyroid hormone (T_3) has been shown to accelerate activity of the osteoclasts via its nuclear receptors and helps explain these widespread changes.[21,24,32] Some data indicate that TSH itself may have a local action, which may normally balance thyroid hormone action on osteoclasts and enhance osteoblast activity.[25,33,34] Such an action by TSH would be absent in hyperthyroidism, allowing accentuation of the thyroid hormone effects. However, not all models recapitulate these findings, and taken together it is likely that excess levels of thyroid hormones have a more profound effect on bone mineral density.[35] As the thyrotoxicosis is treated, bone density may normalize in many younger patients but not all.[36] Postmenopausal women, however, may have an accelerated reduction in bone density that requires treatment (see Chapter 30). Much controversy has existed over the induction of decreased bone density by TSH-suppression therapy in patients with thyroid cancer. Suffice it to say that postmenopausal, but not premenopausal, women given a TSH-suppressive dosage of thyroid hormones are at risk of osteopenia and require prophylaxis with calcium and vitamin D or more aggressive approaches.[37,38] The decision to relax TSH suppression in low-risk patients may be influenced by their bone status.

For all the same reasons, hypercalcemia may occur in patients with severe thyrotoxicosis. The total serum calcium concentration is increased in as many as 27% of patients, and the ionized serum calcium is elevated in 47%. The concentrations of heat labile serum alkaline phosphatase and osteocalcin are also frequently elevated. These findings resemble those of primary hyperparathyroidism, but the concentration of parathyroid hormone in serum is low-normal in most. True primary hyperparathyroidism and thyrotoxicosis sometimes coexist. Plasma 25-hydroxycholecalciferol levels are decreased in thyrotoxic patients, and this alteration could contribute to the decreased intestinal absorption of calcium and osteomalacia noted in some.

Renal Function: Water and Electrolyte Metabolism

Thyrotoxicosis produces no symptoms referable to the urinary tract save for mild polyuria, which may lead to nocturia. Nevertheless renal blood flow, glomerular filtration, and tubular reabsorptive and secretory maxima are increased. Total exchangeable potassium is decreased, possibly due to a decrease in lean body mass, but electrolytes are normal except when hypokalemic periodic paralysis occurs.

Hematopoietic System

The red blood cells are usually normal, as judged by the usual indices, but red blood cell mass is increased. The increase in erythropoiesis is due to the direct effect of thyroid hormones on the erythroid marrow, as patients that harbor mutations in the thyroid hormone receptor alpha (TRα) have mild anemia secondary to defects in erythropoiesis.[39] A parallel increase in plasma volume also occurs, with the result that the hematocrit is normal in hyperthyroid patients.

Approximately 3% of patients with Graves disease have pernicious anemia, and a further 3% have antibodies to intrinsic factor but normal absorption of vitamin B_{12}. Autoantibodies against gastric parietal cells may also be present in patients with Graves disease, and the requirements for vitamin B_{12} and folic acid appear to be increased. The total white blood cell count is often low because of a decrease in the number of neutrophils. The absolute lymphocyte count is normal or increased, leading to a relative lymphocytosis. The numbers of monocytes and eosinophils may also be increased. Splenic enlargement occurs in about 10% of the patients, and thymic enlargement is common in Graves disease.[40] The latter may present as a mediastinal mass. Thymic hyperplasia is also due to thyrotoxicosis because it is sometimes seen in patients receiving excess exogenous T_4 for suppression.[41]

Platelet levels and the intrinsic clotting mechanism are normal, but the concentration of factor VIII is often increased and returns to normal when the thyrotoxicosis is treated. Despite this increase, there is an enhanced sensitivity to warfarin because of the accelerated clearance of the vitamin K–dependent clotting factors. Therefore the dosage of warfarin needs to be reduced in thyrotoxic patients.[42] This must be kept in mind if initiating anticoagulant treatment for atrial fibrillation in older patients.[43] Coincidental autoimmune thrombocytopenia may also occur.

Pituitary and Adrenocortical Function

The thyrotoxic state imposes several challenges on pituitary and adrenocortical function. The hepatic inactivation of cortisol is accelerated, including enhanced 5α/5β-reductases and 11β hydroxysteroid dehydrogenase. As a result of these changes, the disposal of cortisol is accelerated, but its rate of secretion is also increased, so the plasma cortisol concentration remains normal. The concentration of corticosteroid-binding globulin in plasma is also normal. The urinary excretion of free cortisol is normal or slightly increased[44] (see Chapter 15). Interestingly, thyroid hormone receptors have now been identified in adrenal cortical cells in the mouse. It is not clear if they are also present similarly in humans.[45]

Reproductive Function

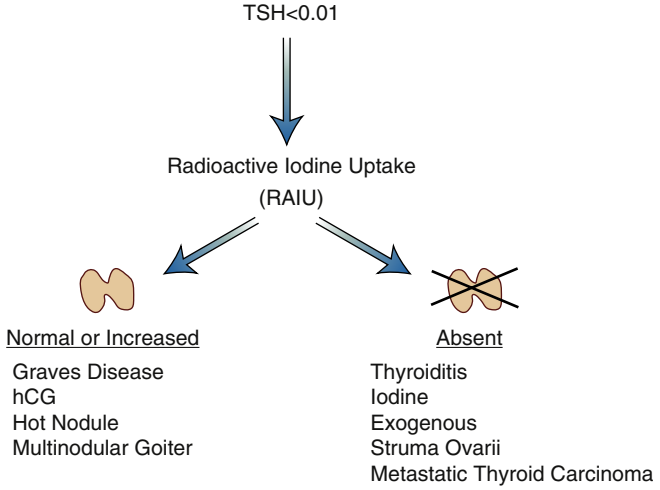
Thyrotoxicosis in early life may cause delayed sexual maturation, although physical development is normal and skeletal growth may be accelerated. Thyrotoxicosis after puberty influences reproductive function, especially in women. The intermenstrual interval may be prolonged or shortened, and menstrual flow is initially diminished and ultimately ceases. Fertility may be reduced, and if conception takes place, there is an increased risk of miscarriage and other complications.[46–48] In some patients, menstrual cycles are predominantly anovulatory with oligomenorrhea, but in most, ovulation occurs as indicated by a secretory endometrium. In the former, a subnormal midcycle surge of luteinizing hormone (LH) may be responsible. In premenopausal women with thyrotoxicosis, basal plasma concentrations of LH and follicle-stimulating hormone (FSH) are reportedly normal but may display enhanced responsiveness to gonadotropin-releasing hormone (GnRH).

Thyrotoxicosis, whether spontaneous or induced by exogenous hormone, is accompanied by an increase in the concentration of sex hormone–binding globulin (SHBG) in plasma.[49] As a result, the plasma concentrations of total testosterone, dihydrotestosterone, and estradiol are increased, but their unbound fractions are normal or transiently decreased. The increased binding in plasma may be responsible for the decreased metabolic clearance rate of testosterone and dihydrotestosterone. In the case of estradiol, however, the metabolic clearance rate is normal, suggesting that tissue metabolism of the hormone is increased. Conversion rates of androstenedione to testosterone, estrone, and estradiol and of testosterone to dihydrotestosterone are increased.[50] The increased rate of conversion of androgens to estrogenic byproducts may be the mechanism for gynecomastia and erectile dysfunction in some 10% of thyrotoxic men and one mechanism for menstrual irregularities in women. Another likely mechanism for menstrual changes is the disruption in amplitude and frequency of LH/FSH pulses due to thyroid hormone influences on GnRH signaling.

Laboratory Diagnosis

The effects of thyrotoxicosis on the major organ systems are the same regardless of the underlying cause. Their frequency and intensity and the other findings with which they are associated are influenced by the cause of the excess thyroid hormone. To a large extent, the same is true of laboratory test results. However, the patient with thyrotoxic symptoms will virtually always have a serum TSH concentration less than 0.1 mU/L and an elevated serum free T_4. In general, serum free T_3 is more elevated than is the free T_4, but free T_4 is relatively high if thyrotoxicosis is caused by thyroiditis or intake of levothyroxine.

If the possibility of exogenous thyroid hormone can be eliminated, the primary differential is between excess thyroid hormone production and excess thyroid hormone release from sick cells, as in thyroiditis. Often this differentiation can be made on the basis of the history and physical. Laboratory tests, including an increased sedimentation rate and a high serum thyroglobulin (Tg), may favor thyroiditis, but the most critical differentiating test is the radioactive iodine uptake (RAIU), which is elevated or inappropriately high-normal given the suppressed serum TSH level with excess thyroid hormone production and very low (<5%) in patients with thyroiditis (Fig. 12.1). However, the RAIU may also be low in a hyperthyroid patient who has recently received an iodine load, usually iodinated contrast for a computed tomography (CT) scan or for angiography. A 24-hour urine iodine measurement can confirm this. Also helpful is measurement of TSH



• **Fig. 12.1** Determination of the cause of hyperthyroidism based on the ^{123}I uptake in the gland. In the setting of a suppressed thyroid-stimulating hormone (TSH) a normal or increased uptake is indicative of something else driving uptake rather than endogenous TSH. In the absence of uptake the gland has either been damaged or an external factor such as exogenous hormone or iodine is playing a role. Rarely, ectopic thyroid hormone production may occur. *hCG*, human chorionic gonadotropin.

receptor antibodies (TSHRAb), which when associated with a suppressed TSH is consistent with Graves disease.

If the physical examination or thyroid ultrasonography indicates the presence of a nodular thyroid, thyroid scanning may confirm which nodules are hyperfunctioning. The association of thyrotoxicosis with an elevated TSH is rare and suggests a TSH-producing pituitary tumor. The possibility of an artifactually elevated TSH in a patient with Graves disease should be ruled out by repeating the assay by a different method in another laboratory (see Chapters 4 and 8). Exceptions to these general guidelines are discussed later within the appropriate subsection.

GRAVES DISEASE

Graves disease is a multisystem autoimmune disorder characterized by TSHRAb. The disease has been described by von Basedow in Germany, Graves in Ireland, and Parry in the United Kingdom, all in the first half of the 19th century and independent of each other.[51] Hallmarks of the disease were palpitations (hyperthyroidism), goiter, and exophthalmos, called the Merseburg triad after the hometown of von Basedow (Merseburg, Germany). The nature of the disease remained unclear for many years, and cardiac, neurologic, and pituitary origins were proposed. The autoimmune nature was not recognized before the late 1950s when Adams reported on the presence of a long-acting thyroid stimulator (LATS) in serum, different from TSH, which turned out to be an antibody capable of stimulating the TSH receptor.[52,53] Self-infusion of sera from patients with Graves disease caused thyroid stimulation and was the first demonstration of the role of TSHRAb in the induction of human hyperthyroidism.[54] Another example of the in vivo effects of TSHRAb is the transplacental passage of maternal TSHRAb, which may stimulate the fetal thyroid gland and cause fetal/neonatal thyrotoxicosis.[55] It is now recognized that TSH receptors are not only expressed on thyrocytes but are also outside the thyroid gland on fibroblasts, fibrocytes, adipocytes, osteoblasts, osteoclasts, and pituitary folliculostellate cells. It is likely that immune responses directed against TSH receptors on orbital fibroblasts and subcutaneous connective tissue cells are involved in other expressions of Graves disease, namely Graves orbitopathy and Graves dermopathy. Besides stimulating TSHRAb there also exist blocking TSHRAb, which are found in a small minority of patients with autoimmune hypothyroidism.[56] The clinical phenotypes of Graves disease are thus manifold (Table 12.2).

TABLE 12.2 Phenotypes of Graves Disease and Their Estimated Incidence Rates

Phenotype	% Affected	Cases/Million/Year
All	100	350
Graves hyperthyroidism	90–95	325
Goiter	50	175
Graves orbitopathy	30	105
Severe orbitopathy	5	17
Hypo + orbitopathy	5	17
Graves dermopathy	0.5	4
Neonatal hyperthyroidism	0.2	1.0
Fetal hyperthyroidism	0.1	0.5
Acropachy	0.1	0.5

Graves Hyperthyroidism

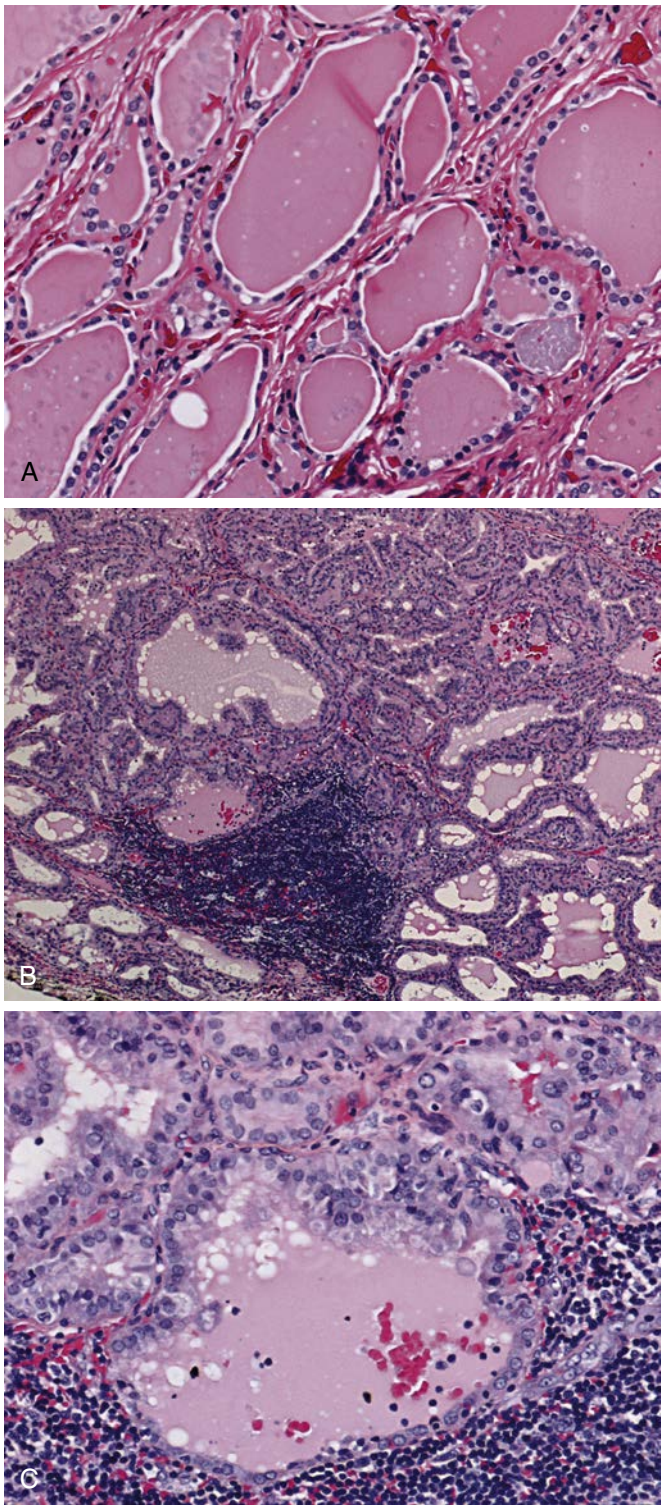
Clinical Presentation

Graves hyperthyroidism (GH) is at least four times more common in women than in men. GH is relatively rare in children. Its incidence starts to increase at the age of 13 years and remains rather stable after the age of 30 years. Average age is 47 years. The typical patient complains about weight loss despite increased appetite, heat intolerance, sweating, palpitations, fine finger tremor, nervousness, and loose stools. Duration of symptoms until diagnosis is less than 6 months in 61% of patients.[57] A positive family history of autoimmune thyroid disease (AITD) is present in about 50%.[57,58] There is some evidence for genetic anticipation, which is a younger age of onset in patients with a family history of AITD.[57–59]

Goiter is present in about half of patients. Typically the goiter is diffuse in nature, with a soft to firm consistency and a smooth surface. In severe cases, a thrill may be felt, usually over the upper or lower poles where the superior and inferior thyroid arteries, respectively, enter the thyroid gland; a thrill is accompanied by an audible bruit in systole. The presence of a nodule in the setting of Graves disease should raise suspicion of thyroid cancer. Advancing age is associated with less severe Graves hyperthyroidism.[58,60] Remarkably symptom-poor hyperthyroidism may occur in elderly people, called apathetic thyrotoxicosis. Graves orbitopathy is present in 26% of patients when Graves hyperthyroidism is diagnosed. Thereafter new cases of GO develop in 9%, rendering a total GO frequency of 35% in Graves hyperthyroidism.[61] Taking into account the severity of the Merseburg triad (as judged from serum free thyroxine [FT_4], thyroid size, and GO signs), 44% of patients have severe Graves disease, 34% moderate disease, and 22% mild disease.[62] The phenotypic appearance of Graves disease is apparently milder than in the past; this may be due to earlier diagnosis and treatment, improved iodine nutrition, and a secular trend to less smoking.

Pathology

The thyroid gland in Graves hyperthyroidism is typically both enlarged and uniformly affected, hence often referred to as diffuse toxic goiter. It is extremely rare that the disease process remains restricted to one lobe.[63] Such unilateral Graves hyperthyroidism is difficult to reconcile with the systemic nature of thyroid-stimulating immunoglobulins. The follicles are small and lined with hyperplastic columnar epithelium and contain scant colloid that displays much marginal scalloping and vacuolization (Fig. 12.2). Papillary projections of the hyperplastic epithelium extend into the lumina of the follicles. Vascularity is increased. There is varying heterogeneous infiltration by lymphocytes and plasma cells that collect in aggregates and may form infrequent B-cell germinal centers (in contrast to their abundance in Hashimoto disease). In such regions, thyroid epithelial cells express human leukocyte antigen (HLA) class II antigens (a phenomenon not seen in normal thyroid glands) and are large (perhaps due to local stimulation by TSHRAb). The intrathyroidal lymphocytic population is mixed, consisting



• **Fig. 12.2** Histopathologic features of the thyroid gland in Graves hyperthyroidism (B and C) as compared to normal tissue (A). (Courtesy Dr. Pamela Unger, Mount Sinai Scholl of Medicine, New York.)

besides B cells mostly of T helper 1 (Th1) and Th2 lymphocytes and less often Th17 and regulatory T cells. When the patient is given iodine or antithyroid drugs (ATDs), the thyroid gland may undergo involution as TSHRAb decrease. Then hyperplasia and vascularity regress, papillary projections recede, and follicles enlarge and become filled with colloid again.

Immunopathogenesis

Autoimmune thyroid diseases can be defined as complex or multifactorial diseases in which autoimmune responses to thyroid antigens develop against a particular genetic background, influenced by exposure to environmental factors. Breakdown of self-tolerance to thyroid antigens results in thyroid autoimmunity. A number of complex regulatory mechanisms serve to protect an immune response directed against self-antigens.[64] During development, immature T cells enter the thymus where they undergo a process of selection.[65] T cells that recognize with high affinity self-peptides expressed on thymic medullary epithelial cells are deleted by apoptosis, and T cells with moderate affinities leave the thymus as mature T cells. The full-length thyroid-stimulating hormone receptor (TSHR) is indeed expressed in the hyperplastic thymus of Graves hyperthyroid patients.[66] Genetic-epigenetic interactions involving a noncoding single-nucleotide polymorphism (SNP) in the *TSHR* gene that regulates thymic *TSHR* gene expression may facilitate escape of TSHR-reactive T cells from central tolerance in the thymus, thereby triggering Graves disease.[67] Central tolerance may not eliminate all self-reactive T cells. Control of autoreactive T cells in the periphery (e.g., by engagement of cytotoxic T-lymphocyte–associated protein 4 [CTLA4] resulting in T-cell anergy) is considered as a secondary or fail-safe mechanism to prevent autoimmune reactions (peripheral tolerance). Self-antigen presentation in the thymus also generates regulatory T cells (T_{reg}) that can inhibit in peripheral tissues those self-reactive T cells that escaped negative selection in the thymus. Besides these natural T_{reg} there are inducible T_{reg} generated in the periphery after antigenic stimulation. T_{reg} are characterized by the expression of CD4, CD25 (the interleukin 2 [IL2] receptor α-chain), and FOXP3 (the transcription factor forkhead box P3 protein); they may act on effector $CD4^+$ and $CD8^+$ lymphocytes by cell-to-cell contact hampering their activation and proliferation or indirectly via secretion of IL10 and transforming growth factor-β (TGFβ). Treg are crucial in maintaining tolerance through the active suppression of self-reactive T-cell activation and expansion. A fourth subset of T helper cells, induced by IL6, are highly proinflammatory and designated Th17 cells. They generate IL17, exacerbating autoimmune responses. Thus a balance between Th17 and T_{reg} is crucial for immune homeostasis. A number of studies now report a decrease in the number of T_{reg} cells and an increase in Th17 cells in peripheral blood of Graves patients, in relationship with stimulating TSHRAb and with improvement upon methimazole treatment.[65,68–70] Low T_{reg} and high IL17 levels are also found in an animal model of Graves disease.[71] Recent studies have identified regulatory beta cells (B_{reg}) that contribute to peripheral tolerance by inhibiting immune reactions to specific self-antigens.[72,73]

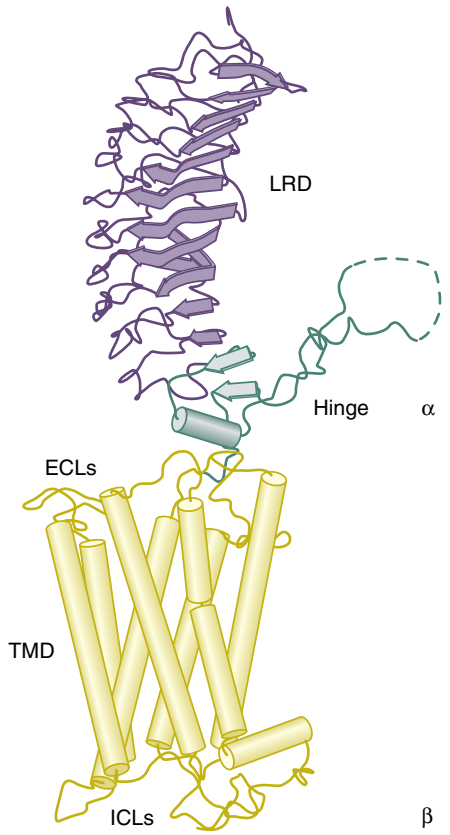
Traditionally Graves disease is viewed as the result of humoral immunity (hallmark TSHR antibodies) and Hashimoto thyroiditis as the result of cell-mediated immunity (hallmark thyroid peroxidase [TPO] antibodies [TPOAb]). However, TPOAb are also present in about 70% of Graves patients, and TSHR antibodies may occur in a minority of Hashimoto patients. Actually, humoral and cellular immune mechanisms are closely connected, and Th1 (interferon gamma [IFNγ]) and Th2 (IL4) subtypes of helper T cell responses are involved in both Graves and Hashimoto disease. IgG1 antibodies arise early in the immune response, whereas IgG4 antibodies (typically Th2 related) arise after prolonged immune stimulation. TPOAb and TgAb may comprise IgG1 as well as IgG4 classes indicating participation of Th1 and Th2 cytokines, respectively. Stimulating TSHRAb are mostly found

in the IgG1 subclass, which is selectively induced by Th1 cells; Graves hyperthyroidism is a predominantly Th1-type cytokine disease.[74] Oligoclonality and light chain restriction of stimulating TSHRAb support their primary role in disease causation.[75,76] Th1 cells may also induce antibody production through secretion of IL10, which in turn activates B cells. B cells may turn into plasma cells secreting antibodies. The thyroidal lymphocytic infiltrate is a major production site of thyroid autoantibodies. Transplantation of Graves thyroid tissue into mice deficient in both T cells and B cells with severe combined immunodeficiency (SCID mice) results in the appearance of human thyroid autoantibodies in serum, including TSHRAb.[77] Thyroid antibodies can also be produced outside the thyroid gland as they may persist after total thyroidectomy.

TSH Receptor, the Major Autoantigen in Graves Disease

A mice animal model of Graves hyperthyroidism is provided by genetic immunization against the TSH receptor, which induces stimulating TSHRAb and hyperthyroidism.[78] The gene encoding the TSH receptor is located on chromosome 14q31. The TSHR belongs to the family of G protein–coupled receptors and has seven transmembrane domains, a large extracellular domain, and a small intracellular domain (Fig. 12.3). The TSH holoreceptor consists of a 100-kDa glycosylated 744–amino acid sequence and a 20–amino acid signal peptide. The holoreceptor is cleaved into two subunits, alpha and beta, which are linked by disulfide bonds. The 50-kDa α-subunit is water soluble and heavily glycosylated. TSH and TSHRAb bind to the leucine-rich repeat regions of the α-subunit. The 30-kDa β-subunit is water insoluble, contains the membrane-spanning domain with its three extracellular loops and three cytoplasmic loops, and is 70% to 75% homologous with the LH/human chorionic gonadotropin (hCG) receptor. The TSHR forms dimers and multimeric complexes on the thyrocyte surface, probably enhancing the stability of the receptor. The holoreceptor undergoes cleavage in the hinge region due to breakage of disulfide bonds. As a result of this post-translational modification, the extracellular α-subunit is shed. The shed TSHR α-subunit, rather than the holoreceptor, is apparently the autoantigen in Graves disease.[79] Enhanced α-subunit shedding from damaged follicular cells may be the cause of the increase of serum TSHRAb concentrations after radioiodine therapy.[80]

Stimulating TSHRAb isolated from patients with Graves hyperthyroidism bind to the TSHR and activate $G\alpha_s$ and G_q signaling pathways, thereby inducing thyroid growth, increased vascularity, and increased production and secretion of thyroid hormones.[81,82] In contrast, some TSHRAb act as TSH antagonists and are referred to as blocking TSHRAb; they may occur in some patients with autoimmune hypothyroidism but also after treatment of Graves hyperthyroidism.[56,81] So-called neutral or cleavage region TSHRAb neither block TSH binding nor block TSH action; they do not induce cAMP but have the potential to induce apoptosis by binding to the hinge region.[81]



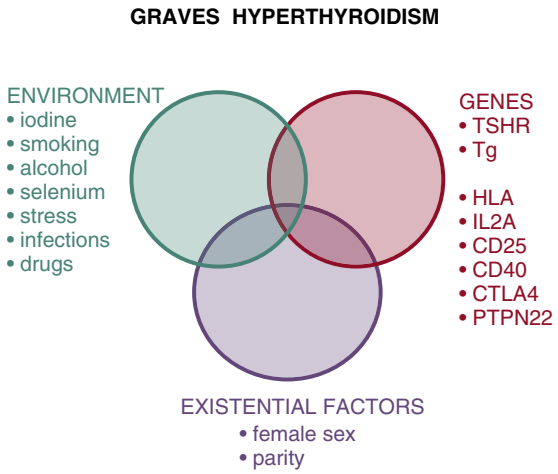
• **Fig. 12.3** Structure of the human thyroid-stimulating hormone receptor (TSHR). *ECLs,* extracellular loops; *ICLs,* small intracellular loops; *LRD,* leucine-rich domain; *TMD,* transmembrane domain. The receptor is cleaved, probably after activation, into α (or A) and β (or B) subunits. The α-subunit is thought to be shed from the cell surface.

Etiology

A complex interaction between existential factors, genetic variants, and environmental insults determines susceptibility of subjects to develop Graves disease[83] (Fig. 12.4).

Existential Factors

The strong female preponderance in Graves patients remains incompletely understood. Among all women with Graves hyperthyroidism, the rate of postpartum onset is 7.2%,[84] and parity as a risk factor has received much attention. Women with children, compared to childless women, have a relative risk for Graves



• **Fig. 12.4** Venn diagram illustrating how the combination of existential factors, genetic variants, and environmental insults may result in susceptibility to Graves hyperthyroidism.

disease of 1.19 (CI 1.14–1.24).[85] Fetal microchimerism (persistence of fetal cells in maternal tissues) may trigger autoimmunity through maternal immune responses against foreign fetal antigens, but its contribution to the female preponderance appears limited.[86] At odds with this hypothesis is a recent report that fetal microchimerism is more frequent in healthy controls than in Graves disease (64% vs. 33%, $p = 0.0004$), suggesting a possible protective role.[87] More relevant might be the epigenetic phenomenon of X-chromosome inactivation (XCI): In female cells, one of the two X chromosomes is inactivated in early embryonic life. Female tissues are thus mosaics of two cell lines, one with the paternal X and the other with the maternal X chromosome, usually in a 50:50 ratio. The consequence of skewed XCI (arbitrarily defined as inactivation of the same X chromosome in ≥80% of cells) might be that self-antigens on one X chromosome are not expressed at sufficiently high levels to induce tolerance.[88] A meta-analysis confirmed significant skewing of XCI in women with Graves disease (odds ratio 2.54, CI 1.58–4.10).[89] *FOXP3* is a key gene in the development of T_{reg}, located on the X chromosome. Polymorphisms in FOXP3 have been linked to Graves disease in some but not all studies.

Genetic Variants

Twin studies suggest that 79% of the liability to develop Graves disease is attributable to genetic factors.[90] Identified susceptibility genes for Graves disease include thyroid-specific genes (*TSHR, Tg*) and genes involved in the regulation of immune responses (*HLA, CD25, CD40, CTLA4,* and *PTPN22*).[91] These genes together probably do not explain more than about 10% of the heritability of Graves disease[92]; it follows there must be many more still undetected genetic loci, each contributing a little. The *TSHR* gene is most tightly associated with Graves disease, but the functional consequences of SNPs in the unusual large intron 1 are not clear.[93] They could give rise to RNA splice variants, increasing the level of autoantigenic TSHR α-subunits. Alternatively, SNP carriers may have fewer thymic *TSHR* transcripts, decreasing central tolerance to TSHR. Multiple SNPs in the thyroglobulin gene are linked to both Graves and Hashimoto disease.[91] Possible interactions between HLA-DRβ1 and thyroglobulin variants have been described in Graves disease, which would result in more effective presentation of disease-associated thyroglobulin-SNP allelles to T cells.[94] The immunoregulatory genes *HLA, CD25, CD40, CTLA4,* and *PTPN22* are all involved in the immunologic synapse, in which antigenic peptides complexed in HLA molecules are presented by antigen-presenting cells (APCs; macrophages, dendritic cells, but also B cells) to T-cell receptors (TCRs) on T cells. Formation of the trimolecular complex (HLA, antigenic peptide, TCR) activates $CD4^+$ T cells via expression of the interleukin 2 receptor (IL2Rα; CD25 is a marker for the IL2R α-chain) and by inducing co-stimulation via induction of CD40 ligand on T cells, which binds to constitutively expressed CD40 on APCs. CTLA4 is finally induced, which should terminate the immune response. Polymorphisms in these genes may functionally hinder the proper development of central and peripheral tolerance and alter T-cell interactions with APCs in the immunologic synapse.[91] They confer susceptibility for AITD but also for other autoimmune diseases, explaining the co-occurrence of various autoimmune diseases.[83] Odds ratios of individual loci for AITD are rather low (<2.0), but slightly higher for *HLA* (2.0–4.0). HLA-C, an HLA class I molecule, is stronger associated with Graves disease than HLA class II molecules (HLA-DRB1, DQA1, and DQB1), at least in Caucasians.[95] This is interesting as HLA class I molecules present endogenous antigens to immune cells, including those derived from viruses, which are possible triggers for AITD. Noteworthy is the lack of an association between Graves disease and mutations in the autoimmune regulator gene (*AIRE*) expressed in thymic medullary epithelial cells, resulting in failure to present self-antigens correctly in the thymus; *AIRE* mutations cause autoimmune polyglandular syndrome type 1.[96] Polymorphisms in the *PTPN22* gene encoding lymphoid protein tyrosine phosphatase is another susceptibility gene, with a gene dose-dependent effect on the age of onset of Graves disease.[97]

Environmental Insults

Iodine

Iodine-induced thyroid autoimmunity is related to TgAb, and the unmasking of a cryptic epitope on Tg contributes to this relationship in humans.[98] Longitudinal epidemiologic studies demonstrate that iodine fortification in iodine-deficient areas initially lead to a transient increase in the incidence of toxic multinodular goiter and Graves hyperthyroidism. In the long term, however, there is a decline in the incidence rate of thyrotoxicosis, mainly due to fewer cases of toxic multinodular goiter but also—although to a lesser extent—to fewer cases of Graves disease.[99,100]

Smoking

Smoking is a well-established risk factor for Graves disease.[101] The odds ratio for Graves hyperthyroidism is 3.30 (CI 2.09–5.22) in current smokers when compared with never smokers. The risk disappears a few years after cessation of smoking.

Alcohol

Moderate alcohol consumption is associated with a considerable reduction in the risk of Graves hyperthyroidism. Odds ratios are 1.73 (CI 1.17–2.56) for 0 units/week, 1.00 for 1 to 2 units/week (reference), 0.56 (0.39–0.79) for 3 to 10 units/week, 0.37 (0.21–0.65) for 11 to 20 units/week, and 0.22 (0.08–0.60) for 21+ units/week.[83,102] No interaction was found with type of alcohol (wine vs beer), smoking habits, gender, or iodine intake.

Selenium

As evident from population-based studies in China, low selenium intake might be a risk factor for autoimmune thyroiditis and hypothyroidism, but not for Graves hyperthyroidism.[103]

Stress

Stressful life events have already been implicated in the early descriptions of Graves hyperthyroidism.[51] Numerous reports on exposure to severe emotional stress prior to the onset of Graves disease support a causal relationship,[104] but prospective studies on this issue are lacking.[83]

Infections

Similarity between different antigens can lead to specificity crossover (molecular mimicry). Antigenic similarity between bacteria/viruses and human proteins is common. The best studied example is infection with *Yersinia enterocolitica* (YE). IgG from Graves patients inhibit TSH binding to outer membranes of YE, and conversely IgG from patients with YE infection inhibit binding of TSH to thyroid membranes. There is cross-reactivity between YE outer membrane proteins and epitopes of TSHR antibodies.[105] Despite this clear evidence of molecular mimicry, epidemiologic studies have not detected an association between YE infection and AITD.[106] A local insult (whether trauma or infection) may cause

an inflammatory infiltrate and production of cytokines in the thyroid gland, which may induce HLA class II expression; this may facilitate presentation of thyroid antigens and activation of local autoreactive thyroid-specific T cells in susceptible individuals.[107] A number of infections (e.g., with enteroviruses, *Helicobacter pylori,* reoviruses) have been implicated in Graves disease, but conclusive evidence for their involvement has not been obtained. The exception is hepatitis C virus (HCV), which seems the only infectious agent that is clearly associated with an increased risk for autoimmune thyroiditis.[108] HCV can infect human thyrocytes resulting in production of proinflammatory cytokines, which may enhance the autoimmune response.[109]

Drugs

Interferon-α has direct cytotoxic effects on thyrocytes but can also provoke destructive bystander immune responses. Treatment of hepatitis C with interferon-α and ribavirin combination therapy is associated with development of a suppressed TSH in 10.4%, due to Graves disease in 0.8%, and to destructive thyroiditis in 9.6%.[110] Exogenous estrogens such as oral contraceptives are associated with a lower risk of Graves hyperthyroidism.[111,112]

Graves hyperthyroidism may occur during periods of lymphocyte recovery after induced lymphopenia, known as the immune reconstitution syndrome. It is observed after bone marrow or hematopoietic stem cell transplantation,[113] during highly active antiretroviral therapy (HAART) for human immunodeficiency virus (HIV) infection in 3%,[114] and during alemtuzumab therapy for multiple sclerosis in 30%.[115] Alemtuzumab is a humanized anti-CD52 monoclonal antibody, inducing a rapid and prolonged depletion of lymphocytes from the circulation, resulting in a profound immunosuppression followed by an immune reconstitution phase. Median onset of Graves hyperthyroidism is 17 months (range 2–107 months) following last dose of alemtuzumab.[116] Graves hyperthyroidism in this context frequently requires definitive or prolonged ATD treatment. Furthermore, fluctuating thyroid status and high frequency of TSHRAb-positive hypothyroidism suggest switches between blocking and stimulating TSHRAb in these patients.

Immune checkpoint inhibitors are emerging as a new class of anticancer drugs associated with frequent thyroidal side effects. Ipilimumab is a monoclonal antibody against CTLA4 that blocks an inhibitory signal to T cells, thereby prolonging a stimulated immune response against tumor cells.[117] Nivolumab and pembrolizumab are antibodies against programmed death protein 1 (PD1), which is upregulated on activated T cells. By interrupting PD1 binding to its ligand PDL1, effector T-cell activity increases in the tumor microenvironment.[117] Treatment with these checkpoint inhibitors may result in subclinical hyperthyroidism due to destructive thyroiditis and, rarely, in Graves hyperthyroidism.[117–119]

Diagnosis and Differential Diagnosis

When the syndromal diagnosis of thyrotoxicosis has been established by the finding of a suppressed serum TSH and an increased serum FT_4 and/or FT_3, a nosologic diagnosis should be reached: Which disease entity causes hyperthyroidism? If Graves orbitopathy is present, it is quite evident Graves hyperthyroidism is present. Otherwise the presence of TSH receptor antibodies (TSHRAb) in serum confirms Graves disease. Most current assays use a competitive binding methodology, measuring TSH-binding inhibitory immunoglobulins (TBII) (Table 12.3). These binding assays do not discriminate between stimulating and blocking TSHRAb. Nevertheless, their sensitivity and specificity for the diagnosis of Graves hyperthyroidism are very high (97% and 98%, respectively).[120] In contrast, cell-based bioassays are able to differentiate between stimulating TSHRAb (TSAb or TSI) and blocking TSHRAb (TBAb).[121,122]

TABLE 12.3 Assays of Thyroid-Stimulating Hormone Receptor Antibodies: Nomenclature and Indications

Nomenclature of TSHRAb Assays	
TBII (TSH binding inhibitory immunoglobulins)	Measurement of inhibition of labelled TSH (or labelled thyroid-stimulating monoclonal antibody) binding to recombinant TSHR by serum antibodies
TSAb or TSI (thyroid-stimulating antibodies)	Measurement of cAMP production by thyroid cell lines transfected with TSHR
TBAb (thyroid-blocking antibodies)	Measurement of inhibition of cAMP production after TSH-mediated stimulation of thyroid cells or TSHR-transfected cells
Indications for Assay of TSHRAb	
Diagnosis	Graves hyperthyroidism Graves orbitopathy and Graves dermopathy Fetal and neonatal thyrotoxicosis
Treatment	Chance of remission of hyperthyroidism at baseline, and during treatment with antithyroid drugs.

cAMP, Cyclic adenosine monophosphate; *TSH*, thyroid-stimulating hormone; *TSHR*, thyroid-stimulating hormone receptor; *TSHRAb*, thyroid-stimulating hormone receptor antibodies.

Large variation exists in the use of diagnostic imaging. A recent study in France among hyperthyroid patients indicated thyroid ultrasonography was done in 94% and isotope scanning in 40%.[123] European Thyroid Association (ETA) guidelines recommend ultrasonography (comprising grey scale analysis and color flow or power Doppler examination) as the preferred imaging procedure for the diagnosis of Graves hyperthyroidism.[124] Graves hyperthyroidism is typically characterized by diffuse thyroid enlargement, hypoechogenicity, and increased vascularity. The latter can be used to differentiate between thyrotoxicosis due to Graves disease and destructive thyroiditis (as in subacute thyroiditis, amiodarone-induced thyrotoxicosis type 2). Typical ultrasound patterns combined with positive TSHRAb may obviate the need for thyroid scintigraphy. ETA guidelines suggest scintigraphy when thyroid nodularity coexists with hyperthyroidism and prior to ^{131}I therapy. The few patients in whom no TSHRAb are detected (TBII <2 U/L) have biochemically less severe Graves hyperthyroidism compared to TSHRAb-positive patients[125]; however, familial nonautoimmune hyperthyroidism due to germline *TSHR* activating mutations is present in 4.5% of such patients.[126]

Natural History and Prognosis

Knowledge about the natural history of Graves hyperthyroidism is limited because nowadays almost no patient escapes therapeutic intervention. Case histories from the older literature and cumulative experience with the outcome of ATDs, however, allow us to hypothesize that patients with Graves hyperthyroidism can be

divided into three groups, each with a different natural history: (1) patients who have a prolonged continuous episode of hyperthyroidism that never goes into remission (~10%), (2) patients who follow a relapsing and remitting course over many years (~50%), and (3) patients who have a single episode of hyperthyroidism followed by permanent remission (~40%). Patients who are in remission after a course of ATDs have a low prevalence of TSHRAb (<30%) and a much higher prevalence of TPOAb (~80%). Long-term follow-up studies of patients in remission indicate development of subclinical hypothyroidism in about 20% and overt hypothyroidism in about 6%, associated with either blocking TSHRAb or TPOAb.[127–129]

A series of population-based studies in Denmark have provided evidence that Graves hyperthyroidism (but also toxic nodular goiter) is associated with increased all-cause mortality (hazard ratio 1.42, CI 1.25–1.60) due to cardiovascular and lung diseases.[130] Excess mortality is related to cumulative periods of low serum TSH.[131] Hyperthyroid patients treated with radioactive iodine remain at a higher risk of cardiovascular diseases compared to patients treated with thyroidectomy, but hypothyroidism during follow-up predicts better cardiovascular outcome.[132]

Treatment

Recent guidelines and reviews give detailed information on the management of Graves hyperthyroidism.[124,133,134] Treatment of hyperthyroidism in the presence of Graves orbitopathy is discussed in the section on Graves orbitopathy. There are three treatment options (ATDs, thyroidectomy, and radioactive iodine) that are effective in restoring euthyroidism. It should be realized, however, that a causal therapy of Graves disease directed against the underlying abnormal immune responses is not yet available.

Antithyroid Drugs: Thionamides

Mechanism of Action

The major agents for treating thyrotoxicosis are drugs of the thionamide class: carbimazole (CBZ), methimazole (MMI), and PTU. CBZ is rapidly decarboxylated in the liver to the active substance MMI. Equivalent doses are 40 mg CBZ, 30 mg MMI, and 400 mg PTU. Each of these agents inhibits the function of thyroid peroxidase, thereby reducing oxidation and organification of thyroid iodide, iodotyrosine coupling, and thyroid hormone biosynthesis. In addition, large doses of PTU, but not methimazole, impair the conversion of T_4 to T_3 by D1 in the thyroid and peripheral tissues.[135] Consequently large doses of PTU may provide more rapid alleviation of very severe thyrotoxicosis.

The plasma half-life of MMI is about 6 hours, whereas that of PTU is about 1.5 hours. Both drugs are accumulated by the thyroid gland. Whereas the daily amount of MMI can be given in one dose, the daily amount of PTU should be divided in three doses with each given every 8 hours. In patients with severe hyperthyroidism, splitting the daily dose of MMI might sometimes be required. Single daily dosing improves compliance and should be used whenever possible. Thionamides cross the placenta and can inhibit fetal thyroid function.

MMI and PTU may also have immunosuppressive effects.[136] In vitro MMI reduces HLA-DR expression on thyroid cells, either directly or indirectly via inhibiting IFNγ. In vivo, MMI decreases the number of intrathyroidal activated T cells and the concentration of serum TSHRAb (but not of nonthyroid antibodies such as parietal cell antibodies). MMI, but not glucocorticoids, given prior to radioiodine therapy blunts the increase in TSHRAb usually seen after ^{131}I.[137] The unresolved question, however, is whether the effects are caused directly by the action of the drug on the immune system or indirectly by restoration of the euthyroid state.

TABLE 12.4 Adverse Events of Antithyroid Drugs

Common (1–5%)	Skin rash Urticaria Arthralgia, polyarthritis Transient mild leukopenia
Rare (0.2–1%)	Gastrointestinal Abnormal smell and taste Agranulocytosis
Very rare (<0.1%)	Aplastic anemia (PTU, CBZ) Thrombocytopenia (PTU, CBZ) Vasculitis, lupus-like, ANCA+ve (PTU) Hepatitis (PTU) Hypoglycemia (anti-insulin antibodies) (PTU) Cholestatic jaundice (CBZ, MMI)

ANCA+ve, Antineutrophil cytoplasmic antibody positive; *CBZ*, carbimazole; *PTU*, propylthiouracil; *MMI*, methimazole.
Adapted from Strieder TG, Prummel MF, Tijssen JG, et al. Risk factors for and prevalence of thyroid disorders in a cross-sectional study among healthy female relatives of patients with autoimmune thyroid disease. *Clin Endocrinol.* 2003;59:396–401.

Adverse Effects (Table 12.4)

Minor cutaneous reactions such as skin rash and urticaria usually can be managed by antihistamine therapy without stopping the drug. The lesions may resolve spontaneously or after switching to another ATD. Prescribing the alternative drug is not recommended in the case of serious allergic reactions.[124,138]

Agranulocytosis (<500 neutrophils/mm^3) is a serious side effect, with an incidence of 0.28% in the first 3 months of therapy.[139] Risk factors are older age, higher doses of ATD, and the presence of particular HLA-B and HLA-DRB1 alleles or rare NOX3 genetic variants.[140–142] The onset of agranulocytosis is rather abrupt, accompanied by fever and sore throat.[138] When therapy with ATD is begun, the patient should be instructed to discontinue the drug and to notify the physician immediately should these symptoms develop. This precaution is more important than the frequent measurement of white blood cell counts because agranulocytosis may develop within 1 to 2 days. Neither the American Thyroid Association (ATA) nor the ETA recommend routine monitoring of white blood cells during ATD therapy. If agranulocytosis occurs, the drug should be discontinued immediately and the patient treated with antibiotics as appropriate. Granulocyte colony-stimulating factor may speed the recovery that invariably takes place. Lymphocytes of patients who have developed agranulocytosis while taking PTU undergo blast transformation when exposed in vitro to PTU or methimazole; consequently, thionamides should not be given again. Granulocytopenia occurs during ATD therapy and is sometimes a forerunner of agranulocytosis, but it can also be a manifestation of thyrotoxicosis itself.

Although rare, PTU has been associated with fulminant hepatic necrosis, and it is the third most common cause of drug-related liver failure, accounting for 10% of all drug-related liver transplants. Children are at a higher risk than adults.[143] Fortunately, stopping PTU results in recovery in most cases. This

PTU-associated liver failure may occur at any time during therapy, so routine monitoring of liver function may not be helpful.[138] Because of this well-known rare but serious PTU side effect of hepatic failure, sometimes requiring liver transplantation, in June 2009 the Food and Drug Administration (FDA) issued an advisory that PTU should not be used as a first-line agent in hyperthyroidism.[144] The use of PTU should be restricted to the first trimester of pregnancy (see later), to thyroid storm, and to patients who experience minor side effects of MMI and are unable or unwilling to undergo ^{131}I therapy or thyroidectomy. MMI is associated in a dose-dependent manner with an increased risk for hepatitis and cholestasis.[145] There are no reported cases of liver transplantation attributed to MMI toxicity.

Practical Use

Guidelines agree MMI (CBZ) should be used in virtually every nonpregnant patient who chooses ATD therapy.[124,134] Guidelines also recommend that patients should be informed of side effects of ATD and the necessity of informing the physician promptly if they should develop jaundice, light-colored stools, dark urine, fever, or pharyngitis. Preferably this information should be in writing. Prior to ATD therapy it is suggested to obtain a baseline complete blood count, including white blood cell count with differential, and a liver profile, including bilirubin and transaminases. Restoration of the euthyroid state by ATD can be done according to the *titration* method or the *block-and-replace* regimen. In the titration method one starts with a relatively high single daily dose of 20 to 30 mg MMI (or 30–40 mg CBZ). Normal FT_4 and T_3 concentrations are usually reached after 4 to 6 weeks, which should be followed by tapering the MMI dose toward a maintenance dose of about 5 to 10 mg MMI, which keeps the patient euthyroid. In the block-and-replace regimen one starts with the same high initial dose of MMI, then adds LT_4 when the patient has become euthyroid under continuation of the high initial MMI dose. In the rare patient given PTU, the high starting PTU dose is 300 to 400 mg daily divided in three to four doses, whereas the maintenance dose is about 50 to 100 mg daily. The advantage of the titration method is the use of lower doses of MMI and thereby slightly fewer side effects; the disadvantage is the need for more frequent blood sampling to adjust the MMI dose and larger fluctuations between hypothyroidism and hyperthyroidism. The advantages of the block-and-replace regimen are fewer blood samples and more stable thyroid function during ATD therapy; the disadvantages are the higher MMI dose and slightly more side effects. The two methods have never been compared in a randomized clinical trial. The recurrence rate of Graves hyperthyroidism is similar between both regimens. In many patients, serum TSH may remain suppressed for a long time despite already normalized serum FT_4 and T_3 concentrations.[146] This phenomenon has been linked to the presence of still high serum concentrations of stimulating TSHRAb, which via binding to TSH receptors in pituitary folliculostellate cells downregulate TSH release.[147]

MMI is administered for 12 to 18 months and then discontinued to see if the disease has gone into remission. Remission

TABLE 12.5 Predictive Scores for the Risk of Recurrent Graves Hyperthyroidism After 1-Year Treatment With Antithyroid Drugs

Items (Assessed Before Starting Therapy)		GREAT Score Range 0–6
Age (yr)	≥40	0
	<40	+1
FT_4 (pmol/L)	<40	0
	≥40	+1
TBII (U/L)	<6	0
	6–19.9	+1
	≥20	+2
Goiter size[a]	gr. 0–I	0
	gr. II–III	+2

GREAT SCORE	
Risk Class	Recurrences
Class I (score 0–1)	16%
Class II (score 2–3)	44%
Class III (score 4–6)	68%

Items Added		GREAT+ Score Range 0–10
PTPN22 C/C wild type		0
	C/T	+1
HLA nr.[b]	0	0
	1–2	+2
	3 (LD)	+3

GREAT+ SCORE	
Risk Class	Recurrences
Class I+ (score 0–2)	4%
Class II+ (score 3–4)	21%
Class III+ (score 5–6)	49%
Class IV+ (score 7–10)	84%

[a]Goiter size: grade 0, thyroid not or distinctly palpable but usually not visible; grade I, thyroid easily palpable and visible with head in normal or raised position; grade II, thyroid easily visible with the head in a normal position; grade III, goiter visible at a distance.

[b]Number of HLA subtypes (*DQB1-02, DQA1-05, DRB1-03)* present.

FT4, Free thyroxine; *HLA*, human leukocyte antigen; *LD*, linkage disequilibrium; *TBII*, thyroid-stimulating hormone–binding inhibitory immunoglobulins.

Modified from Vos XG, Endert E, Zwinderman AH, et al. Predicting the risk of recurrence before the start of antithyroid drug therapy in patients with Graves' hyperthyroidism. *J Clin Endocrinol Metab.* 2016;101:1381–1389.

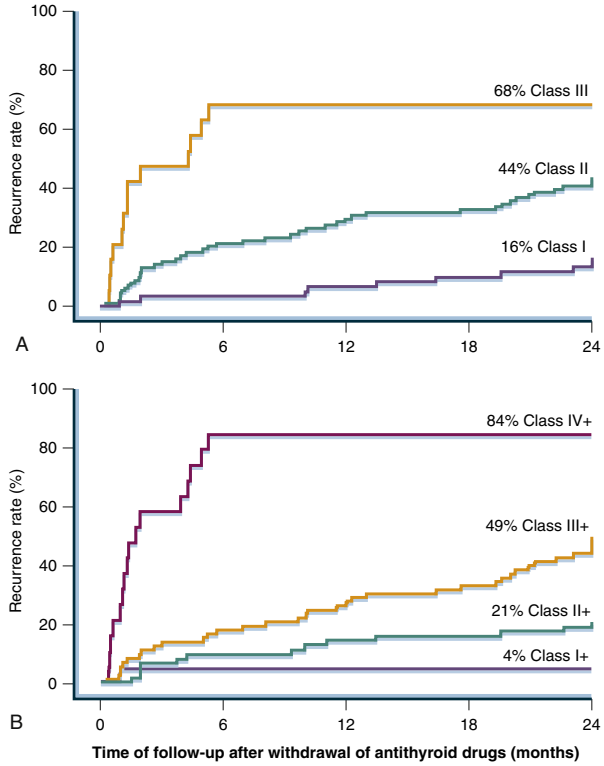
rate is between 40% and 60%; it is not influenced very much by dose or duration of ATD therapy. Most recurrences occur in the first year after stopping ATD. Exposure to stressful life events and daily hassles after withdrawal of ATD increase the risk of recurrent hyperthyroidism.[104,148] It is recommended to check thyroid function annually to detect late recurrences or development of hypothyroidism. Recurrences should be treated with radioiodine or surgery. About one-third of patients experience a lasting remission.

Chances of remission increase if during ATD therapy goiter size and/or TSHRAb decrease and TSH has become normal. It has been recommended to measure TSHRAb just prior to stopping ATD. If TSHRAb have disappeared, chances of remission are high. If TSHRAb can still be detected, one may consider prolonging ATD therapy because chances of remission are low. A major advantage of a more prolonged therapy is that nearly all patients remain euthyroid as long as therapy is given, even if the dose of the drug is low.

Predicting who will experience relapsing hyperthyroidism after stopping ATD has proven to be difficult. A change from stimulating to blocking TSHRAb might play a role, as well as many other factors.[149] A systematic review and meta-analysis of 7595 patients, of whom 48.7% relapsed, identified a significant association with relapse of the following items, all assessed before starting treatment with ATD: smoking, thyroid size (either by sonography or by inspection and palpation), orbitopathy, FT_4, FT_3, and TBII.[150] These risk factors by themselves, however, have not sufficient power for accurate prediction in individual patients. Combining a number of independent risk factors led to a predictive score composed of age, FT_4, TBII, and goiter size (by inspection and palpation), called the GREAT score (Graves Recurrent Events After Therapy) (Table 12.5).[151] The clinical relevance is that the GREAT score provides a reasonable prediction of recurrence risk after a course of ATDs based on just four items, readily available before the start of treatment (Fig. 12.5). It might allow for discussions with the patient of whether the treatment option of ATDs is optimal for them. If the recurrence risk is low, ATD might be a good choice; if the recurrence risk is rather high, surgery or radioiodine could be a better option. The GREAT score has been validated in an independent study.[152] Adding the results of specific genotypes provides the GREAT score with even better prediction. It can be foreseen that such predictive scores will be of great value in personalized medicine.

Other Drugs Used in Hyperthyroidism

Beta-Adrenoceptor Blocking Agents. Thyroid hormone excess increases sensitivity of the sympathetic nervous system to catecholamines. Drugs that block the response to catecholamines at the receptor site (e.g., propranolol) ameliorate some of the manifestations of thyrotoxicosis and are often used as adjuncts in management. Beta blockers rapidly improve complaints of tremulousness, palpitations, excessive sweating, and eyelid retraction. Beta blockers are recommended in all patients with symptomatic thyrotoxicosis, especially in elderly patients and patients with resting heart rates in excess of 90 beats per minute or coexistent cardiovascular



• **Fig. 12.5** Kaplan-Meier curves for recurrent Graves hyperthyroidism after a 1-year course of antithyroid drugs according to risk classes I to III of the GREAT score (A) and risk classes I+ to IV+ of the GREAT+ score (B). (Redrawn from Vos XG, Endert E, Zwinderman AH, et al. Predicting the risk of recurrence before the start of antithyroid drug therapy in patients with Graves' hyperthyroidism. *J Clin Endocrinol Metab.* 2016;101:1381–1389.)

disease.[124,134] Beta blockers are most useful in the interval before the response to thionamides or radioiodine therapy occurs. Propranolol, in addition to its action as a β-adrenoreceptor antagonist, also inhibits 5′-deiodination resulting in a decrease of plasma T_3 and an increase of plasma reverse T_3.[153] Plasma T_3 decreases by 20% at a daily dose of 80 mg propranolol (four 20-mg doses) and by 30% at 160 mg propranolol (four 40-mg doses). Beta blockers without membrane-stabilizing activity do not decrease plasma T_3, but the clinical response to β-blockers is independent of the decrease in T_3. The largest experience is with propranolol, but the drug can be contraindicated (e.g., in asthma and chronic obstructive pulmonary disease). Longer acting drugs with relative β1 selectivity might then be preferred, such as atenolol (25–100 mg once or twice daily) and metoprolol (25–50 mg twice or three times daily).[124]

Perchlorate. Perchlorate inhibits thyroid iodide transport and has been used in the past to treat Graves hyperthyroidism. Although it was effective in restoring euthyroidism and decreasing TSHRAb, it is no longer used in view of its side effects (except in amiodarone-induced thyrotoxicosis type 1).[154,155]

Iodine. Iodine is now rarely used as a sole therapy. The mechanism of action of iodine in relieving thyrotoxicosis differs from that of the thionamides. Although quantities of iodine in excess of several milligrams can acutely inhibit organic binding (acute Wolff-Chaikoff effect), this transient phenomenon probably does not contribute to the therapeutic effect. Instead, the major action of iodine is to inhibit hormone release. Administration of iodine increases glandular stores of organic iodine, but the beneficial effect of iodine is evident more quickly than the effects of even large doses of agents that inhibit hormone synthesis. In patients with Graves disease, iodine acutely retards the rate of secretion of T_4, an effect that is rapidly lost when iodine is withdrawn. These features of iodine action provide both disadvantages and advantages. The enrichment of glandular organic iodine stores that occurs when this agent is given alone may retard the clinical response to subsequently administered thionamides, and the decrease in RAIU produced by iodine prevents the use of radioiodine as treatment for several weeks. Furthermore, if iodine is withdrawn, resumption of accelerated release of hormone from an enriched glandular hormone pool may exacerbate the disorder. Another reason for not using iodine alone is that the therapeutic response on occasion is either incomplete or absent. Even if initially effective, iodine treatment may lose its effect with time. This phenomenon, termed *iodine escape*, should not be confused with the escape from the acute Wolff-Chaikoff effect.[156] Nevertheless, the rapid slowing of hormone release by iodine makes it more effective than the thionamide drugs when prompt relief of thyrotoxicosis is mandatory. Therefore, aside from its use in preparation for thyroid surgery, iodine is useful mainly in patients with actual or impending thyrotoxic crisis, severe thyrocardiac disease, or acute surgical emergencies. If iodine is used in these circumstances, it should be administered with large doses of a thionamide.

Recent studies suggest a potential role for iodine in patients who have adverse reactions to ATD or contraindications for radioiodine or surgery.[157,158] Sometimes iodine is used as a beneficial adjunct to ATD: 38 mg potassium iodide (KI) + 15 mg MMI resulted in better control of hyperthyroidism and fewer adverse reactions than 30 mg MMI alone.[158]

The lowest dose of iodine required for control of thyrotoxicosis is approximately 6 mg daily. Six milligrams of iodine are present in one-eighth of a drop of saturated solution of potassium iodide (SSKI) or approximately 1 drop of Lugol solution; many physicians, however, prescribe 5 to 10 drops of one of these agents three times daily. Although it is advisable to administer amounts larger than the suggested minimal effective dose, huge quantities of iodine are more likely to produce adverse reactions. We recommend the use of a maximum 2 to 3 drops of SSKI twice daily. Adverse reactions to iodine are unusual and in general not serious. They include rash, which may be acneiform; drug fever; sialadenitis; conjunctivitis and rhinitis; vasculitis; and a leukemoid eosinophilic granulocytosis. Sialadenitis may respond to reduction of dosage and the addition of lemon/lime candies to increase salivary flow; in the case of the other reactions, iodine should be stopped.

Lithium. Lithium carbonate inhibits thyroid hormone secretion, but unlike iodine it does not interfere with the accumulation of radioiodine. Lithium, 300 to 450 mg every 8 hours, is used only to provide temporary control of thyrotoxicosis in patients who are allergic to both thionamides and iodide.[159] Another short-term use for lithium has been as an adjunct to radioiodine therapy because the drug slows the release of iodine from the thyroid.[160]

Selenium. Selenium levels were higher in patients in remission and correlated inversely to TSHRAb.[161] Therefore it was hypothesized that selenium supplementation might increase remission rate. Addition of 300 μg sodium selenite daily to methimazole did not, however, increase remission rate in a placebo-controlled trial.[162]

Cholecystographic Agents. The oral iodine-containing cholecystographic contrast agent sodium ipodate causes a prompt decrease in serum T_4 and serum T_3 in Graves hyperthyroidism. After a course of 500 mg sodium ipodate daily for 5 days, plasma T_3 is normalized in all patients, allowing uneventful thyroidectomy on day 5.[163] However, supplies of such agents are generally no longer available.

Cholestyramine. Thyroxine is metabolized in the liver to glucuronides and sulfates that enter the enterohepatic circulation. Cholestyramine interferes with the enterohepatic cycle, thereby acting as an effective and well-tolerated adjunctive therapy in patients with resistant Graves hyperthyroidism.[164,165] It can produce a rapid and complete decline in thyroid hormone levels.

Immunosuppressive Drugs. Because of the autoimmune nature of Graves disease, additional use of immunosuppressive agents might improve outcomes. A systematic review identified seven randomized or controlled trials in which the effect of addition of glucocorticoids or rituximab to standard treatment was compared to standard treatment alone.[166] Relapse rate was much lower in the intervention group with immunosuppressive drugs (24%) than in the control group (59%), with a risk ratio of 0.55 (CI 0.41–0.75, $p < 0.001$). However, the study has several limitations, such as small sample sizes and moderate to high risk of bias.

Future Developments. It is foreseen that novel treatment modalities for Graves hyperthyroidism will become available in the next decade. There may be causal therapies directed against stimulating TSHRAb, the immediate cause of Graves disease. Examples are antigen-specific immunotherapy with tolerogenic peptides of the TSH receptor, monoclonal TSH receptor–blocking antibodies, and low-molecular-weight TSH receptor antagonists.[167,168]

Thyroidectomy. Thyroidectomy has a high cure rate for Graves hyperthyroidism. Total thyroidectomy has a nearly 0% risk of recurrence, whereas subtotal thyroidectomy may have an 8% chance of persistent or recurrent hyperthyroidism at 5 years.[124,134]

Near-total or total thyroidectomy is therefore the procedure of choice. It is recommended to refer the patient to a high-volume thyroid surgeon. Average complication rates, length of hospital stay, and cost are reduced when the operation is performed by a surgeon who conducts many thyroidectomies. Surgeons who perform more than 25 thyroid surgeries per year have superior outcomes compared to surgeons who perform fewer.[169] Complication rates are on average 51% higher when surgery is performed by low-volume surgeons.[134]

Complications. In the hands of high-volume thyroid surgeons the rate of permanent hypoparathyroidism is less than 2% and that of permanent recurrent laryngeal nerve injury is less than 1%. Bleeding into the operative site necessitating reoperation occurs in 0.3% to 0.7%; it is the most serious postoperative complication, which can rapidly produce death by asphyxia and requires immediate evacuation of the blood and ligation of the bleeding vessel. Even with subtotal surgery, the recurrent laryngeal nerve can be damaged. If such damage is unilateral, it causes dysphonia that usually improves in a few weeks but may leave the patient slightly hoarse. Intraoperative recurrent laryngeal nerve monitoring does not necessarily improve long-term outcomes. Hypoparathyroidism can be either transient or permanent. Transient hypoparathyroidism results from inadvertent removal of some parathyroids and/or impairment of blood supply to those that remain. Depending on the severity of these insults, symptoms and signs of hypocalcemia appear, usually within 1 to 7 days after surgery. Severe hypoparathyroidism should be treated with intravenous calcium gluconate. Milder cases can be treated with oral calcium carbonate and cholecalciferol, although the active form of vitamin D (calcitriol) is more effective and preferred in most cases. However, the hypocalcemia that occurs immediately after surgery for thyrotoxicosis may not be due to transient hypoparathyroidism because it occurs more frequently in the Graves patient than after surgery for other thyroid disorders. Instead it may be due to "hungry bones" because of the demineralization of bone that occurs in hyperthyroidism. This begins to be reversed after cure of the hyperthyroid state and may contribute to the modest elevation in alkaline phosphatase during recovery unless the patients have been rendered euthyroid for some time prior to surgery. Many surgeons who fear that they have caused damage to the parathyroid glands at total thyroidectomy may reimplant the apparent parathyroid tissue into local muscles.

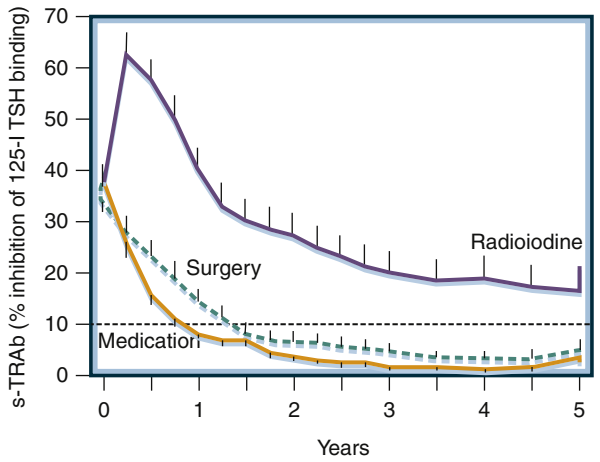
Preparation for Surgery. If surgery is chosen, patients should be rendered euthyroid prior to the procedure with ATD pretreatment, with or without β-adrenergic blockade. These agents do not improve the hyperplasia and hypervascularity of the gland in the short term. Iodine, however, is reported to cause a decrease in height of the follicular cells, enlargement of follicles with retention of colloid, and reduction of hypervascularity. Hence the recommendation to give a KI-containing preparation in the immediate preoperative period should be made.[124,134] SSKI 2 to 3 drops twice daily might be initiated 7 to 10 days before surgery to decrease thyroid blood flow and vascularity and hence intraoperative blood loss during thyroidectomy. During this period a preexisting bruit or thrill may decrease in intensity or disappear entirely, and the gland may become firm. However, little clinical evidence exists that postoperative outcomes are any different following a course of iodine.[170] A recent prospective controlled trial observed that preoperative use of KI decreased gland vascularity but not the overall difficulty of thyroidectomy; however, KI was associated with less transient hypoparathyroidism and transient hoarseness, suggesting KI improves the safety of thyroidectomy.[171] KI or Lugol solution is used by less than 40% of thyroidologists in Europe.[172] In exceptional circumstances, when it is not possible to render a patient euthyroid prior to thyroidectomy, the patient should be adequately treated with KI and β-blockers (eventually also with glucocorticoids and cholestyramine) in the immediate preoperative period.[134] Lastly, checking for calcium and 25-hydroxy vitamin D preoperatively is recommended. Preoperative vitamin D deficiency is a risk factor for postoperative hypocalcemia. Supplementing calcitriol for a brief period preoperatively helps to reduce postoperative hypocalcemia.[124,134]

After thyroidectomy, ATDs are stopped immediately and β-blockers should be weaned. Serum calcium with or without parathyroid hormone (PTH) levels can be measured and oral calcium and calcitriol supplementation be given based on these results; alternatively, prophylactic calcium with or without calcitriol is prescribed empirically. L-Thyroxine should be started at a daily dose appropriate for the patient's weight (1.6 μg/kg) and serum TSH measured 6 weeks postoperatively.[134]

Radioactive Iodine

Radioactive iodine (RAI) has been used since 1941. Prospective trials in this area are few, leaving many questions.[173] The cellular effect of the ionizing radiation leads to cell death and thereby to a decrease in thyroid function and a reduction in thyroid size. One year after ^{131}I therapy, thyroid size is mostly normalized, hyperthyroidism has disappeared in 50% to 90% of patients, and hypothyroidism has developed in up to 50% of patients directly related to the thyroid RAI dose.[173] This is followed by a yearly hypothyroidism rate of 3% to 5%, largely independent of RAI dose.[124] A seminal question thus arises: What is the goal of ^{131}I therapy in Graves hyperthyroidism? Is it to get rid of hyperthyroidism and restore euthyroidism? That has proven to be an elusive goal, as even meticulous calculation of a seemingly appropriate ^{131}I dose does not prevent a high incidence of post-radioiodine hypothyroidism. The ATA therefore recommends the following: "Sufficient activity of RAI should be administered in a single application, typically a mean dose of 10–15 mCi (370–555 MBq), to render the patient with Graves disease hypothyroid."[134] It means that cure of one disease (hyperthyroidism) is exchanged for the creation of another disease (hypothyroidism). ETA guidelines agree: "No dose calculation can secure long-term euthyroidism and it is fully acceptable to offer a fixed dose of RAI."[124] Therefore many have given up meticulous dose calculation and offer fixed activities of, for example, 185, 370, or 555 MBq, depending on thyroid size. An increased mortality rate has been reported in hyperthyroid patients treated with RAI.[174] This was not observed in patients rendered hypothyroid, and these findings support the practice of treating hyperthyroidism with doses of radioiodine sufficient to induce overt hypothyroidism.

There has been concern that RAI therapy might produce cancer. A hypothetical 0.8% lifetime cancer risk attributable to a 15-mCi ^{131}I dose at the age of 20 years has been calculated. This is only a small increase in baseline cancer risk, and most studies have found no significant increase in the prevalence of thyroid cancer or secondary malignancies in adult patients treated with RAI. Also the frequency of genetic damage in the offspring of patients treated earlier with radioiodine does not appear to be increased. In view of the lack of evidence of serious toxicity from RAI in doses generally used for treating adults with hyperthyroidism, the age limit for the use of RAI has been lowered progressively from the initial lower limit of 40 years to age 10 or younger. However, in a 5-year-old child the theoretical lifetime cancer risk



• **Fig. 12.6** Course of TSH receptor antibodies after treatment of Graves hyperthyroidism with antithyroid drugs, thyroidectomy, or radioactive iodine. (Redrawn from Leimberg P, Wallen G, Tallstedt L, et al. TSH-receptor autoimmunity in Graves' disease after therapy with anti-thyroid drugs, surgery, or radioiodine: a 5-year prospective randomized study. *Eur J Endocrinol*. 2008;158:69–75.)

TABLE 12.6 Advantages and Disadvantages of Treatment Options for Graves Hyperthyroidism

Treatment Option	Advantages	Disadvantages
Antithyroid drugs	Chance of permanent remission (~35%)	Side effects of ATDs Long duration (12–18 months) High recurrence risk
Radioactive iodine	Simplicity Low recurrence risk	Risk of orbitopathy Lifelong LT_4 needed Possible small increase in cancer risk
Thyroidectomy	Rapidity Almost no recurrences	Low but unavoidable morbidity Lifelong LT_4 needed

ATDs, Antithyroid drugs; *LT_4*, L-thyroxine.

after 15 mCi ^{131}I is 4%, so in very young children ATDs should be considered. The use of RAI in reproductive-age women also remains unpopular, and RAI is contraindicated during pregnancy. Fetuses exposed to ^{131}I after 10 weeks of gestation may be born athyreotic. In addition, ^{131}I should not be administered for at least 8 weeks after cessation of lactation because it is concentrated in breast milk.

Complications of RAI Therapy. The early induction of euthyroidism and later the development of hypothyroidism are both consequences of radiation-induced destruction of thyroid parenchyma. With large doses of RAI a tender radiation thyroiditis may develop within the first week of treatment, as evidenced by epithelial swelling and necrosis, disruption of follicular architecture, edema, and infiltration with mononuclear cells. Resolution of the acute phase is followed by fibrosis, vascular narrowing, and further lymphocytic infiltration. Radiation thyroiditis may lead to an exacerbation of thyrotoxicosis 10 to 14 days after RAI is administered. The effect of RAI on other tissues that concentrate iodide (e.g., the salivary glands, the gastric glands, and the breasts) is not likely to be a problem with the relatively low doses prescribed for Graves hyperthyroidism.

RAI therapy is associated with development or worsening of Graves orbitopathy in about 15% of cases compared to ATDs or thyroidectomy, as evident from three randomized clinical trials.[175–177] This effect is presumably related to the substantial increase in serum TSHRAb after RAI therapy, whereas in contrast TSHRAb decrease after thyroidectomy or upon treatment with ATD.[80] Five years later the level of TSHRAb is still higher after RAI than after ATD or surgery (Fig. 12.6). Thus the presence of Graves orbitopathy may influence which treatment modality is chosen for hyperthyroidism (see section on Graves orbitopathy).

Preparation for ^{131}I Therapy. Because ^{131}I therapy can cause a transient exacerbation of hyperthyroidism, β-blockers should be considered even in asymptomatic patients who are at increased risk for complications due to worsening of hyperthyroidism (i.e., elderly patients and patients with comorbidities). In addition to β-adrenergic blockade, pretreatment with MMI should also be considered in patients at increased risk for complications. ATD should be paused around 1 week before and after ^{131}I therapy to avoid decreasing RAI efficacy.[124,134] A pregnancy test should be obtained within 48 hours prior to RAI treatment in any woman with childbearing potential. Pregnancy and breastfeeding constitute absolute contraindications to RAI therapy.

The physician administering RAI should provide written advice concerning radiation safety precautions following treatment.[124,134] National differences in radiation regulations have considerable impact on the way RAI therapy is given in different countries (e.g., in the criteria for hospitalization). Attempts have been made to standardize the radiation delivered to the thyroid gland by varying the dose of radioiodine according to the size of the gland, the uptake of ^{131}I, and its subsequent rate of release (*dosimetry*). However, no data support an advantage of dosimetry over a fixed-dose regimen. Most clinics have redefined the goal of RAI therapy from making patients euthyroid to ablating the thyroid with a permanent need for thyroid hormone replacement. A dose of 20 mCi alleviates hyperthyroidism in almost all patients and results in approximately 90% hypothyroidism.

After RAI therapy, patients are seen at intervals of 4 to 6 weeks for 6 months, and FT_4 and TSH levels are monitored. However, TSH is not a reliable guide as to when to begin levothyroxine replacement therapy, as it can remain suppressed for a considerable period of time even after the FT_4 falls below normal. To avoid overt hypothyroidism, levothyroxine replacement therapy may be initiated when the FT_4 reaches the lower portion of the reference range. The starting dose should be relatively low to avoid overtreatment given that the residual thyroid function will not be subject to feedback regulation. When hyperthyroidism persists after 6 months, retreatment with RAI is suggested, generally with about 1.5 times the initial dose of ^{131}I. Conception should be postponed until at least 6 months after RAI therapy, both in males and females.[124]

Choice of Therapy

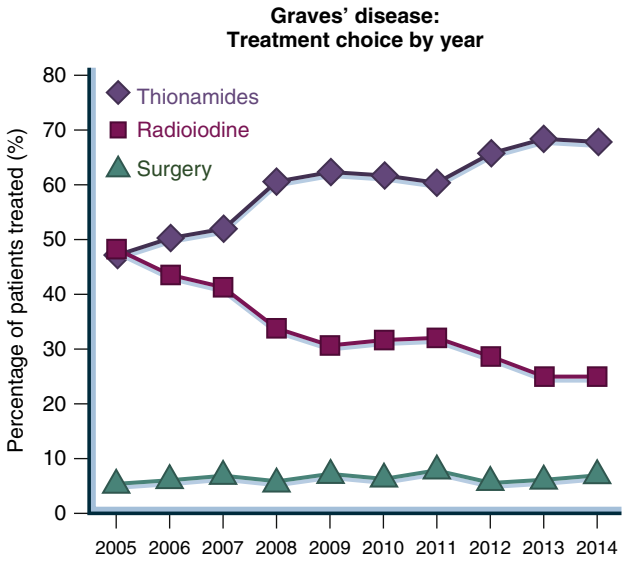
Advantages and disadvantages of each of the three treatment modalities are listed in Table 12.6. Weighing the pros and cons of each treatment by patients varies greatly. Clinical conditions leading to a preferred therapy are summarized in Table 12.7. Patients with high likelihood of remission are ideal candidates for ATD therapy; application of the GREAT score might identify such patients.[151]

TABLE 12.7 Clinical Conditions That Favor a Particular Treatment Modality for Graves Hyperthyroidism

Condition	ATD	RAI	Surgery
High chance of remission	+		
Active Graves orbitopathy	+		
Elderly with comorbidities	+	+	
Increased surgical risk	+	+	
Liver disease		+	
Major adverse reactions ATD		+	
Hypokalemic periodic paralysis		+	
Pulmonary hypertension or congestive heart failure		+	
Previous neck surgery or irradiation		+	
Recurrent hyperthyroidism		+	+
Malignancy suspected			+
Large thyroid nodules			+
Coexistent hyperparathyroidism			+

ATD, Antithyroid drug; *RAI*, radioactive iodine

Modified from Ross DS, Burch HB, Cooper DS, et al. 2016 American Thyroid Association guidelines for diagnosis and management of hyperthyroidism and other causes of thyrotoxicosis. *Thyroid*. 2016;26:1343–1421.



• **Fig. 12.7** Antithyroid drugs have become the most common treatment modality for Graves hyperthyroidism in the last decade in the United States. (Redrawn from Brito JP, Schilz S, Singh Ospina N, et al. Antithyroid drugs—the most common treatment for Graves' disease in the United States: a nationwide population-based study. *Thyroid*. 2016;26:1144–1145.)

ATD might also be preferred in patients with active Graves orbitopathy. Contraindications are major adverse reactions to ATD. RAI therapy is preferred in patients with contraindications for ATD or surgery, in case of recurrences after ATD, and in patients with hypokalemic periodic paralysis, pulmonary hypertension, or congestive heart failure. Contraindications for RAI are pregnancy or planning pregnancy within 6 months, lactation, and suspicion of thyroid cancer. Thyroidectomy might be preferred in women planning pregnancy within 6 months, in large or compressive goiters (>80 g), when thyroid malignancy is suspected, and in case of coexisting hyperparathyroidism. Thyroidectomy is best avoided in the first and third trimesters of pregnancy and in patients with increased surgical risk and substantial comorbidity. Long-term follow-up of patients randomized to receive one of the three treatment options did not disclose differences in perceived quality-of-life between treatments.[178]

The choice of the most appropriate treatment in a particular patient thus depends on a multitude of factors, including personal ones such as emotional attitudes, economic considerations, and family issues. It is obvious that a satisfactory choice can only be made in close consultation with the patient. One approach is to start with ATD in all patients. This would be useful also in patients who opt later for RAI or surgery. The patient will become euthyroid in 4 to 6 weeks, and this period can be used to discuss with the patient what the optimal treatment option would be. This approach allows the establishment of a workable physician-patient relationship, which is especially important in addressing anxieties about the use of radioiodine.

First-line treatment of uncomplicated Graves hyperthyroidism in Europe is with ATD in 84%, with RAI in 14%, and with surgery in 2%.[172] In contrast, the first-line treatment in North America had been RAI in the vast majority of cases in the 20th century. Recently this has changed dramatically; as of 2014, ATD also is the preferred treatment option in the United States, followed by RAI and then surgery[179] (Fig. 12.7).

Graves Orbitopathy

Graves orbitopathy is also known as Graves ophthalmopathy, thyroid-associated ophthalmopathy (TAO), and thyroid eye disease (TED). It is one of the phenotypes of Graves disease. Graves hyperthyroidism is present in about 90% of GO patients, whereas 5% to 10% of GO patients are euthyroid or hypothyroid (Fig. 12.8).[180]

Clinical Presentation

Most patients initially notice a change in appearance. There is redness in the eyes or lids and swelling or feeling of fullness in the upper eyelids and/or bags under the eyes.[181] The most common presenting sign is eyelid swelling, followed by eyelid lagging behind eyeball movement on downgaze (von Graefe sign). Early symptoms are a gritty sensation in the eyes, light sensitivity (photophobia), and excess tearing. With ongoing disease, upper eyelid retraction occurs in most patients. Exophthalmos (also referred to as proptosis) develops in about 60% of patients. These patients are more likely to show incomplete eyelid closure (lagophthalmos); many such patients, especially those with a wide palpebral fissure, will show punctate inferior corneal staining with fluorescein. Patients may complain about retrobulbar pressure and blurred vision. Extraocular muscle involvement may result in aberrant position of the globe or, in extreme cases, fixation of the globe. More common is limitation of eye muscle movements in certain directions of gaze, especially in upward gaze. This may cause diplopia (double vision), occurring in about 50% of patients.

• **Fig. 12.8** Patient with Graves orbitopathy. Note the typical bilateral rather symmetrical eye disease with periorbital swelling, stare, and exophthalmos (A), subsequently corrected by orbital decompression surgery (B). (Courtesy Dr. Jack Rootman, University of British Columbia, Vancouver, BC, Canada.)

Diplopia will not occur if the vision of one eye is very low (such as in amblyopia) or if the impairment of muscle motility is strictly symmetrical. Impairment of elevation and of abduction are most common, related to swollen inferior and medial rectus muscles, respectively, whereas impairment of depression and adduction are less frequent. Corneal ulceration nowadays is rare. It develops only when normal corneal protection is lost.[181] This may happen in patients with lagophthalmos in whom the cornea remains visible when the eyelids are closed. Sight loss due to optic nerve involvement (referred to as dysthyroid optic neuropathy [DON]) occurs in about 5%. Patients with DON may complain about decrease of visual acuity, loss of color vision, visual field defects, and blurred vision.[182] Visual blurring may disappear after blinking (caused by alteration of the tear film on the surface of the cornea due to lacrimation or dry eyes) or after closing one eye (caused by eye muscle imbalance). Visual blurring that persists is of concern as it may indicate DON.

The average age of presentation is 49 years, a few years after the average age of presenting with Graves hyperthyroidism. Female preponderance is obvious, but GO is more severe in males and the elderly. GO is a typical bilateral and rather symmetrical eye disease. Unilateral GO, however, occurs in about 10% of all GO patients. There is good evidence that the GO presentation is changing. Upon referral, GO patients in 2012 had less severe and less active disease than in 2000.[183]

Epidemiology

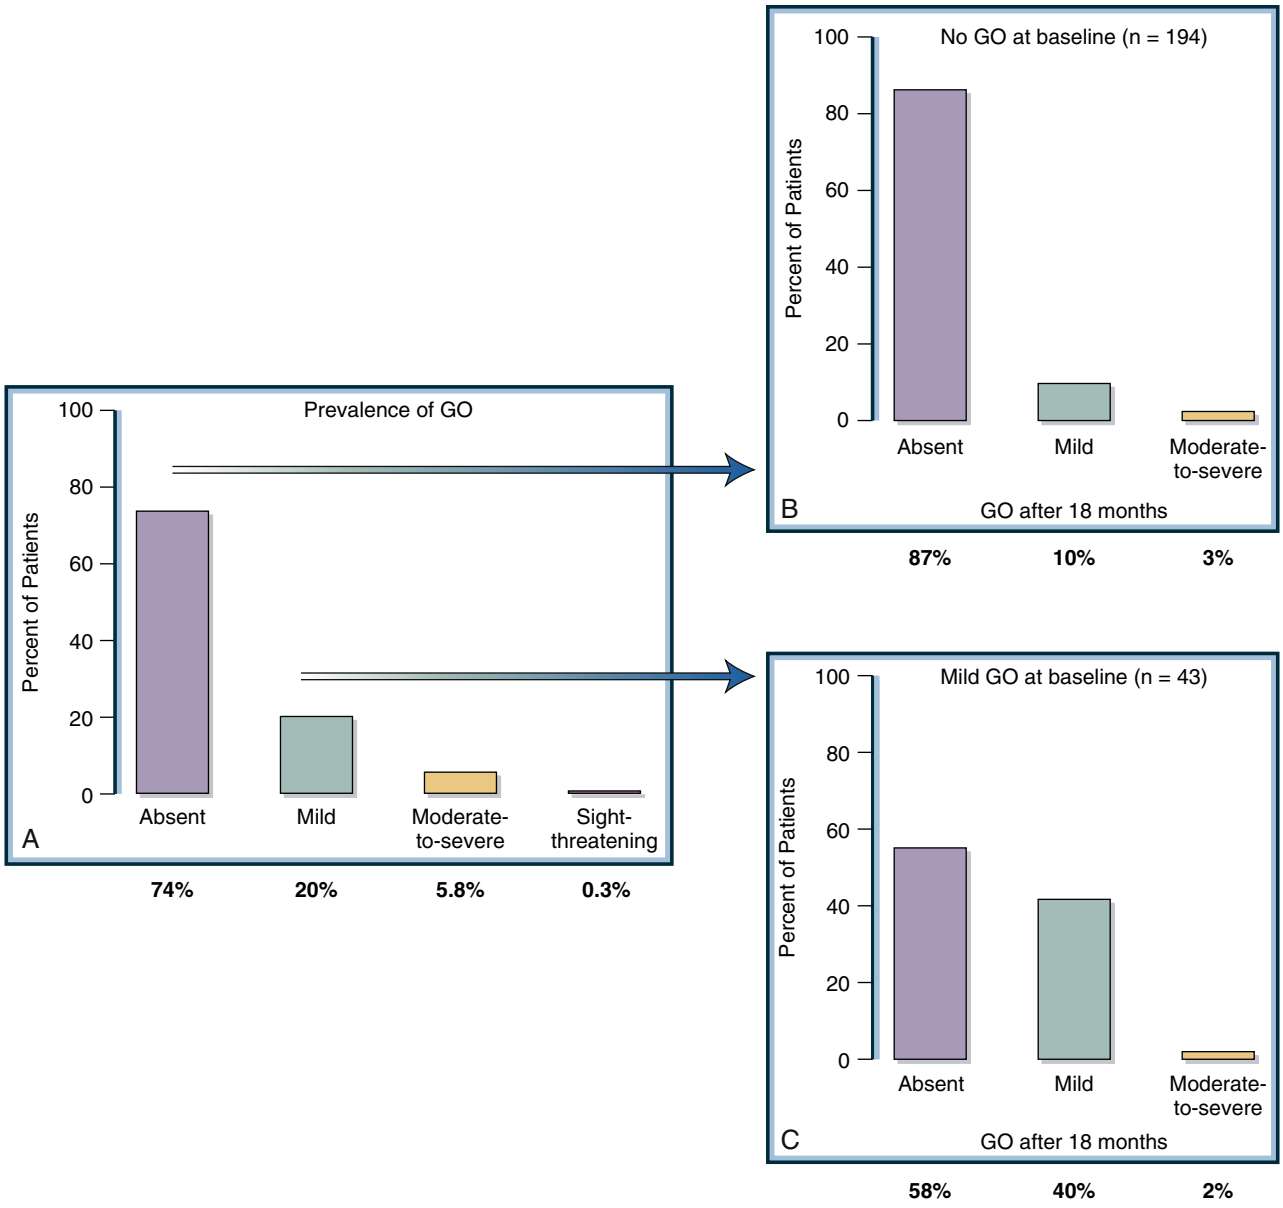
In the general Swedish population the incidence rate of Graves hyperthyroidism is 210 per million per year, and the incidence rate of GO is 42 per million per year.[184] It means 20% of patients with Graves hyperthyroidism also develop GO, which is mild in 15% and more severe in 5%. The data are in good agreement with studies from Denmark and Italy, reporting that moderate-to-severe GO occurs in about 5% of all patients with Graves hyperthyroidism.[61,185] When Graves hyperthyroidism is diagnosed, 74% have no GO, but 13% in this group will develop GO (mild in 10% and moderate to severe in 3%) during subsequent ATD therapy (Fig. 12.9). Mild GO at the time of diagnosing hyperthyroidism disappears spontaneously in 58% of these cases.[61] Thus GO is diagnosed at the same time as Graves hyperthyroidism in about 75% of GO patients, whereas GO is diagnosed later in about 25%.[186] In a few patients GO onset is before that of Graves hyperthyroidism.

There seems to be a secular trend to a lower incidence of GO.[187] Earlier diagnosis and treatment of hyperthyroidism, identification of risks conferred by ^{131}I therapy and postradioiodine hypothyroidism, and focus on the detrimental effects of smoking have likely contributed to this decline.[183,186]

Pathology

The pathologic anatomy of GO orbits is characterized by enlargement of the extraocular muscles and the retrobulbar fat/connective tissue compartment. The increased volumes of muscles and fat are attributed to an increase of the ground substance consisting of collagen and glycosaminoglycans (GAGs). GAGs (mainly hyaluronate) are very hydrophilic and thus attract much water, resulting in edematous swelling. The ground substance accumulates in the endomysial space between muscle fibers. The number of muscle fibers is not increased, and there is no damage to the muscle cells except in very advanced cases. The number of fibroblasts is increased in the endomysial space and in the fat/connective tissue compartment. The orbital fibroblasts (OFs) are responsible for the excessive production of GAGs. A subset of OFs may differentiate into mature adipocytes thereby adding to the volume expansion. OFs have been recognized as the target of the autoimmune attack in GO.

The increased muscle and fat volumes within the confined space of the bony orbit allow a mechanistic explanation of the

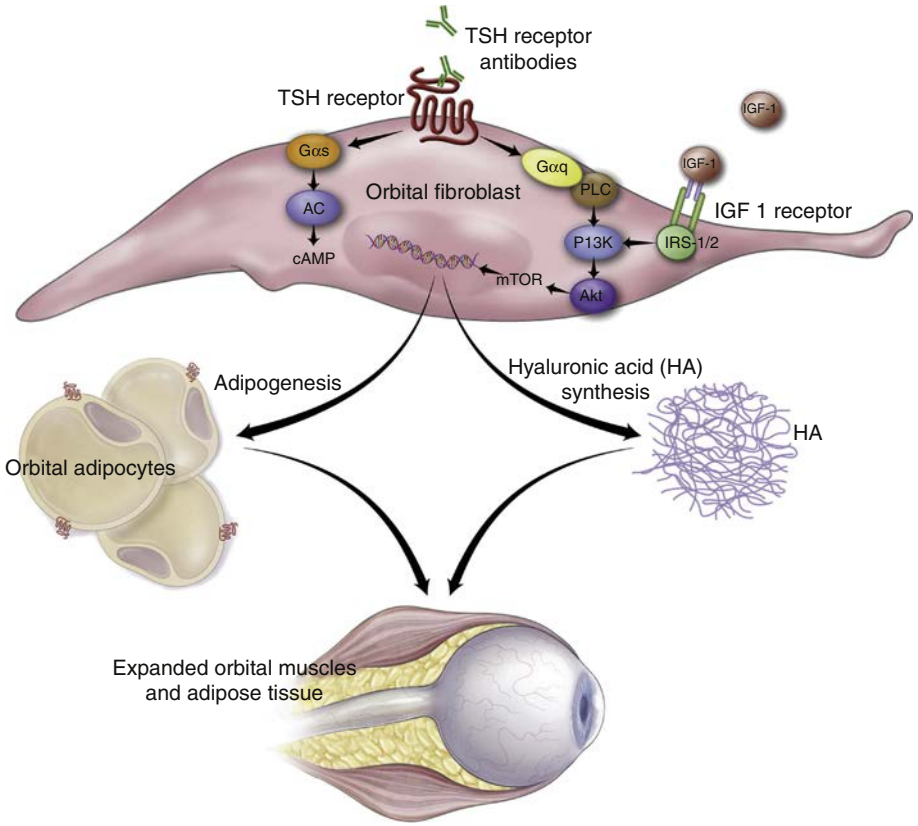


• **Fig. 12.9** (A) Prevalence of Graves orbitopathy (GO) in patients with newly diagnosed Graves hyperthyroidism and during subsequent treatment with antithyroid drugs in those with initially absent GO (B) or mild GO (C). (Modified from Tanda ML, Piantanida E, Liparulo L, et al. Prevalence of natural history of Graves' orbitopathy in a large series of patients with newly diagnosed Graves' hyperthyroidism seen in a single center. *J Clin Endocrinol Metab.* 2013;98:1443–1449.)

eye changes. The swollen retrobulbar tissues will impair venous drainage of eyelids and conjunctiva, resulting in eyelid edema and chemosis. Eyelid swelling can also be caused by herniation of retrobulbar fat through openings in the orbital septum. Increased retrobulbar pressure will push the globe forward, resulting in exophthalmos. Upper eyelid retraction and proptosis contribute to overexposure of the cornea, which may become dry and inflamed. The enlargement of extraocular muscles impairs muscle relaxation, not the ability for muscle contraction. For instance, impairment of elevation is caused by insufficient relaxation of the rectus inferior muscle, which may cause diplopia when gazing up. Marked swelling of rectus muscles in the apex of the orbit (known as apical crowding), close to the entrance of the optic nerve in the optic canal, may compress the optic nerve, resulting in DON.

Immunopathogenesis

Microscopy reveals orbital lymphocytic infiltration, edema, and fibrosis. The lymphocytic infiltration is often focal and consists of T helper cells, cytotoxic T cells, many macrophages, and a few B cells. The infiltrating immunocompetent cells produce cytokines capable of remodeling orbital tissues. The cytokine profile in the early stages of GO is predominantly that of Th1 cells, whereas cytokines are mostly



• **Fig. 12.10** Role of the thyroid-stimulating hormone (TSH) receptor in the immunopathogenesis of Graves orbitopathy. Ligation of the TSH receptor on orbital fibroblasts with stimulating TSH receptor antibodies results in activation of the adenylyl/cyclic adenosine monophosphate (cAMP) pathway and the phosphoinositide 3-kinase (PI3K)/Akt signaling cascade. It induces hyaluronic acid production by the orbital fibroblasts, with a subset exhibiting enhanced adipogenesis. (From Iyer S, Bahn RS. Immunopathogenesis of Graves' ophthalmopathy: the role of the TSH receptor. *Best Pract Res Clin Endocrinol Metab.* 2012;26:281–289.)

derived from Th2 cells in patients with a duration of GO for more than 2 years.[188] The data suggest GO is primarily a T-cell–mediated disease. The cytokines induce expression of immunomodulatory proteins on endothelial cells and fibroblasts, including HLA-DR, heat shock protein 72, and several adhesion molecules. Cytokine-activated OF synthesize IL16 and RANTES (regulated on activation, normal T cell expressed and secreted, also known as CCL5) attracting more T cells to the orbit. Macrophages present antigen to T cells; activated T cells may bind to OF, inducing hyaluronan synthesis, cytokines, COX2, and PGE2. OF are considered the target (and effector) cells of the autoimmune attack in GO. Retrobulbar T cells of GO patients recognize autologous OF (but not eye muscle extract) and proliferate in response to proteins from autologous OF (but not from orbital myoblasts); conversely, OF proliferate in response to autologous T cells dependent on MHC class II and CD40/CD40L signaling.[189]

The TSH receptor is presently viewed as the major autoantigen in GO. OF express full-length functional TSH receptors; the expression is more abundant in active than in inactive GO and is directly related to IL1β levels.[190] Graves immunoglobulins as well as monoclonal TSHR-stimulating antibodies recognize TSHR on OF as evident from increased cAMP and hyaluronan production in cell cultures of OF exposed to these agents. OF not expressing THY1 (present in orbital fat but not in extraocular muscles) may under the influence of IL1 or PPARγ agonists differentiate into mature adipocytes, associated with increased TSHR expression. The role of TSHR is underscored by a direct relationship between TSHRAb and both activity and severity of GO.[191] Genetic immunization against the TSH receptor (but not against the IGF1 receptor) also gives rise to a fair although not perfect animal model of GO.[192,193]

The IGF1 receptor (IGF1R) has been proposed as another major autoantigen in GO. IGF1Rs are indeed overexpressed in OF of GO patients. Graves IgG can induce hyaluronan production in OF, effects that can be attenuated by IGF1R-blocking antibody.[194] Stimulating IGF1R autoantibodies (IGF1RAb) thus have been postulated and have been found in 10% of GO samples and in 10% of control samples; however, the IGF1RAb failed to stimulate IGF1R autophosphorylation but instead inhibited IGF1-induced signaling.[195] These data do not support the hypothesis that IGF1RAb contribute to GO pathogenesis. Immunoglobulins of GO patients stimulate Akt in OF as well as in cells expressing TSHR and IGF1R; knockdown of IGF1R causes a 65% decrease in IGF1-stimulated Akt but has no effect on GO-Ig stimulation of Akt.[196] GO immunoglobulins thus do not activate the IGF1R, and there is no evidence of stimulating IGF1R antibodies (Fig. 12.10).[197] The implication is that TSHRAb stimulate Akt via the PI3K pathway. The therapeutic effect of teprotumumab, an IGF1R-blocking monoclonal antibody, in GO thus could be explained at least in part by decreasing Akt, thereby also impairing the effects of TSHR signaling via the PI3K pathway.[198]

Whereas postreceptor signaling pathways of TSHR and IGF1R partly overlap, it has further been suggested that TSHR and IGF1R form a physical and functional complex in OF[199,200] and

that GO immunoglobulins exert their action via TSHR/IGF1R crosstalk rather than direct binding to IGF1R.[201] A subset of OF are CD34+, and they might be derived from circulating CD34+ fibrocytes, which unexpectedly express relatively high levels of TSH receptors.[202] The relevance of these findings is subject of active research.

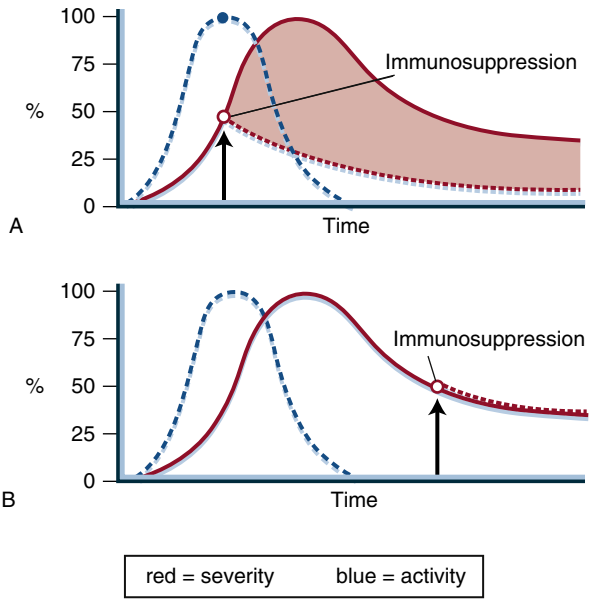
Genetics and Environment

No differences are found in the frequency of known susceptibility genes for Graves disease between patients with Graves hyperthyroidism and Graves orbitopathy. The genetic makeup in both phenotypes seems largely the same.[203] Smoking is a risk factor for GO, as in Graves hyperthyroidism, but the odds ratio is much higher (OR 4.40, CI 2.88–6.73).[101] The risk is dose dependent and decreases in ex-smokers. Exposure of OF in vitro to cigarette smoke extract dose-dependently increases hyaluronan production and adipogenesis.[204]

Exposure to ionizing radiation in the form of RAI therapy is associated with a relative risk for progression of GO of 4.23 (CI 2.04–8.77) when compared to ATD.[205] The immediate and substantial rise of TSHRAb after ^{131}I therapy might be causally connected to the worsening of GO.[80] Risk factors for developing GO in Graves hyperthyroidism were evaluated in a large longitudinal cohort study from Australia.[206] The odds of GO increased by 17% for each decade increase in the age of onset of Graves hyperthyroidism and by 7% for each year increase in the duration of Graves hyperthyroidism. Smoking increased the odds for GO to 2.22 for current smokers and 2.07 for ex-smokers compared with never smokers. The odds for GO were 86% less in patients using ATD than those not (OR 0.14, CI 0.06–0.34). Risk factors for the development of GO in Graves hyperthyroid patients treated for 18 months with ATD were current smoking, mild conjunctival redness or mild eyelid swelling, duration of hyperthyroid symptoms, and TBII.[186] These items, assessed before starting ATD, can be combined in a quantitative manner in a predictive score (called PREDIGO), which is better in predicting those patients who will not develop GO than who will. Another longitudinal study used a large database of a US managed care network.[207] Of Graves hyperthyroid patients, 8.8% developed GO; surgical thyroidectomy alone or in combination with medical therapy was associated with a 74% decreased hazard for GO (HR 0.26, CI 0.12–0.51) compared with RAI therapy alone.[207] Statin use also decreased the risk of GO (HR 0.60, CI 0.37–0.93), an unexpected and hard-to-understand finding.

Natural History and Prognosis

GO has a tendency to spontaneous improvement. Early studies from Rundle in the 1940s and 1950s about the natural history of GO describe the initial development of upper eyelid retraction, exophthalmos, and restricted eye muscle motility, followed by spontaneous but incomplete recovery.[208] Thus in about 60% of patients some eye changes persist. In GO patients who did not require immediate treatment, a 1-year follow-up revealed substantial improvement in 22%, slight improvement in 42%, no change in 22%, and worsening in 14%.[209] The available data suggest there is initially an active stage of the disease characterized by inflammatory edema and lymphocytic infiltration; immunosuppression given in this stage is likely to improve GO (Fig. 12.11).[210] The early active stage is followed by a late inactive



• **Fig. 12.11** Natural history of Graves orbitopathy, as reflected by a curve describing disease severity *(red continuous line)* and a curve describing disease activity *(blue discontinuous line)* over time. Intervention with immunosuppressive agents at peak activity is likely to result in modification of the natural course (gain reflected by the *red stippled area*) (A), whereas late intervention when the disease has become inactive, is unlikely to modify the natural course (B). (Modified from Wiersinga WM. Advances in medical therapy of thyroid-associated ophthalmopathy. *Orbit.* 1996;15:177–186.)

stage of the disease characterized by fibrosis, with immunosuppression less likely to be effective. The time interval between onset of GO and reaching the late inactive stage of the disease varies considerably between patients, from several months to several years. Assessment of GO activity may thus influence the treatment plan. The prognosis of GO has improved substantially in the last few decades, thanks to earlier diagnosis and treatment, more attention to risk factors, and better organization of care. Nowadays it is the rare patient who becomes blind as a result of GO. But the sequelae of GO are substantial: 45% of patients are restricted in their daily activities, 36% are on sick leave, 28% are disabled, 5% went into early retirement, and 3% lost their jobs, all because of GO.[211]

Diagnosis and Differential Diagnosis

Diagnosis of GO can be very easy in the case of a bilateral symmetric ophthalmopathy in a patient with Graves hyperthyroidism. Diagnosis can be difficult in euthyroid or hypothyroid patients presenting with eye changes; in euthyroid or hypothyroid GO patients, GO is milder and more often asymmetric.[180] Unilateral GO occurs in about 10% of all GO patients, whereas GO is the most prevalent cause of unilateral exophthalmos. Schematically, GO is diagnosed along three avenues: ocular symptoms and signs, thyroid autoimmunity, and orbital imaging.

Ocular Symptoms and Signs

It should be realized that none of the symptoms and signs is specific for GO. Guidelines recommend to assess severity and activity of the disease in every patient.[134,212] GO severity is assessed using

TABLE 12.8 Clinical Assessment of the Patient With Graves Orbitopathy

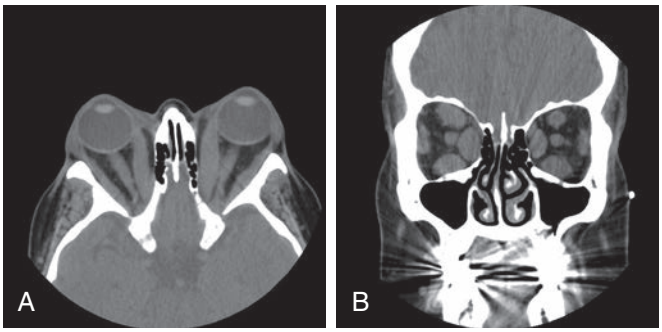
SEVERITY MEASURES (USING THE MNEMONIC NO SPECS)		
NO SPECS Class	**Item**	**Method**
0. **N**o signs or symptoms		
1. **O**nly signs, no symptoms	Lid aperture	With ruler in midline in mm
2. **S**oft tissue involvement	Eyelid and conjunctiva swelling and redness	Inspection, color pictures[a]
3. **P**roptosis	Exophthalmos	Hertel in mm
4. **E**xtraocular muscle involvement	Eye muscle motility Diplopia	Impaired elevation, abduction Subjective grading[b]
5. **C**orneal involvement	Keratitis, ulcer	Fluoresceine
6. **S**ight loss due to optic nerve involvement	Dysthyroid optic neuropathy (DON)	Visual acuity, color vision, visual fields, optic disc

ACTIVITY MEASURES (USING THE CLINICAL ACTIVITY SCORE [CAS])		
Inflammatory Sign	**Item**	**Score**
Pain	Spontaneous retrobulbar pain	1
	Pain on up gaze, side gaze, or down gaze	1
Redness	Redness of the eyelids	1
	Redness of the conjunctiva	1
Swelling	Swelling of the eyelids	1
	Swelling of the caruncle and/or plica	1
	Chemosis	1
Maximum CAS score (assessed momently)		*7*
Impaired function	Increase in proptosis ≥2 mm in 1–3 months	1
	Decrease of ≥8° in eye muscle motility in any direction in 1–3 months	1
	Decrease in visual acuity of more than one line on the Snellen chart (using pinhole) in 1–3 months	1
Maximum CAS score (assessed over time)		*10*

[a]Color atlas in Dickinson AJ, Perros P. Controversies in the clinical evaluation of active thyroid-associated orbitopathy: use of a detailed protocol with comparative photographs for objective assessment. *Clin Endocrinol (Oxf)*. 2001;55:283–303.

[b]Intermittent diplopia = at awakening or when tired; inconstant diplopia = at extremes of gaze; constant diplopia = in primary or reading position.

the mnemonic NOSPECS (Table 12.8). Three degrees of severity are distinguished: mild GO (characterized by lid retraction <2 mm, mild soft tissue involvement, proptosis <3 mm above upper normal limit, absent or intermittent diplopia, absent corneal exposure, and normal optic nerve status), moderate-to-severe GO (lid retraction ≥2 mm, moderate to severe soft tissue involvement, proptosis ≥3 mm above upper normal limit, inconstant or constant diplopia, mild punctuate keratopathy, and normal optic nerve status), and very severe sight-threatening GO (corneal breakdown, or DON). Upper normal limits of proptosis are 23/24 mm in African Americans, 19/21 mm in whites, and 16/17 mm in Asians (female/male values, respectively). Disease activity is best assessed by the clinical activity score (CAS), based on the classic signs of inflammation (see Table 12.8).[213] GO is likely to be inactive at CAS values below 3 and active at CAS values of 3 or greater.



• **Fig. 12.12** Axial (A) and coronal (B) CT scans of a patient with Graves orbitopathy demonstrating generalized enlargement of all extraocular muscles, expansion of the orbital fat, and marked bilateral proptosis.

Thyroid Autoimmunity

Besides assay of TSH and FT_4 to determine thyroid function, assay of TPOAb and TSHRAb are useful to assess whether thyroid autoimmunity is present. This is especially relevant in euthyroid and hypothyroid cases. Knowledge of the level of TSHRAb would anyway be useful in view of their direct relationship with disease activity and severity and their prognostic value for the course of GO.[214]

Orbital Imaging

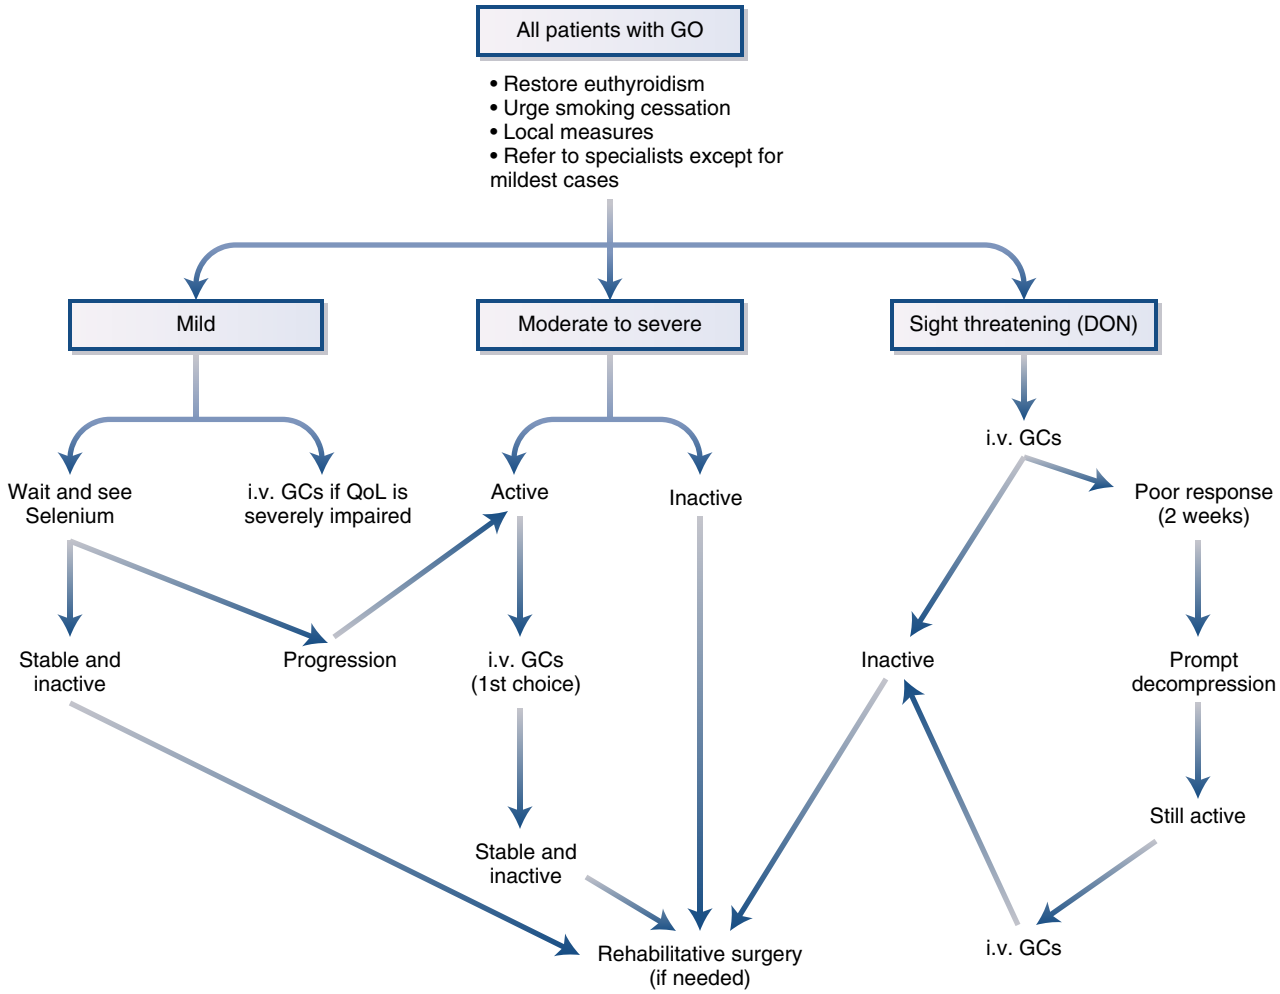
Orbital imaging is not always necessary. It is indicated in patients with suspected DON (to look for apical crowding of enlarged muscles), in euthyroid or hypothyroid GO, and in unilateral GO to exclude alternative diagnoses. Orbital imaging is performed by CT or magnetic resonance imaging (MRI). Orbital CT scanning is indicated before surgical orbital decompression to have a close look at the bony orbit (Fig. 12.12). GO activity might be assessed by MRI provided sophisticated programs are installed measuring T2-weighted relaxation time and/or short tau inversion recovery sequence. The most frequent diseases mimicking GO are orbital myositis, caroticocavernous fistula, non-Hodgkin lymphoma, orbital meningioma, and IgG4-related orbital disease.[215]

Treatment

Specific guidelines for the management of Graves orbitopathy are available.[212] Recommendations are divided into three groups, dealing with general measures, thyroid treatment, and eye treatment.

General Measures

It is recommended that GO patients—except the mildest cases—should be referred to combined thyroid-eye clinics or specialized centers providing endocrinologic and ophthalmologic expertise. A multidisciplinary approach is likely to improve outcomes.[216] A patient-focused approach to the treatment is also advocated, which encompasses the effects of the disease and its treatment on quality of life (QoL) and psychosocial well-being. Use of the GO-QoL, a



• **Fig. 12.13** Algorithm for the management of patients with Graves orbitopathy. (Redrawn from Bartalena L, Baldeschi L, Boboridis K, et al. The 2016 European Thyroid Association/European Group on Graves Orbitopathy guidelines for the management of Graves' orbitopathy. *Eur Thyroid J.* 2016;5:9–26.)

disease-specific QoL questionnaire and well-validated tool, is recommended in routine clinical practice and is available in several languages (www.eugogo.eu).[212,217] It consists of eight questions about visual functioning and eight questions about appearance. It may serve as the primary outcome measure in clinical trials. Treatment should not only *work* from the physician's perspective but also *help* from the patient's perspective. It can also be useful in daily clinical practice to facilitate discussion with the patient on the most disturbing features and to identify patients in need of further counseling. Counseling may reduce anxiety, provide reassurance, and help in developing better coping strategies.

Smokers should be urged to refrain from smoking, and specialized smoking cessation programs or clinics should be offered. The success rate of quitting smoking is rather low, but success rate could be somewhat higher in GO because many patients are very much concerned about their appearance. Patients should be confronted with the evidence that (a) smokers have more severe GO, (b) smokers are more likely to have progression of GO after ^{131}I therapy, and (c) smoking delays or worsens the outcome of immunosuppressive treatment.

Simple measures that may be helpful in any stage of the disease are (1) artificial tears to reduce surface symptoms and protect the epithelium, (2) sunglasses to reduce photophobia but also to comfort patients who are self-conscious of their appearance, (3) lubricant ointments to protect from exposure keratopathy during sleep, (4) prisms to improve diplopia, and (5) botulinum toxin A injections to possibly provide temporary control of eyelid retraction.

Thyroid Treatment

Euthyroidism should be promptly restored and maintained. Antithyroid drugs or thyroidectomy is preferred as neither modifies the natural history of GO, whereas ample evidence indicates ^{131}I therapy carries a risk of developing or worsening of GO. The risk can be reduced by concomitant oral prednisone in a daily dose of 0.3 to 0.5 mg/kg for 3 months. This steroid prophylaxis should be considered in high-risk patients (i.e., in smokers, in active GO, and when TSHRAb are high). Lower doses (0.2 mg/kg prednisone for 6 weeks) can be used in low-risk patients. Patients with inactive GO can safely receive RAI without steroid cover as long as post-radioiodine hypothyroidism is avoided.[218,219] Some experts prefer very long-term ATD treatment until GO has become inactive and no further treatment of GO is required; if a relapse of Graves hyperthyroidism occurs after discontinuation of ATD, it can be safely managed with RAI without flare-up of GO.[218]

Eye Treatment

Management depends on severity and activity of GO (Fig. 12.13).[212] *Mild GO* is best managed by a wait-and-see policy or selenium. Spontaneous improvement is to be expected in about

one-third of cases. Intervention with a 6-month course of selenium (100 µg sodium selenite twice daily) improves QoL and eye manifestations (in 61% vs 36% in placebo) and prevents progression to more severe GO (which occurred in 7% vs 26% in the placebo group).[220] These results were obtained in European countries in which selenium intake is relatively low. It is not known if selenium supplementation is also effective in areas with sufficient selenium intake. Steroids could be considered if the QoL is severely impaired.

Active moderate-to-severe GO qualifies for immunosuppression. Steroids are considered as first-line treatment; they are rather effective in reducing swelling and redness of eyelids and conjunctiva and in improving diplopia, less so in reducing exophthalmos. Intravenous methylprednisolone pulses (IVMP) rather than oral prednisone are recommended because IVMP have greater efficacy than oral prednisone (74% vs 51%) and fewer side effects (56% vs 81%).[212] A dose-finding study indicated a cumulative dose of 4.5 g IVMP is appropriate for most patients, administered as 500 mg IV once weekly for 6 weeks followed by 250 mg IV once weekly for another 6 weeks.[221] Higher doses (750 mg once weekly for 6 weeks followed by 500 mg once weekly for another 6 weeks for a cumulative dose of 7.5 g) are slightly more effective at the expense of more side effects and should be reserved for worst cases. IVMP have been associated with significant cardiovascular or cerebrovascular morbidity and hepatic toxicity if administered in high single doses of 1000 mg or more, in cumulative doses of more than 8 g, and/or as repeat infusions on consecutive days. It is therefore recommended that cumulative doses of IVMP should not exceed 8 g and that IVMP should not be given in patients with recent viral hepatitis, significant hepatic dysfunction, and severe cardiovascular morbidity or psychiatric disorders.[212] Severe hypertension, inadequately managed diabetes, and glaucoma are other contraindications. IVMP therapy should be monitored by regular measurements of blood pressure, blood glucose, and liver function tests. Efficacy of IVMP can be slightly enhanced by coadministration of mycophenolate (one 360-mg tablet twice daily for 24 weeks).[222]

Patients who do not or partially respond to IVMP and patients in whom GO flares up after discontinuation of IVMP may require a second-line therapy. Shared decision making is recommended to select one of the available treatment options: low-dose oral prednisone + either cyclosporine or retrobulbar irradiation (usually 20 Gy fractionated in 10 daily doses of 2 Gy over a 2-week period), repeat IVMP, or rituximab (RTX; 1 g twice at a 2-week interval). RTX is an anti-CD20 monoclonal antibody that effectively causes B-cell depletion. Open studies report a remarkable improvement in CAS and GO severity.[223] Side effects occur in about 30%; notable is the risk of the cytokine-release syndrome with the development of DON. RTX has been tested in two randomized clinical trials. One compared RTX with placebo: CAS decreased similarly in both treatment arms, and RTX was not better than placebo.[224] The other compared RTX with IVMP (cumulative dose 7.5 g). The decrease in CAS was greater in the RTX group than in the placebo group, and RTX was judged to be slightly better than IVMP.[225] Sample size in both trials was very modest, and some differences in patient characteristics and trial execution have been noted.[226] Nevertheless, it remains difficult to reconcile the difference in outcomes. It seems too early to accept RTX as an alternative for IVMP but also too early to dismiss RTX as a disease-modifying drug. The same holds true for tocilizumab, a monoclonal antibody directed against the IL6 receptor. It had good efficacy in GO patients refractory to IVMP in an open study, but the drug has not been tested in a RCT.[227] Teprotumumab is a monoclonal antibody inhibitor of IGF1 receptors. In a placebo-controlled RCT it had great efficacy in reducing CAS, reducing exophthalmos, and improving diplopia and GO-QoL scores.[228] Its potential to reduce exophthalmos is remarkable, and in this respect the drug could be superior to IVMP. However, to displace IVMP as first-line treatment, teprotumumab should be compared to IVMP in a RCT.

Very severe GO, DON requires urgent intervention. It is recommended to start with IVMP: 1 g IV on 3 consecutive days in the first week, followed by 1 g IV on 3 consecutive days in the second week. If visual functions improve by the end of the second week, continue with oral prednisone; if not, then urgent surgical decompression is indicated.[229]

Inactive GO indicates rehabilitative surgery can be done when GO has reached this state. If surgery is performed while the disease is still active, results might be lost because of ongoing disease. Most orbital surgeons require stable eye disease for 6 months before surgery. Rehabilitative surgery includes orbital decompression, eye muscle surgery, and eyelid surgery and should be carried out in this sequence if several procedures are needed.

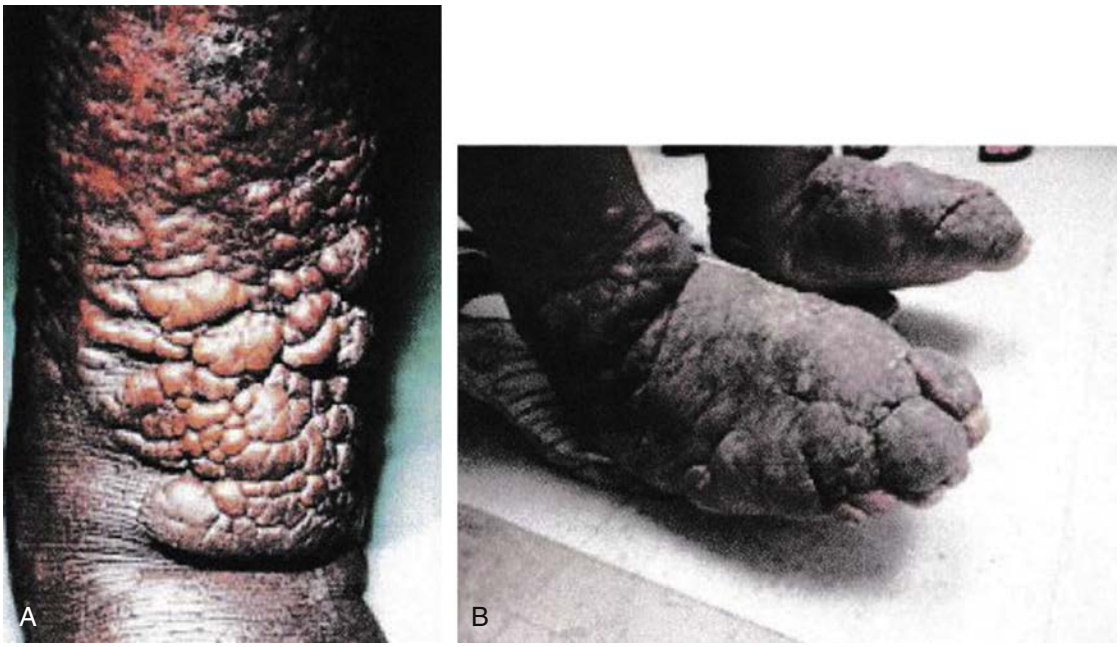
Graves Dermopathy

Graves dermopathy is also known as pretibial myxedema or local myxedema. It is a rather rare phenotype of Graves disease occurring almost always in the presence of Graves orbitopathy and associated with very high levels of TSHRAb. Thus the typical patient with Graves dermopathy has also Graves orbitopathy and Graves hyperthyroidism (sometimes also thyroid acropachy), constituting the most severe expression of Graves disease. The skin lesion consists usually of nonpitting edema with violet discoloration, induration, and prominent hair follicles, giving the appearance and texture of an orange peel *(peau d'orange)*.[230] Other forms are plaques, nodules, and elephantiasis (Fig. 12.14). Its predilection site is the pretibial area (hence the name *pretibial myxedema*), but it has been observed at other sites also exposed to local mechanical pressure.[231] Local trauma may provoke Graves dermopathy as well. Its pathogenesis looks similar to that of Graves orbitopathy, which likewise develops in a confined space with increased local pressure. Dermal fibroblasts seem the target of the autoimmune attack. There is an upregulated expression of TSH receptors on dermal fibroblasts, which also produce cytokine-induced glycosaminoglycans. Treatment is not always required. Spontaneous regression occurs in the long term. If treatment is necessary because of functional or cosmetic complaints, nighttime occlusive dressings with 0.05% to 0.1% triamcinolone acetonide in a cream base might be helpful as well as compressive bandages or stockings. Treatment of GO with glucocorticoids or biologics may also cause regression of Graves dermopathy.

Pregnancy and the Thyroid

Human Chorionic Gonadotropin

hCG is a glycoprotein heterodimer composed of an α-subunit that is common to all glycoprotein hormones (TSH, LH, and FSH) and a specific β-subunit that allows for biologic specificity. Despite this separate structure hCG can bind to and stimulate the hTSHR,[232–234] with an in vitro potency of about 1 U hCG = 0.7 µU of human TSH, depending on its carbohydrate content. In high concentrations as found in hyperemesis gravidarum, multiple gestation, or molar pregnancy hCG will cause hyperthyroidism characterized by a diffuse goiter, elevated free T_4, and a suppressed TSH.



• **Fig. 12.14** (A) Chronic pretibial myxedema in a patient with Graves disease and orbitopathy. The lesions are firm and nonpitting, with a clear edge to feel. (B) Here the chronic myxedema has continued to spread to the foot, causing severe disfiguration and immobility. (A, Courtesy Dr. Andrew Werner, Mount Sinai School of Medicine, New York, NY.)

Transient Gestational Thyrotoxicosis

In the late first trimester of normal pregnancy in humans there is often a physiologic mild transient gestational thyrotoxicosis or hyperthyroidism.[235,236] An exaggeration of this physiologic increase in thyroid stimulation in the first trimester may also be seen in some women and is associated with high levels of hCG (100,000–200,000 U/L), such as those found in twin pregnancies, and is often accompanied by hyperemesis.[237–239] In most patients, the condition is self-limited and the risk of birth defects warrants against the use of antithyroid drugs in early pregnancy. It may be difficult to separate this syndrome from early Graves disease, and a TSHRAb test may be helpful.[240]

Abnormal Responses to Human Chorionic Gonadotropin

A few patients have been reported with an inherited variant of gestational thyrotoxicosis in which a mutation in the *TSHR* gene resulted in a receptor protein with an increase in its responsiveness to hCG.[241] Such patients develop hyperthyroidism with each pregnancy due to even physiologic serum hCG concentrations. Similarly, the use of gonadotropins in in vitro fertilization and indirectly the use of GnRH agonists have been associated with cases of thyroid dysfunction.[242]

Graves Disease During Pregnancy and the Postpartum Period

Although seen more regularly in clinical practice, a truly overactive thyroid gland is uncommon in established pregnancy, affecting approximately 0.2% of women. This low rate is because pregnancy tends to suppress autoimmune responses during pregnancy, and Graves disease, an autoimmune disorder, is the most common cause of thyrotoxicosis in young women. Furthermore, although thyrotoxicosis has a variety of negative influences on fertility itself, it is also associated with increased pregnancy loss and serious medical complications for both the mother and the infant if it should persist.[47,48,243–245] More commonly, a woman under treatment for hyperthyroidism becomes pregnant. Whatever the sequence, pregnancy complicates the diagnosis and treatment of hyperthyroidism in Graves disease and influences its severity and course.

Influence of Pregnancy on the Immune System

The development of pregnancy and the growth of the placenta have profound influences on the immune system, as discussed earlier. The overall suppression of autoimmune responses, which occurs in pregnancy and is mediated by a variety of placental factors, is designed to allow the fetus with its 50% paternal antigens to survive immune assault.[246,247] These changes promote maternal-fetal tolerance, but the increased role of the regulatory T cells and their suppression of maternal responses to the fetus appears to be predominant and long lived.[248,249] It has been shown that a major shift in such T-cell control reduces the effectiveness of all inflammatory T cells.

Thyroid Antibodies in Pregnant Patients With Graves Disease

The hallmark of the immune effects initiated by the placenta is the fall in thyroid autoantibody secretion—TPOAb, TgAb, and TSHRAbs—that is seen in almost all patients as pregnancy progresses.[250,251] This is now considered secondary to enhanced regulatory T-cell activity[252] and precedes a rapid increase in autoantibody levels after the immunosuppression is lost in the postpartum period. Assays for TSHRAbs in the serum of pregnant women with Graves disease may be of clinical value in selected cases because a failure of this immunosuppression may indicate potential fetal problems.[55,253] Because maternal antibodies cross the placenta, there is a correlation between the maternal level of stimulatory TSHRAbs and the development

of fetal thyrotoxicosis. Fortunately fetal and neonatal thyrotoxicosis occurs in only 1% of infants of mothers with Graves disease, and high levels of TSHRAbs, usually greater than three times the upper normal limit, are correlated with fetal thyroid stimulation.[254,255] Pregnant women at risk for failure to suppress thyroid autoantibodies include those with more severe hyperthyroidism and those with significant GO or infiltrative dermopathy. In addition, the prior treatment of the mother, especially with radioiodine, may not always be accompanied by a sufficient reduction in TRAbs. Thus the fetus of a treated patient with Graves disease may still be at risk for development of fetal or neonatal thyrotoxicosis, and the mother may need antithyroid drug treatment and the fetus monitored by umbilic cord blood testing and ultrasonography.[256]

Differential Diagnosis

When mild thyrotoxicosis is present during early pregnancy, it may be due to gestational thyrotoxicosis secondary to hCG stimulation of the thyroid gland (see later).[257,258] When it is more severe it is usually due to Graves disease because toxic multinodular goiters and hot nodules are uncommon in this age group.

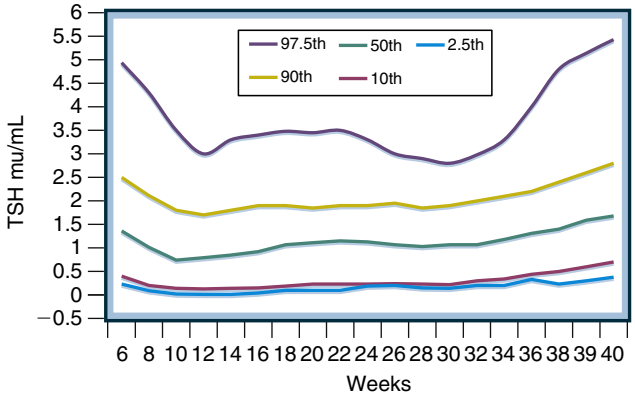
Diagnosis

Pregnancy and hyperthyroidism are both accompanied by thyroid stimulation, a hyperdynamic circulation, and hypermetabolism. In pregnancy, serum TBG levels are increased by estrogen-induced changes in glycosylation, which increases TBG production and lengthens its half-life, and thus in both conditions the total serum T_4 and T_3 levels are elevated so that the upper limit of the normal range during second and third trimesters of gestation is about 1.5 times the upper nonpregnant reference limit.[254] However, serum free T_4 levels, as measured by both analog and equilibrium dialysis methodologies, may actually decrease as pregnancy progresses and the normal third trimester reference range for a given assay is significantly less than its nonpregnant reference range.[236] Serum TSH levels also tend to decrease in early pregnancy and up to 15% of women can have TSH levels below the normal limit.[235] The 95th percentile confidence interval lower limits for serum TSH levels are 0.06 mU/L, 0.3 mU/L, and 0.3 mU/L, respectively, for the first, second, and third trimesters. Nevertheless, each laboratory needs to establish its own normal ranges for thyroid testing in pregnancy.[259,260]

Biochemically, the diagnosis of thyrotoxicosis is confirmed when the serum TSH level is below the trimester-specific lower limit and the total or free T_4 levels are above the normative range for pregnancy (Fig. 12.15). Detection of TSHRAbs can confirm the diagnosis of Graves disease, which may or may not be obvious from the clinical history and examination.

Treatment During Pregnancy

Hyperthyroidism in pregnancy is associated with a variety of complications for mother and child (Table 12.9). Although mild hyperthyroidism in pregnancy does not lead to a significant increase in risk for mother or fetus, severe thyrotoxicosis can lead to many complications and endanger the life of the mother and fetus. Furthermore, the management of hyperthyroidism during pregnancy can be an even greater problem than its diagnosis. Graves disease can worsen in the first trimester, but the subsequent trimesters have an attenuating influence on the hyperthyroid state because of the immunosuppression associated with pregnancy. Pregnancy is also one of the few clinical situations in which an assay of the biologic activity of the TSHRAbs is helpful in predicting its potential effect on the newborn. This assay is especially useful in pregnant women who previously received ablative therapy for Graves hyperthyroidism and who still have high levels of TSHRAb.



• **Fig. 12.15** Gestation age-specific thyroid-stimulating hormone nomogram derived from 13,599 singleton and 132 twin pregnancies. Different percentiles are shown by *colored lines*. TABLE 12.9 Complications of Hyperthyroidism in Pregnancy

Increased and recurrent pregnancy loss
Preterm delivery
Preeclampsia
Fetal growth restriction
Fetal thyroid hyperfunction or hypofunction caused by TRAb
Fetal goiter from excessive antithyroid drug treatment
Neonatal thyrotoxicosis
Increased perinatal and maternal mortality risk
Potential for decreased IQ of offspring because of excessive use of antithyroid drugs

IQ, Intelligence quotient; *TRAb*, thyrotropin receptor antibodies.

Antithyroid Drugs in Pregnancy

Medical therapy is the usual method of choice in pregnancy. Because of the usual improvement in the disease, the dosage of antithyroid drug required to control the disease in the later phases of pregnancy is generally much less than that required in the same patient were she not pregnant. Overtreatment of the hyperthyroid pregnant woman remains a common but avoidable clinical problem with potentially severe consequences for the fetus. Thus the clinician should prefer mild undertreatment to the risk of hypothyroidism.[256,261–263] Therefore it is imperative for the clinician to understand the therapeutic targets for titrating antithyroid drug dosages during pregnancy.[264]

Certain aspects of placental physiology are relevant to the use of antithyroid drugs. PTU and methimazole readily and rapidly cross the placenta equally well and are concentrated in the fetal thyroid. In excess quantity these agents can cause goitrous hypothyroidism in the fetus.[265] Maternal T_4 crosses the placenta (as evidenced by infants born with significant circulating serum T_4 concentrations despite congenital hypothyroidism) and is the major source of fetal thyroid hormone prior to the complete functional development of

• **Fig. 12.16** Examples of methimazole embryopathy. (A) Dysmorphic astigmatism. (B) Aplasia cutis. (From Bowman P, Osborne NJ, Sturley R, et al. Carbimazole embryopathy: implications for the choice of antithyroid drugs in pregnancy. *QJM*. 2012;105:189–193.)

the hypothalamic-pituitary axis in the fetus at around 20 weeks of gestation. Furthermore, the transplacental passage of maternal TSHRAbs in the latter half of pregnancy can result in fetal thyroid stimulation. Therefore the fetal thyroid is subject to the same factors that influence maternal thyroid hormone production.

Previously, the antithyroid drug of choice throughout pregnancy in the United States was PTU, but because of the rare yet serious side effect of PTU-induced hepatic failure, in June 2009 the FDA issued an advisory that PTU should be reserved for the first trimester of pregnancy while organogenesis is occurring[144] (see later). Subsequently, methimazole could be prescribed. One must keep in mind that the therapeutic antithyroid potency ratio of methimazole to PTU is around 20:1. Thus a patient who requires only 50 mg of PTU in the first trimester may be given 2.5 mg methimazole, and she may not even require a thionamide during the latter part of pregnancy. Of course, the best practice is to ensure definitive treatment prior to pregnancy so that antithyroid drugs are not needed at all.

Danger of Antithyroid Drugs in Pregnancy

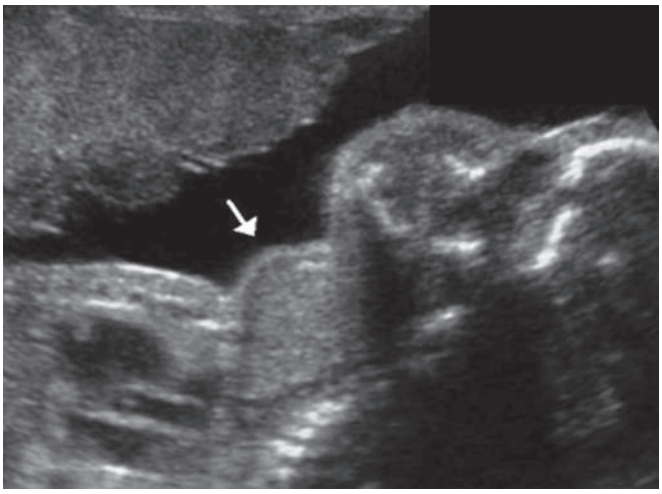
The first report of birth defects after maternal use of antithyroid drugs was a brief letter reporting on congenital scalp skin defects after the use of methimazole.[266,267] Subsequently, several case reports confirmed the association, and other types of defects were described as well.[268] Such defects included a specific combination of facial features, and the condition was termed *methimazole/carbimazole embryopathy*. Because PTU was not at first associated with such birth defects, guidelines have been proposed that recommend the use of PTU in the first trimester and to consider shifting from methimazole to PTU in women planning a pregnancy.[269,270] Recent larger studies have since expanded our knowledge on methimazole-associated birth defects.[271,272] Apart from aplasia cutis, defects are seen in the abdominal wall (gastroschisis, omphalocele), gut (esophageal atresia), upper airways (choanal atresia), urinary system, heart (ventricular septum defect), and eye (Fig. 12.16). Around 1 in 30 women exposed to methimazole or carbimazole in early pregnancy will give birth to children with defects associated with this therapy. This is in addition to the 5% general population risk of giving birth to a child who has a birth defect diagnosed before the age of 2 years.[273] However, PTU also is teratogenic,[274,275] and the use of PTU is also associated with birth defects (estimated to be around 1 in 40 exposed).[272] These abnormalities tend to be milder than with methimazole-associated defects and include preauricular sinuses and cysts and urinary abnormalities.[276]

The period of risk when these drugs may be teratogenic is especially weeks 6 to 10 of pregnancy.[277] Accordingly, to reduce the risk of birth defects, withdrawal of antithyroid medication in patients who are considered in remission of Graves disease or an unavoidable shift from methimazole to PTU has to take place very early in pregnancy. Additionally, the lowest possible dose of an antithyroid drug must be used.[278] The risk of birth defects has to be balanced against the risk of abnormal maternal thyroid function in early pregnancy. It is therefore wise to recommend to young women who receive antithyroid drugs for Graves disease that they test for pregnancy just a few days after a missing menstruation and immediately contact their physician to plan future therapy or withdrawal of medication. No firm international consensus has yet been reached on how to minimize the risk of birth defects from antithyroid drug use in early pregnancy.

Caring for the Pregnant Patient

The therapeutic target for a pregnant Graves patient is a healthy infant. In the second half of pregnancy both the untreated pregnant woman with hyperthyroidism caused by Graves disease and her fetus will be thyrotoxic because TSHRAb passes the placenta and stimulates the fetal thyroid. Antithyroid drugs given to the mother also pass through the placenta and thus treat both the maternal and the fetal hyperthyroidism. However, the drugs may overtreat the fetus compared with the mother, and accordingly the aim of therapy is to keep the mother in a state of subclinical hyperthyroidism analogous to the normal gestational physiology of the first trimester.[264] This is associated with the lowest impact on fetal thyroid function and the highest rate of normal neonatal thyroid hormone levels.[279] The maternal serum free T_4 level should be maintained at or just above the upper normal *nonpregnant* range, and no attempt should be made to normalize the serum TSH concentration. Indeed, a normal TSH during drug therapy is an indication that the dose of drug should be reduced.[280] The clinical status of the patient is an important indication for treatment or increases in dosage. A modest tachycardia is a physiologic response to the increased metabolic demands of pregnancy, and pulse rates of 90 to 100 beats/minute are well tolerated without evidence of myocardial decompensation during delivery. The natural amelioration of Graves disease in the third trimester should be kept in mind, and repeated attempts should be made to reduce or discontinue the thionamide as the delivery date approaches to avoid TSH-induced fetal/newborn goiter, which may cause asphyxia (Fig. 12.17). The serum TSH concentration should be monitored monthly—more to avoid inadvertent overtreatment rather than as the target for normalization. Because thionamides, but not thyroid hormone given to the mother, pass the placenta rather freely, a block-and-replace strategy may induce severe fetal hypothyroidism and goiter, and it is in general not appropriate in the pregnant patient. The rare exception is a pregnant woman who was previously given ablative therapy for Graves disease but who still produces TSHRAb that leads to isolated fetal hyperthyroidism.

All pregnant patients with significant Graves disease should be managed in close cooperation with obstetricians experienced with modern techniques for monitoring the fetus for intrauterine



• **Fig. 12.17** Sagittal view of a fetus at 23.9 weeks showing a large goiter *(arrow)* preventing neck flexion. (From Mayor-Lynn KA, Rohrs JH III, Cruz AC, et al. Antenatal diagnosis and treatment of a dyshormonogenetic fetal goiter. *J Ultrasound Med*. 2009;28:67–71.)

thyroid dysfunction. These techniques normally include fetal heart rate monitoring and ultrasonographic assessment of fetal growth rate. With advanced ultrasonography it is usually possible to examine the fetus for the presence of goiter. Fetal goiter can develop both from the stimulatory effect of maternal TSHRAb passing through the placenta and secondary to antithyroid drugs given to the mother. Occasionally, cordocentesis with fetal thyroid function testing may be appropriate. The amount of fetal monitoring necessary can be judged based on the degree of hyperthyroidism present, which is indicative of the potency of TRAb present and also by the increase in circulating TRAb levels in mothers previously treated for Graves. A recent systematic review demonstrated that values of TRAb of over 3.7 times the upper limit of normal could be associated with fetal thyrotoxicosis.[281] This is consistent with the American Thyroid Association guidelines where fetal monitoring is recommended in mothers who have TSHRAb levels greater than three times the upper limit of normal at any time during pregnancy.[235]

Iodide and Beta Blockers

Obviously therapeutic radioiodine is contraindicated in pregnancy, although no harm has been found after diagnostic doses of ^{123}I.[282] Iodide itself should also not be used as therapy for more than 2 to 3 weeks in the pregnant woman because it readily crosses the placenta and can induce a large goiter that may cause airway obstruction in the newborn. Large amounts of iodide are contraindicated in the last month of pregnancy but can be used at earlier times in emergent situations. Whether propranolol or other beta blockers should be used in the pregnant woman with hyperthyroidism has been a matter of debate. In the experience of some, it can cause intrauterine growth retardation, delayed lung development, and neonatal hypoglycemia or depression,[283] but large studies have suggested that it can be used with safety for short periods or at very low doses.[284,285]

Surgery

Surgery during the first and third trimesters is not desirable because of the possible induction of early pregnancy loss and later premature labor, respectively. Surgery may be successful during the second trimester, but it is best to avoid major surgery during pregnancy if possible. Nevertheless, if antithyroid drug requirements are very high or cannot be used, surgery may be indicated. Iodide can be given for 7 to 10 days to aid in patient preparation with large and highly vascular thyroid glands. Importantly, thyroid surgery may cure the hyperthyroidism of the mother, but TRAb will not disappear immediately. Thus the fetal thyroid may still be stimulated, and withdrawal of antithyroid drugs from the pregnant woman may lead to isolated fetal hyperthyroidism, especially in mothers with high levels of TSHRAb.[286]

Consequences of Overtreatment

The influence of maternal hypothyroidism on fetal brain development and the subsequently reduced IQ of the children of hypothyroid mothers are discussed in Chapter 13. Needless to say, the overuse of antithyroid drugs in pregnancy may lead to the same consequences. There is considerable evidence that many pregnant patients with Graves disease were overtreated in the past as far as the fetus is concerned, as evidenced by transiently elevated serum TSH levels on newborn screening tests.[287] This is another reason why one should accept patients being slightly hyperthyroid rather than slightly hypothyroid.

Graves Disease in the Postpartum Period

Changes in the Immune Response in the Postpartum Period

As discussed earlier, pregnancy induces a variety of immune changes that are responses to placental influences and the paternal foreign antigens and that are designed to prevent rejection of the foreign fetus. These changes include enhanced regulatory T-cell influences and a T-cell shift from Th1 to Th2, resulting in an overall decrease in all autoimmune responses as evidenced by marked decreases in thyroid autoantibodies.[251] Following delivery, these immune changes are slowly lost and a return to normal is observed but only after a period of exacerbated autoimmune reactivity in which large increases in T-cell and autoantibody activity occur. It is at this time—4 to 12 months postpartum—that new-onset or recurrent thyrotoxicosis is seen. Such thyroid dysfunction may be transient or permanent.

Transient Postpartum Thyroiditis

Transient postpartum thyroiditis remains the most common form of hyperthyroidism in the postpartum period and usually precedes a period of hypothyroidism.[288] The transient thyrotoxicosis is due to thyroid cell destruction and may occur in approximately 5% to 10% of patients during the 4 to 12 months postpartum.[289] This can be double in those with other autoimmune diseases. However, the rapid return of true Graves hyperthyroidism is less common but is similarly dependent on the subsequent changes in the immune response.

Presentation of Postpartum Graves Disease

A high percentage of women with Graves disease age 20 to 35 years give a history of pregnancy in the 12 months before the onset of Graves disease.[290,291] Pregnancy and the postpartum state also apparently influence the course of preexisting Graves disease. Patients in clinical remission during pregnancy are prone to postpartum relapse. In 41 pregnancies in 35 patients in remission, 78% were followed by development of thyrotoxicosis during the postpartum period. The patients with Graves disease and postpartum thyrotoxicosis were classified into three categories: (1) Some had persistent recurrent hyperthyroidism with an elevated RAIU (classic Graves disease). (2) Some had a transient disorder associated with a normal or an elevated RAIU (transient Graves

disease). (3) Some patients, especially those with the highest titers of TPOAb, experienced transient thyrotoxicosis with a decreased RAIU (the thyrotoxic phase of postpartum thyroiditis referred to earlier). This phase in turn may be followed by a hypothyroid phase.[292]

Preconception Counseling

A special problem related to hyperthyroidism and pregnancy is presented by the patient who wishes to conceive in the near future and is either in early remission after a course of antithyroid drug treatment or is being treated with antithyroid agents for active Graves disease.[293] For the first scenario, antithyroid drugs can be reluctantly reintroduced if required during pregnancy if symptomatic thyrotoxicosis recurs. In the second situation, definitive therapy (radioiodine therapy or surgery) should be considered to forestall the complexities of managing hyperthyroidism during pregnancy. As with the therapy of Graves disease in general, such decisions must involve education of the patient so that the risks and benefits of the various alternatives are clearly appreciated. Fertile women who receive antithyroid drugs should be educated to perform pregnancy testing already within the first days after a missed menstrual period if pregnancy is possible, and if the test is positive they should immediately contact the physician for further planning of therapy. The 1-year surge in TSHRAb after radioiodine therapy[80,294] may increase the risk of fetal exposure to high TSHRAb levels if the woman is treated with radioiodine shortly before she becomes pregnant. In all cases where radioiodine therapy is used, pregnancy should be delayed for at least 6 months and until normal thyroid function has returned on replacement therapy.

Nursing and Antithyroid Drugs

Older studies suggested that relatively more methimazole than PTU appeared in breast milk of women receiving these drugs during lactation, but more recent evidence shows little difference between them.[265,295,296] It is occasionally recommended that women who take high doses of antithyroid drugs not nurse their infants because of the difficulty in monitoring thyroid function in infants. The drug doses transferred via breast milk are very small, and no drug side effects have been reported in neonates whose mothers were taking antithyroid drugs, including neurologic function.[297]

Inherited Nonimmune Hyperthyroidism

Toxic diffuse thyroid hyperplasia without the pathologic characteristics of autoimmune disease has been reported in families and appears to be inherited as an autosomal dominant condition.[298–300] Polymorphic genomic mutations in the *TSHR* gene have been reported to cause constitutively activated TSHRs differing from family to family.[301] Recessive mutations on both chromosomes have also been described as causing hyperthyroidism while the parents remained euthyroid. These gain of function mutations, mostly in the transmembrane regions of the TSHR, are similar to those somatic mutations seen in toxic adenomas but are in the germline.[302] Treatment is by radioiodine ablation or thyroidectomy, depending on the age of the patient.

Toxic Multinodular Goiter

Toxic multinodular goiter is a disorder in which hyperthyroidism arises in a multinodular goiter, usually of long standing, and is the result of one of several pathogenetic factors.[303] Its incidence is highly dependent on the iodine intake of the population.

Pathogenesis

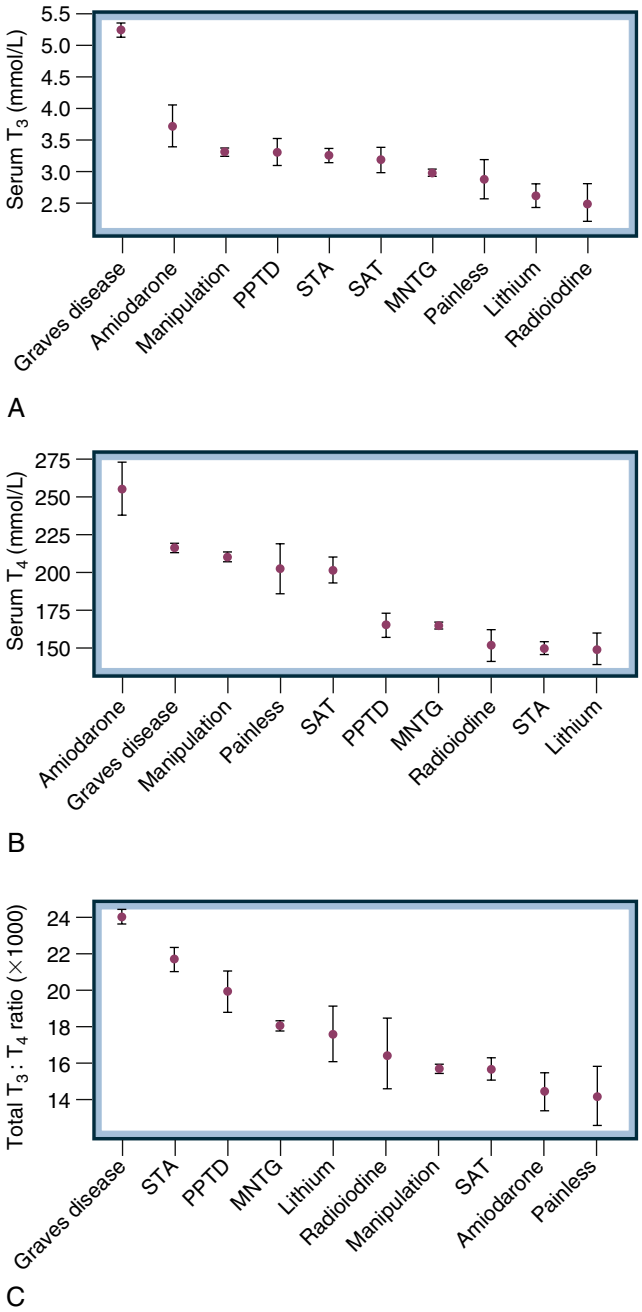
The pathogenesis of toxic multinodular goiter cannot be considered apart from that of its invariable forerunner, nontoxic multinodular goiter, from which it may slowly emerge. Two hallmarks of the disorder, structural and functional heterogeneity and functional autonomy, evolve over time; the increase in the extent of autonomous function causes the disease to move from the nontoxic to the toxic phase. Somatic mutations in the *TSHR* gene, first demonstrated in toxic adenomas,[298] have been demonstrated in toxic multinodular goiter, and the individual mutations appear to differ from nodule to nodule. However, only about 60% of toxic nodules have reported *TSHR* mutations, and only a very few have G protein mutations. Hence there are many nodules with autonomy of undetermined cause[304] and that presumably involve mutations in additional parts of the signaling pathways.

Radioiodine scans show localization of isotope in one or more discrete nodules, whereas iodine accumulation in the remainder of the gland is usually suppressed because TSH is suppressed by the hyperthyroidism. However, the degree of hyperthyroidism can be variable and TSH may not be totally inhibited, so the background uptake of radioisotope may also be variable. Histopathologically the functioning areas may resemble adenomas in being reasonably well demarcated from surrounding tissue. They generally consist of large follicles, sometimes with hyperplastic epithelium, but here, too, architecture correlates poorly with functional state. The remaining tissue appears inactive, and zones of degeneration are present in both functioning and nonfunctioning areas. Hence, from the pathophysiologic standpoint, these thyroids harbor multiple solitary hyperfunctioning and hypofunctioning adenomas interspersed by suppressed normal thyroid tissue.

Clinical Presentation

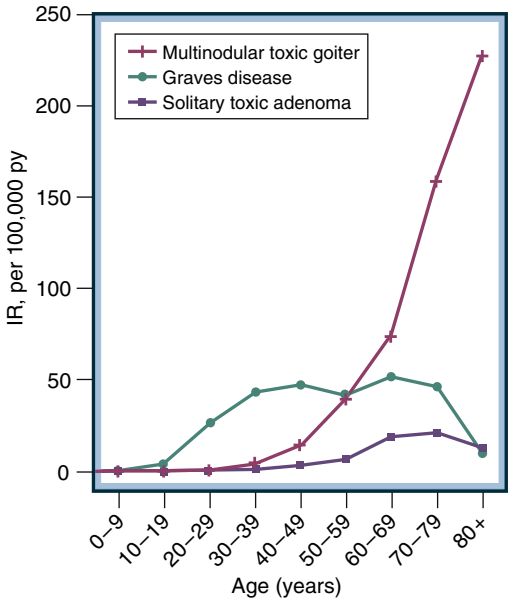
The overproduction of thyroid hormone in toxic multinodular goiter is usually less than that in Graves disease, and the disease presentation is milder (Fig. 12.18); in addition, toxic multinodular goiter usually occurs after the age of 50 in patients who have had nontoxic multinodular goiter for many years (Fig. 12.19). Like its forerunner, toxic multinodular goiter is more common in women than in men (6:1).[305] Sometimes hyperthyroidism develops abruptly, often after exposure to increased quantities of iodine such as the contrast media for CT scanning, which permits autonomous foci to increase hormone secretion to excessive levels and which may simply exacerbate already established mild hyperthyroidism (see "Iodide-Induced Hyperthyroidism"). The serum T_4 and T_3 concentrations may be only marginally increased, and a suppressed TSH may be the major abnormality. The total RAIU is only slightly increased or within the normal range unless following iodine exposure.

A toxic multinodular goiter may also be found as part of Graves disease as confirmed by the presence of TSHRAb of the stimulating variety.[306] Presumably this represents two separate diseases, although TSHRAbs have growth-stimulating activity but this should apply to all cells. Toxic multinodular goiter alone is not accompanied by infiltrative ophthalmopathy, and when the two coexist it represents the emergence of Graves disease.



• **Fig. 12.18** Serum T_3 (A), T_4 (B), and T_3:T_4 ratio (C) in 10 types of hyperthyroidism. Means (±SEM) are shown. *MNTG,* multinodular toxic goiter; *PPTD,* postpartum thyroid disease; *SAT,* subacute thyroiditis; *SEM,* standard error of the mean; *STA,* solitary toxic adenoma; *T_3,* triiodothyronine; *T_4,* thyroxine. (From Carlé A, Knudsen N, Pedersen IB, et al. Determinants of serum T4 and T3 at the time of diagnosis in nosological types of thyrotoxicosis: a population-based study. *Eur J Endocrinol*. 2013;169:537–545.)

Cardiovascular manifestations often predominate, possibly because of patient age, and include atrial fibrillation or tachycardia with or without heart failure. Weakness and wasting of muscles are common, the so-called *apathetic* or *masked thyrotoxicosis*. The nervous manifestations are less prominent than in younger patients with thyrotoxicosis, but emotional lability may be pronounced, and even osteoporosis may be the factor leading to thyroid function testing and diagnosis. Because of the physical characteristics of the thyroid gland and its frequent retrosternal extension, obstructive symptoms are more common than in Graves disease.



• **Fig. 12.19** An example of age-specific incidence rates *(IR)* of the three most common types of hyperthyroidism. *py,* person-years. (From Carlé A, Pedersen IB, Knudsen N, et al. Epidemiology of subtypes of hyperthyroidism in Denmark: a population-based study. *Eur J Endocrinol*. 2011;164:801–809.)

On palpation, the characteristics of the goiter are the same as those of the more common nontoxic multinodular goiter. In as many as 20% of elderly patients with thyrotoxicosis, the thyroid gland is firm and irregular but not distinctly enlarged. A thyroid scan and ultrasound examination will confirm the diagnosis as toxic multinodular goiter rather than a single toxic adenoma or Graves disease.

Laboratory Tests and Differential Diagnosis

All patients with a multinodular goiter should be screened annually with a serum TSH. If suppressed, the free T_4 should be determined. Serum TSH levels intermediate between 0.1 and 0.4 mU/L are not usually associated with significant clinical symptoms. Such patients have thyroid autonomy but are not thyrotoxic (see "Subclinical Hyperthyroidism"). For patients with established thyrotoxicosis, an RAIU with scan will help in gauging the dose of ^{131}I to be administered as well as identify the autonomously functioning nodules. The latter can then be followed by ^{131}I therapy.

Treatment

The treatment of toxic multinodular goiter with overt hyperthyroidism can be approached with surgery, radioactive iodine therapy, or in some cases antithyroid drug therapy. The correct choice depends upon a combination of patient preference with associated risk factors. For example, a gland with significantly high radioactive iodine uptake in select nodules would be ideal for radioiodine therapy. In contrast, a large gland with compressive symptoms could be better addressed with surgery.[134]

Radioiodine Therapy

Radioiodine may be the treatment of choice for patients with toxic multinodular goiter despite disagreement about the size and number of doses required to achieve a therapeutic response.[303,307] In the United States, iodine intake is higher than in many regions

in Europe so that 24-hour RAIU values of 20% to 30% are not unusual. Such patients will require significant doses of radioiodine to restore a euthyroid state and may even require a second treatment.

Because a number of patients with this disorder have underlying or the potential for heart disease, the administration of radioiodine should be preceded by a course of antithyroid therapy with methimazole until a near eumetabolic state is achieved, but still with a suppressed TSH to avoid iodine uptake in normal thyroid tissue. Medication is then discontinued for at least 4 to 7 days before radioiodine is administered. A week later the antithyroid drug may be reinstituted so that the thyrotoxicosis is controlled until radioiodine takes effect, which typically requires 3 to 4 months. A decrease in size of the hyperfunctioning nodules is a positive sign. At that time, the antithyroid drug can be tapered, but if the TSH level remains below 0.1 mU/L after 6 months, a second dose may be required.

Surgery

Surgical therapy is often recommended after adequate preoperative preparation in patients with large goiters or obstructive manifestations. In these patients, a CT scan or MRI is recommended to define the extent of the goiter and the adequacy of the tracheal walls. Respiratory function studies may also be helpful in assessing the need for surgery. Patients with fixed, especially partially retrosternal, goiter should be considered for surgery because of the risk of more complete obstruction should hemorrhage into a nodule occur. However, when surgery is contraindicated, even significant obstructive symptoms can be relieved by adequate radioiodine therapy.[308] In elderly patients who are not candidates for either radioiodine therapy or surgery, lifelong low-dose antithyroid drug therapy remains an option.

Additional Treatment Options

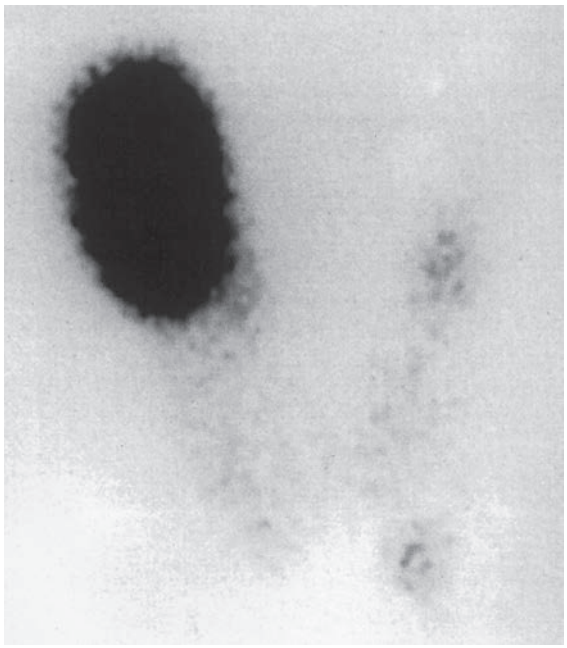
Outside of the United States there is greater experience with newer treatment options, including ethanol ablation and radiofrequency ablation. Success with these techniques in context of diminished nodule size and function is reported. However, their utility has not been broadly studied and they should likely only be used when the more standard modalities of radioactive iodine therapy, surgery, or antithyroid drugs are not possible or contraindicated.[309,310]

Toxic Adenoma

A third, less common form of hyperthyroidism (~5% of cases)[305] is caused by one or more autonomous adenomas of the thyroid gland. As herein used, the term *toxic adenoma* refers to a tumor in a thyroid that is otherwise intrinsically normal. The disorder is usually caused by a single adenoma that is either palpable or seen on ultrasound as a solitary nodule and hence is sometimes referred to as a *hyperfunctioning solitary nodule* or *toxic nodule*. Occasionally two or three adenomas of similar character are present.

Pathogenesis

Toxic adenomas are true follicular adenomas (for histopathologic characteristics, see Chapter 14). The basic pathogenesis of many toxic adenomas (up to 70%) is one of several somatic point mutations in the *TSHR* gene, commonly in the third transmembrane loop.[301,311] These single nucleotide substitutions cause amino acid changes that lead to constitutive activation of the TSHR in the absence of TSH.[312] It appears therefore that the TSHR is allosterically switched from an *off* state to an *on* state. Similarly, loss-of-function rather than gain-of-function mutations may also occur in the *TSHR* gene and cause hypothyroidism (see later). A small number of autonomous adenomas have mutations in the G stimulatory protein genes downstream of the TSH receptor that lead to a similar state of constitutive activation.[304] More recently, mutations have also been identified in the *EZH1* genes in toxic adenomas from patients who possess a TSH receptor activating mutation implying that a second hit may be necessary for full activation of the toxic adenoma phenotype.[313]



• **Fig. 12.20** Radioiodine (^{123}I) thyroid scan shows a hyperfunctioning hot nodule corresponding to physical examination findings with a faint outline of the remaining suppressed gland. In this unusual case, Graves disease developed a few months later after an oral contrast agent load. (From Soule J, Mayfield R. Graves' disease after 131I therapy for toxic nodule. *Thyroid*. 2001;11:91–92.)

Clinical Presentation

The toxic adenoma often presents as a nodule in a patient with a suppressed TSH; on ultrasound it appears as a single hypoechogenic nodule. A radioiodine thyroid scan shows a localized area of increased radioiodine accumulation (Fig. 12.20). This condition may occur at a younger age than toxic multinodular goiter and may be seen in patients in their 30s and 40s.

Frequently there is a history of a long-standing, slowly growing lump in the neck. It is unusual for adenomas to produce thyrotoxicosis until they have achieved a diameter of greater than 3 cm[303]; up to that point, patients have subclinical hyperthyroidism. The adenoma can undergo central necrosis and hemorrhage spontaneously, relieving the thyrotoxicosis, and the remainder of the thyroid may then resume its function. Calcification in the area of hemorrhage may take place and may be evident on sonogram examination. Such calcification is usually macroscopic and irregular and does not resemble the finely stippled calcification suggestive of papillary cancers. The peripheral clinical manifestations of a toxic adenoma are generally milder than those of Graves disease and are notable for the absence of infiltrative orbitopathy and myopathy, although cardiovascular manifestations may occur.

Laboratory Tests

The results of laboratory tests depend on the stage and function of the adenoma. At first, serum thyroid hormone concentrations are normal except for borderline suppression of the serum TSH. This, together with ultrasound examination to exclude multiple nodules, confirms the diagnosis. Later a thyroid scan may show localization of radioisotope in the palpated nodule, but this is not obvious until TSH secretion is suppressed. If the nodule continues to grow, frank hyperthyroidism is accompanied by elevation of serum thyroid hormone levels. Occasionally the serum free T_4 concentration is normal, and only the serum T_3 level is increased (T_3 thyrotoxicosis). Incidental thyroid carcinoma may rarely coexist within a gland exhibiting a hyperfunctioning adenoma. The incidence of carcinoma in these nodules is rare, but there are few clinical indicators of malignancy should it be present. Thus if the nodule is not treated surgically it is reasonable to follow closely if any clinical or radiographic features of malignancy are seen.[314]

Treatment

Although hyperfunctioning adenomas may eventually cause clinical hyperthyroidism, many do so slowly and others not at all.[303] Therefore treatment of asymptomatic patients with functional adenomas is decided on an individual basis. Clinically euthyroid subjects who wish to avoid both surgery and radioiodine can in theory be followed with annual assessments. However, suppression of TSH below normal (particularly to <0.1 mU/L) indicates hyperthyroidism, and therapy may be warranted. Two definitive therapies are available: radioiodine and surgery.

Radioiodine Therapy

In terms of the specificity of treatment, functioning thyroid nodules are candidates for radioiodine therapy. The radiation should in theory be directed almost exclusively to the diseased tissue. This is because TSH is suppressed and the normal thyroid tissue surrounding the nodule does not take up excess radioiodine. However, this suppression may be incomplete, and a significant fraction of patients receiving radioiodine develop thyroid failure. For the patient over age 18 with a nodule 5 cm in diameter or smaller, ^{131}I is an appropriate treatment if the risk of eventual hypothyroidism is acceptable to the patient. For such lesions, doses of radioiodine are given sufficient to result in the presence of 300 to 370 MBq (8–10 mCi) in the nodule at 24 hours based on the uptake.[303] Clearly higher doses of RAI result in enhanced success in treatment of the hyperthyroidism but also lead to an increased incidence of hypothyroidism.[316] Recombinant TSH, used to enhance the RAIU to avoid a large treatment dose in nontoxic multinodular goiters, is not appropriate here because it will direct radioiodine into surrounding normal thyroid tissue. The potential for hypothyroidism also indicates the need for prolonged follow-up.

Surgery

Toxic nodules are readily treated by surgical excision. A hemithyroidectomy may avoid the long-term development of hypothyroidism and with modern surgical procedures can be performed on an outpatient basis or even under local anesthesia. Surgical excision is always preferable in patients younger than 18 years of age to avoid the long-term consequences of irradiation, including effects on perinodular tissue. The toxic adenoma is not diffusely hypervascular, and consequently preoperative preparation with iodine is not required. In the patient with overt thyrotoxicosis, however, a normal metabolic state should be restored with an antithyroid drug before surgery.

Subclinical Hyperthyroidism

Definition

The availability of sensitive assays for TSH allowed the recognition of mild hyperthyroidism, in which there are no signs or symptoms of thyrotoxicosis but the serum TSH is subnormal despite normal serum free thyroid hormone concentrations. The term *subclinical* is somewhat of a misnomer because the condition is defined by biochemical characteristics, and it is preferable to use the term *mild thyroid dysfunction*.[317] Nonetheless, it is still not clear whether a patient is classified as having mild hyperthyroidism simply because our ability to detect physiologic evidence of excess thyroid hormone is less sensitive than our capacity to measure changes in TSH. This is further complicated by the fact that the hypothalamic-pituitary axis is sensitive to both serum free T_4 and T_3, whereas the peripheral tissues such as the heart primarily sense the free T_3 (see Chapter 11).[318,319] It is easy to assume, given the wide normal range for free thyroid hormone concentrations, that an individual with a low-normal free T_4 setpoint for TSH secretion would have a reduced TSH if that concentration were increased by 50% but could still remain within the normal range. In fact, in patients with primary hypothyroidism, small additional quantities of levothyroxine given to patients with normal TSH will decrease TSH below normal without a supranormal free T_4.[318] Thus the true lack of additional sensitive biomarkers in the periphery makes it difficult to determine whether all tissues are in fact hyperthyroid when the TSH is suppressed.

On the other hand, in the now classic studies in the Framingham population over 60 years of age, the cumulative incidence of atrial fibrillation over 10 years was 28% in patients with a serum TSH concentration of 0.1 mU/L or less, whereas it was only 11% in those with serum TSH concentrations falling between 0.1 and 0.4 mU/L. The latter was only slightly higher than that in the normal population.[10,11] Similar results have been obtained in one other prospective study.[11] Furthermore, heart failure is the leading cause of increased cardiovascular mortality rate in both overt and mild hyperthyroidism.[320] Taken together these data support the notion that a suppressed TSH is indicative of hyperthyroidism in the heart.

Bone density is another end point for such studies because it is well known that thyroid hormone causes a net resorption of cortical bone[321] and that lack of TSH may contribute to this phenomenon.[34] Several studies demonstrate lower bone density in patients with mild thyrotoxicosis, although others do not.[38,322] This is a subject of considerable interest because the condition is much more common than overt thyrotoxicosis (0.7% of the population in NHANES III) and has broad implications with respect to the cost of diagnosis, treatment, and follow-up.[323] In general, normalization of thyroid function in postmenopausal women with subclinical hyperthyroidism seems to improve bone density and certain aspects of cardiac function.[324]

Overall these data would generally favor treatment in the older population, but unfortunately there are still no large, long-term randomized studies to allow evidence-based conclusions as to the risk-benefit ratio.[325,326]

Diagnosis

The diagnosis of subclinical hyperthyroidism requires tests revealing several subnormal TSH concentration results spaced months apart in the presence of normal free T_3 and T_4 concentrations. Several studies show that suppressed TSH can normalize spontaneously over several years, particularly in patients without nodular goiter.[327,328] As with overt thyrotoxicosis, there are two sources of excess thyroid hormones, endogenous and exogenous. In a study of over 25,000 individuals attending health fairs in Colorado, 58% of those with a TSH less than 0.3 mU/L were receiving thyroid hormones.[329] When this is not being done intentionally for the treatment of persistent thyroid carcinoma, it is easily treated by more careful monitoring of the levothyroxine dosage using serum TSH concentrations. Endogenous subclinical thyrotoxicosis has the same causes as overt thyrotoxicosis. In the population over 60, multinodular goiter is a more likely cause of hyperthyroidism than it is in younger individuals especially in the United States.

Treatment

There are insufficient data to conclude that individuals with serum TSH concentrations greater than 0.1 mU/L due to hyperthyroidism will benefit from treatment.[134,325] However, treatment should be considered in those over age 65 with cardiac disease or osteoporosis. There is increasing support for treatment of individuals with persistently subnormal TSH concentrations less than 0.1 mU/L (with normal free thyroid hormones) who are over age 65 and for those younger than age 65 with cardiac disease or risk factors for cardiac disease or significant risk for osteoporosis.[134]

Identifying the cause of the hyperthyroidism allows assessment of the potential risks of treatment. At one extreme, the treatment of mild Graves disease with radioiodine usually causes hypothyroidism, whereas this typically does not occur in patients with multinodular toxic goiter. Thus, in an asymptomatic patient with mild Graves disease, watchful waiting for several years, awaiting a possible spontaneous remission, may be the best course of action[330]; if therapy is considered necessary, the chance of prolonged remission after a course of antithyroid drug therapy is good. On the other hand, patients with subclinical hyperthyroidism due to toxic nodular goiter or a solitary hyperfunctioning adenoma can often be treated with a single dose of radioactive iodine with a relatively low risk of subsequent hypothyroidism. Thus the threshold for treatment of such patients is lower. As always, the rationale for treatment, its risks, and its benefits should be carefully discussed with the patient, and one should be guided by common sense and not by the principle of simply treating an abnormal test result.[331]

Induced Hyperthyroidism

The incidence of hyperthyroidism corresponds in general to population iodine nutrition. Rates are lower in iodine-sufficient countries and higher in iodine-deficient countries mostly due to an excess of nodular thyroid disease in the elderly.[332–334] In China, the prevalence of overt and subclinical hyperthyroidism was likewise higher in iodine-deficient areas compared with iodine-sufficient areas.[335] Iodine fortification in previously iodine-deficient regions will result in an adequate iodine intake but is associated with a transient increase in the incidence of hyperthyroidism (mainly due to toxic nodular goiter); in the long run, however, the incidence of hyperthyroidism may be lower than the initial rate due to a decrease in the prevalence of thyroid nodules in the population.[99,333] Exposure to pharmacologic quantities of iodine may cause occasionally iodide-induced thyrotoxicosis (IIT), also called *Jod-Basedow,* more so in iodine-deficient areas than in iodine-sufficient areas.[336,337] Elderly subjects with nodular thyroid disease or latent Graves disease (i.e., with autonomous thyroid function and low TSH) are at risk. Such patients with underlying thyroid disease may have normal or even high thyroidal radioiodine uptake. In contrast, radioiodine uptake is low in IIT patients without preexistent thyroid disease, obviously caused by the cytotoxic effect of iodine excess on thyrocytes resulting in destructive thyroiditis. IIT usually resolves spontaneously in 6 months.

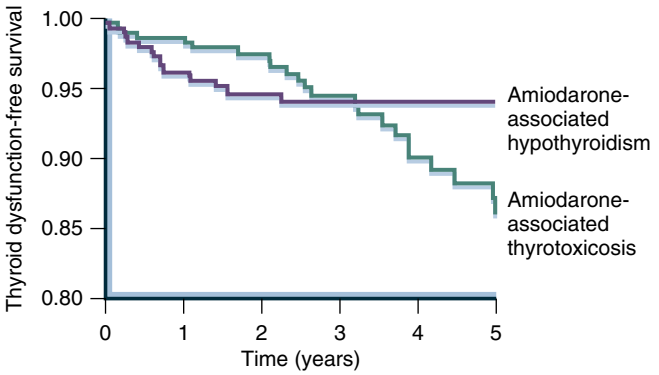
Many drugs contain huge quantities of iodine, such as expectorants, kelp tablets, and iodinated contrast agents. The risk for developing IIT is 0.3% in unselected people after coronary angiography in iodine-deficient areas.[338] Treatment of patients who had thyroid autonomy before coronary angiography (with 20 mg thiamazole and/or 900 mg sodium perchlorate, starting the day before angiography and continued for 2 weeks) was not effective in preventing IIT.[339,340] Close monitoring of high-risk patients rather than prophylaxis is thus recommended, with beta blockers if thyrotoxicosis occurs.[341]

Amiodarone-Induced Thyrotoxicosis

Amiodarone is a potent class III antiarrhythmic drug. It has hypothyroid-like effects such as bradycardia, reduction of myocardial oxygen consumption, lengthening of the cardiac action potential, and hypercholesterolemia[342]; these effects can be reversed by thyroid hormone. Its main metabolite desethylamiodarone acts as a competitive inhibitor of T_3 binding to thyroid hormone receptor α (TRα) and as a noncompetitive inhibitor of T_3 binding to TRβ.[343] One of the mechanisms of action of amiodarone might thus be induction of a hypothyroid-like condition in extrathyroidal tissues. The drug contains 37% iodine by weight and generates iodine excess; one 200-mg tablet/day releases 6 mg of iodide daily. Amiodarone has obligatory and facultative effects on the thyroid. Obligatory effects occur in everyone taking the drug. They consist of a transient rise of serum TSH up to 5 to 10 mU/L, caused by the Wolff-Chaikoff effect induced by the iodine overload, usually followed by an escape of the Wolff-Chaikoff effect and spontaneous normalization of TSH in 3 months. Serum total and free T_4 and reverse T_3 increase, and total and free T_3 decrease due to decreased metabolic clearance rate of T_4 and inhibition of liver deiodinase type 1. Facultative effects of amiodarone develop in a subset of patients. Amiodarone-induced hypothyroidisim (AIH) is caused by a failure to escape from the Wolff-Chaikoff effect. It occurs especially in women with TPO antibodies and is more prevalent in iodine-sufficient regions. Amiodarone-induced thyrotoxicosis (AIT), in contrast, is more prevalent in iodine-deficient regions. AIT type 1 is caused by iodine excess superimposed on preexistent thyroid disease such as Graves disease or nontoxic goiter. AIT type 2 is due to the cytotoxic effect of amiodarone on thyrocytes resulting in transient destructive thyroiditis.[344]

Epidemiology and Screening

In a prospective study with a median follow-up of 3.3 years in an area with an average daily iodine intake of 150 μg, 8% of patients taking amiodarone developed AIT and 6% AIH.[345] Incidence rates of AIT were 1.9 and of AIH 1.6 per 100 person-years (Fig. 12.21). It is striking that no new cases of AIH developed after 2 years on amiodarone therapy, whereas new cases of AIT



• **Fig. 12.21** Kaplan-Meier curve depicting the incidence of amiodarone-associated thyrotoxicosis and hypothyroidism. (Redrawn from Ahmed S, Van Gelder IC, Wiesfeld AC, et al. Determinants of outcome of amiodarone-associated dysfunction. *Clin Endocrinol*. 2011;75:388–394.)

continued to occur with continuation of amiodarone.[345,346] Thus one of every five to six patients taking amiodarone will develop overt thyroid dysfunction. It provides the rationale for the recommendation to measure TSH before starting amiodarone and at regular intervals during amiodarone.[347] Limitations of regular tests are, however, twofold. First, AIT type 2 often has a sudden, unpredictable onset. It may happen shortly after a previous blood test found a perfectly normal TSH, which may thus give rise to a false sense of security. Second, a suppressed TSH might just indicate subclinical hyperthyroidism, which spontaneously reverts to a normal TSH in 30% to 50% of cases despite continuation of amiodarone.[346,348] AIT occurs without preceding subclinical AIT in 64% of patients, and only 25% of patients with subclinical AIT progress to overt AIT.[348] AIT type 1 develops rather shortly after the start of amiodarone (median onset time is 3.5 months with just a single case occurring after 2.5 years), whereas the median onset time of AIT type 2 is 30 months.[349] Nowadays most AIT patients have AIT type 2. An iodine-free analog of amiodarone has been developed, called dronedarone, to get rid of the side effects caused by iodine excess. The pharmacologic properties of dronedarone, however, do not match those of amiodarone, and dronedarone has not displaced amiodarone in clinical practice.

Diagnosis

About half of AIT patients experience complaints, mainly palpitations but also weight loss and agitation.[345] Biochemical diagnosis of AIT is by suppressed TSH and elevated FT_4. FT_3 can be normal, however, due to the drug's inhibition of type I deiodinase, and cases of T_4 toxicosis occur. Although AIT type 1 currently appears to be much less common than type 2, identifying the type may still be of value because the treatments of types 1 and 2 differ. Diagnostic features are listed in Table 12.10. Type 2 patients usually have no goiter and no thyroid antibodies. Most useful is color flow Doppler sonography that provides a noninvasive, real-time assessment of thyroid vascularity.

Management

Specific ETA guidelines recommend treatment with antithyroid drugs in AIT type 1[344] (Fig. 12.22). The iodine-replete thyroid gland of AIT patients is less sensitive to methimazole, requiring rather high daily doses of 40 to 60 mg for longer periods than usual. To increase the response to methimazole, one may opt to coadminister sodium perchlorate (not available in the United States), which acutely inhibits further thyroidal iodine uptake. To restrict its toxic side effects, $NaClO_4$ should be used no longer than 4 to 6 weeks in a daily dose not exceeding 1 g (e.g., 500 mg twice daily). Amiodarone itself should be stopped, if feasible. Management is completely different in AIT type 2. Here the preferred drug is oral prednisone, in a daily dose of 30 mg.[344] Tapering down prednisone can be started when TSH has become normal, which takes about 3 months. In view of the self-limiting character of AIT type 2, it is possible to continue amiodarone in these patients.[350] Time to restoration of euthyroidism is little affected by continuation of amiodarone in type 2 patients.

Occasionally it is difficult to decide whether type 1 or type 2 AIT exists, and mixed forms do occur. One may opt for triple therapy (prednisone + methimazole + $NaClO_4$) under such circumstances, also when the response to instituted treatment is too slow. Some patients do not fare well, and guidelines recommend total thyroidectomy to be performed without delay in AIT patients with deterioration of cardiac function (reduced left ventricular ejection fraction) or severe underlying cardiac disease and in those patients whose thyrotoxicosis is unresponsive to medical therapies.[344]

TABLE 12.10 Differences Between Amiodarone-Induced Thyrotoxicosis Type 1 and Type 2

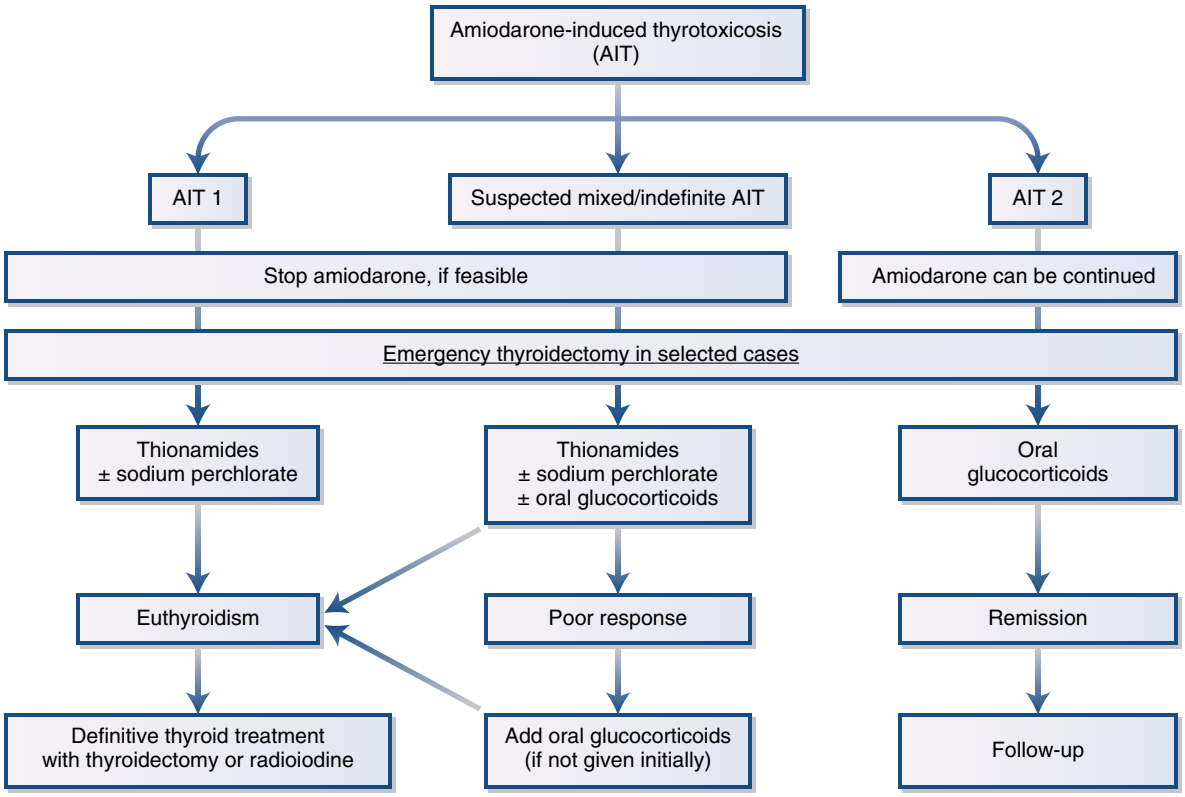
	AIT Type 1	AIT Type 2
Underlying thyroid abnormality	Yes	No
Onset after start amiodarone	Short (3 months)	Long (30 months)
Thyroid antibodies	Present in Graves	Usually absent
Color flow Doppler sonography	High vascularity	Low/absent vascularity
Thyroid radioiodine uptake	Low, normal, high	Suppressed
Preferred treatment	Antithyroid drugs	Oral prednisone
Amiodarone continuation	No	Possible
Spontaneous remission	No	Frequent
Subsequent hypothyroidism	No	Possible (17%)
Subsequent definitive treatment	Generally yes	No

AIT, Amiodarone-induced thyrotoxicosis.

Prognosis

Patients with AIT have more major adverse cardiovascular events than patients who remain euthyroid (31.6% vs. 10.7%, $p < 0.01$).[351] Mortality is also higher in AIT patients with severe left ventricle dysfunction (31% at ejection fraction <50% vs 14% at ejection fraction ≥50%).[352] Total thyroidectomy improves cardiac function and mortality, especially in those with ejection fraction below 40% preoperatively.[353]

Thyroid ablation is preferred before reintroduction of amiodarone after successful treatment of AIT type 1.[354] Continuation of



• **Fig. 12.22** Algorithm for the management of amiodarone-induced thyrotoxicosis. (Redrawn from Bartalena L, Bogazzi F, Chiovato L, et al. 2018 European Thyroid Association (ETA) guidelines for the management of amiodarone-associated thyroid dysfunction. *Eur Thyroid J.* 2018;7:55–66.)

amiodarone after cure of AIT type 2 is feasible; some patients will experience recurrent AIT (6–18%), which apparently is less severe and more easy to handle.[354,355] Permanent hypothyroidism develops in 17% of cured AIT type 2 patients, occurring at 10 months (range 6–24 months) after reaching euthyroidism.[350,356]

Hyperthyroidism Due to Thyrotropin Secretion

Pituitary Tumor

Excess TSH is an exceedingly rare cause of hyperthyroidism. However, pituitary thyrotroph tumors cause this condition and may present as a Graves-like syndrome with diffuse goiter and substantial thyrotoxicosis. Only 1% of pituitary adenomas are TSH producing and 25% may co-secrete growth hormone or prolactin.[357] Guidelines for the management of such patients have recently been released.[358] Laboratory studies demonstrating an inappropriately detectable or somewhat elevated TSH in the presence of elevated thyroid hormone levels must first be confirmed by eliminating assay artifacts. This condition is discussed in depth in Chapter 9 and must be differentiated from the rare patient who has resistance to thyroid hormone (RTH).[359–361]

Thyroid Hormone Resistance

The syndromes of RTH are now known to be caused by inherited mutations in both of the thyroid hormone receptor isoforms. RTHβ (due to mutations in the beta isoform) leads to a syndrome of inappropriate TSH secretion in the presence of elevated circulating levels of thyroid hormones because the beta isoform is responsible for the regulation of TSH. Similarly, TRβ is highly expressed in the liver, which is also functionally hypothyroid in RTHβ patients. However, in tissues that express primarily the TRα isoform, such as the heart and bone, tissue-specific hyperthyroidism may be present because these TRα expressing tissues sense the higher circulating thyroid hormone levels appropriately as high.[359–361] These patients may therefore present with a hyperthyroid appearance with tachycardia, nervousness, and goiter associated with an elevated free T_4 and may require tissue-specific treatment such as with β-adrenergic receptor blocking agents rather than antithyroid drugs (see Chapter 13 for a more extensive discussion of RTH). RTHβ should be suspected in patients who present with hyperthyroidism and inappropriate TSH secretion without an apparent pituitary adenoma. Furthermore, a careful family history should be taken as the disorder is inherited in an autosomal dominant fashion. In contrast to RTHβ, RTHα due to mutations in TRα isoform leads to a syndrome of tissue-specific hypothyroidism because the TRα isoform is not involved in the regulation of the HPT axis and thus thyroid hormone levels are not elevated.[362]

Tumor Chorionic Gonadotropin-Induced Hyperthyroidism

hCG exhibits specificity crossover with the TSHR (see earlier discussion under "Pregnancy and the Thyroid"). Thyroid hyperfunction may therefore accompany hydatidiform mole,

choriocarcinoma, or metastatic embryonal carcinoma of the testis.[258] Such neoplasms, particularly hydatidiform mole, elaborate differentially glycosylated hCG molecules that exhibit crossover specificity for binding to the TSHR and can induce variable degrees of thyroid overactivity.[232,363] Some patients have clinically overt thyrotoxicosis; however, clinical manifestations are usually not prominent, and goiter is absent or minimal. The free T_4 and free T_3 levels are increased, and TSH values are suppressed. The possibility of a molar pregnancy should be considered in a young woman with hyperthyroidism and amenorrhea because the appropriate therapy is evacuation of the uterus.

Transient Thyrotoxicosis

Overview

As mentioned at the outset of this chapter, transient thyrotoxicosis must be differentiated from the sustained hyperthyroidism of Graves disease and other causes of hyperthyroidism. Transient thyrotoxicosis is caused by thyroid cell breakdown, and the hyperthyroid symptoms are of abrupt onset and shorter duration. This process may be followed by recovery of thyroid function or the development of transient or permanent thyroid failure. The discussion in this chapter focuses on thyroiditis as the most common cause of transient thyrotoxicosis, and this disorder is covered more completely in Chapter 13 because Hashimoto disease most commonly causes hypothyroidism after the initial phase of transient hyperthyroidism. Unfortunately transient thyrotoxicosis continues to have a confusing nomenclature, which can be clarified as follows:

Autoimmune thyroiditis: In the autoimmune forms (Hashimoto thyroiditis) there are typically no local symptoms of thyroid inflammation, leading to the terms *silent* or *painless thyroiditis*, also referred to as *lymphocytic thyroiditis* or *hashitoxicosis.* This condition may uncommonly present with thyroid tenderness if the thyroid has expanded rapidly, stretching the capsule.

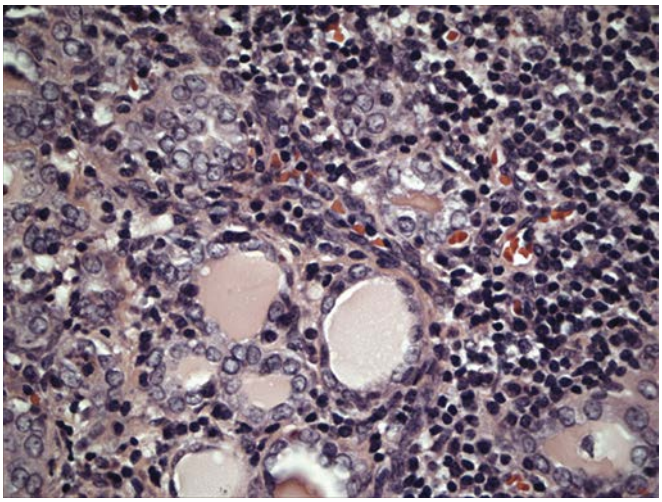
Viral thyroiditis: In what is thought to be postviral thyroiditis (also termed *subacute, de Quervain*, or *granulomatous thyroiditis*), thyroid tenderness may be the most prominent symptom, and thyrotoxicosis is rare and typically self-limited, although this form may rarely also be painless.

Acute thyroiditis: Acute thyroiditis due to bacterial or fungal infections is only rarely accompanied by thyrotoxicosis, and the local symptoms predominate (see Chapter 13).

Drug-induced thyroiditis: Thyroiditis may also be drug induced, the principal offenders being amiodarone and lithium. Some of the new small molecule kinase inhibitors (such as sunitinib) may also cause this form of thyroiditis, resulting eventually in hypothyroidism.[364,365] In addition, the introduction of immunotherapy for cancer treatment, including CTLA4 inhibitors and PD1 inhibitors, has dramatically increased the incidence of several endocrine toxicities, including transient hyperthyroidism.[366]

Transient Thyrotoxicosis Due to Autoimmune (Hashimoto) Thyroiditis

As described earlier, Hashimoto disease causes two different thyrotoxicosis-associated transient syndromes. The most common is the painless form in which the symptoms of thyrotoxicosis are usually mild and predominate; the much more uncommon form has a painful presentation probably secondary to a more acute onset. Histopathologic examination in such patients with thyroiditis shows diffuse or local lymphocytic infiltration, varying degrees of fibrosis, and disruption of the follicular architecture (Fig. 12.23).



• **Fig. 12.23** Lymphocytic thyroiditis in a patient with transient thyrotoxicosis (painless thyroiditis) secondary to autoimmune (Hashimoto) thyroiditis. Notice the diffuse lymphocytic invasion of the tissue, including the follicular epithelium, and the loss of follicles. Multinucleated giant cells may also be seen in the follicular lumen. (Courtesy Dr. Vania Nosé, Brigham and Women's Hospital, Boston, MA.)

Transient Thyrotoxicosis From Painless Autoimmune Thyroiditis

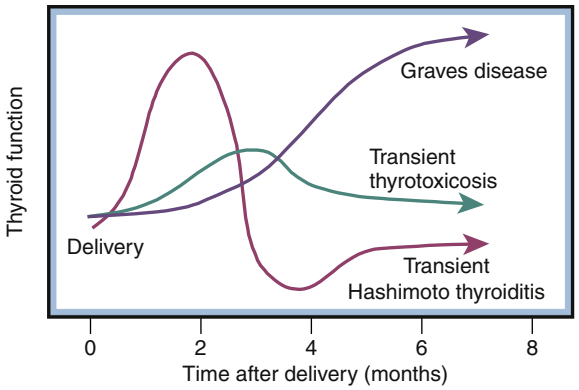
Painless autoimmune thyroiditis may occur postpartum or spontaneously. Postpartum thyroiditis is the most common example; its pathophysiology, postpartum enhancement of thyroid-directed autoimmunity (Hashimoto disease), is analogous to the postpartum exacerbation of Graves disease (see "Graves Disease in the Postpartum Period"). The incidence of postpartum thyroiditis varies but may occur in as many as 10% of women and in more than 30% of those with positive TPOAb and even a larger fraction in patients with type 1 diabetes mellitus.[245,289] In women found to be TPOAb positive prenatally, postpartum assessment of thyroid function is recommended at 3, 6, and 12 months. Thyrotoxicosis from spontaneous autoimmune thyroiditis has all the same characteristics as postpartum thyroiditis and is seen in patients early in their development of classic Hashimoto disease and before the onset of hypothyroidism.

Transient Thyrotoxicosis from Painful Autoimmune Thyroiditis

Although some patients may present with local thyroid tenderness, this occurrence is uncommon. Such tender episodes, which may be unilateral, may recur until the thyroid gland is completely destroyed by the disease process. Only rarely does the pain persist, sometimes requiring surgical intervention.

Clinical Presentation of Transient Autoimmune Thyrotoxicosis

More than 75% of patients are women who present with the acute onset of symptoms of thyrotoxicosis, usually nervousness, palpitations, and irritability; they can often pinpoint the time of recent onset. In the postpartum syndrome, symptoms present 4 to 12 months after delivery but may be mild and overlooked in the myriad of events involved in the care of the newborn.[288] After 1 to



• **Fig. 12.24** The postpartum thyroid syndromes. These potential patterns of thyroid dysfunction may be seen in the postpartum period.

2 months the thyrotoxic symptoms fade but are often replaced by those suggesting hypothyroidism (Fig. 12.24).

In a significant number of postpartum patients the thyrotoxic phase is too mild to be noticed, and the patient presents somewhat later after delivery with hypothyroid symptoms. The physical examination shows mild signs of thyrotoxicosis, tachycardia being the most prominent, without the specific eye signs or dermopathy associated with Graves disease. The thyroid gland is normal in size but may be firm if the Hashimoto disease is chronic.

Diagnosis

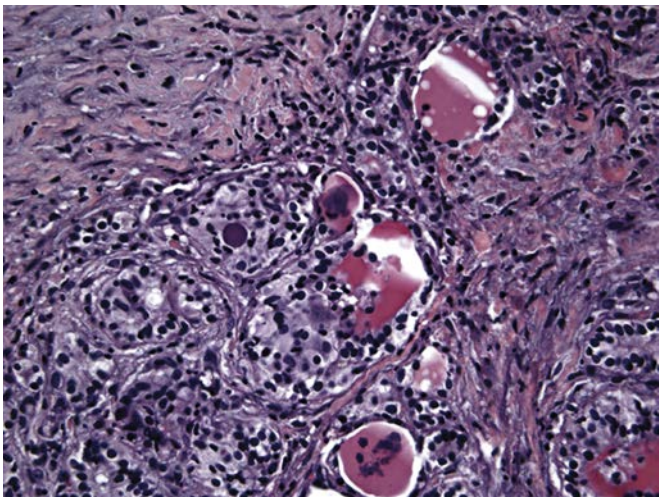
Thyrotoxicosis is usually mild and is reflected in the degree of suppression of the serum TSH level and elevation of the serum free T_4. Significant elevation of the TPOAb is typical. Systemic manifestations of inflammation are lacking, and the erythrocyte sedimentation rate is normal or nearly normal, but the ultrasound may indicate the heterogeneity of an inflamed gland. If true hyperthyroidism cannot be eliminated as a diagnosis on clinical grounds, TRAb should be measured or an RAIU test should be performed unless the patient is nursing. The classic decreased RAIU is due partly to feedback suppression of TSH secretion but also to thyroid follicular cell destruction. The tendency of the disorder to pass through a hypothyroid phase is not surprising in view of the extensive depletion of Tg, which is processed to T_4 and not replaced by the dysfunctional cells.

Natural History

The duration of the thyrotoxic phase, typically not severe enough to require treatment, averages about 1 to 2 months. About one-half of the patients return to a euthyroid phase and remain well in the short term. In the remaining half, a hypothyroid phase may follow and may last from 2 to 9 months. In most, there is eventual restoration of euthyroidism, but some develop permanent hypothyroidism years later.[367,368] About one-third retain a goiter, usually with persistence of thyroid autoantibodies in the serum. The opposite sequela, recurrence of thyrotoxicosis, may also occur months or years after restoration of a euthyroid state or particularly after pregnancy.

Treatment

The thyrotoxic phase may require alleviation of the peripheral manifestations through the use of beta blockers. Prednisone (20–40 mg/day) may decrease the duration of the thyrotoxic phase but is typically not needed except when the painful form of the disease is present. If mild and brief, the hypothyroid phase may also not require treatment. When treatment with levothyroxine is required, it should be withdrawn slowly approximately 6 months later because the hypothyroidism is often not permanent.



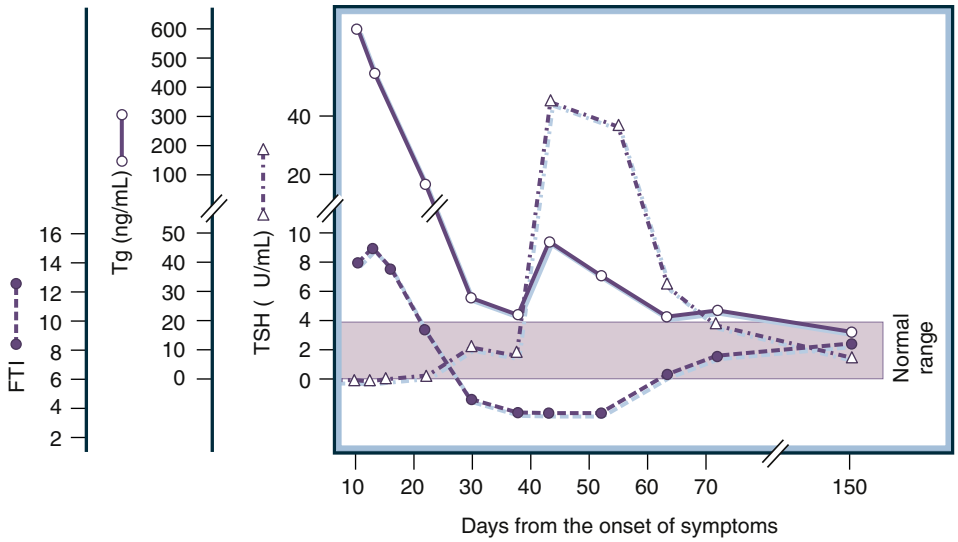
• **Fig. 12.25** Subacute (viral or postviral) thyroiditis. Diffuse neutrophilic invasion with active destruction of follicles and a multinucleated giant cell. Fibrosis and near-complete loss of follicles have occurred. (Courtesy Dr. Vania Nose, Brigham and Women's Hospital, Boston, MA.)

Subacute Thyroiditis

Subacute thyroiditis (also termed *granulomatous, giant cell*, or *de Quervain thyroiditis*) is thought to be caused directly or indirectly by a viral infection of the thyroid gland and often follows an upper respiratory illness. A tendency to appear in the spring in the northern latitudes has been noted, and again it predominates in the female. The mumps virus has been implicated in some cases; coxsackievirus, influenza virus, echovirus, and adenoviruses may also be etiologic agents. Positive TPOAb are present transiently during the active phase of the disease, although some patients may retain evidence of thyroid autoimmunity for many years. A small number of patients eventually develop AITD.[369] Subacute thyroiditis is uncommon, but mild cases may be mistakenly diagnosed as pharyngitis.

Pathology

The histopathologic changes are different from those in Hashimoto disease. The lesions are patchy in distribution and vary in their stage of development from area to area. Affected follicles are infiltrated predominantly with mononuclear cells and show disruption of epithelium, partial or complete loss of colloid, and fragmentation and duplication of the basement membrane (Fig. 12.25). To this extent, the histopathologic appearance may resemble that in Hashimoto disease. A characteristic feature is the well-developed follicular lesion that consists of a central core of colloid surrounded by the multinucleated giant cells (MNGCs), from which stems the designation *giant cell thyroiditis*. Colloid may be found in the interstitium or within the giant cells. The follicular changes progress to form granulomas. Interfollicular fibrosis and an interstitial inflammatory reaction are present to varying degrees. When the disease subsides, an essentially normal histologic appearance is restored.



• **Fig. 12.26** Thyroid function in a patient during the course of subacute (viral or postviral) thyroiditis. During the thyrotoxic phase (days 10–20), the serum thyroglobulin (Tg) concentration was greatly elevated, the free thyroxine index (FTI) was high, and the thyroid-stimulating hormone (TSH) was suppressed; the erythrocyte sedimentation rate was 86 mm/hour, and the thyroidal radioactive iodine uptake (RAIU) was 2%. The Tg level and the FTI declined in parallel. During the phase of hypothyroidism (days 30–63), when the FTI was below normal, a modest transient increase in serum Tg occurred in parallel with the increase in serum TSH. All parameters of thyroid function were normal by day 150, 5 months after the onset of symptoms. (From DeGroot LJ, Larsen PR, Hennemann G. Acute and subacute thyroiditis. In: DeGroot LJ, Larsen PR, Hennemann G, eds. *The Thyroid and Its Diseases*. 6th ed. New York: Churchill Livingstone; 1996:705.)

Pathophysiology

Apoptosis of follicular epithelium and loss of follicular integrity are the primary events in the pathophysiology. Tg, T_4, and iodinated Tg fragments are released into the circulation, often in quantities sufficient to elevate not just the serum Tg level but also the serum free T_4 level, producing clinical thyrotoxicosis and suppressing TSH secretion. As a result, the RAIU decreases to low levels, and hormone synthesis ceases. Later in the disease, when stores of preformed hormone are depleted, serum T_4 and T_3 concentrations decline, sometimes into the hypothyroid range, and the serum TSH level rises, often to elevated values exactly as occurs in silent thyroiditis (Fig. 12.26). As the disease becomes inactive, the RAIU may be greater than normal for a time as hormone stores are repleted. Ultimately, when hormone secretion resumes, serum T_4 and T_3 concentrations rise, and serum TSH concentration decreases to normal values.

Clinical Picture

The characteristic feature is the gradual or sudden appearance of pain in the region of the thyroid gland with or without fever. The pain, which is aggravated by turning the head or swallowing, characteristically radiates to the ear, jaw, or occiput and may mimic disorders arising in these areas. The absence of pain does not exclude the diagnosis, because biopsy-proven painless subacute thyroiditis occurs, but it must be distinguished from acute autoimmune thyroiditis. Hoarseness and dysphagia may be present; patients may complain of palpitation, nervousness, and lassitude. The latter symptoms can be extreme, considering the local nature of the disease, and suggest a systemic component. Although acute manifestations are present in severe cases, in milder disease symptoms may be present for months yet are often overlooked.

On palpation at least part of the thyroid is slightly to moderately enlarged, firm, often nodular, and usually exquisitely tender, one lobe frequently being more severely affected than the other. Indeed the symptoms may be truly unilateral. The overlying skin may be warm and erythematous. Occasionally the locus of maximal involvement migrates over the course of a few weeks to other parts of the gland. The disease usually subsides within a few months, leaving no residual deficiency of thyroid function in 90% of patients. In rare patients the disease smolders, with repeated exacerbations over many months, hypothyroidism sometimes being the final result.

Diagnosis

The laboratory findings vary with the phase of the disease. During the active phase, the erythrocyte sedimentation rate is increased, often to a remarkable extent (>100 mm/hour). Indeed a diagnosis of active subacute thyroiditis is hardly tenable when the sedimentation rate is normal. The white blood cell count is normal or, at most, moderately increased. The serum Tg level is characteristically high, in keeping with the degree of thyroid destruction.

Subacute thyroiditis must be differentiated from acute hemorrhagic degeneration in a preexisting thyroid nodule, Hashimoto disease with painful recurrence (see earlier), acute pyogenic thyroiditis or fungal infection, and rarely thyroid malignancy with painful nodules. Acute painful exacerbations of Hashimoto thyroiditis may be difficult to distinguish from subacute thyroiditis. Lack of elevation of the erythrocyte sedimentation rate and high titers of thyroid autoantibodies strongly suggest the former. Acute pyogenic thyroiditis is distinguished by the presence of a septic focus elsewhere, by a greater inflammatory reaction in the tissues adjacent to the thyroid, and by much greater leukocytic and febrile responses (see Chapter 13). The RAIU and thyroid function are

usually preserved in acute pyogenic thyroiditis. Rarely, widespread infiltrating cancer of the thyroid can present with a clinical and laboratory picture almost indistinguishable from that of subacute thyroiditis. Ultrasound and fine-needle aspiration should be performed if this is a consideration.

Treatment

In mild cases, aspirin or nonsteroidal antiinflammatory drugs or cyclooxygenase 2 (COX2) inhibitors may control the symptoms. With more severe pain, glucocorticoids (e.g., prednisone up to 40 mg/day) are the only solution for the extreme discomfort. This drug may be required for several months and should then be withdrawn gradually. If the TSH is not suppressed, TSH-suppressive therapy with levothyroxine may decrease the size of the gland, relieving the pressure on the thyroid capsule. TSH is needed for thyroid cell regeneration, so such therapy should be decreased as the symptoms subside.

Drug-Associated Thyroiditis

Thyroiditis is an uncommon complication of pharmacotherapy. Amiodarone is an important exception and was discussed earlier. Most of the thyroiditis associated with various therapeutic agents appears to be due to drug-induced exacerbation of underlying autoimmune disease. This effect is understandable with agents that are specifically administered to modify the immune system. They include IL2, interferon alpha, granulocyte/macrophage colony-stimulating factor (GM-CSF), and the newer immune therapy modulators, all of which can precipitate silent thyroiditis.[108,366,370,371] This has also been described with lithium and the GnRH agonist leuprolide, but the pathophysiologic mechanism is obscure.[372–374]

Thyroiditis has been found in association with multitargeting kinase inhibitors such as sunitinib and sorafenib given for a variety of tumors, including gastrointestinal stromal tumors, hepatocellular carcinoma, and renal cell carcinoma.[365,375] This may present as subacute thyroiditis with a suppressed TSH as the major manifestation of the early phase but then progress to destruction of the gland through an unclear mechanism. Although imatinib has been associated with an increase in levothyroxine requirements in hypothyroid patients (analogous to the effects of phenytoin, carbamazepine, and rifampin), those changes are independent of thyroid function.[376]

Other Causes of Thyrotoxicosis With a Low Radioiodine Uptake

In addition to silent and subacute thyroiditis, several other entities should be considered in the patient with thyrotoxicosis in whom the thyroid gland is either not palpable or not enlarged and who has biochemical findings of thyrotoxicosis accompanied by a low RAIU.

Thyrotoxicosis Factitia

Thyrotoxicosis that arises from the ingestion, usually chronic, of excessive quantities of thyroid hormone usually occurs in individuals with a background of underlying psychiatric disease, especially in paramedical personnel who have access to thyroid hormone or in patients for whom thyroid hormone medication has been prescribed in the past. Generally the patient is aware of taking thyroid hormone but may adamantly deny it. In other instances, large doses of thyroid hormone or other thyroactive material may be given without the knowledge of the patient, usually as part of a regimen for weight reduction. Some "natural" products for weight reduction stated not to contain thyroid hormone nonetheless do. Symptoms are typical of thyrotoxicosis and may be severe.

In the absence of preexisting disease of the thyroid, the diagnosis is made from the combination of typical thyrotoxic manifestations, together with thyroid atrophy and hypofunction. Infiltrative ophthalmopathy never occurs, but lid lag, stare, and other thyrotoxic eye signs may be present; TSH levels are suppressed. Serum T_4 concentrations are increased unless the patient is taking T_3, in which case they will be subnormal. Serum T_3 concentrations are increased in either case. Hypofunction of the thyroid gland is evidenced by the subnormal values of RAIU. The presence of low, rather than elevated, values of serum Tg is a clear indication that the thyrotoxicosis results from exogenous hormone rather than thyroid hyperfunction.

This disorder may be confused with other varieties of thyrotoxicosis associated with a subnormal RAIU and absence of goiter, including silent thyroiditis, ectopic thyroid tissue, and hyperfunctioning metastatic follicular carcinoma. Evidence for the two latter disorders can be obtained by demonstration of the ectopic focus or foci by external radioiodine scanning or the presence of normal to elevated serum Tg concentrations. Differentiation from silent thyroiditis may be difficult. The presence of TPOAb points to painless chronic autoimmune thyroiditis, whereas a firm thyroid and brief history suggest the painless variant of subacute thyroiditis. Treatment of thyrotoxicosis factitia consists of withdrawing the offending medication. Psychiatric consultation is often required.

Hamburger Thyrotoxicosis

An unusual form of exogenous thyrotoxicosis occurred in the midwestern portion of the United States in 1984 and 1985. The source was the inclusion of large quantities of bovine thyroid in ground beef preparations.[377] When the slaughtering practices were changed, this condition disappeared. Such a possibility, although remote, should be considered, especially if one is confronted with epidemic exogenous thyrotoxicosis.

Thyrotoxicosis Due to Extrathyroidal Tissue

Struma Ovarii

Thyroid tissue may be present in 5% to 10% of ovarian teratomas, and occasionally such foci are hyperfunctional.[378,379] About 5% to 10% of these tumors are bilateral. Although thyrotoxicosis is unusual, it may occur in as many as 8% to 10% of patients. Rarely, males with germ cell tumors may also develop hCG-induced hyperthyroidism.[380]

Clinical Presentation

Patients present with variable degrees of thyrotoxicosis but without goiter and generally have lower abdominal symptoms such as pain or a mass. Rarely ascites is present. Laboratory studies show reduced TSH and increased free T_4 of a variable degree, but the RAIU is low. The Tg may be elevated, particularly if the teratoma is malignant and has metastasized to the peritoneum. Abdominal CT scan or MRI shows a multilocular ovarian mass or masses.[381] Rarely a struma ovarii is accompanied by Graves disease.[382]

Treatment

The patient should be rendered euthyroid if thyrotoxicosis is significant, followed by removal of the involved ovary or ovaries. Therapeutic radioiodine will be required for metastatic disease after ablation of the normal thyroid gland.

Thyrotoxicosis Due to Metastatic Thyroid Carcinoma

In general, thyroid carcinomas are made up of poorly functioning tissue. On occasion, follicular thyroid carcinomas will have sufficient function when combined with the total mass of the metastases to result in an elevation in serum free T_4 or T_3 and may even be seen in Graves disease with TRAbs activating the tissue.[383] Typically such a course is a complication of a previously diagnosed lesion.[384] The symptoms of thyrotoxicosis will vary and the metastatic disease is usually obvious from radiologic studies. On occasion, the presentation may be confusing if the patient is receiving TSH-suppressive therapy, and diagnosis will require its discontinuation. In spite of that, TSH will remain suppressed and the serum free T_4 is elevated. Treatment of this condition is typical for that of thyroid carcinoma and is described in Chapter 14. In patients with thyrotoxicosis due to metastatic tumor, serum Tg is quite elevated, indicating that the thyrotoxicosis is caused by thyroidal tissue that is not located in the neck. An RAIU during the thyrotoxic phase will show no neck uptake due to TSH suppression even if the thyroid is still present.

Hypothyroidism and Thyroiditis

GREGORY A. BRENT AND ANTHONY P. WEETMAN

CHAPTER OUTLINE

KEY POINTS

- Autoimmunity is responsible for over 90% of noniatrogenic hypothyroidism in iodine-sufficient areas.
- A variety of genetic factors contribute to susceptibility in autoimmune thyroiditis, but epidemiologic data suggest a strong influence of environmental factors to explain the recent increase in prevalence.
- The risk of progression from *subclinical* to *overt* hypothyroidism is most closely related to the magnitude of serum thyrotropin (thyroid-stimulating hormone [TSH]) elevation and the presence of antithyroid peroxidase (TPO) antibodies.
- In some patients with autoimmune hypothyroidism, a transient exacerbation of thyroiditis or a fluctuation in the balance between TSH receptor-blocking and receptor-stimulating autoantibodies may result in episodes of thyrotoxicosis.
- Hypothyroidism due to direct thyroidal inflammation or activation of autoimmune destruction has been associated with a number of drugs, including tyrosine kinase inhibitors (TKIs).
- The quantity of levothyroxine required to normalize TSH in an athyreotic patient results in a slightly higher serum free thyroxine (T_4) concentration than is present in normal individuals.
- The current approach to thyroid replacement using levothyroxine alone, although not a perfect replication of normal physiology, is satisfactory for virtually all patients.
- Levothyroxine requirements are increased in malabsorption due to bowel diseases and impaired gastric acid secretion or adsorption of levothyroxine to coadministered medications.
- Athyreotic patients who are planning a pregnancy should be advised to increase the dose of levothyroxine by around 30% as soon as the diagnosis is confirmed; the increased dose requirement persists throughout pregnancy, but dosage can return to normal within a few weeks after delivery.

Hypothyroidism

Reduced production of thyroid hormone is the central feature of the clinical state termed *hypothyroidism*.[1,2] Permanent loss or destruction of the thyroid through processes such as autoimmune destruction, referred to as Hashimoto disease,[3] or irradiation injury is described as *primary hypothyroidism* (Table 13.1). Hypothyroidism due to transient or progressive impairment of hormone biosynthesis is typically associated with compensatory thyroid enlargement. Central or secondary hypothyroidism due to insufficient stimulation of a normal gland is the result of hypothalamic or pituitary disease or defects in the TSH molecule.[4] Transient or temporary hypothyroidism can be observed as a phase of subacute thyroiditis.[5] Primary hypothyroidism is the cause in approximately 99% of cases of hypothyroidism, with less than 1% being due to TSH deficiency or other causes. Central hypothyroidism is discussed in Chapter 11.

Reduced action of thyroid hormone at the tissue level, despite normal or increased thyroid hormone production from the thyroid gland, can also be associated with clinical hypothyroidism. Conditions associated with reduced thyroid hormone action are rare and include abnormalities of thyroid hormone metabolism and defects in nuclear signaling.[6] Consumptive hypothyroidism, identified in an increasing number of clinical settings, is the result of accelerated inactivation of thyroid hormone by the type 3 iodothyronine deiodinase (D3).[7] Defects of activation of the prohormone, T_4, to the active form, triiodothyronine (T_3), have also been identified.[8] Polymorphisms in genes regulating thyroid hormone production and activation may influence thyroid hormone action in some tissues.[9,10] Resistance to thyroid hormone (RTH), the result of defects in the thyroid hormone nuclear receptor (TR) or nuclear cofactors, is associated with elevated circulating levels of thyroid hormone. Some tissues, depending on the level of expression of the mutant receptor and other forms of local compensation, have evidence of reduced thyroid hormone action.[11]

Estimates of the incidence of hypothyroidism vary depending on the population studied.[12,13] In the United States, 0.3% have overt hypothyroidism, defined as an elevated serum TSH concentration and reduced free thyroxine concentration (FT_4), and 4.3% have what has been described as subclinical or mild

TABLE 13.1 Causes of Hypothyroidism

Primary Hypothyroidism

Acquired

Hashimoto thyroiditis
Iodine deficiency (endemic goiter)
Drugs blocking synthesis or release of T_4 (e.g., lithium, ethionamide, sulfonamides, iodide)
Drug-induced thyroid destruction (e.g., interferon alpha, interleukin 2, tyrosine kinase inhibitors, blockers of CTLA4 or PD1)
Amiodarone (reversible or permanent)
Goitrogens in foodstuffs or as endemic substances or pollutants
Thyroid infiltration (amyloidosis, hemochromatosis, sarcoidosis, Riedel struma, cystinosis, scleroderma)
Postablative thyroiditis due to ^{131}I, surgery, or therapeutic irradiation for nonthyroidal malignancy
Transient hypothyroidism following painless thyroiditis (including postpartum) or painful subacute thyroiditis

Congenital

Iodide transport or utilization defect (NIS or pendrin mutations)
Iodotyrosine dehalogenase deficiency
Organification disorders (TPO deficiency or dysfunction)
Defects in thyroglobulin synthesis or processing
Thyroid agenesis or dysplasia
TSH receptor defects
Thyroidal G_s protein abnormalities (pseudohypoparathyroidism type 1a)
Idiopathic TSH unresponsiveness

Consumptive Hypothyroidism

Rapid destruction of thyroid hormone due to D3 expression in large hemangiomas or hemangioendotheliomas

Defects of Thyroxine to Triiodothyronine Conversion

Selenocysteine insertion sequence–binding protein 2 (SECISBP2) defect

Central Hypothyroidism

Acquired

Pituitary origin (secondary)
Hypothalamic disorders (tertiary)
Bexarotene (retinoid X receptor agonist)
Dopamine or severe illness

Congenital

TSH deficiency or structural abnormality
TSH receptor defect

Resistance to Thyroid Hormone

Generalized
"Pituitary" dominant

NIS, Sodium-iodide symporter; *TPO,* thyroid peroxidase; *TSH,* thyroid-stimulating hormone (thyrotropin).

hypothyroidism.[13] Although a number of clinical manifestations have been associated with this early or mild phase of hypothyroidism, we will use the term *subclinical* to describe this group, as is used in most clinical studies. Subclinical hypothyroidism is defined as an elevated serum TSH level with a normal serum FT_4 concentration.[14,15] Subclinical hypothyroidism can progress to overt hypothyroidism and be associated with manifestations that, in some patients, may benefit from treatment.[16] The incidence of hypothyroidism is higher among women, in the elderly, and in some racial and ethnic groups.[17] Neonatal screening programs for congenital hypothyroidism identify hypothyroidism (almost all primary) in almost 1 in 3000 newborns.[18]

Clinical Presentation

Hypothyroidism can affect all organ systems, and these manifestations are largely independent of the underlying disorder but are a function of the degree of hormone deficiency. The following sections discuss the pathophysiology of each organ system at various levels of thyroid hormone deficiency, from mild to severe. The term *myxedema,* formerly used as a synonym for hypothyroidism, refers to the appearance of the skin and subcutaneous tissues in the patient in a severely hypothyroid state (Fig. 13.1). Hypothyroidism of this severity is rarely seen today, and the term should be reserved to describe the physical signs.

Skin and Appendages

Hypothyroidism causes an accumulation of hyaluronic acid that alters the composition of the ground substance in the dermis and other tissues.[19,20] This material is hygroscopic, producing the mucinous edema that is responsible for the thickened features and puffy appearance (myxedema) with full-blown hypothyroidism. Myxedematous tissue is characteristically boggy and nonpitting and is apparent around the eyes, on the dorsa of the hands and feet, and in the supraclavicular fossae (see Fig. 13.1). It causes enlargement of the tongue and thickening of the pharyngeal and laryngeal mucous membranes.

A clinically similar deposit may occur in patients with Graves disease, usually over the pretibial area (infiltrative dermopathy or pretibial myxedema), but it can be differentiated histologically.[21] In addition to having a puffy appearance, the skin in hypothyroidism is pale and cool as a result of cutaneous vasoconstriction. Anemia may contribute to the pallor; hypercarotenemia gives the skin a yellow tint but does not cause scleral icterus (see Fig. 13.1). The secretions of the sweat glands and sebaceous glands are reduced, leading to dryness and coarseness of the skin, which in extreme cases may resemble that seen in patients with ichthyosis.

Wounds of the skin tend to heal slowly. Easy bruising is due to an increase in capillary fragility. Head and body hair is dry and brittle, lacks luster, and tends to fall out. Hair may be lost from the temporal aspects of the eyebrows, although this is not specific for hypothyroidism (see Fig. 13.1B). Growth of hair is retarded so that haircuts and shaves are required less often. The nails are brittle and grow slowly. Topical T_3 has been shown to accelerate wound healing and stimulate hair growth in a euthyroid mouse model, demonstrating a role for thyroid hormone in these processes.[20]

Histopathologic examination of the skin reveals hyperkeratosis with plugging of hair follicles and sweat glands. The dermis is edematous, and the connective tissue fibers are separated by an increased amount of metachromatically staining, periodic acid–Schiff (PAS)–positive mucinous material. This material consists of protein complexed with two mucopolysaccharides: hyaluronic acid and chondroitin sulfate B. The hygroscopic glycosaminoglycans are mobilized early during treatment with thyroid hormone, leading to an increase in urinary excretion of nitrogen and hexosamine as well as tissue water.[19]

Patients with hypothyroidism due to Hashimoto thyroiditis may also have skin lesions with loss of pigmentation characteristic of the autoimmune skin condition vitiligo. This feature is not a

• **Fig. 13.1** (A and B) Typical appearance with moderately severe primary hypothyroidism or myxedema. Note dry skin and sallow complexion; the absence of scleral pigmentation differentiates the carotenemia from jaundice. Both individuals demonstrate periorbital myxedema. (B) This patient illustrates the loss of the lateral aspect of the eyebrow, sometimes termed *Queen Anne sign.* That finding is not unusual in the age group that is commonly affected by severe hypothyroidism and should not be considered to be a specific sign of the condition.

manifestation of reduced thyroid hormone action but reflects the common association of autoimmune endocrine disease and this skin condition, which is recognized as a component of autoimmune polyendocrine syndromes.[22,23]

Cardiovascular System

The cardiac output at rest is decreased because of reduction in both stroke volume and heart rate, reflecting loss of the inotropic and chronotropic effects of thyroid hormones. Peripheral vascular resistance at rest is increased, and blood volume is reduced. These hemodynamic alterations cause narrowing of pulse pressure, prolongation of circulation time, and decrease in blood flow to the tissues.[24,25] The reduction in cutaneous circulation is responsible for the coolness and pallor of the skin and the sensitivity to cold. In most tissues, the decrease in blood flow is proportional to the decrease in oxygen consumption, so the arteriovenous oxygen difference remains normal. The hemodynamic alterations at rest resemble those of congestive heart failure. However, in hypothyroidism, cardiac output increases and peripheral vascular resistance decreases normally in response to exercise unless the hypothyroid state is severe and of long standing.

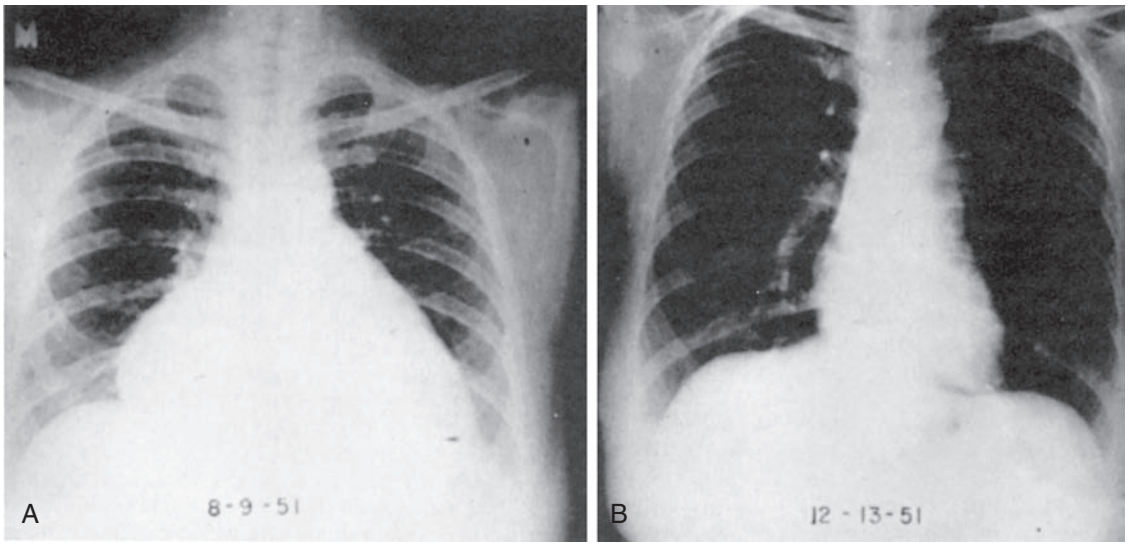
In severe primary hypothyroidism the cardiac silhouette is enlarged (Fig. 13.2), and the heart sounds are diminished in intensity. These findings are the result largely of effusion into the pericardial sac of fluid rich in protein and glycosaminoglycans, but the myocardium may also be dilated. Pericardial effusion is rarely of sufficient magnitude to cause tamponade.

Angina pectoris may first appear or worsen during treatment of the hypothyroid state with thyroid hormone, although most patients with hypothyroidism and coronary artery disease have no change, or improvement, in anginal symptoms with T_4 treatment.[26] Electrocardiographic changes include sinus bradycardia, prolongation of the PR interval, low amplitude of the P wave and QRS complex, alterations of the ST segment, and flattened or inverted T waves. Pericardial effusion is probably responsible for the low amplitude in severe hypothyroidism. Systolic time intervals are altered; the preejection period is prolonged, and the ratio of preejection period to left ventricular ejection time is increased. Echocardiographic studies have revealed resting left ventricular diastolic dysfunction in overt and, in some studies, subclinical hypothyroidism.[27] These findings normalize when the hypothyroidism is treated.

Serum levels of homocysteine, creatine kinase, aspartate aminotransferase, and lactate dehydrogenase may be increased in hypothyroidism.[25,28] Typically the isoenzyme patterns suggest that the source of the increased creatine kinase and lactate dehydrogenase is skeletal, not cardiac, muscle. All levels return to normal with therapy. Sequential cardiac biopsies in a hypothyroid patient with heart failure showed that messenger RNA (mRNA) levels from genes regulated by thyroid hormone and important for the strength of myocardial contraction were normalized after T_4 treatment.[29]

The combination of large heart, hemodynamic and electrocardiographic alterations, and serum enzyme changes has been termed *myxedema heart.* In the absence of coexisting organic heart disease, treatment with thyroid hormone corrects the hemodynamic, electrocardiographic, and serum enzyme alterations of myxedema heart and restores heart size to normal (see Fig. 13.2).

Hypothyroidism is consistently associated with elevations of total and low-density lipoprotein (LDL) cholesterol, which



• **Fig. 13.2** (A and B) Chest roentgenograms in a patient with myxedema heart disease. The patient had signs of severe congestive heart failure and was given thyroid hormone alone. Within 4 months, the heart had returned to normal size (B) and there was no evidence of underlying heart disease.

improve with T_4 replacement.[30] The higher the original serum TSH concentration and elevation of serum LDL, the greater the magnitude of reduction in LDL cholesterol after T_4 therapy. Lipoprotein fractionation has shown that the cholesterol elevation is predominantly due to the less atherogenic large LDL particles. A subset of younger (<50 years) male hypothyroid patients had elevated serum triglycerides and C-reactive protein that improved with T_4 treatment.[31] Most studies have shown that serum high-density lipoprotein (HDL) levels are not influenced by thyroid status.

Hypothyroidism has been shown to be a risk factor for atherosclerosis and cardiovascular disease by several studies, although others have not shown this association.[32] The Whickham Study showed no increase in cardiovascular mortality rate in patients with subclinical hypothyroidism followed for more than 20 years.[12] A prospective study in the United States, following men and women age 65 or older for more than 10 years, showed no influence of hypothyroidism (overt or subclinical) on cardiovascular outcome or mortality rate.[33] Cardiovascular outcome studies suggest that improvement from treatment of hypothyroidism, especially subclinical hypothyroidism, is primarily in those who are middle age and not older individuals (older than 65 years of age).[15,34,35]

Respiratory System

Hypothyroidism affects breathing by actions on the central regulation of respiration as well as the innervation and function of the respiratory muscles, upper airways, and tongue.[36] Pleural effusions usually are evident only on radiologic examination but in rare instances may cause dyspnea. Lung volumes are usually normal, but maximal breathing capacity and diffusing capacity are reduced. In severe hypothyroidism, myxedematous involvement of respiratory muscles and depression of both the hypoxic and the hypercapnic ventilatory drives may cause alveolar hypoventilation and carbon dioxide retention, which in turn can contribute to the development of myxedema coma. An increased prevalence of obstructive sleep apnea is seen in hypothyroid patients, and it is usually reversed with restoration of a euthyroid state.[37]

Alimentary System

Although most patients experience a modest gain in weight, appetite is usually reduced. The weight gain that occurs is caused partly by retention of fluid by the hydrophilic glycoprotein deposits in the tissues but generally does not exceed 10% of body weight. Peristaltic activity is decreased and, together with the decreased food intake, is responsible for the frequent complaint of constipation. The latter may lead to fecal impaction (myxedema megacolon). Gaseous distention of the abdomen (myxedema ileus), if accompanied by colicky pain and vomiting, may mimic mechanical ileus.[38]

Elevations in the serum levels of carcinoembryonic antigen, which may occur on the basis of hypothyroidism alone, add to the impression that an obstruction is present. Ascites in the absence of another cause is unusual in hypothyroidism, but it can occur, usually in association with pleural and pericardial effusions. Like pericardial and pleural effusions, the ascitic fluid is rich in protein and glycosaminoglycans.

Achlorhydria after maximal histamine stimulation may be present in patients with primary hypothyroidism. Circulating antibodies against gastric parietal cells have been found in about one-third of patients with primary hypothyroidism and may be secondary to atrophy of the gastric mucosa. Hypothyroid patients with positive parietal cell antibodies have a higher T_4 requirement compared with antibody-negative patients.[39] Among Swedish celiac disease patients there was a 4.4-fold increased risk for hypothyroidism compared with the general population.[40] Overt pernicious anemia is reported in about 12% of patients with primary hypothyroidism. The coexistence of pernicious anemia and other autoimmune diseases with primary hypothyroidism reflects the fact that autoimmunity plays the central role in the pathogenesis of these diseases (see Chapter 43).[22]

Hypothyroidism has complex effects on intestinal absorption. Although the rates of absorption for many substances are decreased, the total amount absorbed may be normal or even increased because the decreased bowel motility may allow more time for absorption. Malabsorption is occasionally overt.

Liver function test results are usually normal, but levels of aminotransaminases may be elevated, probably because of impaired

clearance.[41] The gallbladder contracts sluggishly and may be distended. In a population study of those without diagnosed thyroid disease, men (but not women) with an elevated TSH had a 3.8-fold increased risk of cholelithiasis.[42] Hypothyroidism is being recognized as a predisposing factor for nonalcoholic fatty liver disease.[43]

Atrophy of the gastric and intestinal mucosa and myxedematous infiltration of the bowel wall may be demonstrated on histologic examination. The colon may be greatly distended, and the volume of fluid in the peritoneal cavity is usually increased. The liver and pancreas are normal.

Central and Peripheral Nervous Systems

Thyroid hormone is essential for the development of the central nervous system.[18,44,45] Deficiency in fetal life or at birth impairs neurologic development, including hypoplasia of cortical neurons with poor development of cellular processes, retarded myelination, and reduced vascularity. If the deficiency is not corrected in early postnatal life, the damage is irreversible. Deficiency of thyroid hormone beginning in adult life causes less severe manifestations that usually respond to treatment with the hormone. Cerebral blood flow is reduced, but cerebral oxygen consumption is usually normal; this finding is in accord with the conclusion that the oxygen consumption of isolated brain tissue in vitro, unlike that of most other tissues, is not stimulated by administration of thyroid hormones. In severe cases, decreased cerebral blood flow may lead to cerebral hypoxia.

All intellectual functions, including speech, are slowed in thyroid hormone deficiency.[46] Loss of initiative is present and memory defects are common, lethargy and somnolence are prominent, and dementia in elderly patients may be mistaken for senile dementia.[47] Positron emission tomography (PET) brain scans of hypothyroid patients before and after T_4 therapy demonstrate reversible reduced glucose uptake in specific brain areas, such as the limbic system, which also correlates with behavioral and psychiatric symptoms.[48] Psychiatric disorders are common and are usually of the paranoid or depressive type and may induce agitation (myxedema madness).[47] Headaches are frequent. Cerebral hypoxia due to circulatory alterations may predispose to confusional attacks and syncope, which may be prolonged and lead to stupor or coma. Other factors predisposing to coma in hypothyroidism include exposure to severe cold, infection, trauma, hypoventilation with carbon dioxide retention, and depressant drugs.

Epileptic seizures have been reported and tend to occur in myxedema coma. Night blindness is due to deficient synthesis of the pigment required for dark adaptation. Hearing loss of the perceptive type is frequent due to myxedema of the eighth cranial nerve and serous otitis media. Perceptive deafness may also occur in association with a defect in the organic binding of thyroidal iodide (Pendred syndrome; see Chapter 11), but in these instances it is not due to hypothyroidism per se.

Thick, slurred speech and hoarseness are due to myxedematous infiltration of the tongue and larynx, respectively.[45] Body movements are slow and clumsy, and cerebellar ataxia may occur. Numbness and tingling of the extremities are frequent; in the fingers these symptoms may be due to compression by glycosaminoglycan deposits in and around the median nerve in the carpal tunnel (carpal tunnel syndrome).[49] The tendon reflexes are slow, especially during the relaxation phase, producing the characteristic "hung-up reflexes"; this phenomenon is due to a decrease in the rate of muscle contraction and relaxation rather than a delay in nerve conduction.

The presence of extensor plantar responses or diminished vibration sense should alert the physician to the possibility of coexisting pernicious anemia with combined system disease. Electroencephalographic changes include slow alpha-wave activity and general loss of amplitude. The concentration of protein in the cerebrospinal fluid is often increased, but cerebrospinal fluid pressure is normal.

Histopathologic examination of the brain in patients with untreated hypothyroidism reveals that the nervous system is edematous with mucinous deposits in and around nerve fibers. In patients with cerebellar ataxia, neural myxedematous infiltrates of glycogen and mucinous material are present in the cerebellum. There may be foci of degeneration and an increase in glial tissue. The cerebral vessels show atherosclerosis, but this finding is much more common if the patient has had coexistent hypertension.

Hypothyroidism has been associated with several neurologic conditions, although a strong etiologic link has not been established. Epidemiologic studies have shown an association between Alzheimer disease and hypothyroidism.[50] It is difficult to convincingly demonstrate this association because the incidence of thyroid disease in the elderly population is high and, like dementia, increases with age. A mechanistic link is suggested by the observation of amyloid deposition in Down syndrome, a condition associated with an increased incidence of Hashimoto disease, and thyroid hormone regulates amyloid gene processing in a number of cellular and animal models. Subclinical hyperthyroidism, however, has also been associated with Alzheimer disease.[51] There is an increase in cerebrospinal fluid reverse T_3 levels in Alzheimer disease patients, all with normal circulating thyroid hormone levels, suggesting the potential for altered thyroid hormone metabolism in the brain.[52] The impact of normalizing T_3 levels in the brain, however, is not known. A corticosteroid-responsive encephalopathy is associated with chronic Hashimoto thyroiditis but may be linked to autoimmunity rather than a process mediated specifically by low thyroid hormone levels or thyroid autoantibodies.[53]

Muscular System

Stiffness and aching of muscles are common in hypothyroidism and are worsened by cold temperatures.[49] Delayed muscle contraction and relaxation cause slowness of movement and delayed tendon jerks.[45] Muscle mass may be reduced or enlarged due to interstitial myxedema. Muscle mass may be slightly increased, and the muscles tend to be firm. Rarely, a profound increase in muscle mass with slowness of muscular activity may be the predominant manifestation (the *Kocher-Debré-Sémélaigne,* or *Hoffmann,* syndrome). Myoclonus may be present. The electromyogram may be normal or may exhibit disordered discharge, hyperirritability, and polyphasic action potentials.

On histopathologic examination, the muscles appear pale and swollen. The muscle fibers may show swelling, loss of normal striations, and separation by mucinous deposits. Type I muscle fibers tend to predominate.

Skeletal System: Calcium and Phosphorus Metabolism

Thyroid hormone is essential for normal growth and maturation of the skeleton, and growth failure is due both to impaired general protein synthesis and to a reduction in growth hormone, but especially of insulin-like growth factor 1 (Fig. 13.3).[54] The thyroid hormone receptor isoforms α and β have specific roles in bone maturation. Before puberty, thyroid hormone plays a major role in the maturation of bone. Deficiency of thyroid hormone in early life leads to both a delay in development and an abnormal, stippled appearance of the epiphyseal centers of ossification

• **Fig. 13.3** The consequences of untreated congenital hypothyroidism are demonstrated in this 17-year-old girl. Her condition had been diagnosed at birth but, through a series of misunderstandings, was not treated with thyroid hormone. Note her size, the poorly developed nasal bridge, the wide-set eyes, and the ears, which are larger than are appropriate for head size. Her tongue is enlarged, and her extremities are inappropriately short in relation to her trunk. (Courtesy Dr. Ronald B. Stein.)

(epiphyseal dysgenesis) (Fig. 13.4). Impairment of linear growth leads to dwarfism, in which the limbs are disproportionately short in relation to the trunk, but cartilage growth is unaffected (see Fig. 13.3). Children with prolonged hypothyroidism, even after adequate treatment, do not reach predicted height based on mid-parental height calculations.[55]

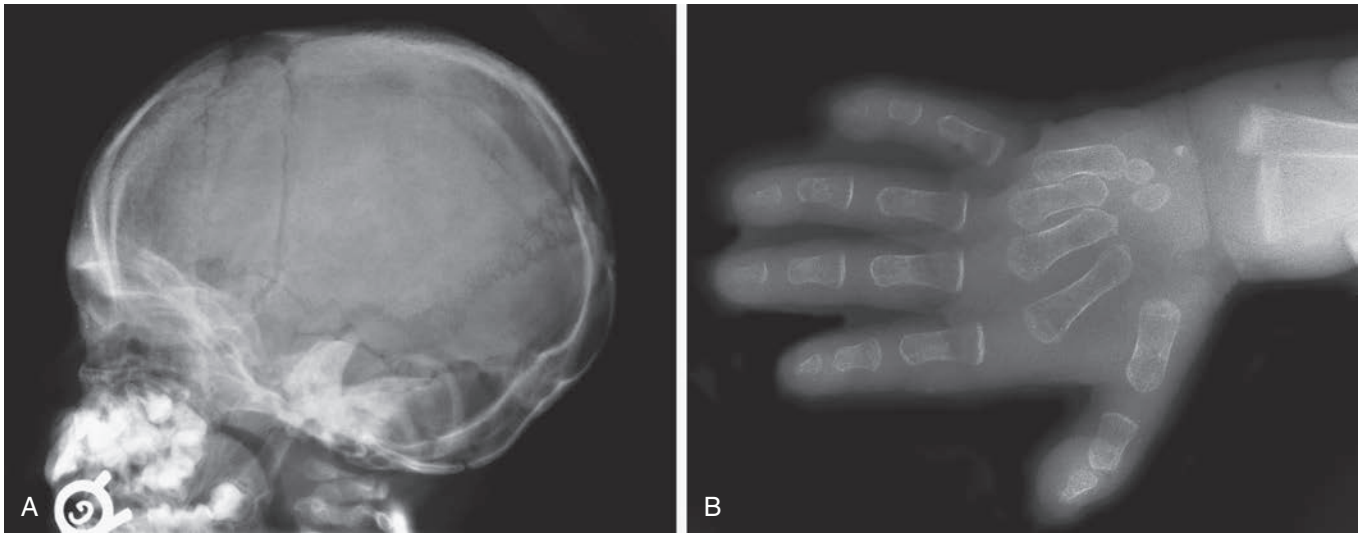
Urinary excretion of calcium is decreased, as is the glomerular filtration rate, whereas fecal excretion of calcium and both urinary and fecal excretion of phosphorus are variable. Calcium balance is also variable, and any changes are slight. The exchangeable pool of calcium and its rate of turnover are reduced, reflecting decreased bone formation and resorption. Because levels of parathyroid hormone are often slightly increased, some degree of resistance to its action may be present; levels of 1,25-dihydroxyvitamin D ($1,25[OH]_2D$) are also increased.

Levels of calcium and phosphorus in serum are usually normal, but calcium may be slightly elevated. The alkaline phosphatase level is usually below normal in infantile and juvenile hypothyroidism. Bone density may be increased. The radiologic appearance of the skeleton in cretinism and juvenile hypothyroidism is discussed subsequently.

Renal Function: Water and Electrolyte Metabolism

Reversible reductions in renal blood flow, glomerular filtration rate, and tubular reabsorptive and secretory maxima are seen in hypothyroidism. Blood urea nitrogen and serum creatinine levels are normal, but uric acid levels may be increased. Urine flow is reduced, and delay in the excretion of a water load may result in reversal of the normal diurnal pattern of urine excretion. The delay in water excretion appears to be due to decreased volume delivery to the distal diluting segment of the nephron as a result of the diminished renal perfusion; evidence supporting inappropriate secretion of vasopressin (syndrome of inappropriate antidiuretic hormone [SIADH] secretion) is less compelling.[56] There is a high prevalence of hypothyroidism in patients with chronic kidney disease, and improvement in renal function has been demonstrated with T_4 treatment.[57]

The impaired renal excretion of water and the retention of water by the hydrophilic deposits in the tissues result in an



• **Fig. 13.4** X-ray films of the skull and hand of the 17-year-old patient illustrated in Fig. 13.3. (A) Skull film shows that the posterior and anterior fontanels are open and that the sutures are not fused. The deciduous and permanent teeth are present. (B) Radiograph of the wrist and hand shows the delayed appearance of the epiphyseal centers of the bones of the hand and the absence of the distal radial epiphysis. The estimated bone age is 9 months. (Courtesy Dr. Ronald B. Stein.)

increase in total body water, even though plasma volume is reduced. This increase accounts for the hyponatremia occasionally noted because the level of exchangeable sodium is increased. The amount of exchangeable potassium is usually normal in relation to lean body mass. Serum magnesium concentration may be increased, but exchangeable magnesium levels and urinary magnesium excretion are decreased.

Hematopoietic System

In response to the diminished oxygen requirements and decreased production of erythropoietin, the red blood cell mass is decreased; this is evident in the mild normocytic, normochromic anemia that often occurs. Less commonly, the anemia is macrocytic, sometimes from deficiency of vitamin B_{12}. Reference has already been made to the high incidence of pernicious anemia (and of achlorhydria and vitamin B_{12} deficiency without overt anemia) in primary hypothyroidism (see Chapter 43). Conversely, overt and subclinical hypothyroidism is present in 12% and 15% of patients, respectively, with pernicious anemia. Folate deficiency from malabsorption or dietary inadequacy may also cause macrocytic anemia. The frequent menorrhagia and the defective absorption of iron resulting from achlorhydria may contribute to a microcytic, hypochromic anemia.

The total and differential white blood cell counts are usually normal, and platelets are adequate, although platelet adhesiveness may be impaired. If pernicious anemia or significant folate deficiency is present, the characteristic changes in peripheral blood and bone marrow will be found. The intrinsic clotting mechanism may be defective because of decreased concentrations in plasma of factors VIII and IX, which, together with an increase in capillary fragility and the decrease in platelet adhesiveness, may account for the bleeding tendency that sometimes occurs.[38,58,59]

Pituitary and Adrenocortical Function

In long-standing primary hypothyroidism, hyperplasia of the thyrotropes may cause the pituitary gland to be enlarged. This feature can be detected radiologically as an increase in the volume of the pituitary gland.[60] Rarely, the pituitary enlargement compromises the function of other pituitary cells and causes pituitary insufficiency or visual field defects. Patients with severe hypothyroidism may have increased serum prolactin levels, stimulated by the elevation in thyrotropin-releasing hormone (TRH) and proportional to the level of serum TSH elevation, and galactorrhea may develop in some patients. Treatment with thyroid hormone normalizes the serum prolactin and TSH levels and causes disappearance of galactorrhea, if present.

In rodents, thyroid hormone directly regulates growth hormone synthesis. Growth hormone is not directly regulated by thyroid hormone in humans, but thyroid status influences the growth hormone axis.[61] Hypothyroid children have delayed growth and the response of growth hormone to provocative stimuli may be subnormal. Individuals affected with RTHα have delayed growth and short stature, indicating the consequences of interference with thyroid hormone signaling through thyroid hormone receptor alpha.[62]

As a result of the decreased rate of turnover of cortisol due to decreased hepatic 11β-hydroxysteroid dehydrogenase type 1 (11βHSD1), the 24-hour urinary excretion of cortisol and 17-hydroxycorticosteroids is decreased, but the plasma cortisol level is usually normal (see Chapter 15). The response of urinary 17-hydroxycorticosteroid to exogenous adrenocorticotropic hormone is usually normal but may be decreased. The response of plasma cortisol to insulin-induced hypoglycemia may be impaired.

In severe, long-standing primary hypothyroidism, pituitary and adrenal function may be secondarily decreased, and adrenal insufficiency may be precipitated by stress or by rapid replacement therapy with thyroid hormone.[61] The rate of turnover of aldosterone is decreased, but the plasma level is normal. Plasma renin activity is decreased, and sensitivity to angiotensin II is increased, which may contribute to the association of hypertension with hypothyroidism (see Chapter 16).[63,64]

Reproductive Function

In both sexes, thyroid hormones influence sexual development and reproductive function.[65] Infantile hypothyroidism, if untreated, leads to sexual immaturity, and juvenile hypothyroidism causes a delay in the onset of puberty followed by anovulatory cycles in girls. Paradoxically, primary hypothyroidism may also rarely cause precocious sexual development and galactorrhea, presumably due to "spillover" of elevated TSH stimulating the luteinizing hormone (LH) receptor and elevated TRH initiating excess prolactin release.

In adult women, severe hypothyroidism may be associated with diminished libido and failure of ovulation. Secretion of progesterone is inadequate, and endometrial proliferation persists, resulting in excessive and irregular breakthrough menstrual bleeding. These changes may be due to deficient secretion of LH and pulse frequency and amplitude. Rarely, in primary hypothyroidism, secondary depression of pituitary function may lead to ovarian atrophy and amenorrhea. Fertility is reduced, and there is an increase in spontaneous abortion and preterm delivery, although many pregnancies are successful.[66] Pregnancy complications are associated with overt and subclinical hypothyroidism, although the impact has varied among different studies.[67] A randomized prospective study of levothyroxine treatment in pregnant women with thyroid peroxidase antibody (TPOAb) positivity but normal range TSH has shown that the increased incidence of preterm delivery and spontaneous abortions is reversed by treatment, although this result remains to be confirmed.[66,68] Primary ovarian failure can also be seen in patients with Hashimoto thyroiditis as part of an autoimmune polyendocrine syndrome.[22,23] Hypothyroidism in men may cause diminished libido, erectile dysfunction, and oligospermia. A significant fraction of men with both hypothyroidism and hyperthyroidism have moderate to severe erectile dysfunction, which improves with treatment of the thyroid disease.[69]

Values for plasma gonadotropins are usually in the normal range in primary hypothyroidism; in postmenopausal women, levels are usually somewhat lower than in euthyroid women of the same age but are nevertheless within the menopausal range. This feature provides a valuable means of differentiating primary from secondary hypothyroidism.

The metabolism of both androgens and estrogens is altered in hypothyroidism. Secretion of androgens is decreased, and the metabolism of testosterone is shifted toward etiocholanolone rather than androsterone. With respect to estradiol and estrone, hypothyroidism favors metabolism of these steroids via 16α-hydroxylation over that via 2-oxygenation, with the result that formation of estriol is increased and that of 2-hydroxyestrone and its derivative, 2-methoxyestrone, is decreased. The sex hormone–binding globulin in plasma is decreased, with the result that the plasma concentrations of both testosterone and estradiol are decreased, but the unbound fractions are increased. The

alterations in steroid metabolism are corrected by restoration of the euthyroid state.[70]

Catecholamines

The plasma cyclic adenosine monophosphate (cAMP) response to epinephrine is decreased in hypothyroidism, suggesting a state of decreased adrenergic responsiveness. The fact that the responses of plasma cAMP to glucagon and parathyroid hormone are also decreased suggests that thyroid hormones have a general modulating influence on cAMP generation.[71] The reduced adrenergic responsiveness associated with hypothyroidism has been linked to all steps of catecholamine signaling, including receptor and postreceptor actions, resulting in an impaired cAMP response. Direct measurement of norepinephrine in abdominal fat of hypothyroid patients shows reduced levels, and there is reduced production of glycerol in response to adrenergic agonist stimulation.[72] Augmentation of α_2-receptor signaling has also been proposed as a factor reducing catecholamine responsiveness.

Energy Metabolism: Protein, Carbohydrate, and Lipid Metabolism

The decrease in energy metabolism and heat production is reflected in a low basal metabolic rate, decreased appetite, cold intolerance, and slightly low basal body temperature.[73–75] Both the synthesis and the degradation of protein are decreased, the latter especially so, with the result that nitrogen balance is usually slightly positive. The decrease in protein synthesis is reflected in retardation of both skeletal and soft tissue growth.

Permeability of capillaries to protein is increased, accounting for the high levels of protein in effusions and in cerebrospinal fluid. In addition, the albumin pool is increased because of the greater decrease in albumin degradation compared to albumin synthesis. A greater than normal fraction of exchangeable albumin is in the extravascular space. The total concentration of serum proteins may be increased.

Hypothyroidism is associated with a reduction in glucose disposal to skeletal muscle and adipose tissue.[76] Thyroid hormone has been shown to stimulate expression of the insulin-sensitive glucose transporter (GLUT4), and the levels of this transporter are reduced in hypothyroidism. Hypothyroidism is also, however, associated with reduced gluconeogenesis. The net effect of these influences is usually a minimal effect of hypothyroidism on serum glucose levels. Thyroid hormone downregulates expression of prohormone processing enzymes, which therefore have increased activity in hypothyroidism. Degradation of insulin therefore is slowed, and the sensitivity to exogenous insulin may be increased. In a patient with preexisting diabetes mellitus who develops hypothyroidism, insulin requirements may be reduced. A further influence on glucose uptake may occur at the tissue level. Polymorphisms in the 5′-deiodinase type 2 (D2) gene, which may affect local T_3 production, have been shown to be associated with impaired glucose disposal.[77]

Both the synthesis and the degradation of lipid are depressed in hypothyroidism. Degradation, however, is reduced to a greater extent, with a net effect of accumulation of LDL and triglycerides.[30,73] The decrease in the lipid degradation rate may reflect the decrease in postheparin lipolytic activity as well as reduced LDL receptors. Plasma free fatty acid levels are decreased, and the mobilization of free fatty acids in response to fasting, catecholamines, and growth hormone is impaired. Impaired lipolysis of white fat in hypothyroid patients at baseline and in response to catecholamine reflects impaired free fatty acid mobilization.[71,72] All of these abnormalities are relieved by treatment.

An elevation in serum LDL cholesterol has been associated, in most studies, with both overt and subclinical hypothyroidism.[30] According to most studies, serum HDL and triglyceride levels are not influenced by hypothyroidism.[73] The reduction in LDL with T_4 therapy is generally related to the original magnitude of LDL and TSH elevation; the higher the initial levels, the greater the reduction in LDL that is observed. A typical reduction in LDL is 5% to 10% of the original level.

The role of adipocytokines, such as leptin, adiponectin, and resistin, in metabolic regulation has been increasingly recognized as well as the potential for interaction with thyroid hormone.[75] Rodent studies have shown that leptin regulates central adaptation between the starved and fed state and that falling leptin levels, associated with starvation, lead to a suppression of the thyroid axis. Hypothyroidism in rodents is associated with reduced leptin and increased resistin levels. Leptin infusion into the cerebral ventricles reverses some of the metabolic changes seen with hypothyroidism, including improved glucose disposal and reduced skeletal muscle fat.[78] Human studies, however, have not shown consistent changes in adipocytokines in hypothyroidism.[79]

Current Clinical Picture

In the adult, the onset of hypothyroidism is usually so insidious that the typical manifestations may take months or years to appear and go unnoticed by family and friends. The gradual development of the hypothyroid state is due to slow progression both of thyroid hypofunction and of the clinical manifestations after thyroid failure is complete. This course is in contrast with the more rapid development of the hypothyroid state when replacement therapy is discontinued in a patient with treated primary hypothyroidism or when the thyroid gland of a normal subject is surgically removed. In such patients, manifestations of frank hypothyroidism are usually present by 6 weeks and myxedema appears by 3 months.

Hypothyroidism continues to be diagnosed at earlier stages.[1,2,80] Based on the most recent data, subclinical or early hypothyroidism is seen approximately 14 times more commonly than overt hypothyroidism. Early symptoms are variable and relatively nonspecific. The reason for the increased prevalence of hypothyroid patients presenting with minimal symptoms is largely the availability of sensitive and specific laboratory tests that allow recognition of the primary form of the disease long before severe symptoms have developed. There should thus be a low threshold to test patients for suspected primary hypothyroidism with a serum TSH determination. Patients with significant biochemical abnormalities of hypothyroidism may not score high on indices of symptoms and signs.[81]

With respect to physical signs of hypothyroidism, the presence of coarse skin, periorbital puffiness that obscures the curve of the malar bone (see Fig. 13.1), cold skin, and delayed ankle reflex relaxation phase are all signs that should lead to appropriate diagnostic tests.

Acute hypothyroidism in the previously hyperthyroid patient seen after radioiodine therapy may also be characterized by painful cramping of large muscle groups, as discussed in Chapter 12 regarding Graves disease.

Hypothyroidism in Infants and Children

Severe hypothyroidism is seldom apparent at birth, perhaps due to the partial protection afforded by transplacental transfer of maternal thyroid hormones, hence the requirement for systematic screening for congenital hypothyroidism.[18] Congenital hypothyroidism can be due to complete thyroid agenesis, ectopic thyroid,

or incomplete thyroid development. Mutations in genes important for thyroid development have been identified in a number of patients and in some cases may explain associated abnormalities in development of other structures, such as the heart, because of their spatial association during development. The age at which symptoms appear depends on the degree of impairment of thyroid function (see Figs. 13.3 and 13.4). Severe hypothyroidism in infancy is termed *cretinism.* As the age at onset increases, the clinical picture of cretinism merges imperceptibly with that of juvenile hypothyroidism. Retardation of mental development and growth, the hallmark of cretinism, becomes manifest only in later infancy, and the former is largely irreversible. Consequently, early recognition is crucial and has been achieved by universal population screening in the developed world by measuring serum T_4 or TSH concentrations routinely in filter paper blood spots from neonates. During the first few months of life, symptoms and signs of hypothyroidism include feeding problems, failure to thrive, constipation, a hoarse cry, somnolence, and jaundice. In succeeding months, especially in severe cases, protuberance of the abdomen, dry skin, poor growth of hair and nails, and delayed eruption of the deciduous teeth become evident. Retardation of mental and physical development is manifested by delay in reaching the normal milestones of development, such as holding up the head, sitting, walking, and talking.

Thyroid hormone plays a major role in bone development, and thyroid hormone receptors are expressed in osteoclasts and osteoblasts.[54] The primary targets of thyroid hormone have been identified in the epiphyseal plates. Impairment of linear growth in congenital hypothyroidism results in dwarfism, with the limbs disproportionately short in relation to the trunk (see Fig. 13.3). Delayed closure of the fontanels causes the head to be large in relation to the body. The naso-orbital configuration remains infantile. Maldevelopment of the femoral epiphyses results in a waddling gait. The teeth are malformed and susceptible to caries. The characteristic appearance includes a broad and flat nose, widely set eyes, periorbital puffiness, large protruding tongue, sparse hair, rough skin, short neck, and protuberant abdomen with an umbilical hernia. Mental deficiency is usually severe.

Radiologic examination of the skeleton is diagnostic. The skull shows a poorly developed base, delayed closure of the fontanels, widely set orbits, and a short and flat nasal bone. The pituitary fossa may be enlarged. Shedding of deciduous teeth and eruption of permanent teeth are delayed (see Fig. 13.4).

The radiologic picture of epiphyseal dysgenesis is virtually pathognomonic of hypothyroidism in infancy and childhood and may involve any center of endochondral ossification, depending on the age at onset of the hypothyroid state; it is usually best seen in the femoral and humeral heads and the navicular bone of the foot. The centers of ossification appear late, so bone age is retarded in relation to chronologic age; when they eventually appear, instead of a single center, multiple small centers are scattered throughout a misshapen epiphysis (see Fig. 13.4). These small centers of ossification eventually coalesce and form a single center with an irregular outline and a stippled appearance (stippled epiphysis). Epiphyseal dysgenesis is evident only in centers that normally ossify at a time after the onset of the hypothyroidism. After a normal metabolic state is restored by treatment, centers destined to ossify at a later age develop normally.

Hypothyroidism that begins in childhood is usually Hashimoto disease and can be transient in this age group. Subclinical hypothyroidism is also seen in children and adolescents, and in one study those affected were more likely to be obese and have a family history of thyroid disease.[82] The clinical manifestations of hypothyroidism in children are intermediate, between those of infantile and those of adult hypothyroidism, in that the developmental retardation is not as severe as that of cretinism, and the manifestations of full-blown adult myxedema are rarely seen. Growth and sexual development are affected predominantly. If left untreated, linear growth is severely retarded and sexual maturation and the onset of puberty are delayed.[55,83] On radiologic examination, epiphyseal dysgenesis may be present, and epiphyseal union is always delayed, resulting in a bone age that is younger relative to chronologic age.

Laboratory Evaluation

Primary and Central Hypothyroidism

A decrease in secretion of the thyroid hormones is common to all varieties of hypothyroidism, except for disorders of thyroid hormone metabolism or action, such as *consumptive hypothyroidism* and *resistance to thyroid hormone* (see later). In patients with primary thyroid disease—the cause of hypothyroidism in more than 99% of the patients—there is a significant increase in basal serum TSH concentration. A strategy for evaluating the patient suspected of hypothyroidism involves a TSH determination (Table 13.2). If the suspicion of hypothyroidism is strong, if a goiter is present, or if central hypothyroidism is part of the differential diagnosis, an FT_4 assay should be included (see Chapter 11). If hypothyroidism is thought to be unlikely but must be excluded, only a TSH determination is required because primary hypothyroidism is almost always the cause. If TSH is elevated, an FT_4 assay can be added to the same determination (Fig. 13.5). As hypothyroidism progresses, the serum TSH increases further, the serum FT_4 falls, and finally at the most severe stage serum T_3 concentrations may become subnormal (see Table 13.2). The persistence of a normal serum T_3 is in part due to preferential synthesis and secretion of T_3 by residual functioning thyroid tissue under the influence of the increased plasma TSH. In addition, the efficiency of conversion of T_4 to T_3 by D2 is increased as the serum T_4 level falls.[84] Consequently, the serum T_3 concentration may remain within the normal range.

The principal differential diagnosis is between primary and central hypothyroidism (see Chapter 9).[85] The serum TSH concentration is the critical laboratory determination that in general allows recognition of the cause of the disease when the serum FT_4 is reduced. An exception is the individual with a recent history of thyrotoxicosis (and suppressed TSH) in whom a low FT_4 level may be associated with a reduced TSH level for several months after treatment of the thyrotoxicosis. In patients with primary hypothyroidism, the absence of TPOAb raises a possible diagnosis of transient hypothyroidism following an undiagnosed episode of painful subacute thyroiditis, also referred to as postviral, de Quervain, granulomatous, or pseudotuberculous thyroiditis.

The differentiation of hypothyroidism due to intrinsic thyroid failure from hypothyroidism due to diminished TSH secretion from hypothalamic or pituitary disease (central or secondary hypothyroidism) is the most critical decision point in this pathway (see Fig. 13.5).[4] A low thyroid hormone level with a normal or low TSH level should lead to an evaluation for the possibility of failure of other endocrine systems that require trophic pituitary hormones for normal function (see Table 13.1) (see Chapters 8 and 9). In some patients with central hypothyroidism, the basal serum TSH concentration (and the response to TRH) may even

TABLE 13.2 Laboratory Evaluation of Patients With Suspected Hypothyroidism or Thyroid Enlargement[a]

TSH, Free T_4	TPOAb	Diagnosis
TSH >10 mU/L		
Low	+	Primary hypothyroidism due to autoimmune thyroid disease
Low-normal	+	Primary "subclinical" hypothyroidism (autoimmune)
Low or low-normal	–	Recovery from systemic illness
		External irradiation, drug-induced, congenital hypothyroidism
		Iodine deficiency
		Seronegative autoimmune thyroid disease
		Rare thyroid disorders (amyloidosis, sarcoidosis, etc.)
		Recovery from subacute granulomatous thyroiditis
Normal	+, –	Consider TSH or T_4 assay artifacts
Elevated	–	Thyroid hormone resistance
		Blockade of T_4 to T_3 conversion (amiodarone) or a congenital 5′-deiodinase deficiency
		Consider assay artifacts
TSH 5–10 mU/L		
Low, low-normal	+	Early primary autoimmune hypothyroidism
Low, low-normal	–	Milder forms of nonautoimmune hypothyroidism (see earlier)
		Central hypothyroidism with impaired TSH bioactivity
Elevated	– (+)	Consider thyroid hormone resistance
		T_4 to T_3 conversion blockade (e.g., amiodarone)
TSH 0.5–5 mU/L		
Low, low-normal	– (+)	Central hypothyroidism
		Salicylate or phenytoin therapy
		Desiccated thyroid or T_3 replacement
TSH <0.5 μU/L		
Low, low-normal	– (+)	"Post-hyperthyroid" hypothyroidism (^{131}I or surgery)
		Central hypothyroidism
		T_3 or desiccated thyroid excess
		Following excess levothyroxine withdrawal

[a]Initial tests: serum TSH, serum free T_4, TPO, or TgAb.

TgAb, Anti-thyroglobulin antibody; *TPOAb,* thyroid peroxidase autoantibody; *TSH,* thyroid-stimulating hormone (thyrotropin); *+,* present; *–,* not present.

be somewhat elevated, but the TSH has reduced biologic potency even though it is immunologically reactive.[4]

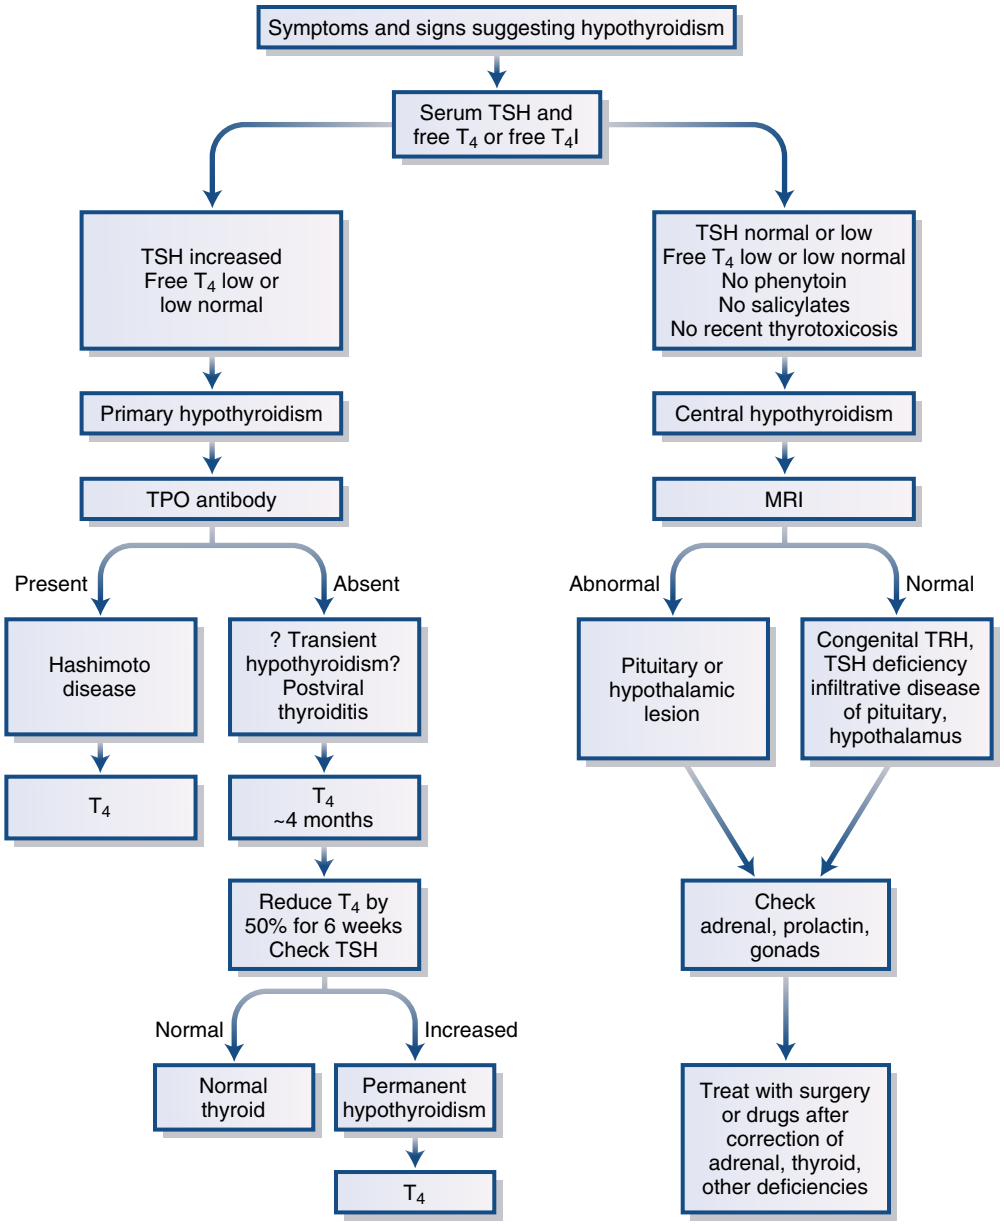
In patients with an elevated TSH level and a reduced FT_4, the presence of TPOAb generally points to autoimmune thyroid disease (Hashimoto disease) as the cause of the hypothyroidism (see Fig. 13.5). On the other hand, the absence of TPOAb raises the possibility of less common causes of hypothyroidism such as transient hypothyroidism, infiltrative thyroid disorders, and external irradiation, as discussed later (see Table 13.1), although rarely patients with Hashimoto disease will not have detectable thyroglobulin or TPOAb.

Measurement of radioactive iodine uptake (RAIU) is rarely required in the evaluation of hypothyroidism. Tests that use radioiodine to assess the function of the thyroid gland display a variable pattern, depending on the underlying thyroid disorder. The diagnostic value of a low RAIU is limited because of the relatively high dietary iodine intake in North America, reducing uptake of the tracer dose of radioiodine, and variation in iodine intake from day to day in the same individual. National surveys of dietary iodine intake had shown a progressive reduction in iodine intake over the past several decades, but the intake has now stabilized.[86] The RAIU may be normal or even increased when hypothyroidism results primarily from a biochemical defect in thyroid hormone synthesis rather than thyroid cell destruction leading to compensatory thyroid enlargement. Specific functional patterns in relation to the causes of hypothyroidism are discussed later. Nonetheless, measurement of RAIU is almost never required in the diagnostic evaluation of the hypothyroid patient.

Differential Diagnosis

The clinical picture of fully developed hypothyroidism is quite characteristic, but the abnormalities can be overlooked, even by experienced clinicians, if the diagnosis is not considered. Despite the availability of inexpensive and specific tests, it is still surprising how often what is retrospectively obvious, severe, primary hypothyroidism is not recognized. A high index of suspicion is required to avoid this oversight.

For the milder forms of hypothyroidism, the clinical presentation overlaps to a significant extent with other conditions. The fact that these disorders often occur in older patients is partly responsible for the diagnostic uncertainty.[2] In some cases, slowing of mental and physical activity, dry skin, and loss of hair may mimic similar findings in hypothyroidism. Furthermore, older people often become hypothermic with cold exposure. In patients with chronic renal insufficiency, anorexia, torpor, periorbital puffiness, sallow complexion, and anemia (e.g., see Fig. 13.1) may suggest hypothyroidism and may call for specific testing. Distinguishing nephrotic states from hypothyroidism by clinical examination alone may be even more difficult. In this disorder, waxy pallor, edema, hypercholesterolemia, and hypometabolism may suggest hypothyroidism. In addition, the total serum T_4 concentration may be decreased if significant thyroid-binding globulin is lost in the urine but the FT_4 and TSH would be normal. In patients with pernicious anemia, psychiatric abnormalities, pallor, and numbness and tingling of the extremities may mimic similar findings in hypothyroidism. Although there is a clinical and immunologic overlap between primary hypothyroidism and pernicious anemia, this association is not invariable (see Chapter 43). The presence of hypothyroidism is often suspected in patients who are severely ill, especially in the elderly.[34,87] In such patients, the total T_4 concentration may be decreased, often markedly so, but the FT_4 is generally normal unless the patient is severely ill (see Chapter 11).



• **Fig. 13.5** Strategy for the laboratory evaluation of patients with suspected hypothyroidism. The principal differential diagnosis is between primary and central hypothyroidism (see Chapter 9). The serum thyrotropin *(TSH)* concentration is the critical laboratory determination that in general allows recognition of the cause of the disease. An exception is the individual with a recent history of thyrotoxicosis (and suppressed TSH) in whom a low free thyroxine *(T_4)* level may be associated with a reduced TSH level for several months after relief of the thyrotoxicosis. In patients with primary hypothyroidism, the absence of thyroid peroxidase *(TPO)* antibodies raises a possible diagnosis of transient hypothyroidism following an undiagnosed episode of subacute or postviral thyroiditis. In such patients, a trial of levothyroxine in reduced dosage after 4 months may reveal recovery of thyroid function, thus avoiding permanent levothyroxine replacement. *MRI,* magnetic resonance imaging; *TRH,* thyrotropin-releasing hormone; *T_4I,* thyroxine index.

These features, together with the absence of an elevation of serum TSH, usually serve to differentiate the ill euthyroid patient from one with primary hypothyroidism. The serum TSH, however, can be transiently increased (up to 20 mU/L) during recovery from severe illness.[88]

Hypothyroidism may develop either because of some extrinsic factor or acquired condition or because of a congenital defect impairing thyroid hormone biosynthesis (see Table 13.1). Inadequate synthesis of hormone leads to hypersecretion of TSH, which in turn produces both goiter and stimulation of all steps in hormone biosynthesis capable of response. In some instances, however, the compensatory TSH response overcomes the impairment in hormone biosynthesis, and the patient is euthyroid with a goiter. The latter condition is discussed in Chapter 14 regarding simple or nontoxic goiter. Less commonly, hypothyroidism is associated with an atrophic gland or, in the case of a congenital abnormality, one that never developed properly. Hypothyroidism occurs in about 20% of patients after surgical lobectomy, with an increased risk in areas of iodine insufficiency or in patients with anti-TPOAb.[89]

Classification

Immune-Mediated

Autoimmune Hypothyroidism

Autoimmunity is responsible for over 90% of noniatrogenic hypothyroidism in countries with iodine sufficiency. The annual incidence of autoimmune hypothyroidism is around 80 per 100,000 men and 350 per 100,000 women.[90] All ages may be affected, although the average age of onset is between 40 and 60 years. The disorder is more frequent in whites and Asians than in African Americans. The initial presentation depends on the stage of disease. Juvenile and adolescent autoimmune thyroiditis may be self-limiting. Hashimoto thyroiditis is the commonest cause of goiter in iodine-sufficient regions; atrophic thyroiditis (primary myxedema) presents as hypothyroidism without a goiter.

Circulating autoantibodies against thyroglobulin and TPO are present in almost all patients with autoimmune hypothyroidism. Up to 20% of patients with autoimmune hypothyroidism have TSH receptor antibodies that block the receptor, rather than stimulating it, as in Graves disease; in rare patients there may be switching from one type of antibody to the other, resulting in alternating hypothyroidism and hyperthyroidism.[91,92] Less commonly, patients produce autoantibodies against the sodium-iodide symporter (NIS), pendrin, and T_4 and T_3, but the functional relevance of these antibodies is not known.

Around 15% of women and 3% of men have positive thyroid autoantibodies but no other clinical features of thyroid disease; most of them, however, will have histologic evidence of focal thyroiditis. Longitudinal studies have shown that euthyroid women with high initial levels of autoantibodies against thyroglobulin or TPO and those whose TSH is within the upper half of the reference interval are the most likely to progress to overt hypothyroidism.[93]

Autoimmune hypothyroidism is commonly found in association with a range of autoimmune disorders, including pernicious anemia, systemic lupus erythematosus, Addison disease, celiac disease, and vitiligo.[23,94] A steroid-responsive encephalopathy (referred to as Hashimoto encephalopathy) has been reported in individuals with positive TPOAb, irrespective of thyroid dysfunction, but it is unclear whether there is a true causal relationship, for instance, through immunologic cross-reactivity with brain tissue.[53,95]

Pathophysiology. The current understanding of autoimmune mechanisms has been discussed in Chapter 12, and the main features associated with autoimmune hypothyroidism are summarized in Fig. 13.6. T-cell–mediated tissue injury is believed to be the most important cause of autoimmune thyroid follicular cell destruction. Perforin-containing cytotoxic $CD8^+$ T cells are abundant in the intrathyroidal lymphocytic infiltrate in Hashimoto thyroiditis. These T cells increase during the evolution of disease and recognize both thyroglobulin and TPO.[96] Apoptosis is an additional pathway for thyroid cell destruction. In Hashimoto thyroiditis, thyroid follicular cells express both Fas (CD95) and Fas ligand (CD95L) and may thus self-destruct when these molecules interact; it is now clear that other decoy death receptors and regulators of apoptosis signaling play an additional role.[97] There is also an increase in the number of intrathyroidal Th17 lymphocytes in Hashimoto thyroiditis, implying a pathogenic role for this proinflammatory T-cell subset.[98] The differentiation of Th17 cells may be enhanced by iodine. Cytokines released by T cells and other inflammatory cells cause Hürthle cell formation and thyroid dysfunction. The thyroid cells also respond to cytokines by expressing a number of proinflammatory molecules, such as chemokines and adhesion molecules, which increase the potential for T-cell binding and cytotoxicity.

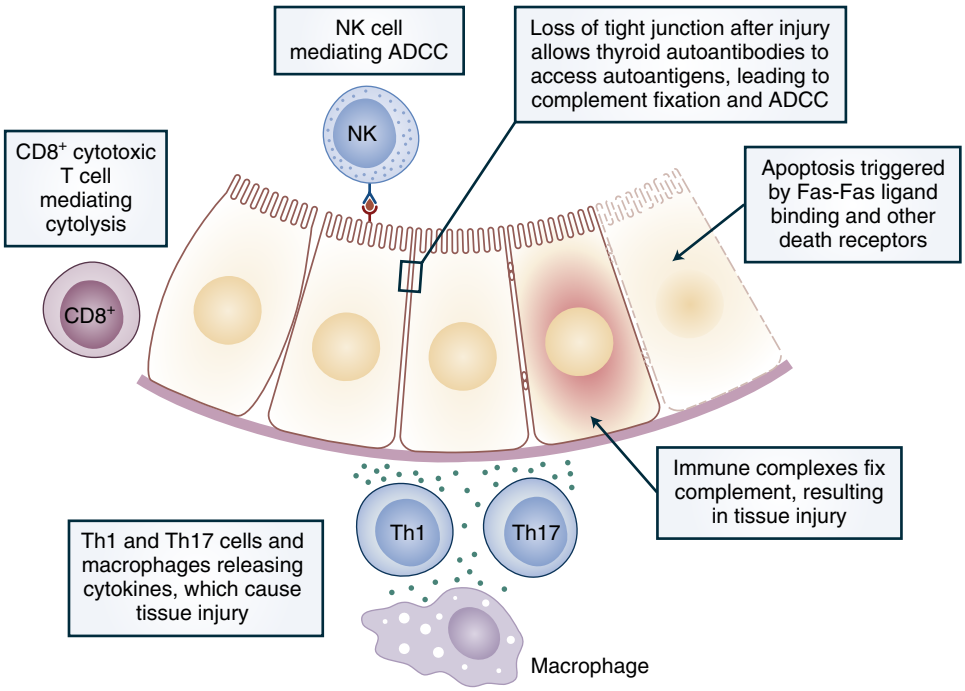
Apart from the striking activity of TSH receptor blocking antibodies, which can induce temporary neonatal hypothyroidism following their transfer across the placenta,[99,100] the pathogenic role of antibodies in autoimmune hypothyroidism is unclear.[101] No neonatal disorders have been associated with the presence of high thyroglobulin or TPO autoantibodies in mothers, indicating that any role in tissue injury is likely to be secondary to an initial phase of T-cell–mediated damage, which allows the autoantibodies to access their target antigens. Such injury may be mediated through antibody-dependent cell-mediated cytotoxicity, involving natural killer (NK) cells, or through complement fixation in the case of TPO antibodies.[102]

Histopathology. The pathologic features of autoimmune hypothyroidism vary from mild focal thyroiditis to extensive lymphocytic infiltration and fibrosis. In classical Hashimoto thyroiditis (originally termed *struma lymphomatosa*), the thyroid gland may be diffusely enlarged or nodular; the tissue is pale and firm and has a rubbery texture (Fig. 13.7A). Typically there is a diffuse lymphocytic infiltration with germinal center formation and obliteration of thyroid follicles, accompanied by a variable degree of fibrosis (see Fig. 13.7B). Destruction of thyroid epithelial cells occurs as disease progresses from euthyroidism to hypothyroidism; in some patients there is follicular cell metaplasia and the formation of Hürthle cells. Rarely, there are concurrent histologic changes of Graves disease, so-called hashitoxicosis. In the other broad type of autoimmune hypothyroidism, termed *atrophic thyroiditis* or *primary myxedema,* the gland is atrophied and consists of extensive fibrotic tissue, moderate lymphocytic infiltration, and widespread loss of thyroid follicles, but the fibrosis is not as extensive as in Riedel thyroiditis (see Fig. 13.7C). The histopathologic changes in painless thyroiditis resemble Hashimoto thyroiditis.

Although it is now generally thought that these variations represent a spectrum of disease arising from a common underlying autoimmune process, a distinct subset of patients with Hashimoto thyroiditis has been delineated recently in whom there are high circulating levels of IgG4 and increased numbers of IgG4-positive plasma cells in the thyroid. Such IgG4-related thyroiditis is characterized pathologically by a greater degree of stromal fibrosis, lymphoplasmacytic infiltration, and hypothyroidism.[103]

Risk Factors

Genetic Susceptibility. The importance of genetic factors in the cause of autoimmune hypothyroidism is indicated by the frequent presence of thyroid autoantibodies, thyroid disease, and other autoimmune disorders in family members and by twin studies, which show a high concordance rate (0.55) in monozygotic but not dizygotic twins.[104] As with all autoimmune endocrinopathies, human leukocyte antigen (HLA)–D region polymorphisms play a role in susceptibility, and Hashimoto thyroiditis is associated with HLA-DR3 and to a lesser extent HLA-DR4.[105] Polymorphisms in the *PD1* gene also confer susceptibility, with lesser contributions from polymorphisms in the *CD40* gene and the gene encoding thyroglobulin, as well as other unconfirmed candidate genes.[106,107] It is clear that new analytic approaches are likely to reveal many other genes, which make small etiologic contributions that account for the diversity of clinical presentation. For example, a combination of novel genetic markers has been described and is associated with an increased risk of progression from TPOAb



• **Fig. 13.6** Summary of the main mechanisms involved in the pathogenesis of autoimmune hypothyroidism. *ADCC,* antibody-dependent cell-mediated cytotoxicity; *NK,* natural killer.

positivity to hypothyroidism, including polymorphism in the *MAGI3* gene.[108]

Shared genetic susceptibility accounts for the frequent occurrence of other autoimmune disorders in patients with autoimmune hypothyroidism. Around half of women with Turner syndrome are positive for thyroid autoantibodies and a third develop hypothyroidism.[109] There is also an increase in autoimmune hypothyroidism in children with Down syndrome, which may evolve into Graves disease in some cases.[110]

Nongenetic Risk Factors. Many of the factors that have been identified as increasing the risk for Graves disease (pregnancy, drugs, age, sex, iodine, and irradiation) apply equally to autoimmune thyroiditis. These factors are detailed in Chapter 12 but briefly considered here. Epidemiologic data suggest a strong influence of environmental factors in Hashimoto thyroiditis, as this was a rare disease before the 1950s but it is now one of the most common autoimmune disorders.[111]

Sex and Pregnancy. The female preponderance of autoimmune hypothyroidism may be due to sex hormones; skewed X-chromosome inactivation has also been proposed as an additional explanation. During pregnancy, fetal tolerance is maintained by changes in immunoregulation that have the coincidental effect of improving thyroid autoimmunity but then lead to postpartum exacerbation of the autoimmune process.[112] This phenomenon results in transient postpartum thyroiditis, a form of painless subacute thyroiditis (see Chapter 12), and in 10% to 50% of these cases permanent hypothyroidism may appear over the next decade.[113] Those women with hypothyroidism and positive TPO antibodies during the phase of postpartum thyroiditis are most at risk of such an outcome.

Iodine and Selenium. An excessive intake of iodine can precipitate autoimmune thyroiditis in susceptible populations.[114] This form of hypothyroidism should be distinguished from direct blockade of a thyroid gland by iodine (the Wolff-Chaikoff effect).[115] Evidence accumulated in animal models suggests that increased iodination of thyroglobulin enhances its immunoreactivity, and iodine may also cause thyroid injury through the generation of reactive oxygen metabolites.[116] There are epidemiologic data to suggest that selenium deficiency exacerbates autoimmune thyroiditis, but trials of selenium supplementation have been inconclusive with regard to clinical benefit.[117,118]

Drugs and Smoking. Treatment of patients with cytokines may precipitate the appearance of autoimmune thyroid disease in the form of Hashimoto thyroiditis or Graves disease (see later).[119] A number of novel anticancer treatments, including TKIs (such as sunitinib), cytotoxic T-lymphocyte–associated protein 4 (CTLA4) blockers (such as ipilimumab), and PD1 blockers (such as pembrolizumab and nivolumab), can also induce autoimmune thyroiditis.[120,121] There is a higher than expected prevalence of autoimmune hypothyroidism in patients treated with lithium. Anthracene derivatives and other chemicals produce autoimmune thyroiditis in animals, but the role of environmental toxins in human disease is poorly studied. Smoking is associated with a decreased risk of autoimmune thyroiditis, but the risk rises temporarily when smoking is stopped.[122] Moderate alcohol consumption is also protective.[123]

Irradiation. Radiation exposure has been shown to induce thyroid autoantibodies and autoimmune thyroid disease in a number of studies. These exposures include radiation from the atomic bomb detonation in Japan[124] and radioactive fallout from the Chernobyl disaster, which was followed by an increase in the prevalence of thyroid autoantibodies in exposed children, with a small overall increase in the prevalence of hypothyroidism 12 to 14 years later.[125] Hodgkin disease survivors have a 17-fold relative risk of developing hypothyroidism, but this may in part be a direct effect of irradiation.[126]

Age. Autoimmune hypothyroidism continues to occur throughout adult life (except in the very elderly whose longevity may be

• **Fig. 13.7** Hashimoto thyroiditis. associated with superior immunoregulation) so that the prevalence of the disease increases markedly with age.[12,17,87] This feature is similar to other types of autoimmunity and may reflect an increasing loss of tolerance to self.

Infection. There is no direct evidence that infection causes autoimmune thyroiditis in humans, although there is some evidence that the hepatitis C virus may precipitate thyroid disease in susceptible patients.[118] In addition, there is follow-up evidence from patients with painful subacute thyroiditis, following a viral infection (see later), that long-term hypothyroidism occurs in around 15% of patients and some of these cases may have an autoimmune basis.

Clinical Picture. Goiter, the hallmark of classic Hashimoto disease, usually develops gradually and may be found during routine examination or by ultrasonography. On occasion, the thyroid gland enlarges rapidly and, when accompanied by pain and tenderness, may mimic painful subacute thyroiditis (see Chapter 12). Some patients are hypothyroid when first seen. The goiter is generally painless, moderate in size, and firm in consistency and moves freely on swallowing. The surface can be either smooth or nodular. Both lobes are enlarged, but the gland may be asymmetric. The pyramidal lobe may also be enlarged; rarely, adjacent structures, such as the trachea, esophagus, and recurrent laryngeal nerves, may be compressed. Enlargement of regional lymph nodes is unusual.

Other patients with hypothyroidism present without a goiter (atrophic thyroiditis), which is thought to be the end result of autoimmune destruction of the thyroid, although the progression of goitrous Hashimoto thyroiditis to the atrophied state is not commonly seen in the individual patient. The atrophic thyroid is likely the reflection of rapid destruction early in the onset of autoimmune thyroiditis, combined in some patients with TSH receptor antibodies of the blocking variety, although such antibodies may also occur in those with a goiter. Generally the disease tends to progress slowly with an increase in fibrous tissue and loss of thyroid follicular cells. A study of thyroid volume by ultrasound in patients with newly diagnosed autoimmune hypothyroidism found that there was a continuum of thyroid size, with atrophy and goiter representing extremes of the distribution, supporting the idea that these are not distinct entities but part of the same underlying autoimmune process.[127]

Clinically the untreated goiter remains unchanged or enlarges gradually over many years. The manifestations of hypothyroidism vary and often develop over many years in patients who are initially euthyroid. Thyroid lymphoma occurs almost exclusively in patients with underlying Hashimoto thyroiditis and should be suspected if there is rapid and sometimes painful enlargement of the thyroid gland.[128] As mentioned earlier, the presence of coexistent Hashimoto thyroiditis may be a favorable prognostic factor in patients with papillary carcinoma, but the risk of papillary carcinoma is probably not increased in Hashimoto thyroiditis.[129]

Occasionally hyperthyroidism due to Graves disease develops in patients with Hashimoto thyroiditis. In other patients with early autoimmune thyroiditis, transitory thyrotoxicosis (painless thyroiditis with thyrotoxicosis) occurs as the result of thyroid cell destruction. In such cases, evidence of ongoing thyroid hyperfunction is lacking because the thyroid RAIU is depressed. As described earlier, 50% of women with thyroid autoantibodies who are euthyroid in the first trimester of pregnancy develop postpartum thyroiditis, accompanied by transient thyrotoxicosis, hypothyroidism, or fluctuation from one state to the other.[130]

Laboratory Tests. The results of the common tests of thyroid function depend on the stage of the disease (see Table 13.2). Rarely, the tests may suggest thyrotoxicosis with a suppressed TSH and elevated serum T_4 and T_3 levels, due to either release of stored thyroid hormone as a result of rapid tissue destruction or the relative overproduction of autoantibodies, which stimulate rather than block the TSH receptor (sometimes called hashitoxicosis). In the latter case, the RAIU may be increased, whereas it is decreased if there is tissue destruction. Typically, patients with Hashimoto thyroiditis present with a goiter, and blood tests show a normal or slightly raised TSH, with normal serum T_4 and T_3 levels. As tissue destruction continues, the TSH level rises further, but the ability of the thyroid to respond to TSH diminishes, and the RAIU and serum T_4 level decline to subnormal values, resulting in overt hypothyroidism. This is the typical biochemical finding in atrophic thyroiditis, in which there is no goiter to alert the patient or physician to the underlying disorder. The serum T_3 level remains normal until late in the disease process, reflecting maximal stimulation of the failing thyroid by the increased serum TSH. The early phase of the foregoing sequence, when the serum TSH is increased but T_4 and T_3 are still normal, is termed *subclinical hypothyroidism* (see Table 13.2).

The diagnosis of autoimmune hypothyroidism is confirmed by the presence of thyroid autoantibodies in the serum, usually in high levels. TPO and thyroglobulin autoantibodies occur in roughly similar frequencies; the presence of both autoantibodies is twice as frequent as the isolated individual autoantibodies.[131] Thyroid autoantibodies may be absent in rare patients due to assay insensitivity or the occurrence of an entirely intrathyroidal autoimmune process. Sometimes part of a gland with autoimmune thyroiditis may look and feel like a firm thyroid nodule, and ultrasonography or even aspiration biopsy should be performed to confirm the diagnosis.

Differential Diagnosis. Differentiation of autoimmune hypothyroidism from other forms of hypothyroidism is facilitated by the demonstration that high levels of thyroid autoantibodies occur more commonly than in other thyroid disorders. The frequent coexistence of hypothyroidism and Hashimoto thyroiditis serves to distinguish this disease from nontoxic goiter and thyroid neoplasia.

Differentiation of a euthyroid Hashimoto goiter from a multinodular goiter is often difficult without ultrasonography, and diffuse nontoxic goiter tends to be softer than that of Hashimoto thyroiditis. Ultrasound examination typically reveals a diffuse and patchy heterogeneous echotexture or hypoechoic micronodules with echogenic septations in Hashimoto thyroiditis. In adolescents, differentiation of Hashimoto goiter from diffuse nontoxic goiter is even more difficult because in this age group Hashimoto thyroiditis may not be accompanied by such high levels of thyroid autoantibodies. The presence of well-defined nodules usually distinguishes nontoxic multinodular goiter from Hashimoto thyroiditis.

Differentiation between euthyroid Hashimoto thyroiditis and thyroid carcinoma can sometimes be made on clinical grounds, but an ultrasound examination and aspiration biopsy are necessary in any case in which there is uncertainty. Lymphoma must always be excluded if there is a sudden change in a known Hashimoto goiter; core needle biopsy or open surgical biopsy may be required for final diagnosis. Thyroid carcinoma usually occurs as a solitary nodule that is firm or hard, and the gland may be fixed to adjacent structures. Compression of the recurrent laryngeal nerve with hoarseness is virtually pathognomonic of thyroid carcinoma but occurs late in the cancer progression. A history of a recent enlargement of the goiter is more common in thyroid malignancies (either carcinoma or lymphoma) than in Hashimoto thyroiditis. Enlargement of regional lymph nodes also suggests thyroid malignancy but can rarely occur in autoimmune thyroiditis.

Treatment. In euthyroid patients with Hashimoto thyroiditis, no treatment is required because the goiter is usually asymptomatic. Levothyroxine treatment may be indicated in patients when the goiter presses on adjacent structures or is unsightly, and it is most effective in goiters of recent onset. The aim is to keep the TSH level in the lower half of the reference interval. In long-standing goiter, treatment with thyroid hormone is usually ineffective, possibly because of fibrosis. Rarely, the goiter may be painful, and this symptom may respond to levothyroxine therapy. Glucocorticoids, such as prednisolone, are usually ineffective. Surgery may be justified if symptoms or unsightly enlargement persists after a trial of levothyroxine therapy.

Replacement doses of thyroid hormone should be given when hypothyroidism is present, appropriate to the degree of hormone deficiency (see later). There may be a spontaneous return to euthyroidism in up to 10% of patients after starting levothyroxine, associated in some cases with the disappearance of TSH receptor blocking antibodies. However, it has not been established that such remissions are durable and there is no need to routinely stop levothyroxine once it has been started. It has recently been suggested that prednisolone treatment can reverse the hypothyroidism of IgG4-related thyroiditis, but the long-term outcome in such cases is not yet known.[132]

Iodine Deficiency (Endemic Goiter)

The term *endemic goiter* denotes any goiter occurring in a region where goiter is prevalent.[132] As mentioned, endemic goiter almost always occurs in areas of environmental iodine deficiency.[133] Although this condition is estimated to affect more than 200 million people throughout the world and is of major public health significance, it is most common in mountainous areas, such as the Alps, Himalayas, and Andes, or in the Great Lakes and Mississippi Valley regions of the United States, owing to the depletion of iodine consequent to the persistent glacial run-off in these regions.

The causative role of iodine deficiency in the genesis of endemic goiter is supported by the inverse correlation between the iodine content of soil and water and the incidence of goiter, the kinetics

of iodine metabolism in patients with the disorder, and a decrease in incidence after iodine prophylaxis. The latter accounts for its absence in the population residing in the Great Plains region of the United States.

The occurrence of endemic goiter can vary, even within an area of known iodine deficiency; the roles of dietary minerals or naturally occurring goitrogens and of pollution of water supplies have been suggested in instances of this type.[134] For example, in the Cauca Valley of Colombia, waterborne goitrogens have been implicated, and in many areas of endemic iodine deficiency, consumption of cassava meal, which gives rise to thiocyanate, aggravates the iodine-deficient state by inhibiting thyroid iodide transport. Familial clustering of goiters within iodine-insufficient areas, usually with an autosomal dominant inheritance, suggests an important genetic component.[135]

Most abnormalities in iodine metabolism in patients with endemic goiter are consistent with the expected effects of iodine deficiency (see Chapter 11 regarding iodine metabolism). Thyroid iodide clearance rates and RAIU are increased in proportion to the decrease in the urinary excretion of stable iodine. The absolute iodine uptake is normal or low. In areas of moderate iodine deficiency, the serum T_4 concentration is usually in the lower range of normal; in areas of severe deficiency, however, values are decreased. Nevertheless, most patients in these areas do not appear to be in a hypothyroid state because of an increase in the synthesis of T_3 at the expense of T_4 and because of an increase in the activity of thyroidal D1 and D2.[84] TSH levels are typically in the upper range of normal.

The incidence and severity of endemic goiter and the metabolic state of the goitrous patient depend mainly on the degree of iodine deficiency. In the absence of hypothyroidism, the effects of the goiter are mainly cosmetic. When the goiter becomes nodular, however, hemorrhage into a nodule may cause acute pain and swelling, mimicking painful subacute thyroiditis or neoplasia. The goiter may also compress adjacent structures, such as the trachea, esophagus, and recurrent laryngeal nerves. The borderline nature of the iodine supply in many countries of Western Europe is exemplified by the development of compensatory maternal and fetal goiter during pregnancy due to the increased requirement for thyroid hormone during gestation.[133]

The incidence of endemic goiter has been greatly reduced in many areas by the introduction of iodized salt.[133] In the United States, table salt is enriched with potassium iodide to a concentration of 0.01%, which, if the intake of salt is average, would provide an iodine intake of approximately 150 to 300 μg/day, the desired amount in an adult (see Table 11.1). The use of iodine-containing flour in bread products and iodized salt in commercially produced food has been markedly reduced.[136] The iodine content of bread and infant formula is variable within a given product and often does not match the measured content.[136] As mentioned, iodine intake in the United States has been decreasing in recent decades, likely due to reduced iodine in commercial food products, although iodine intake has now stabilized. Pregnant women, however, remain a susceptible population because of their increased iodine requirements.[134] Most prescription prenatal vitamins do not contain iodine.[137] An annual injection of iodized oil is another effective means of administering iodine, and endemic goiter can be treated by the addition of iodine to communal drinking water.

Administration of iodine has little if any effect on a long-standing endemic goiter, but it causes the early endemic hyperplastic goiter of iodine deficiency to regress. Similarly, thyroid hormone usually has no effect on long-standing goiter or on established mental or skeletal changes, but it should be given in full-replacement doses if there is evidence of hypothyroidism. This is of paramount importance in pregnant women. Surgical treatment is indicated if the adjacent structures are compressed or if the goiter is either very large or enlarging rapidly.

Endemic Cretinism

Endemic cretinism is a developmental disorder that occurs in regions of severe endemic goiter.[133] Both parents of an endemic cretin are usually goitrous, and in addition to the features of sporadic cretinism described earlier, endemic cretins often have deafmutism, spasticity, motor dysfunction, and abnormalities in the basal ganglia demonstrable by magnetic resonance imaging.

Three types of cretins can be discerned: (1) hypothyroid cretins, (2) neurologic cretins, and (3) cretins with combined features of the two. The pathogenesis of neurologic cretinism is obscure but may be due to severe thyroid hormone deficiency during a critical early phase of central nervous system development in utero.[44] Some cretins are goitrous, but the thyroid may also be atrophic, possibly as a consequence of exhaustion atrophy from continuous overstimulation or the lack of iodine.

Iodide Excess

Goiter and hypothyroidism, either alone or in combination, are sometimes induced by chronic administration of large doses of iodine in either organic or inorganic form (see Table 11.7).[133,138] Iodide-induced goiter was formerly seen in patients with chronic respiratory disease who were given potassium iodide as an expectorant. The development of iodide goiter has also been reported after a single administration of radiographic contrast medium from which iodide is released slowly over a long period and may also occur during amiodarone administration. Iodide goiter without hypothyroidism may occur endemically, such as on the island of Hokkaido, Japan, where seaweed products are consumed in large quantities.

From an analysis of reported cases and from the fact that only a small percentage of patients who receive iodides chronically develop goiter, it appears that the disorder evolves on a background of underlying thyroid dysfunction.[138] Categories of susceptible individuals include the following: patients with Hashimoto disease, patients with Graves disease especially after treatment with radioiodine, and patients with cystic fibrosis.

Among these groups, many individuals display a positive iodide-perchlorate discharge test, indicating a defect in the thyroidal organic iodine-binding mechanism (see Chapter 11 regarding iodine metabolism). However, intrinsic thyroid disease need not be present because a propensity to develop iodide goiter and hypothyroidism has also been demonstrated in patients who have undergone hemithyroidectomy for a solitary thyroid nodule in whom the remaining lobe was histologically normal.[89] In these patients, as in those with Hashimoto disease or Graves disease studied prospectively, individuals with the highest basal serum TSH concentrations, even within the normal range, were those who developed iodide goiter. Iodinated contrast material, amiodarone, and povidone-iodine are common sources.[138]

Goiter and hypothyroidism commonly occur in newborns of women given large quantities of iodine during pregnancy, and death from neonatal asphyxia has been reported (see Fig. 11.11). In such cases, the mother is usually free from goiter. Pregnant women should not receive large doses of iodine (>1 mg/day) over prolonged periods (>10 days), especially near term. Maternal

amiodarone therapy causes thyroidal dysfunction in up to 20% of newborns.[133] It is not known whether iodide goiter in newborns results from an inherent hypersensitivity of the fetal thyroid or from the fact that the placenta concentrates iodide several-fold, or both.

As discussed earlier (see Chapter 11, "Regulation of Thyroid Function"), large doses of iodine cause an acute inhibition of organic binding that abates in the normal individual, despite continued iodine administration (acute Wolff-Chaikoff effect and escape).[139] Iodide goiter appears to result from a more pronounced inhibition of organic binding and the failure of the escape phenomenon. As a consequence of decreased hormone synthesis and the consequent increase in TSH, iodide transport is enhanced. Because inhibition of organic binding is a function of the intrathyroidal concentration of iodide, a vicious circle, augmented by this increase in serum TSH, is set in motion.

The disorder usually appears as a goiter with or without hypothyroidism, although in rare instances iodine may produce hypothyroidism unaccompanied by goiter. Usually the thyroid gland is firm and diffusely enlarged, often greatly so. Histopathologic examination reveals intense hyperplasia. The FT_4 concentration is low, TSH concentration is increased, and the 24-hour urinary iodine excretion and the serum inorganic iodide concentration are increased. The disorder regresses after iodine is withdrawn. Thyroid hormone may also be given to relieve severe symptoms.

Drugs Blocking Thyroid Hormone Synthesis or Release, Causing Goiter Formation

Ingestion of compounds that block thyroid hormone synthesis or release may cause goiter with or without hypothyroidism. Apart from the agents used in the treatment of hyperthyroidism, antithyroid agents may be encountered either as drugs for the treatment of disorders unrelated to the thyroid gland or as natural agents in foodstuffs.

Goiter with or without hypothyroidism can occur in patients given lithium, usually for bipolar manic-depressive psychosis.[140] Like iodide, lithium inhibits thyroid hormone release, and in high concentrations it can inhibit organic binding reactions. At least acutely, iodide and lithium act synergistically in the latter respect. The mechanisms underlying the several effects of lithium are uncertain; what differentiates patients who develop thyroid disease during lithium therapy from those who do not is also unclear. A promoting effect on underlying autoimmune thyroiditis may be at least one factor because many patients with this combination have autoimmune thyroid disease.

Other drugs that occasionally produce goitrous hypothyroidism include para-aminosalicylic acid, phenylbutazone, aminoglutethimide, and ethionamide. Like the thionamides, these drugs interfere with both the organic binding of iodine and perhaps in later steps in hormone biosynthesis. Although soybean flour is not an antithyroid agent, soybean products in feeding formulas formerly resulted in goiter in infants by enhancing fecal loss of hormone, which, together with the low iodine content of soybean products, produced a state of iodine deficiency. Feeding formulas containing soybean products are now enriched with iodine.

Cigarette smoking reduces the hypothyroidism in patients with underlying autoimmune thyroid disease, although the risk is transiently increased if smoking is stopped.[122] Thiocyanate, hydroxypyridine, and benzopyrene derivatives found in cigarette smoke may also interfere with thyroid hormone action.[141]

Both the goiter and the hypothyroidism usually subside after the antithyroid agent is withdrawn. If continued administration of pharmacologic goitrogens is required, however, replacement therapy with thyroid hormone causes the goiter to regress.

Goitrogens in Foodstuffs or as Endemic Substances or Pollutants

Antithyroid agents also occur naturally in foods. They are widely distributed in the family Cruciferae or Brassicaceae, particularly in the genus *Brassica,* including cabbages, turnips, kale, kohlrabi, rutabaga, mustard, and various plants that are not eaten by humans but that serve as animal fodder.[142] It is likely that some thiocyanate is present in such plants (particularly cabbage).[143] Cassava meal, a dietary staple in many regions of the world, contains linamarin, a cyanogenic glycoside, the preparation of which leads to the formation of thiocyanate. Ingestion of cassava can accentuate goiter formation in areas of endemic iodine deficiency. Except for thiocyanate, dietary goitrogens influence thyroid iodine metabolism in the same manner as do the thionamides, which they resemble chemically; their role in the induction of disease in humans is uncertain. Waterborne, sulfur-containing goitrogens of mineral origin are believed to contribute to the development of endemic goiter in certain areas of Colombia.

A number of synthetic chemical pollutants have been implicated as a cause of goitrous hypothyroidism, including polychlorinated biphenyls and resorcinol derivatives.[144] Perchlorate has also been noted in high concentrations in geographic regions in which explosives and rocket fuel were made. Perchlorate has been detected in water, food, and breast milk, although the amount does not appear to be sufficient to disrupt thyroid function. In an area of Chile with a high level of natural perchlorate contamination in the water, thyroid function in pregnant women was not different from that in a region with no perchlorate, although iodine intake is quite high in this area.[145]

Cytokines

Patients with chronic hepatitis C or various malignancies may be given interferon-α or interleukin 2.[119,146] Such patients may experience hypothyroidism, which is often a transient destructive thyroiditis and associated with an initial thyrotoxic phase but in other cases may persist. Graves disease with hyperthyroidism may also develop, and ablative therapy may be required to treat this condition. Women and those who have positive TPOAb prior to treatment are at higher risk for these complications and should be monitored especially carefully during and after a course of treatment with either of these cytokines.

Congenital Causes of Goiter

Inherited defects in hormone biosynthesis are rare causes of goitrous hypothyroidism and account for only about 10% to 15% of the 1 in 3000 newborns with congenital hypothyroidism.[18,147,148] In most instances, the defect appears to be transmitted as an autosomal recessive trait. Individuals with goitrous hypothyroidism are believed to be homozygous for the abnormal gene, whereas euthyroid relatives with slightly enlarged thyroids are presumably heterozygous. In the latter group, appropriate functional testing may disclose a mild abnormality of the same biosynthetic step that is defective in the homozygous individual. In contrast with nontoxic goiter, which is more common in females than in males, these defects, as a group, affect females only slightly more commonly than males.

Although goiter may be present at birth, it usually does not appear until several years later. Therefore the absence of goiter in a child with functioning thyroid tissue does not exclude

the presence of hypothyroidism. The goiter is initially diffusely hyperplastic, often intensely so, suggesting papillary carcinoma, but eventually it becomes nodular. In general, the more severe the biosynthetic defect, the earlier the goiter appears, the larger it is, and the greater the likelihood of early development of hypothyroidism or even cretinism.[147] Five specific defects in the pathways of hormone synthesis have been identified.

Iodide Transport Defect. An iodide transport defect, a result of impaired iodide transport by the NIS protein mechanism, is rare and is reflected in defective iodide transport in the thyroid, salivary gland, and gastric mucosa.[149,150] Some mutations in such patients produce reduced activity, and others completely inactivate NIS by preventing the protein from being transported and inserted into the membrane. With the milder NIS mutations, administration of iodide raises the plasma and intrathyroidal iodide concentration, permitting the synthesis of normal quantities of hormone.

Defects in Expression or Function of Thyroid Peroxidase. TPO is a protein that is required for normal synthesis of iodothyronines. Quantitative or qualitative abnormalities of TPO have been identified in 1 in 66,000 infants in the Netherlands. The most common of the 16 mutations identified in 35 families was a GGCC insertion in exon 8, leading to a premature stop codon.[151]

Pendred Syndrome. The most common presentation in patients with Pendred syndrome is a defect in iodine organification accompanied by sensory nerve deafness.[152] The abnormality is in the *PDS* gene encoding pendrin, which is involved in the apical secretion of iodide into the follicular lumen (see Fig. 11.1 and the discussion regarding iodine metabolism in Chapter 11). Thyroid function is only mildly impaired in this disorder.

Defects in Thyroglobulin Synthesis. Defects in the synthesis of thyroglobulin due to genetic causes are rare, having been identified only in a small number of families with congenital hypothyroidism.[147] Some defects lead to premature termination of translation, whereas another defect causes deficiency in endoplasmic reticulum processing of the thyroglobulin molecule. The complex regulation and the huge size of this gene make screening for mutations a difficult task, and considerable work is still required to unravel the extent of the defects in this gene.

Iodotyrosine Dehalogenase Defect. The pathogenesis of goiter and hypothyroidism in the iodotyrosine dehalogenase defect is complex. The major abnormality is an impairment of both intrathyroidal and peripheral deiodination of iodotyrosines, presumably because of the dysfunction of the iodotyrosine *DEHAL1B* gene (see discussion regarding iodide metabolism in Chapter 11).[153,154]

As a consequence of intense thyroid stimulation and lack of intrathyroidal recycling of iodide derived from dehalogenation, iodide is rapidly accumulated by the thyroid gland and is rapidly released; monoiodotyrosine (MIT) and diiodotyrosine (DIT) are elevated in plasma and, together with their deaminated derivatives, in the urine. Hypothyroidism is presumed to result from the loss of large quantities of MIT and DIT in the urine and to secondary iodine deficiency. The goiter and hypothyroidism are relieved by administration of high doses of iodine.

Thyroid Infiltration Causing Hypothyroidism and Goiter

A number of infiltrative or fibrosing conditions may cause hypothyroidism. Some are often associated with goiter, such as Riedel struma (see later).[155] Others, such as amyloidosis,[156] hemochromatosis,[157] or scleroderma,[158] may not be. Although the other manifestations of these conditions are usually obvious and hypothyroidism is only a complication, the presence of significant hypothyroidism without evidence of autoimmune thyroiditis should lead to a consideration of these rare causes of this condition.

Postablative Hypothyroidism

Postablative hypothyroidism is a common cause of thyroid failure in adults. One type follows total thyroidectomy usually performed for thyroid carcinoma. Although functioning remnants may be present, as indicated by foci of radioiodine accumulation, hypothyroidism invariably develops. Another etiologic mechanism is subtotal resection of the diffuse goiter of Graves disease or multinodular goiter. Its frequency depends on the amount of tissue remaining, but continued autoimmune destruction of the thyroid remnant in patients with Graves disease may be a factor because some studies suggest a correlation between the presence of circulating thyroid autoantibodies in thyrotoxicosis and the development of hypothyroidism after surgery. Hypothyroidism can be manifested during the first year after surgery, but as with postradioiodine hypothyroidism, the incidence increases with time. In some patients, mild hypothyroidism appears during the early postoperative period and then may occasionally remit, as also occurs after radioiodine treatment.

Hypothyroidism after destruction of thyroid tissue with radioiodine is common and is the one established disadvantage of this form of treatment for hyperthyroidism in adults. Its frequency is determined in large part by the dose of radioiodine and radioiodine uptake, but it is also influenced by other factors, including age, thyroid gland size, magnitude of thyroid hormone elevations, and use of antithyroid drugs.[159] The incidence of postradioiodine hypothyroidism increases with time, approaching 100%. Although the FT_4 is low in patients with postablative hypothyroidism, serum TSH levels may be anomalously low for several months after either surgical or ^{132}I-induced hypothyroidism if TSH synthesis has been suppressed for a long period prior to treatment.

Primary atrophic thyroid failure may also develop in patients with Hodgkin disease after treatment with mantle irradiation or after high-dose neck irradiation for other forms of lymphoma or carcinoma.[126] Surgical, radioiodine, or external beam therapy may also lead to a state of subclinical hypothyroidism (see Table 13.2).

Thyroid Agenesis or Dysplasia

Developmental defects of the thyroid are often responsible for the hypothyroidism that occurs in 1 in 3000 newborns.[18] These defects may take the form of complete absence of thyroid tissue or failure of the thyroid to descend properly during embryologic development. Thyroid tissue may then be found anywhere along its normal route of descent from the foramen cecum at the junction of the anterior two-thirds and posterior third of the tongue (lingual thyroid) to the normal site or below. Absence of thyroid tissue or its ectopic location can be ascertained by scintiscanning.

As indicated, a number of proteins are known to be crucial for normal thyroid gland development.[18] These proteins include the thyroid-specific transcription factor PAX8 as well as thyroid transcription factors 1 and 2 (TTF1 and TTF2, respectively). It might be anticipated that defects in one or more of these proteins may explain abnormalities in thyroidal development. These abnormalities have been identified in several patients with *PAX8* mutations, and a mutation in the human *TTF2* gene was associated with

thyroid agenesis, cleft palate, and choanal atresia. Despite a specific search, no mutations have been found in the *TTF1* gene in infants with congenital hypothyroidism.

Thyroid Aplasia Due to Thyrotropin Receptor Unresponsiveness

Several families exist in which thyroid hypoplasia, high TSH concentrations, and a low FT_4 level are associated with loss-of-function mutations in the TSH receptor.[160] The thyroid gland of these patients was in the normal location but did not trap pertechnetate (TcO_4^-). Somewhat surprisingly, thyroglobulin levels were still detectable. The molecular details of these patients are still under study.

A second type of abnormality that may cause TSH unresponsiveness is a mutation in the G_s protein that occurs in pseudohypoparathyroidism type 1A. These patients have inactivating mutations in the α-subunit of the G_s protein and, consequently, mild hypothyroidism.[161] Other as yet unexplained patients with elevated TSH levels and hypothyroidism in which the molecular nature of the defect has not been defined have been reported.[162]

Transient Hypothyroidism

Transient hypothyroidism is defined as a period of reduced FT_4 with suppressed, normal, or elevated TSH levels that are eventually followed by a euthyroid state. This form of hypothyroidism usually occurs in the clinical context of a patient with painful or painless subacute thyroiditis.[130] These conditions are reviewed in detail in Chapter 12.

The patient reports mild to moderate symptoms of hypothyroidism of short duration, and serum TSH concentrations are typically elevated, although not greatly so. The patient often has a preceding episode of symptoms consistent with mild or moderate thyrotoxicosis. If these symptoms cannot be elucidated from the history, it may be difficult to distinguish such patients from those with a permanent form of hypothyroidism. In the early phases of post-thyroiditis hypothyroidism, TSH concentrations may still be suppressed even though the FT_4 is low because of the delayed recovery of pituitary TSH synthesis, such as in patients with Graves disease or with toxic nodules who have undergone surgery and who have experienced rapid relief of hypothyroidism (see Table 13.2). In that situation, the TSH response to hypothyroidism may be suppressed for many months; in post-thyroiditis hypothyroidism, this period is rarely longer than 3 to 4 weeks.

A significant fraction (50%) of women with autoimmune thyroiditis but normal thyroid function have episodes of hypothyroidism during the postpartum period.[130] In some, the preceding thyrotoxicosis is relatively asymptomatic, which can make an accurate clinical diagnosis difficult. Patients who have had an episode of typical painful subacute thyroiditis, with pain, tenderness, and thyrotoxicosis, are not difficult to recognize.

Diagnostic evaluation should include a determination of TSH, FT_4, and TPOAb. Negative or low antibodies argue strongly for a nonautoimmune cause. This is significant, in that it may be possible for the patient to be treated only temporarily for hypothyroidism. In such patients, a trial of a lower levothyroxine dosage after 3 to 6 months may reveal that thyroid function has recovered (see Fig. 13.5). This may also occur in patients with hypothyroidism that follows painless subacute thyroiditis (e.g., in the postpartum period), but it is somewhat less likely to occur because of the underlying progressive nature of the autoimmune thyroiditis.

In patients with hypothyroidism due to painful subacute thyroiditis, the thyroid gland is usually relatively small and atrophic. In patients with hypothyroidism that follows an episode of painless subacute thyroiditis, the gland is usually slightly enlarged and somewhat firm, reflecting the underlying scarring and infiltration associated with that condition.

Consumptive Hypothyroidism

Consumptive hypothyroidism is the term given to an unusual cause of hypothyroidism that has been identified in infants with visceral hemangiomas or related tumors.[7,163] The first patient reported with this syndrome presented with abdominal distention caused by a large hepatic hemangioma with respiratory compromise secondary to upward displacement of the diaphragm. However, clinical signs suggested hypothyroidism, which was confirmed by finding a markedly elevated TSH level and undetectable T_4 and T_3 levels. The infant's response to an initial intravenous infusion of liothyronine (T_3) was transient, leading to the decision to use parenteral thyroid hormone replacement to relieve the severe hypothyroidism. The accelerated degradation of thyroid hormone was apparent from the fact that 96 μg of liothyronine plus 50 μg of levothyroxine were required to normalize the TSH level. The equivalent dosage of levothyroxine alone is roughly nine times that ordinarily required for treatment of infants with congenital hypothyroidism. The infant succumbed to complications of the hemangioma, and a postmortem tumor biopsy showed D3 activity in the tumor at levels eightfold higher than those normally present in term placenta. The serum reverse T_3 was extremely elevated (400 ng/dL), and the serum thyroglobulin was greater than 1000 ng/mL, indicating the presence of a highly stimulated thyroid gland. Retrospective search revealed two other patients with similar pathophysiology in whom the cause of the hypothyroidism had not been recognized. Significant D3 expression has subsequently been noted in all proliferating cutaneous hemangiomas studied to date. The cutaneous hemangiomas of infancy, although they express D3, are not associated with hypothyroidism owing to their small size. Most infantile hemangiomas involute with propranolol therapy, but such patients must also receive adequate doses of thyroid hormone to prevent the permanent neurologic complications associated with untreated hypothyroidism during this critical phase of neurologic development.[164] Subsequent reports have identified a similar syndrome in adults, including a patient with an epithelioid hemangioendothelioma and an individual with a fibrous tumor as well as extensive gastrointestinal stromal tumors (GISTs).[165] Some of these tumors express D3, or this deiodinase may be induced during treatment with TKIs (see later).[166–169]

Defects in Conversion of Thyroxine to Triiodothyronine

The enzymes that convert the precursor T_4 to the active form, T_3, are 5′-deiodinase 1 (D1) and D2, both of which contain selenocysteine in their active site.[84] A stem loop structure in the 3′-untranslated region of the mRNA, termed a *SECIS element,* directs insertion of selenocysteine at the UGA codon, rather than allowing it to function as a stop codon. Defects in a SECIS-binding protein (selenocysteine insertion sequence–binding protein 2 [SECISBP2]) were found in two families with an elevated FT_4, reduced T_3, and elevated TSH.[170] Affected individuals have growth retardation, compared with unaffected family members.

Polymorphisms in genes associated with thyroid hormone metabolism have been associated with patterns of thyroid function studies as well as obesity. The D2 polymorphism resulting in a change from threonine (Thr) to alanine (Ala) at codon 92 (Thr92Ala) has been associated with obesity, reduced glucose disposal, and lower D2 activity in skeletal muscle.[171] This

polymorphism also has a higher frequency in groups with a high incidence of obesity and type 2 diabetes such as Mexican Americans and Pima Indians.[171] The D2 polymorphism has also been associated with a distinct pattern of gene expression in the cortex, associated with inflammation and chronic disease, linked to prolonged half-life of the D2 protein in the Golgi.[172]

Hypothyroidism Due to Drug-Induced Thyroid Destruction

Thyroid inflammation or activation of autoimmune thyroid destruction has been associated with a number of drugs.[146,173] The TKIs, such as sunitinib, have been associated with a high incidence of hypothyroidism due to thyroid destruction.[166,167] Sunitinib is used to treat renal cell carcinoma and GISTs and inhibits multiple tyrosine protein kinases, including KIT, PDGF, VEGF, and RET. An abnormal TSH was found in 62% of patients receiving sunitinib who were followed for 37 weeks.[168] Patients studied by ultrasound demonstrated no thyroid tissue. Although 40% of hypothyroid patients initially had a suppressed TSH, suggesting thyroiditis, the long-term course was most consistent with sunitinib-induced follicular cell apoptosis. Thus such patients require repeated thyroid function testing. These agents have now been shown to slow disease progression in advanced thyroid cancer unresponsive to radioiodine but may increase thyroid hormone requirements due to increased D3 expression.[174]

Central Hypothyroidism

Central hypothyroidism is due to TSH deficiency caused by either acquired or congenital hypothalamic or pituitary gland disorders (see Chapters 8 and 9). The causes of TSH deficiency may be classified as those of pituitary (*secondary* hypothyroidism) and hypothalamic (*tertiary* hypothyroidism) origins, but this distinction is not necessary in the initial separation of primary from central hypothyroidism.

In many cases, hyposecretion of TSH is accompanied by decreased secretion of other pituitary hormones, with the result that evidence of somatotroph, gonadotroph, and corticotroph failure is also present. Hyposecretion of TSH as the sole demonstrable abnormality (monotropic deficiency) is less common but does occur in both acquired and congenital forms. Hypothyroidism due to pituitary insufficiency varies in severity from instances in which it is mild and overshadowed by features of gonadal and adrenocortical failure to those in which the features of the hypothyroid state are predominant. Because a small but significant fraction of thyroid gland function is independent of TSH (~10–15%), hypothyroidism due to central causes is less severe than primary hypothyroidism.

The causes of central hypothyroidism are both acquired and congenital. The general subject is discussed in Chapters 8 and 9, and those causes with relatively specific thyroid-related deficiencies are mentioned here for completeness. In addition to pituitary tumors, hypothalamic disorders, and the like, an unusual cause of secondary hypothyroidism occurs in individuals given bexarotene (a retinoid X receptor [RXR] agonist) for T-cell lymphoma.[175,176] This drug suppresses the activity of the human TSH β-subunit promoter in vitro. Serum T_4 concentrations are reduced about 50%, and patients experience clinical benefit from thyroid hormone replacement. Dopamine, dobutamine, high-dose glucocorticoids, or severe illness may suppress TSH release transiently, leading to a pattern of thyroid hormone abnormalities suggesting central hypothyroidism.[176] As discussed earlier (see Chapter 11 discussion regarding changes in thyroid function during severe illness), this severe state of hypothalamic-pituitary-thyroid suppression is a manifestation of stage 3 illness (see Table 11.10). Although these agents may be expected to have similar effects when given long term, they do not, nor does somatostatin have a similar effect when given for acromegaly, although it does block the response of TSH to TRH and it has been administered to patients with thyrotropin-secreting pituitary adenomas.[177]

Congenital defects in either the stimulation or the synthesis of TSH or in its structure have been identified as rare causes of congenital hypothyroidism[18] and include the consequences of defects in several of the homeobox genes, including *POU1F1* (formerly termed *Pit1*), *PROP1,* and *HESX1.* The last gene encodes a factor necessary for the development of the hypothalamus, pituitary, and olfactory portions of the brain. Defects in *POU1F1* and *PROP1* cause hereditary hypothyroidism usually accompanied by deficiencies in growth hormone and prolactin.[178] One patient has been identified with a familial defect in the TRH receptor gene.[179] All of these conditions are associated with the typical pattern of central hypothyroidism, a reduced FT_4, and inappropriately low TSH.

Structural defects in TSH have also been described. They include those with a mutation in the CAGYC peptide sequence of the β-subunit, thought to be necessary for its association with the α-subunit,[180] and defects that produce premature termination of the TSH β-subunit gene.[181] As mentioned, some of these abnormalities may be associated with elevations in TSH, suggesting the diagnosis of primary hypothyroidism, but the TSH molecule is immunologically, but not biologically, intact.

Resistance to Thyroid Hormone

The clinical manifestations of resistance to thyroid hormone depend on the nature of the mutation.[6,11,182] The majority of patients with RTH have a mutation in the gene encoding the thyroid hormone receptor β (*TRβ* gene, *THRB*) that interferes with the capacity of that receptor to respond normally to T_3, usually by reducing its T_3-binding affinity (see Chapter 2). A small number of individuals have been identified with *TRα* gene *(THRA)* mutations, referred to as RTHα1,[183] who differ in significant ways from patients with RTH due to *THRB* mutations.[184–186]

RTH is probably produced by the heterodimerization of the mutant *TRβ* with RXR or homodimerization with a normal *TRβ* or *TRα*. These mutant *TRβ*-containing dimers compete with wild-type TR-containing dimers for binding to the thyroid hormone response elements (TREs) of thyroid hormone–dependent genes.[182] Because these complexes bind corepressor molecules that cannot be released in the absence of T_3 binding, genes containing these TREs are more repressed than they would be normally at the prevailing concentrations of circulating thyroid hormones (see Chapter 2).[6] Receptors that contain mutations in the activation domain may have a combination of both decreased affinity for T_3 and impaired activating potential.

Thus the mutant *TRβ* complex can interfere with the function of the wild-type TRs, producing a pattern termed *dominant negative inhibition* with an autosomal dominant pattern of inheritance. At least 400 families have been identified with this condition, and there are probably many more unreported cases. The gene frequency estimate is about 1:50,000 for mutations in *TRβ* and the study of the function of the mutant receptors in this disorder has provided valuable insights into the mechanism of thyroid hormone action.[182] The frequency of *TRα* mutations is probably much lower but undefined.

Patients with RTH usually are recognized because of thyroid enlargement, which is present in about two-thirds of these

individuals. Patients usually report a mixture of symptoms of hyperthyroidism and hypothyroidism. With respect to the heart, palpitations and tachycardia are more common than a reduced heart rate; however, patients may also demonstrate growth retardation and retarded skeletal maturation.[187] This has been attributed to the fact that thyroid hormone effects in the heart and bone appear to be primarily dependent on *TRα* rather than *TRβ*, whereas the hypothalamic-pituitary axis is primarily regulated through *TRβ*.

Abnormalities in neuropsychologic development exist, with an increased prevalence of attention-deficit/hyperactivity disorder, which is found in approximately 10% of such individuals.[187] Other neuropsychologic abnormalities have also been described. Deafness in patients with RTH reflects the important role of *TRβ* and thyroid hormone in the normal development of auditory function. The mixture of symptoms, some suggesting hypothyroidism and others suggesting hyperthyroidism, may even differ in individuals within the same family, despite the identical mutation, thus confusing the clinical picture.

Because patients may present with symptoms suggesting hyperthyroidism, it is important to keep this diagnosis in mind in a patient with tachycardia, goiter, and elevated thyroid hormones. RTH is discussed here because a reduced response to thyroid hormone is the biochemical basis for the condition. However, the laboratory results may be the first clear evidence that a patient, otherwise thought to have hyperthyroidism, has RTH. These tests show the unusual combination of an increased FT_4 accompanied by normal or slightly increased TSH levels (see Table 13.2). Thus the principal differential diagnosis is between a TSH-secreting pituitary tumor causing hyperthyroidism and RTH.[188]

Factors that may assist in the differential diagnosis are as follows: absence of a family history in patients with TSH-producing tumors, normal thyroid hormone levels in family members of individuals with TSH-induced hyperthyroidism due to pituitary tumor, and the presence of an elevated glycoprotein α-subunit in patients with pituitary tumor but not in those with RTH.

A definitive diagnosis requires sequencing of the *TRβ* gene demonstrating the abnormality. Mutations in the *TRβ* gene are found in about 90% of individuals with a clinical diagnosis. In a few individuals this is not the case, suggesting that there may be mutations in coactivator proteins or one of the RXR receptors, which can also present in a similar fashion.[189]

Treatment is difficult because thyroid hormone analogues designed to suppress TSH, thereby relieving the hyperthyroxinemia, may lead to worsening of the cardiovascular manifestations of the condition.[190] Therapy with 3,5,3′-triiodothyroacetic acid (TRIAC) has been used in several patients. The development of analogues of thyroid hormone with *TRβ*, as opposed to mixed or *TRα* preferential effects, as well as analogues that selectively bind mutant TRs, may eventually prove useful in treatment.

Individuals with RTHα1 have more subtle changes in thyroid function studies, compared with RTH due to *TRβ* gene mutations, and a clinical phenotype consistent with hypothyroidism in tissue that predominantly expresses the *TRα* isoform.[184,185] Because regulation of TSH is predominantly mediated by *TRβ*, these individuals have a normal serum TSH but a reduced T_4/T_3 ratio and low concentration of serum reverse T_3, presumably due to reduced activity of the D3 enzyme. Common phenotypic features include growth failure, developmental delays, constipation, and delayed bone maturation, with some improvement associated with T_4 treatment.[186]

Treatment

Hypothyroidism, either primary or central, is gratifying to treat because of the ease and completeness with which it responds to thyroid hormone.[81,191] Treatment is nearly always with levothyroxine, and the proper use of this medication has been reviewed extensively.[80] A primary advantage of levothyroxine therapy is that the peripheral deiodination mechanisms can continue to produce the amount of T_3 required in tissues under the normal physiologic control.[84] If one accepts the principle that replicating the natural state is the goal of hormone replacement, it is logical to provide the "prohormone" and allow the peripheral tissues to activate it by physiologically regulated mechanisms. There is, however, significant interest in combined T_4 and T_3 therapy.[192,193]

Pharmacologic and Physiologic Considerations

Levothyroxine has a 7-day half-life; about 80% of the hormone is absorbed relatively slowly (over hours) and it equilibrates rapidly in its extracellular distribution volume, therefore avoiding large postabsorptive perturbations in FT_4 levels. With its long half-life, omission of a single day's tablet has no significant effect and the patient may safely take an omitted tablet the following day. In fact, the levothyroxine dosage can be calculated almost as satisfactorily on a weekly, as on a daily, basis. Although T_4 is well absorbed and does not require fasting, regular ingestion of levothyroxine on an empty stomach results in the least variation in serum TSH concentration.[194]

The Food and Drug Administration (FDA) has issued standards for single-dose bioequivalence studies in normal volunteers to assess and compare T_4 products in the United States.[195] The area under the curve (AUC) confidence interval must fall within 80% to 125% of the comparison product for a preparation to be considered equivalent. The desirability of a pharmacotherapeutic measurement, such as TSH level as an end point, has been suggested by many professional organizations.[195] The guidelines for measured T_4 content have narrowed from 90% to 110% to 95% to 105% of the stated tablet dose and require that content to be maintained for the entire shelf life.[196] The availability in many countries of a multiplicity of tablet strengths with content ranging from 25 to 300 μg allows precise titration of the daily levothyroxine dosage for most patients with a single daily tablet, improving compliance significantly.

The typical dose of levothyroxine, approximately 1.6 to 1.8 μg/kg ideal body weight per day (0.7 to 0.8 μg/lb), generally results in the prescription of between 75 and 125 μg/day for women and 125 to 200 μg/day for men. Replacement doses need not be adjusted upward in obese patients and should be based on lean body mass.[197] Levothyroxine dose reduction is often required after bariatric surgery, but the dose reduction is proportional to the reduction in lean body mass.[198] This dosage is about 20% greater than the T_4 production rate owing to incomplete absorption of the levothyroxine. In patients with primary hypothyroidism, these amounts usually result in serum TSH concentrations that are within the normal range. Because of the 7-day half-life, approximately 6 weeks are required before there is complete equilibration of the FT_4 and the biologic effects of levothyroxine. Accordingly, assessments of the adequacy of a given dose or the effects of a change in dosage, with rare exceptions such as pregnancy, should not be made until this interval has passed. This long half-life also means that it is safe for a patient to take any missed doses of T_4 for up to 1 week after missing tablets.

By and large, levothyroxine products are clinically equivalent, although problems do occur.[199] However, the variation permitted by the FDA in tablet content can result in slight variations in serum TSH in patients with primary hypothyroidism even when the same brand is used. Using levothyroxine from a single manufacturer reduces variability that may be relevant for patients, such as elderly, pregnant, and thyroid cancer patients, when close titration is required. Although the serum TSH level is an indirect reflection of the levothyroxine effect in patients with primary hypothyroidism, it is far superior to any other readily available method of assessing the adequacy of therapy. Return of the serum TSH level to normal is therefore the goal of levothyroxine therapy in the patient with primary hypothyroidism. Some patients may require slightly higher or lower doses than generally used, owing to individual variations in absorption, and a number of conditions or associated medications may change levothyroxine requirements in patients with established hypothyroidism (see later). Liquid preparations of levothyroxine, including preparations in capsules, may be better absorbed in select patients.[200]

In decades past, desiccated thyroid was successfully used for the treatment of hypothyroidism and still accounts for a small fraction of the prescriptions written for thyroid replacement in the United States. Although this approach was successful, desiccated thyroid preparations contain thyroid hormone derived from animal thyroids that have twofold to threefold higher ratios of T_3 to T_4 than the 1:15 value in normal human thyroglobulin.[201] Accordingly, these preparations may lead to superphysiologic levels of T_3 in the immediate postabsorptive period (2–4 hours) owing to the rapid release of T_3 from thyroglobulin, its immediate and nearly complete absorption, and the 1-day period required for T_3 to equilibrate with its 40-L volume of distribution (see Table 11.5).[202] A prospective double-blind randomized crossover study compared 4 months of levothyroxine monotherapy with desiccated thyroid preparations in the same hypothyroid patients.[203] There were no significant differences in outcomes, although among patients who had a preference, more preferred desiccated thyroid extract, and these patients lost a modest amount of weight.

Mixtures of liothyronine and levothyroxine (liotrix) contain in a 1-grain (64-μg) equivalent tablet (Thyrolar-1 in the United States) the amounts of T_3 (12.5 μg) and T_4 (50 μg) present in the most popular desiccated thyroid tablet.[204] The levothyroxine equivalency of a 1-grain desiccated thyroid tablet or its liotrix equivalent can be estimated as follows: The 12.5 μg of liothyronine (T_3) is completely absorbed from desiccated thyroid or from liotrix tablets.[202] Levothyroxine is approximately 80% absorbed,[205] and about 36% of the 40 μg of levothyroxine absorbed is converted to T_3, with the molecular weight of T_3 (651) being 84% that of T_4 (777). Accordingly, a 1-grain tablet should provide about 25 μg of T_3, which would be approximately equivalent to that obtained from 100 μg of levothyroxine. This equivalency ratio can be used as an initial guide in switching patients from desiccated thyroid or liotrix to levothyroxine. Although levothyroxine is absorbed in the stomach and small intestine, normal gastric acid secretion is required for complete absorption.[206] Patients with impaired acid secretion on levothyroxine therapy require a 22% to 34% higher dose of levothyroxine to maintain the desired serum TSH. In those patients in whom acid secretion was normalized therapeutically, the levothyroxine dose returned to baseline.[206]

As indicated earlier, the use of levothyroxine as thyroid hormone replacement is a compromise with the normal pathway of T_3 production, in which about 80% of T_3 is derived from T_4 5′-monodeiodination and approximately 20% (~6 μg) is secreted directly from the thyroid gland.[84] Studies in thyroidectomized rats, for example, show that it is not possible to normalize T_3 simultaneously in all tissues by an intravenous infusion of T_4.[207] However, it should be recalled from the earlier discussion of T_4 deiodination that the ratio of T_3 to T_4 in the human thyroid gland is about 0.09 but is 0.17 in the rat thyroid gland.[84] Thus about 40% of the rat's daily T_3 production is derived from the thyroid versus about 20% in humans.[84] Accordingly, the demonstration that T_4 alone cannot provide normal levels of T_3 in all tissues in the rat is of interest but is not strictly applicable to thyroid hormone replacement in humans. Nonetheless, the ratio of T_3 to T_4 in the serum of a patient receiving levothyroxine as the only source of T_3 is about 20% lower than that in a normal individual.

Similarly, the quantity of levothyroxine required to normalize TSH in an athyreotic patient results in a slightly higher serum FT_4 concentration than is present in normal individuals. This has been shown in a comparison of thyroid function in the same patient before and after thyroidectomy.[208] Although serum T_3 was the same level in patients before or after thyroidectomy, a higher serum T_4 concentration was necessary when on T_4 replacement to maintain the same serum T_3.[208] T_4 has an independent mechanism for TSH suppression, owing to the intracellular generation of T_3 in the hypothalamic-pituitary-thyroid axis, resulting in a portion of the feedback TSH regulation being independent of the plasma T_3. A retrospective, cross-sectional study compared thyroid function studies in 1800 athyreotic thyroid cancer patients on levothyroxine monotherapy compared to control subjects.[209] In these patients, the serum FT_4 levels were significantly higher, and free T_3 levels significantly lower, than euthyroid control subjects. However, these patients came from a region of variable iodine intake, which makes interpretation of the control data difficult.

Although the concept of combined T_4/T_3 therapy has been recognized for many years, a positive study generated a great deal of interest in this approach.[210] Patients received 12.5 μg of T_3 as a substitution for 50 μg of their levothyroxine preparation and scored, on average, somewhat higher on tests of mood than when they were taking levothyroxine alone. The dosage of thyroid hormone used in these studies was excessive, as judged by the fact that 20% of the group had serum TSH values below normal on either regimen and the test period was only a few months. A large number of subsequent studies using a wide range of replacement strategies and relative T_4/T_3 content were performed in different populations, and none has shown an advantage of combination therapy over T_4 alone.[211] A study that compared T_4 monotherapy to T_4/T_3 combined therapy in hypothyroid patients evaluated the results based on the presence or absence of D2 gene polymorphisms.[212] The hypothyroid patients homozygous for the D2 polymorphism showed greater improvement in measures of well-being while on T_4/T_3 combination therapy compared to T_4 monotherapy. This study requires replication in a separate population but may indicate that T_4/T_3 combination therapy can be targeted to specific hypothyroid patients who will benefit based on a genetic profile of genes important for thyroid hormone metabolism and action.[9,193,213]

On the other hand, the FT_4 index correlated as closely with the resting energy expenditure as TSH levels in a group of patients in whom small adjustments above or below their ideal replacement levothyroxine dosage were made.[214] The correlation with serum T_3 was not statistically significant, suggesting that in humans, perhaps as a result of differences in the peripheral metabolism of T_4 from that in rodents, the FT_4 concentration may be as accurate as the TSH value as an index of satisfactory thyroid hormone

replacement. The practical difficulty with the design of tablets providing combinations of T_3 and T_4 is that the approximate dose of 6 μg of T_3 provided would need to be released in a sustained fashion over 24 hours, as well as replicating the diurnal rhythm of T_3,[215] which is quite different from the rapid absorption of T_3 with a peak at 2 to 4 hours when given in its conventional form. Thus, for the present, it appears that the current approach to thyroid replacement using levothyroxine alone, although not a perfect replication of normal physiology, is satisfactory for virtually all patients. A sustained-release T_3 preparation has been developed and produces more stable levels of serum T_3.[216] The clinical effects of this more "physiologic" replacement are not known.

Institution of Replacement Therapy

The initial dose of levothyroxine prescribed depends on the degree of hypothyroidism and the age and general health of the patient. Patients who are young or middle aged and otherwise healthy with no associated cardiovascular or other abnormalities and mild to moderate hypothyroidism (TSH concentrations of 5–50 mU/L) can be given an initial complete replacement dose of about 1.7 μg/kg of ideal body weight. The resulting increase in serum T_4 concentration to normal requires 5 to 6 weeks, and the biologic effects of T_3 are sufficiently delayed that these patients do not experience adverse effects. At the other extreme, the elderly patient with heart disease, particularly angina pectoris, without reversible coronary lesions, should be given a small initial dose of levothyroxine (25 μg/day), and the dosage should be increased in 12.5-μg increments at intervals of 2 to 3 months with careful clinical and laboratory evaluation.

The goal in the patient with primary hypothyroidism is to return serum TSH concentrations to normal, reflecting normalization of that patient's thyroid hormone supply. This usually results in a mid-normal to high-normal serum FT_4. The serum TSH should be evaluated 6 weeks after a theoretically complete replacement dose has been instituted to allow minor adjustments to optimize the individual dose.[217] In patients with central hypothyroidism, serum TSH is not a reliable index of adequate replacement, and the serum FT_4 should be restored to a concentration in the upper half of the normal range. T_4 dosing based on body weight and a serum FT_4 in the upper reference range improved markers of thyroid hormone action and was superior to replacement with a combination of T_4/T_3.[218] Patients with central hypothyroidism should also be evaluated and treated for glucocorticoid deficiency, if necessary, before institution of thyroid replacement (see Chapter 9).

Although the adverse effects of the rapid institution of therapy are unusual, pseudotumor cerebri has been reported in profoundly hypothyroid juveniles between ages 8 and 12 years who were given even modest initial levothyroxine replacement.[219] This complication appears 1 to 10 months after initiation of treatment and responds to acetazolamide and dexamethasone.

The interval between the initiation of treatment and the first evidence of improvement depends on the strength of dose given and the degree of the deficit. An early clinical response in moderate to severe hypothyroidism is a diuresis of 2 to 4 kg. The serum sodium (Na^+) level increases even sooner if hyponatremia was present initially. Thereafter, pulse rate and pulse pressure increase, appetite improves, and constipation may disappear. Later, psychomotor activity increases and the delay in the deep tendon reflex disappears. Hoarseness abates slowly, and changes in skin and hair do not disappear for several months. In individuals started on a complete replacement dose, the serum FT_4 level should normalize after 6 weeks; a somewhat longer period may be necessary for serum TSH levels to return to normal, perhaps up to 3 months.

In some cases (e.g., myxedema coma [see later]), it is clinically appropriate to alleviate hypothyroidism rapidly. For example, patients with severe hypothyroidism withstand acute infections or other serious illnesses poorly, and myxedema coma may develop as a complication. In such circumstances, rapid near repletion of the peripheral hormone pool in the average adult can be accomplished by a single intravenous dose of 500 μg of levothyroxine. Alternatively, by virtue of its rapid onset of action, liothyronine (25 μg orally every 12 hours) can be administered if the patient can take medication by mouth. With both approaches, an initial biologic effect is achieved within 24 hours. Parenteral therapy with levothyroxine is then continued with a dose that is 80% of the appropriate oral dose but not in excess of 1.4 μg/kg of ideal body weight. Because of the possibility that rapid increases in metabolic rate will overtax the existing pituitary-adrenocortical reserve, supplemental glucocorticoid (intravenous hydrocortisone 5 mg/hour) should also be given to patients with severe hypothyroidism receiving high initial doses of thyroid hormones. Finally, in view of the tendency of hypothyroid patients to retain free water, intravenous fluids containing only dextrose should not be given.

When replacement therapy is withdrawn for short periods (4–6 weeks) for purposes of evaluating therapy for thyroid cancer, rapid reinstitution of levothyroxine using a loading dose of three times the daily replacement dose for 3 days can usually be given unless there are other complicating medical illnesses.

When hypothyroidism results from administration of iodine-containing or antithyroid drugs, withdrawal of the offending agent usually relieves both the hypothyroidism and the accompanying goiter, although it is appropriate to provide interim replacement until the gland recovers its function.[138,220] This is especially true for amiodarone, which may remain in tissues for up to 1 year.

Infants and Children

In infants with congenital hypothyroidism, the determining factor for eventual intellectual attainment is the age at which adequate treatment with thyroid hormone is begun.[18,221] The therapy for infants with congenital hypothyroidism should consist initially of raising the serum T_4 level to more than 130 nmol/L (10 μg/dL) as rapidly as possible and maintaining it at that level for the first 3 to 4 years of life. This is usually accomplished by administering an initial levothyroxine dose of 50 μg/day, which is higher than the adult dose on a weight basis and in keeping with the higher metabolic clearance of the hormone in the infant. The serum TSH concentration may not return to normal even with this high dose because of residual reset of the pituitary feedback mechanism. After 2 years of age, however, a TSH level in the normal range is an index of optimal therapy as it is in adults.[222]

Monitoring Replacement Therapy

Monitoring the adequacy of, and compliance with, thyroid hormone therapy in patients with primary hypothyroidism is easily done by measurement of serum TSH.[9] This value should be within the normal range for an assay sufficiently sensitive to measure, with confidence, the lower limit of the normal range. The normal serum TSH concentration varies between 0.5 and 4 mU/L in most second-generation and third-generation assays, and results within this range are associated with the elimination of all clinical and biochemical manifestations of primary hypothyroidism, except in patients with RTH. Based on analysis of the National Health and Nutrition Examination Survey (NHANES III) reference group,[13]

a reference TSH range with an upper limit of 2.5 mU/L has been suggested. This adjustment, however, would identify a large number of individuals as having abnormal thyroid function, without a clear indication of the clinical significance of TSH levels in this range. A more recent analysis, based on age-specific reference ranges, indicates that older adults, without thyroid autoantibodies, have an increased upper limit TSH (>4.5 mU/L) that is not associated with thyroid disease.[223] In related studies, this progressive shift with age to higher levels of TSH has been associated with extreme longevity in several populations.[224]

After the first 6 months of therapy, the dose should be reassessed because restoration of euthyroidism increases the metabolic clearance of T_4. A dose that was adequate during the early phases of therapy may not be so when the same patient is euthyroid owing to an acceleration in the clearance of thyroid hormone.

Under normal circumstances, the finding of a normal serum TSH level on an annual basis is adequate to ensure that the proper levothyroxine dose is being taken by the patient. If the serum TSH level is above the normal range and noncompliance is not the explanation, small adjustments, usually in 12-μg increments, can be made with reassessment of TSH concentrations after the 6 weeks required for full equilibration have passed. In North America, this strategy is simplified by the availability of multiple tablet strengths, many of which differ by only 12 μg. Most patients can receive the same dose until they reach their seventh or eighth decade, at which point a downward adjustment of 20% to 30% may be indicated because thyroid hormone clearance decreases in the elderly.

Thyroid hormone requirements may be altered in several situations (Table 13.3). Most conditions or medications increase the levothyroxine requirement in patients receiving maintenance therapy. During pregnancy, the levothyroxine requirement is increased by 25% to 50% in most hypothyroid women, and a prospective study demonstrated that the increased requirement occurs early in the first trimester.[225] The required increment is higher in athyreotic patients compared to those with autoimmune hypothyroidism.[226] Athyreotic patients who are planning a pregnancy should be advised to increase the dose by around 30% as soon as the diagnosis is confirmed because the change in requirement appears soon after implantation.[9,113] The increased requirement is probably due to a combination of factors, including increases in T_4-binding globulin and the volume of distribution of T_4, an increase in body mass, and an increase in D3 in the placenta and uterus probably due to estradiol-induced increases in *Dio3* gene transcription.[84] The increased requirement persists throughout pregnancy but returns to normal within a few weeks after delivery. Therefore the dose should be reduced to the original prepregnancy level at the time of delivery. Maternal T_4 is critically important to the athyreotic fetus and in the normal fetus in the first trimester before fetal thyroid function and feedback regulation mature.[227] Maternal hypothyroidism has been associated with fetal loss, preterm delivery, and intellectual deficit in the offspring.[67,113] These findings are not seen in hypothyroid women on T_4 replacement sufficient to normalize their TSH, suggesting that these associations are directly related to maternal thyroid hormone status. A randomized prospective study in pregnant women with anti-TPOAb and normal range TSH demonstrated the benefit of levothyroxine treatment to prevent these complications.[228]

Other conditions in which levothyroxine requirements are increased (see Table 13.3)[9,80,146] include malabsorption due to bowel diseases, impaired gastric acid secretion,[206] and adsorption of levothyroxine to coadministered medications such as sucralfate, aluminum hydroxide, calcium carbonate, ferrous sulfate, lovastatin, or various resins. Certain medications, notably rifampin, carbamazepine, phenytoin, and sertraline, increase the clearance of levothyroxine by inducing CYP3A4 in the liver. Estrogen given to postmenopausal women may act in the same way, although the increases in D3 also play a role.[229] Soy protein and soybean isoflavones have been proposed to interfere directly with thyroid hormone action as well as synthetic T_4 absorption.[230] There is no evidence that soy interferes with thyroid function in euthyroid individuals who are iodine sufficient, and the effect of soy on T_4 absorption in hypothyroid patients is modest.[230] Amiodarone increases levothyroxine requirements by blocking conversion of T_4 to T_3 and perhaps by interfering with T_3–thyroid hormone receptor binding.[231] Selenium deficiency is rare, but because it is rate limiting in the synthesis of D1 (see Fig. 11.2),[84] any significant deficiency, such as may occur in patients receiving diets restricted in protein, may increase levothyroxine requirements.

Occasionally in patients who have been treated with radioactive iodine for Graves disease or toxic nodular goiter, some degree of thyroid hormone secretion persists and, although insufficient to sustain normal thyroid hormone levels, is autonomous. Such patients may have a suppressed TSH on what otherwise would

TABLE 13.3 Conditions That Alter Levothyroxine Requirements

Increased Levothyroxine Requirements

Pregnancy

Gastrointestinal Disorders

Mucosal diseases of the small bowel (e.g., sprue)
After jejunoileal bypass and small bowel resection
Impaired gastric acid secretion (e.g., atrophic gastritis)
Diabetic diarrhea

Therapy With Certain Pharmacologic Agents

Drugs That Interfere With Levothyroxine Absorption

Cholestyramine
Sucralfate
Aluminum hydroxide
Calcium carbonate
Ferrous sulfate

Drugs That Increase the Cytochrome P450 Enzyme (CYP3A4)

Rifampin
Carbamazepine
Estrogen
Phenytoin
Sertraline
? Statins

Drugs That Block T_4 to T_3 Conversion

Amiodarone

Conditions That May Block Deiodinase Synthesis

Selenium deficiency
Cirrhosis

Decreased Levothyroxine Requirements

Aging (≥65 years)
Androgen therapy in women

T_4, Thyroxine; *T_3*, triiodothyronine.

be considered a replacement dose of levothyroxine. The levothyroxine dose in these individuals should be reduced until TSH levels rise to normal, keeping in mind that several months may be required before TSH secretion recovers after its prolonged suppression. Because of either the delayed effects of radioiodine or the natural history of Graves disease per se, this autonomous T_4 secretion may decrease with time, leading to an increase in levothyroxine requirements in subsequent years. Rarely, the opposite occurs; that is, a patient treated with radioiodine develops an increased TSH level, but after several months of therapy the requirement for such replacement is either reduced or eliminated. This response may reflect transient impairment of thyroid function by a combination of preirradiation antithyroid drug therapy and immediate but transient effects of irradiation on the thyroid. In such patients, frequent monitoring of levothyroxine replacement is required to avoid overreplacement.

In North America, based on the recent previously discussed changes in assessment of levothyroxine bioequivalence, the possibility of a difference in tablet levothyroxine content should be considered if a new preparation changes the biologic or biochemical effects of the same dosage. Although the difference in preparation is unlikely to cause a significant difference in most patients, the change in manufacturer introduces another potential source of variability.

Adverse Effects of Levothyroxine Therapy

Although the administration of excessive doses of levothyroxine causes accelerated bone loss in postmenopausal patients, most authorities believe that returning thyroid status to normal does not have adverse effects on bone density.[232] Administration of excessive doses also increases cardiac wall thickness and contractility and, in elderly patients, increases the risk of atrial fibrillation.[16,25]

In some patients, TSH levels remain elevated despite the prescription of adequate replacement doses.[233] This response is most often a consequence of poor adherence. The combination of normal or even elevated serum FT_4 values and elevated TSH levels can occur if the patient does not take levothyroxine regularly but ingests several pills the day before testing. The integrated dose of levothyroxine over prior weeks is best reflected in the serum TSH level, and nonadherent patients require careful education as to the rationale for treatment. Subtle changes in dietary habits, such as increasing the ingestion of bran-containing products, soy, or calcium or proton pump inhibitors, may decrease levothyroxine absorption, and their recognition requires a careful history.[80,146,233] In patients on T_4 replacement with erratic TSH levels and consideration of inconsistent adherence with therapy or malabsorption, a protocol has been developed to evaluate such patients with weekly supervised dosing of LT_4 and monitoring of serum TSH and FT_4 concentrations.[1] Use of weekly dosing of LT_4 should be done very cautiously in older patients or those with known cardiac disease.

Patients With Hypothyroid Symptoms Despite Restitution of Normal Thyroid Function

In patients taking levothyroxine replacement with a normal serum TSH concentration, symptoms consistent with hypothyroidism may persist.[234] A survey of hypothyroid patients on levothyroxine with normal TSH and control patients included questions about symptoms that might be associated with thyroid hormone deficiency.[235] Although a significant fraction of both groups reported such symptoms, a greater fraction of patients on levothyroxine replacement had these symptoms. Patients on thyroxine replacement post-thyroidectomy consistently require a higher serum T_4 than preoperatively to maintain the same serum T_3 concentration.[208] The addition of thyroid replacement containing triiodothyronine continues to be a focus in these patients but has not been shown to confer long-term relief of symptoms.[234] Additionally, such patients should be educated as to the relationship between symptoms of hypothyroidism and the role of thyroid hormone in relieving them, and other causes should be sought for the symptoms.

Special Aspects of Hypothyroidism

Subclinical Hypothyroidism

The term *subclinical hypothyroidism* was originally used to describe the patient with a low-normal FT_4 but a slightly elevated serum TSH level. Other terms for this condition are *mild hypothyroidism, early thyroid failure, preclinical hypothyroidism,* and *decreased thyroid reserve* (see Table 13.2). The TSH elevation in such patients is modest, with values typically between 5 and 15 mU/L, although patients with a TSH above 10 mU/L more often have a reduced FT_4 and may have true hypothyroid symptoms. The definition of this syndrome depends significantly on the reference range for a normal TSH concentration. This syndrome is most often seen in patients with early Hashimoto disease and is a common phenomenon, occurring in 7% to 10% of older women.[14–16]

A number of studies on the effects of thyroid hormone treatment in such patients have used physiologic end points (e.g., measurements of various serum enzymes, systolic time intervals, serum lipids, psychometric testing), and results have been variable.[14–16] In the most carefully controlled studies, one or another of the parameters has returned to normal in about 25% to 50% of patients. A prospective randomized trial of subclinical hypothyroidism in elderly males showed no benefit of therapy.[236] Among those men originally enrolled based on an elevated TSH, 62% had a normal TSH on subsequent measurement, indicating the importance of repeating a TSH measurement in suspected subclinical hypothyroidism. In general, FT_4 and TSH levels normalize, but free T_3, usually normal at the outset, does not change. Modest improvements in cardiac indices and lipid profiles have been noted in most but not all studies, although the benefit on cardiovascular risk is seen in middle-aged patients.[30,34] The association of mild hypothyroidism with an increase in risk for atherosclerotic heart disease has been shown by some studies but not others.[14,16] The impact of treatment to reduce the risk of atherosclerotic heart disease, other than reduction in risk factors such as cholesterol and C-reactive protein, have not yet been studied.

One factor favoring a decision to recommend levothyroxine therapy is the likelihood of developing overt hypothyroidism. The risk of progression from *subclinical* to *overt* hypothyroidism (elevated serum TSH and reduced FT_4) is most closely related to the magnitude of serum TSH elevation and the presence of anti-TPOAb. Prospective studies of women with subclinical hypothyroidism have shown rates of progression from approximately 3% to 8% per year, with the higher rates seen in individuals with initial TSH concentration greater than 10 and those with positive anti-TPOAb.[237] Although most individuals progress slowly to overt hypothyroidism, rapid progression over weeks to months has been reported.[238] Factors that may predispose to rapid progression include increased age, high levels of TPOAb, intercurrent systemic infection or inflammation, iodine contrast agents, and medications such as amiodarone and lithium. The decision to treat with levothyroxine must also take into account the expense

and inconvenience of a daily medication, which is not acceptable to some patients, and the possibility that unintended overdosage may exacerbate osteoporosis or cause cardiac arrhythmias. Ultimately the decision to treat must depend on a careful consideration of the individual clinical situation and patient preference. If a therapeutic trial is performed, the TSH concentration should be monitored carefully and should not be reduced below normal. If no therapy is given, such patients should be monitored at intervals of 6 to 12 months both clinically and biochemically.

Metabolic Insufficiency

Nonspecific symptoms of true hypothyroidism include mild lassitude, fatigue, slight anemia, constipation, apathy, cold intolerance, menstrual irregularities, loss of hair, and weight gain. For this reason, some patients with such complaints but with normal laboratory results for thyroid function have been considered candidates for levothyroxine therapy. The response to thyroid hormone therapy is sometimes gratifying, at least initially, but symptomatic improvement usually disappears after a time unless the dose is increased. Eventually, even larger doses fail to alleviate the symptoms, confirming that they do not arise from a deficiency of thyroid hormone.

Thus thyroid hormone therapy should be avoided in patients with no biochemical documentation of impaired thyroid function. Furthermore, even in patients with subclinical hypothyroidism, symptoms may be out of proportion to abnormalities in the FT_4. It is unwise to raise a patient's expectations that such symptoms will be relieved by correction of mild biochemical abnormalities.

Thyroid Function Testing in Patients Receiving Replacement Therapy for Unclear Reasons

Physicians are frequently confronted with patients receiving levothyroxine in whom the basis for the diagnosis cannot be established. It may be difficult to document previous clinical findings or laboratory data to determine whether thyroid hormone replacement is indicated. If serum TSH is in the normal range and primary hypothyroidism is suspected, a simple way of assessing the need for levothyroxine therapy is to switch levothyroxine to an every-other-day dosage or to reduce the daily dose by 50% and to reevaluate TSH and FT_4 after 4 weeks. If there is no significant increase in TSH concentration and FT_4 remains constant during that period, residual thyroid function is present, although it may still not be completely normal. To answer this question, levothyroxine can then be withdrawn and blood tests repeated 4 to 8 weeks later.

If the initial TSH level is suppressed, indicating overreplacement, the levothyroxine dose should be reduced until TSH becomes detectable before this trial is instituted. If central hypothyroidism is suspected, the FT_4 must be monitored.

Emergent Surgery in the Hypothyroid Patient

The perioperative course of patients with untreated hypothyroidism has been evaluated in several studies. In general, such patients were not recognized to be hypothyroid or did not require surgery despite the presence of significant hypothyroidism. Complications were uncommon. Perioperative hypotension, ileus, and central nervous system disturbances were more common in hypothyroid patients, and patients with major infections had fewer episodes of fever than did euthyroid control subjects.[239] Other complications were delayed recovery from anesthesia and abnormal hemostasis, possibly owing to an acquired form of von Willebrand disease.[59]

From these studies one may conclude that emergent surgery should not be postponed in hypothyroid patients but that such patients should be rigorously monitored for evidence of carbon dioxide retention, bleeding, infection, and hyponatremia. These findings are also relevant to the treatment of hypothyroid individuals with symptomatic coronary artery disease. Considering the lack of significant increase in perioperative complications in the hypothyroid patient, the option of surgery for remediable coronary artery lesions is open to hypothyroid individuals without the risk of a myocardial infarction in association with restitution of the euthyroid state (see later).[240]

Heart Disease and Thyroid Hormone Therapy

Coexisting Coronary Artery Disease and Hypothyroidism

In many patients with coronary artery disease and primary hypothyroidism, cardiac function is improved in response to levothyroxine therapy because of a decrease in peripheral vascular resistance and improvement in myocardial function. However, patients with preexisting angina pectoris should be evaluated for correctable lesions of the coronary arteries and treated appropriately before levothyroxine is administered.[240,241] Retrospective studies indicate that this approach is safer than the institution of replacement therapy prior to angiography and angioplasty or even coronary artery bypass grafting (CABG).[240]

In a few patients, lesions may not be remediable, or small-vessel disease is severe even after stenting or bypass grafting, so that complete replacement cannot be instituted. Such patients must receive optimal antianginal therapy combined with β-adrenergic receptor blockers in judicious quantities, and complete restitution of the euthyroid state may not be possible.

Thyroid Hormone for Compromised Cardiovascular Function

In addition to the issues raised in patients with combined hypothyroidism and coronary artery disease, there is interest in the potential therapeutic use of thyroid hormone in the treatment of patients with cardiomyopathy or those who have undergone CABG or other cardiac procedures.[25] As expected, T_3 levels are reduced in patients with advanced congestive heart failure, as with any illness. In one report, 23 patients with advanced heart failure (mean ejection fraction, 22%) were given up to 2.7 μg/kg of liothyronine over 6 hours with an increase in cardiac output and decrease in systemic vascular resistance but without increase in heart or metabolic rate.[242] Similar effects were seen with a dose of 110 μg liothyronine over 6 hours after CABG.[243]

Liothyronine has also been given postoperatively for congenital heart disease and, again, an improvement in cardiac output and decrease in vascular resistance occurred without adverse side effects.[209] These results suggest that, in certain selected circumstances, liothyronine may be useful as adjunctive therapy in patients with congestive heart failure because of its effect of relaxing vascular smooth muscle.

Although most therapeutic trials of thyroid hormone treatment have used T_3, thyroid hormone analogues have also been used.[25] The most extensively studied is 3,5-diiodothyropropionic acid (DITPA), an analogue that binds both *TRα* and *TRβ* with low affinity. A randomized study of DITPA in heart failure showed some improved cardiac performance,[244] but the study was terminated because of significant metabolic side effects, including weight loss.[245]

Screening for Primary Hypothyroidism

The use of screening for hypothyroidism has been addressed by a number of studies but remains controversial.[191] The conclusions depend, to a great extent, on assumptions regarding the effectiveness and economic value of identifying and treating patients with subclinical hypothyroidism. An evidenced-based medicine review of the literature by an expert panel concluded that there was insufficient evidence to support population-based screening.[246] Aggressive "case finding," based on identification of risk factors such as family history, was advocated for pregnant women, women older than 60 years, and others at high risk. The fraction of patients with hypothyroidism missed when a "case finding" strategy is used, however, is not known. A updated report from the US Preventive Services Task Force concluded that there is still insufficient data to recommend population screening for hypothyroidism in nonpregnant adults.[247] Large, randomized, prospective studies of levothyroxine treatment in patients with subclinical hypothyroidism to establish benefit, however, have not yet been performed. Given the very high incidence of hypothyroidism in older women and the absence of robust clinical symptoms, an assessment of TSH levels at 5-year intervals in women older than age 50 years seems justified until more extensive studies have been performed.

A second complex issue involves whether women planning pregnancy should be screened for the presence of hypothyroidism as a routine part of a prenatal visit.[113] This question is raised because of increasing association of adverse outcomes in pregnancy, even with subclinical hypothyroidism, including impairment of mental development in infants, fetal loss, and preterm delivery.[66,67] The prevalence of overt hypothyroidism during pregnancy is approximately 2%, and screening of all patients has been advocated by several professional organizations. Thyroid testing in high-risk patients, "case finding," has been advocated, although a prospective study showed that approximately a third of pregnant women with underlying thyroid disease are missed by this testing approach.[248]

Isolated maternal hypothyroxinemia in pregnancy, generally defined as a FT_4 in the lowest 2.5 to 5th percentile, with a normal reference range TSH, has been associated with a range of neurologic deficits, including reduced IQ, reduced cortical volume, language delay, and autism.[67] Treatment of hypothyroxinemic women during pregnancy has not been associated with improved cognitive outcome of the offspring,[249,250] and routine treatment is not currently recommended.[113]

A number of questions are raised regarding the appropriate timing of testing, whether thyroid autoantibodies should be measured, the relative importance of TSH and FT_4, the influence of trimester on the normal ranges, and the threshold for intervention. The association of maternal subclinical hypothyroidism and preterm delivery is a much more proximal and defined end point to study compared to intellectual performance in offspring. The morbidity and mortality rates from preterm delivery are significant for the newborn, and these findings are likely to allow for more focused intervention studies to determine the response to T_4 treatment.[66]

For the moment, it appears that any patient with a family history of autoimmune thyroid disease, with symptoms suggesting hypothyroidism, or with thyroid enlargement should be tested for thyroid dysfunction prior to pregnancy or as soon after conception as is feasible. Optimization of levothyroxine therapy for women known to have hypothyroidism prior to conception, when possible, may be the most effective intervention to prevent hypothyroid-related complications of pregnancy. Although the data do not yet reach the threshold to mandate universal screening, the ease of testing, associated adverse outcomes, and demonstrated benefit of intervention make thyroid testing of all pregnant women a reasonable choice.

Myxedema Coma

Myxedema coma is the ultimate stage of severe long-standing hypothyroidism.[251,252] This state, which almost invariably affects older patients, occurs most commonly during the winter months and is associated with a high mortality rate. It is usually accompanied by a subnormal temperature. Values as low as 23°C have been recorded. The external manifestations of severe myxedema, bradycardia, and severe hypotension are invariably present. The characteristic delay in deep tendon reflexes may be lacking if the patient is areflexic. Seizures may accompany the comatose state. Although the pathogenesis of myxedema coma is not clear, factors that predispose to its development include exposure to cold, infection, trauma, and central nervous system depressants or anesthetics. Alveolar hypoventilation, leading to carbon dioxide retention and narcosis, and dilutional hyponatremia resembling that seen with inappropriate ADH secretion may also contribute to the clinical state.

From the foregoing, it appears that myxedema coma should be readily recognized from its clinical signs, but this is not the case. Hypothermia of any cause (e.g., to cold exposure) may cause changes suggestive of myxedema, including delayed relaxation of deep tendon reflexes. The importance of diagnosing myxedema coma is that a delay in therapy worsens the prognosis. Consequently, a rapid serum FT_4 and TSH should be obtained whenever this diagnosis is being considered. Otherwise the diagnosis should be made on clinical grounds; after serum has been sent for thyroid function tests, therapy should be initiated without awaiting the results of delayed confirmatory tests because the mortality rate may be 20% or higher.

Treatment consists of administration of thyroid hormone and correction of the associated physiologic disturbances.[251,252] Because of the sluggish circulation and severe hypometabolism, absorption of therapeutic agents from the gut or from subcutaneous or intramuscular sites is unpredictable, and medications should be administered intravenously if possible. Administration of levothyroxine as a single intravenous dose of 500 to 800 μg repletes the peripheral hormone pool and may cause improvement within hours. Daily doses of intravenous levothyroxine, 100 μg, are given thereafter. Hydrocortisone (5–10 mg/hour) should also be given because of the possibility of relative adrenocortical insufficiency as the metabolic rate increases.

Alternatively, intravenous liothyronine may be given at a dose of 25 μg every 12 hours. Others have used a combination of 200 to 300 μg T_4 and 25 μg T_3 intravenously as a single dose, followed by 25 μg T_3 and 100 μg T_4 24 hours later, and then 50 μg T_4 daily until the patient regains consciousness. *Hypotonic* fluids should not be given because of the danger of water intoxication owing to the reduced free water clearance of the hypothyroid patient. *Hypertonic* saline and glucose may be required to alleviate severe dilutional hyponatremia and the occasional hypoglycemia.

A critical element in therapy is support of respiratory function by means of assisted ventilation and controlled oxygen administration. Internal warming by gastric perfusion may be useful, but external warming should be avoided because it may lead to vascular collapse due to peripheral vasodilatation. Further heat loss can be prevented with blankets. An increase in temperature may be seen within 24 hours in response to levothyroxine. General measures applicable to the comatose patient should be undertaken, such as frequent turning, prevention of aspiration, and attention to fecal impaction and urinary retention.

TABLE 13.4 Causes of Thyroiditis

Autoimmune thyroiditis
Painless subacute thyroiditis, including postpartum thyroiditis (see Chapter 12)
Painful subacute thyroiditis (see Chapter 12)
Acute infectious thyroiditis
Riedel thyroiditis
Postirradiation (^{131}I or external-beam therapy)
Sarcoidosis

Finally, the physician should assess the patient for the presence of coexisting disease, especially infection, cardiac disease, or cerebrovascular disease. The myxedematous patient may be afebrile despite a significant infection. As soon as the patient is able to take medication by mouth, treatment with oral levothyroxine should be instituted.

Thyroiditis

Thyroiditis is a term indicating the presence of thyroid inflammation and thus comprises a large group of diverse inflammatory conditions. These conditions include the following: autoimmune or quasi-autoimmune causes and viral or postviral conditions and infections, including those of bacterial and fungal origins; a chronic sclerosing form of thyroiditis, termed *Riedel thyroiditis* (or struma); and miscellaneous causes of various types, including radiation-induced and granulomatous causes, such as sarcoidosis, as well as lithium.[5]

Not only are the causes of thyroiditis extremely varied, their clinical presentations may also be diverse and are difficult to categorize in a simple fashion (Table 13.4). Thus, as already discussed, autoimmune thyroiditis may present with hypothyroidism but often patients remain euthyroid for long periods after the disease begins. On the other hand, in a euthyroid patient with Hashimoto disease who becomes pregnant, the postpartum period is often complicated by an acute form of thyrotoxicosis due to the transient exacerbation of thyroiditis, often followed by a period of hypothyroidism (see Chapter 12).[66]

A similar syndrome has been observed in nonpregnant patients, called *painless subacute thyroiditis.* It is manifested primarily as thyrotoxicosis of sudden onset without localized pain and often without evidence of autoimmune disease. This condition may be viral in origin in some patients; however, the classic presentation of postviral thyroiditis, a condition referred to as *painful subacute thyroiditis*, is characterized by extreme thyroid tenderness, with pain radiating to the oropharynx and ears, and must be differentiated from acute infectious thyroiditis caused by bacterial or fungal infection.[253]

Thus inflammatory conditions of the thyroid present a didactic dilemma because one must decide whether to discuss these entities as a group with the common denominator of inflammation or to categorize them according to their principal clinical effects, namely, thyrotoxicosis or thyroid hormone deficiency. We have chosen the latter approach and have already discussed autoimmune thyroiditis, the major cause of thyroid gland failure (see Table 13.1). However, patients with acute autoimmune thyroiditis may also develop thyrotoxicosis, such as in postpartum painless thyroiditis (see Chapter 12 discussion regarding autoimmune thyroiditis).[66] These patients must be differentiated from those with Graves disease. In addition, some patients with painful subacute thyroiditis have thyrotoxicosis as a major manifestation with varying degrees of neck discomfort. For that reason, this thyroiditis syndrome is also discussed in Chapter 12, even though the pain associated with the typical form of this condition makes the principal differential diagnosis lie between that and infectious thyroiditis. In that context, subacute thyroiditis is also mentioned later.

Acute Infectious Thyroiditis

Although the thyroid gland is remarkably resistant to infection, congenital abnormalities of the piriform sinus, underlying autoimmune disease, or immunocompromise of the host may lead to the development of an infectious disease of the thyroid gland, acute infectious thyroiditis.[253,254] The cause may be any bacterium, including *Staphylococcus, Pneumococcus, Salmonella,* or *Mycobacterium tuberculosis.* In addition, infections with certain fungi, including *Coccidioides immitis, Candida, Aspergillus,* and *Histoplasma,* have been reported.

The most common cause of repeated childhood infectious thyroiditis, particularly in the left lobe, is a consequence of an internal fistula extending from the piriform sinus to the thyroid.[254] This sinus is the residual connection following the path of migration of the ultimobranchial body from the fifth pharyngeal pouch to the thyroid gland. The predominance of thyroiditis of the left lobe is explained by the fact that the right ultimobranchial body is often atrophic, whereas this is not the case for the left side. Nonetheless, a patient with a completely normal thyroid gland may develop bacterial thyroiditis. This is an extremely rare disease even as a complication of direct puncture of the thyroid gland, such as in fine-needle aspiration. In individuals with midline infections, persistence of the thyroglossal duct should be considered.

Incidence

Infectious thyroiditis is extremely rare, with no more than a few cases being seen in large tertiary care centers.

Clinical Manifestations

The clinical manifestations of infectious thyroiditis are dominated by local pain and tenderness in the affected lobe or entire gland. This is accompanied by painful and difficult swallowing. Because of the tendency for referral of pain to the pharynx or ear, the patient may not recognize the tenderness in the anterior neck. Depending on the virulence of the organism and the presence of septicemia, symptoms such as fever and chills may also accompany the condition.

The major differential diagnosis lies between an infectious form of thyroiditis and painful subacute thyroiditis. It is instructive to compare the principal features of these two diseases to arrive at an accurate diagnosis (Table 13.5). By and large, patients with acute infectious thyroiditis caused by a bacterium are much sicker than patients with painful subacute thyroiditis; they have more severe and localized tenderness and are less likely to have laboratory evidence of thyrotoxicosis, which is present in approximately 60% of patients with painful subacute thyroiditis. Ultrasonographic examination often reveals the abscess in the thyroid gland or evidence of swelling, and needle aspiration may help pinpoint the responsible organism. A gallium scan will be positive as a result of the diffuseness of the inflammation and, particularly in children with infectious thyroiditis of the left lobe, a barium swallow showing a fistula connecting the piriform sinus and left lobe of the thyroid is diagnostic.[254]

Occasionally, pertechnetate scanning is useful in showing normal function of one lobe of the thyroid gland, which is much less common in painful subacute thyroiditis (which more often affects the entire gland). Needle aspiration should be used to drain the affected lobe, although occasionally surgical drainage may be

TABLE 13.5 Features Useful in Differentiating Between Acute Infectious Thyroiditis and Subacute Thyroiditis

Characteristic	Acute Thyroiditis (% with Feature)	Subacute Thyroiditis (% with Feature)
History		
Preceding upper respiratory infection	88	17
Fever	100	54
Symptoms of thyrotoxicosis	Uncommon	47
Sore throat	90	36
Physical Examination of the Thyroid		
Painful thyroid swelling	100	77
Left side affected	85	Not specific
Migrating thyroid tenderness	Possible	27
Erythema of overlying skin	83	Not usually
Laboratory Findings		
Elevated white blood cell count	57	25–50
Elevated ESR (>30 mm/hr)	100	85
Abnormal thyroid hormone levels (elevated or depressed)	5–10	60
Alkaline phosphatase, transaminases increased	Rare	Common
Results of Needle Aspiration		
Purulent, bacteria or fungi present	~100	0
Lymphocytes, macrophages, some polyps, giant cells	0	~100
^{123}I uptake low	Uncommon	~100
Radiologic Findings		
Abnormal thyroid scan	92	—
Thyroid scan or ultrasound helpful in diagnosis	75	—
Gallium scan positive	~100	~100
Barium swallow showing fistula	Common	0
CT scan useful	Rarely	Not indicated
Clinical Course		
Clinical response to glucocorticoid treatment	Transient	100
Incision and drainage required	85	No
Recurrence following operative drainage	16	No
Piriform sinus fistula discovered	96	No

CT, Computed tomography; *ESR,* erythrocyte sedimentation rate.

From DeGroot LJ, Larsen PR, Hennemann G. Acute and subacute thyroiditis. In: *The Thyroid and Its Diseases.* 6th ed. New York: Churchill Livingstone; 1996:700.

required. If a piriform sinus fistula can be demonstrated, it must be removed to prevent recurrence of the problem.

Antibiotics should be administered appropriate to the offending organism. Fungal infections should be treated appropriately, especially because many of these individuals are immunocompromised. Endemic organisms should be kept in mind as a cause, in that both *Echinococcus* and *Trypanosomiasis* infections of the thyroid gland have been reported.

The prognosis is excellent with preservation of thyroid function in general, although post-thyroiditis thyroid function tests should be monitored to ascertain that thyroid failure has not occurred.

Riedel Thyroiditis

Riedel chronic sclerosing thyroiditis is rare and occurs primarily in middle-age women.[155,255,256] The etiologic mechanism is uncertain, and any association with autoimmune thyroid disease is probably coincidental.[257] The morphologic similarities between the fibrosis of Riedel thyroiditis and IgG4-related sclerosing disease suggest that these entities are closely related, with thyroiditis representing an initial manifestation of a more generalized process.[258] Retroperitoneal, orbital, and mediastinal fibrosis, as well as rarer fibrotic syndromes, are associated with Riedel thyroiditis.[259]

Symptoms develop insidiously and are related chiefly to compression of adjacent structures, including the trachea, esophagus, and recurrent laryngeal nerves. Systemic evidence of inflammation is uncommon. The thyroid gland is moderately enlarged, stony hard, and usually asymmetric. The consistency of the gland and the invasion of adjacent structures suggest carcinoma, but there is no enlargement of regional lymph nodes. Temperature, pulse, and leukocyte count are normal. Severe hypothyroidism is unusual but does occur, as does loss of parathyroid function. The RAIU may be normal or low. Elevated circulating thyroid autoantibodies are much less common and are found in lower titers than in Hashimoto disease.

Tamoxifen, 10 to 20 mg/day (with or without corticosteroids), has been successful in many of these patients and is thought to suppress transforming growth factor beta (TGFβ).[155] Surgery may be required to preserve tracheal and esophageal function, although the response to tamoxifen will often preclude the necessity for this. Treatment with thyroid hormone relieves the hypothyroidism but has no effect on the primary process.

Miscellaneous Causes

Only a few causes of generalized inflammation of the thyroid gland have been reported. These include inflammation arising after ^{131}I treatment for Graves disease, a residual thyroid lobe in a patient with thyroid cancer of the contralateral lobe, and thyroiditis arising from external beam therapy for conditions such as Hodgkin or non-Hodgkin lymphoma, breast carcinoma, or other lesions of the oropharynx. Anaplastic thyroid carcinoma may rarely be associated with a diffuse thyroiditis and elevation of thyroid hormone levels.[260] In general, only radioiodine-induced thyroiditis is associated with pain, and glucocorticoid treatment may be useful in symptomatic therapy.

Nontoxic Diffuse Goiter, Nodular Thyroid Disorders, and Thyroid Malignancies

SEBASTIANO FILETTI, R. MICHAEL TUTTLE, SOPHIE LEBOULLEUX, AND ERIK K. ALEXANDER

CHAPTER OUTLINE

KEY POINTS

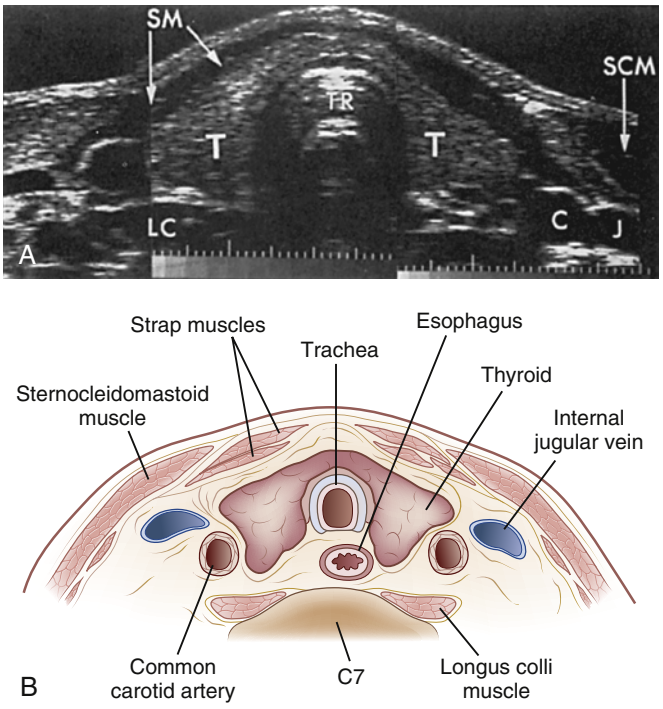
- Neck sonography has become an integral part of the clinical evaluation of thyroid patients and a useful tool in low-risk thyroid cancer patients.
- A more precise risk stratification of thyroid cancer patients has been achieved.
- Surveillance or less invasive surgical strategies can be safely pursued for low-risk thyroid cancer patients.
- Radioiodine treatment for ablation and as adjuvant therapy for intermediate and high-risk patients should be used selectively.
- A more detailed molecular profile of thyroid nodules and thyroid cancer has been achieved. This allows for improved presurgical detection of benign or malignant thyroid nodules, and a more precise profile for high-risk thyroid cancer.
- Targeted therapy has changed the approach to patients with metastatic differentiated and medullary thyroid cancer.

This chapter reviews the imaging techniques available for evaluating thyroid structural abnormalities. Moreover, it deals with the management of nontoxic diffuse goiter as well as benign and malignant thyroid neoplasia. Goiter resulting in thyrotoxicosis and other thyroid conditions arising from autoimmune thyroid disease are considered in Chapters 11–13. The section on management of thyroid nodules and thyroid malignancies is largely based on recently available guidelines from the American Thyroid Association (ATA).[1]

Structural and Functional Imaging of the Thyroid

Ultrasonography

Sonography is a noninvasive technique that has become an integral part of the clinical evaluation of a thyroid patient.[2] High-frequency sound waves are emitted by a transducer and reflected as they pass through the body, whereupon the returning echoes are received by the transducer, which also acts as a receiver. The amplitude of the reflected sound waves is influenced by differences in the acoustic impedance of tissues encountered by the sound; for example, fluid-filled structures reflect few echoes and therefore have no or few internal echoes and well-defined margins, solid structures reflect varying amounts of sound and thus have varying degrees of internal echoes and less well-defined margins, and calcified structures reflect virtually all incoming sound and yield pronounced echoes with an acoustic shadow posteriorly. Thyroid parenchyma, surrounding anatomic structures, and thyroid nodules as small as 2 mm in diameter can be readily detected. Color flow Doppler ultrasonography allows visualization of vessels as well as assessment of nodular vascularity. The thyroid gland must be examined thoroughly in transverse and longitudinal planes. Imaging of patients with thyroid nodules and during follow-up of thyroid cancer should also include evaluation of the regional neck lymph node compartments, with the goal of identifying enlarged and pathologic nodes.[3] The normal thyroid parenchyma has a characteristic homogeneous medium-level echogenicity, with little identifiable internal architecture (Fig. 14.1). The surrounding muscles typically have a hypoechoic appearance. The air-filled



• **Fig. 14.1** Transverse composite sonogram (A) and corresponding anatomic map (B) of the normal thyroid gland. *C,* common carotid artery; *C7,* seventh cervical vertebra; *J,* internal jugular vein; *LC,* longus colli muscle; *SM,* strap muscles; *SCM,* sternocleidomastoid muscle; *T,* thyroid; *TR,* trachea. (From Rifkin MD, Charboneau JW, Laing FC. Special course: ultrasound 1991. In: Reading CC, ed. *Syllabus: Thyroid, Parathyroid, and Cervical Lymph Nodes*. Oak Brook, IL: Radiological Society of North America; 1991:363–377.)

trachea in the midline gives a characteristic curvilinear reflecting surface with an associated reverberation artifact.

A diagrammatic representation of the neck showing the location(s) of any abnormal finding and their characteristics is a useful supplement to the routine film images recorded during an ultrasound examination. Such a cervical map with compartments[4] (Fig. 14.2) can help communicate the anatomic relationships of the findings (and/or pathology) more clearly to the referring clinician and serves as a reference for the sonographer on follow-up examinations.

Neck ultrasonography is clinically useful at each step of thyroid evaluation (Table 14.1). It confirms the presence or absence of a thyroid nodule when the findings on physical examination are equivocal and may reveal the presence of other nonpalpable nodules. Gray-scale and color Doppler ultrasound are used to evaluate the nodule's sonographic features, including size, shape, echogenicity (markedly or mildly hypoechoic, isoechoic, or hyperechoic), margins (irregular or smooth), composition (cystic, solid, or mixed), the presence of coarse or fine (microscopic) calcifications, and internal blood flow. This assessment can be highly useful for estimating the cancer risk in a given nodule. However, descriptions of single ultrasonographic features display wide interobserver variability. In part because of this, the American Thyroid Association[1] and other scientific bodies[5–8] have proposed tiered systems that can be used to estimate a nodule's risk of malignancy (based on its sonographic features) and determine whether it requires fine-needle aspiration biopsy (FNAB) based on size. In 2017, the American College of Radiology (ACR)[6] published a scoring system that promotes systematic assessment of the imaging features of thyroid nodules, the Thyroid Imaging Reporting and Data System (TIRADS), which is inspired by the ACR's recommended approaches to the imaging of the breast (BIRADS) and other organs. Five ultrasound features are assessed and numerically scored, and based on the sum of the five scores, the nodule is assigned to one of five TIRADS classes, each reflecting an estimated risk of cancer and recommendations for management (often including FNAB or surveillance). These classification systems have been shown to improve interobserver agreement.[9] Ultrasound also permits a comprehensive evaluation of regional lymph node compartments.

Elastography assesses tissue stiffness within an isolated, solid thyroid nodule and may prove useful as an indicator of malignancy risk (particularly in nodules that are cytologically indeterminate).[10] Early reports suggested very high specificity and sensitivity, independent of the nodule size. More recent reports suggest that elastographic cancer risk assessment may be inferior to gray-scale ultrasound,[11] with positive predictive values of only 30% to 40%.[12] These contradictory data suggest that elastographic evaluation of thyroid nodules is highly user dependent. Furthermore, it requires special software packages. Elastography cannot be applied to partly or mostly cystic nodules and can prove difficult in a multinodular goiter.

In patients with known thyroid cancer, sonography can be useful in evaluating the extent of disease, both preoperatively and postoperatively.[13] Thus in patients who present with cervical lymphadenopathy caused by papillary thyroid carcinoma (PTC) but in whom the gland is palpably normal, sonography may be used preoperatively to detect an occult primary intrathyroid focus. A preoperative sonogram should be obtained in all patients with differentiated thyroid carcinoma or medullary thyroid carcinoma (MTC) to preoperatively identify the anatomic locations of any sonographically suspicious regional lymph nodes and thereby permit planning of nodal dissection.[1,14] Occasionally impalpable residual cancer that had been identified by preoperative ultrasonography and found cytologically positive by ultrasound-guided FNAB can be identified intraoperatively by the use of a handheld ultrasound probe or by preoperative ultrasound-guided charcoal tattooing.[15]

After initial therapy for follicular cell–derived thyroid cancer (FCTC), sonography (together with measurement of serum thyroglobulin [Tg]) represents the most useful method for detecting residual, recurrent, or metastatic disease in the neck.[3,16,17] In patients who have undergone less than a total thyroidectomy, the sonographic appearance of the remaining thyroid tissue may be an important factor in the decision whether to recommend completion thyroidectomy. Also, it is more sensitive than neck palpation in detecting recurrent disease within the thyroid bed and metastatic disease in cervical lymph nodes.

Sonography is also the standard modality for guiding FNAB of most thyroid nodules and cervical lymph nodes, demonstrating improved accuracy and a reduction in nondiagnostic specimens.[1]

External Scintiscanning

Localization of functioning or nonfunctioning thyroid tissue in the area of the thyroid gland or elsewhere is made possible by techniques of external scintiscanning. The underlying principle is that isotopes that are selectively accumulated by thyroid tissue can be detected by a gamma camera and the data transformed into a visual display. Radioactivity in specific areas can be quantified.[18–20] The units of measurement used in evaluation of the radiation dose and radioactivity are defined in Table 14.2.

Several radioisotopes are used in thyroid imaging. Technetium-99m (^{99m}Tc) pertechnetate is a monovalent anion that is actively concentrated by the thyroid gland but undergoes negligible organic binding and diffuses out of the thyroid gland as its concentration in the blood decreases. The short physical half-life of ^{99m}Tc (6 hours), its low fractional uptake, and its transient stay

Revised management guidelines for patients with thyroid nodules and differentiated thyroid cancer. *Thyroid*. 2009;19:1167–1214, used with permission; B, courtesy J.W. Charboneau, Mayo Clinic, used with permission.)

TABLE 14.1 Clinical Utility of Neck Ultrasound

Map of the neck (thyroid and lymph node areas)
Thyroid gland: size, volume, characteristics
Nodules: number and characteristics of each nodule: diameter, shape, echogenicity, composition, limits, presence of calcifications, vascularization
Lymph node compartments
Follow-up: numbers and diameters of nodules
Guidance for fine-needle aspiration biopsy
Follow-up of thyroid cancer: thyroid bed and regional lymph nodes
Guidance for thermal and ethanol ablation

within the thyroid make the radiation delivered to the thyroid gland by standard activity very low. Consequently, the intravenous administration of radioactivities greater than 37 MBq (1 mCi) permits adequate imaging of the thyroid about 30 minutes later.

Two radioactive isotopes of iodine have been used in thyroid imaging. Iodine-131 (^{131}I) was commonly used in the past. Contrary to ^{99m}Tc, iodine isotopes undergo organic binding. However, ^{131}I is a beta emitter, its physical half-life is 8.1 days, and the energy of its main gamma ray is high. Because of this, ^{131}I is poorly adapted for its detection.[20] In many respects, ^{123}I is an ideal isotope for thyroid imaging because of its short half-life (0.55 day) and the absence of beta radiation, but it is unfortunately much more expensive.[21]

TABLE 14.2 Radiation Nomenclature: Traditional and International System (SI) Units

Absorbed Radiation Dose

Units

Gy (gray) and rad (radiation absorbed dose)

Conversions

1 Gy = 100 rad = absorption of 1 J/kg
1 rad = 0.01 Gy = 1 cGy

Dose Equivalent Radiation

Units

Sv (sievert) and rem (roentgen equivalent in man)

Conversion

1 Sv = 100 rem

Radioactivity (or Activity)

Units

Bq (becquerel) and Ci (curie)

Conversions

1 Bq = 1 disintegration per second = 27 pCi
1 mCi = 37 MBq
1 GBq = 10^3 MBq = 10^6 kBq = 10^9 Bq

Notes

Because the becquerel is extremely small, commonly used multiples of the Bq unit are kBq (kilobecquerel), MBq (megabecquerel), and GBq (gigabecquerel).
A curie, however, is extremely large, so commonly used subunits are mCi (millicurie), μCi (microcurie), nCi (nanocurie), and pCi (picocurie).
Gy, Sv, and Bq are SI units; the rad, rem, and Ci are non-SI units.

The most important use of scintigraphic imaging of thyroid tissue is in defining areas of increased or decreased function (hot or cold areas, respectively) relative to the function of the remainder of the gland. Almost all malignant nodules are hypofunctioning, but more than 80% to 85% of benign nodules are also nonfunctioning. Conversely, functioning nodules (hot nodules), particularly if the function of the surrounding tissue is decreased or absent, are rarely malignant.

Scintiscanning with radioactive iodine can also be used to demonstrate that intrathoracic masses represent thyroid tissue and to detect ectopic thyroid tissue in the neck. In FCTC patients, whole-body scanning (WBS) is used to detect functioning metastases.[22,23] This scan is performed after the administration of larger activities of radioiodine, for diagnosis (1–5 mCi ^{131}I or 1–5 mCi ^{123}I), or more commonly for therapy (≥30 mCi ^{131}I). Such dosing must follow intense stimulation with endogenous or exogenous thyroid-stimulating hormone (TSH, thyrotropin) and be performed in the absence of iodine contamination. Superimposition of computed tomography (CT) and gamma camera images (single-photon emission computed tomography [SPECT]/CT) greatly improves both the sensitivity and specificity of the technique and the anatomic localization of any focus of uptake.[24–27]

Computed Tomography

The CT appearance of the anatomic structures depends on the attenuation of the tissue examined. The thyroid gland, because of its high concentration of iodine, has a higher attenuation than the surrounding soft tissues. Recent advances with spiral CT and reconstruction algorithms have improved the performance of this method.[28,29]

CT scanning cannot distinguish benign from malignant nodules or provide information on a nodule's functional status. However, it can define the anatomic extent of large goiters with great clarity. CT scanning can provide useful information regarding the presence and extent of intrathoracic (substernal) goiters. The CT findings of an intrathoracic mass in continuity with the thyroid gland, with high attenuation on non–contrast-enhanced images and marked enhancement after intravenous contrast material injection, all suggest intrathoracic goiter. Radioiodine scanning can also be performed in this clinical setting, but false-negative results can occur when little or no functional tissue is present in the intrathoracic goiter.

In aggressive pathologic processes, such as anaplastic thyroid carcinoma (ATC), CT with infusion of contrast medium is the most frequently recommended first-line technique to identify lymph node metastases and to define the tumor's relationships to surrounding structures, including vessels and the aerodigestive tract.[28,29] CT imaging is less sensitive than neck ultrasonography for the detection of lymph node metastases. However, contrast-enhanced CT can be a useful complement to ultrasound for exploring the mediastinum and for preoperative assessments of vascular invasion and involvement of the retrotracheal space. High-resolution CT without contrast enhancement is the most sensitive method for the detection of micrometastases in the lungs. Because of the necessity of infusing iodine-containing contrast agents for CT scanning of the neck and mediastinum, CT should be performed at least 4 weeks before any administration of radioiodine.[30]

Magnetic Resonance Imaging

Because the hydrogen atoms of different tissues have different relaxation times (termed *T1* and *T2*), a computer-assisted analysis of T1-weighted and T2-weighted signals is used to differentiate the thyroid gland from skeletal muscles, blood vessels, or regional lymph nodes. Normal thyroid tissue tends to be slightly more intense than muscles on a T1-weighted image, and tumors often appear more intense than normal thyroid tissue.

Magnetic resonance imaging (MRI) does not distinguish benign from malignant nodules and does not assess functional status. Recurrent neoplasms in the thyroid bed or regional lymph nodes can be detected with MRI. Recurrence is characterized by a mass with low to medium intensity on T1-weighted images and medium to high signal intensity on T2-weighted images. Conversely, scar tissue or fibrous tissue has low signal intensity on both T1-weighted and T2-weighted images.[28,29] Tumor invasion of adjacent skeletal muscle has high signal intensity on T2-weighted images. Edema or inflammation in the muscle can cause a similar appearance and can be difficult to differentiate from recurrent tumor.

Compared with CT scan, MRI may better delineate any involvement of the aerodigestive axis. It is often used as a second-line imaging technique in patients with demonstrated or suspicious lesions in the upper part of the neck on CT scan to better delineate these lesions from soft tissues. In the lower part of the neck, movements of the aerodigestive axis during the procedure that may last several minutes will decrease the quality of images. Endoscopy of the trachea and/or esophagus, with or without

ultrasonography, looking for evidence of intraluminal extension, can also be helpful in cases of suspected aerodigestive tract invasion.

MRI is superior to CT for detecting brain metastases from solid tumors because it offers higher soft tissue contrast with no bone artifacts and relatively few partial volume effects. The paramagnetic contrast agents used with MRI also produce significantly stronger enhancement than those used with CT. For these reasons, in patients with multiple brain lesions, CT scanning will miss approximately one in five of those seen on MRI.[31] MRI is useful for assessment of the extent of bone involvement in cases of axial bone metastases from follicular cell–derived carcinomas and MTC, which are poorly visualized on bone scintigraphy.[32,33] For MTC patients, contrast-enhanced MRI is more sensitive than three-phase contrast-enhanced CT for the detection of liver metastases.[33]

Positron Emission Tomography (PET)

PET is both quantitative and tomographic. The radionuclide used emits a positron that is converted into a pair of photons after a short path of a few millimeters in the tissue. The coincident detection of the two photons, which travel on a line in opposite directions, permits the localization of the site of the radionuclide decay.

PET is being used with increasing frequency for the assessment of all types of cancers. The tracer used most often in clinical settings is the glucose analog [^{18}F]fluorodeoxyglucose (^{18}FDG). It is taken up by both neoplastic and benign cells and remains metabolically trapped inside tumor cells because of its inability to undergo glycolysis. PET scanners permit in vivo images related to regional glucose metabolism, with high sensitivity and spatial resolution. Superimposition of CT and PET images greatly improves both the sensitivity and specificity of the technique and the anatomic localization of any focus of abnormal uptake. The uptake in any focus can be quantified, and the most frequently used parameter is the maximum standardized uptake value (SUVmax). The sensitivity of ^{18}FDG-PET scanning may be improved with TSH stimulation.[34,35]

PET scanning should be performed in only selected patients with thyroid carcinoma. Low-risk patients are very unlikely to require ^{18}FDG-PET scanning as part of initial staging or follow-up. ^{18}FDG-PET scanning in thyroid cancer[23,34] may be used as follows:

- To localize disease in Tg-positive patients (having serum Tg levels >10 ng/mL) with no other abnormality on diagnostic imaging; it is mostly useful for the detection of lymph node metastases in the posterior neck and mediastinum or distant metastases. In two meta-analyses, the patient-based sensitivity of ^{18}FDG-PET/CT for detecting persistent or recurrent differentiated thyroid cancer (DTC) was found to be appreciably higher than that of PET alone (93–94% vs 83–84%, respectively).[36,37]
- For the initial staging and follow-up of patients with anaplastic, poorly differentiated, or Hürthle cell thyroid cancers to identify sites of disease that may be missed with conventional imaging; in these cancers, FDG uptake is usually high and ^{131}I uptake is either low or absent.
- In patients with known distant metastases in whom high FDG uptake in large metastases indicates a high risk for disease-specific fatality and poor response to ^{131}I therapy.[38,39]
- As a measurement of posttreatment response following local (external beam irradiation, surgical resection, thermal ablation, embolization) or systemic therapy.[40]

Inflammatory lymph nodes, suture granulomas, and increased muscle activity are common causes of false-positive ^{18}FDG-PET findings. Also, asymmetric laryngeal uptake is frequently observed in patients with vocal cord paralysis. Therefore cytologic or histologic confirmation is required before one can be certain that an ^{18}FDG-positive lesion represents metastatic disease. High uptake has also been observed in several thyroid diseases, such as Hashimoto thyroiditis, and PET cannot be used to differentiate benign from malignant thyroid nodules. The discovery of focal thyroid uptake *(thyroid incidentaloma)* on a FDG-PET scan performed for other reasons should lead to a complete workup, including ultrasound and fine-needle aspiration (FNA) cytologic testing, because one-third of these nodules may prove to be malignant.[41,42] Delineation between lymph node metastases or local extension of the tumor and vessels or the aerodigestive axis is often not well visualized on ^{18}FDG-PET/CT in the absence of contrast injection; if necessary, other imaging techniques (CT and MRI with contrast medium) may be performed, especially for a preoperative workup.

PET scans can also be done with iodine-124 (^{124}I) (although this approach is currently used almost exclusively in research settings).[13] Thanks to its tomographic capacity and superior resolution, ^{124}I PET is more sensitive than diagnostic and therapeutic WBS performed with ^{131}I. PET scanning with ^{18}F-labeled dihydroxyphenylalanine (^{18}F-DOPA) can be gainfully used to visualize neoplastic foci of MTC[43,44] because the ^{18}FDG uptake is usually low in MTC patients, and ^{18}FDG-PET scan in that clinical setting is therefore rarely informative.[33,45]

Nontoxic Goiter and Thyroid Nodular Disease

Definitions

Nontoxic goiter is defined as any thyroid enlargement that is characterized by uniform or selective (i.e., restricted to one or more areas) expansion of thyroid tissue separate from a nodule or neoplastic growth. A goiter may or may not be associated with overt hyperthyroidism or hypothyroidism. A thyroid nodule is defined as a discrete lesion within the thyroid gland due to an abnormal focal growth of thyroid cells.

Epidemiology of Goiter

The prevalence of goiter varies widely by global location and can depend on the iodine intake of a given population. Thus goiter may occur endemically, due mainly to iodine deficiency, or sporadically, depending on whether the goiter prevalence in children is more or less than 5%, respectively. In pregnancy, goitrous enlargement is physiologic and usually regresses postpartum. In an adult nonpregnant population, the Framingham survey revealed a 4.6% prevalence of goiter, with a strong female predominance (6.4% in women and 1.5% in men), whereas the Wickham study displayed a 3.2% prevalence (6.6:1 hazard ratio of women to men).[46,47] However, different variables (regional variation in the iodine intake, smoking habits, age and sex distribution, and primarily the methodology [palpation vs. sonography] used to determine thyroid volume) may have influenced these data. Using sonography as the screening method, the prevalence of goiter in an unselected adult population has been reported to be as high as 30% to 50%. This prevalence is even higher in iodine-deficient areas and in older populations. Similarly, a prevalence of thyroid nodules nearing 50% has been described in adult and geriatric

autopsy series[48] and up to 65% in healthy adults screened with sonography. [49]

Etiology and Pathophysiology of Diffuse Goiter

Diffuse goiter has been traditionally regarded as the adaptive response of the thyroid follicular cell to any factor that impairs thyroid hormone synthesis. This classic concept, however, no longer appears to encompass the many aspects of goiters. Indeed, goiter is characterized by a variety of clinical, functional, and morphologic presentations, and whether this heterogeneity represents different entities remains to be clarified. Also, iodine deficiency as the sole factor responsible for goiter appears to be an oversimplification. Thus not all inhabitants in an iodine-deficient region develop goiter; moreover, endemic goiter has been observed in countries with no iodine deficiency, and even in some regions with iodine excess, and has not been observed in some regions with severe iodine deficiency. These findings suggest that other factors (genetic, demographic, and environmental) may play a role in the genesis of diffuse and nodular goiter, and some of these factors may act synergistically. Multiple nodules causing a goiter are often caused by somatic mutations leading to neoplastic growth.

The role of genetic factors in goiter formation is suggested by several lines of evidence,[50] such as (1) the clustering of goiters within families, (2) the higher concordance rate for goiters in monozygotic than in dizygotic twins, (3) the female-to-male ratio (1:1 in endemic vs. 7:1 to 9:1 in sporadic goiters), and (4) the persistence of goiters in areas where a widespread iodine prophylaxis program has been properly implemented. By studying families affected by diffuse goiter, researchers have been able to detect several gene abnormalities involving proteins related to thyroid hormone synthesis, such as mutations in genes encoding TG, sodium/iodide symporter (NIS), thyroid peroxidase (TPO), dual oxidase 2 (DUOX2), pendrin (Pendred syndrome [PDS]), and TSH receptor (TSHR). In addition, three loci for this disorder have been identified that map to chromosomes 14q, Xp22, and 3q26, respectively.[51,52] Although an autosomal dominant inheritance has been demonstrated in several families, multiple genes may be involved in other families, indicating a marked genetic background underlying the cause of the goiter. This complicated genetic pattern may explain why predisposing gene alterations remain unidentified in most patients with nontoxic goiter.

In addition to iodine deficiency and genetic susceptibility, the exposure to a variety of environmental factors has been linked to goiter generation.[53,54] Thus certain endocrine disrupters have been suggested to be involved in goiter development, including phthalates,[55,56] perchlorate, thiocyanate, and nitrate; isoflavones; and organochlorines as well as drugs, smoking, selenium deficiency, insulin resistance, oral contraceptives, parity, and alcohol.[57,58]

TSH has long been considered the major stimulus for thyroid growth in response to any factor impairing thyroid hormone synthesis. Indeed, in the rare clinical setting of a functioning TSH-secreting pituitary adenoma, the increased serum TSH concentrations typically cause enlargement of the thyroid gland.[59] Similarly, goiter is also a typical feature of Graves disease, in which a stimulatory growth effect on thyroid tissue is induced by thyroid-stimulating immunoglobulin (TSI) antibody through TSHR activation. Moreover, thyroid enlargement may appear during the course of Graves disease when increased TSH levels result from overtreatment with antithyroid drugs. In addition, toxic thyroid hyperplasia is usually present in nonautoimmune autosomal dominant hyperthyroidism, a disorder related to germline-activating mutations of the TSHR gene.[60] This clinical condition further emphasizes the role of TSH-TSHR system activation in the genesis of thyroid hyperplasia.[50] Serum TSH concentration is normal in most patients with nontoxic goiter.[53] Experimentally, it has been demonstrated that in rats iodine depletion enhances the promotion of thyroid growth by normal levels of TSH. Hence, any factor that impairs intrathyroidal iodine levels may lead to gradual development of goiter in response to normal concentrations of TSH.

More intriguing is the relationship between TSH levels and iodine supply. Indeed, even small differences in the level of iodine intake are correlated with significant differences in TSH levels; this change has been demonstrated after the 11-year follow-up in the longitudinal population-based Danish program monitoring the nationwide iodine fortification (DanThyr study).[61] A complex network of both TSH-dependent and TSH-independent pathways directs thyroid follicular cell growth and function and plays a role in the goitrogenic process. In particular, a variety of growth factors, derived either from the bloodstream or through autocrine or paracrine secretion, may serve to regulate thyroid cell proliferation and differentiation processes.[50] Typically, early in the course of goiter formation, areas of microheterogeneity of structure and function are intermixed and include areas of functional autonomy and areas of focal hemorrhage. Analysis of hyperplastic nodules by rigid criteria also indicated that morphologically indistinguishable hyperplastic thyroid nodules may be either monoclonal or polyclonal. Monoclonal adenomas within hyperplastic thyroid glands may reflect a stage in progression along the hyperplasia-neoplasia spectrum; accumulation of multiple somatic mutations may subsequently confer a selective growth advantage to this single-cell clone. [62]

Histologically, thyroid nodules contain irregularly enlarged, involuted follicles distended with colloid or clusters of smaller follicles lined by taller epithelium and containing small colloid droplets. The nodules tend to be incompletely encapsulated and are poorly demarcated from and merge with the internodular tissue, which also has an altered architecture. However, the nodules in some glands appear to be localized, with areas of apparently normal architecture elsewhere. Here, the distinction from a follicular adenoma may be difficult, and some pathologists apply terms such as colloid or adenomatous nodules to such lesions. Adenomatoid nodules show distinct gene expression patterns separate from those found in malignant lesions. Recent data have confirmed that distinct somatic mutations in SPOP, *ZNF148*, and *EZH1* are responsible for the formation and growth of most benign nodules.[63]

Natural History of Goiter and Thyroid Nodules

Nontoxic diffuse goiter has a female preponderance. There appears to be no physiologic increase in thyroid volume during normal adolescence. Development of a diffuse goiter during adolescence therefore is a pathologic rather than a physiologic process.[64] A notable exception in women of childbearing age is pregnancy, which causes a diffuse enlargement of the gland as hormone demand and production increase.

Iodine intake influences the natural history of nodular goiter disease. In the DanThyr follow-up study[58] it was demonstrated that 11 years after the iodization program, one-third of solitary thyroid nodules identified at baseline had disappeared; interestingly, one-fifth of previous multinodular goiters turned out to be diffuse. This finding suggested that the iodine intake is the main factor in determining the nodular thyroid disease appearance in

a given area. Furthermore, the survey demonstrated that thyroid nodularity is a dynamic and not necessarily an irreversible process. Therefore dissimilar iodine intake may account for the epidemiologic thyroid nodular disease differences between the United States, which carries an adequate iodine supply, and European as well other countries, which previously displayed a mild to moderate iodine deficiency.

The natural history of benign thyroid nodules, once detected, is to grow slowly if followed long enough, though there is extensive heterogeneity within any population of nodules. While on average nodules will slowly grow,[65,66] many will stay dormant for years or decades.[67] Rarely, benign nodules will shrink. When this happens, it is most often associated with the resorption of cystic fluid in a nodule.[68]

Clinical Presentation of Goiter and Nodules

For most patients, the finding of a palpable abnormality in such a superficial location as the thyroid gland is disconcerting, and the affected patient is likely to seek medical evaluation. At the end of an appropriate investigation, the clinician can usually reassure the patient that the goiter or the nodule is benign. Autonomous nodules or autonomous functional areas in the context of a multinodular goiter may result in an increased thyroid hormone secretion and subsequently a subclinical or overt thyrotoxicosis. This feature is, however, a rare event, especially in the United States, being mainly linked to the iodine deficiency. However, in general, thyroid nodules are usually not associated with abnormal thyroid hormone secretion. Therefore affected patients do not exhibit clinical signs of thyroid dysfunction and are often asymptomatic. The only clinical features of nontoxic goiter may be those of thyroid enlargement. In a health care system in which the extent of cross-sectional imaging has increased, a large proportion of clinically relevant nodules are incidentally detected during carotid ultrasonography or CT and MRI studies of the chest, neck, or head. Such incidentally detected nodules carry the same risk of malignancy as do nodules identified on clinical examination. However, an incidentally discovered thyroid nodule with increased metabolism on ^{18}FDG-PET is different, as discrete uptake of ^{18}FDG in a thyroid nodule is associated with an increased risk of thyroid cancer.[69]

Most thyroid nodules are asymptomatic. However, large nodules, which may displace or compress the trachea, esophagus, and neck vessels, can be rarely associated with symptoms and signs, including neck tightness, dysphagia, and a choking sensation. These obstructive symptoms may be accentuated by the so-called Pemberton maneuver (see Chapter 11). Invasion or compression of the recurrent laryngeal nerve, causing hoarseness, rarely occurs, though when present, it often suggests advanced thyroid carcinoma. More commonly, acute hemorrhage into a cystic nodule may produce acute, painful asymmetric enlargement of the neck and can enhance or induce obstructive symptoms.[53]

The Approach to Thyroid Nodular Disease

Thyroid nodules are generally benign hyperplastic (or colloid) nodules or benign follicular adenomas. However, multiple retrospective studies confirm that about 5% to 15% of clinically relevant nodules prove cancerous.[70,71] The prevalence of thyroid cancer in the United States, as well as in most industrialized countries, has been steadily increasing.[72] There is debate if this increase is mostly due to increased detection (and increased reporting) of small, indolent malignancies or represents a true increase in thyroid cancer incidence.[73–75] An increase in more advanced thyroid cancer has been detected in some studies, raising questions that other factors beyond simply sampling bias may impact this finding. Regardless, the mortality rate attributable to thyroid cancer remains very low.[74]

In general, thyroid nodules larger than 1 to 1.5 cm in diameter are generally considered clinically relevant. Nodules smaller than this size, even if malignant, rarely cause harm and therefore are typically followed conservatively. Recent guidelines of the American Thyroid Association provide guidance for how ultrasound assessment of a nodule can be used to determine the size cutoff at which evaluation is recommended.[1]

In the evaluation of a clinically relevant thyroid nodule (Table 14.3), a thorough history and careful physical examination should be supplemented with laboratory testing, imaging procedures (including neck ultrasonography), and most importantly consideration of fine-needle aspiration for cytologic and/or molecular assessment. With this approach, an individualized assessment of malignancy risk and the specific morbidity and mortality risks attributable to such malignancy can be made. This evaluation allows the health care worker to advise appropriate treatment in relation to the patient's other illnesses and desires. Historic features that suggest malignancy include young age under approximately 30 years,[76] male sex, a history of external neck radiation during childhood or adolescence, total-body radiation for bone marrow transplant, and rapid nodule growth or persistent changes in speaking, breathing, or swallowing. Rarely, a family history of multiple endocrine neoplasia (MEN) type 2, PTEN hamartoma tumor syndrome (Cowden disease), familial adenomatous polyposis, or Carney complex is detected. When identified, this should prompt thyroid evaluation in the family members.[53]

On physical examination, a large, fixed, and firm nodule is worrisome for malignancy, especially when suspicious regional lymphadenopathy is detected.[3,4] It should be noted, however, that most patients are asymptomatic at presentation, and physical examination simply detects a nodule 1 to 3 cm in size that is nontender and mobile with swallowing.

Many studies have shown that nodule size minimally impacts the risk of malignancy[77] and that the incidence of cancer in incidentally identified nodules is the same as in those with palpable nodules. However, in nodules larger than 4 cm in diameter, the incidence of carcinoma may be higher.[78] The presence of multiple nodules does not decrease the likelihood of thyroid cancer. In patients with multiple clinically relevant nodules, the rate of malignancy per nodule decreases, but the decrease is approximately proportional to the number of detected nodules. Therefore

TABLE 14.3 Clinical Findings Associated With Malignant Thyroid Nodules

Historic Features
Young age (<20–30 years old)
Male sex
Neck irradiation during childhood or adolescence
Rapid growth
Recent, persistent changes in speaking, breathing, or swallowing
Family history of multiple endocrine neoplasia type 2
Physical Examination
Firm, fixed, and irregular consistency of nodule
Vocal cord paralysis or hoarseness
Persistent regional lymph adenopathy

the overall cancer rate per patient is the same in those with multiple nodules as in those with a solitary nodule. Importantly, when multiple nodules are present, each must be separately evaluated because the dominant (largest) nodule is not solely representative of thyroid cancer risk.[65]

The Evaluation of Patients With Nodular Disease

In all patients with suspected or known thyroid nodules, measurement of serum TSH is recommended. A low or undetectable serum TSH, even if associated with normal free thyroid hormone levels, should suggest the possibility of toxic, autonomously functioning nodules and prompt thyroid scintigraphy. Higher serum TSH concentrations, even within the normal reference range, may increase the risk that a thyroid nodule is cancerous.[79,80]

Measurement of serum anti-TPO antibody (TPOAb) concentration may assist with the diagnosis of chronic lymphocytic thyroiditis (Hashimoto thyroiditis) when the serum TSH level is elevated. Hashimoto thyroiditis causes a heterogeneous parenchymal appearance on sonography that at times can mimic a pseudonodule. When an elevated TPOAb and heterogeneous sonographic pattern are detected, a thyroid nodule must be sonographically discrete in three separate dimensions to warrant evaluation. Hashimoto disease may also be associated with the presence of bilateral, enlarged but benign-appearing lymphadenopathy. This feature is due to the immune nature of this disease and should not necessarily cause alarm. In some patients, an FNA (described later) will be required to help distinguish benign from suspicious disease.

FCTCs may release increased amounts of Tg into the bloodstream. Unfortunately, there is overlap of serum Tg levels in FCTCs and in most benign conditions. Therefore the measurement of serum Tg levels is not useful in the initial workup of nodular thyroid disease. Some investigators recommend routine measurement of serum calcitonin levels in all patients with nodular thyroid disease to screen for MTC.[81,82] However, because of the rarity of unsuspected MTC, the high frequency of false-positive results that often prompts further workup or thyroidectomy, and the unknown clinical relevance of medullary microcarcinomas (<1 cm), it is neither cost-effective nor necessary to measure serum calcitonin levels in the initial evaluation of patients with nodular thyroid disease. In circumstances of greater suspicion (e.g., the presence of microcalcifications in the nodule), however, the measurement of serum calcitonin may prove useful.[3,53] If the unstimulated serum calcitonin determination is greater than 100 pg/mL, MTC is likely present.[82]

Ultrasonographic evaluation is the optimal means of evaluating the anatomic structure of the thyroid. Ultrasonography allows the health care provider to assess both the morphologic appearance and the size of the gland, while also assessing cancer risk in thyroid nodules.[1,3,5,53] Ultrasonography is capable of detecting even minute thyroid nodules. In fact, of 1000 normal control subjects, 65% had detectable nodularity on high-resolution sonography.[49] Numerous studies demonstrate that ultrasound can effectively stratify malignancy risk in thyroid nodules (Figs. 14.3 and 14.4). Such risk assessment then guides diagnostic and evaluative strategies for any given patient. For example, FNA of higher risk nodules is generally recommended when equal to or larger than 1 cm. In contrast, very low-risk nodules may not require FNA until growth beyond 2 cm is detected.[1] Features with the highest specificity for thyroid cancer include the presence of microcalcifications, hypoechoic parenchyma, and infiltrative or irregular margins.[83–87] Such features are most predictive when present in combination. The presence of abnormal adenopathy, especially when unilateral and in the lower neck, also increases the risk of cancer when a thyroid nodule is confirmed. Macrocalcifications, however, do not predict malignancy, unless seen in combination with microcalcifications.[83,87] A taller-than-wider shape (i.e., the anteroposterior dimension is larger than the transverse dimension on a transverse image) has been associated with increased malignancy risk in some studies, though this remains controversial, especially given the lack of a clear hypothesis suggesting why such a growth pattern would prove more malignant. In contrast, purely cystic nodules, a spongiform parenchyma, and homogeneously hyperechoic lesions carry the lowest risk of malignancy.[5,49,83,84,88]

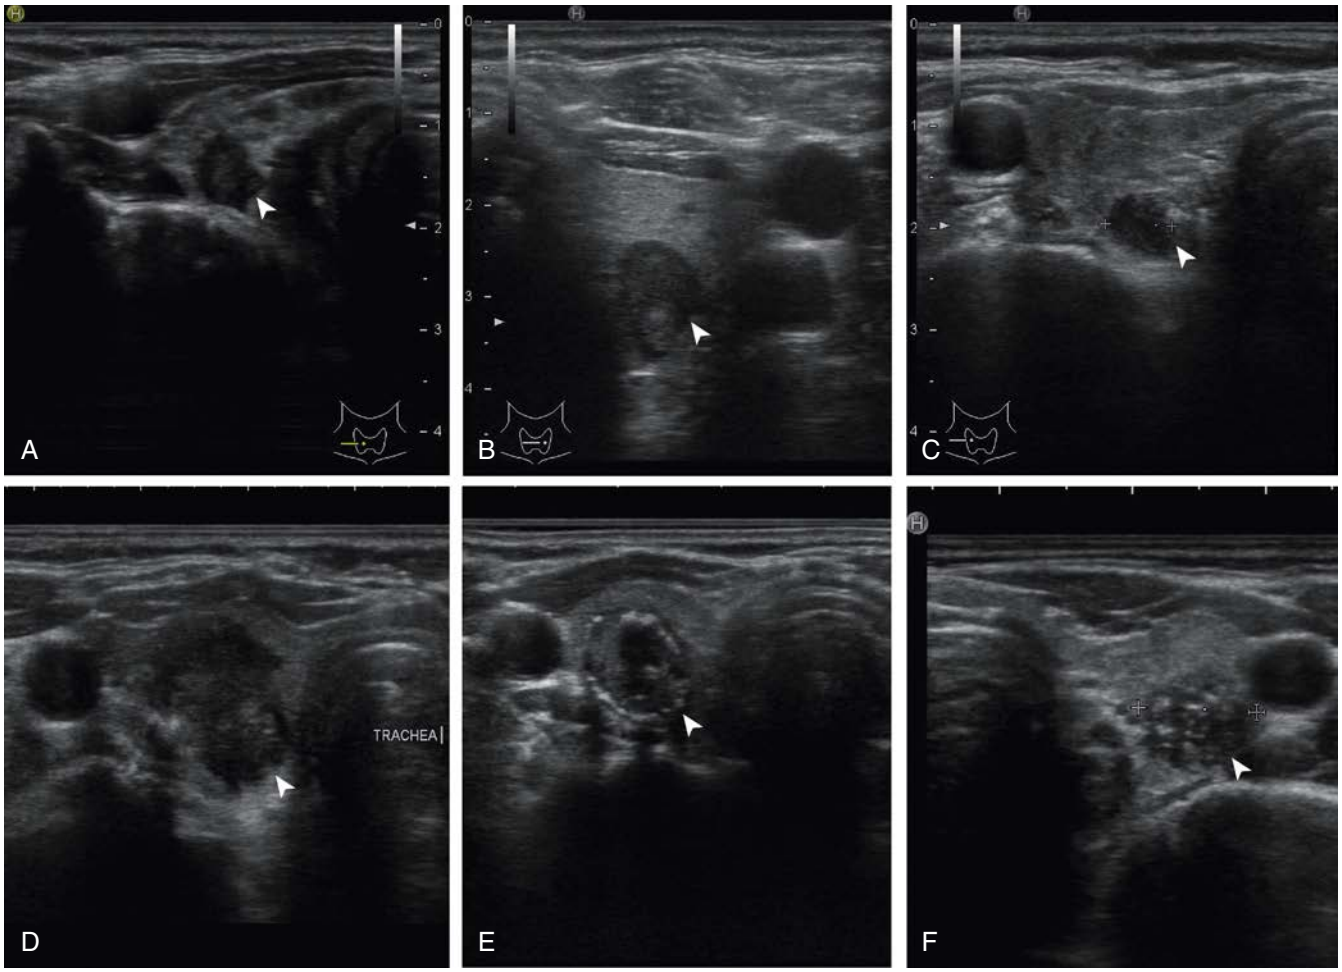
Extensive published research confirming the utility of sonographic risk assessment, combined with substantial advances in ultrasound technology, has led experts to now routinely recommend a sonographic risk classification for all thyroid nodules (ATA guidelines, European Thyroid Association [ETA], American Association of Clinical Endocrinologists [AACE], TIRADS). Nodules should be classified into suspicion categories (high, intermediate, low, and very low), as this allows an evidenced-based strategy to support future intervention such as FNA versus conservative follow-up.

High-risk nodules are solid and hypoechoic with additional findings of microcalcifications or an irregular border. Cancer risk is estimated at 70% to 90% in such lesions. Intermediate-risk and low-risk nodules constitute the majority of nodules seen in clinical practice. Intermediate-risk nodules are solid and hypoechoic but without the additional concerning features listed for high-risk nodules. Low-risk nodules are solid, isoechoic or hyperechoic, or partially cystic, yet they also lack concerning features of microcalcifications, irregular margins, and abnormal adenopathy. Cancer risk in these two groups is approximately 25% and 10%, respectively. Nodules at high or indeterminate risk are generally recommended for FNA if their maximal diameter exceeds 1 cm, whereas low-risk nodules can be followed until growth exceeds 1.5 cm. Very low-risk nodules are mostly cystic or spongiform, and risk of malignancy is very low. For this reason, growing consensus suggests that FNA should not be performed in such nodules unless the maximal nodule diameter exceeds 2 cm.[88–91] Importantly, purely cystic nodules are so rarely malignant that FNA is not indicated for diagnostic purposes.

Such guidelines can provide a roadmap for clinicians to consider, though individual assessment of every patient is nonetheless required. Certain clinical factors, patient or physician concerns, or other findings may appropriately sway a practitioner to biopsy a low-risk nodule even when it is less than 1 cm, or conversely to choose to follow a high-risk nodule even without FNA. These are reasonable decisions, as the overall risk of thyroid cancer is considered in conjunction with the patient's comorbid illnesses, desires, and risks of intervention.

Ultrasound elastography (USE) is a technique that seeks to use pressure and ultrasound as a measurement of tissue stiffness. In general, the stiffer the nodule, the higher the risk of cancer. USE was initially reported as highly predictive of benign or malignant disease.[92] However, more recent trials indicate inferior performance of USE in comparison to ultrasound assessment.

CT and MRI studies of the neck have also been used. Although such tests are highly useful to assess surrounding neck structures in preparation for surgery, their performance is generally inferior to that of thyroid ultrasound. Furthermore, cancer risk characteristics cannot be as readily defined (such as hypoechoic parenchyma or irregular margins) as with ultrasound.

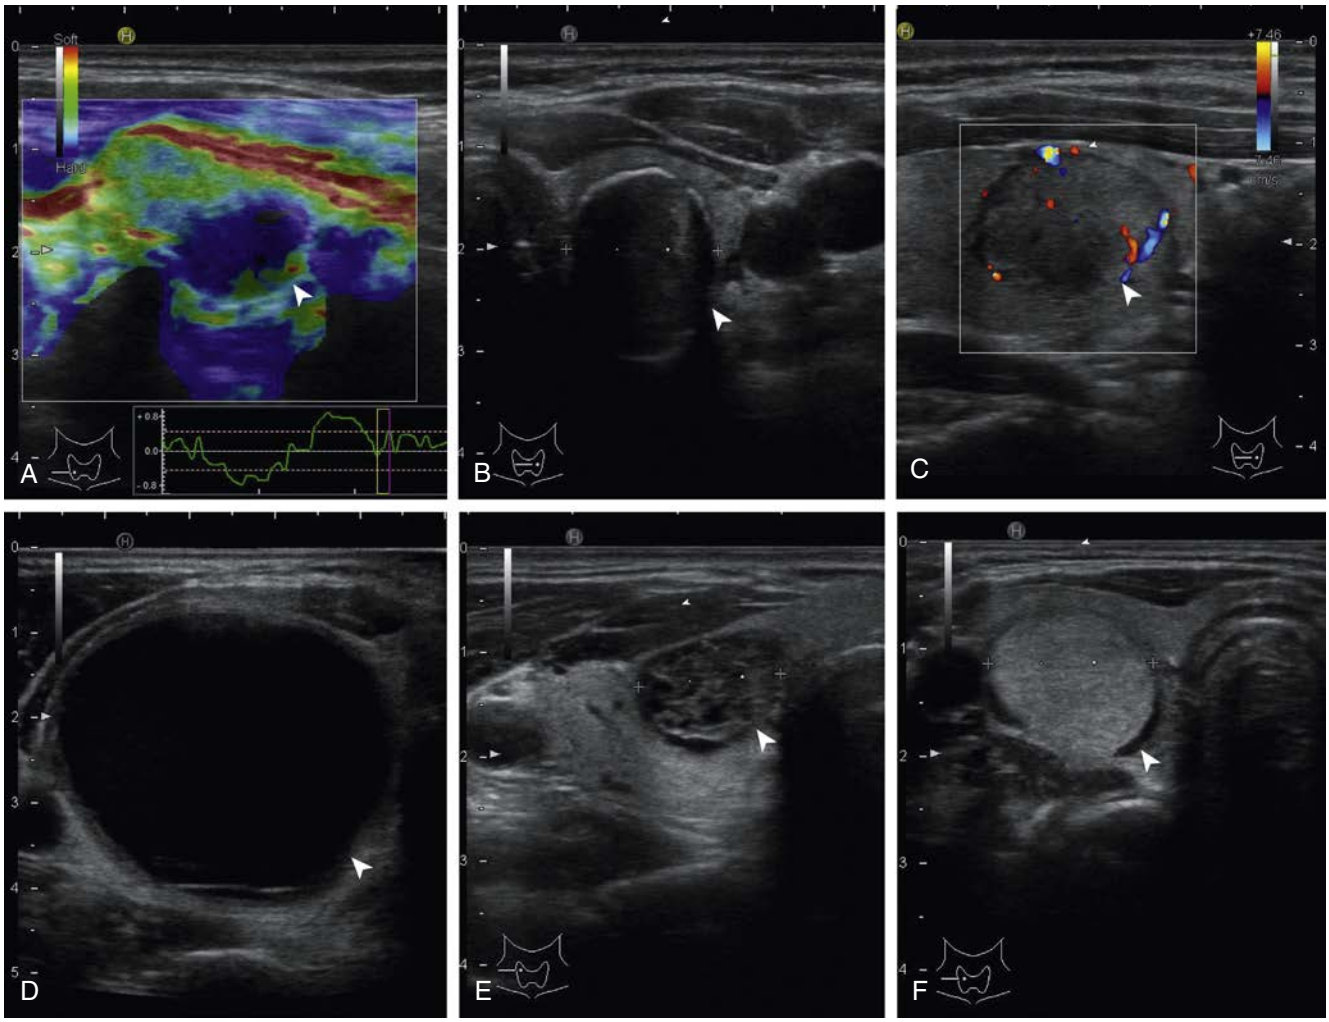


• **Fig. 14.3** Suspicious nodule ultrasound features. (A) Markedly hypoechoic nodule (similar echogenicity as the surrounding strap muscles) with irregular margins. (B) Taller-than-wide hypoechoic nodule. (C) Markedly hypoechoic nodule with regular margins. (D) Hypoechoic nodule with infiltrative margins and suspicious extrathyroidal extension. (E) Multiple interruptions in calcific rim with evidence of extrusive tissue (echogenicity is difficult to interpret because of acoustic shadowing of the calcific rim). (F) Hypoechoic solid nodule with microcalcifications and irregular margins. The *arrows* indicate the thyroid nodule. The gray scale graphically represents the shades of gray that can be provided by the ultrasound equipment. (Modified from Durante C, Grani G, Lamartina L, et al. The diagnosis and management of thyroid nodules: a review. *JAMA*. 2018;319:914–924.)

Before the advent of ultrasound-guided FNA, thyroid scintigraphy with ^{131}I, ^{123}I, or ^{99m}Tc was used to image the gland. Most thyroid carcinomas are inefficient in trapping and organifying iodine and appear on scans as areas of diminished isotope uptake, referred to as a cold nodule. This feature reflects the early decrease of NIS expression during tumorigenesis.[93] Unfortunately, most benign nodules also do not concentrate iodine. Furthermore, not all nodules with normal or slightly increased ^{99m}Tc uptake are benign and some may appear cold on a thyroid scan with radioactive iodine.[15,16] This confirms the limited utility of thyroid scintigraphy. The only situation in which an iodine scan can exclude malignancy with reasonable certainty is in the case of a toxic (hot) adenoma. Such a nodule demonstrates focal ^{123}I uptake though markedly suppressed or absent uptake in the remainder of the gland. These lesions are typically associated with a suppressed serum TSH level. They account for fewer than 5% to 10% of thyroid nodules and are almost invariably benign.[53] Thyroid scintigraphy is used much less often than previously, though it can still prove valuable in the assessment of a patient with multiple thyroid nodules or a borderline low serum TSH concentration. Scintigraphy in such cases allows the practitioner to initially target aspiration of the nonfunctional nodules. Finally, ^{18}FDG-PET is increasingly performed during the evaluation of patients with various illnesses. Although not recommended for the routine evaluation of thyroid nodules, incidental PET-positive nodules have a cancer risk of 30% to 40%.[33,34,69,94–96] In such patients, FNA is warranted. Importantly, diffuse FDG-PET uptake most often is found in the setting of Hashimoto disease and should not be considered pathologic or malignant if ultrasound confirms the absence of any nodularity.

Thyroid Nodule Fine-Needle Aspiration

FNA of thyroid nodules has eclipsed all other techniques for diagnosing thyroid cancer, with reported overall rates of sensitivity and specificity exceeding 90% in iodine-sufficient areas.[3,5,53,87] The technique is easy to perform and safe, with only a handful of complications having been reported in the literature, and causes only mild discomfort. However, care must be taken to obtain an



• **Fig. 14.4** Indeterminate ultrasound features. (A) Elevated stiffness at elastography (*red* indicates soft tissues, *blue* hard tissues, and *green* intermediate values of stiffness). (B) Complete rim calcification. (C) Slightly hypoechoic nodule with intranodular vascularization (the mean flow velocity is converted into a color scale: flow toward the transducer is represented in *red,* while away from the transducer is depicted in *blue*). Low-or very-low suspicion US features: (D) Pure cyst. (E) Mixed composition nodule with isoechoic solid component, without any suspicious features. (F) Solid hyperechoic nodule. The *arrows* indicate the thyroid nodule. The gray scale graphically represents the shades of gray that can be provided by the ultrasound equipment. (Modified from Durante C, Grani G, Lamartina L, et al. The diagnosis and management of thyroid nodules: a review. *JAMA*. 2018;319:914–924.)

adequate specimen; most authors recommend two to four aspirations per nodule. Routine use of ultrasound-guided biopsy even for clinically palpable solid nodules combined with onsite cytologic examination decreases the risk of inadequate sampling.[97,98] A satisfactory specimen must contain at least five groups of 10 to 15 well-preserved cells. FNA samples are routinely evaluated microscopically for cytologic features of benign or malignant disease and classified using the Bethesda system for reporting thyroid cytopathology.[99] Separately, FNA samples can be sent for molecular analysis using RNA expression–based tests or single gene mutation panels.

Not all thyroid nodules require FNA, and many can be safely followed without intervention over time and pose minimal risk. A decision to consider thyroid nodule FNA should initially rest upon an assessment of whether cytologic interpretation would modify the clinical care ahead. If, for example, advancing patient age and comorbid conditions would render further surgical intervention unlikely, FNA may be unnecessary. For those in whom evaluation is warranted, however, recommendation for FNA is then based on nodule size and sonographic features. As mentioned, for those with high-risk or intermediate-risk features, most nodules should generally be considered for FNA when larger than 1 cm. In contrast, low-suspicion and very low-suspicion nodules should be considered for FNA when larger than 1.5 cm and 2 cm, respectively. These guidelines were developed with the hope of identifying clinically relevant thyroid cancer that benefits from therapeutic intervention while avoiding excessive diagnostic intervention, but prospective investigations of this approach are not yet available. Smaller nodules (generally <1 cm) can most often be conservatively followed with repeat sonographic assessment in 1 to 2 years unless unique circumstances or symptoms raise concern.

Thyroid nodule FNA cytologic findings should be reported using diagnostic categories outlined in the Bethesda System for Reporting Thyroid Cytopathology (Table 14.4).[99] The diagnosis

TABLE 14.4 Probability of Malignancy Based on Fine-Needle Aspiration Cytologic Categorization

Cytologic Appearance	% of Results	% of Malignancy, for Each Category
Insufficient/non-diagnostic	~5–10	<5% if cystic nodule; 10–20% in solid nodules
Benign	70 (53–90)	1–5%
Indeterminate	20 (5–23)	
Suspicious for papillary carcinoma		60–70%
Suspicious for a follicular neoplasm (SFN/FN)		15–30%
Atypia (follicular lesion) of undetermined significance (AUS/FLUS)		10–25%
Malignant	5 (1–10)	>97%

of PTC (Bethesda category: malignant) by FNA on the basis of characteristic nuclear changes is both reliable and accurate, with sensitivity and specificity both approaching 100% provided that these changes are evaluated by an experienced cytopathologist. Similarly, a benign result should be viewed as highly accurate, as data confirm a low risk (~1–5%) of false-negative results and negligible mortality risk from false-negative aspirates during an 8.5-year follow-up.[77] However, cytologically indeterminate nodules harbor malignant risk. Bethesda classification allows malignancy risk stratification within this category, ranging from those with highest indeterminate risk (suspicious for papillary carcinoma [SUSP]) to those with lower risk (suspicious for a follicular neoplasm [SFN/FN] or atypia/follicular lesion of undetermined significance [AUS/FLUS]). Regardless, an indeterminate FNA cytologic finding implies concern that such a nodule may be a thyroid malignancy. Cytologic results should be combined with clinical and ultrasound characteristics, allowing further individual assessment. At times, such indeterminate cytologic findings—especially if SUSP, or combined with other clinical factors such as large nodule size, cosmetic concerns, or difficulty swallowing—may prove concerning enough to warrant a recommendation for surgical removal. This approach is reasonable.

Recently, a new diagnostic term was applied to thyroid lesions formerly classified as low-risk malignancy but felt to harbor a very indolent course. Such lesions have been labeled *noninvasive follicular thyroid neoplasm with papillary-like nuclear features* (NIFTP).[100] Such lesions cannot be reliably diagnosed preoperatively and typically harbor *RAS* mutations. FNA cytology of NIFTP lesions often reveals cytology classified as *atypia of undetermined significance*[101] or *suspicious for malignancy*.[102] Increasingly, certain microscopic features can be detected in FNA cytology specimens that allow preoperative concern for an NIFTP diagnosis to be conveyed.[101–103]

Low-risk indeterminate nodules (SFN/FN or AUS/FLUS) often harbor a relatively lower risk of malignancy, and if malignant, often harbor less aggressive variants of cancer.[104] However, the interobserver reproducibility of these diagnoses is poor.[105] Historically, surgical intervention was commonly recommended for nodules with SFN/FN or AUS/FLUS cytologic findings, though the majority of patients would prove to have benign disease. For such patients, surgery was unnecessary yet exposed them to substantial morbidity, time lost for recovery, and excess health care cost. To address these issues, the field has witnessed a rapid expansion in the discovery, development, and validation of thyroid-specific molecular diagnostic tests.

Historically, immunostaining for galectin 3 either alone or combined with TPO was suggested as a valuable adjunct to indeterminate nodules.[106] A series of 17 single-gene oncogenic mutations or translocations in *BRAF, RAS, RET/PTC,* and *PAX8/PPARγ* first demonstrated promise as an effective diagnostic marker for cytologically indeterminate thyroid nodules.[107–111] When detected, such mutations were initially felt to convey a very high positive predictive value and therefore hold promise as a "rule in" test. However, a blinded, multicenter prospective trial confirmed worse test performance for the full 17-gene mutation panel than previously reported.[110] These data raise questions about the overall transferability of initial data into clinical practice, especially when applied to nodules with AUS/FLUS cytologic findings.[110]

Newer versions of this DNA-based mutation panel have been created that also identify genetic rearrangements and copy number derangements.[112,113] With these updated versions, both test sensitivity and specificity have improved, though real-world use of this test has demonstrated lower than expected performance in both blinded and nonblinded analyses.[114–116] Most recently, analytic performance of a third version of this test has been reported.[117] In general, data increasingly suggest that such a test is not robust for ruling in malignancy when applied to low-risk, cytologically indeterminate nodules. However, the test's negative predictive value appears high.[107,111] The most complex output from such DNA-based mutation panels is the finding of a mutation in the *RAS* gene. Many have associated *RAS* mutations with papillary carcinoma.[118] However, *RAS* gene mutations have frequently been identified in benign thyroid nodules that show no evidence of malignant transformation.[119,120]

A separate diagnostic molecular test has investigated the utility of an RNA gene expression classifier (GEC) using microarray technology. Via initial analysis of the expression patterns from 162 genes, a first-generation test was developed for use with nodules with SFN/FN and AUS/FLUS cytologic findings, with the goal of maximizing sensitivity and negative predictive value. A prospective, blinded, multicenter validation trial was performed enrolling nearly 4000 thyroid nodules with SFN/FN or AUS/FLUS cytologic findings.[121] A benign GEC test resulted in negative predictive values of 94% and 95%, respectively, which is similar to the findings of a benign FNA cytologic result itself. The positive predictive values were 37% and 38%, respectively. Follow-up analyses of real-world use confirmed variability from site to site, largely influenced by patient population and variation in the distribution of Bethesda cytologic classification.[122] A recent study compared the long-term follow-up of cytologically indeterminate but GEC benign nodules with the follow-up of cytologically benign nodules using high-resolution ultrasound. Over a mean of about 14 months (duration up to 40 months), no difference between these groups was identified, confirming that GEC benign nodules behave like true

benign lesions.[123] More recently, some data have suggested that GEC performance may be lower when applied to nodules containing abundant Hürthle cells.[124] A newer version of this RNA-based expression classifier has been developed, called the gene sequencing classifier (GSC), demonstrating improved performance.

Increasingly, molecular testing of cytologically indeterminate thyroid nodules is endorsed because of its ability to substantially improve preoperative cancer risk assessment and modify clinical care. Specifically, most molecular tests are demonstrating high sensitivity and thus high negative predicative value. Until recently, use of the GSC is favored because of the strength of its clinical validation. Furthermore, initial cost-effectiveness analyses have demonstrated, in the United States, a cost savings via this approach.[125] The gene mutation panels may prove to have superior specificity and positive predictive values, though the utility of this metric is of limited use as the decision for hemithyroidectomy versus near-total thyroidectomy takes into account variables such as patient demographic and preference, ultrasound findings, and molecular analysis. To date, there has been no head-to-head prospective or blinded investigations comparing the various molecular tests.

MicroRNA testing has been proposed as a separate molecular test for use in cytologically indeterminate nodules. Initial data suggest potential for this approach, though strong validation studies performed in the United States are still pending.[126,127] Thus further prospective validations of these tests are required. The use of large-needle core biopsy in addition to standard FNAB may improve diagnostic accuracy in difficult FNA cases, but the technique is associated with increased morbidity.[128] Particularly for cystic thyroid nodules, sampling from the margin of the nodule under ultrasound guidance, rather than from the cystic fluid and debris in the center, increases accuracy.

Initial nondiagnostic cytologic testing should prompt repeat ultrasound-guided FNA. If available, onsite cytologic evaluation will assist in ensuring an adequate specimen for evaluation.[98,129] When the sonographic pattern of a nondiagnostic nodule is concerning, close observation or consideration for surgical excision should be given.[130] Although most nondiagnostic aspirates are due to cystic content, solid nodules with persistent nondiagnostic aspirates are associated with higher malignant risk. Repeat FNA of an initially nondiagnostic thyroid nodule yields adequate results in 60% to 80% of specimens.[68,131]

Management Options for Patients With Nontoxic Diffuse Goiter and Nodular Thyroid Disease

Patients with small, asymptomatic, nontoxic goiters can be monitored by clinical examination and evaluated periodically with ultrasound measurements. In fact, goiter growth can be variable, and some patients have stable goiters for many years. For more than a century, thyroid hormone supplementation was used to reduce the size of nontoxic goiters. A 1953 report of Greer and Astwood, in which two-thirds of patients' goiters regressed with thyroid therapy, led to widespread acceptance of suppressive therapy[132] despite some doubts about its value.[133] An overview of studies performed from 1960 to 1992 suggested that 60% or more of sporadic nontoxic goiters responded to suppressive therapy. In a prospective placebo-controlled, double-blind randomized clinical trial, 58% of the thyroxine-treated group had a significant response at 9 months, as measured by ultrasonography, in contrast with 5% after placebo.[134]

Patients with nodular thyroid disease appear to be less responsive to suppressive therapy than those with diffuse nontoxic goiters. A meta-analysis failed to demonstrate a significant benefit of thyroxine therapy, which was found to carry a relative risk of nodule shrinkage of only 1.9 (95% confidence interval [CI], 0.95–3.81).[135] Statistical significance emerged from a multicenter, randomized, double-blind, placebo-controlled trial: After 18 months of follow-up the nodule shrinkage was significantly greater in the levothyroxine group than in the placebo group ($p = 0.01$), as well as the proportion of responders ($p = 0.04$).[136] It is likely that a subset of patients respond to thyroxine suppressive therapy, particularly younger patients with small or recently diagnosed nodules.[135] However, thyroid nodules rapidly return to the pretreatment size after discontinuation of therapy. Therefore maintenance of the size reduction may require continuous treatment, which carries long-term risk.

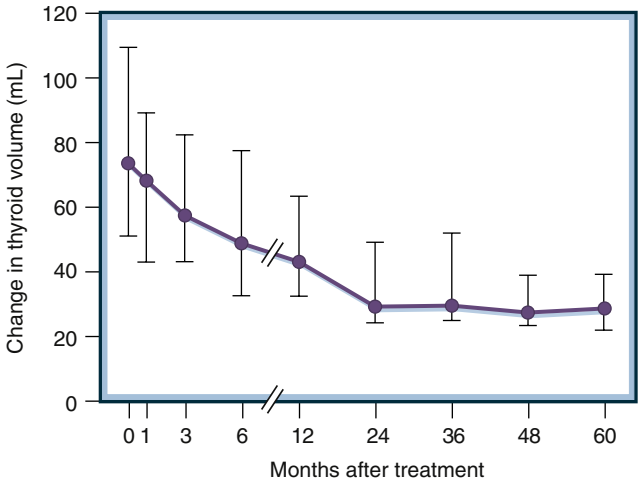
A major concern in relation to long-term thyroxine suppression therapy is the possibility of detrimental effects on the skeleton and heart. TSH suppression therapy is generally associated with variable degrees of bone loss, particularly in postmenopausal women.[137] Furthermore, there is evidence that levothyroxine suppressive therapy is detrimental to the heart, especially in older patients.[137]

Surgery for nontoxic goiter is physiologically unsound because it further restricts the ability of the thyroid to meet hormone requirements. Nevertheless, surgery may become necessary because of persistence of obstructive manifestations despite a trial of levothyroxine. Surgery should consist of a near-total or total thyroidectomy, but recurrence is seen in about 10% to 20% within 10 years.[138] Surgical complications have been reported in 7% to 10% of cases and are more common with large goiters and with reoperation. Prophylactic treatment with levothyroxine after goiter resection probably does not prevent goiter recurrence.[139]

Traditionally, the role of ^{131}I therapy for nontoxic goiter was to reduce the size of a massive goiter in elderly patients who were poor candidates for surgery or to treat goiter that recurs after resection. However, several studies have demonstrated that primary treatment of nontoxic goiter with ^{131}I is followed by a reduction in thyroid volume. In one study, thyroid volume (assessed by ultrasonography) was reduced by 40% after 1 year and 55% after 2 years with no further reduction thereafter, and 60% of the total reduction occurred within the first 3 months.[140]

Considering its effectiveness in reducing the size of the thyroid gland, ^{131}I therapy has also been used for the treatment of nonautonomous thyroid nodules where significant shrinkage has been observed, ranging from 31% to 60%[141] (Fig. 14.5). It was formerly argued that treatment of large goiters or goiters with substernal extension with ^{131}I should be avoided because of the risks of acute swelling of the gland and consequent tracheal compression. Ultrasonographic studies of thyroid volume after ^{131}I have failed to demonstrate significant early volume increase. Moreover, decreased tracheal deviation and increased tracheal lumen size were demonstrable by MRI in patients who had compression by nontoxic goiters with substernal extension.[140]

Therefore it appears that ^{131}I treatment of nontoxic diffuse goiter or multinodular thyroid disease is effective and safe. Hypothyroidism has been reported in 20% to 40%; transient thyrotoxicosis and mild pain can occur.[140] Regular follow-up, preferably by a systematic annual recall scheme, is necessary. The activities used are in the range of those used for ^{131}I treatment of hyperthyroidism, and thus radiation doses are comparable, and long-term thyroid and



• **Fig. 14.5** Median changes in thyroid volume alterations after ^{131}I treatment in 39 patients with nontoxic multinodular thyroid disease who remained euthyroid after a single dose. *Vertical bars* represent quartiles. nonthyroidal cancer risk after ^{131}I treatment for hyperthyroidism is reassuring. Stimulation with low doses of recombinant human TSH (rhTSH) (0.01–0.03 mg) increases thyroid ^{131}I uptake and therefore may allow the administration of a lower dosage of ^{131}I, but rhTSH also increases thyroid hormone production, and overproduction of thyroid hormones should be excluded before its use.[142] Long-term randomized studies comparing the effects, side effects, and costs and benefits of surgery and ^{131}I treatment need to be performed.

Percutaneous ethanol injection (PEI) should be used only for recurrent symptomatic cystic nodules.[143] Laser ablation, cryoablation, and radiofrequency ablation are still generally experimental procedures and can be proposed, in experienced centers, for selected patients with symptomatic nodular goiters when surgery is not possible.[144]

Malignant Thyroid Disorders

Thyroid tumors are the most common endocrine neoplasms. The management of a patient with typical well-differentiated, follicular cell–derived thyroid cancer is effective and usually consists of surgical resection, followed by medical therapy and regular surveillance.[1,14,22,145] Some degree of consensus has been achieved regarding the initial management of differentiated thyroid cancer, but many important clinical and biologic questions remain unanswered. In the following discussion, a widely used scheme for classifying and staging tumors of the thyroid gland is presented. The distinguishing features of the principal types of benign and malignant thyroid neoplasms and the controversies in the management of differentiated thyroid carcinoma, based on recent consensus and guidelines, are also reviewed.[1,14,22]

Classification and Staging of Thyroid Cancer

Two monographs have had a major impact on the histologic classification of thyroid tumors. One is from the World Health Organization (WHO); the other was developed by the Armed Forces Institute of Pathology (AFIP).[146] The WHO classification was updated in 2017[147] and is described in Table 14.5.

Lesions of follicular cell origin constitute more than 95% of the cases, and the remainder are largely made up of tumors exhibiting C-cell differentiation. Mixed medullary and follicular carcinomas, made up of cells with both C-cell and follicular differentiation, are rare and of uncertain histogenesis. Nonepithelial thyroid tumors mainly include malignant lymphomas, which may involve the thyroid gland as the only manifestation of the disease or as part of a systemic disease. True sarcomas and malignant hemangioendotheliomas are exceptionally rare. Blood-borne metastases from separate malignancies to the thyroid are not uncommon at autopsy in patients with widespread malignancy, but rarely cause clinically detectable thyroid enlargement.

In addition to the histologic classification of thyroid tumors developed by the WHO and AFIP groups, the Union for International Cancer Control (UICC) and the American Joint Committee on Cancer (AJCC) have agreed on a staging system for thyroid cancer.[148–151] As stated by the AJCC, "The principal purpose served by international agreement on the classification of cancer cases by extent of disease was to provide a method of conveying clinical experience to others without ambiguity."[149]

The main goal of the AJCC-IUCC staging system is to predict disease-specific survival. It is based on the TNM (tumor-node-metastasis) classification system, which focuses on (1) the extent of the primary tumor (T), (2) the absence or presence of regional lymph node metastases (N), and (3) the absence or presence of distant metastases (M). The classification may be either *clinical* (cTNM), based on evidence (often from FNA cytology) acquired before treatment, or *pathologic* (pTNM) when intraoperative and surgical pathologic data are available. The pTNM classification is preferable as this allows a precise size to be assigned to the primary tumor, the type of cancer to be clarified histologically, and the presence of extrathyroid invasion to be demonstrated unequivocally. Whereas head and neck cancers are most often staged entirely on the basis of anatomic extent, for well-differentiated thyroid cancer staging, both the histologic diagnosis and the age of the patient are included because of their importance in predicting the behavior and prognosis ahead. It is noteworthy that in children the risk of recurrence is

high and may be underestimated by the TNM staging system.[152] The most recent (eighth) edition of the AJCC staging system for thyroid cancer was published in 2017 and implemented on January 1, 2018. Table 14.6 summarizes its features and highlights changes introduced since the 2010 edition. The main changes are (1) an increase in the age threshold (>55 years versus >45 years) for defining cases at high risk for thyroid cancer–related death, and (2) attenuation of the previous unfavorable prognostic significance attributed to small cervical lymph node metastasis and microscopic extrathyroidal extension. The age criterion for defining high-risk disease has been raised from 45 years to 55 years. This change increases the proportion of relatively young patients whose mortality risk can be defined solely on the basis of the absence or presence of distant metastases (stages I and II, respectively). As for microscopic extension of the tumor to the perithyroidal soft tissues, this finding is no longer considered an absolute indication for assigning the tumor to the T3 category. The ability to recognize this minimal extrathyroidal invasion can vary widely, even between skilled pathologists. The T3 category now includes tumors whose largest diameter exceeds 4 cm and those that invade the perithyroidal muscles (sternohyoid, sternothyroid, thyroidhyoid, omohyoid). Upper mediastinal lymph node metastases (level VII) are now considered features of N1a disease, which was formerly used solely in the presence of central neck node lesions. The expanded definition reflects the well-known difficulties in distinguishing level VI and VII nodes from an anatomic point of view. Stage I thyroid cancer now refers exclusively to T1 or T2 tumors with no lymph node metastases, whereas stage II includes T3, N0, M0 tumors and any T1-T3 tumor with metastatic lymph node disease (either N1a or N1b).

TABLE 14.6 The Tumor-Node-Metastasis (TNM) Scoring System

	DEFINITION OF TNM	
Category	**2010 Version (AJCC 7th Edition)**	**2017 Version (AJCC 8th Edition)**
Primary Tumor (T)		
T0	No evidence of primary tumor	No evidence of primary tumor
T1	Tumor ≤2 cm limited to the thyroid T1a: ≤1 cm T1b: >1 cm to 2 cm	Tumor ≤2 cm limited to the thyroid T1a: ≤1 cm T1b: >1 cm to 2 cm
T2	Tumor >2 to ≤4 cm limited to the thyroid	Tumor >2 to ≤4 cm limited to the thyroid
T3	Tumor >4 cm limited to the thyroid or any tumor with minimal extrathyroid extension (e.g., extension to sternothyroid muscle or perithyroid soft tissues)	Tumor >4 cm limited to the thyroid or gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, thyroidhyoid, omohyoid) from a tumor of any size
T4	No evidence of primary tumor	No evidence of primary tumor
T4a	Gross extrathyroidal extension invading subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve from a tumor of any size or intrathyroidal anaplastic thyroid cancer of any size	Gross extrathyroidal extension invading subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve from a tumor of any size
T4b	Gross extrathyroidal extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels from a tumor of any size or anaplastic thyroid cancer of any size with extrathyroidal extension	Gross extrathyroidal extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels from a tumor of any size
Regional Lymph Node (N)		
N0	No regional lymph node metastasis	No evidence of locoregional lymph node metastasis
		N0a: one or more cytologically or histologically confirmed benign lymph nodes N0b: no radiologic or clinical evidence of locoregional lymph node metastasis
N1	Regional lymph node metastasis	Regional lymph node metastasis
N1a	Metastases in pretracheal and paratracheal lymph nodes, including prelaryngeal and delphian lymph nodes, unilateral or bilateral	Metastasis in pretracheal, paratracheal, prelaryngeal/delphian, or upper mediastinal lymph nodes, unilateral or bilateral
N1b	Metastases in lateral neck lymph nodes or upper mediastinal lymph nodes, unilateral or bilateral	Metastases in lateral neck lymph nodes, unilateral or bilateral disease

AJCC, American Joint Committee on Cancer.

To date, prognostic differences and, especially, the differing risk of cause-specific mortality between central lymph node metastases (N1a) and other regional metastases (N1b) have yet to be widely validated. Indeed, the risk of persistent/recurrent disease appears to be more closely related to the number and size of involved lymph nodes as well as the number of lymph nodes with extracapsular extension. These characteristics, however, are not taken into account in the TNM AJCC staging system.[153,154] Stages III and IVa include T4a and T4b tumors, respectively, regardless of their lymph node status. Stage IVb includes any tumor with distant

metastases, and stage IVc has been eliminated entirely in the new eighth edition system.

For MTC, the scheme is similar, in that T1 N0 M0 carcinoma is stage I, but T2-T3 N0 M0 is stage II and a T1-T3 N1a M0 tumor is stage III, underlying the prognostic impact of lymph node involvement. There is no age distinction for MTC, although age is a significant independent prognostic indicator in most multivariate analyses.[155,156]

All anaplastic carcinomas were considered T4 tumors in the 1992, 2002, and 2010 editions of the AJCC/UICC classification. With the eighth edition (2017), the T categories for anaplastic carcinomas are the same as those used for differentiated carcinomas. All anaplastic carcinomas are considered stage IV tumors, with stage IVA referring to intrathyroidal tumors, whereas stage IVB tumors are cases with gross extrathyroidal extension or lymph node metastases. Stage IVC is assigned to anaplastic malignancies with distant metastases.

Although the AJCC staging system has been designed to predict disease mortality risk, it has also been used in practice to predict the risk of persistent/recurrent disease. Other systems, designed specifically to predict postoperative tumor recurrence, are available and are discussed later in this chapter.

Follicular Adenomas and Borderline Thyroid Lesions With Malignant Potential

A follicular adenoma is a benign, encapsulated tumor with evidence of follicular cell differentiation.[146] It is the most common thyroid neoplasm and may be found in 4% to 20% of glands examined at autopsy.[157] The tumor has a well-defined fibrous capsule that is grossly and microscopically complete. There is a sharp demarcation and distinct structural difference from the surrounding parenchyma. These adenomas vary in size, but most have a diameter of 1 to 3 cm at the time of excision. Degenerative changes, including necrosis, hemorrhage, edema, fibrosis, or calcification, are common features, particularly in larger tumors.

Follicular adenomas can be classified into subtypes according to the size or presence of follicles and degree of cellularity. Each adenoma tends to have a consistent architectural pattern. Microfollicular, normofollicular, and macrofollicular adenomas owe their names to the size of their follicles compared with follicles in the neighboring, nonneoplastic areas of the gland. Trabecular adenomas are cellular and consist of columns of cells arranged in compact cords. They show little follicle formation and rarely contain colloid. Hyalinizing trabecular tumor, considered a variant of adenoma, has unusually elongated cells and prominent hyaline changes in the extracellular space.[158] The histologic differences among these subtypes are striking but of no clinical importance. The only practical value of the classification is that the more cellular a follicular nodule is, the more one should search for evidence of malignancy in the form of invasion of blood vessels and capsule, either singly or in combination.[146]

Atypical adenomas are hypercellular or heterogeneous, or both, with gross and histologic appearances that suggest the possibility of malignancy but without invasion. Classification of these tumors is difficult and poorly reproducible among pathologists. They account for fewer than 3% of all follicular adenomas. Follow-up indicates that this lesion behaves in a benign fashion. However, the fact that the tumor does not recur or produce metastases after removal does not prove that it is actually benign. Removal may have interrupted a natural history in such nodules that would have culminated in invasion and metastases. For this reason, they are classified as tumors of uncertain malignancy. Increasingly, molecular analysis of such lesions helps to better define their prognosis and associated risk.

The most important cytologic variant is the oxyphilic or oncocytic (Hürthle cell) adenoma, which is composed predominantly (at least 75%) or entirely of large cells with granular, eosinophilic cytoplasm. Ultrastructurally, the cells are rich in mitochondria and may exhibit nuclear pleomorphism with distinct nucleoli. Although all such neoplasms are thought by some to be potentially malignant, the biologic behavior and clinical course of oncocytic tumors correlate closely with the histologic appearance and the size of the initial lesion. The absence of invasion predicts a benign outcome, but larger tumors may rarely be associated with later recurrence or metastases, even in the absence of obvious microscopic evidence of invasion; fortunately, such an occurrence is rare, and generally a diagnosis of benign Hürthle cell adenoma is reliable.[159]

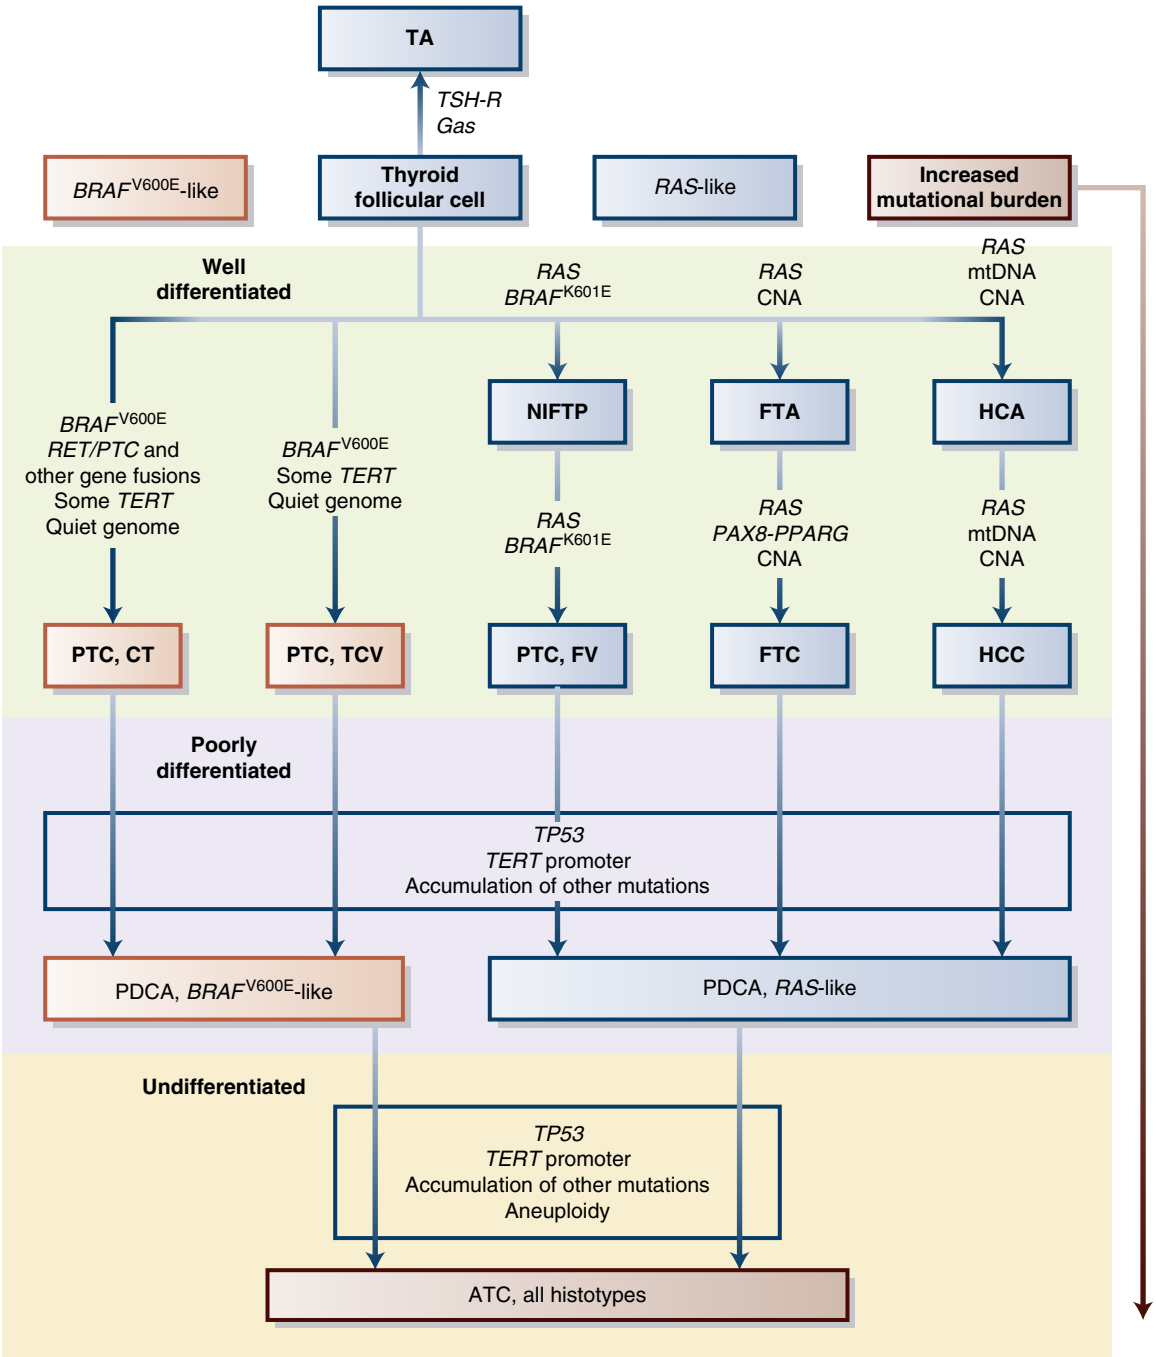
Some follicular adenomas may contain pseudopapillary structures that can be confused with the papillae of papillary carcinoma. These structures are probably an expression of localized hyperactivity and are most common in adenomas that show autonomous function.

In the majority of hyperfunctioning follicular adenomas, activating point mutations have been identified in the *TSHR* or in the α-subunit of the stimulatory guanyl nucleotide protein ($G\alpha_s$) (Fig. 14.6).[60,160] Such mutations result in a constitutive hyperstimulation of the cells. Genetic abnormalities found in hypofunctioning adenomas are detailed later.

In 2017, the WHO introduced a new entity, included in the group of thyroid tumors of follicular origin with borderline histologic features. Such lesions, as mentioned previously, are NIFTP.[100,147,161] These neoplasms are encapsulated follicular variants of papillary thyroid carcinoma (FVPTC) without evidence of either capsular or vascular invasion. Proper pathologic processing is essential for confident exclusion of capsular or vascular spread. NIFTPs are thought to represent up to 18.6% of tumors previously classified as low-risk PTCs. Adverse events, such as cancer-related death, distant or regional metastases, and structural or biochemical recurrence do not occur in patients with NIFTPs that are properly diagnosed. Because of this, the word *cancer* has been eliminated from the definition of these tumors to underscore their outstanding prognosis, thereby discouraging overly aggressive treatment and follow-up. This borderline thyroid entity was first proposed by an international panel of experts and subsequently endorsed by the ATA. However, the presumably excellent outcomes associated with NIFTPs have yet to be independently confirmed with long-term prospective studies. Importantly, the current body of evidence supporting our approach to NIFTPs comes from retrospective studies and is thus of only moderate quality.

Papillary Thyroid Carcinoma

PTC is defined as "a malignant epithelial tumor showing evidence of follicular cell differentiation and a set of distinctive nuclear feature. Papillae, invasion or cytological features of papillary thyroid carcinoma are required" (WHO 2017).[146,162] The most common thyroid malignancy, PTC constitutes 50% to 90% of differentiated FCTCs worldwide.[72,163] The 2017 WHO classification recognizes 15 PTC subtypes (or variants), but the vast majority of PTCs belong to one of the following five subtypes (or variants): classic variant, follicular variant, diffuse sclerosing variant, encapsulated variant, and tall cell variant.[147]



• **Fig. 14.6** Model of thyroid carcinoma (TC) initiation and progression with primary genetic alterations. Benign thyroid tumors (FTA and HCA) and differentiated TCs (PTC, FTC, and HCC) develop from follicular cells and follow two distinct pathways, *BRAF*^{V600E}-like and *RAS*-like, depending on the specific driver mutations present. Some differentiated TCs accumulate additional mutations and progress to more clinically aggressive and less differentiated types (PDCA and ATC). ATC represents the most aggressive form of TC with a high mutational burden, genomic instability, aneuploidy, and high rates of *TP53* and *TERT* promoter mutations. *ATC,* anaplastic thyroid (undifferentiated) carcinoma; *CNA,* copy number alterations; *CT,* classical type; *FTA,* follicular thyroid adenoma; *FTC,* follicular thyroid carcinoma; *FV,* follicular variant; *HCA,* Hürthle cell/oncocytic adenoma; *HCC,* Hürthle cell/oncocytic carcinoma; *mtDNA,* mitochondrial deoxyribonucleic acid; *NIFTP,* noninvasive follicular neoplasm with papillary-like nuclear features; *PDCA,* poorly differentiated carcinoma; *PTC,* papillary thyroid cancer; *TA,* toxic adenoma; *TC,* thyroid carcinoma; *TCV,* tall cell variant; *TSH-R*, thyrotropin receptor. (Modified from Giordano TJ. Genomic hallmarks of thyroid neoplasia. *Annu Rev Pathol*. 2018;13:141–162.)

Papillary thyroid microcarcinomas (PTMs), or pT1a lesions are defined by WHO as PTCs whose largest diameter measures 1 cm or less.[164,165] In the United States, the reported incidence of clinically diagnosed PTMs (approximately 1 per 100,000 persons) is considerably lower than that reported for larger PTCs (approximately 5 per 100,000). It is also lower than the reported incidence of PTMs found at autopsy in various parts of the world (4–36%).[72,146] The increasing detection of small PTCs throughout the industrialized world can be attributed in large part to screening programs.[72–74,166] The incidence of larger tumors has remained essentially stable since the 1980s. Therefore most thyroid cancers being diagnosed today are small tumors with limited extension and excellent prognoses,[167] and protocols for their initial treatment and follow-up must therefore be revised to avoid overzealous management.

Classic PTCs appear as firm, unencapsulated or partially encapsulated tumors. PTCs may be partly necrotic, and some are cystic. The presence of necrosis and a high mitotic rate are associated with aggressive behavior similar to that of poorly differentiated thyroid cancer (PDTC).[39,168] Typically PTC shows a predominance of papillary structures, consisting of a fibrovascular core lined by a single layer of epithelial cells, but the papillae are usually admixed with neoplastic follicles having characteristic nuclear features. The nuclei of PTC cells have a distinctive appearance, which has a diagnostic significance comparable to that of the papillae. Indeed, the preoperative diagnosis of PTC can often be made on the basis of the characteristic nuclear changes seen in FNA material: Nuclei are larger than in normal follicular cells and overlap; they may be fissured like coffee beans; chromatin is hypodense (ground-glass nuclei); limits are irregular; and they frequently contain an inclusion corresponding to a cytoplasmic invagination. Psammoma bodies are often present in the core of papillae or in the tumor stroma; they are microscopic structures of calcified layers.

The term *encapsulated variant of PTC* is used to describe a classic PTC surrounded by a fibrous capsule, regardless of whether the capsule shows signs of tumor infiltration. The tumor is designated a *follicular variant of PTC* when the lining cells of the neoplastic follicles have the same nuclear features as seen in typical PTC and the follicular predominance over the papillae is complete. The encapsulated FVPTC is associated with a favorable outcome, unless extensive vascular invasion is present.[146] The *diffuse sclerosing variant of PTC* is characterized by diffuse involvement of one or both thyroid lobes, widespread lymphatic permeation, prominent fibrosis, and lymphoid infiltration. The *tall cell variant of PTC* is characterized by well-formed papillae that are covered by cells that are twice to three times tall as they are wide. Other rare variants of PTC include the *columnar cell variant,* which differs from other forms of PTC because of the presence of prominent nuclear stratification of elongated cells. The *hobnail variant of PTC* is a recently recognized variant with poor prognostic findings.[169] The tall cell and columnar cell variants are more aggressive, but controversy exists regarding outcome for the diffuse sclerosing variant.

In children, PTCs represent the large majority of newly diagnosed cases, and histologic subtypes include the classic PTC, the presence of the *solid/trabecular variant* features (of unknown prognostic significance), the follicular variant, and the diffuse sclerosing variant. Tumor extension is usually substantial at diagnosis: tumors are large, multifocal, unencapsulated, and invasive. Extension beyond the thyroid capsule, lymph node metastases, and lung metastases are frequently observed.[152,170,171]

Molecular Pathogenesis of Papillary Thyroid Carcinoma

Nearly all PTCs arise as the result of alterations in genes encoding components of the mitogen-activated protein kinase (MAPK) and PI3K/PTEN/AKT/mTOR signaling pathways. The gene most frequently mutated in PTCs is the proto-oncogene *BRAF,* which encodes a serine-threonine protein kinase that plays a central role in regulating signaling through the MAPK pathway. In most cases, *BRAF* is activated as a result of a point mutation that causes a glutamate-for-valine substitution at residue 600 (p.V600E). This alteration is found in up to 40% to 60% of all PTCs,[118,172,173] primarily the classic and tall cell variants.[118] The $BRAF^{V600E}$ mutation occurs early in tumorigenesis,[174] inducing loss of differentiation[175] and promoting tumor invasion and progression.[176]

The second most prevalent mutations found in PTCs involve the Ras family of genes, which encode proteins that act as signal transduction switches to regulate diverse cytoplasmic signaling pathways.[177] Although *RAS* is a classic activator of both the MAPK and PI3K-AKT pathways, the *RAS* mutations associated with thyroid tumorigenesis seem to preferentially activate the PI3K-AKT pathway. Missense mutations at codons 12, 13, and 61 result in constitutive *RAS* signaling, and they are found in 10% to 30% of PTCs[118,178] (FVPTCs and NIFTPs in particular).[100,179]

Of all PTCs, 5% to 10% are characterized by genetic recombination of the *RET* proto-oncogene, which encodes a transmembrane receptor with a tyrosine kinase domain.[118,180] These alterations are characteristic of PTCs linked to radiation exposure (environmental or therapeutic).[180] There are at least 10 different types of *RET/PTC,* all resulting from the fusion of the tyrosine kinase domain of *RET* to the 5′ portion of different genes. *RET/PTC1* and *RET/PTC3* are the most common types, followed by *RET/PTC2*. *RET/PTC1* is formed by an intrachromosomal rearrangement fusing the *RET* tyrosine kinase domain to a gene designated *H4 (CCDC6)*. *RET/PTC2* is formed by an interchromosomal rearrangement fusing the *RET* tyrosine kinase domain to a gene located on chromosome 17 encoding the RIα regulatory subunit of protein kinase A. *RET/PTC3* is formed by an intrachromosomal rearrangement fusing the *RET* tyrosine kinase domain to a gene designated *RFG (NCOA4)*. *RET/PTC3* was more frequently found in aggressive tumors that occurred early after the Chernobyl disaster, and *RET/PTC1* was found in classic variant tumors that are less aggressive and occurred later.

In addition to *RET/PTC* rearrangements, PTCs have been found to harbor fusion genes involving *NRTK1,*[181] *NTRK3,*[182] *BRAF,*[183] *ALK,*[184] *FGFR2, THADA, MET, LTK,*[118] and *ROS1*.[185] PTCs with oncogenic gene fusions are closely associated with radiation exposure, and these tumors usually have distinctive clinicopathologic features.[182] Fusions (especially those involving *NRTK1/3*) are particularly common in PTCs that develop in pediatric patients, where they are associated with more aggressive disease.[186,187] On the whole, adult PTCs with gene fusions are usually associated with an intermediate risk of recurrence.[1] Fusions involving the *PAX8* and *PPARG* genes, which are frequently found in FTCs, have also been reported in a small subset of PTCs, particularly FVPTCs.[118,188]

Telomerase reverse transcriptase *(TERT)* promoter mutations are identified in 8% to 27% of PTCs, particularly those that also harbor mutations affecting the MAPK pathways (e.g., $BRAF^{V600E}$, activating *RAS* mutations).[189–192] They upregulate the expression of TERT, thereby reactivating telomerase to promote cellular immortality. The C228T substitution is the most common (7%), and the C228A and C250T substitutions are less common (0.3%

and 2.1%, respectively).[118] *TERT* mutations are associated with aggressive clinicopathologic features and a high risk of recurrence, particularly when coexisting with *BRAF,* suggesting a synergistic interaction between *BRAF* and *TERT*.[193]

In 2014 there was a major advance in defining the genomic landscape of PTCs: the comprehensive multiplatform analysis of nearly 500 adult tumors carried out as part of The Cancer Genome Atlas (TCGA).[118] Characterization of these tumors in terms of genomic variants, gene expression, microRNA (miR) expression, alterations in methylation, and proteomic profiles shed new light on the genomic hallmarks of PTC, which have greatly enhanced our understanding of its pathogenesis. The overarching conclusion is that PTCs are relatively simple cancers with fairly low mutational burdens (0.41 nonsynonymous mutations per megabase on the average) and with a few copy number variations.

The TCGA study has also identified *EIF1AX* as a novel driver oncogene, whose mutations are nearly mutually exclusive with other MAPK pathway mutations and occur in 1% of PTCs, mostly in FVPTC.[118] An increased prevalence of *EIF1AX* mutations has also been reported in PDTC and ATC (~10% in both), particularly in those that also harbor *RAS* mutations.[194] This intriguing association between *RAS* and *EIF1AX* mutations suggests that the ribosomal protein might also contribute significantly to tumor progression, making it an attractive potential target for further investigation.

Mutations in the DNA repair genes *CHEK2* and *PPMID* have also been found in PTCs, each affecting approximately 1% of all tumors. These mutations occurred concomitantly with MAPK-pathway driver mutations, suggesting that they are late genetic events in PTC tumorigenesis and that the development of particularly aggressive phenotypes may be triggered by an acquired defect in DNA repair.[118]

TCGA data have demonstrated that *BRAF* and *RAS* mutations are almost always mutually exclusive in PTCs. This knowledge has been leveraged to develop the $BRAF^{V600E}$*-RAS* gene expression score (BRS), which has been used to highlight the remarkable biologic differences between *RAS*-driven and $BRAF^{V600E}$-driven PTCs. Using the BRS scheme, tumors with the biologic properties of *RAS*-mutated tumors are designated *RAS*-like, in contrast to tumors with the biologic properties of $BRAF^{V600E}$, which are designated $BRAF^{V600E}$-like. $BRAF^{V600E}$-mutated PTCs are strongly $BRAF^{V600E}$-like with the strongest activation of the MAPK pathway. One tumor harboring a $BRAF^{K601E}$ mutation paradoxically displayed *RAS*-like features consisting of more limited MAPK signaling than that [typically] observed in $BRAF^{V600E}$-driven cancers. Interestingly, PTCs with $BRAF^{K601E}$ (like those bearing *RAS* mutations) are enriched among PTCs with follicular patterns.[195–197] PTCs with *BRAF* indels have also been found to have gene expression patterns that are surprisingly *RAS*-like.

The thyroid differentiation score (TDS) was developed as a measure of the thyroid-specific differentiation of PTCs, based on the expression levels of 16 thyroid-related genes. TDS classification of PTCs characterizes $BRAF^{V600E}$-like PTCs as a whole as less differentiated than *RAS*-like tumors, whose differentiation scores are closer to those of normal thyroid tissue. The distinctive intracellular signaling profiles of $BRAF^{V600E}$-like and *RAS*-like PTCs have also been documented at the transcriptional and protein expression levels.[118]

The pan-genomic differences between $BRAF^{V600E}$-like and *RAS*-like tumors documented by TCGA data are striking, and a revised classification of thyroid carcinomas is needed to reflect these findings. One possible solution would entail the creation of a new entity—separate from PTC—that includes the follicular-patterned tumors (FTC, FVPTC) and highlights the typically *RAS*-like nature of their underlying biology.

TCGA data have also been used to identify subgroups of $BRAF^{V600E}$-like tumors with distinct biologic and pathologic features. This molecular heterogeneity of $BRAF^{V600E}$-like PTCs thus appears to be more substantial than previously believed, and it might at least partially explain the conflicting findings published on the prognostic significance of the $BRAF^{V600E}$ mutation in PTCs.[198] The heterogeneity was particularly evident when the miRNA expression profiles of these PTCs were analyzed: six distinct clusters were identified. Cluster 1 was characterized by relatively high expression of miR-182-5p and miR-183-5p and was enriched for *RAS*-mutated tumors and the follicular variant. *BRAF*-like tumors comprised five miRNA-defined clusters. Three clusters were associated with highly differentiated, relatively nonaggressive PTCs. The other two were associated with less differentiated tumors and a higher likelihood of recurrence. Cluster 5 was characterized by higher levels of miR-146b (3p and 5p isoforms) and miR-375, relatively low levels of miR-204-5p, and overrepresentation of classic PTCs harboring the $BRAF^{V600E}$ mutation. Cluster 6 presented high levels of miR-21-5p, low levels of miR-204-5p, and enrichment for tall cell variant and classic PTCs. This cluster had the highest frequency of $BRAF^{V600E}$ mutation, the lowest differentiation scores, and a very high risk of recurrence.

It remains to be seen whether miRNA profiles can help differentiate low-risk from high-risk *BRAF*-like PTCs, but recent studies have yielded promising findings.[199,200] In addition to clinically informative miRNA expression patterns, several specific miRNAs have roles in thyroid carcinogenesis that have been experimentally demonstrated. MiR-146b-5p, which is currently one of the most thoroughly studied miRNAs in PTC, has been linked to aggressive clinicopathologic features and poor outcomes.[199,201] Both isoforms of this miRNA specifically repress the expression of *PAX8* and *NIS,* which are essential determinants of the differentiated thyroid cancer phenotype.[202] Antagonism of miR-146b in human thyroid cancer cells has been shown to restore *NIS*-mediated iodide uptake.[202] This miRNA is also predicted to repress the expression of other iodide-metabolizing proteins, such as *DEHAL* and *DIO2*.[202] In addition, the transcription of miR-146b is regulated by *PAX8*. As a result, a negative feedback loop is created whereby *PAX8* limits its own activity by inducing the expression of its repressor, miR-146b. This repression also extends to *NIS, DEHAL*, and *DIO2*, which are downstream targets of *PAX8*.[203]

NIS expression is also repressed by miR-21-5p,[202] a miRNA that has been associated with poor differentiation and high recurrence rates in PTC.[118,199] MiR-182, which is predominant in *RAS*-mutated PTCs, is predicted to repress *PAX8* and DEHAL, whereas miR-375, which is more prominent in *BRAF* tumors, is predicted to repress *DEHAL* and *NKX2.1*.[202] Therapies targeting miRNAs in thyroid cancer can thus disrupt regulatory circuits that help maintain tumor cells in a poorly differentiated state, and this approach might be an effective new strategy for inducing redifferentiation and increased iodide uptake in these cells.

A high incidence of PTC has been reported in patients with adenomatous polyposis coli who have a peculiar histologic appearance, with solid areas and elongated cells, and Cowden disease (the multiple hamartoma syndrome), suggesting that the predisposing genes may play a role in the occurrence of papillary carcinoma. The familial risk of thyroid cancer is higher than for other

cancers, and about 3% to 10% of cases of PTC are familial[204]; their behavior is similar to or slightly more aggressive than that of nonfamilial cases.[205] At least five loci of predisposition have been individualized but they do not explain all hereditary cases.[206–210] The gene predisposing to familial thyroid tumors with cellular oxyphilia has been mapped to chromosome 19q13.2, and in a family with PTC and renal carcinoma, a separate gene was mapped to chromosome 1p13.2.q22. Variants of two genes, *FOXE1 (TTF2)* located at chromosomal locus at 9q22, and *NKX2-1 (TTF1)* on 14q, both coding for thyroid-specific transcription factors, confer an increased risk of thyroid cancer.

Presenting Features of Papillary Thyroid Carcinoma

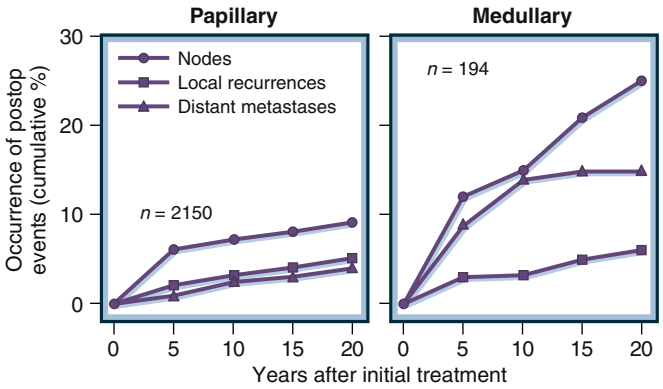
Although PTCs can occur at any age, most occur in patients between 30 and 50 years of age (mean age, 45 years). Women are affected more frequently (female predominance, 60–80%). Most primary tumors are 1 to 3 cm, and in recent years the proportion of small tumors has increased, largely due to detection of small PTCs by screening.[72,73,163,211–213] PTC is frequently multifocal when it occurs in a single lobe and is bilateral in 20% to 80% of cases, depending on whether the thyroid is meticulously examined. Some studies have suggested that contralateral PTCs may have independent clonal origins, but this idea remains controversial.[214] Extrathyroidal invasion of adjacent soft tissues is present in about 15% (range 5–34%) at the time of primary diagnosis.[145,163] About 35% to 50% of excised neck lymph nodes have histologic evidence of involvement (microscopic foci of metastases in most of the cases), though in patients 17 years of age or younger, nodal involvement may be present in up to 90%.[152,170,171,215] Only 1% to 7% of patients with PTC have distant metastases at diagnosis.[163] Spread to superior mediastinal nodes is usually associated with extensive neck nodal involvement.

At presentation, most PTCs were classified as TNM stage I or II tumors (60% and 22%, respectively) using the seventh edition of the AJCC staging system. With the implementation of the eighth edition in 2018, stage I and II tumors account for an even larger proportion of PTCs.[216,217] Fewer than 10% of all PTCs will be classified as stage III or IV using this newer system; these are reserved for cases in which the risk of cancer-related death is substantial.

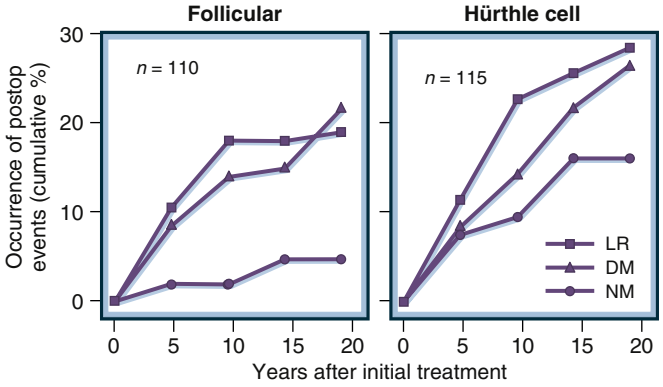
Risk of Papillary Thyroid Carcinoma Recurrence and Mortality

Three types of tumor recurrences may occur following the initial therapy for PTC, including local recurrence (LR), nodal metastases (NM), and distant metastases (DM). Local recurrence may be defined as "histologically confirmed tumor occurring in the resected thyroid bed, thyroid remnant, or other adjacent tissues of the neck (excluding lymph nodes)" after complete surgical removal of the primary tumor.[218] Fig. 14.7 illustrates rates of PTC recurrence at local, nodal, and distant sites in 2150 patients with PTC treated at one institution from 1940 to 1997. After 20 years of follow-up, postoperative NM had been discovered in 9%, and LR and DM occurred in 5% and 4%, respectively. Both local recurrence and distant metastases are less common in PTC than in FTC (Fig. 14.8), though postoperative cases of nodal metastases are more frequent in PTC. Another series of 1020 patients diagnosed between 1990 and 2000 demonstrated a rate of recurrence of only 1.4%, and most such relapses (80%) occurred within 5 years of diagnosis.[219]

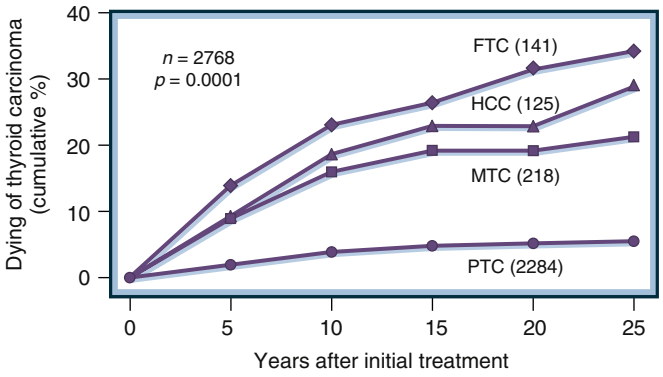
Cause-specific mortality (CSM) rates for differentiated thyroid cancer are shown in Fig. 14.9. CSM rates for PTC were 2% at 5 years, 4% at 10 years, and 5% at 20 years. Among



• **Fig. 14.7** Development of neck nodal metastases, local recurrences, and distant metastases in the first 20 years after definitive surgery for papillary thyroid cancer (PTC) or medullary thyroid cancer (MTC) performed at the Mayo Clinic from 1940 to 1997. Based on 2150 consecutive PTC *(left)* and 194 MTC *(right)* patients who had complete surgical resection (i.e., had no gross residual disease) and were without distant metastases on initial examination. *Postop,* postoperative.



• **Fig. 14.8** Development of neck nodal metastases (NM), local recurrences (LR), and distant metastases (DM) in the first 20 years after definitive surgery for follicular thyroid cancer (FTC) or Hürthle cell cancer (HCC) performed at the Mayo Clinic from 1940 to 1997. Based on 110 consecutive FTC patients *(left)* and 115 HCC patients *(right)* who had complete surgical resection and were without distant metastases on initial examination. *Postop,* postoperative.



• **Fig. 14.9** Cumulative cause-specific mortality rates for patients with differentiated thyroid carcinoma in the first 25 years after treatment with initial surgery performed at the Mayo Clinic from 1940 to 1997. Based on 2768 consecutively treated patients (2284 with papillary thyroid carcinoma [PTC], 141 with follicular thyroid cancer [FTC], 125 with Hürthle cell cancer [HCC], and 218 with medullary thyroid cancer [MTC]).

those with lethal PTC, 20% of deaths occurred in the first year after diagnosis, and 80% of the deaths occurred within 10 years. The 25-year cause-specific survival rate of 95% for PTC was significantly higher than the 79%, 71%, and 66% rates seen with MTC, Hürthle cell cancer (HCC), and FTC, respectively.[163] Survival outcomes according to the 2017 TNM eighth edition staging system were retrospectively evaluated in two large US registry cohorts (Surveillance, Epidemiology, and End Results [SEER] and National Cancer Data Base [NCDB]).[220] Five-year disease-specific survival (DSS) was 99.7% to 96.6% for stage I, 96.7% to 88% for stage II, 85.2% to 74.3% for stage III, and 66.9% to 49.5% for stage IV patients. Fig. 14.10 shows the distribution of SEER and NCDB papillary thyroid cancer populations according to both the TNM seventh and eighth editions. Fig. 14.11 illustrates the rates of DSS according to the TNM eighth edition staging system.

Prediction of Papillary Thyroid Carcinoma Recurrence

Only a fraction (~15–25%) of patients with PTC are likely to experience relapse of disease, and even fewer (~5%) will prove to have a lethal outcome. Exceptional patients who have an aggressive course tend to experience relapse early, and the rare fatalities usually occur within 5 to 10 years of diagnosis.[163] Multivariate analyses have been used to identify variables predictive of CSM.Multivariate analyses have been used to identify variables predictive of CSM.[221–223] Increasing age of the patient and the presence of extrathyroidal invasion (especially gross extrathyroidal invasion) are independent prognostic factors in all studies.

The presence of initial distant metastases and large size of the primary tumor are also significant variables in most studies,[163,221,223] and some groups[163,221,222,224] have reported that histopathologic grade (degree of differentiation) is an independent variable. The completeness of initial tumor resection (postoperative status) is also a predictor of fatality.[221,223] The presence of initial neck nodal metastases, although relevant to future nodal recurrence, surprisingly does not influence CSM rate (Fig. 14.12).[163,223]

Several scoring systems based on these significant prognostic indicators have been devised. Each system allows one to assign the majority of PTC patients (≥80%) to a low-risk group, in which the CSM rate at 25 years is less than 2%, and the others (a small minority) to a high-risk group, in which almost all cancer-related deaths are observed. In general, these systems provide prediction of postoperative events comparable to that of the internationally accepted TNM staging system.[225]

A scoring index devised to assign PTC patients to prognostic risk groups[226] was named the AGES scheme after the four independent variables: patient's *a*ge, tumor *g*rade, tumor *e*xtent (local invasion, distant metastases), and tumor *s*ize. With the use of such a scoring system, 86% of patients were in the minimal risk group (AGES score <4) and they experienced a 20-year CSM rate of only 1%. By contrast, patients with AGES scores of 4 or above (high risk; 14% of the total) had a 20-year CSM rate of 36%. Such prognostic scoring systems make it possible to counsel patients and to aid in the planning of individualized postoperative management programs in PTC.[223,226]

Although the AGES scheme had the potential for universal application, some centers could not include the differentiation (G) variable because their surgical pathologists did not recognize higher-grade PTC tumors.[225] Accordingly, a prognostic scoring system for predicting PTC mortality rates was devised with the use of candidate variables that included completeness of primary tumor resection but excluded histologic grade.[223] Cox model analysis and stepwise variable selection led to a final prognostic model that included five variables: *m*etastasis, *a*ge, *c*ompleteness of resection, *i*nvasion, and *s*ize. This model was termed the MACIS prognostic scoring system. The final score utilized a calculation of (3.1 [age ≤39 years] or 0.08 × age [age ≥40 years]) + (0.3 × tumor size [in centimeters]) + (1 [if tumor not completely resected]) + (1 [if locally invasive]) + (3 [if distant metastases present]).

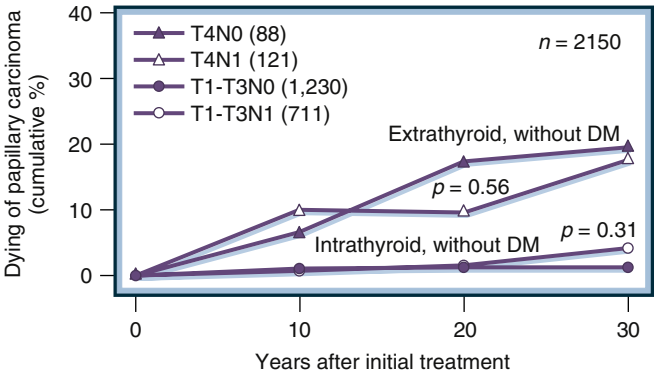
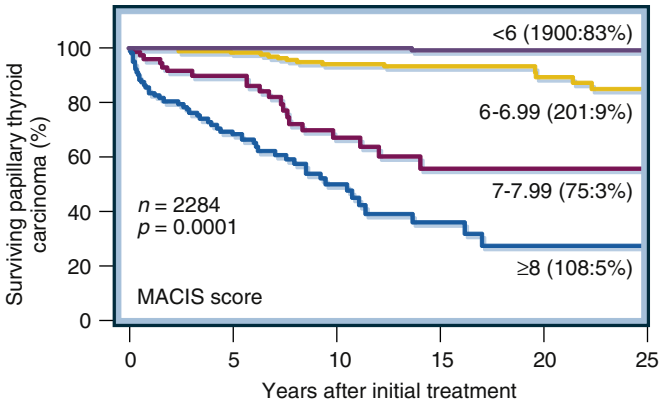
Projecting survival in papillary thyroid cancer: a comparison of the seventh and eighth editions of the American Joint Commission on Cancer/Union for International Cancer Control Staging Systems in two contemporary national patient cohorts. *Thyroid.* 2017;27:1408–1416.)



• **Fig. 14.12** Lack of influence of nodal metastases at initial operation on cumulative mortality from papillary thyroid carcinoma in 1941 patients with pathologic T1 to T3 intrathyroidal tumors (completely confined to the thyroid gland) and 209 pathologic T4 patients with extrathyroidal (locally invasive) tumors. All patients had initial surgical treatment at the Mayo Clinic from 1940 to 1997. *DM,* distant metastases.



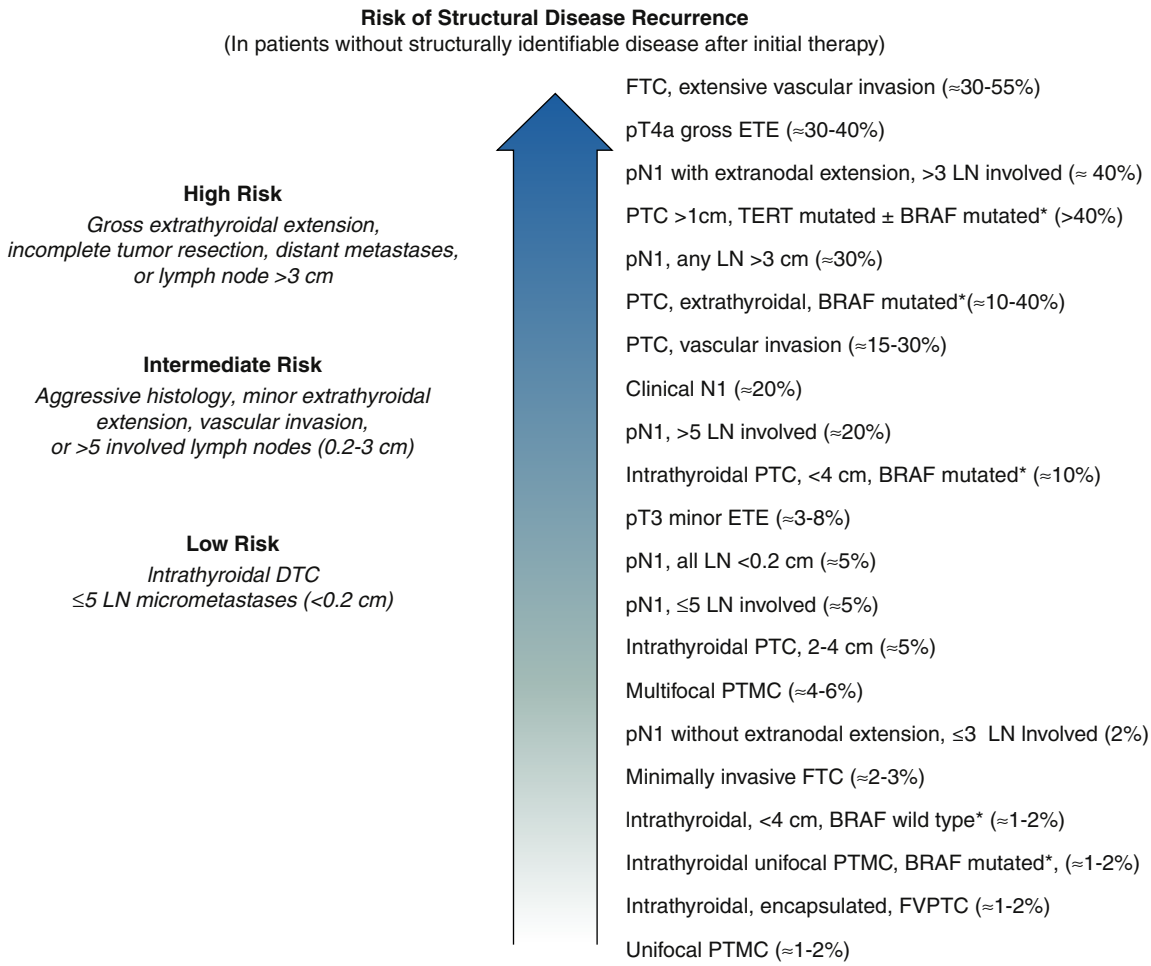
• **Fig. 14.13** Cause-specific survival according to MACIS (*m*etastases, *a*ge, *c*ompleteness of resection, *i*nvasion, and *s*ize) scores of less than 6, 6 to 6.99, 7 to 7.99, and 8+ in a cohort of 2284 consecutive patients with papillary thyroid carcinoma (PTC) undergoing initial treatment at the Mayo Clinic from 1940 to 1997. The numbers in parentheses represent the numbers and percentages of PTC patients in each of the four risk groups.

As illustrated by Fig. 14.13, the MACIS scoring system permits identification of groups of patients with a broad range of risk of death from PTC. Twenty-year cause-specific survival rates for patients with MACIS scores of less than 6, 6 to 6.99, 7 to 7.99, and 8+ were 99%, 89%, 56%, and 27%, respectively (p <0.0001). When the cumulative mortality rate from all causes of death was considered, approximately 85% of PTC patients with AGES scores below 4 or MACIS scores below 6 had no excess mortality rate over rates predicted for control subjects.[223,226]

It should be emphasized that the five variables in MACIS scoring are easy to define after primary operation; consequently, the system can be applied in any clinical setting. The MACIS system can be used for counseling individual PTC patients and can help guide decision making concerning the intensity of the postoperative tumor surveillance and the appropriateness of adjunctive radioiodine therapy. Because the CIS (completeness of resection, invasion, and size) variables require information obtained at surgery, the system should not be used to decide the extent of primary surgery.[227,228]

An important consideration for patients with well-differentiated thyroid cancer is that the risk of thyroid cancer *recurrence* is higher than the risk of thyroid cancer–related *death*. To address this important shortcoming impacting clinical care, the ATA proposed a stratification system predicting the risk of recurrence after initial treatment,[1] which should be taken into account for the indication of postoperative administration of radioiodine and for the subsequent follow-up strategy. The stratification is based on individual factors from various studies and reports a continuous increasing risk of recurrence according to each factor (Fig. 14.14). No multivariate analysis is thus far available. Of note, the age of the patient at the time of initial treatment is not taken into account for the risk of recurrence, but many other prognostic factors for thyroid cancer death are also prognostic for the risk of recurrence, such as some histologic characteristics, the size of the thyroid tumor, the extension of the tumor beyond the thyroid capsule, the presence of lymph node metastases, and the presence of residual disease due to either incomplete surgical resection or presence of distant metastases. The encapsulated follicular variant is associated with a low risk of recurrence. Aggressive histologic subtypes, the presence of necrosis, a high mitotic count, and vascular invasion are, in contrast, associated with higher risk. Indeed, the risk of recurrence is minimal (<2%) for unifocal micropapillary carcinoma, but higher for multifocal micropapillary carcinoma (~4%), and increases with the size of the thyroid tumor but is still low (~5%) in patients with an intrathyroid tumor of 3 to 4 cm without extension beyond the thyroid capsule.[229]

The prognostic impact of extension beyond the thyroid capsule is low in micropapillary carcinomas that are classified as N0. This risk increases with the size of the thyroid tumor and with the extent of the extension.[230–232] Minimal lymph node involvement (i.e., less than three lymph node metastases each <2 mm) is



• **Fig. 14.14** Differentiated thyroid cancer risk of recurrence. *DTC*, differentiated thyroid cancer; *ETE,* extrathyroidal extension; *FTC,* follicular thyroid cancer; *FVPTC,* follicular variants of papillary thyroid carcinoma; *LN,* lymph node; *PTC,* papillary thyroid carcinoma; *PTMC,* papillary thyroid microcarcinoma. (From Haugen BR, Alexander EK, Bible KC, et al. 2015 American Thyroid Association management guidelines for adult patients with thyroid nodules and differentiated thyroid cancer: the American Thyroid Association guidelines task force on thyroid nodules and differentiated thyroid cancer. *Thyroid*. 2016;26:1–133.)

associated with a low risk of recurrence. This risk again increases with the number of lymph node metastases, with the size of the lymph node metastases, and with the presence of extranodal extension.[153,154,233] Therefore minimal lymph node involvement that is usually found at prophylactic lymph node dissection may have a minimal prognostic impact and may not change the indication for postoperative treatment with radioiodine. However, large lymph node metastases (>3 cm) that are usually palpable and easily visualized on neck ultrasonography and are frequently multiple and associated with extracapsular nodal extension have a major prognostic impact on recurrence that may occur in up to 40% of patients.

The risk of PTC recurrence is also associated with the molecular profile and with the presence of *BRAF* mutation associated with a higher risk of recurrence for most tumor stages.[111,234,235] This risk is even higher when both *BRAF* and *TERT* mutations are present in the tumor.[111,193] Each of these characteristics is associated with a risk of tumor recurrence that may range from less than 2% up to more than 40%. For practical purposes, cases can be divided into three discrete groups based on their estimated risk of recurrence (low, <5%; intermediate, 5–20%; high, >20%), and the group to which the case is assigned can be used as a guide for planning subsequent treatment and follow-up (Table 14.7). (See also "Outcome Prediction for Follicular Thyroid Carcinoma.")

Follicular Thyroid Carcinoma

WHO defines follicular thyroid cancer as a malignant epithelial tumor characterized by follicular cell differentiation and absence of the nuclear features typical of PTC.[147] This definition excludes the follicular variant of PTC, and it is also customary to exclude both the poorly differentiated carcinoma[236] and the rare mixed medullary and follicular carcinoma.[237]

Thus FTC is a relatively rare neoplasm whose identification requires invasion of the capsule, blood vessel, or adjacent thyroid. In initial epidemiologic surveys, FTC constituted 5% to 50% of differentiated thyroid cancers and tended to be more common in areas with iodine deficiency.[238] Changing diagnostic criteria and increases in the incidence of PTC associated with dietary iodine supplementation have reduced the frequency of FTC diagnoses. Data from the SEER program from 1980 to 2009 show incidence rates for FTCs (1.19 per 100,000 woman-years, 0.55 per 100,000 man-years) that are markedly lower than those for PTCs (9.21 per 100,000 woman-years, 3.10 per 100,000 man-years).[239]

TABLE 14.7 2015 American Thyroid Association (ATA) Risk Stratification System

ATA Low Risk	Papillary thyroid cancer (with all of the following): • No local or distant metastases • All macroscopic tumor has been resected • No tumor invasion of locoregional tissues or structures • The tumor does not have aggressive histology (e.g., tall cell, hobnail variant, columnar cell carcinoma) • If ^{131}I is given, there are no RAI-avid metastatic foci outside the thyroid bed on the first posttreatment whole-body RAI scan • No vascular invasion • Clinical N0 or ≤5 pathologic N1 micrometastases (<0.2 cm in largest dimension) Intrathyroidal, encapsulated follicular variant of papillary thyroid cancer Intrathyroidal, well-differentiated follicular thyroid cancer with capsular invasion and no or minimal (<4 foci) vascular invasion Intrathyroidal, papillary microcarcinoma, unifocal or multifocal, including *BRAF*^{V600E} mutated (if known)
ATA Intermediate Risk	Microscopic invasion of tumor into the perithyroidal soft tissues RAI-avid metastatic foci in the neck on the first posttreatment whole-body RAI scan Aggressive histology (e.g., tall cell, hobnail variant, columnar cell carcinoma) Papillary thyroid cancer with vascular invasion Clinical N1 or >5 pathologic N1 with all involved lymph nodes <3 cm in largest dimension Multifocal papillary microcarcinoma with extrathyroidal extension and BRAF^{V600E} mutated (if known)
ATA High Risk	Macroscopic invasion of tumor into the perithyroidal soft tissues (gross extrathyroidal extension) Incomplete tumor resection Distant metastases Postoperative serum thyroglobulin suggestive of distant metastases Pathologic N1 with any metastatic lymph node ≥3 cm in largest dimension Follicular thyroid cancer with extensive vascular invasion (>4 foci of vascular invasion)

ATA, American Thyroid Association; *RAI*, radioactive iodine

From Haugen BR, Alexander EK, Bible KC, et al. 2015 American Thyroid Association management guidelines for adult patients with thyroid nodules and differentiated thyroid cancer: the American Thyroid Association guidelines task force on thyroid nodules and differentiated thyroid cancer. *Thyroid.* 2016;26:1–133.

The microscopic appearance of FTC varies from well-formed follicles to a predominantly solid growth pattern.[146] Poorly formed follicles and atypical patterns (e.g., cribriform) may occur, and multiple architectural types may coexist. FTC is best divided into three categories on the basis of degree of invasiveness: (1) minimally invasive or encapsulated, (2) encapsulated angioinvasive, and (3) widely invasive. Minimally invasive FTC is an encapsulated tumor whose growth pattern resembles that of a trabecular or solid microfollicular or atypical adenoma. The diagnosis of malignancy depends on the demonstration of capsular invasion. The criteria for invasion must therefore be strict.[146,147] Interruption of the capsule must involve the full thickness to qualify as capsular invasion. Penetration of only the inner half or the presence of tumor cells embedded in the capsule does not qualify for the diagnosis of FTC. Foci of capsular invasion must be distinguished from the capsular rupture that can result from FNA. The acronym WHAFFT (worrisome histologic alterations following FNA of the thyroid) is applied to such changes.[240] Extensive histologic sampling may be required to distinguish minimally invasive FTCs from follicular adenomas, and the ability to discriminate between the two varies substantially from one pathologist to another.[241] The diagnosis of malignancy of these tumors may be difficult and not reproducible among pathologists, and immunohistochemistry with markers such as TPO, galectin 3, or HMBE1 may help for this purpose,[106] but these techniques did not reliably improve the accuracy in case of suspicious findings. Global gene expression studies with the microarray technology and more recently the gene classifier or a panel of gene mutations may help to differentiate malignant from benign follicular tumors.[242]

Minimally invasive FTC with vascular invasion (encapsulated angioinvasive, defined by some authors as moderately invasive) must also be distinguished from minimally invasive FTCs with capsular invasion alone because vascular invasion increases the risks of recurrence and metastasis. Vascular spread should be diagnosed even when there is only a single focus of angioinvasion. Grossly evident blood vessel invasion is almost never seen.

In contrast, the rare, widely invasive form of FTC can be distinguished easily from benign lesions. Although the tumor may be partially encapsulated, the margins are infiltrative even on gross examination, and vascular invasion is often extensive. The structural features are variable, but a follicular element is always present. When follicular differentiation is poor or absent, or in the presence of trabecular, insular, or solid components, the tumor may be classified as a poorly differentiated carcinoma (see later).[146,236] Focal or extensive clear cell changes can also be seen on histologic analysis. A rare clear cell variant of FTC has been described in which glycogen accumulation or dilatation of the granular endoplasmic reticulum is responsible for the clear cells.[243]

Molecular Pathogenesis of Follicular Thyroid Carcinoma

There is still no accepted paradigm for the pathogenesis of FTC. A multistep adenoma-to-carcinoma pathogenesis, similar to that for colon cancer and other adenocarcinomas, is not universally accepted because pathologists do not recognize follicular carcinoma in situ, and documentation of the evolution of adenoma to carcinoma is rare. Nevertheless, several facts about the pathogenesis of FTC are firmly established.[111,160,244,245] First, most follicular adenomas and all FTCs are probably of monoclonal origin. Second, oncogene activation, particularly by point mutation of the *RAS* oncogene, is common both in follicular adenomas (~20%) and in FTCs (~40%), supporting a role for these mutations in early tumorigenesis.[245,246] This commonality suggests that FTA and FTC are etiologically related or, more specifically, that FTAs are premalignant neoplasms that can (at least in some cases, but likely not all) progress to become FTC.[245] Moreover, the fact that *RAS* mutations are common in FTA, FTC, and FVPTC implies that all these follicular-patterned neoplasms share a common pathogenesis.[247] The *RET* and *BRAF* oncogenes do not appear to be involved in follicular tumors.[111,160,248] Third, cytogenetic abnormalities and evidence of genetic loss are

more common in FTC than in PTC and also occur in follicular adenomas.[244,248]

Of the cytogenetic abnormalities described in FTC, the most common are deletions, partial deletions, and deletion rearrangements involving the p arm of chromosome 3. Loss of heterozygosity (LOH) on chromosome 3p appears to be limited to FTC because no evidence for 3p LOH has been found in follicular adenomas or PTC. A translocation, t(2;3)(q13;p25), resulting in the fusion of the DNA binding domains of the thyroid transcription factor PAX8 to domains of the peroxisome proliferator–activated receptor gamma 1 (PPARγ1) was detected in 30% (range 11–63%) of FTCs, 10% of follicular adenomas, and a smaller percentage of FVPTCs.[249–253] PAX8 encodes a paired-box transcription factor that is highly expressed in thyroid follicular cells, where it plays a key role in their development.[254,255] The fusion gene mentioned earlier therefore results in increased expression of *PPARγ*.[256] *CREB3L2-PPARγ* fusions have also been described in a small number of FTCs,[257] suggesting that *PPARγ* may play a role in the development of these tumors. Compared with classic FTCs, *PAX8-PPARγ* FTCs are more frequently diagnosed in younger patients, and they are more likely to be associated with vascular invasion, although their clinical behavior is relatively indolent.[251] The *PAX8-PPARγ* tumors' gene expression profiles are also distinctive, reflecting as they do the transcriptional output of the PAX8-PPARγ fusion protein.[258]

Genes encoding components of the PI3K/PTEN/AKT signaling pathway are also likely to be genetically altered or epigenetically silenced in FTCs.[259] Somatic mutations involving the tumor suppressor gene *PTEN* are found in up to 1 of 10 sporadic FTCs,[260] and germline *PTEN* mutations are associated with the Cowden syndrome (CS). Up to 10% of all FTCs also harbor activating PIK3CA mutations.[261]

Mutations of the *TERT* promoter are also found in some FTCs, and they are associated with aggressive disease and poor outcomes.[192] Interestingly, *TERT* promoter mutations have also been reportedly found in a small subset of FTAs and atypical adenomas. Some of these tumors ultimately displayed cancer-like behavior, raising the possibility that TERT mutations may be a potential biomarker of FTC for use in cases with nondiagnostic histologic features.[262]

In a recent genomic study of FTA, FTC, and PTC,[263] the transcriptomes of FTA, minimally invasive FTC, and noninvasive FVPTC proved to be indistinguishable, while that of the infiltrative FVPTC was more similar to the classic PTC transcriptome.[263] These findings add support to the view that follicular-patterned tumors are characterized by a common *RAS*-like pathogenesis. The strong biologic relation between FVPTC and FTC has also been confirmed by miRNA expression profiling, which revealed upregulated expression of miR-182-5p and miR-183-5p exclusively in these thyroid carcinoma histotypes.[118,264,265] Nearly 90% of the miRNAs found to be dysregulated in FTC were similarly dysregulated in follicular adenomas (FA), including miR-182-5p, miR-183-5p, and miR-96, which were upregulated, and miR-1247, which was downregulated with respect to levels found in normal thyroid tissues.[264] In contrast, downregulation of miR-150 seemed to be an FTC-specific change[264] and may function as a suppressor gene in tumor cells by inhibiting the RAB11A/WNT/β-catenin pathway.[266] Three well-characterized miRNAs—miR-146b-5p, miR-221-3p, and miR-222-3p—are commonly upregulated in FTCs, PTCs, and ATC. Their dysregulation thus appears to be an early event in the development of follicular cell–derived thyroid cancers that is essential for sustaining the oncogenic process.[118,265,267]

Hürthle Cell Carcinoma

When more than 75% of cells in an FTC exhibit Hürthle cell (or oncocytic) features, the tumor is classified as a Hürthle cell (oncocytic) carcinoma.[146,238] The current version of the WHO classification includes this tumor as a separate entity,[147] although in the past it was considered an oxyphilic variant of FTC.[162] The AFIP monograph already stated that "the tumors made up of this cell type have gross, microscopic, behavioral, cytogenetic features that set them apart from all others and justify discussing them in a separate section."[146] The mutational, transcriptional, and copy number profiles of HCC were distinct from those of PTC and FTC, indicating HCC to be a unique type of thyroid malignancy. Molecular pathways that differentiate Hürthle cell adenoma from widely invasive HCC included the PIK3CA-Akt-mTOR (mammalian target of rapamycin) and Wnt/β-catenin pathways, potentially providing a rationale for new targets for this type of malignancy. Recent data have confirmed that molecular abnormalities are different from those found in follicular cancer.[268]

Presenting Features of Follicular Thyroid Carcinoma

FTC tends to occur in older individuals.[238] The mean age at diagnosis of FTC (49 years) is slightly higher than those for both PTC and follicular variant PTCs (44 and 46 years, respectively).[269] The median age of patients with HCC is about 60 years. As in most thyroid malignancies, women outnumber men (>2:1). Most patients with FTC present with a painless thyroid nodule, with or without background thyroid nodularity, and they rarely (2–8%) have clinically evident lymphadenopathy at presentation.[238] Lymph node metastases to the neck in FTC are so exceptional that "wherever they are observed, the alternative possibilities of follicular variant papillary carcinoma, oncocytic carcinoma, and poorly differentiated carcinoma should be considered."[146] HCC are the exception where up to one-third of these FTCs have cervical lymph node metastases at the time of diagnosis.[238]

In most series in which tumor sizes were reported, the average tumor in FTC and HCC was larger than those seen with PTC.[270] Direct extrathyroidal extension, by definition, does not occur with minimally invasive FTC but is common in the rare patients with widely invasive FTC. Between 15% and 27% of patients may have distant metastases at presentation.[238] The most common sites for distant metastases in FTC are lung and bone.[238] The bones most often involved are long bones (e.g., femur), flat bones (particularly the pelvis, sternum, and skull), and vertebrae. When a distant metastasis is the first manifestation of the disease, definitive proof of its thyroid origin should be obtained, usually by biopsy of a metastasis, before performing any thyroid surgery. It is unusual but possible for patients with FTC to have thyrotoxicosis caused by massive tumor burden producing thyroid hormone.[271]

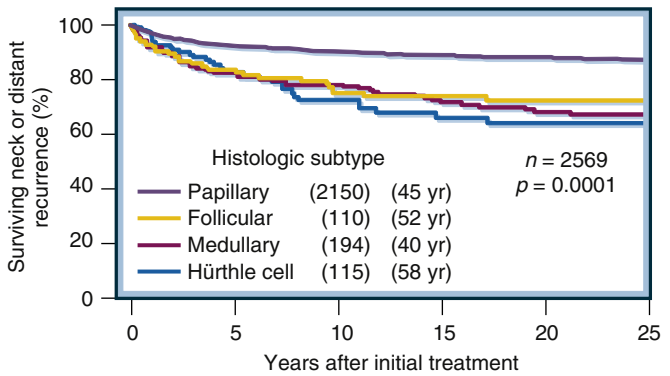
Risk of Follicular Thyroid Carcinoma Recurrence and Mortality

Recurrence rates reported in patients with FTCs vary widely, from 3% to 43.5%, and recurrence is most frequent in widely invasive FTC. Similar recurrence rates are seen in HCC (14–44%). Over half of all FTC recurrences are detected within the 3 years following diagnosis, and 80% are found within the first 6 years. The vast majority of recurrences (up to 85%) occur at distant sites, but lesions can also be found in the thyroid bed and regional lymph nodes.

Nodal metastases are rare in typical FTC, and the nodal recurrence rate at 20 postoperative years is the lowest among differentiated thyroid carcinoma, being around 2% (see Fig. 14.8),

although it is higher (about 17%) in HCC patients.[272] When recurrences at either the neck or distant sites are taken into consideration, patients with HCC (Fig. 14.15) have the highest numbers of tumor recurrences after 10 to 20 years. As illustrated by Fig. 14.8, local recurrences at 20 years have occurred in 20% of FTCs and 30% of HCCs. Comparable distant metastasis rates are 23% and 28%, respectively.

The mortality rate from FTC exceeds that of PTC (Fig. 14.16). CSMs vary with the presenting TNM stage in both FTC and HCC (Fig. 14.17). The death rates tend to parallel the curves for development of distant metastases (see Fig. 14.8). In more than 50 years of experience at the Mayo Clinic, the mortality rate for FTC initially exceeds that of HCC, but by 20 to 30 postoperative years, there are no significant differences in cause-specific survival rates between FTC and HCC, both being around 80% at 20 years and 70% at 30 postoperative years.[270] Curves representing death from all causes differ in FTC and HCC. On average, patients with FTC are about 5 years younger, tend to die within the first 10 postoperative years, and have a high all-cause mortality rate for 10 to 30 postoperative years. Deaths related to HCC occur gradually over the first 15 years. However, by 25 years, the average survivor of HCC is 84 years old, and by that time, almost 50% of the treated cohort would be predicted by the actuarial curve to have died from all causes.

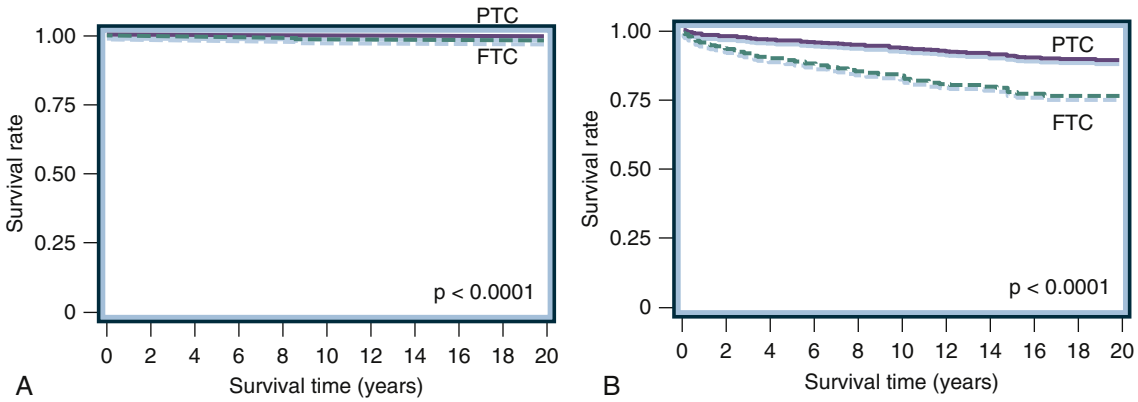


• **Fig. 14.15** Postoperative recurrence (any site) in the first 20 years after definitive surgery for differentiated thyroid carcinoma performed at the Mayo Clinic from 1940 to 1997. Based on 2569 consecutive patients (2150 papillary thyroid carcinoma, 110 follicular thyroid carcinoma, 115 Hürthle cell carcinoma, and 194 medullary thyroid carcinoma) who had complete tumor resection and had no distant metastases at presentation. The ages in parentheses represent the median age at diagnosis for each of the four histologic subtypes.

Outcome Prediction for Follicular Thyroid Carcinoma

The risk factors that predict outcome in FTC are similar to those recognized in PTC[273–276] and include distant metastases at presentation, advanced age at diagnosis (>45 years for most studies), large primary tumors (>4 cm), the presence and extent of local (extrathyroidal) invasion, and the completeness of excision. To a lesser degree, increased mortality risk is associated with male sex. The number of vessels involved (<4 or ≥4) has also prognostic value for both cancer-specific survival and disease-free survival (Fig. 14.18).[238,275]

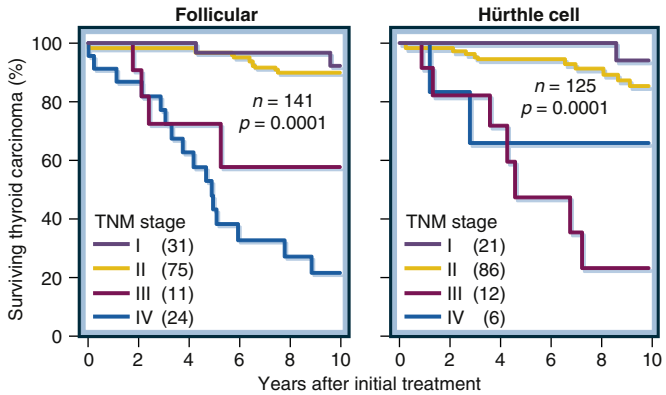
Inconsistencies between the results of different studies in predicting the outcome of FTC patients may reflect the use of different classification systems over long follow-up periods, the quality of the pathologic reviews, and/or the small sample sizes. Several systems have been proposed for staging thyroid cancer. Some were developed solely for use with PTC, others were derived from data on PTC and FTC *(differentiated thyroid cancer),* and still others were developed for use with all histologic types of thyroid cancers (including medullary and anaplastic forms). The AIM (age, invasion, metastases) system is the only one developed specifically for staging FTC. In some of these systems, FTC patients are classified in a higher risk category (GAMES [grade, age, metastases, extent, size], National Thyroid Cancer Treatment Cooperative Study Group [NTCTCSG]). On the contrary, the AMES (age, metastases, extent, size), Clinical Class, MACIS, and AGES prognostic scoring systems and various versions of the UICC/AJCC pTNM system do not include FTC histology as an independent risk factor.[274] The UICC/AJCC pTNM (tumor, nodes, metastasis) system is still the most widely used staging system for thyroid carcinoma and provides fairly accurate prognostic information on the tumors (see Fig. 14.17). One of the most hotly debated staging criteria is the age threshold for defining higher risk disease. In the recently implemented eighth edition of the AJCC/IUCC staging system, the threshold was raised from 45 years to 55 years to avoid encouraging overtreatment. Moreover, a recent reassessment of the NTCTCSG thyroid cancer staging system showed that a new model for FTC, with a threshold of 50 years, outperformed the current system.[277]



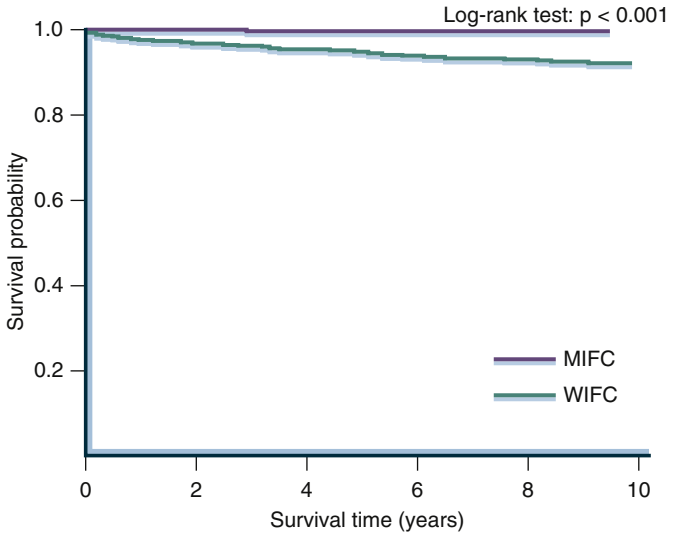
• **Fig. 14.16** Comparison of disease-specific survival by carcinoma type (papillary [PTC] vs follicular thyroid cancer [FTC]) in patients less than 45 years (A) or at least 45 years old (B). (Redrawn from Oyer SL, Fritsch VA, Lentsch EJ. Comparison of survival rates between papillary and follicular thyroid carcinomas among 36,725 patients. *Ann Otol Rhinol Laryngol*. 2014;123:94–100.)

Poorly Differentiated Carcinoma

Poorly differentiated thyroid carcinoma is rare, representing less than 5% of all thyroid cancers. It has been defined as "a tumor of follicular cell origin with morphological and biologic attributes intermediate between differentiated and anaplastic carcinomas of the thyroid."[146] A consensus conference proposed the following diagnostic criteria (the *Turin criteria*) for poorly differentiated carcinoma: (1) solid, trabecular, and insular pattern of growth; (2) absence of the conventional nuclear features of papillary carcinomas; and (3) presence of at least convoluted nuclei, mitotic activity greater than 3 × 10 high-power fields, and tumor necrosis.[236] Similarly, in well-differentiated cancer, necrosis, mitosis, and cellular atypia associated with vascular invasion are considered as features of poor prognosis and aggressiveness.[39,274] Most poorly differentiated tumors are larger than 5 cm in diameter at diagnosis, with extrathyroidal extension and blood vessel invasion.



• **Fig. 14.17** Cause-specific survival according to pathologic tumor-node-metastasis (pTNM) stages in a cohort of 141 patients with follicular thyroid carcinoma *(left panel)* and 125 patients with Hürthle cell carcinoma *(right panel)* treated at the Mayo Clinic from 1940 to 1997. Numbers in parentheses represent the number of patients in each pTNM stage grouping.



• **Fig. 14.18** Disease-specific survival of minimally invasive follicular thyroid cancer (MIFC) versus widely invasive follicular thyroid cancer (WIFC). (From Goffredo P, Cheung K, Roman SA, et al. Can minimally invasive follicular thyroid cancer be approached as a benign lesion? A population-level analysis of survival among 1200 patients. *Ann Surg Oncol*. 2013;20:767–772.)

RAS mutations appear to be a common molecular signature in poorly differentiated tumors, although they were found at a highly variable frequency and wide variation in specific types of *RAS* mutations. The occurrence of β-catenin mutations in PDTC is controversial, ranging from 0% to 32% of tumors. Finally, *TERT* promoter mutations, which have been described in a subset of PDTC, have been proposed as a molecular marker of thyroid tumor dedifferentiation and progression, and they are considered to be a molecular signature of aggressive tumors. *TERT* promoter mutations are found in around 40% of PDTCs, particularly those that also harbor an additional *BRAF* or *RAS* mutation. *TP53* mutations are reported in 10% of the cases, but are more common in anaplastic thyroid cancer (Fig. 14.19).[278] Recently, a prognostic role of specific microRNAs has been demonstrated in PDTC.

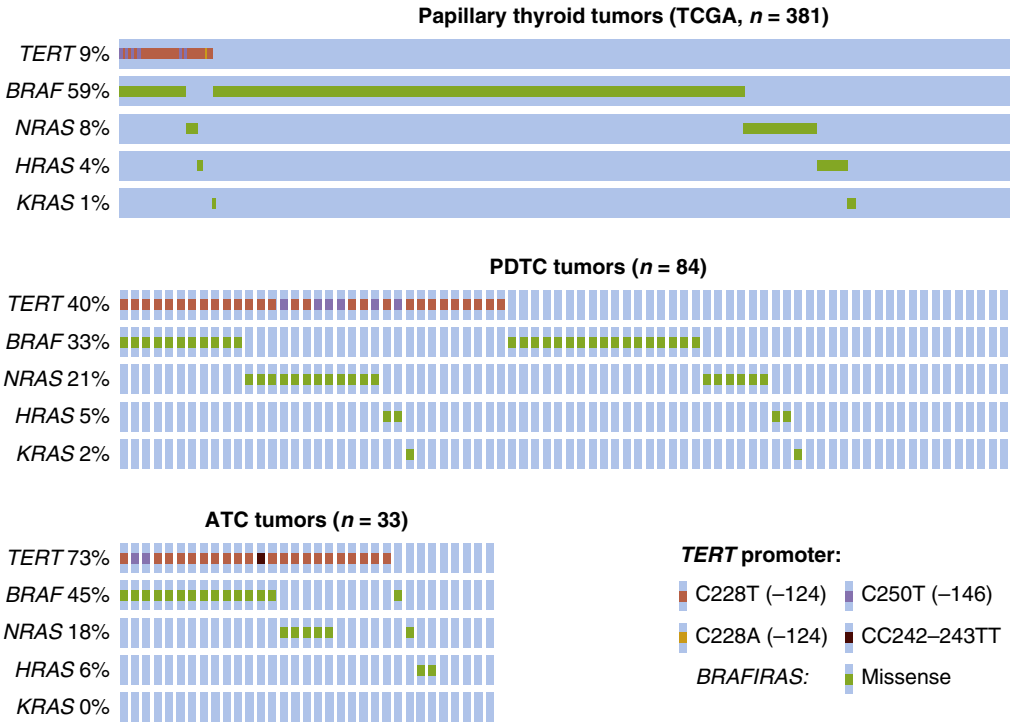
The mean age at diagnosis is about 55 years, and the female-to-male ratio is about 2:1. Poorly differentiated carcinoma is aggressive and can be lethal. Radioiodine uptake is rarely present, and FDG uptake on PET is frequently high; production of Tg in blood may be lower than in differentiated carcinomas. Metastases are common in regional nodes and distant sites (lung, bone, brain). In one series, 56% of patients died from their tumor within 8 years of initial therapy, though not all have replicated these findings.[236,279,280]

Undifferentiated (Anaplastic) Carcinoma

Anaplastic carcinoma constitutes about 1% to 2% of all thyroid carcinomas, usually occurs after the age of 60 years, and is slightly more common in women than men (1.3:1 to 1.5:1).[281] This carcinoma is highly malignant, nonencapsulated, and extends widely. Evidence of invasion of adjacent structures, such as the skin, muscles, nerves, blood vessels, larynx, and esophagus, is common. Distant metastases occur early in the course of the disease in lungs, liver, bones, and brain.

On histopathologic examination, the lesion is composed of atypical cells that exhibit numerous mitoses and form a variety of patterns. Spindled, pleomorphic, squamoid, and even rhabdoid cells have been described. Areas of necrosis and polymorphonuclear infiltration are common, and the presence of PTC or FTC suggests that they may be the precursors of anaplastic carcinoma. Immunohistochemistry revealed that a significant proportion of cells are tumor-associated macrophages.[282,283]

Mutations of the *TP53* gene are present in many (60–80%) undifferentiated carcinomas but may not be found in the residual well-differentiated component, suggesting that these mutations occurred after the development of the original tumor and may have played a key role in tumor progression.[163,284] *BRAF* mutation is found mostly in anaplastic thyroid carcinoma with a papillary component, and *RAS* mutation is found in 20% or more of anaplastic thyroid carcinomas; *PI3KCA* mutation is rare in differentiated thyroid cancer and was found in 23% of anaplastic thyroid carcinoma; finally, *ALK* rearrangement was found in about 10% of anaplastic thyroid carcinomas.[184] *BRAF* and *RAS* mutations are still the principal genetic drivers of thyroid carcinomas, but additional mutations accumulate in ATCs, including those affecting the *TERT* promoter (see Fig. 14.19), mismatch repair genes, and genes encoding components of the PIK3CA-PTEN-AKT-mTOR pathway, the SWI-SNF complex, or histomethyltransferases. Several alterations may serve as adverse prognostic markers in ATC, including *EIF1AX* mutations, loss of chromosome 13q, and gain of chromosome 20q.[278]



• **Fig. 14.19** Oncoprints of *TERT* promoter mutations, *BRAF*, and *RAS* mutations (with reported rate) in PTCs from TCGA (*n* = 381), PDTCs (*n* = 84), and ATCs (*n* = 33). (From Landa I, Ibrahimpasic T, Boucai L, et al. Genomic and transcriptomic hallmarks of poorly differentiated and anaplastic thyroid cancers. *J Clin Invest*. 2016;126:1052–1066.)

The usual clinical complaint is of rapid, often painful enlargement of a mass that may have been present in the thyroid gland for many years. The tumor invades adjacent structures, causing hoarseness, inspiratory stridor, and difficulty in swallowing. On examination, the overlying skin is often warm and discolored. The mass is tender and is often fixed to adjacent structures. The regional lymph nodes are enlarged, and there may be evidence of distant metastases. Anaplastic carcinomas do not accumulate iodine and do not typically produce Tg; high FDG uptake is usually found on PET, which is the best tool for tumor staging and for control of treatment efficacy.[285,286]

Treatment should be initiated rapidly to avoid death from locally infiltrative disease and possible suffocation. It consists of surgical resection of the tumor tissue present in the neck, when this is feasible, followed by a combination of external irradiation and chemotherapy. The overall prognosis for ATC remains poor despite recent advances (Fig. 14.20). The median overall survival remains around 3 to 5 months with a 1-year survival of approximately 20%. Patient factors associated with poorer prognosis include advanced age (>60–70 years), male gender, presence of leukocytosis (>10,000), and symptoms (such as rapidly growing tumor, pain in the neck, dyspnea, dysphagia, and hoarseness).

However, treatment paradigms for ATC are evolving rapidly. Patients with *BRAF*-mutant ATCs can now be treated with a combination of selective BRAF and MEK inhibitors. For patients whose disease was initially regarded as unresectable, response to this combination therapy can render them eligible for surgery. For patients interested in taking part in a clinical trial, the tumor should be assessed for a broad range of mutations and fusions. This helps determine whether the patient is suitable for enrollment in trials testing selective inhibitors, such as the selective NTRK or RET inhibitor trials. Other driver mutations that are identified may help identify a clinical trial that is appropriate for the patient, particularly as more targeted therapies become available.[287]

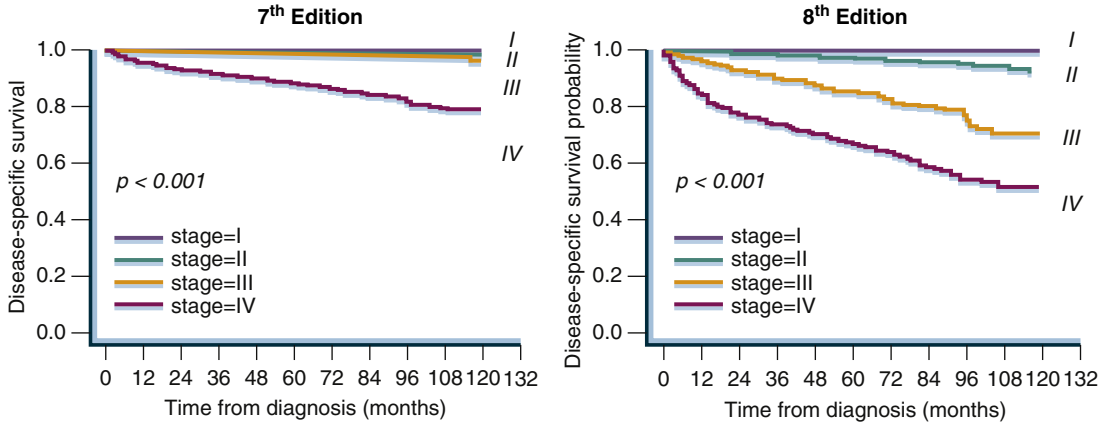
Medullary Thyroid Carcinoma

Medullary thyroid carcinoma accounts for approximately 2% of all thyroid cancers. MTCs are rare neuroendocrine cancers that arise from the parafollicular C cells of the thyroid gland. Compared with differentiated thyroid cancers, MTC is associated with less favorable outcomes (Fig. 14.21), including persistent or recurrent disease, need for reoperation, and mortality.[288] However, the prognosis and associated risk are highly variable, in large part determined by the specific molecular mutation detected in the MTC. On histologic assessment, MTC readily invades the intraglandular lymphatics and spreads to other parts of the gland, in addition to the pericapsular and regional lymph nodes. It also regularly spreads through the bloodstream to the lungs, bones, and liver.[14,155,156,289–291]

Histologic Diagnosis of Medullary Thyroid Carcinoma

MTC tumors are firm and usually unencapsulated. On histopathologic examination, the tumor is composed of cells that vary in morphologic features and arrangement. Round, polyhedral, and spindle-shaped cells form a variety of patterns, which may vary from solid and trabecular to endocrine or glandular-like structures. An amyloid stroma is commonly present.[146] Gross or microscopic foci of carcinoma may be present in other parts of the gland, and blood vessels may be invaded. In all cases, the diagnosis can be confirmed by positive immunostaining of tumor tissue for calcitonin and carcinoembryonic antigen (CEA).

Impact of timeliness of resection and thyroidectomy margin status on survival for patients with anaplastic thyroid cancer: an analysis of 335 cases. *Ann Surg Oncol*. 2015;22:4166–4174.)



• **Fig. 14.21** Overall survival according to pathologic tumor-node-metastasis (pTNM) in the National Cancer Database Cohort. (Redrawn from Pontius LN, Oyekunle TO, Thomas SM, et al. Projecting survival in papillary thyroid cancer: a comparison of the seventh and eighth editions of the American Joint Commission on Cancer/Union for International Cancer Control staging systems in two contemporary national patient cohorts. *Thyroid*. 2017;27:1408–1416.)

Clinical Presentation of Medullary Thyroid Carcinoma

MTC first appears either as a hard nodule or mass in the thyroid gland or as an enlargement of the regional lymph nodes. Occasionally a metastatic lesion in a distant site is found first. The neck masses are frequently painful; they are sometimes bilateral and are often localized to the upper two-thirds of each lobe of the gland, which reflects the anatomic location of the parafollicular cells.

Differentiation of sporadic MTC from other types of thyroid nodules on clinical grounds alone may be difficult. FNAB has made it possible to diagnose MTC before surgery. In some

patients, however, cytologic findings may be misleading because the type of carcinoma is difficult to determine and HCC may occasionally be confused with MTC.[146,162] Positive immunocytochemical staining for calcitonin allows confirmation of the diagnosis. Basal plasma calcitonin levels are elevated in virtually all patients with clinical MTC, but it is still controversial whether it should be performed in all patients with thyroid nodules or only in those with suspicious or malignant cytologic findings.[81,82]

When the diagnosis of MTC is made from calcitonin measurements or FNAB, patients should be evaluated for hyperparathyroidism and for pheochromocytoma, unless a hereditary form of the disease has been excluded. If these diagnoses are satisfactorily excluded, total thyroidectomy with removal of regional nodes can safely be performed.[14,292–295]

The tumor occurs in both sporadic and hereditary forms, the latter making up about 20% to 30% of the total. The hereditary variety arises as part of MEN syndrome type 2A or 2B. A germline-activating *RET* point mutation is found in almost all hereditary cases, and *RET* proto-oncogene testing should be performed in all MTC patients. The finding of a germline *RET* mutation indicates a hereditary disease; the mutation should then be sought in all first-degree family members. The hereditary form is typically bilateral and is usually preceded by a premalignant C-cell hyperplasia. Total thyroidectomy at this premalignant stage can cure the disease in more than 95% of cases.[14,81,82,291–293]

As mentioned, there is a strong relationship in MTC between genotype and phenotype: most MEN2B are due to a codon 918 mutation in exon 16; the most frequent mutation found in patients with MEN2A is a codon 634 mutation in exon 11; the other mutations are located in exons 10, 13, 14, and 15 and are usually associated with less aggressive phenotypes. Somatic *RET* mutations are found in 40% of sporadic MTCs, with the codon 918 mutation being the most frequent and associated with a more aggressive course.[296] In up to two-thirds of tumors with no *RET* mutation, a *RAS* point mutation was found in most studies[297–299] but not in all.[300]

Cushing syndrome may occur at an advanced stage of the disease because of secretion of corticotropin by the tumor. Prostaglandins, serotonin, kinins, and vasoactive intestinal peptide may also be secreted and are variously responsible for flushing and for the attacks of watery diarrhea that about one-third of patients experience, usually at an advanced stage of the disease.[155,156,290,291] In MEN2A, hyperparathyroidism occurs late and is usually mild. Pheochromocytomas invariably occur later than MTC; they are often bilateral and may be clinically silent, and patients at risk should be screened with measurements of urinary metanephrine excretion. Familial MTC is a variant of MEN2A. MTC is transmitted as a single entity without any associated abnormality in the family and usually occurs later in life and is less aggressive than MTC occurring in the context of other subgroups of MEN2A; pheochromocytoma should be screened even if its risk is low because it cannot be totally excluded in any hereditary form. In MEN2B, MTC and pheochromocytomas are associated with multiple mucosal neuromas (bumpy lip syndrome), a marfanoid habitus, and typical facies, but such patients do not have hyperparathyroidism.[14,291]

In patients with a family history of thyroid cancer associated with hypertension or hyperparathyroidism, the MEN2A syndrome should be suspected. In patients with MEN2, surgery should be performed for pheochromocytomas before surgery for MTC is performed.

First-degree relatives of patients with MEN should undergo DNA testing for the presence of the mutant *RET* gene (see Chapter 42). Gene carriers should undergo a prophylactic total thyroidectomy at an age that depends on the mutation: within the first year of life for those with MEN2B and before age 5 years for those with the 634 *RET* mutation (the most frequent).[14,292,293] For carriers of other mutations, prophylactic total thyroidectomy may be delayed beyond age 5 years in the setting of a normal annual basal serum calcitonin, normal annual neck ultrasonography, less aggressive MTC family history, and family preference. Surgery is indicated if all of these features are not present and consists of a total thyroidectomy with lymph node dissection; lymph node dissection may be obviated when the thyroid nodule is smaller than 5 mm, when there is no lymph node abnormality on neck ultrasonography, and when the plasma calcitonin level is less than 40 pg/mL.[14]

Prognosis for Medullary Thyroid Carcinoma

Early series of MTC mainly described sporadic cases in which 80% of patients presented with TNM stage II or III. Patients with MEN2A are diagnosed earlier and have curable (stage I) disease.[291,292] Patients with MTC now have outcomes similar to or better than those of patients with nonpapillary FCTC (see Fig. 14.7). In a study of patients undergoing surgery for MTC in California, independent risk factors for disease-specific mortality were older age (HR, 1.36 per decade; 95% CI, 1.17–1.59), tumor size exceeding 2 cm (HR, 2.83; 95% CI, 1.08–7.44 for >2 to 4 cm and HR, 2.89; 95% CI, 1.09–7.71 for >4 cm), and the administration of external beam radiotherapy (HR, 2.14; 95% CI, 1.23–3.71). Disease stage was the strongest predictor of mortality from regional (HR, 4.77; 95% CI, 2.29–9.94) or metastatic (HR, 21.08; 95% CI, 9.90–44.89) disease.[288]

Primary Malignant Lymphoma of the Thyroid

Primary thyroid lymphomas are rare tumors, accounting for less than 2% of all extranodal lymphomas and less than 3% of all malignant thyroid tumors. The peak incidence is during the seventh decade of life and the male-to-female ratio is 1:2–8.[301]

Primary thyroid lymphoma almost always has a B-cell lineage.[301] The majority of thyroid malignant lymphomas are mucosa-associated lymphoid tissue (MALT) lymphomas that usually arise in a background of Hashimoto thyroiditis. These small cell lymphomas are characterized by a low grade of malignancy, a slow growth rate, and a tendency for recurrence at other MALT sites such as the gastrointestinal or respiratory tract, the thymus, or the salivary glands. At diagnosis, diffuse large cell lymphomas account for about 70% to 80% of tumors, and a substantial proportion of clinical cases arise from the transformation of low-grade MALT lymphoma to high-grade B-cell lymphoma. Other histologic findings are rare.

Clinical thyroid lymphomas almost invariably present as a rapidly enlarging, painless neck mass. One-third of the patients have compressive symptoms. The mass is often fixed to surrounding tissues, and half of the patients have unilateral or bilateral cervical lymph node enlargement. Clinically evident distant disease is uncommon. About 20% of patients already have a long-standing goiter, and hypothyroidism is reported in up to 40% of cases. The palpated mass is solid and hypoechoic on ultrasonography, which often depicts a characteristic asymmetric pseudocystic pattern. Most patients have serum antiperoxidase and anti-Tg antibodies.

The diagnosis of lymphoma can often be established by FNA cytologic and flow cytometric tests, particularly in diffuse large B-cell type. The need for core-needle or surgical biopsies has

decreased, but they can still be helpful for distinguishing thyroiditis from low-grade MALT lymphoma and for reliably excluding aggressive histologies because histology, immunostaining, and testing for gene rearrangements may be needed.

Accurate staging is critical for treatment planning. Staging includes a physical examination; complete blood count; serum lactate dehydrogenase; liver function tests; bone marrow biopsy; CT scan or MRI of the neck; CT scan of the thorax, abdomen, and pelvis; and appropriate biopsies at other sites where tumor is suspected. ^{18}FDG-PET scanning may be useful for the initial diagnosis and for monitoring responses to treatment. Involvement of the Waldeyer ring and the gastrointestinal tract has been associated with thyroid lymphomas, and therefore upper gastrointestinal tract radiographs or endoscopy should be performed.

Treatment is guided by the histologic subtype, the extent of the disease, and (in case of diffuse large B-cell lymphoma) the age-adjusted international prognostic index.[302,303] Surgical debulking of thyroid lymphomas is neither feasible nor necessary. Small tumors are often treated initially as primary thyroid carcinomas with surgery, and additional radiotherapy may be necessary in case of indolent lymphoma.

For high-grade B-cell lymphoma, chemotherapy combined with rituximab (chimeric human-mouse anti-CD20 monoclonal antibody) has become the standard treatment.[304] The chemotherapy prescribed should be an anthracycline-based regimen. It usually consists of four to six cycles of the CHOP regimen (cyclophosphamide 750 mg/m^2 on day 1, doxorubicin 50 mg/m^2 on day 1, vincristine 1.4 mg/m^2 on day 1, and prednisone 40 mg/m^2 per day on days 1–5) every 3 weeks. For localized aggressive lymphoma, the combination of chemotherapy and radiotherapy used before the era of rituximab reduced distant recurrence compared with radiotherapy alone, which should be used only for elderly patients who cannot receive medical treatment because a recurrence at distant sites will occur in one third of the patients and generally within the first year of treatment.

For MALT lymphomas, if disease is localized after accurate staging, total thyroidectomy (predicted overall survival rate and disease-free survival, 100% at 5 years) or involved field radiation therapy alone, 2 Gy per fraction for 5 days per week up to a total dose of 30 to 40 Gy (5-year overall survival rate, 90%) may be adequate.[305] For disseminated MALT lymphoma, chemotherapy alone with a single agent such as chlorambucil or combined with local radiation therapy can be proposed.

The Surgical Treatment of Thyroid Malignancy

Surgical resection of the primary tumor, gross disease that has extended beyond the thyroid capsule, and clinically significant lymph node metastases remains the mainstay of initial therapy in thyroid cancer.[1] Effective initial surgery minimizes the risk of disease recurrence, improves disease-specific survival, prevents complications associated with local growth of tumor into important structures in the neck, facilitates postoperative radioactive iodine therapy if indicated, and facilitates accurate staging and risk stratification.

Until recently, a one-size-fits-all approach to the management of thyroid cancer meant that the vast majority of thyroid cancer patients were subjected to high-intensity management approaches (total thyroidectomy with or without prophylactic central neck dissection, radioactive iodine therapy, prolonged TSH suppression, and highly sensitive follow-up evaluations).[23,306] However, the increasing incidence of very low-risk thyroid cancers (which usually display an indolent disease course) coupled with a much more selective use of radioactive iodine (RAI) therapy has resulted in a reevaluation of the need for immediate high-intensity treatment options in low-risk differentiated thyroid cancer patients.[307–310] The current thyroid cancer guidelines now endorse consideration of low-intensity treatment options (observation or thyroid lobectomy without the need for RAI therapy or prolonged TSH suppressive therapy) in properly selected patients.[1,311] Nonetheless, it is important to emphasize that some combination of high-intensity treatment options is still recommended for most patients with intermediate-risk or high-risk thyroid cancers. Because the evidence evaluating the comparative effectiveness of high-intensity versus low-intensity treatment options is largely retrospective, observational and devoid of high-quality prospective randomized clinical trials, the recommendations in these major guidelines are largely based on expert opinion in which the committees are trying to balance the risk and benefits of immediate therapy in low-risk thyroid cancer patients. Reevaluation of the intensity of thyroid cancer therapies is imperative because thyroid cancer mortality has remained stable or slightly increased over the last several decades[75] despite widespread use of highly sensitive disease detection tools (such as high-resolution neck ultrasonography, FNA of small thyroid nodules, and ultrasensitive thyroglobulin assays) and increasing use of aggressive therapies (such as prophylactic and therapeutic neck dissections for small volume disease and repeated administrations of RAI for biochemical evidence of persistent disease).

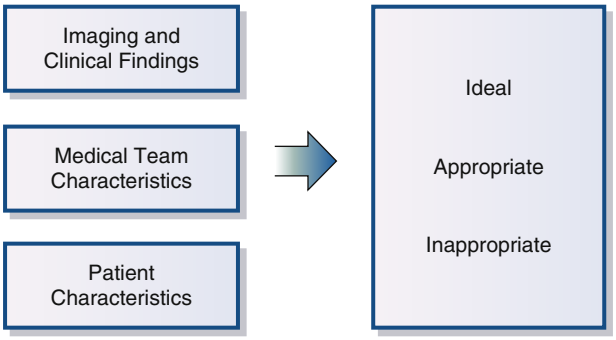
Active Surveillance as an Alternative to Immediate Surgery in Low-Risk Differentiated Thyroid Cancer

When thyroid nodule evaluations are done according to the recommendations of the American Thyroid Association, FNA cytology that is diagnostic for thyroid cancer will almost always lead to thyroid surgery.[1] However, an active surveillance management approach (also known as deferred surgical intervention) can be considered as an alternative to immediate surgery in (a) healthy patients with very low-risk intrathyroidal papillary thyroid cancers, (b) patients with comorbid conditions that would increase the risk of surgery or be associated with relatively short life expectancy, or (c) patients with more pressing concurrent medical or surgical issues that take precedence over treatment of the thyroid cancer.[1]

Building on the experience of our Japanese colleagues, several publications now support the effectiveness of an observational, active surveillance management approach to low-risk papillary thyroid cancers.[1,312–315] In these studies, serial neck ultrasound evaluations of the thyroid and cervical lymph nodes at intervals of 6 to 12 months are offered to properly selected patients as an alternative to immediate surgery. While the majority of patients demonstrate little if any disease progression during observation, salvage therapy at the time of disease progression is very effective when needed.[312]

Obviously the key to safe and effective implementation of an active surveillance management program is proper patient selection. A recent clinical framework describes how consideration of (a) imaging and clinical findings, (b) medical team characteristics, and (c) patient characteristics can be used to classify patients as ideal, appropriate, or inappropriate for low-risk treatment options

(active surveillance or thyroid lobectomy) (Fig. 14.22).[316,317] The definitions associated with the ideal, appropriate, and inappropriate patients with regard to the selection for active surveillance are given in Table 14.8. Although there are multiple patient characteristics that influence decision making, the construct that describes patients as medical maximalists or medical minimalists appears to be particularly relevant.[318] Given the choice, a medical maximalist often chooses high-intensity treatment options while a medical minimalist will often select low-intensity treatment options.[318]



• **Fig. 14.22** A clinical framework to guide proper patient selection for low-intensity therapy.

Patients classified as ideal or appropriate for active surveillance are offered observation as an alternative to immediate surgery. Patients choosing active surveillance are followed with neck ultrasound evaluations every 6 to 12 months for several years (then less frequently over time) unless disease progression occurs or the patient opts for surgery even in the absence of disease progression. Interestingly, it appears that only about 50% of patients eligible for active surveillance will choose an initial observational management program while the remainder elect to proceed with immediate surgery.[312] Patients classified as being inappropriate for active surveillance are recommended to have appropriate surgical resection.[316,317]

Selecting Total Thyroidectomy or Thyroid Lobectomy in Differentiated Thyroid Cancer: A Risk-Adapted Approach

There continues to be uniform agreement that total thyroidectomy is the preferred treatment option for patients with (a) differentiated thyroid cancers with primary tumors larger than 4 cm, (b) gross extrathyroidal extension, (c) clinically apparent disease

TABLE 14.8 Classification System to Aid in Proper Patient Selection for Active Surveillance

Patient Classification	Tumor/Imaging Characteristics	Patient Characteristics	Medical Team Characteristics
Ideal	• Solitary thyroid nodule confined to thyroid • ≤1 cm • Well-defined tumor margins by ultrasound • Surrounded by ≥2 mm normal thyroid parenchyma • Previous US documenting stability • cN0 • cM0	• Medical minimalist • Older patients (>60 yr) • Willing to accept active surveillance • Understands that future surgery may be necessary (deferred intervention) • Understands that lymph node metastases may be identified during follow-up • Compliant with follow-up plans • Supportive significant others (including family and other members of the health care team) • Life-threatening comorbidities or medical conditions requiring therapy	• Experienced team • Expeditious evaluation by multidisciplinary team • High-quality neck US • Prospective data collection • Tracking/reminder program to ensure proper follow-up
Appropriate	• Multifocal papillary microcarcinoma • 1–1.5 cm maximal dimension • Subcapsular location not adjacent to RLN without evidence of extrathyroidal extension • Ill-defined tumor margins • Background US findings that will make follow-up difficult (thyroiditis, reactive lymph nodes, multiple other benign-appearing nodules) • FDG-avid papillary microcarcinomas • Isolated *BRAF*^{V600E} mutation	• Minimalist/maximalist • Patients aged 18–59 yr • Strong family history of PTC • Childbearing potential	• Experienced endocrinologists or thyroid surgeon • Neck US routinely available
Inappropriate	• Aggressive cytologic features (rare) • Location adjacent to RLN/trachea • Evidence of extrathyroidal extension • N1 or M1 disease • High-risk molecular profile • Demonstrated increase of 3 mm diameter or 50% increase in tumor volume over a relatively short period	• Medical maximalist • Young patients (<18 yr) • Unlikely to be compliant with follow-up plans • Not willing to accept an observation approach • Severe anxiety regarding diagnosis	• Reliable neck US not available • Little experience with thyroid cancer management

FDG, Fluorodeoxyglucose; *PTC*, papillary thyroid carcinoma; *RLN*, recurrent laryngeal nerve; *US*, ultrasound.

of the cervical lymph nodes, or (d) known distant metastases.[1,311] Likewise, there is a general consensus that thyroid lobectomy is an adequate oncologic procedure for papillary thyroid cancers smaller than 1 cm without extrathyroidal extension or clinically apparent lymph node metastases.

Thus preoperative evaluations designed to carefully determine the size of the primary tumor, the presence of extrathyroidal extension, and/or metastatic disease assume primary importance in medical decision making. These evaluations include neck ultrasonography (evaluation of the thyroid gland, surrounding structures, and cervical lymph nodes) and voice evaluation in all patients being considered for surgery for differentiated thyroid cancer.[319] Additional functional and imaging studies are usually required for surgical planning and adequate initial staging in patients demonstrating bulky lymph node metastases, evidence of local invasion, or distant metastases. Endoscopic evaluation of the airway or gastrointestinal tract may be necessary to determine the extent of involvement in locally invasive disease.

Decision making in patients with intrathyroidal differentiated thyroid cancers with primary tumors larger than 1 cm and smaller than 4 cm without evidence of extrathyroidal extension or clinically apparent lymph node metastases has become complicated since both the National Comprehensive Cancer Network (NCCN) and the ATA guidelines allow for either thyroid lobectomy or total thyroidectomy in this setting.[1,311] Largely based on the assumption that nearly all of these patients would require RAI therapy and further strengthened by the Bilimoria report demonstrating 10-year survival of 98.4% for total thyroidectomy versus 97.1% for thyroid lobectomy (p <0.05),[320] the ATA guidelines had previously strongly recommended total thyroidectomy for all tumors over 1 cm.[23,306,311] However, multiple publications have failed to convincingly demonstrate a statistically significant survival benefit for total thyroidectomy versus lobectomy in differentiated thyroid cancers less than 4 cm when patients are properly selected and the statistical analysis controls for important confounding variables.[321–327] Decision making must also consider the risk of surgical complications and recognize that the risks of recurrent laryngeal nerve injury, transient and permanent hypoparathyroidism, and hemorrhage/hematoma are increased following total thyroidectomy compared with thyroid lobectomy.[328–330] However, total thyroidectomy is associated with a slightly lower risk of recurrence than a thyroid lobectomy.[327] Nonetheless, experienced centers report recurrence rates of less than 1% to 4% by combining high-quality preoperative ultrasound with appropriate clinical judgment.[325–327,331] These same studies show that salvage therapy is very effective in the few patients who have disease recurrence after low-intensity initial therapy.

Building on the same basic clinical framework described for active surveillance (see Fig. 14.22), patients can be classified as ideal, appropriate, or inappropriate for thyroid lobectomy (or isthmusectomy) (Table 14.9).[317] However, unlike active surveillance, patients selected for lobectomy must understand that information may become available either intraoperatively or postoperatively (primarily the final pathology report) that could result in a recommendation for complete removal of the thyroid gland. Thus the final classification of the patient as ideal, appropriate,

TABLE 14.9 Preoperative Classification System to Aid in Proper Patient Selection for Lobectomy/Isthmusectomy in Differentiated Thyroid Cancer

Patient Classification	Tumor/Imaging Characteristics	Patient Characteristics	Medical Team Characteristics
Ideal	• <1 cm • Intrathyroidal • Thyroid US otherwise normal • Clinical N0 neck	• Medical minimalist • Motivated patient • Willing to accept possibility of small volume disease in contralateral lobe • Desire to preserve normal thyroid function • Desire to minimize surgical complications • Open to intraoperative decision making • Willing to accept a low risk of needing an immediate completion thyroidectomy based on histology findings • TSH <2 mIU/L • Antithyroid antibodies undetectable • Anti-Tg antibodies undetectable	• Experienced MDT • Experienced US • Shared treatment philosophy • Uses RAI very selectively for ablation/adjuvant therapy and follow-up • Frozen section available
Appropriate	• 1–4 cm • Benign-appearing changes on US (thyroiditis, benign nodules) • Clinical N0 neck	• Minimalist/maximalist • Desire to keep normal thyroid (or avoidance of surgical complications) outweighs concern for disease in the contralateral lobe or the desire for RAI • TSH >2 • Antithyroid antibodies present • Anti-Tg antibodies	• Surgeon and endocrinologist agree on postoperative management plan • Unlikely to include need for RAI • Comfortable that follow-up US is adequate for low-risk patient
Inappropriate	• Extrathyroidal extension • Clinical N1 metastases • Distant metastases • High-risk molecular profile	• Medical maximalist • Patient desires total thyroidectomy and/or RAI • Clinical indications for RAI for ablation/adjuvant therapy/staging	• Treatment team desires RAI for ablation/adjuvant therapy/staging/follow-up

MDT, Multidisciplinary team; *RAI,* radioactive iodine; *TSH,* thyroid-stimulating hormone; *US,* ultrasound.

TABLE 14.10 Postoperative Histologic Confirmation of Proper Patient Selection Following Lobectomy/Isthmusectomy in Differentiated Thyroid Cancer

Ideal	• Intrathyroidal unifocal or multifocal papillary microcarcinoma with or without *BRAF*^{V600E} mutation • Intrathyroidal FVPTC with capsular invasion only (no vascular invasion) • NIFTP • Intrathyroidal well-differentiated FTC (invasion of tumor capsule without vascular invasion) • Clinical N0 and pathology N0/Nx neck • Small differentiated thyroid cancers confined to the isthmus
Appropriate	• 1–4 cm intrathyroidal PTC • Minor extrathyroidal extension • Clinical N0 but pathology N1 micrometastases (includes pN1a/b disease with ≤5 microscopic lymph node metastases, all of which are <0.5 cm in maximum diameter) • FVPTC, FTC, or PTC with minor vascular invasion (<4 microscopic foci of vascular invasion) • 1–2 cm, intrathyroidal tumors with potentially aggressive histology (e.g., tall cell, hobnail variant, columnar cell carcinoma)
Inappropriate	• Extensive vascular invasion (FTC or HCC with ≥4 microscopic foci of vascular invasion) • Larger potentially aggressive variants (e.g., poorly differentiated thyroid cancer, tall cell, hobnail variant, diffuse sclerosing, or columnar cell carcinoma with primary tumor >2 cm) • Clinical N1 or pathology N1 disease (includes N1a/b disease involving >5 lymph node metastases or any lymph node metastasis >0.5 cm in maximum diameter) • Gross extrathyroidal extension

or inappropriate requires consideration of additional factors that can only be known postoperatively (Table 14.10). In centers that practice a very risk-adapted management approach and a selective approach to RAI therapy, immediate completion thyroidectomy after lobectomy is only required in 5% to 6% of properly selected patients.[325–327,331] However, other centers report that the findings on the lobectomy final histology report result in recommendations for immediate completion thyroidectomy in up to 20% of the patients selected for thyroid lobectomy.[332–334]

Determining the Extent of Initial Cervical Lymph Node Dissection in Differentiated Thyroid Cancer

Consistent with the goal of primary therapy to remove all visible gross disease, compartment-oriented resection of clinically apparent metastatic cervical lymphadenopathy is routinely recommended.[1,311] This would include removal of all visible metastatic lymph nodes in the central neck (level VI/VII) and/or lateral neck (levels II, III, IV, and V). Rather than "berry picking" abnormal lymph nodes, a compartment-oriented neck dissection is designed to clear all metastatic lymph nodes by systematically removing the fibroadipose tissue in the compartment (which often contains additional subclinical metastatic lymph nodes) with the clinically apparent lymph node metastases. This compartment-oriented approach to the removal of clinically apparent lymph node metastases is associated with decreased rates of recurrent/persistent disease.

Since very small-volume, subclinical lymph node micrometastases are present in up to 70% to 80% of patients with papillary microcarcinomas, it is not surprising that meticulous dissection of central neck lymph nodes would often yield metastatic disease.[335] However, preoperative neck ultrasonography identifies suspicious cervical lymphadenopathy (clinical N1a or N1b disease) in only 20% to 30% of cases.[336–341] It remains controversial whether routine removal of subclinical central neck lymph nodes (prophylactic dissection) has a clinically significant impact on the risk of recurrence or disease-specific survival in papillary thyroid cancer.[342] Prophylactic neck dissections are not routinely recommended for follicular thyroid cancer because they are associated with a much lower rate of subclinical lymph node metastases. While prophylactic neck dissection can be done safely with a low risk of complications in experienced hands, the increased risk of hypoparathyroidism and recurrent laryngeal nerve injury may outweigh the potential benefit when performed by less experienced surgeons.[342]

Surgical Approach to Medullary Thyroid Cancer

Medullary thyroid cancer is usually treated with total thyroidectomy and surgical resection of clinically apparent central or lateral neck lymph nodes in a standard compartment-oriented fashion.[14,311] Depending on the results of preoperative calcitonin and neck ultrasound, prophylactic central or lateral neck dissections may also be recommended.

Surgical Approach to Anaplastic Thyroid Cancer

Ideally, patients with anaplastic carcinoma should be treated with total thyroidectomy and therapeutic lymph node dissection, but these tumors usually present with locally invasive disease, which is seldom amenable to effective surgical resection.[343] In the setting of unresectable disease, patients desiring high-intensity therapies are usually treated with a combination of systemic therapy and external beam irradiation.

Postoperative Management of Thyroid Malignancy

In view of disease-specific uncertainties and the unique needs of individual patients, the postoperative treatment of thyroid carcinoma does not occur with a rigid algorithm.[1] Indeed, physicians must consider the extent of disease at surgery, the histopathology and differentiation of the tumor, the age of the patient and his or her risk group category for tumor-related death and recurrence, and the results of postoperative serum Tg determination with neck ultrasonography.

^{131}I Administration

^{131}I is an effective agent for delivering high radiation doses to the thyroid tissue with low spillover to other portions of the body.

The radiation dose to the thyroid tissue is related to the tissue concentration (the ratio between the total tissue uptake and the volume of functional tissue) and the effective half-life of ^{131}I in the tissue.[93,344] Thyroid tissue is able to concentrate iodine only after TSH stimulation, but even after optimal TSH stimulation, iodine uptake in neoplastic tissue is always lower than in normal thyroid tissue and may not be detectable in about one-third of cases.[93]

^{131}I therapy is given postoperatively for three reasons.[1] First, it destroys normal thyroid remnants *(ablation),* thereby increasing the sensitivity and the specificity of measurements of serum Tg for the detection of persistent or recurrent disease. Ablation is mandatory for interpreting TSH-stimulated Tg determination because Tg may be produced by normal thyroid remnants and by neoplastic foci. During levothyroxine treatment, the production of Tg by normal thyroid cells may be low or suppressed, and serum Tg can be used for the follow-up of these patients.[345] Second, ^{131}I therapy may destroy occult or known microscopic carcinoma, thereby potentially decreasing the long-term recurrence rate. Third, ^{131}I therapy makes it possible to perform a postablative ^{131}I total-body scan (TBS), which is a sensitive tool for detecting persistent carcinoma.

It cannot be emphasized enough that postoperative ^{131}I therapy should be used selectively and that not all patients with a diagnosis of FCTC benefit from routine postoperative radioiodine ablative therapy.[1,22,23,224,346] The classification of the risk of recurrence (low, intermediate, or high) from the 2009 ATA guidelines was redefined in the 2015 guidelines, taking into account (among other criteria) the extent of lymph node involvement and pathologic features.[1,23] In low-risk thyroid cancer, the long-term prognosis after surgery alone is so favorable that ^{131}I ablation is not routinely recommended.[1,22,23,347,348] This is widely applied to patients with microcarcinoma, but unfortunately routine treatment is still given routinely to low-risk patients in some countries. In high-risk patients with a risk of recurrence above 40%, postoperative radioactive iodine administration (see Table 14.7) is routinely performed because such therapy can potentially decrease both recurrence and death rates. Also, radioiodine is administered postoperatively when surgery has not been complete or its success is doubtful. Young children have traditionally been considered as candidates for postoperative radioiodine therapy because they may have extensive neck lymph node involvement and frequently harbor pulmonary metastases that may not be detectable even with CT imaging of the chest.[152,171,215] Finally, in the other patients (intermediate risk of recurrence, and some low risk), there is currently no evidence that radioiodine remnant ablation (RRA) may improve the long-term disease-specific mortality, and prospective randomized trials are needed to validate its current indications.

When the risk of persistent disease is low and postoperative serum Tg is undetectable, ^{131}I administration may not be justified. This is especially true in patients with a low risk of recurrence.[349–353] This recommendation is particularly relevant to patients with N0 disease.[349] On the contrary, the likelihood of identifying ^{131}I avid metastatic disease on the post-therapy ^{131}I TBS increases when postoperative Tg values are greater than 5 to 10 ng/mL, suggesting that ^{131}I should be administered to such patients. Postoperative neck ultrasonography may also provide reassuring data or show abnormalities that should lead to ^{131}I administration.[354]

When considering ^{131}I therapy, levothyroxine treatment is most often administered following surgery, and both the indication and the protocol of stimulation and the ^{131}I activity to be administered are decided according to the ATA risk stratification. Data from postoperative serum Tg determination and neck ultrasonography may also be taken into account because the risk of persistent/recurrent disease in case of undetectable Tg levels (<0.2 ng/mL under thyroid hormones or <1 ng/mL after TSH stimulation) in the absence of Tg antibodies with normal neck ultrasonography is very low (<3%).

To administer ^{131}I therapy, levothyroxine treatment is typically withheld for 3 to 4 weeks. Another approach allows liothyronine to be substituted for 3 to 4 weeks and then discontinued for 1 to 2 weeks before radioiodine studies. At the time of treatment, the serum TSH level should be greater than an empirically determined level of 25 to 30 mU/L. Intramuscular injections of rhTSH (0.9 mg for 2 consecutive days, with ^{131}I administered 1 day after the second injection) given while on levothyroxine treatment may achieve an equally effective stimulation of radioiodine uptake by normal thyroid remnant, with ablation rates similar to those obtained with withdrawal using either a high (100 mCi) or a low (30 mCi) activity.[352,355,356] The use of rhTSH prevents hypothyroidism (as the patient remains on levothyroxine) and induces lower radiation exposure to the body, permitting an earlier discharge from the hospital.[352,355–359] However, in the United States, most ^{131}I therapy is now administered in the outpatient setting, making this latter issue less of a concern. Similar outcomes were reported in intermediate-risk and high-risk patients prepared for ^{131}I therapy using rhTSH versus thyroid hormone withdrawal.[360–362] In addition, short-term recurrence rates have been found to be similar in patients prepared with thyroid hormone withdrawal or rhTSH, even in those with initial lymph node involvement.[363,364] A retrospective study reported a similar outcome at 10 years after ablation with a low activity in patients prepared with either withdrawal or rhTSH.[365] rhTSH is approved for radioactive iodine administration with 100 mCi (or more) or 30 mCi in the United States, Europe, and many other countries around the world. The cost of rhTSH, however, must be factored into care, as thyroid hormone withdrawal is much less costly.

In a patient who has undergone an incomplete thyroidectomy, neck uptake may be measured with a tracer activity of ^{123}I (or rarely, ^{131}I). The activity used should be small enough to avoid stunning (i.e., a decrease of thyroid uptake with the subsequent high activity of therapeutic radioiodine).[366,367] High uptake (>10%) and high risk of persistent disease should lead to completion surgery. Following administration, a total body scan is performed and is highly informative in patients with low uptake (<1%) in the thyroid bed. However, additional metastatic foci have been reported in 10% to 26% of patients scanned following high-dose radioiodine treatment compared with the diagnostic scan.[368] ^{131}I SPECT/CT fusion imaging may provide superior lesion localization.[24–27]

After radioiodine therapy, levothyroxine therapy is then resumed and maintained. Total ablation (defined as no visible uptake) was previously verified by ^{131}I TBS 6 to 12 months following initial therapy, typically with 2 to 5 mCi (74–185 MBq). However, a follow-up ^{131}I TBS is no longer routinely performed when postablation scans have been informative because such repeat scanning does not afford any further information.[369,370] Moreover, total ablation is now currently defined by an undetectable serum Tg level following rhTSH stimulation in the absence of anti-Tg antibody (or a serum Tg level <0.2–0.3 ng/mL on levothyroxine treatment when using a sensitive assay) and unremarkable neck ultrasonography.[1]

Total ablation (eradication of normal thyroid remnants) is achieved after administration of either 100 mCi (3700 MBq) or 30 mCi (1100 MBq) in more than 80% of patients who had at least a near-total thyroidectomy. This is similar whether preparation is with withdrawal or rhTSH.[352,355,356,371,372] After less extensive surgery, ablation is achieved in only two thirds of patients with 30 mCi (1100 MBq). Therefore a total thyroidectomy should be performed in all patients who are to be treated with ^{131}I. Also, in low-risk or intermediate-risk patients, levothyroxine treatment is initiated soon after surgery and 30 mCi (1100 MBq) is administered following injections of rhTSH, with the aim of irradiating normal thyroid remnants. In high-risk patients, higher activity (≥100 mCi) is administered with the aims of both ablating normal thyroid remnants and irradiating residual neoplastic tissue. In patients with known distant metastases, ^{131}I is administered following thyroid hormone withdrawal, but in low-risk or intermediate-risk patients, rhTSH injections represent a valid alternative. High activities should be administered with caution to elderly patients.[373]

^{131}I ablation therapy has no role in the management of patients with anaplastic thyroid cancer, MTC, or thyroid lymphoma.

External Radiotherapy

External radiotherapy to the neck and mediastinum is indicated only for older patients (>55 years) with extensive and aggressive pathology subtypes in whom complete surgical excision is impossible, invasion of critical neck structures is likely, and tumor tissue does not take up ^{131}I. Retrospective studies have shown that in these selected patients, external radiotherapy decreases the risk of neck recurrence.[374,375] The target volume encompasses the thyroid bed, bilateral neck lymph node areas, and the upper part of the mediastinum. Typically, 50 Gy (5000 rad) is delivered in 25 fractions over 5 weeks, with a boost of 5 to 10 Gy on any residual macroscopic focus. The current approach with intensity-modulated radiation therapy permits the delivery of 63 to 66 Gy to gross disease and high-risk areas and 54 to 56 Gy in 30 to 33 fractions to cervical and mediastinal nodal regions. Its use may decrease late morbidity.

In patients with anaplastic thyroid carcinoma, when the extent of disease is limited and surgery is feasible, accelerated external radiotherapy in combination with chemotherapy permits local control of the disease in two-thirds of the patients and long-term survival in about 20%.[281,376,377]

TSH Suppressive Therapy

The growth of thyroid tumor cells is controlled by TSH, and inhibition of TSH secretion with levothyroxine is thought to improve the recurrence and survival rates.[22,23,137] Therefore levothyroxine should be given to all patients with FCTC, whatever the extent of thyroid surgery and other treatment. The initial effective dose is about 1.6 to 2 μg/kg body weight in adults, though children require a higher dose and elderly patients a lower dose. The adequacy of therapy is monitored by measuring serum TSH approximately 3 months after initiation. The initial goal is a serum TSH concentration below about 0.1 mU/L for high-risk thyroid cancer patients and maintenance of the TSH at or slightly below the lower limit of normal (0.1–1.5 mU/L) for low-risk patients. Similar recommendations apply to low-risk patients who have not undergone remnant ablation (i.e., serum TSH 0.1–1.5 mU/L). All TSH targets must also weigh the individual risks associated with TSH suppressive therapy. The dose of levothyroxine is then modified according to the ATA initial response to therapy. In patients with no evidence of disease, the dose of levothyroxine is decreased to maintain the serum TSH level within the normal range. Thus the dosing of levothyroxine (and target TSH concentration) must be continually reevaluated based on disease risk and potential side effects of long-term TSH suppression.

In patients with MTC or thyroid lymphoma, a replacement dose of levothyroxine is given with the aim of obtaining a serum TSH level in the normal range.

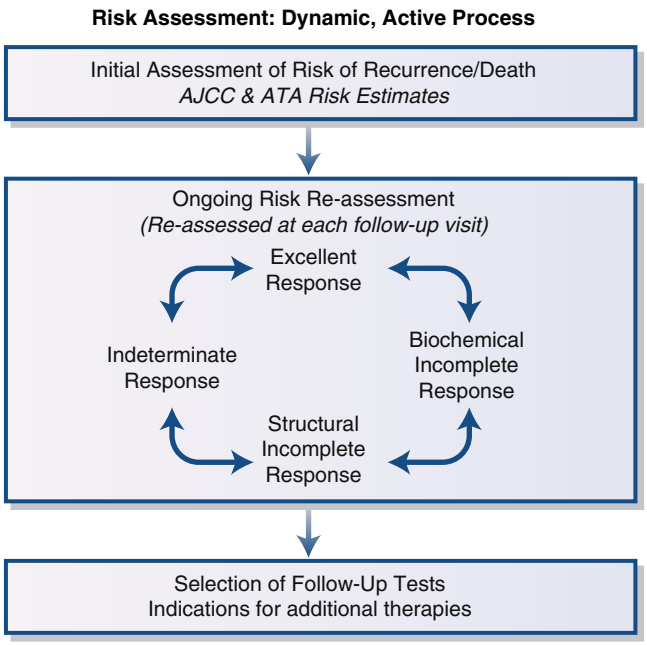
TABLE 14.11 Response to Therapy Definitions

Excellent response	No clinical, biochemical, or structural evidence of disease
Biochemical incomplete response	Persistent abnormal thyroglobulin values or rising antithyroglobulin antibody levels in the absence of localizable disease
Structural incomplete response	Persistent or newly identified locoregional or distant metastases
Indeterminate response	Nonspecific biochemical or structural findings that cannot be confidently classified as either benign or malignant

Regardless of the extent of initial therapy, this provides the general description of each of the responses to therapy categories that can be used to describe the clinical status of a patient with either differentiated or medullary thyroid cancer at any point during follow-up. See text for precise definitions of *excellent, indeterminate,* and *biochemical incomplete responses,* which will vary by tumor type and extent of initial therapy.

Long-Term Follow-Up of Patients With Thyroid Cancer Following Initial Therapy

After completion of initial therapy, the risk-adapted approach to the management of thyroid cancer continues by tailoring the types, extent, and timing of follow-up evaluations to the predicted risks of recurrence and disease-specific survival.[307] Initial treatment and early follow-up recommendations are based on the initial static risk assessments provided by AJCC staging (stage I, II, III, or IV) and ATA risk stratification (low, intermediate, or high).[1,217] These initial risk estimates are then continually modified over time as new data become available so that the management plan can be appropriately altered to become either more or less intensive, depending on the biologic course of the disease and the response to therapy.[1] Over the last several years, a nomenclature has been developed to describe the response to therapy and clinical status of patients during follow-up (Table 14.11).[1,378,379] Unlike the AJCC stage and the ATA risk category, which do not change over the lifetime of the patient, the response to therapy definitions may change during follow-up as new data become available (Fig. 14.23). This approach allows for characterization of the clinical status of each patient based on initial AJCC stage, ATA risk, and response to therapy at each follow-up visit. This information can then be used to guide management recommendations both with regard to the selection of follow-up test and also possible indications for additional therapies or ongoing observational management.



• **Fig. 14.23** Risk-adapted approach to follow-up. Management plans for the first year of follow-up are based on initial assessment of the risk of recurrence and death provided by American Joint Commission on Cancer (AJCC) and American Thyroid Association (ATA) risk staging. These plans are continually modified during follow-up as new data become available, with ongoing risk stratification defined by response to therapy assessments (*excellent, biochemical incomplete, structural incomplete,* or *indeterminate response*). Unlike the AJCC and ATA risk staging, the response to therapy status may change over time, depending on disease behavior and response to therapy.

TABLE 14.12 Overview of Plans for First Year of Follow-Up Following Initial Therapy

Initial Plan Based on ATA Risk for the First Year of Follow-Up	ATA Low Risk	ATA Intermediate Risk	ATA High Risk
Tg, TgAb, TFTs, every 3–6 months	√	√	√
Neck US in 3–6 months	–	√	√
Neck/chest CT with contrast in 6–12 months	–	Consider[a]	√[b]
Cross-sectional imaging of other sites (brain, abdomen, pelvis)	–	–	Consider[c]
Routine surveillance diagnostic RAI scan	–	–	Consider
^{18}FDG-PET scan	–	–	Consider
Dynamic risk assessment at each visit	√	√	√

While most patients will return for physical examination and biochemical testing every 3–6 months for the first year, consideration for additional testing is based on ATA risk and on the dynamic risk assessment done at each follow-up visit.

[a]Considered for intermediate-risk patient status postresection clinical N1a or N1b disease.

[b]Depending on presenting features, CT of the neck/chest may need to be done as early as 2–3 months after initial therapy.

[c]Depending on presenting features, functional imaging results, and serum Tg levels.

ATA, American Thyroid Association; *CT,* computed tomography; ^{18}*FDG-PET,* fluorodeoxyglucose positron emission tomography; *RAI,* radioactive iodine; *Tg,* thyroglobulin; *TgAb,* antithyroglobulin antibodies; *TFTs,* thyroid function tests; *US,* ultrasound;

Initial Follow-Up Recommendations for Differentiated Thyroid Cancer (First Year After Initial Therapy)

Regardless of ATA risk, most patients are seen at intervals of 3 to 6 months with biochemical testing during the first year of follow-up (Table 14.12). ATA low-risk patients are expected to do exceptionally well with very low recurrence rates that probably would not become apparent for at least 3 to 5 years.[167,219] Thus the primary follow-up tools for these patients will be physical examination, serum thyroglobulin, thyroglobulin antibody, and thyroid function test.[1] In these low-risk patients, the primary goal of follow-up is to confirm the absence of disease in early follow-up so that they can rapidly be transitioned to less intensive management approaches. They usually return for follow-up visits every 6 to 12 months for the first year then less frequently after that if they demonstrate the expected excellent response to therapy. Neck ultrasonography is usually done about 1 year after surgery, although the utility of this test is unproven and has the potential to identify more false-positive findings than real disease given the high likelihood of nonspecific findings on surveillance neck ultrasonography coupled with a very low recurrence risk.[380,381] Diagnostic whole-body scans, additional cross-sectional imaging, or FDG-PET scans are not routinely used for follow-up surveillance. Stimulated thyroglobulin values are only done if the available thyroglobulin assay does not reliably read down to less than 0.2 ng/mL.

ATA intermediate-risk patients are initially followed at 6-month intervals for the first year with the same biochemical testing as the low-risk patients but with more intensive ultrasound follow-up, given their higher risk of disease.[1] Intermediate-risk patients usually have follow-up ultrasound in 6 months to establish the baseline and verify the completeness of initial resection. Additional ultrasounds during the first year may be required if this initial evaluation identifies worrisome nonspecific findings or persistent disease. In patients who had extensive bulky metastatic lymphadenopathy, a CT scan of the neck and chest with contrast is usually considered at 6 to 12 months to definitively establish the presence or absence of clinically significant persistent disease. Radioactive iodine scans are not routinely obtained for surveillance in these patients but can be important tools to characterize the functional status of suspicious lesions identified during follow-up and can be considered if thyroglobulin antibodies are rising during follow-up. Additional testing is not routinely planned but may be required, depending on the response to therapy, as described later in the chapter.

ATA high-risk patients require a much more individualized management approach.[1] While still utilizing the same biochemical evaluations as the ATA low-risk and intermediate-risk patients, ATA high-risk patients may also require a wide variety of cross-sectional and imaging studies on the basis of either a structural incomplete response to initial therapy or their high risk of local recurrence and distant metastases. In general, high-risk patients are evaluated every 2 to 3 months with appropriate cross-sectional and functional imaging. Because of the aggressive nature of their disease, their response to therapy can often be characterized within the first 6 to 12 months, leading to early alterations in the initial management plans.

Modifying Initial Follow-Up Recommendations for Differentiated Thyroid Cancer Using Response to Therapy Definitions

While originally conceived to be used as a restaging system to be utilized after 2 years of follow-up, the dynamic risk assessment approach has evolved such that the response to therapy definitions can be used at any point during follow-up to describe the clinical status of a patient.[378,382,383] Thus it is appropriate even within the first year of follow-up to describe the clinical status of a patient using the response to therapy nomenclature (*excellent response, biochemical incomplete response, structural incomplete response, indeterminate*) (see Table 14.11). Even at these early time points, the response to therapy can be used to alter the initial management plans. This is most apparent in patients who have ATA intermediate-risk disease who manifest an excellent response within the first year of initial therapy and can therefore have their management intensity decreased. Or alternatively, ATA low-risk or intermediate-risk patients demonstrating a biochemical or structural incomplete response may require more aggressive follow-up, disease detection studies, or therapy.

In oncologic terms, *excellent response* can be thought of as "remission" as it describes patients who have no biochemical, clinical, or structural evidence of disease (see Table 14.11). Patients with abnormal thyroglobulin values or rising antithyroglobulin antibodies in the absence of localizable disease are described as having a biochemical incomplete response. *Structural incomplete response* is used to describe patients who have persistent or recurrent imaging evidence of disease. The *indeterminate response* category describes patients who have nonspecific either low-level thyroglobulin values or nonspecific findings on imaging that cannot be confidently classified as either benign or malignant. Over time, most patients can be moved out of the indeterminate response category as follow-up studies help to define whether the nonspecific findings are actually benign or malignant.

The precise definitions for each of the response to therapy categories and the management implications are given in Table 14.13.[1] An excellent response to therapy should lead to an early decrease in the intensity and frequency of follow-up and the degree of TSH suppression as these patients do exceptionally well with essentially no mortality and very low recurrence rates. Interestingly, at least 30% of the biochemical incomplete response patients will eventually evolve to having no evidence of disease with observation alone. Unfortunately, patients with a structural incomplete response usually maintained persistent disease (either biochemical or structural incomplete response) despite additional therapies. Fortunately, the majority of patients classified as having an indeterminate response remain disease-free with only 15% to 20% of these patients eventually being classified as having either biochemical or structural incomplete response.

TABLE 14.13 Clinical Implications of Response to Therapy Reclassification in Differentiated Thyroid Cancer Patients Treated With Total Thyroidectomy and RAI Remnant Ablation

Category	Definitions	Clinical Outcomes	Management Implications
Excellent Response	Negative imaging *and either* suppressed Tg <0.2 ng/mL[a] *or* TSH-stimulated Tg <1 ng/mL[a]	1–4% recurrence <1% disease-specific death	An excellent response to therapy should lead to an early decrease in the intensity and frequency of follow-up and the degree of TSH suppression
Biochemical Incomplete Response	Negative imaging *and* suppressed Tg >1 ng/mL[a] *or* stimulated Tg >10 ng/mL[a] *or* rising anti-TgAb levels	At least 30% spontaneously evolve to NED; 20% achieve NED after additional therapy; 20% develop structural disease; <1% disease-specific death	If associated with stable or declining serum Tg values, a biochemical incomplete response should lead to continued observation with ongoing TSH suppression in most patients Rising Tg or Tg antibody values should prompt additional investigations and potentially additional therapies
Structural Incomplete Response	Structural or functional evidence of disease with any Tg level +/- TgAb	50–85% continue to have persistent disease despite additional therapy Disease-specific death rates as high as 11% with locoregional metastases and 50% with structural distant metastases	A structural incomplete response may lead to additional treatments or ongoing observation, depending on multiple clinicopathologic factors, including the size, location, rate of growth, RAI avidity, FDG avidity, and specific pathology of the structural lesions
Indeterminate Response	Nonspecific findings on imaging studies Faint uptake in thyroid bed on RAI scanning Nonstimulated Tg detectable, but <1 ng/mL Stimulated Tg detectable, but <10 ng/mL *or* TgAb stable or declining in the absence of structural or functional disease	15–20% will have structural disease identified during follow-up In the remainder, the nonspecific changes are either stable or resolve <1% disease-specific death	An indeterminate response should lead to continued observation with appropriate serial imaging of the nonspecific lesions and serum Tg monitoring Nonspecific findings that become suspicious over time can be further evaluated with additional imaging or biopsy

[a]In the absence of anti-TgAb.

NED denotes a patient as having no evidence of disease at final follow-up.

FDG, Fluorodeoxyglucose; *NED,* no evidence of disease; *RAI,* radioactive iodine; *Tg,* thyroglobulin; *TgAb,* antithyroglobulin antibodies; *TSH,* thyroid-stimulating hormone.

From Haugen BR, Alexander EK, Bible KC, et al. 2015 American Thyroid Association management guidelines for adult patients with thyroid nodules and differentiated thyroid cancer: the American Thyroid Association guidelines task force on thyroid nodules and differentiated thyroid cancer. *Thyroid.* 2016;26:1–133.

In the past, stimulated thyroglobulin values were a key component of follow-up testing. However, with the development of new ultrasensitive assays, the definition of excellent response to therapy can be established with the suppressed thyroglobulin value of less than 0.2 ng/mL.[1] However, if reliable ultrasensitive thyroglobulin values are not available, then stimulated thyroglobulin values will be needed to establish an excellent response to therapy.

Because the response to therapy definitions rely heavily on serum thyroglobulin measurements, patients with antithyroglobulin antibodies present a challenge. In these cases, the serum thyroglobulin measurement may or may not be reliable and therefore cannot be trusted. Antithyroglobulin antibodies that decline by at least 50% over the first 6 months usually indicate the absence of persistent disease.[384] Conversely, rising thyroglobulin values over time are often an early indicator of subsequent structural incomplete response and would lead to additional structural or functional imaging.

Additionally, the response to therapy definitions were originally developed for patients who had total thyroidectomy and radioactive iodine ablation. Therefore the definitions need to be modified slightly to be able to accommodate patients who were treated with lobectomy alone or total thyroidectomy without radioactive iodine.[385,386] In patients who underwent total thyroidectomy without radioactive iodine, an excellent response to therapy requires a nonstimulated thyroglobulin less than 0.2 ng/mL, an indeterminate response is defined as a serum thyroglobulin of 0.2 to 5 ng/mL, and a biochemical incomplete response requires a serum thyroglobulin greater than 5 ng/mL. In patients treated with lobectomy, any thyroglobulin value less than 30 ng/mL is classified as excellent, whereas a value greater than 30 ng/mL is classified as biochemical incomplete.

Follow-Up Recommendations Based on Response to Therapy Status

ATA low-risk and intermediate-risk patients who demonstrate an excellent response to therapy can transition to low-intensity follow-up. In the long term, patients with an excellent response to therapy are followed primarily with serum thyroglobulin, thyroglobulin antibody, and physical examination every 1 to 2 years. Routine use of neck ultrasonography in the follow-up of these excellent response to therapy patients is likely to yield more false-positive findings than true structural disease and therefore is not routinely recommended.[380,381] While an excellent response to therapy almost always leads to less aggressive follow-up, it is important to note that ATA high-risk patients can still have a risk of recurrence in the 5% to 10% range, despite having been classified as an excellent response to therapy, because they often manifest distant sites of disease that are not apparent on early imaging or they are poor thyroglobulin producers, leading to them being inappropriately classified as excellent response to therapy.[378,382] As a result, we consider cross-sectional imaging in ATA high-risk patients every 3 to 5 years, depending on the specifics of individual cases.

The evaluation of the patient with biochemical incomplete response begins first with an assessment of whether appropriate imaging studies have been done. The level of serum thyroglobulin roughly correlates with the location of disease, with nonstimulated Tg values less than 10 ng/mL usually identifying persistent/recurrent disease in the neck, values in the 10 to 100 range suggesting pulmonary metastasis, and values in the thousands suggesting bone metastases.[387] In addition to meticulous cross-sectional imaging, functional imaging with radioactive iodine or ^{18}FDG-PET may identify the source of the abnormal thyroglobulin. Once appropriate imaging has been done to definitively rule out structurally identifiable disease, then the follow-up of patients with biochemical incomplete response depends on the trend over time in their thyroglobulin and thyroglobulin antibodies. Patients with stable or declining thyroglobulin and thyroglobulin antibodies are usually followed with observation. Patients with rising thyroglobulin or thyroglobulin antibodies are followed with additional cross-sectional imaging with the type, intensity, and frequency of testing dependent on the rate of rise of the biochemical markers. Studies have now verified correlation between thyroglobulin doubling time and clinical outcomes.[388]

Patients with a structural incomplete response are particularly problematic as the majority will maintain persistent biochemical or structural evidence of disease despite additional therapies.[1] Possible treatment options for structural incomplete response include observation, surgical intervention, radioactive iodine therapy, external beam radiation therapy, focal therapies, and systemic therapies. Decision making in this setting is best done in a multidisciplinary team setting. Indications for intervention in patients with a structural incomplete response should be guided by factors such as the size, location, rate of growth, radioactive iodine avidity, FDG avidity, and underlying histology of the metastatic disease.

Patients with an indeterminate response are usually followed with additional observation with serial evaluations of the indeterminate biochemical or structural area of interest.[1] In many cases, the nonspecific biochemical markers or structural findings resolve spontaneously, in which case the patients can be reclassified as having an excellent response to therapy. In other cases, the indeterminate findings become more clearly abnormal and the patient is then reclassified as biochemical or structural incomplete.

While these response to therapy recommendations have been primarily based on patients who underwent total thyroidectomy and radioactive iodine ablation, follow-up recommendations are essentially the same in patients treated either with lobectomy or with total thyroidectomy without radioactive iodine.[385,386] By definition, these patients are low risk and thus are not expected to have early recurrences or distant metastasis. While the significance of a single serum thyroglobulin determination is uncertain in the majority of these patients, the trend and thyroglobulin over time can be informative despite being less sensitive and more nonspecific. Because of the lack of sensitivity in the thyroglobulin measurements or persistent thyroglobulin antibodies, follow-up in these patients relies more heavily on neck ultrasonography done every 3 to 5 years at least for the first decade.

Risk-Adapted Follow-Up Recommendations for Medullary Thyroid Cancer

Recommendations regarding the extent, intensity, and timing of follow-up in medullary thyroid cancer will largely be dependent on postoperative calcitonin and CEA values. As with thyroglobulin values, the calcitonin and CEA doubling-time values provide important clinical insights into both the rate of disease progression and disease-specific survival.[14] Similar to the approach used in differentiated thyroid cancer, ongoing follow-up recommendations are based on response to therapy reevaluations in which the definitions of excellent, biochemical incomplete, and structural

incomplete response are modified using calcitonin and CEA values rather than thyroglobulin values.[389–391] For medullary cancer, an excellent response is defined as an undetectable serum calcitonin and normal range CEA value. Biochemical incomplete response is defined as a measurable postsurgical serum calcitonin or elevated CEA value. Just as with differentiated thyroid cancer, the follow-up plans are adjusted based on response to therapy.

Treatment of Thyroid Cancer Recurrence and Distant Disease

Locoregional Recurrences of PTC and FTC

Locoregional recurrences occur in 5% to 20% of patients with PTC and FTC. However, more than a third of reoperations for persistent or recurrent disease are related to inadequate initial thyroid surgery.[392] Small lymph node metastases may be treated with radioiodine, but their persistence or growth should lead to consideration of surgery.[393] A recurrence larger than 8 to 10 mm in diameter should be excised.[393,394] Compartmental dissection of previously unexplored compartments with clinically significant persistent/recurrent disease while sparing vital structures is performed because microscopic lymph node metastases are commonly more extensive than would appear from imaging studies alone. This dissection provides long-term local control of the disease in the majority of patients.[395] Conversely, compartmental surgical dissections may not be feasible in the setting of compartments that have been previously explored because of extensive scarring, and only a more limited or targeted lymph node resection may be possible.

Total excision can be facilitated by TBS 3 to 5 days after administration of 100 mCi (3700 MBq) of ^{131}I because additional tissue that should be excised may be identified. In rare cases, surgery has been performed 1 day after the total body scan is done, typically using an intraoperative probe. The completeness of resection is verified 1 to 2 days after surgery by another total-body scan, and in one series total excision was achieved in 92% of cases.[394] Other methods may be used to facilitate the excision of small neoplastic foci located in scar tissue or in sites that are difficult to redissect, primarily using intraoperative ultrasound or preoperative ultrasound-guided charcoal tattooing.[15] Considering both normal neck ultrasonography and undetectable Tg levels (<1 ng/mL after TSH stimulation or <0.2 ng/mL under thyroid hormones) to define excellent response after a reoperation for persistent/recurrent disease as defined by the ATA guidelines, the rate of excellent response reaches 63%.[396] In general, external radiotherapy is indicated in FCTC patients with soft tissue recurrences that cannot be completely excised and that do not take up ^{131}I.

In rare cases, patients with DTC who are not eligible for further surgery or ^{131}I therapy have been treated for regional nodal recurrence with ultrasound-guided radiofrequency ablation or percutaneous ethanol injection.[397–403] No studies prospectively and respectively compared the two techniques. Both should be avoided, however, for the treatment of central lesions close to the trachea and/or the laryngeal nerve and/or the esophagus, as well as locations where surgery is also challenging. These procedures are especially safe for nodes not adjacent to critical structures such as lateral neck recurrences. For tumors that invade the upper aerodigestive tract, patient outcome is related to complete resection of all gross disease, with techniques ranging from shaving tumor off the trachea or esophagus for superficial invasion with the preservation of function to more aggressive techniques in case of direct intraluminal invasion, including tracheal resection and anastomosis or laryngopharyngoesophagectomy.[404,405] In these cases, surgery is usually combined with ^{131}I and external beam radiation.

Management of Distant Metastatic Disease

Among patients with differentiated carcinoma (PTC, FTC, and HCC), only 9% develop distant metastases.[406] Mortality rates at 5 and 10 years after the diagnosis of metastasis were 65% and 75% for all patients with distant metastases, and nearly 80% of the deaths were due to thyroid cancer.[406–408] Of note, up to 20% of deaths were due to locoregional disease.[409] Thus the development of distant metastases in FCTC has traditionally foreseen an ominous prognosis. Lung metastases are more frequent in young patients with PTC, and the lung is almost always the only site of distant spread in children. Bone metastases are more common in older patients and in those with FTC. Other less common sites are the brain, liver, and skin.[406–408]

Clinical symptoms of lung involvement are uncommon. By contrast, pain, swelling, or fracture occurs in more than 80% of patients with bone metastases. They are a poor prognostic indicator.[410] The pattern of lung involvement may vary from macronodular to diffuse infiltrates. The latter are usually diagnosed with ^{131}I TBS and may be confirmed by spiral CT; enlarged mediastinal lymph nodes are often present in patients with PTC, especially children. Bone metastases are osteolytic and are better visualized by CT scan, MRI, or ^{18}FDG-PET. ^{18}FDG-PET scanning is useful in these patients for determining the extent of disease and for prognostic assessment.[23,34,38,39] Nearly all patients with distant metastases have high serum Tg concentrations unless the lung metastases are not visible on CT scan, and two-thirds of such patients have ^{131}I uptake in their sites of metastasis.[407]

Focal treatment of bone metastases includes surgery, external beam radiation therapy, or thermal ablation (radiofrequency ablation or cryoablation) and cement injection.[411] Focal treatment is indicated when there are neurologic or orthopedic complications or a high risk of such complications and when bone metastases are visible on CT scan or MRI, even in the presence of ^{131}I uptake, because radioiodine alone will not control the disease. In patients with a single or a few bone metastases, focal treatment may also be performed with curative intent.[412] Surgery and stereotaxic radiation therapy may be indicated in patients with brain metastases. Thermal ablation or stereotaxic radiation therapy may be used in case of a few lung metastases. Completeness of thermal ablation and outcome of the treated lesions can be assessed with ^{18}FDG-PET scanning.[40]

Patients with distant metastases that take up ^{131}I are treated with 100 to 200 mCi (3700–7400 MBq) every 4 to 6 months during the first 2 years and then at longer intervals. Between ^{131}I treatments, suppressive doses of levothyroxine are given to maintain the serum TSH level below 0.1 mUI/L. In one study, the radiation dose to the tumor tissue and outcome of ^{131}I therapy are correlated.[344] A radiation dose higher than 80 Gy (8000 rads) should be delivered to obtain cure; with radiation doses less than 35 Gy (3500 rads), there is little chance for success. This is the rationale for using higher activities of radioiodine either as standard activity or based on individual dosimetry. However, the comparison between repeated administrations of a standard activity of 100 mCi (3.7 GBq) to the administration of higher activities after dosimetric study did not show a benefit of dosimetry over standard activities in terms of overall survival.[413] In patients with functioning metastases, PET scanning with ^{124}I showed that in a given patient uptake may vary between metastases and also within a given metastasis.[414,415] Finally, uptake may be heterogeneous at the cellular level.[93,414] This heterogeneity in the dose distribution in neoplastic foci may explain the ineffectiveness of ^{131}I treatment, despite significant mean uptake on total-body scan. For treatment to be effective in this clinical setting, appropriate

levels of TSH stimulation and absence of iodine contamination are essential. Excess iodine is eliminated 1 month after administration of an iodinated CT scan.[30] The urinary iodine excretion can be obtained to confirm clearance. Similar short-term survival rates were observed in patients with distant metastases after ^{131}I treatment prepared with either withdrawal or rhTSH.[416] However, most patients with ^{131}I uptake in their metastases are alive at 5 years, and there are no available data on long-term outcome after preparation with rhTSH. Prolonged withdrawal usually induces higher uptake in neoplastic foci than rhTSH and should be the preferred method of TSH stimulation in patients with metastatic disease.[417] rhTSH-mediated therapy may be indicated in selected patients with underlying comorbid conditions, making iatrogenic hypothyroidism potentially risky, and in patients with pituitary disease who are unable to raise their serum TSH.[358] Such patients should be given the same or higher activity than would have been given had they been prepared with hypothyroidism or a dosimetrically determined activity. Lower activities (1–2 mCi [37–74 MBq]/kg body weight) are given to children. There is no absolute limit to the cumulative activity of ^{131}I that can be given to patients with distant metastases as long as treatment is efficient. There is, however, an increased risk of leukemia and of solid cancer, especially when the cumulative activity rises above 600 mCi (22,000 MBq)[418–420]; also, above this activity, further ^{131}I therapy may rarely provide a cure.[407]

Disappearance of imaging abnormalities has been obtained overall in about 45% of patients with distant metastases showing avidity for ^{131}I, and responses are more frequent in younger patients, those with small pulmonary metastases, those who had a well-differentiated cancer, and those who have no ^{18}FDG uptake on PET scan; complete responses may be obtained several years after initiation of therapy.[406–408] When response was judged to have been complete after ^{131}I therapy, subsequent relapse rarely (<10%) occurred even though serum Tg levels were persistently detectable in some patients.[407]

Complications of Treatment With ^{131}I

Acute side effects (nausea, sialadenitis, loss of taste) after treatment with ^{131}I are common but are typically mild and resolve rapidly.[421] Radiation thyroiditis is usually trivial, but if the thyroid remnant is large, the patient may have enough pain to warrant corticosteroid therapy for a few days. Tumor in certain locations, such as the brain, spinal cord, and paratracheal region, may swell in response to TSH stimulation or after ^{131}I therapy, causing compressive symptoms, and this problem should be prevented with corticosteroid therapy. Xerostomia and obstruction of lacrimal ducts may occur in 5% to 10% of patients treated with ^{131}I.[422,423] Radiation fibrosis may rarely develop in patients with diffuse lung metastases and can eventually prove fatal if high activities (>150 mCi [5550 MBq]) are administered at short intervals (<3 months).[248]

Particular attention must be paid to avoid administration of ^{131}I to pregnant women. After ^{131}I treatment, spermatogenesis may be transiently depressed,[424] and women may have transient ovarian failure. Genetic damage induced by exposure to ^{131}I before conception has been a major subject of concern. However, no anomaly has been reported to date. Therefore it is recommended that conception be postponed for at least 6 months after treatment with ^{131}I.[425] There is no clear evidence that pregnancy affects tumor growth in women receiving adequate levothyroxine therapy. In case of pregnancy in a patient treated with a replacement dose of levothyroxine, the dose of levothyroxine is increased by 30% as soon as the pregnancy is confirmed and serum TSH, T_3, and T_4 levels are measured every month during the first half of pregnancy.[426] In a patient treated with a suppressive dose of levothyroxine, serum TSH, T_3, and T_4 levels are controlled every month, and the daily dose of levothyroxine is increased when serum TSH is increased or when T_3 and T_4 decrease.

Mild pancytopenia may occur after repeated or high-dose ^{131}I therapy, especially in patients with bone metastases who are also treated with external radiotherapy. The overall relative risk of leukemia and solid tumors was found to be increased in patients treated with radioactive iodine, especially in case of high cumulative activity of ^{131}I (>600 mCi [22,000 MBq]) or in association with external radiotherapy.[418–420]

Refractoriness to Radioactive Iodine

Two-thirds of distant metastases will become refractory to radioiodine, and treatment with ^{131}I will not provide any benefit. This group includes patients with metastatic disease who do not take up ^{131}I at the time of initial treatment or who lose the ability to take up ^{131}I after previous evidence of uptake, patients with ^{131}I uptake retained in some lesions but not in others, and patients with metastatic disease that progresses despite significant uptake of ^{131}I in the metastases.[427] Less clear is the situation for patients with persistent ^{131}I uptake in all lesions who are not cured despite several treatment courses (particularly after receiving >22,000 MBq [600 mCi] of ^{131}I) and whose disease does not progress according to Response Evaluation Criteria in Solid Tumors (RECIST) criteria.[407] The decision to continue ^{131}I treatment in such patients is generally based on their response to previous treatment courses, persistence of a significant level of ^{131}I uptake on the previous post-therapy TBS, low FDG uptake in tumor foci, and absence of side effects.[427] Large distant metastases with high FDG uptake on PET scanning almost never respond to ^{131}I therapy and usually rapidly progress, confirming the clinical prognostic classification.[38,39]

In patients with refractory disease, ^{131}I treatment should be abandoned, and follow-up is performed with imaging every 4 to 6 months on levothyroxine treatment that should maintain serum TSH below 0.1 mUI/L.[427–429] Optimal TSH goals for individual patients must, however, balance the potential benefit of TSH suppression with the possible harm from subclinical thyrotoxicosis, especially in patients with medical conditions that can be exacerbated with aggressive TSH suppression. Focal treatment modalities are used as previously described. In patients with multiple lesions greater than 1 to 2 cm in diameter with documented progression on imaging within 12 months, a systemic treatment may be indicated.[427] Of note, within a given patient, the intensity of FDG uptake cannot be used to determine the lesions at higher risk of progression.[430] Molecular targeted therapies with antiangiogenic effects are used as first-line treatment. [1]

Molecular Targeted Systemic Therapies

An initiating carcinogenic event can be found in most DTC and thus molecular targeted therapy is based upon a sound scientific rationale.[118] The MAP kinase pathway is activated in the majority of papillary thyroid cancers, mainly by either gene rearrangements (RET-PTC and NTRK) or point mutations of the *RAS* and *BRAF* genes. *RAS* point mutations are frequently found in follicular and poorly differentiated carcinomas. Additional genetic abnormalities may be found in poorly differentiated thyroid carcinomas. Angiogenesis is also activated in thyroid cancers,[431] by activation of the VEGFR pathway. Other pathways may also be activated, including the FGFR and PDGFR pathways.

TABLE 14.14 Drugs Used in Refractory Differentiated Thyroid Cancer

Drugs	*N*	Targets(s)	Partial Response (RECIST) (%)	Median Progression-Free Survival (Months)
Axitinib Cohen[432] Locati[433] Capdevilla[434]	45 45 47	*VEGF, RET, PDGFR, KIT*	31 38 28	18.1 16.1 8
Cabozantinib Cabanillas[436] Cabanillas[435]	15 25	*VEGFR, RET, CMET*	53 40	>12.2, not reached 12.7
Lenvatinib Schlumberger[437] (phase III trial)	392	*VEGFR RET, FGFR, PDGFR, C-KIT*	65	18.3 vs 3.6
Pazopanib Bible[439]	37	*VEGFR, PDGFR, KIT*	49	11.7
Motesanib Sherman[438]	93	*VEGFR, PDGFR, KIT, RET*	14	10

Sunitinib Carr[441]	28	*VEGFR, RET, PDGFR, KIT*	11	NA
Vandetanib Leboulleux[443] (phase II vs placebo)	145	*VEGFR, RET, EGFR*	0	11.1 vs 5.9
Vemurafenib Brose[442]	51	*BRAF*	31	18 TKI naïve, 9 prior TKI
Dabrafenib Falchook[444]	13	*BRAF*	29	11.3

NA, Not applicable; *RECIST,* Response Evaluation Criteria in Solid Tumors; *TKI,* tyrosine kinase inhibitor.

Up to now, most drugs used in refractory DTC had an anti-angiogenic action, and some also target from the MAP kinase pathway. With these agents, the rate of partial response observed ranges from 0% to 65% (Table 14.14), with three drugs showing response rates close to or higher than 50% (lenvatinib, cabozantinib, and pazopanib).[432–444] Improvement of progression-free survival (PFS) has also been demonstrated in two phase III trials: sorafenib in the DECISION trial and lenvatinib in the SELECT trial.[437,440,443]

Vandetanib

The ZACTHYF phase II randomized trial with vandetanib produced a significant prolongation of the PFS compared with placebo (HR, 0.63, p = 0.008; median, 11.1 vs 5.9 months, respectively), and an objective partial response rate of 8%.[443] The subsequent VERIFY phase III trial with vandetanib versus placebo has been conducted, and the results are pending (NCT01876784).

Sorafenib

The DECISION phase III trial with sorafenib showed a prolongation of the PFS compared with placebo (HR, 0.587; 95% CI, 0.454–0.758; p <0.0001; median PFS, 10.8 vs 5.8 months, respectively). The improvement in PFS was seen in all clinical subgroups. The partial response rate was 12%, and stable disease for 6 months or longer was achieved in 41.8 % of patients. PFS was improved in all biomarker subgroups, irrespective of *BRAF* and *RAS* mutation status.

Lenvatinib

The SELECT phase III trial with lenvatinib significantly improved the median PFS compared with placebo (HR, 0.21; 99% CI, 0.14–0.31, p <0.001; median PFS, 18.3 vs 3.6 months, respectively) and the objective response rate was 65% with complete responses in 2%. The improvement in PFS was seen in all clinical subgroups, including in the 20% of patients who had received prior vascular endothelial growth factor (VEGF)–targeted therapy and irrespective of *BRAF* and *RAS* mutation status.

None of the studies demonstrated an improvement in overall survival, which might have been related to the crossover design of the studies with treatment in an open phase in case of progression in the placebo arm and the long survival of some patients after their participation in the trial during which other treatment modalities

were used. However, in a subgroup analysis of the SELECT study, a significant benefit in overall survival was observed in patients aged above 65 years, related to the beneficial effects of lenvatinib in patients with more aggressive disease.[445] In a subsequent analysis, a rapid decline in tumor size by 25% was reported at the 8-week evaluation; the duration of PFS was related to the magnitude of the initial tumor size decrease, and a multivariate analysis identified two prognostic indicators, performance Eastern Cooperative Oncology Group (ECOG) status of 0 or 1 and small size of metastases.[446]

The safety profile of sorafenib was as expected, but with a higher incidence of adverse effects than in patients with other cancer types. Most adverse effects were grade 1 and 2, the most common being hand-foot skin reaction (76%), diarrhea (69%), alopecia (67%), and rash/desquamation (50%). Toxicities led to dose reduction in 64% of patients and to drug withdrawal in 19%.

The safety profile of the lenvatinib group includes hypertension (68%), fatigue (64%), diarrhea (59%), and decreased appetite (50%). Proteinuria occurred in 32% and thromboembolic events in 11%. A total of 68% of the patients required dose reduction, 82% required dose interruption, and 14% of patients were taken off the drug.

Prevention and early diagnosis of toxicity are the best ways to decrease the frequency and gravity of the secondary effects. Prior to starting treatment, patients should have normal blood pressure and should be educated for self–blood pressure measurements. They should be educated to use moisturizing lotion and to protect themselves from the sun. They should be checked for normal heart function, normal electrolytes, normal renal function, and the absence of proteinuria. Interactions with concomitant drugs should be checked to avoid drugs interacting with the cytochrome P450 and drugs prolonging QTc.

It is highly recommended after initiation of treatment that clinicians follow up patients at 2-week intervals for the first 2 to 3 months and then once a month, to proactively manage adverse events in accordance with the tolerance of each individual patient.

Tyrosine kinase inhibitors interacting in the MAP kinase pathway have been used to redifferentiate tumor cells and reinduce RAI uptake. A *MEK* inhibitor (selumetinib) and *BRAF* inhibitor (dabrafenib) have been given prior to radioactive iodine administration with partial response in 20% to 25% of the cases.[447,448] The concept is appealing, but these results have to be confirmed in larger prospective studies.

In conclusion, results of DECISION and SELECT led to the approval of sorafenib and lenvatinib for advanced, refractory, and progressive DTC by the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA). In the SELECT trial and in real life, maximal benefits were achieved in patients with an ECOG performance status of 0 to 1 who were not heavily pretreated and who had a limited tumor burden. There was no unexpected toxicity, but toxicities were significant and led to dose reduction and to drug withdrawal in a significant proportion of patients. This suggests that these treatments should be initiated only in patients with significant tumor burden and with documented progression of the disease, and they should be managed by experienced teams.

Therapy for Recurrence of Medullary Thyroid Carcinoma

Patients with locoregional recurrence of MTC are at high risk of distant metastases, particularly when calcitonin levels exceed 150 pg/mL.[14] Distant metastases frequently involve multiple organs and are usually multifocal in each involved organ. The most frequently invaded organs are liver, lungs, and bones. For a complete workup, the best imaging combination includes a neck ultrasonography, a liver MRI, and a neck-chest and abdominopelvic CT scan, together with a spine MRI or a bone scintigraphy.[33] ^{18}FDG-PET/CT is useful for initial workup, especially when morphologic images are normal or doubtful.

Patients with distant metastases may progress slowly and may be compatible with decades of survival. Calcitonin and CEA doubling time are prognostic of survival, with short doubling time being in favor of a shorter survival, and are correlated to RECIST progression.[449,450] Symptomatic treatments may be necessary, in particular against pain and diarrhea. Cytotoxic chemotherapy is poorly efficient and may be indicated only in cases of rapid tumor progression.[451] Chemoembolization with doxorubicin (Adriamycin) of liver metastases provides a high response rate for both symptoms and tumor masses.[452] Kinase inhibitors directed against tumor cells (RET and other kinases) and endothelial cells (VEGF receptors) provide a high response rate and should be used as first-line treatment.

Vandetanib and Cabozantinib (XL184)

Vandetanib inhibits kinases of VEGFR1, VEGFR2, RET, and EGFR. In a phase II trial, including 30 patients with hereditary MTC, vandetanib given at the dose of 300 mg/day showed a partial RECIST response in 10 patients and stable disease lasting longer than 24 weeks in 16 other patients.[456] In another phase II trial, including 19 patients with hereditary MTC, vandetanib given at the dose of 100 mg/day showed a partial response in 3 patients and prolonged stabilization in 10 cases. There were, however, no differences in the rate of toxicity.[467] Vandetanib also proved its efficacy in children with advanced MTC in the context of multiple endocrine neoplasia type 2B.[468]

The phase II trial with vandetanib randomized the drug at the dose of 300 mg against placebo in patients with metastatic and aggressive MTC.[466] Patients with MTC-related symptoms were included even in the absence of RECIST progression. The PFS under vandetanib was longer (>30.5 months) than under placebo (19.3 months; HR, 0.46; p <0.001). Partial responses were observed in 45% of the cases, with a median length of 22 months. The subgroup analyses showed a benefit of vandetanib in patients regardless of their WHO and RET status. The study did not show an improvement in the overall survival, but a crossover was allowed in the study, and patients under placebo were treated with vandetanib after unblinding of the study. Vandetanib use in real life has demonstrated a response rate in 22% of the patients.[469]

Cabozantinib inhibits kinases of RET, VEGFR2, and c-MET. In a phase I trial of 34 patients with MTC, partial responses were observed in 17 patients and stable disease in 15 other patients.[460] The phase III trial with cabozantinib randomized the drug at the dose of 140 mg against placebo in patients with metastatic and RECIST progressive MTC. The study did not allow crossover.[465] Median PFS was 11.2 months for cabozantinib versus 4 months for placebo (HR, 0.28; p <0.001). The benefits of cabozantinib on PFS were observed in all groups of patients regardless of age, sex, WHO performance status, tumor location, and previous treatment with TKI. The benefits of cabozantinib on PFS were observed in all patients except those without *RET* mutation.[470] The response rate was 28% with a median length of response of 14.7 months. Response rates ranged from 20% to 34% depending on the *RET* and *RAS* status.[470] The median overall survival was 26.6 months in cabozantinib-treated patients versus 21.1 months for placebo (HR, 0.85, p = 0.24). However, in the group of 126 patients with the *RET M918T* mutation, patient overall

TABLE 14.15 Phase II Prospective Trials in Medullary Thyroid Cancer

Drugs	n	Targets(s)	Partial Response (RECIST) (%)	Progression-Free Survival (Months)
Vandetanib Wells[456]	30	*VEGFR, RET, EGFR*	30	27.9
Sorafenib Lam[457]	19	*VEGFR, BRAF*	11	17.9
Motesanib Schlumberger[458]	83	*VEGFR, PDGFR, C-KIT*	2	12.0
Axitinib Cohen[432] Capdevilla[434]	12 3	*VEGFR1,2,3*	22 23	NA 9.4
Sunitinib Carr[441]	6	*VEGFR, RET*	50	NA
Lenvatinib Schlumberger[459]	59	*RET, VEGFR, FGFR, PDGFR, C-KIT*	36	9.0
Cabozantinib Kurzrock[460]	35	*VEGFR, RET, C-MET*	49	NA
Pazopanib Bible[461]	35	*VEGFR, PDGFR, RET, C-KIT*	14	9.4
Gefitinib Pennell[462]	4	*EGFR*	0	NA
Imatinib De Groot[463] Frank-Raue[464]	15 9	*C-KIT, PDGFR*	0 0	NA NA

NA, Not applicable; *RECIST*, Response Evaluation Criteria in Solid Tumors.

survival was 44.3 months in cabozantinib-treated patients compared with 18.9 months for placebo (HR, 0.60, $p = 0.3$) in favor of *RET M918T* being a predictive factor of treatment efficacy of cabozantinib.[471]

The most frequent secondary effects of vandetanib are diarrhea, fatigue, cutaneous manifestations (folliculitis, photosensitivity, rash), hypertension, and QTc segment prolongation on electrocardiogram (EKG). In the phase III trial, 12% of the patients stopped the drug due to toxicity and 35% decreased the doses.[466] The most frequent secondary effects of cabozantinib are diarrhea, abdominal pain, hypertension, hand-foot syndrome, mucositis, loss of weight, nausea, and fatigue. In the phase III trial, 16% of the patients stopped the drug due to toxicity and 79% decreased the doses.[465] In general, prevention and early diagnosis are the best ways to decrease the frequency and gravity of the secondary effects. Prior to starting treatment, patients should have normal blood pressure and should be educated on self–blood pressure measurements. They should be educated to use moisturizing lotion and to protect themselves from the sun. They should be checked for normal heart function, normal electrolytes, normal renal function, and the absence of proteinuria. Diarrhea should be controlled if possible. Interactions with concomitant drugs should be checked to avoid drugs interacting with the cytochrome P450 and drugs prolonging QTc. After starting the drug, patients should be monitored closely to detect prolongation of QTc and to monitor calcium, vitamin D, and thyroid hormone levels.[472] It is highly recommended after initiation of treatment that clinicians follow up with patients at 2-week intervals for the first 2 to 3 months and then once a month to proactively manage adverse events in accordance with the tolerance of each individual patient.

Vandetanib (Caprelsa) and cabozantinib (Cometriq) are both FDA and EMA approved. Vandetanib is approved for the treatment of symptomatic or progressive MTC with unresectable locally advanced or metastatic disease. The use of vandetanib in patients with indolent asymptomatic or slowly progressive disease should be considered carefully because of the treatment-related risks of vandetanib. Cabozantinib is approved for the treatment of progressive, unresectable, locally advanced or metastatic MTC. These drugs should not be used for patients with isolated elevated calcitonin levels with normal morphologic imaging or in patients with a small tumor burden and stable disease. They should be proposed only to MTC patients with large tumor foci and progressive disease on imaging.

Targeted Molecular Therapy

Activating mutations of the proto-oncogene *RET* are involved in the oncogenesis of MTC. They are found in all hereditary MTC and in 50% to 60% of sporadic MTC.[297–299,453] In selected patients with distant and progressive metastases, they are found

TABLE 14.16 Phase III Trials in Metastatic or Locally Advanced MTC

	Vandetanib: ZETA Study Wells[466]	Cabozantinib: EXAM Study Elisei[465]
Patient Characteristics		
Number of patients included	331	330
Frequency of hereditary MTC	10%	6%
RET mutation: present unknown *RETM918T* mutation	38% 41% 31%	45% 39% 35%
Distant metastases	94%	95%
Previous treatment with TKI	Unknown	20%
RECIST progression prior enrollment	Not mandatory	Yes, within 14 months
Results		
Median follow-up	24 months	14 months
Median PFS	>30.5 months (vandetanib) vs 19.3 months (placebo)	11,2 (cabozantinib) vs 4 months (placebo)
Complete response	0%	0%
Partial RECIST response	45%	28%
Overall survival	Not available	26.6 months (cabozantinib) vs 21.1 months (placebo)
Toxicity		
Toxicity any grade (≥ grade 3)	55% (24%)	69% (33%)
Decrease in dose due to toxicity	35%	65%
Stop for toxicity	12%	16%
Deaths	2% (vandetanib) vs 2% (placebo)	5.6% (cabozantinib) vs 2.8% (placebo)

EXAM, Efficacy of XL184 in Advanced Medullary Thyroid Cancer; *MTC,* medullary thyroid carcinoma; *PFS,* progression-free survival; *RECIST*, Response Evaluation Criteria in Solid Tumors; *TKI,* tyrosine kinase inhibitor.

in 91% of the cases.[297–299,453] The most frequent *RET* mutation found is the M918T mutation. In the absence of *RET* mutation, *RAS* mutations are found in 10% to 45% of the cases, with the *HRAS* mutation being more frequent than *KRAS,* which is more frequent than *NRAS.*[297–299,453] ALK rearrangement and *MET* mutation have also been found, but in less than 5% of the specimens.[454] VEGF receptors 1 and 2 also often are overexpressed in MTC, which together with the fibroblast growth factor (FGF) and platelet-derived growth factor (PDGF) play a role in tumor angiogenesis.[455] In general, tyrosine kinase inhibitors (TKIs) have shown significant results in patients with advanced MTC.

Many TKIs targeting RET and VEGFR2, among other targets, have been used in phase II trials, with significant tumor response rates ranging from none to 50%[432,434,441,456–464] (Table 14.15). Two drugs outlined next have been evaluated in phase III trials: vandetanib and cabozantinib in prospective randomized double-blind studies.[465,466] Their main objective was to show a benefit in PFS (Table 14.16).

The Adrenal Cortex

JOHN D.C. NEWELL-PRICE AND RICHARD J. AUCHUS

CHAPTER OUTLINE

KEY POINTS

- This chapter discusses mechanisms and regulation of adrenal steroid production, function of the hypothalamic-pituitary-adrenal axis, and negative regulation.
- The chapter goes on to describe the transactivating and transrepressive actions of glucocorticoids.
- Glucocorticoid excess and Cushing syndrome, adrenal insufficiency and Addison disease, and inherited disorders of the adrenal gland are also discussed.
- Optimizing corticosteroid replacement therapies is addressed.
- The chapter concludes with discussion of adrenal incidentalomas, adenomas, and carcinomas.

The Adrenal Cortex—Historical Milestones

The anatomy of the adrenal glands was described almost 450 years ago by Bartolomeo Eustachius,[1] and the zonation of the gland and its distinction from the medulla were elucidated shortly thereafter. However, a functional role for the adrenal glands was not accurately defined until the pioneering work of Thomas Addison, who described the clinical and autopsy findings in 11 cases of Addison disease in his classic monograph in 1855.[2] Just a year later, Brown-Séquard demonstrated that the adrenal glands were "organs essential for life" by performing adrenalectomies in dogs, cats, and guinea pigs.[3] In 1896, William Osler first administered adrenal extract to a patient with Addison disease, a feat that was repeated by others in animal and human studies over the next 40 years. Between 1937 and 1955, the adrenocorticosteroid hormones were isolated, and their structures were defined and synthesized.[4] Notable breakthroughs included the discovery of cortisone and clinical evaluation of its anti-inflammatory effect in patients with rheumatoid arthritis[5] and the isolation of aldosterone.[6]

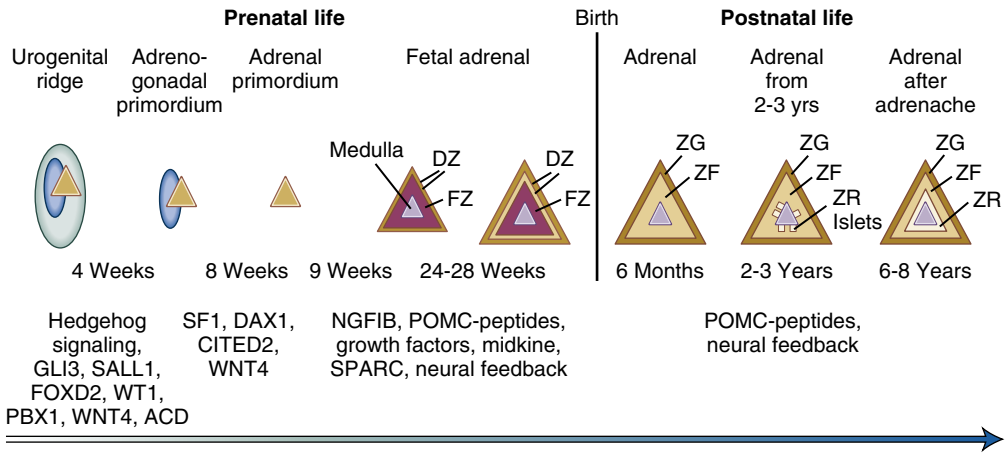
The control of adrenocortical function by a pituitary factor was demonstrated in the 1920s, and this led to the isolation of sheep adrenocorticotropic hormone (ACTH) by Li, Evans, and Simpson in 1943.[7] Such a concept was supported through clinical studies, notably by Harvey Cushing in 1932, who associated his original clinical observations of 1912 (a "polyglandular syndrome" caused by pituitary basophilism) with adrenal hyperactivity.[8] The neural control of pituitary ACTH secretion by corticotropin-releasing factor (later renamed corticotropin-releasing hormone [CRH]) was defined by Harris and other workers in the 1940s, but CRH was not characterized and synthesized until 1981 in the laboratory of Wylie Vale.[9] Jerome Conn described primary aldosteronism in 1955,[10] and the control of adrenal aldosterone secretion by angiotensin II was confirmed shortly afterward. Advances in radioimmunoassay, and particularly molecular biology, have facilitated an exponential increase in the understanding of adrenal physiology and pathophysiology (Table 15.1).

Anatomy and Development

The cells forming the adrenal cortex originate from the intermediate mesoderm. These cells derive from the urogenital ridge and have a common embryologic origin with the gonad and the kidney. Early differentiation of the adrenogonadal primordium from the urogenital ridge requires signaling cascades and transcription factors GLI3, SALL1, FOXD2, WT1, PBX1, and WNT4, and the regulator of telomerase activity, ACD (Fig. 15.1). The adrenogonadal primordium can be seen as the medial part of the urogenital ridge at 4 weeks. Separation of the adrenogonadal primordium and formation of the adrenal primordium seem to depend on the actions of transcription factors SF1 (steroidogenic factor 1),

TABLE 15.1 History of the Adrenal Cortex: Important Milestones

Year	Event
1563	Eustachius describes the adrenals (published by Lancisi in 1714).
1849	Thomas Addison, while searching for the cause of pernicious anemia, stumbles on a bronzed appearance associated with the adrenal glands—*melasma suprarenale.*
1855	Thomas Addison describes the clinical features and autopsy findings in 11 cases of diseases of the suprarenal capsules, at least 6 of which were tuberculous in origin.
1856	In adrenalectomy experiments, Brown-Séquard demonstrates that the adrenal glands are essential for life.
1896	William Osler prepares an oral glycerin extract derived from pig adrenals and demonstrates that it has clinical benefit in patients with Addison disease.
1905	Bulloch and Sequeira describe patients with congenital adrenal hyperplasia.
1929	Liquid extracts of cortical tissue are used to keep adrenalectomized cats alive indefinitely (Swingle and Pfiffner); subsequently, this extract was used successfully to treat a patient with Addison disease (Rowntree and Greene).
1932	Harvey Cushing associates the polyglandular syndrome of pituitary basophilism, which he first described in 1912, with hyperactivity of the pituitary-adrenal glands.
1936	The concept of stress and its effect on pituitary-adrenal function are described by Selye.
1937–1952	Isolation and structural characterization of adrenocortical hormones are reported by Kendall and Reichstein.
1943	Li and colleagues isolate pure adrenocorticotropic hormone from sheep pituitary.
1950	Hench, Kendall, and Reichstein share the Nobel Prize in Medicine for describing the anti-inflammatory effects of cortisone in patients with rheumatoid arthritis.
1953	Isolation and analysis of the structure of aldosterone are reported by Simpson and Tait.
1956	Conn describes primary aldosteronism.
1981	Characterization and synthesis of corticotropin-releasing hormone are reported by Vale.
1980–present	The *molecular era:* cloning and functional characterization of steroid receptors, steroidogenic enzymes, and adrenal transcription factors are reported, and the molecular basis for human adrenal diseases is defined.



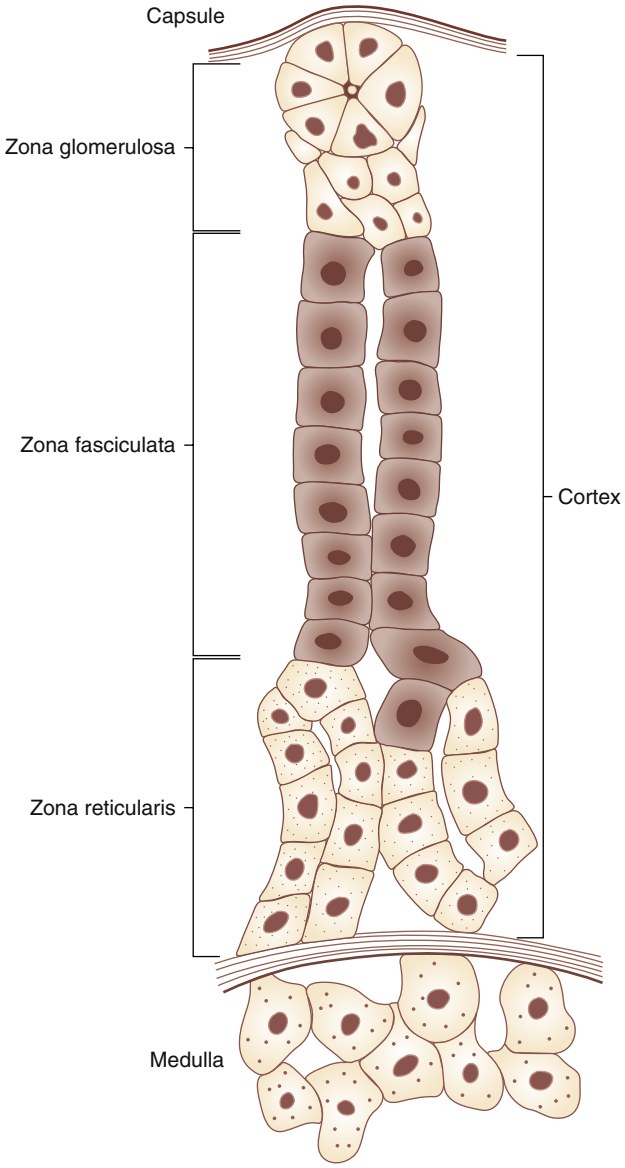
• **Fig. 15.1** Schematic diagram of the development of the human adrenal cortex during prenatal and postnatal life showing transcription factors that are active at each stage (see text for details). *DZ,* definitive zone; *FZ,* fetal zone; *POMC,* pro-opiomelanocortin; *SPARC,* secreted protein, acidic, cysteine-rich (osteonectin); *ZF,* zona fasciculata; *ZG,* zona glomerulosa; *ZR,* zona reticularis.

DAX1, WNT4, and CITED2. The adrenocortical primordium develops at approximately 8 weeks of gestation and can be differentiated into two distinct layers, the inner fetal zone (FZ) and the outer definitive zone (DZ). At approximately 9 weeks, the adrenal blastema encapsulates and the adrenal medulla develops when neural crest cells migrate into the adrenal gland.[11] During the second trimester, the FZ enlarges, becomes larger than the fetal kidney, and secretes abundant amounts of dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS). Concentrations of these hormones abruptly decline postnatally, in parallel with the postnatal involution of the FZ. The neocortex develops over the subsequent years into the adult adrenal gland.

In fetal life and up to 12 months of age, two distinct zones are evident, an inner prominent FZ and an outer DZ that differentiates into the adult adrenal gland. After birth, the FZ regresses and the DZ, which contains an inner zona fasciculata (ZF) and an outer zona glomerulosa (ZG), proliferates.[12,13] The innermost zone, the zona reticularis (ZR), is evident after 2 years of life. The differentiation of the adrenal cortex into distinct zones has important functional consequences and is thought to depend on the temporal expression of transcription factors, including Pref1/ZOG, inner zone antigen, and SF1.[14,15] In preadrenarchal children, focal reticular zone islets can be found, but the ZG and ZF are clearly differentiated.[16] The occurrence of these ZR islets is consistent with the observation that DHEA and DHEAS synthesis gradually begins to rise from about 3 years of age.[17] At adrenarche, the inner zone (ZR) thickens, corresponding with increased production of DHEA and DHEAS. Concurrently, changes in zone-specific enzyme expression patterns, such as decreased 3β-hydroxysteroid dehydrogenase type 2 (3βHSD2) and increased cytochrome b_5 and sulfotransferase (SULT2A1) in the ZR, lead to increased flux toward DHEA. Clinically, adrenarche becomes apparent at 6 to 8 years of age. Adrenal androgen production peaks in the third decade and then declines at a variable rate. Mineralocorticoids and glucocorticoids show a less age-specific variation.

The adult adrenal gland is a pyramidal structure, approximately 4 g in weight, 2 cm wide, 5 cm long, and 1 cm thick, that lies immediately above the kidney on its posteromedial surface. Beneath the capsule, the ZG makes up approximately 15% of the cortex (depending on sodium intake) (Fig. 15.2). Cells are clustered in spherical nests and are small, with smaller nuclei in comparison with cells in other zones. The ZF makes up 75% of the cortex; cells are large and lipid laden and form radial cords within the fibrovascular radial network. The innermost ZR is sharply demarcated from both the ZF and the adrenal medulla. Cells there are irregular with little lipid content. The maintenance of normal adrenal size appears to involve a progenitor cell population lying between the ZG and ZF; cell migration and differentiation occur within the ZF, and senescence occurs within the ZR, but the factors regulating this important aspect of adrenal regeneration are unknown. Fetal cells give rise to a subcapsular stem cell population that differentiates in a centripetal direction.[18] ACTH administration results in glomerulosa cells adopting a fasciculata phenotype, and in turn, the innermost fasciculata cells adopt a reticularis phenotype that is reversible on withdrawal of ACTH.

The vasculature of the adrenal cortex is complex. Arterial supply is conveyed by up to 12 small arteries from the aorta and the inferior phrenic, renal, and intercostal arteries. These arteries branch to form a subcapsular arteriolar plexus from which radial capillaries penetrate deeper into the cortex. In the ZR, a dense sinusoidal plexus is created, which empties into a central vein. The right adrenal vein is short, draining directly into the inferior vena cava, whereas the longer left adrenal vein usually drains into the left renal vein.



• **Fig. 15.2** Schematic diagram of the structure of the human adrenal cortex, depicting the outer zona glomerulosa and inner zona fasciculata and zona reticularis.

Adrenal Steroids and Steroidogenesis

Three main types of hormones are produced by the adrenal cortex—glucocorticoids (cortisol, corticosterone), mineralocorticoids (aldosterone, deoxycorticosterone [DOC]), androgen precursors (DHEA, DHEAS, androstenedione), and a small amount of androgens (testosterone and 11-oxygenated 19-carbon androgens/precursors). All steroid hormones are derived from the cyclopentanoperhydrophenanthrene structure, that is, three cyclohexane rings and a single cyclopentane ring (Fig. 15.3). Steroid nomenclature is defined in one of two ways: by trivial names (e.g., cortisol, aldosterone) or by the chemical structure as defined by the International Union of Pure and Applied Chemistry (IUPAC).[19] The IUPAC classification is inappropriate for clinical use but does provide an invaluable insight into steroid structure. The basic structure, trivial name, and IUPAC name of some common steroids are given in Fig. 15.3 and Table 15.2. Estrogens have 18 carbon atoms (C18 steroids) and androgens have 19 carbon atoms (C19), whereas glucocorticoids, mineralocorticoids, and progestogens are C21-steroid derivatives.

Cholesterol is the precursor for adrenal steroidogenesis. It is provided principally from the circulation, in the form of low-density lipoprotein (LDL) cholesterol.[20] Uptake is by specific cell-surface LDL receptors present on adrenal tissue[21]; LDL is then internalized via receptor-mediated endocytosis,[22] the resulting vesicles fuse with lysozymes, and free cholesterol is produced after hydrolysis. However, it is clear that this cannot be the sole source

of adrenal cholesterol, because patients with abetalipoproteinemia who have undetectable circulating LDL and patients with defective LDL receptors in the setting of familial hypercholesterolemia still have normal basal adrenal steroidogenesis. Cholesterol can be generated de novo within the adrenal cortex from acetyl coenzyme A (CoA). In addition, there is evidence that the adrenal gland can utilize high-density lipoprotein (HDL) cholesterol after uptake through the putative HDL receptor, SR-B1.[23]

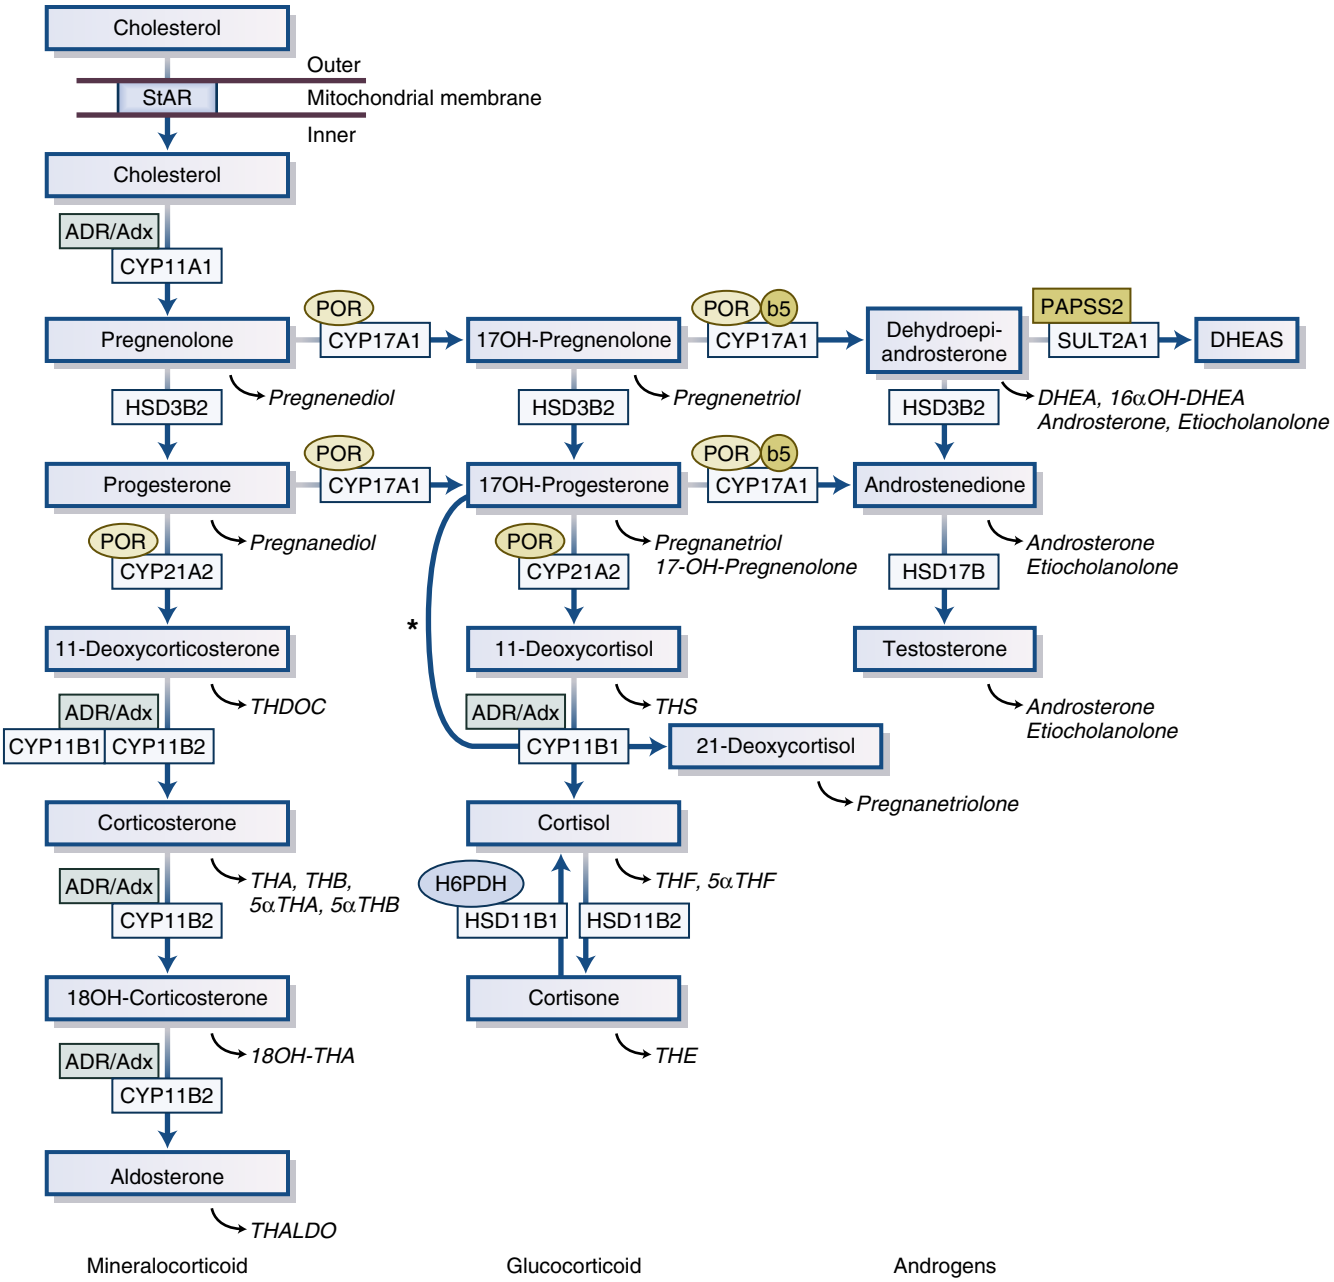
The biochemical pathways involved in adrenal steroidogenesis are shown in Fig. 15.4. The initial hormone-dependent, rate-limiting step is the transport of intracellular cholesterol from the outer to inner mitochondrial membrane for conversion to pregnenolone by cytochrome P450 side-chain cleavage enzyme (P450 11A1). Naturally occurring human mutations have confirmed the importance of a 30-kDa protein, steroidogenic acute regulatory protein (StAR), in mediating this effect. StAR is induced by an increase in intracellular cyclic adenosine monophosphate (cAMP) after binding of ACTH to its cognate receptor, providing the first important rate-limiting step in adrenal steroidogenesis.[24] Other transporters, including the peripheral benzodiazepine-like receptor, may be involved.[25]

Steroidogenesis involves the concerted action of several enzymes, including a series of cytochrome P450 enzymes, all of which have been cloned and characterized (Table 15.3). Cytochrome P450 enzymes are classified into two types, according to their subcellular localization and their specific electron shuttle system. Mitochondrial (type I) cytochrome P450 enzymes such as CYP11A1 (P450 11A1), 11α-hydroxylase (CYP11B1, or P45011B1), and aldosterone synthase (CYP11B2, or P450 11B2) rely on electron transfer facilitated by adrenodoxin and adrenodoxin reductase.[26,27] Micrososomal (type II) cytochrome P450 enzymes localized to the endoplasmic reticulum include the steroidogenic enzymes 17α-hydroxylase (CYP17A1, or P450 17A1), 21-hydroxylase (CYP21A2, or P450 21A2), and P450 aromatase (CYP19A1, or P450 19A1). The functions of cytochrome P450 type II enzymes crucially depend on P450 oxidoreductase (POR), which provides electrons required for monooxygenase reactions catalyzed by the P450 enzyme.[27,28] This category also includes hepatic P450 enzymes involved in drug metabolism and enzymes involved in sterol and bile acid synthesis.[27,28] In addition, the 17,20-lyase activity of P450 17A1 is dependent on a hemoprotein cytochrome b_5, which αβ functions as an allosteric facilitator of P450 17A1 with POR (Fig. 15.5; see also Fig. 15.4).[29]

Mutations in the genes encoding these enzymes result in human disease, so some understanding of the underlying pathways and steroid precursors is required.[30] After uptake of cholesterol to the mitochondrion, cholesterol is cleaved by the P450 11A1 enzyme to form pregnenolone.[31] In the cytoplasm, pregnenolone is converted to progesterone by the type II isozyme 3βHSD through a reaction involving dehydrogenation of the 3-hydroxyl group and isomerization of the double bond at C5.[32] Progesterone is hydroxylated to 17-hydroxyprogesterone (17OHP) through the 17α-hydroxylase activity of P450 17A1. 17α-Hydroxylation is an essential prerequisite for cortisol synthesis, and the ZG does not express 17α-hydroxylase. P450 17A1 also possesses 17,20-lyase activity, which results in production of the C19 adrenal androgens DHEA and androstenedione.[33] In humans, however, 17OHP is not an efficient substrate for P450 17A1, and there is negligible conversion of 17OHP to androstenedione. Adrenal androstenedione secretion is dependent on the conversion of DHEA to androstenedione by 3βHSD. This enzyme also converts 17-hydroxypregnenolone to 17OHP, but the preferred substrate is pregnenolone. The human adrenal gland is capable of synthesis of small but significant amounts of testosterone, which increases in clinical conditions associated with androgen excess. This conversion is facilitated by the enzyme 17βHSD type 5 (17βHSD5), also called aldo-keto reductase 1C3 (AKR1C3).[34] 21-Hydroxylation of either progesterone (in the ZG) or 17OHP (in the ZF) is carried out by the product of the *CYP21A2* gene, 21-hydroxylase, to yield DOC or 11-deoxycortisol, respectively.[35] The final step in cortisol biosynthesis takes place in the mitochondria and involves the conversion of 11-deoxycortisol to cortisol by the enzyme P450 11B1 (11β-hydroxylase).[36] In the ZG, 11β-hydroxylase may also convert DOC to corticosterone. The enzyme P450 11B2 (aldosterone synthase) may also carry out this reaction; in addition, P450 11B2 is required for conversion of corticosterone to aldosterone via the intermediate 18OH corticosterone; CYP11B1 lacks these two enzymatic activities.[37,38] Therefore P450 11B2 can carry out 11β-hydroxylation, 18-hydroxylation, and 18-methyl oxidation to yield the characteristic C11-18 hemiacetyl structure of aldosterone.

Regulation of Adrenal Steroidogenesis: Functional Zonation of the Adrenal Cortex

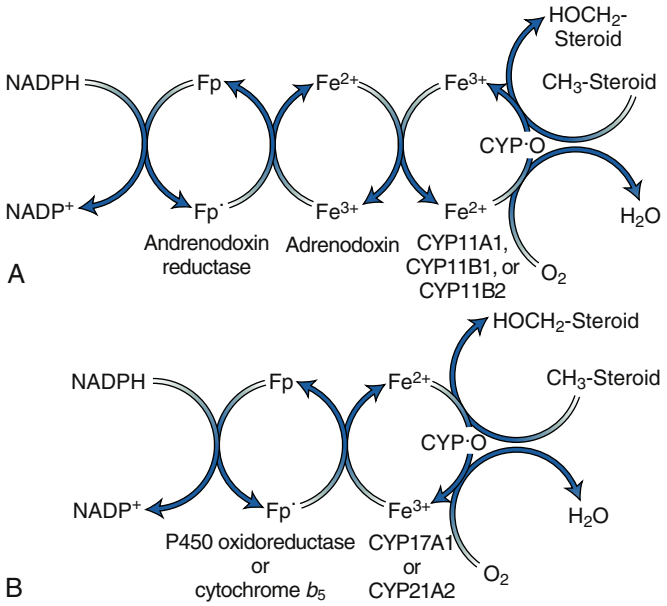
Glucocorticoids are secreted in relatively high amounts (cortisol, 10–20 mg/day) from the ZF under the control of ACTH; mineralocorticoids are secreted in low amounts (aldosterone, 100–150 μg/day) from the ZG under the principal control of angiotensin II. As a class, adrenal androgen precursors (DHEA, DHEAS, androstenedione, 11β-hydroxyandrostenedione) are the most abundant steroids secreted from the adult adrenal gland (>20 mg/day). In each case, secretion is facilitated through the expression of steroidogenic enzymes in a specific zonal manner. The ZG cannot



• **Fig. 15.4** Adrenal steroidogenesis. After the steroidogenic acute regulatory *(StAR)* protein-mediated uptake of cholesterol into mitochondria within adrenocortical cells, aldosterone, cortisol, and adrenal androgens are synthesized through the coordinated action of a series of steroidogenic enzymes in a zone-specific fashion. The mitochondrial cytochrome P450 (CYP) type I enzymes (CYP11A1, CYP11B1, CYP11B2) requiring electron transfer via adrenodoxin reductase (ADR) and adrenodoxin (Adx) are marked with a *box labeled ADR/Adx*. The microsomal CYP type II enzymes *(CYP17A1, CYP21A2)* receive electrons from P450 oxidoreductase *(circle labeled POR)*. The 17,20-lyase reaction catalyzed by CYP17A1 requires, in addition to POR, cytochrome b_5, indicated by a *circle labeled b5*. Urinary steroid hormone metabolites are given in italics below the plasma hormones. The asterisk *(*)* indicates 11-hydroxylation of 17OH-progesterone to 21-deoxycortisol in cases of 21-hydroxylase deficiency. The adrenal conversion of androstenedione to testosterone is catalyzed by the aldo-keto reductase AKR1C3 (HSD17B5). *CYP11A1,* P450 side-chain cleavage enzyme; *CYP11B1,* 11β-hydroxylase; *CYP11B2,* aldosterone synthase; *CYP17A1,* 17α-hydroxylase; *CYP21A2,* 21-hydroxylase; *DHEA,* dehydroepiandrosterone; *DHEAS,* dehydroepiandrosterone sulfate; *H6PDH,* hexose-6-phosphate dehydrogenase; *HSD11B1,* 11β-hydroxysteroid dehydrogenase 1; *HSD11B2,* 11β-hydroxysteroid dehydrogenase 2; *HSD17B,* 17β-hydroxysteroid dehydrogenase; *HSD3B2,* 3β-hydroxysteroid dehydrogenase type 2; *17OH-progesterone,* 17α-hydroxyprogesterone; *PAPSS2,* 3′-phosphoadenosine, 5′-phosphosulfate synthase 2; *SULT2A1,* sulfotransferase 2A1; *THA,* tetrahydro-11-dehydrocorticosterone; *THB,* tetrahydro-corticosterone; *THALDO,* tetrahydro-aldosterone; *THDOC,* tetrahydro-11-deoxycorticosterone; *THF,* tetrahydrocortisol; *THS,* tetrahydro-11-deoxycortisol.

TABLE 15.3 Nomenclature for Adrenal Steroidogenic Enzymes and Their Genes

Enzyme Name	Enzyme Family	Gene	Chromosome
P450 11A1, Cholesterol side-chain cleavage (SCC) (desmolase)	Cytochrome P450 type I	*CYP11A1*	15q23-q24
3β-Hydroxysteroid dehydrogenase (3βHSD) (type II isozyme)	Short-chain alcohol dehydrogenase reductase superfamily	*HSD3B2*	1p13.1
P450 17A1, 17α-Hydroxylase/17,20-lyase	Cytochrome P450 type II	*CYP17A1*	10q24.3
P450 21A2, 21-Hydroxylase	Cytochrome P450 type II	*CYP21A2*	6p21.3
P450 11B1, 11β-Hydroxylase	Cytochrome P450 type I	*CYP11B1*	8q24.3
P450 11B2, Aldosterone synthase	Cytochrome P450 type I	*CYP11B2*	8q24.3



• **Fig. 15.5** (A) Electron shuttle system for the mitochondrial enzymes CYP11A1, CYP11B1, and CYP11B2. Adrenodoxin reductase receives electrons from reduced nicotinamide adenine dinucleotide phosphate *(NADPH)* and reduces adrenodoxin, which transfers reducing equivalents to the cytochrome P450 *(CYP)* enzyme. The enzyme then uses these electrons, plus molecular oxygen, to oxygenate the steroid. (B) Electron shuttle system for the microsomal enzymes CYP17A1 and CYP21A2. P450 oxidoreductase, a flavoprotein, accepts electrons from NADPH and transfers them to the NADPH-P450 enzyme. The enzyme then uses these electrons, plus molecular oxygen, to oxygenate the steroid. A second reducing equivalent may be supplied to CYP17A1 by NADPH-P450 oxidoreductase or cytochrome b_5. *Fp,* flavoprotein; *Fp•,* reduced form of flavoprotein; *$NADP^+$,* nicotinamide adenine dinucleotide phosphate.

synthesize cortisol because it does not express 17α-hydroxylase. In contrast, aldosterone secretion is confined to the outer ZG because of the restricted expression of P450 11B2. Although P450 11B1 and P450 11B2 share 95% homology, the 5′ promoter sequences differ, permitting regulation of the final steps in glucocorticoid and mineralocorticoid biosynthesis by ACTH and angiotensin II, respectively. In the ZR, high levels of cytochrome b_5 confer 17,20-lyase activity on P450 17A1 and androgen precursor production. DHEA is sulfated in the ZR by the DHEA SULT2A1 to form DHEAS. This sulfonation reaction facilitated by SULT2A1 relies on the donor 3′-phosphoadenosine 5′-phosphosulfate (PAPS) to transfer a sulfonate group to an acceptor molecule. PAPS is synthesized by PAPS synthase, of which two isoenzymes exist (PAPSS1 and PAPSS2).[39]

In the fetal adrenal, steroidogenesis occurs primarily within the inner FZ. The FZ is a characteristic feature of higher primates, but the biologic role of fetal androgen production remains unclear. Because of a relative lack of 3βHSD and high SULT2A1 activity, the principal steroidogenic products are DHEA and DHEAS, which are then aromatized by placental trophoblast to estrogens. Therefore the majority of maternal estrogen across pregnancy is, indirectly, fetally derived.[40]

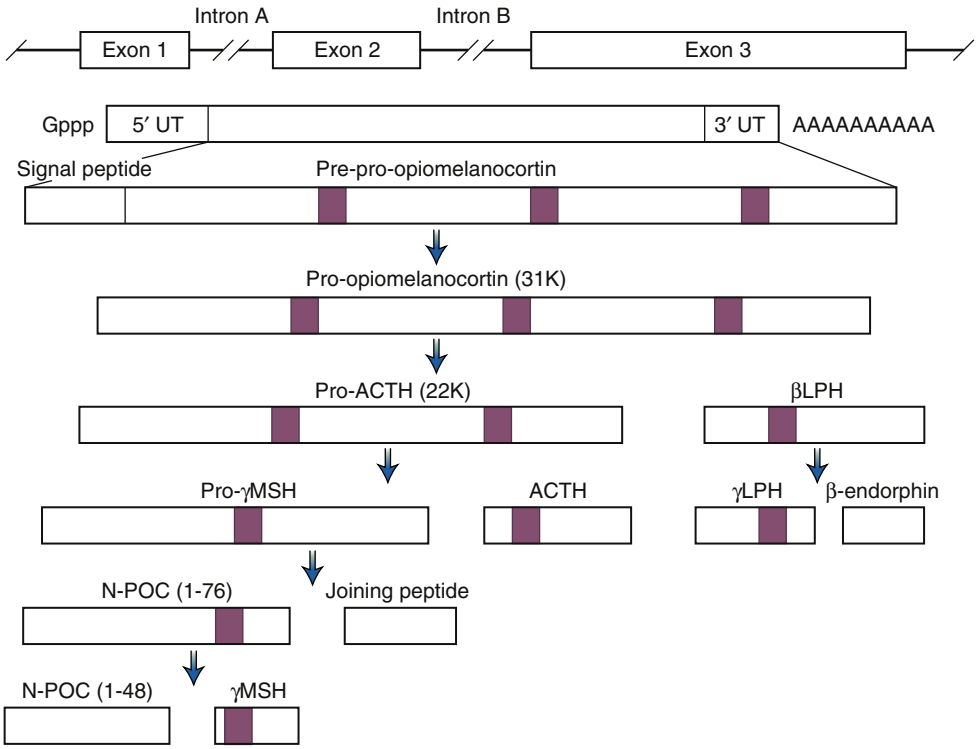
Classic endocrine feedback loops are in place to control the secretion of both hormones. Cortisol inhibits the secretion of CRH from the hypothalamus and ACTH from the pituitary, and aldosterone-induced sodium retention inhibits renal renin secretion.

Glucocorticoid Secretion: The Hypothalamic-Pituitary-Adrenal Axis

Pro-opiomelanocortin and ACTH

ACTH is the principal hormone stimulating adrenal glucocorticoid biosynthesis and secretion. ACTH has 39 amino acids but is synthesized within the anterior pituitary as part of a much larger, 241–amino acid precursor called *pro-opiomelanocortin* (POMC). A transcription factor, TPIT, appears to be essential for differentiation of POMC-expressing cells within the anterior pituitary.[41] POMC is cleaved in a tissue-specific fashion by prohormone convertases to yield smaller peptide hormones. In the anterior pituitary, this results in the secretion of β-lipoprotein (βLPH) and pro-ACTH, the latter being further cleaved to an amino-terminal peptide, joining peptide, and ACTH itself (Fig. 15.6).[42,43] Post-secretion cleavage of the precursor to γ-melanocyte-stimulating hormone (pro-γMSH) by a serine protease (AsP) expressed in the outer adrenal cortex is thought to mediate the trophic action of ACTH on the adrenal cortex.[44] The first 24 amino acids of ACTH are common to all species, and a synthetic ACTH(1-24), tetracosactide or cosyntropin (Synacthen, Cortrosyn), is available commercially for clinical testing of the hypothalamic-pituitary-adrenal (HPA) axis and assessing adrenal glucocorticoid reserve. The hormones αMSH, βMSH, and γMSH are also cleaved products from POMC, but the increased pigmentation characteristic of Addison disease is thought to arise directly from increased ACTH concentrations binding to the melanocortin-1 receptor (MC1R) rather than from αMSH secretion.[45]

POMC is also transcribed in many extrapituitary tissues, notably brain, liver, kidney, gonad, and placenta.[42,46,47] In these



• **Fig. 15.6** Synthesis and cleavage of pro-opiomelanocortin (POMC) within the human anterior pituitary gland. Prohormone convertase enzymes sequentially cleave POMC to adrenocorticotropic hormone *(ACTH)*. Shaded areas represent melanocyte-stimulating hormone *(MSH)* structural units. *βLPH,* β-lipoprotein; *γLPH,* γ-lipoprotein; *N-POC,* amino-terminal pro-opiomelanocortin.

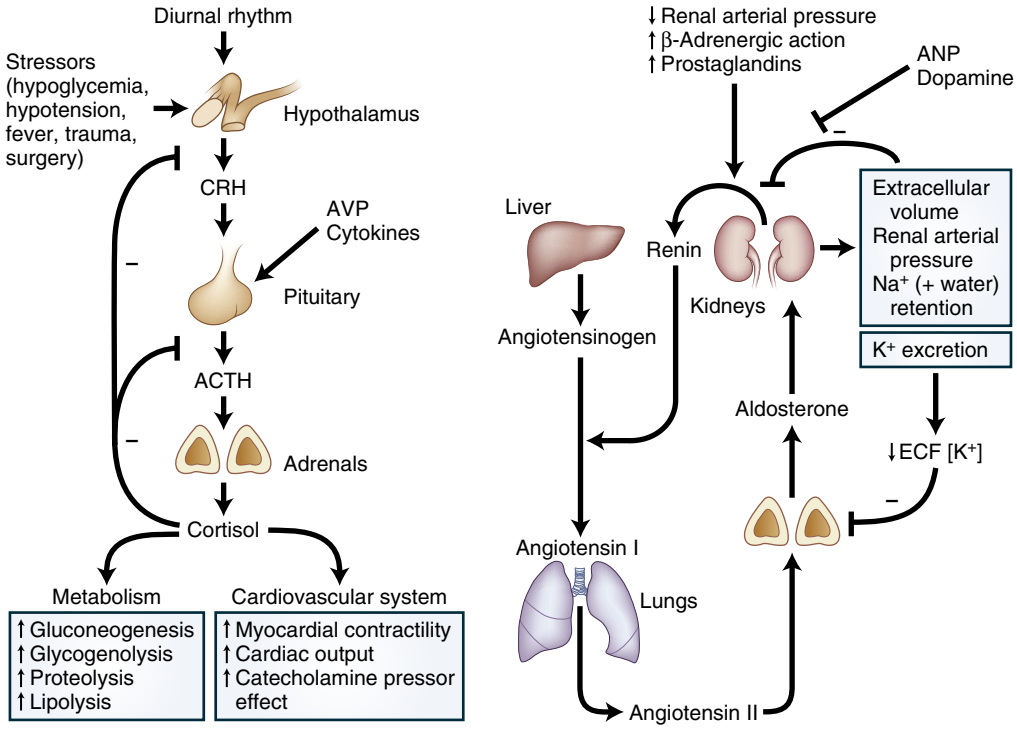
normal tissues, POMC messenger RNA (mRNA) is usually shorter (800nt) than the pituitary 1200nt transcript because of lack of exons 1 and 2 and the 5′ region of exon 3.[48] Because the POMC-like peptide product from this shorter transcript lacks a signal sequence needed to cross the endoplasmic reticulum, it is probable that it is neither secreted nor active in normal circumstances. However, in ectopic ACTH syndrome, additional POMC mRNA species are described that are longer than the normal pituitary POMC species (typically 1450nt) as a result of the use of alternative promoters in the 5′ region of the gene.[49,50] This may, in part, explain the resistance of POMC expression to glucocorticoid feedback in these tumors. Other factors, including interaction with tissue-specific transcription factors[51] and lack of *POMC* promoter methylation,[52] may explain the ectopic expression of ACTH in some malignant tissues. The cleavage of POMC is also tissue specific,[53] and it is possible, at least in some cases of ectopic ACTH syndrome, that circulating ACTH precursors (notably pro-ACTH) may cross-react in current ACTH radioimmunoassays.[54,55] The biologic activity of POMC itself on adrenal function is thought to be negligible.

POMC expression and processing within neurons in the hypothalamus, specifically the generation of αMSH that interacts with melanocortin-4 receptors (MC4R), appears to be of crucial importance in appetite control and energy homeostasis (see later discussion).[56]

Corticotropin-Releasing Hormone and Arginine Vasopressin

POMC secretion is tightly controlled by numerous factors, notably CRH and arginine vasopressin (AVP) (Fig. 15.7).[57,58] Additional control is provided through an endogenous circadian rhythm and by stress and feedback inhibition by cortisol itself. CRH is a 41–amino acid peptide that is synthesized in neurons within the paraventricular nucleus of the hypothalamus.[9,59,60] Human and rat CRH are identical, but ovine CRH differs by seven amino acids[61,62]; ovine-sequence CRH is slightly more potent than human-sequence CRH in stimulating ACTH secretion and has a longer half-life, but both are used diagnostically.

CRH is secreted into the hypophyseal portal blood, where it binds to specific type I CRH receptors on anterior pituitary corticotrophs[63] to stimulate *POMC* transcription through a process that includes activation of adenylyl cyclase. It is unclear whether hypothalamic CRH contributes in any way to circulating levels; CRH is also synthesized in other tissues, and it is likely that circulating CRH reflects synthesis from testis, gastrointestinal tract, adrenal medulla, and particularly the placenta,[64] in which the increased secretion across pregnancy results in a threefold increase in circulating CRH levels.[65] In the circulation, CRH is bound to CRH-binding protein (CRH-BP); levels of CRH-BP also increase during pregnancy so that cortisol secretion is not markedly elevated.[66] CRH is the principal stimulus for ACTH secretion,[67] but AVP is able to potentiate CRH-mediated secretion.[68] In this case, AVP acts through the V_{1b} receptor to activate protein kinase C. The peak response of ACTH to CRH does not differ across the day, but it is affected by endogenous function of the HPA axis in that responsiveness is reduced in subjects treated with corticosteroids but increased in subjects with Cushing disease. Other reported ACTH secretagogues, including angiotensin II, cholecystokinin, atrial natriuretic factor, and vasoactive peptides, probably act to modulate the CRH control of ACTH secretion.[69]



• **Fig. 15.7** Normal negative feedback regulation of cortisol and aldosterone secretion. (A) Hypothalamic-pituitary-adrenal axis. Adrenocorticotropic hormone (ACTH) is secreted from the anterior pituitary under the influence of two principal secretagogues, corticotropin-releasing hormone (CRH) and arginine vasopressin; other factors, including cytokines, also play a role. CRH secretion is regulated by an inbuilt circadian rhythm and by additional stressors operating through the hypothalamus. Secretion of CRH and ACTH is inhibited by cortisol, highlighting the importance of negative feedback control. (B) Renin-angiotensin-aldosterone system (RAAS). Renin is secreted from the juxtaglomerular cells in the kidney dependent on renal arterial blood pressure. Renin converts angiotensinogen to angiotensin I, which is converted in the lungs by angiotensin-converting enzyme (ACE) into angiotensin II. Angiotensin stimulates adrenal aldosterone synthesis. Extracellular fraction (ECF) of potassium has an important direct inhibitory influence on aldosterone secretion. *AVP,* arginine vasopressin (antidiuretic hormone); *ANP,* atrial natriuretic peptide.

The Stress Response and Immune-Endocrine Axis

The proinflammatory cytokines, notably interleukin 1 (IL1), IL6, and tumor necrosis factor-α, also increase ACTH secretion, either directly or by augmenting the effect of CRH.[70,71] Leukemia inhibitory factor (LIF), a cytokine of the IL6 family, is a further activator of the HPA axis.[72] This explains the response of the HPA axis to an inflammatory stimulus and is an important immune-endocrine interaction (see Chapter 7). Physical stresses increase ACTH and cortisol secretion, again through central actions mediated via CRH and AVP. Cortisol secretion rises in response to fever, surgery,[73] burn injury,[74] hypoglycemia,[75] hypotension, and exercise.[76] In all of these cases, this increased secretion can be viewed as a normal counterregulatory response to the insult. Acute psychologic stress raises cortisol levels,[77] but secretion rates appear to be normal in patients with chronic anxiety states and underlying psychotic illness. However, depression is associated with high circulating cortisol concentrations, and this is an important consideration in the differential diagnosis of Cushing syndrome (see later discussion).

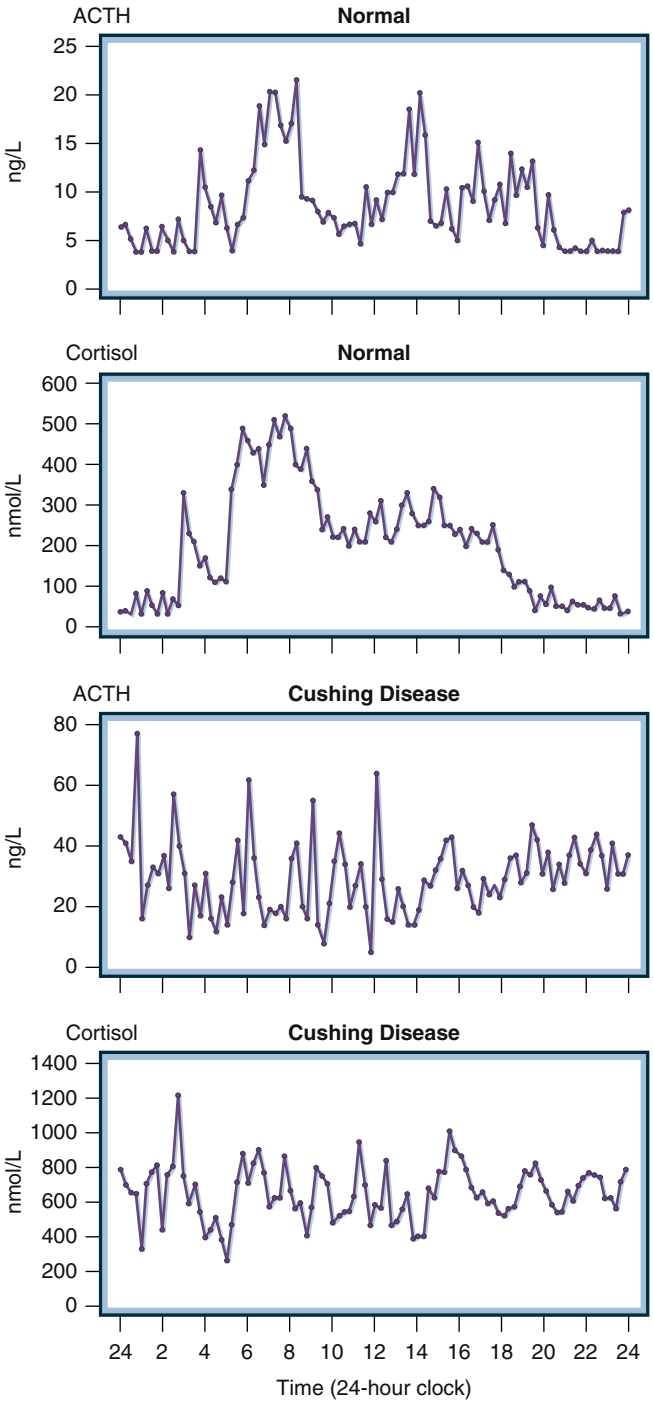
Circadian Rhythm

ACTH, and hence cortisol, is secreted in a pulsatile fashion with a circadian rhythm; levels are highest on awakening and decline throughout the day, reaching nadir values in the evening (Fig. 15.8).[78] The average ACTH pulse frequency is higher in normal adult men compared with women (18 vs. 10 pulses/24 hours, respectively). The circadian ACTH rhythm appears to be mediated principally by an increased ACTH pulse amplitude occurring between 5 and 9 AM but also by a reduction in ACTH pulse frequency occurring between 6 PM and midnight.[79,80] Food ingestion is a further stimulus to ACTH secretion. An ultradian rhythm overlies the circadian and appears to be driven by an oscillator created between the secretion of ACTH, the short delay in response at the adrenal, and the subsequent negative feedback by cortisol at the hypothalamus and pituitary.[81]

Circadian rhythm is dependent on both day-night[82] and sleep-wake[83] patterns and is disrupted by alternating day-night shift work and by long-distance travel across time zones.[84] It can take up to 2 weeks for the circadian rhythm to reset to an altered day-night cycle.

Negative Feedback

An important aspect of CRH and ACTH secretion is the negative feedback control exerted by glucocorticoids themselves. Glucocorticoids inhibit *POMC* transcription in the anterior pituitary[57] and CRH and AVP mRNA synthesis and secretion in the hypothalamus.[85,86] Annexin 1 (formerly called *lipocortin 1*) may also play a critical role in effecting the negative feedback of



• **Fig. 15.8** Circadian and pulsatile secretion of adrenocorticotropic hormone (ACTH) and cortisol in a normal subject *(top two panels)* and in a patient with Cushing disease. In a normal subject, secretion of ACTH and cortisol is highest in early morning and falls to a nadir at midnight. ACTH pulse frequency and pulse amplitude are increased in Cushing disease, and circadian rhythmic secretion is lost.

glucocorticoids on ACTH and CRH release.[87] The negative feedback effect depends on the dose, potency, half-life, and duration of administration of the glucocorticoid and has important physiologic and diagnostic consequences. Suppression of the HPA axis by pharmacologic corticosteroids may persist for many months after cessation of therapy, and adrenocortical insufficiency should be anticipated. Diagnostically, the feedback mechanism explains ACTH hypersecretion in Addison disease, as well as undetectable ACTH levels in patients with a cortisol-secreting adrenal adenoma. Feedback inhibition is principally mediated via the glucocorticoid receptor (GR); patients with glucocorticoid resistance resulting from mutations in the GR[88] and mice lacking the GR gene *(Nr3c1)*[89] have ACTH and cortisol hypersecretion due to perceived lack of negative feedback.

The ACTH Receptor and ACTH Effects on the Adrenal Gland

ACTH binds to a G protein–coupled, melanocortin-2 receptor (MC2R),[90] of which there are approximately 3500 on each adrenocortical cell. Melanocortin-2 receptor accessory protein (MRAP) is required for correct localization and signaling of MC2R.[91] Current data suggest that MRAP might promote three different activities: as a chaperone assisting correct folding of MC2R in the endoplasmic reticulum, as an accessory protein essential for trafficking of MC2R to the plasma membrane, and as a coreceptor enabling MC2R to bind or to signal ACTH response.[92] Downstream signal transduction is mediated principally through the stimulation of adenylyl cyclase and intracellular cAMP,[93] although both extracellular and intracellular Ca^{2+} play a role.[94] Other factors synergize with or inhibit the effects of ACTH on the adrenal cortex, including angiotensin II, activin, inhibin, and cytokines (tumor necrosis factor-α and leptin).[95] Cell-to-cell communication via gap junctions is also important in mediating the effects of ACTH.[96]

ACTH produces both immediate and chronic effects on the adrenal gland; the end result is the stimulation of adrenal steroidogenesis and growth. Acutely, steroidogenesis is stimulated through a StAR-mediated increase in cholesterol delivery to the P450 11A1 enzyme in the inner mitochondrial membrane.[24] Chronically (within 24–26 hours of exposure), ACTH acts to increase the synthesis of all steroidogenic CYP enzymes (P450 11A1, P450 17A1, P450 21A2, P450 11B1) in addition to adrenodoxin,[97,98] the effects of which are mediated at the transcriptional level. ACTH increases synthesis of the LDL and HDL receptors and possibly also synthesis of 3-hydroxy-3-methylglutaryl (HMG)–CoA reductase, the rate-limiting step in cholesterol biosynthesis. ACTH increases adrenal weight by inducing both hyperplasia and hypertrophy. Adrenal atrophy is a feature of ACTH deficiency.

Mineralocorticoid Secretion: The Renin-Angiotensin-Aldosterone Axis

Aldosterone is secreted from the ZG under the control of three principal secretagogues: angiotensin II, potassium, and, to a lesser extent, ACTH (see Fig. 15.7). Other factors, notably somatostatin, heparin, atrial natriuretic factor, and dopamine, can directly inhibit aldosterone synthesis. The secretion of aldosterone and its intermediary 18-hydroxylated metabolites is restricted to the ZG because of the zone-specific expression of P450 11B2 (aldosterone synthase).[99] Corticosterone and DOC, synthesized in both the ZF and ZG, can act as mineralocorticoids, which becomes significant in some clinical diseases, notably some forms of congenital adrenal hyperplasia (CAH) and adrenal tumors. Similarly, it is now established that cortisol can act as a mineralocorticoid in the setting of impaired metabolism of cortisol to cortisone by the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2); this is important in patients with hypertension, ectopic ACTH syndrome, or renal disease. The renin-angiotensin system is described in detail in Chapter 16.

Angiotensin II and potassium stimulate aldosterone secretion principally by increasing the transcription of *CYP11B2* through common intracellular signaling pathways. cAMP response elements in the 5′ region of the *CYP11B2* gene are activated after an increase in intracellular Ca^{2+} and activation of calmodulin kinases. The potassium effect is mediated through membrane depolarization and opening of calcium channels and the angiotensin II effect after binding of angiotensin II to the surface AT_1 receptor and activation of phospholipase C.[99]

The effect of ACTH on aldosterone secretion is modest and differs in the acute and chronic situation (see Chapter 16). An acute bolus of ACTH will increase aldosterone secretion, principally by stimulating the early pathways of adrenal steroidogenesis (see earlier discussion), but circulating levels increase by no more than 10% to 20% above baseline values. ACTH has no effect on *CYP11B2* gene transcription or enzyme activity. Chronic continual ACTH stimulation has either no effect or an inhibitory effect on aldosterone production, possibly because of receptor downregulation or suppression of angiotensin II–stimulated secretion because of a mineralocorticoid effect of cortisol, DOC, or corticosterone. Dopamine and atrial natriuretic peptide inhibit aldosterone secretion, as does heparin.

These separate lines of control—through the HPA axis for glucocorticoid biosynthesis and via the renin-angiotensin system for mineralocorticoid synthesis—have important clinical consequences. Patients with primary adrenal failure invariably have both cortisol and aldosterone deficiency, whereas patients with ACTH deficiency due to pituitary disease have glucocorticoid deficiency but normal aldosterone concentrations because the renin-angiotensin system is intact.

Adrenal Androgen Secretion

Adrenal-derived androgens represent an important component (>50%) of circulating androgens in premenopausal women.[100] In men, this contribution is much smaller because of the testicular production of androgens, but adrenal androgen excess even in men may be of clinical significance, notably in patients with CAH, which results in a suppression of the hypothalamic-pituitary-gonadal axis. The adult adrenal secretes approximately 4 mg per day of DHEA, 7 to 15 mg per day of DHEAS, 1.5 mg of androstenedione (AD), and 0.05 mg per day of testosterone. More recently it has been recognized that the 11-oxygenated 19-carbon androgens are important adrenal androgens, with 11β-hydroxyandrostenedione (11OHAD) being the most highly secreted, being derived from AD via the actions of P450 11B1.[101] 11-ketotestosterone (11KT) is derived from 11OHAD following oxidation and reduction, and has equimolar affinity at the androgen receptor as testosterone. These androgens, and 11-ketoandrostendione and 11β-hydroxytestosterone, are significantly increased in patients with CAH due to 21-hydroxylase deficiency and are adrenal-specific biomarkers of androgen excess.[102]

DHEA is a crucial precursor of human sex steroid biosynthesis and exerts androgenic or estrogenic activity after conversion by the activities of 3βHSD, 17βHSD, and aromatase; these enzymes are expressed in peripheral target tissues, a fact that is of clinical importance in many diseases.[103] Some studies have postulated direct effects of DHEA acting as a classic hormone in peripheral tissues. Specific plasma membrane receptors have been identified but await full characterization.[104] Conventionally, desulfated DHEA is thought to be converted downstream to a biologically active hormone. Serum DHEAS was previously thought to represent a circulating storage pool for DHEA regeneration, but it was later suggested that conversion of DHEAS to DHEA by steroid sulfatase plays a minor role in adult physiology and that the equilibrium between serum DHEA and DHEAS is mainly regulated by SULT2A1 activity. This implies that serum DHEAS may not always appropriately reflect the active DHEA pool, particularly if SULT2A1 activity is impaired, as in the inflammatory stress response.[105]

ACTH stimulates androgen secretion; DHEA (but not DHEAS because of its increased plasma half-life) and androstenedione demonstrate a circadian rhythm similar to that of cortisol.[106] However, there are many discrepancies between adrenal androgen and glucocorticoid secretion, leading to the suggestion of an additional cortical androgen-stimulating hormone (CASH). Many putative CASHs have been proposed, including POMC derivatives such as joining peptide, prolactin, and insulin-like growth factor type 1 (IGF1), but conclusive proof is lacking. Efficient adrenal steroidogenesis toward androgen synthesis is crucially dependent on the relative activities of 3βHSD and 17α-hydroxylase and, in particular, on the 17,20-lyase activity of 17α-hydroxylase. Factors that determine whether the 17-hydroxylated substrates will undergo 21-hydroxylation to form glucocorticoid or side-chain cleavage by 17α-hydroxylase to form DHEA and androstenedione are unresolved and seem likely to be important in defining the activity of any putative CASH (Table 15.4).

TABLE 15.4 Dissociation of Adrenal Androgen and Glucocorticoid Secretion: Evidence for an Adrenal-Stimulating Hormone

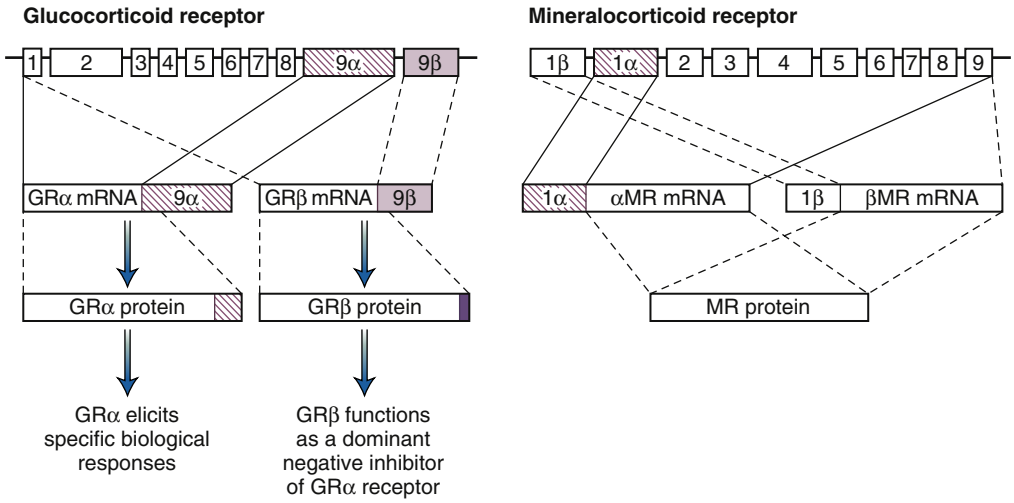
Dexamethasone studies: Complete cortisol suppression with chronic high-dose dexamethasone; DHEA falls by only 20% (lower sensitivity of DHEA to acute low-dose dexamethasone administration causing ACTH suppression).
Adrenarche: Clinically significant rise in circulating DHEA at 6–8 years of age; cortisol production unaltered.
Aging: Reduction in DHEA production; no change in cortisol.
Anorexia nervosa and illness: Fall in DHEA, no change (or increase) in cortisol.

DHEA, Dehydroepiandrosterone.

Corticosteroid Hormone Action

Receptors and Gene Transcription

Both cortisol and aldosterone exert their effects after uptake of free hormone from the circulation and binding to intracellular receptors; these are termed, respectively, the *glucocorticoid receptor* (GR, encoded by *NR3C1*) and the *mineralocorticoid receptor* (MR, encoded by *NR3C2*).[107–109] These are members of the thyroid/steroid hormone receptor superfamily of transcription factors; they consist of a carboxy-terminal ligand-binding domain, a central DNA-binding domain that interacts with specific DNA sequences on target genes, and an amino-terminal hypervariable region. Although only single genes encode the GR and MR, splice variants (i.e., GRα and GRβ) have been described in both receptor types; this, together with tissue-specific post-translational modification (phosphorylation, sumoylation, and ubiquitination), is thought to account for many of the diverse actions of corticosteroids (Fig. 15.9).[110,111]



• **Fig. 15.9** Schematic structure of the human genes encoding the glucocorticoid receptor (GR) and mineralocorticoid receptor (MR). In both cases, splice variants have been described. In the case of the GR, there is evidence that the GRβ isoform can act as a dominant negative inhibitor of GRα action. *mRNA,* messenger ribonucleic acid.

Glucocorticoid hormone action has been studied in more depth than mineralocorticoid action. The binding of steroid to the GRα in the cytosol results in activation of the steroid-receptor complex through a process that involves the dissociation of heat shock proteins (HSP90 and HSP70).[112] Following translocation to the nucleus, gene transcription is stimulated or repressed after binding of the dimerized GR-ligand complex to a specific DNA sequence in the promoter regions of target genes.[113] This sequence, known as the *glucocorticoid-response element* (GRE), is invariably a palindromic CGTACAnnnTGTACT sequence that binds with high affinity to two loops of DNA within the DNA-binding domain of the GR (zinc fingers). This stabilizes the RNA polymerase II complex, facilitating gene transcription. The GRβ variant may act as a dominant negative regulator of GRα transactivation.[110]

Naturally occurring mutations in the GR (as seen in patients with glucocorticoid resistance) and GR mutants generated in vitro have highlighted critical regions of the receptor that are responsible for binding and transactivation,[114] but numerous other factors are required (e.g., coactivators, corepressors[115]), and this may make responses tissue specific. This is a rapidly evolving field and beyond the scope of this chapter. However, the interaction between GR and two particular transcription factors are important in mediating the anti-inflammatory effects of glucocorticoids and explain the effect of glucocorticoids on genes that do not contain obvious GREs in their promoter regions.[116] Activator protein 1 (AP1) comprises Fos and Jun subunits and is a proinflammatory transcription factor induced by a series of cytokines and phorbol ester. The GR-ligand complex can bind to c-Jun and prevent interaction with the AP1 site, thereby mediating the so-called transrepressive effects of glucocorticoids.[117] Similarly, functional antagonism exists between the GR and nuclear factor-κB (NF-κB), a ubiquitously expressed transcription factor that activates a series of genes involved in lymphocyte development, inflammatory response, host defense, and apoptosis (Fig. 15.10).[118] In keeping with the diverse array of actions of cortisol, many hundreds of glucocorticoid-responsive genes have been identified. Some glucocorticoid-induced genes and repressed genes are listed in Table 15.5.

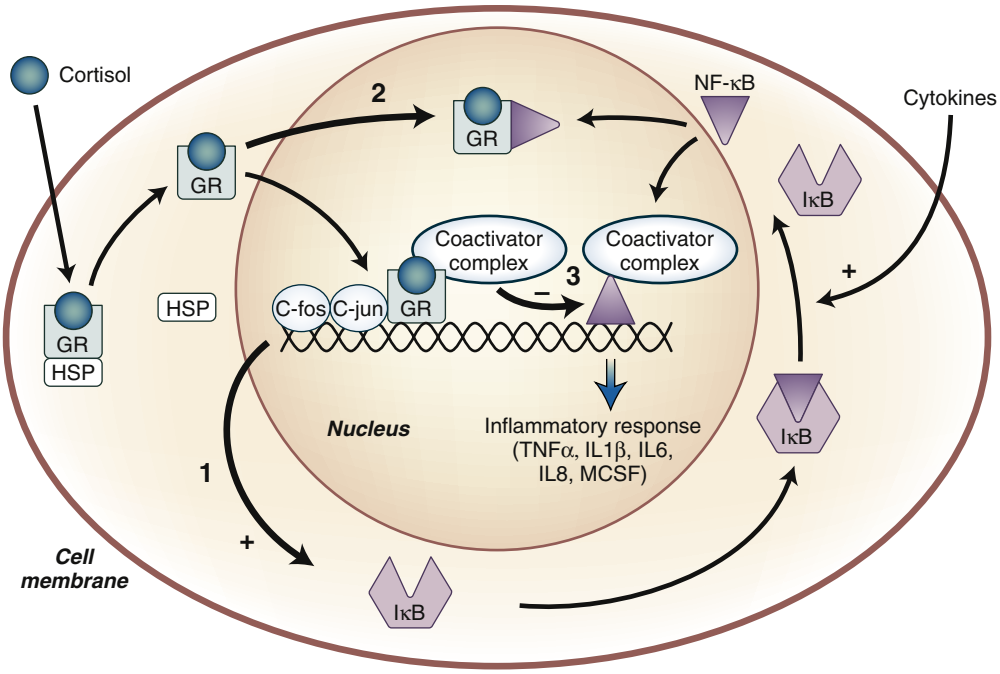
In contrast to the diverse actions of glucocorticoids, mineralocorticoids have a more restricted role, principally stimulation of epithelial sodium transport in the distal nephron, distal colon, and salivary glands.[119] This action is mediated through induction of the apical sodium channel (comprising three subunits—α, β, and γ)[120] and the α_1 and β_1 subunits of the basolateral sodium-potassium adenosine triphosphatase pump (Na^+/K^+-ATPase)[121] through transcriptional regulation of serum-induced and glucocorticoid-induced kinase (SGK).[122] Aldosterone binds to the MR, principally in the cytosol (although there is evidence for expression of the unliganded MR in the nucleus), and the hormone-receptor complex is then translocated to the nucleus (Fig. 15.11).

The MR and GR share considerable homology—57% in the steroid-binding domain and 94% in the DNA-binding domain. It is perhaps not surprising, therefore, that there is promiscuity of ligand binding, with aldosterone (and the synthetic mineralocorticoid, fludrocortisone) binding to the GR and cortisol binding to the MR. For the MR, this is particularly impressive: in vitro, the MR has the same inherent affinity for aldosterone, corticosterone, or cortisol.[108] Specificity on the MR is conferred through the "prereceptor" metabolism of cortisol via the enzyme 11βHSD2, which converts cortisol and corticosterone to inactive 11-keto metabolites, enabling aldosterone to bind to the MR.[123,124] Mineralocorticoid hormone action was extended beyond this classic action in sodium-transporting epithelia with the demonstration that aldosterone can induce cardiac fibrosis and inflammatory changes in renal vasculature. The underlying signaling pathways remain to be fully clarified, but the effects are reversible with MR antagonists.[125]

Finally, for both glucocorticoids and mineralocorticoids, there is accumulating evidence for so-called nongenomic effects involving hormone response obviating the genomic GR or MR. A series of responses have been reported to occur within seconds or minutes after exposure to corticosteroids and are thought to be mediated by as yet uncharacterized membrane-coupled receptors.[126–128]

Corticosteroid-Binding Globulin and Corticosteroid Hormone Metabolism

More than 90% of circulating cortisol is bound predominantly to the α_2-globulin, corticosteroid-binding globulin (CBG).[129] This 383–amino acid protein is synthesized in the liver and binds



• **Fig. 15.10** The anti-inflammatory action of glucocorticoids. Cortisol binds to the cytoplasmic glucocorticoid receptor (GR). Conformational changes in the receptor-ligand complex result in dissociation from heat shock proteins (HSP70 and HSP90) and migration to the nucleus. Binding occurs to specific DNA motifs—glucocorticoid response elements—in association with the activator protein 1 (AP1) comprising C-fos and C-jun. Glucocorticoids mediate their anti-inflammatory effects through several mechanisms: (1) the inhibitory protein IκB, which binds and inactivates nuclear factor-κB (NF-κB), is induced; (2) the GR-cortisol complex is able to bind NF-κB and thereby prevent initiation of an inflammatory process; (3) GR and NF-κB compete for the limited availability of coactivators, which include cyclic adenosine monophosphate response element–binding protein (CREB) and steroid receptor coactivator-1. *IL,* interleukin; *MCSF,* macrophage colony-stimulating factor; *TNFα,* tumor necrosis factor-α.

TABLE 15.5 Some of the Genes Regulated by Glucocorticoids or Glucocorticoid Receptors

Site of Action	Induced Genes	Repressed Genes
Immune system	IκB (nuclear factor-κB inhibitor) Haptoglobin T-cell receptor (TCR)–ζ p21, p27, and p57 Lipocortin	Interleukins Tumor necrosis factor-α (TNFα) Interferon-γ E-selectin Intercellular adhesion molecule-1 Cyclooxygenase 2 Inducible nitric oxide synthase (iNOS)
Metabolic	PPAR-γ Tyrosine aminotransferase Glutamine synthase Glycogen synthase Glucose-6-phosphatase PEPCK Leptin γ-Fibrinogen Cholesterol 7α-hydroxylase C/EBP/β	Tryptophan hydroxylase Metalloprotease
Bone	Androgen receptor Calcitonin receptor Alkaline phosphatase IGFBP6	Osteocalcin Collagenase
Channels and transporters	ENaCα, ENaCβ, and ENaCγ SGK Aquaporin 1	

TABLE 15.5 Some of the Genes Regulated by Glucocorticoids or Glucocorticoid Receptors—cont'd

Site of Action	Induced Genes	Repressed Genes
Endocrine	Basic fibroblast growth factor (bFGF) Vasoactive intestinal peptide Endothelin Retinoid X receptor GHRH receptor Natriuretic peptide receptors	Glucocorticoid receptor Prolactin POMC/CRH PTHrP Vasopressin

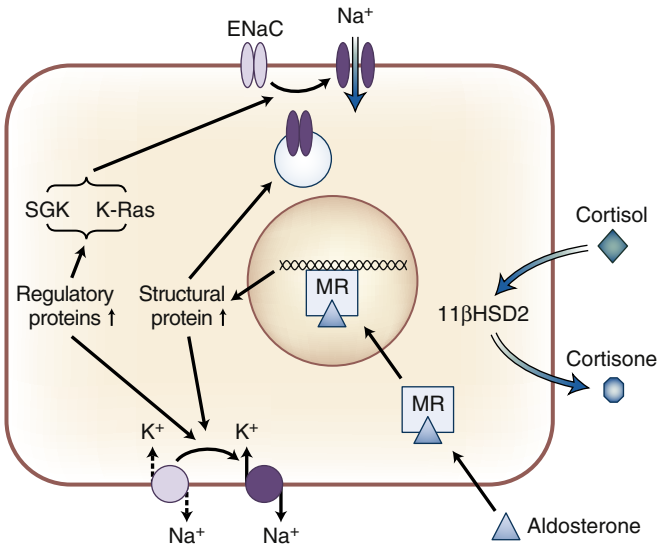
CRH, Corticotropin-releasing hormone; *C/EBP/β*, CAAT-enhancer binding protein-β; *ENaC*, epithelial sodium channel; *GHRH*, growth hormone–releasing hormone; *IGFBP6*, insulin-like growth factor–binding protein 6; *PEPCK*, phosphoenolpyruvate carboxykinase; *POMC*, pro-opiomelanocortin; *PPAR*, peroxisome proliferator-activated receptor; *PTHrP*, parathyroid hormone-related protein; *SGK*, serum- and glucocorticoid-induced kinase.

Modified from McKay LI, Cidlowski JA. Molecular control of immune/inflammatory responses: interactions between nuclear factor-κB and steroid receptor-signalling pathways. *Endocr Rev.* 1999;20:435–459.



• **Fig. 15.11** Mineralocorticoid hormone action. An epithelial cell in the distal nephron or distal colon is depicted. The much higher concentrations of cortisol are inactivated by the type 2 isozyme of 11β-hydroxysteroid dehydrogenase (11βHSD2) to cortisone, permitting the endogenous ligand, aldosterone, to bind to the mineralocorticoid receptor (MR). Relatively few mineralocorticoid target genes have been identified, but they include serum-induced and glucocorticoid-induced kinase (SGK), subunits of the epithelial sodium channel (ENaC), and basolateral Na^+/K^+-adenosine triphosphatase.

cortisol with high affinity. Affinity for synthetic corticosteroids is negligible except for prednisolone, which has an affinity for CBG approximately half that of cortisol. Circulating CBG concentrations are approximately 700 nmol/L. Levels are increased by estrogens and in some patients with chronic active hepatitis; they are reduced by glucocorticoids and in patients with cirrhosis, nephrosis, and hyperthyroidism. The estrogen effect can be marked, with levels increasing twofold to threefold across pregnancy, a fact that should be taken into account when measuring plasma total cortisol in pregnancy and in women taking estrogens.

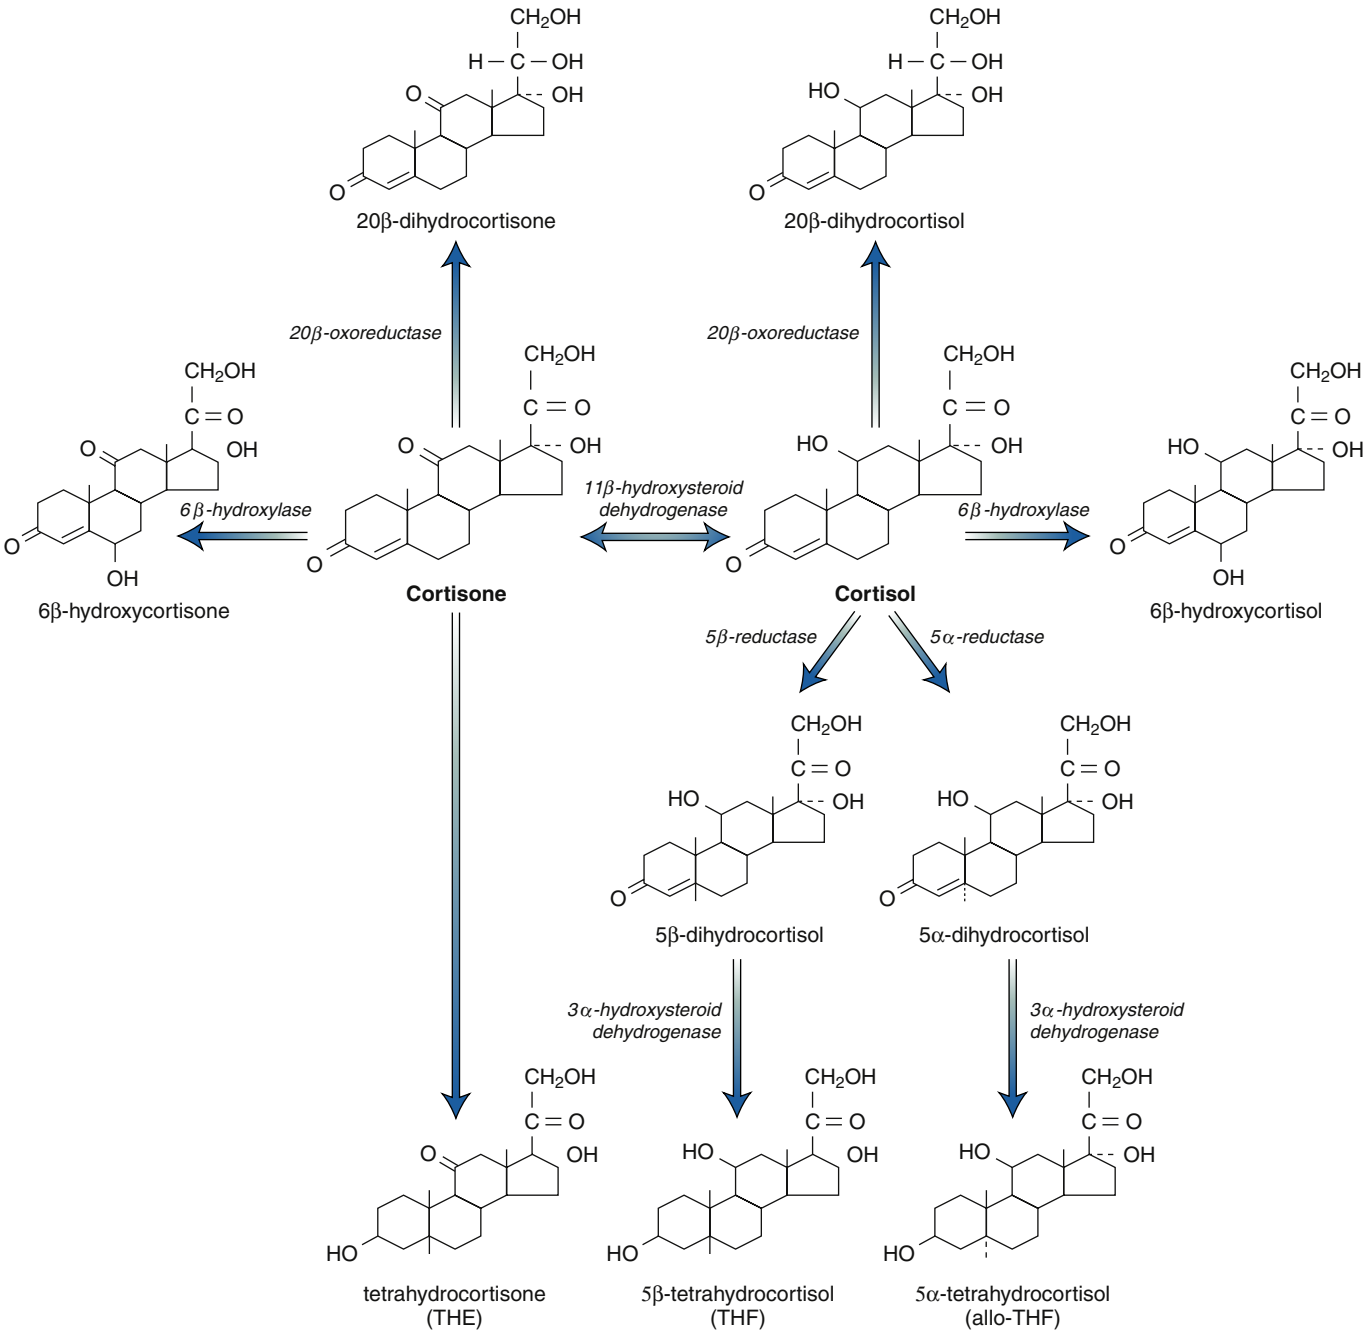
CBG plays a key role in determining circulating cortisol levels.[130] Inherited abnormalities in CBG synthesis are much rarer than those described for thyroxine-binding globulin but include cases of elevated CBG, partial or complete deficiency of CBG, and CBG variants with reduced affinity for cortisol.[131,132] In each case, alterations in CBG concentrations change the total circulating cortisol concentrations accordingly, but free cortisol concentrations are normal. Only this free circulating fraction is available for transport into tissues for biologic activity. The excretion of free cortisol through the kidneys results in *urinary free cortisol*, which represents less than 1% of the total cortisol secretion.

The circulating half-life of cortisol varies between 70 and 120 minutes. The major steps in cortisol metabolism are depicted in Fig. 15.12[133] and can be summarized as follows:

- Interconversion of the 11-hydroxyl group (cortisol, Kendall compound F) to the 11-oxo group (cortisone, compound E) through activity of the 11βHSD system (EC 1.1.1.146).[134,135] The metabolism of cortisol and that of cortisone then follow similar pathways.
- Reduction of the C4-5 double bond to form dihydrocortisol or dihydrocortisone, followed by reduction of the 3-oxo group to form tetrahydrocortisol (THF) or tetrahydrocortisone (THE). The reduction of the C4-5 double bond can be carried out by either 5β-reductase or 5α-reductase, yielding, respectively, 5β-tetrahydrocortisol (THF) and 5α-THF (allo-THF). In normal subjects, the ratio of THF to allo-THF is 2:1. THF, allo-THF, and THE are rapidly conjugated with glucuronic acid and excreted in the urine.
- Further reduction of the 20-oxo group by either 20αHSD or 20βHSD to yield α-cortols and β-cortols and cortolones from cortisol and cortisone, respectively. Reduction of the C20 position may also occur without A-ring reduction, giving rise to 20α-hydroxycortisol and 20β-hydroxycortisol.
- Hydroxylation at C6 primarily by P450 3A4 to form 6β-hydroxycortisol.
- Cleavage of THF and THE to the C19 steroids, 11-hydroxyandrosterone or 11-oxo-androsterone, or etiocholanolone.
- Oxidation of the C21 position or cortols and cortolones to form the extremely polar metabolites, cortolic and cortolonic acids.

Approximately 50% of secreted cortisol appears in the urine as THF, allo-THF, and THE; 25% as cortols/cortolones; 10% as C19 steroids; and 10% as cortolic/cortolonic acids. The remaining metabolites are free unconjugated steroids (cortisol, cortisone, and their 6β-metabolites, and 20α/20β-metabolites).

The principal site of cortisol metabolism has been considered to be the liver, but many of the enzymes listed have been described in mammalian kidney, notably the interconversion of cortisol to cortisone by 11βHSD2. Quantitatively, this is the most important pathway. Furthermore, the bioactivity of glucocorticoids is in part related to the hydroxyl group at C11; because cortisone with a C11-oxo group is an inactive steroid, expression of 11βHSD in peripheral tissues plays a crucial role in regulating corticosteroid hormone action. Two distinct 11βHSD isozymes have been reported: type 1, reduced nicotinamide adenine dinucleotide phosphate (NADPH)–dependent oxo-reductase expressed principally in the liver, which confers bioactivity on orally administered cortisone by converting it to cortisol,[135] and a type 2, nicotinamide adenine dinucleotide (NAD)–dependent dehydrogenase. It is the 11βHSD2, coexpressed with the MR in



• **Fig. 15.12** The principal pathways of cortisol metabolism. Interconversion of hormonally active cortisol to inactive cortisone is catalyzed by two isozymes of 11β-hydroxysteroid dehydrogenase (11βHSD), with 11βHSD1 principally converting cortisone to cortisol and 11βHSD2 doing the reverse. Cortisol can be hydroxylated at the C6 and C20 positions. A ring reduction is undertaken by 5α-reductase or 5β-reductase and 3αHSD.

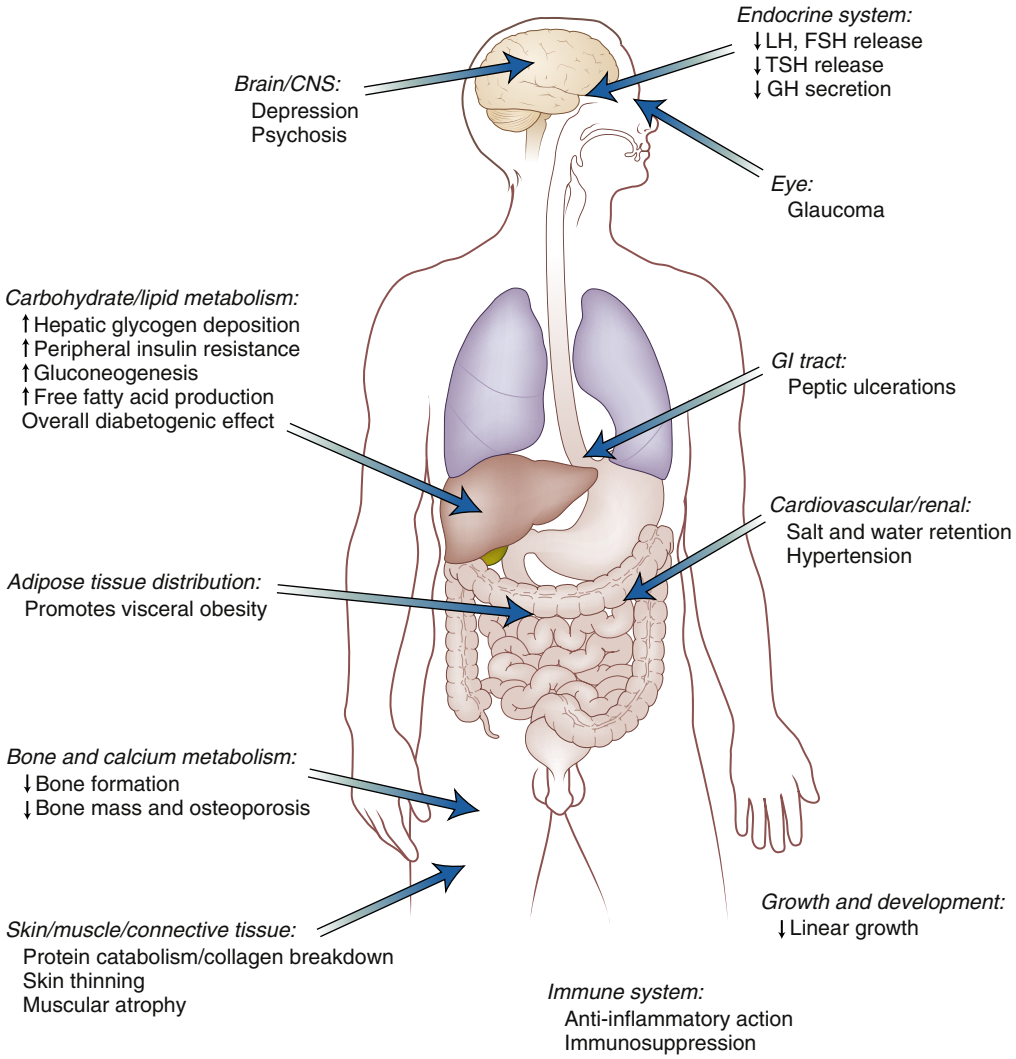
the kidney, colon, and salivary gland, that inactivates cortisol to cortisone and permits aldosterone to bind to the MR in vivo. If this enzyme-protective mechanism is impaired, cortisol is able to act as a mineralocorticoid; this explains some forms of endocrine hypertension (apparent mineralocorticoid excess, licorice ingestion) and the mineralocorticoid excess state that characterizes the ectopic ACTH syndrome.[132,136]

Hyperthyroidism results in increased cortisol metabolism and clearance, and hypothyroidism produces the converse, principally because of an effect of thyroid hormone on hepatic 11βHSD1 and 5α/5β-reductases.[135] IGF1 increases cortisol clearance by inhibiting hepatic 11βHSD1 (conversion of cortisone to cortisol).[137] 6β-Hydroxylation is normally a minor pathway, but cortisol itself induces 6β-hydroxylase activity, so that 6β-hydroxycortisol excretion is markedly increased in patients with Cushing syndrome.[138] Some drugs, notably rifampicin and phenytoin, induce P450 3A4 expression and increase cortisol clearance through this pathway.[139] Patients with renal disease have impaired cortisol clearance because of reduced conversion of renal cortisol to cortisone.[140] These observations have clinical implications for patients with thyroid disease, acromegaly, or renal disease and for patients taking cortisol replacement therapy. Adrenal crisis has been reported in steroid-replaced addisonian patients given rifampicin,[141] and hydrocortisone replacement therapy may need to be increased in treated patients who develop hyperthyroidism or reduced in patients with untreated growth hormone (GH) deficiency.

Aldosterone is also metabolized in the liver and kidneys. In the liver, it undergoes tetrahydro reduction and is excreted in the urine as a tetrahydroaldosterone 3-glucuronide derivative. However, glucuronide conjugation at the 18 position occurs directly in the kidney, as does 3α and 5α/5β metabolism of the free steroid.[142] Because of the aldehyde group at the C18 position, aldosterone is not metabolized by 11βHSD2.[143] Hepatic aldosterone clearance is reduced in patients with cirrhosis, ascites, or severe congestive heart failure.

Effects of Glucocorticoids

The principal sites of action of glucocorticoids and some of the consequences of glucocorticoid excess are shown in Fig. 15.13.



• **Fig. 15.13** The principal sites of action of glucocorticoids in humans, highlighting some of the consequences of glucocorticoid excess. *CNS,* central nervous system; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GI,* gastrointestinal; *LH,* luteinizing hormone; *TSH,* thyroid-stimulating hormone.

Carbohydrate, Protein, and Lipid Metabolism

Glucocorticoids increase blood glucose concentrations through their action on glycogen, protein, and lipid metabolism. In the liver, cortisol stimulates glycogen deposition by increasing glycogen synthase and inhibiting the glycogen-mobilizing enzyme, glycogen phosphorylase.[144] Hepatic glucose output increases through the activation of key enzymes involved in gluconeogenesis, principally glucose-6-phosphatase and phosphoenolpyruvate carboxykinase (PEPCK).[145,146] In peripheral tissues (e.g., muscle, fat), cortisol inhibits glucose uptake and utilization.[147] In adipose tissue, lipolysis is activated, resulting in the release of free fatty acids into the circulation. An increase in total circulating cholesterol and triglycerides is observed, but HDL cholesterol levels fall. Glucocorticoids also have a permissive effect on other hormones, including catecholamines and glucagon. The result is insulin resistance and an increase in blood glucose concentrations, at the expense of protein and lipid catabolism.

Glucocorticoids stimulate adipocyte differentiation, promoting adipogenesis through the transcriptional activation of key differentiation genes, including lipoprotein lipase, glycerol-3-phosphate dehydrogenase, and leptin.[148] Long-term effects of glucocorticoid excess on adipose tissue are more complex, at least in humans, in whom the deposition of visceral or central adipose tissue is stimulated,[149] providing a useful discriminatory sign for the diagnosis of Cushing syndrome. The predilection for visceral obesity may relate to the increased expression of the GR[150] and 11βHSD1 in omental compared with subcutaneous adipose tissue.[151]

Skin, Muscle, and Connective Tissue

In addition to inducing insulin resistance in muscle tissue, glucocorticoids also cause catabolic changes in muscle, skin, and connective tissue. In the skin and connective tissue, glucocorticoids inhibit epidermal cell division and DNA synthesis and reduce synthesis and production of collagen.[152] In muscle, glucocorticoids cause atrophy (but not necrosis), which seems to be specific for type II (phasic) muscle fibers. Muscle protein synthesis is reduced.

Bone and Calcium Metabolism

Glucocorticoids inhibit osteoblast function, which is thought to account for the osteopenia and osteoporosis that especially affect the axial skeleton and characterize glucocorticoid excess.[153] Up to 1% of Western populations are taking long-term glucocorticoid therapy,[154] and glucocorticoid-induced osteoporosis is becoming a prevalent health concern, affecting 50% of patients treated with corticosteroids for longer than 12 months. However, the complication perhaps most feared by physicians is osteonecrosis. Osteonecrosis (also termed *avascular necrosis*) produces rapid and focal deterioration of bone quality and primarily affects the femoral head, leading to pain and ultimately to collapse of the bone, often necessitating hip replacement. It can affect individuals of any age and may occur with relatively low doses of glucocorticoids (e.g., during corticosteroid replacement therapy for adrenal failure).[155] Importantly, defects may not be detectable on conventional radiographs but are readily seen on magnetic resonance imaging (MRI). Glucocorticoid-induced osteocyte apoptosis has been implicated in the pathogenesis of the condition,[156] and the lack of a direct role for an interrupted blood supply suggests that the term *osteonecrosis* is preferable to *avascular femoral necrosis*. However, there is still no explanation for individual susceptibility.

Glucocorticoids also induce negative calcium balance by inhibiting intestinal calcium absorption and increasing renal calcium excretion. As a consequence, parathyroid secretion is usually increased. In children, glucocorticoids suppress growth, but the increases in body mass index (BMI) are thought to offset a deleterious effect on bone mineral density.[157]

Salt and Water Homeostasis and Blood Pressure Control

Glucocorticoids increase blood pressure by a variety of mechanisms involving actions on the kidney and vasculature.[158] In vascular smooth muscle, they increase sensitivity to pressor agents such as catecholamines and angiotensin II while reducing nitric oxide–mediated endothelial dilatation. Angiotensinogen synthesis is increased by glucocorticoids.[159] In the kidney, depending on the activity of 11βHSD2, cortisol can act on the distal nephron to cause sodium retention and potassium loss (mediated via the MR).[136] Elsewhere across the nephron, glucocorticoids increase the glomerular filtration rate, proximal tubular epithelial sodium transport, and free water clearance.[160] This last effect involves antagonism of the action of vasopressin and explains the dilutional hyponatremia seen in patients with glucocorticoid deficiency.[161]

Anti-inflammatory Actions and the Immune System

Glucocorticoids suppress immunologic responses, and this action has been the stimulus to develop a series of highly potent pharmacologic glucocorticoids to treat a variety of autoimmune and inflammatory conditions. The inhibitory effects are mediated at many levels. In the peripheral blood, glucocorticoids reduce lymphocyte counts acutely (T lymphocytes > B lymphocytes) by redistributing lymphocytes from the intravascular compartment to the spleen, lymph nodes, and bone marrow. Conversely, neutrophil counts increase after glucocorticoid administration. Eosinophil counts rapidly fall, an effect that was historically used as a bioassay for glucocorticoids. The immunologic actions of glucocorticoids involve direct actions on both T and B lymphocytes, including inhibition of immunoglobulin synthesis and stimulation of lymphocyte apoptosis. Inhibition of cytokine production from lymphocytes is mediated through inhibition of the action of NF-κB. NF-κB plays a crucial and generalized role in inducing cytokine gene transcription; glucocorticoids can bind directly to NF-κB to prevent nuclear translocation, and they induce NF-κB inhibitor, which sequesters NF-κB in the cytoplasm, thereby inactivating its effect.[118]

Additional anti-inflammatory effects involve the inhibition of monocyte differentiation into macrophages and macrophage phagocytosis and cytotoxic activity. Glucocorticoids reduce the local inflammatory response by preventing the actions of histamine and plasminogen activators. Prostaglandin synthesis is impaired through the induction of lipocortins, which inhibit phospholipase A2 activity.[162]

Central Nervous System and Mood

Clinical observations of patients with glucocorticoid excess and deficiency reveal that the brain is an important target tissue for glucocorticoids, with depression, euphoria, psychosis, apathy, and lethargy being important manifestations. Both GRs and MRs are expressed in discrete regions of the rodent brain, including hippocampus, hypothalamus, cerebellum, and cortex.[163] Glucocorticoids cause neuronal death, notably in the hippocampus[164]; this effect may underlie the interest in glucocorticoids in relation to cognitive function, memory, and neurodegenerative diseases such as Alzheimer disease.[165] Local blockade of cortisol generation by

11βHSD1 has been shown to improve cognitive function.[166] DHEA has been shown to have neuroprotective effects in the hippocampus region.[167] P450 7B1, an enzyme that metabolizes DHEA to its 7α-hydroxylated metabolite, is highly expressed in brain, but expression was decreased in dentate neurons in the hippocampus.[168]

Eye

In the eye, glucocorticoids act to raise intraocular pressure through an increase in aqueous humor production and deposition of matrix within the trabecular meshwork, which inhibits aqueous drainage. Steroid-induced glaucoma appears to have a genetic predisposition, but the underlying mechanisms are unknown.[169]

Gut

Long-term but not acute administration of glucocorticoids increases the risk of developing peptic ulcer disease.[170] Pancreatitis with fat necrosis is reported in patients with glucocorticoid excess. The GR is expressed throughout the gastrointestinal tract, and the MR is expressed in the distal colon; they mediate the corticosteroid control of epithelial ion transport.

Growth and Development

Although glucocorticoids stimulate transcription of the gene encoding GH in vitro, glucocorticoids in excess inhibit linear skeletal growth,[157,171] probably as a result of catabolic effects on connective tissue, muscle, and bone and through inhibition of the effects of IGF1. The results of experiments on mice lacking the GR gene[89] have emphasized the role of glucocorticoids in normal fetal development. In particular, glucocorticoids stimulate lung maturation through the synthesis of surfactant proteins (SP-A, SP-B, and SP-C),[172] and mice lacking the GR die shortly after birth due to hypoxia from lung atelectasis. Glucocorticoids also stimulate the enzyme phenylethanolamine *N*-methyltransferase (PNMT), which converts norepinephrine to epinephrine in adrenal medulla and chromaffin tissue. Mice lacking the GR do not develop an adrenal medulla.[89] There is also adrenomedullary dysplasia and hypofunction in patients with classic 21-hydroxylase deficiency.[173,174]

Endocrine Effects

Glucocorticoids suppress the thyroid axis, probably through a direct action on the secretion of thyroid-stimulating hormone (TSH, thyrotropin). In addition, they inhibit 5′ deiodinase activity that mediates the conversion of thyroxine to active triiodothyronine.

Glucocorticoids also act centrally to inhibit gonadotropin-releasing hormone (GnRH) pulsatility and release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Therapeutic Corticosteroids

Since the dramatic anti-inflammatory effect of cortisone was first demonstrated in the 1950s, a series of synthetic corticosteroids have been developed for therapeutic purposes. These agents are used to treat a diverse variety of human diseases, principally relying on their anti-inflammatory and immunologic actions (Table 15.6). The main corticosteroids used in clinical practice, together with their relative glucocorticoid and mineralocorticoid potencies, are listed in Table 15.7.

The structures of common synthetic steroids are depicted in Fig. 15.14. The biologic activity of a corticosteroid depends on a delta-4, 3-keto, 11β,17α,21-trihydroxyl configuration.[175] Conversion of the C11 hydroxyl group to a C11 keto group (i.e., cortisol to cortisone) inactivates the steroid. The addition of a 1,2 unsaturated bond to cortisol results in prednisolone, which is four times more potent than cortisol in classic glucocorticoid bioassays such as hepatic glycogen deposition, suppression of eosinophils, and anti-inflammatory actions. Prednisone, widely prescribed in the United States, is the cortisone equivalent of prednisolone and relies on conversion by 11βHSD1 in the liver for bioactivity.[176] Potency is further increased by the addition of a 6α-methyl group to prednisolone (methylprednisolone).

Fludrocortisone is a synthetic mineralocorticoid having 125-fold greater potency than cortisol in stimulating sodium reabsorption. This effect is achieved through the addition of a 9α-fluoro group to cortisol. Fludrocortisone also has glucocorticoid potency (12-fold greater than cortisol). The addition of a 16α-methyl group and 1,2 saturated bond to fludrocortisone results in dexamethasone, a highly potent glucocorticoid (25-fold greater potency than cortisol) that has negligible mineralocorticoid activity.[175,177]

TABLE 15.6 Therapeutic Use of Corticosteroids

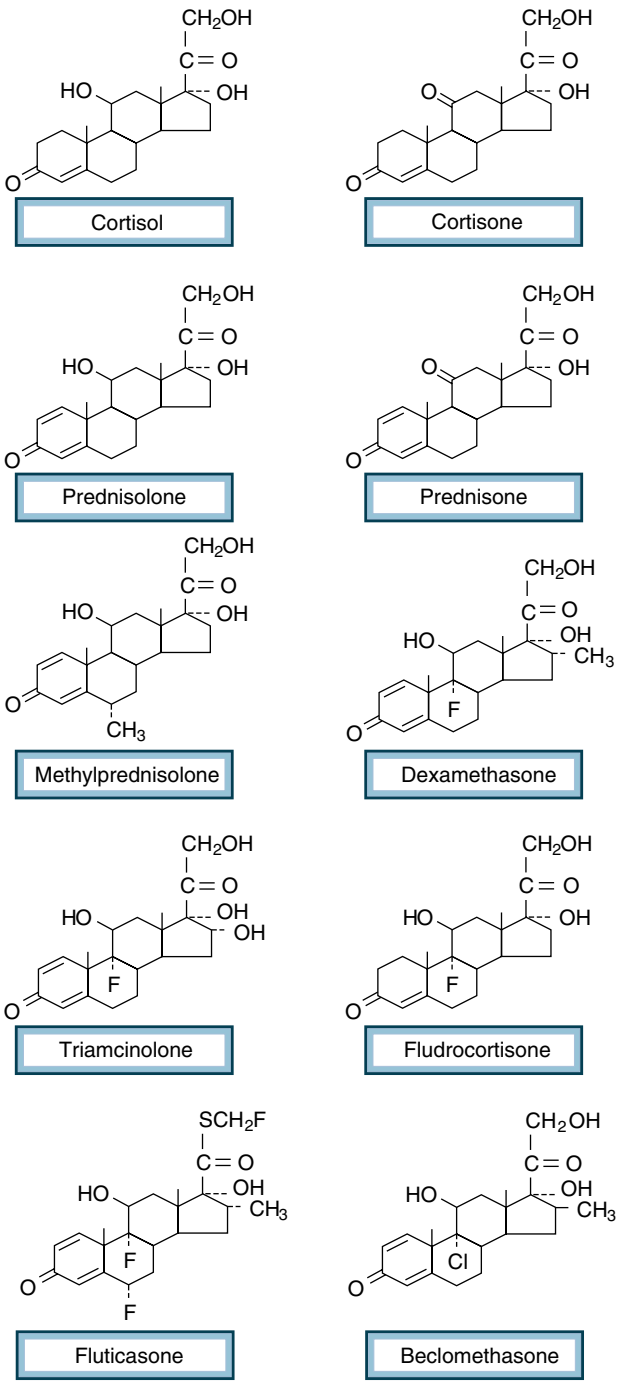
Endocrine: Replacement therapy (Addison disease, pituitary disease, congenital adrenal hyperplasia), Graves orbitopathy
Skin: Dermatitis, pemphigus
Hematology: Leukemia, lymphoma, hemolytic anemia, idiopathic thrombocytopenic purpura
Gastrointestinal: Inflammatory bowel disease (ulcerative colitis, Crohn disease)
Liver: Chronic active hepatitis, transplantation, organ rejection
Renal: Nephrotic syndrome, vasculitides, transplantation, rejection
Central nervous system: Cerebral edema, raised intracranial pressure
Respiratory: Angioedema, anaphylaxis, asthma, sarcoidosis, tuberculosis, obstructive airway disease
Rheumatology: Systemic lupus erythematosus, polyarteritis, temporal arteritis, rheumatoid arthritis
Muscle: Polymyalgia rheumatica, myasthenia gravis

TABLE 15.7 Relative Biologic Potencies of Synthetic Steroids in Bioassay Systems

Steroid	Anti-Inflammatory Action	Hypothalamic-Pituitary-Adrenal Suppression	Salt Retention
Cortisol	1	1	1
Prednisone	3	4	0.75
Prednisolone	3	4	0.75
Methylprednisolone	6.2	4	0.5
Fludrocortisone	12	12	125
Triamcinolone	5	4	0
Dexamethasone	26	17	0

Administration

Widely used synthetic glucocorticoids in respiratory and nasal aerosol sprays are betamethasone, beclomethasone, and fluticasone. Betamethasone has the same structure as dexamethasone but with a 16α-methyl group. Beclomethasone has the same structure as betamethasone apart from the replacement of the 9α-fluoro group with a 9α-chloro group. Fluticasone has the same structure



• **Fig. 15.14** Structures of the natural glucocorticoid cortisol, some of the more commonly prescribed synthetic glucocorticoids, and the mineralocorticoid fludrocortisone. Triamcinolone is identical to dexamethasone except that a 16α-hydroxyl group is substituted for the 16α-methyl group. Betamethasone, another widely used glucocorticoid, has a 16β-methyl group. Beclomethasone is derived from betamethasone by replacement of the 9α-fluoro group with a chloro group. Fluticasone is identical to dexamethasone except that an additional 6α-fluoro group has been added, and the hydroxymethyl group at position 21 has been exchanged by a thiofluoromethyl group.

as dexamethasone with an additional 6α-fluoro group and a 5-fluoromethyl group replacing the hydroxymethyl group.

Corticosteroids are given orally, parenterally, and by numerous topical routes (e.g., eyes, skin, nose, inhalation, rectal suppositories).[177] Unlike hydrocortisone, which has a high affinity for CBG, most synthetic steroids have low affinity for this binding protein and circulate as free steroid (~30%) or bound to albumin (~70%). Circulating half-lives vary depending on individual variability and underlying disease, particularly renal and hepatic impairment. Cortisone acetate should not be used parenterally because it requires metabolism by the liver to active cortisol.

It is beyond the scope of this chapter to describe which steroid should be given and by which route for the nonendocrine conditions listed in Table 15.6. Acute and long-term corticosteroid therapy in patients with hypoadrenalism or CAH is discussed in later sections.

Long-Term Therapy

In addition to the undoubted benefit that corticosteroids provide, there is an increasing incidence of overuse, particularly in patients with respiratory or rheumatologic disease, to such an extent that up to 1% of the population is now prescribed long-term corticosteroid therapy.[154] Because of their established euphoric effect, corticosteroids often make patients feel better but without any objective improvements in underlying disease parameters. In view of the long-term harm of chronic glucocorticoid excess,[178] decisions regarding treatment should be evidence based and subject to regular review based on efficacy and side effects. The endocrinologic consequences of chronic glucocorticoid excess, notably suppression of the HPA axis, are an important aspect of modern clinical practice and are described later (see "Primary and Central Hypoadrenalism"). Endocrinologists need to be aware of the effects of long-term therapy and of steroid withdrawal. Selective glucocorticoid receptor agonists (SEGRAs) are being developed with the aim of dissociating the transrepressive, anti-inflammatory actions of glucocorticoids from the transactivating effects that, by and large, mediate deleterious side effects.[179]

Adrenocortical Diseases

With the exception of common adrenocortical incidentalomas (see upcoming discussion) adrenocortical diseases with a clear clinical phenotype are relatively rare. Their importance lies in their high rates of morbidity and mortality if untreated, coupled with the relative ease of diagnosis and the availability of effective therapy. The diseases are most readily classified on the basis of hormone excess or deficiency (Table 15.8).

Glucocorticoid Excess

Cushing Syndrome

In 1912, Harvey Cushing first described a 23-year-old female with obesity, hirsutism, and amenorrhea, and 20 years later, he postulated that this "polyglandular syndrome" was due to a primary pituitary abnormality causing adrenal hyperplasia.[8] Adrenal tumors were shown to cause the syndrome in some cases,[180] but ectopic ACTH production was not characterized until much later, in 1962.[181] The term *Cushing syndrome* is used to describe all causes, whereas *Cushing disease* is reserved for pituitary-dependent Cushing syndrome.

Cushing syndrome comprises the symptoms and signs associated with prolonged exposure to inappropriately elevated levels of free plasma glucocorticoids. The use of the term *glucocorticoid* in the definition covers excess from both endogenous (cortisol) and exogenous (e.g., prednisolone, dexamethasone) sources. Iatrogenic Cushing syndrome is common,[177,182] occurring to some degree in most patients taking long-term corticosteroid therapy.

TABLE 15.8 Adrenocortical Diseases

Glucocorticoid Excess

Cushing syndrome (pathologic/neoplastic hypercortisolism)
Pseudo-Cushing syndromes (physiologic/nonneoplastic hypercortisolism)

Glucocorticoid Resistance

Glucocorticoid Deficiency

Primary hypoadrenalism
Secondary hypoadrenalism
Postchronic corticosteroid replacement therapy

Congenital Adrenal Hyperplasia

Deficiencies of 21-hydroxylase, 3βHSD, 17α-hydroxylase, 11β-hydroxylase, P450 oxidoreductase, P450 side-chain cleavage, and StAR

Mineralocorticoid Excess

Mineralocorticoid Deficiency

Defects in aldosterone synthesis
Defects in aldosterone action
Hyporeninemic hypoaldosteronism

Adrenal Incidentalomas, Adenomas, and Carcinomas

HSD, Hydroxysteroid dehydrogenase; *StAR,* steroidogenic acute regulatory (protein).

Endogenous causes of Cushing syndrome are rare and result in loss of the normal feedback mechanism of the HPA axis and the normal circadian rhythm of cortisol secretion.

The incidence of Cushing disease is estimated to be 2 to 3 cases per 1 million population per year. The incidence of ectopic ACTH syndrome parallels that of bronchogenic carcinoma, and although 0.5% of lung cancer patients have ectopic ACTH syndrome, rapid progression of the underlying disease often precludes an early diagnosis. Cushing disease and adrenal adenomas are four times more common in women, whereas ectopic ACTH syndrome is more common in men. Neuroendocrine tumors have an incidence of 7 to 8 per 100,000 and may be a rare cause of the ectopic ACTH syndrome.

Clinical Features of Cushing Syndrome

The classic features of Cushing syndrome—centripetal obesity, moon face, hirsutism, and plethora—have been well known since Cushing's initial descriptions in 1912 and 1932 (Figs. 15.15, 15.16, and 15.17). However, this gross clinical picture is not always present, and a high index of suspicion is required in many cases. Once the normal physiologic effects of glucocorticoids are appreciated (see Fig. 15.13), the clinical features of glucocorticoid excess are easier to define. They are summarized in Table 15.9, together with the most discriminatory features that will assist in distinguishing Cushing syndrome from simple obesity.[183,184]

Obesity and Weight Gain

Weight gain and obesity are the most common signs of Cushing syndrome. At least in adults, this weight gain is invariably centripetal in nature.[149,185] In fact, generalized obesity is more common in the general population than it is in patients with Cushing syndrome. One exception is seen in pediatric patients, in whom glucocorticoid excess may result in generalized obesity. In addition to centripetal obesity, patients develop fat depots over the thoracocervical spine (buffalo hump), in the supraclavicular region, and over the cheeks and temporal regions, giving rise to the rounded, moon-like facies. The epidural space, another site of abnormal fat deposition, may lead to neurologic deficits.

Reproductive Organs

Gonadal dysfunction is common, with menstrual irregularity in females and loss of libido in both sexes. Hirsutism is frequently found in female patients, as is acne. The most common form of hirsutism is vellus hypertrichosis on the face; this type should be distinguished from the darker, terminal differentiated hirsutism that may occur because of ACTH-mediated adrenal androgen excess. Hypogonadotropic hypogonadism occurs because of a direct inhibitory effect of cortisol on GnRH pulsatility and LH/FSH secretion, and it is reversible on correction of the hypercortisolism.[186,187]

Psychiatric Features

Psychiatric abnormalities occur in approximately 50% of patients with Cushing syndrome, regardless of cause.[188,189] Agitated depression and lethargy are among the most common problems, but paranoia and overt psychosis are also well recognized. Memory and cognitive function may also be affected, and increased irritability may be an early feature. Insomnia is common, and both rapid eye movement and delta-wave sleep patterns are reduced.[190] Lowering of plasma cortisol by medical or surgical therapy usually results in a rapid improvement in the psychiatric state. Overall quality of life is significantly reduced in patients with Cushing syndrome, particularly affecting physical health and functioning. Quality-of-life scores improve after treatment but do not return to normal.[191]

• **Fig. 15.16** Clinical features of Cushing syndrome. (A) Centripetal and some generalized obesity and dorsal kyphosis in a 30-year-old woman with Cushing disease. (B) Same patient as in (A), showing moon facies, plethora, hirsutism, and enlarged supraclavicular fat pads. (C) Facial rounding, hirsutism, and acne in a 14-year-old girl with Cushing disease. (D) Central and generalized obesity and moon facies in a 14-year-old boy with Cushing disease. (E, F) Typical centripetal obesity with livid abdominal striae seen in a 41-year-old woman (E) and a 40-year-old man (F) with Cushing syndrome. (G) Striae in a 24-year-old patient with congenital adrenal hyperplasia treated with excessive doses of dexamethasone as replacement therapy. (H) Typical bruising and thin skin of a patient with Cushing syndrome. In this case, the bruising occurred without obvious injury.

Bone

In childhood, the most common presentation is poor linear growth and weight gain[155]; as discussed earlier, glucocorticoids have profound effects on growth and development.[171] Many patients with long-standing Cushing syndrome have lost height because of osteoporotic vertebral collapse. This can be assessed by measuring the patient's sitting height or comparing the height with arm span; in normal subjects, height and arm span should be equal. Pathologic fractures, occurring spontaneously or after minor trauma, are not uncommon. Rib fractures, in contrast to those of the vertebrae, are often painless. The radiographic appearance is typical, with exuberant callus formation at the site of the healing fracture. In addition, osteonecrosis of the femoral and humeral heads is a recognized feature of endogenous (although less commonly seen than in exogenous) Cushing syndrome (see Fig. 15.17). Hypercalciuria may lead to renal calculi, but hypercalcemia is not a feature.

Skin

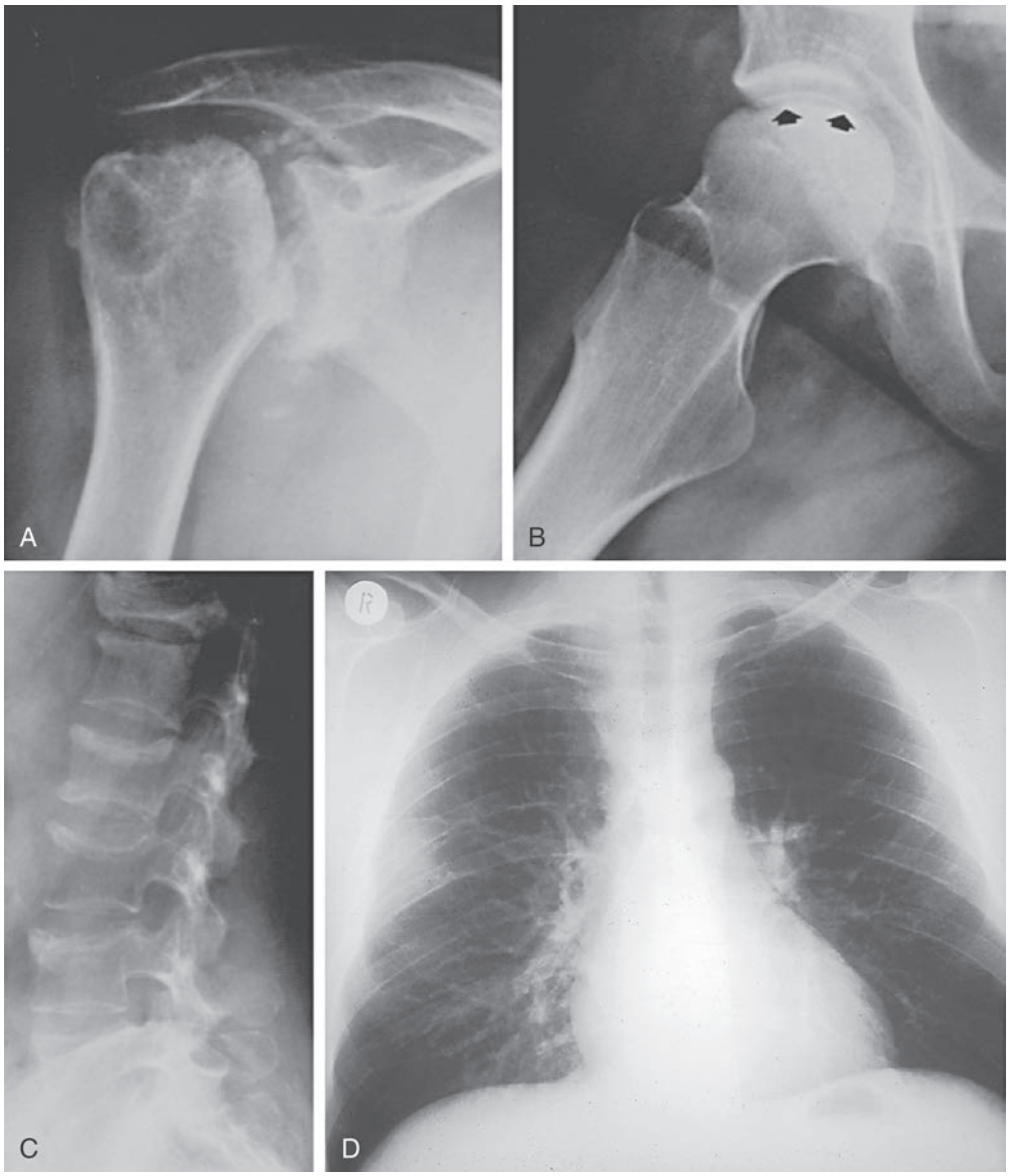
Hypercortisolism results in thinning of the skin and separation and exposure of the subcutaneous vascular tissue. On examination, wrinkling of the skin on the dorsum of the hand may be seen, resulting in a "cigarette paper" appearance (Liddle sign). Minimal trauma may result in bruising, which frequently resembles the appearance of senile purpura. The plethoric appearance of the patient with Cushing syndrome is secondary to the thinning of the skin[192] combined with loss of facial subcutaneous fat and is not caused by true polycythemia. Acne and papular lesions may occur over the face, chest, and back.

The typical, almost pathognomonic, red-purple, nonblanching, livid striae greater than 1 cm in width are most frequently found on the abdomen but may also be present on the upper thighs, breasts, and arms. They are very common in younger patients and less so in those older than 50 years of age. They must be differentiated from the paler, less pigmented striae that occur as a result of pregnancy (striae gravidarum) or in association with rapid weight loss.

Skin pigmentation is rare in Cushing disease but common in the ectopic ACTH syndrome. It arises because of overstimulation of melanocyte receptors by ACTH and possibly POMC-derived peptides.

Muscle

Myopathy and bruising are two of the most discriminatory features of the syndrome.[183] The myopathy of Cushing syndrome involves the proximal muscles of the lower limbs and the shoulder girdle.[193] Complaints of weakness, such as inability to climb stairs or get up from a deep chair, are relatively uncommon, but testing for proximal myopathy by asking the patient to rise from a crouching position often reveals the problem.



• **Fig. 15.17** Bone abnormalities in Cushing disease. (A) Aseptic necrosis of the right humeral head in a 43-year-old woman with Cushing disease of about 8 months of duration. (B) Aseptic necrosis of the right femoral head in a 24-year-old woman with Cushing disease of about 4.5 years of duration. The *arrows* indicate the crescent subchondral radiolucency, best seen in this lateral view. (C) Diffuse osteoporosis, vertebral collapse, and subchondral sclerosis in the same patient shown in (A). (D) Rib fracture in a 38-year-old man with Cushing disease. (A–C, from Phillips KA, Nance Jr EP, Rodriguez RM, et al. Avascular necrosis of bone: a manifestation of Cushing's disease. *South Med J*. 1986;79:825–829.)

Cardiovascular Features

Hypertension is another prominent feature, occurring in up to 75% of cases. Even though epidemiologic data show a strong association between high blood pressure and obesity, hypertension is much more common in patients with Cushing syndrome than in those with simple obesity.[158] This, together with the established metabolic consequences of the disease (diabetes, hyperlipidemia), is thought to explain the increased cardiovascular mortality rate in untreated cases.[194–196] Cardiovascular events are also more common in patients with presumed iatrogenic Cushing syndrome, which results from prescribed corticosteroids.[176] In addition, thromboembolic events may be more common in Cushing patients, but this development appears to be limited to those with ACTH-dependent disease.[197]

Infections

Infections are more common in patients with Cushing syndrome.[198,199] In many instances, infections are asymptomatic and occur because the normal inflammatory response is suppressed. Reactivation of tuberculosis has been reported[200] and has even been the presenting feature in some cases. Fungal infections of the skin (notably tinea versicolor) and nails may occur, as may opportunistic fungal infections. Bowel perforation is more common in patients with extreme hypercortisolism, and the hypercortisolism may mask

TABLE 15.9 Symptoms and Signs for the Diagnosis of Cushing Syndrome

Discriminatory	Less Discriminatory
Signs • Facial plethora • Proximal myopathy • Cutaneous striae (red-purple, >1 cm wide) • Bruising • In children—weight gain with reduced height percentile	Signs • Central obesity • Buffalo hump, supraclavicular fullness • Facial fullness • Acne and hirsutism • Skin thinning • Poor wound healing • Peripheral edema
Symptoms and complications (especially at a young age) • Hypertension • Diabetes mellitus • Osteoporosis and vertebral fractures	Symptoms and complications • Fatigue • Weight gain • Depression, mood and appetite change, impairment of concentration and memory • Back pain • Oligomenorrhea, polycystic ovary syndrome • Recurrent infections • Kidney stones

TABLE 15.10 Classification of Causes of Cushing Syndrome

ACTH-Dependent Causes

Cushing disease (pituitary dependent)
Ectopic ACTH syndrome
Ectopic CRH syndrome
Macronodular adrenal hyperplasia
Iatrogenic (treatment with [1-24]ACTH)

ACTH-Independent Causes

Adrenal adenoma and carcinoma
Primary pigmented nodular adrenal hyperplasia and Carney syndrome
McCune-Albright syndrome
Aberrant receptor expression (gastric inhibitory polypeptide, interleukin-1β)
Iatrogenic (e.g., pharmacologic doses of prednisolone, dexamethasone)

Other Causes of Hypercortisolism (non-neoplastic)

Alcoholism
Depression
Obesity
Pregnancy

ACTH, Adrenocorticotropic hormone; *CRH,* corticotropin-releasing hormone.

the usual symptoms and signs of the condition. Wound infections are more common and contribute to poor wound healing.

Metabolic and Endocrine Features

Glucose intolerance occurs, and overt diabetes mellitus is present in up to one-third of patients in some series. Hepatic lipoprotein synthesis is stimulated, and increases in circulating cholesterol and triglycerides may be found.[201] Hypokalemic alkalosis is found in 10% to 15% of patients with Cushing disease but in more than 95% of patients with ectopic ACTH syndrome. Several factors may contribute to this mineralocorticoid excess state, including corticosterone and DOC excess, but the principal culprit is thought to be cortisol itself. Depending on the prevailing cortisol production rate, cortisol swamps 11βHSD2 in the kidney and acts as a mineralocorticoid. Hypokalemic alkalosis is more common in ectopic ACTH syndrome because cortisol production rates are higher than in patients with Cushing disease.[136] This can be diagnosed by documenting an increase in the ratio of urinary cortisol to cortisone metabolites. In addition, hepatic 5α-reductase activity is inhibited, resulting in disproportionately greater excretion of 5β-cortisol metabolites.[202]

The functions of the pituitary-thyroid axis and the pituitary-gonadal axis are suppressed in patients with Cushing syndrome because of a direct effect of cortisol on TSH and gonadotropin secretion.[203,204] Cortisol causes a reversible form of hypogonadotropic hypogonadism but also directly inhibits Leydig cell function. GH secretion is reduced, possibly mediated through an increase in somatostatinergic tone.

Eye

Ocular effects include raised intraocular pressure[205] and exophthalmos[206] (in up to one-third of patients in Cushing's original series), the latter occurring because of increased retroorbital fat deposition. Cataracts, a well-recognized complication of corticosteroid therapy, seem to be uncommon,[207] except as a complication of diabetes. In our experience, chemosis is a sensitive and underreported feature of Cushing syndrome.

Classification and Pathophysiology of Cushing Syndrome

Cushing syndrome is most readily classified into ACTH-dependent and ACTH-independent causes (Table 15.10).

ACTH-Dependent Causes

Cushing Disease

When iatrogenic causes are excluded, the most common cause of Cushing syndrome is Cushing disease, accounting for approximately 70% of cases. The adrenal glands in these patients show bilateral adrenocortical hyperplasia with widening of the ZF and ZR.[184]

Cushing himself raised the question as to whether this disease was a primary pituitary condition or secondary to an abnormality in the hypothalamus. The hypothalamus may have an initiating role, but the overwhelming evidence is that, at presentation, the condition is pituitary dependent (Table 15.11). In 85% to 90% of cases, the disease is caused by a pituitary adenoma of monoclonal origin[208,209]; basophil hyperplasia alone is found in 9% to 33% of pathologic series.[210] The majority of tumors are small microadenomas (<1 cm), but larger macroadenomas occur in up to 10% of cases and usually signify a more invasive tumor.[211] Selective surgical removal of a causative corticotroph adenoma results in remission, but on very long-term follow-up, relapse may occur in up to 20% to 30% of microadenoma and macroadenoma patients.[212] Moreover, recent data demonstrate that around 40% of patients with Cushing disease have somatic missense mutations in ubiquitin-specific protease 8 (USP8).[213,214] These mutations cluster in a hotspot region of exon 14 and are not found in other

TABLE 15.11 Etiology of Cushing Disease: Hypothalamic Theory Versus Pituitary Theory

Hypothalamic Theory	Pituitary Theory
Neuroendocrine abnormalities[290,291]	Lack of cure after pituitary stalk section
Loss of circadian rhythm, sleep disturbance, other hypothalamic defects (TSH, LH/FSH secretion)	Circulating and CSF CRH levels are suppressed[292] Reversal of hypothalamic defects on correction of hypercortisolism
Efficacy of centrally acting drugs[293,294] (bromocriptine, cyproheptadine, sodium valproate) Recurrences after pituitary surgery Ectopic CRH-secreting tumors cause Cushing disease,[289] but pathologic examination shows basophil hyperplasia, not adenomas	High surgical cure rate (recurrences resulting from regrowth of inadequately resected tumor rather than real recurrence)[295,300] Secondary hypoadrenalism after successful pituitary surgery (may be prolonged and associated with reduced ACTH expression in surrounding adjacent normal corticotrophs)[514] Pituitary ACTH-secreting adenoma in almost 90% of cases are monoclonal in origin[301,515]

pituitary tumors. *USP8* codes for a deubiquitinating enzyme, and the mutations affect the binding of an inhibitory 14-3-3 protein that keeps the deubiquitinating activity in check. Ubiquitination of cell surface receptors usually marks them for degradation by the endosome-lysosome system, downregulating expression. As a result of the *USP8* mutations, deubiquitination is enhanced, and the epidermal growth factor receptor (EGFR) is recycled with enhanced signaling. EGF[213,214] increases POMC mRNA transcription, cell proliferation, and ACTH secretion. Corticotroph[215] adenomas with the USP8 mutant thus express higher levels of EGFR and produce increased amounts of *POMC* mRNA and ACTH compared to tumors with wild-type USP8.[213,214] It is possible that targeting EGFR may have therapeutic potential in Cushing disease.

A key biochemical hallmark of the disease is a relative resistance of ACTH secretion to normal glucocorticoid feedback inhibition.[216] ACTH-secreting pituitary adenomas function at a higher than normal set-point for cortisol feedback. The predominant finding in Cushing disease is an increase in ACTH pulse amplitude with loss of normal circadian rhythm, but ACTH pulse frequency is also increased in some cases (see Fig. 15.8).[217]

Ectopic ACTH Syndrome

In 15% of cases, Cushing syndrome is associated with nonpituitary tumors secreting ACTH—the ectopic ACTH syndrome.[218] On clinical grounds, these tumors can be divided into two entities: highly malignant tumors such as small cell carcinoma of bronchus (Table 15.12) and highly proliferative neuroendocrine carcinoma (e.g., pancreas), and more indolent tumors occurring in patients with underlying neuroendocrine tumors such as bronchial neuroendocrine tumors (carcinoids) with a low proliferative rate. In the former group, the clinical presentation is often that of a wasting syndrome with weakness and pigmentation. Circulating ACTH concentrations and cortisol secretion rates can be extremely high. As a result, duration of symptoms from onset to presentation is short (<3 months); patients are commonly pigmented, and the metabolic manifestations of glucocorticoid excess are often rapid and progressive. Weight loss, myopathy, and glucose intolerance are prominent symptoms and signs. The association of these features with hypokalemic alkalosis and peripheral edema should alert the clinician to the diagnosis.

Depending on local referral practice, approximately 20% of cases of ectopic ACTH syndrome are explained by indolent tumors, such as benign bronchial neuroendocrine tumors, that produce ACTH.[218,219] In these cases, symptoms and signs are commonly present for 18 months before clinical presentation. Such patients present with the typical features of Cushing syndrome and may be biochemically similar to patients with Cushing disease. Therefore, once a diagnosis of Cushing syndrome is established, the principal diagnostic dilemma is in the distinction of pituitary-dependent Cushing disease from these indolent causes of ectopic ACTH syndrome.

Tumors most commonly associated with ectopic ACTH syndrome arise from neuroendocrine tissues, the cells of which possess the ability to uptake and decarboxylate amine precursors (APUD cells). Although *POMC* transcripts of 1200-1450nt are frequently found in small cell lung cancer, only 0.5% to 1% of tumors are associated with ectopic ACTH syndrome, and the explanation for the development of ectopic ACTH secretion remains unclear. In contrast, *POMC* mRNA transcripts of the short 800nt length may be found in tumors not associated with ectopic ACTH syndrome. In addition to aberrant transcriptional regulation of the *POMC*, interaction with tissue-specific transcription factors or the promoter methylation status of *POMC* may be involved. Once translated, POMC is cleaved in the pituitary by specific serine endoproteases to produce ACTH precursors; in ectopic ACTH syndrome, aberrant peripheral processing of POMC may lead to increased concentrations of circulating ACTH precursors (pro-ACTH, N-POC) (see Fig. 15.6). In contrast to ACTH secretion from pituitary adenomas, ectopic POMC/ACTH production is not responsive to normal glucocorticoid feedback[220] because of the defective GR or GR-signaling mechanism.[221] However, this

sensitivity to glucocorticoid feedback is far from absolute, which is one reason why the differential diagnosis of ACTH-dependent Cushing syndrome can be challenging.[218]

Ectopic Corticotropin-Releasing Hormone Syndrome

Ectopic production of CRH is a very rare cause of pituitary-dependent Cushing disease. A number of cases have now been described in which a tumor (usually bronchial carcinoid, medullary thyroid, or prostate carcinoma) has been shown to secrete CRH alone or in combination with ACTH.[222–224] When available, pituitary histologic examination has revealed corticotroph hyperplasia but not adenoma formation. Biochemically, these patients, like those with ectopic ACTH syndrome, lose the normal negative glucocorticoid feedback mechanism—50% have resistance to high-dose dexamethasone therapy. Ectopic CRH production may explain the suppression of cortisol secretion after high-dose dexamethasone that is observed in some patients with the ectopic ACTH syndrome.

Macronodular Adrenal Hyperplasia

In 10% to 40% of patients with Cushing disease, there is bilateral adrenocortical hyperplasia associated with one or more nodules, which may be up to several centimeters in diameter.[225–228] Patients tend to be older and to have had symptoms for a longer time, but they otherwise present with the classic clinical features of Cushing syndrome. Pathologically, the nodules are lobulated and can be markedly enlarged, but internodular hyperplasia is invariably found. Macronodular adrenal hyperplasia (MAH) is thought to result from long-standing adrenal ACTH stimulation, which leads to autonomous adrenal adenoma formation. Therefore, as the adrenals in a patient with Cushing disease become more hyperplastic, they secrete more cortisol for a given ACTH level, which ultimately can lead to autosuppression. Individual clinical cases support this hypothesis, and MAH should be regarded as an ACTH-dependent form of Cushing syndrome, even though ACTH levels may be relatively low and dexamethasone suppressibility less marked than in other cases of Cushing disease.[229] These features can be a trap for the unwary because they may be mistaken for primary adrenal tumors, especially as up to 30% of patients with Cushing disease have asymmetric adrenal hyperplasia.

ACTH-Independent Causes

Cortisol-Secreting Adrenal Adenoma and Carcinoma

Excluding iatrogenic cases, adrenal adenomas are responsible for about 10% to 15% of Cushing syndrome cases, and carcinomas for less than 5%. By contrast, 65% of cases of Cushing syndrome in children have an adrenal cause (15% adenomas, 50% carcinomas).[227–229] Onset of clinical features is gradual in patients with adenomas, but it is often rapid in adrenal carcinoma. Mutations of *PRKACA*, which encodes the catalytic subunit of cAMP-dependent protein kinase A (PKA), at the hotspot L205R have been shown by several independent groups to be the cause of approximately 50% of adrenal adenomas causing overt Cushing syndrome.[230–233]

In addition to the features of hypercortisolism, patients may complain of loin or abdominal pain, and a tumor may be palpable. Adrenal carcinoma may secrete other steroids, such as androgens or mineralocorticoids, but this is very unusual in adenomas. Therefore, in females, there may be features of virilization, with hirsutism, clitoromegaly, breast atrophy, deepening of the voice, temporal recession, and severe acne. In pure cortisol-secreting adenomas, hirsutism is uncommon. Subclinical Cushing syndrome has been reported in up to 10% of patients with adrenal incidentalomas (see later discussion).

TABLE 15.13 Clinical Features of Carney Complex

Feature	Prevalence (%)
Skin lesions	80
Pigmented lesions	
Blue nevi	
Cutaneous myxomas	
Cardiac myxomas	72
Pigmented nodular adrenal hyperplasia	45
Breast lesions	
Bilateral fibroadenomas	45 (females only)

Neural lesions (gastric schwannomas)	<5
Miscellaneous	
Thyroid cancers	Rare
Acoustic neuromas	Rare
Hepatomas	Rare

Primary Pigmented Nodular Adrenal Hyperplasia and Carney Syndrome

Less than 2% of all Cushing syndrome is caused by ACTH-independent bilateral, small, often pigmented adrenal nodules. Pathologically, these nodules are usually 2 to 4 mm in diameter (although they can be larger) and black or brown on cut section. Adjacent adrenal tissue is atrophic, distinguishing this primary pigmented nodular adrenocortical disease (PPNAD) from MAH. Presentation is with typical features of Cushing syndrome in persons younger than 30 years of age and, in 50% of cases, in persons younger than 15 years of age.[234] Cases of PPNAD have been reported without Cushing syndrome. Bilateral adrenalectomy is curative.

A familial autosomal dominant variant, called *Carney complex* (Table 15.13), comprises mesenchymal tumors (especially atrial myxomas), spotty skin pigmentation, peripheral nerve tumors, and various other tumors, including breast lesions, testicular tumors, and GH-secreting pituitary tumors.[235] Mutations of the gene encoding the PKA regulatory subunit type IA *(PRKAR1A)* lead to abnormal PKA signaling and explain the phenotype in some cases.[236] Other cases have been mapped to chromosome 2p16, but the underlying genetic mutation is unknown.

McCune-Albright Syndrome

In McCune-Albright syndrome, fibrous dysplasia and cutaneous pigmentation may be associated with pituitary, thyroid, adrenal, and gonadal hyperfunction. The most common manifestation is with sexual precocity and GH excess, but Cushing syndrome has been reported.[237] The underlying abnormality is a somatic mutation in the α-subunit of the stimulatory G protein, which is linked to adenylyl cyclase, with a mosaic tissue distribution. The mutation results in constitutive activation of the G protein, mimicking constant ACTH stimulation at the level of the adrenal. ACTH levels are suppressed, and adrenal adenomas may occur.

Macronodular Hyperplasia

Although MAH commonly occurs in patients with ACTH-dependent Cushing syndrome, truly ACTH-independent macronodular adrenal hyperplasia (AIMAH) is also recognized as a distinct entity.[238] The nodules are nonpigmented and greater than 5 mm in diameter; occasionally, the adrenals are massively enlarged. Most cases are explained on the basis of aberrant receptor expression within the adrenal cortex.[239] Food-induced hypercortisolism due to enhanced adrenal responsiveness to gastric inhibitory polypeptide (GIP) was the first cause of AIMAH described, due to expression of GIP receptors within the adrenal cortex, but aberrant expression of the vasopressin V_1, β-adrenergic, LH, serotonin, and angiotensin (AT_1) receptors have also been linked to AIMAH. Protocols have been suggested for the further investigation of AIMAH.[239]

Familial cases suggest a genetic cause for this condition in some patients, and inactivating mutations Armadillo repeat 5 (*ARMC5*) have been demonstrated as a cause.[240]

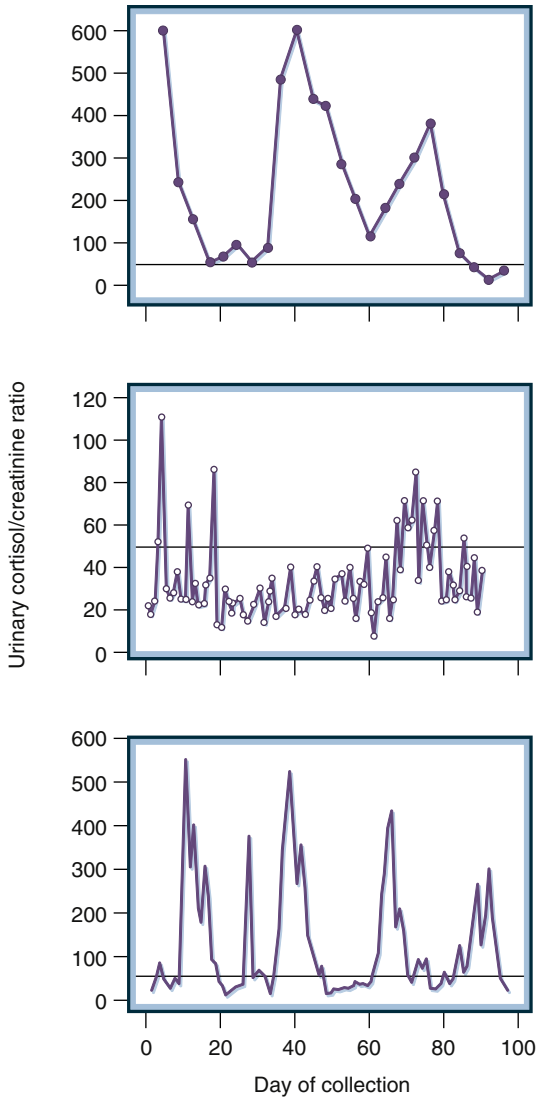
Iatrogenic Cushing Syndrome

A careful drug history is required to exclude iatrogenic Cushing syndrome. Development of the features of Cushing syndrome depends on the dose, duration, and potency of the corticosteroids used in clinical practice. ACTH is rarely prescribed, but long-term administration will also result in cushingoid features. Some features, such as an increase in intraocular pressure, cataracts, benign intracranial hypertension, aseptic necrosis of the femoral head, osteoporosis, and pancreatitis, are more common in iatrogenic than endogenous Cushing syndrome, whereas other features, notably hypertension, hirsutism, and oligomenorrhea/amenorrhea, are less prevalent.

Special Features of Cushing Syndrome

Cyclic Cushing Syndrome

Of particular clinical interest has been a group of patients with cyclic Cushing syndrome, characterized by periods of excess cortisol production interspersed with intervals of normal cortisol production (Fig. 15.18). Some of these patients demonstrate a paradoxic rise in plasma ACTH and cortisol when treated with dexamethasone, and occasionally, a patient is benefited by dopamine agonist (bromocriptine or cabergoline) therapy. Most patients have been thought to have pituitary-dependent disease, and in many of these patients, basophil adenomas have been removed, with long-term cure in some cases. However, cortisol secretion may show some evidence of cyclicity in patients with an ectopic source of ACTH and in PPNAD.[241,242]

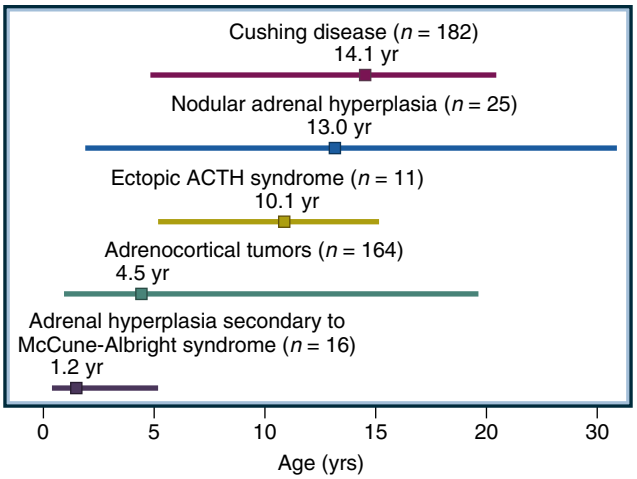


• **Fig. 15.18** Patterns of cortisol secretion in three patients with cyclic Cushing syndrome. In each case, the ratio of early-morning urinary cortisol (in nanomoles per liter) to creatinine (in millimoles per liter) are plotted against time. Variable periodicity in cortisol hypersecretion is shown. (From Atkinson AB, McCance DR, Kennedy L, et al. Cyclical Cushing's syndrome first diagnosed after pituitary surgery: a trap for the unwary. *Clin Endocrinol*. 1992;36:297–299.)

Cushing Syndrome in Children

Cushing syndrome can occur at any age, but the causes differ across age groups (Fig. 15.19). In children, adrenal causes account for 65% of all cases, and in addition to the previously mentioned features, growth arrest is almost invariable.[243] The dissociation between height and weight is obvious, with the height most commonly below the mean, whereas the BMI is almost always above the mean. If the height and weight are increasing along the same percentile line, then the diagnosis of Cushing syndrome is highly unlikely. Obesity in childhood Cushing syndrome tends to be generalized. Most patients have a delayed bone age that is negatively correlated with height standard deviation score (SDS), duration of symptoms, and age at diagnosis. The observed growth failure often precedes other manifestations such as weight gain, pubertal arrest, fatigue, depression, hypertension, and acne. Pubertal development can be advanced in patients with virilizing tumors causing precocious pseudopuberty. However, in patients with true puberty, glucocorticoid-mediated suppression of gonadotropins may occur.[244]

Glucocorticoid excess influences not only the hypothalamic-pituitary-gonadal axis but also the GH/IGF1 axis, leading to both reduction of spontaneous GH secretion and pharmacologic GH response. Furthermore, direct effects of glucocorticoids on epiphyseal chondrocytes, probably together with disturbance of microvascularization of the growth plate, result in a negative effect on growth. Poor catch-up has been reported in children after cure of Cushing disease, and evidence exists for GH inhibition by hypercortisolemia for 1 to 2 years after cure of Cushing disease. GH secretion should be assessed 3 months after treatment. If GH deficiency is demonstrated, GH in a replacement dose of



• **Fig. 15.19** Etiology and age-dependency of pediatric Cushing syndrome. Note how the causes differ across age groups. (From Storr HL, Chan LF, Grossman AB, et al. Paediatric Cushing's syndrome: epidemiology, investigation and therapeutic advances. *Trends Endocrinol Metab*. 2007;18:167–174.)

25 μg/kg per day should be given. Catch-up growth is observed in most patients, and target adult height is achieved. However, many patients remain obese.

Pregnancy

Pregnancy is rare in women with Cushing syndrome because of associated amenorrhea due to androgen excess or hypercortisolism, but when present is due to an adrenal adenoma in 50% of cases.[245] A few cases of true pregnancy-induced Cushing syndrome have been described, with regression after delivery.[246] In these cases, the cause is unknown. Establishing a diagnosis and a cause can be difficult. Clinically, striae, hypertension, and gestational diabetes are common features in normal pregnancies, yet hypertension and diabetes are also the most common signs of Cushing syndrome in a pregnant woman (70% and 30% of all cases, respectively). Furthermore, biochemically normal pregnancy is associated with a threefold increase in plasma cortisol due to increased production of cortisol and CBG. Urinary free cortisol also rises, and dexamethasone does not suppress plasma cortisol to the same degree as the nonpregnant state. Left untreated, the condition is associated with high rates of maternal and fetal morbidity and mortality. Any adrenal or pituitary adenomas should be excised. Metyrapone, which is not teratogenic, has been effective in many cases in controlling the hypercortisolism.

Other Syndromes of Hypercortisolemia

Other states occur when there are clinical and biochemical features of Cushing syndrome, but when hypercortisolemia is secondary to other factors it is often referred to as *pseudo-Cushing syndrome*. Resolution of the underlying cause results in disappearance of the cushingoid state. Several causes are described.

Alcohol

In the original description of alcohol-related pseudo-Cushing syndrome, urinary and plasma cortisol levels were elevated and failed to suppress with dexamethasone. Plasma ACTH has been found to be normal or suppressed. The condition is rare but should be suspected in a patient with an ongoing history of heavy alcohol intake and biochemical or clinical evidence of chronic liver disease.[247] The pathogenesis of this condition remains unknown, but a two-hit hypothesis has been put forward. Chronic liver disease of any cause is associated with impaired cortisol metabolism, but in alcoholic patients there is an increased cortisol secretion rate, rather than concomitant suppression in the face of impaired metabolism.[248] In some studies, alcohol has directly stimulated cortisol secretion; alternatively, AVP levels are elevated in patients with decompensated liver disease and may stimulate the HPA axis. With abstinence from alcohol, the biochemical abnormalities revert to normal within days.

Depression

Although the cause is unknown, it is recognized that patients with depression may exhibit the hormonal abnormalities of patients with Cushing syndrome.[249] These abnormalities are reversible on correction of the psychiatric condition. Conversely, patients with Cushing syndrome are frequently depressed, and a careful clinical and endocrinologic assessment is required.

Obesity

Although one of the most common referrals to a clinical endocrinologist is for exclusion of an underlying endocrine cause in a patient with obesity, the diagnosis of Cushing syndrome in such patients should not cause difficulties. Patients with obesity have mildly increased cortisol secretion rates, and the data suggest that this is due to activation of the HPA axis.[250,251] However, circulating cortisol concentrations are invariably normal, and urinary free cortisol excretion rates are either normal or only slightly elevated. The stimulus for the increased secretion of cortisol appears to be increased peripheral metabolism and clearance of cortisol—principally, reduced hepatic conversion of cortisone to cortisol by 11βHSD1 and increased conversion of cortisol to 5α-reduced derivatives.[251]

Investigation of Patients With Suspected Cushing Syndrome

There are two stages in the investigation of suspected Cushing syndrome: (1) Does this patient have Cushing syndrome? (2) If so, what is the cause? Unfortunately, many investigators fail to make this distinction and ill advisedly use tests that are relevant to the second question in trying to answer the first question. In particular, it is essential that radiologic investigations not be undertaken until Cushing syndrome has been confirmed biochemically. The starting point should be to investigate patients in whom there is a high clinical index of suspicion for the diagnosis of Cushing syndrome, focusing on the features that are most discriminating for the condition (see Table 15.9). Widespread indiscriminate biochemical screening in obese, hypertensive, and diabetic populations is not recommended. Very few laboratories have developed methods for the measurement of free serum cortisol.[252] Because more than 90% of serum cortisol is protein bound, the results of the conventional assay are affected by drugs and by conditions that alter CBG levels. Oral estrogen therapy or pregnancy may elevate CBG and total serum cortisol, and should be stopped for 6 weeks prior to assessment by tests using serum cortisol. The major tests are listed in Table 15.14.[184,249,253,254]

Question 1: Does This Patient Have Cushing Syndrome?

Circadian Rhythm of Plasma Cortisol

In normal subjects, plasma cortisol levels are at their highest early in the morning and reach a nadir (<50 nmol/L [<2 μg/dL] in a nonstressed subject) at about midnight.[255] This circadian rhythm

ACTH, Adrenocorticotropic hormone; *CT,* computed tomography; *MRI,* magnetic resonance imaging.

is lost in patients with Cushing syndrome; in the majority, the 9 AM plasma cortisol is normal but nocturnal levels are raised. Random morning plasma cortisol levels are therefore of little value in making the diagnosis, whereas a midnight cortisol level greater than 200 nmol/L (>7.5 μg/dL) indicates Cushing syndrome. However, various factors such as stress of venipuncture, intercurrent illness, and admission to hospital may lead to false-positive results. Conversely, if a serum cortisol value is less than 50 nmol/L at midnight, Cushing syndrome is excluded at that time. Ideally, patients should be hospitalized for 24 to 48 hours before the midnight cortisol level is measured, but some centers have reported discriminant results for midnight levels measured in outpatients. Nevertheless, this is a cumbersome test and has been largely supplanted by measurement of salivary cortisol (see next).

Salivary Cortisol

CBG is absent from saliva, and the use of salivary cortisol measurements offers a sensible alternative in that the test does not require hospitalization. The diagnostic accuracy of a single midnight salivary cortisol level has been established in several studies. The cutoff points that define disease vary depending on the assay used. In one study, a cortisol value greater than 2.0 ng/mL (>5.5 nmol/L) had a 100% sensitivity and a 96% specificity for diagnosis of Cushing syndrome.[253,256,257] It is important to note, however, that late-night salivary cortisol tends to increase with age and cardiovascular comorbid conditions such as hypertension and diabetes, and thus the discriminating power diminishes in the elderly population.[258]

Urinary Free Cortisol Excretion

For many years, the diagnosis of Cushing syndrome was based on the measurement of urinary metabolites of cortisol (24-hour urinary 17-hydroxycorticosteroid or 17-oxogenic steroid excretion, depending on the method used). However, the sensitivity and specificity of these methods are poor, and most centers have replaced these assays with the more sensitive measurement of urinary free cortisol. This is an integrated measure of plasma free cortisol: As cortisol secretion increases, the binding capacity of CBG is exceeded, resulting in a disproportionate rise in urinary free cortisol. Normal values depend on the assay used and tend to be lower when analyzed by liquid chromatography and tandem mass spectrometry (LC-MS/MS). Although in widespread use, urinary free cortisol is less sensitive than salivary cortisol and dexamethasone suppression testing. Patients should make two or three complete consecutive collections to account for patient error in collecting samples and for episodic cortisol secretion, notably from adrenal adenomas. Simultaneous creatinine excretion (which differs by no more than 10% from day to day) may be used to ensure adequacy of collection. Urinary free cortisol is a useful screening test, although it is accepted that the value can be normal in up to 8% to 15% of patients with Cushing syndrome.[253,254,259] Conversely, moderately elevated results should always be verified by further testing before a diagnosis of Cushing syndrome is made. In addition, variations in levels of up to 50% have been observed in patients with proven Cushing disease, reinforcing the need for multiple collections.[260]

Measurement of the cortisol-to-creatinine ratio in the first urine specimen passed on waking obviates the need for a timed collection and has been used as a screening test, particularly when cyclic Cushing syndrome is suspected.[261] Urine aliquots may be sent to the local endocrinology laboratory, with cortisol-to-creatinine ratios greater than 25 nmol/mmol on repeated measurement being indicative of hypercortisolism.

Low-Dose Overnight Dexamethasone Suppression Tests

In normal subjects, the administration of a supraphysiologic dose of glucocorticoid results in suppression of ACTH and cortisol secretion. In Cushing syndrome of whatever cause, there is a failure of this suppression when low doses of the synthetic glucocorticoid dexamethasone are given.[216]

The overnight test is a useful outpatient screening test,[249,253,262] in which 1 mg of dexamethasone is given at 11 PM. A normal response is a plasma cortisol level of less than 50 nmol/L (<1.8 μg/dL) between 8 and 9 AM the following morning. The outpatient overnight test has high sensitivity (95%) but lower specificity, and further investigation is often required.[263,264]

In the 48-hour low-dose dexamethasone test, plasma cortisol is measured at 9 AM on day 0 and again 48 hours later, after administration of dexamethasone 0.5 mg every 6 hours for 48 hours. Using a postdexamethasone plasma cortisol concentration of less than 50 nmol/L (<1.8 μg/dL) as the cutoff point, this test is reported to have a 97% to 100% true-positive rate and a false-positive rate of less than 1%.[249,263]

Certain drugs (e.g., phenytoin, rifampicin) may increase the metabolic clearance rate of dexamethasone, leading to false-positive results. Simultaneous measurement of plasma dexamethasone may be useful in such cases and will also detect whether patients failed to take the drug, and a value of greater than 3.3 nmo/L as measure by LC-MS/MS appears to improve the accuracy of the test.[265]

Other Causes of Hypercortisolemia: Pseudo-Cushing or True Cushing Syndrome?

In patients with depression, urinary free cortisol excretion may be elevated and may overlap with those seen in patients with true Cushing syndrome. Compared with patients with Cushing disease, depressed patients have greater suppressibility after dexamethasone and reduced response to CRH, but neither test is diagnostic.[249,266] The dexamethasone-suppressed CRH test has been proposed as a tool to discriminate between true Cushing syndrome and other states but has been shown to have no advantage over the standard low-dose dexamethasone suppression

test. In normal subjects and in patients with endogenous depression, insulin-induced hypoglycemia results in a rise in ACTH and cortisol levels, a response that usually is not seen in patients with Cushing syndrome, but this test has largely been abandoned for this purpose.[249]

Diagnostic Guidelines

The Endocrine Society, in collaboration with the European Society for Endocrinology, has issued evidence-based guidelines for the diagnosis of Cushing syndrome.[267] Recommendations are to proceed initially with one of four highly sensitive screening tests: urinary free cortisol, late-night salivary cortisol, overnight dexamethasone, or the 2-mg/48-hour dexamethasone suppression test. Abnormality detected by any of these tests in a patient with clinically suspected Cushing syndrome should be confirmed with one of the additional tests; if both test results are abnormal, patients should then undergo testing for the cause of the Cushing syndrome (Fig. 15.20).

Question 2: What Is the Cause of Cushing Syndrome in This Patient?

Having confirmed Cushing syndrome clinically and biochemically, the clinician's next step is to determine the cause (Fig. 15.21).

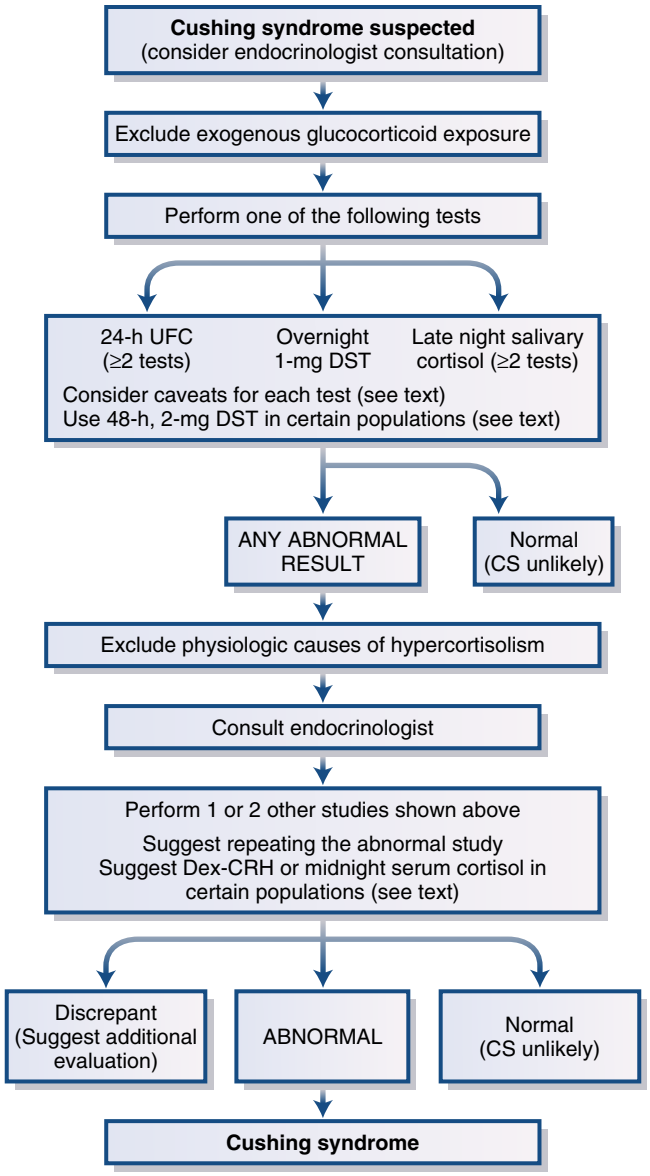
Morning Plasma ACTH

Ideally, ACTH should be measured with the use of a modern, two-site immunoradiometric assay. Such a test differentiates ACTH-dependent from ACTH-independent causes. The samples should be taken in ice cold tubes and immediately separated ahead of storage at −40°C ahead of analysis to prevent inadvertent degradation. In Cushing disease, 50% of patients have a 9 AM ACTH level within the normal reference range (2–11 pmol/L [9–52 pg/mL]); in the remainder, it is modestly elevated. Occasionally, due to episodic secretion, levels may be very low, and thus measurement of at least two values is recommended to avoid misclassification of mild Cushing disease as ACTH independent. ACTH levels in the ectopic ACTH syndrome are high (usually >20 pmol/L [>90 pg/mL]); nevertheless, overlap values are seen in Cushing disease in 30% of cases.[257] Therefore this test cannot be used to differentiate the two conditions (Fig. 15.22). The measurement of ACTH precursors (pro-ACTH, POMC) has been suggested, but it is not routinely available and has not been proven to detect an ectopic source of ACTH.

In patients with adrenal tumors and clear clinical features, plasma ACTH is invariably undetectable (<1 pmol/L) unless there is assay interference. The presence of plasma ACTH levels that are low-normal or intermittently detectable, which may occur in MAH, is problematic. The danger is that in some patients the asymmetry of the nodular hyperplasia may lead to a diagnosis of adrenal adenoma, the plasma ACTH is ignored, and an inappropriate adrenalectomy is performed. Conversely, in some patients with this syndrome, an autonomous adrenal tumor develops, and unilateral adrenalectomy is required despite the detectable ACTH.

Plasma Potassium

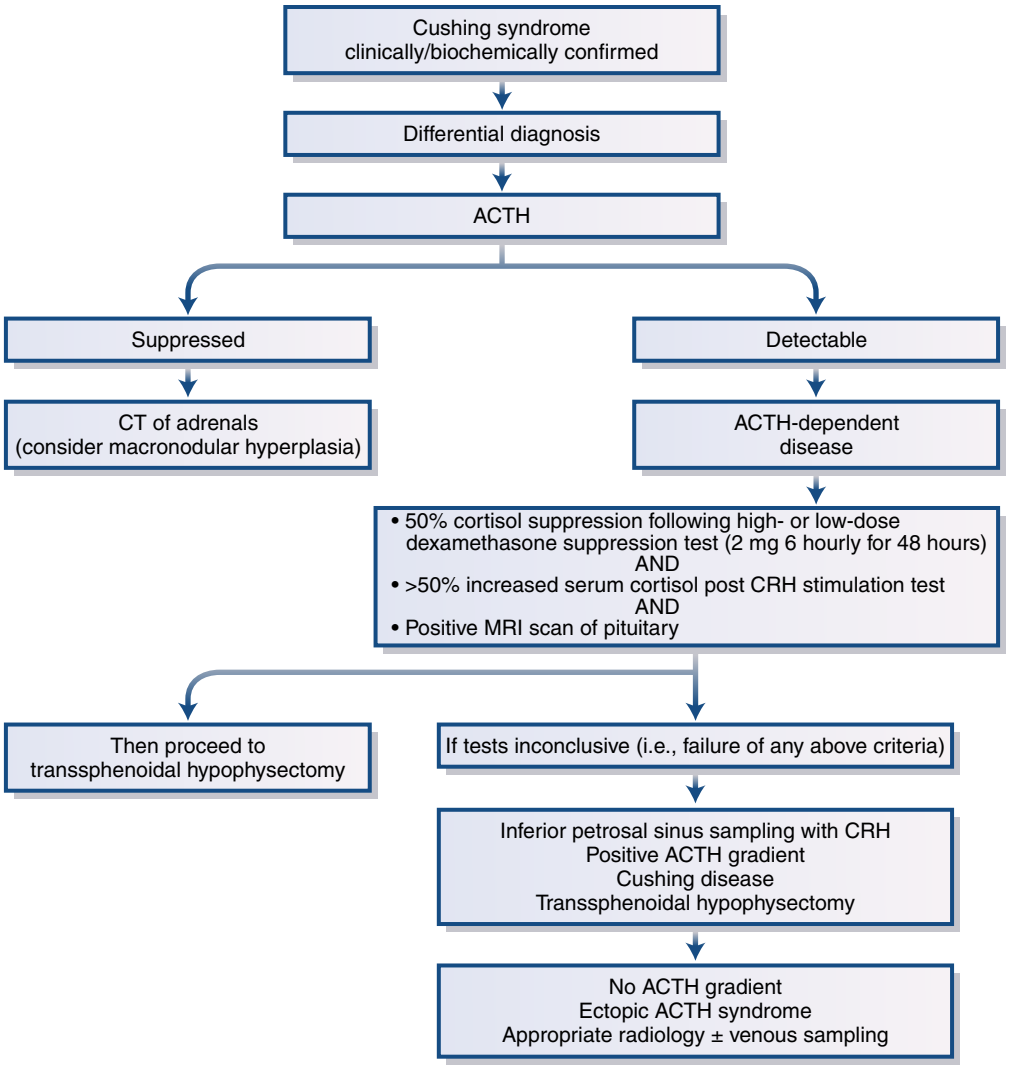
Hypokalemic alkalosis is present in more than 95% of patients with the ectopic ACTH syndrome but in fewer than 10% of those with Cushing disease. The cause of this mineralocorticoid excess state is now established. Patients with the ectopic syndrome usually have higher rates of cortisol secretion. Cortisol saturates the renal-protective 11βHSD2 enzyme, resulting in cortisol-induced mineralocorticoid hypertension (see Chapter 16).[136] In addition, these patients have higher levels of the ACTH-dependent mineralocorticoid, DOC.



• **Fig. 15.20** Algorithm for testing patients with suspected Cushing syndrome *(CS)* according to the 2008 Endocrine Society clinical practice guideline. All statements are recommendations except for those prefaced by the word *Suggest*. Diagnostic criteria that point to Cushing syndrome are a urinary free cortisol *(UFC)* value greater than the normal range for the assay, a serum cortisol level greater than 1.8 μg/dL (>50 nmol/L) after administration of 1 mg dexamethasone *(1-mg DST),* and a late-night salivary cortisol concentration greater than 145 ng/dL (>4 nmol/L). *CRH,* corticotropin-releasing hormone; *Dex,* dexamethasone; *DST,* dexamethasone suppression test. (From Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing's syndrome: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab*. 2008;93:1526–1540.)

High-Dose Dexamethasone Suppression Test

The rationale for the high-dose dexamethasone suppression test is that in Cushing disease the negative feedback control of ACTH is reset to a higher level than normal. Therefore cortisol levels do not suppress with low-dose dexamethasone but do so after high doses.



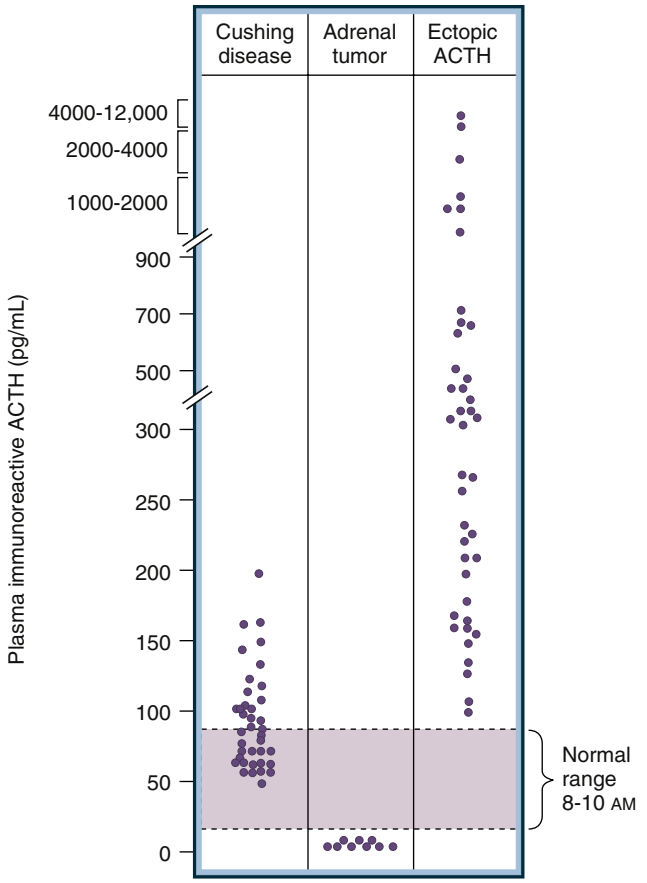
• **Fig. 15.21** The tests to uncover the cause of Cushing syndrome are debatable and differ in any given center depending on many factors, including familiarity and turnaround time of hormone assays and local expertise in techniques such as inferior petrosal sinus sampling. Depicted here is an algorithm in use within many endocrine units based on the reported sensitivity and specificity of each endocrine test. *ACTH,* adrenocorticotropic hormone; *CRH,* corticotropin-releasing hormone; *CT,* computed tomography; *MRI,* magnetic resonance imaging.

The original test introduced by Liddle was based on giving 2 mg dexamethasone every 6 hours for 48 hours and demonstrating a fall of greater than 50% in urinary 17-hydroxycorticosteroids.[216] In the modern test, the plasma or urinary free cortisol (or both) is measured at 0 and +48 hours, and a greater than 50% suppression of plasma cortisol from the basal value has been used to define a positive response. In all cases, the response is graded and is dependent on the original cortisol secretion rate: Greater suppression is often observed in patients with lower basal cortisol values. In women with ACTH-dependent Cushing syndrome, in whom the a priori likelihood of Cushing disease is 90%, the sensitivity of this test for the Cushing disease is 80%, lower than the pretest probability. Because of this, there is little logic to the continued use of this test when inferior petrosal sinus sampling (IPSS) is available (see later). Moreover, if the low-dose dexamethasone suppression test has been used in the diagnosis of Cushing syndrome and a greater than 50% fall in cortisol is observed, there is no added value in the high-dose dexamethasone suppression test.[263]

Corticotropin-Releasing Hormone Test

CRH is a 41–amino acid peptide that was identified by Vale in 1981 from ovine hypothalami. The ovine sequence differs by seven amino acid residues from that of the human hormone but is slightly more effective in stimulating the release of ACTH in humans.[268] The test involves the intravenous injection of either ovine or human sequence CRH in a dose of 1 μg/kg body weight or a single dose of 100 μg (Fig. 15.23). The test can be performed in the morning or afternoon. After basal sampling, CRH is administered, and blood samples for ACTH and cortisol are then taken every 15 minutes for 1 to 2 hours.[261,264,269,270]

In normal subjects, CRH produces a rise in ACTH and cortisol of 15% to 20%. This response is exaggerated in Cushing disease, in which typically an ACTH increase greater than 50% and a cortisol rise greater than 20% over baseline values are seen. Responses are seldom seen in the ectopic ACTH syndrome, but false-positive results have been reported. In distinguishing pituitary-dependent Cushing disease from the ectopic ACTH syndrome, the response



• **Fig. 15.22** Plasma adrenocorticotropic hormone *(ACTH)* concentrations in patients with Cushing disease, Cushing syndrome associated with adrenocortical tumors, or the ectopic ACTH syndrome. To convert values to picomoles per liter, multiply by 0.2202. (From Besser GM, Edwards CRW. Cushing's syndrome. *Clin Endocrinol Metab*. 1972;1:451–490.)

of ACTH and cortisol to CRH has a specificity and a sensitivity of approximately 90%. However, a positive response defined as an ACTH increase of 100% or a cortisol rise of 50% over baseline values effectively eliminates a diagnosis of ectopic ACTH syndrome, which is the real benefit of this test. Up to 10% of patients with Cushing disease do not respond to CRH.

Inferior Petrosal Sinus Sampling and Selective Venous Catheterization

The most robust test to distinguish Cushing disease from the ectopic ACTH syndrome is IPSS.[184] Because blood from each half of the pituitary drains into the ipsilateral inferior petrosal sinus, catheterization and venous sampling of both sinuses simultaneously can distinguish a pituitary from an ectopic source of ACTH (Fig. 15.24).[271,272] In virtually all patients with the ectopic ACTH syndrome, the ratio of the ACTH concentration in the inferior petrosal sinus and that in simultaneously drawn peripheral venous blood is less than 1.4:1. In contrast, the ratio is elevated to greater than 2 in Cushing disease. However, because of the problem of intermittent ACTH secretion, it is useful to take measurements before and at intervals (e.g., 2, 5, and 15 minutes) after intravenous injection of 100 µg synthetic ovine or human CRH.[273,274] Using this approach, an ACTH petrosal sinus/peripheral ratio greater than 3 after CRH administration has a sensitivity of 95% and specificity of nearly 100% for diagnosing Cushing disease.[274] When CRH is not available, some centers use desmopressin as a secretagogue, but central to peripheral gradients have been observed in some patients with ectopic ACTH when using this peptide. When no gradient is found and venograms confirm correct catheter placement, measurement of prolactin in the samples and correction of the ACTH values can reduce the false-negative rate in Cushing disease.[275]

IPSS may also be of value in lateralizing a pituitary tumor in a patient in whom imaging techniques have failed to demonstrate a microadenoma; however, some centers have found this procedure to be of little value in predicting tumor location. Because many tumors are central and drain into both sinuses, current evidence suggests that it is unwise to base the surgical procedure on the results of IPSS studies alone.

IPSS is technically demanding; it has been associated with complications (referred aural pain, thrombosis) and should be performed only in an experienced tertiary referral center. In some centers, a clinical diagnostic algorithm is used (see Fig. 15.21), and IPSS is performed if the differential diagnosis remains in doubt (i.e., lack of adequate suppression after high-dose dexamethasone or CRH response or the absence of a macroadenoma on pituitary MRI scanning).

Imaging

CT/MRI Scanning of Pituitary and Adrenal Glands

High-resolution, thin-section, contrast-enhanced computed tomography (CT) or MRI imaging has revolutionized the investigation of Cushing syndrome.[271,272] However, it is essential that the results of any imaging technique be interpreted alongside the biochemical results if mistakes are to be avoided. When the adrenals are imaged, asymmetric nodular hyperplasia may lead to a false diagnosis of adrenal adenoma. In the general population there is an approximately 10% rate of small abnormalities on pituitary MRI, so-called pituitary incidentalomas, which may mimic a corticotrope adenoma to the unwary, thus emphasizing the need for careful biochemical assessment.[276]

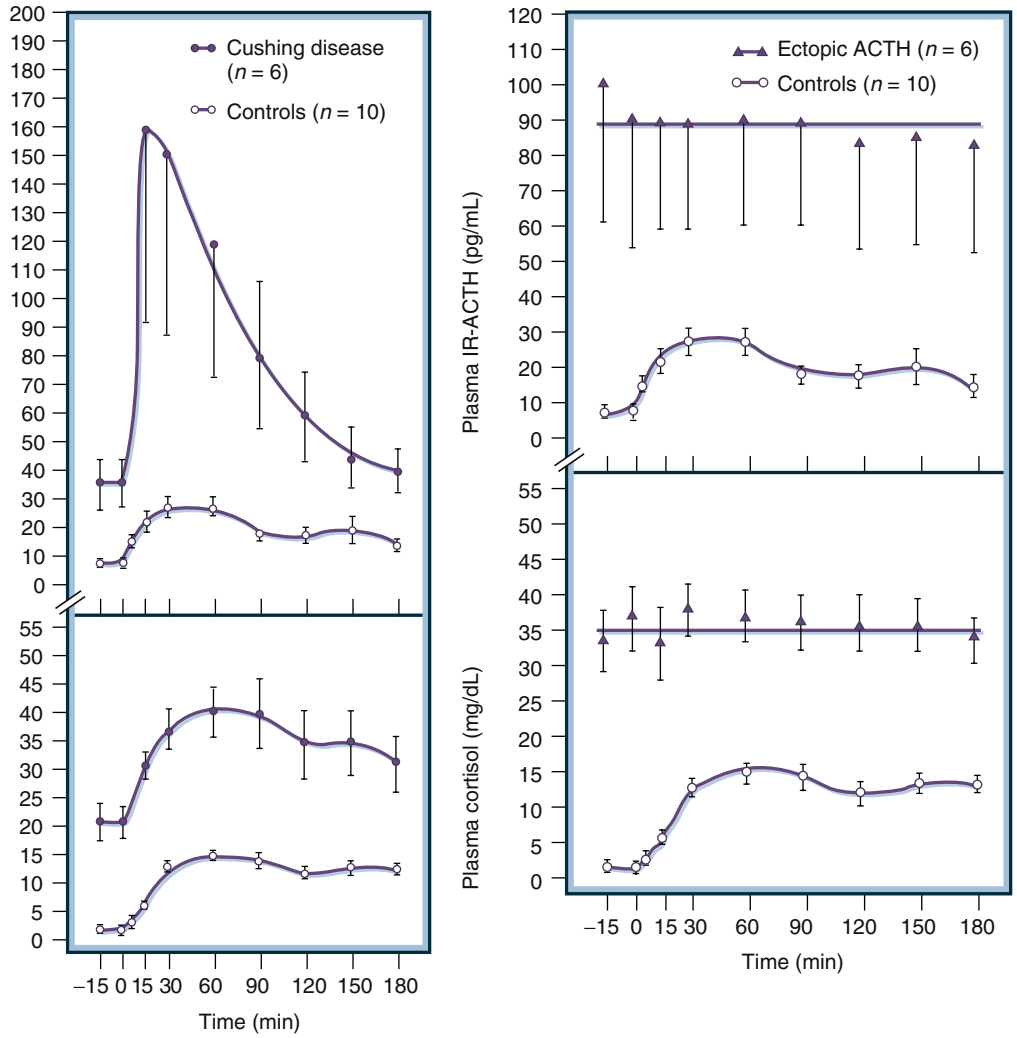
Pituitary MRI is the investigation of choice once the biochemical tests have suggested Cushing disease, with a sensitivity of 60% and specificity of 87%. About 90% of ACTH-secreting pituitary tumors are microadenomas (i.e., <10 mm in diameter). The classic features of a pituitary microadenoma are a hypointense lesion on T1-weighted images after gadolinium contrast enhancement, which may be associated with deviation of the pituitary stalk, and a convex upper surface of the pituitary gland (Fig. 15.25).

For adrenal imaging, CT offers better spatial resolution[277] (Fig. 15.26) and is the procedure of choice, but MRI may provide diagnostic information in patients with suspected adrenal carcinoma. Once again, so-called adrenal incidentalomas are present in up to 5% of normal subjects, so adrenal imaging should not be performed unless biochemical investigation has suggested a primary adrenal cause (i.e., undetectable ACTH concentrations). Adrenal carcinomas are usually large and are often associated with metastatic spread at presentation (Fig. 15.27).

In patients with occult ectopic ACTH syndrome, high-definition CT/MRI scanning of thorax, abdomen, and pelvis with images obtained every 0.1 to 0.5 cm may be required to detect small ACTH-secreting neuroendocrine tumors (Fig. 15.28).

Nuclear Medicine and Molecular Imaging Studies

Scintigraphy is used in some centers for patients with primary adrenal disease. The most commonly used agent is ^{136}I-labeled 6β-iodomethyl-19-norcholesterol,[278] a marker of adrenocortical cholesterol uptake. In patients with adrenal adenomas, the



• **Fig. 15.23** Comparison of cortisol and adrenocorticotropic hormone (ACTH) responses to an intravenous injection of ovine corticotropin-releasing hormone (1 μg/kg) in normal subjects, patients with Cushing disease, and patients with the ectopic ACTH syndrome. *IR,* immunoreactive. (From Chrousos GP, Schulte HM, Oldfield EH, et al. The corticotropin-releasing factor stimulation test: an aid in the evaluation of patients with Cushing's syndrome. *N Engl J Med*. 1984;310:622–626.)

isotope is taken up by the adenoma but not by the contralateral suppressed adrenal gland. Adrenal scintigraphy may be useful in patients with suspected adrenocortical macronodular hyperplasia, although it is not in widespread use; CT scanning may misleadingly suggest unilateral disease, whereas isotope scanning identifies bilateral adrenal involvement.

Many neuroendocrine tumors giving rise to the ectopic ACTH syndrome express somatostatin receptors (sst) and can be imaged by administering radiolabeled analogues of somatostatin, most commonly [^{114}In]-labeled octreotide, or with more sensitive [^{69}Ga]-DOTATATE PET-CT. This latter technique can detect tumors as small as a few millimeters in diameter and should be considered for patients with ACTH-dependent Cushing syndrome in whom pituitary disease has been excluded, although discovery of a lesion that has not been seen on axial imaging is rare.[279] Because the sst2 receptor on the causative tumor to which these analogues bind may be downregulated in Cushing syndrome, medical therapy to either lower or offset the actions of cortisol may allow an initially negative scan to be repeated after some months and detect an occult source.[280]

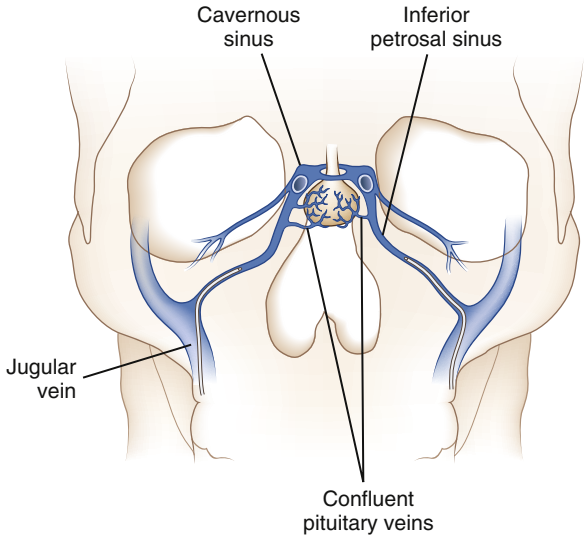
Treatment of Cushing Syndrome

The Endocrine Society has produced evidence-based clinical practice guidelines for the treatment of Cushing syndrome.[281]

Adrenal Causes

Unilateral adrenal adenomas should be removed by adrenalectomy; the cure rate approaches 100%, with success reflected by postoperative serum cortisol values that are less than 50 nmol/L at 9 AM, or even lower in many modern assays.[281,282] Laparoscopic adrenalectomy by an expert surgeon is the standard of care for unilateral tumors, offering reduced surgical morbidity and postoperative hospital stay compared with traditional open approaches.[281,283] After surgery, it may take many months or even years for the contralateral suppressed adrenal to recover. Glucocorticoid replacement regimens vary, but many centers use low doses (15–20 mg) of hydrocortisone, and withdrawal regimens differ. One practical approach is to measure the morning plasma cortisol having omitted the dose of hydrocortisone in the morning at 3-month intervals. Patients with serum

cortisol values less than 200 nmol/L (<7.5 μg/dL) should continue glucocorticoid replacement, whereas in patients with values above 500 nmol/L (>18.3 μg/dL), this replacement can be stopped. In patients with values between 200 and 500 nmol/L, ACTH(1-24) testing can be used to assess whether there is sufficient response to stress, although insulin tolerance testing may be used in some centers. In the interim, all patients should carry a steroid alert card and increase their dose of replacement therapy in the event of an intercurrent illness.



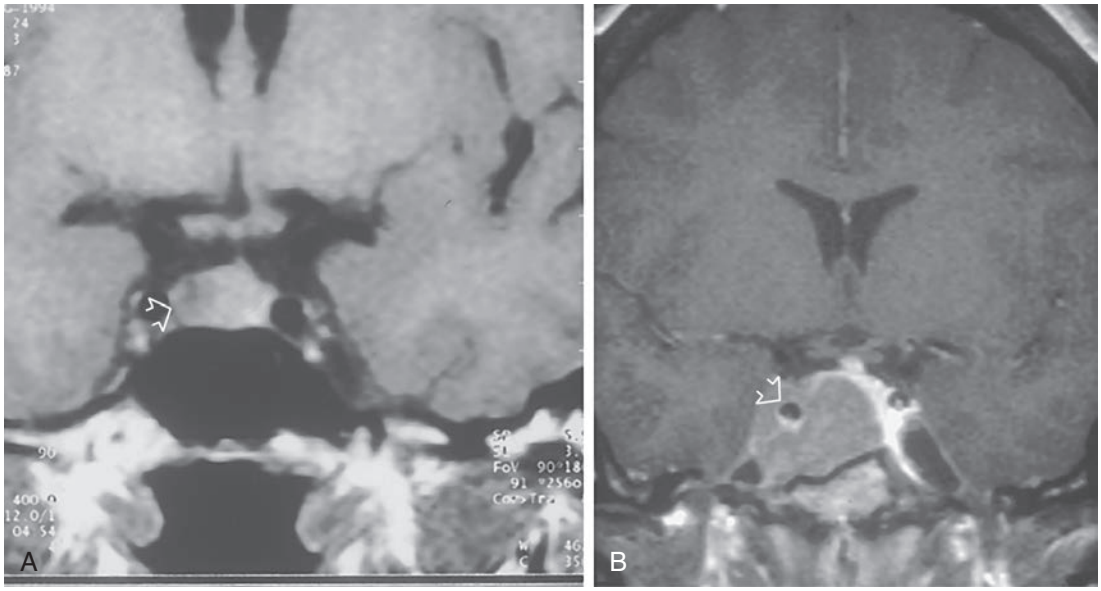
• **Fig. 15.24** Anatomy of the venous drainage of the pituitary gland through the inferior petrosal venous sinuses. (From Oldfield EH, Chrousos GP, Schulte HM, et al. Preoperative lateralization of ACTH-secreting pituitary microadenomas by bilateral and simultaneous inferior petrosal sinus sampling. *N Engl J Med*. 1985;312:100–103.)

Adrenal carcinomas have had a very poor prognosis, and most patients have died within 2 years of diagnosis.[284] It is usual practice to try to remove the primary tumor, even though metastases may be present, so as to enhance the response to the adrenolytic agent *o,p'*-DDD[285] (mitotane). Radiotherapy to the tumor bed and to some metastases, such as those in the spine, may be of limited value. However, in recent years, significant progress has been made by implementing collaborative multicenter studies. Phase III trials of mitotane therapy achieving therapeutic plasma mitotane levels have shown significant benefit[286]; drug combinations include etoposide, doxorubicin, and cisplatin plus mitotane or streptozotocin plus mitotane. Several targeted therapies, including IGF1 inhibitors, sunitinib, and sorafenib, have been tried in cases of mitotane failure, but there are no consistent responses. The 10-year survival rate for patients with T1 N0 M0 disease is about 80% but is significantly impaired with increased tumor mass, positive lymph nodes, and distant metastases, reaching less than 20% for patients with T1-4 N0-1 M1.[287]

Pituitary-Dependent Cushing Syndrome

The treatment of Cushing disease has been significantly enhanced with transsphenoidal surgery conducted by an experienced surgeon.[281,288]

The surgical outcome for transsphenoidal hypophysectomy varies from center to center and with surgical expertise.[289] Because of the hazards of untreated Cushing disease and the potential complications of surgery, the endocrinologist should refer patients only to a recognized surgical specialist at a center in which outcome data have been established. In optimal centers, remission rates are 70% to 90% for microadenomas and 50% for macroadenomas.[290] Rates for postoperative hypopituitarism and permanent diabetes insipidus depend on how aggressive the surgeon was in removing pituitary tissue. The ideal outcome is a cured patient with intact pituitary function, but this result may



• **Fig. 15.25** (A) Magnetic resonance imaging (MRI) scan of pituitary demonstrates the typical appearance of a pituitary microadenoma. A hypodense lesion is seen in the right side of the gland *(arrow)*, with deviation of the pituitary stalk away from the lesion. After a biochemical diagnosis of Cushing disease, this patient was cured by transsphenoidal hypophysectomy. (B) MRI scan of the pituitary gland demonstrates a large macroadenoma *(arrow)* in a patient with Cushing disease. In contrast to smaller tumors, large macroadenomas are usually invasive and recur after surgery.

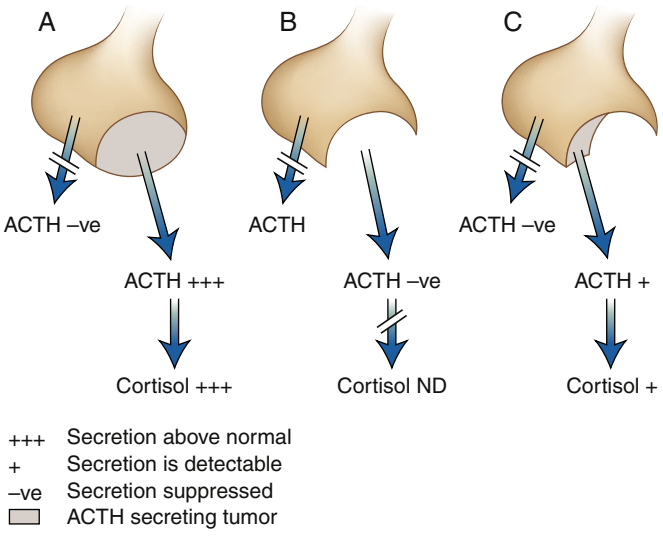
The diagnosis and differential diagnosis of Cushing's syndrome and pseudo-Cushing's states. *Endocr Rev*. 1998;19:647–672.)

not be possible for a patient with Cushing disease in whom a pituitary adenoma was not identified preoperatively or during the operation itself.

In centers that lack facilities for frequent monitoring of cortisol levels, perioperative and postoperative hydrocortisone cover is advised; this can be reduced to maintenance replacement doses usually within 3 to 7 days. On days 2 to 5, postoperatively, a 9 AM plasma cortisol level should be measured with the patient having omitted hydrocortisone for 24 hours. After selective removal of a microadenoma, the surrounding corticotrophs are usually suppressed (Fig. 15.29). As a result, plasma cortisol levels are less than 30 nmol/L (<1 μg/dL) postoperatively, and ongoing glucocorticoid replacement therapy is required. The HPA axis usually (but not invariably) exhibits gradual recovery, and glucocorticoid therapy is needed until this occurs (Fig. 15.30). A nonsuppressed plasma cortisol postoperatively suggests that the patient is not in remission even though cortisol secretion may have fallen to normal or subnormal values.[291,292] The overall recurrence rate on long-term follow-up even for patients in remission after pituitary surgery is up to 30%, but this value is higher in children (up to 40%).[281,293,294] This emphasizes the need for long-term monitoring. A detailed assessment of residual pituitary function is required in each patient, and close follow-up of such individuals is warranted.

In the past, pituitary irradiation was often used in the treatment of Cushing disease. However, because of the improvements in pituitary surgery, far fewer patients are so treated. In children, pituitary irradiation appears to be more effective.[295] Radiotherapy



• **Fig. 15.29** Selective removal of a microadenoma and its effect on the hypothalamic-pituitary-adrenal axis. (A) Before treatment. (B) After total removal of adenoma. (C) After incomplete excision. Because the surrounding normal pituitary corticotrophs are suppressed in a patient with an adrenocorticotropic hormone (ACTH)-secreting pituitary adenoma, successful removal of the tumor results in ACTH, and hence adrenocortical, deficiency, with an undetectable (<50 nmol/L [2 μg/dL]) plasma cortisol level. A postoperative plasma cortisol level higher than 50 nmol/L (2 μg/dL) implies that the patient is not cured. (Courtesy Professor Peter Trainer.)

is not recommended as a primary treatment but is reserved for patients who are not responding to pituitary microsurgery, patients who have undergone bilateral adrenalectomy, and patients with established Nelson syndrome (see upcoming discussion).

The management of recurrent Cushing disease involves a consideration of repeat pituitary surgery, Gamma Knife radiosurgery, medical therapies, and adrenal surgery.[281,288,296] Bilateral adrenalectomy carries a cure rate approaching 100%. The major risk is the subsequent development of Nelson syndrome (postadrenalectomy hyperpigmentation with a locally aggressive pituitary tumor) (Fig. 15.31), which was attributed to loss of any negative feedback after adrenalectomy but is more likely to be due to an aggressive pituitary tumor from the outset.[297] In an attempt to avoid this complication, pituitary irradiation was often carried out at the time of bilateral adrenalectomy, but this is not widely practiced today.[298] If a pituitary corticotroph tumor is not visible at the time of surgery, the risk of Nelson syndrome is reduced; monitoring is by plasma ACTH and MRI of the pituitary.[297] In addition, these patients require lifelong replacement therapy with hydrocortisone and fludrocortisone. Currently, bilateral adrenalectomy is indicated for patients with Cushing disease if pituitary surgery has failed or if the condition has recurred.

Ectopic ACTH Syndrome

Treatment of the ectopic ACTH syndrome depends on the cause. If the tumor can be found and has not spread, then its removal can lead to cure (e.g., neuroendocrine tumor of the bronchus or thymus). However, the prognosis for small cell lung cancer associated with the ectopic ACTH syndrome is poor. The cortisol excess and associated hypokalemic alkalosis and diabetes mellitus can be ameliorated by medical therapy. Treatment of the small cell tumor itself will also, at least initially, produce improvement. Sometimes, if the ectopic source of ACTH cannot be found, it may be necessary to perform bilateral adrenalectomy and then monitor the patient carefully (sometimes for several years) before the primary tumor becomes apparent.

• **Fig. 15.31** A young woman with Cushing disease, photographed initially beside her identical twin sister (A). In this case, treatment with bilateral adrenalectomy was undertaken. Several years later, the patient presented with Nelson syndrome and a right third cranial nerve palsy (B, C) related to cavernous sinus infiltration from a locally invasive corticotropinoma (D). Hypophysectomy and radiotherapy were performed with reversal of the third cranial nerve palsy (E). Note the advancing skin pigmentation of Nelson syndrome.

Medical Treatment of Cushing Syndrome

Several drugs have been used in the treatment of Cushing syndrome.[288] Metyrapone inhibits 11β-hydroxylase, with a goal of lowering cortisol concentrations, often before definitive therapy or while awaiting benefit from pituitary irradiation. The daily dose must be determined by measurements of plasma or urinary free cortisol. The aim should be to achieve a mean plasma cortisol concentration of about 300 nmol/L (11 μg/dL) during the day or a normal urinary free cortisol level. Since levels of 11-deoxycortisol are increased, use of LC-MS/MS assays are encouraged for monitoring due the potential cross-reactivity with cortisol in immunoassays.[281] The drug is usually given in doses ranging from 250 mg

twice daily to 1.5 g every 6 hours, with lower doses for adrenal adenoma and higher for ectopic ACTH, and overall is effective in around 50% of all patients.[299] Nausea is a side effect that can be helped (if it is not caused by adrenal insufficiency) by giving the drug with milk.[300]

Ketoconazole is an imidazole that has been widely used as an antifungal agent but causes abnormal liver function tests in about 15% of patients. Ketoconazole blocks a variety of steroidogenic cytochrome P450–dependent enzymes and thus lowers plasma cortisol levels. For effective control of Cushing syndrome, 400 to 1600 mg daily has been required, and an acidic stomach is needed for absorption; the drug is effective in around 50% of patients.[301,302] Ketoconazole frequently causes an increase in hepatic enzyme values, and if this level remains less than three times the upper limit of normal, the drug may be continued, but hepatic failure has been described, and the drug has been withdrawn from the market for the treatment of fungal infections.

Mitotane (*o,p′*-DDD) is an adrenolytic drug that is taken up by both normal and malignant adrenal tissue, causing adrenal atrophy and necrosis.[285] Because of its toxicity, it has been used mainly in the management of adrenocortical carcinoma (ACC). Doses of up to 5 g/day are required to control glucocorticoid excess, although evidence that the drug causes tumor shrinkage or improves long-term survival is lacking. This agent also produces mineralocorticoid deficiency, and concomitant high-dose glucocorticoid therapy is required, often with mineralocorticoid replacement if there is no prior glucocorticoid excess due to the ACC. High-dose hydrocortisone replacement is needed in patients with ACC causing Cushing syndrome when mitotane is used in a "block and replace" regime due to the increases in CBG, and induction of CYP3A4 due to the mitotane, which then causes less bioavailability and increased metabolism of hydrocortisone.[303] Side effects are common and include fatigue, skin rashes, neurotoxicity, and gastrointestinal disturbance, and therapeutic drug monitoring is essential during use. It has also been used at lower doses in Cushing disease.[304]

Somatostatin analogues such as octreotide and lanreotide are generally ineffective in Cushing disease. However, the multireceptor somatostatin analogue, pasireotide, which demonstrates high-affinity binding to somatostatin receptor subtypes 1, 2, 3, and 5, normalizes urinary free cortisol in 17% to 40% of patients with Cushing disease depending on the severity of disease, with hyperglycemia being a common side effect.[305,306] The GR antagonist mifepristone has been shown to improve diabetes in patients with Cushing syndrome, but biochemical monitoring is not possible when using this drug.[307]

Prognosis of Cushing Syndrome

Studies performed before the introduction of effective therapy revealed that 50% of patients with untreated Cushing syndrome died within 5 years, principally from vascular disease.[194] Even with modern management, an increased prevalence of cardiovascular risk factors persists for many years after an apparent remission.[195,196] If remission is achieved at the first pituitary surgery the standardized mortality rate approaches the normal population, emphasizing the need for expert surgeons.[308] Paradoxically, on correction of the hypercortisolism, patients often feel worse. Skin desquamation, steroid-withdrawal arthropathy, profound lethargy, and mood changes may occur and can take several weeks or months to resolve.[309] They can usually be ameliorated by a transient increase in glucocorticoid replacement therapy. Patients are invariably GH deficient, and GH replacement therapy may produce clinical benefit.

Features of Cushing syndrome disappear over a period of 2 to 12 months after treatment. Hypertension and diabetes mellitus improve, but as with other secondary causes, they may not resolve completely. The osteopenia of Cushing syndrome improves rapidly during the first 2 years after treatment but resolves more slowly thereafter.[310] Vertebral fractures and osteonecrosis are irreversible, and permanent deformity results. Visceral obesity and myopathy are both reversible features. Reproductive and sexual function usually return to normal within 6 months, provided that anterior pituitary function was not compromised. Long-term health-related quality of life in adults significantly improves after treatment, but quality-of-life scores do not return to normal levels.[191] Similar observations have been made in pediatric patients, in whom significant improvement was noted before and after treatment but residual impairment of health-related quality of life persisted 1 year after cure.[311]

Glucocorticoid Resistance

A small number of patients have been described as having increased cortisol secretion but without the stigmata of Cushing syndrome.[88,312] These patients are resistant to suppression of cortisol with low-dose dexamethasone but respond to high doses. ACTH levels are elevated and lead to increased adrenal production of androgens and DOC. Therefore these patients may present with the features of androgen or mineralocorticoid excess, or both. Treatment with a dose of dexamethasone (usually >3 mg/day) adequate to suppress ACTH results in a fall in adrenal androgens and often returns plasma potassium and blood pressure to normal levels. Many of these patients have been found to have point mutations in the steroid-binding domain of the GR, with consequent reduction of glucocorticoid-binding affinity, but this finding is not invariable. A useful clinical discriminatory test to differentiate this condition from Cushing syndrome is to measure bone mineral density: It is preserved in patients with glucocorticoid resistance or even increased in females because of the androgen excess. In addition, the circadian rhythm for ACTH and cortisol is preserved in patients with glucocorticoid resistance.

Glucocorticoid Deficiency

Primary and Central Hypoadrenalism

Primary hypoadrenalism refers to glucocorticoid deficiency occurring in the setting of adrenal disease, whereas central hypoadrenalism arises because of deficiency of ACTH (Table 15.15). A major distinction between these forms of hypoadrenalism is that mineralocorticoid deficiency invariably accompanies primary hypoadrenalism, but this does not occur in central hypoadrenalism: Here, only ACTH is deficient, and the renin-angiotensin-aldosterone (RAA) axis is intact. A further important cause of adrenal insufficiency in which there may be dissociation of glucocorticoid and mineralocorticoid secretion is CAH.

Primary Hypoadrenalism

Addison Disease

Thomas Addison described the condition now known as *primary hypoadrenalism* in his classic monograph published in 1855.[2]

TABLE 15.15 Etiology of Adrenocortical Insufficiency (Excluding Congenital Adrenal Hyperplasia)

Primary Causes: Addison Disease

- Autoimmune
  - Sporadic
  - Autoimmune polyendocrine syndrome type I (Addison disease, chronic mucocutaneous candidiasis, hypoparathyroidism, dental enamel hypoplasia, alopecia, primary gonadal failure—see Chapter 43)
  - Autoimmune polyendocrine syndrome type II (Schmidt syndrome) (Addison disease, primary hypothyroidism, primary hypogonadism, insulin-dependent diabetes, pernicious anemia, vitiligo—see Chapter 43)
- Infections
  - Tuberculosis
  - Fungal infections
  - Cytomegalovirus
  - HIV
- Metastatic tumor
- Infiltrations
  - Amyloid
  - Hemochromatosis
- Intra-adrenal hemorrhage (Waterhouse-Friderichsen syndrome) after meningococcal septicemia
- Adrenoleukodystrophies
- Congenital adrenal hypoplasia
  - DAX1 *(NR0B1)* mutations
  - *SF1* mutations
- ACTH resistance syndromes
  - *MC2R* gene mutations
  - *MRAP* gene mutations
  - *AAAS* (ALADIN) gene mutations (triple-A syndrome)
- Bilateral adrenalectomy

Secondary Causes: Central Hypoadrenalism

- Exogenous glucocorticoid therapy
- Hypopituitarism
- Selective removal of ACTH-secreting pituitary adenoma
- Pituitary tumors and pituitary surgery, craniopharyngiomas
- Pituitary apoplexy
- Granulomatous disease (tuberculosis, sarcoid, eosinophilic granuloma)
- Secondary tumor deposits (breast, bronchus)
- Postpartum pituitary infarction (Sheehan syndrome)
- Pituitary irradiation (effect usually delayed for several years)
- Isolated ACTH deficiency
  - Idiopathic
  - Lymphocytic hypophysitis
  - TPIT *(TBX19)* gene mutations
  - *PCSK1* gene mutation (POMC processing defect)
  - *POMC* gene mutations
- Multiple pituitary hormone deficiencies
  - *HESX1* gene mutations
  - *LHX4* gene mutations
  - *SOX3* gene mutations
  - *PROP1* gene mutations

ACTH, Adrenocorticotropic hormone; *HIV,* human immunodeficiency virus; *POMC,* pro-opiomelanocortin.

Addison disease is a rare condition with an estimated incidence in the developed world of 0.8 cases per 100,000 and a prevalence of 4 to 11 cases per 100,000 population. Nevertheless, it is associated with significant morbidity and a twofold excess mortality rate,[313] but once the diagnosis is made it can be easily treated.[314,315] Despite treatment, however, patients carry significant burden of metabolic and psychologic comorbidities.[316] Causes of Addison disease are listed in Table 15.15.

TABLE 15.16 Incidence of Other Endocrine and Autoimmune Diseases in Patients With Autoimmune Adrenal Insufficiency

Disease	Incidence (%)
Thyroid disease	
Hypothyroidism	8
Nontoxic goiter	7
Thyrotoxicosis	7
Gonadal failure	
Ovarian	20
Testicular	2
Insulin-dependent diabetes mellitus	11
Hypoparathyroidism	10
Pernicious anemia	5
None	53

Autoimmune Adrenalitis

In the Western world, autoimmune adrenalitis accounts for more than 70% of all cases of primary hypoadrenalism.[317] Pathologically, the adrenal glands are atrophic with loss of most of the cortical cells, but the medulla is usually intact. In 75% of cases, adrenal autoantibodies—specifically anti-21-hydroxylase antibodies—can be detected.[318] Fifty percent of patients with this form of Addison disease have an associated autoimmune disease (Table 15.16), thyroid disease being the most common. Conversely, only 1% to 2% of patients with more common autoimmune diseases such as insulin-dependent diabetes mellitus or thyrotoxicosis have antiadrenal autoantibodies and develop adrenal disease, although the figure is higher in patients with autoimmune hypoparathyroidism (16%). These autoimmune polyglandular syndromes (APSs) have been classified into two distinct variants.[318] APS type I, or autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia (APECED), is a rare autosomal recessive condition comprising Addison disease, chronic mucocutaneous candidiasis, and hypoparathyroidism. The more common APS type II comprises Addison disease, autoimmune thyroid disease, diabetes mellitus, and hypogonadism. Here, autoantibodies to 21-hydroxylase are usually present and are predictive for the development of adrenal destruction, particularly for APS type I.[318] Polyglandular autoimmune syndromes are discussed in greater detail in Chapter 43.

Infections

Worldwide, infectious diseases are the most common cause of primary adrenal insufficiency. These diseases include tuberculosis, fungal infections (histoplasmosis, cryptococcosis), and cytomegalovirus infection. Adrenal failure may also occur in the acquired immunodeficiency syndrome (AIDS).[319]

Tuberculous Addison disease results from hematogenous spread of the infection from elsewhere in the body; extra-adrenal disease is usually evident. The adrenals are initially enlarged, with extensive epithelioid granulomas and caseation, and both the

cortex and the medulla are affected. Fibrosis ensues, and the adrenals become normal in size or smaller, with calcification evident in 50% of cases.

The adrenals are frequently involved in patients with AIDS[319,320]; adrenalitis may occur after infection with cytomegalovirus or atypical mycobacteria, and Kaposi sarcoma may result in adrenal replacement. Onset is often insidious, but if tested, more than 10% of patients with AIDS will demonstrate a subnormal cortisol response to a short synacthen test (SST). Adrenal insufficiency may be precipitated through the concomitant administration of appropriate anti-infectives such as ketoconazole (which inhibits cortisol synthesis) or rifampicin (which increases cortisol metabolism). Rarely, patients with AIDS and features of adrenal insufficiency are found to have elevated circulating ACTH and cortisol concentrations that fail to suppress normally after low-dose dexamethasone administration. This is thought to reflect an acquired form of glucocorticoid resistance resulting from reduced GR affinity, but the underlying cause remains unknown.[321]

Acquired Primary Adrenal Insufficiency

With the exception of tuberculosis and autoimmune adrenal failure, other causes of Addison disease are rare (see Table 15.15). With the exception of lymphoma, adrenal metastases (most commonly from primary tumors in the lung or breast) uncommonly cause adrenal insufficiency,[322] perhaps because more than 90% of the adrenal cortex must be compromised before symptoms and signs become apparent. Necrosis of the adrenals due to intra-adrenal hemorrhage should be considered in any severely sick patient, particularly a patient with underlying infection, trauma, or coagulopathy.[323] Intra-adrenal bleeding may be found in patients with severe septicemia of any cause, particularly in children, in whom a common cause is infection with *Pseudomonas aeruginosa*. When caused by meningococci, the association with adrenal insufficiency is known as the Waterhouse-Friderichsen syndrome. Adrenal replacement may also occur with amyloidosis and hemochromatosis.

Inherited Primary Adrenal Insufficiency

Adrenal hypoplasia congenita (AHC) is an X-linked disorder comprising congenital adrenal insufficiency and combined primary and central hypogonadotropic hypogonadism. The condition is caused by mutations in the *DAX1 (NR0B1)* gene, a member of a nuclear receptor family that is expressed in the adrenal cortex, gonads, and hypothalamus.[324,325] Depending on the molecular defect, the clinical presentation can be highly variable. Severe cases often manifest with mineralocorticoid deficiency and gradually develop glucocorticoid deficiency. Hypogonadism is combined with primary testicular abnormalities and low gonadotropin levels. However, the so-called minipuberty of infancy can be normal.[326,327] Patients presenting with late-onset adrenal failure have also been described.[328]

Mutations in another transcription factor, SF1, may also result in adrenal insufficiency due to lack of development of a functional adrenal cortex. The transcriptional regulation of many P450 steroidogenic enzymes is dependent on SF1.[15] When it was first described, SF1 mutation was associated with complete sex reversal causing 46,XY disorder of sex development (DSD).[329] However, novel clinical phenotypes in SF1-deficient patients are now emerging; they range from isolated adrenal failure[330] to isolated gonadal failure[331] and ovarian insufficiency.[332] AHC may also occur in association with glycerol kinase deficiency and Duchenne muscular dystrophy caused by a contiguous gene deletion, including the *DAX1* gene.[333]

Adrenoleukodystrophy has a prevalence rate of 1:20,000 and is a cause of adrenal insufficiency in association with demyelination within the nervous system; demyelination results from a failure of β-oxidation of fatty acids within peroxisomes. Increased accumulation of very long-chain fatty acids (VLCFAs) occurs in many tissues, and serum assays can be used diagnostically. Only males have the fully expressed condition, and carrier females are usually normal. Several forms are recognized: a childhood cerebral form (30–40% of cases), adult adrenomyeloneuropathy (40%), and Addison disease (7%). The childhood-onset form manifests at 5 to 10 years of age with progression eventually to a blind, mute, and severely spastic tetraplegic state. Adrenal insufficiency is usually present but does not appear to correlate with the neurologic deficit. Nevertheless, this is the most common form of adrenal insufficiency in a child younger than age 7 years.[334] Adrenomyeloneuropathy, by contrast, manifests later in life with the gradual development of spastic paresis and peripheral neuropathy. Both the childhood and the adult condition result from mutations in the *ABCD1* gene on chromosome Xq28, which encodes for an ABC peroxisomal membrane protein involved in the import of VLCFA into the peroxisome.[335] So far, more than 400 mutations have been reported in the *ABCD1* gene with no relationship between genotype and phenotype.[336,337] Treatment options are few. Monounsaturated fatty acids, which block the synthesis of the saturated VLCFA, have been used; a combination of erucic acid and oleic acid (Lorenzo oil) has led to normal levels of VLCFA. Treatment does not alter the rate of neurologic deterioration but may prevent new neurologic damage in asymptomatic cases.[337] Bone marrow transplantation is a further possibility.

Familial glucocorticoid deficiency (FGD), or inherited unresponsiveness to ACTH, is a rare autosomal recessive cause of hypoadrenalism that usually manifests in childhood. Most patients present with neonatal hypoglycemia or later in life with increasing pigmentation, and they often have enhanced growth velocity. Primary adrenal failure in a child with normal activity of the RAA system is highly suggestive of FGD. The diagnosis can be confirmed by demonstrating low cortisol in combination with increased ACTH concentrations and normal plasma renin and aldosterone measurements.[92] The type 1 variant accounts for approximately 25% of all cases and is explained by inactivating mutations in the ACTH-binding receptor, MC2R.[338–340] The FGD type 2 variant caused by mutations in the *MRAP* gene, which is thought to mediate intracellular trafficking of the *MC2R*, has been reported in some families.[91] However, 50% of patients with FGD do not have mutations in either *MC2R* or *MRAP;* other loci that have been defined include *MCM4, TXNRD2, NNT*, and partial mutations in *STAR* and *CYP11A1*.[341,342]

A variant called the *triple A syndrome* or *Allgrove syndrome* refers to the triad of adrenal insufficiency due to ACTH resistance, achalasia, and alacrima. It is caused by mutations in the *AAAS* gene, which encodes ALADIN, a tryptophan/aspartate WD-repeat–containing protein of the nuclear pore complex.[343,344] The exact function of ALADIN is unknown, but its interaction with other proteins of the nuclear pore complex suggests that it is part of a structural scaffold.

Several syndromic disorders are associated with adrenal insufficiency for which the underlying molecular genetic defect remains to be elucidated.[11]

Secondary Hypoadrenalism

Inherited Central Hypoadrenalism

Central hypoadrenalism may be defined as hypocortisolemia secondary to a deficiency in ACTH. The prevalence of central hypoadrenalism is 125 to 280 per million,[1,345] which is likely to be an underestimate considering the use of therapeutic corticosteroids in the general population. It occurs in up to one-third of patients with pituitary disease.[3,346] ACTH deficiency is an important diagnosis to make; in subjects with tumoral and posttraumatic hypopituitarism, central hypoadrenalism is associated with increased mortality rates.[4–6,347–349] The causes of central hypoadrenalism are outlined in Table 15.15; the most common reason is ACTH suppression by exogenous glucocorticoid treatment.[7,185]

When caused by pituitary disease, other pituitary hormones are often deficient, so the patient presents with partial or complete hypopituitarism. The clinical features of hypopituitarism make this a relatively easy diagnosis. By contrast, isolated ACTH deficiency is rare, and the diagnosis is difficult to make.[350] It may occur in patients with lymphocytic hypophysitis. Mutations in the *TBX19* gene, the product of which (Tpit) regulates *POMC* expression, have been reported in a few cases of isolated ACTH deficiency occurring in neonatal life.[351] A rare but fascinating cause relates to a defect in the normal post-translational processing of POMC to ACTH by the prohormone convertase enzymes (PC1/3 and PC2).[352] Such patients may have more generalized defects in peptide processing (e.g., cleavage of proinsulin to insulin) giving rise to diabetes mellitus.

Some patients have mutations in the *POMC* gene that interrupt the synthesis of ACTH and cause ACTH deficiency. Elucidation of the phenotype of these patients has uncovered a novel role for POMC peptides in regulating appetite and hair color: In addition to adrenal insufficiency, *POMC* mutations result in severe obesity and often red hair pigmentation.[353] A central role for αMSH in regulating food intake via the hypothalamic MC4R has been established,[56] and in recombinant mice lacking the POMC gene, the obese phenotype can be reversed by giving an αMSH agonist peripherally.[354]

Other rare inborn causes of secondary insufficiency are the result of mutations in genes involved in pituitary development, such as *HESX1*,[355] *LHX4*,[356] *SOX3*,[357] and *PROP1*.[358] These defects result in congenital hypopituitarism with multiple pituitary hormone deficiencies: ACTH deficiency may not be present at the time of diagnosis, but it develops progressively over time.

Secondary hypoadrenalism is also observed in patients with Cushing disease after successful and selective removal of the ACTH-secreting pituitary adenoma. The function of adjacent normal pituitary corticotrophs is suppressed and may remain so for many months after curative surgery.[291–293]

ACTH Suppression by Exogenous Glucocorticoids

The ability of exogenously administered corticosteroids to cause adrenal atrophy has been appreciated since their discovery in the 1940s. HPA axis suppression by exogenous glucocorticoid is a serious medical problem and has been described with intra-articular, topical, ocular, rectal, and inhaled, as well as systemic, therapy.[359–361]

There is considerable interindividual variability in response to glucocorticoids; there are no absolute cutoff values for the type of steroid taken, dose, route of administration, duration of treatment, or time since steroid withdrawal that predict adrenal suppression. However, there are some generic issues that can guide diagnosis and therapy. Relative steroid potencies in their affinity/transactivation of the GR have been described based on suppression of corticosterone production, in vitro binding to the glucocorticoid (GR), and functional changes in GC target tissues by individual steroids[362]; these suggest that oral doses of 20 mg of hydrocortisone, 5 mg of prednisolone, and 0.75 mg of dexamethasone are bioequivalent. Dexamethasone has a longer half-life and higher affinity for the GR than hydrocortisone and exerts a more sustained suppressive effect on the HPA axis. Similarly, it is unclear how the potency of oral hydrocortisone compares to that of glucocorticoids taken by other routes. Budesonide has more potent action at the GR than dexamethasone or prednisolone,[363] but its effect on adrenal suppression is dependent on systemic absorption of the inhaled compound. Comparison of inhaled fluticasone with inhaled steroids such as budesonide or beclomethasone indicated that fluticasone was more frequently associated with suppression of the HPA axis and that adults using over 1000 μg of inhaled fluticasone for over a year were at risk of adrenal suppression.[364]

Concomitant therapies can augment potency and adrenal suppression. The coadministration of inhaled fluticasone with one of the many medications that suppress its clearance by inhibition of CYP3A4 is associated with adrenal suppression (e.g., ritonavir).[365] Co-prescriptions of agents that do not affect glucocorticoid clearance but have affinity for the GR are also associated with adrenal suppression, an example being progesterone derivatives such as medroxyprogesterone acetate given in high dose to oncology patients.[179]

In terms of dose and duration, adrenal atrophy and subsequent deficiency should be anticipated in any subject who has taken more than the equivalent of 30 mg hydrocortisone per day orally (>7.5 mg/day prednisolone or >0.75 mg/day dexamethasone) for longer than 3 weeks. In addition to the magnitude of the dose of glucocorticoid, the timing of administration may affect the degree of adrenal suppression. If prednisolone is given as 5 mg at night and 2.5 mg in the morning, there will be more marked suppression of the HPA axis compared with 2.5 mg at night and 5 mg in the morning, because the larger evening dose blocks the early-morning surge of ACTH. LaRochelle and colleagues reported that adrenal function recovered if patients' steroid doses could be tapered to 5 mg of prednisone daily.[366] This report has formed the basis of the practice of assessing HPA axis function in patients who have been on more than 5 mg of prednisolone or equivalent for more than 3 months. Lower doses of glucocorticoid have been shown to suppress cortisol production; in one study, more than 60% of subjects on a glucocorticoid dose equivalent of less than 5 mg of prednisolone per day had a subnormal ACTH or cortisol response to CRH.[367] In patients on long-term tapering of prednisolone who were considered for steroid withdrawal once they had reached a dose of 7 mg/day, 48% had adrenal insufficiency defined by basal cortisol (<100 nmol/L) or response to 250 μg synthetic ACTH (<550 nmol/L); a longer duration of prednisolone therapy (13.7 years) was seen in the hypoadrenal group defined by a low baseline cortisol but not in the group defined by cortisol response to 250 μg synthetic ACTH (6.1 years).[368] Dynamic testing of adrenal function, such as the SST and CRH tests, suggests that cortisol production recovers after withdrawal of long-term glucocorticoids; in a meta-analysis of patients receiving glucocorticoid therapy, 46% to 100% had insufficient cortisol response 1 day after withdrawal, which improved to 26% to 49% in patients at assessment 1 week later.[37] Up to 10% of patients still

TABLE 15.17 Suggested Plan for Steroid Replacement in Patients Withdrawing From Chronic Corticosteroid Therapy

	DURATION OF GLUCOCORTICOID TREATMENT			
Pred Dose (mg/day)	**≤3 wk[a]**		**>3 wk**	
≥7.5	Can stop	↓ rapidly (e.g., 2.5 mg q3-4d)		
		THEN		
5–7.5	Can stop	↓ 1 mg q2-4 wk	OR	Convert 5 mg pred to 20 mg HC, then ↓ 2.5 mg/wk to 10 mg/day
		THEN		THEN
<5	Can stop	↓ 1 mg q2-4 wk		After 2-3 mo HC 10 mg/day, administer SST/ITT: Pass → Withdraw Fail → Continue

[a]Beware of frequent steroid courses (e.g., in asthma).

HC, Hydrocortisone; *ITT,* insulin tolerance test; *pred,* prednisolone; *SST,* short synacthen test. Basal 0900h ACTH can be used to monitor for recovery of HPA axis and levels may be above the normal range ahead of a "pass" on an SST.

have biochemical evidence of hypoadrenalism between 6 and 20 months after withdrawal of glucocorticoids.[369]

All patients receiving long-term therapy with corticosteroids should be treated in a similar fashion to patients with chronic ACTH deficiency; they should carry steroid cards and be offered steroid alert bracelets or necklaces. In the event of an intercurrent stress (e.g., infection, surgery), supplemental steroid cover should be given. If the patient is unable to take drugs orally, parenteral therapy is required.

During recovery from suppression and without replacement therapy, patients may experience symptoms of glucocorticoid deficiency, including anorexia, nausea, weight loss, arthralgia, lethargy, skin desquamation, and postural dizziness (see the later discussions of adrenal insufficiency).[370] To avoid these symptoms, steroids should be cautiously withdrawn over a period of months.[182] Assuming that the underlying disease permits steroid reduction, doses should be reduced from pharmacologic levels to physiologic levels (equivalent to 7.5 mg/day prednisolone) over a few weeks. Thereafter doses should be reduced by 1 mg per day of prednisolone every 2 to 4 weeks depending on patient well-being. An alternative approach is to switch the patient to hydrocortisone 20 mg/day and reduce the daily dose by 2.5 mg/day every week to a level of 10 mg/day. After 2 to 3 months on reduced doses, endogenous function of the HPA axis can be assessed by basal 9:00 AM serum cortisol values and an SST or an insulin-induced hypoglycemia test, as needed. A "pass" response to these tests indicates adequate function of the HPA axis, and corticosteroid therapy can be safely withdrawn. The level of basal 9:00 AM serum cortisol that predicts a pass on an SST varies by the assay used from 336 to 506 nmol/L, indicating the importance of knowledge of assay characteristics.[371] In those patients who are taking physiologic doses of prednisolone (<5–7.5 mg/day) or equivalent corticosteroid, an SST given 12 to 24 hours after omitted steroid therapy will provide an immediate answer as to whether sudden or gradual withdrawal of steroid therapy is indicated (Table 15.17).[361]

Iatrogenic-induced Cushing syndrome occurs in patients who take suppressive doses of corticosteroids for longer than 3 weeks.[182] The rapidity of onset of clinical features depends on the administered dose but can occur within 1 month of therapy.

Hypoadrenalism During Critical Illness

Hypoadrenalism may also complicate critical illness, even in individuals with a previously intact HPA axis.[372] This has been termed *functional adrenal insufficiency* to reflect the notion that hypoadrenalism is transient and is not caused by a structural lesion. Functional adrenal insufficiency has been difficult to define biochemically and is of uncertain cause. Moreover, in patients with hypoproteinemia, with serum albumin less than 2.5 g/dL, total serum cortisol may be low, but free cortisol is normal.[252] Nevertheless, an inability to mount an adequate and appropriate cortisol response to overwhelming stress or sepsis is frequently encountered in intensive care units and substantially increases the risk of death during acute illness.[373] This has stimulated attempts to define functional adrenal insufficiency quantitatively and to treat it with supplemental corticosteroids. Although this diagnosis remains highly contentious, if a suboptimal cortisol response is suspected, the current recommendations suggest (1) treatment with hydrocortisone, 200 mg/day in four divided doses or, preferably, 10 mg/hour as a continuous infusion, for patients with septic shock and (2) treatment with methylprednisolone, 1 mg/kg per day, for patients with severe early acute respiratory distress syndrome. Glucocorticoid treatment should be tapered off rather than stopped abruptly. Treatment of critical illness–related adrenal insufficiency with dexamethasone is not recommended.[374]

Clinical Features of Adrenal Insufficiency

Patients with primary adrenal failure usually have both glucocorticoid and mineralocorticoid deficiencies. In contrast, those with secondary adrenal insufficiency have an intact RAA system. This accounts for differences in salt and water balance in the two groups of patients, which in turn result in different clinical presentations. The most obvious feature that differentiates primary from secondary hypoadrenalism is skin pigmentation (Table 15.18), which is almost always present in cases of primary adrenal insufficiency (unless of short duration) and absent in secondary insufficiency. The pigmentation is seen in sun-exposed areas, recent rather than old scars, axillae, nipples, palmar creases, pressure points, and mucous membranes (buccal, vaginal, vulval, anal). The cause of the pigmentation has long been debated but is

TABLE 15.18 Clinical Features of Primary Adrenal Insufficiency

Feature	Frequency (%)
Symptoms	
Weakness, tiredness, fatigue	100

thought to reflect increased stimulation of the MC1R by ACTH itself. In autoimmune Addison disease, there may be associated vitiligo (Fig. 15.32).

The clinical features relate to the rate of onset and the severity of adrenal deficiency.[314] In many cases, the disease has an insidious onset, and a diagnosis is made only when the patient presents with an acute crisis during an intercurrent illness. Acute adrenal insufficiency, termed an *adrenal crisis* or *addisonian crisis,* is a medical emergency manifesting as hypotension and acute circulatory failure (Table 15.19). Anorexia may be an early feature; it progresses to nausea, vomiting, diarrhea, and sometimes abdominal pain. Fever may be present, and hypoglycemia may occur. Patients presenting acutely with adrenal hemorrhage have hypotension; abdominal, flank, or lower chest pain; anorexia; and vomiting. The condition is difficult to diagnose, but evidence of occult hemorrhage (rapidly falling hemoglobin), progressive hyperkalemia, and shock should alert the clinician to the diagnosis.

Alternatively, the patient may present with vague features of chronic adrenal insufficiency—weakness, tiredness, weight loss, anorexia or nausea, intermittent vomiting, abdominal pain, diarrhea or constipation, general malaise, muscle cramps, arthralgia, and symptoms suggestive of postural hypotension (see Table 15.18). Salt craving may be a feature, and a low-grade fever may be present. Supine blood pressure is usually normal, but almost invariably there is a fall in blood pressure on standing. Adrenal androgen secretion is lost; this is clinically more apparent in women, who may notice loss of axillary and pubic hair and frequently have dry and itchy skin. Psychiatric symptoms may occur in long-standing cases and include memory impairment, depression, and psychosis. Formal quality-of-life measures indicate significant impairment in patients with primary or secondary adrenal insufficiency.[375] Tiredness is often profound, and patients may be inappropriately diagnosed with chronic fatigue syndrome or anorexia nervosa.[376]

In secondary adrenal insufficiency due to hypopituitarism, the presentation may relate to deficiency of hormones other than ACTH, notably LH/FSH (infertility, oligomenorrhea/amenorrhea, poor libido) and TSH (weight gain, cold intolerance). Fasting hypoglycemia occurs because of loss of the gluconeogenic effects of cortisol. It is rare in adults unless there is concomitant alcohol abuse or additional GH deficiency. However, hypoglycemia is a common presenting feature of ACTH/adrenal insufficiency in childhood.[377] In addition, patients with ACTH deficiency present with malaise, weight loss, and other features of chronic adrenal insufficiency. Rarely, the presentation is more acute in patients with pituitary apoplexy.

Investigation of Hypoadrenalism

Routine Biochemical Profile

Among patients with established primary adrenal insufficiency, hyponatremia is present in about 90% and hyperkalemia in 65%. The blood urea concentration is usually elevated. Hyperkalemia occurs because of aldosterone deficiency, so it is usually absent in patients with secondary adrenal failure. Hyponatremia may be depletional in an addisonian crisis, but vasopressin levels are elevated, resulting in increased free water retention.[378] Therefore, in secondary adrenal insufficiency, there may be a dilutional hyponatremia with normal or low blood urea.

Reversible abnormalities in liver transaminases frequently occur. Hypercalcemia occurs in 6% of all cases[379] and may be particularly marked in patients with coexisting thyrotoxicosis. Free thyroxine concentrations are usually low or normal, but TSH values are frequently moderately elevated.[380] This is a direct effect of glucocorticoid deficiency and reverses with replacement therapy. Persistent elevation of TSH in association with positive thyroid autoantibodies suggests concomitant autoimmune thyroid disease.

Mineralocorticoid Status

In primary hypoadrenalism, mineralocorticoid deficiency usually occurs, manifested by elevated plasma renin activity and either low or low-normal plasma aldosterone. The investigation of ZG activity is frequently neglected in Addison disease, compared with assessment of ZF function. In secondary adrenal insufficiency, the RAA system is intact.

Assessing Adequacy of Function of the HPA Axis

Clinical suspicion of the diagnosis should be confirmed with definitive diagnostic tests. Basal plasma cortisol and urinary free cortisol levels are often in the low-normal range and cannot be used to exclude the diagnosis. However, a basal cortisol value greater than 400 nmol/L (>14.5 μg/dL) indicates an intact HPA axis. In patients with a suspected addisonian crisis, however, treatment should be instigated immediately and prior to the result of biochemical testing being available. The SST involves intramuscular or intravenous administration of 250 μg tetracosactrin, synthetic ACTH(1-24).[381] Plasma cortisol levels are measured at 0 and 30 to 60 minutes after ACTH administration, and a normal response has previously been defined by a peak plasma cortisol level greater than 550 nmol/L (>20 μg/dL).[382] This value equates to the 5th percentile response in normal subjects but is very much assay dependent, with different cortisol radioimmunoassays giving different results. With more recent immunoassays and LC-MS/MS assays that read lower, levels above 430 to 450 nmol/L are usually consistent with normal adrenal function.[383] Incremental responses (i.e., the difference between peak and basal values) are of no value in defining a "pass" response, with the possible exception of diagnosing functional adrenal insufficiency in patients with critical illness. Response is unaffected by the time of day of the test, and the test can be performed in patients who

TABLE 15.19 Clinical and Laboratory Features of an Adrenal Crisis

Dehydration, hypotension, or shock out of proportion to severity of current illness
Nausea and vomiting with a history of weight loss and anorexia
Abdominal pain, so-called acute abdomen

Hyperpigmentation or vitiligo
Other autoimmune endocrine deficiencies, such as hypothyroidism or gonadal failure

have commenced corticosteroid replacement therapy, as long as this therapy is of short duration and does not include hydrocortisone (which would be detected in the cortisol assay). Depot or prolonged ACTH stimulation tests to discriminate between primary and secondary adrenal insufficiency are no longer indicated if plasma ACTH has been appropriately measured at baseline.

For investigation of secondary adrenal insufficiency the insulin-induced hypoglycemia test or insulin tolerance test (ITT) remains the gold standard test of the integrity of the HPA axis.[384] It should not be performed in patients with ischemic heart disease (always check an electrocardiogram before the test), epilepsy, or severe hypopituitarism (i.e., 9 AM plasma cortisol <180 nmol/L [<6.5 μg/dL]). The test involves the intravenous administration of soluble insulin in a dose of 0.1 to 0.15 U/kg body weight, with measurement of plasma cortisol at 0, 30, 45, 60, 90, and 120 minutes. Adequate hypoglycemia (blood glucose <2.2 mmol/L with signs of neuroglycopenia—sweating and tachycardia) is required for a fail result. In normal subjects, the peak plasma cortisol concentration exceeds 500 nmol/L (18 μg/dL). However, the cortisol response to hypoglycemia can be reliably predicted by the SST—a safer, cheaper, and quicker test.[381,385]

The SST relies on the principle that the cortisol response to an exogenous bolus of ACTH is determined by the endogenous ACTH trophic drive to the adrenal cortex; impaired ACTH secretion from the anterior pituitary results in an impaired cortisol response after synacthen administration. However, the ACTH test should not be used to diagnose central hypoadrenalism in patients with a recent pituitary insult (e.g., surgery, apoplexy). Total hypophysectomy results in a failed cortisol response to ITT immediately thereafter, but it takes 6 weeks for the adrenal cortex to readjust to the reduced level of ACTH secretion; in the interim, a false-positive (normal) cortisol response is seen. The SST should also be avoided in patients with a primary diagnosis of Cushing disease, in whom an exaggerated cortisol response to ACTH may persist following surgical removal of the adenoma.

In clinical practice, if the SST is normal, insulin hypoglycemia testing is not necessary in most cases unless there is also a need to document endogenous GH reserve in a patient with pituitary disease. Some patients have an inadequate SST response but then respond normally to hypoglycemia[385]; they do not require corticosteroid replacement therapy. Conversely, falsely normal results have been reported for the SST.[386] Although these are rare (<2%), the possibility should be noted, particularly in patients with ongoing symptoms and signs indicative of hypoadrenalism.

A low-dose SST giving only 1 μg ACTH(1-24) has been proposed as a screen for adequacy of function of the HPA axis, with the suggestion that it may be more sensitive than the conventional 250-μg test.[387–389] Other researchers dispute this suggestion,[390,391] and although popular with pediatric endocrinologists, wide variations in the dose administered using differing dilutional methods to prepare the 1-μg dose preclude reliance on this test.[392]

Two other tests have been advocated to assess adequacy of function of the HPA axis, but their use in modern clinical practice should be restricted to difficult diagnostic cases. In the overnight metyrapone test, 30 mg/kg (maximum, 3 g) metyrapone is given at midnight, and plasma cortisol and 11-deoxycortisol are measured at 8 AM the following morning. In patients with an intact HPA axis, ACTH levels rise after the blockade of cortisol synthesis by metyrapone (documented with a serum cortisol <5 μg/dL), and a normal result is signified by a peak 11-deoxycortisol value greater than 7 μg/dL.[393] The CRH stimulation test has been used to diagnose adrenal insufficiency; unlike the metyrapone test, it differentiates primary from secondary causes. Patients with primary adrenal failure have high ACTH levels that rise further after CRH stimulation. Patients with secondary adrenal failure have low ACTH levels that fail to respond to CRH. Patients with hypothalamic disease show a steady rise in ACTH levels after CRH administration.[394]

Testing the HPA Axis During Critical Illness

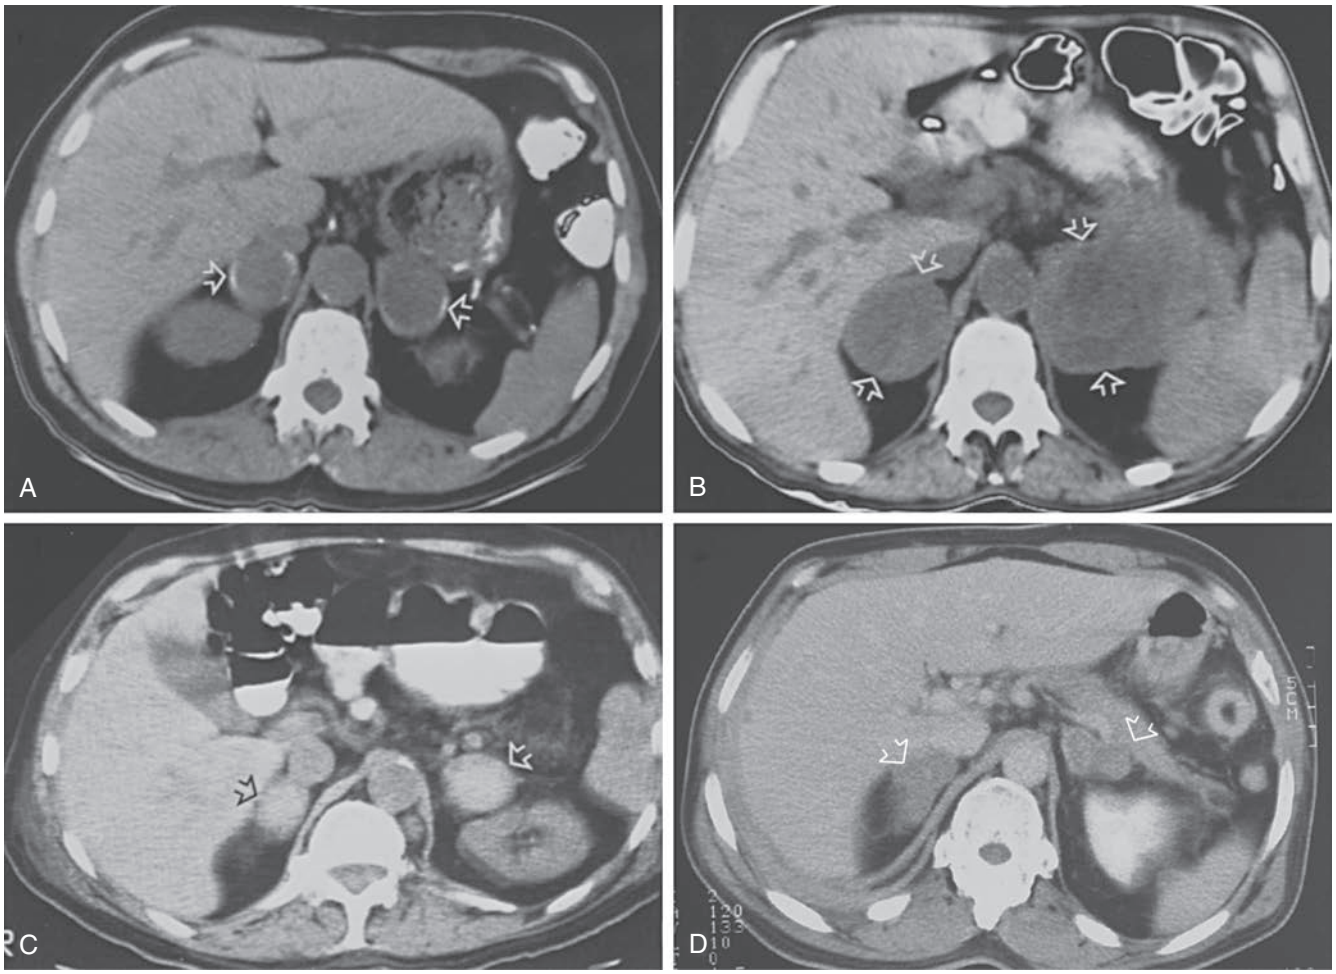
Many factors complicate investigation of the HPA axis during critical illness. Cortisol levels vary broadly with disease severity, making it difficult to define appropriate responses. Additionally, CBG levels decrease substantially, leading to increases in the ratio of free to bound serum cortisol; for this reason, tests that assess the whole axis (e.g., ITT) are not appropriate in the critical care setting. Investigations are therefore limited mainly to basal cortisol levels, with the caveat of low total but preserved free serum cortisol.[252] Methylprednisolone is recommended for patients with severe early acute respiratory distress syndrome, particularly those with poor response to fluid resuscitation and vasopressor agents.[395] The role of glucocorticoids in the management of critically ill patients with other conditions requires further research.

Other Tests

Autoantibodies to 21-hydroxylase should be analyzed in patients with primary adrenal failure. In autoimmune Addison disease, it is also important to look for evidence of other organ-specific autoimmune disease. A CT scan may reveal enlarged or calcified adrenals, suggesting an infective, hemorrhagic, or malignant diagnosis (Fig. 15.33). Chest radiography, tuberculin testing, and early-morning urine samples cultured for *Mycobacterium tuberculosis* should be performed if tuberculosis is suspected. CT-guided adrenal biopsy may reveal an underlying diagnosis in patients with suspected malignant deposits in the adrenal gland. Adrenoleukodystrophy can be diagnosed by measuring circulating levels of VLCFA, which should be obtained in males with primary adrenal insufficiency and negative 21-hydroxylase antibodies. Finally, appropriate investigations, including pituitary MRI scans and an assessment of anterior function, are required for patients with suspected secondary hypoadrenalism who are not taking corticosteroid therapy.

Treatment of Acute Adrenal Insufficiency

Acute adrenal insufficiency is a life-threatening emergency, and treatment should not be delayed while waiting for definitive proof of diagnosis (Table 15.20). However, in addition to measurement



• **Fig. 15.33** Computed tomographic (CT) scans of patients with primary adrenal insufficiency. The affected adrenal glands are indicated by *arrows*. (A) CT scan of a 59-year-old man with histoplasmosis. Notice the subcapsular calcium in both glands. (B) CT scan of a 59-year-old man with metastatic melanoma. (C) CT scan of an 80-year-old man with bilateral adrenal hemorrhage resulting from anticoagulation for pulmonary emboli. of plasma electrolytes and blood glucose, appropriate samples for ACTH and cortisol should be taken before corticosteroid therapy is given. If the patient is not critically ill, an SST can be performed.

In adults, intravenous hydrocortisone should be given in a dose of 100 mg every 6 to 8 hours. If venous access is not possible, then the intramuscular route should be used. In the patient with shock, 1 L of normal saline should be given intravenously over the first hour. Because of possible hypoglycemia, it is normal to give 5% dextrose in saline. Subsequent saline and dextrose therapy will depend on biochemical monitoring and the patient's condition. Clinical improvement, especially in the blood pressure, should be seen within 4 to 6 hours if the diagnosis is correct. It is important to recognize and treat any associated condition (e.g., infection) that may have precipitated the acute adrenal crisis.

After the first 24 hours, the dose of hydrocortisone can be reduced, usually to 50 mg intramuscularly every 6 hours and then to oral hydrocortisone, 40 mg in the morning and 20 mg at 3 to 6 PM. This dose can then be rapidly reduced to a more standard replacement dose of 10 to 20 mg on awakening and 5 to 10 mg at 3 to 6 PM.

Long-Term Replacement Therapy

The aim of long-term therapy is to give replacement doses of hydrocortisone to mimic the normal cortisol secretion rate (Table 15.21). In the past, this rate was thought to be approximately 25 to 30 mg/day, but stable isotope studies have indicated lower normal cortisol production rates of 8 to 15 mg/day.[396] Most patients are adequately treated with less than 30 mg/day (usually 15–25 mg/day in divided doses). Doses are usually given on awakening, with a smaller dose at 3 to 6 PM, but some patients feel better with three-times-a-day dosing. In cases of primary adrenal failure, some clinicians advocate cortisol day curves with simultaneous ACTH measurements to provide some insight into the adequacy of replacement therapy.[397] A simple weight-adjusted regime significantly reduces intraindividual variation in circulating levels.[398] There are no good biomarkers of glucocorticoid adequacy in patients with central hypoadrenalism. Decisions regarding doses of replacement therapy are largely based on crude, yet important, end points such as weight, well-being, and blood pressure.[399] Bone mineral density is moderately reduced in a dose-dependent manner in patients treated with more than

TABLE 15.20 Treatment of Acute Adrenal Insufficiency (Adrenal Crisis) in Adults

Emergency Measures

1. Establish intravenous access with a large-gauge needle.
2. Draw blood for immediate serum electrolytes and glucose and routine measurement of plasma cortisol and ACTH. Do not wait for laboratory results.
3. Infuse 2–3 L of 154 mmol/L NaCl (0.9% saline) solution, or 50 g/L (5%) dextrose in 154 mmol/L NaCl (0.9% saline) solution, as quickly as possible. Monitor for signs of fluid overload by measuring central or peripheral venous pressure and listening for pulmonary rales. Reduce infusion rate if indicated.
4. Inject intravenous hydrocortisone (100 mg immediately and every 6 hours).
5. Use supportive measures as needed.

Subacute Measures After Stabilization of the Patient

1. Continue intravenous 154 mmol/L NaCl (0.9% saline) solution at a slower rate for next 24–48 hours.
2. Search for and treat possible infectious precipitating causes of the adrenal crisis.
3. Perform a short ACTH stimulation test to confirm the diagnosis of adrenal insufficiency (if patient does not have known adrenal insufficiency).
4. Determine the type of adrenal insufficiency and its cause, if not already known.
5. Taper glucocorticoids to maintenance dosage over 1–3 days, if precipitating or complicating illness permits.
6. Begin mineralocorticoid replacement with fludrocortisone (0.1 mg by mouth daily) when saline infusion is stopped.

ACTH, Adrenocorticotropic hormone.

TABLE 15.21 Treatment of Chronic Primary Adrenal Insufficiency in Adults

Maintenance Therapy

Glucocorticoid Replacement

- Hydrocortisone 15–20 mg on awakening and 5–10 mg in early afternoon
- Monitor clinical symptoms and morning plasma ACTH.

Mineralocorticoid Replacement

- Fludrocortisone 0.1 (0.05–0.4) mg orally
- Liberal salt intake
- Monitor lying and standing blood pressure and pulse, edema, serum potassium, and plasma renin activity.
- Educate patient about the disease, how to manage minor illnesses and major stresses, and how to inject steroid intramuscularly.
- Obtain MedicAlert bracelet/necklace, Emergency Medical Information card.

Treatment of Minor Febrile Illness or Stress

- Increase glucocorticoid dose twofold to threefold for the few days of illness; do not change mineralocorticoid dose.
- Contact physician if illness worsens or persists for more than 3 days or if vomiting develops.
- No extra supplementation is needed for most uncomplicated, outpatient dental procedures with local anesthesia. General anesthesia or intravenous sedation should not be used in the office.

Emergency Treatment of Severe Stress or Trauma

- Inject contents of prefilled dexamethasone (4-mg) syringe or contents of hydrocortisone hemisuccinate rapid reconstitution vial (100-mg) intramuscularly.
- Get to physician as quickly as possible.

Steroid Coverage for Illness or Surgery in Hospital

- For moderate illness, give hydrocortisone 50 mg bid PO or IV. Taper rapidly to maintenance dose as patient recovers.
- For severe illness, give hydrocortisone 100 mg IV q8h. Taper to maintenance level by decreasing by half every day. Adjust dose according to course of illness.
- For minor procedures under local anesthesia and most radiologic studies, no extra supplementation is needed.
- For moderately stressful procedures such as barium enema, endoscopy, or arteriography, give a single 100-mg IV dose of hydrocortisone just before the procedure.
- For major surgery, give hydrocortisone 100 mg IV just before induction of anesthesia and continue q8h for first 24 hours. Taper dose rapidly, decreasing by half per day, to maintenance level.

ACTH, Adrenocorticotropic hormone; *bid,* twice a day; *IV,* intravenous; *PO,* orally; *q,* every.

25 mg/day of hydrocortisone,[400] highlighting the need to strive for minimally effective but safe doses.[401,402] Possibly because of the known action of IGF1 to increase cortisol clearance,[137] glucocorticoid requirements are slightly lower in hypopituitary, GH-deficient subjects than in patients with primary adrenal insufficiency.

In primary adrenal failure, mineralocorticoid replacement is usually also required in the form of fludrocortisone (or 9α-fluorinated hydrocortisone), 0.05 to 0.2 mg/day. The mineralocorticoid activity of this drug is about 125 times that of hydrocortisone. After the acute phase has passed, the adequacy of mineralocorticoid replacement should be assessed by measuring electrolytes, supine and erect blood pressures, and plasma renin activity or mass.[403] Too little fludrocortisone may cause postural hypotension with elevated plasma renin activity, whereas too much causes the converse. Mineralocorticoid replacement therapy is all too frequently neglected in patients with adrenal failure.[404]

Patients on glucocorticoid replacement therapy should be advised to double their daily dose in the event of intercurrent febrile illness or accidents. If the patient is vomiting and cannot take medication by mouth, parenteral hydrocortisone must be given urgently. For minor surgery, 50 to 100 mg hydrocortisone hemisuccinate is given with the premedication. For major operations, this pretreatment is followed by the same regimen as for acute adrenal insufficiency (see Table 15.21). Pregnancy proceeds normally in patients taking replacement therapy, but daily doses of hydrocortisone are usually increased modestly (5–10 mg/day) in the last trimester. Progesterone is a mineralocorticoid antagonist, and the rising levels across pregnancy may necessitate an increased dose of fludrocortisone. During labor, patients should be well hydrated with a saline drip and should receive hydrocortisone 50 mg intramuscularly every 6 hours until delivery. Thereafter, doses can be rapidly tapered to prepregnancy levels.

Every patient on glucocorticoid therapy should be advised to register for a medical alert bracelet or necklace and to carry information describing their condition, treatment, and doctors. Patients should receive regular education regarding the requirements of stress-related glucocorticoid dose adjustment, which should involve the patient's partner and family as well. Parenteral preparations of hydrocortisone for self-administration may be required for patients living far from hospitals and those traveling.

For women with both primary and secondary adrenal failure, beneficial effects of adrenal androgen replacement therapy with 25 to 50 mg/day of DHEA have been reported. To date, reported benefit is principally confined to female patients and includes improvement in sexual function and well-being.[405] However, patients with adrenal insufficiency on current steroid replacement regimens have significantly impaired health-related subjective health status irrespective of the origin of disease or concomitant disease.[375] Delayed-release hydrocortisone preparations, such as Plenadren, that more closely replicate normal circadian cortisol concentrations have recently been licensed and approved; early clinical trials show improved quality of life in both primary and central hypoadrenalism compared to conventional twice-daily or thrice-daily hydrocortisone administration.[406]

Congenital Adrenal Hyperplasia

CAH comprises a group of autosomal recessive disorders caused by deficient adrenal corticosteroid biosynthesis.[407,408] It results from defects in one of the steroidogenic enzymes involved in cortisol biosynthesis or in the electron-providing factor, POR. Congenital lipoid adrenal hyperplasia, caused by StAR deficiency affecting mitochondrial cholesterol uptake, is a subform of this disease complex with the unique feature of lipid accumulation leading to cell destruction. In each case, there is reduced negative feedback inhibition of cortisol and, depending on the steroidogenic pathway involved, alteration in adrenal mineralocorticoid and androgen secretion (Table 15.22).

Aldosterone synthase deficiency does not affect glucocorticoid biosynthesis and does not lead to adrenal hyperplasia, but it has been historically grouped into this disease complex. All forms of CAH together represent a disease continuum, ranging from severe forms caused by complete loss-of-function defects to milder forms in which the defective proteins have partial residual activity.

21-Hydroxylase Deficiency

Between 90% and 95% of cases of CAH are caused by 21-hydroxylase deficiency.[407,408] In Western societies, the incidence of classic 21-hydroxylase deficiency (defined by cortisol deficiency) varies from 1 in 10,000 to 1 in 15,000 live births, but in isolated communities the incidence may be much higher (e.g., 1:300 in Alaskan Yupik populations). Nonclassic 21-hydroxylase deficiency is more common, with an incidence of about 1 in 500 to 1000 live births. The condition arises because of defective conversion of 17OHP to 11-deoxycortisol. Reduced cortisol biosynthesis results in reduced negative feedback drive and increased ACTH secretion; as a consequence, adrenal androgens are produced in excess (Fig. 15.34). Seventy-five percent of patients with classic 21-hydroxylase deficiency have clinically manifest mineralocorticoid deficiency because of failure to convert sufficient progesterone to DOC in the ZG. Clinically, several distinct variants of 21-hydroxylase deficiency have been recognized (Table 15.23).

Simple Virilizing Form

In the simple virilizing form of 21-hydroxylase deficiency, the enhanced ACTH drive to adrenal androgen secretion in utero leads to virilization of an affected female fetus. Depending on the severity, clitoral enlargement, labial fusion, and development of a urogenital sinus may occur, leading to sexual ambiguity at birth and even inappropriate sex assignment. Males are phenotypically normal at birth and are at risk of not being diagnosed; this explains the skewed female-to-male ratio of simple virilizing CAH diagnosed in the preneonatal screening era. Such patients may present in early childhood with signs of precocious pseudopuberty such as sexual precocity, pubic hair development, or growth acceleration due to premature androgen excess. If left untreated, this sex steroid production stimulates premature epiphyseal closure, and final adult height is invariably diminished.[409,410]

Salt-Wasting Form

Seventy-five percent of patients of both sexes with classic 21-hydroxylase deficiency have the salt-wasting form and also have concomitant, clinically manifested aldosterone deficiency. In addition to the described features, neonates commonly present after the first 2 weeks of life with a salt-wasting crisis and hypotension if not diagnosed from screening. The clinical signs and symptoms of salt wasting include poor feeding, vomiting, failure to thrive, lethargy, and sepsis-like symptoms. These features may alert the clinician to the diagnosis in a male baby, but the diagnosis is still delayed in many cases, and the condition carries a significant neonatal mortality rate.

Nonclassic or Late-Onset 21-Hydroxylase Deficiency

Patients with nonclassic 21-hydroxylase (NCAH) deficiency present in childhood or early adulthood with premature pubarche or with a phenotype that may masquerade as polycystic ovary syndrome (PCOS).[407,411,412] Indeed, nonclassic 21-hydroxylase deficiency is a recognized secondary cause of PCOS and is far more common than the classic variant. Some evidence suggests that at least 30% of adult patients have an impaired cortisol response to ACTH(1-24)[413] and may be prone to stress-induced adrenal insufficiency, but the rates of adrenal crises in untreated patients appear to be very low. There is overlap in the effects of mutations that cause NCAH and classic 21-hydroxylase deficiency, and if patients fail an SST they are better characterised as occult classic 21-hydroxylase deficiency. In some series from tertiary referral centers, nonclassic 21-hydroxylase deficiency accounts for up to 12% of all PCOS patients, but more realistic prevalence rates are probably 1% to 3%.[414] Females present with hirsutism, primary or secondary amenorrhea, or anovulatory infertility.[411] Androgenic alopecia and acne may be other presenting features.

Heterozygote 21-Hydroxylase Deficiency

Salt wasting, simple virilizing, and late-onset 21-hydroxylase deficiency are all caused by homozygous or compound heterozygote mutations in the human 21-hydroxylase gene *(CYP21A2)*. In the carrier or heterozygote state, only one allele is mutated. The clinical significance of the heterozygote state is uncertain; it does not appear to disadvantage reproductive capability but may cause signs of hyperandrogenism in adult women.[407]

Molecular Genetics

21-Hydroxylase deficiency is inherited as an autosomal recessive trait, and the higher incidence of the condition in some ethnic communities almost certainly relates to consanguinity. The *CYP21A2* gene and its highly homologous pseudogene *(CYP21A1P)* are located on the short arm of chromosome 6 (6p21.3). Because of the genomic localization within the human leukocyte antigen (HLA) locus, a region with a high frequency of genomic recombinations, most of the mutations causing 21-hydroxylase deficiency are generated by gene conversion events from the *CYP21A1P* pseudogene. Complete gene deletions or conversions of the *CYP21A2* gene, eight pseudogene-derived point mutations, and an 8–base

TABLE 15.22 Congenital Adrenal Hyperplasia: Features for Each Enzyme Defect

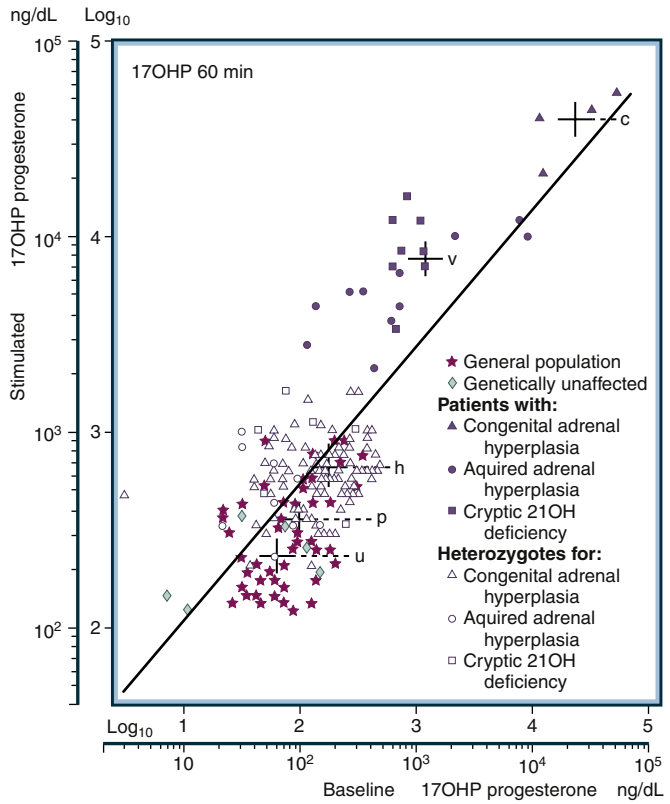
• **Fig. 15.35** Genetics of 21-hydroxylase deficiency. (A) Genomic organization of the functional *CYP21A2* gene and its nonfunctional *CYP21A1P* pseudogene. (B) Nine of 10 common mutations are transferred by microconversions from the *CYP21A1P* pseudogene into the *CYP21A2* gene. (C) Genotype-phenotype correlation in 21-hydroxylase deficiency is well established. Based on the in vitro enzyme activity, the *CYP21A2* gene-inactivating mutations can be categorized into four major mutation groups. Although variation has been reported for the milder mutations, the overall correlation is high regarding expression of the adrenal phenotype. Considerable variability exists for the correlation with genital virilization. *CAH,* congenital adrenal hyperplasia.

pair deletion are found in more than 95% of cases. Other rare pseudogene-independent *CYP21A2*-inactivating mutations have been reported in single families or small populations. Approximately 65% to 75% of CAH patients are compound heterozygous for the disease-causing mutations.[415]

The genotype-phenotype correlation in CAH due to the 21-hydroxylase deficiency is well established. The clinical phenotype correlates with the less severely mutated allele and, consequently, with the residual 21-hydroxylase activity (Fig. 15.35).[416,417] This correlation appears to be high in populations, although divergence between genotype and phenotype has been observed for individuals.[418] The 21-hydroxylase activity measured by in vitro analysis provides a possibility for estimating disease severity, although some phenotypic variability (e.g., salt wasting, age at onset) seems likely to depend on other interacting genes and maturation processes rather than *CYP21A2* itself. One such factor might be the length of the CAG repeats in the androgen receptor modulating androgen action.[419] Potential variations in the degree of recovery from



• **Fig. 15.36** Basal and stimulated plasma 17α-hydroxyprogesterone (17OHP) concentrations in patients with 21-hydroxylase (21OH, CYP21A2) deficiency. To convert values to nmol/L, multiply by 0.0303. The mean for each group is indicated by a large cross and an adjacent letter: *c*, patients with classic CYP21A2 deficiency; *h*, heterozygotes for all forms of CYP21A2 deficiency; *p*, general population; *u*, known unaffected persons (e.g., siblings of patients with CYP21A2 deficiency who carry neither affected parental haplotype as determined by human leukocyte antigen typing); *v*, patients with nonclassic (acquired and cryptic) CYP21A2 deficiency. (From White PC, New MI, Dupont B. Congenital adrenal hyperplasia: part 1. *N Engl J Med*. 1987;316:1519–1524.)

glucocorticoid and mineralocorticoid deficiency during later life might be explained by significant 21-hydroxylase activity of the enzymes cytochrome P450 2C19 and P450 3A4.[420]

Diagnostic Criteria

A diagnosis of 21-hydroxylase deficiency should be considered in any newborn infant with genital ambiguity and salt wasting, hypotension, or hypoglycemia. Hyponatremia and hyperkalemia with raised plasma renin activity are found in salt-wasters. In later life, adrenal androgen excess (DHEAS, androstenedione) is found in patients presenting with sexual precocity or a PCOS-like phenotype. Randomly timed measurements of the plasma 17OHP concentration are significantly increased in classic 21-hydroxylase deficiency. Commonly, 17OHP concentrations in patients with salt-wasting CAH are higher than in non–salt-losing patients.

In nonclassic 21-hydroxylase deficiency, an SST is required to establish normal adrenal glucocorticoid reserve. Clinically useful nomograms have been developed that compare circulating concentrations of 17OHP before and 60 minutes after stimulation to investigate borderline cases and to differentiate between nonclassic 21-hydroxylase deficiency and heterozygous carriers (Fig. 15.36).[421] This test separates patients with classic and nonclassic 21-hydroxylase deficiency from heterozygote carriers and normal subjects, but there is some overlap between values seen in heterozygotes and in normal subjects. 17OHP and cortisol are measured basally and then 60 minutes after administration of 250 μg synacthen. Stimulated values are invariably grossly elevated (>35 nmol/L [>1100 ng/dL]) in patients with classic and nonclassic forms of the disorder. Heterozygote patients usually have stimulated values between 10 and 30 nmol/L (330 and 1000 ng/dL) (see Fig. 15.36). Stimulation tests are not always required to make a diagnosis; for example, a basal 17OHP concentration of less than 5 nmol/L (<150 ng/dL) in the follicular phase of the menstrual cycle effectively excludes nonclassic 21-hydroxylase deficiency.[411] *CYP21A2* genotyping to confirm the clinical and biochemical diagnosis is a useful adjunct to hormonal measurements.[422,423] Androgen excess in 21-hydroxylase deficiency is readily suppressed after glucocorticoid administration.

Prenatal diagnosis of 21-hydroxylase deficiency has been advocated, because treatment of an affected female may prevent masculinization in utero.[424] 17OHP can be assayed in amniotic fluid, but the most robust approach is the rapid genotyping of fetal cells obtained by chorionic villous sampling in early gestation. In patients with known 21-hydroxylase deficiency (male or female) seeking fertility, genotyping the partner before conception will uncover nonclassic or heterozygote cases and provide the endocrinologist/geneticist with some assignment of risk before pregnancy.

Treatment

The objectives for treatment of 21-hydroxylase deficiency differ with age, but at all ages treatment and overall patient management can be fraught with difficulties. In childhood, the overall goal is to replace glucocorticoid and mineralocorticoid, thereby preventing further salt-wasting crises, but also to normalize adrenal androgen secretion so that normal growth and skeletal maturation can proceed. Accurate replacement is essential; in excess, glucocorticoids will suppress growth, whereas inadequate replacement will result initially in accelerated linear growth and ultimately in short stature due to premature epiphyseal closure.[407] Response is best monitored through growth velocity and bone age, with biochemical markers from blood (17OHP, androstenedione, testosterone), urine, and saliva (17OHP, androstenedione, testosterone) being useful adjuncts. In difficult cases, a day curve study, as described for patients with primary adrenal failure but measuring the ACTH and 17OHP response before and after corticosteroid replacement, may confirm overreplacement or underreplacement. The optimal glucocorticoid dose fails to suppress 17OHP and its metabolites and maintains sex hormone concentrations in the middle of the age-specific and sex-specific normal range. Ideally, the biochemical investigations will indicate the need for dose adjustments before physical changes, growth, and skeletal maturation indicate inadequate or excessive glucocorticoid treatment.[424]

Corrective surgery (e.g., clitoral reduction, vaginoplasty) is frequently addressed during childhood. The method of choice should be a one-stage complete repair using the newest techniques of vaginoplasty, clitoral, and labial surgery.[425]

In late childhood and adolescence, appropriate replacement therapy is equally important. Overtreatment may result in obesity and delayed menarche/puberty with sexual infantilism, whereas underreplacement will result in sexual precocity. Compliance with regular medication is often an issue throughout adolescence.

Although much has been written about adequate control in childhood, adults with 21-hydroxylase deficiency often provide an ongoing dilemma for the endocrinologist. The follow-up of such patients should involve multidisciplinary clinics, initially

with transition adolescence clinics to facilitate transfer from pediatric to adult care. Problems in adulthood relate to fertility concerns, hirsutism, and menstrual irregularity in women; obesity, metabolic consequences, and impact of short stature; probable increased cardiovascular risk; sexual dysfunction; and psychologic problems.[407,426,427] Counseling is often required in addition to endocrine support. Males may develop enlargement of the testes due to so-called testicular adrenal rest tumors (TART)—that is, ectopic adrenal tissue, which may regress after glucocorticoid suppression, and if untreated can lead to infertility and affect around one in three male patients. These patients need adequate endocrine therapy rather than urologic referral with ensuing risk of removal of testis mistaken for a tumor.[428]

In the absence of any evidence-based data, there are no prescriptive steroid regimens to treat patients with 21-hydroxylase deficiency at any age, and as a result, many individualized regimens are used in clinical practice. Hydrocortisone is recommended for replacement therapy from the newborn period to adolescence.[425] Usual starting doses of hydrocortisone in childhood are 10 to 15 mg/m^2 per day in three divided doses, with up to 25 mg/m^2 in infancy only seldom required. These doses are higher than those used for replacement of adrenal insufficiency because treatment also aims at normalization of ACTH-driven adrenal androgen excess. The optimal timing for providing the highest dose of hydrocortisone remains an ongoing matter of debate, with no data supporting either circadian replacement (giving the highest dose in the morning) or reverse-phase therapy (giving the largest dose of hydrocortisone at night). Long-acting steroids such as prednisone, prednisolone, and dexamethasone are more effective in this regard but should not be given before the end of puberty to avoid oversuppression and reduction in linear growth.

Fludrocortisone is required for infants with classic 21-hydroxylase deficiency, although this need may spontaneously change with age. Fludrocortisone doses during the first year of life are commonly 150 μg/m^2 per day. Sodium needs to be supplemented, as milk feeds provide only minimal sodium amounts. Adequate mineralocorticoid replacement usually allows hydrocortisone dose reduction. The relative dose in relation to body surface decreases throughout life. Fludrocortisone doses of 100 μg/m^2 per day after the first 2 years of life are commonly sufficient. This requirement drops further with adolescence and adulthood to a daily dose of 100 to 200 μg (50–100 μg/m^2 per day). Mineralocorticoid substitution is monitored by measurements of plasma renin activity (low or suppressed levels indicating overtreatment), serum potassium, and standing blood pressure.[429]

Adrenomedullary dysfunction has been reported in the 21-hydroxylase–deficient adrenal gland, probably because of relative glucocorticoid deficiency, which results in epinephrine deficiency.[173,430] In clinical practice, sufficient supplementation of glucose during exercise and illness should be guaranteed, to prevent hypoglycemic episodes. Bilateral adrenalectomy might appear effective in the short term but should be regarded as a last resort[174]; adrenal rest tumor has appeared after adrenalectomy even in women.[431] In addition, because of the requirement for lifelong corticosteroid replacement therapy, patients could also develop ACTH-secreting pituitary tumors.[432] The adrenalectomy procedure also bears a number of risks, including surgical and anesthetic complications, and the patient is left completely adrenal insufficient.

Prenatal dexamethasone treatment has been proposed to avoid virilization of the external genitalia in the female fetus.[407] Unlike hydrocortisone, which is inactivated by placental 11βHSD2, maternally administered dexamethasone can cross the placenta to suppress the fetal HPA axis. However, due to concerns over the long-term effects of dexamethasone on the mother and fetus, prenatal therapy is not recommended outside research studies.[433,434] Fetal sex and *CYP21A2* genotype can be determined as early as week 6 of gestation with the use of novel molecular diagnostic methods that analyze cell-free fetal DNA from maternal blood using real-time polymerase chain reaction.[435] In this way, the number of unnecessarily treated cases can be substantially reduced. Dexamethasone can lead to maternal cushingoid effects in pregnancy[434,436] and may in turn have long-term, deleterious effects on the fetus, including metabolic, psychologic, and intellectual consequences. Prenatal treatment is controversial and has to be regarded as experimental; patients treated should be included in ongoing multicenter studies.[437]

In adult women with hyperandrogenism and untreated nonclassic 21-hydroxylase deficiency, there is no evidence that final height is affected. In this setting, glucocorticoid therapy in isolation rarely controls hirsutism, and additional antiandrogen therapy is often required (e.g., cyproterone acetate, spironolactone, flutamide together with an oral estrogen-containing contraceptive pill). Most studies have found increased risk of miscarriage in women with nonclassic 21-hydroxylase deficiency, and some retrospective series suggest that the risk is lower in women treated with glucocorticoid replacement during pregnancy.[438,439] Hypogonadotropic hypogonadism in male patients is a consequence of increased aromatization of adrenal androgens, in particular androstenedione to estrone, resulting in suppression of pituitary LH and FSH secretion.[440] The condition is reversible after optimization of glucocorticoid therapy. However, overreplacement in men or women may also lead to hypogonadotropic hypogonadism due to glucocorticoid-mediated suppression of GnRH secretion.

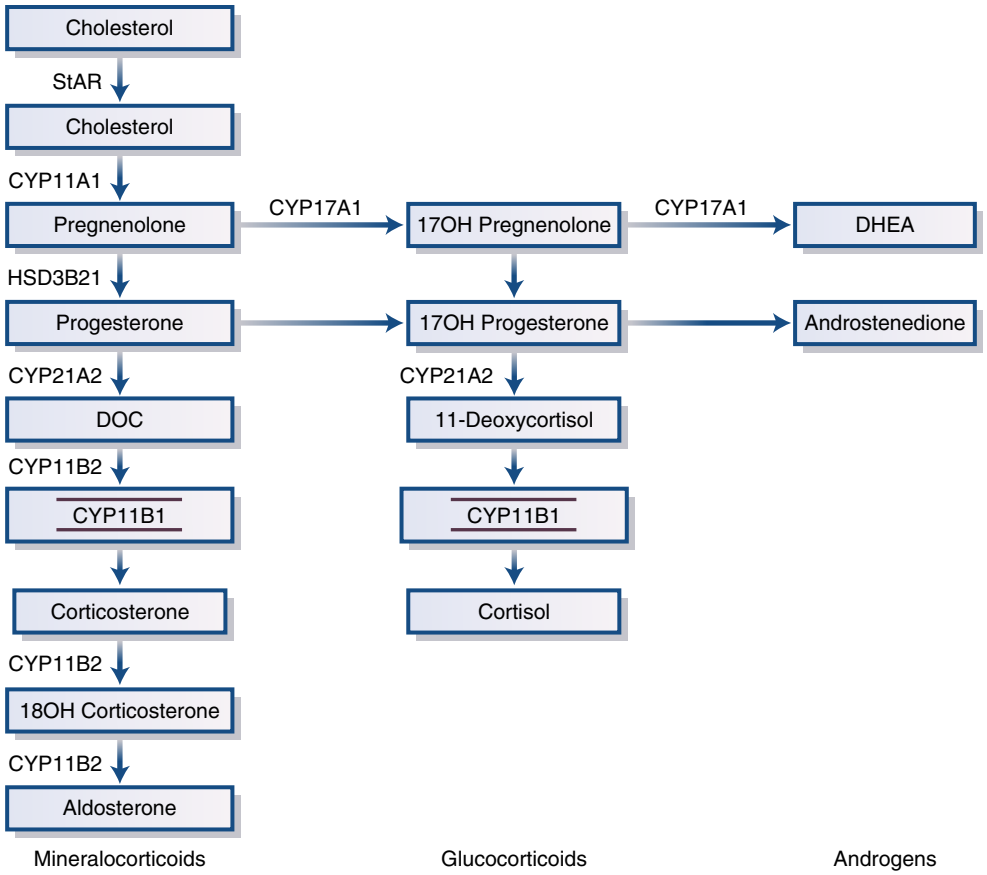
Long-Term Complications and Comorbid Conditions

Outcome assessed by final height is not optimal in many patients treated for 21-hydroxylase deficiency. In a large UK cohort the mean adult height of patients with classic 21-hydroxylase deficiency was 14 cm and 8 cm below the population mean for men and women, respectively.[441] Similar data from the United States shows that final height is -1.1 SDS compared to the control population.[442] The pubertal growth spurt occurs earlier and is less pronounced than normal. An often overlooked problem is glucocorticoid overtreatment during the first 2 years of life; overtreatment suppresses the infant growth spurt, which is characterized by the highest postnatal growth velocity. Therefore the lowest optimal dose of glucocorticoid replacement should be established as early in life as possible.

Increased fat mass and obesity are common among children and adolescents with 21-hydroxylase deficiency.[443–445] Glucocorticoid dose, chronologic age, advanced bone age maturation, and parental obesity all contribute to elevated BMI SDS.[444]

Increased fat mass and higher insulin levels have been described in women older than 30 years of age with 21-hydroxylase deficiency. However, clear evidence of cardiovascular risk factors had not been shown. Women with classic 21-hydroxylase deficiency do have a significantly higher rate of gestational diabetes, a possible forerunner for the development of type 2 diabetes,[446] and women with nonclassic[447] and young adults with classic 21-hydroxylase deficiency[448] have reduced insulin sensitivity. Increased intima media thickness as a marker of atherosclerosis has been detected.[448]

Daytime systolic blood pressure in children and adolescents with 21-hydroxylase deficiency is elevated, and the physiologic



• **Fig. 15.37** Congenital adrenal hyperplasia related to 11β-hydroxylase deficiency. The normal synthesis of cortisol is impaired, and adrenocorticotropic hormone (ACTH) levels increase because of the loss of normal negative feedback inhibition, which results in an increase in adrenal steroid precursors proximal to the block. The results are cortisol deficiency, mineralocorticoid excess related to excessive deoxycorticosterone *(DOC)* secretion, and excessive secretion of adrenal androgens. *CYP,* cytochrome P450; *DHEA,* dehydroepiandrosterone; *HSD,* hydroxysteroid dehydrogenase; *StAR,* steroidogenic acute regulatory protein.

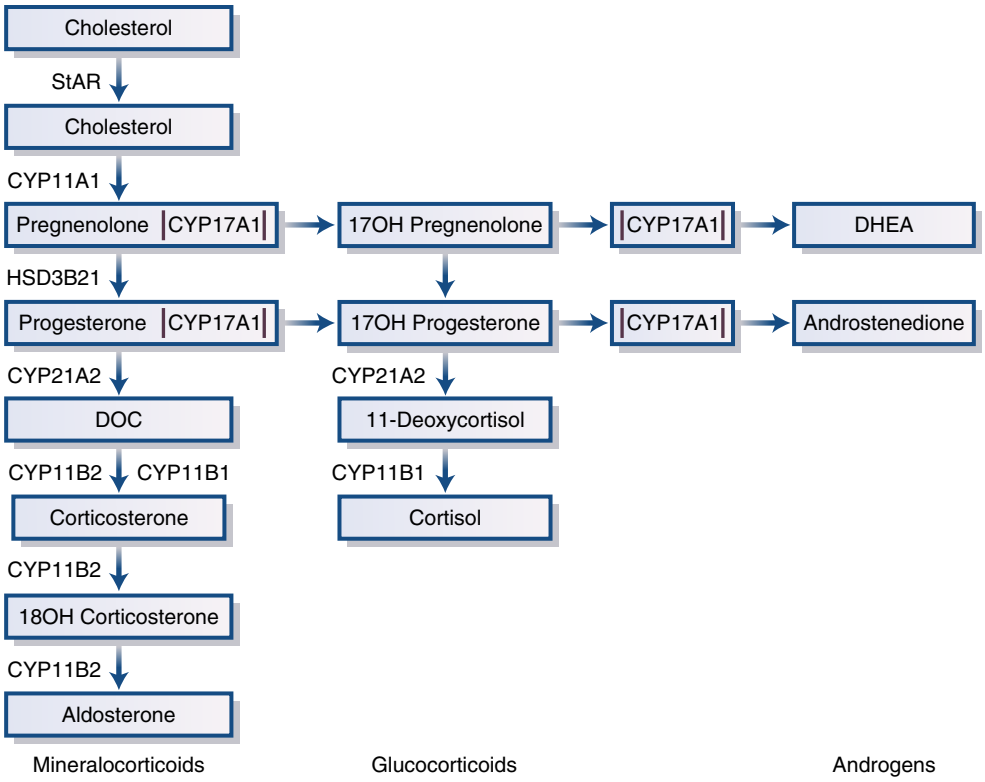
nocturnal dip in blood pressure is absent.[449] Elevated systolic blood pressure correlates with the degree of overweight and obesity.[450] In adults, hypertension was found to be more common in men and in patients with elevated 17OHP,[442] in data from the United States, but in the large UK Congenital adrenal Hyperplasia Adult Study Executive (CaHASE) cohort men with CAH had blood pressure significantly lower than controls. The reasons for these discrepancies are not established.

11β-Hydroxylase Deficiency

11β-Hydroxylase deficiency accounts for up to 7% of all cases of CAH, with an incidence of 1 in 100,000 live births.[451] The condition arises because of mutations in the 11β-hydroxylase *(CYP11B1)* gene that result in loss of enzyme activity and a block in the conversion of 11-deoxycortisol to cortisol. The *CYP11B1* gene is located on chromosome 8q24.3, approximately 40 kilobases from the highly homologous aldosterone synthase gene *(CYP11B2).*[451] *CYP11B1*-inactivating mutations have been shown to be distributed over the entire coding region consisting of nine exons. Although mutation clusters are reported in exons 2, 6, 7, and 8,[415,451] real hot spots, as seen in 21-hydroxylase deficiency, do not exist. Most of the reported mutations lead to absent or almost absent 11β-hydroxylase enzyme activity, with only some cases of mild or nonclassic 11β-hydroxylase deficiency reported.[452–454]

Loss of negative cortisol feedback and enhanced ACTH-mediated adrenal androgen excess occur in 11β-hydroxylase deficiency (Fig. 15.37). Clinical features therefore are very similar to those reported in the simple virilizing form of 21-hydroxylase deficiency (46,XX DSD, including virilization of the external genitalia and sexual ambiguity); again, milder cases can manifest later in childhood or even young adulthood. The principal difference from 21-hydroxylase deficiency is hypertension, which is thought to be secondary to the mineralocorticoid effect of DOC excess. However, there is a poor correlation between DOC secretion and the presence of hypertension, and unexplained salt wasting has been reported in few patients during early life. On this clinical background, the diagnosis can be made by measuring a plasma synacthen–stimulated 11-deoxycortisol value, which will be greater than 52 nmol/L (>1800 ng/dL) and often much higher.[455] Basal concentrations of 17OHP are commonly increased but may be normal even during the first weeks of life.[455]

Treatment is with replacement glucocorticoid therapy; with suppression of DOC secretion, the plasma renin activity, which is suppressed at baseline, increases into the normal range. In general, higher glucocorticoid doses are needed to suppress hyperandrogenism compared with the situation in 21-hydroxylase



• **Fig. 15.38** Congenital adrenal hyperplasia related to 17α-hydroxylase deficiency. The normal synthesis of cortisol is impaired, and adrenocorticotropic hormone (ACTH) levels increase because of loss of normal negative feedback inhibition resulting in an increase in adrenal steroid precursors proximal to the block. The result is cortisol deficiency and mineralocorticoid excess usually related to deoxycorticosterone *(DOC)* excess. Because gonadal 17α-hydroxylase activity is also absent, sex steroid secretion in addition to adrenal androgen secretion is severely impaired, resulting in hypogonadism. *CYP,* cytochrome P450; *DHEA,* dehydroepiandrosterone; *HSD,* hydroxysteroid dehydrogenase; *StAR,* steroidogenic acute regulatory protein.

deficiency, and add-on antihypertensive therapy may be necessary in some cases. Antihypertensive treatment should be commenced at an early stage to avoid excessive glucocorticoid exposure.

17α-Hydroxylase Deficiency

17α-hydroxylase deficiency is less common than 11β-hydroxylase deficiency, except in Brazil.[456–459] Mutations within the *CYP17A1* gene result in failure to synthesize cortisol (17α-hydroxylase activity), adrenal androgens (17,20-lyase activity), and gonadal steroids (Fig. 15.38). Therefore, in contrast to 21-hydroxylase and 11β-hydroxylase deficiencies, 17α-hydroxylase deficiency results in adrenal and gonadal insufficiency and causes 46,XY DSD. A single enzyme is expressed in the adrenal and the gonads and possesses both 17α-hydroxylation and 17,20-lyase activities, but rare patients with isolated deficiency of 17,20-lyase deficiency have been reported.[457,460,461] Loss of negative feedback results in increased secretion of steroids proximal to the block, and mineralocorticoid synthesis is enhanced. Corticosterone has weaker glucocorticoid activity than cortisol, but corticosterone excess generally prevents adrenal crises. Accumulation of corticosterone and DOC results in severe hypokalemic hypertension. Sex steroid deficiency caused by loss of 17,20-lyase activity results in 46,XY DSD; this manifests as undervirilization in male newborns and primary amenorrhea in 46,XX individuals. There is lack of pubertal development due to hypergonadotropic hypogonadism in both sexes.[458]

The 17α-hydroxylase enzyme is a microsomal cytochrome P450 type II enzyme that requires electron transfer from NADPH via POR for catalytic activity.[27] For efficient catalysis of the 17,20-lyase reaction, the P450 17A1-POR complex requires additional allosteric interaction with cytochrome b_5.[460,462] The *CYP17A1* gene consists of eight exons and is located on chromosome 10q24.3. A variety of different mutations have been described, without evidence of a hot spot.[415,463] Relative hydroxylase/lyase activities of P450 17A1 mutants have been shown to vary in in vitro functional assays, but correlations with clinical phenotype are lacking. Patients with clinically pure 17,20-lyase deficiency have P450 17A1 mutations that selectively compromise 17,20-lyase activity.[460,461,464] Mutations underlying isolated 17,20-lyase deficiency are located within the area of the P450 17A1 molecule that is thought to interact with the cofactor cytochrome b_5, thereby disrupting the electron transfer from POR to P450 17A1, specifically for the conversion of 17-hydroxypregnenolone to DHEA.[460,464]

The diagnosis is usually made at the time of puberty when patients present with hypertension, hypokalemia, and hypergonadotropic hypogonadism, the last occurring because of lack of P450 17A1 activities within the gonad and impaired gonadal steroidogenesis. As a result, LH and FSH levels are elevated. Female patients (XX) have primary amenorrhea with absent sexual

characteristics, whereas 46,XY individuals present with 46,XY DSD with female external genitalia but absent uterus and fallopian tubes. The intra-abdominal testes should be removed due to the risk of malignancies, and such patients are usually reared as females.

Glucocorticoid replacement reverses the DOC-induced suppression of the renin-angiotensin system and lowers blood pressure. Additional sex steroid replacement is required from puberty onward.

P450 Oxidoreductase Deficiency: Apparent Combined 17α-Hydroxylase and 21-Hydroxylase Deficiencies

Very few patients have been described with biochemical evidence of apparent combined 17α-hydroxylase and 21-hydroxylase deficiencies.[465] Urinary gas chromatography/mass spectrometry analysis reveals a typical pattern comprising increased pregnenolone and progesterone metabolites, slightly increased corticosterone metabolites, increased pregnanetriolone excretion, and low androgen metabolites (see Fig. 15.4). Mothers pregnant with an affected child present with low serum estriol and a characteristic urinary steroid profile, allowing for prenatal biochemical diagnosis.[466,467] Limited analysis of serum steroids only may lead to misdiagnosis.[468] Cortisol baseline secretion may be normal, but most if not all patients show an insufficient cortisol response to synacthen stimulation and therefore require glucocorticoid replacement. Impaired 17,20-lyase activity results in deficient androgen synthesis, and affected boys are often born undervirilized. Most of the affected girls are born with virilized genitalia. Therefore patients can present with 46,XY or 46,XX DSD or with appropriate development of the external genitalia in both sexes. After birth, virilization does not progress, and circulating androgen concentrations are typically low. Some mothers develop signs of virilization during midpregnancy with an affected child; this commonly resolves soon after birth, further indicating intrauterine androgen excess.[466] In addition to these features of CAH, affected children may also present with bone malformations, including midface hypoplasia, craniosynostosis, and radiohumeral synostosis, in some cases meeting criteria for the Antley-Bixler congenital malformation syndrome.[469,470] The bone phenotype in affected patients with POR deficiency is most likely caused by an impairment of sterol biosynthesis, specifically of POR-dependent 14α-lanosterol demethylase (P450 51A1).

The paradox of fetal virilization but sex hormone deficiency in postnatal life might be mediated by a newly discovered "backdoor" pathway of androgen synthesis in fetal life that relies on neither androstenedione nor testosterone as an intermediate.[470–472] Pubertal development in POR deficiency appears to be dominated by the consequences of sex steroid deficiency,[472] and most patients require sex hormone substitution. The overall incidence of POR deficiency has not been established. However, a relatively large number of patients with POR deficiency were reported within a short period after the initial description of the molecular cause of the disease.[472,473]

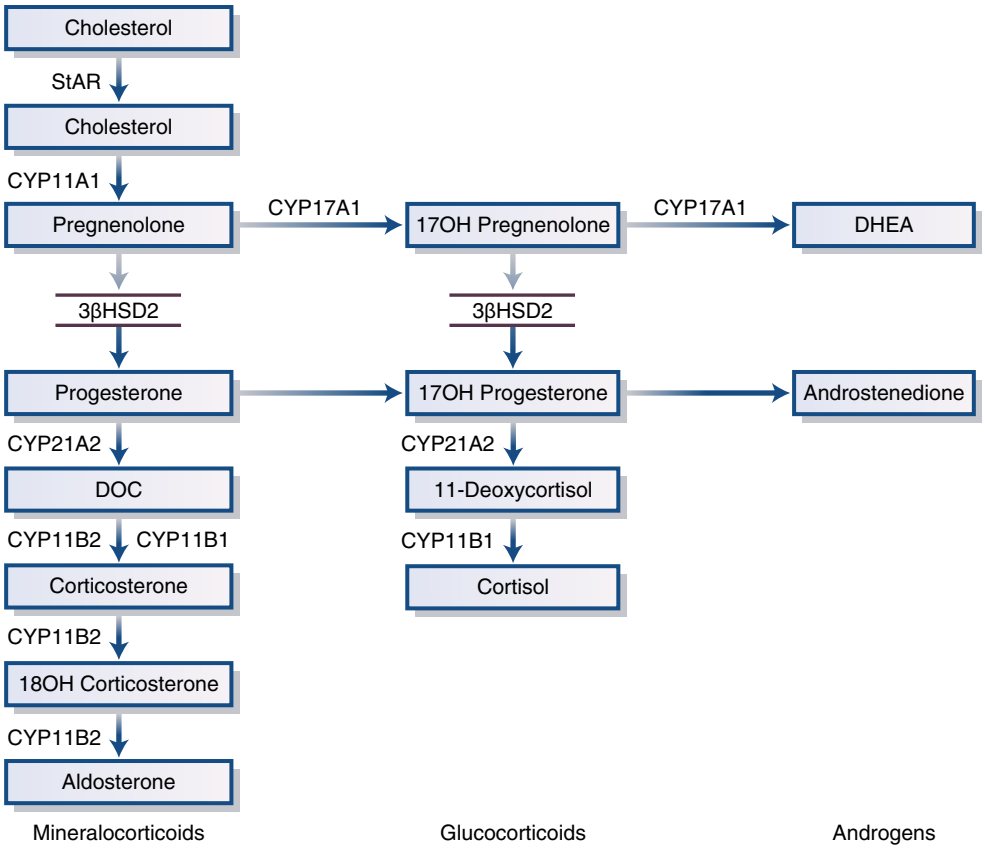
The *POR* gene is located on chromosome 7q11.2 and consists of 15 translated exons spanning 32.9 kilobytes and encoding a protein of 680 amino acids. A variety of *POR*-inactivating mutations have been reported, including missense, frameshift, and splice site mutations. A287P is the most common mutation in Caucasians, whereas R457H is the most frequent founder mutation in the Japanese population. All patients carry *POR* mutations that are either partially inactivating or, in case of major loss-of-function mutations, manifest only in the compound heterozygous state. Homozygous mutations with total loss of function are most likely not viable—a view supported by the nonviability of complete *POR* gene deletion in the murine model.[474]

3β-Hydroxysteroid Dehydrogenase Deficiency

In this rare form of CAH, the secretion of all classes of adrenal and ovarian steroids is impaired due to mutations within the *HSD3B2* gene encoding 3βHSD2.[475,476] There are two isoforms of 3βHSD, encoded by *HSD3B1* and *HSD3B2*, respectively. The *HSD3B2* gene is located on chromosome 1p13.1 and consists of four exons. 3βHSD2 is expressed mainly in the adrenal and the gonad, whereas 3βHSD1 is expressed in the placenta and almost ubiquitously in peripheral target tissues.[28,476] The enzyme 3βHSD2 catalyzes three key reactions in adrenal steroidogenesis: the conversion of the Δ^5 steroids pregnenolone, 17-hydroxypregnenolone, and DHEA to the Δ^4 steroids progesterone, 17OHP, and androstenedione, respectively. 3βHSD2 deficiency affects all three steroid hormone pathways (i.e., mineralocorticoids, glucocorticoids, and sex steroids).

The clinical spectrum shows a wide variety of disease expression. Patients usually present in early infancy with adrenal insufficiency. Loss of mineralocorticoid secretion results in salt wasting, although this is absent in 30% to 40% of cases (Fig. 15.39). As with 21-hydroxylase deficiency, absence of salt wasting may delay the presentation into childhood or puberty, ranging from a severe salt-wasting form with or without ambiguous genitalia in affected male neonates to isolated premature pubarche in infants and children of both sexes and a rare nonclassic variant manifesting with hirsutism and menstrual irregularities. In general, the functional and biochemical data are in close agreement with the expressed phenotype in patients with the non–salt-wasting form of 3βHSD2 deficiency. However, some variability exists, and identical mutations have been found in the *HSD3B2* gene in both salt-wasters and non–salt-wasters.[475,476] The correlation between the impairment in male sexual differentiation and salt wasting is poor. The spectrum of genital development is variable in both sexes. In males, because the 3βHSD2 enzyme is also expressed within the gonad, 46,XY DSD may occur, resulting in female external genitalia. However, most patients present with hypospadias, and even normal male genitalia may be found. In females, genital development can be normal, but usually there is evidence of mild virilization, presumably because of enhanced adrenal DHEA secretion, which is converted peripherally to testosterone. A nonclassic form has been described in patients with premature pubarche and a PCOS-like phenotype (i.e., hirsutism, oligomenorrhea/amenorrhea).[477]

Because activity of the 3βHSD1 enzyme, present in peripheral tissues, is intact, levels of circulating Δ^4 steroids (progesterone, 17OHP, androstenedione) may be normal (or even increased). However, a diagnosis is established by demonstration of an increased ratio of Δ^5 steroids (pregnenolone, 17-hydroxypregnenolone, DHEA) to Δ^4 steroids in plasma or urine. Hormonal criteria have been refined for the diagnosis of 3βHSD2 deficiency based on genotyping of the *HSD3B2* gene. The 17-hydroxypregnenolone concentrations and the ratios of 17-hydroxypregnenolone to cortisol at baseline and after ACTH stimulation are of the highest discriminatory value in differentiating between patients affected by 3βHSD2 deficiency and those with milder biochemical abnormalities, who are commonly negative for *HSD3B2* mutations.[478,479]



• **Fig. 15.39** Congenital adrenal hyperplasia related to 3β-hydroxysteroid dehydrogenase type 2 (3βHSD2) deficiency resulting in cortisol deficiency and variable mineralocorticoid deficiency. Gonadal 3βHSD2 activity is also absent, resulting in 46,XY DSD and hypogonadism or primary amenorrhea in females. Virilization in females can occur due to 3β-hydroxysteroid dehydrogenase type 1 activity. *DOC,* deoxycorticosterone; *DHEA,* dehydroepiandrosterone; *DSD,* disorder of sex development; *StAR,* steroidogenic acute regulatory protein.

StAR Deficiency: Congenital Lipoid Adrenal Hyperplasia

Mutations in the gene encoding StAR result in a failure of transport of cholesterol from the outer to the inner mitochondrial membrane in steroidogenic tissues. StAR-independent cholesterol transport occurs only at a low rate. As a result, there is deficiency of all adrenal and gonadal steroid hormones.[24,480] The adrenal glands are often massively enlarged and full of lipid; before the characterization of StAR, the condition was termed *congenital lipoid adrenal hyperplasia*.[480] StAR deficiency severely but incompletely abolishes pregnenolone synthesis. Cholesterol esters accumulate under the increased tone of ACTH stimulation. Consequently, the lipid accumulation worsens the dysfunction and leads to adrenal cell destruction. Presentation is with acute adrenal insufficiency in the neonatal period, and males exhibit 46,XY DSD due to absent gonadal steroids.

The most severe form of this disorder manifests with 46,XY DSD and combined adrenal insufficiency. Salt wasting typically develops in the neonatal period or after a few weeks of life, but later onset may also occur. Females can show spontaneous pubertal development. A milder form of StAR deficiency has also been described in normally virilized 46,XY individuals who present with adrenal failure during early childhood.[481] Treatment consists of glucocorticoid and mineralocorticoid replacement and substitution of sex hormones in later life.

P450 Side-Chain Cleavage Deficiency

Deficiency of P450scc (P450 11A1) enzyme is a rare inborn error of steroidogenesis. It was previously thought that such mutations would not be viable, because the maintenance of human pregnancy relies on progesterone that is produced by the fetal part of the placenta from the second trimester onward. P450 11A1 deficiency manifests clinically and biochemically with similar signs and symptoms as StAR deficiency, but patients do not have enlarged adrenals.[482–484] Depending on the impairment of P450 11A1 function, a spectrum of clinical presentation ranges from 46,XY DSD with severe adrenal insufficiency in the newborn period to hypospadias and cryptorchidism and later manifestation of adrenal insufficiency during childhood.[485] Concentrations of all steroid hormones are decreased, in keeping with impaired conversion of cholesterol to pregnenolone. Treatment with glucocorticoid, mineralocorticoid, and sex steroid replacement is required.

Cortisone Reductase Deficiency

In cortisone reductase deficiency, adrenal glands become hyperplastic because of ACTH stimulation due to a defect in cortisol metabolism rather than an inherent defect within the gland itself.[135,486,487] Patients with this condition have a defect in the conversion of cortisone to cortisol, suggesting inhibition of 11-oxoreductase activity and, by implication, inhibition of 11βHSD1

Drug induced

(see Fig. 15.12). Cortisol clearance is increased; consequently, ACTH secretion is elevated to maintain normal circulating cortisol concentrations but at the expense of adrenal androgen excess. Female patients present with hirsutism, menstrual irregularity, androgenic alopecia, or some combination of these features. Males may present with premature pubarche. Dexamethasone treatment to suppress ACTH has been used with some success to control the hyperandrogenism in these cases. Urinary tetrahydrometabolites of cortisol and cortisone show almost exclusively THE with little or no detectable THF or allo-THF; the ratio of THF+allo-THF to THE is less than 0.05 (reference range, 0.8–1.3). The molecular bases for cortisone reductase deficiency are inactivating mutations in hexose-6-phosphate dehydrogenase (H6PDH)[487] and dominant negative mutations of 11βHSD1.[488] H6PDH, located in the endoplasmic reticulum, catalyzes the conversion of glucose-6-phosphate to glucose-6-phosphogluconate, thereby generating NADPH, which is crucial in conveying oxo-reductase activity on 11βHSD1.

Patients with PCOS share many of the same clinical characteristics as those with cortisone reductase deficiency. Whereas there is evidence to support increased cortisol secretion rates in PCOS, perhaps indicating a defect in the conversion of cortisone to cortisol, a consensus with respect to THF+allo-THF to THE ratios is still lacking.[489] Association studies using single-nucleotide polymorphic markers in the *HSD11B1* and *H6PDH* genes have largely been negative.

Mineralocorticoid Deficiency

The mineralocorticoid deficiency syndromes are listed in Table 15.24. They can be divided into congenital and acquired syndromes. Mineralocorticoid deficiency may occur in some forms of CAH and with other causes of adrenal insufficiency (e.g., Addison disease, CAH).

Primary Defects in Aldosterone Biosynthesis: Aldosterone Synthase Deficiency

Before the characterization of the *CYP11B2* gene, two diseases were recognized: *corticosterone methyl oxidase type I (CMO I) deficiency* and *corticosterone methyl oxidase type II (CMO II) deficiency.*[490] Subsequently, both variants were shown to be secondary to mutations in aldosterone synthase (P450 11B2), and they are now termed *aldosterone synthase deficiency, types I and II.*[491] Aldosterone synthase catalyzes the three terminal steps of aldosterone biosynthesis, 11β-hydroxylation of DOC to corticosterone, 18-hydroxylation to 18-hydroxycorticosterone, and 18-oxidation to aldosterone. Patients with type I aldosterone synthase deficiency have low to normal levels of 18-hydroxycorticosterone but undetectable levels of aldosterone (or urinary tetrahydroaldosterone), whereas patients with the type II variant have high levels of 18-hydroxycorticosterone and only subnormal or even normal levels of aldosterone. This suggests blockade of only the terminal 18-oxidation step, with some residual aldosterone synthase activity remaining. The explanation for the variable biochemical phenotype is unknown, particularly now that the same mutation in aldosterone synthase has been uncovered in both variants. It is possible that the phenotypic variation may reflect polymorphic variants in the residual and normal product of the *CYP11B1* gene, 11β-hydroxylase.

Both variants are rare and are inherited as autosomal recessive traits.[491] Patients usually present in neonatal life with a salt-wasting crisis involving severe dehydration, vomiting, and failure to grow and thrive. Hyperkalemia, metabolic acidosis, dehydration, and hyponatremia are found. The plasma renin activity is elevated, and plasma aldosterone levels are low. Plasma 18-hydroxycorticosterone levels, the ratio of plasma 18-hydroxycorticosterone to aldosterone, and the levels of their urinary metabolites are used to differentiate the type I and II variants. In most infants, the disorders become less severe as the child ages; indeed, in older children, adolescents, and adults, the abnormal steroid pattern described may be present and may persist throughout life without clinical manifestations.

Patients with P450 11B2 deficiency typically respond well to 9α-fludrocortisone (starting dose, 150 μg/m^2 per day in neonates and infants) and may also benefit from salt supplementation. Patients with failure to grow and thrive usually show a good catch-up growth. Electrolytes often tend to normalize spontaneously between 3 and 4 years of age. However, untreated patients are at significant risk for being growth retarded, although spontaneous normalization of growth can occur. Adults are usually asymptomatic but are more susceptible to salt loss. Rarely, presentation is in adulthood.[492] Mineralocorticoid treatment in later life has to be established on an individual basis.

Postadrenalectomy Hypoaldosteronism

In a patient with a unilateral aldosteronoma (Conn syndrome), the contralateral ZG is frequently suppressed. Without reversal of the chronic volume expansion preoperatively, patients may develop severe hyperkalemia and hypotension lasting several days to several weeks after adrenalectomy. This effect may be exacerbated by the use of spironolactone preoperatively, and is more likely with older age, renal impairment, and proteinuria.[493] Spironolactone has a long half-life and should be discontinued 2 to 3 days before surgery to minimize the risk of postoperative mineralocorticoid deficiency.

Defects in Aldosterone Action: Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) is a rare, inherited salt-wasting disorder that was first described by Cheek and Perry in 1958 as a defective renal tubular response to mineralocorticoid in infancy. Patients present in the neonatal period with dehydration, hyponatremia, hyperkalemia, metabolic acidosis, and failure to thrive despite normal glomerular filtration and normal renal and adrenal function.[494] Renin levels and plasma aldosterone are grossly elevated. When patients fail to respond to mineralocorticoid therapy, PHA is suspected as the underlying disorder.

PHA type I can be divided into two distinct disorders based on unique physiologic and genetic characteristics: the renal form of PHA, which is inherited as an autosomal dominant trait, and a generalized autosomal recessive form of PHA. The autosomal dominant form is usually less severe; the patient's condition often improves spontaneously within the first several years of life,

allowing discontinuation of therapy. By contrast, the autosomal recessive form produces a multiorgan disorder, with mineralocorticoid resistance seen in the kidney, sweat and salivary glands, and the colonic mucosa. The condition does not spontaneously improve with age and is generally more severe than the autosomal dominant form.

The underlying basis for the autosomal dominant form of PHA is explained on the basis of inactivating, dominant-negative mutations in the MR (hMR, NR3C2).[494,495] By contrast, inactivating mutations in the α-subunit and, to a lesser extent, in the β-subunit and γ-subunit of the epithelial sodium channel (ENaC) account for the generalized autosomal recessive form of mineralocorticoid resistance.[496,497] (In effect, this represents the opposite of Liddle syndrome—see Chapter 16.) Generalized loss of ENaC activity leads to renal salt wasting (as seen in the renal form) in addition to recurrent respiratory infections and neonatal respiratory distress, cholelithiasis, and polyhydramnios.

PHA type I (PHA-I) is resistant to mineralocorticoid therapy, so standard treatment involves supplementation with salt (2–8 g/day) in the form of sodium chloride and sodium bicarbonate as well as cation exchange resins. This supplementation usually corrects the patient's biochemical imbalance. However, if a patient shows signs of severe hyperkalemia, peritoneal dialysis may be necessary. Hypercalciuria has been reported in some cases of PHA-I. The recommended course of treatment for these patients usually involves indomethacin or hydrochlorothiazide. Indomethacin is thought to act by causing a reduction in the glomerular filtration rate or an inhibition of the effect of prostaglandin E_2 on renal tubules. Indomethacin has been shown to reduce polyuria, sodium loss, and hypercalciuria. Hydrochlorothiazide has been used to diminish hyperkalemia and reduce hypercalciuria in patients with PHA-I.

In patients with the autosomal dominant or renal form of PHA-I, the signs and symptoms of PHA decrease with age; nevertheless, these patients usually require salt supplementation for the first 2 to 3 years of life. In patients with the autosomal recessive or multiorgan type of PHA-I, resistance to therapy with sodium chloride or drugs that decrease serum potassium concentrations often occurs and may even lead to death in infancy from hyperkalemia. PHA-I patients with multiorgan involvement often require very high amounts of salt in their diet (up to 45 g NaCl per day). Carbenoxolone, a derivative of glycyrrhetinic acid in licorice, has been used with moderate success in helping to reduce the high levels of dietary salt needed by renal PHA-I patients. Carbenoxolone acts by inhibiting 11βHSD2 activity and allows unmetabolized cortisol to bind to and activate MRs in a manner similar to that of aldosterone.[498] Carbenoxolone was found to be ineffective in patients with multiorgan PHA-I.

Two other variants of PHA have been described—types II and III. Type II PHA, or Gordon syndrome, is in retrospect a misnomer. Patients with Gordon syndrome share some of the features of patients with PHA-I, notably hyperkalemia and metabolic acidosis, but they exhibit salt retention with mild hypertension and suppressed plasma renin activity rather than salt wasting. The condition is explained by mutations in a serine threonine kinase family (WNK1 and WNK4) that result in increased expression of these proteins with activation of the thiazide-sensitive sodium chloride cotransporter in the cortical and medullary collecting ducts.[499] The condition represents the exact opposite of Gitelman syndrome but is not a true form of PHA.

Type III PHA is an acquired and usually transient form of mineralocorticoid resistance seen in patients with underlying renal diseases, including obstruction and infection and in patients with excessive loss of salt through the gut or skin. Reduced glomerular filtration rate is a hallmark of the condition. The cause is unknown, although increased transforming growth factor-β–mediated aldosterone resistance has been suggested to be an underlying factor.

Hyporeninemic Hypoaldosteronism

Angiotensin II is a key stimulus to aldosterone secretion, and damage or blockade of the renin-angiotensin system may result in mineralocorticoid deficiency. Various renal diseases have been associated with damage to the juxtaglomerular apparatus and subsequent renin deficiency. These include systemic lupus erythematosus, myeloma, amyloid, AIDS, and damage related to use of nonsteroidal anti-inflammatory drugs, but the most common (>75% of cases) is diabetic nephropathy.[500,501]

The usual picture is that of an elderly patient with hyperkalemia, acidosis, and mild to moderate impairment of renal function. Plasma renin activity and aldosterone levels are low and fail to respond to sodium depletion, erect posture, or furosemide administration. In contrast to adrenal insufficiency, patients have normal or elevated blood pressure and no postural hypotension. Muscle weakness and cardiac arrhythmias may also occur. Other factors may contribute to the hyperkalemia, including the use of potassium-sparing diuretics, potassium supplementation, insulin deficiency, and use of β-adrenoceptor blocking drugs or prostaglandin synthetase inhibitors, which inhibit renin release.

Treatment of primary renin deficiency is with fludrocortisone in the first instance together with dietary potassium restriction. However, these patients are not salt depleted and may become hypertensive with fludrocortisone. In such a scenario, the addition of a loop-acting diuretic, such as furosemide, is appropriate. This will increase acid excretion and improve the metabolic acidosis.

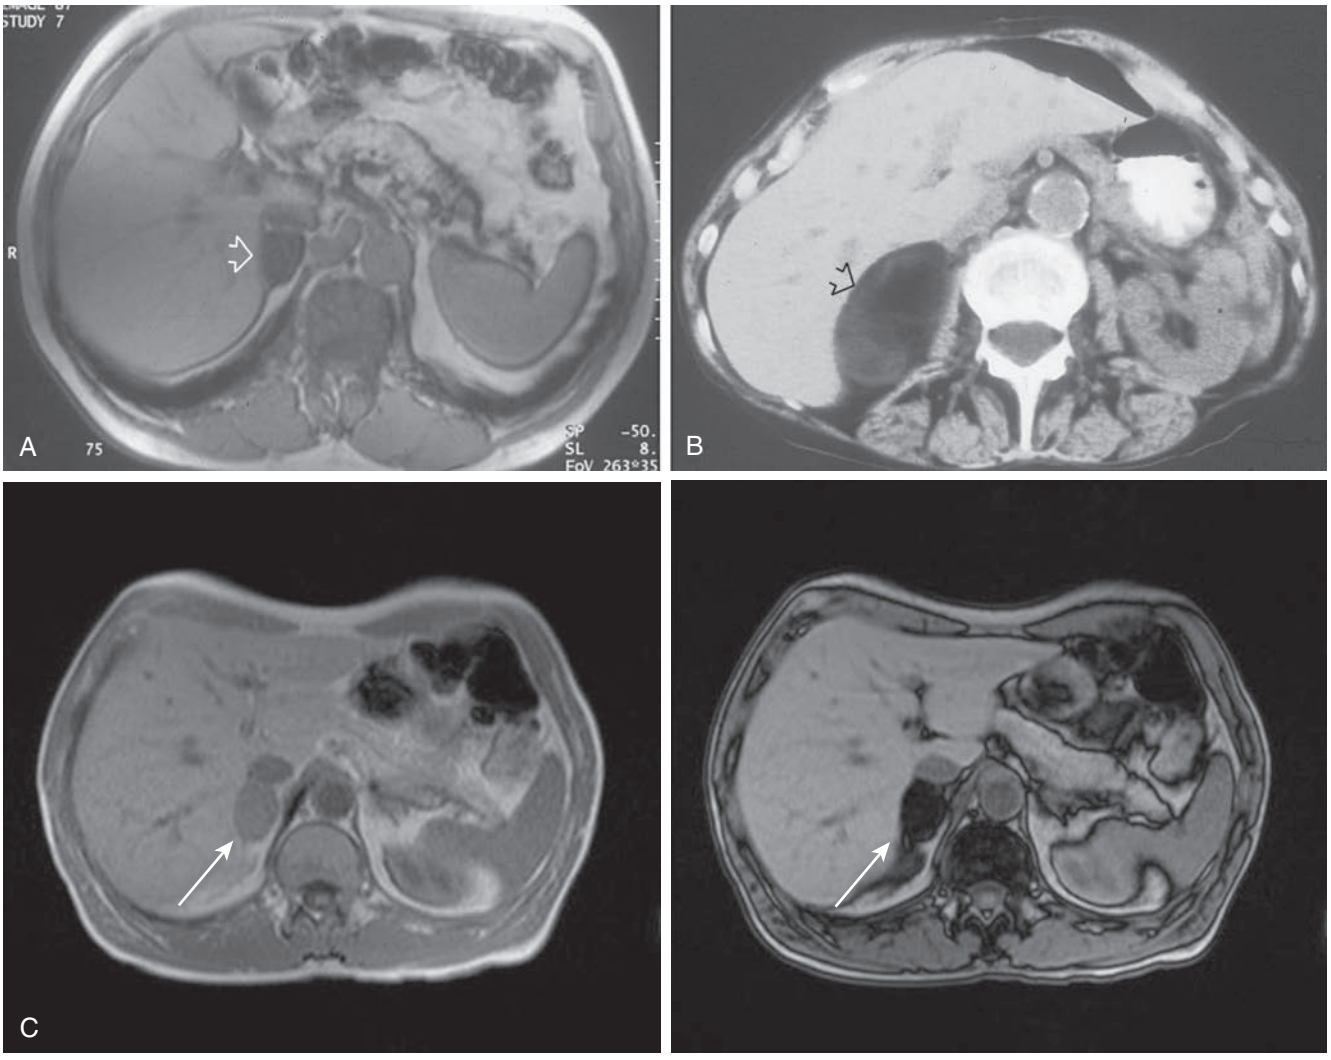
Adrenal Adenomas, Incidentalomas, and Carcinomas

Adenomas

Cortisol-secreting adrenal adenomas were discussed earlier, and aldosterone-secreting adenomas (Conn syndrome) are discussed in Chapter 16. Pure virilizing benign adrenal adenomas are very rare. Most cases occur in women; in males, the disorder is generally recognized in childhood, when presentation is with sexual precocity and accelerated bone age. Such tumors have to be considered in the differential diagnosis of CAH in patients presenting during childhood. In females, most patients present before menopause with marked hirsutism, deepening of the voice, and amenorrhea. Clitoromegaly is found in 80% of cases. Testosterone is usually strikingly elevated, but gonadotropin levels may not be suppressed. By definition, urinary free cortisol is normal. Tumors vary in size and should be treated surgically. Postoperatively, clinical features invariably improve, and normal menses return.[502]

Incidentalomas

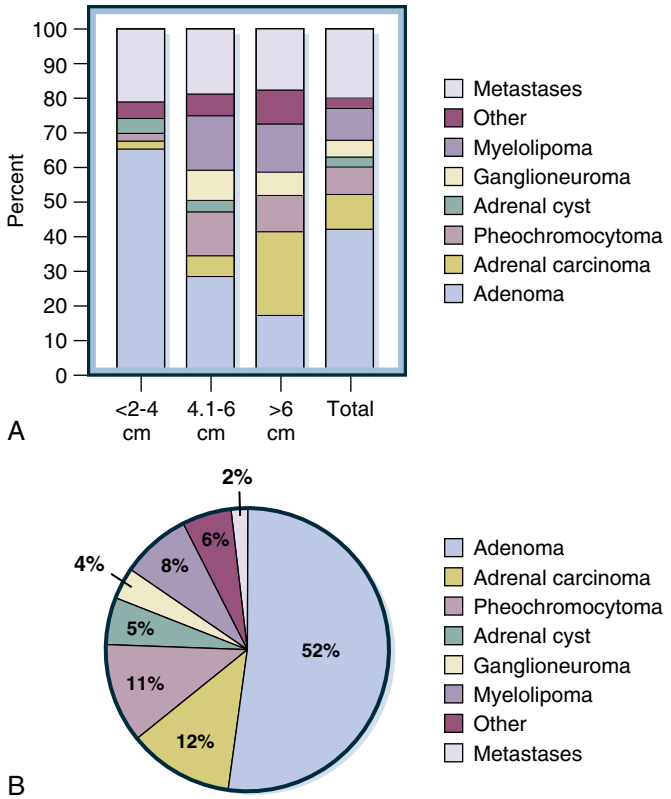
Incidentally discovered adrenal masses have become a common clinical problem. An adrenal mass is uncovered in up to 4% of patients imaged for nonadrenal disease.[503] Incidentalomas are uncommon in patients younger than 30 years of age but increase in frequency with age; they occur more frequent in females, most commonly in the sixth and seventh decades. Clinically, two issues



• **Fig. 15.40** (A) Adrenal incidentaloma *(arrow)* discovered in a woman undergoing investigation for abdominal pain. (B) Incidentally discovered right adrenal myelolipoma *(arrow)*. (C) Chemical shift MRI of adrenal incidentaloma demonstrating signal dropout *(arrow)* for out-of-phase image, consistent with benign disease.

arise: whether the lesion is functional (i.e., secreting hormones) and whether it is malignant. Most incidentalomas are adrenocortical adenomas, but occasionally they represent myelolipomas, hamartomas, or granulomatous infiltrations of the adrenal gland and result in a characteristic CT/MRI appearance (Fig. 15.40). Functioning tumors with a clear clinical phenotype (pheochromocytomas and those secreting cortisol, aldosterone, or sex steroids) and carcinomas account for around 4% of all incidentalomas. In addition, it is established that some incidentalomas cause abnormal hormone secretion without obvious clinical manifestations of a hormone excess state. The best example is so-called subclinical Cushing syndrome, which occurs in up to 20% to 30% of all patients with adrenocortical incidentalomas.[503–505] There is debate as to the best means to biochemically define this phenomenon, but serum cortisol after dexamethasone testing has the widest acceptance, although cutoff values vary. The European Society of Endocrinology and European Network for the Study of Adrenal Tumors (ENSAT) have published guidelines for diagnosis and management.[506] When there is evidence of low-grade excess biochemical hypercortisolism, there is an associated increase in the prevalence of diabetes, obesity, hypertension, new cardiovascular events, osteoporosis, and fatality. However, no prospective study has proven that the adrenal adenoma is the cause of the observed complications, as these are highly prevalent in the population at this age. Intervention by adrenalectomy has shown some benefit, particularly lower blood pressure,[507] but the studies performed have been largely retrospective and highly selected, and hence the approach to each patient needs individualization with most being observed in current clinical practice.

As a result, all patients with incidentally discovered adrenal masses should undergo appropriate endocrine screening tests. This testing should comprise 24-hour urinary metanephrine collection or measurement of plasma metanephrines, an overnight dexamethasone suppression test, and for those with hypertension, measurement of plasma renin and aldosterone. DHEAS should be measured as a marker of adrenal androgen secretion. Low levels may occur in patients with suppressed ACTH concentrations due to autonomous cortisol secretion from the adenoma.[508] Some



• **Fig. 15.41** Distribution of diagnosis of adrenal incidentalomas. (A) Data from eight studies with histologically determined diagnoses (n = 103) relating to tumor size. (B) Distribution of 380 incidental adrenal masses by histologic diagnosis. (From Mansmann G, Lau L, Balk E, et al. The clinically inapparent adrenal mass: update in diagnosis and management. *Endocr Rev.* 2004;25:309–340.)

studies have also documented high levels of 17OHP after ACTH stimulation tests, suggesting partial defects in 21-hydroxylase in some tumors, and this should be measured in cases of bilateral disease.

The possibility of malignancy should be considered in each case. In patients with a known extra-adrenal primary tumor, the incidence of malignancy is obviously much higher; for example, up to 20% of patients with lung cancer have adrenal metastases on CT scanning. In those with no evidence of malignancy, adrenal carcinoma is rare.[509] In true incidentalomas, size appears to be predictive of malignancy: Fewer than 2% of incidentalomas smaller than 4 cm but 25% of those larger than 6 cm in diameter are malignant (Fig. 15.41).[510] Smooth, homogeneous adenomas on an enhanced adrenal scan with a Hounsfield unit (HU) score (a marker of radiodensity) less than 10 HU or signal dropout on out-of-phase MRI sequences (see Fig. 15.40) are invariably benign; malignancy is suspected in irregular, inhomogeneous adenomas with a score greater than 20 HU. On this background, adrenalectomy is considered for functional tumors and for tumors larger than 4 cm in diameter, although if the imaging characteristics are unequivocally benign tumors greater than this size may be left.[506] Repeat CT scanning in patients with smaller tumors can be used to guide management, but development of functional autonomy is very rare, and patients may be discharged if tumors are static. If surgery is indicated, laparoscopic adrenalectomy is the treatment of choice, offering shorter hospital stays and reduced operative complications (e.g., blood loss, morbidity) compared with open adrenalectomy. The exception is the patient with highly suggestive invasive adrenal carcinoma, because breach of the tumor capsule is associated with a poorer outcome. Adequate preparation and close endocrine supervision perioperatively and postoperatively are required for functional tumors.

Carcinomas

Primary adrenal carcinoma is very rare, with an annual incidence of 1 per 1 million population. Women are more commonly affected than men, with a ratio of 2.5:1. The mean age at onset is between 40 and 50 years, although men tend to be older at presentation. Eighty percent of tumors are functional, most commonly secreting glucocorticoids alone (45%), glucocorticoids and androgens (45%), or androgens alone (10%). Fewer than 1% of all tumors secrete aldosterone, and production of hormone precursors is common.[511] Patients present with features of the hormone excess state (glucocorticoid, androgen, or both), but abdominal pain, weight loss, anorexia, and fever occur in 25% of cases. An abdominal mass may be palpable. Current treatment choices for what is often an aggressive tumor are poor. Surgery offers the only chance of cure for patients with local disease, but metastatic spread is evident in 75% of cases at presentation. Radiotherapy is ineffective, as are most chemotherapeutic regimens. Mitotane in high dose, in conjunction with therapeutic drug monitoring, offers benefit in reducing tumor growth[286] and in controlling hormonal hypersecretion in 75% of cases.[285] Overall, the prognosis is poor, with 5-year survival rates of less than 20%. Newer chemotherapies are being evaluated.[287]

Etiology of Adrenal Tumors

Other than the factors discussed under adrenal Cushing syndrome, the underlying basis for adrenal tumorigenesis is unknown. Clonal analysis suggests progression from a normal to an adenomatous to a carcinomatous lesion, but the molecular pathways involved remain obscure. Several factors have been associated with malignant transformation, including the genes encoding p53, p57, cyclin-dependent kinase, menin, IGF2, MC2R, and inhibin-α.[512] Mice lacking the inhibin-α gene develop adrenal tumors through a process that is also gonadotropin dependent.[513]

Endocrine Hypertension

WILLIAM F. YOUNG, JR.

CHAPTER OUTLINE

KEY POINTS

- There are at least 14 endocrine disorders for which hypertension may be the initial clinical presentation. An accurate diagnosis of endocrine hypertension provides the clinician with a unique treatment opportunity: to render a surgical cure or to achieve a dramatic response with pharmacologic therapy.
- Catecholamines affect many cardiovascular and metabolic processes—they increase heart rate, blood pressure, myocardial contractility, and cardiac conduction velocity. The identification of three types of adrenergic receptors (α, β, and dopaminergic receptors) and their subtypes (α_1, α_2, β_1, β_2, β_3, D_1, and D_2) has led to understanding of the physiologic responses to endogenous and exogenous administration of catecholamines.
- Catecholamine-secreting tumors are rare, with an annual incidence of 2 to 8 cases per 1 million people. Nevertheless, it is important to suspect, confirm, localize, and resect these tumors because (1) the associated hypertension is curable with surgical removal of the tumor, (2) a risk of lethal paroxysm exists, (3) at least 10% of the tumors are malignant, and (4) 40% of these tumors are familial and their detection in the proband may result in early diagnosis in other family members.
- Germline mutations are responsible for approximately 40% of all catecholamine-secreting tumors. Mutations contributing to pheochromocytoma and paraganglioma have two general transcription signatures: cluster 1—genes encoding proteins that function in the cellular response to hypoxia, and cluster 2—genes encoding proteins that activate kinase signaling.
- Pheochromocytoma/paraganglioma must be confirmed biochemically by the presence of increased concentrations of fractionated metanephrines and catecholamines in urine or plasma. Then the tumor should be localized with computed tomography (CT) of the abdomen and pelvis. Approximately 85% of these tumors are found in the adrenal glands, and 95% are found in the abdomen and pelvis.
- Some form of preoperative pharmacologic preparation is indicated for all patients with catecholamine-secreting neoplasms, including those who are asymptomatic and normotensive. Surgical resection of a catecholamine-secreting tumor is a high-risk surgical procedure, and an experienced surgeon-anesthesiologist team is required.
- Hypertension, suppressed plasma renin activity, and increased aldosterone excretion characterize the syndrome of primary aldosteronism, which was first described in 1955.
- Aldosterone-producing adenoma and bilateral idiopathic hyperaldosteronism are the most common subtypes of primary aldosteronism. Somatic mutations account for the majority of aldosterone-producing adenomas and include mutations in genes encoding components of the potassium channel *(KCNJ5),* the sodium/potassium and calcium adenosine triphosphatases (ATPases) (*ATP1A1* and *ATP2B3*), a voltage-dependent C-type calcium channel *(CACNA1D),* and β-catenin–activating *CTNNB1* mutations.
- Use of the plasma aldosterone to plasma renin activity ratio as a case-detection test, followed by aldosterone suppression for confirmatory testing, has resulted in prevalence estimates for primary aldosteronism of 5% to 10% of all patients with hypertension.
- The treatment goal in patients with primary aldosteronism is to prevent the morbidity and fatality associated with hypertension, hypokalemia, nephrotoxicity, and cardiovascular damage. Knowing the cause of the primary aldosteronism helps to determine the appropriate treatment. Normalization of blood pressure should not be the only goal—normalization of circulating aldosterone or mineralocorticoid receptor blockade should be part of the management plan for all patients with primary aldosteronism.

An estimated 68 million people in the United States are hypertensive.[1,2] In most, hypertension is *primary* (i.e., *essential* or *idiopathic*), but a subgroup of approximately 15% have *secondary* hypertension. The secondary causes of hypertension can be divided into renal causes, such as renal parenchymal or renovascular disease, and endocrine causes. There are at least 14 endocrine disorders for which hypertension may be the initial clinical presentation (Table 16.1). An accurate diagnosis of endocrine hypertension provides the clinician with a unique treatment opportunity: to render a surgical cure or to achieve a dramatic response with pharmacologic therapy. The diagnostic and therapeutic approaches to endocrine hypertension—ranging from the classic adrenal causes of hypertension (e.g., pheochromocytoma, primary aldosteronism) to pituitary-dependent hypertension (e.g., Cushing syndrome, acromegaly)—are reviewed in this chapter.

Adrenal Medulla and Catecholamines

The adrenal medulla occupies the central portion of the adrenal gland and accounts for 10% of total adrenal gland volume. There is no clear demarcation between the adrenal cortex and the adrenal medulla. The adrenal glands derive blood supply from the superior, middle, and inferior branches of the inferior phrenic artery; from the renal arteries; and directly from the aorta. The adrenal arteries branch and form a plexus under the capsule. This plexus supplies the cortex. Some of the plexus arteries penetrate the cortex and supply the medulla, as do capillaries draining the cortical cells, forming the corticomedullary portal system. The right adrenal vein is short and drains directly into the inferior vena cava (IVC). The left adrenal vein merges with the inferior phrenic vein, and this larger vein (the common phrenic vein) drains into the left renal vein.

TABLE 16.1 Endocrine Causes of Hypertension

Adrenal-Dependent Causes

- Pheochromocytoma
- Primary aldosteronism
- Hyperdeoxycorticosteronism
  - Congenital adrenal hyperplasia
  - 11β-Hydroxylase deficiency
  - 17α-Hydroxylase deficiency
  - Deoxycorticosterone-producing tumor
- Primary cortisol resistance
- Cushing syndrome

AME/11βHSD Deficiency

- Genetic
  - Type 1 AME
  - Type 2 AME
- Acquired
  - Licorice or carbenoxolone ingestion (type 1 AME)
  - Cushing syndrome (type 2 AME)

Thyroid-Dependent Causes

- Hypothyroidism
- Hyperthyroidism

Renin-Secreting Tumor

Pituitary-Dependent Causes

- Acromegaly
- Cushing syndrome

AME, Apparent mineralocorticoid excess; *HSD*, hydroxysteroid dehydrogenase.

Adrenomedullary cells are called *chromaffin cells* (stain brown with chromium salts) or *pheochromocytes*. Cytoplasmic granules turn dark when stained with chromic acid because of the oxidation of epinephrine and norepinephrine to melanin. Chromaffin cells differentiate in the center of the adrenal gland in response to cortisol; some chromaffin cells also migrate to form paraganglia, collections of chromaffin cells located on both sides of the aorta. The largest cluster of chromaffin cells outside the adrenal medulla is located near the level of the inferior mesenteric artery and is referred to as the *organ of Zuckerkandl;* it is quite prominent in the fetus and is a major source of catecholamines during the first year of life. The preganglionic sympathetic neurons receive synaptic input from neurons within the pons, medulla, and hypothalamus, providing regulation of sympathetic activity by the brain. Axons from the lower thoracic and lumbar preganglionic neurons, via splanchnic nerves, directly innervate the cells of the adrenal medulla.

The term *catecholamine* refers to substances that contain catechol (ortho-dihydroxybenzene) and a side chain with an amino group—the catechol nucleus (Fig. 16.1).[3] Epinephrine is synthesized and stored in the adrenal medulla and released into the systemic circulation. Norepinephrine is synthesized and stored not only in the adrenal medulla but also in the peripheral sympathetic nerves. Dopamine, the precursor of norepinephrine, is found in the adrenal medulla and peripheral sympathetic nerves and acts primarily as a neurotransmitter in the central nervous system.

Catecholamines affect many cardiovascular and metabolic processes. They increase the heart rate, blood pressure, myocardial contractility, and cardiac conduction velocity. Activation of G protein–coupled receptors mediates the biologic actions of catecholamines. The identification of three types of adrenergic receptors (α, β, and dopaminergic receptors) and their subtypes (α_1, α_2, β_1, β_2, β_3, D_1, and D_2) has led to understanding of the physiologic responses to endogenous and exogenous administration of catecholamines.[4] The 2012 Nobel Prize in Chemistry was awarded to Brian K. Kobilka and Robert J. Lefkowitz for their studies of G protein–coupled receptors. The α_1 subtype is a postsynaptic receptor that mediates vascular and smooth muscle contraction; stimulation causes vasoconstriction and increases blood pressure. The α_2 receptors are located on presynaptic sympathetic nerve endings; when activated, they inhibit release of norepinephrine. Stimulation causes suppression of central sympathetic outflow and decreased blood pressure.

There are three major β-receptor subtypes. The β_1 receptor mediates cardiac effects and is more responsive to isoproterenol than to epinephrine or norepinephrine. Stimulation causes positive inotropic and chronotropic effects on the heart, increased renin secretion in the kidney, and lipolysis in adipocytes. The β_2 receptor mediates bronchial, vascular, and uterine smooth muscle relaxation. Stimulation causes bronchodilation, vasodilatation in skeletal muscle, glycogenolysis, and increased release of norepinephrine from sympathetic nerve terminals. The β_3 receptor regulates energy expenditure and lipolysis.

D_1 receptors are localized to the cerebral, renal, mesenteric, and coronary vasculatures; stimulation causes vasodilation in these vascular beds. D_2 receptors are presynaptic; they are localized to sympathetic nerve endings, sympathetic ganglia, and the brain.

Stimulation of D_2 receptors in these locations inhibits the release of norepinephrine, inhibits ganglionic transmission, and inhibits prolactin release, respectively.

Most cells in the body have adrenergic receptors. The pharmacologic development of selective α-adrenergic and β-adrenergic agonists and antagonists has advanced pharmacotherapy for various clinical disorders. For example, β_1 antagonists (e.g., atenolol, metoprolol) are now considered standard therapies for angina pectoris, hypertension, and cardiac arrhythmias.[5] Administration of β_2 agonists (e.g., terbutaline, albuterol) causes bronchial smooth muscle relaxation; these agents are commonly prescribed in inhaled formulations for the treatment of asthma.[6]

Catecholamine Synthesis

Catecholamines are synthesized from tyrosine by a process of hydroxylation and decarboxylation (see Fig. 16.1). Tyrosine is derived from ingested food or synthesized from phenylalanine in the liver, and it enters neurons and chromaffin cells by active transport. Tyrosine is converted to 3,4-dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase, the rate-limiting step in catecholamine synthesis. Increased intracellular levels of catechols downregulate the activity of tyrosine hydroxylase; as catecholamines are released from secretory granules in response to a stimulus, cytoplasmic catecholamines are depleted and the feedback inhibition of tyrosine hydroxylase is released. Transcription of tyrosine hydroxylase is stimulated by glucocorticoids, cyclic adenosine monophosphate (cAMP)–dependent protein kinases, calcium/phospholipid-dependent protein kinase, and calcium/calmodulin-dependent protein kinase. α-Methyl-paratyrosine (metyrosine) is a tyrosine hydroxylase inhibitor that may be used therapeutically in patients with catecholamine-secreting neoplasms to decrease tumoral synthesis of catecholamines.[7]

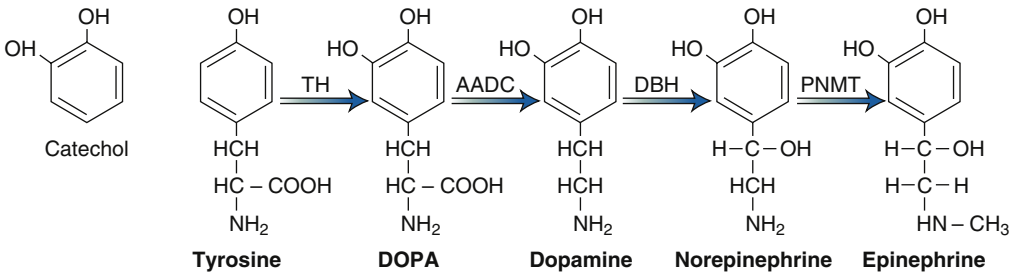
Aromatic L-amino acid decarboxylase catalyzes the decarboxylation of DOPA to dopamine (see Fig. 16.1). Dopamine is actively transported into granulated vesicles to be hydroxylated to norepinephrine by the copper-containing enzyme dopamine β-hydroxylase. Ascorbic acid is a cofactor and electron donor. The enzyme is structurally similar to tyrosine hydroxylase and may share similar transcriptional regulatory elements, and both are stimulated by glucocorticoids and cAMP-dependent kinases. These reactions occur in the synaptic vesicle of adrenergic neurons in the central nervous system, the peripheral nervous system, and the chromaffin cells of the adrenal medulla. The major constituents of the granulated vesicle are dopamine β-hydroxylase, ascorbic acid, chromogranin A, and adenosine triphosphate (ATP).

In the adrenal medulla, norepinephrine is released from the granule into the cytoplasm, where the cytosolic enzyme phenylethanolamine *N*-methyltransferase (PNMT) converts it to epinephrine (see Fig. 16.1). Epinephrine is then transported back into another storage vesicle. The *N*-methylation reaction by PNMT involves *S*-adenosylmethionine as the methyl donor as well as oxygen and magnesium. PNMT expression is regulated by the presence of glucocorticoids, which are in high concentration in the adrenal medulla through the corticomedullary portal system. Therefore, catecholamine-secreting tumors that secrete primarily epinephrine are localized to the adrenal medulla. In normal adrenal medullary tissue, approximately 80% of the catecholamines released are epinephrine.

Catecholamine Storage and Secretion

Catecholamines are found in the adrenal medulla and in sympathetically innervated organs. Catecholamines are stored in electron-dense granules that also contain ATP, neuropeptides (e.g., adrenomedullin, corticotropin [i.e., adrenocorticotropic hormone (ACTH)], vasoactive intestinal polypeptide), calcium, magnesium, and chromogranins. Uptake into the storage vesicles is facilitated by active transport by vesicular monoamine transporters (VMAT).[8] The VMAT ATP-driven pump maintains a steep electrical gradient. For every monoamine transported, ATP is hydrolyzed, and two hydrogen ions are transported from the vesicle into the cytosol. Iodine-123 (^{123}I) and ^{131}I-labeled metaiodobenzylguanidine (MIBG) are imported by VMAT into the storage vesicles in the adrenal medulla, which makes ^{123}I-MIBG useful for imaging localization of catecholamine-secreting tumors and ^{131}I-MIBG potentially useful in treating malignant catecholamine-secreting tumors.[9–11] Catecholamine uptake, as well as that of MIBG, is inhibited by reserpine. The catecholamine stores are dynamic, with constant leakage and reuptake.[8]

Stressful stimuli (e.g., myocardial infarction, anesthesia, hypoglycemia) trigger adrenal medullary catecholamine secretion. Acetylcholine from preganglionic sympathetic fibers stimulates



• **Fig. 16.1** Biosynthetic pathway for catecholamines. The term *catecholamine* comes from the catechol (ortho-dihydroxybenzene) structure and a side chain with an amino group—the catechol nucleus *(shown on left).* Tyrosine is converted to 3,4-dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase (TH); this rate-limiting step provides the clinician with the option to treat pheochromocytoma with a TH inhibitor, α-methyl-paratyrosine (metyrosine). Aromatic L-amino acid decarboxylase (AADC) converts DOPA to dopamine. Dopamine is hydroxylated to norepinephrine by dopamine β-hydroxylase (DBH). Norepinephrine is converted to epinephrine by phenylethanolamine N-methyltransferase (PNMT). Cortisol induces the expression of PNMT, which explains why epinephrine-secreting neoplasms are almost exclusively localized to the adrenal medulla.

nicotinic cholinergic receptors and causes depolarization of adrenomedullary chromaffin cells. Depolarization leads to activation of voltage-gated calcium channels, which results in exocytosis of secretory vesicle contents. A calcium-sensing receptor appears to be involved in the process of exocytosis. During exocytosis, all the granular contents are released into the extracellular space. Norepinephrine modulates its own release by activating the α_2 receptors on the presynaptic membrane. Stimulation of the presynaptic α_2 receptors inhibits norepinephrine release (the mechanism of action of some antihypertensive medications such as clonidine and guanfacine). Catecholamines are among the shortest lived signaling molecules in plasma; the initial biologic half-life of circulating catecholamines is between 10 and 100 seconds. Approximately one-half of the catecholamines circulate in plasma in loose association with albumin. Therefore plasma concentrations of catecholamines fluctuate widely.

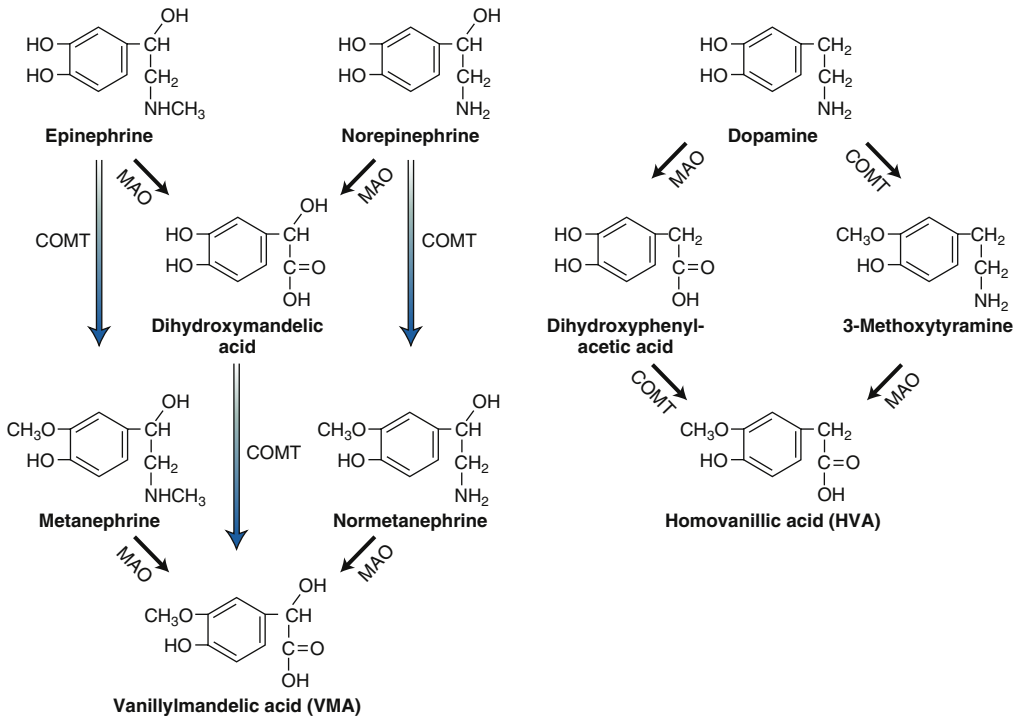
Catecholamine Metabolism and Inactivation

Catecholamines are removed from the circulation either by reuptake in sympathetic nerve terminals or by metabolism through two enzyme pathways (Fig. 16.2), followed by sulfate conjugation and renal excretion. Most of the metabolism of catecholamines occurs in the same cell in which they are synthesized.[8] Almost 90% of catecholamines released at sympathetic synapses are taken up locally by the nerve endings, termed *uptake 1*. Uptake 1 can be blocked by cocaine, tricyclic antidepressants, and phenothiazines. Extraneuronal tissues also take up catecholamines, and this is termed *uptake 2*. Most of these catecholamines are metabolized by catechol-*O*-methyltransferase (COMT).

Although COMT is found primarily outside neural tissue, *O*-methylation in the adrenal medulla is the predominant source of metanephrine (COMT converts epinephrine to metanephrine) and a major source of normetanephrine (COMT converts norepinephrine to normetanephrine) through methylation of the 3-hydroxy group.[8] *S*-Adenosylmethionine is used as the methyl donor, and calcium is required for this enzymatic step. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid (VMA) by oxidative deamination. MAO may also oxidize epinephrine and norepinephrine to 3,4-dihydroxymandelic acid, which is then converted by COMT to VMA. MAO is located on the outer membrane of mitochondria. In the storage vesicle, norepinephrine is protected from metabolism by MAO. MAO and COMT metabolize dopamine to homovanillic acid (see Fig. 16.2).

Pheochromocytoma and Paraganglioma

Catecholamine-secreting tumors that arise from chromaffin cells of the adrenal medulla and the sympathetic ganglia are referred to as *pheochromocytomas* and *catecholamine-secreting paragangliomas*, respectively.[12] Because the tumors have similar clinical presentations and are treated with similar approaches, many clinicians use the term *pheochromocytoma* to refer to both adrenal pheochromocytomas and extra-adrenal catecholamine-secreting paragangliomas. However, the distinction between pheochromocytoma and paraganglioma is an important one because of implications for associated neoplasms, risk for malignancy, and genetic testing. Catecholamine-secreting tumors are rare, with an annual incidence of 2 to 8 cases per 1 million people.[13] Based on screening



• **Fig. 16.2** Catecholamine metabolism. Metabolism of catecholamines occurs through two enzymatic pathways. Catechol-*O*-methyltransferase (COMT) converts epinephrine to metanephrine and converts norepinephrine to normetanephrine through meta-*O*-methylation. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid (VMA) by oxidative deamination. MAO also may oxidize epinephrine and norepinephrine to dihydroxymandelic acid, which is then converted by COMT to VMA. Dopamine is also metabolized by MAO and COMT to the final metabolite, homovanillic acid (HVA).

studies for secondary causes of hypertension in outpatients, the prevalence of pheochromocytoma has been estimated at 0.1% to 0.6%.[14,15] Nevertheless, it is important to suspect, confirm, localize, and resect these tumors because (1) the associated hypertension is curable with surgical removal of the tumor, (2) a risk of lethal paroxysm exists, (3) at least 10% of the tumors are malignant, and (4) 40% of these tumors are familial, and their detection in the proband may result in early diagnosis in other family members.

History

The association between adrenal medullary tumors and symptoms was first recognized by Fränkel in 1886.[16] He described Fraulein Minna Roll, age 18 years, who had intermittent attacks of palpitation, anxiety, vertigo, headache, chest pain, cold sweats, and vomiting. She had a hard, noncompressible pulse and retinitis. Despite champagne therapy and injections of ether, she died. At autopsy, bilateral adrenal tumors were initially thought to be angiosarcomas, but later a positive chromaffin reaction confirmed pheochromocytoma. A subsequent study published in 2007 documented the presence of a germline *RET* proto-oncogene mutation in four living relatives of Fraulein Roll—proving that the original patient and her family had multiple endocrine neoplasia type 2 (MEN2).[17]

The term *pheochromocytoma*, proposed by Pick in 1912,[18] comes from the Greek words *phaios* (dusky), *chroma* (color), and *cytoma* (tumor)—words that describe the dark staining reaction that is caused by the oxidation of intracellular catecholamines when they are exposed to dichromate salts. In 1926, César Roux in Lausanne, Switzerland, and Charles Mayo in Rochester, Minnesota, successfully surgically removed abdominal catecholamine-secreting tumors.[19,20] In 1929, it was discovered that a pheochromocytoma contained an excess amount of a pressor agent. Subsequently, epinephrine (in 1936) and norepinephrine (in 1949) were isolated from pheochromocytoma tissue. In 1950, it was found that patients with pheochromocytoma excreted increased amounts of epinephrine, norepinephrine, and dopamine in the urine.[21]

Clinical Presentation

Catecholamine-secreting tumors occur with equal frequency in men and women, primarily in the third, fourth, and fifth decades. These tumors are rare in children, and when discovered, they may be multifocal and associated with a hereditary syndrome. The symptoms, listed in Table 16.2, are caused by the pharmacologic effects of excess concentrations of circulating catecholamines. The associated hypertension may be sustained or paroxysmal, and patients whose pheochromocytoma is diagnosed in the presymptomatic stage may have normal blood pressure. The lability in blood pressure can be attributed to episodic release of catecholamines, chronic volume depletion, and impaired sympathetic reflexes. In addition to volume depletion, altered sympathetic vascular regulation may have a role in orthostasis, which may be observed in patients with pheochromocytoma. Symptoms of orthostatic hypotension (e.g., lightheadedness, presyncope, syncope) may dominate the presentation, especially in patients with epinephrine-predominant or dopamine-predominant tumors.

Episodic symptoms may occur in spells, or paroxysms, that can be extremely variable in presentation but typically include forceful heartbeat, pallor, tremor, headache, and diaphoresis.[22] The spell may start with a sensation of a "rush" in the chest and a sense of shortness of breath, followed by a forceful heartbeat and a throbbing headache. Peripheral vasoconstriction associated with a spell results in cool or cold hands and feet and facial pallor. Increased sense of body heat and sweating are common symptoms that occur toward the end of the spell. Spells may be either spontaneous or precipitated by postural change, anxiety, medications (e.g., β-adrenergic antagonists, metoclopramide, anesthetic agents), exercise, or maneuvers that increase intra-abdominal pressure (e.g., change in position, lifting, defecation, exercise, colonoscopy, pregnancy, trauma). Although the types of spells experienced across the patient population are highly variable, spells tend to be stereotypical for each patient. Spells may occur multiple times daily or as infrequently as once monthly. The typical duration of a pheochromocytoma spell is 15 to 20 minutes, but it may be much shorter or last several hours. However, the clinician must recognize that most patients with spells do not have a pheochromocytoma (Table 16.3).[23]

Additional clinical signs of pheochromocytoma include hypertensive retinopathy, orthostatic hypotension, angina, nausea,

TABLE 16.2 Signs and Symptoms Associated With Catecholamine-Secreting Tumors

Spell-Related Signs and Symptoms

Anxiety and fear of impending death
Diaphoresis
Dyspnea
Epigastric and chest pain
Headache
Hypertension
Nausea and vomiting
Pallor
Palpitation (forceful heartbeat)
Tremor

Chronic Signs and Symptoms

Cold hands and feet
Congestive heart failure—dilated or hypertrophic cardiomyopathy
Constipation
Diaphoresis
Dyspnea
Ectopic hormone secretion–dependent symptoms (e.g., CRH/ACTH, GHRH, PTHrP, VIP)
Epigastric and chest pain
Fatigue
Fever
General increase in sweating
Grade II to IV hypertensive retinopathy
Headache
Hyperglycemia
Hypertension
Nausea and vomiting
Orthostatic hypotension
Painless hematuria (associated with urinary bladder paraganglioma)
Pallor
Palpitation (forceful heartbeat)
Tremor
Weight loss

Not Typical of Pheochromocytoma

Flushing

ACTH, Adrenocorticotropic hormone; *CRH,* corticotropin-releasing hormone; *GHRH,* growth hormone–releasing hormone; *PTHrP,* parathyroid hormone–related peptide; *VIP,* vasoactive intestinal polypeptide.

Adapted from Young WF Jr. Pheochromocytoma, 1926-1993. *Trends Endocrinol Metab.* 1993;4:122–127.

constipation (megacolon may be the presenting symptom), hyperglycemia, diabetes mellitus, hypercalcemia, Raynaud phenomenon, livedo reticularis, erythrocytosis, and mass effects from the tumor. Although hypercalcemia may be a sign of primary hyperparathyroidism in patients with MEN2A, in most patients with pheochromocytoma, it is an isolated finding and resolves with resection of the catecholamine-secreting tumor. In addition, calcitonin secretion is in part a catecholamine-dependent process; serum calcitonin concentrations are frequently mildly elevated in patients with pheochromocytoma, usually unrelated to MEN2. Fasting hyperglycemia and diabetes mellitus are caused in part by the α-adrenergic inhibition of insulin release. Painless hematuria and paroxysmal attacks induced by micturition and defecation are associated with urinary bladder paragangliomas.

TABLE 16.3 Differential Diagnosis of Pheochromocytoma-Type Spells

Endocrine Causes
Carbohydrate intolerance
Hyperadrenergic spells
Hypoglycemia
Pancreatic tumors (e.g., insulinoma)
Pheochromocytoma
Primary hypogonadism (menopausal syndrome)
Thyrotoxicosis

Cardiovascular Causes
Angina
Cardiovascular deconditioning
Labile essential hypertension
Orthostatic hypotension
Paroxysmal cardiac arrhythmia
Pulmonary edema
Renovascular disease
Syncope (e.g., vasovagal reaction)

Psychologic Causes
Factitious (e.g., drugs, Valsalva maneuver)
Hyperventilation
Severe anxiety and panic disorders
Somatization disorder

Pharmacologic Causes
Chlorpropamide-alcohol flush
Combination of a monoamine oxidase inhibitor and a decongestant
Illegal drug ingestion (cocaine, phencyclidine, lysergic acid diethylamide)
Sympathomimetic drug ingestion
Vancomycin (red man syndrome)
Withdrawal of adrenergic-inhibitor

Neurologic Causes
Autonomic neuropathy
Cerebrovascular insufficiency
Diencephalic epilepsy (autonomic seizures)
Migraine headache
Postural orthostatic tachycardia syndrome
Stroke

Other Causes
Carcinoid syndrome
Mast cell disease
Recurrent idiopathic anaphylaxis
Unexplained flushing spells

Some of the cosecreted hormones that may dominate the clinical presentation include ACTH (Cushing syndrome), parathyroid hormone–related peptide (hypercalcemia), vasopressin (syndrome of inappropriate antidiuretic hormone secretion), vasoactive intestinal peptide (watery diarrhea), and growth hormone–releasing hormone (acromegaly). Cardiomyopathy and congestive heart failure are the symptomatic presentations caused by pheochromocytoma that are most frequently unrecognized by clinicians.[24] The cardiomyopathy, whether dilated or hypertrophic, may be totally reversible with tumor resection.[24,25] In addition, Takotsubo cardiomyopathy with ventricular apical ballooning can also be a presentation of pheochromocytoma.[26] Myocarditis and myocardial infarction with normal coronary arteries seen on angiography are also cardiac-based presentations of pheochromocytoma.[24] The myocarditis is characterized by infiltration of inflammatory cells and focal contraction-band necrosis.[24,27] Many physical examination findings can be associated with genetic syndromes that predispose to pheochromocytoma; these findings include retinal angiomas, iris hamartomas, marfanoid body habitus, café au lait spots, axillary freckling, subcutaneous neurofibromas, and mucosal neuromas on the eyelids and tongue. Some patients with pheochromocytoma are asymptomatic despite high circulating levels of catecholamines; this type most likely reflects adrenergic receptor desensitization related to chronic stimulation.

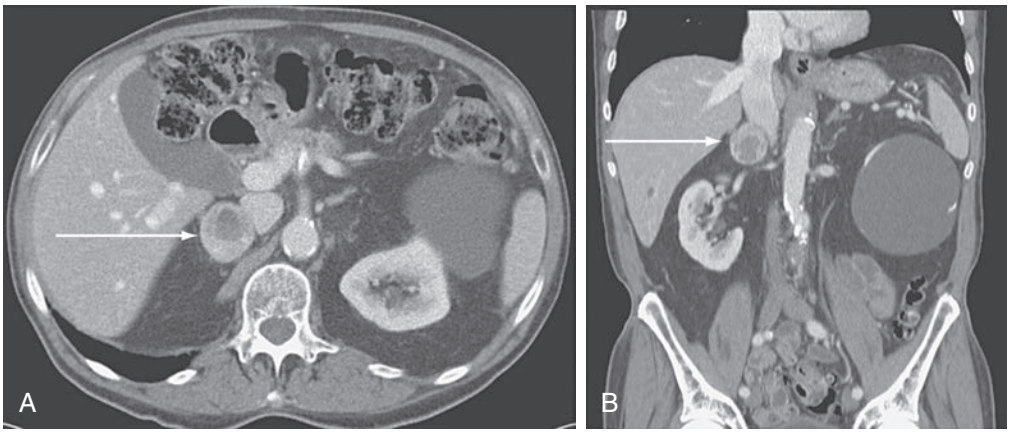
Because of the increased and widespread use of computed tomography (CT) and magnetic resonance imaging (MRI) in patients with abdominal symptoms, pheochromocytoma and abdominal paraganglioma may be detected as an incidental adrenal mass in many patients before any symptoms develop.[28] In the era of widespread use of computed cross-sectional imaging, approximately 60% of adrenal pheochromocytoma patients had their adrenal tumors discovered incidentally on imaging performed for other reasons.[29–31] Although typically these incidentally discovered tumors in asymptomatic patients are small (<3 cm), they may be up to 10 cm in largest diameter.

At the time of symptom-based detection, pheochromocytomas have an average diameter of 4.5 cm (Fig. 16.3).[32] Paragangliomas are found where there is chromaffin tissue: along the para-aortic sympathetic chain, within the organ of Zuckerkandl (at the origin of the inferior mesenteric artery), in the wall of the urinary bladder, and along the sympathetic chain in the neck or mediastinum.[33] During early postnatal life, the extra-adrenal sympathetic paraganglionic tissues are prominent; later they degenerate, leaving residual foci associated with the vagus nerves, carotid vessels, aortic arch, pulmonary vessels, and mesenteric arteries. Odd locations for paragangliomas include the neck, intra-atrial cardiac septum, spermatic cord, vagina, scrotum, and sacrococcygeal region. Paragangliomas in the head and neck region (e.g., carotid body tumors, glomus tumors, chemodectomas) usually arise from parasympathetic tissue and typically do not hypersecrete catecholamines and metanephrines. Paragangliomas in the mediastinum, abdomen, and pelvis usually arise from sympathetic chromaffin tissue and usually hypersecrete catecholamines and metanephrines.

Syndromic Forms of Pheochromocytoma and Paraganglioma

Multiple Endocrine Neoplasia Type 2A

MEN2A (previously known as Sipple syndrome) is an autosomal dominant disorder with age-related penetrance.[34] MEN2A is characterized by medullary thyroid cancer (MTC) in all patients,



• **Fig. 16.3** A computed tomographic (CT) scan of the abdomen with intravenous contrast in a 71-year-old man with an incidentally discovered right adrenal mass. The concentrations of plasma fractionated free metanephrines were abnormal: metanephrine, 0.34 nmol/L (normal, <0.5 nmol/L) and normetanephrine, 8.59 nmol/L (normal, <0.9 nmol/L). The 24-hour urine studies were abnormal: norepinephrine, 455 μg (normal, <170 μg); epinephrine, 7.2 μg (normal, <35 μg); dopamine, 160 μg (normal, <700 μg); metanephrine, 173 μg (normal, <400 μg); and normetanephrine, 3147 μg (normal, <900 μg). (A) The axial CT image shows a typical 3.8-cm heterogeneously enhancing right adrenal mass just lateral to the inferior vena cava and consistent with pheochromocytoma *(arrow)*. (B) Coronal view shows the location *(arrow)* of the mass superior to the right kidney and inferior and medial to the liver. After α-adrenergic and β-adrenergic blockade, a 20-g (2.5 × 1.5 × 1.5 cm) pheochromocytoma was removed laparoscopically.

adrenergic (epinephrine and metanephrines are predominant) pheochromocytoma in 50% (usually bilateral and frequently asynchronous), primary hyperparathyroidism in 20%, cutaneous lichen amyloidosis in 5%, and very rarely Hirschsprung disease. Cutaneous lichen amyloidosis is a pruritic, papular, scaly, and pigmented skin lesion that is typically located in the interscapular region or on the extensor surfaces of the extremities.

MTC is usually detected before the pheochromocytoma is diagnosed. The prevalence of MEN2A is approximately 1 in 200,000 live births. Numerous activating mutations throughout the *RET* (*re*arranged during *t*ransfection) proto-oncogene have been documented in persons with MEN2A. *RET*, located on chromosome 10q11.2, encodes a transmembrane receptor tyrosine kinase that is involved in the regulation of cell proliferation and apoptosis by activation of the PI3K/AKT (phosphoinositide 3-kinase) and MAPK/ERK (mitogen-activated protein kinase/extracellular signal-regulated kinase) signaling pathways. *RET* can be constitutively activated by gain-of-function mutations in seven specific exons of the *RET* gene (exons 8, 10, 11, 13, 14, 15, or 16). Most mutations in MEN2A kindreds (>90%) involve *RET* exons 10 (codons 609, 611, 618, and 620) or 11 (codons 630 or 634). Eighty-five percent of individuals with MEN2A have a mutation in codon 634, particularly p.Cys634Arg (c.1900C>T).

Hirschsprung disease is characterized by the absence of autonomic ganglion cells within the distal colon parasympathetic plexus, which results in constipation, megacolon, or obstipation. Hirschsprung disease may occur in patients with MEN2A who have a Janus mutation—a mutation that acts simultaneously as both a gain-in-function and a loss-of-function mutation—in the *RET* proto-oncogene (exon 10: codons 609, 611, 618, 620).[35] It is important to distinguish the constipation/obstipation due to Hirschsprung disease in patients with MEN2A from that due to ganglioneuromatosis of MEN2B or from the colonic paralytic effects seen in patients with massive elevations in catecholamines (most commonly seen in patients with widespread metastatic paraganglioma or pheochromocytoma).

Multiple Endocrine Neoplasia Type 2B

MEN2B (previously known as Gorlin syndrome) is also an autosomal dominant disorder with age-related penetrance, and it represents approximately 5% of all MEN2 cases.[34] MEN2B is characterized by MTC in all patients, adrenergic (epinephrine and metanephrine predominant) pheochromocytoma in 50%, mucocutaneous neuromas (typically involving the tongue, lips, and eyelids) in most patients, and by skeletal deformities (e.g., kyphoscoliosis, lordosis), joint laxity, myelinated corneal nerves, and intestinal ganglioneuromas.

MEN2B-associated tumors are caused by mutations in the *RET* protein's intracellular domain. A single methionine-to-threonine missense mutation in exon 16 (p.Met918Thr; c.2753T>C) is responsible for more than 95% of MEN2B cases. Another mutation, alanine to phenylalanine at codon 883 in exon 15, has been found in 4% of MEN2B kindreds.

More than 95% of patients with MEN2A and more than 98% of those with MEN2B have an identifiable mutation in the *RET* proto-oncogene. Pheochromocytoma in MEN2 has an adrenergic (epinephrine and metanephrine are predominant) biochemical phenotype, and this knowledge directs genetic testing.[36] Genetic testing for mutations in the *RET* proto-oncogene should be considered for patients with co-phenotype disorders (e.g., MTC) or adrenergic biochemical phenotype pheochromocytoma (unilateral or bilateral). In a family with MEN2, a family member with a clinical diagnosis of MEN2 should be the first to have genetic testing. If a *RET* mutation is found, all family members of unknown status should be offered genotyping. Genetic consultation should be considered before genetic testing is performed. In families with known MEN2, genetic testing shortly after birth facilitates prompt surgical management of the thyroid gland (see Chapter 42 for further discussion of MEN2).

von Hippel-Lindau Disease

von Hippel-Lindau (VHL) syndrome is an autosomal dominant disorder that may manifest with a variety of benign and malignant

neoplasms: noradrenergic (norepinephrine and normetanephrine are predominant) pheochromocytoma or paraganglioma (mediastinal, abdominal, pelvic), hemangioblastoma (involving the cerebellum, spinal cord, or brainstem), retinal angioma, clear cell renal cell carcinoma, pancreatic neuroendocrine tumors, endolymphatic sac tumors of the middle ear, serous cystadenomas of the pancreas, and papillary cystadenomas of the epididymis and broad ligament.[37] The appearance of these VHL-related neoplasms in mutation-positive individuals is close to 100% by age 65 years. The average age of detection of pheochromocytoma is 20 to 29 years of age.[37]

The prevalence of VHL syndrome is between 1 in 35,000 and 1 in 91,000 people.[38,39] The *VHL* tumor suppressor gene, located on chromosome 3p25-26, encodes a protein that regulates ubiquitination and proteosomal degradation of hypoxia-inducible factors (HIFs). Loss-of-function mutations in VHL lead to the inappropriate activation of the hypoxic response—promoting glycolysis, angiogenesis, and proliferation. Genotype-phenotype correlations may be used to divide patients into two groups: type 1 and type 2. Patients from kindreds with the type 1 syndrome have mutations that lead to total loss of biologic activity of the VHL protein and are at very low risk to develop pheochromocytoma; those from kindreds with the type 2 syndrome have missense mutations that allow residual activity of the VHL protein and are at high risk for developing pheochromocytoma.

Genetic testing for VHL syndrome should be considered for patients with bilateral noradrenergic (norepinephrine and normetanephrine predominant) pheochromocytoma, diagnosis of unilateral noradrenergic pheochromocytoma at a young age (e.g., ≤45 years), or pheochromocytoma/paraganglioma patients with co-phenotype disorders (e.g., retinal angioma).

Pheochromocytomas occurring in patients with MEN2 produce predominantly epinephrine and its major metabolite, metanephrine, whereas those occurring in patients with VHL syndrome produce predominantly norepinephrine and its major metabolite, normetanephrine.[36] These biochemical phenotypes result from mutation-specific differential gene expression. PNMT is overexpressed in MEN2-associated tumors (epinephrine and metanephrine profile) and underexpressed in VHL-associated tumors (norepinephrine and normetanephrine profile).[40] In addition, pheochromocytomas occurring in patients with MEN2 have increased tyrosine hydroxylase activity compared with those occurring in patients with VHL; this difference accounts for higher levels of catecholamines and metabolites in patients with MEN2.

Neurofibromatosis Type 1

Neurofibromatosis 1 (NF1), previously known as von Recklinghausen disease, is one of the most common genetic syndromes, with a prevalence of 1 in 2000 to 1 in 5000 persons.[41] NF1 is an autosomal dominant disorder with 100% penetrance and is characterized by neurofibromas, multiple café au lait spots, axillary and inguinal freckling, iris hamartomas (Lisch nodules), bony abnormalities, central nervous system gliomas, pheochromocytoma and paraganglioma, macrocephaly, and cognitive deficits. Although penetrance is 100%, the expression of NF1 features is variable. Approximately 3% of patients with NF1 develop catecholamine-secreting tumors.[42] In these patients, the catecholamine-secreting tumor is usually a solitary, benign adrenal pheochromocytoma, occasionally a bilateral adrenal pheochromocytoma, and rarely an abdominal periadrenal paraganglioma.[42] Frequently the adrenal pheochromocytoma is detected as an incidental adrenal mass on imaging performed for other reasons.[42]

The *NF1* tumor suppressor gene, located on chromosome 17q11.2, encodes neurofibromin, which downregulates RAS proteins and the downstream RAS-RAF-MAPK signaling cascade. Inactivating *NF1* mutations cause the disorder. Unless a patient with pheochromocytoma presents with additional clinical characteristics consistent with an NF1 diagnosis, genetic testing of the *NF1* gene is not recommended.

Congenital Polycythemia

The most common congenital polycythemia-associated somatic mutations that also predispose to pheochromocytoma and paraganglioma occur in HIF2α, which lead to stabilization of HIF2α, resulting in the upregulation of HIF2α-related genes (e.g., erythropoietin gene). Patients with HIF2α mutations are at risk for congenital polycythemia, multiple paragangliomas, and somatostatinomas.[43,44] These HIF2α somatic mutations occur exclusively in females in the postzygotic neural crest precursor cells.[45] Two other congenital polycythemia-associated mutations with potential links to pheochromocytoma and paraganglioma include VHL (Chuvash polycythemia; however, these patients have not been reported to develop pheochromocytoma or paraganglioma) and prolyl hydroxylase domain 2 (PHD2)–containing protein (with only one patient reported to date).[46]

Carney Triad

The Carney triad (gastrointestinal stromal tumor, pulmonary chondroma, and catecholamine-secreting paraganglioma; less frequent neoplasms include esophageal leiomyoma and adrenal adenoma) is another syndrome associated with catecholamine-secreting tumors.[47] This syndrome is a rare (~150 patients have been reported) disorder of unknown cause that primarily affects young women.[48] The gastric stromal tumors are frequently multicentric and associated with early liver metastases; however, most affected patients have a very indolent course.[49] The pulmonary chondromas are benign and, if asymptomatic, require no specific therapy. The paragangliomas secrete catecholamines and should be resected when discovered. Additional features of the Carney triad include esophageal leiomyomas and adrenocortical adenomas. The esophageal leiomyomas are benign and usually asymptomatic. The adrenocortical adenomas may be nonfunctioning or may secrete cortisol autonomously.[50] The molecular pathogenesis of Carney triad is related to the downregulation of the succinate dehydrogenase (SDH) enzyme complex through site-specific hypermethylation of the *SDHC* gene.[51,52]

Congenital Heart Disease

The association between cyanotic congenital heart disease and pheochromocytoma/paraganglioma has been recognized for more than 50 years.[53–56] The underlying pathogenesis appears to be gain-of-function somatic mutations of *EPAS1*, which encodes HIF2α.[57] Mutations in residues 530 and 531 of *EPAS1* result in constitutive HIF2α activation, leading to development of pheochromocytoma and paraganglioma in patients with cyanotic congenital heart disease. *EPAS1* mutations in the setting of chronic hypoxia amplify the oncogenic properties of HIF2α.[57]

Other Genetic Forms of Pheochromocytoma and Paraganglioma

Mutations contributing to pheochromocytoma and paraganglioma have two general transcription signatures: cluster 1—genes encoding proteins that function in the cellular response

to hypoxia, and cluster 2—genes encoding proteins that activate kinase signaling (Table 16.4). Cluster 1 tumors are mostly extra-adrenal paragangliomas (except in VHL, in which most tumors are localized to the adrenal gland), and nearly all have a noradrenergic biochemical phenotype. Cluster 2 tumors are usually adrenal pheochromocytomas with an adrenergic biochemical phenotype (see Table 16.4). Since 1990, 18 pheochromocytoma/paraganglioma susceptibility genes have been reported: *NF1*, *RET*, *VHL*, *SDHD*, *SDHC*, *SDHB*, *EGLN1 (PHD2)*, *EGLN2* (*PDH1*), *KIF1B*, *SDHAF2*, *IDH1*, *TMEM127*, *SDHA*, *MAX*, *HIF2A*, *MDH2*, *FH*, and *DNMT3A*.[58,59]

Succinate Dehydrogenase Gene Mutations

Most cases of familial paraganglioma are caused by mutations in the SDH (succinate:ubiquinone oxidoreductase) subunit genes (*SDHB*, *SDHC*, *SDHD*, *SHDA*, and *SDHAF2*), which make up portions of mitochondrial complex II.[60] The SDHx genes are considered tumor suppressor genes and encode the proteins that form the mitochondrial complex II, a crucial link between the Krebs cycle and mitochondrial electron transport chain. SDH is a heterotetramer protein complex consisting of four subunits encoded by nuclear genes. *SDHA* and *SDHB* form the catalytic domain, and *SDHC* and *SDHD* anchor the complex to the inner mitochondrial membrane. The assembly factors, *SDHAF1* and *SDHAF2*, are needed for functional and structural integrity of the complex. Defects in the *SDH* genes result in succinate accumulation, which is a competitive inhibitor of the 2-oxoglutarate-dependent dioxygenases (e.g., HIF prolyl hydroxylases and histone or DNA demethylases), which leads to the stabilization of HIF isoforms and the activation of hypoxic signaling and to epigenetic modifications.

In patients with *SDHD* or *SDHAF2* mutations, penetrance depends on the mutation's parent of origin. With rare exceptions,[61,62] the disease is not manifested when the mutation is inherited from the mother but is highly penetrant when inherited from the father.[63] This phenomenon is known as *maternal imprinting*.[64]

TABLE 16.4 Germline Mutations Associated With Pheochromocytoma and Paraganglioma

Syndrome/Name	Gene	Typical Tumor Location and Other Associations
Hypoxic Pathway: Cluster 1[a]		
SDHD mutation (familial paraganglioma type 1)[b]	*SDHD*	Primarily skull base and neck; occasionally adrenal medulla, mediastinum, abdomen, pelvis; GIST; possible pituitary adenoma
SDHAF2 mutation (familial paraganglioma type 2)[b]	*SDHAF2*	Primarily skull base and neck; occasionally abdomen and pelvis
SDHC mutation (familial paraganglioma type 3)	*SDHC*	Primarily skull base and neck; occasionally abdomen, pelvis, or chest; GIST; possible pituitary adenoma
SDHB mutation (familial paraganglioma type 4)	*SDHB*	Abdomen, pelvis, and mediastinum; rarely adrenal medulla, skull base, and neck; GIST; renal cell carcinoma; possible pituitary adenoma
SDHA mutation	*SDHA*	Primarily skull base and neck; occasionally abdomen and pelvis; GIST; possible pituitary adenoma
von Hippel-Lindau (VHL) disease	*VHL*	Adrenal medulla, frequently bilateral; occasionally paraganglioma that may be localized from skull base to pelvis; see text for VHL-associated findings
Hereditary leiomyomatosis and renal cell carcinoma (Reed syndrome)—fumarate hydratase mutation	*FH*	Multifocal and metastatic; associated with hereditary leiomyomatosis, uterine fibroids, and renal cell cancer
Hypoxia-inducible factor (HIF) 2α	*HIF2A*	Paraganglioma, polycythemia, and rarely somatostatinoma
Familial erythrocytosis associated with mutation in prolyl hydroxylase isoform 1 (PDH1)	*EGLN2*	Polycythemia associated with pheochromocytoma and paraganglioma
Familial erythrocytosis associated with mutation in prolyl hydroxylase isoform 2 (PDH2)	*EGLN1*	Polycythemia associated with pheochromocytoma and paraganglioma
KIF1B	*KIF1B*	Neuroblastoma
Kinase Signaling Pathway: Cluster 2[c]		
MEN2A and MEN2B	*RET*	Adrenal medulla, frequently bilateral; see text for MEN2A and MEN2B associated findings
Neurofibromatosis type 1 (NF1)	*NF1*	Adrenal or periadrenal; see text for NF1 associated findings
MAX[b]	*MAX*	Adrenal medulla
Familial pheochromocytoma	*TMEM127*	Adrenal medulla; possible renal cell carcinoma

[a]Cluster 1 tumors are mostly extra-adrenal paragangliomas (except in VHL where most tumors are localized to the adrenal) and nearly all have a noradrenergic biochemical phenotype.

[b]Associated with maternal imprinting—see text.

[c]Cluster 2 tumors are usually adrenal pheochromocytomas with an adrenergic biochemical phenotype.

GIST, Gastrointestinal stromal tumor; *MEN,* multiple endocrine neoplasia; *SDH,* succinate dehydrogenase.

TMEM127 *Mutations*

TMEM127 is a negative regulator of mammalian target of rapamycin (mTOR) effector proteins. In a study of 990 individuals with pheochromocytoma or paraganglioma, germline mutations in *TMEM127* were identified in 20 individuals with adrenal tumors (7 bilateral), 5 of whom had a family history of pheochromocytoma.[65] Among 547 patients who presented with sporadic pheochromocytoma (unilateral adrenal tumor with negative family history), 11 (2%) had *TMEM127* mutations.

MAX *Mutations*

Loss-of-function mutations in the MYC-associated factor X *(MAX)* gene are associated with familial pheochromocytoma.[66] In an initial study of three individuals with familial pheochromocytoma (who did not have mutations in any of the nine previously described susceptibility genes), *MAX* germline mutations were found. *MAX* is a component of the MYC-MAX-MXD1 transcription factors that regulate cell proliferation, differentiation, and apoptosis. In an extension of this study, *MAX* mutations were found in 5 of 59 patients (8.5%) with suspected familial pheochromocytoma (based on age of onset <30 years, bilateral pheochromocytoma, or positive family history).[66]

FH *Mutations*

Germline mutations in the *FH* gene encoding fumarate hydratase were identified in 5 of 598 patients (1%) with pheochromocytoma/paraganglioma without mutations in known susceptibility gene mutations.[67] Clinically, a metastatic phenotype and multiple tumors were significantly more frequent in patients with *FH* mutations than those without such mutations.

Genetic Testing

Genetic testing should be considered if a patient has one or more of the following: (1) paraganglioma, (2) bilateral adrenal pheochromocytoma, (3) unilateral adrenal pheochromocytoma and a family history of pheochromocytoma/paraganglioma, (4) unilateral adrenal pheochromocytoma with onset at a young age (<45 years), or (5) other clinical findings suggestive of one of the previously discussed syndromic disorders. An asymptomatic person at risk for disease on the basis of family history of pheochromocytoma/paraganglioma should have genetic testing only if an affected family member has a known mutation. Genetic testing can be complex, and testing of one family member has implications for related individuals. Genetic counseling is recommended to help families understand the implications of genetic test results, to coordinate testing of at-risk individuals, and to help families work through the psychosocial issues that may arise before, during, or after the testing process.

A sequential genetic testing algorithm based on biochemical phenotype, age, and tumor has been proposed.[22] However, the field of genetic testing is rapidly evolving, and at many clinical laboratories, sequential genetic testing is no longer done as it is less expensive to utilize next-generation sequencing technology for all clinically available mutations as a package.[68]

Evaluation and Monitoring of Carriers of Succinate Dehydrogenase Mutations

If an SDHx mutation is identified in a relative of a proband, annual clinical assessment (including blood pressure check and biochemical testing) is indicated for early detection of pheochromocytoma/paraganglioma. Prospective studies to guide the clinician in the frequency, age to start, and type of testing are lacking. Biochemical testing for fractionated metanephrines in plasma or in a 24-hour urine collection for fractionated metanephrines and catecholamines should be performed annually in all carriers of an SDHx mutation starting around age 10 years. Because paragangliomas may be nonfunctioning or may be detected before catecholamine-secretory autonomy is evident, periodic imaging studies are advised. For example, at-risk SDHx (e.g., paternally inherited for *SDHD* and *SDHAF2*) mutation carriers should have MRI of the abdomen, pelvis, chest, and neck every 2 to 3 years; total body imaging with either ^{123}I-MIBG scintigraphy or Gallium 68 (68-Ga) 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)-octreotate (DOTATATE) positron emission tomography (PET) CT should be performed every 5 years. Patients with SDHx mutations are at risk (albeit low) to develop renal cell carcinoma, and the periodic abdominal cross-section imaging also screens for this possibility.[69] In addition, as new tumor associations are identified, additional surveillance testing will be indicated. For example, several reports have identified an association between SDHx mutations and pituitary tumor risk.[70,71] If this risk proves to be real and clinically important, then pituitary-directed MRI may become part of the surveillance program.

Diagnostic Investigation

Differential Diagnosis

Numerous disorders can cause signs and symptoms that may prompt the clinician to test for pheochromocytoma (see Table 16.3). The disorders span much of medicine and include endocrine disorders (e.g., primary hypogonadism), cardiovascular disorders (e.g., idiopathic orthostatic hypotension), psychologic disorders (e.g., panic disorder), pharmacologic causes (e.g., withdrawal from an adrenergic inhibitor), neurologic disorders (e.g., postural orthostatic tachycardia syndrome), and miscellaneous disorders (e.g., mast cell disease). Indeed, most patients tested for pheochromocytoma do not have it. In addition, levels of fractionated catecholamines and metanephrines may be elevated in several clinical scenarios, including withdrawal from medications or drugs (e.g., clonidine, alcohol), any acute illness (e.g., subarachnoid hemorrhage, migraine headache, preeclampsia), and administration of many drugs and medications (e.g., tricyclic antidepressants, levodopa, buspirone, antipsychotic agents, cocaine, phencyclidine, amphetamines, ephedrine, pseudoephedrine, phenylpropanolamine, isoproterenol) (Table 16.5).[22]

Case Detection

Pheochromocytoma should be suspected in patients who have one or more of the following:

- Hyperadrenergic spells (e.g., self-limited episodes of nonexertional forceful palpitations, diaphoresis, headache, tremor, or pallor)

TABLE 16.5 Medications that May Increase Measured Levels of Fractionated Catecholamines and Metanephrines

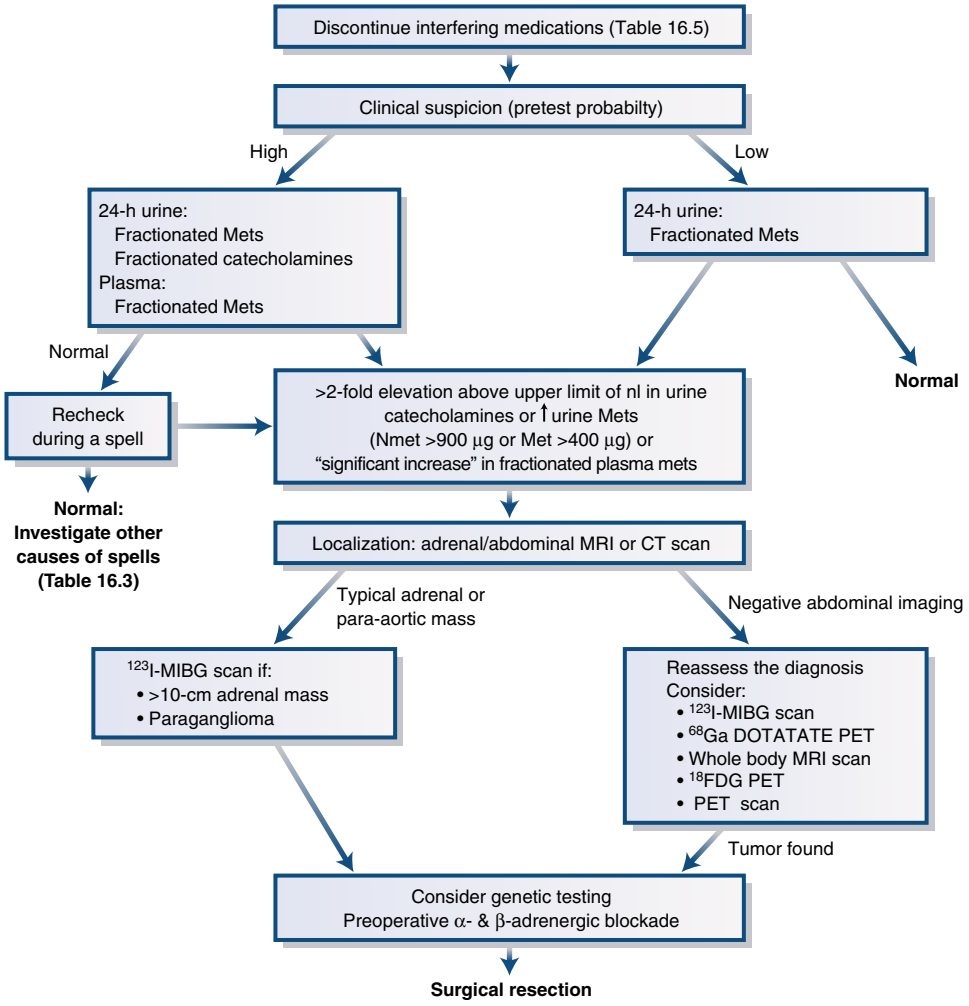
Tricyclic antidepressants (including cyclobenzaprine)
Levodopa
Drugs containing adrenergic receptor agonists (e.g., decongestants)
Amphetamines
Buspirone and antipsychotic agents
Prochlorperazine
Reserpine
Withdrawal from clonidine and other drugs (e.g., illicit drugs)
Illicit drugs (e.g., cocaine, heroin)
Ethanol

- Resistant hypertension
- A familial syndrome that predisposes to catecholamine-secreting tumors (e.g., MEN2, NF1, VHL)
- A family history of pheochromocytoma
- An incidentally discovered adrenal mass with imaging characteristics consistent with pheochromocytoma
- Pressor response during anesthesia, surgery, or angiography
- Onset of hypertension at a young age (<20 years)
- Idiopathic dilated cardiomyopathy
- Cyanotic congenital heart disease

Measurement of Fractionated Metanephrines and Catecholamines in Urine and Plasma

The diagnosis must be confirmed biochemically by the presence of increased concentrations of fractionated metanephrines and catecholamines in urine or plasma (Fig. 16.4).[22,72,73] The metabolism of catecholamines is primarily intratumoral, with formation of metanephrine from epinephrine and normetanephrine from norepinephrine.[8] Most laboratories now measure fractionated catecholamines (dopamine, norepinephrine, and epinephrine) and fractionated metanephrines (metanephrine and normetanephrine) by high-performance liquid chromatography with electrochemical detection or tandem mass spectrometry. These techniques have overcome the problems with fluorometric analysis, which include false-positive results caused by α-methyldopa, labetalol, sotalol, and imaging contrast agents.

At Mayo Clinic, the most reliable case-detection strategy is measurement of fractionated metanephrines and catecholamines in a 24-hour urine collection (sensitivity, 98%; specificity, 98%).[72,74] Because of the higher false-positive rate with plasma fractionated metanephrines, they should be reserved for high clinical suspicion cases. The index of suspicion for pheochromocytoma should be high in the following scenarios: resistant hypertension, spells with associated pallor, a family history of pheochromocytoma, a genetic syndrome that predisposes to pheochromocytoma (e.g., MEN2), a past history of resected pheochromocytoma and present history of recurrent hypertension or spells, and an incidentally discovered adrenal mass that has imaging characteristics consistent with pheochromocytoma (Table 16.6).[28] In addition, measurement of plasma fractionated metanephrines is a good first-line



• **Fig. 16.4** Evaluation and treatment of catecholamine-secreting tumors. Clinical suspicion is triggered by paroxysmal symptoms (especially hypertension); hypertension that is intermittent, unusually labile, or resistant to treatment; a family history of pheochromocytoma or associated conditions; or an incidentally discovered adrenal mass (see text for details). *CT,* computed tomography; *^{18}FDG,* ^{18}F-fluorodeoxyglucose; *^{68}Ga-DOTATATE,* Gallium-68 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)-octreotate; *^{123}I-MIBG,* iodine-123–labeled metaiodobenzylguanidine; *Mets,* metanephrines; *MRI,* magnetic resonance imaging; *nl,* normal; *Nmet,* normetanephrine; *PET,* positron emission tomography. (Modified from Young Jr WF. Pheochromocytoma, 1926-1993. *Trends Endocrinol Metab.* 1993;4:122–127, used with permission.)

test for children because obtaining a complete 24-hour urine collection is difficult in pediatric patients. Measurement of urinary dopamine or plasma methoxytyramine can be very useful in detecting the rare tumor with selective dopamine hypersecretion because plasma metanephrine fractions are not direct metabolites of dopamine and may be normal in the setting of a dopamine-secreting tumor.[74–76]

The 24-hour urine collection for fractionated metanephrines and catecholamines should include measurement of urinary creatinine to verify an adequate collection. The diagnostic cutoffs for most 24-hour urinary fractionated metanephrine assays are based on normal ranges derived from normotensive volunteer reference groups, and this can result in excessive false-positive test results. For example, in normotensive laboratory volunteers, the 95th percentiles are 428 μg for normetanephrine and 200 μg for metanephrine, whereas the corresponding values in individuals who are being tested for pheochromocytoma as part of routine clinical practice but who do not have the neoplasm are, respectively, 71% and 51% higher than those of the normal volunteers (<900 μg for normetanephrine and <400 μg for metanephrines).[73]

Although it is preferred that patients not receive any medication during the diagnostic evaluation, treatment with most medications may be continued. Tricyclic antidepressants are the drugs that interfere most frequently with the interpretation of 24-hour urinary catecholamines and metabolites. To effectively screen for catecholamine-secreting tumors, treatment with tricyclic antidepressants and other psychoactive agents listed in Table 16.5 should be tapered and discontinued at least 2 weeks before any hormonal assessments. In some clinical situations it is contraindicated to discontinue certain medications (e.g., antipsychotics), and if case-detection testing is positive, then CT or MRI of the abdomen and pelvis would be needed to exclude a catecholamine-secreting tumor. Furthermore, catecholamine secretion may be appropriately increased in situations of physical stress or illness (e.g., stroke, myocardial infarction, congestive heart failure, obstructive sleep apnea). There are no reliable reference ranges for fractionated metanephrines or catecholamines in patients requiring intensive care unit hospitalization. Therefore the clinical circumstances under which catecholamines and metanephrines are measured must be assessed in each case.

Other Tests That Have Been Used to Assess for Pheochromocytoma

Because of poor overall accuracy in testing for pheochromocytoma, measurement of plasma catecholamines no longer has a role except to detect dopamine-secreting paragangliomas. Chromogranin A is stored and released from dense-core secretory granules of neuroendocrine cells and is increased in 80% of patients with pheochromocytoma. Chromogranin A is not specific for pheochromocytoma, and elevations may be seen with other neuroendocrine tumors. The 24-hour urinary VMA excretion has poor diagnostic sensitivity and specificity compared with fractionated 24-hour urinary metanephrines.

The high false-positive rate for plasma fractionated catecholamines and fractionated metanephrines triggered the development of a confirmatory test, the clonidine suppression test.[77] This test is intended to distinguish between pheochromocytoma and false-positive increases in plasma fractionated catecholamines and metanephrines. Clonidine is a centrally acting α_2-adrenergic receptor agonist that normally suppresses the release of catecholamines from neurons but does not affect the catecholamine secretion from a pheochromocytoma.[78]

TABLE 16.6 Typical Imaging Phenotypes of Adrenal Masses

Tumor Type	Size (cm)	Shape	Texture	Laterality	Contrast Enhancement	CT[a]	MRI[b]	Necrosis, Hemorrhage, or Calcifications	Growth
Cortical adenoma	≤3	Round to oval with smooth margins	Homogeneous	Usually unilateral	Limited	<10 HU; >50% washout	Isointense	Rare	Slow
Cortical carcinoma	>4	Irregular with unclear margins	Inhomogeneous	Usually unilateral	Marked	>10 HU; <50% washout	Hyperintense	Common	Rapid
Pheochromocytoma	>3	Round to oval with smooth margins	Inhomogeneous with areas of cystic degeneration	Usually solitary and unilateral	Marked	>10 HU; <50% washout	Hyperintense	Common	0.5–1 cm/yr
Metastasis	Variable	Oval to irregular with unclear margins	Inhomogeneous	Often bilateral	Marked	>10 HU; <50% washout	Hyperintense	Common	Variable

[a]Precontrast CT attenuation (measured in HU) and percentage of contrast medium washout at 10 min.

[b]Relative intensity compared with liver on T2-weighted images.

CT, Computed tomography; *HU,* Hounsfield unit; *MRI,* magnetic resonance imaging.

Because of advances in the methodology for measuring catecholamines and metanephrines, phentolamine, glucagon, histamine, metoclopramide, and tyramine tests are rarely needed. From 1975 to 1994 at Mayo Clinic, we performed histamine and glucagon stimulation testing in 542 patients in whom pheochromocytoma was highly suspected despite normal 24-hour urinary excretion of total metanephrines or catecholamines; not one patient had a positive stimulation test in this setting.[79]

Renal Failure

Measurements of urinary catecholamines and metabolites may be invalid if the patient has advanced renal insufficiency.[80] Serum chromogranin A levels have poor diagnostic specificity in these patients.[81] In patients without pheochromocytoma who are receiving hemodialysis, plasma norepinephrine and dopamine concentrations are increased, respectively, threefold and twofold above the upper limit of normal.[82] However, standard normal ranges can be used for interpreting plasma epinephrine concentrations.[83] Therefore when patients with renal failure have plasma norepinephrine concentrations more than three times above the upper normal limit or epinephrine concentrations greater than the upper normal limit, pheochromocytoma should be suspected. The findings of one study suggested that plasma concentrations of fractionated metanephrines are increased approximately twofold in patients with renal failure and may be useful in the biochemical evaluation of patients with marked renal insufficiency or renal failure.[84] However, the results from other studies suggested that concentrations of plasma fractionated metanephrines cannot distinguish between patients with pheochromocytoma and end-stage renal disease.[85,86]

Factitious Pheochromocytoma

As with other similar disorders, factitious pheochromocytoma can be very difficult to confirm.[87] The patient usually has a medical background. The patient may "spike" the 24-hour urine container, or the catecholamines may be administered systemically.[88] Other patients take drugs that mimic the symptoms of pheochromocytoma and can cause false-positive biochemical testing.

Localization

Localization studies should not be initiated until biochemical studies have confirmed the diagnosis of a catecholamine-secreting tumor (see Fig. 16.4). CT or MRI of the abdomen and pelvis should be the first localization test (sensitivity, >95%; specificity, >65%).[22] Approximately 85% of these tumors are found in the adrenal glands, and 95% are found in the abdomen and pelvis. The most common locations of catecholamine-secreting paragangliomas include superior abdominal para-aortic region, 46%; inferior abdominal para-aortic region, 29%; urinary bladder, 10%; mediastinum, 10%; head and neck, 3%; and pelvis, 2%.[33]

Imaging Phenotype

The term *imaging phenotype* refers to the characteristics of the mass on CT or MRI (see Table 16.6).[28] The lipid-rich nature of cortical adenomas is helpful in distinguishing these benign neoplasms from pheochromocytoma. On CT scans, the density of the image (with darker tissues being less dense) is attributed to x-ray attenuation. At the extremes of the CT density spectrum are air (black) and bone (white). The Hounsfield scale is a semiquantitative method of measuring x-ray attenuation. Typical Hounsfield unit (HU) values are -20 to -150 HU for adipose tissue and 20 to 50 HU for kidney. If an adrenal mass is less than 10 HU on unenhanced CT, it cannot be a pheochromocytoma.[89] Adrenal cortical adenomas show a much earlier washout of contrast enhancement than do nonadenomas.[90] For example, Korobkin and colleagues[90] found that the mean percentage washout for adenomas was 51% at 5 minutes and 70% at 15 minutes, compared with 8% and 20%, respectively, for nonadenomas.

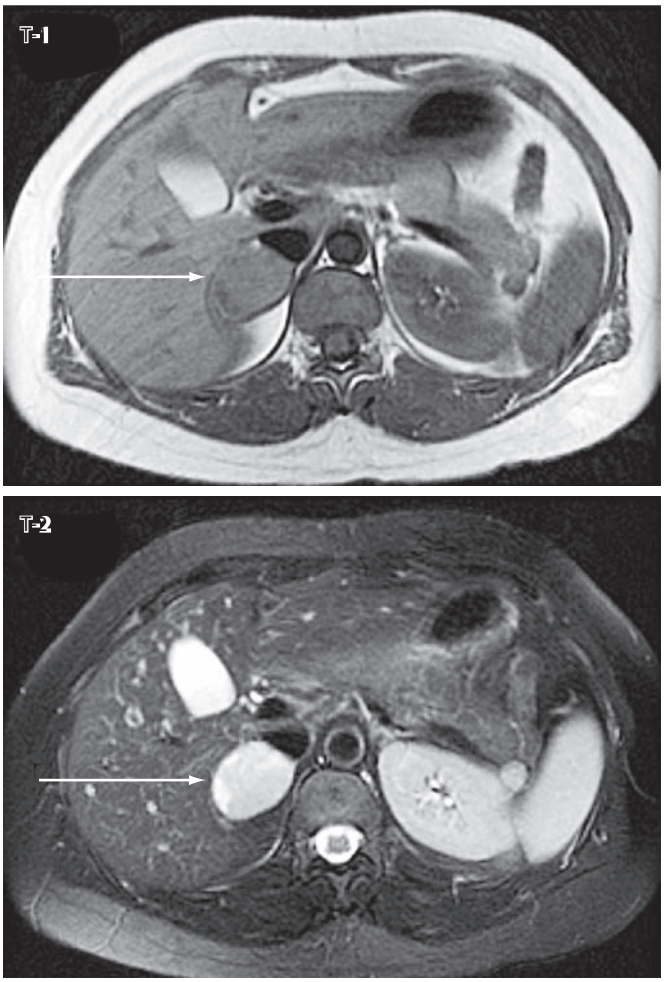
Although CT is still the primary adrenal imaging modality, MRI has advantages in certain clinical situations.[91] Several different MRI techniques have been used to characterize adrenal masses. Conventional spin-echo MRI was the first and is still the most frequently used technique. Early in the history of abdominal MRI, it became clear that with low-strength or midfield-strength magnets, T1-weighted and T2-weighted imaging could be used to differentiate pheochromocytoma and malignancies from benign adenomas. On gadolinium-diethylenetriamine penta-acetic acid (DPTA)–enhanced MRI, pheochromocytomas and malignant lesions show rapid and marked enhancement and a slower washout pattern, whereas adenomas demonstrate mild enhancement and a rapid washout of contrast agent.[90] Similar findings are made with CT.

Chemical shift MRI is a form of lipid-sensitive imaging. Chemical shift MRI is based on the principle that the hydrogen protons in water and lipid molecules resonate at different frequencies. Benign cortical adenomas contain approximately equal amounts of lipid and water, whereas the lipid content of pheochromocytomas is usually low. When the protons of water and lipid are aligned, they are said to be in phase, and when opposite each other, they are out of phase. When fat and water are in phase on MRI, the signal intensity is maximized; when they are out of phase, the signal intensity is reduced. This in-phase and out-of-phase process is the chemical shift technique. Benign adrenal cortical adenomas lose signal on out-of-phase images due to high lipid content but appear relatively bright on in-phase images. A modification of the chemical shift MRI technique uses gradient echo pulse sequences to produce a similar effect.

Imaging characteristics consistent with a benign cortical adenoma include round and homogeneous density, smooth contour with sharp margination, diameter usually less than 3 cm, unilateral location, low unenhanced CT attenuation values (e.g., <10 HU) with rapid contrast medium washout at 10 minutes after administration of contrast medium,[90,92] isointensity with liver on both T1-weighted and T2-weighted MRI sequences, and chemical shift evidence of lipid on MRI (see Table 16.6). The imaging phenotype consistent with pheochromocytoma includes noncontrast CT attenuation above 20 HU, marked enhancement with intravenous contrast medium on CT (see Fig. 16.3), high signal intensity on T2-weighted MRI and no signal loss on out-of-phase images (Fig. 16.5), cystic and hemorrhagic changes, and variable size with potential to be bilateral. Although it has been suggested that patients with apparent simple adrenal cysts do not require hormonal evaluation, pheochromocytoma can mimic an adrenal cyst.[93]

^{68}Ga-DOTATATE PET/CT and ^{123}I-MIBG Scintigraphy

In patients with a biochemically confirmed catecholamine-secreting tumor where the results of abdominal and pelvic imaging are negative, additional localization studies are indicated with either ^{68}Ga-DOTATATE PET/CT or scintigraphy with ^{123}I-MIBG (Fig. 16.6). These agents accumulate preferentially in catecholamine-producing tumors. ^{123}I-MIBG scintigraphy is not as sensitive as was initially hoped (sensitivity, 80%; specificity, 99%).[10] In a study of 282 patients with catecholamine-secreting tumors that were surgically confirmed, the overall sensitivity was 89% for CT,



• **Fig. 16.5** Magnetic resonance images of the abdomen of a 34-year-old woman with a recent onset of palpitations and hypertension. She presented with acute left ventricular failure after a single dose of a β-adrenergic blocker. The 24-hour urine test for total metanephrines and catecholamines showed the following: total metanephrines, 3800 μg (normal, <1000 μg); norepinephrine, 37 μg (normal, <170 μg); epinephrine, 7.7 μg (normal, <35 μg); and dopamine, 147 μg (normal, <700 μg). The images show a slightly heterogeneous, right adrenal mass (3.3 × 3.5 × 4.5 cm) consistent with pheochromocytoma *(arrows)* that has increased signal intensity on T2-weighted images *(lower panel)*. After α-adrenergic blockade and restoration of normal left ventricular function, the patient had a laparoscopic adrenalectomy to remove a 5 cm × 4 cm × 3 cm, 33-g pheochromocytoma. Postoperatively, the 24-hour urinary excretion of total metanephrines normalized.

• **Fig. 16.6** Gallium-68 (^{68}Ga) 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)-octreotate (DOTATATE) positron emission tomography (PET) and ^{123}I-metaiodobenzylguanidine (^{123}I-MIBG) imaging from a 57-year-old woman who had an 8.7-cm right adrenal pheochromocytoma resected 7 years previously. The results from a 24-hour urine for fractionated metanephrines and catecholamines suggested recurrent disease. Contemporaneous ^{123}I-MIBG and ^{68}Ga-DOTATATE PET scans demonstrate the superiority of ^{68}Ga-DOTATATE PET. (A) ^{68}Ga-DOTATATE PET scan shows widespread metastatic lesions that were seen throughout the axial and appendicular skeleton and retroperitoneal lymph node involvement. (B) ^{123}I-MIBG scintigraphy shows very faint increased radiotracer uptake in three vertebral bodies (T3, T8, and T10) and medial right iliac bone.

98% for MRI, and 81% for ^{131}I-MIBG.[10] If a typical (<10 cm) unilateral adrenal pheochromocytoma is found on CT or MRI, ^{123}I-MIBG scintigraphy is superfluous, and the results may even confuse the clinician.[94,95] On the other hand, if the adrenal pheochromocytoma is more than 10 cm in diameter or if a paraganglioma is identified on CT or MRI, then ^{68}Ga-DOTATATE PET/CT or ^{123}I-MIBG scintigraphy is indicated because the patient has increased risk of metastatic disease and additional paragangliomas. It is important for the clinician to recognize the medications that may interfere with ^{123}I-MIBG uptake and have the patient discontinue them before imaging is performed (Table 16.7).[96]

^{68}Ga-DOTATATE PET/CT is proving to be more sensitive in some patients than ^{123}I-MIBG, CT/MRI, or ^{18}F-fluorodeoxyglucose (FDG) PET/CT for detection of metastatic disease (see Fig. 16.6).[97] In addition, ^{68}Ga-DOTATATE PET/CT offers higher spatial resolution than conventional ^{111}In-pentetreotide scintigraphy. ^{68}Ga-DOTATATE injection as a radioactive diagnostic agent for PET imaging was approved by the US Food and Drug Administration (FDA) in June 2016.

Other Localizing Procedures

Other localizing procedures that may be used include computer-assisted cross-sectional imaging of the chest, neck, and skull base. Because of activation of aerobic glycolysis in patients with pheochromocytoma or paraganglioma associated with SDHx mutations, ^{18}FDG-PET/CT is an ideal imaging technique for localization of primary and metastatic tumors.[98] Selective adrenal venous sampling (AVS) for catecholamines is usually misleading and should be avoided.[99]

Treatment

The treatment of choice for pheochromocytoma is complete surgical resection. Surgical survival rates are 98% to 100% and are highly dependent on the skill of the endocrinologist, endocrine surgeon, and anesthesiologist team.[22,32] The most common complications are intraoperative blood pressure lability and postoperative hypotension. Careful preoperative pharmacologic preparation is crucial for successful treatment.[22,100] Most catecholamine-secreting tumors are benign and can be totally excised. Tumor excision usually cures hypertension.

TABLE 16.7 Drugs That May Interfere With Metaiodobenzylguanidine (MIBG) Uptake

Uptake-1 Inhibition[a]

Antiemetics (e.g., prochlorperazine)
Antipsychotics (e.g., chlorpromazine, haloperidol)
Cocaine
Labetalol
Phenylpropanolamine
Tricyclic antidepressants (e.g., amitriptyline, amoxapine, desipramine, doxepin, imipramine, nortriptyline)

Depletion of Storage Vesicle Contents[b]

Amphetamines (e.g., dextroamphetamine, fenfluramine, phentermine)
Dopamine
Labetalol
Reserpine
Sympathomimetics (e.g., ephedrine, phenylephrine, pseudoephedrine, salbutamol, terbutaline)

Inhibition of Vesicular Monoamine Transporters[b]

Reserpine

Unknown Mechanism[a]

Calcium channel blockers (e.g., diltiazem, nicardipine, nifedipine, nimodipine, verapamil)

[a]Should be stopped at least 48 hours before MIBG administration.
[b]Should be stopped at least 72 hours before MIBG administration.

TABLE 16.8 Orally Administered Drugs Used to Treat Pheochromocytoma

Drug	Initial Dosage, mg/day[a] (Maximum)	Side Effects
α-Adrenergic Blocking Agents		
Phenoxybenzamine	10[b] (100)[b]	Postural hypotension, tachycardia, miosis, nasal congestion, diarrhea, retrograde ejaculation, fatigue
Prazosin	1 (20)[c]	First-dose effect, dizziness, drowsiness, headache, fatigue, palpitations, nausea
Terazosin	1 (20)[b]	First-dose effect, asthenia, blurred vision, dizziness, nasal congestion, nausea, peripheral edema, palpitations, somnolence
Doxazosin	1 (20)	First-dose effect, orthostasis, peripheral edema, fatigue, somnolence
Combined α-Adrenergic and β-Adrenergic Blocking Agent		
Labetalol	200[b] (1200)[b]	Dizziness, fatigue, nausea, nasal congestion, impotence
Calcium Channel Blocker		
Nicardipine sustained-release	30[b] (120)[b]	Edema, dizziness, headache, flushing, nausea, dyspepsia
Catecholamine Synthesis Inhibitor		
α-Methyl-p-L-tyrosine (metyrosine)	1000[c] (4000)[c]	Sedation, diarrhea, anxiety, nightmares, crystalluria, galactorrhea, extrapyramidal symptoms

[a]Given once daily unless otherwise indicated.
[b]Given in two doses daily.
[c]Given in three or four doses daily.

Preoperative Management

Some form of preoperative pharmacologic preparation is indicated for all patients with catecholamine-secreting neoplasms, including those who are asymptomatic and normotensive.[22,100] However, no randomized controlled trials have compared the different approaches.[101] Combined α-adrenergic and β-adrenergic blockade is one approach to control blood pressure and prevent intraoperative hypertensive crises.[100] α-Adrenergic blockade should be started 7 to 10 days preoperatively to normalize blood pressure and expand the contracted blood volume. A longer duration of preoperative α-adrenergic blockade is indicated for patients with recent myocardial infarction, catecholamine cardiomyopathy, or catecholamine-induced vasculitis. Blood pressure should be monitored with the patient in the seated and standing positions twice daily. Target blood pressure is low-normal blood pressure for age (e.g., <120/80 mm Hg in the seated position), with systolic blood pressure greater than 90 mm Hg (standing); both targets should be modified on the basis of the patient's age and comorbid disease. Orthostasis is not a goal of treatment but rather a side effect. Therefore, on the second or third day of α-adrenergic blockade, patients are encouraged to start a diet high in sodium content (≥5000 mg/day) because of the catecholamine-induced volume contraction and the orthostasis associated with α-adrenergic blockade. This degree of volume expansion may be contraindicated in patients with congestive heart failure or renal insufficiency. After adequate α-adrenergic blockade has been achieved, β-adrenergic blockade is initiated, typically 2 to 3 days preoperatively.

α-Adrenergic Blockade

Phenoxybenzamine is the preferred drug for preoperative preparation to control blood pressure and arrhythmia. It is an irreversible, long-acting, nonspecific α-adrenergic blocking agent. The initial dosage is 10 mg once or twice daily, and the dose is increased by 10 to 20 mg in divided doses every 2 to 3 days as needed to control blood pressure and spells (Table 16.8). The final dosage of phenoxybenzamine is typically between 20 and 100 mg daily. The patient should be warned about the orthostasis, nasal congestion, retrograde ejaculation in men, and marked fatigue that occur in almost all patients. With their more favorable side effect profiles, selective α_1-adrenergic blocking agents (e.g., prazosin, terazosin, doxazosin) are preferable to phenoxybenzamine when long-term pharmacologic treatment is indicated (e.g., for metastatic pheochromocytoma). However, due to the high cost of phenoxybenzamine, selective α_1-adrenergic blocking agents are being used more commonly for preoperative preparation.

β-Adrenergic Blockade

The β-adrenergic antagonist should be administered only after α-adrenergic blockade is effective because with β-adrenergic blockade alone, severe hypertension or cardiopulmonary decompensation may occur as a result of the unopposed α-adrenergic

stimulation. Preoperative β-adrenergic blockade is indicated to control the tachycardia associated with both the high concentrations of circulating catecholamines and the α-adrenergic blockade. The clinician should exercise caution if the patient is asthmatic or has congestive heart failure. Chronic catecholamine excess can produce a myocardiopathy that may become evident with the initiation of β-adrenergic blockade, resulting in acute pulmonary edema. Therefore, when the β-adrenergic blocker is administered, it should be used cautiously and at a low dose. For example, a patient is usually given 10 mg of propranolol every 6 hours to start. On the second day of treatment, the β-adrenergic blockade (assuming the patient tolerates the drug) is converted to a single long-acting dose. The dose is then increased as necessary to control the tachycardia (goal heart rate is 60–80 beats/minute).

Catecholamine Synthesis Inhibitor

Metyrosine should be used with caution and only after other agents have been ineffective or in patients in whom tumor manipulation or destruction (e.g., radiofrequency ablation of metastatic sites) will be marked.[102] Most centers reserve metyrosine for patients who cannot be treated with the typical combined α-adrenergic and β-adrenergic blockade protocol for cardiopulmonary reasons.[7] Metyrosine inhibits catecholamine synthesis by blocking the enzyme tyrosine hydroxylase.[103] The side effects of metyrosine can be disabling; with long-term therapy, they include sedation, depression, diarrhea, anxiety, nightmares, crystalluria and urolithiasis, galactorrhea, and extrapyramidal signs. Metyrosine may be added to α-adrenergic and β-adrenergic blockade if the resection will be difficult (e.g., malignant paraganglioma) or if destructive therapy is planned (e.g., radiofrequency ablation of hepatic metastases).[7] Our typical protocol with short-term preprocedure preparation is to start with metyrosine 250 mg every 6 hours on day 1, 500 mg every 6 hours on day 2, 750 mg every 6 hours on day 3, and 1000 mg every 6 hours on the day before the procedure, with the last dose (1000 mg) given on the morning of the procedure.[7] With this short-course therapy, the main side effect is hypersomnolence.

Calcium Channel Blockers

Calcium channel blockers, which block norepinephrine-mediated calcium transport into vascular smooth muscle, have been used successfully at several medical centers to preoperatively prepare patients with pheochromocytoma.[104] Nicardipine is the most commonly used calcium channel blocker in this setting; the starting dose is 30 mg twice daily of the sustained-release preparation (see Table 16.8).[105,106] Nicardipine is given orally to control blood pressure preoperatively and if needed is given as an intravenous infusion intraoperatively (Table 16.9). Although there is less collective experience with calcium channel blockers than with α-adrenergic and β-adrenergic blockers, when calcium channel blockers are used as the primary mode of antihypertensive therapy, they may be just as effective.[106,107] Clearly, the exclusive use of calcium channel blockers for the perioperative management of patients with catecholamine-secreting tumors does not prevent all hemodynamic changes; however, its use has been associated with low morbidity and mortality rates.[107] The main role for this class of drugs may be either to supplement the combined α-adrenergic and β-adrenergic blockade protocol when blood pressure control is inadequate or to replace the adrenergic blockade protocol in patients with intolerable side effects.

Acute Hypertensive Crises

Acute hypertensive crises may occur before or during an operation, and they should be treated with intravenously administered sodium nitroprusside, phentolamine, or nicardipine (see Table 16.9). Sodium nitroprusside is an ideal vasodilator for intraoperative management of hypertensive episodes because of its rapid onset of action and short duration of effect. It is administered as an intravenous infusion at 0.5 to 5 μg/kg of body weight per minute and adjusted every few minutes for target blood pressure response; to keep the steady-state thiocyanate concentration below 1 mmol/L, the rate of a prolonged infusion should be no more than 3 μg/kg per minute. Phentolamine is a short-acting, nonselective α-adrenergic blocker that is available in lyophilized form in 5-mg vials. An initial test dose of 1 mg is administered and is followed, if necessary, by repeat 5-mg boluses or continuous infusion. The response to phentolamine is maximal 2 to 3 minutes after a bolus injection and lasts 10 to 15 minutes. Nicardipine can be started at an infusion rate of 5 mg per hour and titrated for blood pressure control (the infusion rate may be increased by 2.5 mg/hour every 15 minutes up to a maximum of 15 mg/hour) (see Table 16.9).

TABLE 16.9 Intravenously Administered Drugs Used to Treat Pheochromocytoma

Agent	Dosage Range
For Hypertension	
Phentolamine	Administer a 1-mg IV test dose, then 2-mg to 5-mg IV boluses as needed or continuous infusion.
Nitroprusside	IV infusion rates of 2 μg/kg of body weight per minute are suggested as safe. Rates >4 μg/kg per minute may lead to cyanide toxicity within 3 hours. Doses >10 μg/kg per minute are rarely required, and the maximal dose should not exceed 800 μg/min.
Nicardipine	Initiate therapy at 5 mg/hr; the IV infusion rate may be increased by 2.5 mg/hr q15 min up to a maximum of 15 mg/hr.
For Cardiac Arrhythmia	
Lidocaine	Initiate therapy with an IV bolus of 1–1.5 mg/kg (75–100 mg); additional boluses of 0.5–0.75 mg/kg (25–50 mg) can be given q5–10 min if needed up to a maximum of 3 mg/kg. Loading is followed by maintenance IV infusion of 2–4 mg/min (30–50 μg/kg per minute) adjusted for effect and settings of altered metabolism (e.g., heart failure, liver congestion) and as guided by blood level monitoring.
Esmolol	An initial IV loading dose of 0.5 mg/kg is infused over 1 minute, followed by a maintenance infusion of 0.05 mg/kg per minute for the next 4 minutes. Depending on the desired ventricular response, the maintenance infusion may then be continued at 0.05 mg/kg per minute or increased stepwise (e.g., by 0.1 mg/kg per minute increments to a maximum of 0.2 mg/kg per minute), with each step being maintained for ≥4 minutes.

IV, Intravenous; *q,* every.

Anesthesia and Surgery

Surgical resection of a catecholamine-secreting tumor is a high-risk surgical procedure, and an experienced surgeon-anesthesiologist team is required. The last oral doses of α-adrenergic and β-adrenergic blockers can be administered early in the morning on the day of the operation. Fentanyl, ketamine, and morphine should be avoided because they potentially can stimulate catecholamine

release from a pheochromocytoma.[108] Also, parasympathetic nervous system blockade with atropine should be avoided because of the associated tachycardia. Anesthesia may be induced with intravenous injection of propofol, etomidate, or barbiturates in combination with synthetic opioids.[108] Most anesthetic gases can be used, but halothane and desflurane should be avoided. Cardiovascular and hemodynamic variables must be monitored closely. Continuous measurement of intra-arterial pressure and heart rhythm is required. If the patient has congestive heart failure or decreased cardiac reserve, monitoring of pulmonary capillary wedge pressure is indicated. The preoperative and perioperative treatment approach outlined here is the same for adults and children.[109,110]

The laparoscopic approach to the adrenal gland is currently the procedure of choice for patients with solitary adrenal pheochromocytomas smaller than 8 cm in diameter.[111–113] If the pheochromocytoma is in the adrenal gland, the entire gland should be removed. Laparoscopic adrenalectomy for pheochromocytoma should be converted to open adrenalectomy in cases of difficult dissection, invasion, adhesions, or surgeon inexperience. Great care should be taken to avoid tumor capsule rupture—this can create incurable diffuse peritoneal disease implants from an apparent benign pheochromocytoma.[114] If the tumor is malignant, as much of the tumor should be removed as possible. If a bilateral adrenalectomy is planned preoperatively, the patient should receive glucocorticoid stress coverage while awaiting transfer to the operating room. In addition, glucocorticoid coverage should be initiated in the operating room if unexpected bilateral adrenalectomy is necessary. Cortical-sparing bilateral adrenalectomies have been used to treat patients with VHL disease.[115,116]

An anterior midline abdominal surgical approach is indicated for abdominal paragangliomas. The midline abdomen should be inspected carefully. Paragangliomas of the neck, chest, and urinary bladder require specialized approaches.[117] Unresectable cardiac pheochromocytomas may require cardiac transplantation.[118]

Hypotension may occur during and after surgical resection of the pheochromocytoma, and it should be treated with fluids and colloids and then intravenous pressor agents if necessary. Postoperative hypotension occurs less frequently in patients who have had adequate preoperative α-adrenergic blockade and volume expansion. If both adrenal glands were manipulated during surgery, adrenocortical insufficiency should be considered as a potential cause of postoperative hypotension. Because hypoglycemia can occur in the immediate postoperative period, blood glucose levels should be monitored, and fluid given intravenously should contain 5% dextrose. Blood pressure is usually normal by the time of hospital discharge. Long-standing, persistent hypertension does occur and may be due to resection-related renal injury, resetting of baroreceptors, hemodynamic changes, structural changes of the blood vessels, altered sensitivity of the vessels to pressor substances, functional or structural renal changes, or coincident primary hypertension.

Long-Term Postoperative Follow-Up

Approximately 1 to 2 weeks after surgery, 24-hour urinary fractionated catecholamines and metanephrines should be measured. If the levels are normal, the resection of the pheochromocytoma should be considered complete. The survival rate after removal of a benign pheochromocytoma is almost equal to that of age-matched and sex-matched normal control subjects. Increased levels of fractionated catecholamines and metanephrines detected postoperatively are consistent with residual tumor (i.e., a second primary lesion or occult metastases). If bilateral adrenalectomy was performed, lifelong glucocorticoid and mineralocorticoid replacement therapy is prescribed.

The risk for recurrent disease (usually metastatic) in patients with apparent benign pheochromocytoma or paraganglioma is approximately 15% on long-term follow-up.[119] The 24-hour urinary excretion of fractionated catecholamines and metanephrines or plasma fractionated metanephrines should be checked annually for life.[22] Annual biochemical testing assesses for metastatic disease (which can occur even 50 years later),[120] tumor recurrence in the adrenal bed, and delayed appearance of multiple primary tumors. Recurrence rates are highest for patients with familial disease, large tumor size (>5 cm), or paraganglioma.[121] Follow-up CT or MRI is not needed unless metanephrine or catecholamine levels become elevated or the original tumor was associated with minimal catecholamine excess.

Genetic testing should be considered for patients younger than 45 years of age or those with one or more of the following: a family history of pheochromocytoma; paraganglioma; and any sign that suggests a genetic cause, such as retinal angiomas, axillary freckling, café au lait spots, cerebellar tumor, MTC, or hyperparathyroidism. In addition, all first-degree relatives of a patient with pheochromocytoma or paraganglioma should have biochemical testing (e.g., 24-hour urine collection for fractionated metanephrines and catecholamines). If mutation testing in a patient is positive, the patient's first-degree relatives should be offered genetic testing.

Metastatic Pheochromocytoma and Paraganglioma

Distinguishing between benign and malignant catecholamine-secreting tumors is difficult on the basis of clinical, biochemical, or histopathologic characteristics.[12] Malignancy is rare in patients with MEN2 or VHL syndrome, but it is common in those with familial paraganglioma caused by mutations in *SDHB*.[122,123] In a series of 272 patients with metastatic pheochromocytoma or paraganglioma, the median age at initial tumor diagnosis was 39 years (range, 7–83 years), and in 65% of patients the metastases developed at a median of 5.5 years (range, 0.3–53.4 years) from the initial diagnosis.[120] The median overall and disease-specific survivals were 24.6 and 33.7 years, respectively.[120] The clinician should first assess the pace of the malignant disease and then target the level of therapy to the aggressiveness of tumor behavior. A multimodality, multidisciplinary, individualized approach is indicated to control catecholamine-dependent symptoms, local mass effect symptoms from the tumor, and overall tumor burden. Long-term pharmacologic therapy for the patient with metastatic pheochromocytoma is similar to that outlined for preoperative preparation in a patient with a catecholamine-secreting tumor.

Metastatic sites include local tissue invasion, bone, liver, lung, omentum, and lymph nodes. Metastatic lesions should be resected, if possible, to decrease tumor burden.[124] Skeletal metastatic lesions that are painful or threaten structural function can be treated with external radiotherapy or thermalablation or approached surgically.[102,125] Thrombotic therapy for large, unresectable liver metastases and radiofrequency ablation for small (<3 cm) liver metastases are options to be considered.[102] In selected cases, long-acting octreotide has been beneficial.[126] Because of the risk of massive catecholamine release, ablative therapy should be performed with great caution and only at centers with experience with these techniques; in addition to α-adrenergic and β-adrenergic blockade, these patients are usually treated with metyrosine before the procedure.[102] External radiotherapy can also be used to treat unresectable soft tissue lesions.[125]

Local tumor irradiation with therapeutic doses of ^{131}I-MIBG has produced partial and temporary responses in approximately one-third of patients.[9,11,127] If the tumor is considered aggressive and the patient's quality of life is affected, combination chemotherapy can provide disease stabilization.[128,129] In a nonrandomized, single-arm trial, the efficacy of chemotherapy with a combination CVD protocol (cyclophosphamide 750 mg/m^2 body surface area on day 1, vincristine 1.4 mg/m^2 on day 1, and dacarbazine 600 mg/m^2 on days 1 and 2; repeated every 21 days) was studied in 14 patients with malignant pheochromocytoma.[130,131] This protocol produced a complete and partial response rate of 57% (median duration, 21 months; range, 7 to >34 months). Complete and partial biochemical responses were seen in 79% of patients (median duration, >22 months; range, 6 to >35 months). All responding patients had objective improvement in performance status and blood pressure.[130,131] CVD chemotherapy can be continued until the patient develops new lesions or there is a significant (e.g., >25%) increase in the size of known tumor sites. Because CVD chemotherapy may induce massive catecholamine release, it is important that the patient be optimally α and β blocked, just as for surgery. In addition, the first cycle of CVD should be completed in the hospital and with close medical observation. Management of metastatic pheochromocytoma can be frustrating because there are no curative options. Tyrosine kinase inhibitors (e.g., sunitinib) may have a role in the treatment of metastatic pheochromocytoma; however, they are not curative.[132]

Pheochromocytoma in Pregnancy

Pheochromocytoma in pregnancy can cause the death of both the fetus and the mother.[133,134] The approach to the biochemical diagnosis is the same as that for the nonpregnant patient. MRI (without gadolinium enhancement) is the preferred imaging modality, and ^{123}I-MIBG scintigraphy and ^{68}Ga-DOTATATE PET/CT are contraindicated. The treatment of hypertensive crises is the same as for nonpregnant patients except that use of nitroprusside should be avoided. Although the most appropriate management is debated, adrenal pheochromocytomas should be removed in the second trimester if diagnosed during the first or second trimester of pregnancy. The preoperative preparation is the same as for a nonpregnant patient. If the pregnancy is already in the third trimester, medical management is indicated and delivery completed by cesarean section. Spontaneous labor and delivery should be avoided. The pheochromocytoma can be resected postpartum. The management of catecholamine-secreting paragangliomas in pregnancy may require modification of these guidelines depending on tumor location.

Renin-Angiotensin-Aldosterone System

The components of the renin-angiotensin-aldosterone (RAA) system are shown in Fig. 16.7.[135] Aldosterone is secreted from the zona glomerulosa under the control of three primary factors: angiotensin II, potassium, and ACTH. The secretion of aldosterone is restricted to the zona glomerulosa because of zone-specific expression of aldosterone synthase (P450 11B2) (see Chapter 15). Dopamine, atrial natriuretic peptide, and heparin inhibit aldosterone secretion.

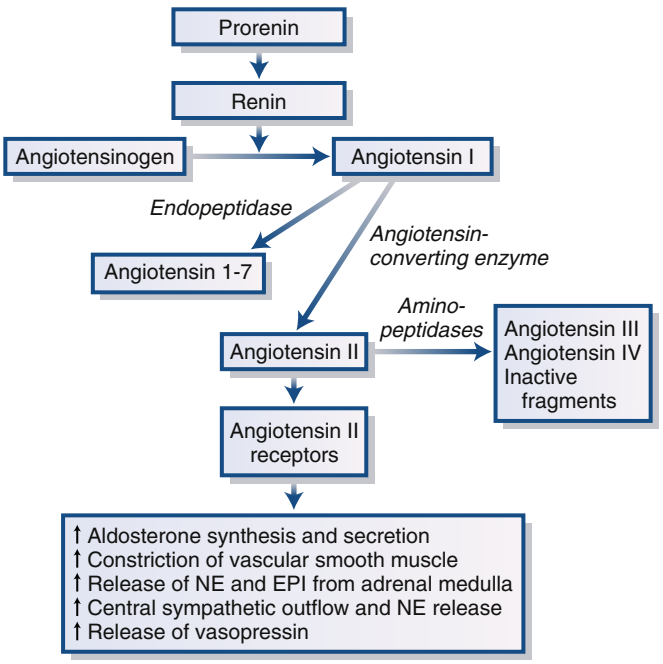
Renin and Angiotensin

Renin is an enzyme that is produced primarily in the juxtaglomerular apparatus of the kidney; it is stored in granules and released in response to specific secretagogues. The protein consists of 340 amino acids, of which the first 43 are a prosegment that is cleaved to produce the active enzyme. The release of renin into the circulation is the rate-limiting step in the RAA system. Renal renin release is controlled by four factors:

1. The macula densa, a specialized group of convoluted distal tubular cells that function as chemoreceptors for monitoring the sodium and chloride loads present in the distal tubule
2. Juxtaglomerular cells acting as pressure transducers that sense stretch of the afferent arteriolar wall and thus renal perfusion pressure
3. The sympathetic nervous system, which modifies the release of renin, particularly in response to upright posture
4. Humoral factors, including potassium, angiotensin II, and atrial natriuretic peptides

Renin release is maximized in conditions of low renal perfusion pressure or low tubular sodium content (e.g., renal artery stenosis, hemorrhage, volume depletion). Renin release is suppressed by elevated perfusion pressure at the kidney (e.g., hypertension) and a high-sodium diet. Renin release is increased directly by hypokalemia and decreased by hyperkalemia.

Angiotensinogen, an α_2-globulin synthesized in the liver, is the only known substrate for renin and is broken down into the angiotensin peptides. The protein consists of 485 amino acids, 33 of which constitute a presegment that is cleaved after secretion. The action of renin on angiotensinogen produces angiotensin I. Angiotensin I comprises the first 10–amino acid sequence after the presegment and does not appear to have biologic activity. Angiotensin II, the main biologically active angiotensin, is created by cleavage of the two carboxy-terminal peptides of angiotensin I by angiotensin-converting enzyme (ACE) (see Fig. 16.7). ACE is localized to cell membranes in the lung and intracellular granules in certain tissues that produce angiotensin II. Amino peptidase A can remove the amino-terminal aspartic acid to produce the



• **Fig. 16.7** Components of the renin-angiotensin system. *EPI,* epinephrine; *NE,* norepinephrine. (Adapted and redrawn from Williams GH, Chao J, Chao L. Kidney hormones. In: Conn PM, Melmed S, eds. *Endocrinology: Basic and Clinical Principles.* Totowa, NJ: Humana Press; 1997:393–404.)

heptapeptide, angiotensin III. Angiotensin II and angiotensin III have equivalent efficacy in promoting aldosterone secretion and modifying renal blood flow. The half-life in the circulation of angiotensin II is short (<60 seconds). Elements of the RAA system are present in the adrenals, kidneys, heart, and brain. For example, the adrenal glomerulosa cells contain the proteins needed to produce and secrete angiotensin II. Other tissues contain one or more components of the system but require other cells or circulating components, or both, to generate angiotensin II.

Angiotensin II functions through the angiotensin receptor to maintain normal extracellular volume and blood pressure by (1) increasing aldosterone secretion from the zona glomerulosa via increased transcription of *CYP11B2*; (2) constricting vascular smooth muscle, thereby increasing blood pressure and reducing renal blood flow; (3) releasing norepinephrine and epinephrine from the adrenal medulla; (4) enhancing the activity of the sympathetic nervous system by increasing central sympathetic outflow, thereby increasing norepinephrine discharge from sympathetic nerve terminals; and (5) promoting the release of vasopressin.

Aldosterone

Approximately 50% to 70% of aldosterone circulates bound to albumin or weakly bound to corticosteroid-binding globulin; 30% to 50% of total plasma aldosterone is free. The half-life is relatively short at 15 to 20 minutes. In the liver, aldosterone is rapidly inactivated to tetrahydroaldosterone. The classic functions of aldosterone are regulation of extracellular volume and control of potassium homeostasis. These effects are mediated by the binding of free aldosterone to the mineralocorticoid receptor in the cytosol of epithelial cells, principally in the kidney.

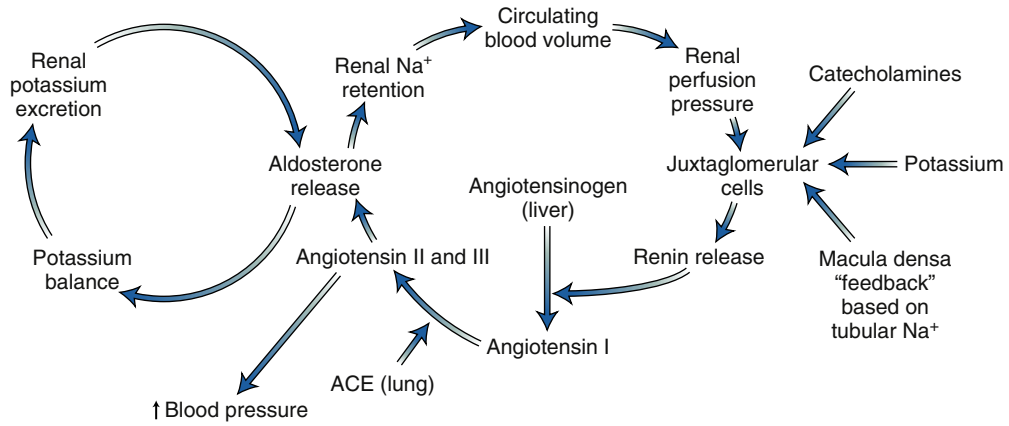
Mineralocorticoid receptors have tissue-specific expression. For example, the tissues with the highest concentrations of these receptors are the distal nephron, colon, and hippocampus. Lower levels of mineralocorticoid receptors are found in the rest of the gastrointestinal tract and heart. Transport to the nucleus and binding to specific binding domains on targeted genes leads to their increased expression. The aldosterone-regulated kinases, primarily serum-inducible and glucocorticoid-inducible kinase-1 (SGK1) appear to be key intermediaries, and increased SGK1 expression leads to modification of the apical sodium channel, resulting in increased sodium ion transport across the cell membrane (see Chapter 15). The increased luminal negativity augments tubular secretion of potassium by the tubular cells and of hydrogen ion by the interstitial cells.

Endogenous glucocorticoids and mineralocorticoids bind equally to the mineralocorticoid receptor. Specificity of action is provided in many tissues by the presence of a glucocorticoid-inactivating enzyme, 11β-hydroxysteroid dehydrogenase 2, which prevents cortisol and corticosterone from interacting with the receptor (see Chapter 15). Mineralocorticoid escape refers to the counterregulatory mechanisms that are manifested after 3 to 5 days of excessive mineralocorticoid administration. Several mechanisms contribute to this escape, including renal hemodynamic factors and increased levels of atrial natriuretic peptide.

In addition to the classic genomic actions mediated by aldosterone binding to cytosolic receptors, mineralocorticoids have acute, nongenomic actions resulting from activation of an unidentified cell surface receptor. This action involves a G protein–signaling pathway and probably a modification of the sodium-hydrogen exchange activity. This effect has been demonstrated in both epithelial and nonepithelial cells.[136]

Aldosterone has additional, nonclassic effects primarily on nonepithelial cells.[137] These actions, although probably genomic and therefore mediated by activation of the cytosolic mineralocorticoid receptor, do not include modification of sodium-potassium balance. Aldosterone-mediated actions include the expression of several collagen genes, genes controlling tissue growth factors (e.g., transforming growth factor-β, plasminogen activator inhibitor type 1) and genes mediating inflammation.[138] The resultant actions lead to microangiopathy, necrosis (acutely), and fibrosis in various tissues, such as the heart, the vasculature, and the kidney.[137] Increased levels of aldosterone are not necessary to cause this damage; an imbalance between the volume or sodium balance state and the level of aldosterone appears to be the critical factors.[137]

The action of angiotensin II on aldosterone involves a negative feedback loop that also includes extracellular fluid volume (Fig. 16.8).[139] The major function of this feedback loop is to modify sodium homeostasis and, secondarily, to regulate blood pressure. Sodium restriction activates the RAA axis. The effects of angiotensin II on both the adrenal cortex and the renal



• **Fig. 16.8** Renin-angiotensin-aldosterone and potassium-aldosterone negative feedback loops. Aldosterone production is determined by input from each loop. *ACE,* angiotensin-converting enzyme; *Na+,* sodium. (Adapted and redrawn from Williams GH, Dluhy RG. Diseases of the adrenal cortex. vasculature promote renal sodium conservation. On the other hand, with suppression of renin release and suppression of the level of circulating angiotensin, aldosterone secretion is reduced and renal blood flow is increased, promoting sodium loss. The RAA loop is very sensitive to dietary sodium intake. Sodium excess enhances the responsiveness of the renal and peripheral vasculature and reduces the adrenal responsiveness to angiotensin II. Sodium restriction has the opposite effect. Therefore, sodium intake modifies target tissue responsiveness to angiotensin II, a fine-tuning mechanism that appears to be critical to maintaining normal sodium homeostasis without a chronic effect on blood pressure. Excess aldosterone secretion causes hypertension through two main mechanisms: mineralocorticoid-induced expansion of plasma and extracellular fluid volume and increased total peripheral vascular resistance.

Primary Aldosteronism

Hypertension, suppressed plasma renin activity (PRA), and increased aldosterone excretion characterize the syndrome of primary aldosteronism, which was first fully described in 1955.[140] Aldosterone-producing adenoma (APA) and bilateral idiopathic hyperaldosteronism (IHA) are the most common subtypes of primary aldosteronism (Table 16.10). Somatic mutations account for nearly all of APAs and include mutations in genes encoding components of the Kir 3.4 (*GIRK4*) potassium channel (*KCNJ5*), the sodium/potassium and calcium ATPases (*ATP1A1* and *ATP2B3*), a voltage-dependent C-type calcium channel (*CACNA1D*), and β-catenin–activating mutations (*CTNNB1*).[141,142] A much less common form, unilateral hyperplasia or primary adrenal hyperplasia (PAH), is caused by micronodular or macronodular hyperplasia of the zona glomerulosa of predominantly one adrenal gland. Familial hyperaldosteronism (FH) is also rare, and four types have been described (see later discussion).[141]

History

In his presidential address at the annual meeting of the Central Society for Clinical Research, Chicago, Illinois, October 29, 1954, Dr. Jerome W. Conn stated[140]: "I have prepared no comprehensive review of my personal philosophy of clinical investigation. Instead, I plan to make a scientific report to you about a clinical syndrome, the investigation of which has been most exciting to me since I initiated it in April of this year." Conn, a professor of medicine at the University of Michigan, had been active in government-funded research on the mechanisms of human acclimatization to humid heat. He established that the body's acclimatization response was to rapidly diminish renal salt and water loss and to abruptly curtail the salt content of body sweat and saliva. He suggested that these responses were the result of increased adrenocortical function with elaboration of salt-retaining steroids. He also showed that intramuscular administration of deoxycorticosterone acetate (DOCA) produced similar changes in the electrolyte composition of urine, sweat, and saliva.

In April 1954, Professor Conn was asked to see M.W., a 34-year-old woman with a 7-year history of muscle spasms, temporary paralysis, tetany, and weakness and a 4-year history of hypertension. She was found to have a blood pressure of 176/104 mm Hg, severe hypokalemia (1.6–2.5 mEq/L), mild hypernatremia (146–151 mEq/L), and alkalosis (serum pH 7.62). Because there were no signs or symptoms of glucocorticoid or androgen excess, Conn suspected, based on his past research, that M.W.'s clinical presentation could result from excess secretion of the adrenal salt-retaining corticoid. Conn studied M.W. in the Metabolism Research Unit for 227 days. The Streeten bioassay technique developed to measure sodium retention in adrenalectomized rats after intraperitoneal injection of human urine was used, and M.W. averaged 1333 μg DOCA equivalent per day, compared with normotensive control subjects at 61.4 μg/day. In his presidential address, Conn stated: "It is believed that these studies delineate a new clinical syndrome, which is designated temporarily as primary aldosteronism."[140] (Note: The word *temporarily* was used because aldosterone was yet to be measured in any human bodily fluid.)

Conn planned for a bilateral adrenalectomy for his patient on December 10, 1954. In 1995, Gittler and Fajans described the surgical scene: "To the immense delight of Conn and those in the operating room, the surgeon, Dr. William Baum, encountered a right 13-g adrenal tumor, which was removed while leaving the contralateral gland intact. The patient's postoperative studies showed an almost total reversal of the preoperative metabolic and

TABLE 16.10 Adrenocortical Causes of Hypertension

Low Renin and High Aldosterone

Primary Aldosteronism

- Aldosterone-producing adenoma (APA)—30% of cases
- Bilateral idiopathic hyperplasia (IHA)—60% of cases
- Primary (unilateral) adrenal hyperplasia—2% of cases
- Aldosterone-producing adrenocortical carcinoma—<1% of cases
- Familial hyperaldosteronism (FH)
  - FH type I (*CYP11B1/CYP11B2* germline chimeric gene)—<1% of cases
  - FH type II (APA or IHA; germline *CLCN2* mutations—<6% of cases
  - FH type III (germline *KCNJ5* mutations)—<1% of cases
  - FH type IV (germline *CACNA1H* mutations)—<0.1% of cases
- Ectopic aldosterone-producing adenoma or carcinoma—<0.1% of cases

Low Renin and Low Aldosterone

- Congenital adrenal hyperplasia
  - 11β-Hydroxylase deficiency
  - 17α-Hydroxylase deficiency
- Deoxycorticosterone-producing tumor
- Primary cortisol resistance
- Apparent mineralocorticoid excess (AME)/11β-HSD 2 deficiency
  - Genetic
    - Type 1 AME
    - Type 2 AME
  - Acquired
    - Licorice or carbenoxolone ingestion (type 1 AME)
    - Cushing syndrome (type 2 AME)

Cushing Syndrome

- Exogenous glucocorticoid administration—most common cause
- Endogenous
  - ACTH-dependent—85% of cases
    - Pituitary
    - Ectopic
  - ACTH-independent—15% of cases
    - Unilateral adrenal disease (adenoma or carcinoma)
    - Bilateral adrenal disease
      - Bilateral adenoma
      - Macronodular hyperplasia
      - Primary pigmented nodular adrenal disease (rare)

ACTH, Corticotropin; *HSD,* hydroxysteroid dehydrogenase.

clinical abnormalities. Conn had achieved irrefutable proof of the validity of his investigative conclusions and established for the first time the relationship among an adrenal aldosterone-producing tumor, hypertension, and hypokalemia. A new era had arrived in the study of hypertension and adrenal mineralocorticoids."[143]

By 1964, Conn had collected 145 cases,[144] and he suggested that up to 20% of patients with essential hypertension might have primary aldosteronism.[145] This suggestion was downplayed by most as a gross overestimate.[146,147] Later, Conn decreased his predicted prevalence of primary aldosteronism to 10% of hypertensives,[148] a prediction that was substantiated nearly 40 years later.

Prevalence

In the past, clinicians would not consider the diagnosis of primary aldosteronism unless the patient presented with spontaneous hypokalemia, and then the diagnostic evaluation would require discontinuation of antihypertensive medications for at least 2 weeks. This diagnostic approach resulted in predicted prevalence rates of less than 0.5% of hypertensive patients.[14,146,147,149–152] However, it is now recognized that most patients with primary aldosteronism are not hypokalemic[153,154] and that screening can be completed while the patient is taking antihypertensive drugs.[153] Measurement of plasma aldosterone concentration (PAC) and renin activity or concentration (PRA or PRC, respectively) as a case-detection test, followed by aldosterone suppression for confirmatory testing, has resulted in much higher prevalence estimates for primary aldosteronism—5% to 10% of all patients with hypertension.[153–158]

Clinical Presentation

The diagnosis of primary aldosteronism is usually made in patients who are in the third to sixth decades of life. Few symptoms are specific to the syndrome. Patients with marked hypokalemia may have muscle weakness and cramping, headaches, palpitations, polydipsia, polyuria, nocturia, or a combination of these.[159] Periodic paralysis is a very rare presentation in Caucasians, but it is not an infrequent presentation in patients of Asian descent.[160] The polyuria and nocturia are a result of hypokalemia-induced renal concentrating defect, and the presentation is frequently mistaken for prostatism in men. There are no specific physical findings. Edema is not a common finding because of the phenomenon of mineralocorticoid escape, described earlier. The degree of hypertension is typically moderate to severe and may be resistant to the usual pharmacologic treatments.[159,161] In the first 262 cases of primary aldosteronism diagnosed at Mayo Clinic (1957–1986), the highest blood pressure was 260/155 mm Hg; the mean (± SD [standard deviation]) was 184/112 ± 28/16 mm Hg.[161] Patients with APA tend to have higher blood pressures than those with IHA.

Hypokalemia is frequently absent, so all patients with hypertension are candidates for this disorder. In other patients, the hypokalemia becomes evident only with the addition of a potassium-wasting diuretic (e.g., hydrochlorothiazide, furosemide). Deep-seated renal cysts are found in up to 60% of patients with chronic hypokalemia.[162] Because of a reset osmostat, the serum sodium concentration tends to be high-normal or slightly above the upper limit of normal. This clinical clue is very useful in the initial assessment for potential primary aldosteronism.

Several studies have shown that patients with primary aldosteronism are at higher risk than other patients with hypertension for target-organ damage of the heart and kidney.[163,164] Chronic kidney disease is common in patients with long-standing primary aldosteronism.[165] When matched for age, blood pressure, and duration of hypertension, patients with primary aldosteronism have greater left ventricular mass measurements than patients with other types of hypertension (e.g., pheochromocytoma, Cushing syndrome, essential hypertension).[166] In patients with APA, the left ventricular wall thickness and mass were markedly decreased 1 year after adrenalectomy.[167] A case control study of 124 patients with primary aldosteronism and 465 patients with essential hypertension (matched for age, sex, and systolic and diastolic blood pressure) found that patients presenting with either APA or IHA had a significantly higher rate of cardiovascular events (e.g., stroke, atrial fibrillation, myocardial infarction) than the matched patients with essential hypertension.[163] A negative effect of circulating aldosterone on cardiac function was found in young nonhypertensive subjects with glucocorticoid-remediable aldosteronism (GRA) who had increased left ventricular wall thickness and reduced diastolic function compared with age-matched and sex-matched control subjects.[168]

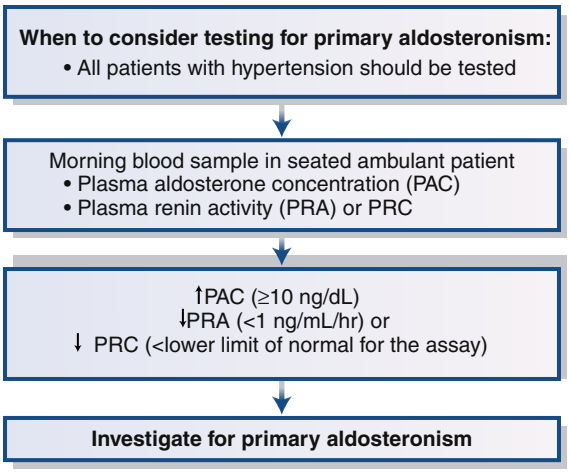
The risk to develop new onset diabetes mellitus was documented in a study of 2367 patients with primary aldosteronism who had no prior diagnosis of diabetes mellitus, where 754 surgically treated patients with APA were matched with 3016 essential hypertension controls.[169] The patients with primary aldosteronism who underwent adrenalectomy had statistically significant reduced risk for incident diabetes and all-cause of mortality, compared with matched hypertensive controls.[169]

Several studies have documented the negative impact of primary aldosteronism on quality of life.[170] Untreated patients with primary aldosteronism have an impaired physical and mental quality of life compared to the general population. Symptoms of anxiety, demoralization, stress, depression, and nervousness were more frequently reported in untreated patients with primary aldosteronism than in the general population and in patients with hypertension.[170] A prospective quality-of-life study compared patients with primary aldosteronism who were managed surgically to those managed medically.[171] After 1 year, almost all quality-of-life measures had normalized for surgically managed patients; whereas for patients on medical treatment, most of the measures had improved but not to the level of the general population.[171]

Diagnosis

There is no typical clinical phenotype to guide the clinician for when to suspect primary aldosteronism—72% of patients with primary aldosteronism are normokalemic.[155,157] Most clinical practice guidelines recommend case-detection testing in high-risk groups for primary aldosteronism (e.g., sustained blood pressure >150/100 mm Hg, hypertension resistant to three conventional antihypertensive drugs, controlled blood pressure on four or more antihypertensive drugs, hypertension and spontaneous or diuretic-induced hypokalemia, hypertension and adrenal incidentaloma, hypertension and sleep apnea, hypertension and a family history of early onset hypertension or cerebrovascular accident at a young age).[153] However, most primary care physicians do not test patients for primary aldosteronism—most patients go undiagnosed and untreated.[172–174] Due to the excess cardiovascular morbidity and nephrotoxicity associated with primary aldosteronism, a case can be made that all patients with hypertension should be tested for this disorder at least once (Fig. 16.9).

The diagnostic approach to primary aldosteronism can be considered in three phases: case-detection tests, confirmatory tests, and subtype evaluation tests.



• **Fig. 16.9** This algorithm provides guidance on when to consider testing for primary aldosteronism and use of plasma aldosterone concentration (PAC) and plasma renin activity (PRA) as a case-detection tool. *PRC,* plasma renin concentration.

Case-Detection Tests

Case-detection testing can be accomplished by paired measurements of PAC and PRA in a random morning ambulatory blood sample (preferably obtained between 8 and 10 AM) (see Fig. 16.9). This test may be performed while the patient is taking antihypertensive medications (with some exceptions, discussed later) and without posture stimulation.[159] Hypokalemia reduces the secretion of aldosterone, and it is optimal to restore the serum level of potassium to normal before performing diagnostic studies.

It may be difficult to interpret data obtained from patients treated with a mineralocorticoid receptor antagonist (MRA) (spironolactone and eplerenone). These drugs prevent aldosterone from activating the receptor, resulting sequentially in sodium loss, a decrease in plasma volume, and an elevation in renin, which can lead to false-negative case-detection testing. For this reason, spironolactone and eplerenone should not be initiated until the evaluation is completed and the final decisions about treatment are made. However, there are exceptions to this rule. For example, if the patient is hypokalemic despite treatment with spironolactone or eplerenone, then the mineralocorticoid receptors are not fully blocked, and PRA or PRC should be suppressed in such a patient with primary aldosteronism. Thus if renin is suppressed, the evaluation for primary aldosteronism (case-detection testing, confirmatory testing, and AVS) can proceed despite treatment with MRAs. Whereas if renin is not suppressed in a patient treated with a mineralocorticoid antagonist, therapy should be discontinued for at least 6 weeks before retesting. Other potassium-sparing diuretics, such as amiloride and triamterene, usually do not interfere with testing unless the patient is on high doses.

ACE inhibitors and angiotensin receptor blockers (ARBs) have the potential to elevate renin in patients with primary aldosteronism. Therefore the finding of detectable renin in a patient taking one of these drugs does not exclude the diagnosis of primary aldosteronism. However, a PRA level less than 1 ng/mL per hour or PRC below the reference range in a patient taking an ACE inhibitor or ARB makes primary aldosteronism likely.

The PAC:PRA ratio, first proposed as a case-detection test for primary aldosteronism in 1981,[175] is based on the concept of paired hormone measurements. The PAC is measured in nanograms per deciliter; the PRA is measured in nanograms per milliliter per hour. In a hypertensive hypokalemic patient, secondary hyperaldosteronism should be considered if both PRA and PAC are increased and the PAC:PRA ratio is less than 10 (e.g., renovascular disease). An alternative source of mineralocorticoid receptor agonism should be considered if both PRA and PAC are suppressed (e.g., hypercortisolism). Primary aldosteronism should be suspected if the PRA is suppressed (e.g., <1.0 ng/mL per hour) and the PAC is increased (e.g., >10 ng/dL) (see Fig. 16.9). It is critical for the clinician to recognize that the measurement of PAC and renin is only a case-detection tool, and most positive results should be followed by a confirmatory aldosterone suppression test to verify autonomous aldosterone production before treatment is initiated.[153] The exception to the requirement for confirmatory testing involves patients with hypertension, spontaneous hypokalemia, and marked primary aldosteronism (e.g., PAC >20 ng/dL and PRA <1.0 ng/mL per hour) (see Fig. 16.9).[153]

Confirmatory Tests

A positive case detection test with PAC above 10 ng/dL and PRA below 1 ng/mL per hour is not diagnostic by itself, and (in the absence of spontaneous hypokalemia—see earlier discussion) primary aldosteronism must be confirmed by demonstration of inappropriate aldosterone secretion.[154] The list of drugs and hormones capable of affecting the RAA axis is extensive, and a medication-contaminated evaluation is frequently unavoidable in patients with poorly controlled hypertension despite a three-drug program. Calcium channel blockers and α_1-adrenergic receptor blockers do not affect the diagnostic accuracy in most cases.[153] However, as long as renin is suppressed and PAC is above 10 ng/dL, the clinician can proceed with confirmatory testing regardless of medications. No medication causes false-positive testing for primary aldosteronism when PAC is above 10 ng/dL.

Aldosterone suppression testing can be performed with orally administered sodium chloride and measurement of urinary aldosterone or with intravenous sodium chloride loading and measurement of PAC.[153,159]

Oral Sodium Loading Test

After hypertension and hypokalemia have been controlled, patients should receive a high-sodium diet (supplemented with sodium chloride tablets if needed) for 3 days, with a goal sodium intake of 5000 mg (equivalent to 218 mEq sodium or 12.8 g sodium chloride).[161] The risk of increasing dietary sodium in patients with severe hypertension must be assessed in each case.[176] Because the high-sodium diet can increase kaliuresis and hypokalemia, vigorous replacement of potassium chloride may be needed, and the serum level of potassium should be monitored daily. On the third day of the high-sodium diet, a 24-hour urine specimen is collected for measurement of aldosterone, sodium, and creatinine. To document adequate sodium repletion, the 24-hour urinary sodium excretion should exceed 200 mEq. Urinary aldosterone excretion of more than 12 µg/24 hours in this setting is consistent with autonomous aldosterone secretion.[161] The sensitivity and specificity of the oral sodium loading test are 96% and 93%, respectively.[177]

Intravenous Saline Infusion Test

The intravenous saline infusion test has also been used widely for the diagnosis of primary aldosteronism.[153,154] Normal subjects show suppression of PAC after volume expansion with isotonic saline; subjects with primary aldosteronism do not show

this suppression. The test is done in the seated position after an overnight fast.[178] Two liters of 0.9% sodium chloride solution is infused intravenously with an infusion pump over 4 hours. Blood pressure and heart rate are monitored during the infusion. At the completion of the infusion, blood is drawn for measurement of PAC. PAC levels in normal subjects decrease to less than 5 ng/dL, whereas most patients with primary aldosteronism do not suppress to less than 10 ng/dL. Postinfusion PAC values between 5 and 10 ng/dL are indeterminate and may be seen in patients with IHA.

Fludrocortisone Suppression Test

In the fludrocortisone suppression test, fludrocortisone acetate is administered for 4 days (0.1 mg every 6 hours) in combination with sodium chloride tablets (2 g three times daily with food). Blood pressure and serum potassium levels must be monitored daily. In the setting of low PRA, failure to suppress the upright 10 AM PAC to less than 6 ng/dL on day 4 is diagnostic of primary aldosteronism.[179] Increased QT interval dispersion and deterioration of left ventricular function have been reported during fludrocortisone suppression tests.[176] Most centers no longer use this test.

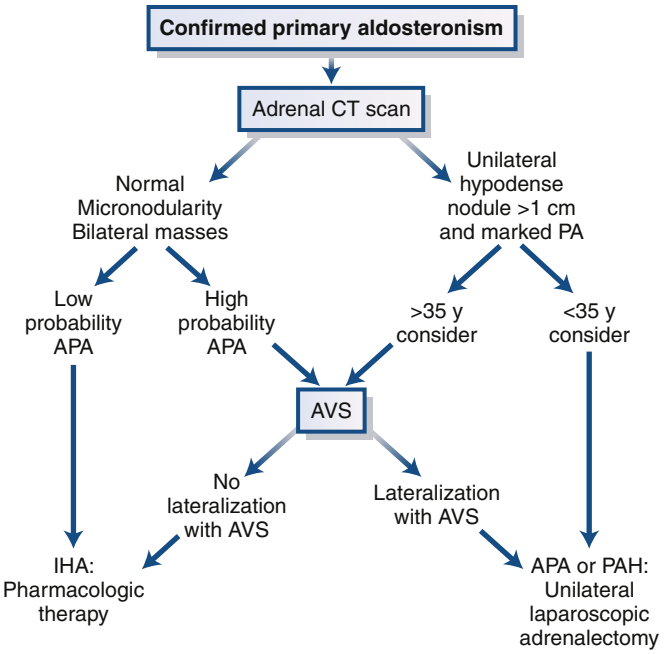
Subtype Studies

After case-detection and confirmatory testing, the third management issue guides the therapeutic approach by distinguishing APA and PAH from IHA and GRA. Unilateral adrenalectomy in patients with APA or PAH results in normalization of hypokalemia in all cases; hypertension is improved in all cases and is cured in 30% to 60%.[88,180–182] In IHA unilateral or bilateral adrenalectomy seldom corrects the hypertension.[161] IHA and GRA should be treated medically. APA is found in approximately 35% of cases and bilateral IHA in approximately 60% (see Table 16.10). APAs are usually small hypodense adrenal nodules (<2 cm in diameter) on CT and are golden yellow when resected. IHA adrenal glands may be normal on CT or may show nodular changes. Aldosterone-producing adrenal carcinomas are almost always larger than 4 cm in diameter and have an inhomogeneous imaging phenotype on CT (see Table 16.6).

Computed Tomography of the Adrenal Glands

Primary aldosteronism subtype evaluation may require one or more tests, the first of which is imaging of the adrenal glands with CT (Fig. 16.10). If a solitary unilateral low noncontrast CT attenuation (<10 HU) macroadenoma (>1 cm) and normal contralateral adrenal morphologic appearance are found on CT in a young patient (<35 years) with severe primary aldosteronism, unilateral adrenalectomy is a reasonable therapeutic option (see Fig. 16.10).[153,183,184] However, most patients with primary aldosteronism are over age 35 years, and in many cases, CT shows normal-appearing adrenals, minimal unilateral adrenal limb thickening, unilateral microadenomas (≤1 cm), or bilateral macroadenomas (Fig. 16.11). In these cases, additional testing is required to determine the source of excess aldosterone secretion.

Small APAs may be labeled incorrectly as IHA on the basis of CT findings of bilateral nodularity or normal-appearing adrenals. Also, apparent adrenal microadenomas may actually represent areas of hyperplasia, and unilateral adrenalectomy would be inappropriate. In addition, nonfunctioning unilateral adrenal macroadenomas are not uncommon, especially in older patients (>40 years).[185] Unilateral PAH may be visible on CT, or the PAH may appear normal on CT. In general, patients with APAs have more severe hypertension, more frequent hypokalemia, higher levels

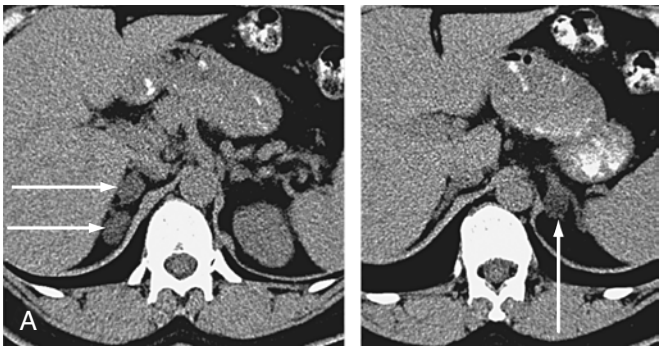


• **Fig. 16.10** Subtype evaluation of primary aldosteronism. For patients who want to pursue a surgical treatment for their hypertension, adrenal venous sampling is frequently a key diagnostic step (see text for details). *APA,* aldosterone-producing adenoma; *AVS,* adrenal venous sampling; *CT,* computed tomography; *IHA,* idiopathic hyperaldosteronism; *PA,* primary aldosteronism; *PAH,* primary adrenal hyperplasia. (Modified from Young Jr WF, Hogan MJ. Renin-independent hypermineralocorticoidism. *Trends Endocrinol Metab.* 1994;5:97–106.)

of plasma aldosterone (>30 ng/dL) and urinary aldosterone (>30 µg/24 hours), and are younger (<50 years), compared with those who have IHA.[161] Patients fitting these descriptors are considered to have a high probability of APA regardless of the CT findings (see Fig. 16.10), and 41% of patients with a high probability of APA and a normal adrenal CT scan prove to have unilateral aldosterone hypersecretion.[186]

Adrenal CT is not accurate in distinguishing between APA and IHA.[183,186–188] In a study of 203 patients with primary aldosteronism who were evaluated with both CT and AVS, CT was accurate in only 53% of patients; based on the CT findings, 42 patients (22%) would have been incorrectly excluded as candidates for adrenalectomy and 48 patients (25%) might have had unnecessary or inappropriate surgery.[186] In another study of 208 patients with primary aldosteronism, based on CT findings, 19 patients (12%) would have been bypassed for curative surgery and 48 patients (30%) would have had noncurative surgery.[188] In a systematic review of 38 studies involving 950 patients with primary aldosteronism, adrenal CT/MRI results did not agree with the findings from AVS in 359 patients (38%); based on CT/MRI, 19% of the 950 patients would have undergone noncurative surgery, and 19% would have been offered medical therapy instead of curative adrenalectomy.[187]

A study published in 2016 caused some confusion regarding the well-documented superiority of AVS compared to CT.[189] The reported success rate of CT and failure rate of AVS were much higher than any other series. In addition, the interpretation of the data was complicated by the use of MRAs postoperatively—leading to blood pressure control in the patients with uncured primary aldosteronism from both groups. The authors used an inappropriately low cutoff for the adrenal-to-IVC cortisol gradient of greater



Results of bilateral adrenal venous sampling

Vein	Aldosterone (A)(ng/dL)	Cortisol (C)(∞g/dL)	A/C Ratio	Aldosterone Ratio*

B

• **Fig. 16.11** A 43-year-old woman had a 2-year history of hypertension and hypokalemia. The screening test for primary aldosteronism was positive, with a plasma aldosterone concentration (PAC) of 37 ng/dL and low plasma renin activity (PRA) at less than 0.6 ng/mL per hour (PAC/PRA ratio >61). The confirmatory test for primary aldosteronism was also positive, with the 24-hour urinary excretion of aldosterone measured at 53 μg on a high-sodium diet (urinary sodium, 196 mEq/24 hours). (A) Adrenal computed tomography shows a 12-mm, low-density mass *(arrow, right panel)* in the medial limb of the left adrenal and two low-density, 10-mm nodules *(arrows, left panel)* within the right adrenal gland. (B) Adrenal venous sampling lateralized aldosterone secretion to the right, and two cortical adenomas (1.8 × 1.2 × 0.8 cm and 2.5 × 1.5 × 1.2 cm) were found at laparoscopic right adrenalectomy. The postoperative plasma aldosterone concentration was less than 1 ng/dL. Hypokalemia was cured, and blood pressure was normal without the aid of antihypertensive medications.

than 3:1.[189] When cosyntropin is used during AVS, the minimal cortisol gradient cutoff to determine successful catheterizations is greater than 5:1 (see AVS discussion to come). The persistent postoperative primary aldosteronism in 11% of the AVS-directed treatment group simply reflected the lack of reliable AVS data—likely related to multiple factors.[189] The key message from this study was not that CT and AVS were equivalent in subtype testing; rather, centers that have a suboptimal AVS program will have poor AVS-directed outcomes. Thus centers that have low-volume AVS programs or enlist multiple interventional radiologists (and dilute the expertise) or simply lack the effort to ensure accurate AVS,[190] should refer their patients with primary aldosteronism to centers that champion expertise in AVS.

Therefore AVS is essential to direct appropriate therapy in patients with primary aldosteronism who have a high probability of APA and are seeking a potential surgical cure.

Adrenal Venous Sampling

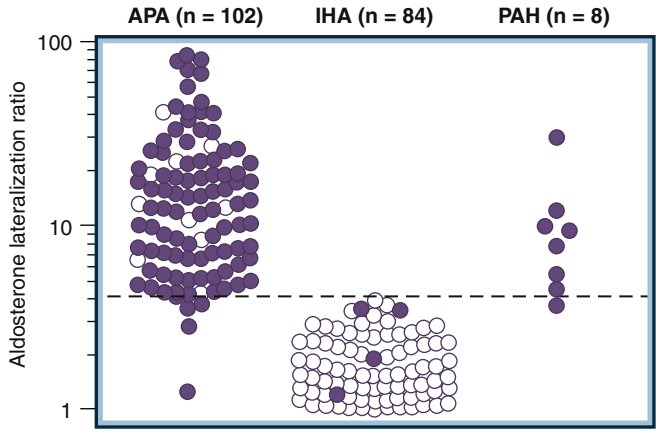
AVS is the criterion standard test to distinguish between unilateral and bilateral disease in patients with primary aldosteronism.[153,183,187,188] AVS is an intricate procedure because the right adrenal vein is small and may be difficult to locate and cannulate; the success rate depends on the proficiency of the angiographer.[191] A review of 47 reports found that the success rate for cannulation of the right adrenal vein in 384 patients was 74%.[161] With experience and focusing the expertise to one or two radiologists at a referral center, the AVS success rate can be as high as 96%.[186,192–194]

The five keys to a successful AVS program are (1) appropriate patient selection, (2) careful patient preparation, (3) focused technical expertise, (4) defined protocol, and (5) accurate data interpretation.[191] A center-specific written protocol is mandatory. The protocol should be developed by an interested group of endocrinologists, hypertension specialists, internists, radiologists, and laboratory personnel. Safeguards should be in place to prevent mislabeling of the blood tubes in the radiology suite and to prevent sample mixup in the laboratory.[191]

At Mayo Clinic, we use continuous cosyntropin infusion during AVS (50 μg/hour starting 30 minutes before sampling and continuing throughout the procedure) for the following reasons: (1) to minimize stress-induced fluctuations in aldosterone secretion during nonsimultaneous AVS, (2) to maximize the gradient in cortisol from adrenal vein to IVC and thus confirm successful sampling of the adrenal veins,[188,195] and (3) to maximize the secretion of aldosterone from an APA.[186,191,195] The adrenal veins are catheterized through the percutaneous femoral vein approach, and the position of the catheter tip is verified by gentle injection of a small amount of nonionic contrast medium and radiographic documentation. Blood is obtained from both adrenal veins and from the IVC below the renal veins and assayed for aldosterone and cortisol concentrations. To be sure that there is no cross-contamination, the IVC sample should be obtained from the external iliac vein. The venous sample from the left side typically is obtained from the common phrenic vein immediately adjacent to the entrance of the adrenal vein. Whereas the blood sample from the right adrenal vein is obtained just at the orifice of the vein—to stabilize the catheter in proper position and avoid the error of advancing the catheter tip too deep into the adrenal vein—a guide wire may be used.[196] The cortisol concentrations from the adrenal veins and IVC are used to confirm successful catheterization—a minimal adrenal vein-to-IVC cortisol gradient is 5:1 or more. At Mayo Clinic, the mean adrenal-to-IVC cortisol gradient was 33.9:1 on the right side and 23.8:1 on the left.[186]

Dividing the right and left adrenal vein PAC values by their respective cortisol concentrations corrects for the dilutional effect of the inferior phrenic vein flow into the left adrenal vein; these are termed *cortisol-corrected ratios* (Fig. 16.12). In patients with APA, the mean cortisol-corrected aldosterone ratio (i.e., the ratio of PAC/cortisol from the APA side to that from the normal side) is 18:1.[186] A cutoff point of more than 4:1 for this ratio is used to indicate unilateral aldosterone excess (see Fig. 16.12). In patients with IHA, the mean cortisol-corrected aldosterone ratio is 1.8:1 (high side to low side), and a ratio of less than 3:1 suggests bilateral aldosterone hypersecretion (see Fig. 16.12).[186] Therefore most patients with a unilateral source of aldosterone have cortisol-corrected aldosterone lateralization ratios greater than 4, and ratios greater than 3 but less than 4 represent a zone of overlap. Ratios no higher than 3 are consistent with bilateral aldosterone secretion.

In addition to the AVS aldosterone lateralization ratio, a contralateral suppression index can be calculated: The contralateral (nondominant adrenal) aldosterone-cortisol (A/C) ratio is divided by the IVC A/C ratio. In the early Mayo Clinic series, the contralateral suppression index was less than 1 in 93.4% of patients with surgically confirmed APA.[186] Although a supportive finding, if the aldosterone lateralization ratio is 4 or above, a contralateral



• **Fig. 16.12** Adrenal vein aldosterone lateralization ratios for patients with unilateral aldosterone-producing adenomas (APA), bilateral idiopathic hyperplasia (IHA), and unilateral primary adrenal hyperplasia (PAH). Shaded symbols indicate that the diagnosis was confirmed surgically. The sensitivity and specificity of a cortisol-corrected plasma aldosterone concentration lateralization ratio greater than 4 for unilateral disease are 95.2% and 100%, respectively. (From Young Jr WF, Stanson AW, Thompson GB, et al. Role for adrenal venous sampling in primary aldosteronism. *Surgery.* 2004;136:1227–1235. Used with permission.)

suppression index less than 1 is not associated with better postoperative blood pressure outcomes and should not be a requirement to send patients to surgery.[197,198] However, there are several situations where the contralateral suppression index can be very helpful. For example, when the aldosterone lateralization ratio is in the gray zone (3–<4), a contralateral suppression index of less than 1 is predictive of good operative outcomes.[199] In addition, if AVS is not bilaterally successful, a contralateral suppression index of less than 0.5 is highly predictive of contralateral disease.[200] Also, patients with a contralateral suppression index of less than 0.47 are at increased risk for postoperative hyperkalemia (see treatment section).[201]

The test characteristics of AVS using an aldosterone lateralization ratio of 4 or above for detection of unilateral aldosterone hypersecretion (APA or PAH) are 95% sensitivity and 98.6% specificity.[186,202] The use of AVS should be based on patient preference, patient age, clinical comorbid conditions, and the clinical probability of finding an APA. A practical approach is the selective use of AVS as outlined in Fig. 16.10.[203]

At centers with experience with AVS, the complication rate is 2.5% or less.[186,192] Complications can include symptomatic groin hematoma, adrenal hemorrhage, and dissection of an adrenal vein.

Noninvasive Alternatives to Adrenal Vein Sampling

Noninvasive alternatives to AVS are being explored. For example, ^{11}C-metomidate can be used as a PET radiotracer. In an initial study of 25 patients with PA, dexamethasone-suppressed ^{11}C-metomidate PET/CT had a specificity of 87% and sensitivity of 76% for unilateral adrenal disease.[204] It was recently reported that there is a high expression of CXC chemokine receptor type 4 (CXCR4) in adrenal glands and APAs, which correlates with the expression of P450 11B2 (aldosterone synthase).[205] The specific CXCR4 ligand ^{68}Ga-pentixafor was used as a PET imaging molecule in localizing APAs in nine patients with primary aldosteronism.[205] Finally, in vitro and animal studies have shown a high selectivity of a ^{18}F PET imaging molecule (CDP2230) for P450 11B2 over P450 11B1 with a favorable biodistribution for imaging P450 11B2.[206] Clinical studies will be needed to see if this ^{18}F-based PET imaging molecule or those similar to it will prove to be clinically useful.

Familial Hyperaldosteronism

Familial hyperaldosteronism should be considered when primary aldosteronism is diagnosed before age 20 years or when it is diagnosed in more than one family member. To date, four forms of FH have been described.[141] However, it is very likely that many more disease-causing germline mutations will be described in the coming years, and labeling each mutation with FH type V, VI, VII, VIII, IX, etc., will become impractical. A more practical approach may be to simply indicate FH due to the specific mutation.

Glucocorticoid-Remediable Aldosteronism: Familial Hyperaldosteronism Type I—*CYP11B1/CYP11B2* Germline Chimeric Gene

GRA (FH type I; Online Mendelian Inheritance in Man [OMIM] 103900) was first described in a single family in 1966.[207] Twenty-six years later the causative *CYP11B1/CYP11B2* chimeric gene was discovered.[208] GRA is a form of hyperaldosteronism in which the hypersecretion of aldosterone can be reversed with physiologic doses of glucocorticoid.[209] It is rare, as illustrated by a study of 300 consecutive patients with primary aldosteronism; only two patients were diagnosed with GRA (prevalence = 0.66%) (see Table 16.10).[210] GRA is characterized by early-onset hypertension that is usually severe and refractory to conventional antihypertensive therapies, aldosterone excess, suppressed PRA, and excess production of 18-hydroxycortisol and 18-oxocortisol. Mineralocorticoid production is regulated by ACTH instead of by the normal secretagogue, angiotensin II. Therefore aldosterone secretion can be suppressed by glucocorticoid therapy. In the absence of glucocorticoid therapy, this mutation results in overproduction of aldosterone and the hybrid steroids 18-hydroxycortisol and 18-oxocortisol, which can be measured in the urine or plasma to make the diagnosis.

Genetic testing is a sensitive and specific means of diagnosing GRA and obviates the need to measure the urinary levels of 18-oxocortisol and 18-hydroxycortisol or to perform dexamethasone suppression testing. Genetic testing for GRA should be considered for patients with primary aldosteronism who have a family history of primary aldosteronism, onset of primary aldosteronism at a young age (<20 years), or family history of strokes at a young age.

Familial Hyperaldosteronism Type II—*CLCN2* Chloride Channel Germline Mutations

FH type II is autosomal dominant in inheritance.[211–213] The hyperaldosteronism in FH type II does not suppress with dexamethasone, and GRA mutation testing is negative. FH type II is more common than FH type I, but it still accounts for fewer than 6% of all patients with primary aldosteronism.[210] In a recent report of a family with FH type II and 80 additional probands with unsolved early-onset primary aldosteronism, a germline *CLCN2* chloride channel mutation was found in 8 of the probands.[214] All relatives with early-onset primary aldosteronism carried the *CLCN2* variant found in the proband. *CLCN2* encodes a voltage-gated chloride channel expressed in adrenal glomerulosa cells. Mutations in the *CLCN2* chloride channel may be responsible for all or some of the individuals who have been classified at FH type II.[215] Over time we may learn of a series of mutations that contribute to what has been classified as FH type II.

Familial Hyperaldosteronism Type III—Germline *KCNJ5* Mutations

FH type III (OMIM 613677) was first described in a 5-year-old boy in 1959.[216] However, the familial nature of the disorder did not become apparent until the detection of primary aldosteronism in the index patient's two daughters in 2008; all presented with refractory hypertension before age 7 years and were treated with bilateral adrenalectomy.[217] The adrenal glands showed massive hyperplasia. Three years later the causative germline mutation in this family was discovered: a point mutation in and near the selectivity filter of the potassium channel *KCNJ5*.[218] This *KCNJ5* mutation produces increased sodium conductance and cell depolarization, triggering calcium entry into glomerulosa cells, the signal for aldosterone production and cell proliferation. Thus far, 12 kindreds carrying 6 different *KCNJ5* mutations have been identified: p.Thr158Ala, p.Gly151Glu, p.Gly151Arg, p. Ile157Ser, p.Tyr152Cys, and p.Glu145Gln.[218–223] The estimated prevalence of germline *KCNJ5* mutations is 0.3% in patients with primary aldosteronism and 8% among patients with familial primary aldosteronism.[220] Most patients with germline *KCNJ5* mutations present with polyuria, polydipsia, and refractory hypertension in childhood—investigations show marked hypokalemia and marked primary aldosteronism. In most cases the degree of aldosterone hypersecretion is so marked that bilateral adrenalectomy is required. However, there is some heterogeneity in age at presentation (as old as 48 years),[221] and the hypertension and hypokalemia in some patients can be controlled with MRAs.

Familial Hyperaldosteronism Type IV—Germline *CACNA1H* Gene Mutations

FH type IV (OMIM 617027) is inherited in an autosomal dominant fashion and with incomplete penetrance and is caused by mutations in the *CACNA1H* gene, which encodes the α-subunit of an L-type voltage-gated calcium channel (Cav3.2).[224,225] A novel germline *CACNA1H* mutation (p.Met1549Val) was identified in 5 of 40 unrelated patients affected by hypertension and primary aldosteronism in childhood.[224] Four additional germline *CACNA1H* mutations have been reported in patients with primary aldosteronism.[225]

Primary Aldosteronism With Seizures and Neurologic Abnormalities (PASNA)—Germline *CACNA1D* Mutations

PASNA is caused by de novo germline mutations in *CACNA1D* (OMIM 615474). *CACNA1D* encodes for the α1D-subunit of a L-type voltage-gated calcium channel (Cav 1.3). PASNA has been reported in two children with primary aldosteronism, seizures, and neurologic abnormalities.[226] The severe neurologic abnormalities do not allow these individuals to reproduce; thus, although due to a germline mutation, it is not technically a familial form of primary aldosteronism. In addition, a missense *CACNA1D* germline mutation was reported in a patient affected by autism and epilepsy.[227]

Primary Aldosteronism and *ARMC5* Mutations

Heterozygous germline mutations of the armadillo repeat containing 5 (*ARMC5*) gene are most commonly linked to subclinical glucocorticoid secretory autonomy or Cushing syndrome in patients with bilateral macronodular adrenal hyperplasia (BMAH).[228] However, there are reports of *ARMC5* mutations in patients with both primary aldosteronism and Cushing syndrome due to BMAH, a co-occurrence seen more commonly in African-American patients.[229]

Somatic Mutations in *KCNJ5, ATP1A1, ATP2B3, CACNA1D,* and *CTNNB1* Genes

Somatic mutations account for the majority of APAs and include mutations in genes encoding components of the Kir 3.4 (GIRK4) potassium channel *(KCNJ5),* the sodium/potassium and calcium ATPases (*ATP1A1* and *ATP2B3*), and a voltage-dependent C-type calcium channel *(CACNA1D).* In a multicenter study of 351 APAs from patients with primary aldosteronism and 130 other adrenocortical lesions, two somatic mutations in *KCNJ5* (G151R or L168R) were identified in 47% of APAs.[230] Somatic *KCNJ5* mutations were absent in adrenal tissue from patients with primary aldosteronism due to unilateral hyperplasia and in 130 non–aldosterone-secreting adrenal lesions. *KCNJ5* mutations were overrepresented in APAs from women compared with men (63% vs 24%), and APAs with *KCNJ5* mutations had larger lesional diameters than those without the mutation (2.7 cm vs 1.7 cm, respectively).[230] The larger size of *KCNJ5* APAs is explained in part by the zona fasciculata–like cells and lower levels of aldosterone synthase expression compared to APAs caused by somatic mutations in *ATP1A1*, *ATP2B3,* or *CACNA1D*.[231] In a meta-analysis including 13 studies with 1636 patients, the overall prevalence of somatic *KCNJ5* mutations in patients with APAs was 43%.[232]

Somatic APA mutations have been identified in three other genes: *ATP1A1* encoding Na^+/K^+-ATPase 1, *ATP2B3* encoding Ca^{2+}-ATPase 3, and *CACNA1D* encoding a voltage-gated calcium channel. In a study of 112 APAs, somatic APA mutations in *KCNJ5, ATP1A1,* and *ATP2B3* were present in 39.2%, 6.3%, and 0.9%, respectively.[233] To date, 13 different *ATP1A1* and 9 *ATP2B3* somatic mutations have been reported.[234] In addition, 31 different *CACNA1D* mutations have been described and account for approximately 9% of sporadic APAs.[234] *CACNA1D* APAs are composed of zona glomerulosa–like cells and are smaller compared with those with either no somatic mutation or *KCNJ5* APAs.[231] Somatic *CACNA1D* mutations are the most frequent somatic mutation in patients with APAs with negative or minimal nodularity (<1 cm) on preoperative cross-sectional imaging.[235]

The *CTNNB1* gene encodes β-catenin, and activating *CTNNB1* mutations have been found in 3% of sporadic APAs.[236] Similar to *KCNJ5* APAs, *CTNNB1* APAs are associated with female sex and larger adenomas. It is likely that nearly 100% of APAs will eventually be associated with somatic driver mutations.

Aldosterone-Producing Cell Clusters

Immunohistochemical staining studies for P450 11B2 and P450 11B1 have detected focal subcapsular nests of adrenocortical cells that extend into the zona fasciculata and stain strongly for P450 11B2 and are termed aldosterone-producing cell clusters (APCCs).[237] APCCs have been identified in normal adrenals and in pathology specimens from patients with primary aldosteronism, where APCCs may occur adjacent to APAs.[237] APCCs have been shown to harbor somatic mutations in *CACNA1D* and *ATP1A1* and raise the possibility that APCCs may secrete aldosterone autonomously and could be precursors to APAs.[238] Interestingly, APCCs increase with age and may in part simply reflect the aging adrenal gland.[239,240] The clinical relevance of APCCs is yet to be determined.

Cortisol Cosecretion

Patients with primary aldosteronism have been shown to be at increased risk for insulin resistance and metabolic syndrome,[241–243] depression,[244] and osteoporotic fractures.[245] These associations are more in keeping with glucocorticoid secretory autonomy or excess. A steroid metabolome study found that (a) patients with primary

aldosteronism (APA and IHA) had significantly increased cortisol and total glucocorticoid metabolite excretion compared to controls and patients with subclinical Cushing syndrome (p <0.001); (b) surrogate parameters of metabolic risk correlated with glucocorticoid, but not mineralocorticoid excretion; and (c) unilateral adrenalectomy in patients with APA resolved both mineralocorticoid and glucocorticoid excess.[246] These findings suggest that some degree of cortisol cosecretion is common in patients with primary aldosteronism and is linked to metabolic risk—a finding that may indicate that treatment with mineralocorticoid receptor antagonists in patients with IHA and APA may not prevent glucocorticoid-dependent metabolic risks.[246] However, these data should be interpreted with caution because this study did not simply identify cortisol cosecretion from APAs but rather an increased corticosteroid metabolome in patients with APA and IHA. The hypothalamic-pituitary-adrenal axis is not suppressed in these patients, and there is no adrenal crisis or steroid withdrawal in patients with APAs who are treated surgically. Thus the etiology of the increased glucocorticoid metabolites in patients with primary aldosteronism is not clear and may be due to a yet to be determined mechanism.

A separate and less common issue is APAs that cosecrete cortisol that may be clinically important for perioperative management (e.g., perioperative corticosteroid coverage and postoperative replacement and taper).[247] When should clinicians test for cortisol cosecretion in patients with APAs? In general, clinically important cortisol secretion from an adrenal adenoma is correlated with tumor size. Unlike aldosterone secretion from an adenoma, clinically important cortisol secretion requires a "large factory"—typically with cortical adenoma diameters greater than 2 cm.[247] Thus it is reasonable to test patients with primary aldosteronism for cortisol cosecretion when the adrenal adenoma is greater than 1.5 cm in diameter; testing should include baseline dehydroepiandrosterone-sulfate and an overnight 1-mg dexamethasone suppression test.[248] When glucocorticoid secretory autonomy is documented in a patient with primary aldosteronism who has a single cortical adenoma greater than 1.5 cm in diameter, AVS is not needed, assuming that the contralateral adrenal appears normal on CT.

Principles of Treatment

The treatment goal is to prevent the morbidity and fatality associated with hypertension, hypokalemia, cardiovascular damage, and nephrotoxicity. Knowing the cause of the primary aldosteronism helps to determine the appropriate treatment. Normalization of blood pressure should not be the only goal. In addition to the kidney and colon, mineralocorticoid receptors are present in the heart, brain, and blood vessels. Excessive secretion of aldosterone is associated with increased risk of cardiovascular disease and morbidity. Therefore normalization of circulating aldosterone or mineralocorticoid receptor blockade should be part of the management plan for all patients with primary aldosteronism. However, clinicians must understand that most patients with long-standing primary aldosteronism have some degree of renal insufficiency that is masked by the glomerular hyperfiltration associated with aldosterone excess.[249,250] The true degree of underlying chronic kidney disease may become evident only after effective pharmacologic or surgical therapy.[249,250]

Surgical Treatment of Aldosterone-Producing Adenoma and Unilateral Hyperplasia

Unilateral laparoscopic adrenalectomy is an excellent treatment option for patients with APA or unilateral hyperplasia.[111] As outlined earlier, in terms of quality-of-life parameters, the beneficial effects of surgery were superior to chronic medical treatment with mineralocorticoid receptor antagonists.[171] Unilateral adrenalectomy is the optimal treatment for patients with unilateral adrenal disease. Surgical treatment with bilateral adrenalectomy is not a good treatment option for patients with IHA; instead lifelong treatment with mineralocorticoid antagonists is the treatment of choice.

Laparoscopic adrenalectomy with an expert adrenal surgeon is the preferred surgical approach. Because APAs are small and may be multiple, the entire adrenal gland should be removed.[188,251] To decrease the surgical risk, hypokalemia should be corrected with potassium supplements or a mineralocorticoid receptor antagonist, or both, preoperatively (but discontinued immediately postoperatively). PAC should be measured 1 to 2 days after surgery to confirm a biochemical cure.[183] In general, the number and dosages of antihypertensive medications can be decreased by 50% postoperatively—discontinuing any that may predispose to hyperkalemia (e.g., ACE-I, ARB). The full impact of surgery on hypertension may take up to 3 months. Because of the risk of temporary hypoaldosteronism due to chronic suppression of the RAA axis, serum potassium levels should be monitored weekly for 4 weeks after surgery, and a generous sodium diet should be followed.[201,252,253] In a multicenter study of 142 surgically treated patients, the prevalence of postoperative hyperkalemia was 9.9%; the hyperkalemic patients were older and had worse renal function than the nonhyperkalemic patient group.[254] In a study of 192 patients with primary aldosteronism who were treated surgically, 12 (6.3%) developed postoperative hyperkalemia (median serum potassium 5.5 mmol/L, range 5.2–6.2 mmol/L); median time to onset was 13.5 days (range, 7–55 days).[201]

Although blood pressure control improves in almost 100% of patients postoperatively, average long-term cure rates of hypertension after unilateral adrenalectomy for APA range from 30% to 60%.[88,182,183] Persistent hypertension after adrenalectomy is directly correlated with having more than one first-degree relative with hypertension, use of more than two antihypertensive agents preoperatively, older age, increased serum creatinine level, and duration of hypertension and is most likely caused by coexistent primary hypertension.[88]

Pharmacologic Treatment

IHA and GRA should be treated medically. In addition, although not optimal, APA may be treated medically if therapy includes mineralocorticoid receptor blockade. A sodium-restricted diet (<100 mEq sodium per day), maintenance of ideal body weight, tobacco avoidance, and regular aerobic exercise contribute significantly to the success of pharmacologic treatment. No placebo-controlled, randomized trials have evaluated the relative efficacy of drugs in the treatment of primary aldosteronism.[255]

In a longitudinal study assessing 602 patients with primary aldosteronism treated with mineralocorticoid receptor antagonists, the incidence of cardiovascular events was higher in patients with primary aldosteronism compared to patients with essential hypertension.[256] The excess risk for cardiovascular events and mortality was limited to patients with primary aldosteronism who had suppressed PRA on medical treatment—suggesting inadequate dosing of mineralocorticoid receptor antagonists.[256] Due to concomitant low-renin essential hypertension in some patients with primary aldosteronism, measurement of PRA may not be optimal to guide management; rather, a more practical treatment target to document effective mineralocorticoid blockade is a high-normal serum potassium without the aid of oral potassium supplements.

Spironolactone has been the drug of choice to treat primary aldosteronism for more than 50 years. It is available as 25-mg, 50-mg, and 100-mg tablets. The dosage is 12.5 to 25 mg per day initially and can be increased to 400 mg per day if necessary to achieve a high-normal serum potassium concentration without the aid of oral potassium chloride supplementation. Hypokalemia responds promptly, but hypertension can take as long as 4 to 8 weeks to be corrected. After several months of therapy, the dosage of spironolactone often can be decreased to as little as 25 to 50 mg per day; dosage titration is based on a goal serum potassium level in the high-normal range. Serum potassium and creatinine should be monitored frequently during the first 4 to 6 weeks of therapy (especially in patients with renal insufficiency or diabetes mellitus). Spironolactone increases the half-life of digoxin, and the digoxin dosage may need to be adjusted when treatment with spironolactone is started. Concomitant therapy with salicylates should be avoided because they interfere with the tubular secretion of an active metabolite and decrease the effectiveness of spironolactone. However, spironolactone is not selective for the mineralocorticoid receptor. For example, antagonism at the androgen receptor may result in painful gynecomastia, erectile dysfunction, and decreased libido in men, and agonist activity at the progesterone receptor results in menstrual irregularity in women.

Eplerenone is a steroid-based antimineralocorticoid that acts as a competitive and selective mineralocorticoid receptor antagonist and was approved by the US Food and Drug Administration for the treatment of uncomplicated essential hypertension in 2003. The 9,11-epoxide group in eplerenone results in a marked reduction of the molecule's progestational and antiandrogenic actions; compared with spironolactone, eplerenone has 0.1% of the binding affinity to androgen receptors and less than 1% of the binding affinity to progesterone receptors. In a randomized, double-blind trial comparing the efficacy, safety, and tolerability of eplerenone to that of spironolactone (100–300 mg vs 75–225 mg, respectively) in patients with primary aldosteronism, researchers found spironolactone to be superior in terms of lowering blood pressure but associated with higher rates of male gynecomastia (21% vs 5% for eplerenone) and female mastodynia (21% vs 0%).[257] Eplerenone is available as 25-mg and 50-mg tablets. For primary aldosteronism, it is reasonable to start with a dose of 25 mg twice daily (twice daily because of the shorter half-life of eplerenone compared with spironolactone) and titrated upward; the target is a high-normal serum potassium concentration without the aid of potassium supplements. The maximum dose approved by the FDA for hypertension is 100 mg per day. However, potency studies with eplerenone show 25% to 50% less milligram-per-milligram potency compared with spironolactone. Thus it is common to treat patients with primary aldosteronism with 200 to 300 mg of eplerenone per day to reach the target serum potassium concentration. As with spironolactone, it is important to monitor blood pressure, serum potassium, and serum creatinine levels closely. Side effects include dizziness, headache, fatigue, diarrhea, hypertriglyceridemia, and elevated liver enzymes.

Patients with IHA frequently require a second antihypertensive agent to achieve good blood pressure control. Hypervolemia is a major reason for resistance to drug therapy, and low doses of a thiazide (e.g., 12.5–50 mg of hydrochlorothiazide daily) or a related sulfonamide diuretic are effective in combination with the mineralocorticoid receptor antagonist. Because these agents often lead to further hypokalemia, serum potassium levels should be monitored.

Before treatment for GRA is initiated, the diagnosis of GRA should be confirmed with genetic testing. In the GRA patient, chronic treatment with physiologic doses of a glucocorticoid normalizes blood pressure and corrects hypokalemia. The clinician should be cautious about iatrogenic Cushing syndrome with excessive doses of glucocorticoids, especially when dexamethasone is used in children. Shorter-acting agents such as prednisone or hydrocortisone should be prescribed, using the smallest effective dose in relation to body surface area (e.g., hydrocortisone, 10–12 mg/m^2/day). Target blood pressure in children should be guided by age-specific blood pressure percentiles. Children should be monitored by pediatricians with expertise in glucocorticoid therapy, with careful attention paid to preventing retardation of linear growth due to overtreatment. Treatment with mineralocorticoid receptor antagonists in these patients may be just as effective as glucocorticoids and avoids the potential disruption of the hypothalamic-pituitary-adrenal axis and risk of iatrogenic side effects. In addition, glucocorticoid therapy or mineralocorticoid receptor blockade may even have a role in normotensive patients with GRA.[168]

Primary Aldosteronism in the Setting of Pregnancy

Primary aldosteronism is uncommon in pregnancy, and fewer than 50 patients are reported in the medical literature.[258–263] Primary aldosteronism in pregnancy can lead to preterm delivery, intrauterine growth retardation, placental abruption, and intrauterine fetal demise.[263–265] In some women, the high blood concentrations of pregnancy-related progesterone are antagonistic at the mineralocorticoid receptor and partially block the action of aldosterone; these patients actually have an improvement in the degree of hypertension and hypokalemia during pregnancy.[266,267] Whereas in other pregnant women, increased expression of the luteinizing hormone/chorionic gonadotropin receptor in APAs harboring β-catenin mutations has been documented, and the degree of hypertension and hypokalemia can be aggravated by the increased pregnancy-related blood levels of human chorionic gonadotropin.[268,269]

Case detection testing is identical to that in nonpregnant women; a morning blood sample should be obtained for the measurement of PAC and renin (PRA or PRC). If spontaneous hypokalemia is present in the pregnant woman with suppressed renin and the PAC is greater than 20 ng/dL, additional confirmatory testing is not needed. However, if the patient is normokalemic, confirmatory testing should be pursued. Confirmatory testing in the setting of pregnancy can be challenging because the captopril challenge test is contraindicated in pregnancy, and the saline infusion test may not be well tolerated because of edema. The optimal confirmatory test in the setting of pregnancy is measurement of aldosterone excretion in a 24-hour urine collection on an ambient sodium diet. To avoid exposure to radiation or contrast material, subtype testing in the setting of pregnancy should start with abdominal MRI without gadolinium. Unilateral APA can be diagnosed in the unique clinical setting of a pregnant woman with marked primary aldosteronism (spontaneous hypokalemia and PAC >30 ng/dL) and a clear-cut unilateral adrenal adenoma on MRI.[202]

The severity of hypertension and hypokalemia dictates the optimal treatment of primary aldosteronism in pregnancy. For example, if the patient is in the subset of patients who have a

remission in the degree of primary aldosteronism, then surgery or treatment with a mineralocorticoid receptor antagonist can be avoided until after delivery. However, if hypertension and hypokalemia are marked, then surgical and/or medical intervention is indicated. Unilateral laparoscopic adrenalectomy during the second trimester can be considered in those women with severe primary aldosteronism and documented unilateral APA. The US FDA lists spironolactone as a pregnancy category C drug because feminization of newborn male rats has been documented. However, only one human case has been reported where treatment with spironolactone in pregnancy led to ambiguous genitalia in a male infant due to spironolactone treatment for polycystic ovary syndrome pre-pregnancy and through the fifth week of gestation.[270] Eplerenone is a FDA pregnancy category B drug. When primary aldosteronism is managed medically in pregnant women, the hypertension should be treated with standard antihypertensive drugs that are approved for use during pregnancy. Hypokalemia should be treated with oral potassium supplements. In those cases of severe primary aldosteronism in pregnancy where surgery is not an option, low-dose eplerenone may be cautiously considered.[258,271,272]

Other Forms of Mineralocorticoid Excess or Effect

The medical disorders associated with excess mineralocorticoid effect from 11-deoxycorticosterone (DOC) and cortisol are listed in Table 16.10. These diagnoses should be considered if PAC and PRA are low in a patient with hypertension and hypokalemia.

Hyperdeoxycorticosteronism

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is a group of autosomal recessive disorders caused by enzymatic defects in adrenal steroidogenesis that result in deficient secretion of cortisol (see Chapter 15).[273] Approximately 90% of CAH cases are caused by 21-hydroxylase deficiency, which does not result in hypertension.[274] Deficiencies of 11β-hydroxylase (CYP11B1, P450 11B1) or 17α-hydroxylase (CYP17A1, P450 17A1) cause hypertension and hypokalemia because of hypersecretion of the mineralocorticoid DOC. The mineralocorticoid effect of increased circulating levels of DOC also decreases renin and aldosterone secretion. These mutations are autosomal recessive in inheritance and typically are diagnosed in childhood. However, partial enzymatic defects have been shown to cause hypertension in adults.

11β-Hydroxylase Deficiency

Approximately 5% of all cases of CAH are caused by 11β-hydroxylase deficiency; the prevalence in Caucasians is 1 in 100,000.[275] More than 40 mutations have been described in *CYP11B1*, the gene encoding 11β-hydroxylase.[276] There is an increased prevalence among Sephardic Jews from Morocco due to a founder effect. The impaired conversion of DOC to corticosterone results in high levels of DOC and 11-deoxycortisol; the substrate mass effect results in increased levels of adrenal androgens. Girls present in infancy or childhood with hypertension, hypokalemia, acne, hirsutism, and virilization. Boys with CAH due to 11β-hydroxylase deficiency present with hypertension, hypokalemia, and precocious pseudopuberty. Approximately two-thirds of patients have mild to moderate hypertension. The initial screening tests include measurement of blood levels of DOC, 11-deoxycortisol, androstenedione, testosterone, and dehydroepiandrosterone sulfate (DHEAS)—all of which should be increased above the upper limit of the respective reference ranges. Confirmatory testing includes germline mutation testing.

17α-Hydroxylase Deficiency

17α-Hydroxylase deficiency is a very rare cause of CAH; good prevalence data are not available, but the prevalence is likely less than 1 in 1 million live births.[277] 17α-Hydroxylase is essential for the synthesis of cortisol and gonadal hormones, and deficiency results in decreased production of cortisol and sex steroids. Genetic 46,XY males present with either genital ambiguity or as phenotypic females, and 46,XX females present with primary amenorrhea. Therefore a person with this form of CAH may not come to medical attention until puberty. Children, adolescents, and young adults present with hypertension and spontaneous hypokalemia and low levels of aldosterone and renin. Although very rare, there is an increased prevalence of 17α-hydroxylase deficiency among Dutch Mennonites. The initial screening tests include measurement of blood levels of androstenedione, testosterone, DHEAS, 17-hydroxyprogesterone, aldosterone, and cortisol—all of which should be either low or at the lower quartile of the respective reference ranges. The plasma concentrations of DOC and corticosterone should be above the upper limit of the respective reference ranges. Confirmatory testing includes germline mutation testing.

Deoxycorticosterone-Producing Tumor

Pure DOC-producing adrenal tumors are very rare and usually large and malignant. Some patients have been documented to have benign DOC-producing adrenocortical adenomas. Some of these adrenal neoplasms cosecrete androgens and estrogens in addition to DOC, which may cause virilization in women or feminization in men. The typical clinical presentation would be that of relatively rapid onset of marked hypertension associated with hypokalemia and low blood levels of aldosterone and renin. A high level of plasma DOC or urinary tetrahydrodeoxycorticosterone and a large adrenal tumor seen on CT confirm the diagnosis. Aldosterone secretion in these patients is typically suppressed.

Primary Cortisol Resistance

Increased cortisol secretion and plasma cortisol concentrations without evidence of Cushing syndrome are found in patients with primary cortisol resistance (or glucocorticoid resistance), a rare familial syndrome.[278,279] Primary cortisol resistance is caused by genetic defects in the glucocorticoid receptor and the steroid-receptor complex. The syndrome is characterized by hypokalemic alkalosis, hypertension, increased plasma concentrations of DOC, and increased adrenal androgen secretion. The hypertension and hypokalemia result from the combined effects of excess DOC and increased cortisol access to the mineralocorticoid receptor, resulting from high rates of cortisol production that overwhelm 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2) activity. Most affected individuals present in childhood with hypertension and spontaneous hypokalemia and low levels of aldosterone and renin. The initial screening tests include measurement of blood levels of cortisol, DOC, 11-deoxycortisol, androstenedione, testosterone, and DHEAS—all of which should be increased above the upper limit of the respective reference ranges. In addition,

24-hour urinary cortisol excretion is above the upper limit of the reference range, and serum ACTH is not suppressed. Confirmatory testing includes germline mutation testing.

Apparent Mineralocorticoid Excess Syndrome

Apparent mineralocorticoid excess is the result of impaired activity of the microsomal enzyme 11βHSD2, which normally inactivates cortisol in the kidney by converting it to the inactive 11-keto compound, cortisone.[280] Cortisol can be a potent mineralocorticoid, and when 11βHSD2 is genetically deficient or its activity blocked, high levels of cortisol accumulate in the kidney. Decreased 11βHSD2 activity may be hereditary or it may be secondary to pharmacologic inhibition of enzyme activity by metabolites of glycyrrhizic acid, the active principle of licorice root *(Glycyrrhiza glabra)*.[281] The congenital forms are rare autosomal recessive disorders; fewer than 50 patients have been identified worldwide.[282] Congenital apparent mineralocorticoid excess typically presents in childhood with hypertension, hypokalemia, low birth weight, failure to thrive, hypertension, polyuria and polydipsia, and poor growth.[276] Acquired apparent mineralocorticoid excess due to licorice root ingestion presents with hypertension and hypokalemia—the cause becomes evident when a good medical history is obtained. In addition, when 11βHSD2 is overwhelmed by massive cortisol hypersecretion associated with Cushing syndrome due to ectopic ACTH syndrome, hypokalemic hypertension may be one of the outcomes. The clinical phenotype of patients with apparent mineralocorticoid excess due to congenital deficiency of or inhibition of 11βHSD2 includes hypertension, hypokalemia, metabolic alkalosis, low renin, low aldosterone, and normal plasma cortisol levels. The diagnosis of apparent mineralocorticoid excess is confirmed by demonstration of an abnormal (high) ratio of cortisol to cortisone in a 24-hour urine collection. The characteristic abnormal urinary cortisol-cortisone metabolite profile reflects decreased 11βHSD2 activity; the ratio of cortisol to cortisone is typically increased 10-fold above the normal value.[280] DOC levels may also be increased in severe ACTH-dependent Cushing syndrome and contribute to the hypertension and hypokalemia in this disorder.

Liddle Syndrome: Abnormal Renal Tubular Ionic Transport

In 1963, Grant Liddle described an autosomal dominant renal disorder with a presentation similar to primary aldosteronism with hypertension, hypokalemia, and inappropriate kaliuresis.[283] However, blood levels of aldosterone and renin were very low, so the disorder was termed *pseudoaldosteronism*. Liddle syndrome is caused by autosomal dominant mutations in the β-unit or γ-subunit of the amiloride-sensitive epithelial sodium channel.[276] It is extremely rare, with fewer than 30 families reported worldwide.[284] This mutation results in enhanced activity of the epithelial sodium channel, and patients present with increased renal sodium reabsorption, potassium wasting, hypertension, and hypokalemia. However, as mentioned earlier, blood levels of aldosterone and renin are low. Affected individuals usually present as children or young adults with hypertension and spontaneous hypokalemia and low levels of aldosterone and renin. A family history of hypertension associated with hypokalemia makes Liddle syndrome more likely. The finding of low aldosterone and renin levels in the hypokalemic hypertensive patient should raise the possibility of Liddle syndrome. When the other causes of this presentation have been excluded, then a treatment trial with amiloride or triamterene should be considered. Liddle syndrome can easily be distinguished from apparent mineralocorticoid excess based on a good clinical response to amiloride or triamterene combined with a sodium-restricted diet, lack of efficacy of spironolactone and dexamethasone, and normal 24-hour urine cortisone/cortisol ratio. Clinical genetic testing is available.

Other Endocrine Disorders Associated With Hypertension

Cushing Syndrome

Iatrogenic Cushing syndrome is relatively common. However, endogenous Cushing disease is rare, with an incidence of less than 1 case per 1 million people per year.[285] Hypertension occurs in 75% to 80% of patients with Cushing syndrome (see Chapter 15). The mechanisms of hypertension include increased production of DOC (in ACTH-dependent Cushing syndrome), enhanced pressor sensitivity to endogenous vasoconstrictors (e.g., epinephrine, angiotensin II), increased cardiac output, activation of the RAA system by increased hepatic production of angiotensinogen, and cortisol activation of the mineralocorticoid receptor.

Thyroid Dysfunction

Hyperthyroidism

When excessive amounts of circulating thyroid hormones interact with thyroid hormone receptors on peripheral tissues, both metabolic activity and sensitivity to circulating catecholamines increase. Thyrotoxic patients usually have tachycardia, high cardiac output, increased stroke volume, decreased peripheral vascular resistance, and increased systolic blood pressure. The initial management in patients with hypertension and hyperthyroidism includes use of a β-adrenergic blocker to treat hypertension, tachycardia, and tremor. The definitive treatment of hyperthyroidism is cause specific (see Chapter 12).

Hypothyroidism

The frequency of hypertension (usually diastolic) is increased threefold in hypothyroid patients and may account for as many as 1% of cases of diastolic hypertension in the general population.[286,287] The mechanisms for the elevation in blood pressure include increased systemic vascular resistance and extracellular volume expansion. Treatment of thyroid hormone deficiency decreases blood pressure in most patients with hypertension and normalizes blood pressure in one-third of them. Synthetic levothyroxine is the treatment of choice for hypothyroidism (see Chapter 13).

Renin-Secreting Tumor

Renin-secreting tumors are rare and usually benign mesenchymal tumors localized to the kidney. These juxtaglomerular cell tumors typically present with secondary hyperaldosteronism (hypertension, hypokalemia, high PAC, and elevated renin) in young adults.[288] The renal neoplasm can usually be localized with contrast-enhanced renal CT or MRI. Occasionally renal vein renins may be needed to confirm localization. Surgical resection cures the secondary hyperaldosteronism.

Acromegaly

Hypertension occurs in 20% to 40% of the patients with acromegaly and is associated with sodium retention and extracellular volume expansion (see Chapter 9).[289,290] The hypertension of acromegaly is treated most effectively by curing the excess of growth hormone.[290] If a surgical cure is not possible, the hypertension usually responds well to medications that either block growth hormone effect (e.g., pegvisomant) or suppress growth hormone secretion (e.g., somatostatin analogs). Residual hypertension can be treated with diuretic therapy.

Physiology and Pathology of the Female Reproductive Axis

SERDAR E. BULUN

CHAPTER OUTLINE

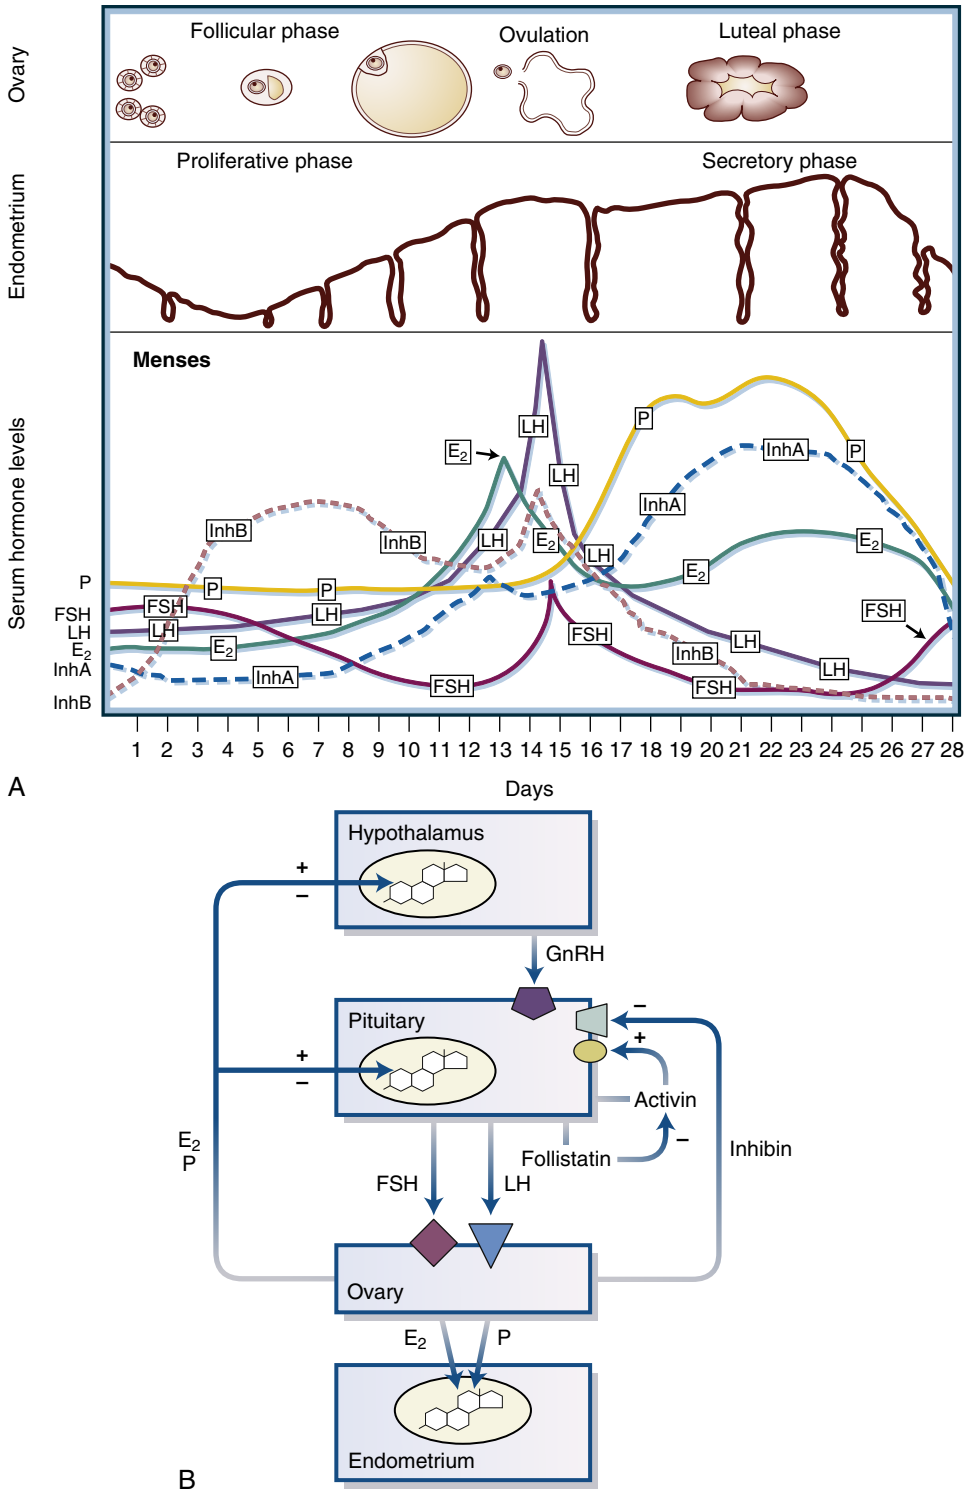
KEY POINTS

- Ovulation and the preparation of the uterus for pregnancy are extremely delicate and parallel physiologic processes that are tightly regulated by a number of hormones released primarily by the hypothalamus, pituitary, and ovary.
- In women, the biologically active steroids—estradiol, testosterone, and dihydrotestosterone (DHT)—are formed in the ovary, peripheral tissues, and locally in androgen or estrogen target tissues. Additionally, the adrenal gland and ovary secrete androgen and estrogen precursors that are converted to biologically active steroids in the peripheral tissues.
- A premenopausal woman often seeks medical help because of disorders that disrupt or complicate ovulation, normal menses, or fertility; the most common disorders include hypothalamic anovulation, hyperprolactinemia, polycystic ovary syndrome, ovarian insufficiency, endometriosis, and uterine fibroids.
- Combination oral contraceptives are commonly prescribed to suppress ovarian activity for the management of various benign causes of anovulatory uterine bleeding or androgen excess, such as polycystic ovary syndrome, and for the management of cyclic or chronic pelvic pain associated with endometriosis.
- Menopause is the depletion of all ovarian follicles; it effectively stops secretion of estradiol and progesterone. The management of postmenopausal ovarian deficiency, characterized thus by vasomotor symptoms, bone loss, and vulvovaginal atrophy, is challenging and still highly debated in regard to the effectiveness and the side effects of existing treatment regimens.

Reproductive Physiology

Tightly coordinated functions of the hypothalamus, pituitary, ovaries, and endometrium give rise to cyclic, predictable menses that indicate regular ovulation. Regular ovulation requires normal functioning of other endocrine glands, such as the thyroid and adrenals, and patients with hypothyroidism, hyperthyroidism, Cushing syndrome, or glucocorticoid resistance may present with anovulation. Clinicians need a thorough knowledge of the functions and interactions of the hypothalamus, pituitary, ovaries, and uterus with other systems to correctly diagnose reproductive disorders and design treatment strategies.

A prominent reproductive function of the hypothalamus is pulsatile secretion of gonadotropin-releasing hormone (GnRH). Negative feedback effects of several factors, including ovarian steroids, regulate hypothalamic GnRH secretion into the portal vessels. Dopamine, norepinephrine, serotonin, and opioids produced in the brain may mediate the regulation of GnRH secretion by ovarian hormones or other stimuli. In response to GnRH, the anterior pituitary cells secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Steroids (e.g., estradiol, progesterone) and peptides (e.g., inhibin) of ovarian origin and activin and follistatin of pituitary origin modify secretion of FSH and LH. LH stimulates androstenedione production in theca cells of the ovary; FSH regulates estradiol and inhibin B production in the granulosa cells and follicular growth. Release of an egg from the mature follicle depends on a sudden rise in LH levels in midcycle. After ovulation, the follicle transforms into a corpus luteum that secretes estradiol and progesterone under the control of FSH and LH. LH also stimulates granulosa-lutein cells of the corpus luteum to secrete inhibin A (Fig. 17.1A).



• **Fig. 17.1** (A) Changes in the ovarian follicle, endometrial thickness, and serum hormone levels during a 28-day menstrual cycle. Menses occur during the first few days of the cycle. (B) Endocrine interactions in the female reproductive axis. Some of the well-characterized endocrine interactions among the hypothalamus, pituitary, ovary, and endometrium for regulation of the menstrual cycle are depicted. *E_2,* estradiol; *FSH,* follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *Inh,* inhibin; *LH,* luteinizing hormone; *P,* progesterone.

The endocrine effects of FSH, LH, estradiol, progesterone, inhibin A, and inhibin B have been deduced from changes in their serum levels throughout the menstrual cycle (see Fig. 17.1A). The postulated endocrine effects were then demonstrated in cell-based and in vivo studies (see Fig. 17.1B). Activin and follistatin are produced in the ovary and the pituitary. They appear to regulate FSH release from the pituitary via autocrine or paracrine but not endocrine pathways. Activin stimulates FSH production, whereas follistatin suppresses this action of activin.

Endometrium, the mucosal lining of the uterine cavity, has extremely high concentrations of nuclear receptors for estrogen and progesterone and is highly sensitive to these hormones. The biologically active estrogen, estradiol, induces the growth of endometrium; progesterone limits this estrogenic effect and enhances differentiation. Sloughing off of the functional layer (stratum functionalis) of the endometrium follows withdrawal of estrogen or progesterone. The remaining basal layer (stratum basalis) is capable of full regeneration in response to estrogen.

Ovaries remain quiescent until puberty because the GnRH-releasing system in the hypothalamus is immature in prepubertal children associated with very low circulating FSH and LH. The entire reproductive function and most of the endocrine function of the ovaries cease after menopause because ovaries are depleted of all oocytes and surrounding steroidogenic cells by this time. These prepubertal and postmenopausal states, characterized by the absence of ovarian function, are associated with the lack of menses.

In summary, the female reproductive function from puberty to menopause can be viewed as an extremely delicate ticking clock. The normal function of this apparatus depends on coordinated actions of the hypothalamus, pituitary, ovaries, and endometrium. The result is regular menses every 24 to 35 days. Any disorder of these tissues or dysfunction of other systems that affect these reproductive units secondarily may result in anovulation and consequent irregular uterine bleeding.

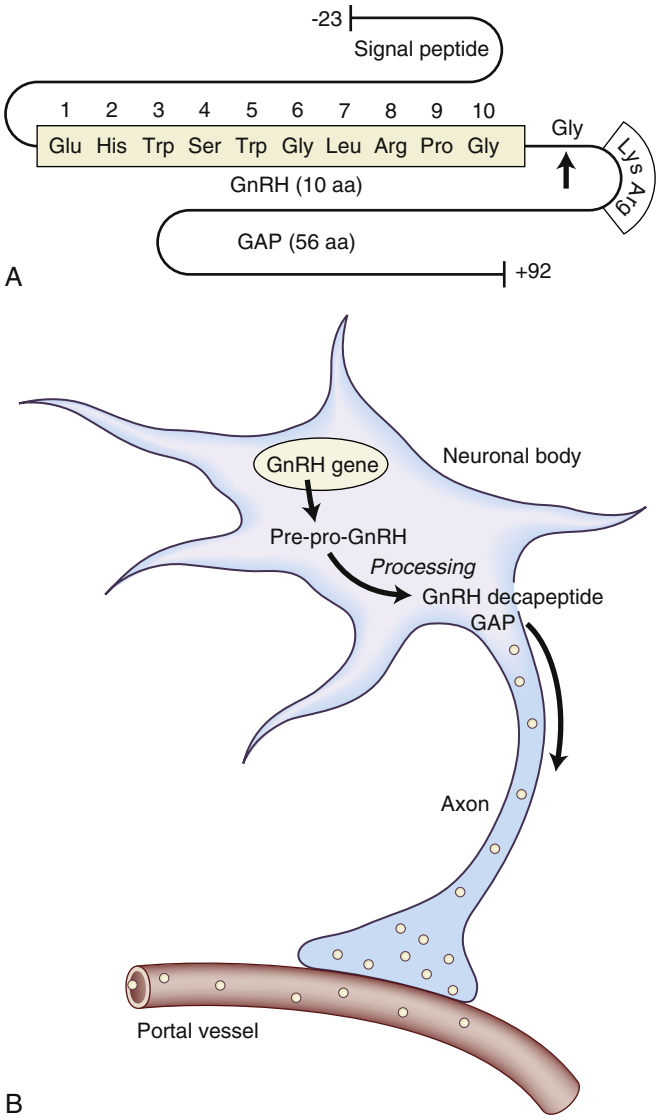
Reproductive Functions of the Hypothalamus

Gonadotropin-Releasing Hormone

GnRH and its analogues are used for the treatment of hormone-dependent disorders and assisted reproductive technologies such as in vitro fertilization (IVF).[1,2] In a number of vertebrates, three GnRHs and three cognate receptors with distinct distributions and functions have been identified. In humans, the hypothalamic GnRH is primarily encoded by the GnRH type I (GnRH-I) gene *(GNRH1)* and regulates gonadotropin secretion through the pituitary GnRH type I receptor, which functions as a G protein–coupled receptor. Binding of GnRH-I to its type I receptor leads primarily to activation of G_q. A second form of GnRH, called *GnRH-II*, is conserved in all higher vertebrates, including humans.[3] In contrast to GnRH-I, GnRH-II is expressed at the highest levels outside the brain. A cognate receptor for GnRH-II has been cloned from various vertebrate species, including primates.[3] The human gene homologue of this receptor has a frameshift and stop codon, and it appears that GnRH-II signaling occurs through the type I GnRH receptor. There seems to be considerable plasticity in the use of different GnRHs, receptors, and signaling pathways for diverse functions.[3] For practical purposes, GnRH-I is referred to as *GnRH* in this chapter.

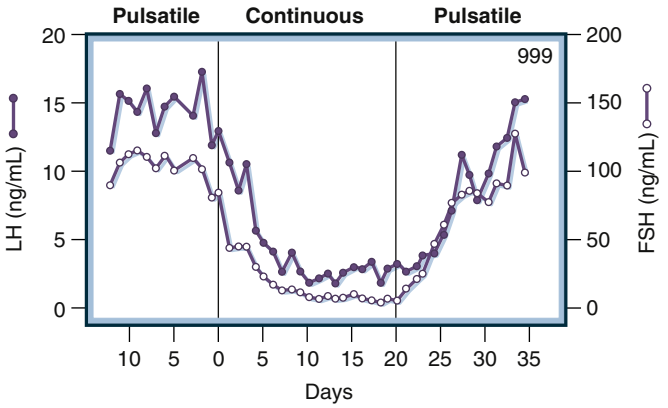
GnRH is a 10–amino acid peptide that is synthesized primarily in specialized neuronal bodies of the arcuate nucleus of the medial basal hypothalamus.[3] Axons from GnRH neurons project to the median eminence and terminate in the capillaries that drain into the portal vessels.

The portal vein is a low-flow transport system that descends along the pituitary stalk and connects the hypothalamus to the anterior pituitary. The direction of the blood flow in this hypophyseal portal circulation is from the hypothalamus to the pituitary. GnRH originating in the neurons of the arcuate nucleus is secreted at the median eminence into the portal circulation, which delivers this hormone to the anterior pituitary (Fig. 17.2).

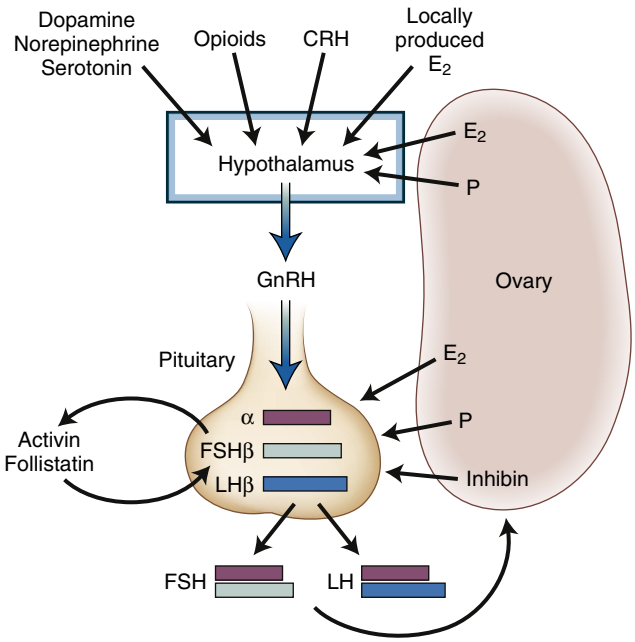


• **Fig. 17.2** Gonadotropin-releasing hormone (GnRH) production. (A) The GnRH gene encodes a precursor protein, pre-pro-GnRH, in the neuronal body. GnRH is released from this protein by proteolytic processing, which gives rise to GnRH and GnRH-associated protein (GAP) within the neuronal body. Both GnRH and GAP are transported in an axon to the nerve terminal and secreted into the portal circulation. (B) Pre-pro-GnRH is a 92–amino acid (aa) protein. The biologically active decapeptide (amino acids 1–10) is sandwiched between the 23–amino acid signal peptide and the Gly-Lys-Arg sequence. The *arrow* indicates the site of proteolytic processing. The C-terminal 56–amino acid peptide is cleaved to produce GAP. *LHRH,* luteinizing hormone–releasing hormone (gonadotropin-releasing hormone 1). (From Yen SSC. Endocrine regulation of the reproductive system. In: Yen SSC, Jaffe RB, Barbieri RL, eds. *Reproductive Endocrinology*. 4th ed. Philadelphia, PA: WB Saunders; 1999:44.)

The mature decapeptide GnRH is derived from the post-translational processing of a large precursor molecule, pre-pro-GnRH (see Fig. 17.2).[4] This precursor peptide is the product of the *GNRH* gene.[3] The pre-pro-GnRH consists of 92 amino acids and contains four parts (from amino-terminal to carboxyl-terminal): a 23–amino acid signal domain, the GnRH decapeptide, a 3–amino acid proteolytic processing site, and a 56–amino acid domain called *GnRH-associated peptide*.[5] The cleavage products of this precursor, GnRH and GnRH-associated peptide (GAP), are transported to the nerve terminals and secreted into the portal



• **Fig. 17.3** Effect of pulsatile or continuous administration of gonadotropin-releasing hormone (GnRH) to ovariectomized monkeys previously rendered GnRH deficient by placement of a lesion in the hypothalamus. Release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) was restored by hourly GnRH infusion, inhibited during a continuous infusion, and again restored after reinstitution of pulsatile GnRH administration. (Adapted from Belchetz PE, Plant TM, Nakai Y, et al. Hypophysial responses to continuous and intermittent delivery of hypothalamic gonadotropin releasing hormone. *Science*. 1978;202:631–633. Copyright © 1978 by American Association for the Advancement of Science.)



• **Fig. 17.4** Regulation of gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) secretion. Locally synthesized and systemic hormones regulate the pulsatile secretion of GnRH from the hypothalamus into the portal circulation. GnRH and a number of steroid and peptide hormones regulate the synthesis of gonadotropin subunits, including the common α-subunit and specific β-subunits for LH and FSH, and the formation and secretion of FSH and LH. *CRH,* corticotropin-releasing hormone; E_2, estradiol; *P,* progesterone.

circulation (see Fig. 17.2).[4,6] A physiologic role for GAP has not been established.[6]

In humans, GnRH neurons are located primarily in the arcuate nucleus of the medial basal hypothalamus and the preoptic area of the anterior hypothalamus.[7] The population of GnRH-producing neurons is relatively limited and is in the range of 1000 to 2000. The neurons that produce GnRH originate from the olfactory area during embryogenesis.[7] GnRH and olfactory neurons migrate together along cranial nerves connecting the nose and forebrain to the hypothalamus during embryologic development, and disruption of this process causes idiopathic hypogonadotropic hypogonadism with anosmia, or Kallmann syndrome.[7] Individuals with Kallmann syndrome usually have lack of pubertal development and subsequent infertility due to deficient GnRH and pituitary gonadotropins. The neuronal proteins anosmin 1 (encoded by the *KAL1* gene) and fibroblast growth factor receptor type 1 (encoded by the *FGFR1* gene) affect olfactory and GnRH neuron migration. Mutations in these genes cause Kallmann syndrome.[7] Data suggest that mutations of the genes for nasal embryonic LH-releasing hormone factor *(NELF)* and chromodomain helicase DNA-binding protein 7 *(CHD7)* may cause Kallmann syndrome, but this correlation is not as conclusively established as it is for *KAL1* and *FGFR1*.[7] Selective clinical phenotypes in men and women are highly associated with genetic causes of Kallman syndrome. Synkinesia *(KAL1)*, dental agenesis *(FGF8/FGFR1)*, digital bony abnormalities *(FGF8/FGFR1)*, and hearing loss *(CHD7)* may be useful for prioritizing genetic testing.[8,9]

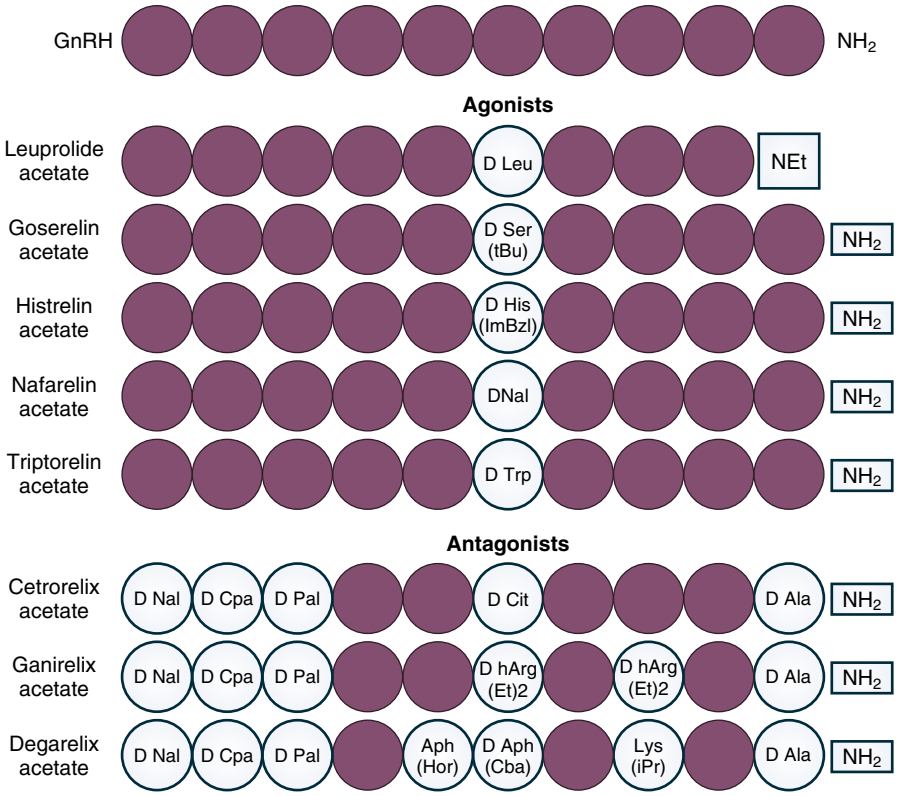
Knobil demonstrated in a pioneering series of experiments that normal gonadotropin secretion requires pulsatile GnRH discharge within a critical frequency and amplitude.[10] The periodicity and amplitude of the pulsatile rhythm of GnRH and gonadotropin secretion are crucial in regulating gonadal activity and therefore the entire reproductive axis (Fig. 17.3). The self-priming effect of GnRH in upregulating its receptors on pituitary gonadotropin-producing cells manifests only at the physiologic periodicity of 60 to 90 minutes.[11,12] Slower frequency causes anovulation and amenorrhea because of inadequate stimulation. Higher frequency or constant exposure to GnRH also gives rise to anovulation by downregulating expression of GnRH receptors, thereby abolishing gonadotropin responses.

The activation of gene expression for gonadotropin subunits, including the common α-subunit and specific β-subunits for LH and FSH, dimerization of αβ subunits, and glycosylation appear to be governed by intermittency of GnRH inputs to pituitary gonadotrophs.[13] In humans, measurement of LH pulses is commonly used as an indication of GnRH pulsatile secretion.[14] The LH pulse frequency is approximately 90 minutes during the early follicular phase, 60 to 70 minutes during the late follicular phase, 100 minutes during the early luteal phase, and 200 minutes during the late luteal phase.[15] This variation is accompanied by predictable changes in FSH and LH levels and ovarian steroid release during these phases of the menstrual cycle. More rapid pulse frequencies favor LH secretion, whereas slower pulse frequencies favor FSH. It appears that variations in GnRH pulse frequency markedly influence both the absolute levels and the ratio of LH and FSH release.

Regulation of Gonadotropin-Releasing Hormone Secretion

Cyclic, predictable menses require the pulsatile release of GnRH within a critical range of frequencies. Pulsatile, rhythmic activity is an intrinsic property of GnRH neurons, and various hormones and neurotransmitters modulate this rhythm (Fig. 17.4).

The variations in GnRH pulse frequency are achieved, in part, by gonadal steroid feedback. Estradiol increases GnRH pulse frequency, and elevated progesterone levels decrease GnRH pulsatility.[13] Increased progesterone levels may decrease GnRH pulse



• **Fig. 17.5** Gonadotropin-releasing hormone (GnRH) agonist and antagonist analogues in clinical practice. *Purple circles* indicate amino acids in the wild-type GnRH decapeptide, and *white circles* are labeled with the changes made to the analogues. (Modified from Millar RP, Lu Z, Pawson AJ, et al. Gonadotropin-releasing hormone receptors. *Endocr Rev*. 2004;25:235–275. Copyright © 2004 by the Endocrine Society.)

frequency and thereby lead to preferential biosynthesis and secretion of FSH, as observed in the late luteal phase.[13]

GnRH pulsatility is also modulated by the actions of locally released neurotransmitters. Norepinephrine stimulates GnRH release, whereas dopamine exerts an inhibitory effect (see Fig. 17.4).[16] β-Endorphin and other opioids may suppress the hypothalamic release of GnRH.[17, 18] It was proposed that sex steroids enhance the activity of endogenous opioids that exert an inhibitory effect on GnRH secretion.[15] The negative effect of opioids on GnRH secretion is clinically explicable because the reduced GnRH secretion associated with hypothalamic amenorrhea may be mediated by an increase in endogenous opioid inhibitory tone.[19]

Estrogen signaling to GnRH neurons appears to be critical for suppressing FSH and LH and for coordinating the preovulatory surge release of LH. The precise roles of estrogen receptors α and β (ERα and ERβ, respectively) within the GnRH neurons or estradiol-sensitive afferent neurons in these negative and positive feedback effects of estrogen are not well understood.[20] Stimulation of FSH release after treatment of premenopausal women with an aromatase inhibitor and in vitro studies suggest that estrogen locally produced by aromatase activity in hypothalamic neurons may regulate gonadotropin secretion.[21,22]

Binding of the peptide kisspeptin to its G protein–coupled receptor KISS1R (previously known as GPR54), which is expressed in GnRH neurons, stimulates GnRH release in the hypothalamus.[23,24] Kisspeptin neurons contact GnRH neurons and act at the cell body and the nerve terminals.[25] Kisspeptin can act directly on GnRH neurons or indirectly through synaptic input from other neurons to inhibit inwardly rectifying potassium channels and activate nonspecific cation channels, producing long-lasting depolarization and an increased action-potential firing rate.[26] Mutations or knockout of KISS1R produces isolated hypogonadotropic hypogonadism in humans and mice, indicating that signaling through this receptor is essential for sexual development and function.[23,24] Moreover, kisspeptin-expressing and KISS1R-expressing neurons may be critical targets for the negative and positive feedback actions of estrogen and progesterone.[27]

Gonadotropin-Releasing Hormone Analogues

The half-life of GnRH is short (2–4 minutes) because it is degraded rapidly by peptidases in the hypothalamus and pituitary gland.[28] These peptidases cleave the bonds between amino acids 5 and 6, 6 and 7, and 9 and 10. Analogues of GnRH with different properties have been synthesized by alteration of amino acids at these positions. Many agonistic and antagonistic GnRH analogues with various biologic effects have been produced.

Peptide Gonadotropin-Releasing Hormone Agonists

Several GnRH agonist peptides are generated by substitution of amino acids at the 6 or 10 position (Fig. 17.5). The increased biologic activity of agonistic peptides has been attributed to their high binding affinity to GnRH receptors and their reduced susceptibility to enzymatic degradation. An amino acid substitution at position 6 gives rise to metabolic stability, whereas replacement of the carboxy-terminal glycinamide residue by an ethylamide group increases strikingly the affinity for the receptors.[28,29]

Peptide GnRH agonists are administered subcutaneously, intranasally, or intramuscularly. An initial agonistic action (i.e., flare effect) is associated with an increase in the circulating levels of LH and FSH. The most prominent agonistic response is observed during the early follicular phase, when the combined effects of GnRH agonist and elevated levels of estradiol create a large reserve pool of gonadotropins.[30]

Administration of a long-acting depot formulation of a GnRH agonist gives rise to an initial flare followed by downregulation of the gonadotropin-gonadal axis within 1 to 3 weeks. The initial downregulation effect is caused by desensitization, whereas the sustained response results from loss of receptors and the uncoupling of the receptor from its effector system.

The US Food and Drug Administration (FDA) approved the use of these agonists for the treatment of GnRH-dependent precocious puberty, endometriosis, and prostate cancer. Another indication is preoperative hematologic improvement of patients with anemia caused by uterine leiomyomas. Off-label indications for GnRH agonists include downregulation of the pituitary during ovulation induction, induction of endometrial atrophy before endometrial ablation surgery, and prevention of menstrual bleeding in patients with coagulation defects. GnRH agonists have also been used to suppress ovarian steroidogenesis in hirsute patients.[31]

The most prominent side effects of long-term use of depot GnRH agonist formulations are caused by estrogen deficiency. Depot GnRH agonists induce a menopause-like state characterized by hot flashes, vaginal dryness, bone resorption, and osteopenia. Osteopenia is reversible in young women if treatment is maintained for no more than 6 months.[32, 33] The risk-benefit ratio must be considered carefully before GnRH agonist treatment is extended for longer periods. Add-back regimens using low-dose estrogens or progestins, or both, administered along with GnRH agonists have provided a means to overcome these side effects and to extend the length of agonist therapy.[34]

Peptide Gonadotropin-Releasing Hormone Antagonists

Inhibition of a premature LH rise by GnRH agonists requires at least 7 days, because it is accompanied by an initial stimulation of GnRH receptors before gonadotroph desensitization is achieved. In contrast, GnRH antagonists compete directly with endogenous GnRH for receptor binding and therefore rapidly inhibit secretion of gonadotropin and steroid hormones (see Fig. 17.5).[35–38] This property conveys a potential advantage over GnRH agonists in the management of ovarian stimulation. However, because of the constant need to block endogenous GnRH, much higher doses of antagonists are required. The GnRH antagonists incorporate a number of amino acid substitutions in the amino-terminal domain (involved in receptor activation) combined with a D-amino acid substitution for Gly6, which enhances the βII-type bend necessary for receptor binding.[3] GnRH antagonists have the advantage of inducing an immediate decrease in circulating gonadotropin levels with rapid reversal.[35–38] GnRH antagonists are alternative drugs to GnRH agonists for the prevention of a natural LH surge during ovulation induction by injectable FSH.[39] Use of GnRH antagonists has become popular in ovulation induction protocols for IVF (see Fig. 17.5).[39]

Nonpeptide Gonadotropin-Releasing Hormone Antagonists

Small molecular compound collections have been screened using mammalian cells that heterologously expressed human GnRH type I receptor. These studies led to the identification of synthetic compounds that bind to the GnRH type I receptor and block signal transduction. Several companies have manufactured orally administered GnRH antagonists intended for various indications, including endometriosis.[1] The FDA approved the oral GnRH antagonist named elagolix to treat endometriosis-associated pelvic pain.[2]

Reproductive Functions of the Anterior Pituitary

Gonadotrophs

Gonadotrophs are specialized cell types of the anterior pituitary that synthesize and secrete LH and FSH. These cells constitute 7% to 15% of the total number of anterior pituitary cells and are detected in this location from early fetal life.[40] Most gonadotrophs are capable of synthesizing both LH and FSH.[40, 41] LH and FSH are each composed of two distinct, noncovalently associated protein α-subunits and β-subunits (see Fig. 17.4). In the gonadotroph, the subunit genes encode the subunit precursors. Gonadotrophs contain cell-surface GnRH type I receptors that mediate the action of GnRH. These receptors belong to the seven-transmembrane domain and G protein–coupled receptor family.

Gonadotropin-Releasing Hormone Receptor

In humans, hypothalamic GnRH regulates gonadotropin secretion through the pituitary GnRH type I receptor by activation of $G_{q/11}$.[42] Although the predominant coupling of the type I GnRH receptor in the gonadotroph is through $G_{q/11}$ stimulation, signal transduction can occur through other G proteins and potentially by G protein–independent means.[3,42] A number of downstream signaling cascades include protein kinase C (PKC)–, Ca^{2+}-, and tyrosine kinase–dependent pathways.[3] In mouse pituitary gonadotrophs, the GnRH receptor activates several mitogen-activated protein (MAP) kinase cascades, including the ERK1/2, the JUN amino-terminal kinase (JNK), the p38 MAP kinase, and the big MAP kinase (BMK1/ERK5).[3] The cross-talk between these pathways remains to be clarified.

Luteinizing Hormone and Follicle-Stimulating Hormone

The α-subunits of human LH, FSH, thyroid-stimulating hormone (TSH), and human chorionic gonadotropin (hCG) have an identical polypeptide structure. In contrast, the β-subunit of each hormone has a unique amino acid sequence and confers the specific activity of the αβ-heterodimer. Each subunit is rich in cysteine and contains multiple disulfide linkages. Each subunit also contains multiple carbohydrate moieties that play important roles in the biologic activity and metabolism of these hormones.

The human common α-subunit gene encodes a precursor polypeptide with a 24–amino acid leader sequence that is cleaved post-translationally to produce the mature 92–amino acid α-subunit. The β-subunits of human FSH, LH, and hCG contain 117, 121, and 145 amino acids, respectively.[43–46] On binding of GnRH to its receptor, the biosynthesis of the gonadotropins proceeds by transcription of the subunit genes, translation of the subunit messenger ribonucleic acids (mRNAs), post-translational modifications of the precursor subunits and subunit folding and combination, mature hormone packaging, and secretion (see Fig. 17.4).

The human LH and hCG β-subunit genes are located on chromosome 19q13.3, which contains a cluster of seven β-subunit–like genes.[44] Five of these sequences are noncoding pseudogenes arranged in groups of tandem and inverted pairs. Only LH and hCG β-subunit genes give rise to two distinct and functional mRNA species. The LH β-subunit mRNA encodes a 145–amino acid precursor protein that is later cleaved to produce a 24–amino acid leader peptide and a 121–amino acid, biologically active, mature peptide. The hCG β-subunit mRNA also encodes a 145–amino acid protein. This protein, however, is not processed post-translationally and functions as the biologically active hCG β-subunit. The amino acid sequences of the human LH and hCG β-subunits are 82% homologous. These two β-subunits confer identical biologic activities when associated with the α-subunit.[44–46]

A single gene encodes the FSH β-subunit.[47] Complementary DNA encoding human FSHβ, LHβ, or hCGβ in combination with the complementary DNA of the α-subunit is expressed in mammalian cells in culture. These cells can synthesize these proteins, modify them after translation, glycosylate and combine the subunits, and secrete them as intact FSH, LH, or hCG.[48] Recombinant gonadotropins are used clinically to stimulate gonadal function.[49]

Regulation of Circulating Levels of Follicle-Stimulating Hormone and Luteinizing Hormone

The molecular mechanisms responsible for formation and combination of the α-subunits and β-subunits of FSH and LH are not completely understood. Production rates of α-subunits and β-subunits are regulated in part by negative feedback by estrogen, which regulates the pulsatile release of GnRH from the hypothalamus.[48,50] The pituitary contains more α-subunit than β-subunit mRNA, and readily detectable levels of free α-subunit are present in serum. The free β-subunit is present at relatively low levels in the pituitary and is rarely found in serum or urine. The specific β-subunit may be the rate-limiting factor in the synthesis of these glycoprotein hormones.

Inhibin, activin, and follistatin were first identified as gonadal hormones that exerted selective effects on FSH secretion.[51] Although the primary source of inhibin remains the ovary, activin and follistatin are produced in extragonadal tissues and can exert effects on FSH through an autocrine-paracrine mechanism. Inhibin-B is secreted by ovarian granulosa cells during the follicular phase (under the control of FSH) and inhibin-A by the corpus luteum in the luteal phase (under the control of LH). Inhibins act synergistically with estradiol to inhibit FSH secretion. Activin can directly stimulate FSH biosynthesis and release from the gonadotroph cells of the pituitary gland.[51] Follistatin can negatively regulate biologic functions of activin via binding and prevent it from interacting with the activin receptor at the cell membrane.[52]

Serum levels of gonadotropins are proportional to their secretion rates and serum half-lives, which are regulated by the number of carbohydrate residues. The sialic acid content of gonadotropic hormones and other glycoproteins has a marked effect on their rate of clearance and influences their apparent molecular size.[53] The higher content of sialic acid in FSH compared with LH is responsible for slower clearance of FSH, which has a half-life of 3 to 4 hours. LH, which has a half-life of 20 minutes, has the most rapid clearance rate. The hCG is highly sialylated and has the longest half-life (24 hours).

Ovary

The ovary is essential for periodic release of oocytes and production of the steroid hormones, estradiol and progesterone. These activities are integrated into the cyclic repetitive process of follicular maturation, ovulation, and formation and regression of the corpus luteum. The ovary fulfills two major objectives: generation of a fertilizable ovum and preparation of the endometrium for implantation through the sequential secretion of estradiol and progesterone.[49] The ovarian follicle comprising the egg and surrounding granulosa and theca cells constitutes the fundamental functional unit of the ovary.

Adult human ovaries are oval bodies with a length of 2 to 5 cm, a width of 1.5 to 3 cm, and a thickness of 0.5 to 1.5 cm. The ovaries lie near the posterior and lateral pelvic wall and are attached to the posterior surface of the broad ligament by the peritoneal fold, called the *mesovarium*.

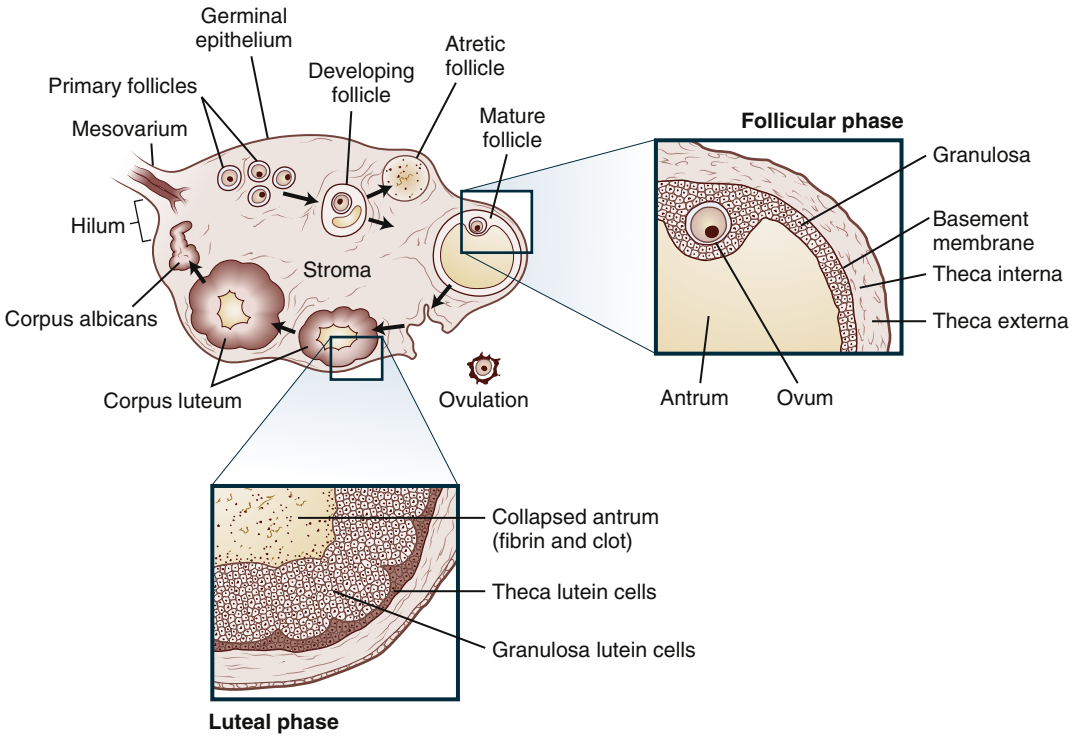
The ovary consists of three structurally distinct regions: an outer cortex containing the surface germinal epithelium and the follicles, a central medulla consisting of stroma, and a hilum around the area of attachment of the ovary to the mesovarium (Fig. 17.6). The hilum is the point of attachment of the ovary to the mesovarium. It contains nerves, blood vessels, and hilus cells, which have the potential to become active in steroidogenesis or to form androgen-secreting tumors. These cells are similar to the testosterone-producing Leydig cells of the testes.

The outermost portion of the cortex, called the *tunica albuginea*, is covered by a single layer of surface cuboidal epithelium called the *germinal epithelium*. The oocytes, enclosed in complexes called *follicles*, are in the inner part of the cortex, embedded in stromal tissue. One dominant follicle is recruited for ovulation during each cycle (see Fig. 17.6). The preovulatory follicle transforms into a corpus luteum after ovulation. In the absence of pregnancy, the corpus luteum regresses to become the corpus albicans (see Fig. 17.6). The stromal tissue is composed of connective tissue and interstitial cells, which are derived from mesenchymal cells and are presumed to have the ability to respond to LH or hCG with the production of androstenedione. The central medullary area of the ovary is derived largely from mesonephric cells.

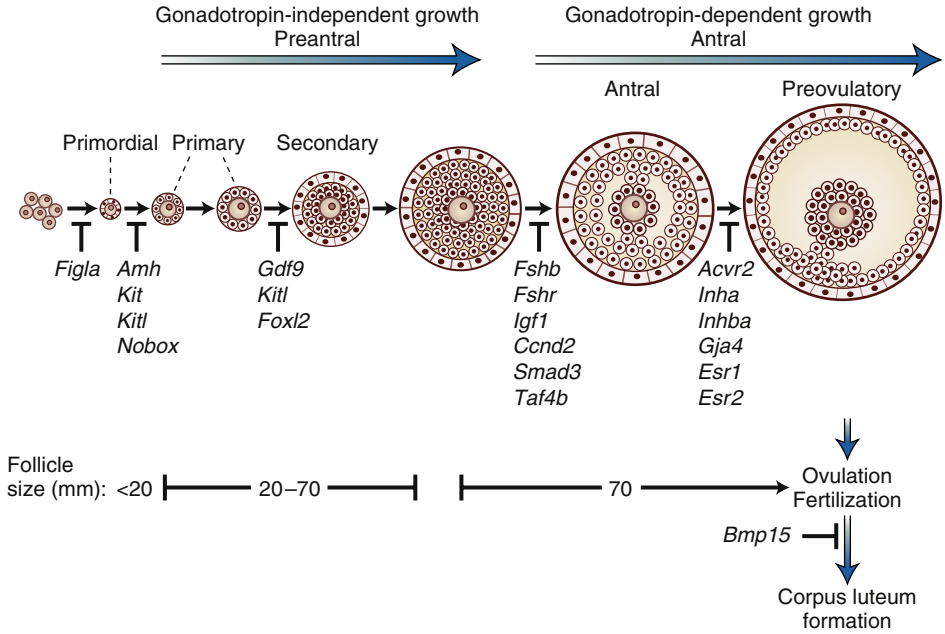
Genetic Determinants of Ovarian Differentiation and Folliculogenesis

Nascent components of the human ovary develop long before a distinct ovary-like organ can be discerned. The female germ cells are formed during embryogenesis when the precursors of primordial germ cells differentiate from somatic lineages of the embryo and take a unique route from the base of the yolk sac along the hindgut to reach the genital ridge. This starts the differentiation of female gonads (ovaries) at the genital ridge. The originally undifferentiated gonad differentiates along a female pathway, and the newly formed oocytes proliferate and subsequently enter meiosis.[49]

Ovarian differentiation and folliculogenesis depend on coordinated expression and interaction of a multitude of genes.[54] Targeted gene disruption or insertion in mice has made it possible to inquire about the function of specific genes in ovarian differentiation and folliculogenesis. Fig. 17.7 summarizes the biologic roles of some of these genes.[54] Genetically altered mice represent a first step in attempts to understand in vivo the various gene interactions that result in a functional ovary. Ovarian pathologic conditions in transgenic mice closely resemble disorders observed in mutant human homologues, as exemplified in cases involving the



• **Fig. 17.6** Functional anatomy and changes in the adult ovary during an ovarian cycle. (From Carr BR, Wilson JD. Disorders of the ovary and female reproductive tract. In: Braunwald E, Isselbacher KJ, Petersdorf RG, et al, eds. *Harrison's Principles of Internal Medicine*. 11th ed. New York, NY: McGraw-Hill; 1987:1818–1837.)



• **Fig. 17.7** Developmental stages at which certain murine genes affect oogenesis. Data from transgenic mice with disruption of various genes have delineated critical roles of several genes during various phases of the follicular development. Preantral follicular growth is thought to be gonadotropin independent, whereas antrum formation and follicular maturation require the action of follicle-stimulating hormone (FSH). *Acvr2,* activin type II receptor; *Amh,* antimüllerian hormone; *Bmp15,* bone morphogenetic protein-15; *Ccnd2,* cyclin d2; *Esr1,* estrogen receptor-α; *Esr2,* estrogen receptor-β; *Figla,* factor in the germline-α; *Foxl2,* forkhead box L2; *Fshb,* FSHβ-subunit; *Fshr,* FSH receptor; *Gdf9,* growth differentiation factor 9; *Gja4,* gap junction protein connexin 37; *Igf1,* insulin-like growth factor 1; *Inha,* inhibin α-subunit; *Inhba,* inhibin subunit-βA; *Kit,* kit receptor; *Kitl,* kit-ligand; *Nobox,* newborn oogenesis homeobox gene; *Smad3,* Sma mothers against decapentaplegic-3; *Taf4b,* TATA-box-binding protein-associated factor-4b. Genetics of mammalian folliculogenesis. *Cell Mol Life Sci*. 2006;63:579–590.)

FSH β-subunit and FSH receptor. Many mouse models of ovarian pathologic conditions are available.[49,54] They can be divided into mice that have prenatal ovarian insufficiency with disordered gonad formation and diminished number of germ cells or absent germ cells and mice that have postnatal ovarian insufficiency as a result of defects at various stages of folliculogenesis (see Fig. 17.7).[54] These models should lead to the identification of genetic and molecular mechanisms responsible for the development and function of the human ovary.

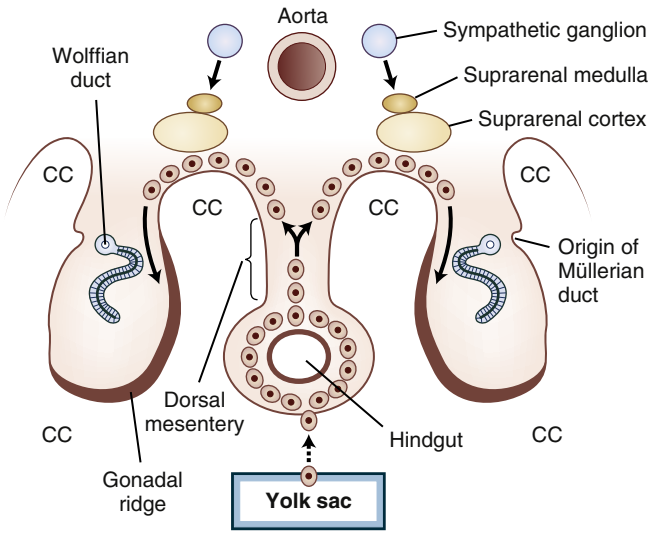
In humans, certain gene defects give rise to specific defects in folliculogenesis. This was demonstrated by the discovery of a heterozygous mutation in the bone morphogenetic protein 15 gene *(BMP15)* that caused ovarian dysgenesis. BMP15 is a growth and differentiation factor that is primarily expressed in the oocyte and stimulates folliculogenesis and granulosa cell growth. In vitro, mutant BMP15 reduced granulosa cell growth and antagonized the stimulatory activity of wild-type protein on granulosa cell proliferation. In vivo, this mutation was associated with familial ovarian dysgenesis, indicating that the action of BMP15 is required for progression of human folliculogenesis.[55] A comprehensive discussion of genes responsible for ovarian development, folliculogenesis, and ovulation is provided in an excellent review article by Edson and colleagues.[49]

Oocytes

The fertilization of an oocyte by a spermatozoon gives rise to a zygote that starts to divide rapidly. An eight-cell embryo is formed usually on the third day after fertilization. Up to that point, all embryonic cells are morphologically identical, truly totipotential, and capable of starting a new individual or any lineage. The formation of a 16-cell morula marks the beginning of the process of differentiation, with cells being allocated to the inside or outside of the embryo. At the next stage, the blastocyst, three lineages are defined: trophectoderm, which is the precursor of the placenta; epiblast, which gives rise to the somatic cells of the embryo; and primitive endoderm, which eventually forms the yolk sac. After the embryo implants, a group of cells within the epiblast form the precursors of the primordial germ cells, the first cells of the future ovary to be defined.[49] The extraembryonic trophectoderm and primitive endoderm, which surround the epiblast cells of the postimplantation egg cylinder, are the sources of signals that instruct this small number of epiblast cells to become primordial germ cells; the rest of the cells commence differentiation into somatic tissues. The first primordial germ cell precursors express a key protein named PRDM1 (PRDI-BF1-RIZ domain containing 1, formerly called BLIMP1); these precursor cells represent the first cells of the mammalian embryo with committed cell fates.[49]

The primordial germ cells first become recognizable as a cluster of cells that stain intensely for alkaline phosphatase activity; these epiblast cells are observed at the base of the yolk sac before formation of the allantois.[49] Studies have confirmed that these cells are the only primordial germ cells because their ablation results in embryos without germ cells, whereas transplantation of these cells leads to their proliferation followed by migration to the genital ridge.[49]

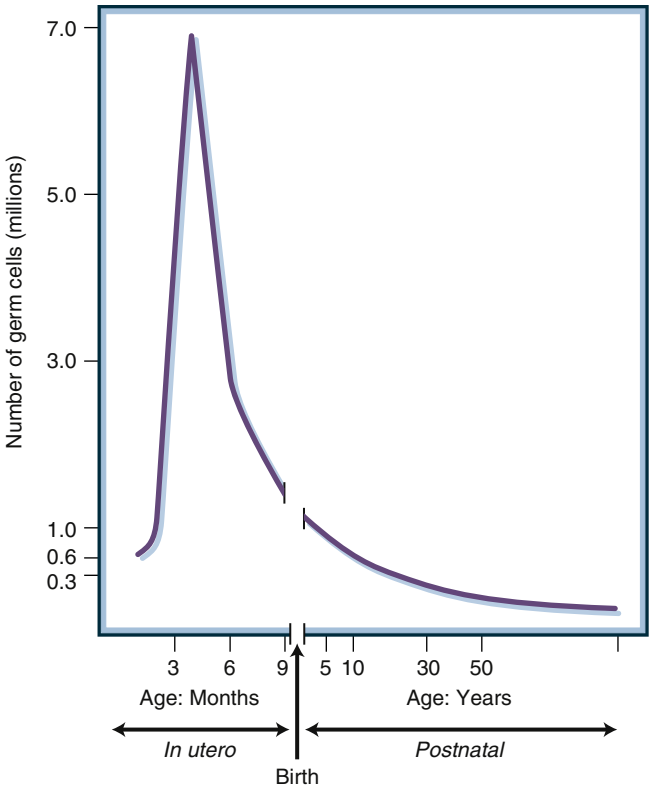
With the use of alkaline phosphatase as a marker, migration of these primordial germ cells from the yolk sac–epiblast junction to the indifferent gonad can be tracked; eventually, the ovary forms and permits the primordial germ cells to differentiate into oocytes. The oocytes enter meiosis and subsequently arrest. Entry into meiosis marks the developmental stage at which any progenitor cells that are capable of differentiating to oocytes disappear. The meiotically arrested oocytes eventually become surrounded by pre-granulosa cells and form individual primordial follicles, the resting pool of oocytes that have the potential to be recruited into the growing follicle pool during the postpubertal stage to be fertilized and to contribute to the next generation. These phenomena have been primarily observed in mice and are thought to be applicable to humans.[49]



• **Fig. 17.8** Transverse section of the caudal region of a 5-week embryo shows the location of gonadal ridges, the primordium of the adrenal glands, and the migration path of primordial germ cells. From the third week on, germ cells of epiblast origin located at the base of the yolk sac cross the dorsal mesentery of the hindgut and migrate to the gonadal ridges. By the end of the fifth week, rapid division of primordial germ cells, gonadal epithelium, and mesenchyme starts the early gonad that differentiates subsequently into the ovary in a 46,XX fetus. *CC,* coelomic cavity. (Modified from Moore K. *The Developing Human.* Philadelphia, PA: WB Saunders; 1983.)

Primordial germ cells of epiblast origin migrate to cross a remarkably long distance from the base of the yolk sac to the genital ridge in the fetus by ameboid movements with the aid of pseudopodia.[56] This long route of migration along the dorsal mesentery of the hindgut is interrupted only by the required lateral crossing of the coelomic angle at the level of the genital ridge (Fig. 17.8). The triggers that initiate primordial germ cell migration and the chemoattractants required for directional movement toward the genital ridge are beginning to be uncovered. A critical trigger may be expression of a key receptor on the primordial germ cell and expression of the secreted chemoattractants from the genital ridge. For example, suppression of transforming growth factor-β (TGFβ) signaling leads to enhanced migration due to reduction in the levels of TGFβ-induced collagen type 1 in the extracellular matrix.[57] An extracellular matrix gradient along the path of migration is important, and if too much matrix is laid down, germ cells show reduced migration. The KIT ligand (KITLG) may function as an effective chemoattractant for the primordial germ cells. The phosphatidylinositol 3-kinase (PI3K)/AKT and SRC kinase pathways are involved downstream of KIT in the primordial germ cell.[58]

Germ cells appear to be unable to persist outside the genital ridge, which may be viewed as the only region competent to sustain gonadal development. By the same token, germ cells play an indispensable role in the induction of gonadal development. No functional gonad can form in the absence of germ cells.



• **Fig. 17.9** Age-dependent changes in germ cell number in the human ovary. The highest number of oocytes is found in the ovaries of a human fetus at midgestation. This number decreases sharply during the third trimester. After birth, the progressive decline in the number of ovarian follicles containing oocytes continues until complete depletion at menopause. (From Baker TG. A quantitative and cytological study of germ cells in the human ovaries. *Proc R Soc Biol Sci*. 1963;158:417–433.)

On arrival at the genital ridge by the fifth week of gestation, the premeiotic germ cells are referred to as *oogonia*.[59] During the subsequent 2 weeks of intrauterine life (weeks 5–7 of gestation, or the *indifferent stage*), the primordial gonadal structure constitutes no more than a bulge on the medial aspect of the urogenital ridge (see Fig. 17.8). This protuberance is created by proliferation of surface (coelomic) germinal epithelium, by growth of the underlying mesenchyme, and by oogonial multiplication. The oogonia total 10,000 by about 6 to 7 weeks of intrauterine life.[59] Because meiosis and oogonial atresia are not occurring, the actual number of germ cells is dictated by mitotic division at this time.[59]

During the indifferent phase, the gonadal cortex and medulla are first delineated. However, short of cytogenetic evidence, the precise sexual identity of the gonadal ridge cannot be ascertained at this point. Nevertheless, the absence of testicular development beyond 7 weeks of gestation is considered presumptive evidence of formation of the ovary. Additional clues to the sexual identity of the gonad can be derived from the detection of oogonial meiosis at about 8 weeks of gestation because no comparable process is observed in the testis until puberty. The sexual identity of the gonadal ridge is histologically clear by 16 weeks of gestation, when the first primordial follicles can be visualized.

By about 8 weeks of intrauterine life, persistent mitosis increases the total number of oogonia to 600,000 (Fig. 17.9). From this point on, the oogonial endowment is subject to three simultaneous processes: mitosis, meiosis, and oogonial atresia. Stated differently, the onset of oogonial meiosis and oogonial atresia is superimposed on oogonial mitosis. As a result of the combined impact of these processes, the number of germ cells peaks at 6 to 7 × 10^6 by 20 weeks of gestation (see Fig. 17.9). At this time, two-thirds of the total germ cells are intrameiotic primary oocytes; the remaining third can still be viewed as oogonial. The midgestational peak and the postpeak decline are accounted for in part by the progressively decreasing rate of oogonial mitosis, a process destined to end entirely by about the seventh month of intrauterine life. Equally relevant is the increasing rate of oogonial atresia, which peaks at 5 months of gestation. During this period, regulation of the ovarian developmental process is complex and probably involves a diverse group of genes (see Fig. 17.7).

From midgestation onward, relentless and irreversible attrition progressively diminishes the germ cell endowment of the gonad.[60] About 50 years later, it is exhausted. For the most part, this is accomplished through follicular atresia rather than oogonial atresia, begins at about month 6 of gestation, and continues throughout life (see Fig. 17.9). In contrast, oogonial atresia is destined to end at 7 months of intrauterine life as follicular atresia sets in. Follicular atresia has a profound effect on germ cell endowment, because only 1 to 2 × 10^6 germ cells are present at birth (see Fig. 17.9).[60] Remarkably, this dramatic depletion of the germ cell mass occurs during a period as short as 20 weeks. No similar rate of depletion occurs earlier or subsequently. Consequently, newborn girls enter life still far from realizing their reproductive potential but having lost as much as 80% of their germ cell endowment. The germ cell mass decreases further to approximately 300,000 by the onset of puberty. Of these follicles, only 400 to 500 (<1% of the total) are recruited for ovulation in the course of a reproductive life span.

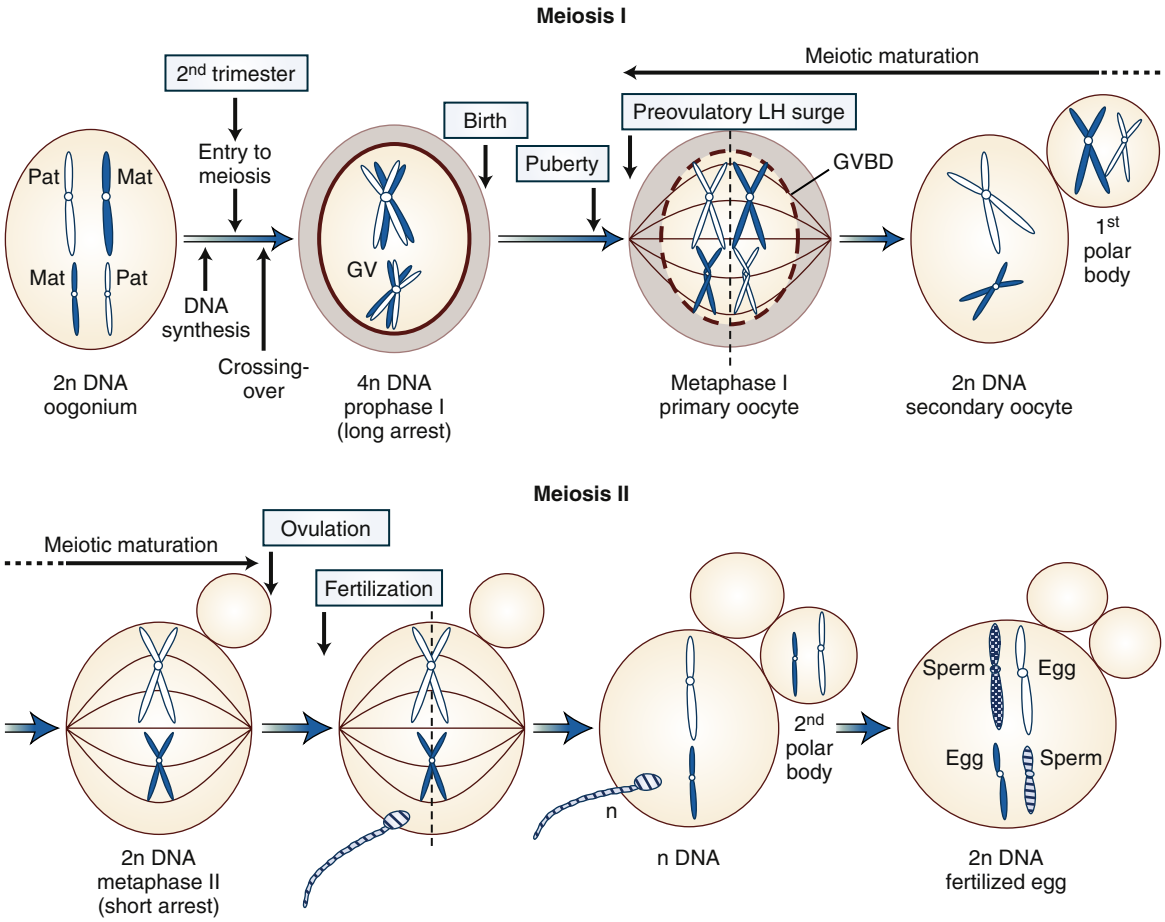
Between weeks 8 and 13 of fetal life, some of the oogonia depart from the mitotic cycle to enter the prophase of the first meiotic division. This change marks the conversion of these cells to primary oocytes well before actual follicle formation. Meiosis (beginning at about 8 weeks of gestation) provides temporary protection from oogonial atresia, allowing the germ cells to invest themselves with granulosa cells and to form primordial follicles. Oogonia that persist beyond the seventh month of gestation and have not entered meiosis are subject to oogonial atresia; consequently, no oogonia are usually present at birth.

Once formed, the primary oocyte persists in prophase of the first meiotic division until the time of ovulation, when meiosis is resumed and the first polar body is formed and extruded (Fig. 17.10). Although the exact cellular mechanisms responsible for this meiotic arrest remain uncertain, it is presumed that a granulosa cell–derived meiosis inhibitor is responsible. This hypothesis is based on the observation that denuded (granulosa-free) oocytes are capable of spontaneously completing meiotic maturation in vitro.

The primary oocyte is converted into a secondary oocyte by completion of the first meiotic metaphase and formation of the first polar body, which occurs before ovulation but after the LH surge. At ovulation, the secondary oocyte and the surrounding granulosa cells (cumulus oophorus) are extruded and enter the fallopian tube. If sperm penetration occurs, the secondary oocyte undergoes a second meiotic division, after which the second polar body is eliminated (see Fig. 17.10).

Granulosa Cell Layer

In the developing ovaries of a human female fetus, oocytes initially exist as germ cell clusters before an ovarian follicle is formed.

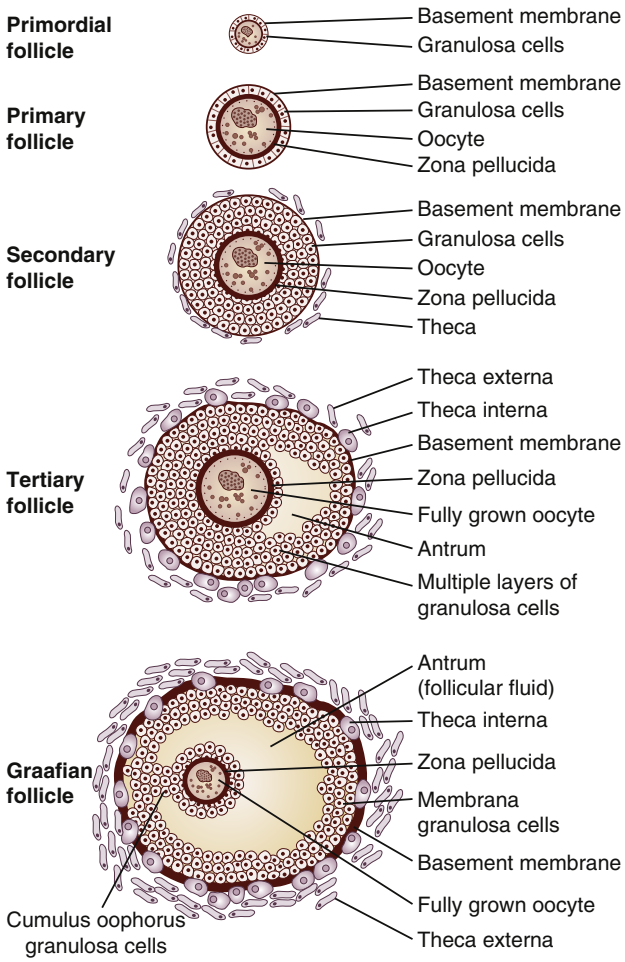


• **Fig. 17.10** Meiotic cell division. During meiosis, the chromosomes that were inherited from the parents of the individual and stored in gonads are processed to prepare their genetic material for transmission to the offspring. Meiosis occurs exclusively in germ cells and serves two critical purposes: generation of germ cells genetically distinct from the somatic cells and generation of a mature egg (or sperm) with a reduction in the number of chromosomes from 46 to 23. Genetic recombination through crossover of genes between homologous chromosomes and random assortment of (grand-) maternal and (grand-) paternal chromosomes into daughter cells during the first meiotic division are responsible for the first function of meiosis, maintenance of genetic diversity. The second function is provided by a reduction in the number of chromosomes so that each daughter cell, or ovum, receives randomly one chromosome from each of the 23 pairs. During fertilization, the fusion of ovum and sperm, each of which contributes 23 chromosomes, produces a genetically novel individual with 46 chromosomes. The chromosome marked as *white* in the oogonium *(upper left corner)* originates from the father of the female fetus, whereas the *blue* chromosome comes from the mother of the fetus. The random exchange of genes (alleles) between homologous chromosomes (crossover) takes place before the meiotic arrest in the prophase I stage before birth. After birth, the oocytes of this child remain in meiotic arrest until puberty. In the developing oocyte in the Graafian follicle, meiosis I is resumed immediately after the preovulatory luteinizing hormone (LH) surge during each ovulatory cycle. Meiotic maturation is defined as the period from the breakdown of the oocyte's nucleus (germinal vesicle [GV]) until the oocyte reaches metaphase II (i.e., transition from oocyte to egg). A second and short meiotic arrest occurs at metaphase II until the oocyte is fertilized by a sperm. *DNA,* deoxyribonucleic acid; *GVBD,* germinal vesicle breakdown; *Mat,* maternal; *n,* amount of DNA material in the haploid number (23) of chromosomes; *Pat,* paternal.

During the second half of in utero life, these germ cell clusters break down, and the surviving oocytes become individually surrounded with squamous pregranulosa cells to give rise to primordial follicles. The transition from primordial to primary follicle is marked histologically by a morphologic change in granulosa cells from squamous to cuboidal. By the secondary stage, there are at least two layers of cuboidal granulosa cells and an additional layer of somatic cells, the theca, which forms outside the basement membrane of the follicle (Fig. 17.11).[49] At puberty, FSH secreted by the pituitary promotes further granulosa cell proliferation and survival.

A basement lamina separates the oocyte and granulosa cells from the surrounding stromal cells.[59] The granulosa cells do not have direct access to the circulation before ovulation (Fig. 17.12).

The avascular nature of the granulosa cell compartment necessitates contact between neighboring cells. The granulosa cells are interconnected by extensive intercellular gap junctions, which result in their coupling to yield an expanded, integrated, and functional syncytium (Fig. 17.13).[61] Gap junctions are composed of proteins called *connexins*. Connexin 37 and other connexins have been demonstrated in gap junctions in follicles. Gap junction



• **Fig. 17.11** Developmental stages of the ovarian follicle. The primordial follicle is composed of a single layer of granulosa cells and a single immature oocyte arrested in the diplotene stage of the first meiotic division. The primordial follicle is separated from the surrounding stroma by a thin basal lamina (i.e., basement membrane). The oocyte and granulosa cells do not have a direct blood supply. The first sign of follicular recruitment is cuboidal differentiation in the spindle-shaped cells inside the basal lamina, which thereafter undergo successive mitotic divisions to form a multilayered granulosa cell zone. The oocyte enlarges and secretes a glycoprotein-containing mucoid substance called the *zona pellucida,* which surrounds the oocyte and separates the granulosa cells from the oocyte. This structure is a primary follicle. The secondary follicle is formed by further proliferation of granulosa cells and by the final phase of oocyte growth, in which the oocyte reaches 120 μm in diameter, coincident with proliferation of layers of cells immediately outside the basal lamina to constitute the theca. The portion of the theca adjacent to the basal lamina is called the *theca interna*. Theca cells that merge with the surrounding stroma are designated the *theca externa*. The secondary follicle acquires an independent blood supply consisting of one or more arterioles that terminate in a capillary bed at the basal lamina. Capillaries do not penetrate the basement membrane, and the granulosa and oocyte remain avascular. The tertiary follicle is characterized by further hypertrophy of the theca and the appearance of a fluid-filled space among the granulosa cells, called the *antrum*. The fluid in the antrum consists of a plasma transudate and secretory products of granulosa cells, some of which (estrogens) are found there in strikingly higher concentrations than in peripheral blood. The follicle rapidly increases in size under the influence of gonadotropins to form the mature or Graafian follicle. In the Graafian follicle, the granulosa and oocyte remain encased by the basal lamina and are devoid of direct vascularization. The antral fluid increases in volume, and the oocyte, surrounded by an accumulation of granulosa cells (i.e., cumulus oophorus), occupies a polar, eccentric position within the follicle. The mature Graafian follicle is then ready to release the ovum by the process of ovulation. (Adapted from Erickson GF, Magoffin DA, Dyer CA. The ovarian androgen producing cells: a review of structure-function relations. *Endocr Rev*. 1985;6:371–379. Copyright © 1985 by The Endocrine Society.)

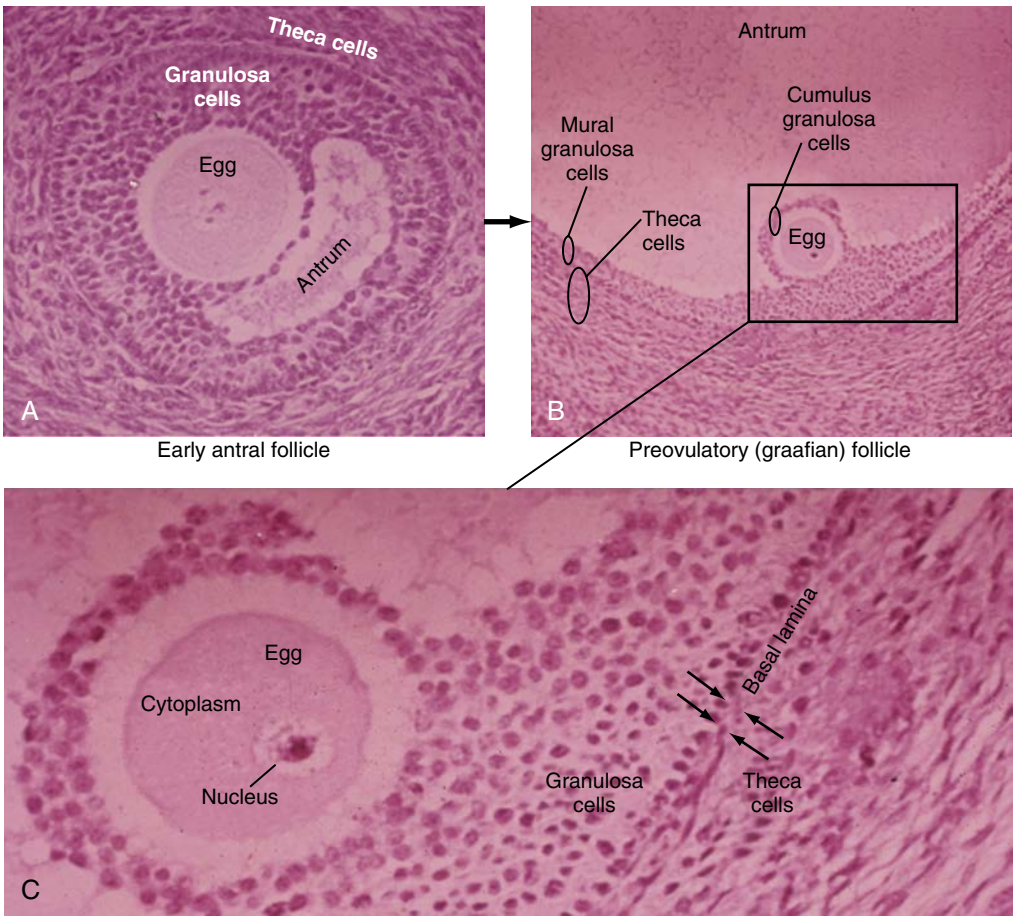
protein connexin 37 (GJA4)–deficient mice lack Graafian follicles, fail to ovulate, and develop inappropriate corpora lutea.[61] These specialized cell junctions may be important in metabolic exchange and in the transport of small molecules between neighboring granulosa cells. Moreover, the granulosa cells extend cytoplasmic processes that penetrate the zona pellucida to form gap junctions with the plasma membrane of the oocyte (see Fig. 17.13). In the GJA4-deficient mice, oocyte development is arrested before meiotic competence.[62] Gap junctions represent a crucial communication system that is needed for the tight control exerted by the cumulus granulosa cells on the resumption of meiosis by the enclosed primary oocyte.

Several gene products regulate the transition from primordial to primary follicle, which is marked by a change in the morphologic appearance of granulosa cells from squamous to cuboidal, followed by an increase in granulosa cell layers in the secondary follicle.[49] These genes are expressed in the oocyte or granulosa cells, emphasizing the active role of the oocyte in granulosa cell differentiation. Newborn oogenesis homeobox (NOBOX), spermatogenesis and oogenesis helix-loop-helix 1 (SOHLH1), and SOHLH2 are critical transcription factors during the transition from primordial to primary follicles.[49] Interactions between KIT ligand expressed in granulosa cells and the KIT tyrosine kinase receptor expressed in oocytes also appear to be critical in early folliculogenesis. The KITLG/KIT pathway induces the PI3K/AKT pathway, leading to phosphorylation and inactivation of forkhead box O3 (FOXO3), an inhibitor of primordial follicle activation.[49] These genetic studies supported a critical role of the PI3K/AKT/FOXO3 pathway in early follicle development and granulosa cell differentiation. Whereas FOXO3 is the key oocyte factor critical for suppressing primordial follicle activation, another forkhead domain transcription factor, forkhead box L2 (FOXL2), is crucial in the transition from squamous to cuboidal granulosa cells.[49]

Antimüllerian hormone (AMH) produced by the granulosa cells of growing follicles appears to inhibit the growth of primordial follicles; in its absence there is a faster depletion of growing follicles, although it is unknown whether this is a direct or indirect effect of AMH.[49] Clinically, serum AMH may be a useful biomarker of ovarian reserve. In humans and mice, serum AMH declines with increasing age. Although it is difficult to establish a direct link between serum AMH and the primordial follicle pool in humans, antral follicle number is positively correlated with AMH levels.[49] More detailed information has been reviewed by Edson and colleagues.[49]

The granulosa cells in the fully developed Graafian follicle shortly before ovulation are stratified in a manner that allows the distinction of a number of populations of cells.[63] Distinct populations of granulosa cells exhibit specific, specialized functions.[63,64] Mural granulosa cells within the outermost layer adjacent to the basement layer contain high levels of gonadotropin hormone receptors and steroidogenic enzymes and account for most of the steroidogenesis in the follicle.[63,64] The *cumulus oophorus* contains the egg and a surrounding mass of granulosa cells that have cell-cell interactions with the egg and seem to have critical roles in oocyte development (Fig. 17.13; see also 17.12).[63,64]

Mural and cumulus granulosa cells also exhibit distinct patterns of gene expression. For example, the tumor suppressor BRCA1 is highly expressed in ovarian granulosa cells of developing follicles.[65] However, in large antral or preovulatory follicles, BRCA1 expression significantly decreases in mural granulosa cells and becomes restricted to cumulus granulosa cells; these cells, unlike the mural ones, do not contain abundant aromatase, so this development gives rise to an intriguing inverse correlation of BRCA1 with aromatase mRNA and protein levels.[65] Stimulation of an FSH-dependent



• **Fig. 17.12** Histology of gonadotropin-dependent ovarian follicle development. (A) Development of an antrum marks gonadotropin dependency. Multiple layers of granulosa and theca cells are present. (B) The follicle destined to ovulate distinguishes itself from the rest of the cohort through accumulation of large quantities of antral fluid. The granulosa cells, which accumulate around the oocyte, are called *cumulus granulosa cells* and primarily function to support egg development. The mural granulosa cells in the periphery primarily serve as steroidogenic cells. (C) A membrane called the *basal lamina (arrows),* which has been formed at the primary stage, separates the granulosa cells from the theca component of the follicle.

signaling pathway greatly induces aromatase but suppresses BRCA1 expression in granulosa cells. Moreover, BRCA1 binds to the aromatase promoter and inhibits its activity.[66] Therefore BRCA1 may exert its tumor suppressor activity, in part, by limiting excessive estrogen formation in the ovary. A summary of ovarian follicle development is presented in Fig. 17.11.

Theca Cell Layer

After the follicle achieves two layers of granulosa cells, another morphologically distinct layer of somatic cells, the theca, differentiates from ovarian stroma (see Figs. 17.11, 17.12, and 17.13).[49] The cells making up the theca-interstitial compartment are heterogeneous in nature.[67] Cells of the theca interna layer, which forms just outside the basement membrane surrounding the granulosa cells, show typical steroidogenic features, including mitochondria with tubular cristae, smooth endoplasmic reticulum, and abundant lipid vesicles (see Figs. 17.11 and 17.12). Theca interna cells are responsible for producing the C19 steroids that diffuse into the neighboring granulosa cells and serve as substrates for estrogen production. Theca externa is the outermost layer of the follicle and is composed of fibroblasts, smooth muscle–like cells, and macrophages (see Figs. 17.11 and 17.12). The theca externa is thought to have an important function during ovulation. Cells that contribute to the theca differentiate from mesenchymal precursor cells present in the ovarian stroma, adjacent to developing follicles. Like preantral folliculogenesis, theca formation is gonadotropin independent. Theca precursor cells lack LH receptors, and the theca layer still forms in the ovaries of FSH-deficient mice.[49] After a discernible theca interna layer has developed, theca cell C19 steroid production is regulated primarily by LH.

The differentiated state of theca interna cells is marked by expression of a number of steroidogenic genes, including those that encode the LH receptor *(LHCGR),* steroidogenic acute regulatory protein *(STAR),* side-chain cleavage enzyme *(CYP11A1),* 3β-hydroxysteroid dehydrogenase-$\Delta^{5,4}$ isomerase type 2 *(HSD3B2),* and 17-hydroxylase/17,20-lyase *(CYP17A1)* in the human. Granulosa cells of the developing follicles appear to secrete factors that regulate theca cell differentiation. Candidate factors that may contribute to theca cell differentiation include insulin-like growth factors (IGFs), KITLG, and growth differentiation factor 9 (GDF9). IGF1 induces expression of *Lhcgr*, *Cyp11a1*, and *Hsd3b1* (counterpart of human *HDS3B2*), whereas KITLG stimulates *Star* and *Cyp17a1* expression in rat theca cells.[49] In mice lacking the *Gdf9* gene, a theca layer fails to form in the ovary. Whether *GDF9* regulates theca cell recruitment or differentiation

directly or indirectly through regulation of preantral granulosa cell development is unknown.[49]

Follicles

The follicle represents the key functional unit in the ovary with respect to germ cell development and steroid production. The follicles are embedded in loose connective tissue of the ovarian cortex and can be subdivided into two functional types: nongrowing (primordial) and growing. Between 90% and 95% of follicles are nongrowing throughout reproductive life. Recruitment of a primordial follicle initiates dramatic changes in growth, structure, and function. The growing follicles are divided into four stages: primary, secondary, tertiary, and graafian (see Figs. 17.7 and 17.11). The first three stages of growth can occur in the absence of the pituitary and therefore appear to be controlled by intraovarian mechanisms (see Figs. 17.7 and 17.11). The follicle destined to ovulate is recruited during the first few days of the current cycle.[68]

The early growth of follicles occurs over several menstrual cycles, but the ovulatory follicle is one of a cohort recruited at the time of transition from the previous cycle's luteal phase to the current cycle's follicular phase.[68] The total time to achieve preovulatory status is approximately 85 days.[68] Most of this developmental period is FSH independent. Eventually this cohort of follicles reaches a stage at which, unless recruited by FSH, the next step is atresia. A cohort of follicles measuring 2 to 5 mm in diameter is continuously available for a response to FSH. The late luteal increase in FSH is the critical feature in rescuing this cohort of follicles from atresia; it allows a dominant follicle to emerge and pursue a path to ovulation. The increase in the FSH level must be maintained for a critical period (see Fig. 17.1).[69]

Recruited primordial follicles either develop into dominant, mature Graafian follicles destined to ovulate or degenerate as a result of atresia.[70] The average time for development of a selected follicle to the point of ovulation is 10 to 14 days. If a follicle is not recruited, it goes through a process called *atresia*, during which the oocyte and granulosa cells within the basal lamina die and are replaced by fibrous tissue. There is general agreement that atresia of follicles occurs through apoptosis.[71]

Ovulation

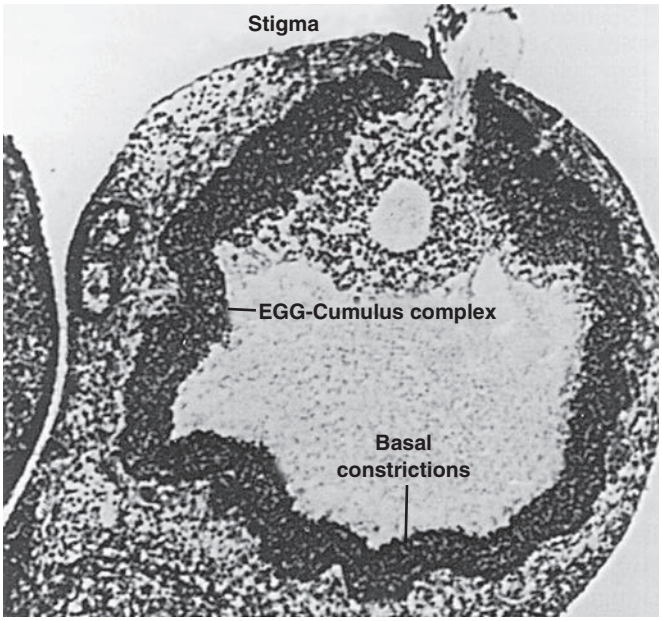
There is a dramatic rise in circulating estradiol level as midcycle approaches. This is followed by a striking LH surge and, to a lesser extent, an FSH surge, which trigger the dominant follicle to ovulate. During each menstrual cycle, usually one follicle ovulates and gives rise to a corpus luteum. In women, LH or its surrogate, hCG, is essential to stimulate rupture of the mature follicle. It has been proposed that increased local prostaglandin biosynthesis in the follicle mediates the ovulatory effect of LH.[72,73]

Ovulation consists of rapid follicular enlargement followed by protrusion of the follicle from the surface of the ovarian cortex. This is followed by the rupture of the follicle and extrusion of an egg-cumulus complex into the peritoneal cavity (Fig. 17.14). Follicular rupture or ovulation occurs predictably 34 to 36 hours after the start of the LH surge. Elevation of a conical *stigma* on the surface of the protruding follicle precedes rupture (see Fig. 17.14). Rupture of this stigma is accompanied by a gentle rather than explosive expulsion of the ovum and antral fluid. A number of transcriptional regulators downstream of the LH receptor are required for ovulation. After the LH surge, progesterone receptor (PR) levels rapidly increase in the mural granulosa cells of the preovulatory follicle.[49] LH-dependent or PR-dependent production of proteases acting locally on protein substrates in the basal lamina may play an important role in stigma formation and follicular rupture.[62,74] In particular, levels of plasminogen activator increase in the follicle before rupture.[75] Plasminogen activator–mediated conversion of plasminogen to plasmin may contribute to the proteolytic digestion of the follicular wall, which is a prerequisite for follicular rupture. Gene knockout studies in mice suggest that other factors important for ovulation or follicular rupture include endothelin 2, peroxisome proliferator-activated

receptor-γ (PPARγ), CCAAT/enhancer-binding protein-β, liver receptor homologue 1 (LRH1), steroidogenic factor 1 (SF1), and nuclear receptor–interacting protein 1.[49]

Corpus Luteum

After ovulation, the dominant follicle reorganizes to become the corpus luteum (Fig. 17.15). After rupture of the follicle, capillaries and fibroblasts from the surrounding stroma proliferate and penetrate the basal lamina (see Fig. 17.11). This rapid vascularization of the corpus luteum may be guided by angiogenic factors, some of which are detected in the follicular fluid.[76] Vascular endothelial growth factor has been isolated from corpora lutea and has been postulated, along with basic fibroblast growth factor, to be a potential angiogenic agent in corpora lutea.[77] Concurrently, the granulosa and theca cells undergo morphologic changes collectively referred to as *luteinization*. The granulosa cells become granulosa-lutein cells (large cells), and the theca cells are transformed into theca-lutein cells (small cells) (see Fig. 17.15).[78] The so-called K cells, scattered throughout the corpus luteum, are believed to be macrophages.

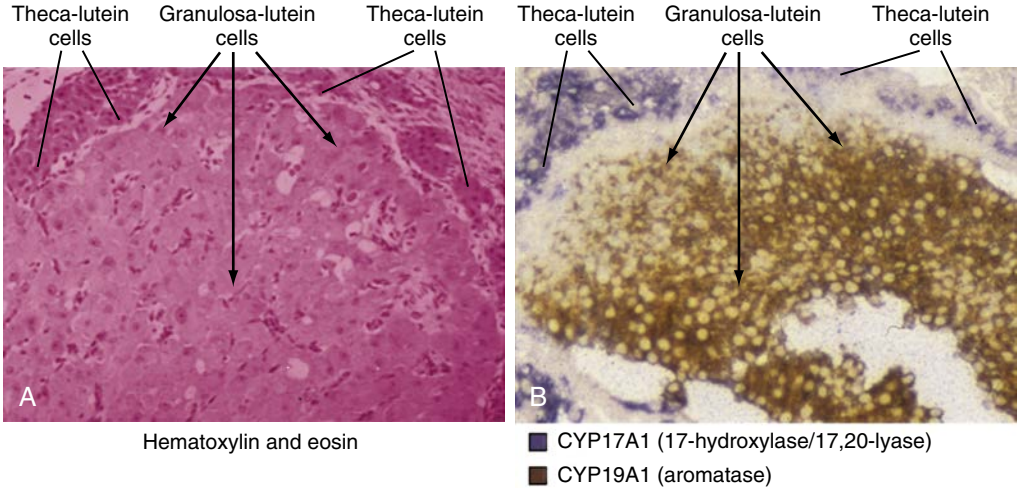


• **Fig. 17.14** Ovulation of the cumulus-oocyte complex through the stigma. (From Erickson GF. An analysis of follicle development and ovum maturation. *Semin Reprod Endocrinol*. 1986;4:233, used with permission of Thieme Medical Publishers, New York.)

The corpus luteum is the major source of sex steroid hormones secreted by the postovulatory ovary. The human corpus luteum secretes as much as 40 mg of progesterone per day during the midluteal phase of the ovarian cycle.[79] In view of the small size of the corpus luteum, it is the most active steroidogenic tissue in humans. An important aspect of corpus luteum formation is the penetration of the follicle basement membrane by blood vessels. This vascularization provides the granulosa-lutein cells with low-density lipoprotein (LDL) cholesterol.[76] LDL cholesterol serves as the primary substrate for corpus luteum progesterone production.

A key regulator of steroidogenesis in the corpus luteum is LH. In humans, the LH receptor is maintained throughout the functional life span of the corpus luteum and is not downregulated during the maternal recognition of pregnancy.[80] The rate-limiting step in LH-mediated progesterone formation in luteinized granulosa cells is the entry of cholesterol into the mitochondria, which is regulated by the steroidogenic acute regulatory (StAR) protein.[81] The availability of LDL cholesterol and the StAR-mediated mitochondrial entry of cholesterol into the mitochondria seem to be the two critical factors that account for the production of large amounts of progesterone in the corpus luteum.

Unless pregnancy occurs, the functional life span of the corpus luteum is normally 14 ± 2 days, after which it spontaneously regresses and is replaced by an avascular scar named the *corpus albicans*. There is little doubt about the central role of LH or hCG in the maintenance of corpus luteum function. Withdrawal of LH support in a variety of experimental circumstances has almost invariably resulted in luteal regression.[82] In pregnancy, however, the LH surrogate, hCG, secreted by the gestational trophoblast, maintains the ability of the corpus luteum to elaborate progesterone; this stimulus helps to maintain the early gestation until the luteoplacental shift.[82] The corpus luteum doubles in size



• **Fig. 17.15** Corpus luteum. (A) Hematoxylin and eosin stain shows the large granulosa-lutein cells occupying the center and smaller theca-lutein cells in the periphery. (B) Immunoreactive aromatase, the product of the *CYP19A1* gene *(brown stain),* is the hallmark of granulosa-lutein cells, whereas immunoreactive 17-hydroxylase/17,20-lyase, the product of the *CYP17A1* gene *(purple stain),* is selectively localized to theca-lutein cells. (compared with the pre-pregnancy size) during the first 6 weeks of gestation because of hypertrophy of the luteinized granulosa and theca cells (see Fig. 17.15). This early hypertrophy is followed by regression. The corpus luteum at term is only one-half of its size during the menstrual cycle.

Hormones such as estrogens and prostaglandins have been suggested to be important factors in the promotion of luteal demise.[83] Immune factors may influence luteal life span because corpus luteum regression is associated with a progressive infiltration of lymphocytes and macrophages. In the absence of LH or hCG, apoptosis is a critical endpoint mechanism by which human corpora lutea are deleted.[84]

Ovarian Follicle-Stimulating Hormone and Luteinizing Hormone Receptors

The FSH receptor is expressed exclusively by granulosa cells. The LH or hCG receptor (LHCGR) is expressed primarily by the theca-interstitial cells of all follicles and by granulosa cells of large preovulatory follicles.

Granulosa cells in primary or secondary follicles that are in the early developmental stages before antrum formation primarily bind FSH but not LH. In these preantral follicles, the binding of LH or hCG is confined to theca-interstitial cells.[85] Granulosa cells in more mature tertiary follicles with an antrum appear capable of binding both LH and FSH. The FSH receptors are found in granulosa cells from follicles of all sizes, but LH receptors are found only in granulosa cells of large preovulatory follicles.[86,87] These observations are consistent with the concept that the acquisition of LH receptors on granulosa cells is under the influence of FSH.[88]

The receptors for the glycoprotein hormones have related structures (see Fig. 17.17, later). The receptors belong to the large family of G protein–coupled receptors, whose members all have a transmembrane domain that consists of seven membrane–traversing α-helices connected by three extracellular and three intracellular loops. The glycoprotein hormone receptors form a separate subgroup within this large family by virtue of their large extracellular hormone-binding domain at the amino-terminus. FSH binds to the FSH receptor, and LH and hCG bind to the same LH receptor. The LH and FSH receptor genes are located on chromosome 2 in the p21 region.[47] The carboxy-terminal half of the receptor is encoded by a single last exon and contains the seven transmembrane segments and the G protein–coupling domain. The unusually large extracellular domain of the glycoprotein hormone receptors, on the other hand, is encoded by the first 9 or 10 exons.

Role of Follicle-Stimulating Hormone in Ovarian Function

FSH is the main promoter of follicular maturation. Given that FSH receptors have been exclusively localized to granulosa cells, it is presumed that FSH action in the ovary involves the granulosa cells. The ability of FSH to orchestrate follicular growth and differentiation depends on its ability to exert multiple actions concurrently.

Phenotypes of women with mutations that disrupt the function of the FSH β-subunit gene are in good agreement and demonstrate that FSH is necessary for normal follicular development, ovulation, and fertility. Pubertal development is hampered in the absence of sufficient numbers of later stage follicles with the granulosa cells needed for adequate estrogen production. Treatment of affected patients with exogenous FSH has resulted in follicular maturation, ovulation, and normal pregnancy.[47] The presenting phenotype of FSH β-subunit deficiency is practically identical to that caused by inactivating mutations of the FSH receptor, except that the latter fail to respond to exogenous FSH.[47]

Women with FSH receptor mutations are clinically similar to patients with gonadal dysgenesis; they have absent or poorly developed secondary sexual characteristics and high serum levels of FSH and LH.[47] The notable difference is the presence of ovarian follicles in women with mutated FSH receptors, consistent with the FSH independence of primordial follicle recruitment and early follicular growth and development. Total absence of any follicles, including those in the primordial stage, occurs in women in whom FSH receptor mutations cannot be demonstrated.[47] The ovarian phenotype of FSH receptor deficiency is distinct from the common form of gonadal dysgenesis (Turner syndrome), which is characterized by streak gonads and an absence of growing follicles.[47]

In vivo rodent studies suggest that FSH is capable of increasing the number of its own receptors in the granulosa cell. Whereas estradiol by itself may be without effect on the distribution, number, or affinity of granulosa cell FSH receptors, estrogens synergize with FSH to enhance the overall number of granulosa cell FSH receptors.[89] Changes in the production of estradiol by preantral follicles can increase their response to FSH through regulation of granulosa cell surface FSH receptors. This interaction between FSH and estradiol in follicular development has been well established in rodents. It appears that ERα and ERβ mediate the estrogenic effect on ovarian development and follicular maturation in mice.[90] However, it is not clear whether a similar relationship exists in the human ovary. ERα is not detected in the human ovary in significant quantities. Nevertheless the demonstration of ERβ in the human ovary suggests an interaction between FSH and estrogen in the regulation of normal follicle development and ovulation in women.[91]

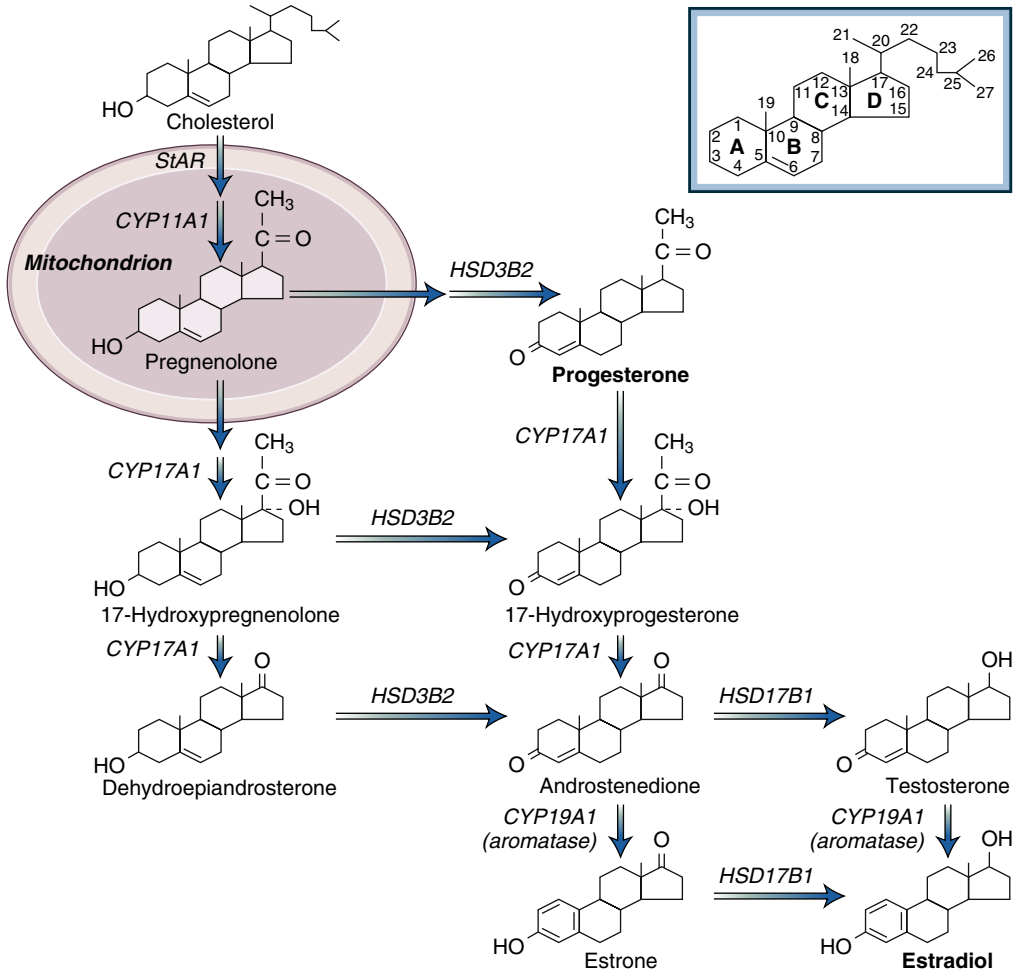
One of the major actions of FSH is induction of granulosa cell aromatase activity.[92] Little or no estrogen can be produced by FSH-unprimed granulosa cells even if they are supplied with aromatizable androgen precursors. Treatment with FSH enhances the aromatization capability of granulosa cells, an effect related to enhancement of the granulosa cell aromatase content.[92]

Treatment with FSH has also been shown to induce LH receptors in granulosa cells. The ability of FSH to induce LH receptors is augmented by the concomitant presence of estrogens.[93] Progestins, androgens, and LH itself may also induce LH receptors. After induction, the granulosa cell LH receptor requires the continued presence of FSH for its maintenance.

Circumstantial evidence, deduced from studies of women with disrupting mutations of the genes that encode FSH and LH receptors and aromatase (CYP19A1), indicates that FSH action, but not estrogen or LH action, is essential for follicular growth in humans.[47,93] Follicular growth and development up to the antral stage were observed in women with deficient LH action or estrogen biosynthesis, although these individuals were anovulatory.[47,93] Women with mutations of the FSH β-subunit or FSH receptor have only primordial follicles in their ovaries.[47] These data indicate that estrogen and LH are not critical for follicular development at least until the tertiary stage (see Figs. 17.11 and 17.12). However, FSH by itself is not sufficient to achieve normal follicular development and ovulation.

Role of Luteinizing Hormone in Ovarian Function

LH is essential for ovulation (follicular rupture) and the sustenance of corpus luteum function; in addition, it plays other important roles in follicular function.[93] First, LH probably plays



• **Fig. 17.16** Steroidogenic pathway in the human ovary. The biologically active steroids progesterone and estradiol are produced primarily in the ovary of a woman of reproductive age. Estradiol production requires the activity of six steroidogenic proteins, including StAR, and six enzymatic steps. 17-Hydroxylase/17,20-lyase, the product of the *CYP17A1* gene, catalyzes two enzymatic reactions. The four rings of the cholesterol molecule and its derivative steroids are identified by the first four letters in the alphabet, and the carbons are numbered in the sequence shown in the *insert*. *CYP17A1,* 17-hydroxylase/17,20-lyase; *CYP19A1,* aromatase; *HSD17B1,* 17β-hydroxysteroid dehydrogenase type 1; *HSD3B2,* 3β-hydroxysteroid dehydrogenase-$\Delta^{5,4}$ isomerase type 2; *StAR,* steroidogenic acute regulatory protein.

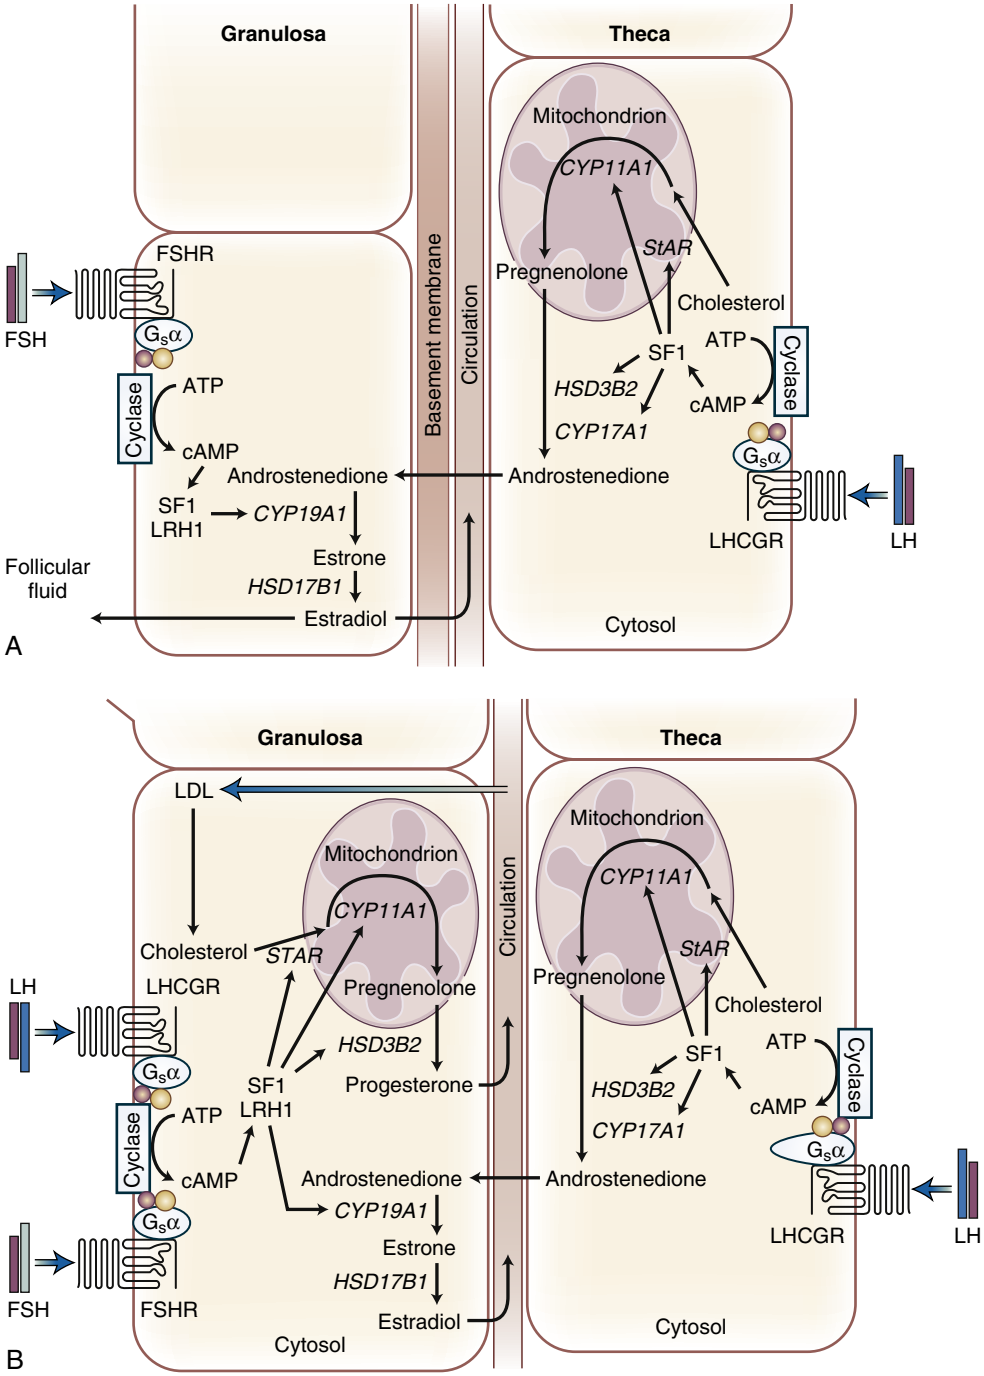
a major role in the promotion of theca-interstitial cell androgen production. Second, LH may well synergize with FSH in the more advanced phases of follicular development. Third, small and sustained increments in the circulating levels of LH are necessary and sufficient to cause small antral follicles to grow and develop to the preovulatory stage.[93]

It is presumed that LH acts on the theca-interstitial cells of small follicles, where it promotes the biosynthesis of C19 steroids.[93] The consequent increase in estrogen production is presumed to contribute to the growth and development of the follicles. Treatment with small doses of LH also results in an increase in LH receptor content and in induction of the key steroidogenic proteins, such as StAR, CYP11A1, HSD3B2, and CYP17A1.[93]

The role of LH action in human ovarian physiology was exemplified by the phenotype of a woman with a disrupting mutation of the LH receptor gene.[47] She presented with amenorrhea, normally developed secondary sexual characteristics, increased circulating FSH and LH levels, and low levels of estradiol and progesterone that were unresponsive to hCG treatment.[47] The ovary contained follicles that developed up to antral stage with a well-developed theca layer but no preovulatory follicles or corpora lutea. These observations collectively support the view that LH is essential for ovulation and sufficient estrogen production, whereas follicular development is initially autonomous but at later stages depends on intact FSH action.[47]

Ovarian Steroidogenesis

The steroid hormone contents of the ovarian vein effluents and peripheral venous blood were compared to distinguish steroids secreted by the ovary from those secreted by the adrenal or produced by peripheral conversion of precursors.[94] These studies revealed that the ovaries secrete pregnenolone, progesterone, 17α-hydroxyprogesterone, dehydroepiandrosterone (DHEA), androstenedione, testosterone, estrone, and estradiol.[95,96] Although such measurements provide insights into the steroidogenic pathways under study, they do not identify the specific ovarian cells involved. Studies using microdissected preovulatory follicles identified estrone and estradiol as the major steroid products (Fig. 17.16). Progesterone and 17α-hydroxyprogesterone proved to be the major products of the corpus luteum (see Fig. 17.16).



• **Fig. 17.17** Two-cell hypothesis for ovarian steroidogenesis. (A) The preovulatory follicle produces estradiol through a paracrine interaction between theca and granulosa cells. In response to stimulation with a gonadotropin, steroidogenic factor 1 (SF1, encoded by NR5A1, a member of the nuclear receptor family) acts as a master switch to initiate transcription of a series of steroidogenic genes in theca cells. In follicular granulosa cells, another nuclear receptor, liver homologue receptor 1 (LRH1, encoded by NR5A2), seems to primarily mediate the downstream effects of follicle-stimulating hormone (FSH) in the rodent ovary. In humans, the roles of SF1 and LRH1 in steroidogenesis in preovulatory granulosa cells are not well understood. Because granulosa cells do not have a direct connection to the circulation, CYP19A1 (aromatase) in granulosa cells depends for substrate on androstenedione that diffuses from theca cells. Two critical steps in estradiol formation are the entry of cholesterol into mitochondria facilitated by steroidogenic acute regulatory protein (StAR) in theca cells and the conversion of androstenedione to estrone catalyzed by CYP19A1 in granulosa cells. (B) In the corpus luteum, granulosa-lutein cells are heavily vascularized, a condition that is critical for entry of abundant quantities of cholesterol into this cell type through primarily low-density lipoprotein (LDL)-cholesterol receptors and for secretion of large amounts of progesterone into the circulation. The entry of cholesterol into mitochondria (mediated by StAR) is probably the most critical steroidogenic step for progesterone formation in granulosa-lutein cells. Androstenedione produced in theca-lutein cells serves as a substrate for estrone, which is further converted to estradiol in granulosa-lutein cells. Human data suggest that LRH1 may mediate at least a portion of gonadotropin-dependent steroidogenesis in the corpus luteum. Gonadotropins, SF1, and possibly LRH1 play key roles for important steroidogenic steps in the ovary. *ATP,* adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate; *FSHR,* FSH receptor; *HSD,* hydroxysteroid dehydrogenase; *LHCGR,* LH receptor.

The general steroidogenic pathway for the production of estrogens and androgens is depicted in Fig. 17.16. The biologically active ovarian steroids are estradiol and progesterone. The major C19 steroid product of the ovary, androstenedione, is not biologically active. However, it acts as a dual precursor and contributes to circulating levels of estrone and testosterone through conversion in extraglandular tissues such as adipose tissue and skin (discussed later).[97] It is likely that estrogenically weak estrone is further converted to the potent estrogen estradiol and that testosterone is converted to the most potent endogenous androgen dihydrotestosterone (DHT) locally in target tissues such as brain, breast, prostate, and genital skin and subsequently exert potent biologic effects. This notion is supported by the presence in many human tissues of multiple proteins with overlapping enzymatic activities that catalyze these conversions (e.g., reductive 17βHSD and 5α-reductase).[98]

The preovulatory follicle secretes estradiol during the first half of the menstrual cycle, and the corpus luteum secretes estradiol and progesterone during the second half of the cycle. The production of these two biologically active steroids is orchestrated in the follicle and corpus luteum in a cell-specific manner that is under the control of LH and FSH.

Steroids formed by the ovary and other steroid-producing organs are derived from cholesterol (see Fig. 17.16). Several sources of cholesterol can provide the ovary with substrate for steroidogenesis, including plasma lipoprotein cholesterol, cholesterol synthesized de novo within the ovary, and cholesterol from intracellular stores of cholesterol esters within lipid droplets. In the human ovary, LDL cholesterol is an important source of cholesterol used for steroidogenesis.[79] LH stimulates the activity of adenylyl cyclase, increasing production of cyclic adenosine monophosphate (cAMP), which serves as a second messenger to increase LDL receptor messenger RNA (mRNA), binding and uptake of LDL cholesterol, and the formation of cholesterol esters.[78,79] LDL-derived cholesterol is particularly essential for normal levels of progesterone production in the granulosa-lutein cells of the corpus luteum.[79]

Steroidogenic Genes and Their Functions in the Ovary

The ovarian granulosa, theca, and corpus luteum cells possess StAR plus five distinct proteins with specific enzyme activities for steroid hormone formation. These steroidogenic enzymes are CYP11A1 (side-chain cleavage of P450), 3βHSD2 (3β-hydroxysteroid dehydrogenase-$\Delta^{5,4}$ isomerase type 2), CYP17A1 (17-hydroxylase/17,20-lyase), CYP19A1 (aromatase), and 17βHSD1 (17β-hydroxysteroid dehydrogenase type 1).[92] These enzymes are responsible for the conversion of cholesterol to the two major biologically active products: estradiol and progesterone.[92,97]

The first and rate-limiting step in the synthesis of all ovarian steroid hormones is the movement of cholesterol into the mitochondrion, which is regulated by a mitochondrial membrane protein encoded by the *STAR* gene (see Fig. 17.16).[99] This movement is followed by conversion of cholesterol to pregnenolone, which is catalyzed by the mitochondrial side-chain cleavage enzyme complex consisting of CYP11A1, adrenodoxin, and flavoprotein. LH induces steroidogenesis by increasing the conversion of cholesterol to pregnenolone in two distinct ways: acute regulation, which occurs over minutes through phosphorylation of preexisting StAR and rapid synthesis of new StAR, and chronic stimulation, which occurs within hours to days through the induction of CYP11A1 expression and consequent increased steroidogenesis (Fig. 17.17). StAR increases the flow of cholesterol to mitochondria, regulating substrate availability to CYP11A1 on the inner mitochondrial membrane.[99] In the absence of StAR, only 14% of the maximal StAR-induced level of steroidogenesis persists.[99]

StAR expression in the preovulatory Graafian follicle is limited primarily to the theca cells (see Fig. 17.17).[100] The most important product of the theca cell during the follicular phase is the estrogen precursor androstenedione, and its production is controlled primarily by StAR. The biologically active steroid product of the ovary during the follicular phase is estradiol, which arises from the granulosa cells located adjacent to theca cells. The rate-limiting step for granulosa cell estradiol production is regulated by the FSH-dependent activity of the aromatase enzyme in a cyclic fashion.[92] During the luteal phase, cells of the corpus luteum, including granulosa-lutein cells, also show intense StAR immunoreactivity with a patchy distribution.[81,100] The delivery of cholesterol to the mitochondrial side-chain cleavage enzyme system in the corpus luteum is the rate-limiting step for progesterone biosynthesis and is regulated by StAR.[81] Thus estradiol production seems to be regulated primarily by StAR and aromatase, whereas progesterone biosynthesis may be primarily under the control of StAR.

Steroidogenesis that depends on LH and FSH in theca and granulosa cells is mediated by common signaling molecules, including cAMP and the specific transcription factors SF1, product of the *NR5A1* gene, and LRH1, product of the *NR5A2* gene, which belong to the nuclear receptor family (see Fig. 17.17).[101,102] SF1 and LRH1 regulate the expression of genes that encode StAR, CYP11A1, 3βHSD2, CYP17A1, and CYP19A1 (see Fig. 17.17). SF1 and possibly LRH1 can be regarded as downstream master switches that orchestrate ovarian steroidogenesis.[102]

All steroid hormones are derived from cholesterol. C27 cholesterol is converted to the carbon steroid hormones 18, 19, and 21 that are secreted by the ovary (see Fig. 17.16).

C21 Steroids
