• **Fig. 34.8** Cellular mechanisms of insulin resistance in overnutrition. Numerous environmental and pathologic insults can combine to impair cellular insulin signaling leading to insulin resistance. Overnutrition leads to adipose tissue inflammation, hyperinsulinemia, hyperglycemia, and microbiome/metabolite alterations in the body. These are associated with ectopic lipid accumulation, mitochondrial dysfunction, and endoplasmic reticulum (ER) stress/unfolded protein response (UPR) in insulin-sensitive tissues. A common mechanism of insulin resistance is activation of serine/threonine kinases (shown in red font) that phosphorylate insulin receptor and IRS proteins leading to feedback inhibition of these proximal signaling intermediates in the insulin cascade. Another mechanism is protein-protein interactions that decrease insulin receptor phosphorylation or inhibit its interaction with IRS proteins. *DAG,* diacylglycerol; *ERK,* extracellular signal–regulated kinase; *FA,* fatty acid; *Grb,* growth factor receptor-bound protein; *IKK,* IκB kinase; *IRS,* insulin receptor substrates; *IL6,* interleukin 6; *Jak,* janus kinase; *JNK,* c-Jun *N*-terminal kinase; *LPS,* lipopolysaccharide; *mTORC1,* mammalian target of rapamycin complex 1; *O-GlcNAc,* O-linked β-*N*-acetylglucosamine; *PI3K,* phosphatidylinositol-3-kinase; *PKC,* protein kinase C; *PTP1B,* protein tyrosine phosphatase 1B; *ROS,* reactive oxygen species; *S6K,* ribosomal protein S6 kinase; *Shc,* SH3-containing protein; *SOCS,* suppressor of cytokine signaling; *SOS,* son of sevenless; *Stat,* Signal transducer and activator of transcription; *TNFα,* tumor necrosis factor α.

in normal persons specifically inhibited the ability of insulin to increase nonoxidative glucose disposal in association with an impaired ability of insulin to stimulate glycogen synthase activity. Suppression of insulin secretion in obese, insulin-resistant persons results in increased insulin sensitivity.[215,216]

In cell systems, serine phosphorylation of IRS proteins inhibits insulin signaling and is mediated by a variety of kinases (see Fig. 34.8), including mammalian target of rapamycin (mTOR)/S6 kinase (S6K), which is downstream of the PI3K-Akt pathway. Feedback serine phosphorylation of IRSs on appropriate residues might increase ubiquitination and degradation IRS isoforms, which would result in decreased insulin signaling.[217] However, the mechanisms appear much more complex in vivo, because a mouse model with a serine to alanine mutation at 302 on IRS1, the prime target of mTOR-induced disruption of IRS signaling, did not prevent insulin resistance from mTOR activation in the liver.[218] Signaling via mTOR can also increase growth factor receptor bound protein 10 (Grb10) levels by phosphorylation.[219] Grb10 and Grb14 are negative regulators of insulin signaling, which act in key metabolic tissues including muscle and adipose,[220] and contain polymorphisms in humans that are linked to development of T2DM.[221] Extracellular signal–regulated kinase

(ERK) has also been shown to feed back and inhibit IRS function and is downstream of insulin-mediated mitogen-activated protein kinase activation. Last, FoxO transcription factors regulate transcription of the insulin receptor and many inhibitors of Akt action, including Tribbles 3 (Trb3) and protein phosphatase 2A (PP2A).[222] Thus, activation of the insulin signaling cascade feeds back at the level of IRS and other insulin targets, with chronic activation from hyperinsulinemia itself impairing insulin signaling by chronic feedback inhibition.

Nutrient Overload and Insulin Resistance

Cells have developed several ways to sense incoming nutrients, including direct and indirect activation of transcription factors and protein kinases. Amino acids stimulate growth by direct activation of mTOR complex 1.[84] Fatty acids are sensed by several mechanisms, including cell surface receptors, such as toll-like receptors (TLRs), and by transcription factors, including PPARα and PPARγ.[223] Glucose itself can be converted to O-linked β-*N*-acetylglucosamine (O-GlcNAC) post-translational modifications that modify enzymes on Ser/Thr residues, acting similar to or opposing phosphorylation.[224] Many of these signals provide feedback inhibition on the insulin receptor cascade through Ser/Thr kinase activation (including S6K, c-Jun N-terminal kinase (JNK), and inhibitor of κB kinase (IKK).[217,225-227] However, chronic overnutrition can alter these normal cellular signals, causing insulin resistance (see Fig. 34.8). In a sense, the reaction of different tissues to obesity may be a relatively normal physiologic response to excess nutrient delivery, with prolonged activation leading to unintended and pathologic states that result in insulin resistance, inflammation, and even cell death.

Adipose Tissue and Insulin Resistance

To maintain metabolic homeostasis when nutrient intake exceeds energy expenditure, the excess calories must be used to increase cellular mass or it must be stored. Most excess nutrients, whether carbohydrate, protein, or lipid, are ultimately stored as triglyceride in white adipose tissue. If the storage capacity of adipose tissue is exceeded, lipids and other nutrients enter nonstorage tissues. This ectopic lipid accumulation occurs in myocytes, hepatocytes, vascular cells, and beta cells, and can produce toxic lipid metabolites (e.g., diacylglycerol or ceramides) that trigger activation of PKC isoforms among other adaptive and maladaptive cellular responses that lead to insulin resistance.[228] Indeed, some data suggest that the inability to expand fat mass in response to overeating may be an important factor in the development of insulin resistance.[229]

Adipocytes are more than storage cells. They regulate the uptake and release of fatty acids; participate in the glycerol–fatty acid cycle; release leptin and other hormones that signal the energy

status of the body; and secrete an ever-expanding number of cytokines that have hormonal, paracrine, and autocrine actions.[230] The adipocyte itself can be adversely affected by accumulation of excess nutrients, leading to events that can have adverse consequences on the body. As adipocyte surface area increases in obesity, there is increased expression of leptin, interleukin 6 (IL6), IL8, monocyte chemoattractant protein 1 (MCP1), and granulocyte colony-stimulating factor. These and possibly other cytokines attract pro-inflammatory macrophages (M1 type), which release factors such as tumor necrosis factor α (TNFα) that may have local and systemic inflammatory effects.[231]

In addition to energy-storing white adipose tissue, humans and other mammals have energy-burning brown adipose tissue. Brown adipose tissue is a thermogenic tissue that contains unique adipocytes with distinct morphology including multiloculated lipid droplets, increased mitochondrial content, and expression of the uncoupling protein 1 (UCP1) to uncouple electron transport and generate heat. Brown adipose tissue is activated by the sympathetic nervous system, which increases the mobilization and oxidation of fatty acids.[232] The content of brown adipose tissue in humans is negatively correlated with age and obesity, which may be a consequence or a contributor to insulin resistance in these conditions.[233] In humans, prolonged or repeated cold exposure can increase the mass and activity of brown adipose tissue in the neck and supraclavicular regions, as defined by the uptake of glucose, and can improve glucose homeostasis.[234] It has been recognized that rodents and humans also have beige or brite (brown in white) adipocytes,[235] which appear mixed into some white adipose tissue depots following cold or hormonal stimuli. Like brown adipocytes, beige adipocytes express UCP1; however, the developmental origin of these cells appears to be distinct from brown adipose tissue. The degree to which humans can increase beige adipocytes and how it may impact metabolism remains unknown but presents a potential therapeutic target.

Ectopic Lipid Accumulation

When the storage capacity of adipose tissue is exceeded, lipids accumulate in tissues such as muscle and the liver that are not well adapted to lipid storage, a process known as ectopic lipid accumulation. This leads to metabolic dysfunction in these tissues. In muscle, insulin-stimulated glucose uptake is inversely related to the amount of intramuscular triglycerides measured by biopsy, computed tomography, and magnetic resonance imaging , which can distinguish intramyocellular from extramyocellular fat.[236] First-degree relatives of T2DM patients have an increase in intramyocellular fat, and in this group there is also a correlation with insulin resistance.[237]

The mechanism for accumulation of triglyceride in the skeletal muscle of obese and insulin-resistant persons is probably related to mismatching of fatty acid uptake and oxidation. During resting postabsorptive conditions, about 30% of fatty acid flux in the plasma pool is accounted for by oxidation, and the remaining 70% of flux is recycled into triglyceride, indicating a physiologic reserve that exceeds immediate tissue needs for oxidative substrates. The uptake, transport, and metabolism of fatty acids are highly regulated processes, and alteration of the balance between uptake and oxidation in skeletal muscle leads to increased intramyocellular triglycerides. The increased lipolysis associated with obesity provides an increased amount of fatty acids presented to muscle, which again appears to activate PKC isoforms to feedback on insulin signaling intermediates.[238,239]

However, increased muscle triglyceride content is not invariably linked to insulin resistance. Indeed, exercise training is associated with increased muscle triglyceride content,[240] and chronic exercise increases both insulin sensitivity and the capacity for fatty acid oxidation.[241-243] The reason for this dissociation is not completely understood, but recent studies show that perilipin proteins PLIN2, PLIN3, and PLIN5 rapidly associate with lipid droplets in muscle from trained individuals but not sedentary individuals.[244] These data suggest that exercise training allows for improved lipid storage in muscle, thereby sequestering lipid intermediates and preventing fatty acid–induced insulin resistance, which is also seen with acute exercise.[245]

Lipid accumulation in the liver is a common feature of insulin resistance and T2DM often referred to as nonalcoholic fatty liver disease (NAFLD).[246] Enhanced substrate delivery to the liver in insulin-resistant states likely plays a key role in this lipid accumulation.[117,228] Enhanced fatty acid delivery from adipose tissue lipolysis and increased postprandial glucose concentrations due to muscle insulin resistance provide excess substrates for the liver that result in accumulation of acetyl-CoA and toxic lipid intermediates.[247] Humans with lipodystrophy and mouse models of lipodystrophy develop NAFLD and severe insulin resistance indicating that without the capacity to store lipids in adipose tissue, the liver becomes metabolically dysfunctional.[107,248,249] However, excess lipid intake is not the only way to develop NAFLD. Indeed, feeding mice excess glucose or fructose induces metabolic pathways in the liver that lead to NAFLD.[250,251] These data indicate that a combination of excess macronutrients and decreased adipose tissue storage promote lipid accumulation in the liver that is concurrent with insulin resistance.

Endoplasmic Reticulum Stress/Unfolded Protein Response

The ER functions in the post-translational processing of protein, including protein folding, maturation, quality control, and trafficking to other cellular compartments. As part of its quality control machinery, when the ER accumulates excess levels of unfolded or misfolded proteins, a distinct series of reactions occurs that slows overall protein synthesis while increasing the production of chaperones and other proteins that increase the fidelity of protein processing. Three pathways are commonly activated to mediate the unfolded protein response (UPR) and alleviate ER workload: RNA-dependent protein kinase–like ER kinase (PERK), inositol-requiring enzyme 1 (IRE1), and activating transcription factor 6 (ATF6). PERK phosphorylates eukaryotic translation initiation factor 2 (eIF2α), resulting in inhibition of most protein synthesis. IRE1 induces cleavage of X-box–binding protein 1 (XBP1) mRNA, which results in production of the active XBP1 transcription factor. XBP1, in combination with ATF6α, activates transcription to produce chaperones and proteins involved in ER biogenesis, phospholipid synthesis, and secretion.[252]

In states of overfeeding and obesity, there can be activation of the UPR in the liver, adipose tissue, pancreatic beta cells, muscle, and other tissues. The activation of UPR in response to overnutrition is thought to have several effects, including activation of the JNK and nuclear factor–κB (NF-κB)/inhibitor of κB kinase (IKK) pathways leading to decreased IRS1 activity; increased levels of endogenous inflammatory mediators; alteration in SREBP1-mediated transcription; reduction in hepatic gluconeogenesis; and, after prolonged activation, cellular dysfunction and apoptosis.[253]

Innate Immunity

The innate immune system was originally thought to be a cellular system that allowed discrimination of self and nonself to adapt cellular metabolism to fight microbial pathogens. However, this system is now recognized as a general response to cellular stress that activates

the inflammation and cellular repair systems. The innate immune system contains a series of pattern-recognition receptors to detect microbial motifs. These proteins, including TLRs and C-type lectins, are expressed on a variety of cell types, including macrophages, monocytes, dendritic cells, neutrophils, epithelial cells, and cells of the adaptive immune system. The pattern-recognition receptors detect extracellular and intracellular pathogen-related molecules, including lipids and nucleic acids, and initiate a stereotypical response, including NF-κB activation and activator protein 1 (AP1) transcription, which increases expression of cytokines and chemokines.

Activation of the innate pathway also increases the production of so-called inflammasomes—large, multisubunit protein complexes that are important in the control of caspase 1–mediated, post-translational maturation and secretion of interleukins, primarily IL1β, that have potent pro-inflammatory responses and are a risk factor for development of T2DM, perhaps through disruption of beta-cell function.[254]

Activation of the innate immune system in acute infection and obesity is associated with significant insulin resistance. In obesity, this is mediated in part by elevated levels of fatty acids. TLRs, especially TLR2 and TLR4, which normally respond to bacterial cell wall lipids to induce the innate inflammatory response, are also activated by circulating saturated fatty acids. Conversely, polyunsaturated fatty acids inhibit TLR signaling. Activation of TLRs in cells results in insulin resistance, whereas genetic disruption of the TLR4 receptor in mice is protective against fatty acid–induced insulin resistance.[227]

Mitochondrial Abnormalities

A decrease in oxidative capacity is seen in both humans and animals with insulin resistance, obesity, and T2DM.[255,256] Studies have suggested that increases in intramyocellular fat content in skeletal muscle associated with insulin resistance may be caused by alterations in mitochondrial mass. In one study, young insulin-resistant offspring of parents with T2DM demonstrated a 60% reduction in insulin-stimulated skeletal muscle glucose uptake compared with control subjects, and this reduction correlated with an increase of approximately 80% in intramyocellular lipid content.[257] The elevated intramyocellular lipid content was attributable to the 30% reduction in mitochondrial oxidative capacity, which may be due to the lower ratio of the mitochondria-rich oxidative type I fibers to glycolytic type II muscle fibers.

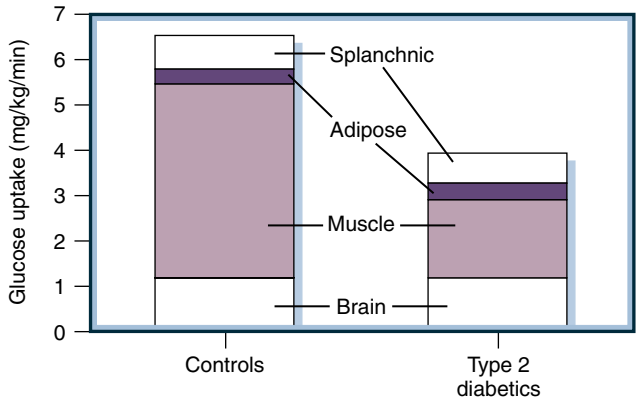
Decreased expression of nuclear-encoded genes that regulate mitochondrial biogenesis, such as PPARγ coactivators 1α and 1β (PGC1α and PGC1β, respectively), have been shown to be important for mitochondrial biogenesis and for fiber type selection during development.[258] PGC1α and PGC1β, and their target genes, were found to be downregulated in obese patients with IGT and T2DM.[259-261] The activity of the electron transport chain is reduced and intramyofibrillar mitochondria are smaller in patients with T2DM, and both of these measures correlate with severity of insulin resistance.[262] A study in which rats were bred for differences in oxidative capacity (determined by their intrinsic ability to run) suggests that the defects found in humans could have a genetic basis.[263] The group with poor aerobic capacity had several significant abnormalities, including obesity, insulin resistance, hypertension, and dyslipidemia. The metabolic decline also correlated with a reduction in mitochondrial gene expression and PGC1α in skeletal muscle, similar to that seen in humans. These data lead to the hypothesis that reversing the observed mitochondrial mass decline in muscle of T2DM patients may be a way to improve their metabolism. However, the potential beneficial effect of increasing mitochondrial mass by activation of PGC1α activity has been dampened by the finding that overexpression of PGC1α in mouse skeletal muscle does not improve metabolic status following a high-fat diet.[264]

Some studies have questioned the cause-effect relationship between alterations in mitochondrial mass/function and skeletal muscle insulin resistance. Rather than mitochondrial insufficiency being an inherited trait, these observed changes could be acquired. First, insulin itself can upregulate mitochondrial biogenesis, and withdrawal of insulin in patients with T1DM leads to reductions in mitochondrial gene transcription and adenosine triphosphate (ATP) synthesis.[265] Second, the observed reduction in ATP synthesis and tricarboxylic acid (TCA) cycle activity could be explained by reduced turnover of ATP in relatively sedentary individuals. In the absence of energy demand (e.g., exercise), the reduction in the adenosine diphosphate/ATP ratio would impair electron transport in the mitochondria, increasing levels of the reduced form of nicotinamide adenine dinucleotide (NADH), which would impair TCA cycle activity. This would result in the generation of reactive oxygen species due to elevated reducing pressure in the mitochondria.[266] Indicative of impaired oxidation in the mitochondria, mice fed a high-fat diet show a reduction in TCA cycle intermediates and an impairment of adequate β-oxidation of fatty acids, marked by increases in even-chained acyl-carnitine levels. Increases in plasma acyl-carnitines are found in obese, insulin-resistant individuals, and it appears that they are markers of resistance.[267,268]

Post-translational modification of mitochondrial proteins by acetylation (as well as succinylation and malonylation) of lysine residues on each protein has a marked effect on their activity and provides a potentially important mechanism for control of mitochondrial flux and insulin resistance.[269] In general, the acetylation events reduce mitochondrial enzyme activity. No enzymes promoting acetylation have been found. Rather, these appear to occur through pH-dependent, nonenzymatic chemical reactions wherein acetyl-CoA or other acyl-CoAs act as donors for exposed lysine residues. An increase in flux of nutrients in the mitochondria is expected to increase acetylation proportional to the steady-state levels of acetylation. An imbalance of formation to utilization, which occurs in overnutrition, would therefore be expected to inhibit further fuel utilization. The mitochondrial sirtuin, Sirt3, is the primary deacetylase of mitochondria[270] that is activated by nicotinamide adenine dinucleotide (NAD^+) and can deacetylate critical metabolic enzymes, including long-chain acyl-CoA dehydrogenase (LCAD) in the liver[271] and pyruvate dehydrogenase complex in muscle.[272] Similarly, the NAD+-dependent Sirt5 leads to desuccinylation and demalonylation of mitochondrial enzymes.[273,274] As ATP use increases, such as with exercise,[275] increased electron flow from NADH to support oxidative phosphorylation will result in increased intramitochondrial NAD^+, leading to Sirt3- and Sirt5-mediated protein deacylation and increased mitochondrial capacity for substrate utilization.

Skeletal Muscle Insulin Resistance

The primary site of glucose disposal after a meal is skeletal muscle, and the primary mechanism of glucose storage is through its conversion to glycogen.[276] In obesity, insulin resistance in skeletal muscle is manifested before abnormalities in insulin signaling in adipose tissue and the liver, possibly reflecting the relatively limited nutrient storage capacity of skeletal muscle. Studies using the hyperinsulinemic-euglycemic clamp technique have demonstrated that in insulin-resistant people (with and without T2DM), there is a deficiency in the nonoxidative disposal of



• **Fig. 34.10** Tissue uptake of glucose in nondiabetic and insulin-resistant diabetic subjects during a hyperinsulinemic-euglycemic clamp. (From DeFronzo RA. The triumvirate: beta-cell, muscle, liver—a collusion responsible for NIDDM. Lilly Lecture 1987. *Diabetes.* 1988;37:667–687.)

glucose related primarily to a defect in glycogen synthesis, which itself is secondary to a decrease in insulin-stimulated glucose uptake[277,278] (Fig. 34.10).

Elevated fatty acids predict the progression from IGT to diabetes,[279,280] although peripheral fatty acids might not be markedly elevated because of efficient extraction by the liver and skeletal muscle. Increased fatty acid flux to skeletal muscle related to increased visceral lipolysis has been implicated in the inhibition of muscle glucose uptake. The glucose–fatty acid cycle was originally proposed to account for the ability of fatty acids to inhibit muscle glucose utilization. Randle's group[281] hypothesized that fatty acids compete with glucose for substrate oxidation in isolated muscle. They found that increased fatty acid metabolism leads to an increase in the ratio of intramitochondrial acetyl-CoA to CoA and reduced nicotinamide adenine dinucleotide (NADH/NAD^+) ratios, which leads to inhibition of pyruvate dehydrogenase. The resulting increased intracellular mitochondrial (and cytosolic) citrate concentrations result in allosteric inhibition of phosphofructokinase, the key rate-controlling enzyme in glycolysis. Subsequent accumulation of glucose 6-phosphate inhibits hexokinase II activity, resulting in an increase in intracellular glucose concentrations and decreased glucose uptake.

More recent in vivo studies in humans suggest that the primary effect of fatty acids, at least in the presence of elevated insulin levels, is a decrease in glucose transport, as measured by a reduction in the rate of accumulation of intracellular glucose and glycogen using ^{13}C and ^{31}P nuclear magnetic resonance spectroscopy. In normal subjects, elevated fatty acids, achieved by infusion of triglyceride emulsions and heparin (which activates lipoprotein lipase resulting to release fatty acids into the circulation), resulted in a fall in intracellular glucose and glucose 6-phosphate concentrations that precede the fall in glycogen accumulation.[282,283] These results challenge the Randle hypothesis (which predicts a rise in intracellular glucose 6-phosphate concentrations) as the basis of the reduction in insulin sensitivity seen with elevated fatty acids. Similar decreases in glucose transport have been seen in patients with T2DM and in lean, normoglycemic, insulin-resistant offspring of T2DM parents.[284] These studies also find decreased activity of PI3K and increased activity of novel forms of protein kinase C, such as PKCθ, PKCδ, and others, that might, in part, mediate the effect of elevated fatty acids.[238,239]

Studies also suggest that PKC-mediated serine phosphorylation of the IKKβ subunit, leading to its degradation, and the unregulated translocation of NF-κB into the nucleus, might also be important to fatty acid–induced insulin resistance.[285] This is the mechanism by which high-dose aspirin and salsalate improve glucose metabolism in T2DM.[285,286] Disruption of the IKKβ inflammatory pathway by high-dose salicylate therapy in a small human trial resulted in improvements in insulin sensitivity.

Fatty Acid Metabolism in Skeletal Muscle

The uptake of fatty acid from the serum, where it is mostly bound to albumin, is mediated by at least three families of proteins: fatty acid translocase, plasma membrane fatty acid–binding proteins (FABPs), and fatty acid transport proteins.[287-289] The levels of the putative transport proteins are regulated by exercise,[290] correlated with body weight (at least in women), and can be modulated by insulin infusion.[291]

FABPs are capable of binding multiple hydrophobic ligands, including fatty acids, eicosanoids, and retinoids, with high affinity.[292] FABPs are thought to facilitate uptake of fatty acids and to promote subsequent intracellular transport to subcellular organelles.[293] There is a direct correlation between heart-type FABP content and oxidative capacity observed during development and among different muscle types.[294,295] In mice that have a disruption of the heart isoform[296] or the adipocyte isoform[297] of FABP, plasma fatty acid concentrations are significantly elevated and plasma glucose is decreased, suggesting a key role in normal regulation of fatty acid oxidation. Some,[297] but not all,[298] studies have shown a decrease in heart-type FABP in insulin-resistant humans.

Carnitine palmitoyltransferase 1 (CPT1) has been the subject of intense scrutiny for many years because of its central role in the balance between mitochondrial glucose and fatty acid metabolism, primarily because malonyl-CoA inhibits mitochondrial fatty acid uptake by inhibiting CPT1 in the liver.[299,300] A specific isoform contributes 97% of the CPT1 in muscle and has 100-fold lower sensitivity to inhibition by malonyl-CoA.[301] This lower sensitivity to malonyl-CoA inhibition suggests that the levels of CPT1 itself, as well as malonyl-CoA, may be important in the balance of uptake and oxidation of fatty acids. Evidence for this in skeletal muscle stems from the finding that overexpression of CPT1 in rodent muscle increased fatty acid oxidation and reduced intramyocellular triglyceride.[302] Furthermore, muscle CPT1 mRNA, as with other fatty acid–oxidizing enzymes, is regulated by PPARα activators, fat feeding, and exercise in rodents and is inversely correlated with obesity in humans.[303-306]

Long-chain fatty acids, after passing through the inner mitochondrial membrane as acylcarnitines, are metabolized at the surface of the inner mitochondrial membrane by CPT2 and the long chain–specific oxidation system consisting of very long chain acyl-CoA dehydrogenase (VLCAD) and the trifunctional protein oxidation complex (Fig. 34.11). Transfer of the acyl chain from carnitine to CoA, catalyzed by CPT2, is followed by one cycle of oxidation. This is catalyzed by VLCAD and trifunctional protein to yield a chain-shortened acyl-CoA that can recycle through the same oxidation system.[307] In vivo, four different acyl-CoA dehydrogenase enzymes catalyze the initial dehydrogenation of straight-chain fatty acids in mitochondria. Three of them—short-chain acyl-CoA dehydrogenase (SCAD), medium-chain acyl-CoA dehydrogenase (MCAD), and LCAD—are soluble enzymes located in the mitochondrial matrix as homotetramers. A fourth, VLCAD, is attached to the inner membrane as a homodimer. Their names derive from the length of the fatty acids that they process. The enzymes can act in tandem. VLCAD and LCAD shorten the long-chain fatty acids into medium-chain fatty acids that can then be processed by MCAD and SCAD.[308] The SCAD, MCAD, and LCAD monomers share a high degree of homology

but do not share homology with VLCAD. At least some of these enzymes can be regulated in humans by exercise training.[309]

UCP1 mediates the uncoupling of oxidative phosphorylation in brown adipose tissue for thermogenesis.[310] UCP2 and UCP3 have structural similarities to UCP1, but it is not clear that they are actually uncouplers of oxidative phosphorylation under physiologic conditions.[311,312] UCP3 mRNA is found primarily in skeletal muscle and in brown adipose tissue. UCP2 has a ubiquitous tissue distribution and may be involved in reactive oxygen species detoxification and CNS regulation of metabolism.[313] UCP2 and UCP3 mRNA levels have been correlated with different physiologic states, and numerous studies indicate that expression of UCP2 and UCP3 are stimulated by thyroid hormones and in the presence of high levels of fatty acids.[314] In humans, the levels of UCP2 and UCP3 mRNAs were upregulated by a high-fat diet, and the upregulation was more pronounced in humans with high percentages of type IIA muscle fibers.[315] In a small study, exercise training in humans increased mitochondrial oxidative capacity but did not change UCP2 or UCP3 levels.[316] Obesity itself was shown to be positively correlated with a splice isoform of UCP3.[317] A unique polymorphism in the promoter region of UCP3 correlated with expression of UCP3 in skeletal muscle.[318]

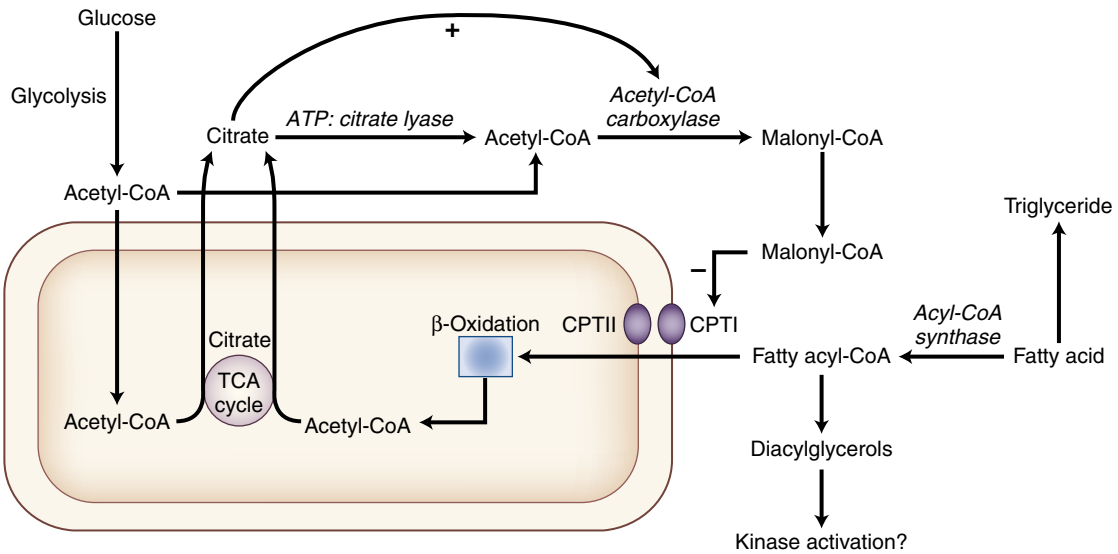
Glucose Influence on Skeletal Muscle Fatty Acid Metabolism

A concept that can help explain glucose elevations leading to the intramyocellular triglyceride accumulation associated with impaired insulin action is the central role of malonyl-CoA in regulating fatty acid and glucose oxidation[319] (see Fig. 34.11). Malonyl-CoA is an allosteric inhibitor of CPT1, the enzyme that controls the transfer of long-chain fatty acyl-CoAs into the mitochondria.[299,300,320] In the presence of elevated glucose and insulin levels, the TCA cycle is activated, resulting in an increase in citrate in the cytoplasm through increased malate cycling in the mitochondria. The increased citrate is converted to acetyl-CoA through citrate lyase and thus provides an indirect substrate for ACC. Citrate also allosterically activates ACC and makes ACC a better substrate for phosphatases that activate the enzyme.[321,322] Even in insulin-resistant skeletal muscle, glucose uptake into the skeletal muscle is higher than normal, especially at the elevated levels of glucose found in T2DM.[323,324] The glucose is shunted toward the glycolytic pathway, generating acetyl-CoA that can be converted to malonyl-CoA in the cytoplasm by the action of the highly regulated ACC. This has been demonstrated in humans where an infusion of insulin and glucose at a high rate leads to increases in the concentration of malonyl-CoA in skeletal muscle and to decreases in whole-body and, presumably, muscle fatty acid oxidation.[325]

ACC is also regulated by AMPK-mediated phosphorylation, which inhibits ACC basal activity and reduces ACC activation by citrate.[326] ACC then generates malonyl-CoA, which in turn allosterically inhibits CPT1 residing on the outer mitochondrial membrane, inhibiting uptake of acyl-CoA. The resulting buildup of long-chain acyl-CoAs and diacylglycerols is proposed to activate one or more PKC isoforms or other lipid-activated proteins, resulting in insulin resistance.[319] In support of this hypothesis, humans with obesity or T2DM show elevated intracellular malonyl-CoA levels associated with reduced ACC phosphorylation, impaired fatty acid oxidation, and accumulation of intramyocellular acyl-CoA and triglyceride, all of which can be reversed with a 3-month treatment with the insulin-sensitizer rosiglitazone.[327]

Circadian Rhythms, Obesity, and Insulin Resistance

Almost all mammals have a well-developed circadian cycle that is controlled by a complex, integrated network of transcription-translation feedback loops that work in a 24-hour cycle. A defined set



• **Fig. 34.11** Glucose effect on triglyceride metabolism. Increased uptake of glucose results in increased production of acetyl coenzyme A (acetyl-CoA) as a product of glycolysis. The increased tricarboxylic acid (TCA) cycle activity associated with oxidation of triglycerides and glucose increases the production of citrate, which is shuttled to the cytoplasm, activates the enzyme acetyl-CoA carboxylase (ACC) by allosteric mechanisms, and increases the susceptibility of ACC to phosphatases. This leads to increased ACC activity, converting acetyl-CoA to malonyl-CoA. Malonyl-CoA is a potent inhibitor of carnitine palmitoyltransferase (CPT) I on the outer mitochondrial membrane, which leads to accumulation of fatty acyl-CoAs in the cytoplasm. This may result in the production of signaling molecules that can increase the activity of kinases and other enzymes and lead to insulin resistance. *ATP,* adenosine triphosphate.

of genes establishes the circadian cycle, which sets behavioral and physiologic functions, including sleep-wake cycles, feeding behaviors, hormone secretion, and metabolism. The core circadian clock genes are present not only in the suprachiasmatic nucleus of the hypothalamus but also in nearly every cell of the body, where they activate specific sets of genes.[328] In mammals, the clock is driven by two transcription factors, CLOCK (circadian locomotor output cycles kaput) and BMAL1 (brain and muscle aryl hydrocarbon receptor nuclear translocator (ARNT)-like 1).[329] CLOCK and BMAL1 dimerize and bind the promoter region of target genes, including period (PER) and cryptochrome (CRY). The increased levels of these proteins promote heterodimerization and translocation to the nucleus, creating a negative feedback loop by suppressing transcriptional activity of CLOCK-BMAL1. In a second negative feedback loop, CLOCK-BMAL1 induce REV-ERBα (encoded by the nuclear receptor subfamily 1, group D, member 1 gene, *NR1D1*), which in turn suppresses BMAL1 transcription. Additional modulation of the activity and stability of these proteins is provided by post-translational modifications such as phosphorylation and ubiquitination.

There are significant epidemiologic associations in humans between reduction of sleep and increased rates of obesity and other metabolic disturbances, including T2DM.[330] Experimental sleep disruption can directly impair insulin action, alter secretion of leptin and ghrelin resulting in stimulation of appetite, increase inflammatory cytokine production, and create alterations in other cardiovascular risk factors. Alterations in normal feeding patterns that are attuned to circadian metabolism can change the relationship between nutrient appearance and nutrient-metabolizing enzymes. For instance, alterations in fatty acid appearance and lipoprotein lipase activity can lead to altered partitioning of lipids to vulnerable tissues, leading to lipotoxicity and decreased secretion of leptin, increasing appetite.[331] Obstructive sleep apnea, which combines sleep fragmentation and hypoxemia, is also a risk factor for insulin resistance and diabetes. There is growing evidence that glucose control in patients with T2DM patients can be improved by treating sleep apnea, although poor compliance to therapy is a major barrier to success.[332]

Role of the Gut Microbiome and Metabolome in Diabetes and Insulin Resistance

There is growing evidence that a major mediator of the effect of diet and other environmental factors in diabetes is the gut microbiome—or, more specifically, the bacteria that reside in the gastrointestinal tract.[333] In mammals, the gut microbiome is seeded at birth; it is reformed during infancy and then becomes relatively stable in adulthood, although it can be remodeled by diet, antibiotics, and a variety of disease states. Most gut microbiota are viewed as commensal (nonharmful) or mutualistic (providing benefit) to the host. These microbes play important roles in nutrient, xenobiotic, and drug metabolism, maintenance of gut mucosal integrity, protection against pathogens, and immunomodulation, and, through these basic functions, affect many aspects of normal physiologic function. Over the past decade, it has become clear that the gut microbiome can also contribute to obesity, diabetes, metabolic syndrome, and insulin resistance in both rodents[334-336] and humans,[337-340] and act as an integrator and mediator of some of the effects of genetics, diet, and bariatric surgery.[341-344] In mice, it has been shown that administration of low-dose antibiotics early in life may predispose to obesity and glucose intolerance by perturbing the development of a normal microbiome.[345]

The mechanisms by which gut microbiota may affect pathogenesis of diabetes, obesity, and insulin resistance are multiple (Fig. 34.12). Gut microbiota have major effects on intestinal barrier function, breakdown of otherwise indigestible dietary components, modification of bile acids and other substances, development of the gut, and education of the immune system.[333,346] These effects can lead to a release of bacterial proteins, endotoxins, and cytokines into the bloodstream,[347,348] as well as produce changes in hundreds of metabolic products, including bile acids, short-chained fatty acids, amino acids, and many other classes of molecules.[343,349-354] Together, these lead to tissue-specific metabolic dysregulation and immune activation, leading to insulin resistance and progression of diabetes pathogenesis. Several metabolites have been shown to correlate with insulin resistance in both mice[355] and humans,[356] and some, such as 2-aminoadipate, α-hydroxybutyrate, and *N*-acetylglycine, are suggested to be biomarkers of T2DM.[357-359] Further studies will be needed to determine exactly how gut microbiota affect insulin sensitivity and diabetes progression, and whether therapies that change gut microbiota can be used to treat or prevent T2DM. In this regard, several options are possible, ranging from administration of prebiotics (nutrients that change the composition of gut microbiota), probiotics (mixtures of bacteria themselves), and even transplant of a healthy microbiome by fecal transfer.

Special Conditions That Induce Insulin Resistance

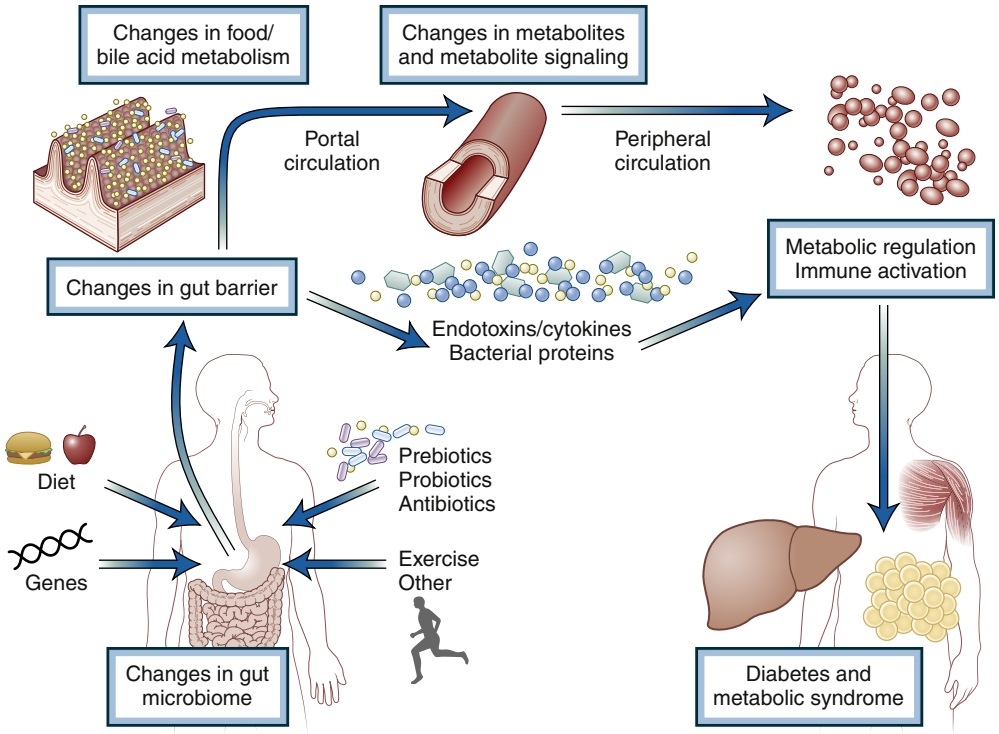
Gestational Diabetes

Diabetes diagnosed during pregnancy is categorized as either preexisting T2DM if diagnosed during the first trimester of pregnancy or gestational diabetes if diagnosed during the second or third trimester.[5] Although gestational diabetes generally resolves with the end of the pregnancy, it is considered a significant risk factor for the future development of T2DM.[360,361] Insulin resistance is a normal consequence of pregnancy. As the pregnancy progresses and insulin resistance builds, maternal insulin secretion increases by as much as 250% to compensate. When this compensation is inadequate, gestational diabetes develops.[362] Pre-pregnancy obesity is a major risk factor for the development of gestational diabetes.

The driver of insulin resistance in pregnancy is not simply the weight gain of pregnancy, as euglycemia generally returns within days of delivery. Rather, placenta-derived factors are believed to drive both the insulin resistance of pregnancy and the beta-cell expansion of pregnancy. Exactly what placental factors contribute remains debated because there are significant differences in beta-cell physiology between rodents and humans, and intervention studies of pregnant patients are challenging.[363] Placenta-derived growth hormone is one hormone that contributes to maternal insulin resistance but can account for only a portion of the change.[364] Other candidates that may contribute include placental lactogen[365,366] and placenta-derived pro-inflammatory exosomes.[367]

Drugs and Stress-Induced Insulin Resistance

In addition to the genetic and epigenetic risk factors discussed previously, there are many disease states and medications that can induce insulin resistance or a combination of insulin resistance and decreased insulin secretion leading to glucose intolerance (Table 34.2).



• **Fig. 34.12** The gut microbiome is impacted by our genes and environment. Changes to the gut microbiome may result in altered gut barrier function and food and bile acid metabolism, leading to immune activation and insulin resistance.

TABLE 34.2 Drugs and Stressors Associated With Insulin Resistance

Drugs

Glucocorticoids
Human immunodeficiency virus medications (all cause varying degrees of metabolic abnormalities)
Calcineurin inhibitors
Mammalian target of rapamycin (mTOR) inhibitors
Phosphoinositide 3-kinase inhibitors
Statins

Stressors

Pregnancy
Glucotoxicity
Surgery
Inflammation (from obesity or infection)
Overnutrition

Glucocorticoid-Induced Insulin Resistance

Cushing syndrome and exogenous glucocorticoid treatment have long been known to induce significant insulin resistance in humans. More than 80% of nondiabetic individuals with rheumatoid arthritis treated with greater than 30 mg/day of prednisone have an increase in their hemoglobin A_{1c}. The mechanism is multifactorial. There are rapid effects related to increasing hepatic glucose production, which occurs via increased gluconeogenesis, as well as acute insulin resistance in skeletal muscle, in part due to downregulation of IRS1.[368] Glucocorticoids also have tissue-specific effects in vivo, because 24-hour treatment of humans with hydrocortisone enhances adipose tissue insulin sensitivity while whole-body insulin sensitivity declines.[369] Tissue crosstalk is important in glucocorticoid-induced insulin resistance: a mouse model lacking glucocorticoid receptors specifically in adipose tissue retains some muscle insulin sensitivity in response to chronic dexamethasone.[370] Long-term glucocorticoid treatment also results in redistribution of fat from the periphery to the central compartment, increased lipolysis and elevations in triglyceride and fatty acid, and a reduction in insulin secretion. There is also increased muscle protein breakdown leading to muscle atrophy and alterations in skin integrity. These effects are due to a combination of modulation of transcriptional events by glucocorticoids and through inhibition of insulin and growth factor signaling.

Post-Transplant Diabetes Mellitus

Patients receiving organ transplants frequently develop IGT or post-transplant diabetes mellitus (PTDM) following the transplant, related to the immunosuppressive regimens. Most patients become transiently hyperglycemic immediately post-transplant due to the stress of surgery and high doses of corticosteroids; thus, diagnosis of PTDM should not be made until the patient has been discharged from the hospital and is on a stable immunosuppressant dose.[371] Consensus recommendations discourage the use of hemoglobin A_{1c} for PTDM screening during the first year following transplant due to significant changes in red blood cell turnover, which can result in missed cases. The doses and drug combinations used in transplant vary by organ but frequently include chronic use of medications that impair glucose metabolism, such as glucocorticoids, mTOR inhibitors (sirolimus and everolimus), and calcineurin inhibitors (tacrolimus and cyclosporine).

The primary mechanism for glucocorticoids and mTOR inhibitors is via induction of insulin resistance. Glucocorticoids

are discussed earlier. mTOR inhibitors induce insulin resistance via inhibition of the mTOR complex downstream of the insulin receptor (see Fig. 34.8). It seems that this inhibition is not enough to cause diabetes in low-risk patients but can induce diabetes in those with risk factors, particularly if used in combination with calcineurin inhibitors.[372] Calcineurin inhibitors appear to contribute to diabetes predominantly by decreasing insulin secretion.[373] This is a result of decreased insulin synthesis and reduced glucokinase activity.[374,375] There is also some evidence for increased insulin resistance in patients treated with calcineurin inhibitors; however, these data are mixed, possibly reflecting increased insulin resistance only in those with underlying risk factors.[372]

Inflammation and Inflammatory Cytokines

Obesity is associated with increased inflammation in adipose tissue, including macrophage infiltration and increased cytokine expression. Inflammation and cytokines drive insulin resistance.[376] This occurs through multiple mechanisms. Studies in humans and in animal models of obesity have identified decreases in the number and the kinase activity of insulin receptors and impairment in the activation of IRS1, PI3K, and Akt. These changes are driven, in part, by increased levels of cytokines, such as TNFα, which is made and secreted by adipocytes, as well as the infiltrating macrophages. TNFα administration reduces the kinase activity of the insulin receptor in rats[377] or in 3T3L1 adipocytes in vitro,[378] possibly by increased activity of JNKs and IKKs, and increased serine phosphorylation of the insulin receptor and IRS1.[379] High fat–fed mice with genetic ablation of TNFα production and rats treated with neutralizing antisera or soluble TNF receptors have increased kinase activity of the insulin receptor,[380,381] indicating increased insulin sensitivity. However, thus far, interventions to decrease TNFα action in humans have had little or no effect in reducing the insulin resistance of obesity or T2DM.[382,383]

Human Immunodeficiency Virus Infection

With the advent of effective medications to manage the infection, human immunodeficiency virus (HIV) infection has become a chronic disease. However, these medications are associated with significant metabolic risk. In a cohort of more than 3800 patients, there was nearly a doubling in the prevalence of T2DM in HIV versus non-HIV patients. A significant portion of this increase may be related to protease inhibitors used to treat chronic HIV. HIV-infected patients also have a 75% increase in the risk for acute myocardial infarction compared with uninfected patients, again related to protease inhibitor use. Other contributing factors to cardiometabolic risk were male sex, diagnosis of acquired immunodeficiency syndrome, responsiveness to antiretroviral treatment, and increases in CD4 T-cell counts.[384]

Both lipoatrophy and lipohypertrophy are seen in HIV-infected patients on antiretroviral therapy. Lipoatrophy is primarily associated with the use of the older thymidine analogue nucleoside reverse transcriptase inhibitors, whereas the contributors to lipohypertrophy are not as well understood.[385] In the setting of multidrug HIV treatment regimens and frequent changes to therapy, it is difficult to determine the relative contributions of individual drugs to metabolic syndrome or distinguish the drug effect from the metabolic consequences of adipose tissue redistribution.

There appear to be multiple mechanisms contributing to metabolic syndrome in HIV. The effects of the major HIV treatments are reviewed in detail by Srinivasa and Grinspoon[384] In brief, several protease inhibitors can inhibit glucose transport in vitro and in vivo, possibly through interaction with the insulin-responsive glucose transporter GLUT4 that could inhibit glucose uptake specifically in insulin-responsive tissue.[386] Mitochondrial abnormalities have been described in adipose tissue biopsy specimens obtained from HIV-infected patients with lipodystrophy, including reductions in mitochondrial number and oxidative function in adipocytes from patients treated with highly active antiretroviral therapy.[387,388] A direct effect of protease inhibitors on differentiation of adipocytes has also been described.[389,390] In adipose tissue of treated HIV patients, especially those with lipodystrophy, there is downregulation of the microRNA-processing enzyme Dicer. This is associated with decreased levels of circulating exosomal microRNAs, which may also contribute to insulin resistance.[391,392]

Treatment of HIV-associated lipodystrophy continues to be inadequate, although the incidence may be less with use of newer protease inhibitors. Switching from thymidine analogues has been shown to improve lipoatrophy in some patients.[393] Treatment with insulin-sensitizing thiazolidinediones has shown mixed results, with improvement in insulin sensitivity but little alteration in fat distribution.[394] Because of the increased risk of cardiovascular disease, treatment of hyperlipidemia is essential in these patients. Treatment guidelines do not differ from the general population; however, current cardiac risk predictors underestimate risk in HIV-infected patients.[395] Tesamorelin, a growth hormone–releasing hormone analogue, is approved to treat abnormal lipids associated with HIV lipodystrophy. The medication causes a modest redistribution of visceral fat with subsequent improvement in the lipid profile.[396]

Statins

The medications and disease states discussed earlier may have profound effects on insulin resistance and glycemia; however, there are other factors that will have much smaller, but potentially significant, impacts on a population basis. One example is the statin class of cholesterol-lowering drugs. These medications do not cause an appreciable change in blood glucose in individual patients, but large clinical trials have demonstrated an increased risk for developing T2DM in patients treated with a statin.[406] Given the multifactorial nature of insulin resistance and T2DM, it is likely that other medications will also increase the risk of T2DM in the right setting of genetic predisposition and environmental factors.

Glucotoxicity, Glucosamine

Hyperglycemia itself can cause insulin resistance, as well as decreased beta-cell function. In Pima Indians, the level of fasting glycemia is strongly correlated with insulin sensitivity.[397] This defect is primarily in skeletal muscle,[398] but its exact mechanism remains controversial.

On entry into cells, glucose is converted to glucose 6-phosphate, which has multiple metabolic fates. The hexosamine pathway is a relatively minor branch of the glycolytic pathway, encompassing less than 3% of total glucose used. Hexosamines, such as glucosamine, when incubated with adipose tissue, induce insulin resistance in fat cells[399] and in skeletal muscle.[400] Infusion of glucosamine into rats resulted in a dose-dependent increase in insulin resistance of skeletal muscle,[400] and transgenic mice that overexpress the rate-limiting enzyme glutamine–fructose-6-phosphate aminotransferase specifically in skeletal muscle acquired severe insulin resistance.[401] By a pathway that is unclear, glucosamine overproduction resulted in a disruption of the ability of insulin to cause translocation of GLUT4 to the cell surface.[402] Through its anti-insulin action, the hexosamine

pathway has been hypothesized to be a glucose sensor that allows the cell to sense and adapt to the prevailing level of glucose.[398]

Postoperative Hyperglycemia

Surgery is a significant stress to the body. This is driven by the surgical wound, anesthesia, and pain, all of which can stimulate the release of stress hormones, including cortisol, epinephrine, and norepinephrine. In addition, particularly following coronary bypass surgery, the use of pressors is common and can cause severe hyperglycemia. Postoperative hyperglycemia predicts mortality in nondiabetic patients following coronary bypass or general surgery.[403,404] Aggressive treatment of postoperative hyperglycemia, with a target blood glucose of between 140 and 180 mg/dL for both diabetic and nondiabetic patients, has been shown to reduce both wound infections and mortality following surgery.[5]

Epinephrine is one of the key mediators of postoperative hyperglycemia. This can be both endogenously derived and delivered through infusions. Epinephrine acts to increase blood glucose through several mechanisms. These include decreased insulin secretion and increased insulin resistance both in muscle and in the liver, where it leads to a failure to suppress hepatic glucose production.[405] When epinephrine infusions are used in an acute care setting, adjustments in the insulin infusion rate are generally necessary due to the rapid and substantial impact of this medication.

Therapeutics of Type 2 Diabetes Mellitus

MATTHEW C. RIDDLE AND ANDREW J. AHMANN

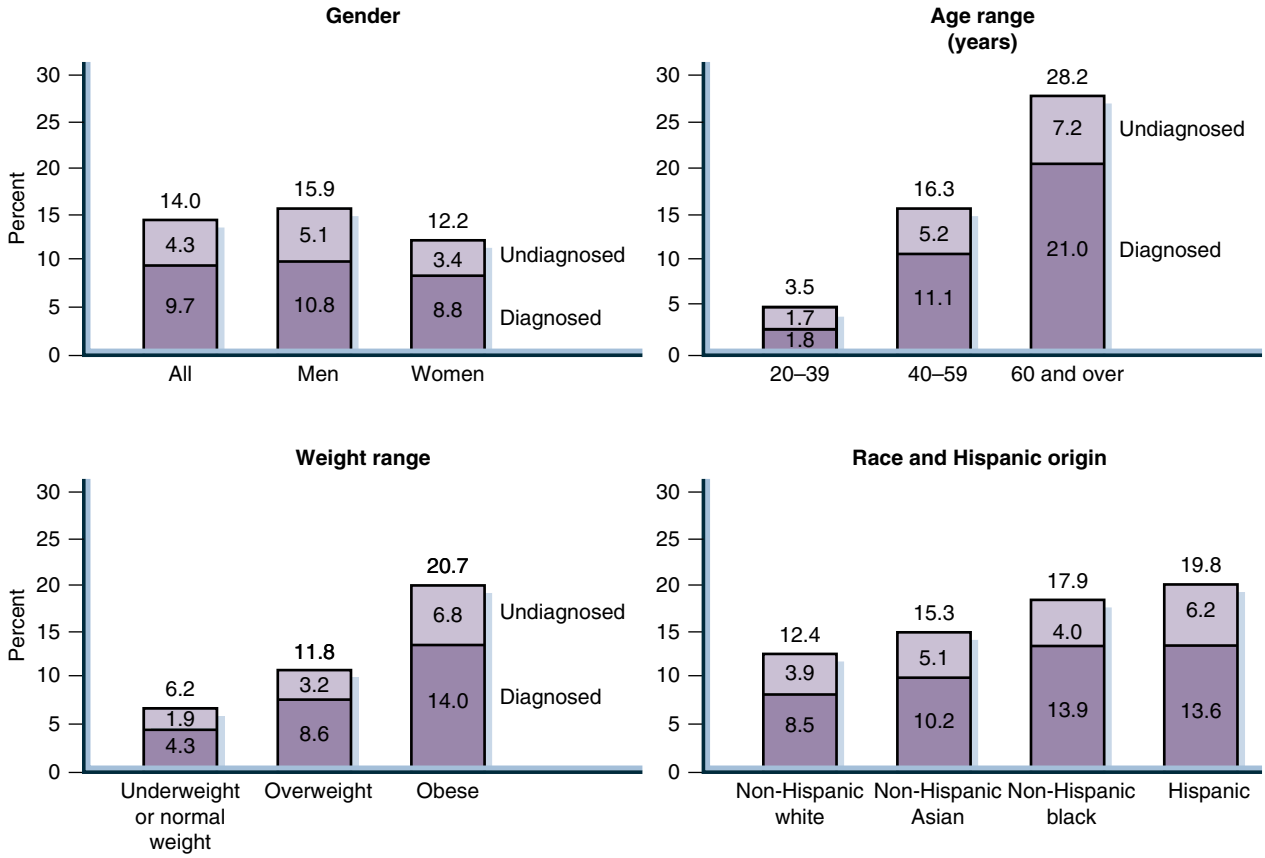
CHAPTER OUTLINE

KEY POINTS

- Type 2 diabetes mellitus (T2DM) is a major public health problem. The World Health Organization estimated in 2014 that 422 million people had diabetes worldwide, and a continuing increase is projected.
- T2DM is the predominant form of diabetes worldwide, accounting for 90% of cases globally.
- The pathogenesis of T2DM is complex and involves the interaction of environmental and genetic factors.
- Environmental factors that contribute to development of T2DM include excessive caloric intake and a sedentary lifestyle leading to obesity.
- Genetically, T2DM includes monogenic and polygenic forms, and some monogenic forms require a specific approach to treatment.
- The typical person developing T2DM is in late middle age and overweight or obese, but the clinical presentation is heterogeneous, with a wide range in age at onset, degree of obesity, and severity of associated hyperglycemia.
- Uncontrolled hyperglycemia is associated with eye, nerve, kidney, and cardiovascular complications that reduce both the quality of life and years of life expectancy.
- Fortunately, hyperglycemia is a modifiable risk factor.
- Attention should also be focused on additional cardiovascular risk factor management.
- Significant advances have been made in the treatment of patients with T2DM over the past 20 years, and a large number of treatment options are available.
- Metformin as initial therapy in combination with diet, exercise, and comprehensive diabetes education effectively lowers glucose with essentially no risk of hypoglycemia.
- If the response to metformin is inadequate initially or subsequently, one or more other agents can be added. There are six recommended second-line therapies: thiazolidinedione, sulfonylurea, dipeptidyl peptidase-4 (DPP4) inhibitor, sodium-glucose cotransporter (SGLT) inhibitor, glucagon-like peptide-1 (GLP1) receptor agonist, and basal insulin. Each has its advantages and disadvantages.
- A team approach to management greatly improves success, especially for patients with diabetes longer than 10 years and therefore requiring greater complexity and personalization of therapy.

Epidemiology

Type 2 diabetes mellitus (T2DM) is the predominant form of diabetes worldwide, accounting for 90% of cases. An epidemic of T2DM is underway in both developed and developing countries, although the brunt of the disorder is felt disproportionately in non-European populations. In the Pacific island of Nauru, diabetes was virtually unknown 50 years ago, but the prevalence among adults rose to nearly 40% before a recent slight decline. The highest prevalence rates remain in Micronesia at 23% to 35%.[1,2] It is projected that South Asia will see a 150% increase in adult diabetes from 2000 to 2025.[3] The International Diabetes Federation (IDF) projects that global prevalence will increase from an estimated 150 million in 2000 and 415 million in 2015 to nearly 600 million by 2035.[2,4] Along with this increase of prevalence, the economic burden of diabetes is expected to rise as well.[5] In the United States, the Centers for Disease Control and Prevention (CDC) has estimated that in 2016 14% of the adult population had diabetes, and 30.7% of those with diabetes were undiagnosed.[6] As shown in Fig. 35.1, among those with diagnosed diabetes, prevalence varied by ethnicity from 8.5% in non-Hispanic white to 10.2% in non-Hispanic Asian, 13.6% in Hispanic, and 13.9% in non-Hispanic black subpopulations.[6] Moreover, 33.9% of US adults (84.1 million) were estimated to have prediabetes and thus be at high risk for developing diabetes.[7] Based on epidemiologic



• **Fig. 35.1** Demographic factors, including gender, age, weight, and race, affecting prevalence of diabetes in adults in the United States in 2013–2016. (Data from Centers for Disease Control and Prevention. National Diabetes Statistics Report, 2017. https://www.cdc.gov/diabetes/pdfs/data/statistics/national-diabetes-statistics-report.pdf.)

trends, for those born in the United States in 2000, the estimated lifetime risk of developing diabetes is 32.8% for men and 38.5% in women.[8]

The metabolic abnormalities of T2DM lead to illness, disability, and early mortality. In the United States, diabetes is the leading cause of blindness and accounts for at least 40% of end-stage renal disease. The risk of heart disease and stroke is commonly stated to be two to four times higher, and that of lower-extremity amputation is approximately 20 times higher for people with diabetes than for those without diabetes. Life expectancy is reduced by approximately 10 years in people with diabetes, and the hazard ratio for death is most pronounced in those having diabetes under age 55 years.[8–10] Although diabetes is considered the seventh leading cause of death in the United States, this figure is surely an underestimate because many illnesses identified as causes of death are in fact complications of diabetes. Only about 35% to 40% of those who die with diabetes have the disease listed anywhere on the death certificate, and 10% to 15% have it listed as the underlying cause of death. Rates of morbidity and mortality differ between countries for various reasons, but the overall patterns are very similar.

Thus, mainly through its long-term complications, T2DM causes a serious burden of illness, much of which might be delayed or prevented by treatment. There is evidence that rates of some complications of diabetes have indeed declined recently. Data from the United States suggest a reduction by 50% or more between 1990 and 2010 for myocardial infarction (MI), stroke, amputations, and death from hyperglycemic crisis, and end-stage renal disease declined approximately 30%.[11] Amputations experienced the greatest relative reduction. However, there are reasons for concern. Although incidence rates have decreased in the United States in the last decade, prevalence rates will continue to be high. More individuals are being diagnosed with T2DM at a younger age, and the complications of diabetes will be occurring more often in middle-aged adults with a prevalence that will cause a significant personal and societal burden.[10]

The economic effect of diabetes is enormous. Recent estimates suggest the worldwide cost of diabetes to be $1.31 trillion, with anticipated increases from 1.8% of the global gross domestic product to 2.2% by 2030, with total costs of $2.2 trillion.[5] Costs directly attributed to diabetes in the United States in 2017 were $327 billion with average expenditures per person, adjusted for age and gender, 2.3-fold higher than in the nondiabetic population.[12] These costs increased by 26% between 2012 and 2017. They result from the complications of diabetes, comorbid conditions, costs of medications, and the frequency of visits, as well as from missed work, reduced productivity, and premature mortality.[12]

Considerable information is available on factors underlying the development of T2DM.[13–18] Overt diabetes is thought to occur mainly in genetically predisposed persons who are exposed to various environmental influences that precipitate the onset of clinical disease. The syndrome consists of monogenic and polygenic forms that can be differentiated both on clinical grounds and in terms of the genes involved in pathogenesis. Greater adiposity

TABLE 35.1 Criteria for Diagnosis of Prediabetes and Diabetes

Measurement	Units	Diagnostic of Prediabetes	Diagnostic of Diabetes[a]	Comments
Fasting plasma glucose (FPG)	mg/dL mmol/L	100–125 5.6–6.9	≥126 ≥7	After no calorie intake at least 8 hours
2-hour plasma glucose (2-hour PG)	mg/dL mmol/L	140–199 7.8–11	≥200 ≥11.1	2 hours after 75 g oral glucose
Random plasma glucose	mg/dL mmol/L	Not applicable	≥200 ≥11.1	Without oral glucose but with classic symptoms
HbA_{1c}	% mmol/mol	5.7–6.4 39–47	≥6.5 ≥48	Measured in certified laboratory

[a]In the absence of unequivocal hyperglycemia, results should be confirmed by repeat testing.

Data from American Diabetes Association. Classification and diagnosis of diabetes. Standards of medical care in diabetes, 2018. *Diabetes Care*. 2018;41:S13–S27.

and restricted physical activity are important factors in determining the risk of developing T2DM. The disorder is more common in men, and the increased prevalence in certain racial and ethnic groups has already been mentioned.[6] As in the past the risk of onset of T2DM increases steadily with age, but in recent years the prevalence in children has risen dramatically, presumably due to increasing obesity. Previously, an overwhelming majority of children with diabetes had type 1 diabetes mellitus (T1DM), and less than 2% were considered to have T2DM or other rare forms of diabetes. More recent reports suggest as many as 20% to 25% of children in the United States with newly diagnosed diabetes have T2DM, with the proportions highest among children of non-European ancestry diagnosed between age 10 and 19 years.[19]

Diagnostic Criteria

The diagnosis of diabetes rests on demonstration of hyperglycemia. Because plasma glucose concentrations range as a continuum, the criteria are based on estimated thresholds for the complications of diabetes. The primary endpoint used to evaluate the relationship between glucose levels and complications is retinopathy. All three commonly used tests—fasting plasma glucose (FPG), 2-hour plasma glucose after a 75-g oral glucose load (2-hour PG), and glycated hemoglobin A_{1c} (HbA_{1c})—predict the presence of retinopathy and, by inference, define the glucose levels that are diagnostic of diabetes.[20] There is a relationship between elevated levels of all three markers and nephropathy, neuropathy, and cardiovascular disease as well as retinopathy.

Current criteria for the diagnosis of prediabetes and diabetes are shown in Table 35.1.[21]

When the present fasting glucose and glucose tolerance test parameters were defined for diagnosing diabetes in 1997 according to the levels associated with an increase in retinopathy, measurement of HbA_{1c} was recognized as a viable alternative but not recommended for diagnostic purposes because assays were not reliably standardized.[22] Current HbA_{1c} assays are standardized and have several technical advantages over the other currently used laboratory measurements of glucose. Furthermore, measures of fasting and post-challenge glucose concentrations in the same individual over time are less reproducible than those for HbA_{1c}. In one study, the coefficient of variation for measurements repeated in single individuals was 6.4% for fasting plasma glucose and 16.7% for 2-hour plasma glucose values, and less than 2% for HbA_{1c}.[20] Use of HbA_{1c} has the added advantage of simplicity in not requiring timing of collection, and it is generally a more stable measure of average glucose control. It has also been shown to be a good indicator of prediabetes with an ability to predict development of T2DM.[23,24] Nevertheless, the HbA_{1c} level is misleading in some situations, and discrepancies must be evaluated.[25–27]

Although the oral glucose tolerance test (OGTT) is very useful for research, it is not recommended for routine use in diagnosing diabetes. It is generally inconvenient, and in most cases the diagnosis can be made by either an elevated fasting plasma glucose concentration, an elevated random glucose determination in the presence of hyperglycemic symptoms, or confirmed elevation of HbA_{1c}. The various glycemic parameters do not always correlate to make the diagnosis. It is possible to see a diagnostic elevation of plasma glucose while the HbA_{1c} is below 6.5% or vice versa. A confirmatory test by the same or a different method is usually required to confirm the diagnosis.[21]

General Approaches to Management

Over the past 20 years a transformation in population-based management of T2DM has occurred. Understanding of the lifetime trajectory of this illness has improved, and there is now greater urgency to identify individuals at risk, make the diagnosis in a timely way, and intervene systematically over time to improve medical outcomes while minimizing risks associated with therapy. The hyperglycemia that defines diabetes is accepted as a modifiable risk factor for microvascular (eye, kidney, and nerve) complications and, to a lesser degree, cardiovascular outcomes.[28–32] The variable but sometimes long delay between appearance of the metabolic abnormalities of diabetes and these complications is now more fully appreciated. Many additions to the available array of pharmacologic agents and monitoring devices have made it possible to lower glucose levels safely to nearly normal ranges in a majority of patients.

In this chapter we address the main features of the diagnostic strategies, treatment guidelines, lifestyle interventions, and pharmacotherapeutic agents before discussing clinical decisions and special considerations in management. The *Clinical Practice Recommendations* of the American Diabetes Association (ADA) is an excellent source of additional information on these matters. It is published each January as a supplement to the journal *Diabetes Care* and is available in a periodically updated version online.[33]

assessment and intervention.[34] This evolution of the disorder over time suggests division of interventions into three categories that are most relevant at specific intervals.

Public Health Measures

For the interval prior to diagnosis, public health interventions are possible. These may include administrative or regulatory efforts to educate families about risks of obesity and diabetes, promote healthful lifestyles, and restrain marketing and distribution of unhealthful foods. Efforts can be made to promote desirable lifestyle choices for at-risk individuals in the setting of primary medical care. A public health approach also includes screening to identify emergence of hyperglycemia as soon as possible.[35]

Primary Care Management

Individuals known to have prediabetes do not routinely require glucose-lowering pharmacotherapy, but attention to other modifiable cardiovascular risk factors is always appropriate.[36] (See the upcoming section regarding diabetes prevention in patients with prediabetes.) More specific medical interventions are needed at the time of diagnosis of overt T2DM.[37] Because the development of tissue complications is related to both the severity and duration of hyperglycemic exposure, the goal of therapy is to maintain glycemic control as close to normal levels as is safely possible from the start. Initial therapy includes enhanced lifestyle efforts together, in most cases, with pharmacotherapy.[33,38] Drug treatment can initially be given in a standardized and relatively simple way, based on medical evidence for both benefits and risks. This approach is most effective in the first 10 years after diagnosis.

Complex Diabetes Care

Progression of the pathophysiologic abnormalities underlying T2DM typically leads to increasing difficulty in controlling hyperglycemia over time. At the same time, an increasing burden of medical illness, both diabetes related and from other causes, adds to potential risks and may limit potential benefits of intensive therapy. By 10 years after diagnosis, progression of the disorder commonly leads to a need for multiple and often injected therapies, more personalized choices of therapies, and greater reliance on treatments with less well-understood long-term benefits versus risks. How to provide these more complex and time-consuming services is one of the dilemmas of health system management. In general, the best results are obtained by access to a specialized team approach.

Screening

As noted, the prevalence of T2DM in the United States and elsewhere continues to increase. The increasing burden of diabetes is driven by aging of the population; by population growth, particularly among ethnic groups with greater susceptibility to the disease; and by increasing obesity related to increasingly sedentary lifestyles and greater consumption of simple sugars, fats, and highly processed calorie-dense foods. Opportunistic screening in high-risk populations is recommended by professional societies and many insurers. In the United States the proportion of people with diabetes who have been diagnosed has increased from approximately 50% in the 1990s to about 70% today.[6] Nonetheless, undiagnosed T2DM is still common. People with undiagnosed T2DM have approximately twofold greater risk for coronary heart disease,

stroke, and peripheral vascular disease. Delay in the diagnosis of T2DM allows hyperglycemia to remain untreated for a period of time, resulting in an increase in microvascular and macrovascular disease. Affected individuals also have a greater likelihood of having dyslipidemia, hypertension, and obesity, all of which are modifiable risk factors for cardiovascular disease. Therefore it is desirable to screen individuals who demonstrate major risk factors for diabetes, as summarized in Table 35.2.

Recent modeling studies based on the US population suggest that universal screening coupled with guideline-based therapy for T2DM is cost effective when initiated between the ages of 30 and 45 and subsequently conducted every 3 to 5 years.[39] In a systematic review of 16 studies, people with an HbA_{1c} of 6% to 6.5% have a 25% to 50% likelihood of developing diabetes within 5 years, a 20-fold excess risk compared to those with an HbA_{1c} of 5%.[40] A more recent study of American Indians found similar predictive value for HbA_{1c} in children and adolescents.[23]

TABLE 35.2 Criteria for Testing for Prediabetes or Diabetes in Asymptomatic Adults

1. Testing should be considered in overweight or obese adults (body mass index ≥25 kg/m² or ≥23 kg/m² in Asians) who have one or more of the following risk factors:
   - First-degree relative with diabetes
   - High-risk ethnicity (e.g., African, Latino, Native American, Asian, Pacific Islander)
   - History of cardiovascular disease
   - Hypertension (blood pressure [BP] ≥140/90 mm Hg or using BP-lowering therapy)
   - High-density lipoprotein cholesterol <35 mg/dL (<0.90 mmol/mol) and/or triglycerides >250 mg/dL
   - Women with polycystic ovary syndrome
   - Physical inactivity
   - Other conditions associated with insulin resistance (e.g., severe obesity, acanthosis nigricans)
2. Patients with prediabetes—test yearly
3. Women with prior gestational diabetes—test at least every 3 years
4. All other people—begin testing at age 45
5. If results are normal—repeat testing at least every 3 years

Interventional Study Results

Prospective, randomized clinical trials have documented reduced rates of microvascular complications in patients with T2DM treated to lower glycemic targets. In the United Kingdom Prospective Diabetes Study (UKPDS),[28,41] patients with new-onset diabetes were treated with diet and exercise for 3 months, with an average reduction in HbA_{1c} from approximately 9% to 7%, still somewhat above the upper limit of the normal range. Patients with fasting plasma glucose remaining greater than 108 mg/dL (6 mmol/L) were then randomly assigned to two treatment policies. In the "conventional" intervention, participants continued lifestyle therapy alone. Pharmacologic therapy was initiated only if fasting plasma glucose reached 270 mg/dL (15 mmol/L) or the patient became symptomatic. In the "intensive" treatment arm, all patients were assigned to treatment with either a sulfonylurea or basal insulin as initial therapy, with the dose increased with the aim of maintaining fasting plasma glucose less than 108 mg/dL. Combinations of agents were used only if the patient became symptomatic or fasting plasma glucose rose to greater than 270 mg/dL. In a secondary study within the UKPDS a similar comparison was made between lifestyle alone and metformin as the intensive intervention for participants who were overweight or obese.[41]

As a consequence of the design, which aimed to test the effects of therapy with only one class of glucose-lowering agents, HbA_{1c} fell initially to about 6% but gradually rose to approximately 8% over 10 years of randomized treatment. During that time the median HbA_{1c} in the conventional treatment group was approximately 1 percentage point higher than with the active treatments. Hypoglycemia needing assistance in the group treated with a sulfonylurea or insulin occurred between 1% and 5% per year in the first few years, with the highest rates seen with glyburide. Weight gain was modest in all groups but higher in patients assigned to sulfonylurea or insulin and lower in those receiving metformin.[41] Associated with this improvement in glycemic control, there was a significant 25% reduction in the risk of microvascular complications (retinopathy, nephropathy, and neuropathy) in the group assigned treatment with a sulfonylurea or insulin (Table 35.3). Although there was also a trend toward a reduced rate of MI with sulfonylurea or insulin, it did not reach statistical significance ($p = 0.052$).[28] In the metformin part of the study, more consistent improvements were found (Table 35.4). Metformin treatment was associated with a nonsignificant 29% reduction

of microvascular disease, but there were statistically and clinically significant reductions of any diabetes-related endpoint (32%), MI (39%), and all-cause mortality (36%).

Similar reductions in microvascular events were observed in the Kumamoto study, a trial of somewhat different design and much smaller size. Japanese patients of normal weight with T2DM receiving insulin were randomly assigned to standard treatment or an intensive program of insulin therapy designed to achieve normal glycemia. The control group maintained HbA_{1c} values at approximately 9%, whereas the HbA_{1c} in the intensive therapy group was reduced to approximately 7%, and the separation was maintained for 6 years. Again, there was a modestly increased risk of hypoglycemia and weight gain, a reduction in microvascular complications, and a (not statistically significant) trend toward reduced rates of cardiovascular events.[42]

In 2008, three studies examining the effects of two levels of glycemic control on cardiovascular endpoints in T2DM were reported. Action to Control Cardiovascular Risk in Diabetes (ACCORD),[43] Action in Diabetes and Vascular Disease—Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE),[44] and the Veterans Affairs Diabetes Trial (VADT)[45] each randomized middle-aged and older individuals who were selected for having high risk for cardiovascular events. Participants randomized to intensive treatment in ACCORD and VADT aimed for an HbA_{1c} target of less than 6% using complex combinations of oral agents and insulin. In ADVANCE the HbA_{1c} target was 6.5% or less using a somewhat less intensive approach based on the addition of the sulfonylurea gliclazide. None of the trials demonstrated a statistically significant benefit in combined cardiovascular endpoints. In ACCORD a 22% increase in total mortality accompanied intensive therapy. Modest improvements in some microvascular endpoints were documented in all three trials. Some secondary analyses of these trials suggested that people without clinical cardiovascular disease and with shorter duration of disease and lower baseline HbA_{1c} had better outcomes with the more intensive glucose-lowering strategies. Meta-analysis of the randomized trials confirmed statistically and clinically significant microvascular benefits from intensive treatment. The same analysis suggested that an average HbA_{1c} reduction of 0.9% correlates with a 17% reduction in nonfatal MI and a 15% reduction in coronary heart disease without significant effects on stroke or all-cause mortality rate. However, there was significant heterogeneity in the results with respect to mortality rates across trials, the cause of which is still unknown.[46]

Continued follow-up of the UKPDS cohort, during which the difference in glycemic control was not maintained, demonstrated that the relative benefits of more intensive management of glucose noted at the end of 10 years of randomized treatment persisted during 10 more years of observation[29] (see Tables 35.3 and 35.4). By 20 years after enrollment, sulfonylurea or insulin treatment still showed a significant 24% relative risk reduction for microvascular outcomes, compared with the conventional intervention with lifestyle alone. For MI and all-cause mortality the relative risk reductions with sulfonylurea or insulin had become statistically significant, 15% ($p = 0.014$) and 13% ($p = 0.007$), respectively. Similarly, the risk reductions for MI and all-cause mortality in the metformin part of the UKPDS remained highly significant after 20 years, 33% ($p = 0.005$) and 27% ($p = 0.002$), respectively. This pattern suggests a "legacy effect" of initially good glycemic control, likely based on persisting changes of tissue structure in blood vessels and elsewhere.

Finally, two post hoc analyses of data from ACCORD have added further insights into the risks associated with intensive management in a high-risk population. First, an analysis of on-treatment HbA_{1c} showed that the individuals who accounted for the excess mortality in the intensive treatment group were not those who attained low HbA_{1c}, levels, but rather those whose average HbA_{1c} remained greater than 7% after starting treatment at a higher level.[32] Thus, aiming for an HbA_{1c} of less than 6% and achieving a target of less than 7% was not associated with excess mortality.[32] On the other hand, those individuals who were seeking the 6% target but failed to attain even 7% after a year of intensive treatment had clearly increased risk. The cause for increased risk in this subgroup remains unknown, but might be related to more advanced physiologic abnormalities or limitations in adherence. In another analysis, an index was calculated based on relationships between baseline HbA_{1c} and fasting glucose. The ACCORD participants in the top tertile of this index (with higher HbA_{1c} than would be predicted based on fasting glucose) had increased mortality and no improvement of the primary cardiovascular endpoint. On the other hand, those in the lower and middle tertiles had no increased risk of mortality and an approximately 25% benefit by the primary endpoint. Whether observations using this index reflect an altered rate of glycation in tissues or disproportionate

TABLE 35.5 American Diabetes Association Recommendations for Typical Target Ranges for Glycemic Control for Many Nonpregnant Adults

Measurement	Units	For Healthy Individuals	For high-Risk Individuals	Comments
Preprandial plasma glucose	mg/dL mmol/L	80–130 4.4–7.2	Not applicable	Fasting, before lunch, and before dinner
Peak postprandial glucose	mg/dL mmol/L	<180 <10	Not applicable	1 to 2 hours after any meal
Mean plasma glucose	mg/dL mmol/L	<154 <8.6	Not applicable	Computed from glucose profile values
HbA_{1c}	% mmol/mol	<7 <53	7–8 53–64	May need adjustment when mismatch between glucose and HbA_{1c} occurs

daytime hyperglycemia, the analysis further suggests that benefits and risks of intensive treatment may differ between subpopulations of T2DM.[47]

Glycemic Treatment Targets

Whereas the glucose levels used for the diagnosis of diabetes were determined by their epidemiologic associations with complications of diabetes, the glycemic targets judged appropriate for treatment meant to reduce or prevent these complications have been derived from the results of the intervention studies described earlier in the chapter. All of these studies obtained HbA_{1c} levels averaging close to or below 7% during randomized assignment to intensive therapy.

Glycemic targets suggested by the ADA are presented in Table 35.5.[48] These guidelines suggest that the goal of treatment should generally be an HbA_{1c} value of less than 7%. Furthermore, the ADA suggests that lower targets may be pursued in selected patients, such as those with recent-onset disease, long life expectancy, and no significant cardiovascular disease, if they can be achieved without significant hypoglycemia or other adverse effects of treatment. The guidelines also recommend that a less stringent HbA_{1c} target, such as 7% to 8% or even higher in some cases, may be appropriate for patients with evidence suggesting high risk, including a history of severe hypoglycemia, limited life expectancy, advanced complications, or extensive comorbid conditions, as well as inability to achieve HbA_{1c} less than 7% despite the usual initial therapeutic efforts.[48] The American College of Endocrinology (ACE) has recommended an HbA_{1c} goal that is less than or equal to 6.5%, again with language suggesting individualization of targets.[38] It is agreed that treatment targets and tactics should be adapted to clinical circumstances and personalized to each patient's needs and preferences, to the extent possible.

With respect to fasting, premeal, or postprandial glucose, there is little experimental support for any particular targets for these measurements in the management of T2DM. The ADA recommendation to seek fasting and premeal plasma glucose levels between 80 and 130 mg/dL (4.4–7.2 mmol/L) was based on an estimate of the range of average glucose values that would be associated with a low risk of hypoglycemia and an HbA_{1c} less than 7%. The ACE fasting glucose target of less than 110 mg/dL (<6.1 mmol/L) is an effort to achieve a normal level. However, fasting and premeal glucose values consistently lower than 110 mg/dL would be expected to be associated with an HbA_{1c} of approximately 5.5%, and such levels are not safely attained by most patients as diabetes progresses.[49]

No published studies have demonstrated safety or improved clinical outcomes for a particular targeted level of postprandial blood glucose. The ADA treatment target for peak postprandial glucose levels is less than 180 mg/dL (<10 mmol/L) in part because such levels would be associated with an HbA_{1c} close to 7% and also because people without diabetes who consume a large evening meal can experience transitory elevations of glucose to that level.[50] The ACE has recommended a 2-hour postprandial glucose target of less than 140 mg/dL (<7.8 mmol/L) in an effort to achieve near-normal glycemia.[51] Consistent postprandial glucose values lower than 140 mg/dL would be associated with an average HbA_{1c} of approximately 5% and are very difficult to attain with current treatments except quite early in the course of T2DM.[49]

Monitoring of Glucose During Treatment

Hemoglobin A_{1c}

Measurement of HbA_{1c} provides an estimate of the average plasma glucose level over a period of 2 to 3 months preceding the test.[52] Use of this indicator of glycemic control not only facilitates clinical trials but also assists routine clinical management. When treatment is started or intensified, measurement at approximately 3-month intervals will reveal the success of the intervention. When treatment is established and glycemic control appears stable, testing one or two times a year is usually sufficient.[48] However, measurement of HbA_{1c} has limitations. Because HbA_{1c} reflects glycemia over a 3-month period, current glucose levels do not always correlate well with current HbA_{1c} measurements. Furthermore, individual patients differ somewhat in the relationship of HbA_{1c} to mean glucose concentrations, due to variations in erythrocyte survival or red cell turnover, hemoglobin variants, late kidney disease, or other factors.[26,27,53,54] Such a mismatch between glucose and HbA_{1c} values has sometimes been termed a "glycation gap." This glycation gap can be due to recent changes in glycemia and may warrant changes in therapy. Lower HbA_{1c} than expected based on blood glucose levels may occur with increased red cell turnover seen in a variety of circumstances, such as occult blood loss or iron treatment of iron deficiency anemia. The inappropriately low HbA_{1c} could be misconstrued as adequate control when intensification of therapy is indicated. Alternatively, low red cell turnover such as with untreated iron deficiency anemia could lead to the opposite conclusion. In many cases, however, the higher HbA_{1c}

level relative to the self-monitored blood glucose results is due to unrecognized high glucose levels such as postprandial or nocturnal times when patients typically are not testing. Comparison of HbA_{1c} values with other measures of glucose is advisable at some stage of management, so that individuals with differences of 0.3% to 0.4% or greater from predicted levels can be identified.[25] Moreover, HbA_{1c} does not assess daily patterns or day-to-day variations of glycemic control.

Self-Monitoring of Blood Glucose

Self-monitoring of capillary blood glucose (SMBG) with glucose-oxidase strips provides that information. Since introduction of SMBG 40 years ago, the convenience and reliability of test strips and meters for use in measuring point-in-time glucose values have improved greatly, and all currently available personal glucose meters are generally accurate.[55] Even so, recent studies have shown variable performance under conditions of daily use, highlighting the need for expertise and care in use of the information thus obtained.[56] At the present time SMBG is widely recommended to monitor the progress of therapy and to identify specific glucose patterns in T2DM. It is especially helpful for patients with T1DM and those with T2DM who use intensive insulin therapy. Testing before-breakfast glucose levels is essential for initiating and guiding titration of basal insulin when it is added to oral agents, and premeal testing is necessary to guide adjustment of further injections of rapid-acting insulin before meals.[57–59] Although clinical trials have not consistently shown SMBG can change outcomes in other groups of patients with T2DM when used in isolation,[60,61] diabetes self-management programs that include SMBG can be beneficial in controlling glucose and reducing complications.[62,63] Potential benefits of SMBG in non–insulin-treated patients include supporting educational concepts of nutrition and exercise, determining a daily glucose pattern to select the best pharmacologic tactics, documenting early responses to pharmacotherapy, and serving generally as a motivational tool.[48,62,64] Use of SMBG is important for all patients with a new diagnosis of diabetes for purposes of education, and it subsequently should be advised selectively according to the duration of diabetes, risks of hypoglycemia, and other factors.[65,66]

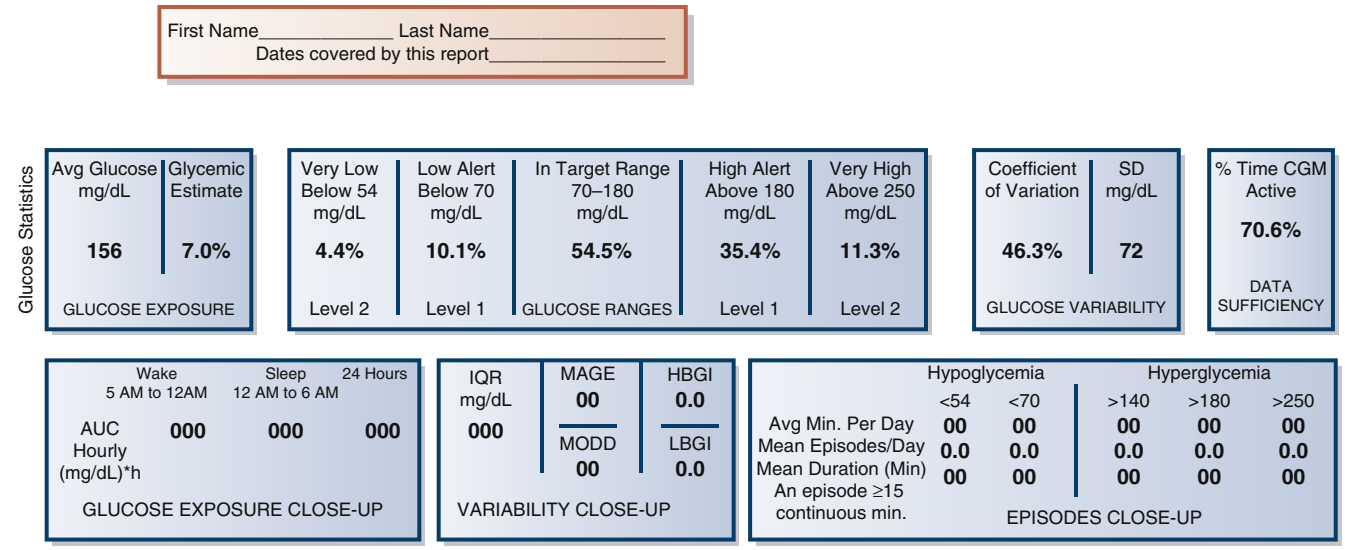
Use of SMBG is particularly recommended for patients with T2DM who are taking insulin or sulfonylureas because it can identify minimal or asymptomatic episodes of hypoglycemia, which may predict increased risk of more severe events. Severe hypoglycemia is relatively rare in T2DM, but it can have devastating consequences such as falls and other trauma, or a change in the ability of a patient to continue to live independently due to risk of confusion or loss of consciousness. Recognition of minor hypoglycemia is also important to avoid undue concern about nonspecific symptoms that may be due to other causes. Monitoring studies show that most symptoms in patients with T2DM are not related to hypoglycemia, but some patients are sufficiently concerned that they may consume extra calories in response to sweating, anxiety, or emotional distress without documenting low glucose levels by SMBG. Fear of hypoglycemia may also lead to lack of adherence to medications or inappropriate reductions of dose, and the ability to document actual glucose values can be reassuring.

The timing of SMBG that is most useful depends on various factors. One basic principle is that patients should periodically vary the time of day at which glucose is tested. For some patients glucose values are highest in the morning, whereas for others glucose is highest in the evening. Times of highest risk of hypoglycemia can vary as well. When glucose control is poor, concentrating on premeal glucose levels is adequate. Once premeal glucose levels are reduced to 120 to 130 mg/dL (6.7–7.2 mmol/L), adding some measurements 1 to 2 hours after meals is appropriate. This calls attention to the effect of diet and enables patients to understand how changes in meals, activity, and medications have significant influences on glycemic control. Postprandial testing also becomes important when the HbA_{1c} remains high despite attainment of reasonably good premeal glucose levels. In such circumstances, postprandial glucose increments can be responsible for the higher-than-expected HbA_{1c} and may require a change in therapy. In recently diagnosed diabetes and gestational diabetes, monitoring only 1 to 2 hours after meals can allow patients to assess the effect of lifestyle and pharmacologic efforts on postprandial glucose levels, which may be the leading glycemic abnormality in those settings.

Clinical trials have confirmed the benefits of structured use of SMBG in patients who have been educated on how to use the information.[67–69] For example, the Structured Testing Program (STeP) trial found use of 7-point daily glucose testing for 3 days each quarter increased the frequency of treatment adjustments and improved HbA_{1c} levels.[70] It is likely that the benefits of SMBG stem from assisting patients in controlling of their own therapy. If patients are aware of the glycemic targets associated with the outcomes they seek to achieve, SMBG enables them to evaluate their responses to therapy and actively participate in reaching their goals. Present meters are downloadable, and clinics should have software that allows reproducing a summary of experience since the last visit, a task once falling to the patients themselves. In some cases it is useful for patients periodically to keep a personal daily diary of SMBG, making them more aware of their results. Unfortunately, patients often fail to bring their meter or their handwritten log to the visit.[71] The importance of this information must be emphasized by the treating clinic. Providers should examine records of SMBG carefully at the time of visit, as it is frustrating for patients to put extensive effort into collection of data that are not taken seriously by their health advisors. In fact, it appears that the more attention that is given to the blood glucose results at a visit, the more frequent the monitoring by the patient and the lower the HbA_{1c}.[72] In some circumstances, such as recent changes in therapy, rapid deterioration of control, or worrisome hypoglycemia, SMBG should be communicated to a member of the health care team by telephone, fax, or privacy-protected email at shortened intervals to facilitate appropriate correction of the problem. Providing adequate financial support for such services may be challenging for health systems, but this is necessary to limit the burden placed upon providers. Similarly, it may also be challenging for patients and providers to keep current on the array of available equipment and supplies for glucose testing and handling of the resulting data. A useful resource in this regard is the annual *Consumer Guide*, which is published as the January issue of *Diabetes Forecast*, a magazine for laypeople with diabetes and their families.[73]

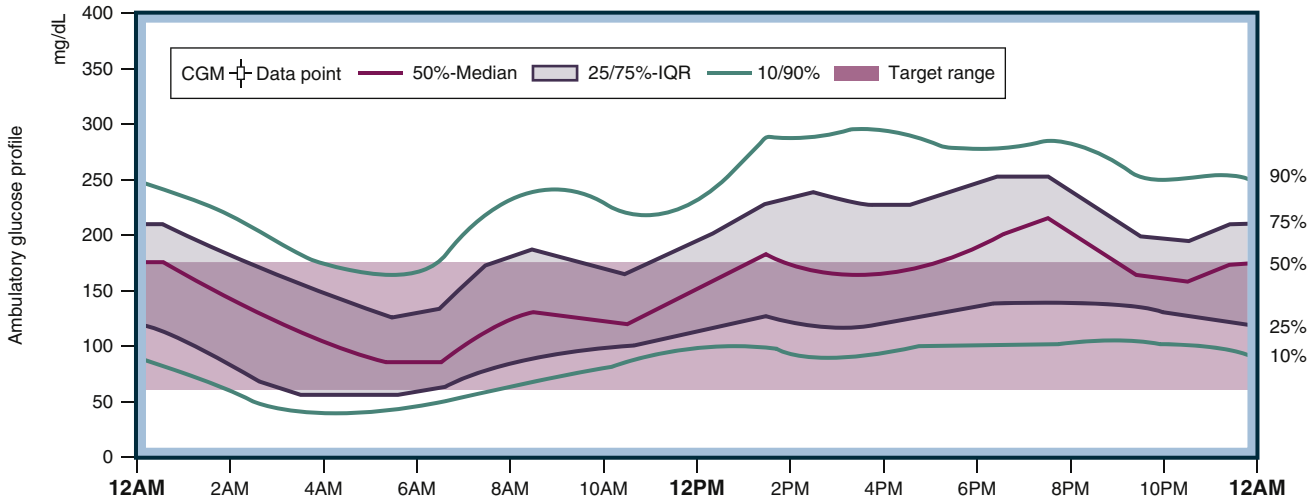
Continuous Glucose Monitoring

Recently, development of continuous glucose monitoring (CGM) systems has added a new dimension to tracking glycemic control. These devices sample subcutaneous interstitial fluids at frequent intervals and can report the results either in real time or upon demand. Their value in T1DM is well documented, and CGM is now frequently recommended for patients with T2DM who embrace newer technologies with the aim of reducing glycemic variability and hypoglycemia while seeking improved HbA_{1c}.[74]



Level 1 = Needs attention. Level 2 = Immediate action.

Curves/plots represent glucose frequency distributions by time regardless of date.



• **Fig. 35.3** An electronic ambulatory glucose profile report that visualizes the key continuous glucose monitoring metrics: (1) mean glucose; (2) hypoglycemia: clinically significant/immediate action required; (3) hypoglycemia alert/low/monitor; (4) target range; (5) hyperglycemia: alert/elevated/monitor; (6) hyperglycemia: clinically significant/very elevated/immediate action required; (7) glycemic variability; (8) estimated HbA_{1c}; (9) time blocks; (10) collection period; (11) percentage of expected readings; (12) hypoglycemia/hyperglycemia episodes; (13) area under the curve; (14) hypoglycemia/hyperglycemia risk; and (15) standardized continuous visualization. *AUC,* area under the curve; *Avg,* average; *IQR,* interquartile range; *MAGE,* mean amplitude of glucose excursions; *MODD,* mean of daily differences; *SD,* standard deviation. (Modified from Danne T, Nimri R, Battelino T, et al. International consensus on use of continuous glucose monitoring. *Diabetes Care*. 2017;40:1631–1640.)

The real-time CGM devices include audible alerts to inform the patient of higher trends as well as low or impending low glucose values. A smartphone may serve as the receiver, and appropriate apps will give real-time glucose information, updating every 5 minutes. Trend arrows are shown, and information can be shared with providers as well as family members or other supporting individuals. The intermittently scanned or "flash" CGM monitors only record glucose results when the reader is passed over the sensor that is in the interstitial space. However, once scanned, the reader will display the present glucose value as well as a rate of change arrow and a recording of the glucose trend over the last 8 hours. If the sensor is scanned every 8 hours, a continuous chart of the glucose trends can be viewed. Favorable effects of using CGM for patients with T2DM who are treated with intensive insulin regimens have also been validated.[75,76] Medicare covers CGM for use by people with T2DM on intensive insulin therapy. A strong rationale for this decision is that protection against hypoglycemia is of heightened importance in older patients.[77,78] Patients with T2DM requiring insulin may also benefit from CGM through promotion of desirable diet and exercise patterns, but the cost effectiveness of this application has not yet been fully assessed. Finally, CGM can provide accurate measurement of mean glucose levels, thereby validating HbA_{1c} values or, alternatively, identifying patients with a significant glycation gap.[25] Fig. 35.3 shows one

TABLE 35.6 American Diabetes Association Classification of Hypoglycemia

Levels of Hypoglycemia	Glucose Units	Criteria	Comments
Level 1 (Alert value)	mg/dL mmol/L	<70 and ≥54 <3.9 and ≥3	Important independent of symptoms, adjustment of therapy may be needed
Level 2 (Clinically significant)	mg/dL mmol/L	≤54 ≤3	Requires immediate action
Level 3 (Severe)	mg/dL mmol/L	Altered mental and/or physical status requiring assistance	Calls for reevaluation of regimen and/or targets

Modified from American Diabetes Association. Glycemic targets: standards of medical care in diabetes, 2018. *Diabetes Care*. 2018;41:S55–S64.

form of display that can be used to summarize and communicate a variety of kinds of clinically useful information provided by CGM systems.[79]

Hypoglycemia

Among the most important purposes of measuring glycemic patterns during treatment of T2DM, as with T1DM, is to identify hypoglycemia.[80,81] The definitions of hypoglycemia have recently been a topic of debate. Table 35.6 summarizes the ADA's most recent statements on this point.[82] Division of hypoglycemia into three levels is based on three kinds of observations. Under normal circumstances a decline of glucose concentrations below 70 mg/dL (<3.9 mmol/L) triggers physiologic responses of the so-called counterregulatory hormones: glucagon, epinephrine and norepinephrine, cortisol, and growth hormone. Symptoms of hypoglycemia may or may not result from these responses, but declines below this threshold, termed level 1 hypoglycemia, are considered important as alerts to allow protection against more worrisome declines of glucose. Level 2 hypoglycemia is defined as glucose documented at or lower than 54 mg/dL (3 mmol/L). Repeated declines to this range are considered clinically significant because they can cause blunting of compensatory hormone responses and loss of warning symptoms ("hypoglycemia unawareness"), and thereby increase the risk of more dangerous lows. Level 3 is considered severe hypoglycemia, defined as requiring assistance by another person, whether a friend or family member or a medical provider. This level of hypoglycemia in T2DM is strongly associated with risk of physical injury, cardiovascular events, and death. Although hypoglycemia can directly cause such events through falls and cardiac arrhythmias, this relationship with serious medical outcomes is thought to be partly related to an association of hypoglycemia with other causes of risk, including concurrent illness, inconsistent eating patterns, malnutrition and weight loss, physical frailty, and cognitive impairment. Nonetheless, level 3 severe events are markers of risk and call for both conservative glycemic management and renewed attention to other aspects of care.

Lifestyle Interventions

The leading lifestyle interventions for management of T2DM are medical nutrition counseling and exercise recommendations. Beyond these traditional pillars of lifestyle management there is growing attention to psychosocial concerns as well as interest in various forms of stress reduction, relaxation, and sleep management. The evidence base supporting such interventions has become much stronger recently, and reimbursement for these efforts has become more frequently available. They are most effective when presented as parts of a comprehensive plan of self-management with the goal of moving the focus of care from the provider to the individual with diabetes.[83–85]

Diabetes Self-Management Education and Support

Diabetes is a chronic, ever-present disease that places the patient in a unique position of self-care, requiring daily decisions and the ability to solve problems when they arise. The provider has little connection with day-to-day care, thus the patient needs the tools, confidence, and a plan for self-management. Professional services promoting this process are now described as diabetes self-management education and support (DSMES). The evidence for benefit of DSME is now quite strong.[86,87] The ADA together with the American Association of Diabetes Educators (AADE) and the Academy of Nutrition and Dietetics recommend that all individuals with diabetes should receive DSMES.[85] As illustrated in Table 35.7, it is recommended that DSMES be emphasized at four critical settings in the evolution of T2DM. These include the time of diagnosis, annual reassessments, when complicating factors arise, and the time of critical transitions in medical care or life circumstances. The importance of ongoing contact and reassessment has proven to be significant.[88] There is also consensus on a core group of considerations, methods, and barriers to address.[85] Unfortunately, there is evidence that DSMES services are underutilized. A review of a large commercial insurance database reported that only 6.8% of patients received DSMES within the first 12 months of diagnosis.[89] When subgroups were considered by ethnicity, socioeconomic groups, age, and other factors, the highest utilization subgroup received DSMES only 15% of the time. Why utilization is so low is not clear, but providers' unawareness of the significance and availability of this important resource are thought to be important factors. The AADE (telephone 800-TEAM-UP4) and the ADA (telephone 800-DIABETES) can provide information regarding diabetes educators and education programs in local areas of the United States.

DSMES refers to all activities and individuals that help patients turn knowledge into action. A summary of the necessary components of an effective DSMES program is provided in Table 35.8.[90,91] Health care providers are seldom adequately trained and often do not have the patient contact time to deal with all these issues alone. The need for a team approach has long been recognized in diabetes care and remains a critical ingredient for success. The providers (physicians and advanced practice providers) enrich their care with the help of nurses, dietitians, exercise specialists, behavioral specialists, pharmacists, podiatrists, and other medical and surgical specialists. Among

TABLE 35.8 Key Components of Effective DSMES Programs

- Evidence based
- Individualized to the needs of the person, including language and culture
- Has a structured theory-driven written curriculum with supporting materials
- Delivered by trained and competent individuals (educators) who are quality assured
- Delivered in group or individual settings
- Aligns with the local population needs
- Supports the person and their family in developing attitudes, beliefs, knowledge, and skills to self-manage diabetes
- Includes core content—i.e., diabetes pathophysiology and treatment options; medication usage; monitoring, preventing, detecting, and treating acute and chronic complications; healthy coping with psychologic issues and concerns; problem solving and dealing with special situations (e.g., travel, fasting)
- Available to patients at critical times—i.e., at diagnosis, annually, when complications arise, and when transitions in care occur
- Includes monitoring of patient progress, including health status, quality of life
- Quality audited regularly

DMES, Diabetes self-management support and education.

From Davies MJ, D'Alessio DA, Fradkin J, et al. Management of hyperglycemia in type 2 diabetes, 2018. A consensus report by the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD). *Diabetes Care.* 2018. [Epub ahead of print.]

the commonly overlooked contributors to ineffective care of T2DM are the barriers created by psychiatric, neurocognitive function, and adjustment disorders, which are largely responsive to psychosocial therapies.[92] Modern diabetes management principles emphasize that the patients are at the center of the team and that the management plan is not dictated by the provider but ultimately determined by informed patients who may include personal health beliefs as well as cultural influences and other factors in their approaches to self-care.[83,85,93]

People other than medical professionals can contribute to DSMES. Group sessions provide added support as do programs that involve peer groups and health coaches without a traditional medical professional directly involved.[94–96] In the last decade we have also seen growing implementation of digital health and telehealth tools that improve communication and otherwise support patients in self-management.[97–102] Finally, the potential role of the community in which the patient lives and works in the diabetes self-care process is enormous; family, friends, employers, and health insurance providers may all be involved.[103] Peer support has proven benefits.

Medical Nutrition Therapy

Medical nutrition therapy (MNT) is an essential component of DSMES. Ideally all patients should have access to a registered dietitian-nutritionist (RDN) to facilitate it.[83,104–106] Recent guidelines recommend three to six MNT sessions in the first 6 months after diagnosis. Medical nutrition therapy has been shown to decrease HbA_{1c} by 0.3% to 2%. In a typically obese and older T2DM population the basic goals of nutrition therapy include weight reduction or maintenance, adequate glucose control, a nutrient-sufficient diet, and nutritional efforts to reduce cardiovascular risk by controlling blood pressure and lipid levels. Nutritional strategies, of course, require individualization based on the patient's clinical profile, personal and cultural factors, health literacy, motivation, and economic limitations. A summary of general nutritional principles for people with diabetes is shown in Table 35.9.[83]

Beyond the general principles, there are specific features of eating patterns that are relevant to the medical management of individual patients, and some of them are directly related to the success of treatment with insulin. It is very helpful to know how many meals the patient eats in a day, and at what times. Does this pattern differ from day to day? Are meals often missed, and if so why? What does the patient view as the primary challenge in healthful eating? Do family members eat with the patient and

TABLE 35.9 Major Nutritional Recommendations for Type 2 Diabetes

Topic	Recommendations
Effectiveness of nutrition therapy	• An individualized MNT program, preferably provided by a registered dietitian, is recommended for all people with type 1 or type 2 diabetes or gestational diabetes mellitus. • A simple and effective approach to glycemia and weight management emphasizing portion control and healthy food choices may be considered for those with type 2 diabetes who are not taking insulin, who have limited health literacy or numeracy, or who are older and prone to hypoglycemia.
Energy balance	• Weight loss (>5%) achievable by the combination of reduction of calorie intake and lifestyle modification benefits overweight or obese adults with type 2 diabetes and also those with prediabetes. Intervention programs to facilitate weight loss are recommended.
Eating patterns and macronutrient distribution	• There is no single ideal dietary distribution of calories among carbohydrates, fats, and proteins for people with diabetes; therefore macronutrient distribution should be individualized while keeping total calorie and metabolic goals in mind. • A variety of eating patterns are acceptable for the management of type 2 diabetes and prediabetes.
Carbohydrates	• Carbohydrate intake from vegetables, fruits, legumes, whole grains, and dairy products, with an emphasis on foods higher in fiber and lower in glycemic load, is preferred over other sources, especially those containing added sugars. • For people with type 1 diabetes and those with type 2 diabetes who are prescribed a flexible insulin therapy program, education on how to use carbohydrate counting and in some cases fat and protein gram estimation to determine mealtime insulin dosing is recommended to improve glycemic control.
	• For individuals whose daily insulin dosing is fixed, a consistent pattern of carbohydrate intake with respect to time and amount may be recommended to improve glycemic control and reduce the risk of hypoglycemia.
	• People with diabetes and those at risk should avoid sugar-sweetened beverages to control weight and reduce their risk for CVD and fatty liver and should minimize the consumption of foods with added sugar that have the capacity to displace healthier, more nutrient-dense food choices.
Protein	• In individuals with type 2 diabetes, ingested protein appears to increase insulin response without increasing plasma glucose concentrations. Therefore carbohydrate sources high in protein should be avoided when trying to treat or prevent hypoglycemia.
Dietary fat	• Data on the ideal total dietary fat content for people with diabetes are inconclusive, so an eating plan emphasizing elements of a Mediterranean-style diet rich in monounsaturated and polyunsaturated fats may be considered to improve glucose metabolism and lower CVD risk and can be an effective alternative to a diet low in total fat but relatively high in carbohydrates.
	• Eating foods rich in long-chain n-3 fatty acids, such as fatty fish (EPA and DHA) and nuts and seeds (ALA), is recommended to prevent or treat CVD; however, evidence does not support a beneficial role for the routine use of n-3 dietary supplements.
Micronutrients and herbal supplements	• There is no clear evidence that dietary supplementation with vitamins, minerals, herbs, or spices can improve outcomes in people with diabetes who do not have underlying deficiencies, and are not generally recommended. There may be safety concerns regarding the long-term use of antioxidant supplements such as vitamins E and C and carotene.
Alcohol	• Adults with diabetes who drink alcohol should do so in moderation (no more than one drink per day for adult women and no more than two drinks per day for adult men). • Alcohol consumption may place people with diabetes at increased risk for hypoglycemia, especially if taking insulin or insulin secretagogues. Education and awareness regarding the recognition and management of delayed hypoglycemia are warranted.
Sodium	• As for the general population, people with diabetes should limit sodium consumption to <2300 mg/day, although further restriction may be indicated for those with both diabetes and hypertension.
Nonnutritive sweeteners	• The use of nonnutritive sweeteners may have the potential to reduce overall calorie and carbohydrate intake if substituted for caloric (sugar) sweeteners and without compensation by intake of additional calories from other food sources. Nonnutritive sweeteners are generally safe to use within the defined acceptable daily intake levels.

ALA, Alpha-lipoic acid; *CVD,* cardiovascular disease; *DHA,* docosahexaenoic acid; *EPA,* eicosapentaenoic acid; *MNT,* medical nutrition therapy.

support the recommended nutrition goals? What beverages does the patient drink? How many alcoholic drinks does the patient take daily? This information should be reassessed periodically, with specific suggestions for changes that are achievable.

Problematic habits may become apparent. Intake of caloric beverages (e.g., juices) or very high glycemic index foods (e.g., cold cereal) might be perceived as healthful but can significantly affect glycemic control.[107,108] Finding foods that the patient may view as healthful due to being "low carb" while ignoring the high fat content or, conversely, foods chosen for being low in fat but having high carbohydrate content can provide opportunities for improvement. A pattern of snacking from dinner until bedtime or consistently overeating on weekends can create difficulties. Portion control techniques, variation in food preparation (e.g., fried vs. grilled), appropriate meal spacing, and mindful eating are important concepts to reinforce for the patient and the family, including a potential benefit for family members who are at risk of developing diabetes.[109] It has also become apparent that diabetes providers should consider food insecurity that is becoming increasingly recognized and relates to high HbA_{1c}.[110] Finally, it is important to track the success of nutrition goals determined in previous visits, setting new goals and potentially offering new resources where appropriate.[111]

Structured lifestyle programs can produce long-term weight loss of 5% to 7% of starting weight and[112] reduce the risk of developing diabetes.[113] Such systems emphasize education, reduced energy intake (especially fat), conscious decisions regarding carbohydrate intake, regular physical activity, and ongoing support from professionals or peers. Achieving a 5% weight loss more consistently yields significant metabolic benefits than lower levels of weight loss.[114] Focusing on a specific macronutrient distribution appears to be less important than reducing overall caloric intake and facilitating maintenance of the weight loss.[115,116]

As an example, it has been demonstrated in a population with T2DM of less than 6 years' duration that consistent application of a specific intervention program, in a primary care setting, can result in significant reduction of weight and HbA_{1c} over a 1-year period.[117] The same report showed glycemic improvement was proportional to the reduction of weight. Patients who lost less than 5% of body weight had insignificant HbA_{1c} reductions, similar to that in the control group. Of those in the intervention group who lost 5% to 10 % of body weight, 34% ended with HbA_{1c} below 6.5%. Among those losing more than 15%, 86% achieved this level of control. The reduction of HbA_{1c} was often accompanied by less use of pharmacologic agents as well. For more information on therapeutic weight loss, see Chapter 40.

Much controversy has surrounded the macronutrient makeup of the diet of people with T2DM. In general, the critical nutrient for glycemic consistency is carbohydrate. Glucose levels after meals are strongly influenced by the carbohydrate content of the diet. For patients with T2DM requiring prandial insulin, the carbohydrate-counting technique is used to facilitate consistent carbohydrate intake or to allow adjustment of insulin doses in response to changes in carbohydrates consumed.[118] However, evidence for the benefit of calculating insulin:carbohydrate ratios in T2DM over other methods of dose adjustment is less compelling than in T1DM.[118,119] For patients not using insulin, carbohydrates still affect postprandial glucose excursions, and consistency of carbohydrate intake is still relevant. However, other methods can be used to assess and modulate carbohydrate intake. These include the "plate method," carbohydrate exchange lists, and even simple portion control tactics.[119,120] Whereas the beta cell in T2DM has usually lost its immediate response to glucose, the second phase of insulin secretion is largely spared in T2DM and is in part driven by amino acids and fatty acids. Therefore including some protein and fat in each meal and snack is useful, and these macronutrient groups along with fiber content can attenuate the effect of carbohydrate on postprandial elevations. Although the carbohydrate content of typical nutrition plans for those with T2DM has generally decreased in the last decade, the optimal proportion of macronutrients is uncertain. Low carbohydrate diets, including ketogenic diets, have grown in popularity and are associated with decreased postprandial glucose and a reduction in HbA_{1c}.[121–123] Even so, the benefit in reducing HbA_{1c} may come more from the frequently associated weight loss as the evidence indicates carbohydrate content, independent of weight loss, does not significantly influence HbA_{1c}. In many cases the postprandial glucose decreases with lower carbohydrate intake, but fasting glucose may be higher. Long-term adherence to very low carbohydrate diets is difficult. The glycemic index refers to the glucose response to equal amounts of carbohydrates in various foods. This index has proven somewhat difficult to use for meal planning, and studies evaluating the benefit of lowering glycemic index have yielded mixed results.[107,108,124] As a practical measure, identifying high glycemic index foods in a patient's diet could help reduce high postprandial blood glucose patterns. Nutrition practice guidelines also recognize the benefit of SMBG in confirming the glucose response to food intake and success of nutritional interventions.[83,85]

Dietary fat is the nutrient that is most closely associated in epidemiologic studies with the risk of developing T2DM. Although dietary fats clearly have an impact on total caloric intake (related to their caloric density) and on circulating lipids, they have little effect on glycemia. Fat intake is a contributor to obesity and is the critical nutrient for cardiovascular risk management. It is recommended that people with diabetes (and everyone in general) consume a diet that is modestly restricted in calories (if overweight) and contains less than 10% of total calories as saturated fat and less than 10% as polyunsaturated fat.[85] Some advocate substituting foods high in monounsaturated fatty acids (i.e., seeds, nuts, avocado, olives, olive oil, and canola oil) for carbohydrate, but most patients do not find adequate variety in the monounsaturated fatty acid category and often overeat these high-calorie foods. Higher carbohydrate diets can raise postprandial glucose and triglycerides but are much less calorically dense than higher fat diets and have a higher thermic effect, both of which tend to promote weight loss.

Dietary protein similarly has little impact on glucose levels, although amino acids do promote insulin secretion. Metabolism of protein results in the formation of acids and nitrogenous waste, which can lead to bone demineralization and glomerular hyperfiltration. At least 0.8 g of high-quality dietary protein per kilogram of body weight is generally recommended. Restriction of protein intake to 10% to 20% of total calories minimizes potential adverse long-term effects of high protein intake. However, recent guidelines do not support the notion that dietary protein need be reduced in those with chronic kidney disease.[105] Likewise, there is no evidence for a distinction between the effects of vegetable-based versus animal-based protein sources in kidney function.

The evidence base for benefit of higher fiber intake is not very convincing. Still, there may be some benefit on HbA_{1c} and lipid profiles for those ingesting at least 15 g of fiber per 1000 kcal compared to lower fiber diets. Alcohol in moderation (up to one drink per day for adult women or two drinks per day in adult men) is not specifically recommended but is considered acceptable. An added risk associated with excessive intake of alcohol by people with T2DM, especially those who use sulfonylureas or insulin, is delayed hypoglycemia, which typically occurs at night when ability to recognize hypoglycemia can be impaired. Moderate red wine intake may result in mild improvement in some lipid parameters but seems to have little effect on glucose control. Nonnutritive sweeteners such as aspartame, ace-K, saccharin, stevia, or sucralose do not appear to impact lipid parameters, insulin secretion, or blood pressure independent of weight loss. They are deemed safe for use in T2DM if consumed within the FDA recommended daily intake amounts. Sodium restriction to less than 2300 mg per day is recommended, and lower sodium diets may have additional benefit in some individuals with hypertension.[85]

The roles of vitamins, trace minerals, and nutritional supplements in the treatment of diabetes are poorly understood. Some clinicians are convinced of the utility of magnesium, chromium, zinc, folic acid, pyridoxine, cyanocobalamin, vitamin A, vitamin C, vitamin E, vanadium, selenium, garlic, and other micronutrients. Clinical trial data regarding their safety and efficacy are inconclusive at best. Many patients are convinced that nutritional supplementation is healthful, and it is often counterproductive to engage in scholarly discussion of the nature of the evidence base for their decision. At a minimum, discussion should include the documented efficacy of more classic lifestyle and pharmacologic interventions and the idea that these efforts should not be ignored.[125]

Although various specific dietary strategies have their proponents, few data from long-term outcome studies are available to support routine use. For example, ketogenic diets or low carbohydrate diets have limited long-term evidence of benefit or risk at the present time. However, if a patient or practitioner wants to use a lower carbohydrate higher protein/fat reduced calorie diet, that choice may be associated with short-term improvements in glycemia, cardiovascular risk markers, and weight. The most validated meal plans in T2DM include the Mediterranean diet, the Dietary Approaches to Stop Hypertension (DASH), and plant-based diets.[115,126–128] A Mediterranean diet emphasizing use of monounsaturated and polyunsaturated fats may have the best experiment support for glycemic control, cardiovascular protection, and perhaps other outcomes.[127]

Physical Activity and Exercise

There is a substantial body of literature supporting exercise as a modality of treatment in T2DM. Exercise is associated with improved glycemic control, insulin sensitivity, cardiovascular fitness, and quality of life.[83,129,132] Aerobic exercise and resistance (strength) training both have positive impact on glucose control.[130] Self-directed structured exercise programs have been associated with mean HbA_{1c} reductions of 0.4% to 0.9%, with the largest reduction seen in those using combined aerobic and resistance exercise.[131,133] Supervised exercise is also effective but too expensive for many and less practical. In many cases the benefits in HbA_{1c} are not accompanied by weight loss. With this independent benefit it is clear why the physician can refer to exercise as a therapeutic modality equivalent to pharmacologic therapies. Improvements in glycemic control are usually apparent immediately, but the improvement in insulin resistance may not last more than 48 to 72 hours. It is often recommended that individuals strive for 150 minutes of moderate-intensity physical activity (50–70% of maximum heart rate) or 75 minutes per week of vigorous exercise (>70% of maximum heart rate) on at least 3 days per week with no more than 2 consecutive days without exercise. Both aerobic and resistance exercise are effective and recommended.[83,132,133]

The key concept is to promote an increase in activity using an approach similar to the one discussed for diet. Goals, methods, intensity, and frequency must be negotiated with patients with great sensitivity to recognizing barriers and helping patients discover solutions. The role of educators, exercise specialists, physical therapists, and social supports in this process is critical. The major role for the physician is to screen for complications (neuropathy, nephropathy, retinopathy, vascular disease) and discover ways for patients to be able to exercise safely.[132] It is also important for the physician to inquire about exercise patterns and potential barriers and consider implications of exercise on hypoglycemia at each clinic visit.

Although it has not been recommended to have all patients formally evaluated for ischemic heart disease with a stress test, conducting a careful history of potential signs and a clinical risk assessment is desirable to identify patients who may warrant additional testing or cautions. Patients at high risk for coronary artery disease should start with short periods of low-intensity exercise and increase the intensity and duration slowly as tolerated.[132] Development of symptoms of coronary ischemia, including dyspnea out of proportion with activity, calls for further evaluation and treatment. It is important to encourage patients not to overexert and to recognize exertional chest, jaw, or arm discomfort as well as palpitations and dyspnea as symptoms of cardiac dysfunction.

For the average patient with T2DM starting an exercise program it is best to start with low-level activity such as walking at a pace of 2 miles per hour. Initially it may be advantageous to start with shorter duration exercise sessions and build up the frequency and duration. Caution is important to avoid overuse injuries that then interrupt the exercise progression. Many different exercise programs are beneficial, and individualization is appropriate. For example, interval training appears to be effective but is not appropriate for all.[134] Aquatic exercise is beneficial and may be particularly useful for those with joint pain.[135] Walking after dinner can have a significant benefit on postprandial hyperglycemia.[136] Consideration of diabetes complications is imperative. For example, in the setting of proliferative diabetic retinopathy intense aerobic and resistance exercise should be avoided. With significant peripheral neuropathy, careful attention must be given to footwear, and weightbearing exercise should be limited. Daily foot inspection for foot ulcers is critical. Autonomic neuropathy requires particular cardiac cautions. Exercise does not appear to accelerate kidney disease but will increase albuminuria acutely and could cause false-positive albumin:creatinine ratios temporarily.[137]

In addition to scheduled exercise, all individuals should be encouraged to reduce sedentary time, particularly by breaking up extended amounts of time spent sitting.[137,138] It is recommended to have some activity break at least every 30 minutes to include brief walks, resistance exercise, or at least standing. This may also help prevent diabetes. Balance training and exercise improving flexibility may be helpful as patients get older, with the aim of decreasing falls and increasing mobility.[139]

Addressing Psychosocial Needs

Many psychosocial factors influence the ability of a patient with T2DM to practice effective self-management.[92] There is a complex interaction of factors such as economic stability, food insecurity, family support or conflict, intellectual abilities and learning skills, and the incessant need to consider the implications of timing and content of food intake, emotional stress, physical activity, and adherence to medications each day. Not surprisingly, patients often experience diabetes distress and depression, two separate but related diagnoses.[140] The incidence of diabetes distress over an 18-month period has been reported to range from 38% to 48%.[141] Diabetes distress screening tools have been developed and utilized in revealing studies where the level of distress impacts glycemic control, adherence to medication regimens, exercise behaviors, self-efficacy, and diet. There are also depression screening tools for use in clinical practice. When clinical depression is diagnosed, the patient should be referred to a mental health provider, preferably one with an understanding of diabetes and its treatment.[92] It is recommended that patients with diabetes be screened at least once yearly as depression is present in about 25% of screened patients, and appropriate treatment can greatly facilitate diabetes self-management and quality of life. Another psychologic comorbidity to be considered in T2DM is chronic anxiety, which often appears as fear of hyperglycemia, hypoglycemia, chronic complications, or injections. On occasion, management may be influenced by obsessive compulsive disorder resulting in inadequate nutrition or overtreatment of hypoglycemia. A few patients on intensive insulin may experience a posttraumatic stress disorder or panic disorder related to a severe episode of hypoglycemia.

The psychosocial aspects of diabetes care are relevant for the entire treatment team, emphasizing the importance of patient-centered care and a collaborative approach.[92] Therefore, in addition to a psychiatric history, the office visit should include basic

TABLE 35.10 Classes of Antihyperglycemic Agents for Type 2 Diabetes

questions on stress levels, family support structures, general mood and energy, and perceived barriers to self-management success. Recognizing that diabetes distress is so prevalent, the practice can facilitate stress reduction through one-on-one discussion and by providing resource lists or directly providing clinic-based support groups, exercise groups with support elements, and mindfulness training. When screening suggests a psychologic barrier beyond the capacity of the clinical practice, referral to a mental health specialist should be proposed to the patient in a sensitive, professional manner.

Glucose-Lowering Pharmacotherapy

A revolution in the treatment of T2DM since 1995 in the United States has been driven by the release of several new classes of drugs that independently address different pathophysiologic mechanisms that contribute to the development of diabetes. Antihyperglycemic agents have commonly been divided into those that improve the sensitivity of tissues to insulin, those that augment insulin availability, and those with other mechanisms of action. This classification has become less helpful as additional classes of agents have been introduced, some of them with multiple pharmacologic and clinical effects. Here we will present each class of oral therapy separately, and then describe the currently available agents that require injection or other means of delivery. Some important properties of various classes of drugs available for the management of T2DM are summarized in Table 35.10. This area has been the subject of extensive reviews.[33,49–51,78,118,125,142–148] In the following discussion, the principles outlined in these reviews are summarized, and a limited number of additional references are provided. In addition, when questions arise regarding the details of handling, dosing, and administering any of the agents available, it is advisable to consult the product information approved by regulatory authorities.

Oral Agents

Some clinically relevant features of the main currently available oral antihyperglycemic agents are summarized in Table 35.11.

Biguanides

Metformin is the only biguanide available in the United States. Phenformin was removed from the market in the 1970s because of deaths associated with lactic acidosis. Phenformin and buformin remain available in some countries, however. The precise mechanism of action of metformin is still not well understood.[149,150] Some studies suggest it activates adenosine monophosphate-activated protein kinase (AMPK), an intracellular signal of depleted cellular energy stores that has been implicated in stimulation of skeletal muscle glucose uptake and inhibition of hepatic gluconeogenesis, whereas more recent studies implicate inhibition of mitochondrial glycerophosphate dehydrogenase. Additional new evidence suggests much of metformin's effect is mediated by direct contact with the intestinal mucosa, provoking neural or hormonal signals to the brain or other tissues.[151] There is some evidence that it can influence the microbiome, and it increases glucagon-like peptide-1 (GLP1) release. It has been suggested the main clinical effect of metformin is to reduce hepatic gluconeogenesis and glucose production, but this does not account for all of its effects.[150] It less consistently improves insulin sensitivity in peripheral tissues. Because of its limited duration of action, it is usually taken at least twice daily, although a sustained-release formulation is available.

TABLE 35.11 Clinical Features of Commonly Used Oral Antihyperglycemic Agents

Classes and Specific Agents (Commercial Names)	Commonly Used Dosages	Contraindications	Side Effects	%HbA_{1c} Reduction as First or Second Therapy
Biguanide				
Metformin (Glucophage)	500–1000 mg BID	T1D, DKA eGFR <30	Nausea, diarrhea, abdominal pain	1 to 2
Metformin-ER	500–1000 mg BID	Severe cardiac, hepatic disease	Vitamin B_{12} deficiency	
Secretagogue				
Glipizide (Glucotrol)	5–20 mg BID	T1D, DKA	Hypoglycemia	1 to 2
Glipizide-ER	2.5–10 mg QD		Weight gain	
Gliclazide (Diamicron)	80–160 BID			
Gliclazide-MR	30–120 QD			
Glimepiride (Amaryl)	0.5–4 mg QD			
Glyburide (Micronase et al)	2.5–10 mg BID			
Repaglinide (Prandin)	0.5–2 mg TID			
Nateglinide (Starlix)	60–120 mg TID			
Thiazolidinedione				
Pioglitazone (Actos)	15–30 mg QD	T1D, DKA	Weight gain	0.75 to 1.5
Rosiglitazone (Avandia)	4–8 mg QD	Symptomatic heart failure	Edema Fractures	
DPP4 inhibitor[a]				
Sitagliptin (Januvia)	25–100 mg QD	T1D, DKA	Hypersensitivity	0.5 to 1
Vildagliptin (Galvus)	50 mg QD or BID			
Saxagliptin (Onglyza)	2.5–5 mg QD			
Linagliptin (Trajenta)	5 mg QD			
Alogliptin (Nesina)	6.25–25 mg QD			
α-Glucosidase inhibitor[b]				
Acarbose (Precose)	25–50 mg TID	T1D, DKA	Flatulence, diarrhea, abdominal discomfort	0.5 to 1
Miglitol (Glyset)	25–50 mg TID			
SGLT inhibitor				
Canagliflozin (Invokana)	100–300 mg QD	TID, DKA eGFR <30	Urinary frequency Urogenital infections Nausea, diarrhea Hypotension	0.5 to 1
Dapagliflozin (Farxiga)	5–10 mg QD			
Empagliflozin (Jardiance)	10–25 mg QD			
Ertugliflozin (Steglatro)	5–15 mg QD			
Bile-acid sequestrant				
Colesevelam (Welchol)	Six 625-mg tabs QD	T1D, DKA Pancreatitis, intestinal disease, hypertriglyceridemia	Constipation	0.5 to 1
Dopamine agonist				
Bromocriptine (Cycloset)	1.6–4.8 mg QD	T1D, DKA	Somnolence, dizziness, hypotension	0.5 to 1

[a]The DPP4 inhibitors listed here are approved in the United States and/or the European Union. Other DPP4 inhibitors are available in certain countries, including anagliptin (Suiny), evogliptin (Suganon), gemigliptin (Zemiglo), gosogliptin (SatRx), omarigliptin (Marizef), teneligliptin (Tenelia), trelagliptin (Zafatek), and vildagliptin (Galvus).

[b]Acarbose and miglitol are available in the United States and the European Union. Voglibose (Basen et al) is available in other countries.

BID, Twice daily; *DKA,* diabetic ketoacidosis; *eGFR,* estimated glomerular filtration rate; *ER,* extended release; *MR,* modified release; *QD,* once daily; *TID,* three times daily.

Because biguanides do not increase insulin levels, they are not associated with a significant risk of hypoglycemia. The most common adverse events are gastrointestinal: nausea, abdominal pain or bloating, and diarrhea. Up to a third of patients have some gastrointestinal distress, especially early in their course of treatment. This can be minimized by starting with a low dose once daily with meals and titrating upward over several weeks to fully effective doses. Sustained-release metformin is associated with less frequent and less severe upper gastrointestinal symptoms, but it can increase the frequency of diarrhea, which is overall less common. Most patients tolerate metformin adequately during long-term use. Perhaps related to clinical or subclinical gastrointestinal effects, metformin is associated with less weight gain than other antihyperglycemic agents and can be associated with a modest weight loss.

Metformin has been said to cause lactic acidosis, which is quite rare and occurs almost exclusively in patients who are at high risk for development of the condition independent of metformin therapy.[152] Metformin is not metabolized and is cleared only through the kidney. Prior to April 2016 the package insert stated that it was contraindicated in patients with renal insufficiency in an effort to avoid lactic acidosis. The revised package insert recommends obtaining an estimated glomerular filtration rate (eGFR) before

starting metformin and at least annually thereafter. Initiation is not recommended if the eGFR is below 45 mL/minute/1.73 m^2 and is contraindicated if the eGFR is below 30 mL/minute/1.73 m^2. Once treatment is established, one should consider a dose reduction if the eGFR is under 45 mL per minute, and metformin should definitely be stopped if the eGFR is less than 30 mL per minute.[153] Metformin remains contraindicated in patients with hepatic insufficiency and in the setting of alcohol abuse. Because some patients taking metformin develop significant vitamin B_{12} deficiency that might exacerbate peripheral neuropathy, supplementation with vitamin B_{12} (e.g., 1000 μg daily) or intermittent monitoring may sometimes be prudent.[154–156]

Both the glucose-lowering efficacy and the frequency of gastrointestinal side effects of metformin increase in the dose range from 500 to 2000 mg per day. The maximal daily dose of 2550 mg does not generally provide additional benefit beyond that seen at 2000 mg daily.[157] To minimize gastrointestinal side effects, dosage should usually be started with 500 mg once or twice daily. Newer formulations of metformin combined with other classes of oral antihyperglycemic agents have been developed to maximize glucose-lowering effectiveness with a single prescription through the synergy of two classes of agents with different actions.

Arguably, metformin has the best record among oral antihyperglycemic agents in medical outcome studies. As previously noted (see Table 35.4) overweight participants in the UKPDS who were randomly assigned to metformin had reduced rates of myocardial infarction and all-cause mortality that persisted long after cessation of randomized therapy.[41] While the number of participants using metformin in the UKPDS was relatively small, other studies have supported its protective effects.[158] A beneficial effect of metformin on cardiovascular complications through mechanisms independent of glycemic control is certainly plausible and is consistent with metformin-associated modest reductions in LDL, triglycerides, blood pressure, and procoagulant factors.

Based on its good tolerability, safety, and effectiveness together with evidence for medical benefits in controlled trials, it is generally recommended that metformin therapy be started in all patients with T2DM at or near the time of diagnosis of diabetes, provided no contraindications are present.[33,38,159]

Insulin Secretagogues

Along with biguanides, this class of oral agents has a long history of clinical use, and mechanisms have been carefully studied. Some characteristics of the most widely used insulin secretagogues are summarized in Table 35.11. Currently available secretagogues all bind to the sulfonylurea receptor-1 (SUR1), a subunit of the K_{ATP} potassium channel on the plasma membrane of pancreatic beta cells. The SUR1 subunit regulates the activity of the channel and also binds adenosine triphosphate (ATP) and adenosine diphosphate (ADP), effectively functioning as a glucose sensor and trigger for insulin secretion. Binding leads to closing of the channel, as do increases in intracellular ATP and decreases in ADP resulting from fuel metabolism. The membrane depolarization that ensues causes the opening of voltage-dependent L-type calcium channels. Subsequent calcium influx results in an increase in intracellular calcium, which leads to insulin secretion. A direct effect on insulin secretion, independent of ambient glucose levels, is seen with the first dose of any secretagogue. However, this direct effect wanes during continued occupancy of SUR1, while potentiation of the effect of current glucose levels continues.

Differences in pharmacokinetic and binding properties of the various agents contribute to their differing clinical effects, as do differences in their formulations and mechanisms of clearance from circulation. These properties are apparent clinically as differences in duration of action and likelihood of causing hypoglycemia. The best uses and also the relative risks versus benefits of the various secretagogues differ considerably.

Sulfonylureas

The sulfonylureas have been available since the 1950s. They are reliably effective in lowering glucose levels early in the natural history of T2DM when considerable beta-cell function is present.[160,161] Glimepiride and extended-release glipizide and gliclazide are generally the most widely used. These currently preferred sulfonylureas share several pharmacologic features. Each has a long duration of action after a single dose, allowing once-daily administration for most patients. Due to these longer profiles, continued SUR1 occupancy limits glucose-independent insulin release accompanying each subsequent dose, while continuing to potentiate glucose-dependent basal insulin secretion. The clinical effect of these agents is to lower fasting glucose levels with little effect on postprandial glucose levels, and relatively low risk of hypoglycemia compared with other secretagogues. Because none of these agents is strongly dependent on renal excretion, declining renal function has less direct effect on risk of hypoglycemia during their use. In contrast, chlorpropamide is a long-acting sulfonylurea that is cleared only by the kidney. Thus it can cause severe hypoglycemia when renal function becomes impaired, and largely for this reason it is now rarely used.

The shorter acting sulfonylureas include standard formulations of glipizide and glyburide. Taken twice daily they can be as effective as the longer-acting agents in overall glucose control. However, they have a greater effect on postprandial hyperglycemia and can cause daytime hypoglycemia when food intake is reduced. Glyburide has an active metabolite that can be cleared only by the kidney, and for this and other reasons it is associated with greater risk of hypoglycemia than other currently used sulfonylureas.[162]

There has been long-standing concern that sulfonylureas might cause increased arrhythmic cardiovascular events in patients with diabetes as a result of an effect on SUR2 subunits of the K_{ATP} complex in vascular and cardiac cells. Binding to SUR2 can blunt ischemic preconditioning, a normal cardioprotective mechanism. Epidemiologic studies assessing whether this effect confers increased cardiovascular risk in clinical practice differ in their conclusions, but more recent ones, including the newer sulfonylureas and accounting for confounding factors, are generally unable to confirm that risks of sulfonylureas outweigh potential benefits.[162] The ADVANCE trial, which used extended-release gliclazide as its dominant glucose-lowering strategy, did not show any evidence of cardiovascular toxicity.[44] The UKPDS similarly demonstrated long-term safety relative to lifestyle intervention for glyburide, glipizide, and chlorpropamide, which were all used in its main (sulfonylurea or insulin) treatment arm.[28] However, the individual sulfonylureas differ in pharmacologic studies of ischemic preconditioning, with this adverse effect confirmed for tolbutamide and glyburide and less apparent with glimepiride, glipizide, and gliclazide. Concern about cardiovascular risk is especially relevant to glyburide, an older sulfonylurea that continues to be prescribed despite its effects on ischemic preconditioning and tendency to cause hypoglycemia.

The maximum approved dose for the sulfonylureas is two to four times higher than the maximum effective dose. Initiating treatment with no more than a quarter of the maximal approved dose provides significant glucose lowering while limiting costs and adverse events. Small doses of the longer-acting modern sulfonylureas (e.g., 0.5–1 mg of glimepiride or 2.5 mg of extended-release glipizide) are often effective, particularly in patients receiving metformin concomitantly, and are almost always well tolerated. The leading

disadvantages of sulfonylureas are their tendency to cause hypoglycemia and usually modest weight gain. These unwanted effects may contribute to their more rapid loss of effectiveness than other agents, another observation best documented with glyburide.[163]

Glinides

Repaglinide is a member of the meglitinide family of insulin secretagogues, distinct from the sulfonylureas. It has a short half-life and a distinct SUR1 binding site. As a result of rapid absorption, it produces a faster and briefer stimulus to insulin secretion than the shorter acting sulfonylureas. It is typically taken with each meal and provides better postprandial control and generally less hypoglycemia and weight gain than glyburide. Repaglinide has a long residence time on the SUR1 and therefore some effect on fasting glucose, even though its pharmacologic half-life is quite short. Repaglinide is available in 0.5-mg, 1-mg, and 2-mg tablets. The maximum dose is 4 mg with each meal. As with the sulfonylureas, there is only a modest glucose-lowering advantage of high compared with moderate doses of repaglinide.

Nateglinide is a derivative of phenylalanine and is structurally distinct from both sulfonylureas and the meglitinides. It has a quicker onset and a shorter duration of action than repaglinide. Its interaction with SUR1 is fleeting. As a result, its effect in lowering postprandial glucose is quite specific, and it has little effect on fasting glucose. This provides both advantages (less overnight hypoglycemia) and disadvantages (less overall glucose-lowering effectiveness). Nateglinide is most appropriately used when glucose levels are modestly elevated in early diabetes or in combination with agents that control overnight glucose levels. It is available as 120-mg tablets and is taken with each meal. A 60-mg tablet is available but is not generally used except in patients with minimal hyperglycemia.

The rationale for using repaglinide or nateglinide to stimulate insulin secretion at mealtime to improve postprandial control without increasing the risk of overnight hypoglycemia is attractive. Furthermore, these newer agents demonstrate little binding to the vascular smooth muscle and cardiac SUR2 receptors. However, use of them has been modest, probably because of the need for multiple daily doses, higher cost than sulfonylureas, and lack of head-to-head comparative studies that demonstrate superiority over the newer sulfonylureas.

Thiazolidinediones

The thiazolidinedione class of drugs (TZDs, or glitazones) has engendered great interest and controversy since the first agent, troglitazone, was approved in 1997. Rare fatal hepatotoxicity was associated with troglitazone, and it was withdrawn from the US market in 2000. The currently available TZDs (pioglitazone and rosiglitazone) are considered safer. These agents bind to and modulate of the activity of a family of nuclear transcription factors termed *peroxisome proliferator-activated receptors* (PPARs), thereby initiating many downstream effects. They are associated with slow improvement in glycemic control over weeks to months in parallel with an improvement in insulin sensitivity and a reduction in free fatty acid levels.

Pioglitazone and rosiglitazone are equally effective in improving glycemic control and provide equivalent improvements in markers of insulin resistance and inflammation. No substantial evidence has linked the newer TZDs to hepatotoxicity, and a record of safety has been established in appropriate patients. The package insert nevertheless calls for liver function tests before beginning TZD therapy, and these agents are contraindicated in patients with active hepatocellular disease or unexplained serum alanine aminotransferase (ALT) levels greater than 2.5 times the upper limit of normal. Nonetheless, recent studies show a favorable effect of pioglitazone on nonalcoholic steatohepatitis, a common and otherwise difficult to treat condition.

Pioglitazone and rosiglitazone differ with respect to lipid effects. In a head-to-head study among dyslipidemic patients, pioglitazone reduced triglycerides by approximately 20%, whereas rosiglitazone increased triglycerides on average by 5%. Pioglitazone is associated with a modestly greater improvement in high-density lipoprotein (HDL) particle number and size and an improvement in low-density lipoprotein (LDL) particle size and number. Rosiglitazone was associated with an increase in LDL particle number and improved LDL particle size.[164]

Early epidemiologic evidence suggested that the ability of TZDs to improve insulin-sensitivity might lead to cardiovascular protective effects. This hypothesis was supported by a series of physiologic associations with TZD use: reduced carotid intimal/medial thickness, improvement of vascular endothelial function, improvements in dyslipidemia, lower blood pressure, and improved fibrinolytic and coagulation parameters. The hypothesis was tested in the PROactive (PROspective pioglitAzone Clinical Trial In macroVascular Events) study, a randomized, double-blind, placebo-controlled trial in 5238 patients with T2DM and documented macrovascular disease. Subjects were randomized to placebo or to 45 mg per day of pioglitazone and otherwise treated according to guidelines for hyperglycemia and major cardiovascular risk factors. The primary endpoint was the time from randomization to a broad set of macrovascular outcomes. Although this endpoint showed no significant improvement with pioglitazone, there was a marginally significant 16% reduction in a secondary, more restrictive cardiovascular composite endpoint. After extensive discussion of this controversial trial, it appears that pioglitazone therapy may be associated with some reduction of cardiovascular risk related to improvements in control of glucose, lipids, and blood pressure, but that these benefits are attenuated by an increased incidence of weight gain and heart failure.[165] Notably, in a recent placebo controlled study in nondiabetic patients with a recent ischemic stroke or transient ischemic attack, pioglitazone reduced the subsequent occurrence of stroke or myocardial infarction.[166]

The Rosiglitazone Evaluated for Cardiovascular Outcomes in Oral Agent Combination Therapy for Type 2 Diabetes (RECORD) trial was an open-label study that compared the effect of adding rosiglitazone versus either metformin or sulfonylurea to patients who had T2DM inadequately controlled with sulfonylurea or metformin. There was no difference in cardiovascular hospitalizations or death.[167] Subsequently, a controversy based on epidemiologic analyses developed as to whether rosiglitazone was associated with increased risk of myocardial infarction.[168] This dispute remains unresolved, but it caused a shift away from use of rosiglitazone.

Another potentially important attribute of the TZDs is an improvement in insulin secretory dynamics. Several trials have demonstrated that TZDs can delay the progression of dysglycemia to diabetes.[33,142] In addition, ADOPT (A Diabetes Outcome Progression Trial) found that patients with early diabetes had a slower rate of secondary glycemic failure when they were treated with rosiglitazone compared with metformin and glyburide. These outcomes were correlated with improved insulin secretion, although it remains unclear whether the improvement resulted mainly from direct effects on the beta cell as opposed to persisting reduction of insulin resistance.[163]

Despite these desirable effects, several adverse effects of the TZDs have raised concerns. These include weight gain, fluid retention, increased risk of bone fractures, and anemia. The weight gain has been shown to result both from extracellular fluid accumulation and an increase of subcutaneous but not visceral fat.[165] There are, in fact, desirable reductions in visceral, hepatic, and intramyocellular fat. The weight gain resulting from TZDs may not have the negative metabolic consequences that are generally ascribed to overweight and obesity, but it is nevertheless viewed negatively by most patients and practitioners. All patients prescribed TZDs should be counseled to enhance lifestyle efforts to limit weight gain.

With appropriate caution, relatively few patients will need to withdraw use of a TZD because of fluid retention. The patients most likely to experience edema are those using insulin and those with preexisting edema.[169,170] It is prudent to teach patients with preexisting edema how to assess pitting pretibial edema at home and to suggest they make a habit of checking nightly. If weight accompanied by increasing edema is noted, patients can be instructed to restrict sodium intake, to start a diuretic, or to increase their diuretic dosage as needed.

It is usually prudent to begin therapy with the lowest available dose, which in the case of pioglitazone is 15 mg daily. If after 3 months the glycemic response has been inadequate and significant edema has not developed, an increase to 30 mg may be considered. The highest approved dose, 45 mg, is less well tolerated. Many patients with mild edema respond to a thiazide diuretic or spironolactone. and combination therapy with a moderate-dose loop diuretic may be considered.[171] Fluid retention to the point of clinically apparent heart failure can occur, in which case the TZD should be discontinued. In the PROactive and RECORD studies, an excess of approximately 2% of patients treated with high-dose TZD required hospitalization for heart failure. There have been conflicting reports of worsened macular edema with thiazolidinediones.[172,173]

A more recent safety concern regarding TZDs is bone health. An excess of fractures has been reported during TZD use in both pharmacoepidemiologic studies and randomized trials, mainly in older women.[174,175] Whereas distal sites were primarily affected in these studies, loss of bone density in the lumbar spine may occur as well. Preclinical studies suggest that activation of PPARγ inhibits bone formation by diverting stem cells from the osteogenic to the adipocytic lineage. To minimize this risk, an assessment of risk factors and measurement of bone density should be considered before prescribing a TZD, especially for women.[176]

Finally, pioglitazone has been suspected of causing bladder cancer as a result of inconsistent preclinical and clinical observations. Large, long-term studies have not confirmed this association.[177] If pioglitazone is associated with bladder cancer, the absolute risk to an individual is low. However, current recommendations to avoid its use in patients with a history of bladder cancer seem prudent.

DPP4 Inhibitors

Oral glucose has a greater stimulatory effect on insulin secretion than does intravenous glucose at the same circulating glucose concentration. In humans this effect is mediated mainly by glucagon-like peptide-1, which is secreted in response to nutrients by intestinal L cells. Its binding to GLP1 receptors stimulates insulin secretion in a glucose-dependent fashion, inhibits inappropriate glucagon secretion, slows gastric emptying, reduces appetite, and improves satiety. Secreted GLP1 is very rapidly (1–2 minutes) inactivated in plasma by the enzyme dipeptidyl peptidase-4. A variety of pharmacologic techniques have been developed to harness the potential of GLP1 signaling to treat diabetes.[178,179] Several injectable drugs that are agonists for GLP1 receptors will be discussed later. Another approach is inhibition of DPP4, resulting in increased blood levels of endogenously produced GLP1 and other circulating peptides.

Five DPP4 inhibitors—sitagliptin, vildagliptin, saxagliptin, linagliptin, and alogliptin—are approved for clinical use in the United States and/or the European Union, and others are available in other countries. Some of their clinical characteristics are shown in Table 35.11. These agents increase fasting and postprandial levels of GLP1 about twofold. This elevation of GLP1 potentiates glucose-dependent insulin secretion and suppresses basal and postprandial glucagon. However, neither satiety nor the rate of gastric emptying is affected. The main clinical effect of DPP4 inhibitors is on fasting glucose levels, leading to HbA_{1c} reductions of 0.5% to 1%. They have no consistent effect on weight and no tendency to cause hypoglycemia when used alone or with metformin.[180]

All agents in this class are remarkably well tolerated, with an adverse effect profile similar to that of placebo. Postmarketing cases of pancreatitis have been reported, and DPP4 inhibitors are contraindicated for use by patients with a prior history. Specificity for DPP4 appears to be crucial, as inhibitors that are less specific for this enzyme been shown to have effects on immune function and cancer growth in animal studies. Further, the biologic effects of all the DPP4 inhibitors are complex, owing to their potential effects on clearance of other peptides that are substrates for this enzyme.[181] In cardiovascular outcome trials, there was an increased risk for heart failure hospitalization with saxagliptin and a numerical imbalance for alogliptin,[182–184] but no increased risk was demonstrated for sitagliptin.[185] It is not clear whether these findings represent an important clinical distinction, the play of chance, or differences in trial populations or conduct. Serious hypersensitivity reactions have been reported, but causality has not been substantiated because of the rarity of events.

Linagliptin is available in only one tablet size. For the other DPP4 inhibitors in current use, which are partially cleared by the kidney, the usual dose is the maximum marketed dose, and smaller doses are recommended in the setting of stage 3 or greater chronic kidney disease. The weight neutrality, lack of hypoglycemia, broad applicability, tolerability, and ease of use of DPP4 inhibitors are appealing properties. Consequently, they have been widely used despite their relatively weak glucose-lowering power that is partly dependent on retained beta-cell function.

α-Glucosidase Inhibitors

α-Glucosidase inhibitors (AGIs) slow the terminal step of carbohydrate digestion at the brush border of the intestinal epithelium. As a result, carbohydrate absorption is shifted more distally in the intestine and is delayed, allowing the sluggish insulin secretory dynamics characteristic of T2DM to catch up with carbohydrate absorption.

The two agents currently available in the United States are acarbose and miglitol. Voglibose is available in other countries. Use of AGIs in the United States has been limited by a number of factors, including the need to administer the medication at the beginning of each meal, flatulence as a common side effect, and only modest reductions in blood glucose levels. These factors should be balanced against the ability of AGIs to lower postprandial glucose without increasing weight or hypoglycemic risk.[186] There is also some evidence suggesting that acarbose improves cardiovascular outcomes better than most antihyperglycemic agents.[187]

TABLE 35.12 Treatment Effects of Empagliflozin and Canagliflozin in the EMPA-REG OUTCOME and CANVAS Program Studies

	EMPAGLIFLOZIN IN EMPA-REG OUTCOME		CANAGLIFLOZIN IN THE CANVAS PROGRAM	
Endpoints	**Hazard Ratio (95% CI)**	***p* Value**	**Hazard Ratio (95% CI)**	***p* Value**

Cardiovascular death	0.62 (0.49–0.77)	<0.001	0.87 (0.72–1.06)	NA
All cause death	0.68 (0.57–0.82)	<0.001	0.87 (0.74–1.01)	NA
Hospitalization for heart failure	0.65 (0.50–0.85)	0.002	0.67 (0.52–0.87)	NA
Progression of albuminuria	0.62 (0.54–0.72)	<0.001	0.73 (0.67–0.79	NA

CI, Confidence interval; *NA,* not available.

Data from Zinman B, Wanner C, Lachin JM, et al. Empagliflozin, cardiovascular outcomes, and mortality in type 2 diabetes. *N Engl J Med.* 2015;373:2117–2128; Neal B, Perkovic V, Mahaffey KW, et al. Canagliflozin and cardiovascular and renal events in type 2 diabetes. *N Engl J Med.* 2017;377:644–657.

To maximize the potential for these agents to be well tolerated, the starting dose should be low (e.g., one-fourth of the maximum dose) and taken just once daily, with slow increases in dosage and frequency of administration over a period of weeks or months.

Sodium-Glucose Transporter Inhibitors

This is the newest class of glucose-lowering medications, first marketed for the treatment of T2DM in 2013.[188–190] These agents depend upon the kidney's central role in the regulation of glucose dynamics and fluid balance. Under normal conditions about 180 g of glucose is filtered from plasma at the glomerulus and reabsorbed in the proximal tubule. That quantity is equal to a fairly standard daily dietary intake of carbohydrate. In the setting of diabetes, glucose appearance in the proximal tubule increases, and glucose reabsorption by SGLT2 increases as well. This high-capacity low-affinity transporter is responsible for 90% of renal tubular glucose reabsorption. There is a second active transport molecule, SGLT1, which is a low-capacity high-affinity transporter responsible for approximately 10% of glucose reabsorption in the kidney but critically important for glucose absorption from the gut. Naturally occurring mutations in the SGLT2 gene cause a rare familial renal glycosuria syndrome associated with up to 170 g glucose lost in the urine daily, lesser rates of obesity and diabetes, and no evidence of long-term renal consequences. When diabetes is poorly controlled, more glucose enters the renal tubules than can be reabsorbed, and glucose appears in the urine. Because increased reabsorption of glucose by SGLT2 is accompanied by increased reabsorption of sodium, sodium balance may also be disrupted in poorly controlled diabetes. Given these renal dynamics, it is not surprising that drugs blocking SGLT2 have important physiologic and clinical effects. They reduce both fasting and postprandial glucose levels and promote modest weight loss through loss of calories as glucosuria. They also reduce blood pressure, at least in part by increasing sodium clearance and reducing extracellular fluid volume.

Four SGLT inhibitors are currently available in the United States for clinical use: canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin. All are relatively specific for inhibiting SGLT2, but others in development also have some effect on SGLT1. The available agents have been studied in T2DM as monotherapy, in combination with other oral antihyperglycemic agents, and with insulin, with results that are quite similar between agents.[191] Studies comparing SGLT inhibitors with metformin, sulfonylurea, and DPP4 inhibitors suggest that these agents are about as effective in HbA_{1c} reduction as the other oral agents when used in combination regimens. In 26-week studies these agents lead to approximately 2 to 3 kg more weight loss than placebo.

Beyond these desirable effects that were expected based on known mechanisms of action, this class of drugs also provides cardiovascular benefits. The Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients—Removing Excess Glucose (EMPA-REG OUTCOME) trial was a large randomized cardiovascular outcome study of empagliflozin. It showed unexpectedly good effects of this agent in T2DM patients who were selected for having high cardiovascular risk. Treatment with empagliflozin for a median time of about 3 years was associated with a 32% relative risk reduction of all-cause mortality, 38% reduction of cardiovascular mortality, and 35% reduction of hospitalization for heart failure. Favorable effects of empagliflozin on established renal disease were also found in this study.[192] A subsequent report of similar studies of canagliflozin described generally similar, although quantitatively less prominent, cardiovascular and renal results.[193] These findings are summarized in Table 35.12.

Demonstration of strong short-term cardioprotective effects of this class of drugs has generated much enthusiasm for their use, supported by relatively consistent findings, including real-world studies.[194–199] It has also led to follow-up studies that should provide more information regarding whether all drugs in this class have similar effects, and to what extent these observations are applicable to T2DM patients without established cardiovascular or renal disease. There is particular interest in the potential value of SGLT inhibitors for patients with heart failure, a cardiovascular complication of diabetes that is increasingly common.[199,200] The mechanisms underlying these cardiovascular and renal effects are not well understood. At present it seems likely that several factors contribute, including improvement of glycemic control, blood pressure, and weight control, together with improved regulation of fluid balance and/or increased availability of ketones as fuel for injured cardiac or renal tissues.

The most common side effects of this class are related to glycosuria and include urinary frequency, genital infections, and relatively rare episodes of lower urinary tract infections as well as dehydration and its consequences. Genital infections are usually related to yeast, occur in approximately 10% to 15% of women (about a fivefold increase of risk), and may recur.[201,202] Genital mycotic infections are much less common in men and predominantly are found in those who have not been circumcised. A cardiovascular outcome trial found increased lower extremity amputations with canagliflozin.[195] There is still uncertainty about this risk and whether it could involve other agents in the class.[195,196,203] Theoretic questions related to bone metabolism have been raised, but an increased risk of fractures has not been found in most completed clinical trials.[190,204]

Good renal function is essential for full efficacy of SGLT inhibitors. Initiation is not recommended when eGFR is below 45 mL/minute per 1.73 m^2, and use should be discontinued when eGFR is lower than 45 mL/minute per 1.73 m^2. Although acute renal insufficiency has been reported, presumably due to changes in renal perfusion, this class of medications shows potential for long-term renal protection as well.[205–207] An unexplained imbalance in bladder cancer without a change in total cancer or cancer fatality was reported in early development of dapagliflozin.[208,209] Dapagliflozin is the only agent in the class with a warning against use of the drug in patients with bladder cancer.

As a final concern, there have been reports of diabetic ketoacidosis occurring without markedly elevated glucose levels (euglycemic diabetic ketoacidosis) during treatment of presumed T2DM with an SGLT inhibitor. Although some of the individuals affected certainly had T2DM, some likely had unrecognized adult-onset T1DM. In many cases the event was preceded by a surgical procedure, an acute illness, or an inappropriate reduction of insulin dosage. The mechanisms underlying this adverse effect are only partly understood, but may include a tendency toward dehydration, elevation of circulating glucagon levels, and accelerated gluconeogenesis due to glucosuria during fasting.[190,210] Any patient treated with an SGLT inhibitor who experiences persistent or recurrent nausea, vomiting, or malaise, or who develops a metabolic acidosis, should be evaluated for the presence of urine and serum ketones, even if glucose levels are near normal.[211]

Colesevelam

Colesevelam is a second-generation bile acid sequestrant. It was observed to mediate modest reductions in glucose during the clinical development program. An expanded program in patients with T2DM resulted in approval for marketing of this drug as an adjunct for the treatment of diabetes. It provides an HbA_{1c} reduction of about 0.5% in addition to approximately 15% improvement in LDL.[212] HDL changes tend to be trivial. Triglycerides can increase by 5% to 20%. Gastrointestinal side effects affect 10% or more of patients but seldom lead to withdrawals. The mechanisms for the glycemic effects are not definitively known.[213]

Bromocriptine

A quick-release formulation of bromocriptine administered within 2 hours of rising in the morning has been developed and is approved for marketing in the United States. It is suggested that creating a circadian peak in central dopaminergic tone improves insulin sensitivity. Nausea is the most common adverse effect, occurring in about 30% of patients and leading to discontinuation in about 10% at highest doses. Lower doses are better tolerated. HbA_{1c} reductions are generally modest but have been reported to be as high as 1.2%. In a 1-year safety study, broad cardiovascular outcomes were improved 40% compared with placebo.[214] Recent studies suggest substantial efficacy in the setting of inadequate glycemic control on high-dose insulin therapy.[215,216]

Glucose-Lowering Agents Requiring Injection

In addition to the glucose-lowering therapies that are orally administered small molecules, there is a group of relatively larger peptide agents that must be administered by other means. At present, these are mostly delivered by subcutaneous injection, but delivery by inhalation, sublingual absorption, nasal spray, or other means may become more common in the future. At present, one formulation of inhalable insulin is available for use, and other products that can be delivered by means other than injection are under study. Because injected therapies require more active participation by the patient, or assistance by others, more education and support in their use is needed than with oral therapies.

Insulins

Insulin has been commercially available since the early 1920s and is arguably the best studied form of therapy for diabetes. It is essential for all patients with T1DM and a mainstay of treatment for T2DM. Subcutaneous injection of insulin can be used to supplement endogenous production of insulin both in the basal state, to modulate hepatic glucose production, and in the postprandial state, in which a surge in insulin release normally further suppresses hepatic glucose production and facilitates glucose uptake by muscle and fat. Almost all insulins currently used worldwide are human insulins synthesized by recombinant technology or synthetic analogues of the human molecule.[217,218] The various formulations differ largely in their pharmacokinetics, as shown in Table 35.13. As patents on insulin analogues expire, equivalent products that are manufactured by different companies are becoming available. These "biosimilar" insulins appear to have effects very like those of the originally patented versions.[219,220]

Insulins are grouped into shorter-acting versus longer-acting formulations. This distinction has practical importance, as these two categories of insulin are used quite differently. Both short-acting and long-acting insulins have profiles of action that vary by the size of the dose injected. With higher doses the onset and time to peak effect become more delayed and the total duration longer.

Long-Acting Insulins

Long-acting insulins are usually initiated before short-acting ones. In the past, formulations of human insulin were modified to prolong its action by slowing absorption. The most widely used formulations were ultralente insulin and protamine zinc insulin (PZI), both of which were very long acting, and lente insulin and neutral protamine Hagedorn (NPH), both considered intermediate acting. Ultralente, lente, and PZI are no longer available, but NPH human insulin is still commonly used. The time to onset, peak effect, and full duration of action of NPH are about twofold greater than those of regular human insulin, with an onset in 1 to 2 hours, a peak usually at 4 to 8 hours, and a duration of 12 to 16 hours. Insulin detemir is a long-acting analogue in which a fatty acid side chain is covalently bound to the insulin molecule, resulting in slowing of both absorption from subcutaneous tissue and clearance from circulation. Detemir's time of onset and duration of action are quite similar to those of NPH, but more consistent from injection to injection.[221] To reliably provide a sustained between-meal and overnight (basal) effect, both NPH and detemir must be taken twice daily, usually before breakfast and either before dinner or at bedtime. However, for patients with

TABLE 35.13 Clinical Features of Commonly Used Insulins

Types and Generic Names (Commercial Names)	Onset of Action (Minutes)	Time to Peak (Hours)	Duration (Hours)	Administration
Rapid Acting				
Aspart (Fiasp)	<5	0.5–1.5	3–5	Just before or just after meals
Aspart (Novolog)	10–20	0.5–1.5	3–5	0–15 minutes before or just after meals
Lispro (Humalog)	10–20	0.5–1.5	3–5	
Glulisine (Apidra)	10–20	0.5–1.5	3–5	
Short Acting				
Regular human (Humulin R, Novolin R)	30–45	2–4	4–8	15-30 minutes before meals
Intermediate Acting				
NPH (Humulin N, Novolin N)	60–120	4–8	12–20	Once or twice daily
Long Acting				
Detemir (Levemir)	60–120	6–10	16–24	Usually once daily
Glargine (Lantus, Basaglar)	60–120	No pronounced peak	~24	
Degludec (Tresiba)	60–120	No pronounced peak	Up to 72	
Premixed				
70/30 NPH/R (Humulin 70/30, Novolin 70/30)	30–40	4–8	12–20	Usually twice daily, 0–30 minutes before meals
75/25 Protamine-lispro/lispro (Humalog Mix 70/30)	10–20	4–8	12–20	
70/30 Protamine-aspart/aspart (Novolog Mix 70/30)	10–20	4–8	12–20	
50/50 Protamine-lispro/lispro (Humalog Mix 50/50)	10–20	4–8	12–20	
50/50 Protamine-aspart/aspart (Novolog Mix 50/50)	15–60	4–8	12–20	
Concentrated				
U-500 human regular (Humulin U-500)	30–45	6–12	12–24	Twice daily
U-200 degludec (Tresiba U-200)	60–120	No pronounced peak	>24	Once daily
U-300 glargine (Toujeo 300 U/mL)	60–120	No pronounced peak	Up to 72	Once daily

T2D who add detemir as basal insulin while continuing noninsulin agents to cover the day, once daily dosing can be sufficient for at least 40% of patients.[58]

Insulin glargine is a long-acting analogue that is soluble at acid pH but precipitates when neutralized in tissues after injection. The resulting gradual absorption leads to a duration of action that, at doses commonly needed in T2DM, usually provides more than 24 hours of basal insulin effect with relatively little peak-to-trough variation. This action profile results in consistently less risk of hypoglycemia than occurs with NPH insulin, and has led to use of insulin glargine taken once daily, either before breakfast or at bedtime, as a reliable way to initiate insulin therapy.

Insulin degludec and a more concentrated formulation (300 units/mL) of insulin glargine have recently been introduced, and both provide even longer and flatter profiles of action than detemir and glargine.[222,223] Further prolongation of action of degludec is due both to slower absorption after injection and to delayed clearance, whereas that of glargine 300 units/mL results entirely from an effect on absorption. The pharmacokinetics of these newer long-acting insulins result in even lower risk of hypoglycemia than with glargine, but their advantage over glargine in this respect appears smaller than that with glargine versus NPH.[224]

Short-Acting Insulins

Regular human insulin and the rapid-acting analogues (insulins lispro, aspart, and glulisine) are all administered by injection with meals to assist in control of postprandial hyperglycemia.[217,218] Regular insulin has an onset of action about 30 minutes after injection, a peak at 2 to 4 hours, and duration of 6 to 8 hours or longer at high doses. The three rapid-acting analogues all have an onset in 5 to 15 minutes, peak activity in approximately 1 hour, and duration of approximately 4 hours. A more rapidly absorbed formulation of insulin aspart with onset of action within 2.5 minutes has recently become available.[225] Other very rapid-acting insulin formulations and delivery technologies are being developed. Regular human insulin administered intravenously is immediately effective, with a half-life on the order of 10 minutes. Lispro, aspart and glulisine are approved in the United States for intravenous use but offer no advantage over regular insulin for this purpose and cost much more.

U-500 regular insulin has been available for decades, but its use has increased in the setting of severe insulin resistance.[226] This concentrated insulin has a delayed and prolonged action profile compared to U-100 regular.[227] It has been administered twice daily, three times daily, and by insulin pump with good efficacy.[228] Pen devices are now available for ease and safety.

One inhaled formulation of human insulin is available.[229,230] The device by which it is delivered is quite convenient to carry and use. The insulin-loaded microparticles produce rapid onset of effect with peak activity in 30 minutes (the t_{max} is about 10 minutes), much earlier than with lispro.[231] The time to peak is extended with higher doses, and the duration also varies from 90 minutes at lower doses to 180 minutes with 12 units. Inhaled insulin may be preferred by patients who are very averse to taking injections, and some patients prefer its more rapid action to help with postprandial glucose control, but the shorter duration can be problematic. The current formulation requires spirometry before initiation, at 6 months, and annually thereafter. This preparation is contraindicated in patients with asthma or chronic obstructive pulmonary disease, and there are advisory precautions for patients with active lung cancer and smokers. Its use is associated with cough or throat irritation in addition to the usual hypoglycemic risk, and is at present limited to 4-unit, 8-unit, and 12-unit doses resulting in limitations of dose adjustments.

TABLE 35.14 Clinical Features of Commonly Used Injectable Agents Other Than Insulin

Types and Generic Names (Commercial Names)	Administration	Main Effects	Contraindications	Side Effects
Short-acting GLP1 agonist				
Exenatide (Byetta)	5–10 μg BID before breakfast and dinner	Postprandial glucose control and weight loss	T1D DKA Pancreatitis History medullary carcinoma	Nausea, diarrhea, abdominal pain Pancreatitis?
Lixisenatide (Adlyxin)	10–20 μg QD before breakfast			
Long-acting GLP1 agonist				
Liraglutide (Victoza)	0.6–1.8 mg daily	Basal glucose control and weight loss	T1D DKA Pancreatitis History medullary carcinoma	Nausea, diarrhea, abdominal pain Pancreatitis?
Dulaglutide (Trulicity)	0.75 or 1.5 mg weekly			
Extended-release exenatide (Bydureon)	2 mg weekly			
Semaglutide (Ozempic)	0.5 or 1 mg weekly			
Fixed-dose GLP1/insulin combination				
Liraglutide/degludec (Xultophy)	Daily, titrated	Glucose and weight control	T1D DKA Pancreatitis History medullary carcinoma	Hypoglycemia Nausea, diarrhea, abdominal pain Pancreatitis?
Lixisenatide/glargine (Soliqua)	Daily before breakfast, titrated			
Amylin agonist				
Pramlintide (Symlin)	TID before meals in T1D or T2D requiring prandial insulin	Postprandial glucose control and weight loss	Confirmed gastroparesis	Nausea Abdominal pain Hypoglycemia

Premixed Insulins

Premixed insulin formulations provide greater convenience and accuracy of dosing than mixing of two formulations in a syringe by the patient at the time of administration, but at the expense of reduced flexibility of dosing. Premixed formulations available in the United States are 70/30 and 50/50 mixtures of NPH and regular insulin, a 75/25 and a 50/50 mixture of lispro insulin in its NPH-like formulation with insulin lispro, and a 70/30 mixture of insulin aspart with its NPH-like congener. Premixed insulins provide a single-peak action at about 4 to 6 hours after each injection, as expected from summation of the activities of their components. In a very instructive study, use of 70/30 insulin in T2DM showed greater improvement in glucose control but at the cost of significantly more hypoglycemia compared to basal insulin.[232]

Human Versus Analogue Insulins

Insulin analogues are clearly helpful in managing T1DM, which requires complete replacement of endogenous insulin and accurate matching of the profile of action to daily needs. The degree to which both long-acting and rapid-acting analogues offer advantages over NPH and regular human insulin for T2DM is less well established and a focus of debate. Among the issues is that both the list price and the direct cost to patients can be much higher for the analogues.[142,233,234] Both long-acting and rapid-acting insulin analogues have been shown in large studies to cause less frequent hypoglycemia than human insulins, but for some patients little difference may be found. The absolute risk of severe hypoglycemia in patients with T2DM is relatively small, approximately one-third to one-tenth as high as in similarly treated patients with T1DM. This risk can be further minimized with appropriate education of patients and expectant monitoring of glucose at times when hypoglycemia is most likely to occur, such as at night or during unplanned or strenuous activity. Allergies to currently available insulins are rare, as are chronic skin reactions, which include lipoatrophy and lipohypertrophy.

Insulin Delivery Devices

Newer insulin needles cause less discomfort than those previously available because of a finer gauge, shorter length, sharper points, and smoother surfaces. Improved insulin pen design has made teaching a patient to take insulin much easier and provides greater convenience and accuracy of dosing. Pen injectors capable of injecting larger doses, up to 160 units, are now available for U-300 glargine and U-200 degludec. Insulin pump therapy has been used in patients with T2DM but is not widely accepted as cost effective in routine practice.[235–237] Insulin pump delivery of U-500 regular insulin has been proposed for highly insulin-resistant T2DM but is still a relatively uncommon application.[226]

GLP1 Receptor Agonists

GLP1 agonists are homologs or analogs of human GLP1 that have significantly changed the landscape of T2DM therapy.[179,238,239] As with insulins, GLP1 agonists divide logically into two groups: those that are short acting and those with longer duration of effects. Important features of the available agents in this class are shown in Table 35.14.

Short-Acting GLP1 Agonists

The first to be developed was exendin-4, a short-acting agent. It is a naturally occurring component of the saliva of the Gila monster *(Heloderma suspectum)* and shares 53% sequence identity with GLP1 but is relatively resistant to degradation by DPP4. Exenatide is synthetic exendin-4 and was the first GLP1-based therapeutic agent to be approved for human use.[240,241] When injected subcutaneously, it has a peak of action at about 2 hours and total duration of no more than 6 hours. Like GLP1 itself, it potentiates insulin secretion in response to rising glucose levels, suppresses postprandial glucagon secretion, delays gastric emptying, and promotes satiety. With twice-daily injection before breakfast and before dinner it produces a reduction of approximately 1% in HbA_{1c}, largely through a reduction of postprandial glucose along

TABLE 35.15 Treatment Effects of Liraglutide and Semaglutide in the LEADER and SUSTAIN-6 Studies

Endpoints	LIRAGLUTIDE IN LEADER		SEMAGLUTIDE IN SUSTAIN-6	
	Hazard Ratio (95% CI)	*p* Value	Hazard Ratio (95% CI)	*p* Value
Primary cardiovascular composite Cardiovascular death, nonfatal myocardial infarction, or nonfatal stroke	0.87 (0.78–0.97)	0.01	0.74 (0.58–0.94)	0.02
Cardiovascular death	0.78 (0.66–0.93)	0.007	0.98 (0.65–1.48)	0.92
All cause death	0.85 (0.74–0.97)	0.02	1.05 (0.74–1.5)	0.79
Hospitalization for heart failure	0.87 (0.73–1.05)	0.14	1.11 (0.77–1.61)	0.57

with modest weight loss (2–4 kg). With prolonged use, these effects can be associated with modest improvements in blood pressure and lipids. The most common adverse effect is nausea, which occurs in up to 50% of patients, is usually mild to moderate in intensity, occurs early in the course of therapy, and typically wanes over time. Nausea leads to withdrawal of therapy in about 5% of patients.

Lixisenatide is a more recently introduced agent that has properties similar to those of exenatide except for a slightly longer duration of action.[242] It has been approved for administration once daily before breakfast. When given in this way it reduces postprandial increments of glucose during the daytime but has much less effect overnight. Both exenatide and lixisenatide are recommended to be started at the lower available dose and advanced to full dosage after several weeks to limit side effects on initiating therapy.

Long-Acting GLP1 Agonists

Newer, longer-acting GLP1 receptor agonists include liraglutide, an extended-release formulation of exenatide, dulaglutide, and semaglutide.[179,239,243] Liraglutide is administered once daily without any restriction as to timing or relation to meals. The other long-acting agents are to be given once weekly. In general, they are associated with greater HbA_{1c}-lowering efficacy than short-acting exenatide and lixisenatide, owing to their greater effects on overnight fasting glucose levels.[179,239] However, they have much less effect on postprandial increments of glucose than the short-acting agents. They also are associated with a lower frequency of gastrointestinal side effects. All the various long-acting agents appear to be quite effective in lowering HbA_{1c}, although some differences are shown in early head-to-head trials.[244–247] Some evidence suggests that semaglutide can cause superior reduction in HbA_{1c} but also more nausea.[245,246,248] Studies under conditions of clinical practice have shown some differences from randomized clinical trials, suggesting that results of treatment can be influenced by differences in adherence to therapy.[249] There are some differences in the pen injectors used for delivering doses of the various agents, and instruction in their use is needed to optimize dosing and adherence.[250]

Weight loss is consistently seen and similar among the various GLP1 receptor agonists, although only liraglutide is currently approved for weight loss in patients with or without diabetes (see Chapter 40). Semaglutide appears to have slightly more weight loss potential when used at doses approved for diabetes in the United States.

Recently, large randomized trials examining cardiovascular safety of two long-acting GLP1 agonists—liraglutide and semaglutide—have shown significant cardiovascular benefit in populations selected for having high cardiovascular risk.[251–255] Details of these studies are shown in Table 35.15. The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) study followed patients randomized to treatment with liraglutide or placebo for a median of more than 3 years. Significant reductions of risk were found for the primary composite cardiovascular endpoint (13%), cardiovascular death (22%), all-cause mortality (15%), and progression of albuminuria (26%).[252] The Trial to Evaluate Cardiovascular and Other Long-term Outcomes with Semaglutide in Subjects with Type 2 Diabetes (SUSTAIN-6) had a generally similar design but studied patients starting with somewhat worse glycemic control who received randomized treatment for about 2 years.[251] This study demonstrated somewhat greater reduction of risk for its primary cardiovascular composite endpoint (26%) compared with LEADER and showed a reduction of renal endpoints. However, no reduction of mortality was found. Neither LEADER nor SUSTAIN-6 showed a reduction of hospitalizations for heart failure. Up to now, these favorable outcomes have not been found with short-acting GLP1 agonists and there has been inconsistency in the specific benefits seen in trials of the other long-acting agents. Many of the variations could relate to the study designs and populations selected in those trials.

Hypoglycemia is not a direct effect of GLP1 receptor agonists but can occur when they are added to other agents. When one is added to prior therapy with a secretagogue, it is prudent to reduce to the minimum dose of secretagogue, at least initially. When a GLP1 receptor agonist is added to insulin, a 20% reduction of insulin dosage is advised unless HbA_{1c} is greater than 8%.

Concern about pancreatitis has emerged from postmarketing reports of GLP1 receptor agonists. A direct causal link has not been proved, although passage of gallstones accompanying weight loss remains a possible mechanism. It is recommended that drugs in this class be avoided in patients with a history of pancreatitis.[256] Exenatide is renally cleared and is contraindicated in the setting

of advanced kidney disease (eGFR <30 mL/minute/1.73 m^2). The other GLP1 receptor agonists do not share this feature with exenatide. Nevertheless, cases of acute renal failure have been reported in association with GLP1 receptor agonist therapy, usually in patients with chronic renal insufficiency who develop superimposed prerenal azotemia in the context of prolonged anorexia, nausea, and vomiting. To mitigate the risk of pancreatitis and renal failure, it is prudent to instruct patients treated with GLP1 receptor agonists to stop their medication if they develop nausea, vomiting, or abdominal pain of more than a few hours' duration and to seek medical attention if they are unable to keep down fluids after 4 hours.

Another safety concern is medullary thyroid cancer. No signal exists for this problem with GLP1-based therapy in humans, but a clear increase in the incidence of these tumors was observed in preclinical testing in rodents, although not in other animal models. It is suggested that these agents be avoided in those with a personal or family history of medullary thyroid cancer.

Amylin Receptor Agonists

Amylin is a neuroendocrine hormone that is cosecreted with insulin by pancreatic beta cells. A deficiency of amylin is therefore evident in patients with T1DM or T2DM, in parallel with insulin deficiency. Amylin and insulin have complementary actions in regulating plasma glucose. Amylin binds to brain nuclei and promotes satiety and reduces appetite. Through efferent neural pathways it mediates a decrease in the rate of gastric emptying and limits inappropriate glucagon secretion in a glucose-dependent fashion. By these means it regulates the rate of plasma glucose appearance from the gastrointestinal tract and the liver. Insulin concurrently regulates the rate of glucose appearance from the liver and stimulates glucose uptake in muscle and fat.

Amylin is relatively insoluble in aqueous solution and aggregates on plastic and glass. Pramlintide was developed as a soluble, nonaggregating amylin analogue, with similar clinical effects, that is administered by injection before meals. It is approved for use by patients with T1DM or T2DM requiring both basal and mealtime insulin.[257] Most of the effect on glycemic patterns is a reduction of postprandial increments, with little effect on overnight control. When pramlintide is added to insulin therapy with or without metformin or a sulfonylurea in T2DM, HbA_{1c} can be reduced by about 0.5 to 0.7 percentage points, and weight is variably reduced as well.[258]

Mild or moderate nausea, which wanes with continued therapy, is pramlintide's most common adverse effect. It is minimized by initiating therapy with 60 μg before meals, with an increase to the full 120 μg dose over 1 to 2 weeks as tolerated. Hypoglycemia is less frequent in patients with T2DM than in patients with T1DM and can be limited by reducing dosage of mealtime insulin by about 50% when initiating therapy, with the option of subsequently returning to higher doses as needed.[257] Oral medications that require rapid absorption for effectiveness should be administered either 1 hour before or 2 hours after injection of pramlintide. Coformulations of pramlintide with regular human insulin are being evaluated.

Practical Aspects of Treatment

A Team Approach

Considering the wide array of interventions available, and the need to adapt to differences between patients as well as changing needs over time, it is obvious that many treatment decisions will be needed for every patient. It is also clear that various kinds of providers with differing training and experience can contribute to making and implementing these decisions. No one provider can do it all, and the concept of a team approach to management of diabetes is well established. Teams may include nurses, nutritionists, pharmacists, educators, and physicians, all with specific interest and experience in diabetes. Although the previous discussion of DSMES describes in detail the services and processes required for care, it does not define specifically the kinds of providers needed. This is because different health systems use different models for providing DSMES, with different configurations of providers. However, in each setting a locally available group of providers should be identified who can function as a team with each individual patient. Providers specialized in other aspects of care commonly needed by people with T2DM—such as cardiology, nephrology, ophthalmology, and podiatry—also can contribute to the team effort. The overall goal of this collaboration is to ensure optimal management of overall metabolic control, other risk factors for complications of diabetes, and the complications themselves. Making the team concept a reality is a major challenge for health systems today.

The specialized team can assist at various points in the natural history of T2DM. As noted in Fig. 35.2 and Table 35.7, these include the time of diagnosis, a later time when injected therapies or use of devices such as CGM systems are needed, or whenever diabetes-related problems such as severe hypoglycemia, ketoacidosis, or repeated hospitalization occur or reoccur.

Identifying Pathophysiologic Subgroups

The time of diagnosis presents an opportunity to favorably influence the entire future experience of the patient. It is typically a teachable moment at which the patient can be introduced to DSMES and develop a long-term plan of management. It is also an opportunity to identify those individuals who do not have the most typical form of T2DM and adjust the plan accordingly. Several of the more common atypical subgroups are discussed in this section.

Latent Autoimmune Diabetes of Adulthood

The largest subgroup is that with diabetes of autoimmune origin, commonly called *latent autoimmune diabetes of adulthood* (LADA) or adult-onset type 1 diabetes. This group comprises up to 12% of patients diagnosed with diabetes after age 20.[259,260] Such individuals may have rapid deterioration of glycemic control prior to diagnosis, sometimes accompanied by prominent symptoms of hyperglycemia and weight loss, but these tend to progress less rapidly than in youth-onset T1DM. They frequently are not obese and may have other autoimmune disorders or a family history of these. Laboratory support can be provided by detection of anti–glutamic acid decarboxylase (GAD) antibodies or anti-islet cell antibodies, although lack of antibodies does not exclude an autoimmune process. Both family history and genetic markers are likely to be more consistent with T1DM, but there is heterogeneity and uncertainty in classifying individual cases.[261,262] Insulin has been considered the main therapy from the outset, but other therapies may be possible in those with slow progression. There is some evidence that early use of insulin may prolong beta-cell function and prevent a period of sustained hyperglycemia that could initiate chronic complications.

Pancreatic Diabetes

Another relatively common subgroup comprises patients with other disorders affecting the pancreas. Pancreatic diabetes has been referred to as type 3c diabetes and is underdiagnosed.[263,264] The leading causes include acute or chronic pancreatitis, pancreatectomy for cancer or pancreatitis, hemochromatosis, and cystic fibrosis. Despite widely differing pathogenesis, patients with pancreatic diabetes share a tendency to have significant deficiency of insulin secretion and prominent postprandial hyperglycemia, and may respond less well than expected to oral therapies.[264] In addition to insulin deficiency, there are significant decreases in glucagon secretion and in the effects of incretin hormones. As in the case of LADA, patients in this subgroup commonly need insulin at or relatively soon after diagnosis and quite frequently require both basal and prandial insulin. In some cases, due to the multihormonal loss, there is more glucose variability than is seen in T2DM or T1DM.[265]

Monogenic Diabetes

A smaller but increasingly recognized subgroup is that with monogenic diabetes. This is a heterogeneous group of heritable disorders, which are often diagnosed in childhood but sometimes present as diabetes diagnosed in adulthood.[266–268] A subset of this group of disorders has been commonly described as maturity-onset diabetes of the young (MODY). The proportion of newly diagnosed adults with one of these conditions is estimated to be between 1% and 2%. The diagnosis should be considered in atypical cases that might otherwise be diagnosed as T1DM or T2DM. A strong family history consistent with autosomal dominant inheritance with high penetrance is typical but not always present. A definitive diagnosis depends on genetic testing that can identify specific subtypes and thus assist in planning treatment. This approach to monogenic diabetes is one of the best present-day examples of precision medicine.

Two of these disorders deserve specific comment. One is a heritable deficiency of glucokinase (GCK-MODY) that alters glucose sensing in the beta cell.[269] It presents typically in youth as mild fasting hyperglycemia (e.g., 100–140 mg/dL) that is not progressive and causes little or no tissue damage over time. The HbA_{1c} may range from 5.6% to 7.8%. In many cases this disorder is not recognized until routine chemistry tests indicate elevated fasting glucose levels typical of prediabetes. It is often recognized in women during testing for gestational diabetes. Recognition of GCK-MODY is important mainly to avoid unnecessary treatment of the patient and other identified members of the family. Current evidence indicates that those with a GCK mutation will not develop chronic complications of diabetes, and treatment is not likely to render significant changes in glucose control. However, longer follow-up of larger numbers or individuals with this disease will be needed to be certain.[270]

In contrast, the most common form of monogenic diabetes, hepatic nucleocyte factor-1A (HNF1A), has direct clinical relevance.[271] It can present in adulthood with progressive hyperglycemia, more postprandial than fasting, that responds very well to sulfonylureas. Other monogenic forms of diabetes, such as HNF4α mutations, may also respond to sulfonylureas, which bind to the molecular complex on the surface of beta cells that is genetically affected. Successful responses to sulfonylureas may persist for extended periods of time. The possibility of sulfonylurea-responsive monogenic diabetes can be suspected when there is a prominent history of adult-onset but quite stable and slowly progressive diabetes on one side of the patient's family, often in the absence of obesity. Laboratory screening for these disorders is now more available than in the past but not always covered by insurance. Identification of affected families can avoid unnecessary or inappropriate therapy for many family members.

Standardized Versus Personalized Tactics

The remaining majority of patients with diabetes newly diagnosed in adulthood can be considered to have T2DM. Although some progress is being made in identifying subgroups based on clinical characteristics,[272] at the present time it is simplest to begin with relatively standardized, algorithmic approaches that will be described later. Moreover, even after separation of subgroups, T2DM remains physiologically heterogeneous and patients also differ markedly in their daily habits, preferences, and capacities for self-management. The metabolic defects leading to diabetes also tend to worsen, and the burden of diabetes-related and other infirmities increases over time. For all these reasons, whatever approach is first used will need to be personalized eventually. This expectation can from the start be shared with the patient, who should be enlisted to participate actively in making decisions beyond any initial algorithm.

A Standardized Initial Therapeutic Approach

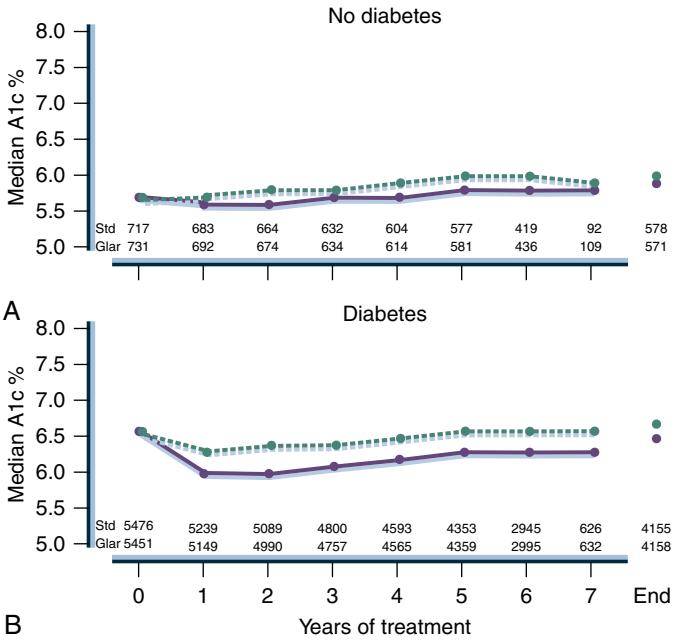
The most critical part of long-term glycemic management is continuing reassessment of glucose patterns and HbA_{1c} values to guide refinement of interventions. The goal is to maintain optimal control with the lowest doses of the fewest medications. In general, initial drug therapy should be considered from the time of diagnosis, along with lifestyle intervention, and by 5 years after diagnosis most patients require two or more drugs to maintain selected targets. Early in therapy it is usually desirable to add additional agents to prior therapies, rather than replacing one agent with another. Guidance from randomized trials, when available, is desirable in making therapeutic choices. A general approach to be considered in the absence of any patient-specific factors is suggested here.[142,159]

Metformin

Metformin is considered the default choice for initial drug therapy. Used in combination with diet, exercise, and a DSMES program it can usually provide impressive lowering of glucose with essentially no risk of hypoglycemia.[273] However, approximately 5% of patients will experience gastrointestinal symptoms with even low doses of metformin, and others should be prescribed metformin only with caution due to impaired renal function or serious cardiac, liver, or intestinal disease. If metformin is contraindicated or poorly tolerated, or when the response to it is inadequate after a trial of 3 to 6 months, various agents can be substituted or added. There are six recommended second-line therapies: sulfonylureas, TZDs, DPP4 inhibitors, SGLT inhibitors, GLP1 receptor agonists, and basal insulins. Each has advantages and disadvantages.

Stepwise Combination Therapy

Because of more than 60 years of experience, widespread current use, and clear evidence of benefit relative to risk from long-term randomized interventional studies, sulfonylureas and basal insulins are still appropriate considerations for second-line therapy. Addition of a sulfonylurea to metformin may serve as an example of the value of combination regimens that is relevant to many other combinations of agents in different classes. Because most classes act through distinctive mechanisms, their glycemic effects



• **Fig. 35.4** Long-term control of HbA_{1c} in the ORIGIN trial. Participants (n = 12,537) with dysglycemia (impaired glucose tolerance or impaired fasting glucose) or diagnosed T2DM on diet with or without one oral agent were randomized to treatment based on insulin glargine *(closed circles, solid lines)* or to sequential use of oral therapies *(open circles, dashed lines)*, seeking fasting plasma glucose 95 mg/dL (5.3 mmol/L) or less. Both regimens maintained HbA_{1c} levels close to 6.5% for the duration of the trial, shown for study participants with dysglycemia at study entry in (A) and for those with diabetes at study entry in (B). (Modified from the ORIGIN Trial Investigators. Characteristics associated with maintenance of mean A1C<6.5% in people with dysglycemia in the ORIGIN trial. *Diabetes Care.* 2013;36:2915–2922.)

are usually additive. Moreover, combining agents generally allows greater glucose lowering without increased side effects. In the case of metformin and the preferred sulfonylureas (glimepiride, long-acting glipizide, and gliclazide), more than half the maximal therapeutic effect is obtained at half maximal dosage. At the same time, the leading side effects—gastrointestinal symptoms with metformin and hypoglycemia with sulfonylureas—are more likely at higher doses. As a specific example, combining metformin 500 mg twice daily with glimepiride 1 mg daily is likely to provide greater therapeutic power and fewer side effects than full dosage of either alone. However, if metformin has previously been titrated to the maximally effective dose of 2000 mg daily and is well tolerated, there is no reason to decrease the metformin dose when adding a second agent, including sulfonylureas, unless renal function is impaired. Continuing metformin and a sulfonylurea when basal insulin is added similarly may allow continuation of good glycemic control while keeping insulin dosage and risk of hypoglycemia low.

The effectiveness of combination therapy approaches using these agents in the Outcome Reduction with an Initial Glargine Intervention (ORIGIN) trial is shown in Fig. 35.4.[274] This trial enrolled participants who had either dysglycemia (impaired glucose tolerance and/or impaired fasting glucose) or T2DM treated with diet and no more than one oral agent. Participants were selected for having high cardiovascular risk. They were randomly assigned to one of two regimens, each seeking fasting glucose no higher than 95 mg/dL (5.3 mmol/L). One regimen was based on glargine as basal insulin with continuation of any prior oral therapy, the other on conventional stepwise use of oral therapies with insulin added only if necessary. Participants were followed an average of about 5 years. Both regimens maintained HbA_{1c} levels close to 6.5% during the study, which for those with T2DM at entry was up to a total of 10 years after diagnosis.[275] Most participants in both randomized arms used only metformin, a sulfonylurea, or basal insulin, confirming the ability of these older agents to provide good glycemic control for many patients up to 10 years after diagnosis. No differences in medical outcomes between the two arms of the trial were observed other than more hypoglycemia in the group assigned to initial glargine therapy and less progression from dysglycemia to overt diabetes in that group.

Considerations in Personalizing Therapy

As the array of glucose-lowering therapies continues to grow, promising results of clinical trials using newer agents are providing additional guidance for therapy. As a result, personalizing drug therapy beyond traditional use of metformin, sulfonylureas, and basal insulin is increasingly common and very appropriate. Any of the classes of agents other than metformin may be considered as second-line therapy when there are specific reasons to do so.[276] In many cases, specific short-term clinical advantages may be judged to outweigh greater cost and lack of long-term experience. The rationale for the choice of therapy should be discussed with the patient, especially in the case of the newest agents.

Oral Agents and Injected Therapies Other than Insulin

The DPP4 inhibitors, the TZD pioglitazone, and long-acting GLP1 agonists are often used in combination with metformin. The glucose-lowering effect of DPP4 inhibitors is often stated to be less than that of sulfonylureas, but they are unlikely to cause hypoglycemia and have few symptomatic side effects.[277] Furthermore, it has been argued that some of the apparent difference in efficacy is due to considering older sulfonylurea studies where baseline HbA_{1c} was higher.[278,279] Pioglitazone is variably effective in controlling glucose and often causes weight gain and edema, among other side effects, but it improves peripheral insulin sensitivity and can reduce hepatic fat content in patients with nonalcoholic steatohepatitis (NASH).[280,281] It is most often prescribed in lower doses now when treating T2DM, although many of the original efficacy studies and the NASH studies have been performed with the 45-mg full dose. Fixed-dose combination formulations of metformin with a DPP4 inhibitor or pioglitazone can facilitate dosing.

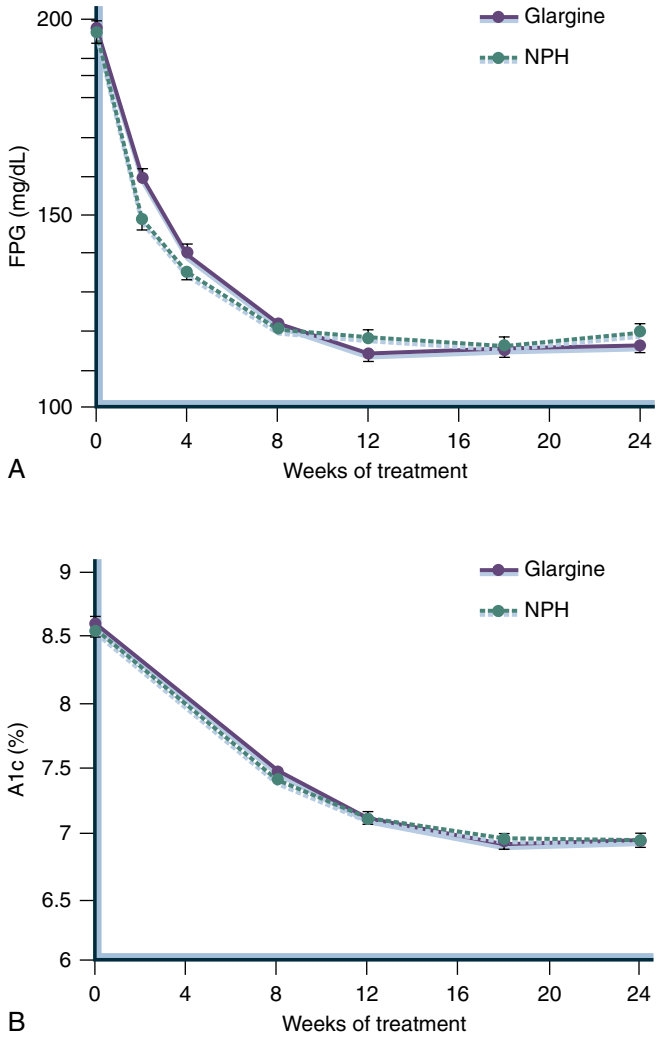
The injectable GLP1 receptor agonists are increasingly proposed as similarly effective alternatives to basal insulin for patients who are known to have high cardiovascular risk because of the cardiovascular protection shown with liraglutide and semaglutide.[251,252] However, they often cause gastrointestinal symptoms requiring thoughtful titration. Use of the long-acting GLP1 agents with once-weekly dosing may improve convenience and reduce symptoms, but even so gastrointestinal side effects can adversely affect adherence. Fixed-dose combinations of basal insulin with GLP1 agonists have been proposed as initial injectable therapy, and while they are reliably effective in reducing glucose the selection of proper doses and the titration process itself require specialized skills.[282,283] Because the mechanism of action of GLP1 agonists is similar to that of DPP4 inhibitors, there is no advantage to continuing the latter agents when an injected GLP1 agonist is started.

Following the studies showing cardiovascular benefits with empagliflozin and canagliflozin, early use of an SGLT inhibitor has been proposed for consideration for patients with established cardiovascular disease, especially when heart failure has been diagnosed or suspected. However, the glucose-lowering effect of these agents is only moderate, and because they are new the magnitude of risk from several side effects has not been fully explored.[198,284,285]

Basal Insulin

Uniquely among the classes of glucose-lowering therapies, use of insulin must always be personalized. The need to personalize dosing of insulin is driven by both physiologic and behavioral factors. The strategy of adding basal insulin when agents other than insulin are no longer successful is well established.[286,287] Some practitioners prefer to stop oral glucose-lowering agents when insulin is started, especially when using twice-daily premixed insulin, but most continue oral therapy while adding NPH or a long-acting analogue as basal insulin. NPH is usually given as a single injection at bedtime or twice daily, before breakfast and at bedtime. The long-acting analogues can be usually given once daily either in the evening or before breakfast, depending on the patient's preference. They are significantly less likely to cause hypoglycemia overall and especially at night, compared with human NPH insulin. The newest long-acting analogues, degludec and the U-300 formulation of glargine, offer a modest further reduction of risk of hypoglycemia compared with U-100 glargine, especially for patients using lower doses and those with prior difficulties with hypoglycemia.[221,223,288–291] There is evidence that hypoglycemia during initiation of basal insulin is associated with lower adherence and higher costs of care.[292] Delays in the initiation of basal insulin as well as its appropriate titration over time and the progression beyond basal insulin have all been characterized as clinical inertia.[293,294]

Personalization of insulin applies particularly to the dose required. The necessary daily dosage of basal insulin ranges between 10 and 200 units, and a given patient's requirement must be determined by titrating to a fasting glucose target. Treatment can be started either with a fixed daily dose of 10 units or with a dose calculated as 0.1 to 0.2 units per kilogram body weight.[159] Dosage should be increased at regular intervals, guided by SMBG before breakfast. Various titration schemes can be used with equal success.[295] Once-weekly titration by 2 to 4 units is commonly used, as is daily titration by a single unit every day until a target level of fasting glucose is attained. For patients continuing metformin alone or with one additional oral agent, a typical dose of basal insulin required to approach the fasting glucose target is 0.4 to 0.5 units per kilogram, but with wide variation between patients. In many clinical trials the titration target has been set at 100 mg/dL (5.5 mmol/L) or less, and early in the natural history of T2DM this is often attainable with little or no risk of hypoglycemia. However, when insulin is started after HbA_{1c} levels have increased to above 8%, an initial target of less than 120 mg/dL (<6.7 mmol/L) is safer and more realistic. The glucose goals and the importance of titration must be emphasized at each visit, as it has been shown that patients often do not remember the initial instructions in basal insulin dosing.[296] In most cases a patient-directed titration is safe and effective, even to fasting goals below 100 mg/dL.[297] Fig. 35.5 illustrates the responses of fasting glucose and HbA_{1c} to this approach to starting basal insulin with use of human NPH versus insulin glargine.[57] A stable level of fasting glucose can often be attained after 12 weeks of careful titration, with HbA_{1c} levels lagging slightly behind as expected. Failure to maintain HbA_{1c} close to 7% despite use of a regimen that includes properly titrated basal insulin calls for attention to postprandial hyperglycemia.



• **Fig. 35.5** Responses of fasting plasma glucose (A) and HbA_{1c} (B) after initiation and titration of neutral protamine Hagedorn (NPH) or glargine as basal insulin with continuation of prior oral therapies. (From Riddle MC, Rosenstock J, Gerich J. Insulin glargine 4002 study investigators. The treat-to-target trial: randomized addition of glargine or human NPH insulin to oral therapy of type 2 diabetic patients. *Diabetes Care*. 2003;26:3080–3086.)

Treating Postprandial Hyperglycemia

The greatest challenge to personalization is presented by therapy of postprandial hyperglycemia. Hyperglycemic exposure in untreated T2DM is quantitatively due more to overnight and between-meal (basal) hyperglycemia than to further elevations after meals. The predominance of basal hyperglycemia is more pronounced when overall control is poor and HbA_{1c} is above 8%.[298] Fortunately most glucose-lowering therapies are more effective in controlling basal hyperglycemia than limiting postprandial increments. Specifically, metformin, the long-acting secretagogues, basal insulin, DPP4 inhibitors, long-acting GLP1 agonists, and SGLT inhibitors have greater basal than postprandial effects. After initial therapy with one or several of these agents, most of the residual glycemic exposure is postprandial.[299] As beta-cell function declines over time, postprandial hyperglycemia becomes more prominent, and maintaining HbA_{1c} in a target range becomes more difficult. After

therapy of basal glucose has been optimized, the postprandial glucose excursion is generally highest after breakfast, and the highest postprandial glucose is after dinner.[300] At this stage of T2DM, which commonly is reached by 10 years after diagnosis, further therapy targeting postprandial control is needed. Use of prandial therapies demands consideration of the patient's eating habits, and these can differ markedly between individuals and in each patient from day to day.

In addition to dietary strategies—more frequent but smaller meals and selection of foods that are absorbed less rapidly and have less tendency to increase glucose—several drugs can be helpful. The short-acting secretagogues modestly limit postprandial increments of glucose when taken at low dosage two or three times a day with meals.[301,302] The alpha-glucosidase inhibitors reduce postprandial hyperglycemia significantly and have favorable effects on weight, but their use is often limited by gastrointestinal side effects.

Short-acting insulins are more effective and are the most widely used approach. Traditionally, a direct change from basal insulin alone to full basal-bolus therapy with injections prior to two or three meals has been recommended. Recent studies suggest that adding a single injection of short-acting insulin (at the morning meal or at the largest meal) is just as effective as basal-bolus therapy at this stage and is less likely to cause weight gain or hypoglycemia.[289,303,304] Initial dosage for the first prandial injection can be 4 to 6 units, with systematic titration upward by 1 to 2 units weekly, aiming for glucose prior to the next meal (or at bedtime if the dose is prior to dinner) approaching 120 mg/dL. When prandial insulin is added to basal insulin with continuation of one or more oral agents, optimal control often requires total daily insulin doses greater than 1 unit per kilogram of body weight daily. In the typical patient with insulin-resistant T2DM, there is usually little advantage to splitting basal insulin into two injections. If a second injection is needed it usually should be prandial insulin. As with basal-bolus insulin therapy in T1DM, close monitoring and effective DSMES are needed.

While adding prandial insulin has been a common practice when basal insulin is not adequately effective in T2DM, an increasingly popular new option is the addition of a GLP1 receptor agonist while continuing basal insulin. The shorter acting drugs in this class have the greater postprandial effect, but the longer acting ones—despite having less ability to control postprandial glucose excursions—may improve overall control sufficiently to equal the effect of added prandial insulin. Compared with addition of prandial insulin, addition of a GLP1 agonist has several advantages: Less SMBG is required, hypoglycemia is less likely, and weight gain will be avoided.[305]

Examples of Personalized Choices of Therapy

Fig. 35.6 illustrates four specific ways in which personalized choices of therapy may be applied.

Minimizing Cardiovascular Risks

Evidence supporting initial use of metformin for reducing cardiovascular risk has established this drug as the fundamental therapy for T2DM.[29,306] Recently, the quest for further therapy for patients with high cardiovascular risk has favored early use of GLP1 agonists and SGLT inhibitors in some settings. An expert group has recently suggested that GLP1 agonists with evidence of cardiovascular benefit should be preferred over insulin as the first injected therapy for T2DM in the setting of established atherosclerotic cardiovascular disease, provided they are locally available and affordable. Similarly, the expert group proposed use of an SGLT inhibitor with evidence for cardiovascular benefit as second-line therapy after metformin for patients with known or suspected heart failure or chronic kidney disease provided eGFR is not seriously reduced.[90] It is still unknown whether benefits of these two classes of drugs for these conditions can be extrapolated to all drugs in each class and whether primary protection against cardiovascular or renal events will be found in the larger numbers of T2DM patients with relatively low cardiovascular risk. More specific information as to which patients will derive the greatest cardiovascular benefit from these newer agents is needed and likely to become available soon.

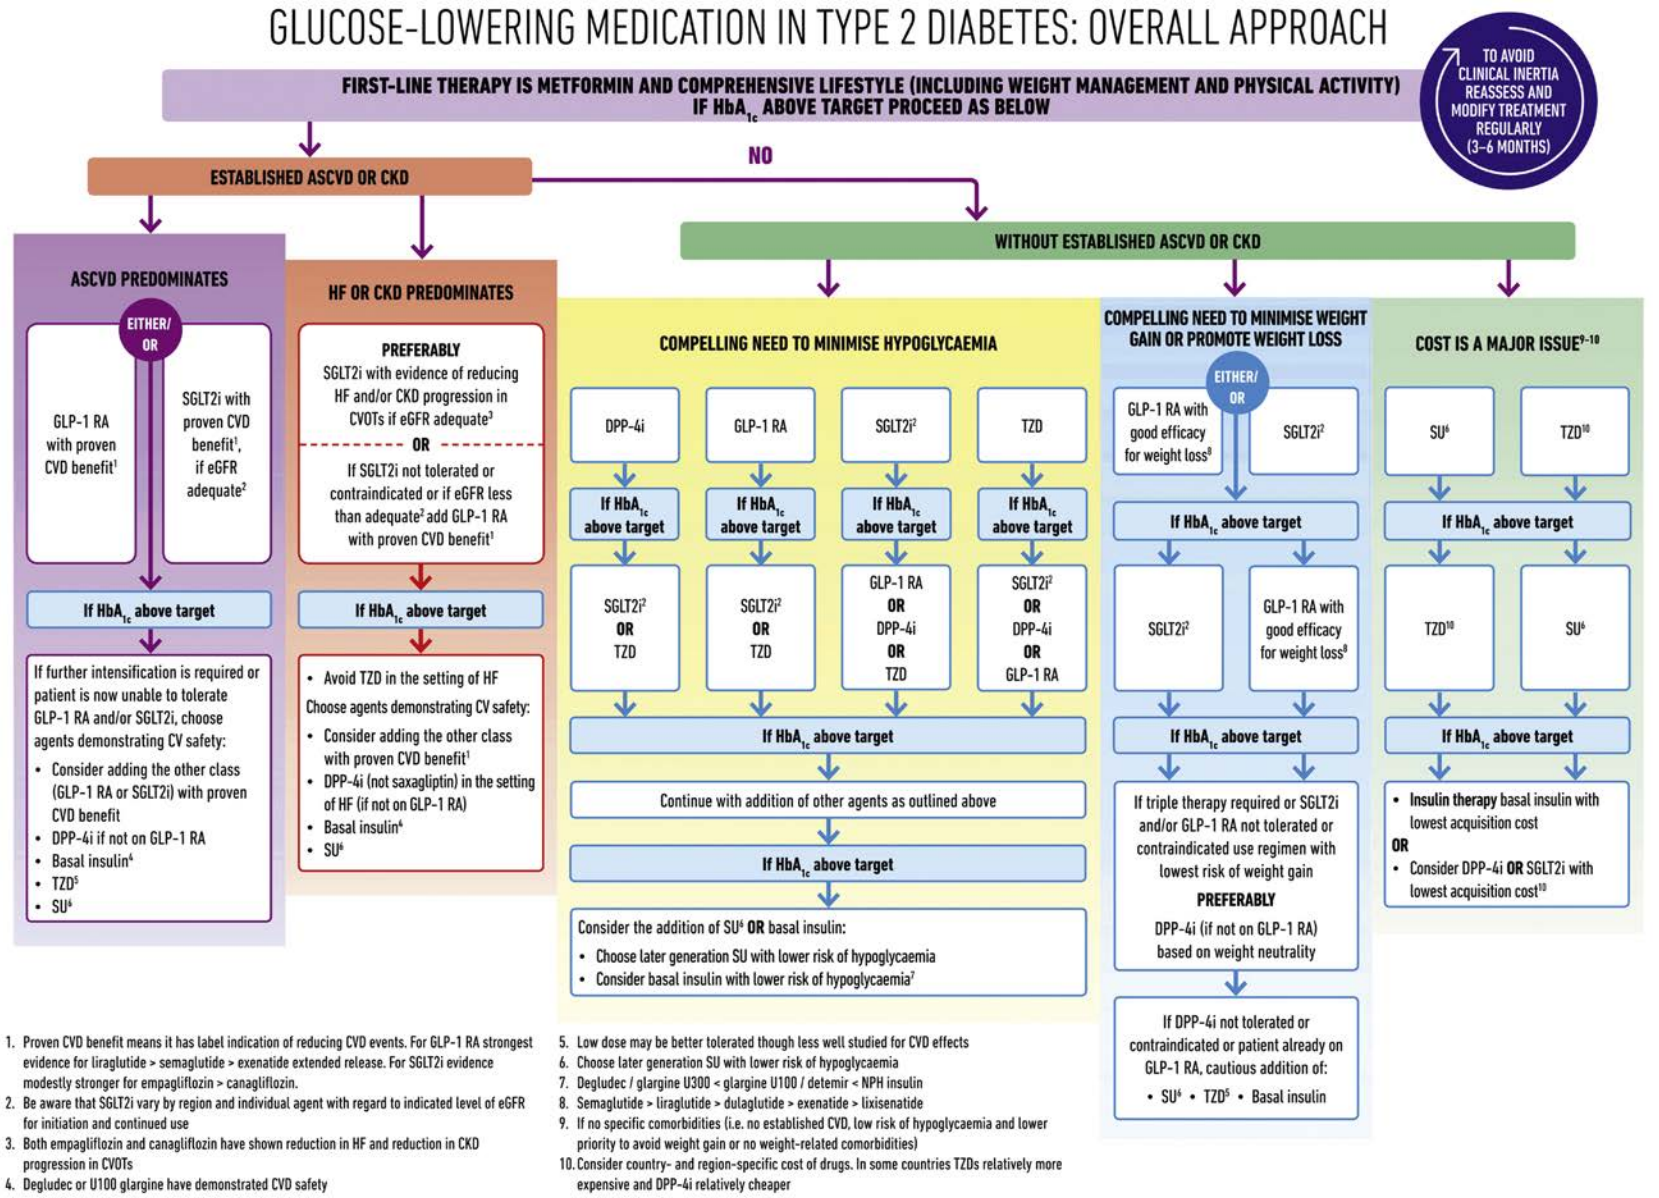
Sulfonylureas and insulin have been suspected of increasing cardiovascular risk. Although direct evidence supporting this contention is weak, the availability of other agents providing glycemic control allows these classes to be moved down the priority list for patients with known cardiovascular disease. It seems especially desirable to avoid use of prandial insulin, which is much more likely to cause weight gain and hypoglycemia than basal insulin. Pioglitazone increases the risk of heart failure in susceptible patients and thus is also less appropriate in this setting.

Minimizing Hypoglycemia

Hypoglycemia is of concern for reasons beyond its possible contribution to cardiovascular events. Older patients with a long duration of diabetes, especially those who have cognitive impairment or nephropathy, have greater risk of hypoglycemia-related falls or other injuries.[307,308] Fear of hypoglycemia can limit attainment of even conservative glycemic treatment goals, either due to therapeutic inertia on the part of the provider or incomplete adherence by the patient. A prior history of hypoglycemia requiring assistance by another person is a strong risk factor for future hypoglycemia. When these considerations apply, therapeutic tactics should be adjusted to avoid hypoglycemia. Metformin does not cause hypoglycemia when used alone, and drug choices after metformin with little or no additional risk include DPP4 inhibitors, GLP1 agonists, SGLT inhibitors, and TZDs.[90,309] Combination therapy using these agents could provide considerable glucose-lowering power with little risk of hypoglycemia. Should insulin eventually become necessary, the newer long-acting insulins will cause the lowest risk of hypoglycemia. Finally, prior occurrence of severe hypoglycemia may be sufficient reason to increase the HbA_{1c} target range to 7% to 8% or even higher.

Minimizing Weight Gain

Weight gain associated with the treatment of diabetes is of concern to most clinicians and can be an overriding issue for some patients. A strategy to minimize weight gain would emphasize diet and exercise and use metformin as initial therapy. Both GLP1 agonists and SGLT inhibitors are options as second-line therapy when weight is a major consideration. Surgical procedures that lead to both weight loss and improved glycemic control are beyond the scope of this chapter, but are increasingly considered when weight control is a primary concern in T2DM.[310–313] Because of their tendency to cause weight gain, sulfonylureas, pioglitazone, and prandial insulin are less desirable. Basal insulin is less likely to cause weight gain than prandial insulin and can be included in the regimen when necessary.



1. Proven CVD benefit means it has label indication of reducing CVD events. For GLP-1 RA strongest evidence for liraglutide > semaglutide > exenatide extended release. For SGLT2i evidence modestly stronger for empagliflozin > canagliflozin.
2. Be aware that SGLT2i vary by region and individual agent with regard to indicated level of eGFR for initiation and continued use
3. Both empagliflozin and canagliflozin have shown reduction in HF and reduction in CKD progression in CVOTs
4. Degludec or U100 glargine have demonstrated CVD safety
5. Low dose may be better tolerated though less well studied for CVD effects
6. Choose later generation SU with lower risk of hypoglycaemia
7. Degludec / glargine U300 < glargine U100 / detemir < NPH insulin
8. Semaglutide > liraglutide > dulaglutide > exenatide > lixisenatide
9. If no specific comorbidities (i.e. no established CVD, low risk of hypoglycaemia and lower priority to avoid weight gain or no weight-related comorbidities)
10. Consider country- and region-specific cost of drugs. In some countries TZDs relatively more expensive and DPP-4i relatively cheaper

A consensus report by the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD). *Diabetes Care*. 2018;41(12):2669–2701.)

Minimizing Costs

For many patients, including large populations in developing countries and individuals with inadequate insurance coverage in developed countries, the cost of drugs limits management of diabetes. Despite the effectiveness of newer agents in clinical trials where they are provided free of charge, no therapy is successful when it is unaffordable. Fortunately, diet and exercise can be effective and are almost cost free. The least expensive drugs for the treatment of diabetes are metformin, sulfonylureas, pioglitazone, alpha-glucosidase inhibitors, and human insulin. There can be marked differences in price between regions and between pharmacies, and websites are available to find the best prices.[314] In the case of insulin, there is a name brand of human regular, NPH, and 70/30 premixed human insulin (ReliOn) that is generally available in the United States for approximately 10% of the list price of analogue insulins. Human insulin remains an effective option for treatment of T2DM, although its use may require twice-daily dosing of NPH, more consistent timing of meals, and slightly higher HbA_{1c} targets (e.g., 7.5–8%) to limit hypoglycemia. A recent statement by the World Health Organization (WHO) has noted and endorsed these considerations for treatment of T2DM in low-resource settings.[315]

Special Situations in Clinical Management

In addition to the principles of treatment described for most T2DM patients in the usual ambulatory setting, some specific therapeutic challenges deserve further comment.

Severe Hyperglycemia at Diagnosis

Some patients will come to diagnosis of T2DM with very poor glycemic control, even ketoacidosis.[316] Those who are especially ill, with serious dehydration, acidosis, impaired mental status, or serious concomitant illness will need hospitalization to receive intravenous fluids and insulin. Some will recover remarkably after in-hospital treatment, with substantial recovery of insulin secretion and tissue responsiveness to insulin. Those with the best metabolic recovery may maintain good glycemic control with lifestyle management and little or no oral therapy. How such patients differ from those who continue to need routine oral therapy or insulin is not entirely clear, but they have been described as having ketosis-prone diabetes.[317]

Many other patients will be diagnosed when they have poor glycemic control, with HbA_{1c} above 9%, but are not acutely ill. Several studies have suggested that intensive glycemic management in this setting may also lead to a substantial remission of diabetes by reversal of glucolipotoxicity in a significant number of patients.[318,319] After 2 to 4 weeks of treatment with oral combination therapy, basal insulin, or basal plus prandial insulin seeking nearly normal glucose levels, HbA_{1c} levels below 6.5% or 7% may persist for up to 1 year, even if pharmacotherapy is completely withdrawn. These proof-of-principle studies have not led to recommendations for this approach routinely in newly diagnosed T2DM but they do suggest that temporary use of insulin to attain excellent glycemic control soon after diagnosis is appropriate for some patients. It has also been proposed that those with very high HbA_{1c} at diagnosis, especially if accompanied by symptoms, could also be treated immediately with dual or triple therapy that may include basal insulin.[38] Multiple drug combinations without insulin are less well validated but may reduce HbA_{1c} to target levels more consistently than a usual single-agent approach. However, independent of the regimen used, rapid reduction of HbA_{1c} in patients who have had many months of poor control has potential risks. Aside from the risk of hypoglycemia from use of insulin by relatively inexperienced patients, there is potential for worsening of retinopathy or neuropathy accompanying overly rapid reduction of glucose. As a general rule, patients diagnosed with HbA_{1c} above 9% should seek a gradual improvement of control with HbA_{1c} below 7% within 6 months, with continuation of at least metformin after that.

Youth-Onset T2DM

The worldwide increase of obesity has led to diagnosis of T2DM in susceptible individuals at earlier ages than in the past. One consequence of this is an alarming increase of onset below age 20.[320] In some regions, the incidence of T2DM in children is approaching that of T1DM. Recent studies of T2DM in adolescence have demonstrated severe insulin resistance and initially high levels of insulin secretion but a relatively rapid decline of beta-cell function that is not slowed by metformin therapy.[321,322] At present there is little evidence as to how treatment of youths with T2DM can be improved, but it is evident that much greater effort to improve dietary and exercise patterns is needed in this population for both prevention and treatment.[323] While the ability of weekly GLP1 receptor agonists to conveniently control both glucose and weight suggests these agents may come to be important, their use in this setting is at present off label, and objective data are limited.

Pregnancy

Management of diabetes during pregnancy is beyond the scope of this chapter. However, because it is centrally important in the natural history of T2DM, some important features must be mentioned. Women with risk factors for diabetes often first develop overt hyperglycemia during pregnancy, otherwise known as gestational diabetes mellitus (GDM). After delivery, some continue to have sufficient hyperglycemia to justify the diagnosis of T2DM, but more revert to having normal glucose levels. For the latter group, the risk of reappearance of hyperglycemia consistent with the diagnosis of T2DM in the absence of pregnancy is 50% to 70% after 15 to 25 years, a risk that is increased 10-fold to 18-fold.[324,325] Consequently, periodic follow-up with testing of glucose or HbA_{1c} is indicated every 1 to 3 years to allow early detection. In addition to signaling a high risk of future development of diabetes, GDM poses more immediate risks to both mother and child. The likelihood of complicated delivery or neonatal complications is greatly increased by GDM. Furthermore, children with exposure to hyperglycemia in utero have increased risk of later obesity and/or T2DM.[326] This risk appears to be attenuated by good maternal glycemic control during gestation. Preconception counseling of women at high risk, routine screening for GDM during pregnancy, careful management of hyperglycemia during pregnancy, and systematic follow-up after delivery should be part of routine clinical practice. For women of childbearing age who already have diabetes, preconception planning and gestational management are even more urgently needed, especially to limit the risk of fetal malformations resulting from poor glycemic control in the first 10 weeks of pregnancy. Glucose targets during gestation are lower than advised in routine management of T2DM. The recommended target ranges are less than 95 mg/dL (<5.3 mmol/L) for fasting glucose, less than 140 mg/dL (<7.8 mmol/L) for 1-hour postprandial glucose, and less than 120 mg/dL (<6.7

mmol/L) for 2-hour postprandial glucose.[327] Careful nutritional therapy is essential, and additional treatment with insulin is often needed. Metformin or the sulfonylurea glyburide are sometimes used instead of insulin, but there are concerns about their safety, particularly with sulfonylureas.[327,328] For women with preexisting T2DM, insulin therapy is generally recommended during gestation. Whenever possible, an experienced specialized team should assist in management of diabetes during pregnancy.

Preventing Type 2 Diabetes Mellitus

The possibility that T2DM can be prevented in high-risk persons has been formally tested in a series of clinical trials reviewed elsewhere. Lifestyle intervention can provide a reduction of 30% to 60% in progression to diabetes over a period of 3 to 5 years. This is sustained and correlates with weight loss. However, the average sustained weight loss in these trials was modest, on the order of 5%.[329–331] Intervention with metformin was associated with a somewhat smaller reduction in progression to diabetes, although the benefit was similar to that of lifestyle in persons younger than 45 years of age, those with body mass index (BMI) greater than 35 kg/m^2, and those with an fasting plasma glucose level greater than 110 mg/dL (>6.1 mmol/L). Metformin had less effect in patients older than 60 years of age, those with a BMI of less than 30 kg/m^2, and those with a fasting plasma glucose of less than 100 mg/dL (<5.6 mmol/L). Metformin's ability to reduce progression to diabetes has been shown to be durable and cost effective.[332]

Acarbose has also been shown to reduce progression to diabetes without evidence of diminished efficacy in different subgroups. The TZDs provide sustained improvement of insulin sensitivity and can delay onset of diabetes. However, concern regarding possible long-term effects on weight, heart, and bones has limited the use of this class for prevention. GLP1 receptor agonists have also shown promise, but the expense and initial adverse effects preclude their promotion for this indication at present. Bariatric surgery has also been shown to reduce incident diabetes in more severely obese patients.

The success of the lifestyle interventions is impressive, showing that by using various techniques at-risk individuals can achieve physiologically relevant changes in body weight. It is unknown whether lifestyle plus medications provides even greater benefit. It seems reasonable to screen on the basis of the recommendations outlined earlier, while recognizing that patients with prediabetes (HbA_{1c} >5.7% and particularly ≥6%, fasting plasma glucose ≥100 mg/dL [≥5.6 mmol/L] and particularly ≥110 mg/dL [≥6.1 mmol/L], or impaired glucose tolerance) are the best candidates for preventive strategies. High-risk persons should be counseled about nutritional approaches to weight loss, instructed to increase physical activity, and monitored for progression of dysglycemia. Translation of the evidence found in the DPP study to practical expansion across the United States has been evolving through the CDC National Diabetes Prevention Program. The program includes a structured curriculum of 22 sessions over 1 year in a group setting or online programs delivered through a diverse group of public and private organizations. Each local program is certified through the CDC Diabetes Prevention Recognition Program to maintain standards, promote utilization, and document outcomes. Providers must increase identification of those with prediabetes or other high-risk characteristics and direct patients to the programs available in the community.[333,334] The status of drug therapy, notably with metformin, is less clear, in part because significant diabetes complications are unlikely to develop in the relatively short window of time during which fasting glucose levels increase from 100 to 126 mg/dL (5.6–7 mmol/L). On the other hand, metformin therapy brings little risk and offers substantial benefit for some individuals, notably those with BMI of 35 kg/m^2 or more, those under age 60 years, and women with previous gestational diabetes.[36] Therefore on balance, consideration of metformin therapy in patients who are at particularly high risk is recommended.[36]

Future Directions

Present-day management of T2DM is significantly more effective and easier for patients than in the past, and it promises to improve further. Development of new drugs and smart devices for tracking glucose levels and administering therapies continues and challenges our ability to evaluate and assimilate these new tools. Notable unmet needs concern controlling glucose after meals, maintaining metabolic control during acute illness and hospitalization, and limiting weight gain. However, it can be argued that the main limitation of therapy at present is not a lack of tools and treatments, but a variety of economic, psychologic, and organizational barriers to using them to full advantage.[335] Practical, cost-effective public health approaches are needed to slow the increase in incidence and prevalence of T2DM.[336] Screening for diabetes or prediabetes may be cost saving and should be made more efficient. Globally, there continues to be inequality in access to medical care for all conditions, including diabetes. Although the prognosis for people with diabetes has never been better, the greatest challenges they face relate to the complexity and cost of care. If both the means of managing diabetes and the organizational structure of health systems are improved simultaneously, the morbidity and mortality of T2DM may be greatly reduced in the near future.

Type 1 Diabetes Mellitus

MARK A. ATKINSON, DAYNA E. MCGILL, EYAL DASSAU, AND LORI LAFFEL

CHAPTER OUTLINE

KEY POINTS

- Type 1 diabetes mellitus (T1DM) is a disorder resulting from a chronic autoimmune destruction of the insulin-producing pancreatic beta cells.
- Worldwide, the incidence of T1DM is increasing by 3% to 5% per year.
- The disorder is clearly polygenic (>50 loci impacting susceptibility have been identified to date), yet more than half of disease susceptibility for T1DM is provided by the major histocompatibility complex; these genes/loci have been combined into a "genetic risk score" to identity a given individual's genetic predisposition to this disease.
- The risk for the disease can be ascertained through a combination of immunologic, genetic, and metabolic markers of disease, with the natural history now defined by a series of "stages."
- There is a growing appreciation that T1DM, rather than being a singular disease, may be a heterogeneous disorder with a common phenotype at clinical presentation/diagnosis.
- The pancreas of T1DM patients possesses an islet immune infiltrate derived from a variety of immunologic phenotypes, is reduced in size and weight, and is subject to unusual exocrine features.
- Significant advances in terms of disease management, afforded by technological innovations related to insulin analogues, advanced diabetes technologies, and more, set the foundation for marked reductions in hemoglobin A_{1c}, enhanced diabetes care, and improved biomedical and psychosocial outcomes.
- Although there have been many advances in the management of T1DM, this disease remains associated with many acute- and chronic complications.
- Numerous metrics (costs, patient outcomes, etc.) demonstrate that specialists (i.e., endocrinologists) provide more effective care for those with T1DM than nonspecialists, with best results arising from multidisciplinary, individualized care.

Where to begin to tell the story of the disorder we now refer to as type 1 diabetes mellitus (T1DM) represents somewhat of a literary challenge. Does one begin with the earliest writings scripted thousands of years ago conveying the disease's symptoms, or is it more fitting to describe exciting works performed in the 1800s and early 1900s that defined both the anatomy of and physiologic roles for the pancreas and insulin-secreting beta cells?[1] Other pieces of literature initiate their narrative on T1DM by sharing an account of the fast-paced and ultimately Nobel Prize–winning efforts in the 1920s by Banting and Best,[2] when the ability to purify insulin from animal pancreata brought forward a means to sustain life to those who, in the absence of such an intervention, met an early demise.

We have elected to begin this chapter by building on the story of a German pathologist named Martin Schmidt,[3] who, in 1902, noted a small peri-islet cellular infiltrate on microscopic evaluation of the pancreas obtained at autopsy from a 10-year-old child with diabetes. This effort represented a key early investigation seeking to better define the pathogenesis of the disorder, a process that was continued by many over the ensuing century. Works shortly thereafter by Shields Warren[4] in the 1920s drew attention to the relationship between this infiltrate and the age of diabetes onset. The term used to define this pancreatic feature, *insulitis*, was coined in 1940 by yet another pathologist, Hanns von Meyenburg.[5] Studies of pancreatic disease over ensuing decades taught us much regarding this inflammatory lesion, including its

relative infrequency in older individuals diagnosed with diabetes, its association with reduction in beta-cell mass, the identification of *pseudoatrophic* islets (i.e., islets devoid of insulin-containing cells), a preferential targeting of insulitis for beta cells containing insulin, and many other findings eventually deemed seminal.[6,7] These conditions, when joined together with immunologic and genetic studies of living patients in the 1970s, noting the presence of self-reactive antibodies (i.e., autoantibodies) against islet cells in persons with T1DM and that disease susceptibility was associated with major histocompatibility complex (MHC) molecules known to influence immune system functions, formed three lines of evidence pointing to an autoimmune basis for T1DM.[8] Built on this foundation, this chapter will share current views on the autoimmune nature of T1DM (including its natural history and pathogenesis); emerging views on genetics, disease biomarkers, and epidemiology; increased information on the contribution of beta cells to their own demise; and perhaps most importantly, how treatments are advancing for this disease—all as we consider how this information is vital to the optimal diagnosis and optimal care of individuals with T1DM.

Diagnosis

A diagnosis of diabetes has historically included an elevated fasting blood glucose level, any glucose value higher than 200 mg/dL (11 mmol/L) with symptoms of hyperglycemia, or an abnormal 2-hour oral glucose tolerance test (OGTT).[9] American Diabetes Association (ADA) guidelines for the diagnosis of diabetes were modified in 2009 to include a hemoglobin A_{1c} (HbA_{1c}) value greater than 6.5%.[10] Under certain settings (e.g., obesity, racial status other than Caucasian) and particularly among adults, the diagnosis of T1DM versus type 2 diabetes mellitus (T2DM) can prove quite challenging. At present, the best criterion for separating the two disorders resides in laboratory identification of any one of a number of islet cell autoantibodies (also known as T1DM-associated autoantibodies; i.e., anti-insulin autoantibodies [IAA], anti–glutamic acid decarboxylase [GADA], anti–insulinoma-associated antigen 2 [IA2A], or anti-zinc-transporter 8 [ZnT8A]). Literally hundreds of studies over the past three decades have suggested that the presence of these autoantibodies provides high sensitivity for diagnosing persons with T1DM.[11] Indeed, more than 90% of Caucasian children presenting with diabetes express at least one of these four T1DM-associated autoantibodies.[12] In terms of disease specificity, T1DM-associated autoantibodies are typically positive in less than 1% to 2% of unaffected (i.e., non-T1DM) individuals, further validating their diagnostic utility. However, among African-American and Latino children and adolescents in the United States diagnosed with diabetes, almost one half lack any T1DM-associated autoantibody. Many patients from these ethnic minorities in the United States present clinically as if they have early-onset T2DM (e.g., mild ketosis, slow symptomatic onset), some have attendant risk factors such as obesity, and many lack human leukocyte antigen (HLA) alleles associated with T1DM. Increasingly diverse genetic admixtures, due to geographic migration and social changes (e.g., multiracial offspring), further contribute to diagnostic complexity.

In childhood and adolescence, two peaks of T1DM presentation occur: a smaller peak between 5 and 7 years of age and a larger peak at or near puberty.[13] Although most autoimmune disorders disproportionately target females, T1DM affects males slightly more than females. The incidence of T1DM varies with seasonal changes and birth month. Incidence of T1DM diagnosis is higher in autumn and winter, whereas being born in the spring is associated with an increased likelihood for T1DM.[14] Interestingly, the development of T1DM-associated autoimmunity (i.e., the formation of islet autoantibodies) in the months to years prior to the onset of symptomatic T1DM also shows a degree of seasonal synchronization.

The measurement and presence of T1DM-associated autoantibodies have also fueled much debate regarding the percentage of T1DM cases that are errantly misclassified as T2DM. Indeed, it is conceivable that 5% to 15% of adults diagnosed with T2DM may have T1DM, given the frequency of T1DM-associated autoantibodies in populations diagnosed with T2DM.[15] This is, in effect, a problem in health care provider recognition of the potential for T1DM disease in adult populations combined with a lack of widespread screening for such autoantibodies in settings in which screening would seem warranted. If this assertion is correct, given the vastly greater number of persons diagnosed with T2DM (relative to that of T1DM), the number of actual T1DM cases in a given population may be massively underestimated. This is therapeutically unfortunate because an accurate diagnosis of T1DM is vital; persons misdiagnosed as having T2DM when they indeed have T1DM experience higher HbA_{1c}, have risk of diabetic ketoacidosis (DKA) due to use of noninsulin therapies, and have accelerated progression toward micro- and macrovascular complications..

Efforts to differentiate adult-onset T1DM from T2DM (Table 36.1) have also resulted in a series of proposed new disease classifications, most notably *ketosis prone diabetes* and *latent autoimmune disease of adults*.[16] The lack of firm diagnostic criteria dampens enthusiasm for adopting these presumed new disease entities as novel categories for diabetes. It is also important to note that T1DM patients can manifest insulin resistance, a feature most often associated with T2DM. Specifically, T1DM patients (including those who are autoantibody-positive) may present with diabetes characterized by high serum levels of fasting insulin or C-peptide but loss of stimulated insulin secretion.

As noted previously, some Caucasian children (~10%) are devoid of a T1DM-associated autoantibody at disease diagnosis (i.e., time of hyperglycemic onset), raising questions as to whether such persons lost their autoantibody expression (or at least the ability to detect it with laboratory testing) by the time of diagnosis, or whether a diagnosis of T1DM is accurate. The notion of autoantibody loss versus the presence of a different form of diabetes is also difficult to ascertain because many have HLA alleles associated with susceptibility for T1DM; are not insulin resistant; present with DKA; and, with time, lose their C-peptide secretion. With appropriate laboratory testing, notation of such persons as T1DM patients negative for T1DM-associated autoantibodies can be an appropriate diagnosis. This said, advances in understanding the heretofore underappreciated disease classifications of monogenic diabetes, including those of maturity onset of diabetes in youth, warrant genetic testing of diabetes cases diagnosed in the very young (i.e., <1 year of age).[17]

Animal Models

Nonobese Diabetic Mouse Model

The nonobese diabetic (NOD) mouse is, without question, the most intensively studied animal model for T1DM.[18] The frequency of diabetes among different colonies ranges from 30% to 100% among female NOD mice, suggesting that housing conditions (i.e., environment) represent an important variable. Unlike human T1DM that has a relatively equal distribution among genders, a

TABLE 36.1 Characteristic Comparison of Type 1 Versus Type 2 Diabetes Mellitus

Characteristic	Type 1	Type 2
Nature *Very different*	Autoimmune disorder marked by destruction of insulin-producing beta cells and loss of insulin production	A disorder of insulin deficiency involving an interplay between both pancreatic and extrapancreatic contributions to disease
Symptoms *Partial overlap*	Rapid onset; very high to extremely high blood glucose levels; polyphagia; polydipsia, polyuria; ketoacidosis	Mild to moderate onset; modest to high elevations in blood glucose; mild polydipsia/polyuria; fatigue; visual changes/headache
Onset *Very different*	Sudden (symptoms for days to weeks)	Slower onset (symptoms for months to years)
Risk factors *Typically different but overlap*	Family history of autoimmune disease but particularly type 1 diabetes mellitus (10-fold increased risk vs. general population)	Overweight/obese; poor diet; sedentary lifestyle; ethnicity (higher in African Americans, Hispanics); family history of type 2 diabetes mellitus; history of gestational diabetes
Onset age *Typically different but overlap*	Typically early life through adolescence but can occur at any age	Typically adults but trending toward earlier age of onset
Treatment strategy *Typically different*	Absolute requirement for insulin (multiple daily injections or insulin pump); self-management lifestyle modification (monitor food types, exercise, etc.)	Dietary modifications and exercise alongside oral agents (for most); increasingly greater percentage of patients require insulin over time
Can it be prevented? *Very different*	Not at present (subject of major research efforts); future cases can be predicted by autoantibodies and genetics	Yes, for more than half of potential cases, with dietary modifications and exercise
Can it be reversed? *Very different*	Not at present (subject of major research efforts)	No, but for a limited few; patients can see disease managed and risk for complications reduced through diet modifications, exercise; growing evidence for disease improvements through combination therapies
Complications *Mostly similar, but some variation*	Acute emergencies of hypoglycemia and ketoacidosis leading to hypoglycemic unawareness; chronic effects of hyperglycemia can lead to retinopathy, nephropathy, neuropathy, cardiovascular disease, etc.	Acute emergencies of hypoglycemia and ketoacidosis leading to hypoglycemic unawareness; chronic effects of hyperglycemia can lead to retinopathy, nephropathy, neuropathy, cardiovascular disease, etc.

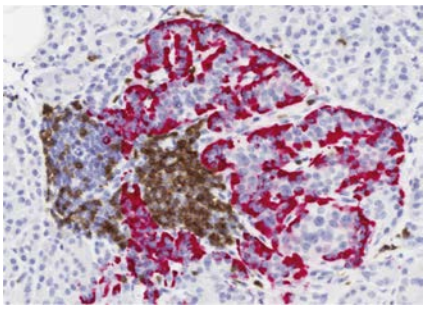
strong female bias with respect to disease exists in NOD mice. As with T1DM of humans, diabetes in the NOD mouse is polygenic with specific MHC class I and II molecules being central for disease pathogenesis[19] and many other genetic loci bearing relatively small contributions neither necessary nor sufficient for disease.[20] NOD mice, like humans, produce IAA before developing diabetes, although T cells, not autoantibodies, appear to mediate the beta-cell destruction. The insulitis lesion, the hallmark facet of T1DM, appears more intense and quantitatively obvious in NOD mice as compared with humans. Interestingly, a relative overrepresentation of T cells bears a receptor specific for the beta-cell antigen, insulin. Although a majority of studies have provided evidence for a central role of T-cell autoimmunity directed at insulin,[21] to be clear, there is considerable debate whether any given beta-cell antigen is primary (i.e., the first, major driver of disease development in an autoimmune response). Studies of islet beta-cell mass indicate that both destruction and replication/regeneration are present months before the onset of T1DM, with an acceleration of beta-cell destruction at disease onset.[22] A seeming plethora of published studies highlight the therapeutic potential from beta-cell replication/regeneration in NOD mice or other rodent strains.[23–25] However, recent convincing evidence suggests that in terms of beta-cell replication, rodent models differ dramatically from human physiology, with beta-cell replication being a rare event in humans from adolescence through adulthood.[26] One of the primary concerns for the NOD mouse relates to the relative ease by which the disease can be prevented or reversed.[18] One can observe clear therapeutic benefits in the NOD mouse (e.g., preserved C-peptide secretion), yet only a limited number these findings have been effectively translated to humans. Animal models (unfortunately) represent somewhat of an idealized situation characterized by features that are not reflective of the sociologic and lifestyle settings in humans, such as limited genetic diversity through selective inbreeding, housing in highly controlled environments devoid of pathogens, uniform diets, and several other facets. It remains unclear which of these or other differences underlie the generally disappointing translation.

Induced Models of T1DM

Diabetes, and even insulitis, can be induced in several strains of rodents with drugs that induce islet cell destruction and broadly activate immune responses, including those directed against beta-cell antigens. For example, the drug streptozotocin is directly toxic to islet beta cells. In high doses, it rapidly induces diabetes (i.e., hyperglycemia). In low doses, a more chronic diabetes develops that is likely to have some immunologic derivation, meaning pathogenesis tied to immune responses against beta cells.[27] Other models are used less frequently.

Histopathology

As noted earlier, T1DM in humans is characterized by selective destruction of beta cells within the pancreatic islets[7] (Fig. 36.1). Although certain exceptions exist, an overall assimilation of the



A

Islet cells in type 1 diabetes

- Insulitis (mixed mononuclear, adjacent or within islet)
- Loss of β cells (increase with disease duration)
- Hyper-expression of class I MHC
- β cell necrosis/apoptosis (?)
- Diminished insulin in remaining β cells
- β cell expression of interferon α

B

Pancreas in type 1 diabetes

- Decreased overall weight
- Atrophy of dorsal region
- Exocrine atrophy
- Hydrophic change (hypertrophy) (?)
- Composed of pseudoatrophic (glucagon staining) islets in type 1A
- Lobular loss of β cells
- Heterogeneous lobular insulitis

C

• **Fig. 36.1** Pathologic characteristics of the pancreas in T1DM. (A) Islet infiltrate (i.e., insulitis) seen in a patient with recent-onset T1DM. Immunohistochemistry shows the intra-islet presence of CD3-positive cells (*brown*) and glucagon-producing alpha cells (*pink*). Histologic features of islet cells (B) and gross pathologic characteristics of the pancreas (C) associated with the natural history of T1DM (i.e., preonset, onset, post onset). *MHC*, major histocompatibility complex; *T1DM*, type 1 diabetes mellitus. literature supports that T1DM patients with a disease onset at age 0 to 14 years and within 1 year of diagnosis show more inflamed islets (68%) and fewer islets with residual beta cells (39%) than in patients with onset at 15 to 39 years of age.[28] This finding suggests that a more vigorous autoimmune response occurs when disease develops in young children.

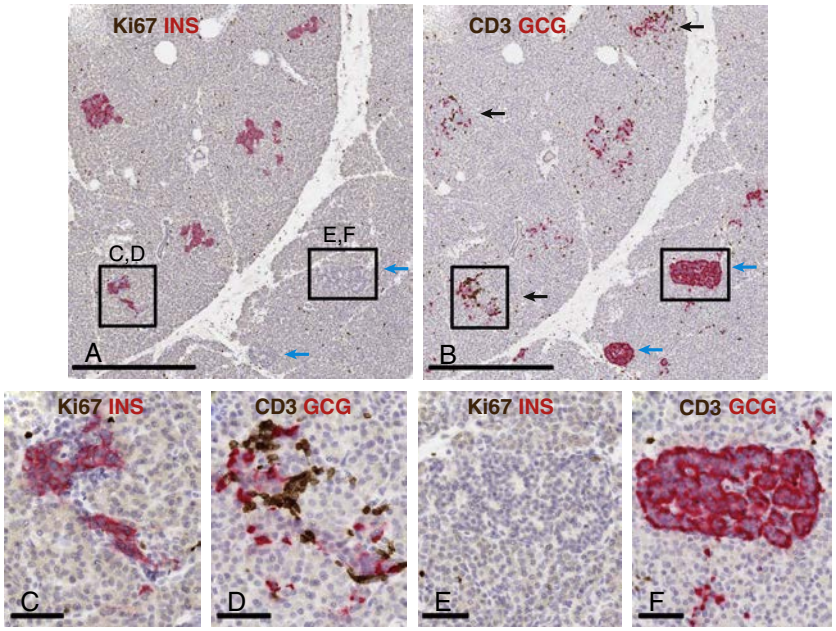
The immunotype of insulitic lesions shows a predominance of $CD8^+$ T lymphocytes and macrophages, but cells of other phenotypes are also observed (e.g., $CD4^+$, $CD20^+$, and $CD68^+$).[29,30] More recent studies have evaluated immunotype as a function of age, with younger age of onset associated with higher levels of $CD20^+$ B cells, $CD45^+$ cells, and $CD8^+$ T cells in insulitis lesions, alongside fewer insulin-positive islets.[28,31] Conversely, infiltrates with fewer $CD20^+$ cells are observed in T1DM patients who are older at onset and associated with lower levels of $CD45^+$ cells and $CD8^+$ T cells, as well as more insulin-positive islets. These same studies also show that islet $CD8^+$ T cells express T-cell receptors that bind MHC class I tetramers loaded with the beta-cell autoantigen G6P2 and other target peptides in recent-onset T1DM patients.[31] These studies are also in agreement with recent findings that the T cells invading pancreatic islets are, in fact, directed at beta-cell antigens.[30] In contrast to long-standing dogma, the presence of insulitis in human T1DM is quantitatively limited, with an expert panel establishing a standardized definition for this lesion of three islets, containing more than 15 $CD45^+$ cells, in a pancreas.[6]

Somewhat surprisingly, inflammation is also present in pancreatic exocrine tissue in T1DM. Specifically, chronic inflammation, including enhanced $CD8^+$ T-cell infiltration (and, to a lesser degree, $CD4^+$ and $CD11c^+$ cells), is present in the exocrine pancreas in T1DM subjects.[32] Other studies report a similar propensity for neutrophil invasion of the pancreas (along with decreased peripheral neutrophil counts) in T1DM.[33] The propensity of this organ for inflammation/pancreatitis induced by multiple factors (e.g., hypertriglyceridemia, virus infection, drugs) could be a result of a susceptibility gene that affects tissue-based inflammation or other facets that have, in the past, been considered "leakiness." Importantly, the inflammatory process in the exocrine pancreas appears to be subclinical, as most new-onset T1DM patients do not present with symptoms of pancreatic inflammation.

Recent studies assessing the persistence of insulin production in patients with long-standing T1DM (i.e., stimulated C-peptide production) using ultrasensitive assays have overturned the long-standing dogma that residual C-peptide secretion is rare.[34] Emerging histopathologic evidence supports this notion through identification of insulin-positive islets, albeit extremely limited in number, in patients with long-standing T1DM.[35] The non–insulin-producing cells of the islets (i.e., alpha, delta, pancreatic polypeptide; see Chapter 33) remain in patients with long-standing T1DM, and these remaining islets, lacking insulitis and beta cells, are termed *pseudoatrophic*. This information sets the stage for another remarkable feature of the pancreas of patients with new-onset T1DM, namely heterogeneity of islet lesions. Histopathologic examination of the same section of pancreas showed that a normal islet with no immune infiltrate can coexist with an islet containing beta cells with intense infiltration, as well as a pseudoatrophic islet that has no infiltrate (Fig. 36.2). This spottiness of the pathologic process is reminiscent of the destruction of areas of the skin in patients with vitiligo, in which melanocytes are destroyed in patches. Such heterogeneity of lesions may underlie the variable natural history of T1DM, in which the time period between initial beta-cell autoimmunity and overt symptoms can be one of months, years, or even many decades. Additionally, pancreata from non-T1DM but autoantibody-positive organ donors often show limited to no insulitis but have shown distinct histologic abnormalities, such as an increased proinsulin to insulin area ratio,[36] that match functional alterations. Such information has been considered to support the notion that T1DM is a relapsing/remitting disease,[37] with waves of immunologic destruction.

The islets of T1DM and T1DM autoantibody-positive nondiabetic patients overexpress class I HLA antigens, interferon-alpha, and potentially Fas molecules.[38,39] The specific means by which the immune system destroys beta cells is not known. Molecules such as Fas may be important because T cells expressing Fas ligand can induce apoptosis of beta cells. This said, more enthusiasm surrounds the notion that cytokines (e.g., interleukin 1 [IL1]) and $CD8^+$ cytotoxic T lymphocytes are likely to be major contributors to beta-cell destruction. With respect to what might induce these features, searches for viral particles and viral RNA within islets of patients with new-onset diabetes have largely been unrewarding. However, newer technologies and concepts should facilitate additional studies, and it is likely that there will be heterogeneity among patients.

Finally, reduced pancreatic weight has been demonstrated at autopsy or in organ donors with recent-onset T1DM, as well as in those with long-standing disease.[40] Reduced pancreatic volume has also been shown in living patients with T1DM through noninvasive imaging techniques.[41] Mechanisms underlying loss of pancreatic size or weight in T1DM are not well understood but have largely been hypothesized to result from loss of insulinotrophic



• **Fig. 36.2** Lobular variability in insulin⁺ Islets and insulitis. Islets were imaged from a 13-year-old patient with type 1 diabetes mellitus for 5 years (nPOD 6243). Serial paraffin sections were stained for Ki67 plus insulin (INS) (A, C, and E) and CD3 plus glucagon (GCG) (B, D, and F), and islets were subtyped as described in research design and methods. Five insulin⁺ islets (A) are seen in a lobule adjacent to a lobule with two insulin⁻ islets in the patient with type 1 diabetes mellitus (A and B, *blue arrows*). Three insulin⁺ islets had insulitis (B, *black arrows*), and both insulin⁻ islets did not have insulitis. One of the insulin⁺ islets with insulitis is shown at higher magnification (C and D), as well as an insulin⁻ insulitis⁻ islet (E and F). Few islet cells were Ki67⁺ (A and C), indicating no effect of insulitis on proliferating cell numbers. Scale bars: A and B, 500 µm; C–F, 50 µm. (From Campbell-Thompson M, Fu A, Kaddis JS, et al. Insulitis and β-cell mass in the natural history of type 1 diabetes. *Diabetes*. 2016;65[3]:719–731.)

effects on the exocrine pancreas, as islets constitute only 1% to 2% of the entire pancreatic volume (see the Pancreatic Exocrine Abnormalities in T1DM section).

Mechanisms of Beta-Cell Death in T1DM

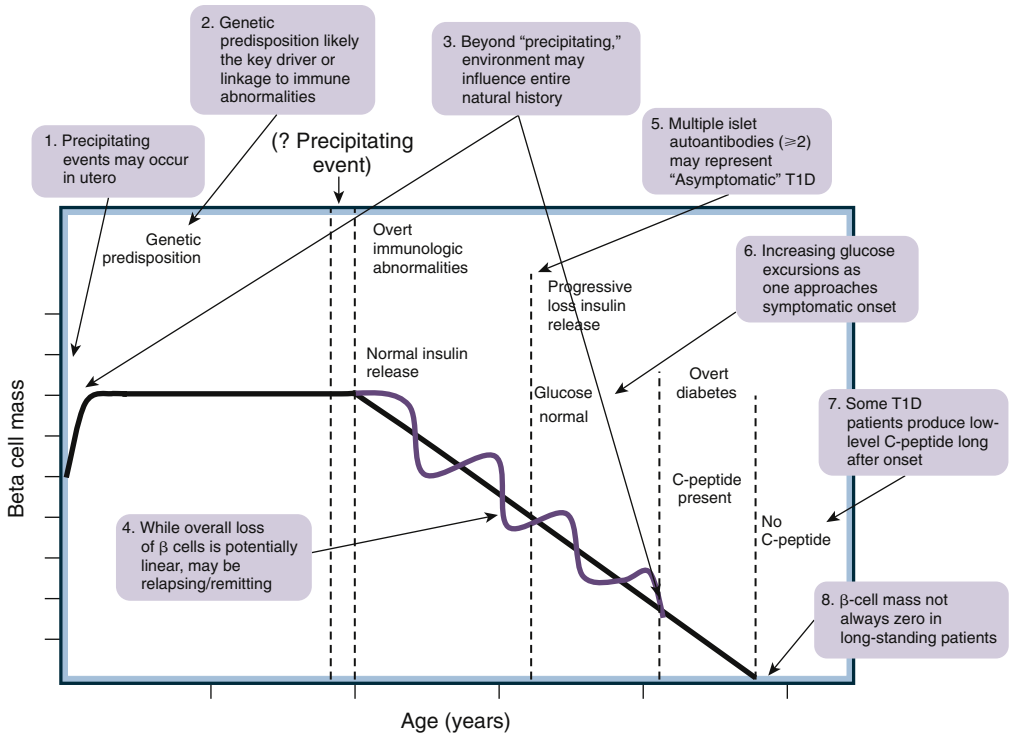
The mechanism(s) by which beta cells die in T1DM remains somewhat controversial. A majority of studies support necrotic cell death, mediated by cytotoxic T cells in response to self-antigens, as one likely mechanism. Evidence from studies of human T1DM pancreas noting the presence of CD8⁺ T cells and macrophages is consistent with this concept.[7] T cells can induce necrosis following release of cytolytic granules containing granzymes and perforin, which act on the beta-cell membrane. Ischemia resulting from impaired vascularity, a process that may result from hyperexpression of extracellular matrix materials (e.g., hyaluronan, hyaluronan-binding proteins) may also lead to necrotic cell death.[42] Additional mediators of necrotic cell death finding support in T1DM studies include reactive oxygen species, which are capable of inducing mitochondrial injury and loss of cell membrane integrity through oxidative DNA damage, lipid peroxidation, and protein damage.[43] Finally, necrosis of beta cells may release factors, including post-translationally modified antigenic peptides[44] or modifications of "normal" antigens (i.e., hybrid peptides[45]) that further stimulate the immune response and thereby perpetuate beta-cell death by necrosis.

Beyond necrosis, apoptosis has also been implicated for its role in beta-cell death in T1DM through activities largely linked to the janus kinases (JAK1, JAK2) and nonreceptor tyrosine-protein kinase (TYK2) pathways.[46] Immunity finds a link here, with apoptosis likely driven by cytokines, including tumor necrosis factor (TNF), that activate Fas/FasL, TNFR1, and TNFR2. Apoptosis can also be initiated through the B-cell lymphoma 2 (BCL2) pathway via cytokine deprivation or endoplasmic reticulum stress, leading to caspase activation. Apoptosis due to the activity of caspases leads to apoptotic cell morphology, nuclear fragmentation, and chromatin condensation—facets that have been observed in human T1DM pancreas. The notion of the so-called unfolded protein response (i.e., how a cell responds to the accumulation of misfolded proteins in the endoplasmic reticulum) and how it may modulate beta-cell inflammation and death in T1DM is also gaining interest in T2DM.[47]

In reality, beta-cell death in T1DM likely sees contributions from both of these mechanisms (i.e., necrosis and apoptosis). The dynamic glycemic fluctuations, ultimately including overt hyperglycemia seen in the period of pre-T1DM (see the Stages in the Natural History of T1DM section), support the notion of ever-increasing functional changes in the beta cells, possibly as a result of immunologic stressors or increased metabolic demand for residual beta cells.

Natural History of T1DM—Historical Concepts

Perhaps the most helpful and beneficial guide to studies pertaining to the natural history of T1DM was the model put forward in 1986 by a previous author of this chapter, the late Dr. George Eisenbarth.[48] In this model (Fig. 36.3), persons destined to develop T1DM were assumed to begin life with a full cadre of beta cells. A triggering insult, likely environmental, was proposed to initiate a process involving recruitment of antigen-presenting cells. The antigen-presenting cells would sequester self-antigens released by injured beta cells, followed by their transport to pancreatic lymph



• **Fig. 36.3** The natural history of type 1 diabetes mellitus—a 25-year-old concept revisited. A re-creation of the model as originally proposed in 1986 is tracked by the *black line*. Several additions and conjectures can be made to this model based on recent knowledge gains (*lavender line*). *T1D*, type 1 diabetes. (Redrawn from Atkinson MA, Eisenbarth GS, Michels AW. Type 1 diabetes. *Lancet*. 2014;383:69–82, used with permission.)

nodes, where they are subsequently presented to autoreactive T cells. These T cells, rogue constituents brought to life because of genetically driven failures of thymic deletion (i.e., central tolerance) combined with defects in mechanisms designed to induce peripheral immune tolerance, would come into play.[49] This toxic duo imparting lack of tolerance formation, again in the context of genetic susceptibility, would allow for migration of self-reactive T cells to islets, mediating beta-cell killing and promoting further inflammation.[50] Symptoms of the disease were thought to appear when 85% to 90% of pancreatic beta cells had met their demise. In the final stage of the model, the autoimmune process ends with the complete elimination of beta cells.

Although this model faithfully served as a guide for multiple decades, and certainly the majority of its aspects hold true to this day, some constituents are under states of correction (e.g., the aforementioned notion that C-peptide production is lost in T1DM at onset) or are still subject to intense investigation—facets that will be discussed throughout this chapter (see the "Natural History of T1DM-Emerging Concepts" section).

Natural History of T1DM From Long-Term Family and Population Studies

The major longitudinal clinical epidemiologic studies of T1DM have included BABYDIAB in Germany[51]; DIPP (T1DM Prediction and Prevention) in Finland[52]; DAISY (Diabetes Autoimmunity Study in the Young) in Denver, Colorado[53]; TEDDY (The Environmental Determinants of Diabetes in the Young) with US sites in the states of Colorado, Georgia, Florida, and Washington, as well as European sites in Germany, Sweden, and Finland[54]; T1DM TrialNet Pathway to Prevention, with more than 200 locations across the United States, Europe, Canada, Australia and New Zealand[55]; and SEARCH (the SEARCH for Diabetes in Youth), with study centers in the US states of South Carolina, Ohio, Colorado, California, and Washington.[56] These efforts, together with cross-sectional investigation of human pancreas tissues obtained through biobanks, such as the Network for Pancreatic Organ donors with Diabetes (nPOD),[57] have reshaped our understanding of the natural history of T1DM and human pancreas pathology with some of the seminal findings reviewed in Table 36.2.

A pivotal discovery was made from combined analysis of data generated in the BABYDIAB, DAISY, and DIPP studies. Namely, once two or more anti-islet autoantibodies are present in a given individual, the individual's 10-year risk for developing diabetes ranges from 60% in older seroconverters (>3 years) to 75% in those who seroconvert before 3 years of age.[11] Recent and ongoing analyses of longitudinal data generated from the DIPP and TEDDY cohorts are unveiling potential environmental influences (e.g., birth by cesarean section, gut microbiome, dietary fiber, early introduction of cow's milk or gluten to an infant's diet, vitamin D, antibiotic use in early life, vaccination, infections)[58–64] and novel biomarkers (e.g., gut microbiome, metabolomics, lipidomic and proteomic profiles) of eventual T1DM progression (see the Emerging Biomarkers of T1DM Natural History and Diagnosis section)[65] that might ultimately enable identification of the disease early in its pathogenesis. The hope is that prevention or delay of T1DM onset may one day be possible through early lifestyle adjustments or tailored intervention.

Genetics

It has long been recognized that diabetes is a heterogeneous group of metabolic disorders, with hyperglycemia representing a common feature. More recently, it has become apparent that T1DM is also heterogeneous as a disease entity. This conclusion is based on a series of observations including the age at disease onset, form of

TABLE 36.2 T1DM Clinical Research Consortia and Natural History Trials

Trial	Enrollment Criteria	Endpoint(s)	Clinical and Mechanistic Outcomes	Reference
BABYDIAB	Offspring of parent with T1DM	1. Anti-islet autoantibody seroconversion 2. T1DM onset	• 4% developed anti-islet autoantibodies by age 2 years • IAA first autoantibody, followed by GADA	51
DIPP T1DM Prediction and Prevention	Neonates and siblings with high-risk HLA from the general population	1. Anti-islet autoantibody seroconversion 2. T1DM onset	• 6% developed anti-islet autoantibodies by age 2 years • 46% of anti-islet autoantibody–positive children reverted to negative serostatus • IA-2A positivity conferred increased risk or protection	52, 393, 394
DAISY Diabetes Autoimmunity Study in the Young	Neonates with high-risk HLA from the general population and first-degree relatives with T1DM	1. Anti-islet autoantibody seroconversion 2. T1DM onset	10-year risk of progression to T1DM: • 15% with one anti-islet autoantibody • 70% with two anti-islet autoantibodies • 74% with three anti-islet autoantibodies • Anti-islet autoantibody seroconversion after 8 years of age was more common in African-American and Hispanic children than in non-Hispanic white children • Age of anti-islet autoantibody seroconversion was a major determinant of age of T1DM progression	53
TEDDY The Environmental Determinants of Diabetes in the Young	Neonates with high-risk HLA from the general population and first-degree relatives with T1DM	1. Anti-islet autoantibody seroconversion 2. T1DM onset	5-year risk of progression to T1DM: • 11% with one anti-islet autoantibody • 36% with two anti-islet autoantibodies • 47% with three anti-islet autoantibodies • IAA+ and GADA+ progressed equally to T1DM but IAA occurred first at a younger age	54, 395
T1DM TrialNet Pathway to Prevention (Formerly TN01 Natural History Study)	Children and adults with anti-islet autoantibodies from the general population and first-degree relatives with T1DM	1. T1DM onset	Risk of T1DM was associated with the following: • Number of anti-islet autoantibodies • Age • Hemoglobin A_{1c} • OGTT	396, 397
SEARCH SEARCH for Diabetes in Youth	Diagnosed diabetes (excluding gestational diabetes) in subjects <20 years of age from the general population at six sites across the United States	N/A	• Between 2002 and 2009, T1DM incidence increased by 2.7% in non-Hispanic white youth • Between 2002 and 2012, the annual rate of incidence increase was 4.2% in Hispanic youth versus 1.2% in non-Hispanic white youth • 30–50% of youth diagnosed with T1DM were also overweight or obese • 26% of anti-islet autoantibody–positive cases also had insulin resistance	56, 398
nPOD Network for Pancreatic Organ donors with Diabetes	Organ donors across the United States: 1. Diagnosed with T1DM 2. Diagnosed with T1DM and pancreas or pancreas/kidney transplant recipient 3. Nondiabetic, anti-islet autoantibody positive and younger than 30 years of age	N/A	• Insulitis is markedly different in human T1DM versus the NOD mouse model • Defined human insulitis as at least three islets with >15 infiltrating immune cells • Pancreas weight is reduced in T1DM • HLA class I is hyperexpressed in islets of the human T1DM pancreas • Insulin-expressing beta cells are reduced but still detectable in the human T1DM pancreas	7, 39, 40, 57, 399–401

symptomatic presentation (i.e., rapid and ketotic vs. mild without ketosis), pancreatic pathologic changes, type and number of autoantibodies, and certainly the genetics.

Indeed, there are likely many genetic forms of T1DM, influenced to a major degree by the presence of specific forms of HLA class II molecules.[66] Beyond HLA, the form of T1DM is also influenced by the presence of abnormalities (immunologic, beta cell, etc.) fostered by the quantity and combinations of genes that influence these aberrancies. The number of specific genes that contribute to T1DM remains in flux, to some degree, as studies of loci validation in varying global populations are conducted. However, current estimates provided by genome-wide association studies (GWAS) support that more than 50 such loci exist, with the majority thought to influence immune responses.[67] Many of the

TABLE 36.3 Risk of Type 1 Diabetes Mellitus

Group	Childhood Annual Incidence
US general population	0.3% (15–25/100,000)
Offspring	1%
Sibling	3.2% (through adolescence); 6% lifetime
Dizygotic twin	6%
Mother	2%
Father	4.6%
Both parents	~10%
Monozygotic twin	50%, but incidence varies with age of index twin

HLA and non-HLA genes underlying T1DM susceptibility are similar in diverse countries, although specific alleles of those genes differ in their frequency. It is generally thought that specific combinations of HLA and non-HLA genes contribute to a loss of tolerance to self-antigens in beta cells, ultimately resulting in T1DM.

Beyond the polymorphisms seen in these HLA and non-HLA genes identified by GWAS, genetics studies have also been extremely helpful in identification and characterization of several monogenic forms of T1DM. Although these disorders often clinically continue to be classified as T1DM, such diseases should strictly be identified as *monogenic diabetes*. Genetic risk scores (GRSs) accounting for HLA and non-HLA risk alleles can discriminate T1DM from other forms of diabetes, including monogenic diabetes and T2DM[68–70] (see The Genetic Risk Score section).

Overview of Disease Prevalence

In the United States, the risk of childhood diabetes is approximately 1 in 300.[71] This risk is 15 times lower than the diabetes risk for a first-degree relative of a patient with T1DM (Table 36.3), which, in turn, is 150 times lower than the risk for a monozygotic twin of a patient with T1DM.[72] Although the risk of diabetes is much greater for relatives of patients with T1DM, it is important to realize that most persons (>85%) in whom T1DM develops do not have a first-degree relative with the disease. The incidence of sporadic cases results, in part, because almost 40% of persons in the general population carry high-risk HLA alleles for T1DM (see The Major Histocompatibility Complex section).

The highest known incidence of T1DM is observed in Finland and Sardinia. Finland now has an annual incidence approaching 60 per 100,000 children.[73] Since the 1950s, the incidence has increased almost fivefold, suggesting a dramatic environmental change (either an increase of causative factors or a decrease of protective factors), and it is doubling in many Western countries, including the United States, every 10 to 15 years (Fig. 36.4). Of note, the increased T1DM incidence in many countries has not been linear but rather fluctuating over the past several decades. In contrast, the disorder is quite uncommon in China, India, and Venezuela (~0.1 per 100,000 per year).

Twin Studies

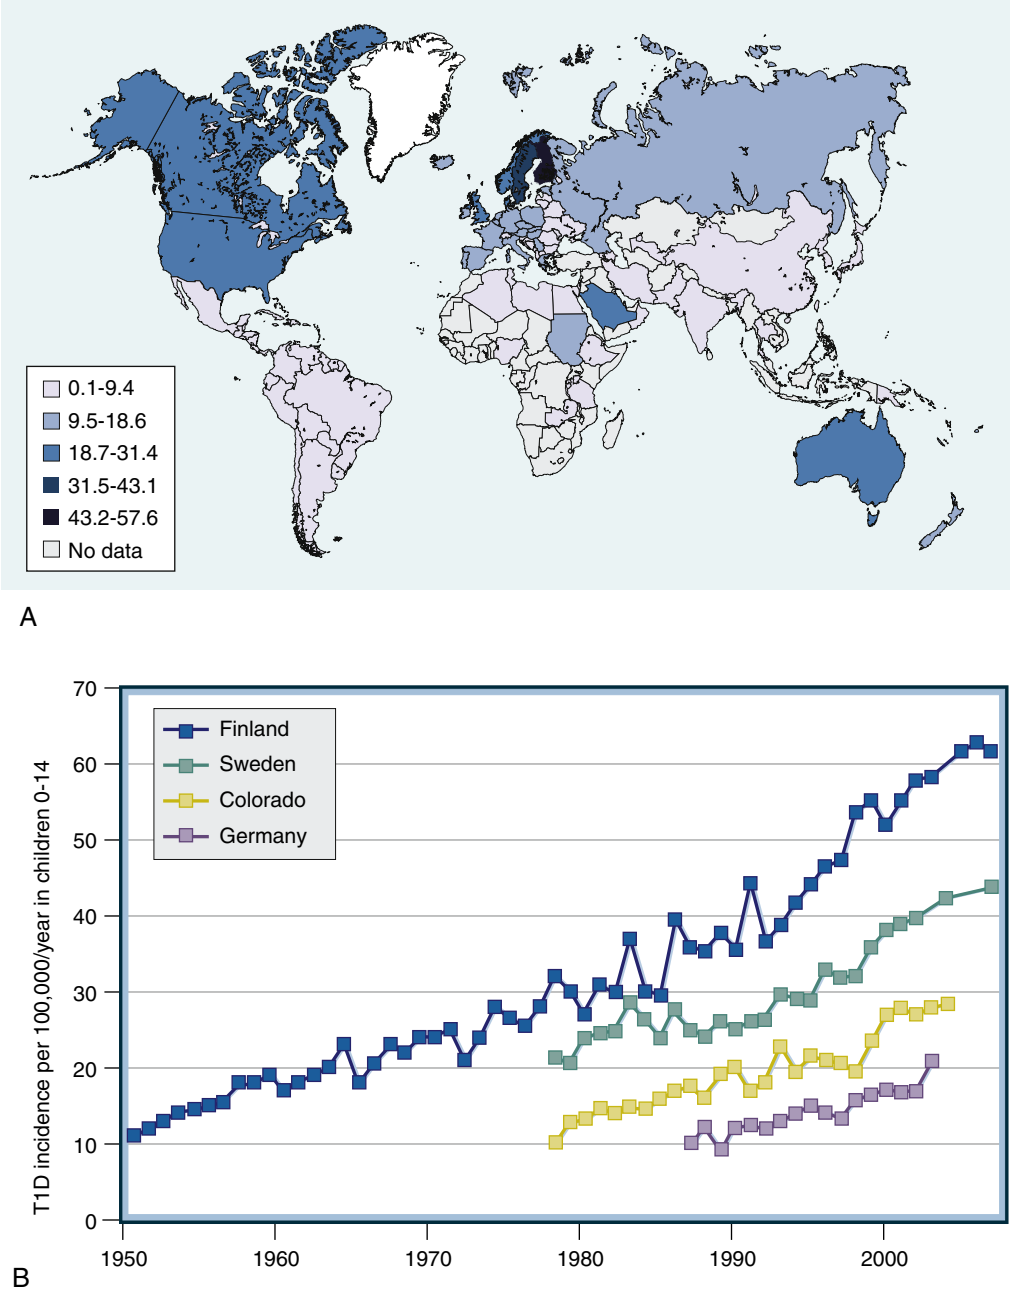
Twin studies of diabetes have made impressive contributions to our understanding of the disease. The study of monozygotic twins of patients with diabetes by Barnett and coworkers[74] contributed to the recognition of distinct forms of diabetes, initially termed *juvenile onset* and *adult onset*, later *insulin dependent* and *non–insulin dependent*, and now T1DM and T2DM. The concordance rates for monozygotic and dizygotic twins provide important information regarding genetic factors contributing to a given disease, because monozygotic twins share all germline-inherited polymorphisms or mutations, whereas dizygotic twins are similar to nontwin siblings of patients with a disease and have only half of their genes in common. For a locus that contributes to disease in a recessive manner, only one quarter of dizygotic twins would be homozygous to a sibling with diabetes at that locus, but all monozygotic twins would be homozygous for all recessive loci of their diabetic twin. As overall concordance rates of monozygotic twins for T1DM vary across studies, it is likely that T1DM is heterogeneous and that groups of monozygotic twins have different genetic causes for their diabetes. With such genetic heterogeneity, one would expect different concordance rates for different genetic causes.

Redondo and coworkers[75] analyzed prospective follow-up data from a large series of initially discordant monozygotic twins from the United Kingdom combined with a series from the United States. Progression to diabetes was identical for both series of twins. There was no length of time of discordance beyond which a monozygotic twin of a patient with T1DM did not have a risk of developing the disease. Nevertheless, the hazard rate for development of diabetes decreased as the period of discordance increased. There was also a marked variation in the risk of diabetes relative to the age at which the disorder developed in the index twin. With long-term follow-up, the overall rate of concordance for monozygotic twins exceeds 50%.[72] However, if T1DM developed in the index twin after age 25 years, the concordance rate by life table analysis in the study of Redondo and coworkers[75] was less than 10%. If diabetes developed in the index twin before age 5 years, the concordance rate was 70% after 40 years of follow-up. Therefore, environmental factors, random factors, and non–germline-inherited variations (e.g., imprinting, T-cell receptor polymorphisms, somatic mutations) likely contribute to lifetime diabetes risk. Interestingly, studies of dizygotic twins suggest that their risk of diabetes may not differ from that of nontwin siblings or, at most, may be increased by a factor of two as compared with the 10-fold increase for monozygotic twins.[76]

Genetic factors influence not only the development of diabetes but also the expression of anti-islet autoantibodies. For identical twins, the expression of anti-islet autoantibodies is tightly linked to the eventual progression to overt diabetes, and, true to form, monozygotic twins have a highly concordant prevalence for the presence or absence of anti-islet autoantibodies. Dizygotic twins much less often exhibit concordant positivity for anti-islet autoantibodies, and the prevalence is similar to that of nontwin siblings.[77]

The Major Histocompatibility Complex

The most important loci determining the risk of T1DM reside within the MHC on chromosome 6p21 and, in particular, the HLA class II molecules (DR, DQ, and DP).[66] The major determinants of T1DM susceptibility are DR and DQ molecules, and specific alleles of both HLA-DR and -DQ can either increase or decrease the risk of diabetes. Table 36.4 summarizes the diabetes risk associated with several DR and DQ haplotypes.[78] In addition, HLA class I loci (HLA-A, -B, and -C) influence disease, and it is likely that additional loci within or linked to the MHC influence immune function and contribute to risk.[79] The nomenclature for alleles of this region is somewhat daunting, but with definitions of



• **Fig. 36.4** Incidence of T1D in children age 0 to 14 years by geographic region and over time. (A) Estimated global incidence of TID, by region, in 2011. (B) Time-based trends for the incidence of TID in children ages 0 to 14 years in areas with high or high-intermediate rates of disease. T1D, type 1 diabetes. (Redrawn from Atkinson MA, Eisenbarth GS, Michels AW. Type 1 diabetes. *Lancet.* 2014;383:69–82, used with permission.)

several terms and a description of the basis for classification, it is comprehensible and quite important to understand.

As noted previously, the function of HLA molecules is to present peptides to T lymphocytes. Each HLA molecule is made up of two chains, and each chain is encoded by a separate gene. These molecules are extremely polymorphic in amino acid sequence. Each polymorphic variant of each chain is designated with a gene locus name (e.g., HLA-DRB1) followed by an asterisk (*), followed by two digits referring to the serologic specificity (from the time in diagnostic history when typing was performed with antibodies), followed by two digits for the specific allele (now determined with DNA-based typing), followed by a single digit to distinguish silent nucleotide polymorphisms (nucleotide differences that do not change the amino acid sequence). For example, the designated allele HLA-DRB1*04:05 has DR4 serologic specificity and is associated with high T1DM risk. There are hundreds of known alleles of HLA-DRB1. Each person inherits two HLA-DRB1 alleles, one from each parent. For HLA-DR alleles, usually only the DRB chain is specified, because the DRA chain is not polymorphic. Likewise, for the class I molecules (A, B, and C), only a single chain is specified, because the other chain, β_2-microglobulin, is minimally polymorphic.

Because HLA gene loci are in close proximity to each other on the sixth chromosome, a group of alleles is usually inherited as a unit, which is termed a *haplotype*. For example, the alleles HLA-A*01:01,

TABLE 36.4 Diabetes Risk of Representative HLA-DR and DQ Haplotypes

DRB1	DQA1	DQB1
High Risk		
0401 or 0403 or 0405	0301	0302 (DQ8)
0301	0501	0201 (DQ2)
Moderate Risk

1401	0101	0503
0701	0201	0303

HLA-B*08:01, and HLA-DRB1*0301-DQA1*0501-DQB1*0201 constitute a common haplotype associated with diabetes risk probably related to the presence of HLA-DRB1*0301. When specific alleles of different genes are nonrandomly associated with each other on a haplotype (e.g., A1, B8, and DR3), the alleles are said to be in linkage disequilibrium. Linkage disequilibrium is not the same as linkage, although to have linkage disequilibrium, genes must be linked. Genes are linked when they are close together on the same chromosome and thus transmitted from parent to child as a haplotype group. If alleles of linked genes are nonrandomly associated with each other in a population, they are in linkage disequilibrium.

Two MHC haplotypes, one inherited from each parent, constitute an individual's MHC genotype. This genotype ultimately determines the MHC-encoded risk of T1DM. For HLA-DQ molecules, both of the chains (DQA and DQB) are polymorphic. This adds an important level of diversity in that the protein chains encoded by the alleles of one haplotype can combine with the chains encoded by the other haplotype. For example, persons with the highest-risk genotype HLA-DRB1*03:01-DQA1*05:01-DQB1*02:01 and HLA-DRB1*04:05-DQA1*03:01-DQB1*03:02 can produce four different DQ molecules: the expected DQA1*05:01-DQB1*02:01 and DQA1*03:01-DQB1*03:02 but also DQA1*05:01-DQB1*03:02 and DQA1*03:01-DQB1*02:01. Studies suggest that the DQA1*05:01-DQB1*03:02 combination determines enhanced diabetes risk for DR3/4 individuals. The DQ molecule DQA1*05:01-DQB1*02:01 is also called *DQ2*, and DQA1*03:01-DQB1*03:02 is called *DQ8*.

A common DQ molecule, HLA-DQA1*01:02-DQB1*06:02, provides dominant protection from T1DM and is termed *DQ6*. A DR allele, HLA-DRB1*14:01, also appears to provide dominant protection.[80] The protective haplotype HLA-DRB1*15:01-DQA1*01:02-DQB1*06:02 is present in 20% of the general population and in fewer than 3% of patients with T1DM.

In several, children from the general population or relatives of patients with T1DM have been HLA typed.[81,82] In the United States, 2.4% of newborns have the highest risk HLA-DR-DQ genotype for T1DM, namely DR3-DQ2 with DR4-DQ8 (DR3/4-DQ2/8 heterozygotes). Fifty percent of children younger than 10 years and approximately 30% of older children who develop T1DM have this highest-risk genotype. Approximately 1 of 16 children with the highest-risk HLA genotype from the general population progresses to T1DM (compared with a population risk of 1 per 300). Alternatively, 15 of 16 children from the general population who are DQ2/DQ8 heterozygotes do not develop T1DM. Studies indicate that newborn siblings of patients with T1DM who have DQ2 and DQ8 have a risk of expressing islet autoantibodies exceeding 40% by age 6 years, and 50% of these newborns will develop diabetes by age 10 years. Ninety-five percent of persons who develop T1DM have either DR3-DQ2 or DR4-DQ8, as does approximately 40% of the general population.

There are additional high-risk haplotypes that are not common, such as HLA-DQA1*04:01-DQB1*04:02. It has been proposed as a simple rule that the presence of aspartic acid at position 57 of the DQβ chain and arginine at DQα 52 is associated with T1DM risk.[83] There are many exceptions to this rule, and knowledge of the complete sequences (allele) rather than dependence on this rule is essential.

Other Loci

In impressive collaborative form, more than a decade of international GWAS efforts led to the definition of many loci that contribute to small but varying degrees toward the development of T1DM.[84] For example, polymorphisms of the cytotoxic T-lymphocyte–associated protein 4 gene contribute to Graves disease and apparently to T1DM in some, but not all, populations, with relative risks less than 1.3.[85] A locus associated with the IL2 receptor has a statistical association based on analysis of thousands of persons.[86] Sequencing in one region has also identified rare mutations of a gene influencing interferon-alpha induction.[87] A curated list of T1DM risk loci can be found at http://www.immunobase.org.

Although much of the attention toward T1DM genetics has resided on HLA, other loci have drawn attention for their potential contributions to disease risk, including those related to insulin. In 1984, Bell and colleagues[88] published their discovery that variations in the number of nucleotide repeat elements located upstream (also known as 5′) of the insulin gene were associated with the development of T1DM. The longest group of repeats was associated with decreased diabetes risk.[89] In a mechanism potentially related to the role of autoimmune regulator (AIRE) in the thymus, the protective insulin gene polymorphism is associated with greater insulin messenger RNA expression within the thymus.[90] Indeed, for both the AIRE mutation of autoimmune polyendocrine syndrome type 1 (APS1) and the effect of insulin gene mutations, the level of expression of insulin in the thymus may be critical.

Additionally, *PTPN22*, a gene encoding a lymphoid-specific phosphatase that influences T-cell receptor signaling, is the third confirmed gene (vs. mere loci) influencing T1DM risk.[91] The polymorphism associated with T1DM (Trp for Arg) blocks binding to a signaling kinase molecule, C-terminal Src kinase (CSK). Nevertheless, the relative risk associated with this polymorphism for T1DM and other autoimmune disorders, such as rheumatoid arthritis, is only 1.7. The variant associated with disease risk results in gain of function and decreased T-cell receptor signaling.[92]

Genetic and Immunologic Heterogeneity by Age of Onset

T1DM can develop at any age, from the neonatal period to the last decades of life. Given that identical twins can become concordant more than 40 years after the first twin develops T1DM, not all age heterogeneity can be ascribed to different genetic syndromes.[77] Nevertheless, there is an overall correlation between the age at which diabetes develops in one twin or sibling and the age of development of diabetes in his or her relative. Children in whom T1DM develops at an early age more often are DR3/4-DQ2/8 heterozygotes. In addition, there is evidence that class I HLA alleles (or other non–class II genes within the HLA region) can influence the age at diabetes onset; an example is the A24 allele.[93] At the other end of the age spectrum, there is evidence that the protective HLA allele DQA1*01:02-DQB1*06:02 is not as protective for young adults as it is for children.[94]

The most characteristic difference related to age at diabetes onset is the presence of higher levels of IAA in children who develop the disease at an early age (e.g., <5 years). The high levels and frequent positivity of IAA make measurement of these autoantibodies the best single marker for diabetes development in young children.[95] In those children in whom autoantibodies arise during the first 3 years of life, IAA often appear first. In contrast, GADA are more often positive in adults who develop T1DM. Seroconversion to IAA or GADA as the first anti-islet autoantibody has also been linked to HLA.[96] The correlation of levels of IAA and age at diabetes onset may be related to faster progression to diabetes in children with higher levels. However, such rapid progression occurs only if IAA are present with another anti-islet autoantibody (discussed in the Stages in the Natural History of T1DM section).

Monogenic Forms of Diabetes

The most common forms of diabetes, T1DM and T2DM, are polygenic, meaning that the risk of developing these disorders is related to multiple genes. Environmental factors (discussed later) also play a part in the development of polygenic forms of diabetes. However, additional and rare forms of diabetes, termed *monogenic*, result from mutations in a single gene. Monogenic forms of diabetes account for about 1% to 5% of all cases of diabetes in young individuals. So far, more than 20 genes have been linked to monogenic diabetes. In most cases of monogenic diabetes, the gene mutation is inherited; in the remaining cases, the gene mutation develops spontaneously. Neonatal diabetes (ND) and maturity-onset diabetes of the young (MODY) are the two main forms of monogenic diabetes (Table 36.5), with ND far less common than MODY.

Genetic testing can diagnose most forms of monogenic diabetes. If genetic testing is not performed, people with monogenic diabetes may appear to have one of the polygenic forms of diabetes (i.e., T1DM or T2DM). When hyperglycemia is first detected in adulthood, monogenic diabetes is often misdiagnosed as general T2DM. Importantly, some monogenic forms of diabetes can be treated with oral diabetes medications, whereas other forms require insulin injections. A correct diagnosis that allows the proper treatment to be selected should lead to better glucose control and improved health in the long term.

Neonatal Diabetes

ND is a monogenic form of diabetes that occurs in newborns through the first 6 months of life. It is a rare condition occurring in only 1 in 100,000 to 500,000 live births. Owing to lack of professional awareness (although at decreasing frequency) or lack of screening, ND can be mistaken for T1DM, a disorder that usually occurs later than the first 6 months of life. For approximately one half of those with ND, the condition is lifelong, yet for the remainder, the condition disappears during infancy but can reappear later in life (i.e., transient ND). Symptoms of ND mimic those of T1DM and include thirst, frequent urination, and dehydration. In severe cases, insulin deficiency can lead to DKA. In addition, fetuses with ND may not see normal growth in utero, with newborns being small for gestational age (i.e., intrauterine growth restriction). Following, some infants demonstrate protracted growth and weight gain, but appropriate therapy has the ability to improve and may in fact normalize growth and development.

Maturity-Onset Diabetes of the Young

Maturity-onset diabetes of the young (MODY) is a monogenic form of diabetes that usually first occurs during adolescence or early adulthood[97] but may remain undiagnosed until later in life, as MODY patients often are asymptomatic or demonstrate only mild hyperglycemia. Several different gene mutations have been shown to cause MODY[98] (see Table 36.5). MODY variants have been estimated to account for about 1% to 5% of all cases of diabetes in the United States.[99] Relatives of those with MODY are at increased risk for the disorder (e.g., children of a MODY parent have a 50% chance of inheriting the disease). MODY patients are generally not overweight. Although both T2DM and MODY can run in families, MODY pedigrees typically portray a family history of diabetes in multiple successive generations.

Autoimmune Polyendocrine Syndrome Type I (AIRE Gene Mutations)

Autoimmune polyendocrine syndrome type 1 (APS1) is rare (<500 cases worldwide), with an increased incidence in Finland and Sardinia and among Iranian Jews, but it has a worldwide occurrence. The disorders of the syndrome, such as T1DM, mucocutaneous candidiasis, hypoparathyroidism, Addison disease, and hepatitis (see Chapter 43 for a more detailed discussion beyond genetics herein), identify a unique syndrome, and patients with this group of disorders almost always have mutations (usually autosomal recessive) of the *AIRE* gene on chromosome 21, a gene that encodes a DNA-binding protein. This gene may play an important role in maintaining self-tolerance, as well as influence the expression of what immunologists term *peripheral antigens* (e.g., insulin) in the thymus. This notion becomes relevant in that it has been hypothesized that greater thymic expression of insulin and other tissue-specific antigens leads to T-cell tolerance and disease suppression. At the same time, the influence on insulin is not specific, as damage to the adrenal glands, parathyroid glands, and other organs underlie the major features of APS1 and are why candidiasis infections predominate.

X-Linked Polyendocrinopathy, Immune Dysfunction, and Diarrhea (Scurfy Gene)

The syndrome of X-linked polyendocrinopathy, immune dysfunction, and diarrhea (*XPID*, also termed *IPEX*) is associated with overwhelming neonatal autoimmunity, and most children die in the first few days of life or in infancy.[100] In this syndrome, lymphocytes invade multiple organs. It is associated with insulitis and beta-cell destruction, as well as lymphocytic intestinal inflammation with flattened villi and severe malabsorption. It is inherited as an X-linked recessive disease affecting only boys, with a frequent clinical history of lack of male births.

TABLE 36.5 Characteristics of Monogenic Diabetes

Type of Diabetes	Gene or Syndrome	Affected Protein	How Common?	Typical Age at Onset	Type of Inheritance or Mutation	Causes Intrauterine Growth Restriction?	Transient or Permanent?	Treatment
Neonatal Diabetes Mellitus (NDM) (Rare; Occurs in ~1 of Every 100,000–500,000 Live Births)								
Permanent Neonatal Diabetes Mellitus (PNDM) (50% of All Cases of NDM)								
PNDM	*KCNJ11*	Kir6.2	Most common type of PNDM	3–6 months	Autosomal dominant (10%) Spontaneous	Yes	Permanent (this gene also causes a transient form of NDM)	Treated with insulin in the past but often can be treated with oral sulfonylureas
PNDM	*ABCC8*	SUR1-sulfonylurea receptor 1	Rare	1–3 months	Autosomal dominant (12% of NDM cases) Spontaneous	No	Permanent (this gene also causes a transient form of NDM)	Treated with insulin in the past but often can be treated with oral sulfonylureas
PNDM	*GCK*	Glucokinase	Rare	1 week	Autosomal recessive	Yes	Permanent	Insulin
PNDM	*IPF1*; also known as *PDX1*	Insulin promoter factor 1	Rare	1 week	Autosomal recessive	Yes	Permanent	Treat to replace endocrine and exocrine pancreas functions
PNDM	*PTF1A*	Pancreas transcription factor 1 A	Rare	At birth	Autosomal recessive	Yes	Permanent	Treat to replace endocrine and exocrine pancreas functions
PNDM	*FOXP3*, IPEX syndrome	Forkhead box P3	Rare	Sometimes present at birth	X-linked	Yes	Permanent	Insulin
PNDM	*EIF2AK3*, Wolcott-Rallison syndrome	Eukaryotic translation initiation factor 2-alpha kinase 3	Rare	3 months	Autosomal recessive	Yes	Permanent	Insulin and treatment for associated conditions
Transient Neonatal Diabetes Mellitus (TNDM) (50% of All Cases of NDM)								
TNDM	*ZAC/HYMAI*	*ZAC*: pleomorphic adenoma gene-like 1 or PLAG1 *HYMAI*: hydatidiform mole–associated and imprinted transcript	Most common form of NDM	Birth to 3 months	Autosomal dominant Spontaneous	Yes	Transient	Initially, treat with insulin; reduce dosage as needed; when diabetes recurs, treat with diet modification and physical activity; may also require insulin
TNDM	*ABCC8*	SUR1 (sulfonylurea receptor 1)	Rare	Birth to 6 months	Autosomal dominant Spontaneous	Varies	Transient (this gene also causes a permanent form of NDM)	Oral sulfonylureas
TNDM	*KCNJ11*	Kir6.2	Uncommon cause of TNDM but most common cause of PNDM	Birth to 6 months	Autosomal dominant Spontaneous	Yes	Transient (this gene also causes a permanent form of NDM)	Oral sulfonylureas
TNDM	*HNF1 β* (beta); also known as *HNF1B*	Hepatocyte nuclear factor 1B	Rare	Birth to 6 months	Autosomal dominant (60%) Spontaneous	Yes	Transient	Insulin

Maturity-Onset Diabetes of the Young (MODY; 1–5% of All Cases of Diabetes in the United States)

MODY 1	*HNF4A*	Hepatocyte nuclear factor 4α (alpha)	Rare	Adolescence or early adulthood	Autosomal dominant	No	Permanent	For most, oral sulfonylureas; some patients may need insulin
MODY 2	*GCK*	Glucokinase	MODY 2 and MODY 3 account for about two thirds of all cases of MODY MODY 2 is the second most common form of MODY	Mild hyperglycemia may be present at birth; otherwise, early childhood	Autosomal dominant	Lower than normal birth weight can occur	Permanent	Diet modification and physical activity; medications usually not required; some patients do not require any treatment during childhood
MODY 3	*TCF1*	Hepatic nuclear factor 1α (alpha) or HNF1α (alpha) or HNF1A	MODY 3 is the most common form of MODY	Adolescence or early adulthood	Autosomal dominant	No	Permanent	Initially, treat with diet modification; can be treated with oral sulfonylureas; some patients may need insulin
MODY 4	*IPF1*; also known as *PDX1*	Insulin promoter factor 1	Rare	Early adulthood; can present later	Autosomal dominant	No	Permanent	Oral sulfonylureas; some patients may need insulin
MODY 5	*TCF2*	Hepatic nuclear factor 1β (beta) or HNF1B	Rare	Adolescence or early adulthood	Autosomal dominant	No	Permanent	Insulin; patients also may need treatment for related conditions such as kidney failure or cysts
MODY 6	*NeuroD1*, or *BETA2*	Neurogenic differentiation factor 1	Rare	In the fourth decade of life	Autosomal dominant	No	Permanent	Insulin

The disease results from mutations of the gene encoding forkhead box P3 (FOXP3), which functions as a transcription factor and master switch for regulatory (suppressor) $CD4^+CD25^+CD127^{-/low}$ T lymphocytes.[101] Lack of such regulatory T cells leads to overwhelming autoimmunity. This is an important syndrome to recognize early, as bone marrow transplantation, affording restoration of functional T-regulatory cells (even with partial chimerism), has proved to be therapeutic.

The Genetic Risk Score

A recent advance in the ability to stratify patients with high risk for developing T1DM has occurred through construction of cumulative genetic risk models utilizing logistic regression algorithms that incorporate HLA and non-HLA alleles associated with T1DM.[68–70] Although HLA predominates risk, the inclusion of non-HLA loci increases model accuracy for classifying individuals as T1DM patients versus those at low risk. Although not currently used in standard clinical care, the GRS is being applied in the research space to improve subject selection and stratification. Genetic risk models enable prediction of T1DM progression,[102] differentiation of T1DM from T2DM and monogenic forms of diabetes,[68,69] and determination of T1DM onset prevalence in individuals older than 30 years. In the prospective TEDDY study, a GRS model improved the ability to identify infants with high risk of developing anti-islet autoantibodies by 6 years of age.[103] One caveat is due to inherent biases resulting from the predominance of GWAS and genotype/phenotype studies being conducted in majority Caucasian populations from Western Europe and the United States. The need for studies characterizing the T1DM genetic risk profile and the development of new GRS models in non-Caucasian populations represents a clear limitation to clinical introduction of current GRS modeling.[70]

Environmental Factors

Environmental factors have long been considered to influence the pathogenesis of T1DM. Regional differences in disease rates based on geography, seasonality in its diagnosis, rising incidence trends, and variance among twins are consistent with this conclusion. However, despite decades of research, no single environmental agent has been identified that would universally explain these observations. Identification of any such agent is especially difficult due to facets of the disorder's pathogenesis (e.g., the long prodromal/prediabetic phase that often precedes T1DM, that 85% of new cases arise from the general population rather than having a family history of T1DM, the limited disease frequency of 1 in 300).

The fivefold increase in T1DM rates over the past half-century has been considered strong evidence that environmental factors related to diabetes risk have changed since the 1960s. Factors that increase diabetes risk may be increasing, or just as likely, factors that suppress the development of T1DM may be decreasing. It is interesting that the rising incidence as a function of age at onset is occurring globally at different rates. The increase in Finland is highest for children in whom the disease develops before age 5 years, yet in the United States, the recent Search for Diabetes in Youth Study (SEARCH) showed the most rapid rise in teenagers.[56,104]

Models to Explain the Influence of Environment

Although the mechanisms by which environment influences T1DM are not known, numerous hypothetical models have been proposed. The accelerator and overload hypotheses suggest that childhood obesity increases insulin demand, overloading the islet cells and accelerating beta-cell autoimmune damage.[105,106] In the Copenhagen model, beta-cell destruction is proposed to result from interactions between the environment, immune system, and the beta cells themselves in genetically susceptible individuals.[107] The hygiene hypothesis attributes the rising incidence of autoimmune disorders to the decline in infections with reduced stimulation of the immune system.[108] Conversely, the fertile field hypothesis proposes that microbial infection induces a temporary state in which other antigens can more easily react to yield autoreactive T cells.[109] Also implicating the gut, the old friends hypothesis implicates dietary exposure as a possible direct regulator of the immune system and of self-tolerance by altering gut microbiota and intestinal permeability.[110] Finally, the threshold hypothesis suggests that the etiologic influences of genetics and environment, when evaluated as intersecting and reciprocal odds-ratio–based trend lines, result in a method to define the attributable risk for T1DM.[111]

A popular model of T1DM involves an environmental "trigger" presumed to initiate disease. Whereas it is true that the underlying genetic susceptibility to T1DM might allow for a triggering of anti–beta-cell immunity by an environmental event, it is increasingly accepted that environmental agents may contribute far beyond an initial triggering and rather act throughout the natural history of T1DM development, such as by modulating the ongoing autoimmune process (e.g., genes controlling immune regulation). There is no shortage of potential environmental candidates (e.g., breastfeeding, antibiotics, infant and childhood diet, viruses) that, either alone or in combination, may contribute to the disorder's pathogenesis. However, most fall into the groups involving infection (particularly viruses), vaccination, and diet.

Candidate Environmental Factors

Infection

The best evidence, if not the only strong evidence, for a specific environmental agent to contribute to T1DM pathogenesis involves congenital rubella infection, which, in contrast to noncongenital infection, greatly increases development of T1DM.[112] The mechanism(s) by which this congenital infection increases diabetes development is currently unknown, with hypotheses ranging from molecular mimicry to long-term alteration in T-cell function secondary to the congenital insult.

Enteroviruses are the most often discussed agents associated with T1DM. Enteroviruses are small RNA viruses that frequently infect young children. Coxsackie virus (a form of enterovirus) infections were implicated after initial anecdotal reports involving children who had severe infections and who died at T1DM onset. These case studies preceded the recognition that T1DM is not an acute disease but one involving a chronic prediabetic period of autoimmunity. At the time of presentation with diabetes, almost all children have a rising elevation in HbA_{1c}, reflecting what is likely months of hyperglycemia preceding diagnosis.[113] Thus, it is likely that viral infection at the onset of T1DM is most often incidental.

The potential importance of enteroviral infection was evaluated in studies from Scandinavia, with enteroviral infection (detected by changes in antiviral antibodies or detection of enteroviral RNA by molecular techniques) assessed during pregnancy and in infancy.[114] Some studies report an increased incidence of enteroviral infection during pregnancy among mothers whose children later developed T1DM, but others have not.[114,115] Considering that infants with a genetic risk for development of diabetes are

followed from birth, it becomes possible to prospectively analyze expression of enterovirus RNA. Enteroviral infections have been associated with appearance of anti-islet autoantibodies in some regions (Finland)[114] but not in others (Colorado),[115] a finding that may be related to differing frequency and/or timing of enteroviral infections in these two populations.

Rotavirus infection, another virus that commonly infects young children, has been associated with increased anti-islet autoantibodies in one study from Australia,[116] but an increase in rotavirus infection was not found in children with T1DM compared with controls. Other viruses are also being evaluated for association with the triggering of autoimmunity.

Vaccines

A series of studies have been performed addressing the concern that childhood vaccine timing might influence development of T1DM, yet none has provided any evidence that childhood vaccinations influence the development of diabetes.[117] This is an important health concern if parents alter their family's childhood vaccination schedule because of concern about development of T1DM.

Dietary Factors

Dietary factors as environmental T1DM triggers have also been extensively investigated. Early introduction of bovine milk in the form of infant formula has been hypothesized to increase T1DM, based primarily on retrospective studies associating early or increased bovine milk ingestion (or less breastfeeding) with an increased risk of disease. Several prospective studies in which infants were observed until the development of anti-islet autoantibodies failed to find any association or found only a weak association with either breastfeeding or bovine milk ingestion. Pilot studies of an infant formula lacking bovine milk proteins were initiated in Finland and suggest that weaning to insulin-free cow's milk formula might reduce the development of anti-islet autoantibodies in the first 3 years of life.[118] In contrast, the TEDDY study found no association between choice of first infant formula and risk of developing anti-islet autoantibodies.[119]

Studies from Germany and Denver, Colorado, in the United States provided evidence that early (<3 months) introduction of cereals may increase development of islet autoimmunity.[120] Both low vitamin D and ω-3 fatty acids, which can influence immune function, have also been associated with risk of T1DM.[121] Dietary interventions with these factors to date have not been shown to be therapeutic.

Natural History of T1DM—Emerging Concepts

Beta-Cell Mass Is Not Equal in All Individuals

Most historical models of T1DM have assumed a normal beta-cell mass at birth that declines once the autoimmune attack occurs (see Fig. 36.3). However, recent studies of cadaveric pancreata have shown beta-cell mass in normal, nondiabetic humans varies threefold to fivefold, independent of adult age or body mass index, with beta-cell mass likely mostly determined in the first two decades of life.[122] This has important implications when one considers the starting point for declining beta-cell mass during autoimmune beta-cell destruction. An individual's timeline to diabetes onset could be determined not by the severity of the autoimmune attack but the starting point for beta-cell mass (see Fig. 36.3). The reasons for variation in beta-cell mass are unknown but could include the in utero environment, events during the first decade of life, and yet unknown genetic or environmental determinants. Given the aforementioned observations of a smaller total pancreatic mass in individuals with new-onset T1DM,[40,41] both pancreatic mass and beta-cell mass might be impacted, because endocrine islet cells and exocrine cells share a common embryologic heritage. Together, these structural changes emphasize the need to better understand the timeline and determinants of human beta-cell mass.

Pancreatic Exocrine Abnormalities in T1DM

Autopsy studies first revealed reduced pancreas weights in deceased persons with T1DM. More recently, studies of higher-quality organ donor tissues reveal that this phenomenon affects not only subjects with long-standing T1DM but also recent-onset T1DM and nondiabetic persons with anti-islet autoantibodies.[40] Noninvasive imaging methods permit studies of pancreas volume in living subjects, which confirm that the pancreas in generally smaller in T1DM patients than in those without disease.[41] Islets constitute only 1% to 2% of the entire pancreatic volume; hence, beta-cell loss alone cannot account for the reduction in total pancreas size. Insulinopenic effects were initially thought to cause loss of pancreatic size or weight following T1DM diagnosis. However, detection of low pancreas weight at T1DM onset and in anti-islet autoantibody–positive organ donors without diabetes,[40,41] together with certain histopathologic findings in the T1DM exocrine pancreas (e.g., invasion of exocrine pancreatic tissue by $CD8^+$ T cells, $CD4^+$ T cells, $CD11c^+$ dendritic cells, and neutrophils[32,33] and C4d complement deposition[123]), suggest early loss of pancreas mass prior to diagnosis. Moreover, serum levels of trypsinogen, which are indicative of exocrine pancreas function, are reduced in patients with long-standing T1DM, in those with recent-onset T1DM, and in nondiabetic individuals with anti-islet autoantibodies[124] implying that disease-related effects within the exocrine pancreas may be present prior to T1DM diagnosis.

Metabolic Progression Before Hyperglycemia

The intravenous glucose tolerance test aids in evaluating the time to onset of diabetes among persons expressing anti-islet autoantibodies. Glucose is given at 0.5 g/kg over 5 minutes (maximum 35 g, 25 g/dL), and insulin levels are measured before and 1 and 3 minutes after the glucose infusion.[125] Most persons who are within 1 year of developing overt T1DM have no first-phase insulin secretion after intravenous glucose administration. A simpler measurement in someone progressing to T1DM is the HbA_{1c}, which in most prediabetic individuals increases progressively (although in the normal range) 1 or 2 years before overt hyperglycemia develops.

The diagnosis of T1DM usually relies on the presence of fasting hyperglycemia (≥126 mg/dL, 7.0 mmol/L), but with prospective evaluation, many persons have diabetes determined by OGTT according to the 120-minute criterion (≥200 mg/dL, 11.1 mmol/L), with a nondiagnostic fasting glucose level. Impaired fasting glucose (100–125 mg/dL, 5.6–6.9 mmol/L) or impaired glucose tolerance (glucose at 120 minutes on OGTT, 140–199 mg/dL, 7.8–11.0 mmol/L) is usually present within 6 months before the onset of overt T1DM.

C-Peptide Loss After Hyperglycemia

After diabetes is diagnosed, levels of C-peptide in serum can be used to assess remaining beta-cell function, because C-peptide is

released from the beta cell in equimolar concentrations with insulin but does not undergo hepatic extraction and has a longer half-life in circulation. C-peptide levels are usually measured in the fasting state, after intravenous glucagon, or with a standard liquid meal. Such measurements are primarily of importance for trials of therapies to alleviate loss of insulin secretion after diagnosis. Determination of the C-peptide concentration provides the best current measure for assessing the impact of new therapies. A small amount of remaining C-peptide is associated with impressive metabolic benefit, as shown in the Diabetes Control and Complications Trial (DCCT).

Transient Hyperglycemia

A significant number of children are evaluated by endocrinologists for transient hyperglycemia. The usual history is one of severe stress associated with hyperglycemia that resolves within days to 1 month. Such children may be in the honeymoon phase of T1DM, or they may truly have a transient episode of hyperglycemia. Rarely, diabetes in children is misdiagnosed. Children without severe stress who have transient hyperglycemia or who have a relative with T1DM are more likely to have early T1DM. Absence of anti-islet autoantibodies and a normal first-phase insulin secretion during an intravenous glucose tolerance test strongly indicate transient hyperglycemia and not T1DM. It is not known whether children with transient hyperglycemia are at increased risk for T2DM later in life.

Emerging Biomarkers of T1DM Natural History and Diagnosis

As mentioned throughout this chapter, seroconversion to anti-islet autoantibody positivity is the most reliable predictive biomarker of T1DM identified to date,[11] but as noted, as many as 10% of T1DM patients are negative for anti-islet autoantibodies at the time of diagnosis.[126] Early diagnosis and treatment with exogenous insulin has been associated with improved disease management and fewer complications. Moreover, there are notions that early intervention prior to the first signs of autoimmunity might offer the greatest chance to successfully prevent T1DM progression and onset in high-risk individuals. Hence, a substantial effort has been directed at the discovery and characterization of new biomarkers to improve our understanding of the disease pathogenesis, as well as our ability to predict and stage disease progression, facilitating early diagnosis.

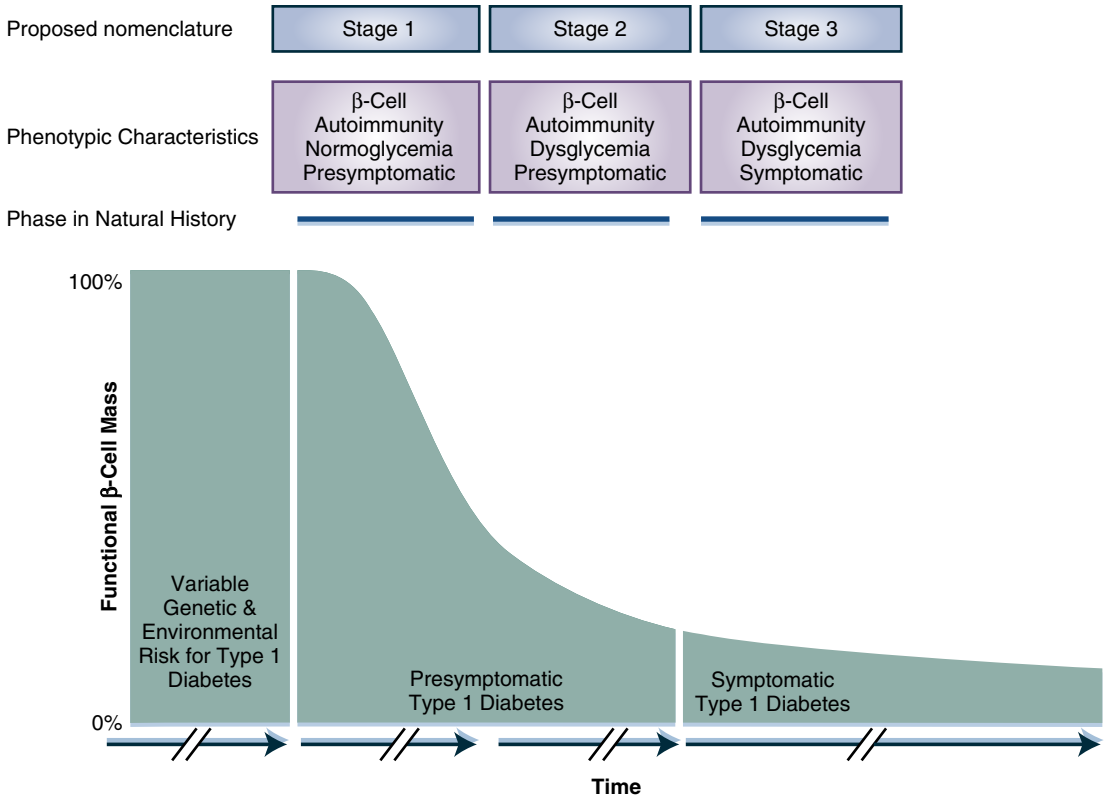
The majority of biomarkers identified signify metabolic defects across T1DM progression. Specifically, so-called beta-cell death assays, proinsulin/C-peptide ratio, and the T1D Diagnostic Index60 (Index60) monitor the decline in functional beta-cell mass related to autoimmune pathology and/or beta-cell stress in T1DM. Specifically, beta-cell death assays involve the measurement of cell-free unmethylated insulin (*INS*) DNA from blood or serum.[127] Cell-specific methylation patterns can be used to identify *INS* DNA released from necrotic beta cells as opposed to other cell types. The short half-life of cell-free DNA in circulation is a notable limitation, but as a single example, cell-free unmethylated *INS* DNA assays were able to detect a decline in beta-cell death consistent with preserved beta-cell function (measured by C-peptide) following treatment with teplizumab (anti-CD3) in a clinical trial setting.[128] Similarly, an elevated serum proinsulin/C-peptide ratio measured under fasting conditions implies impaired processing of proinsulin to insulin and C-peptide within the beta cell, suggesting duress related to metabolic, oxidative, or immunologic stress.[129] These assays are expected to have the greatest utility in the research setting, but the ability to evaluate changes in beta-cell death and dysfunction in real time represents a massive step forward. Meanwhile, the Index60 has been introduced as a clinical/diagnostic biomarker measuring functional beta-cell mass. The test requires an OGTT with calculations incorporating the log-adjusted fasting C-peptide level, 60-minute C-peptide level, and 60-minute blood glucose level.[130] An Index60 value greater than 2 in an individual with anti-islet autoantibodies is considered indicative of T1DM onset, but the need for standard clinical C-peptide assays has limited its widespread implementation.

Alterations to the microbiome have been suggested as yet another biomarker of T1DM. Although less conclusive than the metabolic markers discussed previously, prospective studies of infants and children with high genetic risk for T1DM have revealed the gut microbiome as an early indicator of disease progression, even prior to seroconversion. Extensive profiling of the gut microbial community is generally accomplished by sequencing the microbial 16S ribosomal RNA gene from fecal samples. Overall, a high Bacteroides to Firmicutes ratio has been associated with anti-islet autoimmunity, whereas the presence of butyrate-producing bacteria may protect against T1DM by promoting the synthesis of mucin and reducing intestinal leakiness.[131] In addition, low diversity and poor stability of the gut microbial community are associated with T1DM,[132] although a cause-and-effect relationship has not been determined. Yet these T1DM-related microbiome biomarkers from high-risk infants enrolled in the TEDDY study have also shown geographically distinct patterns with the relative abundance of the most prominent strains and overall microbial diversity differing across six study sites (the US states of Colorado, Georgia/Florida, and Washington, as well as Finland, Germany, and Sweden).[58] At present, it is unknown what factors contribute toward these shifts in the pre-T1DM gut microbiome, but they have been hypothesized to include diet, antibiotics, infections, and/or household environment (e.g., exposure to pets, allergens, pollutants).

Stages in the Natural History of T1DM

Whereas the etiology and precise mechanisms leading to T1DM remain somewhat elusive, studies over the past three to four decades have generated, without question, a wealth of information—be it immunologic, serologic, metabolic, or genetics based—regarding the natural history of pre-T1DM through the time of its formal diagnosis.[133] As but one example and as noted earlier, anti-islet autoimmunity in the form of anti-islet autoantibodies, in the context of genetic susceptibility and metabolic assessments, have clearly been identified as predictive tools for progression to overt disease.[11] Large international cohorts (e.g., TEDDY, Diabetes Prevention Trial Type 1 [DPT-1], DAISY, BabyDiab) have been studied in both relatives of patients with T1DM and in the general population who are at high genetic risk; this, to better understand the disease, reduced rates of DKA, decrease mortality, and set the stage for research-based efforts seeking T1DM prevention. Indeed, these natural history studies often led to the earlier diagnosis of T1DM and a reduced frequency of DKA at onset in those followed prospectively.[134] Several recent studies have also demonstrated long-term glycemic benefits seen for those patients who did not experience the severe metabolic derangement of DKA at formal diagnosis.[135]

Although the diagnosis of diabetes has traditionally been based on ADA criteria,[136] it is increasingly clear that the actual onset of



• **Fig. 36.5** Staging of pre–type 1 diabetes mellitus. (Redrawn from Insel RA, Dunne JL, Atkinson MA, et al. Staging presymptomatic type 1 diabetes: a scientific statement of JDRF, the Endocrine Society, and the American Diabetes Association. *Diabetes Care*. 2015;38[10]:1964–1974.)

the disease, per se, often occurs months to years before the onset of symptoms. Thus, T1DM is a unique physiologic state where autoimmunity is present and progression to metabolic derangement and clinical onset can be predicted, especially in younger children and adolescents. As such, the ADA, JDRF, and Endocrine Society released a joint position statement calling for the staging of pre-T1DM[137] (Fig. 36.5). Stage 1 is defined by the presence of two or more anti-islet autoantibodies with normoglycemia (normal glucose tolerance on 2-hour OGTT). Stage 2 shows progression to dysglycemia (impaired glucose tolerance) in the setting of two or more anti-islet autoantibodies. Stage 3 occurs when a patient meets ADA criteria for the diagnosis of diabetes.

To be clear, there are no evidence-based recommendations for practitioners caring for anti-islet autoantibody–positive patients, or for performing formal "T1DM staging," other than to encourage enrollment in research studies. Nonetheless, close monitoring of high-risk patients in natural history studies markedly reduces DKA rates at diagnosis, and when combined with the notion that partaking in research is critical to finding a means of preventing T1DM, research participation in family members of those with T1DM should be encouraged. Yet only when an effective preventative strategy for T1DM is identified will the notion of universal risk screening and T1DM staging for all children be considered justifiable.

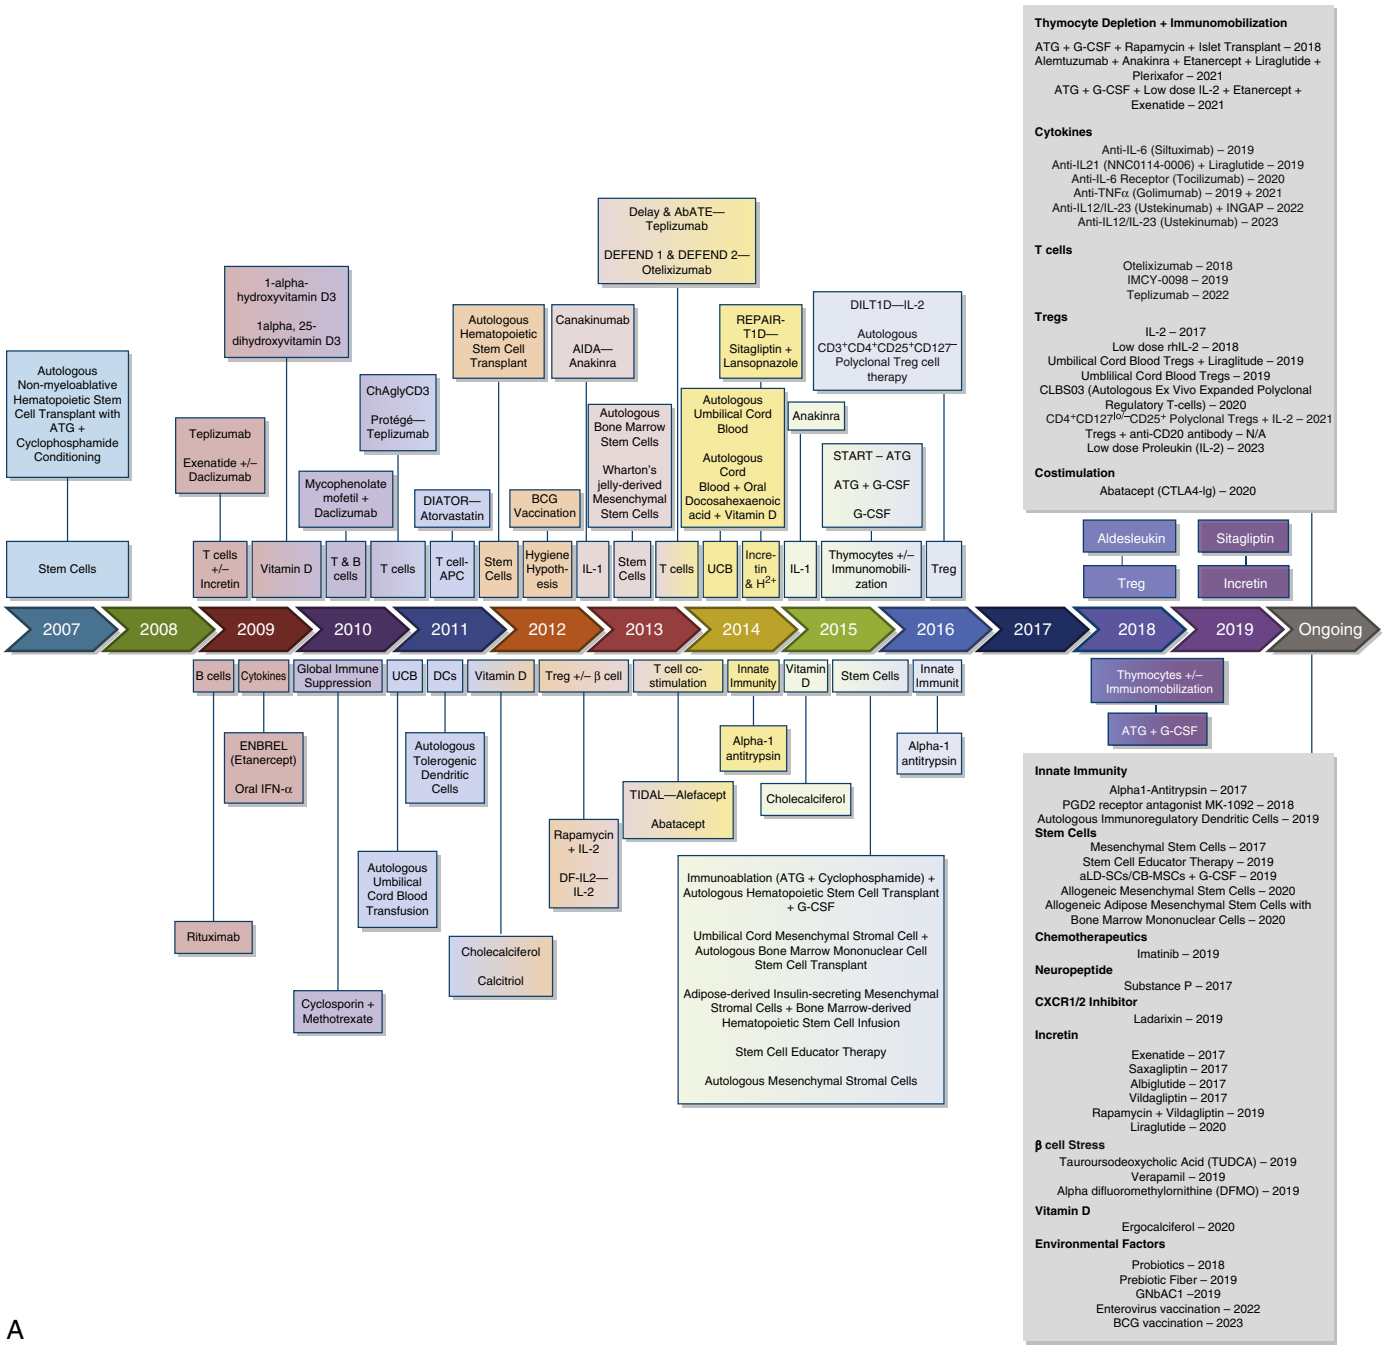
Immunotherapy for the Prevention and Reversal of T1DM

The intersection of two independent events in the 1970s—the generalized acknowledgment that T1DM represents an autoimmune disease, alongside the development of immunosuppressive agents—led to decades of efforts directed toward immunotherapy as a means to either prevent T1DM (i.e., avert symptomatic onset) or, once diagnosed, reverse it (commonly termed *intervention*). To be clear, studies attempting to prevent the development of T1DM involve treatment of persons at varying stages of disease risk based on a combination of genetic susceptibility, the number of T1DM-associated autoantibodies, and the degree to which glucose levels are elevated.[138] Although the populations subject to such procedures would differ, the common goal is to prevent further loss of beta-cell function.

At present, in a setting of either disease prevention or intervention, there is no proven safe and effective immunotherapy for use in a general public health care setting that prevents T1DM or reverses the disease, as judged by preservation of C-peptide. However, in research settings, potentially promising candidates do exist for disease prevention (e.g., oral insulin, GAD vaccine) or intervention (e.g., anti-CD3, antithymocyte globulin [ATG], ATG plus granulocyte colony stimulating factor, CTLA4-Ig).[139–143] Indeed, dozens of clinical trials, ranging from small to large, have been completed in both settings; a limited number are discussed later based on their proposed method of action (Fig. 36.6).

Immunosuppression

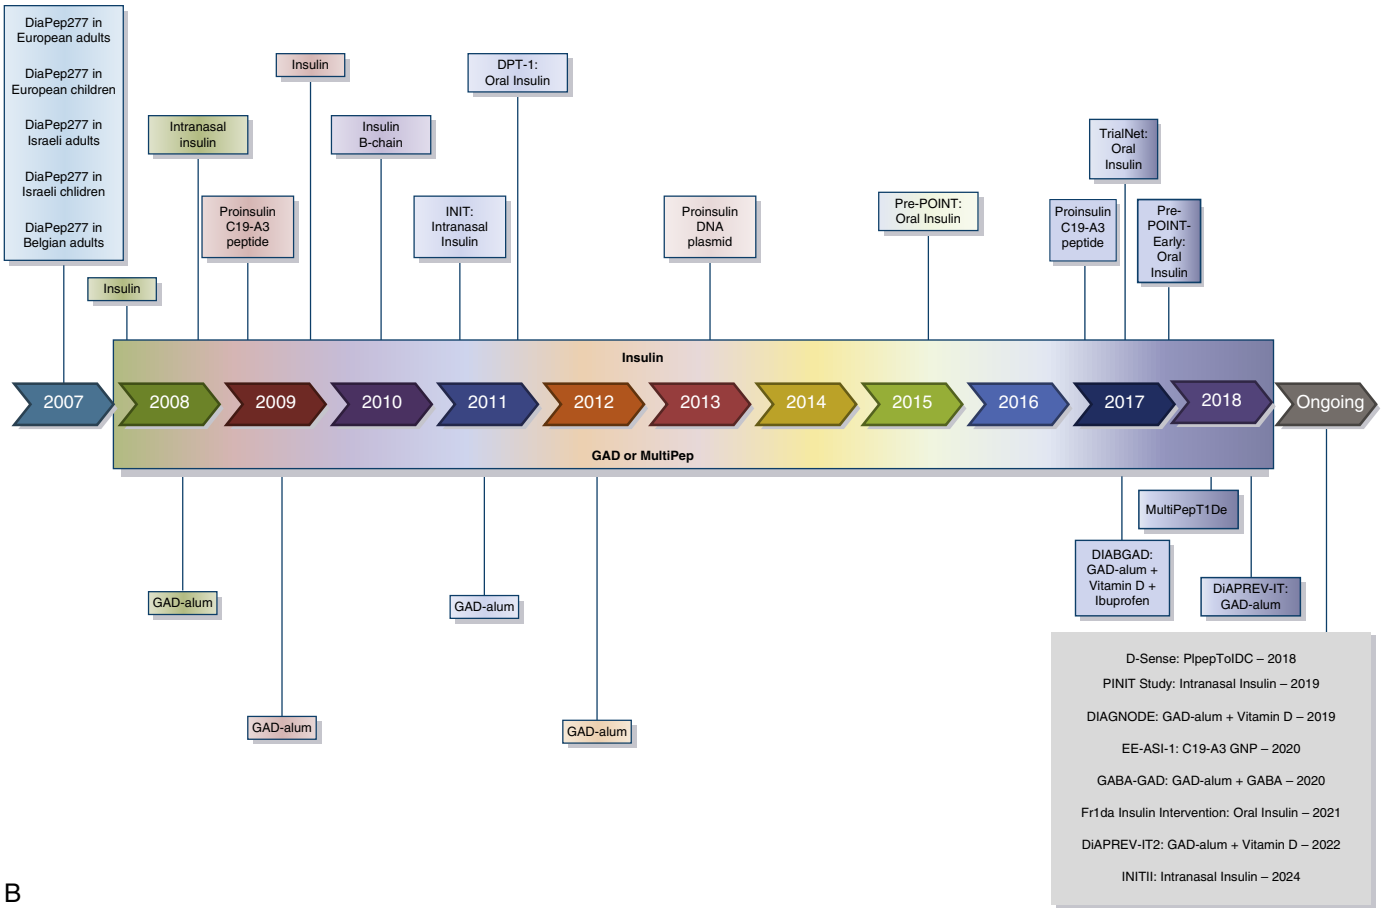
The earliest studies of therapies to prevent beta-cell destruction used immunosuppressive agents. Large intervention trials of cyclosporine indicated that this agent prevented further loss of C-peptide secretion and improved metabolic function when it was administered in recent-onset T1DM cases. Cyclosporine therapy



A

• **Fig. 36.6** (A) Shifts in T1DM clinical research emphasis over 10 years from 2007 to 2017. Therapeutic agents and target mechanisms/objectives are noted for T1DM clinical trials over the past decade, organized by their year of first publication. Current ongoing studies are noted with their expected year of completion. *AIDA,* Anti-Interleukin-1 in Diabetes Action trial; *APC,* antigen-presenting cell; *ATG,* antithymocyte globulin; *BCG,* bacillus Calmette-Guérin; *DCs,* dendritic cells; *DF,* dose finding; *G-CSF,* granulocyte colony-stimulating factor; *IL,* interleukin; *T1DM,* type 1 diabetes mellitus; *UCB,* umbilical cord blood. (A, modified from Atkinson MA, Posgai A, Wheeler DCS, Peakman M. The challenge of modulating β-cell autoimmunity in type 1 diabetes. *Lancet Diabetes Endocrinol.* 2019;7[1]:52–64.

did not, however, maintain a nondiabetic state when therapy was instituted after the onset of diabetes, and with discontinuation of the drug, patients rapidly lost C-peptide reserve. The combination of inability to cure diabetes and toxicities associated with cyclosporine (particularly nephrotoxicity and concern about increased risk of malignancy) ruled out its acceptance for use. Other immunosuppressive agents used in subsequent studies, such as prednisone and azathioprine, demonstrated relatively little effect in disease intervention. In the time since, a litany of agents (e.g., anti-CD20, ATG, mycophenolate plus anti-IL2 receptor α-monoclonal antibody) thought to act at least in part via immune depletion, a form of immune suppression, have demonstrated mixed results in T1DM intervention efforts (see Fig. 36.6A). Some provide no therapeutic benefit (i.e., preservation of C-peptide, reduced



B

insulin needs, reduction in hypoglycemic events), whereas others have achieved at least one of these beneficial parameters, usually C-peptide preservation. However, even when efficacious, for most subjects, the beneficial effect was not durable (i.e., 6 months to 1 year of benefit).[141,143] It is possible that the treatment effect may persist for a longer term with repeat dosing, although this approach has not been tested. Therefore, at present, although T1DM is an immune-mediated disorder, it is not treated with immunotherapeutic agents in clinical practice. This is not to say that hope is lost for such being the case in the future. Indeed, in recent times (e.g., year 2000 to the present), studies related to two forms of modified antibodies against the CD3 molecule have, without question, generated the most research interest and offer some degree of eventual optimism.

Throughout several phase I and phase II intervention studies, a single course of anti-CD3 therapy decreased the loss of C-peptide secretion over a 12- to 24-month period in new-onset T1DM patients.[141] However, phase III trials were not considered of therapeutic benefit to the extent that commercialization of these agents was to some degree disrupted. Concerns related to the activation of Epstein-Barr virus infection, the duration of C-peptide preservation, and the protocol by which the drugs are administered have further limited their development. Thus, limited efforts continue to move anti-CD3 back into the therapeutic setting. A recent study demonstrated that a short course of the anti-CD3 monoclonal antibody, teplizumab, delayed progression to clinical T1DM in high-risk patients.[144]

Immunologic Vaccination

In animal models (especially the NOD mouse), it is relatively easy to prevent T1DM. Indeed, although somewhat dated, a widely recognized effort notes more than 200 such means.[145] Yet animal models have permitted development of the most exciting potential prevention or intervention modality of immunologic vaccination. Excitement is derived from the specificity and the relatively low risk of these therapies compared with immunosuppression. The basic concept behind immunologic vaccination is the induction of regulatory T lymphocytes that target a given beta-cell antigen and, on encountering the target antigen (e.g., insulin, GAD) in the context of the vaccine formula or route of administration, produce cytokines and cell-mediated effects that suppress autoimmunity and tissue destruction.[146]

Induction of a protective immune response may depend on the route of administration of the given antigen (e.g., oral, nasal, intradermal) or on the use of an altered antigen (e.g., altered peptide ligands). For example, insulin given either orally or by subcutaneous injection prevents diabetes in NOD mice.[147,148] Intact insulin is not necessary, because the insulin B chain and an immunodominant B(9-23) peptide of insulin were also effective.[149] The latter molecules have no insulin-like metabolic effect but are able to activate regulatory T lymphocytes that target insulin.

In terms of translation, DPT-1 studied both oral insulin and parenteral injections of low doses of insulin (see Fig. 36.6B). The results of the parenteral trial did not demonstrate a reduction in

the risk of developing diabetes. The oral trial did not document an overall benefit of insulin, but in the subgroup with higher levels of IAA at entry, a statistically significant delay in progression to diabetes was observed.[150] Although the National Institutes of Health TrialNet conducted a follow-up study testing the efficacy of oral insulin to prevent T1DM in those having certain criteria related to age and IAA level, no benefit of oral insulin for delay or prevention of T1DM was seen.[151] Nevertheless, a pilot trial (Pre-POINT) led by investigators in Germany involving the administration of high-dose oral insulin in children at high genetic risk for T1DM with a family history of the disease reported that this form of therapy was capable of altering the anti-insulin immune response without inducing hypoglycemia.[152] Thus, potential value of oral insulin remains uncertain.

Therapeutic Targeting for Mechanisms of Beta-Cell Death

As noted, the most prominent cell found in human islets in settings of T1DM is the $CD8^+$ cytotoxic T cell, which likely participates in beta-cell killing because of its ability to recognize targets via antigen in the context of MHC class I, which is elevated in many islets in those with the disease.[39] Therapeutically, lymphocytes and memory lymphocytes of the adaptive immune response can be targeted by anti–T-cell drugs directed at CD3 (teplizumab), CD2 (LFA3-Ig), and certain co-stimulatory blockers.[141,153,154] Indeed, partial success of such compounds in recently diagnosed T1DM, defined by preservation of C-peptide production over several months to years, speaks toward an important role for such autoreactive lymphocytes in beta-cell destruction, at least late in the pathogenesis of this disease. Inflammatory cytokines are also known to harm islets, and therefore anti-inflammatory therapies targeting cytokines may hold promise, as observed in a trial blocking TNF.[155] These observations provide further support for the concept of combination therapies.

With the growing concept that multiple mechanisms likely contribute to the pathogenesis of T1DM, enthusiasm has increased for utilizing combination therapies to prevent or reverse the disease. Examples of combinations with respect to immune intervention would include an induction component using drugs targeting inflammation and T-/B-cell memory and a maintenance component that could involve antigens to induce tolerance to beta cells. At the same time, emerging data support an increasing role for beta-cell stress and loss of function as potential contributing factors for T1DM development; therefore, combination therapy involving the addition of drugs that stabilize and maintain beta-cell survival and function should be considered.[156]

Pancreas and Islet Cell Transplantation

Pancreatic transplantation for patients requiring a kidney transplant has become an accepted clinical procedure, but one that for a variety of reasons, particularly the shortage of organ donors, remains relatively rare. Patients with a kidney transplant receive immunosuppressive drugs that, given the nature of clinical monitoring for renal transplant rejection (e.g., creatinine, albumin), allow for careful (i.e., tailored) drug delivery for optimal care. Several studies suggest that improved results for pancreatic transplantation occur in the setting of simultaneous pancreas and kidney transplantation versus transplantation of pancreas alone.[157] Indeed, there is considerable debate concerning pancreas transplantation without transplantation of a kidney. With a successful pancreas transplant, hyperglycemia is immediately reversed for most, and there is growing evidence of improved long-term outcomes. Nevertheless, the surgery is extensive, and there are many potential complications associated with the transplant. Perhaps for these reasons, along with improvements in diabetes management (and thus reducing long-term complications, including kidney failure), it appears that the procedure peaked in the mid- to late 2000s, with declines in the number of procedures performed in the United States thereafter.[158]

Beyond therapeutic interest in pancreatic transplantation, additional research has focused on the mechanisms of pancreas rejection for what it might reveal regarding the immunologic mechanisms of T1DM. In that regard, in T1DM patients provided with a pancreatic transplant, diabetes (i.e., a repeated need for exogenous insulin replacement therapy) can recur as a result of mechanisms considered attributable to either recurrent autoimmunity (as typified by the recurrence of T1DM-associated autoantibodies once lost) or, more often, allograft rejection.[159] It is difficult to monitor and determine which of these two forms of islet destruction are occurring with the development of hyperglycemia, and currently there are no specific means in terms of treatment that would separate the two, although at least one study has provided evidence for recurrent autoimmunity manifested by the induction of anti-islet autoantibodies prior to graft rejection.[160]

With respect to islet (vs. pancreas) transplant, therapeutic hopes for this procedure have been high since the late 1960s when early pioneering approaches were developed for islet isolation from whole pancreata. Indeed, with islet autotransplantation in patients with pancreatitis, most patients become insulin independent and remain so.[161] Yet it was not until the early 2000s that a group from Edmonton, Canada, used meticulous islet isolation techniques, transplantation of islets from multiple pancreata, avoided the use of steroids, and utilized an immunosuppressive regimen involving the drug rapamycin, resulting in improved outcomes for patients with T1DM. This so-called Edmonton protocol has subsequently been tested in a series of specialized centers throughout North America and Europe. It is clear that in many centers, albeit with varying degrees of success, islet cell transplant can prove effective (i.e., ~60% insulin independent at 1 year), especially for patients with severe hypoglycemia when the goal is long-term prevention of severe hypoglycemic episodes. For most of the patients who achieve insulin independence, resumption of use of low doses of insulin is necessary within 2 years, and by 5 years the benefits of the form of therapy wane.[162] Even with these positive results, the number of islets available from cadaveric donors for transplantation is quite limited, and the toxicities of the drugs used probably exceed the level of benefit achieved, except for those most subject to disease-associated complications (e.g., severe, recurrent hypoglycemia). Further research to achieve tolerance without long-term immunosuppression is essential, as is continued development of systems allowing for xenogeneic transplantation.

Of immense promise for the future are therapies involving the use of surrogate beta-like cells (i.e., insulin producing, glucose responsive) produced from stem cells, either embryonic or induced from pluripotent cells originating from a variety of tissues. In addition, use of encapsulation or biosynthetic membranes to protect transplanted islets, combined with the increasing use of long-term continuous glucose monitoring (CGM), combined with improvements in modes of insulin delivery (e.g., analogues, pumps) or use of secondary agents in

patients with T1DM, will almost certainly raise the bar for consideration of the risks and benefits of both islet and pancreatic transplantation.

Stem Cell or Xenogeneic Islet Cell Transplantation

As noted, improved metabolic control averting the need for exogenous insulin replacement can be achieved with beta-cell replacement in those with T1DM, either through whole-pancreas transplantation or via pancreatic islet cell transplantation. Therefore, although whole-pancreas and islet cell transplantation have both become highly operationalized and often effective procedures, the quantitative paucity of suitable organ donor tissues, taken together with complications associated with immune suppression, have severely limited their widespread therapeutic application.[163] As a result, numerous research efforts have been extended over the past decade toward the development of sustainable sources of "surrogate" insulin-producing cells (e.g., xenogeneic islets, induced pluripotent stem cells, fetal stem cells) alongside additional methodological investigations, all designed to improve therapeutic outcomes utilizing such cells (e.g., genetic modification, encapsulation).[164,165] Importantly, engineering and/or genetic modification–based systems have been proposed to avert aberrant and deleterious immune responses associated with T1DM and/or the use of allogenic cells.[166]

Indeed, remarkable progress has been made over a relatively short period of time with respect to generating beta-cell equivalents (i.e., glucose-responsive insulin-producing cells) from human stem cell populations, be they derived from induced pluripotent stem cells or embryonic stem cells.[167] Xenogeneic efforts (e.g., porcine islets), for a variety of reasons, although still a potential therapeutic option, are currently less favored than stem cells due to a variety of technical challenges, as well as concerns over safety.[168]

Stem cell therapy–based efforts as a therapy for T1DM largely arose from a strategy designed in laboratory-based settings to recapitulate the islet cell developmental pathway while generating single hormone-positive beta cells capable of glucose-stimulated insulin secretion.[169] Progress has been remarkable, with clinical trials already planned involving the use of stem cell–derived pancreatic progenitors capable of developing into functional beta and islet cells.[170]

Although the future of stem cells as a clinical therapy is promising, a series of concerns/limitations remain. First, beta cells, the primary cell sought for stem cell development, in their natural setting do not exist in isolation (i.e., beta cells alone) but rather exist in a heterogenous three-dimensional structure comprised of the islets of Langerhans. Hence, the notion of generating a cell therapy in the absence of a full complement of islet cells (i.e., alpha, beta, delta, pancreatic polypeptide; see Chapter 33) must be considered moving forward, especially in the context of hormonal counterregulation. In addition strong consideration must continue to be given toward averting what likely would be an assault on the target tissue—both autoimmune and alloimmune, depending on the setting. To this end, effort for any so-called protective devices should encompass a need to (1) provide biocompatibility; (2) see ample blood supply to sustain cellular survival and functional beta-cell mass capable of imparting normoglycemia; (3) prevent sensitization and be immune protective; (4) trap potentially oncogenic cells; and (5) allow for rapid response of insulin, in terms of both activating and suppressing insulin secretion, to changing glucose concentrations.[166]

Disorders Associated With Immunity to Insulin/Insulin Receptor

Insulin Autoimmune Syndrome

The insulin autoimmune syndrome, also termed *Hirata syndrome*, is rare and is typically associated with hypoglycemia.[171] These patients have extremely high concentrations of autoantibodies reacting with human insulin in the absence of exogenous insulin therapy. It is thought that inappropriate (i.e., nonregulated by the overall blood glucose level) release of autoantibody-bound insulin produces the hypoglycemia. Interestingly, and for reasons unknown, the disease occurs most commonly in persons of Asian descent.[172] Among 50 Japanese patients with the syndrome and possessing the typical polyclonal anti-IAA, 96% had an HLA-DR4 allele, and 84% possessed a DRB1*04:06 allele. In contrast, patients with monoclonal anti-IAA do not possess such a profound and specific HLA association.[173] Most patients with this disorder develop the disease in association with treatment of sulfhydryl-containing medications, particularly methimazole, as well as alpha-lipoic acid.[174] Treatment usually consists of stopping these medications, and for more than 75% of the patients, the disease remits.

Insulin Allergy

Mild immune reactivity against exogenously administered insulin is not an uncommon feature in T1DM management. Indeed, essentially all patients treated with recombinant human insulin produce anti-insulin antibodies.[175] The levels of these antibodies are relatively low, and they do not appear to interfere with insulin therapy for the majority of individuals. Most studies show no relationship between the presence of anti-insulin antibodies and complications associated with T1DM (e.g., retinopathy, neuropathy).[175] However, there are reports correlating insulin antibodies with macrosomia.[176] With the introduction of recombinant human insulin replacing animal insulins, symptomatic immune responses to insulin such as immediate hypersensitivity, delayed hypersensitivity, lipoatrophy, and lipohypertrophy have decreased.

Allergic reactions can occur with insulin analogues, modifications of recombinant human insulin, although this is uncommon. More common features include allergies to affiliated lubricants; preservatives; and plastics in bottles, stoppers, syringes, and needles. The usual mode of therapy for such situations consists of substituting the type or formulation of insulin and administration of oral antihistamines or topical mast cell stabilizers for immunoglobulin E–mediated local reactions, followed by insulin desensitization or addition of small amounts of glucocorticoids to the insulin injected for local delayed hypersensitivity reactions.[177,178]

Anti-Insulin Receptor Autoantibodies

Anti-insulin receptor autoantibodies (i.e., type B insulin resistance) are associated with hypoglycemia, hypercatabolism, severe acanthosis nigricans, and insulin resistance. It appears that anti-insulin receptor autoantibodies can act as either antagonists or agonists for this disease. This syndrome is quite rare, is often associated with non–organ-specific autoimmunity, and treatments usually involve various forms of immunosuppression (e.g., rituximab (anti-CD20), steroids, intravenous immune globulin, cyclophosphamide), albeit with mixed success.[179]

Clinical Presentation

The peak age for presentation of T1DM is at or during puberty, with a smaller peak in children between 5 and 7 years of age. The symptoms and signs are related to the presence of hyperglycemia and the resulting effects on fluid and electrolyte balance, which include polyuria, polydipsia, polyphagia, weight loss, and blurred vision.[9] Because infection may have precipitated or preceded the initial presentation, symptoms of infection may also be present, such as fever, sore throat, cough, or dysuria. Particularly in children, the onset of symptoms can occur over a brief period, and families may be able to date the onset with considerable accuracy. In older persons with T1DM, the onset of symptoms may be insidious over months, and many are mistakenly diagnosed as having T2DM by screening during this asymptomatic period.

If onset of T1DM is associated with DKA, which is not uncommon, additional symptoms related to this acute metabolic complication of diabetes are also present. These symptoms can include abdominal pain, nausea, and vomiting. Variable effects on mental status may be seen, ranging from slight drowsiness to profound lethargy and even coma if the condition has been untreated for a significant period.

Laboratory Findings at Presentation

Plasma glucose concentrations at presentation of T1DM are elevated, usually in the range of 300 to 500 mg/dL (16.7–27.8 mmol/L). If the presentation is uncomplicated, the remainder of the fluid and electrolyte measurements may be completely normal. However, if DKA is present, the measurements will reflect the presence of an acidosis, as well as more severe dehydration. DKA is discussed more fully later in this chapter.

At presentation, the C-peptide level (a surrogate marker for insulin secretion) is generally in the low-normal range and declines over time. However, residual C-peptide may be detected throughout the natural history of diabetes. In reference laboratories, pancreatic autoantibodies are present in approximately 98% of individuals at diagnosis, but most commercial laboratories do not provide either the full spectrum of assays or equivalently sensitive or specific assays, resulting in both false-negative and -positive assays (discussed previously). Furthermore, antibody titers diminish over time and may be less prevalent in certain ethnicities.[180]

Treatment

Principles of T1DM Management

Despite advances in understanding the autoimmune nature of T1DM, this disease remains incurable yet manageable. Management requires orchestrated efforts on the part of the person with diabetes, family members, and the multidisciplinary health care team. Important stakeholders may vary, depending on the age of onset of the disease, comorbid conditions, stages of transition throughout the life span, from early childhood through adolescence and young adulthood to adulthood and the middle-age years, then finally culminating in the advancing years of the geriatric population. Although diabetes diagnosed in childhood is predominantly due to T1DM,[181] there is increasing recognition that T1DM is diagnosed in adulthood.[182] The likelihood for residual beta-cell function is greater with an older age of onset of disease.[183] Nonetheless, a diagnosis of T1DM at any age requires exogenous insulin therapy given by injection or continuous subcutaneous insulin infusion (CSII); careful attention to dietary intake, especially with regard to carbohydrates, the major contributor to glycemic excursions; frequent or continuous monitoring of glucose levels with a blood glucose meter or CGM, respectively; and an exercise program that is as much therapeutic as recreational in nature. These management activities require constant vigilance, with attention to treatment needs 24 hours per day, 7 days a week, every year.

Such a rigorous management program requires input of a multidisciplinary treatment team, composed of an endocrinologist or physician with specific training and interest in diabetes, a certified diabetes educator, a dietician, and a mental health professional (either a social worker or psychologist) with diabetes behavioral health expertise. Other team members can include an exercise physiologist, an ophthalmologist or optometrist with diabetes expertise, a podiatrist, a nephrologist, and other specialists as indicated. Most importantly, persons with T1DM of all ages require continuous access to a health care provider through an emergency contact number in case of emergence of acute complications, such as severe hypoglycemia or DKA.

Visit frequency for diabetes care depends on the age at diagnosis, duration of disease, and presence of comorbidities. At T1DM diagnosis, initiation of insulin therapy is amenable to outpatient management when electrolytes are stable and in the absence of acidosis. Initial visits usually entail 2 to 3 sequential days of multidisciplinary visits, followed by visits in 2 to 3 weeks, then 1 to 2 months later. Thereafter, diabetes follow-up care generally occurs quarterly, especially in childhood when there is need to monitor growth and development. Both weight and height, along with vital signs, should be obtained at every quarterly visit, and Tanner staging should be performed at least annually for pediatric patients. Similarly, weights and vital signs should be obtained at each visit along with timely screening for complications and cardiovascular risk factors.

In childhood, initial management education is directed to the parents/guardians, whereas a family-based approach to care continues throughout adolescence.[184,185] As children get older, diabetes management tasks and the delivery of medical care gradually shift onto the person with diabetes, although T1DM at any age is not a do-it-yourself condition, given the many daily treatment demands and nuances of advanced diabetes technologies. In adulthood, following the visit frequency required for all persons newly diagnosed with T1DM, follow-up visits may occur every 3 to 6 months, depending on the achievement of glycemic goals and the presence of comorbidities.[180,186,187]

Diabetes education for all stakeholders occurs in a developmentally appropriate manner, geared to ensure comprehension of all involved in care. Diabetes management is also tailored to the needs and desires of the person with diabetes, creating an individualized care approach. Thus, a collaborative care model allows for optimal selection of one of the various approaches to insulin delivery, from the simpler two-injection-per-day regimen to the more complex semiautomated approach to insulin delivery using CSII and CGM. It remains important to reassess management approaches during the various developmental stages, especially during puberty, when physiologic insulin resistance coupled with psychosocial turmoil can lead to increased insulin needs and deteriorating glycemic control.[188,189] Similarly, adult needs change and require equal attention by the provider to the individual's preferences.

Glycemic Targets

The fundamental approach of individualized care is based on the treatment goal of achieving glycemic targets. The DCCT was the randomized clinical trial that laid the foundation of intensive insulin therapy as the standard of care.[190] In the DCCT, intensive insulin was compared with conventional insulin therapy in 1441 persons, 13 to 39 years old, with established T1DM. Intensive insulin therapy consisted of physiologic insulin replacement with either basal bolus therapy or CSII; conventional therapy included one to two injections of insulin daily. Notably, at the time of that clinical trial, there were no rapid-acting or long-acting insulin analogues; only short- and intermediate-acting insulin preparations were available (see insulin regimens in the following).

Intensive insulin therapy yielded superior glycemic control to conventional insulin therapy, with HbA_{1c} levels that were approximately 2% lower in the intensively treated group than in the conventionally treated group, medians of 7% and 9%, respectively.[190] The intensively treated group experienced a 35% to 76% reduction in the occurrence of microvascular complications, including retinopathy, nephropathy, and neuropathy compared than in the conventionally treated group. During the subsequent 20 to 25 years of the DCCT observational follow-up study, the Epidemiology of Diabetes Interventions and Complications (EDIC) study, the intensively treated group compared with the conventionally treated group continued to demonstrate a reduced risk of both micro- and macrovascular complications and overall mortality, mainly attributable to the difference in glycemic control during the DCCT.[191–196] These findings help derive glycemic targets in practice today.

Glycemic targets are based on HbA_{1c} levels, especially given that the explanation for complication risk in the DCCT and EDIC studies was attributable to glycemia.[197] Various national and international professional organizations have created HbA_{1c} goals. The ADA recommends HbA_{1c} levels of less than 7% for adults and less than 7.5% for younger children and adolescents; additionally, HbA_{1c} levels should be routinely monitored quarterly.[180,186,187]

Prior to 2014, the ADA's pediatric HbA_{1c} goals were higher for younger children at less than 8.5% for those younger than 6 years and less than 8% for those 6 to 12 years old, whereas the goal was less than 7.5% for those 13 to 19 years old, due to previous concerns regarding neurocognitive damage from severe, recurrent hypoglycemia in young children.[198,199] The earlier data suggesting neurocognitive damage from hypoglycemia occurred during the era prior to modern insulins and physiologic insulin replacement. Recent data demonstrate that intensive insulin therapy confers no additional risk to neurocognitive function in young children with T1DM.[200,201] Additional research suggests that hyperglycemia and glycemic variability may incur adverse short-term outcomes on neurocognitive function and risk on central nervous system development based on magnetic resonance imaging changes of white matter.[202–205]

In consideration of emerging data on risk of hyperglycemia for the central nervous system, along with available management tools to minimize risk of hypoglycemia in young persons with T1DM, HbA_{1c} targets have been lowered by some professional organizations, including the International Society for Pediatric and Adolescent Diabetes (ISPAD) and the National Institute for Health and Clinical Excellence Guidelines in the United Kingdom. ISPAD now recommends HbA_{1c} targets of less than 7%, and the National Institute for Health and Clinical Excellence recommends targets HbA_{1c} of 6.5% or less.[206] Similarly, for adults, the American Association of Clinical Endocrinologists recommends an HbA_{1c} target of 6.5% or less.[207]

Although HbA_{1c} target recommendations may have become more rigorous over recent years, the ADA and other organizations emphasize that glycemic targets need to be individualized. The target HbA_{1c} goal for any single person with diabetes needs to reflect his or her risk of severe hypoglycemia, as well as hyperglycemia, considering the presence of comorbidities that may interfere with survival. For example, now the ADA offers higher HbA_{1c} goals of less than 8% for persons with a history of severe hypoglycemia, limited life expectancy, or advanced complications, as well as more stringent HbA_{1c} goals of less than 6.5% for those without hypoglycemia risk.[187] ISPAD also considers less stringent goals for regions of the world where advanced diabetes therapies and technologies may be unavailable to reduce risk of severe hypoglycemia.[206] Thus, personalized glycemic goals are tailored to individual needs and consideration of risk of severe hypoglycemia (see Chapter 38).

Lifestyle Management: Nutrition and Exercise

Lifestyle management is a major component of the care of persons with T1DM. Attention to both nutrition and exercise is fundamental in glycemic management, as well for overall health and cardiovascular disease prevention. There is need to provide education on these lifestyle issues to the persons with diabetes and to the family members of young children and adolescents with diabetes, especially given the global epidemic of childhood and adult overweight/obesity.[208,209] Overall, all diet and exercise recommendations are individualized to meet the patient's and family's needs. These knowledge areas are addressed in diabetes self-management education and support and should begin at diagnosis and progress as disease duration increases and the needs of the person with diabetes change.

Nutrition Therapy

Medical nutrition therapy addresses diabetes-specific issues, such as those related to the carbohydrate content of foods, to limit postprandial glycemic excursions, as well as ways to maintain normal growth in the pediatric population and to avoid excessive weight gain across the life span. Nutrition education, generally provided by a registered dietitian annually following the initial education at diagnosis, includes both personal and family dietary choices, food preference changes over time, challenges regarding access to food, meal schedules, patterns of exercise, growth and development, weight status, cardiovascular risk factors, and consideration of disordered eating behaviors.

For the growing child with diabetes, provision of adequate calories to maintain normal growth and development is fundamental. Underweight is a rare occurrence today in youth with T1DM. In fact, one third of pediatric patients with T1DM are overweight or obese.[210–212] Diet prescriptions for adults with T1DM should also account for weight status, given the rise in overweight and obesity among those with T1DM, affecting up to 50%,[213] and the association of increased weight with cardiovascular risk in T1DM.[214]

Nutrition education addresses the way foods impact glucose excursions, how diet can help achieve glycemic goals, and dietary approaches to avoiding hypo- and hyperglycemia with exercise. Nutrition education addresses numeracy, literacy, and self-management abilities of those with diabetes and their family members. Overall, adherence to nutrition management is associated with better glycemic control in youth with T1DM.[215]

Principles of general nutrition include a focus on whole foods and the standard composition of macronutrients with approximately 50% of energy intake as carbohydrates, 20% as protein, and 30% as fat. Fat intake should include less than 10% of energy intake as saturated fat, less than 10% as polyunsaturated fat, and greater than 10% as monounsaturated fat. One should try to eat five portions of fruits and vegetables daily. Often, young persons with diabetes, with the support of their parents, may choose to eat less healthy food choices, like prepackaged foods that include the carbohydrate content on the label, instead of fruits or vegetables.[216] Nutrition education follows published guidelines by professional organizations, such as the ADA[187] and ISPAD.[217] Very low carbohydrates should be avoided, as such diets can lead to elevations in lipid levels and there can be risk for ketosis, especially with insulin dose reductions, disordered eating behaviors, or use of the sodium-glucose cotransporter 2 (SGLT2) class of oral agents, currently unapproved for use in persons with T1DM (see discussion of adjunctive therapies in the following).

The major focus of nutrition education is on carbohydrate counting, because carbohydrates have the largest impact on glycemic excursions. So-called carbohydrate counting can provide flexible diet management by allowing for a wide range of food choices. It can also offer a way to select insulin doses based on food intake. When numeracy skills are deficient, experienced estimation of carbohydrate intake suffices. In fact, previous studies have shown that exactitude in carbohydrate counting is unnecessary, because under- or overestimating the carbohydrate content by 5 to 7 g, or by +/–15%, does not produce significant hypo- or hyperglycemia, respectively.[218,219] Furthermore, it is more important to be consistent rather than exact with carbohydrate counting, because the former is associated with better glycemic control.[220]

Additional studies have addressed the need to consider protein and fat intake on glycemic excursions.[221–223] After one has mastered carbohydrate counting, additional advanced nutrition education can include issues related to meal composition, carbohydrate quality (the glycemic index), and the contributions of protein and fat to glycemic excursions. Considering that meals containing substantial protein and fat can delay gastric emptying and the subsequent postprandial glycemic excursion, nutrition education can address advanced approaches to insulin bolusing. For example, one can use a square (or extended) wave bolus or dual (or combination) wave bolus with CSII, or one can divide the injected bolus doses into two separate injections separated in time by 60 to 90 minutes.

Physical Activity and Exercise

Physical activity is important for persons with and without diabetes. Exercise offers physical fitness, strength building, weight management, socialization, enhancement of self-esteem, and cardiovascular risk factor management. Exercise is a key component of diabetes management. It is important to recognize how exercise affects glycemic excursions, as exercise can lead to both hypoglycemia and hyperglycemia. Recommendations for youth include 60 minutes or more of daily physical activity, which should include muscle- and bone-strengthening activities on 3 or more days each week.[224] Recommendations for adults include at least 150 minutes of moderate-intensity aerobic activity or 75 minutes of vigorous-intensity aerobic activity each week plus muscle-strengthening activities on 2 or more days each week.[225] Adults with diabetes, and occasionally pediatric patients with diabetes, should receive medical clearance before embarking on an exercise program to evaluate the presence of any comorbid conditions or diabetes complications that could limit exercise participation, such as previously undiagnosed coronary heart disease.

Exercise impacts fuel metabolism through the recruitment of various hormones (insulin, glucagon, catecholamines, and glucocorticoids), and the impact of exercise on metabolism varies by the type, intensity, and duration of the activity.[226,227] With intact islet cells, including fully functioning beta cells, the body maintains euglycemia during exercise by balancing glucose uptake with hepatic glucose production. In T1DM, it is not possible to reduce insulin production following administration of an insulin dose; therefore, the circulating insulin can lead to hypoglycemia by both inhibiting hepatic glucose production and promoting exercise-related glucose uptake. Alternatively, in T1DM, high-intensity activities, such as sprints or resistance training, can lead to hyperglycemia when there is not enough circulating insulin due to the intense exercise's stimulation of counterregulatory hormone release, which, in turn, will increase hepatic glucose production and inhibit glucose uptake into skeletal muscle.

In general, most persons with T1DM, as well as their family members, worry more about exercise-induced hypoglycemia. Further, they are often frustrated and puzzled by the appearance of hyperglycemia with exercise. Hypoglycemia can occur during and immediately following the activity, and again 7 to 11 hours after the exercise, corresponding to the so-called lag effect of exercise. The latter phenomenon was shown in insulin clamp studies[228] and likely results from enhanced insulin sensitivity, blunted counterregulatory hormone release, and increased glucose uptake by the liver and skeletal muscles to replenish glycogen stores after exercise. The late risk of hypoglycemia often occurs overnight when persons with diabetes exercise in the late afternoon or evening, causing particular concern for patients and family members. For some persons with T1DM, there can be additional impairment of counterregulatory hormone responses due to blunting during sleep, antecedent hypoglycemia, and autonomic failure.[229–231] Thus, exercise-related hypoglycemia, along with fear of hypoglycemia, can curtail exercise participation. Fortunately, there are ways to limit the risk of exercise-related hypoglycemia and hyperglycemia while managing glycemia with exercise. Management approaches follow; for more in-depth discussion, there are recently published exercise management guidelines.[226,227,232]

To prevent hypoglycemia, one should begin exercise with a glucose of 100 mg/dL (5.6 mmol/L) or higher and plan to ingest carbohydrates during and/or after the exercise according to its duration and intensity. One can consider providing 0.25 g to up to 1.00 g of carbohydrate per minute of exercise when the activity lasts 40 minutes or longer, individualized based on the person's size (i.e., toddler or child), his or her needs, and past experience. The additional carbohydrates can be provided by increasing food intake. Alternatively, one can reduce bolus insulin doses, by approximately 50% as a starting point, for any meal or snack within 2 hours of the planned activity, which may be preferable to increasing carbohydrate ingestion for weight management. For those receiving CSII, basal rates can also be lowered by approximately 50% or even suspended for periods of 1 to 2 hours for exercise based on the patient's needs.[233] To manage the lag effect or late hypoglycemia risk after exercise, basal rates can be reduced by approximately 20% for up to 6 hours at bedtime for those treated with CSII, or long-acting insulin doses can be reduced by approximately 20% at bedtime.[234] Despite these insulin-dosing strategies, it remains important to have carbohydrates available for ingestion and to ensure continuous or frequent glucose monitoring for safe exercise.

To prevent significant hyperglycemia with exercise and induction of ketosis, it is important not to exercise when one is in an insulin-deficient state. The person with diabetes should exercise only when feeling well and in the absence of significant ketosis, defined as more than small urinary ketones or a blood beta-hydroxybutyrate level of 1.5 mmol/L or more.[226,227,232] One should also postpone intense exercise with significant hyperglycemia, defined as a glucose level of 350 mg/dL (19.4 mmol/L) or more, until corrected with insulin.

Exercise education can help limit the hypo- and hyperglycemic effects of exercise. When available, an exercise physiologist can add training with respect to exercise management, which can be especially important for the competitive athlete.

Insulin Therapy

Background

Normal physiologic insulin secretion results in low levels of insulin in the fasting and overnight period, and rapid increases in insulin following food intake, stress, and certain medications. Low levels of basal insulin secretion are necessary for covering basal metabolic needs, suppressing lipolysis, and balancing glucose utilization by organs such as the brain with hepatic glucose production.[235] Increases in insulin in response to rising blood glucose levels facilitate cellular glucose uptake and suppress hepatic glucose production. Normally, this is achieved through a substantial initial first-phase release, followed by an extended second-phase secretion into the portal circulation. The goal of insulin therapy in persons with T1DM is to mirror pancreatic insulin patterns, and this biphasic insulin release is particularly difficult to replicate.[235] Fortunately, incremental improvements in the pharmacology and delivery of insulin have made it increasingly possible to achieve reasonable insulin levels in persons with diabetes. The discovery and initial isolation of animal insulin in 1921 first made it possible to treat persons with T1DM. In the late 1940s, regular animal insulin was combined with protamine (neutral protamine Hagedorn insulin, NPH) to delay absorption and increase duration of action. In 1977, recombinant DNA technology allowed purification of insulin and production of synthetic "human" insulin. This major breakthrough generated the production of large amounts of insulin and also resulted in a reduction of insulin antibodies and insulin allergies. This development was followed by the biochemical modification of the insulin molecule to vary insulin action, giving rise to the so-called insulin analogues.

In 1993, the DCCT established a reduced risk of the development and progression of both micro- and macrovascular complications and all-cause mortality among those treated with intensive insulin therapy with the goal of achieving near-normal blood glucose levels.[190,191] In the DCCT, intensive insulin therapy was associated with a high rate of severe hypoglycemia (62 episodes per 100 patient-years of intensive insulin therapy); this related, in part, to the utilization of older nonanalogue insulin formulations.[190] The treatment of diabetes was further improved by subsequent development of rapid-acting insulin analogues in the 1990s and long-acting (basal) insulin analogues in the early 2000s, which has led to lower rates of hypoglycemia, along with less weight gain and improved glycemic control, in persons with T1DM.[236–238]

Insulin Preparations

Examples of commercially available insulin preparations are shown in Table 36.6 and vary in time to onset, peak, and duration of action. The typical insulin concentration is U-100 (100 units of insulin per 1 mL); however, more concentrated preparations are commercially available, including U-200 insulin degludec (Novo Nordisk Tresiba pen), U-300 insulin glargine (Sanofi Toujeo pen), U-200 lispro (Humalog U-200 KwikPen), and U-500 regular human insulin (Lilly Humulin pen or vial). These concentrated insulin preparations are most commonly used in patients with T2DM, but they are beneficial for some individuals with T1DM who have significant insulin resistance and high insulin requirements.[239] In very young children requiring small doses of insulin (e.g., <0.5 unit bolus doses), rapid-acting insulin diluted to a tenth

TABLE 36.6 Insulin Types and Action Profiles

	Product	Onset of Action	Peak Action	Duration
Rapid acting	Aspart (*Novolog* [Novo Nordisk, Princeton, NJ]) Lispro (*Humalog U-100* [Eli Lilly, Indianapoils, IN], *Humalog U-200* [Eli Lilly, Indianapoils, IN], *Admelog* [Sanofi, Bridgewater, NJ]) Glulisine (*Apidra* [Sanofi, Bridgewater, NJ])	10–30 min	30–180 min	3–5 h
	Aspart (*Fiasp* [Novo Nordisk, Princeton, NJ]) Insulin human (*Afrezza* [MannKind, Westlake Village, CA]) inhalation powder	2.5 min 12 min	40–50 min 35–45 min	 1.5–3 h
Short acting	Regular U-100 (Humulin R U-100 [Eli Lilly, Indianapolis, IN]) Regular U-100 (Novolin R [Novo Nordisk, Princeton, NJ]) Regular U-500 (Humulin U-500)	30–60 min	2–4 h	U-100: Up to 10 h U-500: Up to 24 h
Intermediate Acting	NPH (Humulin N) NPH (Novolin N)	2–4 h	4–8 h	12–18 h
Long Acting	Detemir (*Levemir* [Novo Nordisk, Princeton, NJ]) Glargine (*Lantus* [Sanofi, Bridgewater, NJ], *Basaglar* [Eli Lilly, Indianapoils, IN], *Toujeo U-300* [Sanofi, Bridgewater, NJ]) Degludec (*Tresiba U-100* [Novo Nordisk, Princeton, NJ], *Tresiba U-200*)	2–4 h	Minimal	Detemir: 12–24 h Glargine: up to 24 h Degludec: up to 48 h
Premixed	70/30 (NPH/Aspart) (*Novolog 70/30*) 70/30 NPH/Regular (*Humulin 70/30*) 75/25 (NPH/Lispro) (*Humalog 75/25*) 50/50 (NPH/Lispro) (*Humalog 50/50*) [Other combinations may be available in Europe.]	5–60 min	Dual	12–18 h

the usual concentration (10 units/mL, often called *U-10*) or other concentrations (U-50, U-25) may be used, after education by the child's diabetes health care team; diluted insulin may be prepared by a compounding pharmacy or by the young child's family using a diluent provided by the insulin manufacturer.

Insulin can be dispensed in vials and administered via syringes or continuous infusion pumps or dispensed and administered in pen form. Rapid-acting inhaled insulin is also available, and it has been demonstrated to be noninferior when compared with insulin aspart for mean change in HbA_{1c}, although more patients treated with insulin aspart achieved an HbA_{1c} of less than 7% compared with patients treated with inhaled insulin (31% vs. 18%)[240]; availability of limited dosing increments has been one barrier to treatment with inhaled insulin.

In light of results from the DCCT, intensive insulin therapy is the standard of care for treatment of T1DM and can be achieved with multiple daily injections (MDI) basal-bolus therapy or insulin pump therapy. In both MDI and pump therapy, rapid-acting insulin is given as a bolus at meals and snacks and periodically to correct hyperglycemia (no more frequently than every 2–3 hours) and as basal insulin given once or twice a day with long-acting insulin (for MDI) or as a basal rate (for insulin pumps). A small proportion of patients and families require simplified insulin regimens rather than intensive insulin therapy, which will be discussed in the following.

Initial Management of Newly Diagnosed T1DM

In pediatric patients with newly diagnosed diabetes, initial management includes resuscitation with oral or intravenous fluids to rehydrate and correct electrolyte imbalances, administration of insulin to halt lipolysis and reverse hepatic gluconeogenesis and ketogenesis, and commencement of diabetes education. Depending on factors such as the age of the individual patient and severity of his or her clinical presentation, family factors, and availability of diabetes-related resources, initial management may occur in an intensive care unit, inpatient hospital setting, or outpatient unit. Initial presentation of T1DM is often DKA. Please refer to the discussion on DKA.

Initiation of Insulin Therapy

For those individuals who do not initially present in DKA, treatment with subcutaneous insulin should be started at diagnosis of diabetes. For those who present in DKA, subcutaneous insulin should begin with resolution of DKA (pH ≥7.3, CO_2 ≥18 mEq/L [18 mmol/L], and normalization of the anion gap) in conjunction with the first meal being eaten post-DKA. Determination of the appropriate starting insulin dose must consider the patient's weight, age, pubertal status, and history of DKA. For young children and postpubertal adults who are not obese and do not present in DKA, a typical starting dose is 0.3 to 0.5 units/kg per day. Higher doses will be needed for individuals who are obese, children in puberty, or following presentation with DKA, such that a pubertal child with obesity and resolved DKA may receive a starting dose of 1 unit/kg per day. This total daily dose (TDD) of insulin is typically given in a divided program of MDI with about 50% of the TDD delivered as a once-daily dose of basal insulin and 50% given as boluses.

Insulin Dose Determination

Treatment with basal-bolus therapy requires the calculation of the appropriate insulin bolus at each meal and snack based on the premeal blood glucose level and the planned carbohydrate intake. To calculate a bolus, the person will first calculate the proper carbohydrate coverage for the meal using his or her individualized insulin-to-carbohydrate ratio. The carbohydrate ratio is the number of grams of carbohydrate covered by 1 unit of insulin (roughly 450 divided by the total daily insulin dose, TDD). Next, the person will determine the amount of insulin required to correct for the premeal blood glucose level, using his or her individualized correction factor (also sometimes called *sensitivity factor* or *sensitivity index*). The correction factor is the expected decrease in blood glucose resulting from 1 unit of insulin (approximately 1650 divided by the total daily insulin dose, TDD). The bolus delivered with the meal or snack is the sum of the calculated carbohydrate coverage and the calculated blood glucose correction. Most patients do these calculations by hand, mental math, or calculators, or with the help of apps or pump pen bolus wizards, but some families require sliding scales or charts for determination of bolus dosing. Rapid-acting insulin boluses should be given 10 to 15 minutes before the start of a meal or snack because onset of action is about 15 minutes. In cases where food intake is less predictable (e.g., very young children, gastroenteritis), postprandial administration of a rapid-acting insulin bolus is safe and effective.[241] Since rapid-acting insulin has a 3-hour action time, a correction factor is usually not given any more frequently than every 3 hours to avoid hypoglycemia from "stacking" of insulin action. Anticipated activity (i.e., recent or planned exercise) may factor into insulin bolus calculations, with less insulin required before, during, or after certain types of exercise. Additionally, a blood glucose trend based on continuous glucose monitor arrows may also factor into the insulin bolus calculation at mealtime.[242,243]

Other Insulin Regimen Options

In individualizing each person's insulin regimen, clinicians must consider the frequency of blood glucose monitoring, number of daily injections, the need for flexibility in meal planning, and family schedule. In a minority of patients with T1DM, treatment with intensive insulin therapy and mealtime bolus calculations may not be feasible or appropriate. In these cases, intermediate-acting insulin (NPH) may be prescribed, often in conjunction with rapid- or short-acting insulin, and sometimes in premixed form (70/30, 75/25, 50/50). To avoid hypoglycemia in such regimens, meals are typically fixed with regard to timing and amount of carbohydrates consumed. Table 36.7 provides examples of insulin regimens.

Blood Glucose Monitoring

Self-management of diabetes requires the routine monitoring of glucose levels to select and adjust insulin doses, to understand the impact of various foods on glycemic excursions, to reduce the risk of exercise related hypo- or hyperglycemia, and to react to periods of illness or stress that can lead to increased glucose variability and hyperglycemia with ketosis along with risk for ketoacidosis. There are numerous glucose meters available that utilize a small volume of blood (<1 mL), provide results in less than 5 seconds, offer alternative site use beyond fingertips, and meet recent standards of accuracy. Accuracy standards include the need for at least 95% of blood glucose meter results to fall within ±15 mg/dL (0.8 mmol/L) for blood glucose <100 mg/dL (5.6 mmol/L) and within ±15% for blood glucose ≥100 mg/dL (5.6 mmol/L) performed with a reference method,[244] with recommendations allowing for ongoing assessment of meter performance.[245] Each year, the ADA provides an update of available meters, along with a cataloging of their various features.[246] Although there may be substantial choice in the selection of glucose meters, one must mainly consider insurance coverage and the need to link the meter with a pump for CSII.

TABLE 36.7 Examples of Insulin Regimens Used in Type 1 Diabetes

Intensive Insulin Regimens
Multiple Daily Injections
Long-acting insulin given once daily, and rapid-acting insulin given at meals, snacks, and periodically to correct high blood sugars
Continuous Subcutaneous Insulin Infusion via Insulin Pump
Rapid-acting insulin given at basal rate (rate can vary throughout the day) and as a bolus at meals, snacks, and as needed to correct high blood sugars
Rapid-acting insulin given via pump according to automated insulin delivery algorithm and based on continuous glucose monitoring
Simplified Insulin Regimens
Multiple Daily Injections
Long-acting insulin given once daily, NPH given at breakfast, and rapid-acting insulin given at breakfast and dinner (may be used when lunchtime insulin dosing is logistically difficult; lunch carbohydrate intake must be consistent)
NPH given twice daily (breakfast and bedtime), and rapid-acting insulin given at meals
NPH and rapid- or short-acting insulin given twice daily (breakfast and dinner)
Premixed insulin (70/30, 75/25, 50/50) given twice daily (breakfast and dinner)

Daily blood glucose monitoring frequency has been repeatedly linked to lower HbA_{1c} levels.[247–249] For persons with T1DM, blood glucose monitoring frequency is generally recommended at least four times daily and up to 10 to 12 times daily. Monitoring generally occurs before meals/snacks and at bedtime, with monitoring at other salient times, such as postprandially, overnight, before/during/after exercise, and during periods of illness or stress. More frequent monitoring is often recommended for persons with hypoglycemic unawareness (i.e., prior to driving) and for those unable to communicate symptoms, such as the very young or the elderly. It is important to download the glucose meter at routine appointments to review glycemic patterns with patients and families and to utilize the data to encourage self-management for insulin dose adjustments. Modern CGM technologies, especially those with nonadjunctive claims for insulin management, have supplanted the need for frequent blood glucose monitoring (see the next section).

Continuous Glucose Monitoring

Real-time CGM is increasingly utilized for routine diabetes care in adults, children, and adolescents with T1DM. CGM is a portable device that allows for measuring and visualizing the glucose concentration continuously in real time for several days to weeks.[250] CGM devices are composed of three main units: a sensor, a transmitter, and a receiver. The sensing electrode is placed in the subcutaneous space and measures glucose in the interstitial fluid, which is correlated to blood glucose via a calibration procedure. The sensing electrode is inserted by the user or a caregiver for most devices or implanted by a clinical team for the new long-term sensor. Each sensor can last between 5 and 14 days for the minimally invasive CGMs, and from 90 to 180 days for the implantable one. Information from the sensing electrode is transmitted to a dedicated receiver or to a smart device like a phone or an insulin pump. The CGM transmitter is attached on top of the sensor and can last 3 to 6 months of use or is rechargeable in some devices. The transmitter unit utilizes either a proprietary radio or Bluetooth Low Energy (BTLE) communication to connect to the receiver unit or mobile device. The dedicated receiver, an app on a smart phone or an insulin pump, receives the glucose readings, which then can be used to visualize glucose trajectories and provide hypoglycemia and hyperglycemia alerts and alarms to the user and followers. The CGM is calibrated using self-monitoring blood glucose (SMBG) devices. Calibration for some of the CGMs occurs as often as every 12 hours. Calibration values can be entered on the mobile device, CGM receiver, or insulin pump. Recent CGM technology enables a calibration-free option or factory calibration without loss of accuracy, which liberates users from capillary glucose measurements, although calibration is still optional.

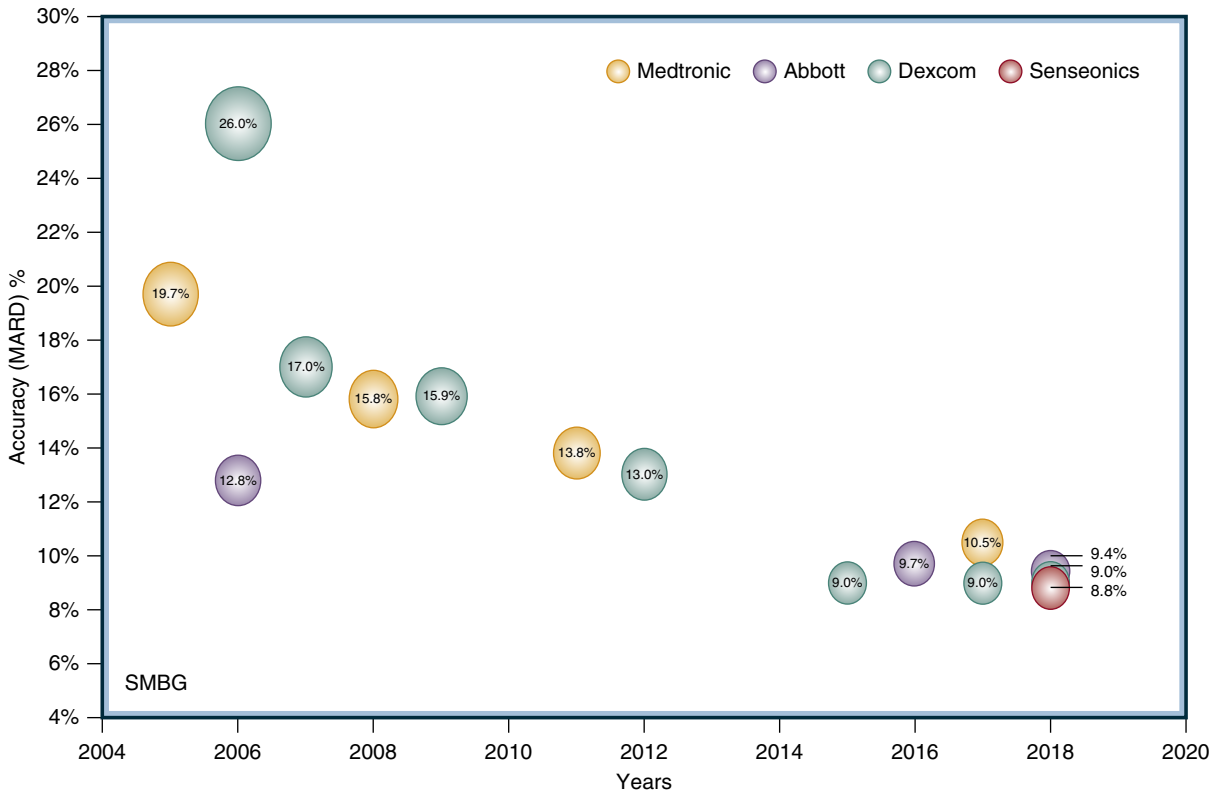
The first modern CGM devices were introduced by Medtronic Diabetes (Northridge, CA) as a diagnostic tool providing 72 hours of retrospective data when calibrated with blood glucose meter values; the latter were to be used for insulin dosing or other therapeutic adjustments. New devices added the use of trend arrows and predictions, and with each newer generation, the sensor use time increased and the accuracy measured as mean absolute relative difference.[251–257] CGM technology, based on electrochemical detection of glucose using enzymatic chemistry that employs a glucose oxidase reaction, has improved dramatically in the past decade, as depicted in Fig. 36.7.[258,259] Modern CGM technology has reached the accuracy of SMBG with the new Dexcom G6 (San Diego, CA), which is factory calibrated and approved for insulin dosing, as well as the new Abbott FreeStyle Libre (Alameda, CA), which has reduced the warm-up time to 1 hour and can run for 14 days (Fig. 36.8). The Senseonics (Germantown, MD) CGM is a new implantable device based on fluorescent chemistry that functions from 90 to 180 days using a removable rechargeable receiver and transmits glucose to a mobile app[260–264] (see Fig. 36.8).

Innovations are ongoing with smaller devices and longer use time between sensor insertions, integration of CGM devices with insulin pumps and mobile apps together enhancing the usability and have opened the door for automated insulin delivery (AID) or artificial pancreas.[259]

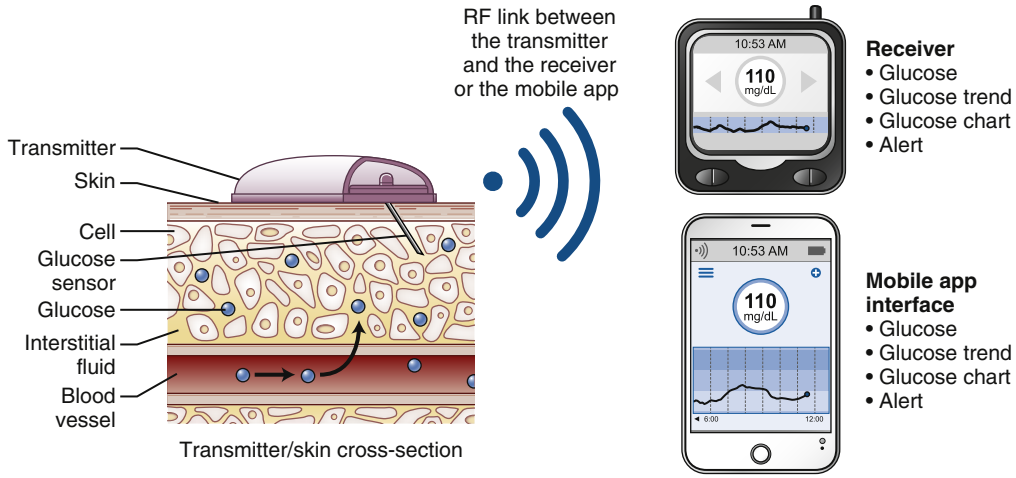
Benefits of CGM devices have accrued with improved performance of the devices over time.[265–267] Consistent CGM use of 6 or more days per week has been associated with improvements in glycemic control, reflected in lower HbA_{1c} levels, more patients achieving HbA_{1c} targets, and reduction in time in the hypoglycemic range of less than 70 mg/dL (<3.9 mmol/L) or less than 54 mg/dL (3 mmol/L).[268–271] Similarly, more frequent scanning of the Freestyle Libre has also been associated with improved glycemic control, noted by an increase of glucose time in range, with reductions of time in hypoglycemia and hyperglycemia; mean scanning frequency was about 16 times per day in one study.[272] Finally, recent publications from the Endocrine Society have advocated the use of CGM trend arrows to fine tune insulin bolus doses at mealtimes in pediatric and adult patients to avoid extreme postprandial glucose excursions, especially given the recognition that the glucose trajectory and the magnitude of the glucose level impact the response to the insulin bolus and ingested meal.[242,273]

Continuous Subcutaneous Insulin Infusion

CSII is a minimally invasive form of insulin delivery that enables intensive insulin therapy. One of the advantages of the use of



• **Fig. 36.7** Accuracy of current continuous glucose monitoring devices in the past decade. *MARD,* mean absolute relative difference; *SMBG,* self-monitoring blood glucose. (Modified from Facchinetti A. Continuous glucose monitoring sensors: past, present and future algorithmic challenges. *Sensors (Basel)*. 2016;16[12]:E2093.)



• **Fig. 36.8** The components of a continuous glucose monitoring system, which include the glucose sensor that resides in the subcutaneous tissue along with the transmitter that wirelessly transmits the glucose data to a separate receiver that can be a stand-alone device or an application on a mobile device. Wireless transmission occurs via radio frequency (RF) and Bluetooth. Both glucose concentrations and trends can be displayed. Alerts can notify the user when glucose levels are rising or falling.

CSII, as its name implies, is its ability to continuously deliver insulin and allow the users to respond more rapidly to any changes in their physiologic insulin requirements. Second, most modern CSII pumps enable the user to program and modify key parameters that effect insulin delivery, such as (1) the basal rate profile, in which several basal rates with multiple insulin segments can be entered to address changes in insulin requirements between workdays and weekends, active days or sick days, and more; (2) the storing of multiple sensitivity factors, as well as carbohydrate to insulin ratio; (3) alerts and alarms; (4) bolus calculators and insulin-on-board estimators, to prevent overstacking of insulin.

CSII therapy has been associated with improved glycemic control, decreased hypoglycemia, and better quality of life.[274–276] Still, there are several disadvantages of this delivery route. Using

TABLE 36.8 Modern Insulin Pumps in the United States

Product	Reservoir	Basal Range	Bolus Range	Main Features
Omnipod INSULET CORP. (Acton, MA)	200 U	0.05–30 U/h in 0.05-U increments	0.05–30 U; Increments of 0.05, 0.1, 0.5, or 1 U	• No tubing • Patch design • Pod is waterproof for up to 25 feet deep for 60 minutes • Personal Diabetes Manager (PDM) controls the pod • New system that uses BTLE communication and a smart PDM
MiniMed 530G System MEDTRONIC DIABETES	300 U	0.025–35 U/h in 0.025-U increments	0.025–25 U; Increments of 0.1 U	The MiniMed 530G combo pump–CGM uses SmartGuard technology to stop insulin delivery for up to 2 hours if the glucose level reaches a preset low limit and the user does not react to a low-glucose alarm.
MiniMed 670G System MEDTRONIC DIABETES	300 U	0.025–35 U/h in 0.025-U increments	0.025–25 U; Increments of 0.1 U	The MiniMed 670G, a hybrid closed-loop pump, uses SmartGuard technology to allow users to choose from increasing levels of automation that best fit their diabetes management needs.
T:slim X2 Pump TANDEM DIABETES CARE (San Diego, CA)	300 U	0.1–15 U/h in 0.001-U increments	0.05–25 U; Increments of 0.01 U	The T:slim X2 uses the Tandem Device Updater to remotely update software from a computer without requiring purchase of a new device. Integrated with Dexcom's G5 CGM. New Basal-IQ pump supports the Dexcom G6 and has a PLGS feature.

BTLE, Bluetooth low energy; *CGM*, continuous glucose monitoring; *PLGS*, predictive low-glucose suspend.

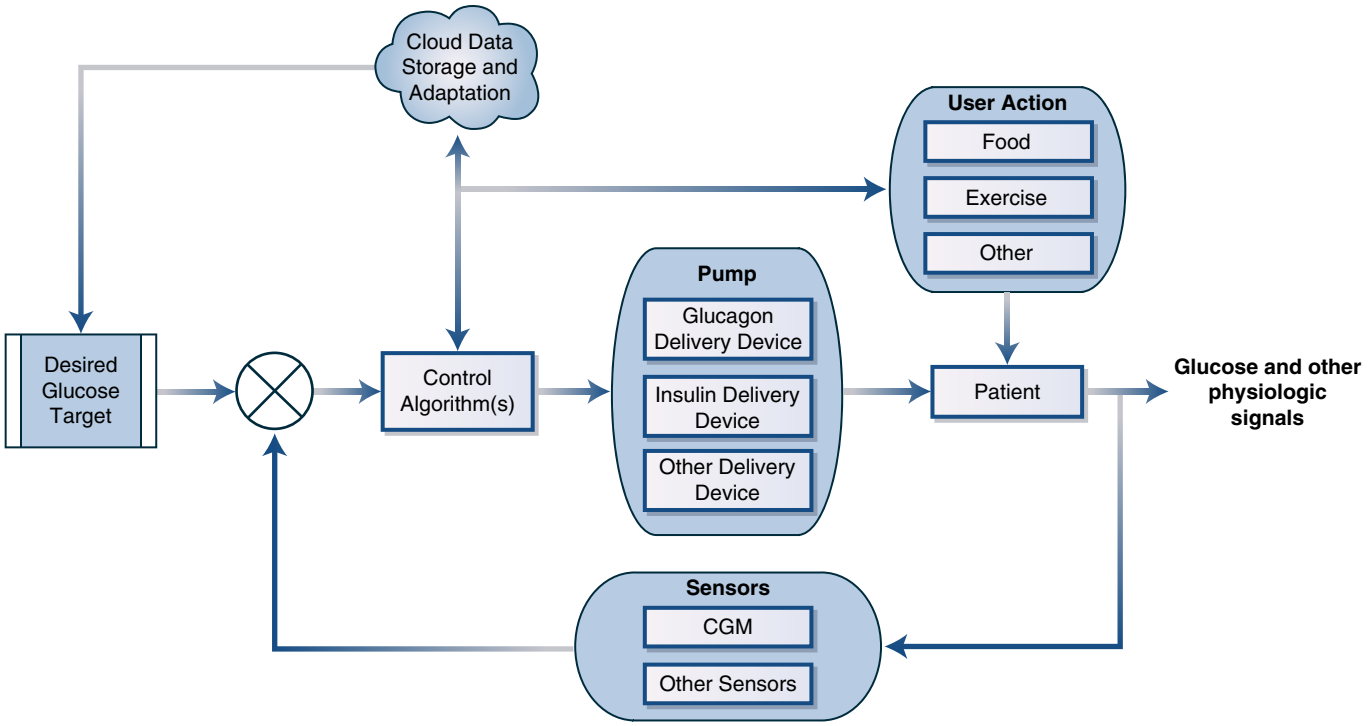
CSII means that the user is attached to an external device, which may be inconvenient in daily life. Additionally, it is recommended to change the infusion set every 3 days to reduce problems with site irritation and irregularity in insulin delivery caused by blocked catheters, insulin leakage, or cannula dislodgement.[277] A failure of the infusion site can lead to hyperglycemia, and potentially DKA, if the problem is not detected in time. Pump technology has progressed to support smarter devices that integrate CGM functionality, as well as algorithms that enable insulin suspension based on fix threshold or predictive design, to minimize hypoglycemia and improve glycemic outcomes. The latest leap forward in pump technology is the development of closed-loop insulin delivery devices that build on top of the current small and smart devices, and add a control algorithm that is tasked with calculating the safe dose of insulin, in most cases, or a combination of insulin and glucagon. As can be seen in Table 36.8, several pumps are available to people with T1DM, with different features, sizes, and technology to support their individual needs and requirements.

The first advantage of connected care between CGM and the insulin pump delivery system is the introduction of integrated or linked systems that enable automated insulin suspension. Suspending basal insulin delivery for low sensor glucose levels has been shown to distinctly reduce hypoglycemia without worsening glycemia.[278] Sensor-augmented pumps that preemptively suspend insulin delivery when sensor glucose levels are predicted to be low show promise in minimizing hypoglycemia.[279–282] The greatest potential for improved glycemic control is the dynamic regulation of insulin delivery for both high and low glucose levels. "Hybrid" closed-loop systems that modulate basal insulin delivery by sensor glucose levels increase time spent within target glucose ranges, reduce hyper- and hypoglycemia exposure, lower HbA_{1C} levels, and improve measures of quality of life in both adult and adolescent subjects.[283–287] Translation of AID from research to clinical care will require educating users and providers to optimize outcomes and understand the new technology and the best way to use it.[288,289] Users of current hybrid closed-loop systems must still count carbohydrates and bolus manually for meals. Systems that reduce reliance on carbohydrate counting, and systems that administer glucagon under automated control to mitigate the risk of hypoglycemia, remain in development.[290] A recent systematic review and meta-analysis of randomized controlled trials suggest that artificial pancreas systems uniformly improve glucose control in outpatient settings despite heterogenous technical and clinical factors.[291]

AID: "The Artificial Pancreas"

The combination of continuous glucose technology with insulin pumps has enabled the development of AID systems (closed-loop or artificial pancreas devices). A controller, an algorithm, adjusts insulin delivery based on CGM data to a glucose target or range that is preset and can be changed based on user lifestyle or need.[292–294] These feedback control algorithms achieve safe and effective glucose regulation for people with T1DM, maximize time spent within the euglycemic safe range of 70 to 180 mg/dL, minimize hypoglycemic events, and prevent postprandial hyperglycemia with little user intervention.

A closed-loop glucose control or AID system is composed of several basic elements, as depicted in Fig. 36.9. The source of information is the sensor module that is based on a CGM. Additional sensors that monitor other physiologic parameters (e.g., heart rate, accelerometry, skin temperature) are being integrated in new AID systems.[295] The delivery module is based on an insulin pump, while a combination of insulin and other hormones or medications are also being explored. The core module, the control algorithm, processes the sensor measurements with or without additional input provided by the user, such as meal or exercise information, to achieve the desired glucose set-point target or range. The control signal is sent to the user's pump to manipulate insulin delivery and other drugs, such as glucagon or pramlintide, in a variable rate or microdose. Current artificial pancreas systems are based on subcutaneous sensing and delivery; however, the intraperitoneal space has been investigated as a potential alternative site to insulin delivery and glucose sensing, one that will be closer to physiologic insulin secretion.[296,297] The core of AID



• **Fig. 36.9** Feedback control loop for automated glucose management. *CGM*, continuous glucose monitoring.

systems is the control algorithm. Many control techniques are being explored in academic studies, and some have translated to industrial development and implementation as part of new AID systems. The lead feedback control algorithms for automated glucose regulation are proportional integral derivative (PID) control, fuzzy logic control, and model predictive control (MPC).

Proportional Integral Derivative AID

The PID controller is the most common strategy of implementing feedback control.[298] PID control consists of the summation of three distinct terms or components: the proportional term that captures the current tracking error (the difference between the current control variable and the desired set-point), the integral term that captures historical accumulation of the error, and the derivative term that captures anticipated change of the error.[298] Steil and colleagues[299] have pioneered the development of PID-based AID systems as part of Medtronic Diabetes. PID control algorithms have been used in several automated closed-loop insulin delivery systems, including the first US Food and Drug Administration (FDA)-approved hybrid closed-loop system—the Medtronic 670G.[299–302]

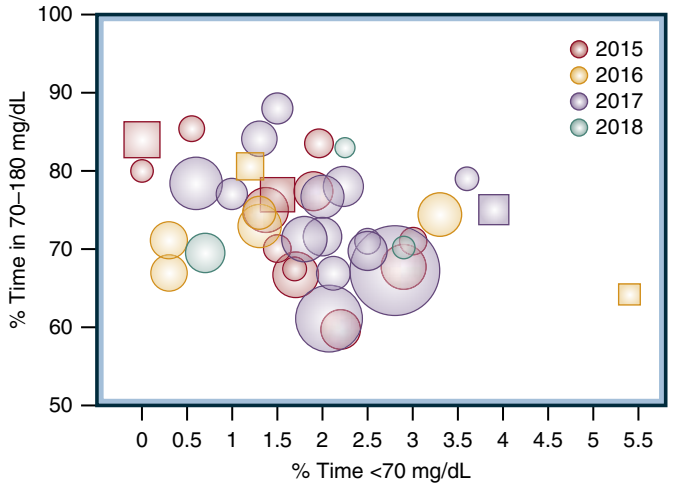
Fuzzy Logic AID

Closed-loop algorithms using fuzzy logic follow specially designed dosing rules to incorporate expert clinical knowledge in diabetes decision making.[303,304] A fuzzy logic–based controller has three main stages: (1) input fuzzification, mapping the glucose and/or its rate of change using membership functions; (2) fuzzy inference, combining the fuzzy inputs from the first stage and a set of fuzzy rules to determine the degree of activation of output membership functions; and (3) output defuzzification, where the final output—insulin dose—is calculated. One fuzzy logic–based artificial pancreas system is known as the MD-Logic Artificial Pancreas, which has been developed by researchers at Schneider Children's Medical Center of Israel. The system has been used in multiple clinical studies and is proven to regulate glucose levels across age groups.[305] The MD-Logic closed-loop algorithm consists of two control modules: a control to range module that aims to keep glucose in the 80 to 120 mg/dL (4.4–6.7 mmol/L) range and a control to target module.

Model Predictive Control AID

MPC is one of the most widely used approaches in advanced control system design of AID devices due to its ability to directly handle practical constraints and multiple inputs and outputs, formulate control objectives into a constrained optimization problem, and find the optimal control inputs by solving the optimization problem in a receding-horizon fashion. MPC is a model-based control strategy using models in two ways: (1) utilizing a reliable model to predict the effect of past control moves on future outputs, assuming no future moves, and (2) using the same model to compute optimal controller moves, implementing the first move and repeat procedure. So far, this approach has been successfully utilized in the development of AID systems by multiple research groups and industry translation of the technology.[284,285,287,290,306,307]

AID systems can be divided into two main classes: insulin-only and bihormonal systems that use insulin and glucagon or other drugs to improve care. In the past decade, multiple clinical studies have been launched to evaluate the safety and efficacy of AID systems in both groups. Different control algorithms, CGMs, and delivery devices were evaluated in these studies. AID systems have been tested with multiple challenges that people with T1DM are facing, such as nocturnal glucose control and both announced and



• **Fig. 36.10** Clinical performance of insulin-only (disks) and insulin and glucagon (squares) automated insulin delivery systems, where the size of the shape depicts the number of subjects in the study and the color depicts the publication year. (Modified from Dassau E. The path to a medical internet of things (IoT) and human-centric design of an artificial pancreas. Presented at the Symposium on Artificial Pancreas and Decision Support Approaches at the American Diabetes Association 78th Scientific Sessions, Orlando, FL, 2018.)

unannounced meals and physical activity. These studies started in a tight, supervised environment and gradually transitioned to hotel and at-home clinical studies that ranged from short visits to prolonged multiweek studies.[284,290,295,300,305,307–317] As depicted in Fig. 36.10, both insulin-only and bihormonal AID have demonstrated safe and effective glucose regulation with minimal time, less than 1.5% spent under 70 mg/dL (3.9 mmol/L) and approximately 75% in the 70 to 180 mg/dL (3.9–10.0 mmol/L) range. Additional work with new technology, as well as added wearable sensors, and/or drugs may improve these remarkable outcomes. Adjunctive therapies to treat T1DM such as pramlintide and glucagon-like peptide 1 (GLP1) receptor agonists (e.g., liraglutide, exenatide) or SGLT2 inhibitors that are used in clinical care are yet to be fully evaluated with AID systems, and only limited clinical studies have been done to evaluate how to integrate them with AID systems.[318,319]

Decision Support Systems

An emerging field in diabetes care is decision support that uses connected care devices such as CGM, smart insulin pens, SMBG, and insulin pumps to provide guidance and advice to people with T1DM via smart apps or cloud-based algorithms. This evolving field can improve care of both MDI and CSII users by providing tools to adjust basal boluses, as well as meal and correction boluses, based on glucose input and peoples' lifestyle. These tools can provide additional insight to the clinical team with enhanced visualization and advice on insulin management.[320–323]

Use of Adjunctive Drugs in T1DM

Advances in treatment for T1DM have primarily targeted the development of insulin analogues and devices that optimize insulin delivery and mimic normal physiologic serum insulin levels. Even with these advances, insulin therapy has been associated with hypoglycemia and weight gain. To offset some of these side effects of insulin therapy, several drugs that are currently used in T2DM have been investigated for adjunctive use in T1DM, to assess potential benefits related to improved glycemic control, less hypoglycemia, reduced glucose variability, and less weight gain. To date, pramlintide is the only drug that is approved by the FDA for adjunctive use in adults with T1DM; no adjunctive treatments have been FDA approved for use in children with T1DM.

Pramlintide

Pramlintide, an injectable amylin analogue, slows gastric emptying, suppresses postprandial glucagon secretion, and enhances satiety. Several large, randomized, placebo-controlled, double-blinded trials have shown that the addition of pramlintide to insulin at mealtime in adults with T1DM improved glycemic control, including modest reductions in HbA_{1c} by 0.3% to 0.6%, and decreased postprandial glucose excursions.[324,325] Pramlintide was also associated with modest weight loss (mean, 0.4–1.3 kg) and reduced insulin dose; nausea was the most frequent side effect. In a recent closed-loop insulin delivery study, the addition of mealtime pramlintide was associated with a reduction in postprandial hyperglycemia compared with closed loop alone.[326] Pramlintide is approved for adjunctive use in adults with T1DM but not in children.

Metformin

Several clinical trials have studied the addition of metformin to target insulin resistance, particularly in individuals who are obese and during puberty. Clinical trials have failed to demonstrate improvement in HbA_{1c} with adjunctive use of metformin, although some studies in youth have shown decreases in weight and insulin requirement.[327,328] In a recent randomized controlled trial of adjunctive metformin in adults with T1DM at risk for cardiovascular disease, the metformin group exhibited improvements in body weight, low-density lipoprotein cholesterol, and estimated glomerular filtration rate, but metformin did not significantly improve carotid artery intima-media thickness (the primary study outcome) or glycemic control.[329] Metformin is not FDA approved for treatment of T1DM.

Incretin-Based Therapies

Incretin-based therapies include GLP1 receptor agonists and dipeptidyl peptidase 4 (DPP4) inhibitors. GLP1 is an incretin hormone produced in the gut that has been shown to boost glucose-dependent insulin secretion, suppress glucagon secretion, delay gastric emptying, and promote satiety. Individuals with T1DM appear to have normal GLP1 production but dysregulation between the pancreas and the gut, leading to ineffective glucagon suppression.[330] A recent 24-week randomized, double-blind, placebo-controlled trial of overweight adults with T1DM and HbA_{1c} greater than 8% showed that the addition of the once-daily injectable GLP1 receptor agonist liraglutide was associated with weight loss and decreased insulin dose, but change in HbA_{1c} from baseline did not differ between groups.[331] In a recent closed-loop insulin delivery study, the addition of once-daily liraglutide was associated with fewer postprandial increases in blood glucose, weight loss, and decreased insulin compared with closed-loop control.[326] Considering that endogenous incretins such as GLP1 are rapidly degraded by the enzyme DPP4, treatment with DPP4 inhibitors has been shown to have many of the same glycemic benefits as GLP1 receptor agonists in the treatment of T2DM. Trials of DPP4 inhibitors in T1DM to date have not yet shown significant clinical benefit.[332] Incretin-based therapies are not FDA approved for use in T1DM.

SGTL1 and SGLT2 Inhibitors

Oral SGLTs reduce postprandial hyperglycemia, reducing glucose reabsorption in the proximal renal tubule (SGLT2) and in some agents decreasing and slowing intestinal glucose absorption (SGLT1).[333] In those with T2DM, they have been associated with improvement of glycemic control, weight loss, and blood pressure reduction,[334–337] lower rates of cardiovascular morbidity and mortality in those at high cardiovascular risk,[338] and decreased albuminuria.[339] Two recent large, double-blinded, phase III randomized control trials studied the efficacy and safety of SGLTs in adults with T1DM combined with optimized insulin therapy.[340,341] The inTandem1 trial (n = 793) was a 1-year study of the dual SGLT1/SGLT2 inhibitor sotagliflozin, 200 or 400 mg once daily before breakfast combined with optimized insulin therapy.[341] The DEPICT-2 trial (n = 813) was a 24-week study of the SGLT2 inhibitor dapagliflozin, 5 or 10 mg once daily.[340] Both studies showed that, compared with placebo, adjunctive use of an SGLT inhibitor was associated with modest but durable dose-dependent improvements in HbA_{1c}, reductions in insulin dose, and weight loss. Unfortunately, those treated with SGLT inhibitors also had higher rates of genital mycotic infections and DKA (in Tandem1 trial participants with ≥1 DKA event in the 1-year study: 0.4% in the placebo group, 3.4% in the 200-mg sotagliflozin group, 4.2% in the 400-mg sotagliflozin group; DEPICT-2 trial participants with a definite DKA event over the 24-week study: 0 in the placebo group, 2.6% in the 5-mg dapagliflozin group, 2.2% in the 10-mg dapagliflozin group). Similar large phase III studies of once-daily oral doses of empagliflozin adjunctive to insulin therapy over 52 weeks in patients with T1DM (EASE-2 and EASE-3) have presented preliminary data showing similar benefits. Risk of DKA with SGLT2 inhibitors might be higher in patients with a history of DKA, individuals on a low-carbohydrate diet, and in those who do not check ketones in the setting of potential symptoms. SGLT inhibitors are yet not FDA approved for use in T1DM.

In considering the addition of adjunctive drugs in a person with T1DM, any potential benefits must be carefully weighed against risks and costs of the medications.

Outcomes Beyond HbA_{1c}

CGM offers a new opportunity to assess glycemic control beyond HbA_{1c}, which assesses average glycemic control over the previous 2 to 3 months, although it is more heavily weighted toward the most recent month. Yet there are challenges with the use of HbA_{1c} as a measure of glycemia, as it can reflect a wide range of mean glucose levels and can vary in persons of different races, in those with different rates of glycation, and according to red cell survival time.[342–346]

CGM data reflect overall glycemia with the collection of just 2 weeks of data.[347] Recent consensus conferences, reflecting major national and international professional organizations, have published a series of CGM metrics important in the assessment of glycemia in persons with diabetes,[348,349] based on the recognition that there can be an improved understanding of a person's glycemia beyond the HbA_{1c}. At present, there is a series of glucose metrics reported on CGM data downloads, along with an effort to standardize the CGM metrics and to include glucose data collected over a 2-week period, with the goal that regulators will also accept these metrics as important glycemic outcomes.[350] The metrics include measures of overall glucose levels and glucose variability. The major measures include glucose mean, glucose standard deviation, coefficient of variation ([standard deviation/mean] × 100 as a percentage), glucose time in range (70–180 mg/dL [3.9–10.0 mmol/L]), time in hyperglycemia (>180 mg/dL [10.0 mmol/L] and >250 mg/dL [13.9 mmol/L]), and time in hypoglycemia (<70 mg/dL [3.9 mmol/L] and <54 mg/dL [3.0 mmol/L]). Glucose time in range, as well as time in hyperglycemia and hypoglycemia, should be reported per unit time, as in the percentage of the values in the specified range of 24 hours/day. A clinically meaningful episode of hypoglycemia has been defined as 15 minutes or more of consecutive CGM readings less than 54 mg/dL (3.0 mmol/L). There is no doubt that CGM has heralded in a new era to enhance our understanding of outcomes beyond HbA_{1c}.

In addition to glycemic metrics beyond HbA_{1c}, there are numerous patient-reported outcomes that warrant attention. These include quality of life, well-being, fear of hypoglycemia, diabetes distress or burden, treatment satisfaction, self-efficacy, disordered eating behaviors, anxiety, depression, diabetes family conflict, sleep deprivation, and others, many of which have been discussed in a recent position statement by the ADA.[351] Several validated surveys to assess such patient-reported outcomes are catalogued in this publication. With the continued development of adjunctive therapies and advanced diabetes technologies, there will be a continued need to consider the patient- and family-reported outcomes in addition to metrics of glycemic control.

Transition in Care From Pediatric to Adult Health Care Settings and Beyond

The delivery of pediatric diabetes care focuses on the young person with diabetes, as well as family members who assist with diabetes management tasks and provide support and guidance. Adult care generally tends to follow a medical model with a focus almost exclusively on the person with diabetes. This variation in approaches can produce a disconnect for the young person with T1DM who transitions between health care settings. Additionally, transition generally occurs between the ages of 18 and 22 years, although it can occur at younger ages (down to age 14–16 years) or older ages (up to 26 years), depending on the health care system. Nonetheless, transition often occurs during the fragile development stage of young adulthood, between the ages of 18 and 25 years, when the young person faces many competing challenges related myriad choices concerning education, occupation, socialization, intimacy, economic self-sufficiency, and potential geographic separation from the family unit, among other issues.[352]

Transition is considered as the process that begins during adolescence when the teen accepts more diabetes self-care responsibilities and attends part of the diabetes encounter without parents or guardians. During transition, the teen or young adult is expected to master self-care skills, as well as learn how to make follow-up appointments, seek on-call help, and obtain prescriptions, for example. At the end of transition, there is the actual transfer to adult care, the final step that entails the need for an introduction to a different health care delivery model.

There has been increased interest in the study of transition from pediatric to adult diabetes care due to the recognition that young adults experience many adverse outcomes, including achieving the highest mean HbA_{1c} level of 9.2% at the age of 19 years.[353] Many young adults with T1DM often have substantial gaps in care exceeding 6 to 12 months between visits, resulting in deteriorating glycemic control, the need for emergency room use, and the potential emergence of diabetes complications that go undetected and untreated in a timely manner.[354–356] The ADA, along with other major national and international societies, created a

joint consensus statement on transition, based mainly on expert consensus, which has helped lay the groundwork for continued research in this area.[185,356,357] There are few published controlled trials, although there are studies evaluating the use of care coordinator, often called a *patient navigator*[358] or care *ambassador*,[359–361] at time of transfer from the pediatric to adult team.[362,363]

In general, growing teens should begin to learn about the process of transition to adult heath care starting in early to mid-adolescence from the pediatric diabetes health care team. In the final year of pediatric care, the young adult should receive names and contact information for adult diabetes care providers. Then, both the pediatric and adult providers can help support the transfer and ensure the appropriate transmission of important diabetes medical information. Numerous online resources have been developed to assist in the transition process.[364,365] Finally, although the topic of transition from pediatric to adult care continues to generate substantial clinical and research interest, another transition period, specifically the one from adulthood to a more mature older adult group, also requires ongoing research. This is especially important given that there are substantial numbers of persons with T1DM living many decades with diabetes and surviving well into the geriatric years, indicating a need to reassess the cognitive abilities and hypoglycemia risk in the older person with diabetes.[366,367]

Acute Diabetic Emergencies

Diabetic Ketoacidosis

DKA is a significant, expensive, and possibly lethal and potentially avoidable acute complication of T1DM.

Pathophysiology of DKA

DKA is defined by hyperglycemia (blood glucose >200 mg/dL, ~11 mmol/L), ketonemia (blood beta-hydroxybutyrate ≥3 mmol/L or moderate/large urine ketones), and acidosis (venous pH <7.3 or serum bicarbonate <15 mmol/L).[368] It is the result of relative or absolute insulin deficiency causing an increase in glucagon concentrations and accompanying increases in epinephrine, norepinephrine, cortisol, and growth hormone levels.[369] These hormone changes lead to a catabolic state in the periphery, mobilizing substrates that the liver then uses to increase production of glucose and ketone bodies. When serum glucose concentrations exceed the renal threshold of approximately 180 mg/dL (10 mmol/L), osmotic diuresis leads to dehydration and loss of electrolytes. Vomiting, which commonly occurs with severe ketosis, can further contribute to dehydration and electrolyte abnormalities. The vicious cycle continues with additional stress hormones production, which leads to worsening insulin resistance, hyperglycemia, and ketosis.[368]

Epidemiology and Risk Factors for DKA

DKA is a common presentation in new-onset T1DM. The estimated proportion of children with new-onset T1DM who present with DKA ranges from 15% to 70% in different studies and in different countries.[368,370–372] Individuals who are young (<5 years), do not have a first-degree relative with T1DM, and with lower socioeconomic status are at a greater risk of DKA at diagnosis.[372] In a review of international DKA rates, higher DKA incidence at first presentation of T1DM was associated with lower gross domestic product, lower latitude, and lower background incidence of T1DM.[371] Most cases of DKA, in fact, occur in those with established diabetes, where the risk of DKA is between 1 and 10 per 100 person-years, and is higher in patients with poor metabolic control and/or history of insulin omission; a history of a prior episode of DKA; gastrointestinal illness; psychiatric disorders, including eating disorders; low socioeconomic status; and, for unclear reasons, females in adolescence.[353,368,373] Insulin pump use is actually associated with lower rates of DKA compared with MDI,[374,375] although insulin pump failure is an important cause of hyperglycemia, ketonemia, and DKA.

Prevention of DKA /Sick Day Management

Appropriate management of sick days in individuals with T1DM can usually be achieved in the outpatient setting with ongoing education and support. Guidelines are available for management of sick days in children and adolescents with diabetes.[376] The prevention of progression to DKA and avoidance of hypoglycemia rely on modifying doses of but never omitting insulin, frequent monitoring of blood glucose and ketone levels every 1 to 3 hours, preventing/treating dehydration and hypoglycemia, treating the underlying illness, and maintaining frequent contact with the diabetes team. Monitoring of ketones using blood ketone meters that measure beta-hydroxybutyrate is preferred over monitoring of urine ketone strips, due to easier sampling, lower rates of hospitalization/emergency department visits, and the potential for earlier and more accurate identification of clinical worsening or improvement.[376–378]

Insulin Dosing During Sick Days

The degree of hyperglycemia and ketosis, along with the rate of change of these parameters, helps guide insulin dose adjustments. Supplemental rapid-acting insulin boluses (correction doses or 5–20% of the total daily insulin dose, TDD) should be given every 2 to 3 hours while ketones persist; see Table 36.9 for bolus dosing suggestions. For ketones with hypoglycemia, consider reducing basal rates for a short period of time for patients on insulin pumps. For ketones, hypoglycemia, and decreased oral intake over a prolonged period, consider reducing the insulin glargine dose for patients on MDI and basal rates for those on insulin pumps.

Prevention/Treatment of Dehydration During Sick Days

Persons with T1DM and ketonemia require extra fluid due to risk of dehydration. A reasonable target oral fluid intake is 0.5 to 1.0 ounce per year of age per hour (maximum of 8 ounces/hour). The type of drink should be adjusted according to blood glucose levels such that when blood glucose is 250 mg/dL (~14 mmol/L) or less, rehydrate with sugar-containing clear liquids (e.g., sports drinks, soda, popsicles, oral electrolyte solution), and when blood glucose is greater than 250 mg/dL (14 mmol/L), give sugar-free clear liquids (e.g., water, diet soda, seltzer, diet juices).

Mini-Dose Glucagon

When blood sugars remain low and ketones remain elevated, small doses of glucagon (mini-dose glucagon) may be given. As long as there are adequate hepatic glycogen stores, mini-dose glucagon can help with resolution of hypoglycemia in the setting of prolonged vomiting or fasting.[379] Glucagon should be reconstituted with the diluent in the glucagon kit, then the desired mini-dose glucagon is drawn up and administered with an insulin syringe. Table 36.10 provides information on dosing.[380]

Education

The ADA recommends yearly education on sick day management and DKA prevention for persons with T1DM and their caregivers,

TABLE 36.9 Guidelines for Insulin Adjustment With Ketones

	BG <90 mg/dL (BG <5 mmol/L)	BG 90–179 mg/dL (BG 5–9.9 mmol/L)	BG 180–249 mg/dL (BG 10–13.9 mmol/L)	BG >250 mg/dL (BG >14 mmol/L)

2–15 years	10 per year of age (range, 20–150)	0.01 per year of age (range, 0.02–0.15)	1 per year of age (range, 1–15)
Age >15 years	150	0.15	15

including the importance of insulin administration, as well as glucose and ketone monitoring.[381] Patients and families should be aware that they should seek immediate medical attention for signs of dehydration, prolonged vomiting for more than a few hours, persistent hyperglycemia (>250–300 mg/dL, >14–16.7 mmol/L), ketones that do not improve after 12 hours, or symptoms of DKA (abdominal pain, nausea, vomiting, fruity-smelling breath, hyperventilation, or altered mental status).

Treatment of DKA

Detailed guidelines for the treatment of DKA are available.[368] Immediate initial treatment of DKA begins with fluid replacement, typically with one to two intravenous fluid boluses with normal saline, 10 mL/kg each. Rehydration should begin before starting insulin therapy, and initial fluid resuscitation is then followed by continued cautious rehydration with the goal of replacing the estimated fluid deficit over the first 24 to 48 hours. Initiation of an insulin drip at a rate of 0.05 to 0.1 units/kg per hour, without an insulin bolus, should begin at least 1 hour after fluid replacement is started. Patients must be monitored very closely for clinical and biochemical response to treatment. Fluid content and rate, and occasionally insulin rate, should be titrated so that blood glucose falls gradually at a rate of 50 to 75 mg/dL per hour (2.8–4.2 mmol/L per hour). Fluid should typically contain saline with potassium, phosphate, and acetate. Bicarbonate is not typically recommended in the treatment of DKA, except in unusual circumstances related to severe acidosis or hyperkalemia. Potassium replacement is usually required due to total-body potassium depletion, but potassium supplementation should be deferred until urine output is documented.

The Pediatric Emergency Care Applied Research Network (PECARN) Fluid Therapies Under Investigation in DKA (FLUID) study was a multisite prospective randomized factorial trial examining long- and short-term neurologic outcomes associated with the rate of intravenous fluid administration (rapid or slow) and the sodium chloride content of intravenous fluids (0.9% or 0.45%).[382] In the 1389 episodes of DKA reported in 1255 children, the primary outcome of a decline in mental status (two consecutive Glasgow Coma Scale scores <14; possible scores range from 3–15) was met in 48 episodes of DKA (3.5%) and was not associated with either the rate of fluid administration or the sodium chloride content of the fluids. Secondary neurologic outcomes including clinically apparent brain injury during treatment for DKA, short-term memory, and memory and IQ measured 2 to 6 months after recovery from DKA were also not associated with fluid administration rate or content.

One important cause of morbidity and mortality in DKA is cerebral edema. Risk factors for cerebral edema include young age (<5 years), new-onset T1DM, longer duration of symptoms, lower initial pH, higher initial blood urea nitrogen, treatment with bicarbonate, and serum sodium concentrations increasing during initial treatment of DKA. In patients at high risk of cerebral edema, or suspected of having cerebral edema, timely intervention with mannitol or hypertonic saline is important.

Other Complications

Hypoglycemia is the other major acute complication of T1DM and is discussed in Chapter 38. Chronic complications are discussed in Chapter 37.

Comorbidities

There is a higher prevalence of additional autoimmune conditions among persons with T1DM compared with the general population. In an analysis of more than 25,000 participants in the T1D Exchange Registry, 27% of children and adults with T1DM were diagnosed with one or more additional autoimmune diseases, and prevalence was higher in those of older age, female sex, and non-Hispanic white race.[383] The most common comorbidities are thyroid dysfunction and celiac disease, but autoimmune primary adrenal insufficiency (Addison disease), Graves disease, inflammatory bowel disease, collagen vascular disease, skin disease, and others can occur as well. Regular assessment for signs and symptoms

of other autoimmune diseases and periodic screening in asymptomatic individuals is recommended.

Thyroid Disease

Approximately 20% of individuals with T1DM have hypothyroidism or hyperthyroidism, making thyroid disease the most common autoimmune disorder associated with T1DM.[383] The ADA and ISPAD recommend measuring thyroid antibodies and thyroid-stimulating hormone (TSH) levels soon after diagnosis of T1DM.[381,384] One large study of children with T1DM found that about 25% of children had positive thyroid peroxidase autoantibodies at the time of T1DM diagnosis.[385] Thyroid function tests may be slightly abnormal at the time of T1DM diagnosis due to sick euthyroid syndrome; if this is the case, thyroid function tests should be reassessed once glycemic control improves. If antibodies are negative and TSH levels are normal soon after diagnosis, regular measurement of TSH concentrations is recommended every 1 to 2 years, and sooner if the patient develops any new symptoms or signs concerning for thyroid dysfunction, including thyromegaly, abnormal growth pattern, or unexplained fluctuations in blood glucose level. There is some evidence that subclinical hypothyroidism is associated with decreased linear growth velocity and increased risk of symptomatic hypoglycemia.[386]

Celiac Disease

Celiac disease is the second most common coexistent autoimmune disorder in patients with T1DM, is diagnosed in 2% to 8% of youth with T1DM and is more prevalent in those who were younger at T1DM diagnosis and those of white race.[383,387,388] Introduction of gluten-containing foods between 4 and 6 months of age (compared with introduction in the first 3 months of life or in the seventh month or later) in infants at increased risk for celiac disease and T1DM appears to mitigate the risk of celiac disease.[389] Individuals with T1DM and celiac disease may experience increased glycemic variability and unexplained hypoglycemia.[390] The ADA and ISPAD recommend screening for celiac disease in children with T1DM soon after diagnosis and at regular intervals after diagnosis (ADA: rescreen within 2 years and again after 5 years; ISPAD: screen every 1–2 years).[381,384] Screening labs include immunoglobulin A (IgA) tissue transglutaminase antibodies, with documentation of normal total serum IgA levels; if an individual is found to be IgA deficient, send immunoglobulin G–specific antibody tests. More frequent screening may be necessary if symptoms develop or in children who have a first-degree relative with celiac disease. If screening tests are positive, referral to gastroenterology is recommended before prescribing a gluten-free diet. Typically, a biopsy is done to confirm the diagnosis of celiac disease, especially in asymptomatic children.[391] In symptomatic individuals with high antibody titers, some providers may prescribe dietary changes without a confirmatory biopsy. Once the diagnosis is confirmed, children with celiac disease should be placed on a gluten-free diet and be referred to a dietitian experienced in managing both diabetes and celiac disease, because the nutritional management of a person with both T1DM and celiac disease can be complex and burdensome. A gluten-free diet may reduce gastrointestinal complaints, metabolic symptoms, and hypoglycemia.[392]

Complications of Diabetes Mellitus

MICHAEL BROWNLEE, LLOYD P. AIELLO, JENNIFER K. SUN, MARK E. COOPER, EVA L. FELDMAN, JORGE PLUTZKY, AND ANDREW J.M. BOULTON

CHAPTER OUTLINE

KEY POINTS

- Chronic hyperglycemia causes retinopathy and nephropathy. The effects of former high HbA_{1c} levels can persist for years of subsequent lower HbA_{1c} values. Both chronic hyperglycemia and the consequences of insulin resistance cause neuropathy, atherosclerosis, and cardiomyopathy. In some patients, chronic unresolved inflammation is as great a cardiovascular disease risk factor as high blood pressure and cholesterol. Mitochondrial dysfunction is a component of many mechanisms underlying complications.
- Proliferative diabetic retinopathy and diabetic macular edema can both cause severe visual loss. Treatment of diabetic macular edema with intraocular injection of vascular endothelial growth factor (VEGF) inhibitors—medications that inhibit vascular endothelial growth factor—reduces diabetes-induced abnormal retinal thickening and improves long-term visual acuity outcomes. Treatment with panretinal photocoagulation reduces blindness from proliferative diabetic retinopathy by over 90%. Intraocular anti-VEGF therapy can now also effectively treat proliferative diabetic retinopathy.
- Chronic diabetic kidney disease increases the risk of cardiovascular disease and death. Optimal management includes early control of blood pressure using renin-angiotensin-aldosterone system blockade and other agents, control of hyperglycemia (glucagon-like peptide-1 [GLP1]) analogs and sodium glucose cotransporter-2 (SGLT2) inhibitors that may be more renoprotective, and control of dyslipidemia.
- Diabetic neuropathies include distal symmetric polyneuropathy, mononeuropathies, and a variety of autonomic neuropathies. Loss of heart rate variability due to autonomic neuropathy increases the risk of cardiac events more than fourfold. The cornerstone of treatment is blood glucose control. Specific antidepressants, anticonvulsants, and the γ-aminobutyric acid (GABA) analogue pregabalin are used to treat painful neuropathy.
- Prediabetes and diabetes both substantially increase risk of coronary disease, early and late myocardial infarction fatality rates, and risk of congestive heart failure, even after adjustment for other cardiovascular risk factors. Hyperglycemia and insulin resistance interact synergistically with hypertension and dyslipidemia. Optimal treatment includes intensive lowering of low-density lipoprotein (LDL) cholesterol with early use of statins or other agents, blood pressure control, and use of glucose-lowering agents that have proven efficacy to reduce cardiovascular events, including metformin, GLP1 receptor agonists, and SGLT2 inhibitors. In general, coronary artery bypass grafting may provide better outcomes than coronary stenting in patients with diabetes. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) reduce post–myocardial infarction mortality risks.
- Diabetic foot ulcers are the major cause of nontraumatic leg amputation. Risk factors are sensory neuropathic loss of proprioception, motor neuropathic foot deformity, and peripheral vascular disease. Simple clinical interventions reduce amputation by up to 80%. Management involves pressure off-loading, parenteral antibiotics for infection, and ensuring adequate arterial inflow.

Biochemistry and Molecular Cell Biology

Clinical Overview

All forms of diabetes mellitus are characterized by insufficient or absolute lack of insulin secretion, insulin resistance, altered fuel metabolism, and development of diabetes-specific complications in the eye, kidney, and peripheral nerve. Diabetes is also associated with accelerated atherosclerosis affecting arteries of the heart, brain, and lower extremities. In coronary arteries, diabetic atherosclerosis is more diffuse, with greater inflammatory infiltrate and larger necrotic core size.[1] Diabetes increases heart failure risk fourfold, and doubles both early and late post–myocardial infarction fatality rates.[2] As a consequence of these complications, diabetes is the leading cause of new blindness in people 20 to 74 years old,[3] the leading cause of end-stage renal disease (ESRD), and the

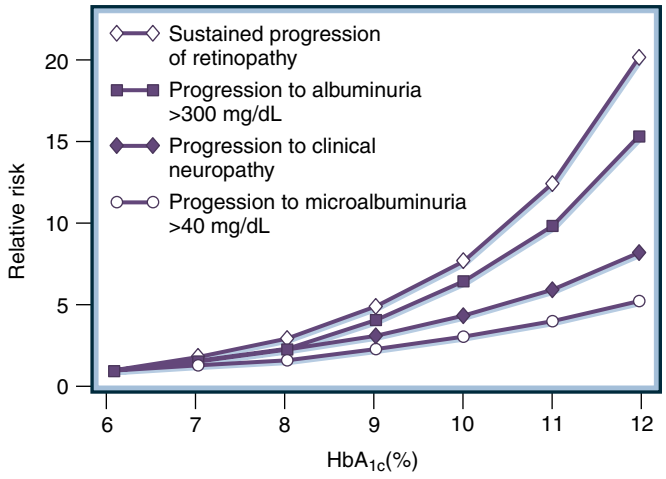
leading cause of both neuropathy and nontraumatic lower extremity amputations. Life expectancy for patients with diabetic ESRD is under 4 years. Neuropathy affects more than 60% of patients with diabetes. Diabetic neuropathy includes distal symmetric polyneuropathy, mononeuropathies, and a variety of autonomic neuropathies causing cardiac arrhythmias, hypotension, erectile dysfunction, urinary incontinence, gastroparesis, and nocturnal diarrhea.

Overall life expectancy is about 11 to 13 years shorter for people with type 1 diabetes mellitus (T1DM), and 7 to 10 years shorter for people with type 2 diabetes mellitus (T2DM) compared to people without diabetes.[4–6] Accelerated cardiovascular disease is the leading cause of death in people with both T1DM and T2DM diabetes. T1DM patients diagnosed before the age of 10 years have a 30-fold increased risk of coronary heart disease and acute myocardial infarction occurring in their early adult years.[7] While the incidence of diabetes-related ESRD, acute myocardial infarction, and amputation has declined over the past 25 years, the rates are still 10-fold higher than for the overall adult population.[8]

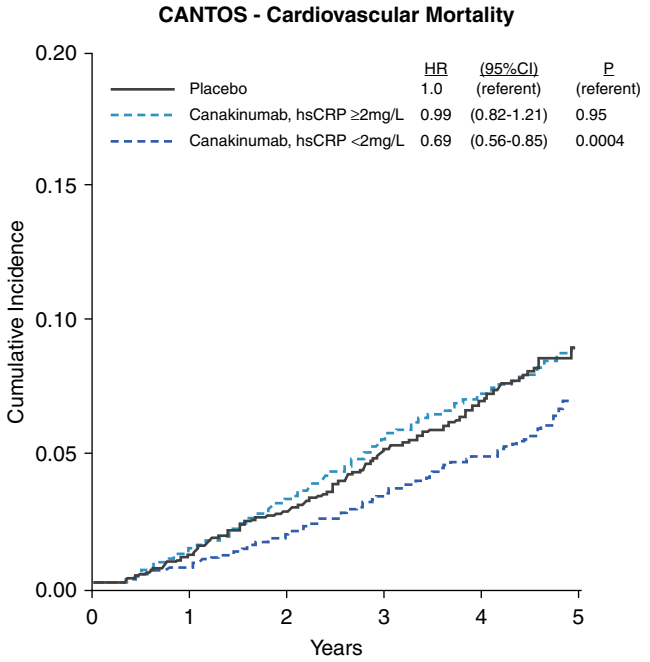
A strong relationship between hyperglycemia and diabetic retinopathy and nephropathy has been demonstrated in both T1DM and T2DM large prospective clinical studies—the Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS), respectively.[9,10] There is a continuous (although not linear) relationship between the level of glycemia and the risk of development and progression of these microvascular complications (Fig. 37.1). In T1DM, hyperglycemia is similarly associated with neuropathy, while in T2DM, it is more closely associated with the consequences of insulin resistance/hyperinsulinemia.[11,12] In contrast to the beneficial effects of glycemic reduction on microvascular complications, a meta-analysis of randomized controlled trials shows reduction in myocardial infarction rates but limited benefits of intensive glucose-lowering treatment on all-cause mortality and deaths from cardiovascular causes.[13] While consequences of insulin resistance/hyperinsulinemia and chronic hyperglycemia both play a role in the pathobiology of diabetic cardiovascular complications, the consequences of insulin resistance/hyperinsulinemia may play a larger role.[14,15] In the San Antonio Heart Study, for example, individuals with normal glucose tolerance and higher insulin resistance had twice the 8-year risk of adverse cardiovascular outcomes than those with lower insulin resistance, even after adjustment for 11 risk factors.[16,17]

Chronic, unresolved systemic inflammation is a cardiovascular risk factor independent of traditional lipid and nonlipid risk factors. In healthy men followed prospectively as part of the Physician's Health Study, those with the highest quartile concentrations of high sensitivity C-reactive protein (hsCRP) had a 2.9-fold greater risk of myocardial infarction than those in the lowest quartile, a magnitude of independent risk as great as hypertension and cholesterol.[18] Directly reducing inflammation with canakinumab, an interleukin 1β (IL1β) neutralizing monoclonal antibody, reduced cardiovascular event rates in a population receiving lipid-lowering therapy at baseline. The greatest reduction occurred among those achieving hsCRP concentrations below 2 mg/L[19] (Fig. 37.2). Individuals with and without diabetes had similar magnitude of benefit from canakinumab suggesting the IL1β pathway is not unique to diabetes. Chronic inflammation also contributes to chronic kidney disease, mediated in part by activation of the NLRP3 (nucleotide-binding oligomerization domain-like receptors [NLR] family pyrin domain containing three) inflammasome in renal cells. Inhibition of IL1β with canakinumab also reduced major cardiovascular event rates among high-risk patients with chronic kidney disease.[20] Recent studies suggest defective resolution of chronic inflammation is also a general feature of most diabetic complications.

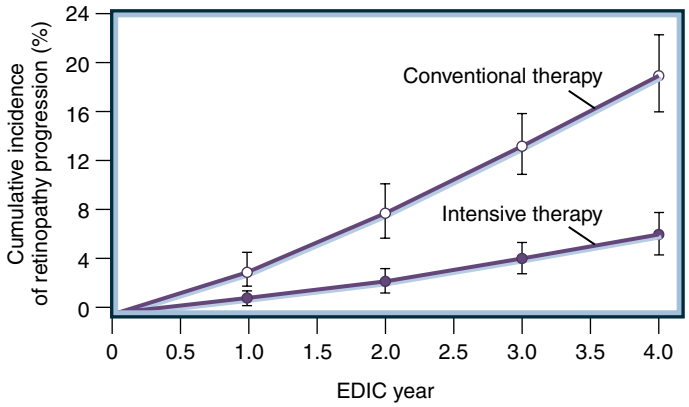
For each of the complications of diabetes, the effects of former high HbA_{1c} levels can persist for years after HbA_{1c} values



• **Fig. 37.1** Relative risks for the development of diabetic complications at different mean levels of glycosylated hemoglobin (HbA_{1c}) in patients with type 1 diabetes obtained from the Diabetes Control and Complications Trial. (Adapted from Skyler J. Diabetic complications: the importance of glucose control. *Endocrinol Metab Clin North Am*. 1996;25:243–254.)



• **Fig. 37.2** Cumulative incidence and hazard ratios of cardiovascular mortality among CANTOS participants allocated to either placebo or canakinumab according to whether postrandomization on-treatment hsCRP levels were above or below 2 mg/L. Hazard ratios are adjusted for age, sex, smoking status, hypertension, diabetes, body mass index, baseline concentration of hsCRP, and baseline concentration of LDL-C. *CI,* Confidence interval; *HR,* hazard ratio. (From Aday AW, Ridker PM. Anti-inflammatory therapy in clinical care: the CANTOS trial and beyond. *Front Cardiovasc Med*. 2018;5:62.)



• **Fig. 37.3** Cumulative incidence of further progression of retinopathy 4 years after the end of the Diabetes Control and Complications Trial. The median glycosylated hemoglobin level was 8.2% for the conventional therapy group and 7.9% for the intensive therapy group. *EDIC,* Epidemiology of Diabetes, Interventions, and Complications Research Group. (Modified from Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Research Group, Lachin JM, Genuth S, et al. Retinopathy and nephropathy in patients with type 1 diabetes four years after a trial of intensive therapy. *N Engl J Med*. 2000;342:381–389.)

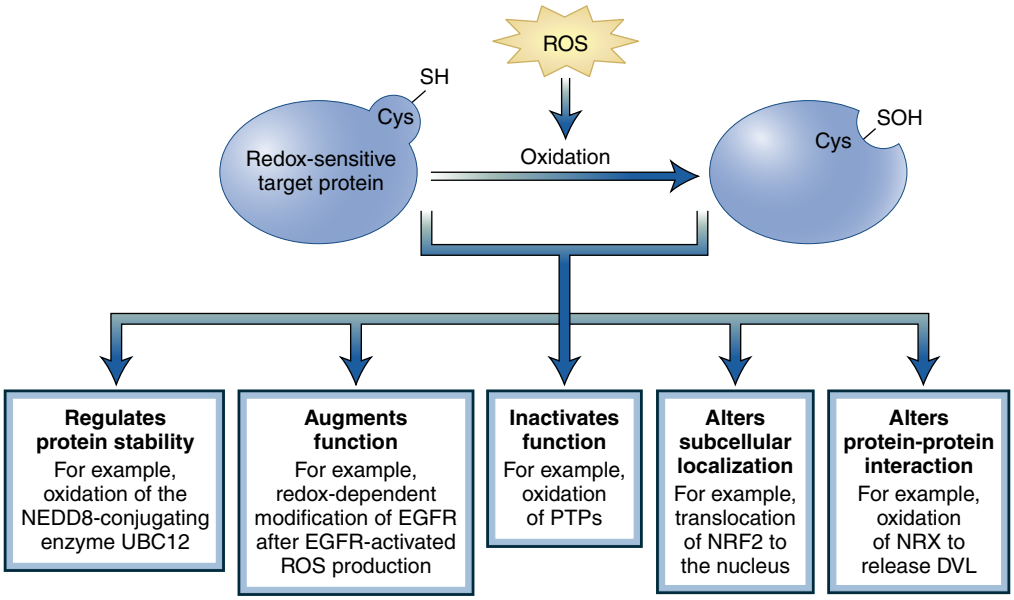
have been lowered (called "metabolic memory" by the DCCT and long-term observational follow-up Epidemiology of Diabetes Interventions and Complications [EDIC] study investigators and "a legacy effect" by the UKPDS investigators). Data from DCCT/EDIC studies proved effects of former intensive and conventional therapy persist for at least 18 years.[21,22] In the conventional therapy group, effects of previous high HbA_{1c} on poststudy retinopathy, nephropathy, and major adverse cardiovascular events (MACE; comprised of nonfatal myocardial infarction or stroke, or cardiovascular death) persisted as if there had been no improvement in HbA_{1c} at all (Fig. 37.3). Atherosclerotic changes not even present at the end of the DCCT appeared subsequently in the previously higher HbA_{1c} group, followed by a twofold increase in heart attacks, strokes, and cardiovascular death, even though the HbA_{1c} level in these patients since the end of the DCCT was identical to that of the formerly intensive-control group during the entire time that these arterial changes developed.[23] On the other hand, the beneficial effects of previous lower HbA_{1c} persisted in the intensive treatment group after their HbA_{1c} increased after the DCCT intervention ended, as if there had been no deterioration in their HbA_{1c}.

Thus T1DM patients in the DCCT with long-term exposure to a higher level of hyperglycemia during the study became more susceptible to damage despite subsequent lower levels of hyperglycemia than when they first started the trial. In contrast, lower levels of hyperglycemia during the trial made patients more resistant to damage from subsequent higher levels. Data from long-term follow-up studies from the UKPDS confirm a similar effect for T2DM patients associated with intensive glucose control, long after the cessation of randomized intervention.[24]

Much current knowledge about diabetic complication mechanisms comes from studies in murine models and of cultured cells. Murine models are valuable tools for defining the pathogenesis of diabetic complications. However, it is important to recognize the limits of murine models. No diabetic animal model, regardless of genetic background, develops the advanced stages of human diabetic complications, such as proliferative retinopathy, end-stage renal failure, significant nerve fiber loss, or complex atherosclerotic plaques and plaque rupture, nor do they develop the degree of fibrosis seen in human hearts with late-stage diabetes–associated heart failure. Also, since much of the mechanistic data currently available from studies of cell and mouse models reflect the earliest stages of each complication, mechanisms dominant in the pathogenesis of later stages of each complication are likely different from those dominant in the early stages. Recent proteomic, genomic, and molecular studies of tissue from patients with longer duration of diabetes have contributed to enormous recent progress in understanding the biochemical, molecular, and cellular mechanisms involved in the pathogenesis of diabetic complications. Many of the multiple mechanisms discussed in this section share a common element: prolonged increases in reactive oxygen species (ROS) production in cells critical for the development of diabetic complications in the retina, kidney, peripheral nerve, arteries, and heart. In diabetic mouse models, transgenic overexpression of mitochondrial superoxide dismutases or catalase prevents retinopathy,[25] nephropathy,[26,27] neuropathy,[28] atherosclerosis,[29] and cardiomyopathy.[30,31]

Physiologic Reactive Oxygen Species Production Is Essential for Normal Intracellular Signaling and Cellular Homeostasis

In normal physiology, ROS production is coupled to metabolic networks and circadian clocks, and ROS species (hydrogen peroxide, H_2O_2) function as signaling molecules essential for normal cellular homeostasis.[32–34] Physiologic ROS (H_2O_2) signaling is essential for normal intracellular communication, cell differentiation, autophagy, response to insulin and growth factor stimulation, and the generation of physiologic inflammatory responses. ROS regulate protein stability, augment protein function, inactivate function, alter subcellular localization, and alter protein-protein interactions (Fig. 37.4). In normal cardiovascular function, for example, enhanced production of H_2O_2 from a mitochondrial source of superoxide leads to increased flow rates in human coronary resistance vessels. H_2O_2 hyperpolarizes and dilates human coronary arterioles through opening of Ca^{2+}-activated K^+ channels. Catalase, a scavenger of H_2O_2, greatly inhibits this flow-induced dilation.[35] Similarly, H_2O_2 exerts a beneficial effect on vasodilator function and reduces blood pressure in transgenic mice with endothelium-targeted nicotinamide adenine dinucleotide phosphate (NADPH) oxidase 4 (Nox4) overexpression.[36] In the heart, low levels of hydrogen peroxide induce proliferation of mouse embryonic stem cells as well as neonatal cardiomyocytes, and ROS induce expression of cardiac-specific genes, transcription factors, and growth factors in embryonic stem cells. These effects are dampened by free radical scavengers. ROS also act as transducers of mechanical strain–induced cardiovascular differentiation of embryonic stem cells.[37] ROS-dependent activation of integrins and subsequent induction of PI3-K/Akt (phosphatidylinositol-4,5-bisphosphate 3-kinase/RACα/β serine/threonine-protein kinase) signaling are also involved in cyclic strain–mediated cardiomyogenesis.[38] Localized ROS production contributes to stretch-induced augmentation of cardiac contractile activity as well.[39] Physiologic excitation–contraction coupling in heart muscle may also involve ROS signaling as physiologic stretch rapidly activates NOX2 located on sarcolemma and T tubule membranes in cardiomyocytes.[39] The local ROS produced sensitizes ryanodine receptors in the sarcoplasmic reticulum. This triggers a burst of Ca^{2+} sparks, thereby increasing Ca^{2+} signaling sensitivity in healthy cardiomyocytes. Thus ROS



• **Fig. 37.4** The multiple ways in which oxidant signaling can affect cellular function. Oxidation of a reactive cysteine residue SH (thiol) to SOH (sulphenic acid) leads to an alteration in the reduction-oxidation (redox)–sensitive target that can then have myriad effects on protein stability, activity, localization, or protein-protein interaction. *Cys,* Cysteine; *DVL,* dishevelled; *EGFR,* epidermal growth factor receptor; *NEDD8,* neural precursor cell expressed developmentally down regulated-8; *NRF2,* nuclear related factor-2; *NRX,* nucleoredoxin; *PTP,* protein tyrosine phosphatase; *ROS,* reactive oxygen species. (From Holmström KM, Finkel T. Cellular mechanisms and physiological consequences of redox-dependent signaling; UBC12, ubiquitin carrier protein 12. *Nat Rev Mol Cell Biol*. 2014;15:411–421.)

production at the right time, place, level, and duration plays a crucial role in physiologic homeostasis.[40] However, ROS production at too high a level, for too long, or at an inappropriate subcellular location, leads to impaired cellular function and diabetic tissue pathology.

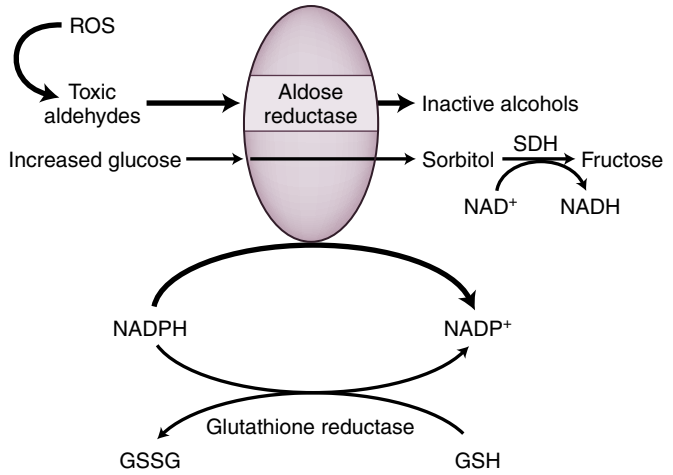
Recent data suggest the site at which ROS are generated is as important as the amount of ROS produced.[41] ROS generated by mitochondrial complex III are released into the mitochondrial matrix, intermembrane space, outer membrane, and cytosol. In contrast, ROS generated by mitochondrial complex I are released into the matrix. ROS from these two sites reacted with distinct subsets of proteins involved in different physiologic pathways.[42] Importantly, ROS from mitochondrial complex I caused a high percentage of irreversible overoxidations of cysteine thiols, consistent with persistent oxidative damage. They also cause nuclear deoxyribonucleic acid (DNA) double-strand breaks and oxidize mitochondrial DNA, both of which have adverse consequences.[43–45] In contrast, ROS from mitochondrial complex III caused reversible oxidation of cysteine thiols, consistent with their function as redox switches in critical signaling pathways. Use of indiscriminate antioxidants, which block both the damaging and the physiologic effects of mitochondrial ROS, likely explain the negative findings of clinical trials with selected antioxidant compounds.

Mechanisms of Hyperglycemia-Induced Damage

Increased Aldose Reductase Substrate Conversion

Aldose reductase (AKR1B1), a member of the large aldo-keto reductase superfamily, catalyzes reduction of a wide variety of hydrophobic and hydrophilic carbonyl-containing compounds—including glucose and several glycolytic intermediates—to their corresponding alcohols. This enzyme is cytosolic and requires NADPH as a cofactor. In some cell types, where glucose is converted to the sugar alcohol sorbitol, sorbitol is then converted to fructose by another enzyme, sorbitol dehydrogenase, using NAD^+ (nicotinamide adenine dinucleotide) as a cofactor. This series of reactions, termed the *polyol pathway,* has been implicated in the pathogenesis of several diabetic complications. However, the amount of substrate converted to product per second (K_{cat}) of human aldose reductase for glucose is 0.15 [s^{-1}]. K_{cat} values for most enzymes are between 1 and 10^4. Moreover, because the intracellular glucose concentration in capillary retinal endothelial cells incubated in 25 mM glucose is approximately 0.15 mM,[46] while the K_m of aldose reductase for glucose reported by Bohren and coworkers is 100 mM and the K_{cat}/K_m is 1.3 [s^{-1} M^{-1}], the predicted rate of aldose reductase reduction of glucose to sorbitol in microvascular endothelial cells would be expected to be rather low. However, aldose reductase has high affinity and enzyme activity for a variety of other substrates, including several glycolytic intermediates such as glyceraldehyde 3-phosphate, and its degradation product, methylglyoxal.[47,48] AKR1B1 also efficiently reduces oxidative stress-generated lipid aldehydes such as 4-hydroxynonenal with a K_m in the micromolar range (10–30 μM) as compared to a K_m of 50–100 mM for glucose[49] (Fig. 37.5).

In vivo studies of aldose reductase inhibition in a 5-year study in dogs showed that diabetic neuropathy was prevented, but aldose reductase inhibition failed to prevent retinopathy or capillary basement membrane thickening in the retina, kidney, or muscle.[50] In response to this preclinical result with neuropathy, 32 clinical trials were completed in the 1990s and early 2000s.[51] None of these trials showed clinical efficacy. In diabetic apolipoprotein E (ApoE) knockout mice, overexpression of human aldose reductase accelerated atherosclerosis, and pharmacologic inhibition of the enzyme

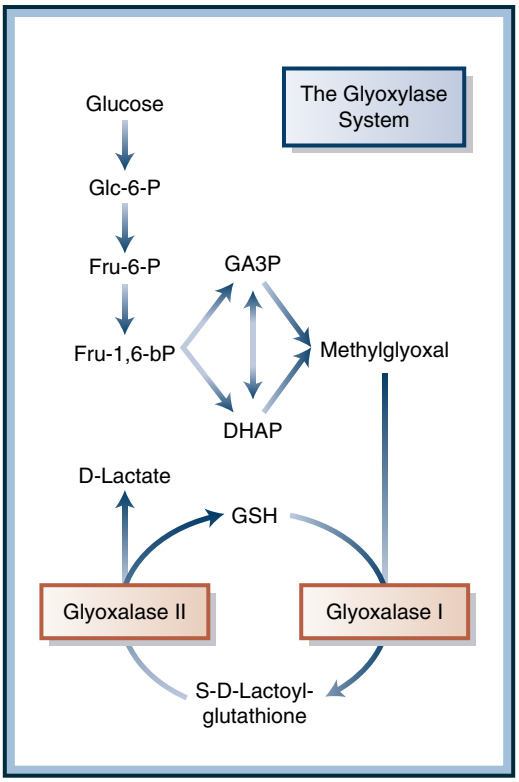


• **Fig. 37.5** Aldose reductase (AKR1B1) catalyzes reduction of the ROS-generated and the polyol pathway. Aldose reductase reduces reactive oxygen species (ROS)–generated toxic aldehydes such as lipid-derived 4-hydroxynonenal to inactive alcohols, and in some cell types, glucose to sorbitol, using triphosphopyridine nucleotide (NADPH), the reduced form of nicotinamide adenine dinucleotide phosphate ($NADP^+$), as a cofactor. It also reduces glyceraldehyde 3-phosphate and its reactive degradation product methylglyoxal. *GSH,* Reduced glutathione; *GSSG,* oxidized glutathione; *SDH,* sorbitol dehydrogenase.

prevented this.[52] In contrast, in mice expressing physiologic levels of aldose reductase, knockout or pharmacologic inhibition of the enzyme unexpectedly caused increased early atherosclerotic lesion size in both diabetic and nondiabetic mice.[53] Differences in total enzyme activity, cofactor levels, and levels of alternative intracellular substrates, coupled with known differences in enzyme kinetics for different substrates, likely explain these seemingly paradoxic observations.

Increased Intracellular Formation of the Major Advanced Glycation End Products—Precursor Methylglyoxal

The post-translational modifications of proteins called advanced glycation end products (AGEs) are formed by glucose-derived dicarbonyls reacting with amino groups of unprotonated lysine and arginine residues of proteins. Methylglyoxal, formed by the nonenzymatic fragmentation of the glycolytic intermediate triose phosphate, accounts for the majority of hyperglycemia-induced increase in AGE adducts in diabetic tissues.[54] Intracellular methylglyoxal is detoxified by the glyoxalase system.[55] The enzyme glyoxalase I, together with glyoxalase II and a catalytic amount of glutathione, reduces this highly reactive α-oxoaldehyde to D-lactate (Fig. 37.6). In cells, methylglyoxal reacts with unprotonated arginine residues to form the major methylglyoxal-derived epitope MG-H1 (methylglyoxal hydroimidazolone 1). Intracellular production of AGE precursors damages target cells by three general mechanisms (Fig. 37.7). First, AGE modification of intracellular proteins changes their function. Second, AGE modification of extracellular matrix components alters their interaction with other matrix components and with integrin matrix receptors. Third, intracellular methylglyoxal increases expression of both the pattern recognition receptor for AGEs (RAGEs) and its major endogenous ligands, the proinflammatory S100 calgranulins.[56] Ligation of these ligands with RAGE causes cooperative interaction with the innate immune system signaling molecule toll-like receptor 4 (TLR4).[57] Expression of RAGE, S100A8, S100A12, and high mobility group box 1 (HMGB1) are all increased by



• **Fig. 37.6** Intracellular methylglyoxal, the major advanced glycation end product (AGE) precursor, is detoxified by the glyoxalase system. The enzyme glyoxalase I, together with glyoxalase II and a catalytic amount of glutathione, reduces this highly reactive α-oxoaldehyde to D-lactate. *DHAP,* Dihydroxyacetone phosphate; *GA3P,* glyceraldehyde 3-phosphate; *GSH,* glutathione; *Glc-6-P,* glucose-6-phosphate; *Fru-6-P,* fructose-6-phosphate; *Fru-1,6-bP,* fructose-1,6-bisphosphate. high glucose concentrations in cell culture and in diabetic animals. This hyperglycemia-induced overexpression is mediated by ROS-induced increases in methylglyoxal, which increase binding of the transcription factors nuclear factor-κB (NFκB) and activator protein 1 (AP1) to the promoters of RAGE and of RAGE ligands, respectively.[56]

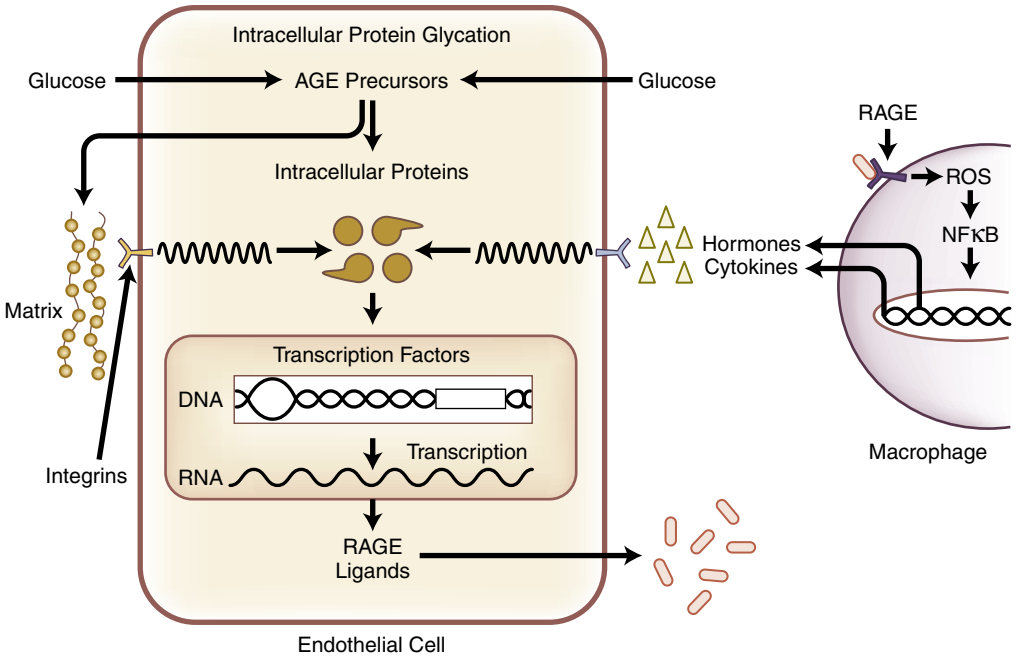
Diabetes increases levels of the major methylglyoxal-derived adduct in retina, renal glomerulus, and sciatic nerve of rats.[58,59] In the retina, diabetic mice with knockouts of four transient receptor potential cation channels (Trpc1/4/5/6 mice) have increased levels of glyoxalase 1 protein and activity, which protects them from the initial phenotype of diabetic retinopathy, pericyte dropout, and acellular capillary formation.[60] In the kidneys of nondiabetic mice, knockdown of glyoxalase I (GLO1) increases to diabetic levels both methylglyoxal modification of glomerular proteins and oxidative stress, causing alterations in kidney morphology indistinguishable from those caused by diabetes, while in kidneys of diabetic mice, GLO1 overexpression completely prevents diabetes-induced increases in methylgloxal modification of glomerular proteins, increased oxidative stress, and the development of diabetic kidney pathology, despite unchanged levels of diabetic hyperglycemia.[61]

Increased levels of methylglyoxal may contribute to painful diabetic neuropathy by altering the function of the voltage-gated sodium channel Nav1.8. Nav1.8 is expressed exclusively



• **Fig. 37.7** Potential mechanisms by which intracellular production of advanced glycation end product (AGE) precursors damage vascular cells. First, intracellular protein modification alters protein function. Second, extracellular matrix modified by AGE precursors has abnormal functional properties. Third, intracellular methylglyoxal increases expression of both the receptor for AGEs (RAGE) and its major endogenous ligands. Ligand binding to RAGE induces receptor-mediated production of deleterious gene products such as cytokines. *NFκB,* Nuclear factor-κB; *ROS,* reactive oxygen species. (Adapted from Brownlee M. Lilly lecture 1993: glycation and diabetic complications. *Diabetes*. 1994;43:836–841.)

in unmyelinated, small-diameter sensory neurons called C fibers. Post-translational modification of Nav1.8 by methylglyoxal depolarizes sensory neurons, facilitating firing of these pain pathway neurons. In streptozotocin-induced and genetic mouse models of diabetes but not in Nav1.8 knockout ($Scn10^{-/-}$) diabetic mice,[62] post-translation modification of Nav1.8 by methylglyoxal increased electrical excitability and facilitated firing of pain pathway neurons, which in turn facilitated neurosecretion of calcitonin gene-related peptide, increasing cyclooxygenase-2 (COX2) expression. Methylglyoxal treatment also evoked thermal and mechanical hyperalgesia, reflected by increased blood flow in brain regions that are involved in pain processing. Plasma methylglyoxal concentrations above 600 nM discriminated between diabetes-affected individuals with painful neuropathy and those without pain.

Increased methylglyoxal is also an important element in the pathogenesis of both diabetic atherosclerosis and diabetic cardiomyopathy. In nondiabetic ApoE null mice, increasing plasma methylglyoxal levels to diabetic levels using a glyoxalase-1 inhibitor caused endothelial inflammation and atherogenesis similar to that induced by diabetes mellitus.[63] In human atherosclerotic plaques, MG-H1 (methylglyoxal hydroimidazolone 1) levels were associated with rupture-prone plaques having increased levels of the inflammatory mediators IL8 and monocyte chemotactic protein-1 (MCP1), and higher matrix metalloproteinase-9 (MMP9) activity. MG-H1 was primarily found in lesion macrophages surrounding the necrotic core, and co-localized with cleaved caspase-3.[64] In the diabetic heart, methylglyoxal preferentially reacts with both ryanodine receptor 2, the major myocardial intracellular mediator of calcium-induced calcium release, and with sarcoplasmic reticulum Ca^{2+} ATPase (SERCA2a), which is responsible for the synchronized reuptake of released intracellular calcium.[65] This coordinated process of calcium cycling is critical for efficient cardiac contractions, and diabetes-induced defects caused by increased methylglyoxal adduct formation likely contribute to impaired systolic function.

Increased methylglyoxal production also seems to be responsible for poor cardiac stem cell–mediated repair and angiogenic capacity.[66] Cardiac stem cells from biopsies of hearts from human diabetics were less able to repair postinfarction damage in immunodeficient mice than cardiac stem cells from nondiabetic patients, and conditioned medium from these cells had less angiogenic capacity. Culture of nondiabetic murine cardiac stem cells in high glucose induced the same cardiac repair and angiogenesis defects seen in human diabetic cells. In both human and mouse cells, overexpression of GLO1 restored the angiogenic defects.[66] In diabetic mice with defective postischemia hindlimb revascularization, overexpression of the methylglyoxal-metabolizing enzyme GLO1 exclusively in bone marrow cells was sufficient to restore bone marrow cell function and neovascularization of ischemic tissue in diabetes mellitus.[67]

Increased methylglyoxal also activates the unfolded protein response in cardiomyocytes.[68] Although transient activation of the unfolded protein response relieves endoplasmic reticulum (ER) stress, prolonged activation of the unfolded protein response in cardiovascular disease triggers apoptosis, mediated by the downstream effector C/EBP-homologous protein (CHOP). CHOP plays a critical role in macrophage apoptosis, a process involved in plaque necrosis in advanced atheromata. In $Chop^{-/-}Apoe^{-/-}$ mice, lesion area plaque necrosis was reduced by 50%. In high fat–fed $ApoE^{-/-}$ and low-density lipoprotein (LDL) $receptor^{-/-}$ mice, CHOP promoted plaque growth, apoptosis, and plaque necrosis.[69] In cardiomyocytes, methylglyoxal also induces apoptosis via CHOP.[68] Infusion of methylglyoxal in nondiabetic mice induced

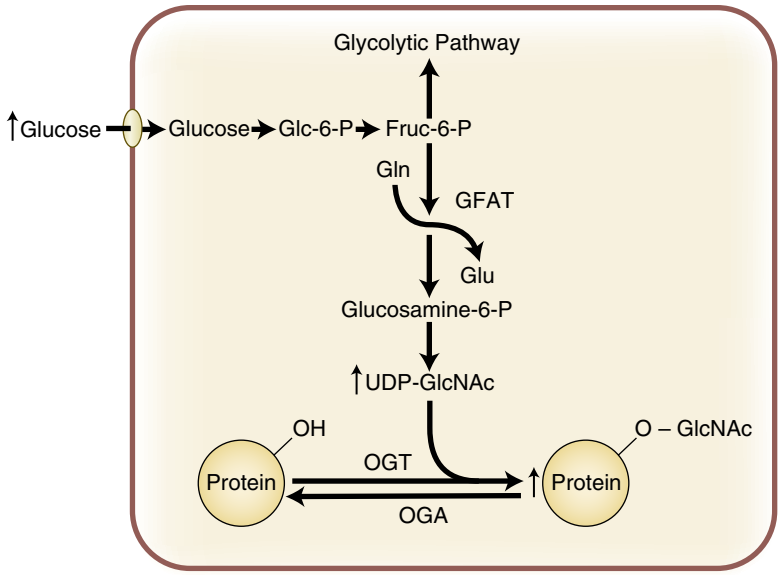
cardiomyocyte apoptosis, inflammation, and a significant reduction in left ventricular fractional shortening and left ventricular ejection fraction. Each of these adverse effects was prevented in *CHOP*$^{-/-}$ mice. In the hearts of diabetic mice, overexpression of GLO1 in the vasculature[70] prevented diabetes mellitus–induced reduction of myocardial capillary density, increased apoptosis, and loss of cardiac function. Neuregulin production, which transduces signals between the heart's microvasculature and cardiomyocytes,[71] endothelial nitric oxide synthase (eNOS) dimerization, and expression of the antiapoptotic protein BCL-2 were also maintained in the diabetic *GLO1* transgenic hearts.

Activation of Protein Kinase C β, δ, and θ

Protein kinase C (PKC) is a family of protein kinase enzymes with 15 isoforms that are involved in the regulation of protein function. Nine of these 15 PKC isoforms are activated by a lipid second messenger, diacylglycerol. Elevated intracellular glucose increases diacylglycerol levels in a variety of diabetic target tissues, including arterial smooth muscle cells and cardiomyocytes, by de novo synthesis.[72–74] Hyperglycemia primarily activates the β and δ isoforms of PKC, but increases in activity of several other isoforms have also been found (Fig. 37.8). These PKC isoforms can also be activated by intracellular ROS in the absence of diacylglycerol or Ca^{2+}. The regulatory domain of these PKC isoforms contains two pairs of zinc fingers with six cysteine residues and two zinc atoms, which can be oxidized by intracellular ROS. Oxidation alters zinc-finger conformation and activates PKC.[75] Intracellular hyperglycemia activates PKC in retina and glomeruli of diabetic animals.[72,76] In contrast to other complication-prone tissues, total PKC activity is reduced in the peripheral nerve of diabetic animals. Schwann cell PKCα activity is reduced, while vascular wall PKCβII activity is increased.[77]

In early experimental diabetes, activation of PKCβ isoforms mediates retinal and renal blood flow abnormalities,[78] perhaps by depressing nitric oxide (NO) production and increasing endothelin-1 activity. In the diabetic retina, hyperglycemia persistently activates PKC and p38a mitogen-activated protein kinase (MAPK) to increase expression of a previously unknown target of PKC signaling, Src homology-2 domain-containing phosphatase-1 (SHP1), a protein tyrosine phosphatase. This signaling cascade leads to platelet-derived growth factor (PDGF) receptor-β dephosphorylation and a reduction in downstream signaling from this receptor, resulting in pericyte apoptosis.[79] Abnormal activation of PKC also has been implicated in the decreased glomerular production of NO induced by experimental diabetes[80] and in the decreased smooth muscle cell NO production induced by hyperglycemia.[81] PKC activation also mediates glucose-enhanced extracellular matrix accumulation in rat glomerular mesangial cells.[82] Hyperglycemia increases endothelin 1–stimulated MAPK activity in glomerular mesangial cells by activating PKC isoforms.[83] The increased endothelial cell permeability induced by high glucose concentrations in cultured cells is mediated by activation of PKCα.[84] Activation of PKC by elevated glucose levels also induces expression of the permeability-enhancing vascular endothelial growth factor (VEGF) in vascular smooth muscle cells.[85] In addition to affecting hyperglycemia-induced abnormalities of blood flow and permeability, activation of PKC contributes to increased matrix protein accumulation, inducing expression of transforming growth factor beta-1 (TGFβ1), fibronectin, and α1 type IV collagen in glomeruli of diabetic rats.[80] Many cellular abnormalities involved in diabetic cardiovascular disease have also been linked to PKC activation. These include endothelial dysfunction, increased vascular permeability, impaired angiogenesis, and increased apoptosis. Molecular mechanisms affected by diabetes-induced PKC



• **Fig. 37.9** Schematic representation of the hexosamine biosynthetic pathway (HBP). The glycolytic intermediate fructose 6-phosphate (Fruc-6-P) is converted to glucosamine 6-phosphate (GlcN-6-P) by the enzyme glutamine:fructose-6-phosphate amidotransferase (GFAT). Increased donation of *N*-acetylglucosamine moieties from UDP-GlcNAc to serine and threonine residues of proteins by *O*-GlcNAc transferase (OGT) and their removal by *O*-GlcNAcase (OGA) affect proteins that regulate gene expression, translation, protein degradation, signal transduction, protein localization, epigenetics, and mitochondrial bioenergetics. *Glc,* Glucose, *GlcNAc, N*-acetylglucosamine; *OGT, O*-linked *N*-acetylglucosamine (GlcNAc) transferase; *UDP,* uridine diphosphate. activation include alterations in functionally significant enzymatic activities, such as mitogen-activated protein kinase, cytosolic phospholipase A2, and Na^+-K^+-ATPase, and alterations in several transcription factors.[86]

Hyperglycemia-induced activation of PKCβ promotes vascular inflammation and acceleration of atherosclerosis in diabetic ApoE null mice by augmenting expression of inflammatory mediators. In addition, it increases macrophage expression of cluster of differentiation 11c (CD11c), chemokines (C-C motif ligand 2), and interleukin-1β, via increased extracellular signal-regulated kinase 1 and 2 (ERK1 and ERK2), and c-Jun-N terminus kinase (JNK)–mitogen-activated kinase.[87] In this same diabetic model, PKCβ activation increased transcription of the proinflammatory cytokine IL18 and inhibited transcription of IL18-binding protein in the aorta. Diabetic mice showed increased plaque formation, cholesteryl ester content, and macrophage infiltration. Treatment with a PKCβ inhibitor prevented these.[88] PKCβ2 in endothelial cells from transgenic ApoE null mice overexpressing PKCβ decreased insulin- stimulated Akt/eNOS (endothelial nitric oxide synthase) activation and increased basal and angiotensin-induced expression of the vasoconstrictor endothelin-1. These dual effects increased endothelial dysfunction and accelerated atherosclerosis in this model compared with $ApoE^{-/-}$ mice.[89]

PKC activity has been linked to myocardial dysfunction, causing cardiomyopathy and cardiac failure. Selective overexpression of PKCβ2 in the myocardium of diabetic mice increased expression of connective tissue growth factor and transforming growth factor-β1, cardiomyopathy, and cardiac fibrosis.[90] More recently, activation of PKCα/β in diabetic hearts has been shown to mediate reactivation of fetal splicing programs by phosphorylation and upregulation of the RNA-binding proteins CUGBP elav-like family member 1 (CELF1) and RNA binding fox-1 homolog 2 (Rbfox2).[91] Chronic activation of PKC isozymes α, β, and δ promotes diastolic and systolic dysfunction, fibrosis, cardiomyocyte hypertrophy, and apoptosis[92] Another PKC isoform, PKCθ, plays crucial roles in the proliferation, differentiation, and activation of mature T cells via activation of several transcription factors in the nuclei of T cells, including nuclear factor of activated T cells (NFAT), c-Jun, c-Fos, and AP1. Diabetes-induced cardiac interstitial fibrosis, reduced contractility, reduced expression of the tight junction maintaining protein ZO1, and T-cell infiltration were all improved by treatment with an isoform-specific PKCθ inhibitor.[93]

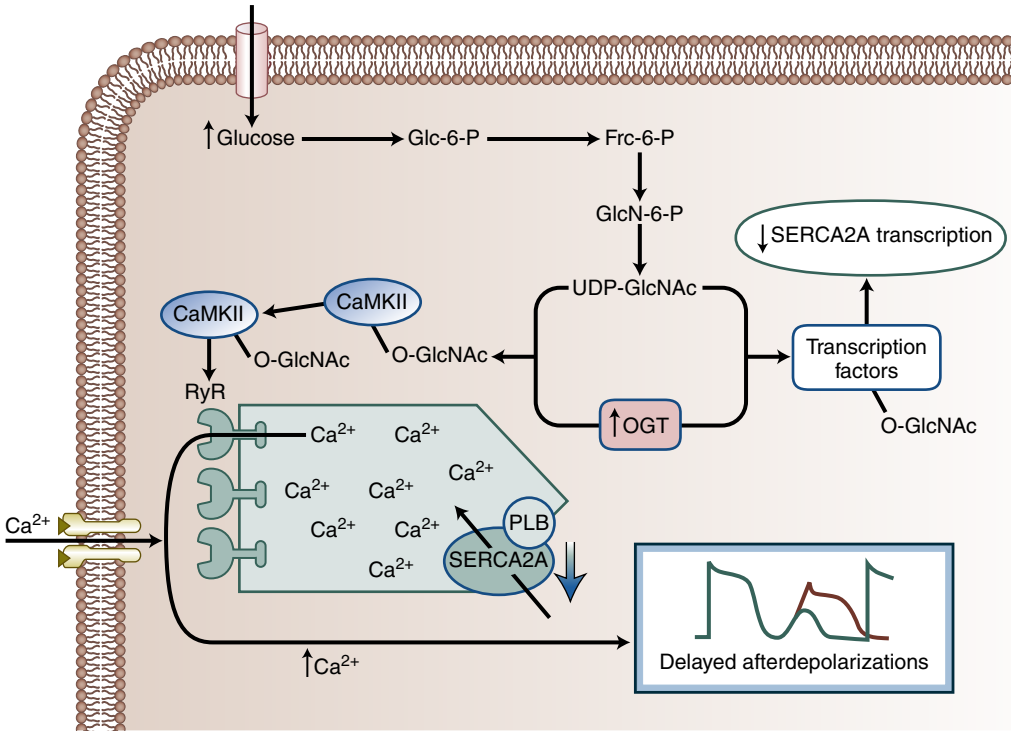
Increased Protein Modification by O-GlcNAc

The hexosamine pathway causes reversible post-translational modification of intracellular protein serine and threonine residues by *N*-acetylglucosamine. *O*-GlcNAc modifies proteins that regulate gene expression, translation, protein degradation, signal transduction, protein localization, epigenetics, and mitochondrial bioenergetics.[94] In cells damaged by hyperglycemia, excess intracellular glucose provides increased fructose-6-phosphate, which is converted to glucosamine-6-phosphate by the rate-limiting enzyme glutamine:fructose-6-phosphate amidotransferase. Glucosamine-6-phosphate is further converted to *N*-acetylglucosamine-6-phosphate (GlcNAc-6-P) and finally to UDP-*N*-acetylglucosamine (UDP-GlcNAc). The enzyme *O*-GlcNAc transferase (OGT) uses UDP-GlcNAc to transfer *N*-acetylglucosamine to a variety of proteins, resulting in increased protein modification by *N*-acetylglucosamine. Another enzyme, *N*-acetylglucosaminidase (*O*-GlcNAcase [OGA]), removes this protein modification (Fig. 37.9). Alternative splicing of the genes encoding the *O*-linked GlcNAc cycling enzymes OGT and OGA yields isoforms targeted to discrete sites in the nucleus,

cytoplasm, and mitochondria. *O*-GlcNAc serves as a nutrient/stress sensor regulating cellular homeostasis by altering signaling, transcription, metabolism, organelle biogenesis, cytoskeletal dynamics, and apoptosis.[95,96] Aberrant *O*-GlcNAc processing reduced mitochondrial protein expression and respiration, mitochondrial proteins involved in the respiratory chain and the tricarboxylic acid (TCA) cycle were decreased, and mitochondrial morphology was altered.[97]

In mouse coronary endothelial cells isolated from diabetic mice, *O*-GlcNAcase protein expression was significantly decreased compared with coronary endothelial cells from control mice. In contrast, OGT protein expression was markedly increased.[98] The resultant increased protein modification by *O*-GlcNAc was responsible for decreased endothelium-dependent relaxation of the coronary arteries and reduced capillary density in the left ventricle. Both of these defects were restored by overexpression of *O*-GlcNAcase. Decreased endothelium-dependent relaxation of the coronary arteries and reduced capillary density both reflect inhibition of eNOS, which is required for endothelium-dependent arterial relaxation and for mobilization of stem and progenitor cells from the bone marrow compartment.[99] In human arterial endothelial cells, activation of eNOS by phosphorylation at serine 1177 is inhibited directly by hyperglycemia-induced *O*-GlcNAcylation at this site.[100] eNOS activity is also affected by several other post-translational modifications, but the effect of diabetes on these has not yet been determined.[101] Carotid plaques from diabetic patients have a marked increase of *O*-GlcNAcylation in both cytoplasm and nuclear compartments of endothelial cells compared with nondiabetic subjects.[102] Increased *O*-GlcNAcylation may also contribute to diabetes-accelerated atherosclerosis by increasing ubiquitination and proteasomal degradation of the anti-inflammatory NFκB inhibitory protein A20 in coronary endothelial and smooth muscle cells.[103]

Chronically elevated *O*-GlcNAc levels also adversely affect myocardial function. Cardiac effects of increased *O*-GlcNAcylation include decreased mitochondrial function, decreased autophagic signaling, and decreased contractile function.[104] Ventricular contraction and relaxation are controlled mainly by release and uptake of Ca^{2+} by the SERCA2 pump. In hypertrophied and failing myocardium, SERCA2 protein level and its Ca^{2+} uptake function are depressed. Overexpression of OGT significantly reduced transcription of SERCA2, causing decreased calcium reuptake and impaired diastolic relaxation.[105] High glucose also increased *O*-GlcNAc modification of the calcium^{2+}/calmodulin-dependent protein kinase IIδ (CaMKIIδ), an enzyme critical for Ca^{2+} homeostasis and reuptake in cardiomyocytes. *O*-GlcNAc-modified CaMKII at serine 279 is increased in the heart of diabetic humans and rats,[106] causing autonomous activation of CaMKII. Thus CaMKII remains activated even after intracellular Ca^{2+} declines. This contributes to decreased cardiac contractility and potentially fatal arrhythmias, such as premature ventricular complexes and delayed afterdepolarizations (Fig. 37.10). Delayed afterdepolarizations are associated with the initiation of long QT-interval arrhythmias such as torsade de pointes. Overexpression of GlcNAcase or



• **Fig. 37.10** Hyperglycemia-induced myocardial protein modification by β-linked *N*-acetylglucosamine (*O*-GlcNAc) causes increased intracellular Ca^{2+} and delayed afterpolarizations. Increased *O*-GlcNAc modification of calcium/calmodulin-dependent protein kinase IIδ (CaMKII) causes autonomous CaMKII activation. CaMKII increases intracellular Ca^{2+} by phosphorylating ryanodine receptor 2 (RyR). *O*-linked *N*-acetylglucosamine (GlcNAc) transferase (OGT) also modifies transcription complex factors regulating expression of sarcoplasmic reticulum Ca^{2+}-ATPase *(SERCA2a),* reducing SERCA2A expression and contributing to increased intracellular Ca^{2+}. Increased *O*-GlcNAc modification of these proteins causes delayed afterdepolarizations in cardiomyocytes. *PLB,* Phospholamban. (Redrawn from Shah M, Brownlee M. Molecular and cellular mechanisms of cardiovascular disorders in diabetes. *Circ Res.* 2016;118:1808–1829.)

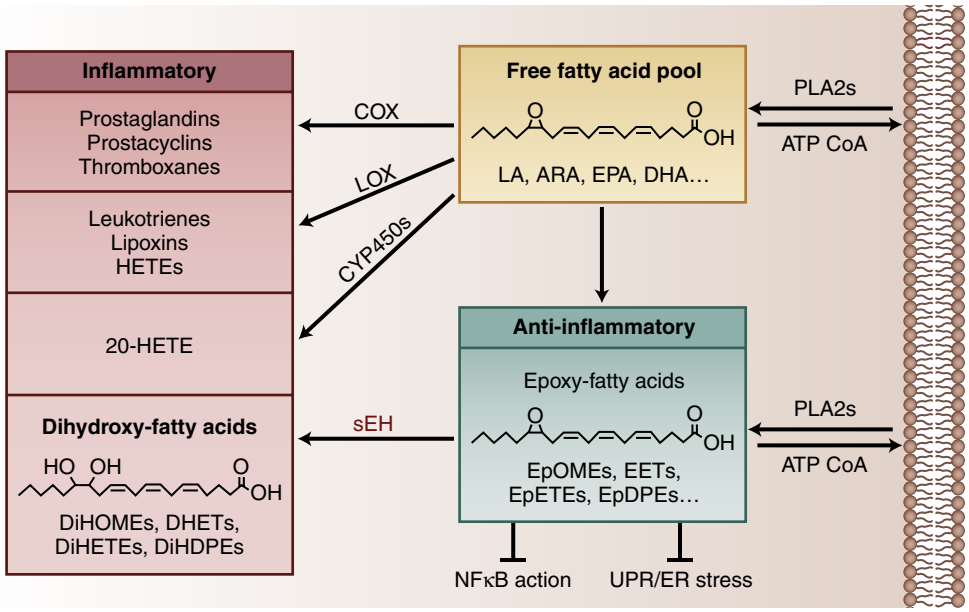
inhibition of GlcNAc modification increased expression of *SERCA2a*, ablated sarcoplasmic reticulum Ca^{2+} leak, improved cardiac contractility, and reduced arrhythmic events. Increased levels of ROS also cause autonomous activation of CaMKII by oxidation of adjacent methionine residues in its regulatory domain.[107] Activation of this mitochondrial ROS–oxidized CaMKII pathway increased mortality after myocardial infarction in diabetic mouse models.[108] Mitochondrial OGT is increased in diabetic cardiac mitochondria, whereas *O*-GlcNAcase (OGA) is reduced, causing increased *O*-GlcNAcylation of cardiac mitochondrial proteins. Inhibition of OGA and the resulting increased mitochondrial protein modification by *O*-GlcNAc increases oxygen consumption and reduces reserve capacity.[109] Reduced bioenergetic reserve capacity makes cells more sensitive to stress and cell death.

Increased Soluble Epoxide Hydrolase

Soluble epoxide hydrolase (sEH) is the dominant member of the epoxide hydrolase family in humans. It binds to specific epoxides such as epoxyeicosatrienoic acids (EETs) and rapidly converts them to less active or inactive dihydrodiols, the dihydroxy-eicosatrienoic acids (diHETrEs). EETs are signaling molecules formed from arachidonic acid by cytochrome P450 enzymes such as CYP2J2. In cell and animal models EETs have major anti-inflammatory activity.[110] They reduce activation of NFκB, causing transcriptional downregulation of the proinflammatory enzymes inducible nitric oxide synthase (iNOS), lipoxygenase 5 (LOX5), cyclooxygenase 2 (COX2), and of several pro-inflammatory cytokines (Fig. 37.11). EETs also prevent the signaling cascade activated by the three major unfolded protein response/ER stress pathway sensors: inositol requiring protein 1α (IRE1α), protein kinase RNA-like endoplasmic reticulum kinase (PERK), and activating transcription factor 6 (ATF6).

Expression of sEH was increased in diabetic mouse retinas and in retinas and vitreous humor of patients with diabetes.[111] As a consequence, levels of the sEH diol product 19,20-dihydroxydocosapentaenoic acid (19,20-DHDP) were increased. Nonproliferative diabetic retinopathy is characterized by pericyte loss and endothelial cell dysfunction. 19,20-DHDP prevented the association of presenilin 1 with N-cadherin and VE-cadherin in retinal vessels, compromising pericyte-endothelial cell interactions and interendothelial cell junctions.[111] Inhibition of sEH prevented the early nonproliferative stage of diabetic retinopathy in animal models. Similarly, sEH in glomerular podocytes is a significant contributor to hyperglycemia-induced renal injury. Podocyte sEH deficiency was associated with attenuated hyperglycemia-induced renal endoplasmic reticulum stress, inflammation and fibrosis, and enhanced autophagy. These effects were recapitulated in immortalized murine podocytes treated with a selective sEH pharmacologic inhibitor.[112] EETs and other epoxides also reduce pain caused by diabetic peripheral neuropathy.[113]

In the arterial wall, anti-inflammatory actions of EETs include attenuation of cytokine-induced endothelial activation and leukocyte adhesion, prevention of endothelium-dependent vascular remodeling, and improvement of vascular inflammation and endothelial dysfunction. EETs also inhibit platelet aggregation and promote fibrinolysis, and may inhibit vascular smooth muscle cell proliferation. In human studies, two single nucleotide polymorphisms in the sEH coding region of the *EPHX2* gene are associated with increased risk of developing coronary artery disease in different populations. Caucasians homozygous for the nonsynonymous K55R allele, with higher apparent soluble epoxide hydrolase activity in vivo, have a 3.5-fold increased risk of developing coronary heart disease.[114] Low levels of EET and high levels of soluble epoxide hydrolase are also associated with cardiac hypertrophy.



• **Fig. 37.11** Overview of the three proinflammatory branches of the arachidonic acid cascade generated by cyclooxygenase (COX), lipoxygenase (LOX), and cytochrome P450 (CYP450s). Opposing these are the anti-inflammatory epoxy fatty acids generated by P450 enzymes such as CYP2J2. These anti-inflammatory epoxides are reduced to their corresponding 1,2-diols by the enzyme soluble epoxide hydrolase. *ARA,* Arachidonic acid; *DHA,* docosahexaenoic acid; *EETs,* epoxyeicosatrienoic acids; *EPA,* eicosapentaenoic acid; *EpDPEs,* DHA epoxygenase metabolites; *EpETEs,* epoxyeicosatetraenoic acids; *EpOMEs,* cis epoxy fatty acids; *ER,* endoplasmic reticulum; *HETE,* hydroxyeicosatetraenoic acid; *LA,* linoleic acid; *NFκB,* nuclear factor kappa-light-chain-enhancer of activated B cells; *PLA2,* phospholipase A2; *sEH,* soluble epoxide hydrolase, *UPR,* unfolded protein response. (Modified from Morisseau C, Hammock BD. Impact of soluble epoxide hydrolase and epoxyeicosanoids on human health. *Annu Rev Pharmacol Toxicol.* 2013;53:37–58.)

Increasing EETs by inhibition of soluble epoxide hydrolase lowers fetal gene markers of cardiac hypertrophy, reduces heart size, and decreases cardiac fibrosis in animal models.[115–118] EETs appear to act in part by reducing inflammation in cardiomyocytes.

Upregulation of sEH decreases levels of the arachidonic acid-derived inflammation stop signal lipoxin A4, while inhibition of sEH increased lipoxin A4 by increasing its EET precursor.[119] Lipoxins are one of four classes of proresolving mediators of inflammation.[120,121] Lipoxin A4 is a polymorphonuclear cell (PMN) stop signal that limits further recruitment. It also stimulates macrophage efferocytosis, the phagocytosis of apoptotic PMNs and debris. A failure to resolve arterial inflammation, which normally involves the suppression of inflammatory cell influx, effective clearance of apoptotic cells, and promotion of inflammatory cell egress, promotes the progression of atherosclerotic lesions into unstable plaques, which can trigger atherothrombotic vascular events.[122,123]

Reduced Pyruvate Kinase M2 Activity

The less active isoform of the glycolytic enzyme, pyruvate kinase M2 (PKM2), is only active as a homotetramer. Its activity can be further inhibited by tyrosine kinases, acetylation, *O*-GlycNAcylation,[124] and oxidation of cysteine residue 358.[125] Although PKM2 is expressed in normal differentiated, nonproliferating cells, the increased expression of this less active isoform in most tumors has focused attention on the potential of PKM2 to divert glycolytic intermediates toward biosynthetic pathways in tumor cells. Independent of its enzymatic activity, PKM2 can also regulate aerobic glycolysis by acting as a dual-specificity protein kinase, increasing transcription of itself, the glucose transporter GLUT1, and lactate dehydrogenase A (LDLA).[126–128] In postmortem kidneys from people with T1DM for more than 50 years, an unbiased proteomic analysis identified expression of glomerular PKM2 as a critical determinant of susceptibility or resistance to diabetic nephropathy (Fig. 37.12).[129] Individuals with no or mild nephropathy showed significant upregulation of mitochondrial encoded cytochrome C oxidase II, a subunit of mitochondrial electron transport chain complex IV, the two methylglyoxal detoxifying enzymes glyoxalase 1 and AKRB1 (aldo/keto reductase family 1 member 1B), and the antioxidant proteins superoxide dismutase 1 (SOD1) and thioredoxin. Interestingly, PKM2 protein levels in the nephropathy susceptible group were identical to nondiabetics, while protein levels in the protected group were 40-fold higher than in nondiabetics. PK enzymatic activity in the protected group were not different from PK activity in nondiabetics, while PK activity in the nonprotected group was significantly lower. The median level of sulfenylated and oxidized PKM2 was fourfold higher in the nonprotected group, consistent with the observed relative differences in PKM2 protein level versus activity. Mitochondrial cytochrome C oxidase II protein levels in glomeruli from protected diabetic individuals were also nearly 30-fold higher than in both nonprotected individuals and nondiabetic controls, and protein levels of the methylglyoxal degrading enzymes glyoxalase 1 and AKR1B1 were 10-fold higher.

Different Hyperglycemia-Induced Pathogenic Mechanisms Reflect a Single Upstream Process: Mitochondrial Overproduction of ROS

A single upstream hyperglycemia–induced process—mitochondrial overproduction of superoxide—activates all the pathogenic mechanisms described in the previous sections.[130,131] Enhanced intracellular glucose transport and oxidation leads to mitochondrial overproduction of superoxide.[43,131] This can, in turn, activate other superoxide production pathways that may amplify the original damaging effect of hyperglycemia. Examples of amplification mechanisms include increased mitochondrial fission mediated by the *rho*-associated protein kinase 1 (ROCK1),[132,133] and ROS-mediated uncoupling of eNOS dimers to superoxide-producing eNOS monomers in endothelial cells.[134] Although NADPH oxidase 4 (Nox4) has been hypothesized to be a direct source of increased ROS in the diabetic kidney,[135,136] it appears to act indirectly by increasing mitochondrial ROS production. Nox4 is constitutively active and associates with mitochondria, inhibiting mitochondrial biogenesis and function.[137] The resultant decrease in maximal respiration suggests oxidative damage to enzymes of the tricarboxylic acid (TCA) cycle, the electron transport chain (ETC), or inner mitochondrial membrane lipids has occurred.[138,139] Knockout of Nox4 increases mitochondrial biogenesis and maximal respiratory capacity dramatically, which would prevent substrate-driven increased mitochondrial ROS production.[137] Mitochondrial ROS cause activation of other NOX isoforms.[140]

The initiating role of mitochondrial ROS is suggested by the observation that cells lacking mitochondrial electron transport chain function (ρ0 cells)[43] fail to increase ROS production in response to high glucose.

Dugan and associates[141] have suggested diabetic nephropathy is caused by reduced, rather than increased, mitochondrial ROS production, based on the observation that AMPK activity is decreased in the diabetic kidney. Protein levels of the master regulator of mitochondrial biogenesis and function, PGC1α, and mitochondrial density were also decreased. These authors proposed a model in which these observations reflect a feed-forward cycle initiated and maintained by decreased mitochondrial ROS. However, in human endothelial cells, silencing of AMPK causes increased, not decreased, ROS.[142] An alternate model of a feed-forward cycle involving decreased AMPK activity and decreased mitochondrial biogenesis caused by increased mitochondrial ROS is more consistent with these and other observations. In this model, increased mitochondrial superoxide causes the release of Fe^{++} from ferritin and iron sulfur cluster–containing proteins. Interaction of this released free iron in the nucleus with mitochondrial superoxide–derived hydrogen peroxide forms hydroxyl radicals, the only ROS species capable of cleaving bonds in macromolecules (Fig. 37.13).[143] This results in ROS-mediated DNA double-strand breaks in the nucleus. DNA double-strand breaks activate DNA repair mechanisms, including the enzyme poly-ADP-ribose polymerase 1 (PARP1). Activation of PARP1 inhibits the key glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase (GAPDH) by poly-ADP-ribosylation, and depletes intracellular NAD^+ by degrading it to synthesize ADP-ribose. Inhibition of GAPDH activity causes upstream accumulation of early glycolytic intermediates, which are diverted into pathogenic signaling pathways.[43] Diversion of glucose increases polyol pathway flux, whereas diversion of fructose-6-phosphate increases hexosamine pathway activity. Diversion of glyceraldehyde-3-phosphate to α-glycerol phosphate activates PKC, and reduced activity of GAPDH diverts accumulated triose phosphates toward methylglyoxal formation. Methylglyoxal increases expression of the receptor for advance glycation end products (RAGE) and its activating ligand S100A8/9. Hyperglycemia-induced ROS reduce intracellular NAD^+ content by 50%.[144] Reduced content of NAD^+ inhibits the activity of the NAD^+-dependent protein deacetylase sirtuin 1 (SIRT1), which normally deacetylates and activates both the master regulator of mitochondrial biogenesis, PGC1α,

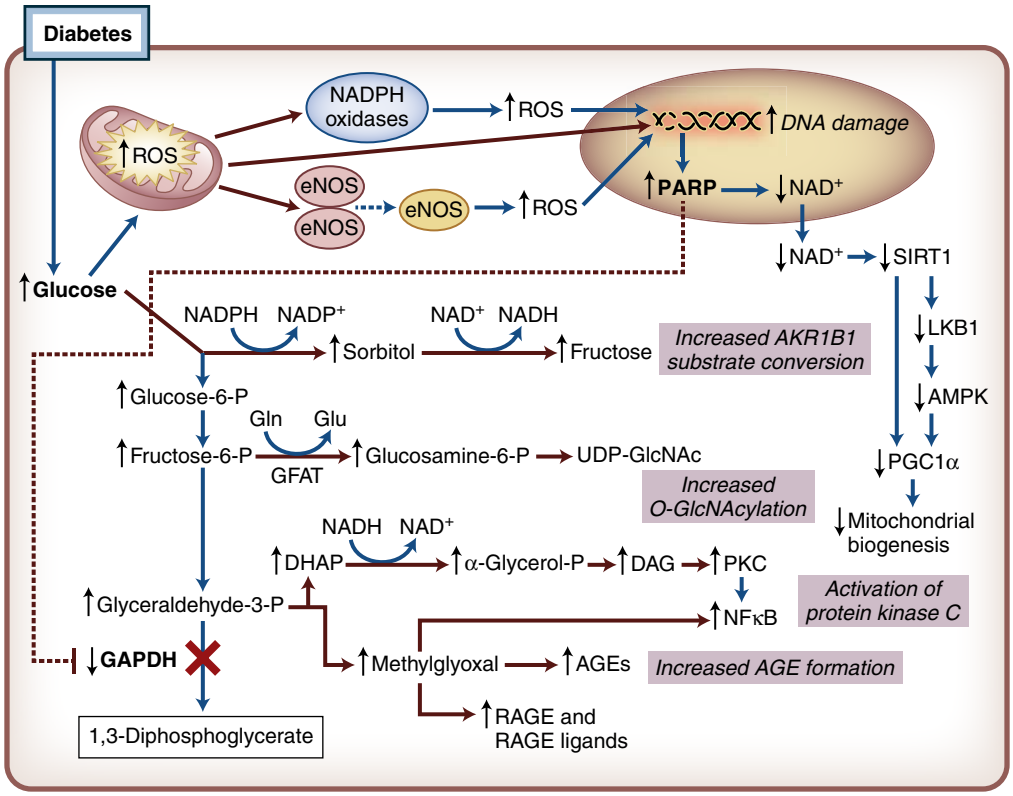
and of liver kinase B1 (LKB1), the kinase that activates AMPK. Thus decreased SIRT1 activity would decrease activity of LKB1, PGC1α, and AMPK, as observed by Nishikawa and coworkers, but causing increased, not decreased, mitochondrial ROS production.[145]

SIRT1 also deacetylates and thereby inactivates the p65 subunit of NFκB, and skews macrophages to their reparative polarity.[146] Consistent with this model, diabetic *db/db* mice with a conditional deletion of SIRT1 in podocytes developed more proteinuria and kidney injury compared with *db/db* control mice,[147]



• **Fig. 37.13** Four hyperglycemia-induced pathogenic mechanisms are activated by overproduction of reactive oxygen species (ROS). Increased intracellular glucose flux causes mitochondrial overproduction of ROS, which can be further amplified by activating NADPH oxidases and uncoupling endothelial nitric oxide synthase (eNOS). Stable ROS species (hydrogen peroxide, H_2O_2) diffuse into the nucleus, where they cause DNA damage, which activates poly(ADPribose) polymerase (PARP). Poly-ADPribosylation of glyceraldehyde-3-dehydrogenase (GAPDH) by PARP reduces GAPDH activity, causing upstream accumulation of early glycolytic intermediates, which are diverted into four pathogenic signaling pathways. PARP activity depletes intracellular NAD^+ by degrading it to synthesize ADPribose. This reduces activity of the NAD^+-dependent deacetylase sirtuin 1 (SIRT1), which reduces activity of liver kinase B1 (LKB1), the enzyme that activates AMP-activated protein kinase (AMPK), which activates peroxisome proliferator-activated receptor gamma coactivator 1α (PGC1α) by phosphorylation, and of PGC1α itself (which requires deacetylation for activation). This results in decreased mitochondrial biogenesis. *AGEs,* Advanced glycation end products; *AKR1B1,* aldose reductase; *DAG,* diacylglycerol; *DHAP,* dihydroxyacetone phosphate; *eNOS,* endothelial nitric oxide synthase; *GAPDH,* glyceraldehyde-3-phosphate dehydrogenase; *GFAT,* glutamine fructose-6-phosphate amidotransferase; *Gln,* glucosamine; *Glu,* glucose; *NAD,* nicotinamide adenine dinucleotide; *NADPH,* nicotinamide adenine dinucleotide phosphate; *NFκB,* nuclear factor-κB; *PKC,* protein kinase C; *RAGE,* receptor for AGEs; *UDP-GlcNAc,* uridine diphosphate *N*-acetylglucosamine. and PGC1α knockout diabetic mice developed a more severe neuropathy, with mitochondrial degeneration and an increase in oxidative modification of intracellular proteins.[148] Recently, real-time in vivo studies using a mitochondrial matrix localized GFP-based redox biosensor in *db*/*db* mice confirmed increased mitochondrial ROS production in diabetic nephropathy.[149]

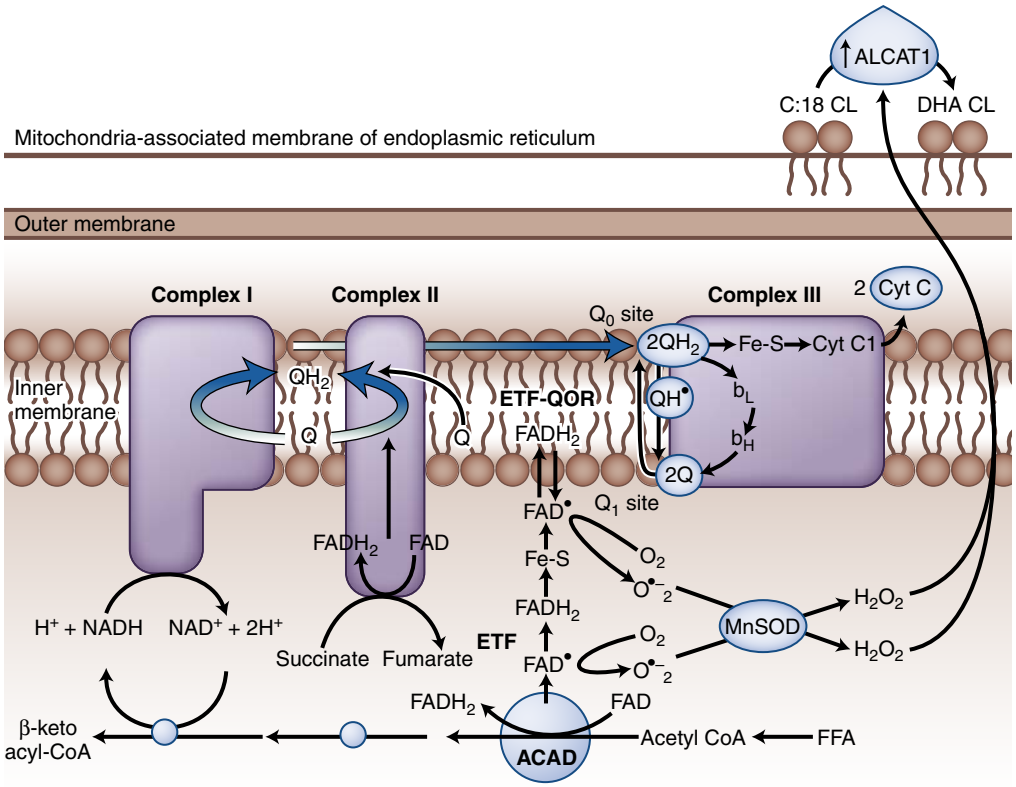
Together, these diversions and pathway activations lead to cellular dysfunction, inflammation, apoptosis, and fibrosis in cells exposed to high intracellular glucose. The central importance of ROS in initiating each of these processes is illustrated by the fact that each can be prevented when hyperglycemia-mediated ROS generation is curtailed by transgenic expression of the enzymes superoxide dismutase or catalase.

Intracellular formation of ROS also upregulates soluble epoxide hydrolase mRNA and protein in mouse endothelial cells.[150] Essential mitochondrial genes are downregulated in glomeruli of the diabetic nephropathy–susceptible mouse strain DBA/2J, but not in the diabetic nephropathy–resistant strain C57BL/6J. Diabetic nephropathy–susceptible DBA/2J mice had increased tissue levels and urinary excretion of 8-oxo-deoxyguanosine, a major product of DNA oxidation. In humans with diabetic kidney disease, biopsies showed increased mitochondrial DNA damage, and increased urinary 8-oxo-deoxyguanosine.[151] Glomerular podocyte-specific knockout of PKM2 in diabetic nephropathy–susceptible mice had reduced expression of PGC1α, reduced mitochondrial mass, increased mitochondrial fission, and increased ROS. Increased ROS caused DNA strand breaks, increased activated PKCδ, and increased methylglyoxal levels. Activities of PARP and GAPDH were not reported. These changes were associated with accelerated podocyte apoptosis and glomerular pathology. Analysis of cellular respiration using Seahorse Extracellular Flux (XF) Analyzers showed that high glucose decreased mitochondrial maximal respiration by about 36%, suggesting that oxidative damage to enzymes of the tricarboxylic acid cycle, the electron transport chain, or the inner mitochondrial membrane lipids had occurred.[138,139] In cultured podocytes and in diabetic mice, activation of PKM2 with a small molecular weight



• **Fig. 37.14** Increased fatty acid oxidation, reactive oxygen species (ROS) formation, and cardiolipin (CL) remodeling. Insulin resistance–induced increased β oxidation of free fatty acids (FFAs) causes greater H_2O_2 production than does increased glucose oxidation because of increased electron leakage from the electron transfer flavoprotein (ETF) complex. These ROS activate acyl-CoA:lysocardiolipin acyltransferase 1 *(ALCAT1)* transcription. ALCAT1, located in the mitochondrial-associated membrane of the endoplasmic reticulum, causes pathologic remodeling of cardiolipin from tetra 18:2 cardiolipin to cardiolipin with highly unsaturated fatty acid side chains and cardiolipin deficiency because of oxidative damage. This reduces ETC (electron transport chain) electron flux, ATP synthesis, and further increases ROS. *ACAD,* acyl-CoA dehydrogenase. (Redrawn from Shah M, Brownlee M. Molecular and cellular mechanisms of cardiovascular disorders in diabetes. *Circ Res.* 2016;118:1808–1829.)

activator increased mitochondrial biogenesis, normalized mitochondrial maximal respiration, prevented high glucose–induced elevated ROS, and restored levels of PKCδ and methylglyoxal to low glucose levels. These effects are consistent with increased shunting of glucose to lactate, thereby reducing nonproductive increased flux through the mitochondrial electron transport chain.

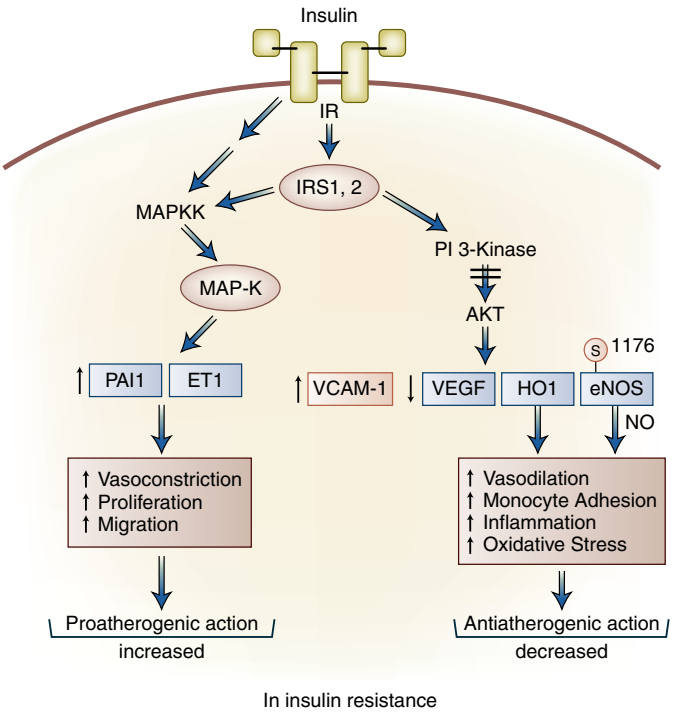
Insulin Resistance Increases Fatty Acid Oxidation, Causing Mitochondrial Overproduction of ROS

Insulin resistance occurs in most patients with T2DM. To isolate the effects of insulin resistance from those of hyperglycemia and diabetes, insulin resistance was evaluated in persons without diabetes or impaired glucose tolerance. Those in the highest quintile of insulin resistance had a 2.5-fold increase in cardiovascular disease risk compared with those in the lowest quintile, after correction for 11 known cardiovascular risk factors, including LDL, triglycerides, systolic blood pressure, and smoking.[17] This observation suggests that insulin resistance itself is a major cause of cardiovascular disease in T2DM. Adipocyte insulin resistance increases lipolysis and circulating free fatty acids (FFAs). Hydrolysis of triglyceride-rich lipoproteins by cell surface lipoprotein lipases floods the coronary arteries, heart, and liver with triglyceride-derived fatty acids. In the liver, this drives hepatic lipoprotein synthesis and secretion, and suppresses hepatic glucose production.[152–154] Patients with T1DM are also insulin resistant, with insulin sensitivity reduced by about 50%. T1DM patients have significant insulin resistance in adipose tissue, as well as in liver and skeletal muscle.[155,156] In T1DM patients, insulin resistance predicts the extent of coronary artery calcification and likely contributes to their increased risk of cardiovascular disease.[157] The role of insulin itself remains controversial. In mice fed a high-fat diet, genetically induced reduction of hyperinsulinemia decreased adipose tissue inflammation and increased insulin responsiveness.[153]

Insulin resistance/hyperinsulinemia increases mitochondrial fatty acid oxidation in arterial endothelial cells, macrophages, and cardiomyocytes, causing excessive ROS production. The major site of electron leakage from increased fatty acid oxidation is electron transfer flavoprotein, which receives electrons from the $FADH_2$ formed during the first oxidation step of β-oxidation[158] (Fig. 37.14). These fatty acid oxidation-derived ROS induce expression of the noncoding RNA *gadd7,* which amplifies oxidative stress and its induction of the endoplasmic reticulum stress response in a feed-forward loop.[159] In two insulin-resistant nondiabetic animal models, inhibition of either FFA release from adipocytes or FFA oxidation in arterial endothelium

prevented the increased production of ROS and its damaging effects.[160] In human arterial endothelial cells, this FFA-induced increase in ROS activates the same damaging pathways seen with high glucose. FFA-induced overproduction of superoxide also inactivates two important antiatherogenic enzymes: prostacyclin synthase and eNOS.[160]

In vitro studies suggest that at the level of the vessel wall, insulin has both antiatherogenic and proatherogenic effects (Fig. 37.15).[161] One major antiatherogenic effect is the stimulation of endothelial NO production. NO released from endothelial cells is a potent inhibitor of platelet aggregation and adhesion to the vascular wall. Endothelial NO also controls the expression of genes involved in atherogenesis. It decreases expression of monocyte chemoattractant protein 1 (MCP1) and of surface adhesion molecules such as CD11/CD18, P-selectin, vascular cell adhesion molecule 1 (VCAM1), and intercellular adhesion molecule 1 (ICAM1). Endothelial cell NO also reduces vascular permeability and decreases the rate of oxidation of LDL to its more proatherogenic form. Finally, endothelial cell NO inhibits proliferation of vascular smooth muscle cells (VSMCs).[162] However, in insulin resistance, overproduction of ROS leads to oxidation of tetrahydrobiopterin (BH_4), the essential cofactor of endothelial nitric oxide synthase. Decreased BH_4 uncouples oxygen reduction from NO synthesis, thereby converting eNOS to a superoxide-producing enzyme.[163] Although this important antiatherogenic effect of insulin is blocked by insulin resistance–induced ROS, two major proatherogenic effects of insulin are not. Insulin both potentiates platelet-derived growth factor (PDGF)–induced VSMC proliferation and stimulates endothelial and VSMC production of the thrombolysis-inhibitor plasminogen activator inhibitor 1 (PAI1).[164–166]



• **Fig. 37.15** Selective insulin resistance in vascular cells. Selective insulin resistance in vascular cells occurs when angiotensin II, elevated free fatty acids (FFAs) and glucose levels, and proinflammatory cytokines induced by diabetes and insulin resistance inhibit only the IRS/PI3K/Akt pathway. In contrast, insulin's stimulation of the SOS/Grb2/MAPK pathway is unaffected or even enhanced. The selective loss of insulin's actions via the IRS/PI3K/Akt pathway causes the reduction of insulin's antiatherosclerotic action and contributes to the acceleration of atherosclerosis and other cardiovascular pathologies in diabetes. *AKT,* protein kinase B; *eNOS,* endothelial nitric oxide synthase; *ET1,* endothelin-1; *HO1,* heme oxygenase-1; *ICAM,* intracellular adhesion molecule; *IR,* insulin receptor; *IRS1,2,* insulin receptor substrate 1,2; *MAP-K,* mitogen-activated protein kinase; *MAPKK,* MAPK kinase; *NO,* nitric oxide; *PAI,* plasminogen activator inhibitor; *PI,* phosphatidylinositol; *TNF,* tumor necrosis factor; *VCAM1,* vascular cell adhesion molecule-1; *VEGF,* vascular endothelial growth factor; *VSMC,* vascular smooth muscle cell. Selective insulin resistance and the development of cardiovascular diseases in diabetes: the 2015 Edwin Bierman Award Lecture. *Diabetes.* 2016;65:1462–1471.)

Macrophages are a central participant in atherogenesis. While most atherosclerotic lesions are stable, insulin resistance increases macrophage ROS, which drive chronic inflammation and accelerate their progression to unstable rupture-prone plaques. These plaques have a greater inflammatory infiltrate, a larger prothrombotic necrotic core, and increased production of matrix metaloproteinases that weaken the fibrous cap. Insulin resistance in macrophages induces mitochondrial ROS production by activating the CHOP branch of the stress unfolded protein response (UPR).[167,168] Plaque necrosis is caused by a combination of increased macrophage apoptosis and decreased phagocytic clearance of the apoptotic macrophages by a process called *efferocytosis,* which results in post–apoptotic necrosis of apoptotic cells and inflammation. Both of these processes are promoted by macrophage insulin resistance.[169] Apoptotic cells can inappropriately express the ROS-TNFα-NFκB-inducible "don't eat me" cell surface signal CD47,[170] and efferocyte receptors on phagocytes such as MER tyrosine kinase (MerTK) can be cleaved and inactivated by the mitochondrial ROS-activated protease ADAM17 (a disintegrin and metalloproteinase).[171] Blocking antibodies to CD47 prevent progression of established lesions, protect against plaque rupture, and induce regression of the necrotic core in several mouse models.[123,170,172,173]

Fatty acid oxidation appears to be the source of mitochondrial ROS production in macrophages, directly or indirectly via altered mitochondrial cardiolipin fatty acid composition.[174,175] When fatty acids are oxidized instead of glucose, the ratio of NADH to $FADH_2$ changes from 5:1 to 2:1. This causes an overreduction of the mitochondrial electron transport chain coenzyme Q (CoQ) pool, and an increase in reverse electron transport (RET) and ROS production by complex I. ROS from mitochondrial electron transport chain complex I cause a high percentage of irreversible overoxidation of cysteine thiols.[41,42] Reverse electron transport to complex I, driven by increased complex II oxidation of the TCA cycle intermediate succinate, drives the polarization of macrophages to a proinflammatory phenotype.[176]

In diabetic heart, increased myocardial ROS production occurs early, before accumulation of triglycerides and subsequent synthesis of C16:0 ceramides are evident.[177,178] This likely reflects increased fatty acid oxidation and resultant oxidative damage to mitochondrial cardiolipin,[179] the specific phospholipid of mitochondrial membranes. Cardiolipin is important for efficient electron flux, ATP synthesis, and reduced ROS formation. In addition, cardiolipin is involved in mitochondrial-mediated apoptosis, and it plays a critical role in regulating mitochondrial fission and fusion.[180–182] In nondiabetic heart, the major species of cardiolipin contains four linoleic acids (tetra 18:2 cardiolipin). This unique acyl composition is not derived from de novo synthesis of cardiolipin, but rather from a remodeling process that involves phospholipases and acyltransferase-transacylases. In diabetic myocardium from murine models with insulin resistance (*ob/ob, db/*

db, and high-fat diet) and in models of severe insulin deficient type 1 diabetes, the fatty acyl content of the more saturated 18:2 cardiolipin is dramatically reduced, whereas the content of longer chain, more unsaturated fatty acyl cardiolipin such as 20:4 is substantially increased.[183] Because of this increase in highly unsaturated side chains, diabetic heart cardiolipin is more vulnerable to oxidative damage. Cardiac overexpression of cardiolipin synthase increases tetra 18:2 cardiolipin in diabetic mice and prevents diabetes-induced changes in cardiolipin lipid remodeling. The cardiolipin deficiency and profound remodeling caused by diabetes and insulin resistance is caused by ROS-induced transcription of acyl-CoA:lysocardiolipin acyltransferase 1 *(ALCAT1)* (see Fig. 37.14). ALCAT1 catalyzes the transfer of linoleoyl-CoA onto monolysocardiolipin or dilysocardiolipin. Overexpression of ALCAT1 caused cardiolipin deficiency and fatty acid compositional changes similar to diabetes and obesity, with increased production of ROS, whereas ALCAT1 deficiency increased levels of tetra 18:2 cardiolipin in mouse heart and reduced ROS production.[184]

High levels of ROS are also a major proximal activator of the FOXO family of transcription factors. Increased ROS stimulate FOXO translocation from the cytosol into the nucleus by increasing FOXO GlcNAcylation, Jun-N-terminus kinase signaling, and CaMKII activation.[185,186] Cysteine oxidation also increases FOXO transcriptional output. In the hearts of diabetic mice and of mice with high-fat diet–induced insulin resistance, FOXO proteins were persistently activated.[187] This persistent activation was associated with downregulation of insulin receptor substrate 1 (IRS1), reduced activity of IRS1 and its downstream target Akt, and the development of cardiomyopathy. In cardiomyocyte-specific FOXO1 knockout mice fed a high-fat diet, neither insulin resistance nor cardiomyopathy occurred.

Diabetes Reduces Activity of Nuclear Erythroid-Related Factor 2, the Master Regulator of Antioxidant Gene Expression

The number of recognized ROS-regulating enzymes has increased substantially over the past 15 years.[40] Examples include superoxide dismutases, catalases, glutathione peroxidases, glutathione reductase, thioredoxins, thioredoxin reductases, methionine sulfoxide reductases, and peroxiredoxins. The activity of these enzymes is largely determined by ROS-induced changes in their transcription. Increased transcription of many of these antioxidant enzymes is mediated by the transcription factor nuclear erythroid–related factor 2 (Nrf2), a member of the cap 'n' collar subfamily of basic region leucine zipper transcription factors.[188] By regulating oxidant levels and oxidant signaling, Nrf2 participates in the control of the unfolded protein response, apoptosis, mitochondrial biogenesis, and stem cell regulation. Nrf2 also increases transcription of GLO1, the rate-limiting enzyme of the glyoxalase system, which prevents post-translational modification of proteins and histones by methylglyoxal, the major AGE precursor.[189,190] It also increases transcription of the rate-controlling enzyme in the nonoxidative branch of the pentose phosphate pathway, transketolase. Activation of transketolase inhibits three of the major hyperglycemia-driven pathways implicated in the pathogenesis of diabetic vascular damage (the diacylglycerol-PKC pathway, the methylglyoxal-AGE formation pathway, and the hexosamine pathway) and inhibits hyperglycemia-induced NFκB activation.[58] Preclinical studies using Nrf2 activators or Nrf2-deficient diabetic mice established that Nrf2 is a crucial endogenous modulator of ROS and protects from experimental diabetic nephropathy.[191–193] In the kidneys of *db/db* mice, treatment with the tetracycline antibiotic minocycline increased Nrf2 protein levels, reduced glomerular oxidative stress markers, and ameliorated diabetic nephropathy.[194]

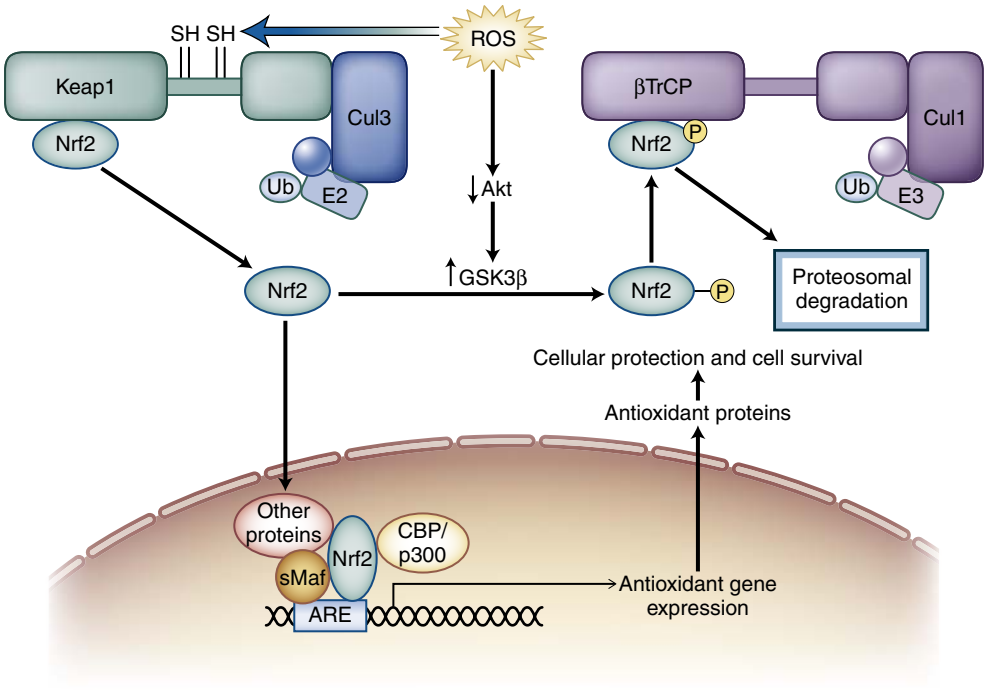
Nrf2 is expressed constitutively, and its intranuclear levels are controlled post-translationally. In the absence of inducers, Nrf2 associates with the redox-sensitive protein Kelch-like erythroid cell–derived protein with cap 'n' collar homology–associated protein 1 (Keap1), where it is rapidly polyubiquinated by Keap1-associated cullin-3–RING E2 ubiquitin ligase proteins and degraded by proteasomes. Nrf2 bound to Keap1 is released by ROS oxidation of critical cysteine thiols of Keap1, or by the reaction of these thiols with ROS-generated electrophiles such as glycolysis-derived methylgloxal and unsaturated fatty acid peroxidation-derived 4-hydroxynonenal. Phosphorylation of Nrf2 by protein kinases such as casein kinase 2 (CK2) may help target Nrf2 to the nucleus. After forming heterodimers with small Maf proteins, Nrf2 binds to the antioxidant response element (ARE) to induce transcription of its target genes. Export of Nrf2 from the nucleus is controlled by phosphorylation. Src family members such as Fyn phosphorylate Nrf2 at Tyr568, causing export from the nucleus and degradation.[195] Reduction of Nrf2 protein in the cytosolic compartment is mediated by β-transducin repeat–containing protein, a substrate adaptor for the S-phase kinase-associated protein 1–Cul1–F-box protein E3 ubiquitin ligase, which targets GSK3β-phosphorylated Nrf2 to the proteosome[196] (Fig. 37.16).

Modification of critical Keap1 cysteine thiols by sulforaphane, a dietary isothiocyanate found in cruciferous vegetables, also releases Nrf2.[199] In endothelial cells, sulforaphane prevented hyperglycemia-induced activation of the hexosamine and PKC pathways and prevented increased cellular accumulation and excretion of the major AGE precursor methylglyoxal.[197] In the aortae of diabetic mice, sulforaphane treatment restored aortic levels of Nrf2 and Nrf2-dependent antioxidant gene expression, preventing diabetes-induced increases in wall thickness, fibrosis, inflammation (tumor necrosis factor-α [TNFα] and vascular cell adhesion molecule-1 expression), apoptosis, and increased cell proliferation.[198] Diabetic cardiomyopathy was also prevented in mouse models by sulforaphane treatment.[199] Normalized Nrf2 activity also prevented diabetes-associated cardiac inflammation, fibrosis, lipid accumulation, and impaired autophagy.

In hearts from diabetic patients, Nrf2 protein is significantly reduced. In mice, cardiac Nrf2 protein was similarly reduced after 5 months of diabetes mellitus.[200] Hyperglycemia-induced mitochondrial overproduction of ROS has been shown to increase glycogen synthase kinase 3 beta (GSK3β) activity by inhibiting Akt1-dependent phosphorylation of GSK3β at serine 9.[143] Activated GSK3β targets cytoplasmic Nrf2 for increased proteasomal degradation mediated by the β transducin repeat–containing protein/S-phase kinase-associated protein 1–Cul1–F-box protein E3 ubiquitin ligase.[196]

Diabetes Activates the NLR Family Pyrin Domain Containing 3 Inflammasome

Dysregulated NLRP3 inflammasome activity underlies many chronic inflammatory states. The NLRP3 inflammasome is formed by oligomerization of inactive NLRP3, associated with apoptosis-associated speck–like protein (ASC), and procaspase-1. This complex, in turn, catalyzes the conversion of procaspase-1 to caspase-1, which contributes to the production and secretion of mature proinflammatory IL1β and IL18.[201] Activation requires two steps. The first, called *priming,* activates the transcription factor NFκB, which promotes transcription of NLRP3, pro-IL1β,



• **Fig. 37.16** Diabetes mellitus reduces nuclear erythroid–related factor 2 (Nrf2) protein in diabetic kidney and heart. Nrf2, the master regulator of antioxidant gene expression, associates with the redox-sensitive protein Kelch-like erythroid cell–derived protein with cap 'n' collar homology–associated protein 1 (Keap1), where it is rapidly polyubiquitinated by Keap1-associated cullin-3 (Cul3)–RING E2 ubiquitin ligase proteins and degraded by proteasomes. Reactive oxygen species (ROS) oxidation of critical cysteine thiols of Keap1 causes release of bound Nrf2 protein. Phosphorylation of Nrf2 by protein kinases such as CK2 help target Nrf2 to the nucleus. Nrf2 forms heterodimers with small Maf proteins, which bind to the antioxidant response element (ARE) in its target gene promoters. After export of Nrf2 from the nucleus, cytosolic Nrf2 is phosphorylated by GSK3β. This phosphorylated Nrf2 is recognized by β-transducin repeat–containing protein (βTrCP), a substrate adaptor for the S-phase kinase–associated protein-1–Cul1–F-box protein E3 ubiquitin ligase, which targets Nrf2 phosphorylated by GSK3β to the proteasome. *Akt,* protein kinase B; *CBP/p300,* CREB-binding protein and its homologue p300; *CK2,* casein kinase II; *E2*, ubiquitin-conjugating enzymes; *GSK3β,* glycogen synthase kinase-3β; *NRF2,* nuclear factor (erythroid-derived 2)–like 2; *sMaf,* small musculoaponeurotic fibrosarcoma proteins; *Ub,* ubiquitin. and pro-IL18.[202] In mononuclear cells from diabetic patients and in vascular endothelial cells from diabetic rats, NFκB is chronically active.[203] This likely results from TLR4 or TLR4/RAGE heterodimer signaling stimulated by binding of ROS-induced S100A8/9 calgranulins. A second signal activates the NLRP3 inflammasome by facilitating the oligomerization of inactive NLRP3, apoptosis-associated speck–like protein, and procaspase-1. Although diverse molecular cues can trigger this step, several studies had suggested that these might all act through a mitochondrial pathway associated with high levels of mitochondrial ROS. Blocking ROS generation by mitochondria has been shown to abolish NLRP3 inflammasome activation, whereas artificial induction of mitochondrial ROS can spontaneously induce NLRP3-mediated IL1β secretion.[204,205] Mitochondrial ROS stimulate calcium influx via the TRPM2 channel (transient receptor potential cation channel subfamily M member 2), and macrophages deficient in TRPM2 have drastically impaired NLRP3 inflammasome activation and IL1β secretion.[206] Synthesis and oxidation of mitochondrial DNA also drive this activation step. TLR4 signaling increases levels of the human mitochondrial CMP kinase enzyme CMPK2, which increases nucleotide cytidine triphosphate, causing synthesis of mitochondrial DNA. Oxidized DNA fragments then exit the mitochondria, bind to the NLRP3 inflammasome, and activate it (Fig. 37.17).

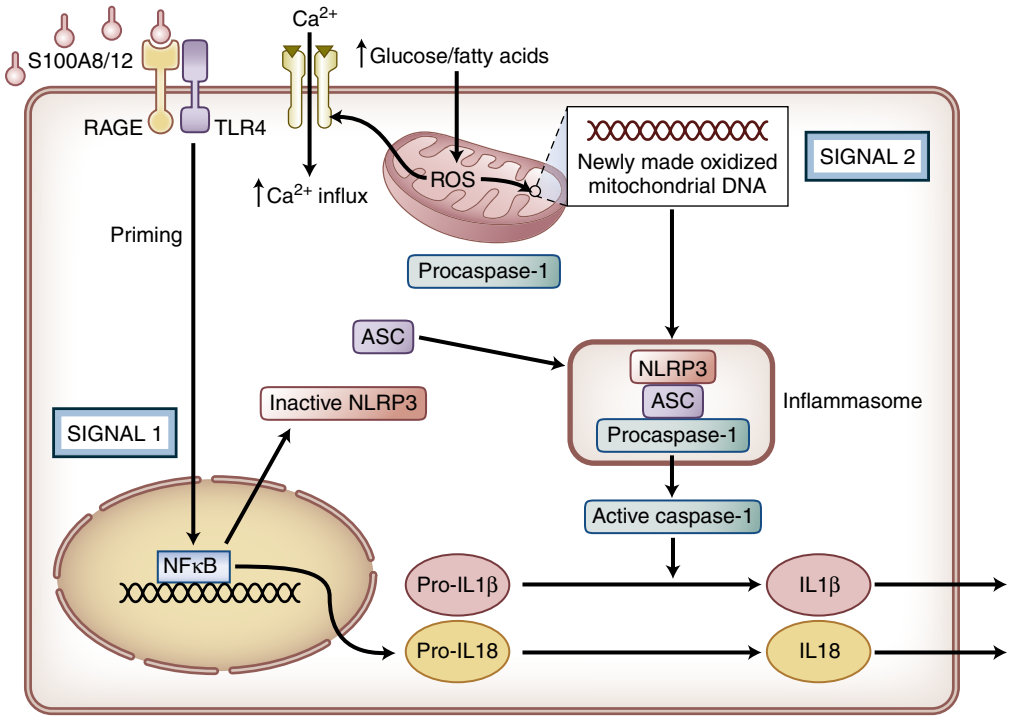
Increased expression of the NLRP3 inflammasome components Nlrp3 and apoptosis-associated speck–like protein was found in monocytes from new, untreated patients with T2DM. Along with increased expression, there was increased inflammasome activation. Consistent with this, drug-naive T2DM patients had significantly higher serum levels of the proinflammatory cytokines IL1β and IL18 than did healthy individuals.[207] In kidneys from diabetic humans and in murine models of both T2DM and T1DM, inflammasome activation was detected in glomerular endothelial cells and podocytes.[208] Nlrp3 deficiency protected these mice from experimental diabetic nephropathy. Analysis of gene expression data in the Nephromine database revealed persistently elevated glomerular expression of inflammasome markers in patients with diabetic nephropathy and in murine models.[209] NLRP3 inflammasome activation also occurs in diabetic renal tubulointerstitial cells. Tubulointerstitial fibrosis is the final common pathway for loss of renal function in diabetic nephropathy, and tubuloepithelial to mesenchymal transdifferentiation is one



• **Fig. 37.17** NOD-like receptor family, pyrin domain-containing 3 (NRLP3) inflammasome activation in diabetic monocytes, kidney, coronary arteries, and heart. Hyperglycemia and increased fatty acids induce reactive oxygen species (ROS). These increase receptor for advanced glycation end products (RAGE) expression, which heterodimerizes with toll-like receptor 4 (TLR4). Signaling from this complex causes nuclear factor-κB (NFκB)–mediated transcription of inactive NRLP3, prointerleukin 1β (Pro-IL1β), and Pro-IL18. Increased intracellular Ca^{2+} and/or newly made oxidized mitochondrial DNA triggers oligomerization of inactive NLRP3, associated with apoptosis-associated speck–like protein (ASC), and procaspase-1. This activated inflammasome complex catalyzes the conversion of procaspase-1 to caspase-1, and of pro-IL1β and proIL-18 to mature IL1β and IL18. *S100A8/12,* Calgranulin A/B heterodimer ligand for RAGE. (Data from Shah M, Brownlee M. Molecular and cellular mechanisms of cardiovascular disorders in diabetes. *Circ Res*. 2016;118:1808–1829; Murphy MP. Newly made mitochondrial DNA drives inflammation. *Nature.* 2018;560:176–177.)

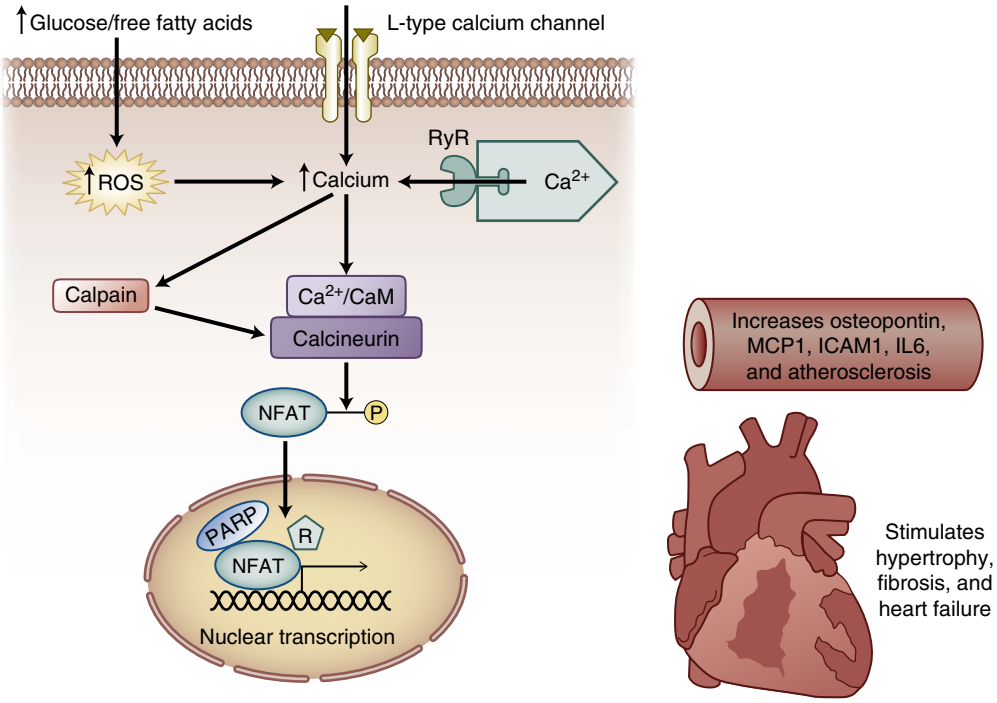
source of renal interstitial fibrogenic myofibroblasts. In diabetic kidney disease, the degree of tubulointerstitial fibrosis is probably a stronger predictor of GFR decline than glomerular changes.[210] A critical mediator of renal fibrosis is the ROS-activated redox-sensitive kinase apoptosis signal-regulating kinase 1 (ASK1), which activates p38 and JNK downstream signaling pathways. In renal biopsies from patients with diabetic kidney disease, ASK1 activation was associated with myofibroblasts, and in *db*/*db* eNOS$^{-/-}$ diabetic mice, inhibition of ASK1 arrested progressive GFR decline, glomerulosclerosis, and proteinuria.[211]

In a T2DM rat model, excessive activation of NLRP3 was associated with cardiac inflammation, cell death, disorganized ultrastructure, and fibrosis. NLRP3 gene silencing ameliorated cardiac inflammation, apoptosis, fibrosis, and left ventricular cardiac dysfunction.[212] In a well-established porcine model of diabetic atherosclerosis, which develops complex atherosclerotic plaques resembling those of humans, the cleavage processing of the sterol regulatory element-binding protein transcription factors (SREBP1 and SREBP2) and expression of their target genes, which increase fatty acid synthesis and cholesterol biosynthesis, were increased in endothelial cells and infiltrating macrophages of both fatty streaks and advanced lesions with fibrous caps, necrotic cores, and cholesterol cores. SIRT1 and AMPK activity were also reduced.[213] Increased SREBP1a in macrophages directly upregulates transcription of NLRP3,[214] and in porcine diabetic atherosclerosis, increased NLRP3 was found both in macrophages of advanced lesions and in endothelial cells and smooth muscle cells. The changes found in porcine diabetic atherosclerosis were also present in coronary atherosclerosis samples from diabetic humans.

Diabetes Activates the Transcription Factor NFAT

The transcription factor NFAT plays a role in the development of diabetic retinopathy, nephropathy, atherosclerosis, and cardiomyopathy. In resting cells, NFAT proteins are phosphorylated and are located in the cytoplasm. In diabetes, intracellular calcium is increased by increased ROS. Increased intracellular calcium then activates NFATc1-c4 by increasing NFAT dephosphorylation by the Ca^{2+}/calmodulin-dependent serine/threonine phosphatase calcineurin, which facilitates NFAT translocation into the nucleus. Once in the nucleus, NFAT interacts with coregulators to achieve optimal NFAT activation.[215] In the nucleus, ADP-ribosylation mediated by PARP1 acts as a molecular switch to positively regulate NFAT-dependent cytokine gene transcription[216] (Fig. 37.18). In diabetes, nuclear PARP1 is activated by intracellular ROS-induced DNA strand breaks (see Fig. 37.13).

In diabetic retinopathy, upregulation of proinflammatory cytokines such as TNFα and upregulation of retinal microvascular endothelial cell adhesion proteins are important components



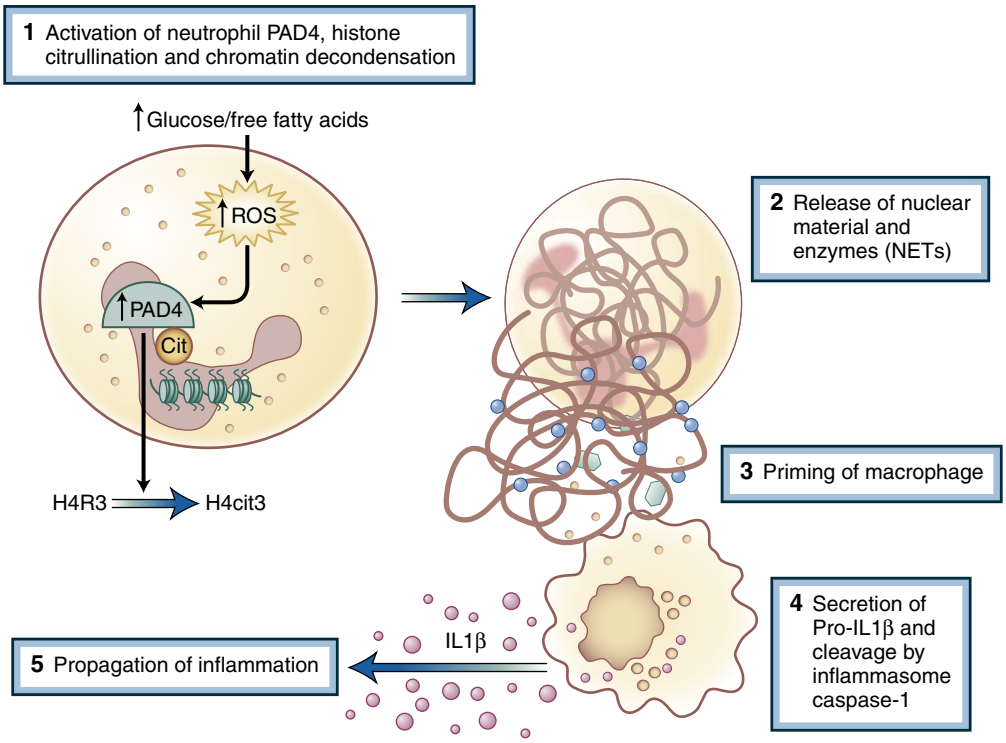
• **Fig. 37.18** Increased mitochondrial oxidation of glucose or fatty acids activates nuclear factor of activated T cells (NFAT)–mediated transcription of genes promoting diabetic retinopathy, nephropathy, atherosclerosis, and cardiomyopathy. Mitochondrial overproduction of reactive oxygen species (ROS) causes increased intracellular Ca^{2+}, which activates the calcium-activated neutral cysteine protease calpain. Calpain then activates the Ca^{2+}/calmodulin-dependent (CaM; Ca^{2+}) serine/threonine phosphatase calcineurin. Dephosphorylation facilitates nuclear translocation of the transcription factor NFAT. In the nucleus, NFAT interacts with poly-ADPribose polymerase (PARP), which increases NFAT transcriptional activity via NFAT poly-ADPribosylation. *ICAM1,* Intercellular adhesion molecule-1; *IL6,* interleukin-6; *MCP1,* monocyte chemoattractant protein-1; *RyR,* ryanodine receptor. (Modified from Shah M, Brownlee M. Molecular and cellular mechanisms of cardiovascular disorders in diabetes. *Circ Res.* 2016;118:1808–1829.)

of chronic inflammation.[217] In human retinal microvascular endothelial cells, TNFα activates NFAT signaling. Activated NFAT specifically upregulated expression of the adhesion protein VCAM1, which increases adhesion of lymphocytes and macrophages to endothelium, the inflammatory cytokine CX3CL1 (C-X3-C motif chemokine ligand 1), which promotes leukocyte adhesion, the neutrophil chemotactic cytokine CXCL6, and the activated T-cell chemotactic cytokine CXC11.[218] In human renal glomerular podocytes exposed to sera from diabetic kidney disease patients, increased TNFα production caused NFATc1-mediated repression of the cholesterol efflux regulator ATP-binding cassette transporter A1 (ABCA1), and reduced activity of sterol-O-acyltransferase 1 (SOAT1), resulting in free cholesterol-mediated podocyte injury.[219]

In arteries of diabetic mice, activated NFATc3 induces arterial smooth muscle cell expression of the proinflammatory matrix protein osteopontin, a cytokine that promotes atherosclerosis and diabetic vascular disease. NFAT inhibition effectively reduced arterial wall osteopontin, IL6, MCP1, intercellular adhesion molecule-1, CD68, and tissue factor expression, and lowered plasma IL6 in diabetic mice.[220] In diabetic $ApoE^{-/-}$mice, inhibition of NFAT-signaling completely suppressed a 2.2-fold increase in atherosclerotic plaque area. Inhibition of NFAT also reduced lipid content in the plaque of diabetic mice independent of plasma glucose and lipid levels.[221] NFATc3 activated by increased mitochondrial ROS production also increases arterial vasoconstrictor reactivity to endothelin-1.[222] NFAT activation also appears to play a role in cardiac hypertrophy, fibrosis, and cardiomyocyte apoptosis.[223] In the diabetic heart, NFAT is activated by the calcium-activated neutral cysteine protease calpain, which in turn activates calcineurin. In cardiomyocytes, increased calpain activity activates NFAT-dependent cardiac hypertrophy and heart failure.[224] In two mouse models of diabetes, cardiac-specific deletion of calpain reduced myocardial hypertrophy and fibrosis, leading to improvement of myocardial function. Calpain activation correlated with increased activity of NFAT and NFκB, consistent with calpain's role in activation of calcineurin and degradation of the cytosolic NFκB inhibitor, NFκB inhibitor α.[225,226]

Diabetes Increases Neutrophil Extracellular Traps

In atherosclerotic plaques, neutrophils prime macrophages for proinflammatory responses.[227] This priming is mediated by extracellular webs of DNA bound to cytotoxic histones, which are released by activated neutrophils, called *neutrophil extracellular traps* (NETs).[228] This process follows a coordinated multistep process: histone citrullination, chromatin decondensation, migration of elastase and other granule enzymes into the nucleus, disintegration of the nuclear membrane, and release of DNA, histones, and granule proteins into the extracellular space.[229] The release of NETs primes macrophages to produce pro-IL1β, which is cleaved to mature proinflammatory IL1β by caspase-1. Caspase-1, in turn, is secreted by macrophages in response to activation of the



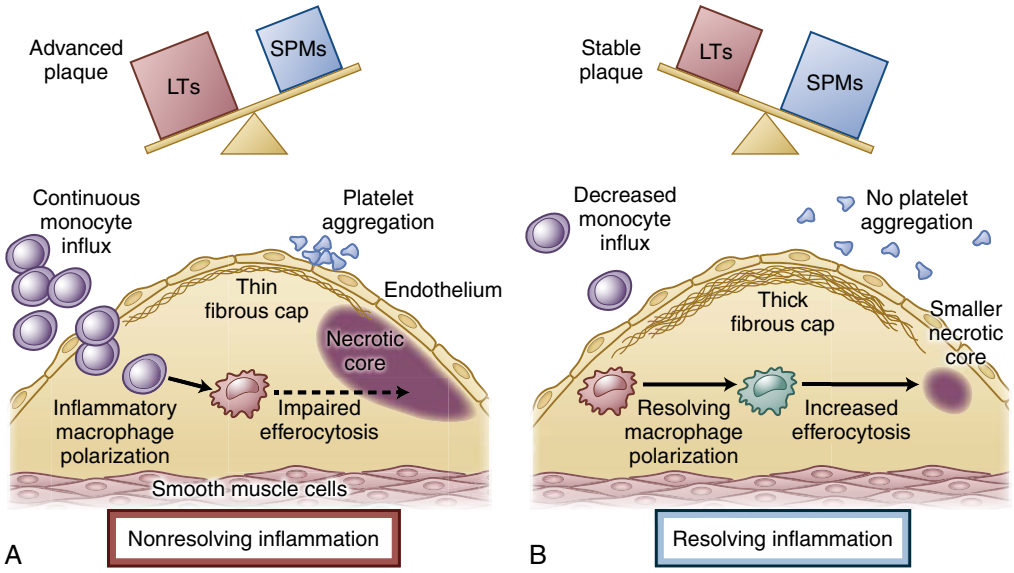
• **Fig. 37.19** Diabetes increases neutrophil extracellular traps (NETs), priming macrophages for inflammation. Increased reactive oxygen species (ROS) increase transcription and activation of peptidylarginine deiminase 4 (PAD4), the enzyme that initiates formation and release of NETs by citrullination (Cit) of histones. Released NETs prime macrophages to produce pro-interleukin 1β (Pro-IL1β), which is cleaved to mature proinflammatory IL1β by caspase-1 secreted by macrophages in response to NOD-like receptor family, pyrin domain-containing 3 inflammasome activation. *H4cit3,* Histone 4 with arginine residue 3 converted to citrulline; *H4R3,* histone 4 arginine 3; ROS, reactive oxygen species. (Modified from Shah M, Brownlee M. Molecular and cellular mechanisms of cardiovascular disorders in diabetes. *Circ Res.* 2016;118:1808–1829.)

NLRP3 inflammasome.[227] Both ROS and increased intracellular Ca^{2+} activate NET formation (Fig. 37.19).[230] Atherosclerosis-prone $Apoe^{-/-}$ mice with deletions of two serine proteases that localize to NETs developed dramatically smaller atherosclerotic lesions compared with $Apoe^{-/-}$ control animals, despite similar lipid concentrations and leukocyte counts in blood. These triple mutant mice had no NETs, lower systemic IL1β concentration, and fewer lesional IL17-producing T cells.[231] Quenching mitochondrial ROS in a mouse model of atherosclerosis (aged myeloid cell mCAT→LDL receptor null [$Ldlr^{-/-}$] chimeric mice) decreased lesional NETs compared with age-matched $Ldlr^{-/-}$ mice, and also decreased total macrophage content in atherosclerotic lesions.[232] Oxidized LDL (oxLDL) and 7-keto-cholesterol, the most abundant oxysterol in human oxLDL, induced mitochondrial ROS production and highly proinflammatory oxidized mitochondrial DNA-bound NETs.[233] Neutrophils from both type 1 and type 2 diabetic humans have elevated expression of peptidyl arginine deiminase 4, the enzyme critical for histone citrullination-mediated chromatin decondensation and NET formation.[234]

Nonresolving Inflammation in Metabolic Syndrome, Diabetes, and Atherosclerosis

Chronic low-grade inflammation is associated with metabolic syndrome, diabetes, and atherosclerosis.[235–240] In normal physiology, inflammation has two temporal phases: an initiation phase of acute inflammation and a resolution phase. The initiation phase involves recruitment of neutrophils followed by monocytes, which differentiate into proinflammatory macrophages. These cells engulf the inflammatory stimulus and remove damaged tissue debris. Resolution of inflammation is an active process involving a switch from synthesis of arachidonic acid–derived proinflammatory prostaglandins and leukotrienes to synthesis of at least four families of specialized proresolving mediators (SPMs). These SPM families are arachidonic acid–derived lipoxins, and omega-3 polyunsaturated fatty acid–derived resolvins, protectins, and maresins.[121] SPMs decrease further recruitment of PMNs, stimulate macrophage uptake and clearance of apoptotic cells (efferocytosis), shift macrophage phenotype from proinflammatory to proresolution, and initiate tissue repair processes. Obesity and diabetes delay PMN apoptosis and impair macrophage efferocytosis. In human arteries, high levels of resolvin D1 and low levels of the proinflammatory leukotriene B4 were associated with plaques having less necrosis and thicker fibrous caps. In contrast, high levels of leukotriene B4 and low levels of resolvin D1 were associated with plaques having large necrotic cores and thin fibrous caps.[241]

Current evidence suggests diabetes causes defective SPM biosynthesis downstream of their fatty acid precursors.[238,239] The resultant nonresolving inflammation causes continuous leukocyte influx into atherosclerotic lesions, inflammatory macrophage polarization, and defective efferocytosis. These drive the progression of atherosclerosis to the development of clinically dangerous lesions with large necrotic, procoagulant cores and thin fibrous caps. SPMs limit plaque progression by suppressing inflammation, enhancing efferocytosis, and promoting an increase in thickness



• **Fig. 37.20** Nonresolving inflammation in atherosclerosis. Reduced specialized proresolving mediators *(SPMs)* and increased leukotrienes (LTs) promotes instability of atherosclerotic plaques. When the SPM:LT ratio is low (A), resolution of inflammation is impaired, leading to sustained inflammatory monocyte influx, platelet aggregation, proinflammatory macrophage polarization, impaired efferocytosis, large necrotic cores, and thin fibrous caps. Conversely, when the SPM:LT ratio is high (B), resolution of inflammation is characterized by decreased monocyte influx, proresolving macrophage polarization, enhanced efferocytosis, decreased necrotic core formation, and thicker fibrous caps. (Redrawn from Kasikara C, Doran A, Cai B, et al. The role of non-resolving inflammation in atherosclerosis. *J Clin Invest.* 2018;128:2713–2723.)

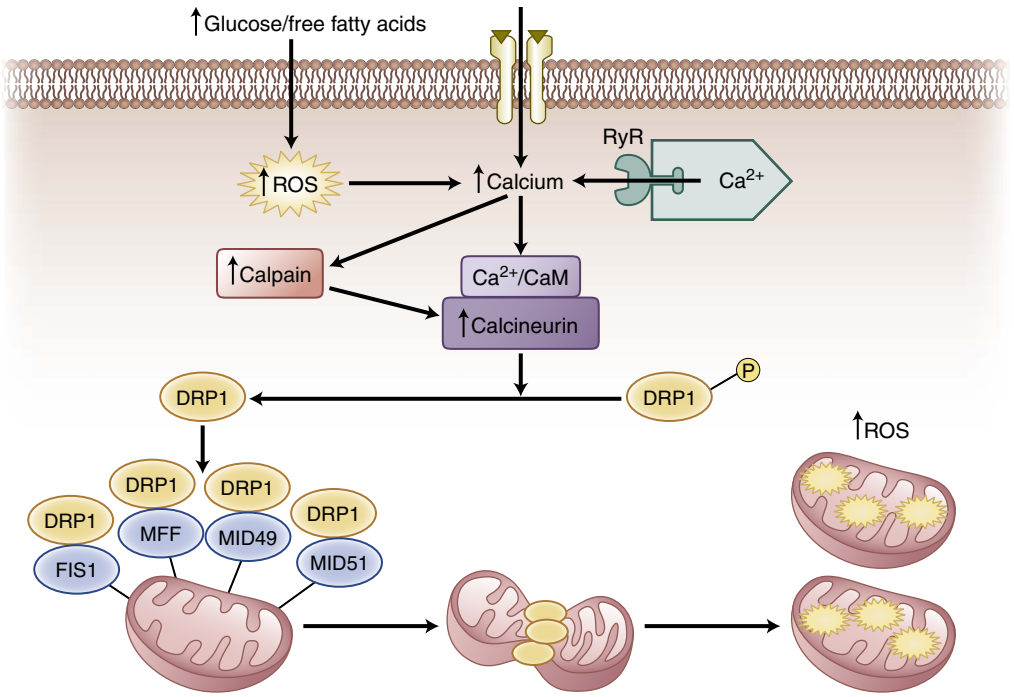
of the fibrous cap (Fig. 37.20). Enhanced efferocytosis promotes macrophage production of several SPMs, including lipoxin A4, resolvin E1, and protectin D1. Lipoxins also recruit monocytes as macrophages further enhance efferocytosis in the resolving lesions. Efferocytosis requires specific phagocytotic receptors, which bind to apoptotic cells. Deletion of one of these receptors, Mer tyrosine kinase (MerTK), caused impaired efferocytosis, accumulation of apoptotic cells, and large necrotic cores in murine atherosclerotic lesions. It also caused impaired SPM production by macrophages, because MerTK signaling decreases proinflammatory leukotriene synthesis and increases synthesis of proresolving lipoxin A4.[239]

MerTK can be inactivated by the metalloproteinase ADAM17, which, when activated by macrophage overproduction of mitochondrial ROS, cleaves the receptor.[171] High levels of soluble MerTK are found in advanced human atherosclerotic lesions, suggesting that this is one mechanism impairing efferocytosis. Increased levels of ROS cause autonomous activation of CaMKII by oxidation of adjacent methionine residues in its regulatory domain.[107] In arteries, activated CaMKII suppresses efferocytosis in macrophages and promotes atherosclerotic plaque necrosis.[242]

Diabetes Alters Mitochondrial Dynamics

Mitochondria dynamics are the continuous processes of mitochondrial fusion, fission, biogenesis, and mitophagy, which together maintain optimal cellular bioenergetics and ROS homeostasis.[243] In normal physiology, fission helps facilitate mitophagy, which degrades and recycles damaged mitochondria and mitochondrial fragments, although fission also increases ROS production due to incomplete transfer of electrons through the electron transport chain. Mitochondrial fission is a critical process that enables macrophages to clear multiple apoptotic cells. When fission is disabled, phagosome formation around secondarily encountered apoptotic cells is impaired.[244] The primary regulators of outer mitochondrial fusion are dynamin-related guanosine triphosphate hydrolases (GTPases), termed mitofusin 1 (Mfn1) and mitofusin 2 (Mfn2), while inner mitochondrial fusion and cristae stabilization involve optic atrophy protein 1 (Opa1). The primary regulator of mammalian mitochondrial fission is the GTPase dynamin-related protein 1 (Drp1), which is recruited from the cytosol to the mitochondrial outer membrane where it binds to four Drp1 receptors: mitochondrial fission factor (MFF), mitochondrial dynamics protein of 49 kDa (miD49) and 51 kDa (miD51), and mitochondrial fission 1 protein (FIS1).[245] Oligomerization of Drp1 is thought to provide the mechanical force to constrict mitochondrial membranes and to fragment the organelle. Mitochondrial fission occurs at mitochondria-endoplasmic reticulum contact sites, with involvement of the mitochondrial phospholipid cardiolipin and calcium transfer.[246]

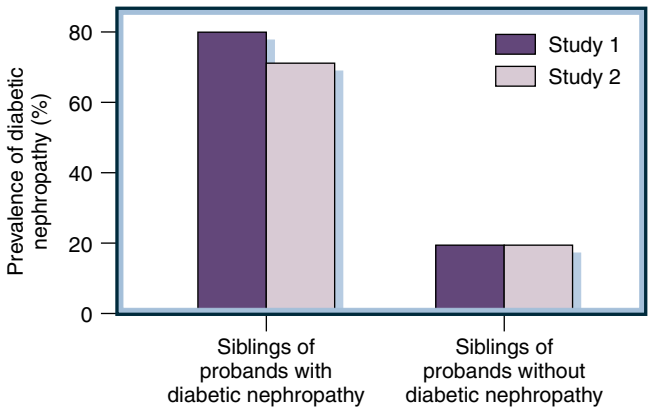
Increased mitochondrial fission caused by increased mitochondrial recruitment of Drp1 is associated with key features of diabetic nephropathy in diabetic mouse models[133] (Fig. 37.21). In diabetic mice lacking Drp1, decreased fission protected against progression of diabetic nephropathy.[247] Increased mitochondrial fission also occurs in mitochondria from mouse coronary endothelial cells, where the level of the fusion protein Opa1 is decreased and the level of Drp1 is increased.[248] This response may represent an important proresolving response in atherosclerotic lesions, since mice lacking myeloid Drp1 have defective efferocytosis.[235,244] Persistent increased fission is also associated with myocardial dysfunction in humans with type 2 diabetes, due in part to decreased expression of the fusion protein mitofusin 1.[249] Drp1 recruitment to mitochondria is regulated by its phosphorylation at serine 616 by either CaMKII or ROCK1. In the diabetic heart and kidney, ROS can activate both of these kinases.[108,133]



• **Fig. 37.21** Diabetes induces increased mitochondrial fission in kidney, coronary artery, and myocardium. Increased reactive oxygen species (ROS) from either excess glucose or fatty acids increases intracellular Ca^{2+}. Increased Ca^{2+} activates the calcium-activated neutral cysteine protease calpain, which activates the Ca^{2+}/calmodulin-dependent (CaM; Ca^{2+}) serine/threonine phosphatase calcineurin. Calcineurin dephosphorylates the GTPase dynamin–related protein 1 (DRP1), which is then recruited from the cytosol to the mitochondrial outer membrane where it binds to four DRP1 receptors—mitochondrial fission factor (MFF), mitochondrial dynamics protein of 49 kDa (MID49), and 51 kDa (MID51), and mitochondrial fission 1 protein (FIS1). Drp1 oligomerization provides the mechanical force to constrict mitochondrial membranes and fragment the organelle (mitochondrial fission). Increased fission causes further increases in ROS production and mitochondrial dysfunction. (Modified from Shah M, Brownlee M. Molecular and cellular mechanisms of cardiovascular disorders in diabetes. *Circ Res.* 2016;118:1808–1829.)

Genetic Determinants of Susceptibility to Microvascular Complications

Clinicians have long observed that different patients with similar duration and degree of hyperglycemia differ markedly in their susceptibility to microvascular complications. Such observations suggested that genetic differences exist that affect the pathways by which hyperglycemia damages microvascular cells. The leveling of risk of overt proteinuria after 30 years' duration of T1DM at 27% is evidence that only a subset of patients are susceptible to development of diabetic nephropathy.[250] A role for genetic determinants of susceptibility to diabetic nephropathy is more directly supported by familial clustering, with an estimated heritability of at least 40%. In two studies of families in which two or more siblings had T1DM, the risk of nephropathy in a diabetic sibling was 83% or 72% if the proband diabetic sibling had advanced diabetic nephropathy, but only 17% or 22% if the index patient did not have diabetic nephropathy (Fig. 37.22).[251,252] Familial clustering for the risk of severe diabetic retinopathy was also reported by the DCCT. Likewise, familial aggregation of coronary artery calcification occurs in families with T2DM.[253] Numerous associations have been made between various candidate gene polymorphisms and the risk of diabetic complications. However, in a meta-analysis of three large cohorts from the Genetics of Nephropathy—an International Effort (GENIE), no associations remained significant after correction for multiple testing or application of stringent significance thresholds.[254]



• **Fig. 37.22** Familial clustering of diabetic nephropathy. Prevalence of diabetic nephropathy in two studies of diabetic siblings of probands with or without diabetic nephropathy. (Adapted from Seaquist ER, Goetz FC, Rich S, et al. Familial clustering of diabetic kidney disease: evidence for genetic susceptibility to diabetic nephropathy. *N Engl J Med.* 1989;320:1161–1165; Quinn M, Angelico MC, Warram JH, et al. Familial factors determine the development of diabetic nephropathy in patients with IDDM. *Diabetologia*. 1996;39:940–945.)

While genome-wide association studies (GWAS) performed in large, well-characterized study populations have identified a few susceptibility loci for diabetic retinopathy, nephropathy, and cardiovascular disease,[255] the cumulative effects of disease-associated

single nucleotide polymorphisms (SNPs) have failed to account for the majority of complex-trait heritability for a large number of diseases, including diabetes and its complications (the "missing heritability" problem). Ultimately, the central unanswered question is: How is coordinated gene expression regulatory information conveyed—the information that determines when, where, at what level, in what combinations, and for how long, genes are expressed? With protein coding sequences representing approximately 2% of the genome, research in the post-GWAS era is currently focused on noncoding RNAs, genetic-epigenetic interactions, and long-range chromatin 3D looping architecture.[256,257]

Noncoding RNAs and Diabetic Complications

Although piwi-interacting RNAs (piRNAs), endogenous small interfering RNAs (siRNAs), intron-derived microRNAs (miRNAs), and a host of long noncoding RNAs all have regulatory roles, the best understood noncoding RNAs with respect to diabetic complications are the miRNAs, which regulate several key biologic pathways and cellular functions involved in diabetic complications. Most individual miRNAs target hundreds of specific mRNAs,[258] thereby coordinately regulating complex gene networks. In the retina, diabetes increased levels of several microRNA mediators of inflammation (miR146, miR155, and miR132),[259] while decreasing levels of the anti-inflammation mediator miR146a. Levels of miR146a are also reduced in sciatic nerve of *db/db* mice. Treatment with a miR146a mimetic reduced macrophage activation and improved nerve conduction velocity, intraepidermal nerve fiber density, and axonal degeneration. miR146a was also decreased in kidneys and hearts of type 1 and type 2 diabetic animals.[260] In diabetic mouse kidney cortex, levels of the profibrotic miR192 are also increased, and miR192 knockdown prevented diabetes-induced proteinuria and renal fibrosis.[261] Diabetes also increased miR29c in the kidney, which induces cell apoptosis and increases extracellular matrix protein accumulation. Knockdown of miR29c prevented high glucose–induced cell apoptosis and significantly reduced albuminuria and kidney mesangial matrix accumulation in *db/db* mice.[262]

miR33 regulates cellular functions associated with cardiovascular disease. It increases macrophage activation, inhibits mitochondrial biogenesis, and represses autophagy.[263] In mice placed on an atherogenic diet for 16 weeks and then made diabetic by streptozotocin injection, anti-miR33 treatment decreased atherosclerotic plaque macrophage content and inflammatory gene expression. The decreased macrophage content in anti-miR33–treated diabetic mice was associated with a blunting of hyperglycemia-induced monocytosis and reduced monocyte recruitment to the plaque.[264] Diabetes increases circulating numbers of neutrophils and monocytes through an ROS-mediated mechanism and impairs regression of early atherosclerosis by increasing macrophage entry into the lesion in mouse models.[265,266]

MicroRNAs may also play a role in the pathogenesis of diabetic cardiomyopathy. miR499, miR133a, and miR373 are downregulated in diabetic cardiomyocytes.[267] Downregulation of miR133a in a normal adult genetic background was sufficient to induce cardiac hypertrophy, and its downregulation is a prerequisite for the development of apoptosis, fibrosis, and prolongation of the QT interval in animal models.[268] The protective capacity of cardiac progenitor cells after myocardial infarction is also enhanced by miR133a.[269]

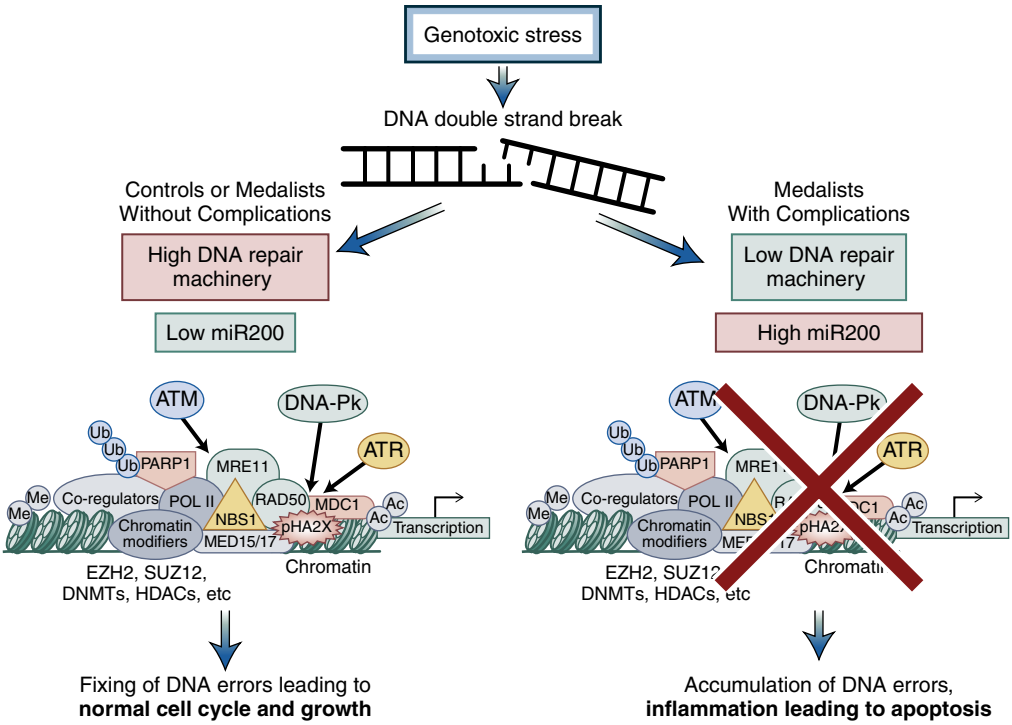
In patients with over 50 years of T1DM, expression levels of miR200 differentiated those with no complications from those with complications.[44] Induced pluripotent stem cells (iPSCs) from fibroblasts of patients with no complications had low miR200 levels, while iPSCs from fibroblasts of patients with complications (retinopathy, nephropathy, neuropathy, and cardiovascular disease) had high miR200 levels. miR200 was found to inhibit DNA damage checkpoint protein expression, causing accumulation of DNA double-strand breaks, inflammation, and apoptosis (Fig. 37.23). Knockdown of miR200 in fibroblasts from patients with complications rescued checkpoint protein expression and reduced DNA damage. In differentiated neurons derived from all clinical backgrounds, exogenous overexpression of miR200 produced the DNA damage mark γH2AX phosphorylation (pH2AX). These data are consistent with the model of ROS-mediated DNA damage activating multiple hyperglycemia/IR-induced pathogenic mechanisms discussed in previous sections.

Molecular Basis for Metabolic Memory

Stable cellular phenotypes are maintained by a multitude of interconnected multilevel positive and negative feedback loops,[270,271] interacting with combinatorial extracellular signals from adjacent cells, from receptor ligands secreted by cells in other tissues, and from changes in metabolite flux and concentration. Familiar examples of stable alterations in cellular phenotype are the induction of pluripotency in terminally differentiated cells, and the differentiation of these iPS cells into a variety of cell types.[272] In preclinical models of T1DM and T2DM, diabetes irreversibly depletes two bone marrow–derived mesenchymal progenitor subpopulations having provasculogenic expression profiles, and this deficit in vascular progenitor cells is not correctable by restoring glucose homeostasis in vitro or in vivo.[273] These data suggest that diabetes causes permanent modifications in subpopulations of mesenchymal progenitor cells that are passed to daughter cells with each division.

Similarly, when fibroblasts from patients with T1DM for more than 50 years with complications were used to make iPS cells, the miR200 family was upregulated in fibroblasts from patients with complications, in the reprogrammed iPS cells from these fibroblasts, and in neurons differentiated from iPS cells from the cohort with complications. These neurons had increased susceptibility to genotoxic stressors, including exposure to high glucose and various sources of increased ROS. The miR200 family target transcripts encoding DNA damage checkpoint proteins, and there was a concomitant increase in DNA damage and a loss of DNA damage checkpoint proteins.[44] These findings were confirmed in aortic tissue from patients with complications and were reversed in fibroblasts and iPS cells by knockdown of miR200. In fibroblasts from patients with complications, there was also a striking impairment in reprogramming efficiency, and the induced iPCs had impaired cellular growth and differentiation. In tissue from patients with complications, there was increased inflammation due to macrophage infiltration. There was also increased apoptosis due to elevated levels of DNA damage, which was not compensated by differentiation of progenitor cells. Taken together, the observations from both these studies could reflect underlying genetic or epigenetic causes. However, since the DCCT study patients were randomly assigned to one of two different treatment groups, treatment-related epigenetic causes are a more likely explanation for the long-term metabolic memory observed subsequently in the EDIC study.

Epigenetic causes are those that change DNA or RNA structure and function, but do not change DNA-RNA sequence. Along with the activities of microRNAs and other noncoding RNAs, a



• **Fig. 37.23** Expression levels of microRNA (miR) miR200 from patients with over 50 years of T1DM differentiate those with no complications from those with complications. Induced pluripotent stem cells (iPSCs) from fibroblasts of patients with no complications had low miR200 levels, while iPSCs from fibroblasts of patients with complications (retinopathy, nephropathy, neuropathy, and cardiovascular disease) had high miR200 levels. miR200 was found to inhibit DNA damage checkpoint protein expression, causing accumulation of DNA double-strand breaks, inflammation, and apoptosis. *ATM,* Ataxia telangiectasia mutated; *ATR,* ataxia telangiectasia and Rad3–related protein; *DNA-PK,* DNA-dependent protein kinase; *DNMTs,* DNA methyltransferases; *EZH2,* enhancer of zeste homolog 2; *HDACs,* histone deacetylases; *MDC1,* mediator of DNA damage checkpoint 1; *Me,* methyl; *MED 15/17,* mediator of RNA polymerase II transcription subunits 15 and 17; *MRE11,* MRE11 homolog, double-strand break repair nuclease; *NBS1,* Nijmegen breakage syndrome protein 1; *PARP1,* poly-ADPribose polymerase 1; *pH2AX,* phosphorylated H2A histone family member X; *POL II,* RNA polymerase II; *RAD 50,* DNA repair protein RAD50; *SUZ12,* suppressor of zeste 12 protein homolog; *Ub,* ubiquitin. variety of enzymes modify chromatin by adding and removing chemical groups to DNA (primarily cytosine methylation) and to the protruding N-terminal tails of nucleosome histone proteins (monomethylation, dimethylation, and trimethylation of lysine and arginine residues, acetylation of lysine residues, and modification of arginines by methylglyoxal and of serines and threonines by *O*-GlcNAc).[190,274] In conjunction with remodeling complexes, these modifications mediate the availability or nonavailability of DNA sequences for transcription (Fig. 37.24). Increased ROS modulate several epigenetic mechanisms in different cell types and contexts.[275–277]

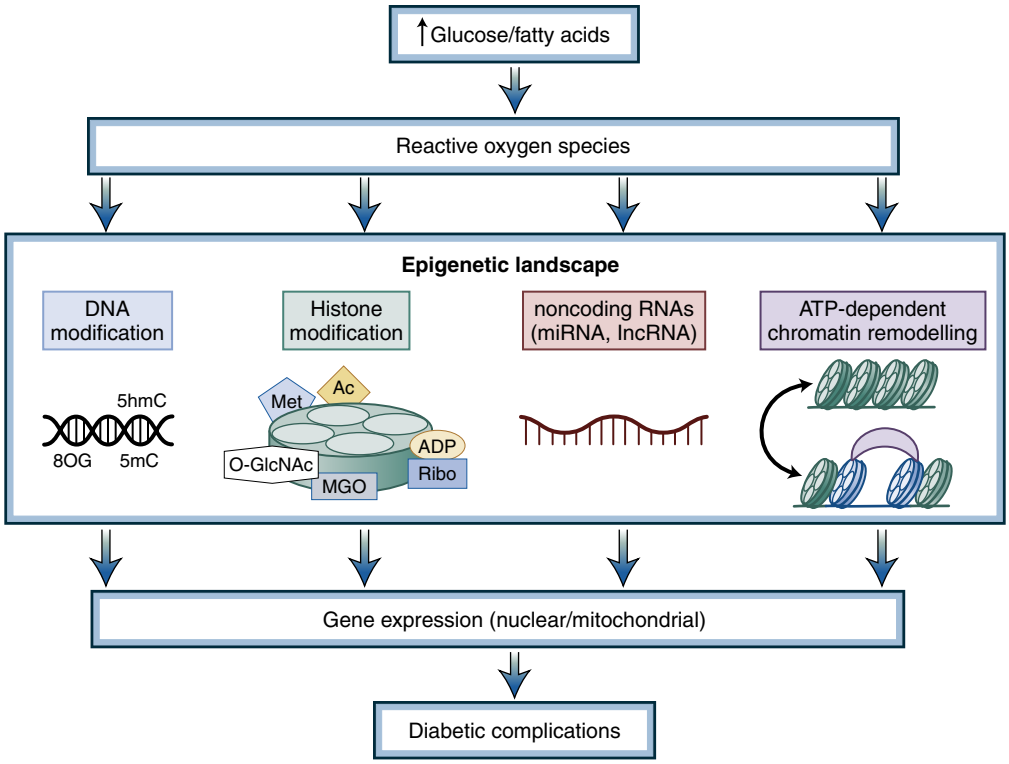
DNA methylation can repress or activate transcription, depending on its location near promoters or near enhancers in intergenic regions.[275] Similarly, methylation of histone tails can repress or activate transcription, depending on the position of the modified residue in a specific histone tail, and on the degree of methylation. Acetylation of histone tails generally facilitates transcription.

In whole blood and isolated monocyte samples from DCCT/EDIC type 1 diabetic patients at the EDIC study baseline and in samples from the same patients obtained during EDIC years 16 to 17, DNA methylation profiling revealed strong connections with networks associated with diabetic complications, even though the post-DCCT HbA_{1c} values for both intensive and standard treatment groups became identical at the end of the DCCT (~8%), and remained identical for the duration of the EDIC study. The most significant persistent DNA methylation change was hypomethylation of thioredoxin-interacting protein (TXNIP).[278] TXNIP binds to and inhibits thioredoxin, increasing ROS production and inhibiting renal tubular autophagy.[279] The importance of this DNA methylation profiling study is that it shows, for the first time, that differential methylation at several loci persists for more than 16 to 17 years in circulating leukocytes from the same diabetic patient cohort. Every diabetic complication is a complex heterocellular process, however, and each different cell type involved has a distinct epigenome regulating gene expression and cell type–specific pathologies despite sharing a common genetic sequence.[275] A similar but technically more limited study of selected histone modifications in monocytes showed enrichment of activating histone 3 lysine 9 acetylation (H3K9Ac) in promoters of more than 15 genes related to the NFκB inflammatory pathway.[280]

Transient hyperglycemia, at a level sufficient to increase mitochondrial ROS production, induces long-lasting activating epigenetic changes (increased monomethylation of histone 3 lysine 4) in the proximal promoter of the NFκB subunit p65 in vitro in

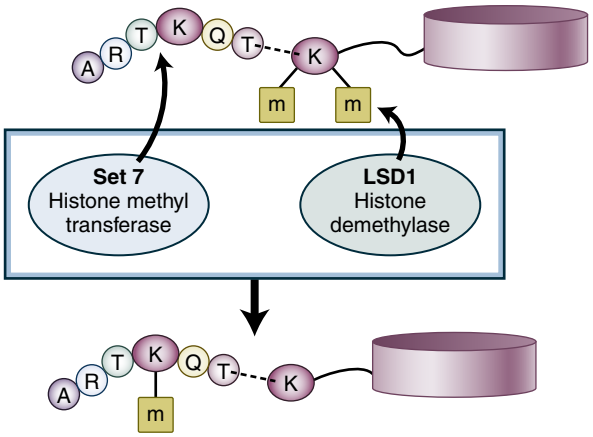


• **Fig. 37.24** Increased metabolite-generated reactive oxygen species (ROS) modulate the epigenetic landscape, altering histone modifications, DNA modifications, expression of noncoding RNAs, and ATP-dependent chromatin remodeling. These changes subsequently affect gene expression patterns implicated in the pathogenesis of diabetic complications. DNA modifications include cytosine methylation (5mC), hydroxymethylation (5hmC), or 8-oxo-2'-deoxyguanosine (8OG) formation. Histone modifications include methylation (Met), acetylation (Ac), ADP-ribosylation (ADP-Ribo), phosphorylation (P), glycation by methylglyoxal (MGO), and glycosylation by *O*-linked *N*-acetylglucosamine (O-GlcNAc). Noncoding RNAs include microRNAs (miRNA) and long noncoding RNAs (lncRNA). ATP-dependent chromatin remodeling includes moving and adding/removing nucleosomes by ATPase-containing complexes. (Modified from Kietzmann T, Petry A, Shvetsova A, et al. The epigenetic landscape related to reactive oxygen species formation in the cardiovascular system. *Br J Pharmacol.* 2017;174:1533–1554.)

human aortic endothelial cells (16-hour exposure), and in vivo in aortic cells in nondiabetic mice (6-hour exposure). These epigenetic changes caused sustained increases in p65 gene expression and in the expression of p65-dependent proinflammatory genes. Both the epigenetic changes and the gene expression changes persist for at least 6 days of subsequent normal glycemia in cultured cells and for months in previously diabetic mice whose beta-cell function had recovered.[281,282] Hyperglycemia-induced epigenetic changes and increased p65 expression are prevented by normalizing mitochondrial superoxide production or superoxide-induced methylglyoxal. Demethylation of another histone lysine residue, histone 3 lysine 9, is also induced by hyperglycemia-induced overproduction of ROS. This reduces inhibition of p65 gene expression, and therefore acts synergistically with the activating methylation of histone 3 lysine 4. The specific H3K4m1 enrichment is mediated by the lysine methyltransferase Set7, which is recruited to the nucleus by high glucose–induced mechanisms.[283] Genome-wide analysis of Set7 function in human vascular endothelial cells confirmed its role in regulating NFκB-dependent pathways, affecting a large number of genes associated with vascular function by both histone lysine methylation and lysine methylation on nonhistone substrates such as transcription factors.[284,285] The demethylation of histone 3 lysine 9 is mediated by the histone demethylase LSD1 (lysine-specific histone demethylase 1) (Fig. 37.25).

Another component of epigenetic regulation is the action of epigenetic reader proteins that bind to modified histone residues and facilitate the formation of transcriptional complexes. In endothelial cells, proinflammatory activation of NFκB led to rapid recruitment of NFκB to newly formed superenhancers, and rapid large-scale redistribution of the epigenetic reader bromodomain and extraterminal domain 4 (abbreviated BET4 or BRD4) from decommissioned preexisting basal enhancers to the newly formed superenhancers.[286] This recruitment caused increased levels of H3K27ac and immediate transcription of inflammatory genes. Blocking the association of BRD4 with acetylated lysines in LDL receptor–deficient hypercholesterolemic mice attenuated both early and late atherosclerosis development.

BRD4 and other members of the BET family are also critical effectors of pathologic cardiac remodeling and heart failure via their ability to coactivate multiple master transcription factors known to initiate and promote heart failure, including NFκB and NFAT.[287] BET inhibition suppresses pathologic cardiac gene expression programs and arrests pathologic hypertrophy and heart failure in vivo. BRD4 (most potently its splice isoform BRD4B) also functions as an endogenous inhibitor of DNA damage response signaling, which enhances radiation ROS-induced cell death. In contrast, knockdown of this isoform caused rapid cell-cycle checkpoint recovery and enhanced cell survival.[288] Much has been learned since the original clinical description of metabolic memory, but much more research remains to be done before the molecular basis for metabolic memory is clearly understood.



• **Fig. 37.25** Transient hyperglycemia induces long-lasting activating epigenetic changes in the proximal promoter of the NFκB subunit p65 in endothelial cells. Hyperglycemia-induced reactive oxygen species (ROS) and methylglyoxal cause activating modifications of histone 3 lysine 4 (monomethylation) and derepressing modifications of histone 3 lysine 9 (removal of two methyl groups) at the NFκB p65 proximal promoter. K is the symbol for the amino acid lysine. The chains of circled letters are the N-terminal tails of histone H3. *LSD1*, lysine-specific histone demethylase 1A; *Set 7*, SET domain-containing protein 7. Hyperglycemia induces a dynamic cooperativity of histone methylase and demethylase enzymes associated with gene-activating epigenetic marks that co-exist on the lysine tail. *Diabetes*. 2009;58:1229–1236; El-Osta A, Brasacchio D, Yao D, et al. Transient high glucose causes persistent epigenetic changes and altered gene expression during subsequent normoglycemia. *J Exp Med.* 2008;205:2409–2417.)

Diabetic Retinopathy and Other Ocular Complications of Diabetes[a]

Diabetic retinopathy is a well-characterized sight-threatening chronic microvascular complication that eventually afflicts virtually all patients with diabetes mellitus.[289] Diabetic retinopathy is characterized by gradually progressive alterations in the retinal microvasculature, leading to areas of retinal nonperfusion, increased vascular permeability, and pathologic intraocular proliferation of retinal vessels. The complications associated with retinal neovascularization, termed *proliferative diabetic retinopathy* (PDR), and increased vascular permeability, termed *diabetic macular edema* (DME), can result in severe and permanent vision loss.

Early-stage diabetic retinopathy eventually occurs in nearly all patients, although early intensive treatment of hyperglycemia delays its onset and progression in T1DM. In selected patients with T2DM, systemic treatment with fenofibrate, ACE inhibitors, and angiotensin II receptor blockers (ARBs) may affect the development and progression of diabetic retinopathy. Multiple phase 3 clinical trials over the past 5 years have now established intravitreously delivered anti-VEGF therapy as the new standard of care for most eyes with visual impairment from center-involved DME.[290,291] Currently, more than 90% of severe vision loss resulting from PDR can be prevented, and approximately 50% of eyes with visual loss from DME can resolve their retinal thickening and/or recover vision of 20/20 or better with appropriate medical and ophthalmologic care.[292,292a] Thus the primary clinical care emphasis for the prevention of vision loss in the diabetic patient is on early identification, accurate classification, and timely treatment of retinopathy through lifelong routine ophthalmologic follow-up appointments and optimized treatment of hyperglycemia, hypertension, and hyperlipidemia.

[a] Portions of this section draw on, among others, Aiello LM, Cavallerano JD, Aiello LP. Diagnosis, management, and treatment of nonproliferative diabetic retinopathy and diabetic macular edema. Epidemiology and Impact of Proliferative Diabetic Retinopathy and Diabetic Macular Edema

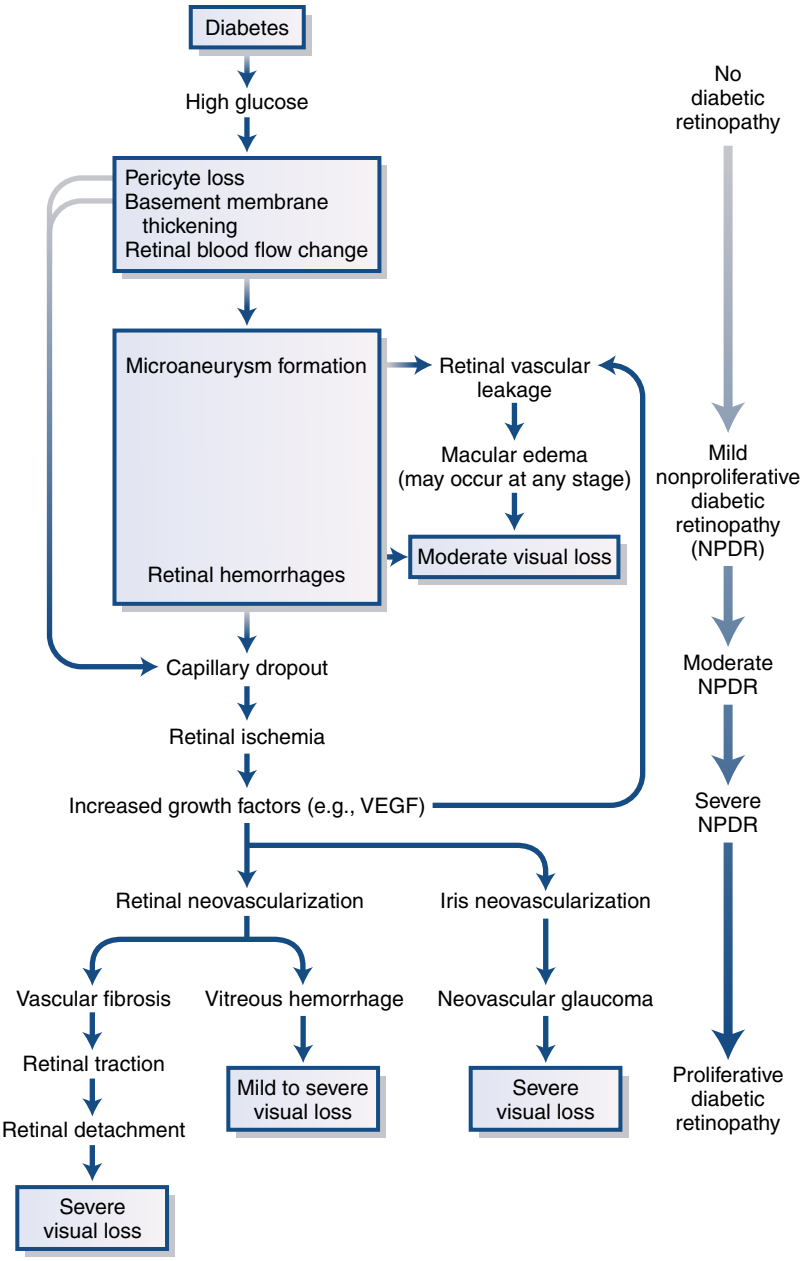
There is a higher risk of more frequent and severe ocular complications in T1DM than T2DM.[293] Approximately 25% of patients with T1DM have retinopathy after 5 years, and this figure increases to 60% and 80% after 10 and 15 years, respectively. The most visually threatening form of retinopathy (PDR) is present in about 67% of T1DM patients who have had diabetes for 35 years.[294] However, because T2DM accounts for 90% to 95% of the diabetic population in the United States, type 2 disease accounts for a higher fraction of patients with vision loss.

In the United States, an estimated 700,000 people have PDR, 130,000 of whom have high-risk PDR. Among people with diabetes, 500,000 have macular edema, of whom 325,000 have clinically significant macular edema (CSME).[295–299] An estimated 63,000 cases of PDR, 29,000 cases of high-risk PDR, 80,000 cases of macular edema, 56,000 cases of CSME, and 12,000 to 24,000 new cases of legal blindness occur each year as a result of diabetic retinopathy.[295,296,300] Blindness is estimated to be 25 times more common in persons with diabetes than in those without the disease.[301,302] Rates of progression to PDR or severe visual loss have declined over the last four decades in developed countries due to improvements in medical management, earlier identification, and treatment of diabetic retinopathy with laser photocoagulation.[303] However, given the dramatically increasing prevalence of diabetes worldwide, with 629 million individuals expected to be affected by diabetes by the year 2045,[304] a proportionally larger number of individuals will be at risk for vision loss from diabetic eye complications over the next few decades. Threefold increases in vision-threatening diabetic retinopathy will affect 3.4 million Americans aged 40 and older by 2050, as estimated by the Centers for Disease Control and Prevention (CDC).[306]

Many individuals with diabetes and vision-threatening diabetic retinopathy are not aware of the presence or the severity of their disease. The 2010 National Health and Nutrition Examination Survey revealed that only 45% of Americans with DME were aware that diabetes had affected their eyes and nearly 60% of these individuals had not had a dilated eye examination within the past year. These findings reflect both a lack of awareness among patients at risk for vision loss from diabetic eye complications and insufficient evaluation for many patients with vision-threatening retinopathy.[306]

Pathophysiology of Diabetic Retinopathy

A detailed discussion of the pathophysiologic mechanisms underlying diabetic retinopathy and other diabetes-related complications has been presented earlier in this chapter. The earliest

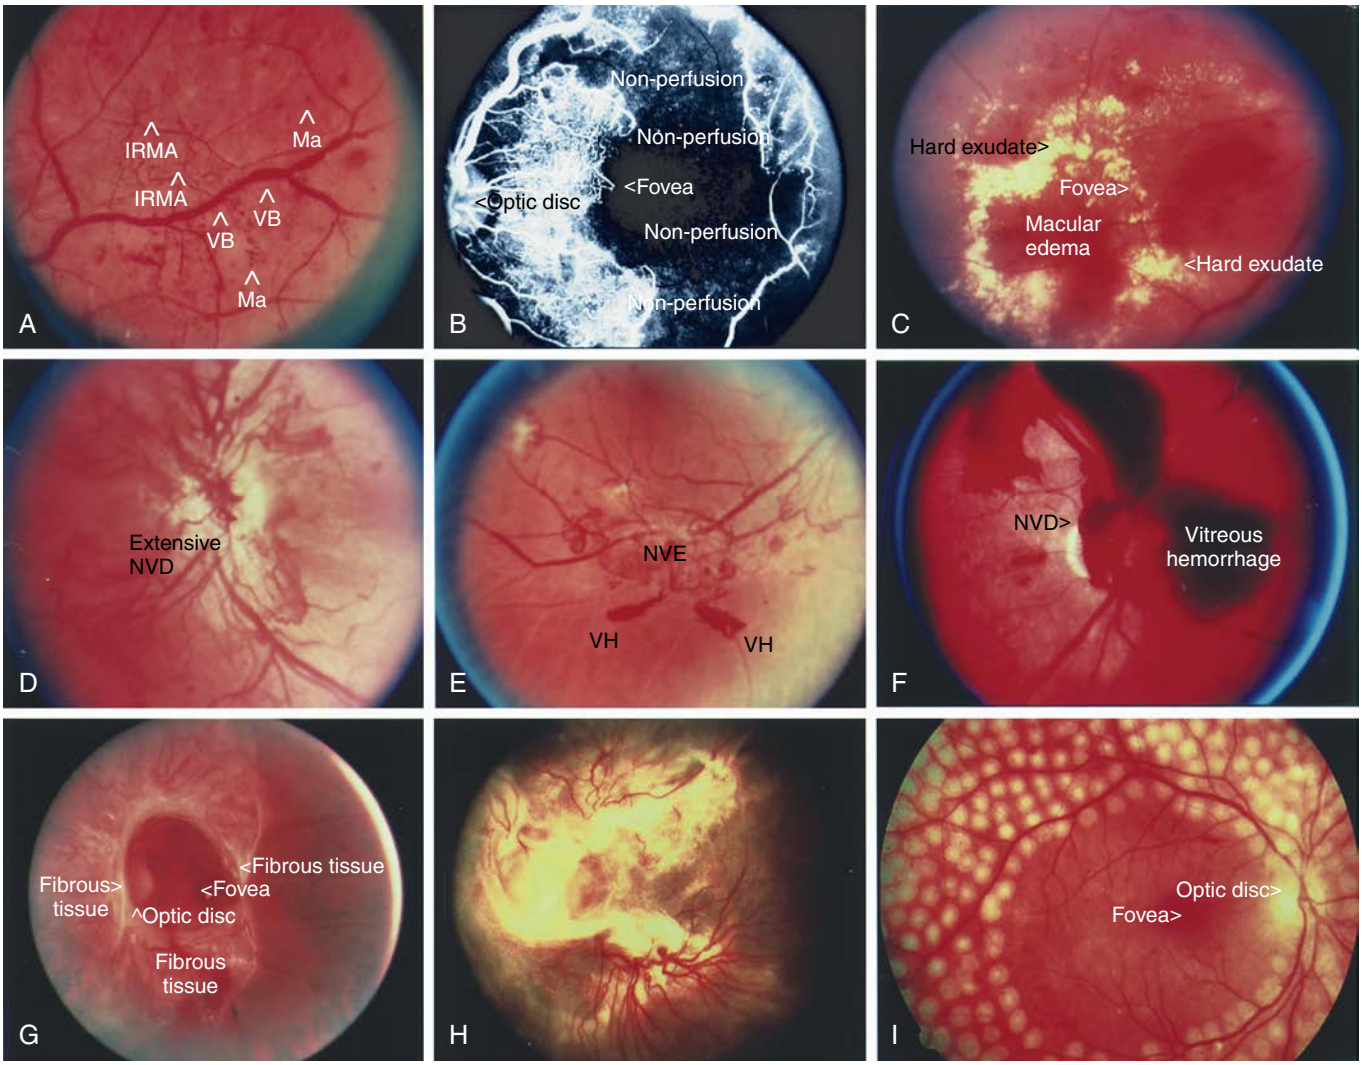


• **Fig. 37.26** Pathogenesis of diabetic retinopathy. This schematic flow chart represents the major preclinical and clinical findings associated with the full spectrum of diabetic retinopathy and macular edema. *VEGF,* Vascular endothelial growth factor.

histologic effects of diabetes mellitus in the eye include loss of retinal vascular pericytes (supporting cells for retinal endothelial cells), thickening of vascular endothelium basement membrane, and alterations in retinal blood flow (Fig. 37.26).[307–310] With increasing loss of retinal pericytes, the retinal vessel wall develops outpouchings (microaneurysms) and becomes fragile.

Clinically, microaneurysms and small retinal hemorrhages might not always be readily distinguishable from each other and are usually evaluated together as "hemorrhages and microaneurysms" (Fig. 37.27A). Rheologic changes occur in diabetic retinopathy and result from increased platelet aggregation, integrin-mediated leukocyte adhesion, and endothelial damage.[311–313] Disruption of the blood-retina barrier can ensue, characterized by increased vascular permeability.[314,315] Subsequent leakage of blood and serum from the retinal vessels results in retinal hemorrhages, retinal edema, and hard exudates (see Fig. 37.27A and C). Vision loss can follow if the fovea is affected by the leakage.[316]

With time, increasing sclerosis and endothelial cell loss lead to narrowing of the retinal vessels, which decreases vascular perfusion and can ultimately lead to obliteration of the capillaries and small vessels (see Fig. 37.27B). The resulting retinal ischemia is a potent inducer of angiogenic growth factors. Several angiogenic growth factors have been isolated from eyes with diabetic retinopathy, including insulin-like growth factors, basic fibroblast growth factor (bFGF), and VEGF.[317,318] These factors promote the development of new vessel growth and retinal vascular permeability.[319,320] Indeed, inhibition of angiogenic molecules such as VEGF and their signaling pathways can suppress the development of retinal



• **Fig. 37.27** Clinical features of diabetic retinopathy: Some typical findings in human diabetic retinopathy. (A) Findings in severe nonproliferative diabetic retinopathy, including microaneurysms (Ma), venous beading *(VB),* and intraretinal microvascular abnormalities (IRMA). (B) Fluorescein angiogram showing marked capillary nonperfusion. (C) Clinically significant macular edema with retinal thickening and hard exudates involving the fovea. (D) Extensive neovascularization of the optic disc (NVD), illustrating high-risk proliferative diabetic retinopathy. (E) Neovascularization elsewhere (NVE) and two small vitreous hemorrhages (VH), also illustrating high-risk proliferative diabetic retinopathy. (F) Extensive vitreous hemorrhage arising from severe neovascularization of the disc (NVD). (G) Severe fibrovascular proliferation surrounding the fovea. (H) Traction retinal detachment from extensive fibrovascular proliferation. (I) Scars from scatter (panretinal) laser photocoagulation. The macula, fovea, and optic disc are not treated to preserve central vision. Laser burns are evident as white retinal lesions. (Adapted from Aiello LP. Eye complications of diabetes. In Korenman SG, Kahn CR, eds. *Atlas of Clinical Endocrinology.* Vol 2: *Diabetes.* Philadelphia, PA: Blackwell Scientific; 1999.)

neovascularization and retinal vascular permeability.[321,322] VEGF-independent endogenous inhibitors of angiogenesis and vascular permeability such as pigment epithelial-derived factor (PEDF), plasma kallikrein, and erythropoietin have also been found in the eye, and these have therapeutic potential.[323,324]

New vessels tend to grow in regions of strong vitreous adhesion to the retina, such as at the optic disc and major vascular arcades (see Fig. 37.27D and E). The posterior vitreous face also serves as a scaffold for pathologic neovascularization, and the new vessels commonly arise at the junctions between perfused and nonperfused retina. When the retina is severely ischemic, the concentration of angiogenic growth factors can reach sufficient concentration in the anterior chamber to cause abnormal new vessel proliferation on the iris and the anterior chamber angle.[318,325] Uncontrolled anterior segment neovascularization can result in neovascular glaucoma because the fibrovascular proliferation in the angle of the eye causes blockage of aqueous outflow through the trabecular meshwork.[305]

Proliferating new vessels in diabetic retinopathy are fragile and have a tendency to bleed, which results in preretinal and vitreous hemorrhages (see Fig. 37.27E and F). Although the presence of a large amount of blood in the preretinal space or vitreous cavity is not damaging to the retina, these intraocular hemorrhages often cause vision loss by blocking the visual axis. Vitreous hemorrhage

can clear spontaneously without intervention, but eyes in which hemorrhage is nonclearing may need vitrectomy surgery to restore vision. Vitreous hemorrhage can also decrease the ability to visualize the retina and thereby limit the ability to adequately diagnose and treat other retinal disease. Membranes on the retinal surface can be induced by blood and result in wrinkling and traction on the retina. Although all retinal neovascularization, given sufficient time, eventually becomes quiescent, as with most scarring processes there is progressive fibrosis of the new vessel complexes that is associated with contraction. In the eye, such forces can exert traction on the retina, leading to tractional retinal detachment and retinal tears that can cause severe and permanent vision loss if left untreated (see Fig. 37.27G and H).

In short, causes of vision loss from complications of diabetes mellitus include retinal ischemia involving the fovea, macular edema at or near the fovea, preretinal or vitreous hemorrhage, retinal detachment, and neovascular glaucoma. Vision loss can also result from more indirect effects of vasculopathy in diabetic patients, such as retinal vessel occlusion, accelerated atherosclerotic disease, and embolic phenomena.

Clinical Features of Diabetic Retinopathy

Risk Factors

Duration of diabetes is closely associated with the onset and severity of diabetic retinopathy. Nearly all patients with T1DM develop some degree of retinopathy after 20 years.[293,296,326] In the United States approximately 20% of patients with newly diagnosed T2DM have retinopathy at the time of diagnosis,[326] and more than 60% develop some degree of retinopathy over subsequent decades. In the UKPDS study of T2DM, 35% of female subjects and 39% of male subjects had some level of diabetic retinopathy at the time of diabetes diagnosis.[327]

Age of onset of diabetes is another risk factor. Diabetic retinopathy is rare in prepubescent patients with T1DM.[87] In the Wisconsin Epidemiologic Study of Diabetic Retinopathy, approximately 4% of patients younger than 30 years of age at diagnosis and nearly 2% of patients older than 30 years of age at diagnosis were legally blind. In the younger-onset group, 86% of blindness was attributable to diabetic retinopathy. In the older-onset group, in which other eye diseases were also common, 33% of the cases of legal blindness were due to diabetic retinopathy.[294,326,328]

Lack of appropriate glycemic control is the most significant known risk factor for the onset and progression of diabetic retinopathy. The DCCT demonstrated a clear relationship between hyperglycemia and higher risk of diabetic microvascular complications, including retinopathy, in 1441 patients with T1DM.[9,329–332] Intensive insulin therapy reduced or prevented the development of retinopathy by 27% as compared with conventional therapy in patients monitored for 4 to 9 years in the DCCT. Additionally, intensive insulin therapy reduced the progression of diabetic retinopathy by 34%, to 76%, and had a substantial beneficial effect over the entire range of retinopathy severity. These results underscore the fact that although intensive therapy might not prevent retinopathy completely, it reduces the risk of retinopathy onset and progression.

Interestingly, the effect of reducing the HbA_{1c} in this group, from 9.1% for conventional treatment to the 7.3% for intensive treatment, resulted in a benefit maintained through 18 years of subsequent follow-up in the EDIC study, even though the difference in mean HbA_{1c} levels of the two former randomized treatment groups was only 0.4% at 1 year ($p < 0.001$), continued to narrow, and became statistically nonsignificant from 5 years onward (8.1% vs. 8.2%, $p = 0.09$). The rate of further progression of complications from their levels at the end of the DCCT remains less in the former intensive treatment group. Thus the benefits of 6.5 years of intensive treatment continue to accrue well beyond the period of initial HbA_{1c} difference.[9,22,330,333–335] Beyond retinopathy progression itself, the risk for diabetes-related ocular surgery was reduced 48% in the intensive therapy group[336] over a median follow-up of 23 years. Applying DCCT intensive insulin therapy to all persons in the United States with T1DM would result in a gain of 920,000 person-years of sight,[331] although the costs of intensive therapy are three times that of conventional therapy.[337]

Presence of renal disease, as manifested by microalbuminuria and proteinuria, is yet another significant risk factor for onset and progression of diabetic retinopathy.[338,339] Hypertension is associated with PDR and is an established risk factor for the development of macular edema.[340] Independent of renal disease, elevated serum lipid levels are associated with extravasated lipid in the retina (hard exudates) and vision loss.[341]

Clinical Findings

Clinical findings associated with early and progressing diabetic retinopathy include microaneurysms, hemorrhages, cotton-wool spots, hard exudates, intraretinal microvascular abnormalities, and venous abnormalities such as venous loops, venous tortuosity, and venous beading (see Fig. 37.27A and C). Microaneurysms are outpouchings of the capillary walls that can leak fluid and result in intraretinal edema and hemorrhages. The intraretinal hemorrhages can be flame shaped or dot-blot–like in appearance, reflecting the architecture of the retinal layer in which they occur. Flame-shaped hemorrhages occur in inner retina closer to the vitreous, and dot-blot hemorrhages occur deeper in the retina. Intraretinal microvascular abnormalities are either new vessel growth within the retinal tissue itself or shunt vessels through areas of poor vascular perfusion. It is common for intraretinal microvascular abnormalities to be located adjacent to cotton-wool spots. Cotton-wool spots are caused by microinfarcts in the nerve fiber layer of the retina. Venous caliber abnormalities, also known as venous beading, are generally a sign of severe retinal hypoxia. In some cases of extensive vascular loss, however, the retina may actually appear free of nonproliferative lesions on clinical examination. Such areas are termed *featureless retina* and are a sign of severe retinal hypoxia.

Vision loss from diabetic retinopathy generally results from persistent nonclearing vitreous hemorrhage, traction retinal detachment, retinal nonperfusion, or DME (see Figs. 37.26 and 37.27). Neovascularization with fibrous tissue contraction can distort the retina and lead to traction retinal detachment. The new vessels can bleed, causing preretinal or vitreous hemorrhage. The most common cause of vision loss from diabetes, however, is macular disease and macular edema. Macular edema is more likely to occur in patients with T2DM. In diabetic macular disease, macular edema involving the fovea or nonperfusion of the capillaries in the central macula is responsible for the loss of vision.

Classification Systems

Classification of Diabetic Retinopathy

Diabetic retinopathy is broadly classified into *nonproliferative diabetic retinopathy* (NPDR) and *proliferative diabetic retinopathy* categories.[342,343] Macular edema can be present in eyes with nonproliferative or proliferative disease and is not used in the classification of level of retinopathy. The historic terms *background retinopathy* and *preproliferative diabetic retinopathy* have been

replaced to reflect the specific characteristics and risk stratification of the prognostically important subgroups in NPDR (Table 37.1).

Generally, diabetic retinopathy progresses from no retinopathy through mild, moderate, severe, and very severe NPDR and eventually to PDR. The level of NPDR is determined by the extent and location of clinical manifestations of retinopathy. Mild NPDR is characterized by limited microvascular abnormalities such as hemorrhages or microaneurysms, cotton-wool spots, and increased vascular permeability. Moderate and severe NPDR is characterized by increasing severity of hemorrhages or microaneurysms, venous caliber abnormalities, intraretinal microvascular abnormalities, and vascular closure. The level of NPDR establishes the risk of progression to sight-threatening retinopathy and dictates appropriate clinical management and follow-up.

TABLE 37.1 Glossary and Abbreviations Pertinent to Diabetic Eye Disease

Term	Definition
Antivascular endothelial growth factor (anti-VEGF) therapies; VEGF inhibitors	For the purposes of this chapter, these refer to VEGF inhibitors (including aflibercept, bevacizumab, and ranibizumab) that are given intravitreously for the treatment of diabetic macular edema and proliferative diabetic retinopathy.
Background diabetic retinopathy (BDR)	An outdated term referring to some stages of NPDR; not closely associated with disease progression; replaced by the various levels of NPDR.
Center-involved (or central-involved) diabetic macular edema (ciDME)	Abnormal thickening of the central retina (usually 1 mm in diameter central retinal subfield) due to increased vascular permeability. Because central involvement is more likely to cause visual impairment, it is commonly used as a threshold for treatment.
Clinically significant macular edema (CSME)	Thickening of the retina in the macular region of sufficient extent and location to threaten central visual function.
Cotton-wool spot	A gray or white area lesion in the nerve fiber layer of the retina resulting from stasis of axoplasmic flow caused by microinfarcts of the retinal nerve fiber layer.
Diabetes Control and Complications Trial (DCCT)	A multicenter, randomized clinical trial designed to address whether intensive insulin therapy could prevent or slow the progression of systemic complications of diabetes mellitus.
Diabetic retinopathy (DR)	Retinal damage related to the underlying systemic disease of diabetes mellitus.
Diabetic Retinopathy Study (DRS)	The first multicenter, randomized clinical trial to demonstrate the value of scatter (panretinal) photocoagulation in reducing the risk of vision loss among patients with all levels of diabetic retinopathy.
Diabetic Retinopathy Vitrectomy Study (DRVS)	A multicenter clinical trial evaluating early vitrectomy for patients with very advanced diabetic retinopathy or nonresolving vitreous hemorrhage.
Early Treatment Diabetic Retinopathy Study (ETDRS)	A multicenter, randomized clinical trial that addressed at what stage of retinopathy scatter (panretinal) photocoagulation was indicated, whether focal photocoagulation was effective for preventing moderate vision loss due to clinically significant macular edema, and whether aspirin therapy altered the progression of diabetic retinopathy.
Focal or grid laser photocoagulation	A type of laser treatment whose main goal is to reduce vascular leakage, either by focal treatment of leaking retinal microaneurysms or by application of therapy in a gridlike pattern for patients with clinically significant macular edema.
Hard exudate	Lipid accumulation within the retina as a result of increased vasopermeability.
High-risk characteristic proliferative diabetic retinopathy (HRC-PDR)	Proliferative diabetic retinopathy of defined extent, location, or clinical findings that is particularly associated with severe vision loss.
Microaneurysm	An early vascular abnormality consisting of an outpouching of the retinal microvasculature.
Neovascular glaucoma (NVG)	Elevation of intraocular pressure caused by the development of neovascularization in the anterior segment of the eye.
Neovascularization at the disc (NVD)	Retinal neovascularization occurring at or within 1500 μm of the optic disc.
Neovascularization elsewhere (NVE)	Retinal neovascularization that is located more than 1500 μm away from the optic disc.
Neovascularization of the iris (NVI)	Neovascularization occurring on the iris (rubeosis iridis), usually as a result of extensive retinal ischemia.
No light perception (NLP)	The inability to perceive light.
Nonproliferative diabetic retinopathy (NPDR)	Severities (mild, moderate, severe) of clinically evident diabetic retinopathy that precede the development of PDR.
Preproliferative diabetic retinopathy (PPDR)	An outdated term referring to more advanced levels of NPDR; not closely associated with disease progression; replaced by the various levels of NPDR.
Proliferative diabetic retinopathy (PDR)	An advanced level of diabetic retinopathy in which proliferation of new vessels or fibrous tissue occurs on or within the retina.
Rubeosis iridis	Neovascularization of the iris.

PDR is characterized by vasoproliferation of the retina and its complications, including new vessels on the optic disc (NVD), new vessels elsewhere on the retina (NVE), preretinal hemorrhage (PRH), vitreous hemorrhage, and fibrous tissue proliferation (FP). On the basis of the extent and location of these lesions, PDR is classified as *early PDR* or *high-risk PDR*. Larger areas of these complications as well as new vessels that are near the optic disc are associated with greater risks of vision loss.

Classification of Diabetic Macular Edema

DME can be present at any severity of diabetic retinopathy. Historically, eyes with DME were categorized as having nonclinically significant or clinically significant macular edema. The term CSME was first introduced in the Early Treatment Diabetic Retinopathy Study (ETDRS) to indicate an increased risk for moderate visual loss and was used as a threshold to determine need for laser treatment. CSME exists if there is retinal thickening at or within 500 μm of the fovea, hard exudates at or within 500 μm of the fovea with adjacent retinal thickening, or an area or areas of retinal thickening one disc area or more in size, any part of which is within 1500 μm of the fovea.[342,344,345] CSME is a clinical diagnosis that is not dependent on visual acuity or results of ancillary testing such as fluorescein angiography and can be present even when vision is 20/20 or better.

In the recent era, with the advent of ocular coherence tomography (OCT) and its objective quantitative measurement of retinal thickness, clinical care and clinical trial endpoints have shifted to evaluating whether the center of the macula is involved or not. Data from the ETDRS evaluating eyes with macular edema have shown the presence or absence of thickening involving the center of the macula, now termed *center-involved DME,* which is highly associated with short-term and long-term visual acuity outcomes. In the ETDRS, eyes with center-involved DME had nearly a 10-fold greater risk for developing moderate visual loss compared to eyes without center involvement. The identification of center-involved DME is critical because it will generally indicate how likely the DME is to cause visual impairment and is a key criteria for determining the need for treatment. Noncenter-involved DME does not typically cause visual loss or symptoms, and frequently does not progress to center-involved DME. Thus if the center of the macula is not involved there is often not a compelling reason to treat. As a result, recent clinical studies and guidelines for clinical care have generally used the presence or absence of thickening of the central 1-mm diameter of retina, along with visual status, as the defining criteria to consider initiation of treatment for eyes with DME.

International Classification of Diabetic Retinopathy and Diabetic Macular Edema

The American Academy of Ophthalmology initiated a project to establish a consensus International Classification of Diabetic Retinopathy and Diabetic Macular Edema in an effort to simplify classification and standardize communication among diabetes health care providers.[346,347] This international classification describes five clinical levels of diabetic retinopathy: no apparent retinopathy (no abnormalities), mild NPDR (microaneurysms only), moderate NPDR (more than microaneurysms only but less than severe NPDR), severe NPDR (any of the following: >20 intraretinal hemorrhages in each of four retinal quadrants, definite venous beading in two or more retinal quadrants, prominent intraretinal microvascular abnormalities in one or more retinal quadrants, and no PDR), and PDR (one or more of retinal neovascularization, vitreous hemorrhage, or preretinal hemorrhage). Table 37.2 compares levels of retinopathy in the international classification to those defined by the landmark ETDRS.

In regard to DME, the international classification identifies two broad categories: macular edema apparently absent (no apparent retinal thickening or hard exudates in the posterior pole) and macular edema apparently present (some apparent retinal thickening or hard exudates in the posterior pole). Macular edema is subclassified as mild (some retinal thickening or hard exudates in the posterior pole but distant from the center of the macula), moderate (retinal thickening or hard exudates approaching the center of the macula but not involving the center), or severe (retinal thickening or hard exudates involving the center of the macula). Table 37.3 compares levels of DME in the international classification to ETDRS levels of DME.

As compared with ETDRS retinopathy grading, the International Classification of Diabetic Retinopathy and Diabetic Macular Edema reduces the number of levels of diabetic retinopathy, simplifies descriptions of the categories, and describes the levels

TABLE 37.2 Levels of Diabetic Retinopathy

International Classification Level	ETDRS Level
No apparent retinopathy	Level 10: DR absent
Mild NPDR	Level 20: very mild NPDR
Moderate NPDR	Levels 35, 43, and 47: moderate NPDR
Severe NPDR	Levels 53A–E: severe to very severe NPDR
PDR	Levels 61, 65, 71, 75, 81, 85: PDR, high-risk PDR, very severe or advanced PDR

DR, Diabetic retinopathy; *ETDRS,* Early Treatment Diabetic Retinopathy Study; *NPDR,* nonproliferative diabetic retinopathy; *PDR,* proliferative diabetic retinopathy.

From Grading diabetic retinopathy from stereoscopic color fundus photographs—an extension of the modified Airlie House classification. ETDRS report number 10. Early Treatment Diabetic Retinopathy Study Research Group. *Ophthalmology.* 1991;98:S786–S806.

TABLE 37.3 International Classification of Diabetic Macular Edema (DME)

Disease Severity Level	Ophthalmic Findings (Retinal Thickening or Hard Exudates in Posterior Pole)	ETDRS Scale Equivalent
DME apparently absent	None apparent	
DME apparently present	Some apparent	
Mild DME	Some findings present but distant from center of the macula	DME but not CSME
Moderate DME	Findings approaching the center but not involving the center	CSME
Severe DME	Findings involving the center of the macula	CSME

CSME, Clinically significant macular edema; *ETDRS,* Early Treatment Diabetic Retinopathy Study.

without relying on reference to the standard photographs of the Airlie House Classification of diabetic retinopathy. This approach makes clinical use easier and more uniform among practitioners not versed in the complexities of the ETDRS grading system. However, because of this simplification, the International Classification of Diabetic Retinopathy and Diabetic Macular Edema is not a replacement for ETDRS levels of diabetic retinopathy in large-scale clinical trials or studies for which precise retinopathy classification is required.

Other Ocular Manifestations of Diabetes

All structures of the eye are susceptible to complications of diabetes. The consequence of these changes can range from being unnoticed by both patient and physician, to symptomatic but not sight threatening, to requiring evaluation to rule out potentially life-threatening underlying causes other than diabetes.

Mononeuropathies of the third, fourth, or sixth cranial nerves can arise in association with diabetes; mononeuropathy of the fourth cranial nerve is least likely associated with diabetes and warrants workup for other causes.[348–350] Nerve palsies present a significant diagnostic challenge because misdiagnosis can result in a life-threatening lesion remaining untreated. In one review of cranial nerve palsies treated in a diabetic patient population in 1967, 42% of mononeuropathies were not diabetic in origin.[349] This finding underscores the danger of routinely attributing mononeuropathies to the diabetic condition itself without carefully ruling out other potential causes. The percentage of all extraocular muscle palsies attributable to diabetes mellitus is estimated at 4.5% to 6%.[350] Mononeuropathies may be the initial presenting sign of new-onset diabetes, and diabetes should therefore be considered in the differential diagnosis of any mononeuropathy affecting the extraocular muscles, even in patients who do not claim a history of diabetes. Diabetes-induced third-nerve, fourth-nerve, and sixth-nerve palsies are usually self-limited and should resolve spontaneously in 2 to 6 months. Palsies can recur or subsequently develop in the contralateral eye.

The optic disc can be affected by diabetes in a variety of ways other than vasoproliferation. Diabetic papillopathy is a diagnosis of exclusion and must be distinguished from other causes of disc swelling such as true papilledema from increased intracranial pressure, pseudopapilledema such as optic nerve head drusen, toxic optic neuropathies, neoplasms of the optic nerve, and hypertension.[351] Optic disc pallor can occur following spontaneous remission of proliferative retinopathy or remission following scatter (panretinal) laser photocoagulation (see Fig. 37.27I). Because diabetes poses an increased risk for developing open-angle glaucoma, the disc pallor following remission of retinopathy or laser photocoagulation must be considered when evaluating the optic nerve head for glaucoma.

A diabetic ocular complication with potentially serious consequences is neovascularization of the iris. Neovascularization of the iris occurs in 4% to 7% of diabetic eyes and may be present in 40% to 60% of eyes with proliferative retinopathy. Usually new iris vessels are first observed at the pupillary border, followed by a fine network of vessels over the iris tissue progressing into the filtration angle of the eye. Closure of the angle by the fibrovascular network results in neovascular glaucoma, which can lead to irreversible optic nerve damage and vision loss due to the rise in intraocular pressure.[354] Neovascular glaucoma is difficult to manage and requires aggressive treatment. Diabetes is the second leading cause of neovascular glaucoma, accounting for 32% of cases.[355] When possible, scatter (panretinal) laser photocoagulation is the primary therapy for neovascular glaucoma and provides durable regression of neovascularization of the iris and angle for most eyes. Other approaches such as goniophotocoagulation, topical or systemic antiglaucoma medications, and antiglaucomatous filtration surgery are available when needed.[356–358] Intravitreal administration of VEGF inhibitors is now frequently utilized in eyes with acute neovascular glaucoma and results in remarkably rapid regression of the neovascularization with resulting normalization of the intraocular pressure.[359] However, the effects of anti-VEGF agents are often transient, and there is frequently recurrence of neovascularization unless injections are given on a monthly basis. Thus a more durable therapy such as scatter laser photocoagulation is often performed.

The cornea of the diabetic person is more susceptible to injury and slower to heal after injury than is the nondiabetic cornea.[359a,360] The diabetic cornea is also more prone to infectious corneal ulcers, which can lead to rapid loss of vision, need for corneal transplant, or loss of the eye if it is not treated aggressively. Consequently, diabetic patients using contact lenses should exercise caution to avoid contact lens overwear and to maintain careful monitoring.

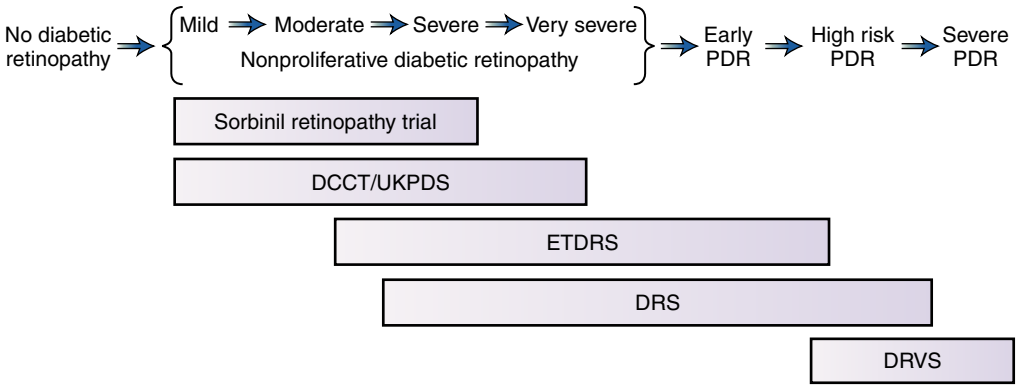
Open-angle glaucoma is 1.4 times more common in the diabetic population than in the nondiabetic population.[361] The prevalence of glaucoma increases with age and duration of diabetes, but medical therapy for open-angle glaucoma is generally effective. In a study of 76,318 women enrolled in the Nurses' Health Study, Pasquale and coworkers found that T2DM is associated with an increased risk of primary open-angle glaucoma in women.[362]

Diabetes effects on the crystalline lens can result in transient refractive changes, alterations in accommodative ability,[363] and cataracts. Refractive change can be significant and is related to fluctuation of blood glucose levels with osmotic lens swelling.[365] Cataracts can occur earlier in life and progress more rapidly in the presence of diabetes.[364,365] Cataracts are 1.6 times more common in people with diabetes than in those without diabetes.[364,365] In patients with earlier onset diabetes, duration of diabetes, retinopathy status, diuretic use, and HbA_{1c} levels are risk factors.[366] In patients with later onset diabetes, age of the patient, lower intraocular pressure, smoking, and lower diastolic BP may be additional risk factors.[367,368] Diabetic patients undergoing simultaneous kidney and pancreas transplantation are at an increased risk of developing all types of cataracts, independent of the use of corticosteroids after transplantation.[369] Both phacoemulsification and extracapsular cataract extraction with intraocular lens implantation are appropriate surgical therapies. The principal determinant of postoperative vision and progression of retinopathy is related to the preoperative presence of DME and the severity of diabetic retinopathy.[370,371]

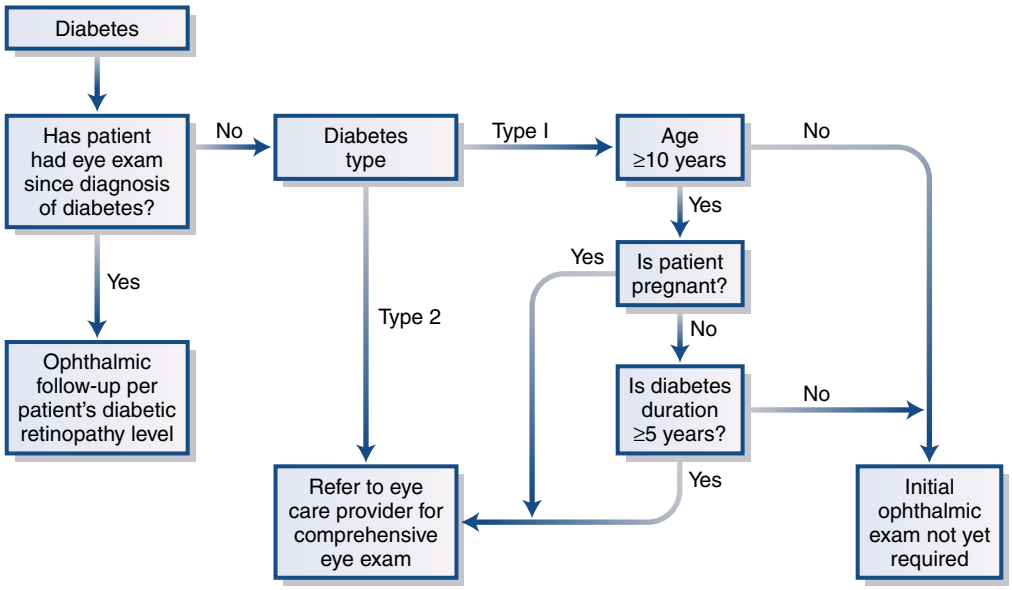
Other findings with higher incidence among patients with diabetes include xanthelasma,[348] microaneurysms of the bulbar conjunctiva,[372] posterior vitreous detachment,[373] and the rare but often fatal orbital fungal infection Mucorales phycomycosis.[352,353] Prompt diagnosis and treatment of phycomycosis caused by *Mucor* species are crucial, although the survival rate remains at only 57%.[353,374]

Monitoring and Treatment of Diabetic Retinopathy

Appropriate clinical management of diabetic retinopathy has been defined by results of major randomized, multicenter clinical trials (Fig. 37.28): the Diabetic Retinopathy Clinical Research Network



• **Fig. 37.28** Schematic representation of the major multicenter clinical trials of diabetic retinopathy and the severity levels of diabetic retinopathy that they primarily addressed. *DCCT,* Diabetes Control and Complications Trial; *DRS,* Diabetic Retinopathy Study; *DRVS,* Diabetic Retinopathy Vitrectomy Study; *ETDRS,* Early Treatment Diabetic Retinopathy Study; *PDR,* proliferative diabetic retinopathy; *UKPDS,* United Kingdom Prospective Diabetes Study.



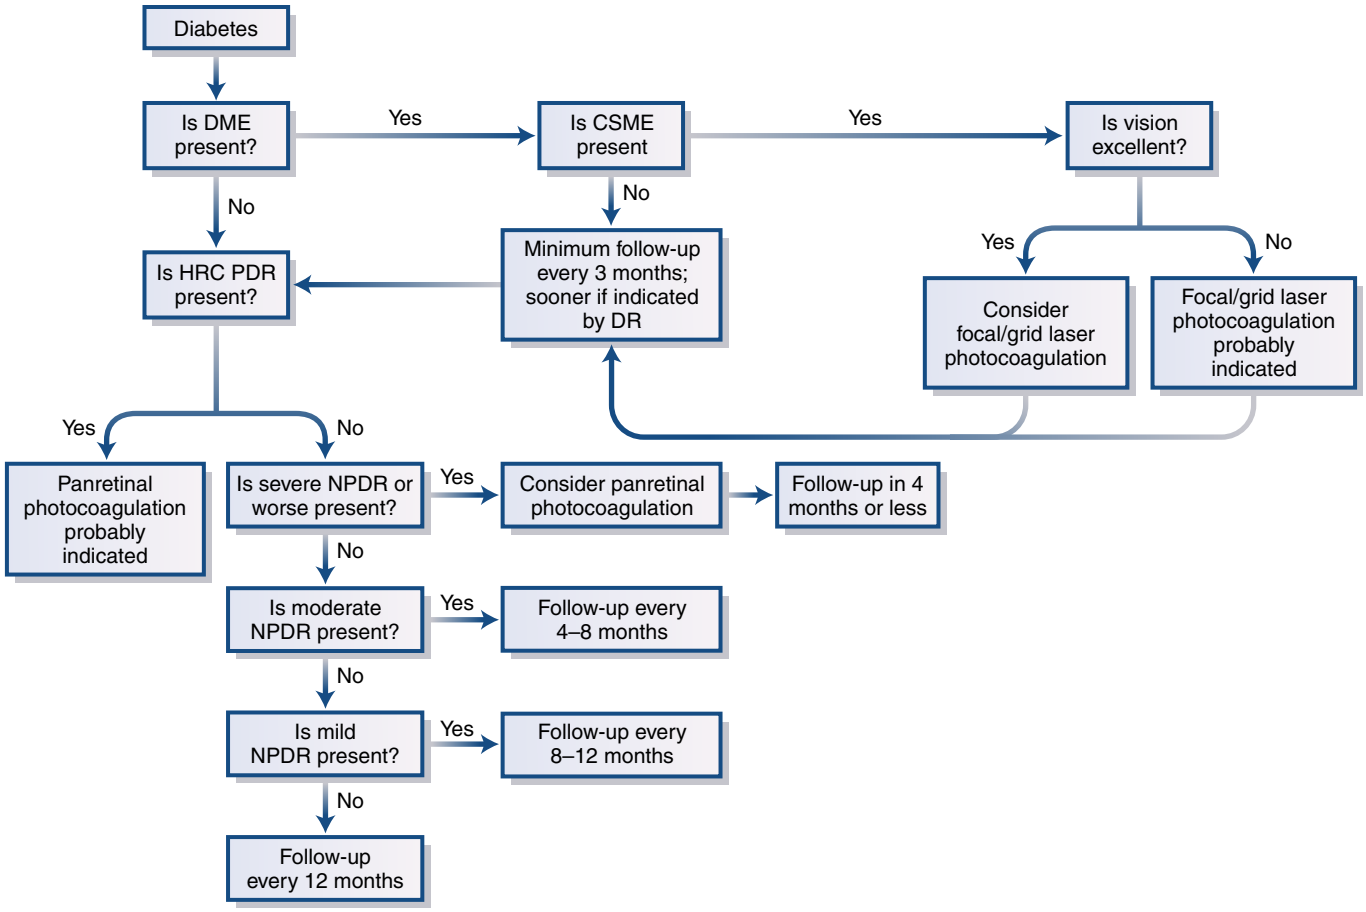
• **Fig. 37.29** Schematic flow chart of major principles involved in determining the timing of initial ophthalmic examination after a diagnosis of diabetes mellitus. These are minimal recommended times. Ocular symptoms, complaints, or other associated medical issues can necessitate earlier evaluation. Guidelines are regularly reevaluated based on new study results.

Protocols I, S, and T,[290,291,375] Diabetic Retinopathy Study (DRS),[376] ETDRS,[316] Diabetic Retinopathy Vitrectomy Study (DRVS),[377] DCCT,[378] and UKPDS.[379] These studies have elucidated the progression rates of each level of diabetic retinopathy, guided follow-up intervals, and demonstrated the proper delivery, timing, and resulting effectiveness of glycemic control, laser photocoagulation, and intravitreous anti-VEGF therapy (Figs. 37.29, 37.30, 37.31, and 37.32). They have also established recommendations for vitrectomy surgery for diabetic eye complications.

Comprehensive Eye Examination

An accurate ocular examination detailing the extent and location of retinopathy-associated findings is critical for determining monitoring and treatment decisions in patients with diabetic retinopathy. As detailed later, most of the blindness associated with advanced stages of retinopathy can be averted with appropriate and timely diagnosis and therapy. Unfortunately, many diabetic patients do not receive adequate eye care at an appropriate stage of their disease.[380,381] In fact, 11% of T1DM and 7% of T2DM patients with high-risk PDR necessitating prompt treatment had not been examined by an ophthalmologist within the past 2 years.[381] In one study, 55% of patients with high-risk PDR or CSME had never had laser photocoagulation.[380]

The comprehensive eye examination is the mainstay of such evaluation and is necessary on a repetitive, lifelong basis for patients with diabetes.[342,382] Such an evaluation has four major components: history, examination, diagnosis, and treatment as needed. Annual retinal evaluation to assess the presence and level of diabetic retinopathy and DME is essential to guide patient care. The fundamentals of a comprehensive eye examination for the nondiabetic patient have been detailed by the American Academy of Ophthalmology[382] and the American Optometric Association.[383]



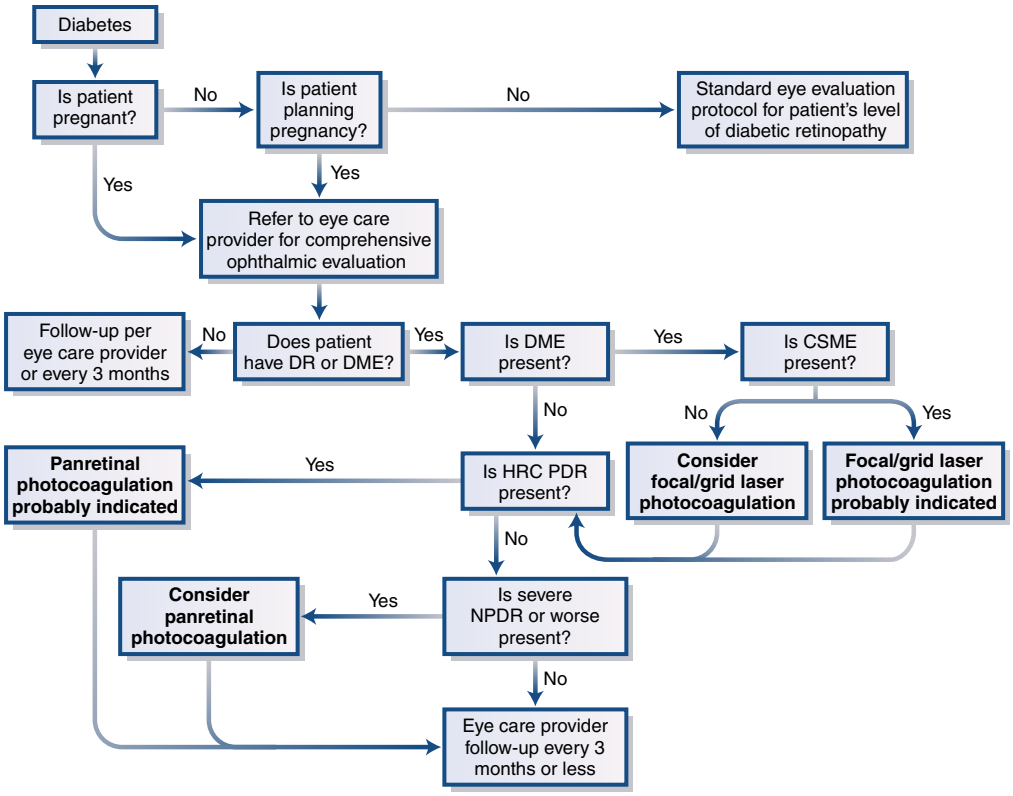
• **Fig. 37.30** Diabetic retinopathy and macular edema examination and treatment flow chart: nonpregnant patients. The schematic flow chart presents major principles involved in determining routine ophthalmic follow-up and indications for treatment in nonpregnant patients with diabetes. These intervals are only general, minimal recommended frequencies. Ocular symptoms, complaints, or other associated ophthalmic or medical issues can necessitate earlier evaluation or an altered approach. Guidelines are regularly reevaluated based on new study results. *CSME,* Clinically significant macular edema; *DME,* diabetic macular edema; *DR,* diabetic retinopathy; *HRC PDR,* high-risk characteristic proliferative diabetic retinopathy; *NPDR,* nonproliferative diabetic retinopathy; *PDR,* proliferative diabetic retinopathy.

The examination of the patient with diabetes should be similar, with additional emphasis on portions of the examination that relate to problems particularly relevant to diabetes.

Dilated ophthalmic examination is superior to undilated evaluation because only 50% of eyes are correctly classified as to presence and severity of retinopathy through undilated pupils.[384,385] Appropriate ophthalmic evaluation entails pupillary dilation, slit-lamp biomicroscopy, examination of the retinal periphery with indirect ophthalmoscopy or mirrored contact lens, and sometimes gonioscopy.[382,383] Because of the complexities of the diagnosis and treatment of PDR and CSME, ophthalmologists with specialized knowledge and experience in the management of diabetic retinopathy are required to determine and provide appropriate surgical intervention.[386] Thus it is recommended that all patients with diabetes should have dilated ocular examinations by an experienced eye care provider (ophthalmologist or optometrist), and diabetic patients should be under the direct or consulting care of an ophthalmologist experienced in the management of diabetic retinopathy at least by the time moderate diabetic retinopathy or DME is present. Retinal imaging that has demonstrated equivalency to dilated retinal fundus examination or the accepted standard of ETDRS seven-standard-field stereoscopic retinal imaging when interpreted by a trained eye care provider can also be appropriate for retinal evaluation.[387,388] Furthermore, ocular telehealth programs for diabetic retinopathy that utilize validated means of retinal imaging have the potential to expand access to highly effective evidence-based diabetes eye care and provide cost-effective alternative methods of care.[389]

Initial Ophthalmic Evaluation

The recommendation for initial ocular examination in persons with diabetes is based on the prevalence rates of retinopathy and the incidence of subsequent vision threatening diabetic eye complications (see Fig. 37.29). Approximately 80% of T1DM patients have retinopathy after 15 years of disease, but only about 25% have any retinopathy after 5 years of diabetes.[385] The prevalence of PDR is less than 2% at 5 years and 25% by 15 years. For T2DM, the onset date of diabetes is usually unknown, and severe retinal disease can be observed even at the time of diabetes diagnosis. Up to 3% of patients whose diabetes is first diagnosed after age 30 years (T2DM) have CSME or high-risk PDR at the time of initial diagnosis of diabetes.[390] Thus in patients older than 10 years, initial ophthalmic examination is recommended beginning 5 years after the diagnosis of T1DM and immediately after diagnosis of T2DM (see Fig. 37.29).[342,391]



• **Fig. 37.31** Diabetic retinopathy and macular edema examination and treatment flow chart: pregnant patients. The schematic flow chart shows major principles involved in determining routine ophthalmic follow-up and indications for treatment in pregnant patients with diabetes. These intervals are only general, minimal recommended frequencies. Ocular symptoms, complaints, or other associated ophthalmic or medical issues can necessitate earlier evaluation or an altered approach. Because retinopathy can progress rapidly in pregnant patients with diabetes, careful and more frequent evaluation is often indicated. Guidelines are regularly reevaluated based on new study results. *CSME,* Clinically significant macular edema; *DME,* diabetic macular edema; *DR,* diabetic retinopathy; *HRC PDR,* high-risk characteristic proliferative diabetic retinopathy; *NPDR,* nonproliferative diabetic retinopathy.

Puberty and pregnancy can accelerate retinopathy progression. The onset of vision-threatening retinopathy is rare in children prior to puberty, regardless of the duration of diabetes[391,392]; however, significant retinopathy can arise within 6 years of disease if diabetes is diagnosed between the ages of 10 and 30 years.[295] Diabetic retinopathy can become particularly aggressive during pregnancy in patients with diabetes.[393,394] In the past, the prognosis for pregnancy in the diabetic patient with microvascular complications was so poor that pregnant diabetic patients were commonly advised to avoid or terminate pregnancies.[395] With recognition of the importance of glycemic control, diabetic patients in the childbearing age now can experience safe pregnancy and childbirth with minimal risk to both the mother and the baby.[396]

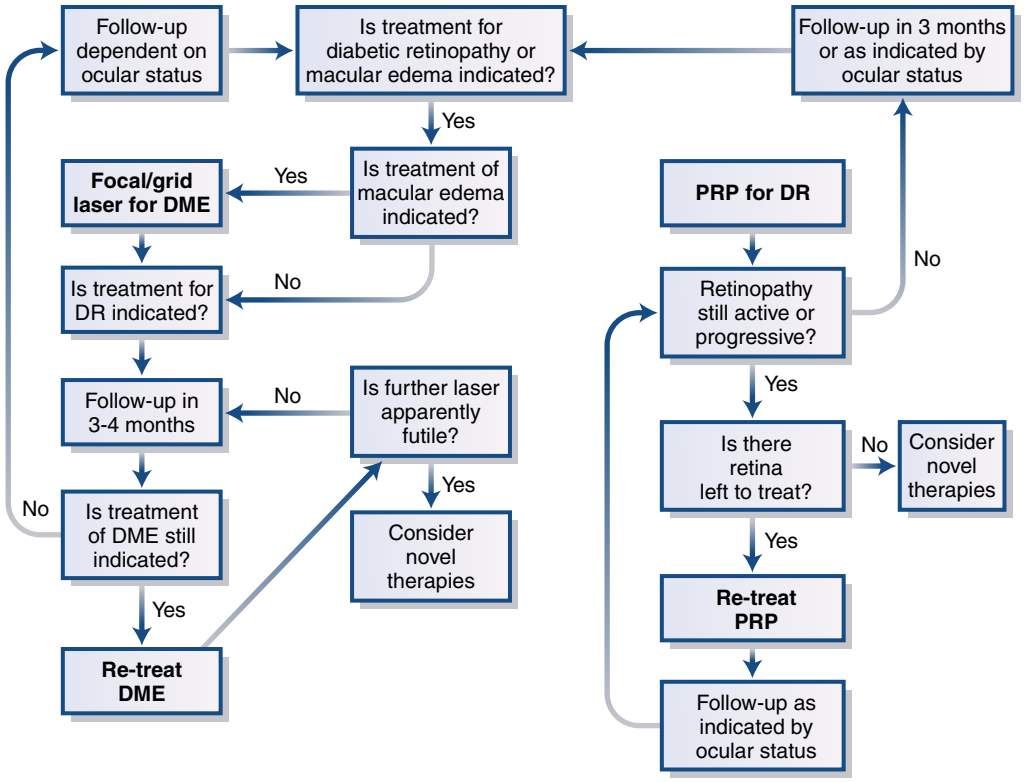
Ideally, patients with diabetes who are planning pregnancy should have a comprehensive eye examination within 1 year prior to conception (see Fig. 37.31). Treatment may be indicated prior to conception for patients who are at risk for vision loss if their diabetic retinopathy were to worsen during pregnancy. Patients who become pregnant should have a comprehensive eye examination in the first trimester of pregnancy. Close follow-up throughout pregnancy is indicated, with subsequent examinations determined by the findings present at the first-trimester examination.[342] This recommendation does not apply to women who develop gestational diabetes because they are not at increased risk of developing diabetic retinopathy.

Follow-Up Ophthalmic Examination

Follow-up ocular examination is determined from the risk of disease progression at any particular retinopathy severity (see Fig. 37.30). NPDR is clinically categorized into four levels of severity based on clinical findings compared to stereo fundus photographic standards: mild, moderate, severe, and very severe.[397] Progression of nonproliferative retinopathy to the visually threatening level of high-risk PDR is closely correlated with baseline NPDR severity (Table 37.4). Progression rates from each individual NPDR level to any other retinopathy level are also known. These are used to define standard minimal follow-up intervals as detailed in Fig. 37.30 and Table 37.5. Because significant sight-threatening retinopathy can initially occur with no or minimal visual symptoms, patients with no clinically evident diabetic retinopathy and no known ocular problems still require annual comprehensive ophthalmic examinations even if they are totally asymptomatic.

Evaluation and Treatment of Proliferative Diabetic Retinopathy

The extent and location of neovascularization determine the level of PDR.[398,399] PDR is best evaluated by dilated fundus examination using slit-lamp biomicroscopy combined with indirect ophthalmoscopy or stereo fundus photography. Fluorescein angiography and optical coherence tomography angiography can also



• **Fig. 37.32** Photocoagulation flow chart. This schematic flow chart details general photocoagulation treatment approaches in patients with diabetic retinopathy or diabetic macular edema. These are only general guidelines, and actual treatment choices can be affected by numerous other factors, including findings in the same eye or in the contralateral eye and systemic issues. *DME,* Diabetic macular edema; *DR,* diabetic retinopathy; *PRP,* scatter (panretinal) photocoagulation.

aid in identifying small, subtle patches of retinal neovascularization. However, these imaging modalities are usually not required for the diagnosis of PDR because these findings are clinically evident in most cases (Fig. 37.33).

The presence of PDR in an eye substantially increases the risk for severe vision loss. Severe visual loss is defined as best corrected acuity of 5/200 or worse on two consecutive visits 4 months apart. This represents vision loss substantially worse than the 20/200 or worse limit defined as legal blindness. Without treatment, eyes with high-risk PDR have a 28% risk of severe vision loss within 2 years. This risk compares with a 7% risk of severe vision loss after 2 years for eyes with PDR but without high-risk characteristics.[398]

Until this decade, scatter (panretinal) laser photocoagulation was the sole therapy shown to be effective against PDR. The DRS demonstrated that panretinal laser photocoagulation was effective in reducing the risk of severe vision loss from PDR by 50% or more. The ETDRS further demonstrated that panretinal laser photocoagulation applied when an eye approaches or just reaches high-risk PDR reduces the risk of severe vision loss to less than 4%. Based on these results, prompt scatter photocoagulation is considered appropriate for all patients with high-risk PDR, usually appropriate for patients with PDR less than high risk, and may be advisable for patients with severe or very severe NPDR, especially in the setting of T2DM (see Fig. 37.30).[316,398-401]

Recent progression of eye disease, status of the fellow eye, compliance with follow-up, concurrent health concerns such as hypertension or kidney disease, and other factors must be considered in determining if laser surgery should be performed in these patients. In particular, patients with T2DM should be considered for scatter photocoagulation before high-risk PDR develops because the risk of severe vision loss and the need for pars plana vitrectomy (PPV) can be reduced by 50% in these patients, especially when macular edema is present.[401]

In scatter photocoagulation, 1200 to 1800 laser burns are applied to the peripheral retinal tissue, actually focally destroying the outer photoreceptor and retinal pigment epithelium of the retina (see Fig. 37.27I). Large vessels are avoided, as are areas of

preretinal hemorrhage. The treatment is thought to exert its effect by increasing oxygen delivery to the inner retina, decreasing viable hypoxic growth factor–producing cells, and increasing the relative perfusion per area of viable retina. The total treatment is usually applied over one to three sessions, spaced 1 to 2 weeks apart. Follow-up evaluation usually occurs at 3 months.

The response to scatter photocoagulation varies. The most desirable effect is to see a regression of the new vessels, although stabilization of the neovascularization with no further growth can result. This latter situation requires careful clinical monitoring. In some cases, new vessels continue to proliferate, requiring additional scatter photocoagulation or adjuvant treatment with intravitreous anti-VEGF agents (see Fig. 37.32).

Recent studies have shown that anti-VEGF treatment with aflibercept or ranibizumab is an effective first-line alternative to scatter photocoagulation in carefully selected patients with PDR[375,402,403] Neovascular processes are exquisitely sensitive to anti-VEGF agents, and eyes with severe neovascularization of the retina or anterior segment have demonstrated dramatic and rapid improvement with anti-VEGF therapy.[322,404] The Diabetic Retinopathy Clinical Research (DRCR) Network Protocol S demonstrated that visual acuity outcomes at 2 and 5 years were noninferior in eyes treated with intravitreal ranibizumab to those obtained with scatter photocoagulation. Anti-VEGF treatment with ranibizumab was associated with several advantages over laser therapy. There was greater average visual gain over the course of the first 2 years, reduced rates of visual impairment from DME onset, less loss of peripheral visual field, and decreased need for vitrectomy surgery at both 2 and 5 years in the ranibizumab group.

When delivered by a standardized retreatment algorithm such as that developed for Protocol S (Fig. 37.34), anti-VEGF therapy is highly effective at reducing retinal neovascularization. In Protocol S, 38% of the eyes treated with ranibizumab were eligible to defer monthly injections due to sustained stability of neovascularization at least once over the first 2 years of follow-up, and retinal neovascularization was completely resolved at 44% of visits through 2 years.[405] Nonetheless, eyes randomized to ranibizumab treatment in Protocol S continued to need a median of three injections per year through 2 to 5 years. It should also be realized that patients with PDR often have systemic comorbidities that may contribute to missed or rescheduled office visits. Thus patient compliance with follow-up and treatment recommendations is a critical aspect of ensuring successful outcomes with anti-VEGF therapy for PDR. If compliance is expected to be a problem for a specific patient, then treatment with laser panretinal photocoagulation alone, or in combination with a VEGF inhibitor, is the preferred therapeutic approach.

Surgical intervention with PPV is usually reserved for eyes with nonclearing vitreous hemorrhage or traction detachment from PDR. The DRVS, completed in 1989, demonstrated that early PPV in persons with severe fibrovascular proliferation was more likely to result in better vision and less likely to result in poor vision, particularly in patients with T1DM.[377] PPV aims primarily to remove abnormal fibrovascular tissue, alleviate retinal traction, allow the retina to obtain a more anatomically normal position, and remove vitreous opacities such as vitreous hemorrhage. The actual outcome data from this study is not entirely applicable today due to dramatic advances in surgical techniques and the advent of laser endophotocoagulation that have occurred in the intervening years. Nevertheless, it is clear that PPV can save and restore vision in many cases of severe retinal disease that are not amenable, or not responsive, to laser photocoagulation.

Treatment of Nonproliferative Diabetic Retinopathy

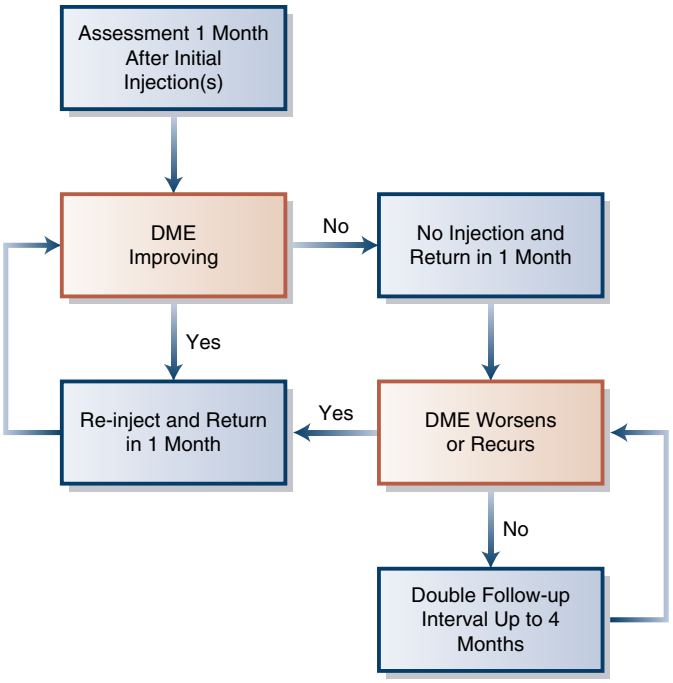
Studies of intravitreous therapy with VEGF inhibitors and steroids have demonstrated beneficial effects of these medications on DR severity and rates of progression to PDR-related complications such as vitreous hemorrhage and need for vitrectomy. Nearly 40% of eyes achieve two or more step regression of diabetic retinopathy severity after 3 years of monthly continuous anti-VEGF therapy for DME.[406–408] Decreased rates of PDR onset and need for PDR treatment are also observed after ranibizumab therapy as compared to sham treatment.[407] After an average of 4.4 injections of aflibercept over 6 months, 58% of eyes experienced a two or more step improvement in diabetic retinopathy severity as compared to 6% of sham-treated eyes.[408] Steroid therapy, whether delivered by the peribulbar or intravitreal route, also resulted in decreased risk of diabetic retinopathy worsening. Over 2 years, intravitreal steroid administration resulted in a 32% relative risk reduction for retinopathy progression as compared to sham treatment.[407] Although these results are promising, there is no treatment mandate at this time for eyes with nonproliferative diabetic retinopathy since long-term visual outcomes have not been definitively shown to be superior after treatment with any of these intraocular therapeutic approaches versus medical care alone.

Treatment of Diabetic Macular Edema

Untreated CSME is associated with an approximately 25% chance of moderate vision loss after 3 years (defined as at least doubling the visual angle; e.g., 20/40 reduced to 20/80).[316] Macular edema is best evaluated clinically by dilated examination using slit-lamp biomicroscopy or stereo fundus photography. The newer diagnostic ophthalmic imaging technique of OCT has provided a means to objectively quantify retinal thickening and is currently the objective method of choice. When used in conjunction with visual acuity measurement, OCT has been used to monitor response to treatment and help determine timing of intervention.[409,410] As discussed earlier, the current standard for macular edema evaluation focuses on determining the presence or absence of edema involving the center of the macula.

Current first-line therapy for most eyes with center-involved DME and DME-related visual impairment of 20/32 or worse is intravitreous injections of VEGF inhibitors following a defined protocol such as that described by the DRCR Network[291] (Fig. 37.35). Typically, injections are performed monthly with a loading dose of at least four to six injections. On average, eight to nine injections are performed in the first year of treatment. The average number of injections required to maintain the beneficial visual acuity gains declines substantially to three or four in the second year, one or two in the third year, and zero to one in years 4 and 5.

Results from an initial multicenter randomized controlled clinical trial evaluating intravitreal administration of ranibizumab either with immediate laser or with deferred laser show a marked benefit of the anti-VEGF agent compared to laser alone. After 1 year, ranibizumab as applied in the trial resulted in a nine-letter mean gain ($p < 0.001$) when combined either with prompt laser or deferral of laser for at least 24 weeks. This was more effective than prompt laser alone (three-letter gain) for the treatment of center-involving DME in eyes with central thickening and vision reduced to 20/32 to 20/320. The number of eyes gaining two or more lines of vision almost doubled in the anti-VEGF groups as compared with laser alone. Conversely, eyes losing two or more lines of vision were about one-third as many in the anti-VEGF groups as compared to laser alone. Results were sustained over 5 years despite a substantially decreased number of injections



• **Fig. 37.35** Diagram showing the Diabetic Retinopathy Clinical Research Network (DRCR.net) rationale for treatment and follow-up of center-involved diabetic macular edema (DME) with antivascular endothelial growth factor therapy. (Modified from Aiello LP, Beck RW, Bressler NM, et al. Rationale for the Diabetic Retinopathy Clinical Research Network intravitreal anti-VEGF treatment and follow-up protocol for center-involved diabetic macular edema. *Ophthalmol.* 2011;118:e5–e14.)

throughout years 2 to 5.[411,412] No increased systemic events or serious ocular adverse events were attributed to the treatment other than the known small risk of endophthalmitis (1 per 1000 injections) associated with intravitreal injections themselves.

A head-to-head comparative effectiveness trial demonstrated overall efficacy of all three currently commercially available intraocular VEGF inhibitors (aflibercept, bevacizumab, and ranibizumab) in improving visual acuity and reducing retinal thickening in eyes with center-involved DME.[291] Eyes with only mild visual impairment from DME and baseline vision of 20/32 to 20/40 had similar visual acuity outcomes on average regardless of therapeutic group assignment. However, in eyes with baseline vision of 20/50 or worse, aflibercept provided visual gains superior to those achieved with bevacizumab at 1 and 2 years, and vision outcomes were superior to ranibizumab at 1 but not 2 years.

Although VEGF inhibitors are highly successful in many eyes, approximately 40% to 50% of eyes still have persistent DME or visual impairment despite chronic monthly therapy. Thus there is a continued unmet need for novel therapies that address VEGF-independent mechanisms for DME onset, persistence, and worsening.

Focal laser photocoagulation may still be indicated for some patients with DME (see Figs. 37.27C and 37.30) without center involvement or in eyes with good vision or in patients who cannot tolerate a regimen of intravitreal injections. The ETDRS demonstrated focal laser photocoagulation for CSME reduced the 5-year risk of moderate vision loss by 50%, but 15% of patients continue to experience vision loss.[345] In focal laser photocoagulation, lesions from 500 to 3000 μm from the center of the macula that are contributing to thickening of the macular area are generally

directly photocoagulated. These lesions are identified clinically or by fluorescein angiography and consist primarily of leaking microaneurysms. When leakage is diffuse or microaneurysms are extensive, photocoagulation may be applied to the macula in a grid configuration, avoiding the fovea region.

If macular laser is planned, fluorescein angiography can be a useful test for guiding the focal treatment of microaneurysm that are leaking fluid into the retina and identifying areas of macular capillary nonperfusion that might benefit from grid laser treatment (see Fig. 37.33). Because there are risks associated with fluorescein angiography, including nausea, urticaria, hives, and rarely death (1 in 222,000 patients) or severe medical sequelae (1 in 2000 patients),[413–415] fluorescein angiography is not otherwise part of the routine examination of a diabetic patient without diabetic retinopathy, and the procedure is usually contraindicated in patients with known allergy to fluorescein dye or during pregnancy.

Follow-up evaluation after focal laser treatment generally occurs after 3 months (see Fig. 37.30). In cases in which macular edema persists, further treatment may be necessary. In the presence of macular edema, patients with PDR or severe NPDR should be considered for anti-VEGF or laser treatment of macular edema whether or not the macular edema is center involved because they are likely to require scatter laser photocoagulation in the near future and because scatter photocoagulation, while beneficial for PDR, can exacerbate existing macular edema.

The ophthalmic use of corticosteroids administered either through the periocular or intravitreal routes for the treatment of DME gained widespread use due to early case reports and uncontrolled clinical trials documenting its rapid and often dramatic effect on retinal thickening. Two multicenter randomized prospective clinical trials were undertaken to address both the effectiveness and safety of both routes of steroid administration. In the first, peribulbar steroid injections were found to have no significant benefit for the treatment of DME.[416] The 3-year results of a second multicenter randomized controlled trial comparing intravitreal steroids to focal laser therapy have shown that despite an initial rapid reduction in retinal thickness and improvement in vision with the intravitreal steroid injection, by 1 year the results were no better than laser photocoagulation, and at 2 years through 3 years, steroid was inferior to the laser treatment in both visual outcome and retinal thickness improvement.[417,418] Intravitreal steroid injections were associated with an approximately fourfold increase in the rate of intraocular pressure complications and fourfold increase in need for cataract surgery compared to laser treatment. The development of cataract was likely a large contributor to declining visual acuity in the steroid-treated group after the first 6 months. This hypothesis is supported by the fact that patients who had already undergone cataract surgery prior to initiating intravitreal steroid treatment demonstrated vision improvement comparable to that seen in the anti-VEGF-treated group.[375]

Intravitreous steroid therapy has also been investigated as a potential additive therapy to intravitreous VEGF inhibitors in patients who have persistent retinal thickening and visual impairment despite at least six injections of anti-VEGF. Although retinal thickening is significantly reduced in eyes after combined steroid and anti-VEGF therapy compared to those receiving anti-VEGF treatment alone, visual acuity outcomes do not appear to be improved.[419] Thus, currently, intravitreal steroid alone is not the preferred primary therapy for DME or a recommended adjuvant therapy in eyes that have not responded successfully to anti-VEGF therapy. Intraocular steroid treatment may have a role, however, for treatment of patients with DME who cannot receive anti-VEGF agents or who are pseudophakic before treatment.

The pathogenesis of DME is highly complex, and a variable response to treatment modalities has been observed in many patients. Investigations of varying drug dosages to identify the optimal treatment concentration and development of sustained drug delivery devices to limit risks, costs, and inconvenience associated with repeated intraocular injections are underway. Multiple potential therapeutics are also being tested in clinical trials for the treatment of DME, including a bispecific antibody against VEGF and angiotensin II, plasma kallikrein inhibition, photobiomodulation therapy, and other novel approaches.

Control of Systemic Disorders and Effect of Systemic Medications

In addition to the importance of intensive glycemic control in reducing the onset and progression of diabetic retinopathy as discussed earlier, it is critical for the optimal ocular health of diabetic patients that several other systemic considerations be optimized.

Elevated blood pressure exacerbates the development and progression of diabetic retinopathy. Concomitant hypertension is common in diabetes. Patients with T1DM have a 17% prevalence of hypertension at baseline and a 25% incidence after 10 years.[420] There is a 38% to 68% prevalence in T2DM.[421–423] In most studies, hypertension correlates with other retinopathy risk factors, including duration of diabetes, higher HbA_{1c} level, presence of proteinuria, and male gender. The risk of PDR is associated with the presence of hypertension at the baseline visit, higher HbA_{1c} levels, and presence of more severe levels of retinopathy at the initial visit.[424] Patients with hypertension are more likely to develop retinopathy, diffuse macular edema, and more severe levels of retinopathy[425–427] and have more rapid progression of retinopathy when compared with diabetic patients who do not have hypertension.[427–429]

The large randomized, prospective UKPDS in 1148 patients with T2DM demonstrated a 34% ($p = 0.0004$) and 47% ($p < 0.004$) reduction in risk of diabetic retinopathy progression and moderate visual acuity loss, respectively, in patients assigned to intensive blood control.[430] Effects were independent of glycemic control, and risk reductions were similar regardless of whether the hypertension was controlled with an angiotensin-converting enzyme (ACE) inhibitor (captopril) or a beta blocker (atenolol). Overall, hypertension appears to be a significant risk factor in the development and progression of diabetic retinopathy and should be rigorously controlled. Until the results of specific trials investigating the blood pressure levels required to minimize end-organ damage in patients with diabetes are known,[431] target blood pressure should most likely be maintained as low as safely possible.

Associations between renal and retinal angiopathy are numerous. Both microalbuminuria and proteinuria are associated with retinopathy.[432–435] The presence and severity of diabetic retinopathy are indicators of the risk of gross proteinuria,[436,437] and conversely, proteinuria predicts PDR.[433,438,439] Half of all T1DM patients with PDR and 10 or more years of diabetes have concomitant proteinuria.[432] In T1DM, the prevalence of PDR increases from 7% at onset of microalbuminuria to 29% 4 years after onset of albuminuria, compared with 3% and 8%, respectively, in patients without persistent microalbuminuria.[440] The Appropriate Blood Pressure Control in Diabetes (ABCD) trial found both the severity and progression of retinopathy were associated with overt albuminuria.[441–443] The presence of gross proteinuria at baseline is associated with 95% increased risk of developing macular edema among patients with T1DM,[424] and dialysis can improve macular edema in diabetic patients with renal failure.

Despite these associations, a causal relationship between diabetic kidney disease and diabetic retinopathy has not been established. The frequent coexistence of retinal and renal microangiopathies with factors that affect both complications, such as associated hypertension and disease duration, make it difficult to establish.[444] Overall, it is important to carefully consider the renal status of any patient with diabetes and to ensure that the patient is receiving optimal care in this regard. In addition, rapidly progressive retinopathy, especially in a patient with a long history of diabetes where retinopathy previously has been stable, should suggest the need for renal evaluation.

Low hematocrit was an independent risk factor in the ETDRS analysis of baseline risk factors for development of high-risk PDR and severe vision loss.[445] A cross-sectional study involving 1691 patients revealed a twofold increased risk of any retinopathy in patients with a hemoglobin level less than 12 g/dL compared to those with a higher hemoglobin concentration, using multivariate analyses controlling for serum creatinine, proteinuria, and other factors.[446] In patients with retinopathy, those with low hemoglobin levels have a fivefold increased risk of severe retinopathy compared with those with higher hemoglobin levels. There have been limited reports of resolution of macular edema and hard exudate with improvement or stabilization of visual acuity in erythropoietin-treated patients after an increase in mean hematocrit.[447] In view of the potential association of low hematocrit and diabetic retinopathy, it is important to ensure that patients with diabetic retinopathy and anemia are receiving appropriate management.

In summary, diabetes is clearly a multisystem disease requiring a comprehensive medical team approach. Even with regard to ocular health, this necessitates the involvement of multiple health care specialists for optimal patient care.

Diabetic Nephropathy

Diabetic nephropathy remains a major cause of morbidity and death for persons with either T1DM or T2DM. In Western countries, diabetes is the leading single cause of end-stage renal disease.[210] Indeed, in many countries such as the United States, more than 50% of patients in renal replacement therapy programs have diabetes as the major cause of their renal failure. However, the full impact of diabetic nephropathy is far greater.[448] Globally most patients with diabetes are in developing countries that do not have the resources or health infrastructure to provide universal renal replacement therapy.[449] Even in developed countries, for every 20 patients with diabetes and chronic kidney disease, less than one will survive to end-stage renal disease, succumbing instead to atherosclerotic cardiovascular disease, heart failure, or infection. Furthermore, the presence and severity of diabetic renal disease significantly contributes to the risk of these conditions. For example, almost all of the excess in cardiovascular deaths in persons with diabetes younger than 50 years can be attributed to nephropathy.[450] Indeed, in T1DM subjects without nephropathy there may be a lower risk of premature death,[451] although a recent review of the FinnDiane cohort indicates that in nonalbuminuric T1DM subjects there is still evidence of increased mortality.[452] In patients with T2DM, microalbuminuria is associated with a twofold to fourfold increase in the risk of death. In patients with overt proteinuria and hypertension, the risk is even higher.[453] Consequently, the goal to reduce ESRD in patients with diabetes is only one component as part of the overall benefit in preventing diabetic kidney disease.

It is estimated that 25% to 40% of patients with T1DM and 5% to 40% of patients with T2DM ultimately develop some features of diabetic kidney disease.[454,455] Over 20% of patients with T2DM already have diabetic kidney disease when they are diagnosed with diabetes,[456] and a further 20% to 40% develop diabetic nephropathy, mostly within 10 years of diagnosis. Although nephropathy appears be more common in T1DM, because of the large and increasing number of persons with T2DM,[449,457] more than 80% of diabetic patients in renal replacement programs have T2DM.

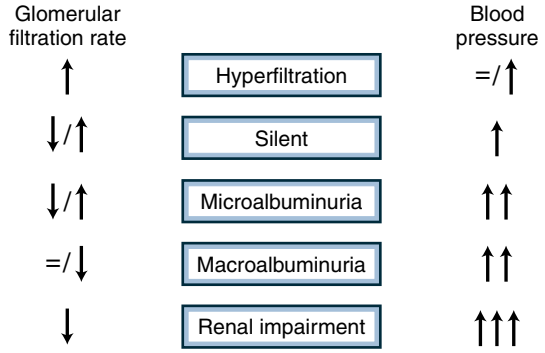
Natural History of Nephropathy in Type 1 Diabetes

Nephropathy and specifically proteinuria in the setting of diabetes have been known for more than 100 years, and the classic structural features of glomerulosclerosis were described more than 70 years ago.[458] However, it is only since the 1980s that the natural history of this condition has been extensively delineated. This is partly because significantly more patients are surviving to see the full presentation of this condition. For example, in 1971, the median survival time of patients with T1DM and overt nephropathy was 5 years, with less than 10% surviving more than 10 years. Consequently, few patients were able to survive the course of their renal disease. By comparison, in 1996, the median survival in an equivalent population was more than 17 years. Not surprisingly, nearly 10 times more patients with T1DM are now entering ESRD programs.

Diabetic nephropathy is characterized clinically as a triad of hypertension, proteinuria, and ultimately renal impairment.[459] The classic five stages of nephropathy as described by Mogensen and colleagues,[460] although not totally accurate, remain the best way of describing this condition (Fig. 37.36). This description relies on functional evaluation of the renal disease and is based on serial measurements of glomerular filtration rate (GFR) and albuminuria.

Stage 1: Hyperfiltration

The initial phase has been termed the *hyperfiltration* phase. It is associated with an elevation of glomerular filtration rate[460] and presumably an increase in capillary glomerular pressure. Although invariably present in animal models of T1DM,[461] an elevation of GFR occurs in up to 40% of type 1 diabetic patients. Hyperfiltration is considered to occur as a result of concomitant renal hypertrophy[462] and partly due to a range of intrarenal hemodynamic abnormalities that occur in the diabetic milieu that contribute to glomerular hypertension.[461] The pathophysiology of



• **Fig. 37.36** The phases (natural history) of diabetic nephropathy.

renal hypertrophy associated with diabetes remains unexplained, although specific growth factors such as the growth hormone (GH)/insulin-like growth hormone (IGF1) system and transforming growth factor β (TGFβ) have been implicated.[463,464] Notably, there is not only glomerular but also tubular hypertrophy. Indeed, the tubular hypertrophy explains the increased kidney weight in diabetes because tubules make up more than 90% of the kidney weight.[465] In addition, increased salt reabsorption associated with proximal tubular hypertrophy can also contribute to glomerular hyperfiltration via tubuloglomerular feedback.[463]

The second explanation for the increase in GFR associated with diabetes relates to hemodynamic changes within the kidney. Although not directly tested in humans, micropuncture studies in rodents, particularly by Brenner's group in the 1980s, revealed that experimental diabetes was associated with a range of intrarenal hemodynamic changes.[461] Alongside hyperfiltration, there is an increase in effective renal plasma flow, and thus some investigators call this the *hyperperfusion-hyperfiltration* phase of diabetic nephropathy. At the same time, intraglomerular capillary pressure is increased, reflecting relative efferent versus afferent arteriolar vasoconstriction[461] with activation of the intrarenal renin-angiotensin system (RAS) and reduced synthesis of the vasodilator nitric oxide.

The importance of this hyperfiltration phase in predicting and leading to diabetic nephropathy remains controversial. Several groups have confirmed the initial relationship between elevated GFR and later development of proteinuria as described by Mogensen and Christensen.[466] However, this has not been a universal finding. Nevertheless, subsequent studies with antihypertensive agents, and in particular agents that interrupt the renin-angiotensin system, have shown attenuation of some of these glomerular hemodynamic abnormalities.[467] This provides justification to consider that at least some of these intrarenal hemodynamic changes in diabetes play a role in the development and progression of nephropathy. However, in insulin-dependent diabetic patients the ACE inhibitor captopril had the smallest effect (17%) in reducing the risk of doubling serum creatinine in patients with serum creatinine of 1 mg/dL and the largest effect (76%) in patients whose serum creatinine was 2 mg/dL. These data do not seem to support a primary role for early hyperfiltration in the development of early diabetic nephropathy. Results suggest that in patients with type 2 diabetes with advanced renal disease, a link to hyperfiltration was not apparent.[468,469]

This field has recently been reactivated with the advent of sodium glucose cotransporter-2 (SGLT2) inhibitors, which influence tubuloglomerular feedback and have been shown to reduce intraglomerular pressure via effects on afferent arteriolar dilation.[470] Indeed, these agents have impressive effects in attenuating diabetes-associated hyperfiltration, as reported initially in T1DM but subsequently in T2DM.[471,472] Whether these hemodynamic benefits explain, at least in part, the renoprotection seen with these agents in large clinical studies, including Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients–Removing Excess Glucose (EMPA-REG OUTCOME) and Canagliflozin Cardiovascular Assessment Study (CANVAS), remains to be determined.[473,474]

Stage 2: The Silent Stage

The next stage is known as the *silent stage,* where, from a clinical point of view, there is no overt evidence of any form of renal dysfunction. Patients usually have normal GFR with no evidence of albuminuria. However, this phase is associated with significant structural changes, including basement membrane thickening and mesangial expansion. More recently, loss of the glomerular cells known as podocytes has also been described as a relatively early structural change in the diabetic kidney. Indeed, by performing detailed quantitative studies of renal morphology it is often possible to detect those who will develop renal damage.[475] This is a very important phase clinically because it is hoped that investigators will be able to develop new tests, such as biomarkers in plasma or urine or sophisticated assessments from renal biopsy material, to identify which patients will progress to more advanced renal disease. Because overall less than 40% of T1DM subjects will progress, it is critical that we detect those who are the potential progressors and could be candidates for early prevention and treatment strategies to avoid end-stage renal disease. As yet, no reliable clinically translatable surrogate markers or predictors have been identified as worth pursuing in clinical practice during this silent phase of the disease.

Extensive studies have tested various plasma markers, such as prorenin,[476] tumor necrosis factor α (TNFα) receptor,[477] advanced glycation end products,[478] and precursors such as methylglyoxal,[479] but the predictive value has not been conclusive. Although diabetic kidney disease probably has at least in part a genetic basis, few potentially relevant gene polymorphisms such as the angiotensin-converting enzyme gene have been identified.[480] Recent genome-wide association studies have not generally been very helpful.[481,482] The measurement of albumin fragments (ghost albumin) in the urine of patients with diabetes may be another, albeit unproven, approach.[483] Serial prospective ambulatory blood pressure monitoring studies have also demonstrated modest rises in blood pressure in patients in this silent phase up to 5 years before urinary albumin excretion begins to increase.[484] However, none of these markers has been proved to be sensitive or specific enough on further clinical evaluation for widespread clinical application.

Stage 3: Microalbuminuria

The third phase is known as *microalbuminuria* or the stage of *incipient nephropathy.* At this stage, often 5 to 15 years after the initial diagnosis of T1DM, the urinary albumin excretion rate has increased into the microalbuminuric range of 20 to 200 μg per minute or 30 to 300 mg per 24 hours.[485] In the past, microalbuminuria was considered to be a predictor rather than a manifestation of diabetic kidney disease. Increasingly it has been appreciated, particularly when based on interpretation of renal morphologic studies, that in the microalbuminuric phase there is often but not always widespread evidence of advanced glomerular structural changes.[486,487] Concomitant with these changes, systolic and diastolic blood pressures are increased. Furthermore, the nocturnal dip in blood pressure seen in normal persons is often lost with the development of microalbuminuria.[488] Renal function during this phase may be increased, normal, or reduced.

The best approach to screen for microalbuminuria remains controversial. The original studies used 24-hour or overnight urine sampling methods. However, a spot urine albumin:creatinine ratio in an early-morning urine specimen has been validated and appears to be a practical option for routine clinical practice.[210,485] Because the onset of persistent microalbuminuria, if left untreated, is often a reliable harbinger of overt nephropathy,[466] it is incumbent on clinicians to perform serial measurements of this parameter and to repeat the measurement if there is an isolated elevation in urinary albumin excretion.

Studies suggest that in many patients with T1DM, microalbuminuria can be transient and can reverse to normoalbuminuria.[489]

Thus the onset of microalbuminuria does not irrevocably seal the fate of the patient. A study of 386 patients with persistent microalbuminuria at study entry showed that regression of microalbuminuria occurred in 58% of patients,[489] although other groups have reported much lower rates of this phenomenon.[490] Notably, in that study, microalbuminuria of short duration, optimal levels of HbA_{1c} (<8%), low systolic blood pressure (<115 mm Hg), and low levels of both cholesterol and triglycerides were independently associated with the regression of microalbuminuria. Therefore screening of diabetic patients for nephropathy is now recommended to include at least twice-annual measurements of urinary albumin concentrations in T1DM patients.

Stage 4: Macroalbuminuria

The next stage is the *macroalbuminuria* phase or *overt nephropathy*. This stage represents the phase that has been previously described as diabetic nephropathy and is highly predictive of subsequent renal failure if left untreated. It is characterized by a urinary albumin excretion rate greater than 300 mg per 24 hours (200 μg/minute). This phase usually occurs after 10 to 15 years of diabetes, but the risk of overt renal disease never truly disappears and can appear after 40 or 50 years of T1DM.

There are at least two peaks of incidence of overt nephropathy, and this has been termed by some investigators as representing slow and fast trackers.[491] The key contributors to this marked variation in the timing of onset of proteinuria, independent of glycemic or blood pressure control, remain elusive, although a range of genetic, molecular, and environmental factors have been proposed. In association with this increase in proteinuria, more than two-thirds of patients have overt systemic hypertension.[492] During this phase, if left untreated, blood pressure continues to rise, accelerating the decline in GFR, which promotes a further rise in blood pressure, creating a vicious cycle of progressive renal impairment that ultimately leads to end-stage renal disease.

Stage 5: Uremia

The final *uremic* phase, which historically occurred in up to 40% of T1DM subjects,[454] requires the institution of renal replacement therapy. As recently as the 1970s, patients with diabetes were not considered candidates for renal replacement therapy because of their abysmal prognosis. However, improvements in the management of cardiovascular disease and renal replacement options have seen the survival on dialysis approach that of patients with renal disease from other causes. Many patients with diabetes and end-stage renal disease are also now considered candidates for renal transplantation, which is associated with better outcomes than remaining on dialysis. However, there is evidence that the renal lesions of diabetes often recur in the transplanted kidney, though the lead time to develop ESRD means that few kidneys are lost through recurrent disease.

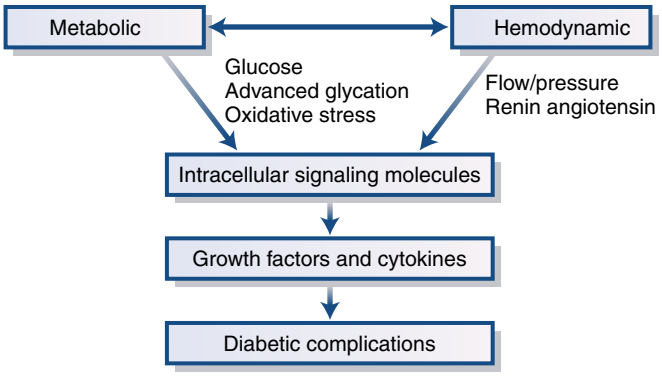
Increasingly, single pancreas-kidney (SPK) and pancreas-after-kidney (PAK) transplantation have become therapeutic options for patients with T1DM and end-stage renal disease, and these newer options appear to offer advantages over kidney-alone transplantation. In particular there is some evidence that maintaining euglycemia following pancreas transplantation can lead to resolution of many diabetes-related renal lesions such as mesangial expansion.[493] This reversal is often not apparent until after 10 years of euglycemia, emphasizing the slow turnover of matrix and the potential long-term effects of hyperglycemic memory on the kidney.

Natural History of Nephropathy in Type 2 Diabetes

The natural history of diabetic nephropathy in patients with T2DM is less well understood than in patients with T1DM. This partly reflects the fact that T2DM is largely a disease of an older population, with associated obesity, hypertension, dyslipidemia, and high rates of cardiovascular disease, which are all factors associated with increased risk of renal disease. In addition, approximately 7% of patients with T2DM already have microalbuminuria at the time of diagnosis. This may be partly related to the fact that most of these patients have had untreated diabetes for 5 to 10 years (on average) before diagnosis. Within 5 years of a diagnosis of T2DM, up to 18% of patients have microalbuminuria, especially those with poor metabolic control and high blood pressure. This has led some investigators to suggest that nephropathy in T2DM is different from that seen in patients with T1DM.

However, the natural history of nephropathy in T2DM has more similarities than differences from that seen in T1DM. Hyperfiltration does occur in T2DM,[494] although it has been reported to be less commonly observed than in T1DM. This observation must be interpreted with caution because GFR normally declines with age, and hyperfiltration can still exist, although the GFR remains in the normal adult range. Microalbuminuria also occurs in T2DM. However, the finding of microalbuminuria in T2DM might not be as specific for diabetic renal disease as described in the seminal studies in T1DM. In the context of a very high prevalence of cardiovascular disease, microalbuminuria may be more closely associated with nonrenal events such as stroke and myocardial infarction.[439] Furthermore, incipient or overt cardiac failure, urinary tract infection, and urinary obstruction (e.g., enlarged prostate) can also lead to microalbuminuria.

Many patients with T2DM and microalbuminuria also progress to overt proteinuria. However, it is increasingly appreciated that the situation has become more complex, and many groups have now described subjects with T1DM[495] as well as T2DM[496] who develop renal impairment with progressive decline in GFR in the absence of significant proteinuria. The exact explanation for this phenomenon is unknown, and ongoing studies are exploring if these patients have different renal morphologic changes from those with the more classic syndrome of diabetic nephropathy: overt proteinuria and declining GFR. Preliminary studies suggest a prominent vascular component for this form of nonproteinuric renal dysfunction. Nonetheless, it appears that the risk of end-stage renal disease in patients with T2DM and renal impairment is similar in the presence or absence of microalbuminuria, underlining the importance of an estimated GFR in the management of patients with T2DM. This has led to many of the national and international guidelines now recommending the inclusion of regular measurements of serum creatinine and determination of estimated GFR using a variety of different formulas. The frequency of these measurements differs among the various guidelines, but at a minimum these measurements should be performed on a yearly basis. Importantly, in T2DM, many subjects will develop a progressive decline in GFR without the development of albuminuria. Indeed, recent renal biopsy studies although not conclusive suggest that there may be a difference in renal morphologic lesions between albuminuric and nonalbuminuric forms of diabetic kidney disease.[497]



• **Fig. 37.37** Interactions between metabolic and hemodynamic factors in promoting diabetic complications, including nephropathy.

Pathogenesis of Diabetic Nephropathy

It is likely that many of the mechanisms implicated in diabetic microvascular complications, in general, play a central role in the development and progression of diabetic nephropathy (Fig. 37.37).[43] It is evident that hyperglycemia is necessary for the initiation of renal injury, because patients without diabetes do not develop this type of nephropathy. Moreover, intensive therapy designed to achieve improved glycemic control is able to attenuate the development of nephropathy, as assessed by urinary albumin excretion, although it is not fully prevented.[334] However, it is now clear that other factors must also be involved because continuous florid hyperglycemia is not necessarily required for diabetic hyperfiltration and kidney growth to occur. Indeed, glomerular hyperfiltration and tubular hypertrophy can persist in patients with T1DM even after euglycemia is achieved through aggressive insulin therapy.[498]

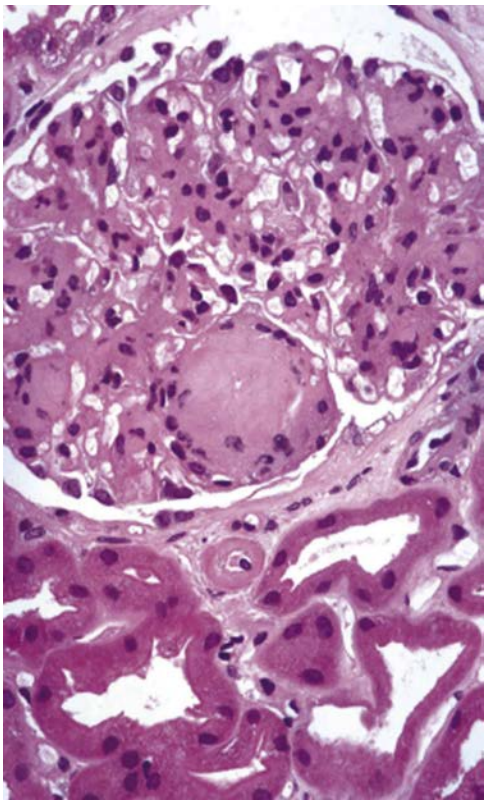
Other pathways that may be involved in diabetic nephropathy include generation of mitochondrial ROS, accumulation of AGEs, and activation of intracellular signaling molecules such as PKC.[131,499] Many of the seminal studies performed in endothelial cells demonstrating a central role for mitochondrial ROS in activating pathways implicated in diabetic vascular complications have been reproduced in mesangial cells.[500] Advanced glycation, which occurs at an accelerated rate in diabetic patients, is a prominent phenomenon in the kidney. Not only is the kidney the major site for excretion of AGEs, but also many of the proteins with a long life, such as collagen, are extensively glycated in patients with diabetes.[501] Furthermore, various AGE receptors (e.g., RAGE) have been described in the kidney, which appear to play a role in mediating some of the deleterious effects of AGEs, such as stimulation of growth factor expression and induction of important phenotypic changes within certain renal cell populations to promote scarring.[56] Preliminary studies have used various approaches to inhibit renal AGE accumulation and action, including a form of soluble RAGE (sRAGE). A range of pharmacologic agents has shown promising results, but clinical translation of these findings remains to be fully defined.[501] Selective PKC isoform inhibitors have been evaluated in small clinical trials, but their role in renal disease remains controversial.[502] Some exciting pilot studies evaluating a number of cytosolic sources of oxidative stress, such as nicotinamide adenine dinucleotide phosphate oxidase, suggest that certain NADPH oxidase isoforms such as Nox4 may be excellent targets for new renoprotective therapies.[503] This is strengthened by the advent of orally bioavailable NADPH oxidase inhibitors,[136] which are now under clinical investigation.

In addition to the mechanisms described here, the diabetic kidney appears to be readily modulated by a range of vasoactive hormones. Indeed, it is increasingly appreciated that there may be important interactions between metabolic pathways and various hemodynamic factors, including vasoactive hormones such as angiotensin II in mediating renal injury in diabetes (see Fig. 37.37).[504,505] Although many drugs that modulate hormone levels or action might not be specific for diabetic kidney disease, interruption of the renin-angiotensin system appears to be an excellent approach not only for reducing blood pressure but also for correcting many of the cellular, biochemical, hemodynamic, and structural abnormalities seen in the diabetic kidney. These agents appear to be very powerful antiproteinuric agents at all stages of renal disease, including microalbuminuria and macroalbuminuria, although the exact mechanism of action remains to be fully defined. Furthermore, these agents influence renal structure although these findings are primarily deduced from preclinical studies. In addition, as seen in the Reduction in Endpoints in Noninsulin-Dependent Diabetes Mellitus with the Angiotensin II Antagonist Losartan (RENAAL) study,[506] they also attenuate decline in renal function in type 2 subjects with advanced renal disease. Based on the discovery in the late 1990s that proteinuria in a range of nephropathies could occur as a result of molecular and structural abnormalities in a highly specialized structure known as the slit diaphragm within the glomerular epithelial cell (podocyte), a number of experimental studies, subsequently confirmed in humans, showed that depletion of one of these slit pore proteins, nephrin, could be attenuated or prevented by agents that interrupt the RAS.[507]

In addition to promoting glomerular nephrin depletion, angiotensin II also appears to have other actions that promote the development of proteinuria, including trophic effects on the kidney and increasing glomerular membrane pore size.[508] Although many investigators have focused on the RAS and, in particular, the vasoconstrictor angiotensin II, it is increasingly appreciated that other vasoconstrictors may be important. These include endothelin and a number of vasodilators, such as nitric oxide, bradykinin, atrial natriuretic peptide, and vasodilatory angiotensins such as angiotensin 1-7.[509] This exploration of the role of vasoactive hormones and their respective receptors in the diabetic kidney is critical for designing new treatments for this condition, because these pathways are ideal targets for drug development. This point has already been demonstrated for agents that interrupt the renin-angiotensin system, including ACE inhibitors and ARBs. However, the use of dual RAS inhibition, specifically the combination of an ACE inhibitor and an ARB, despite positive effects on albuminuria,[510] is not recommended due to increased risks of hyperkalemia and acute kidney injury, as was also seen with RAS blockade with a combination of a renin inhibitor and an ARB.[511]

Pathology of Diabetic Renal Disease

Diabetic renal disease was originally described as a glomerulopathy associated with diffuse or nodular glomerulosclerosis.[458] Subsequent studies using electron microscopy have revealed that glomerular basement membrane thickening and mesangial expansion are prominent glomerular abnormalities in diabetes[475] (Fig. 37.38). Indeed, prospective studies have shown that these changes predict to a certain degree the development of overt renal disease in patients with T1DM. However, fewer than one-third of diabetic patients with microalbuminuria have the



• **Fig. 37.38** Glomerular and tubular manifestations of diabetic nephropathy. *GBM,* Glomerular basement membrane; *TBM,* tubular basement membrane.

typical glomerulopathy described by Kimmelsteil and Wilson in 1936.[458,512] Although initial studies emphasized the mesangial cell changes in the glomerulus, glomerular epithelial cell abnormalities represent new areas of active research.[507] Podocyte dysfunction and subsequent apoptosis, ultimately leading to depletion of podocytes within the glomerulus appears to play a pivotal role in the development of proteinuria in diabetes.[513]

Although most of the focus has been on glomerular changes in the diabetic kidney, more recent studies have identified important changes in the other sites within the kidney, including the tubules, interstitium, medulla, and papilla.[465] *Diabetic tubulopathy* is characterized by a variety of structural and functional changes, including tubuloepithelial cell hypertrophy, tubular basement membrane thickening, epithelial-mesenchymal transition,[514] and the accumulation of glycogen (see Fig. 37.38). There is also an expansion of the interstitial space with infiltration of various cell types, including myofibroblasts and macrophages.

These tubular changes represent more than just the aftermath of diabetic nephropathy. The dysregulation of tubular functions in diabetes can precede or at least accompany the changes in the renal glomerulus and the onset of albuminuria.[512] Indeed, the functional and structural changes in the proximal tubule may be key to contributing to the development and progression of diabetic nephropathy.[465] For example, it has been suggested that tubuloglomerular feedback mechanisms can drive hyperfiltration associated with diabetes[462] and that tubular dysfunction can contribute to albuminuria due to defective uptake and lysosomal processing.[483] Indeed, renal function and prognosis correlate better with structural lesions in the tubules and cortical interstitium than with classic glomerular changes of diabetic nephropathy.

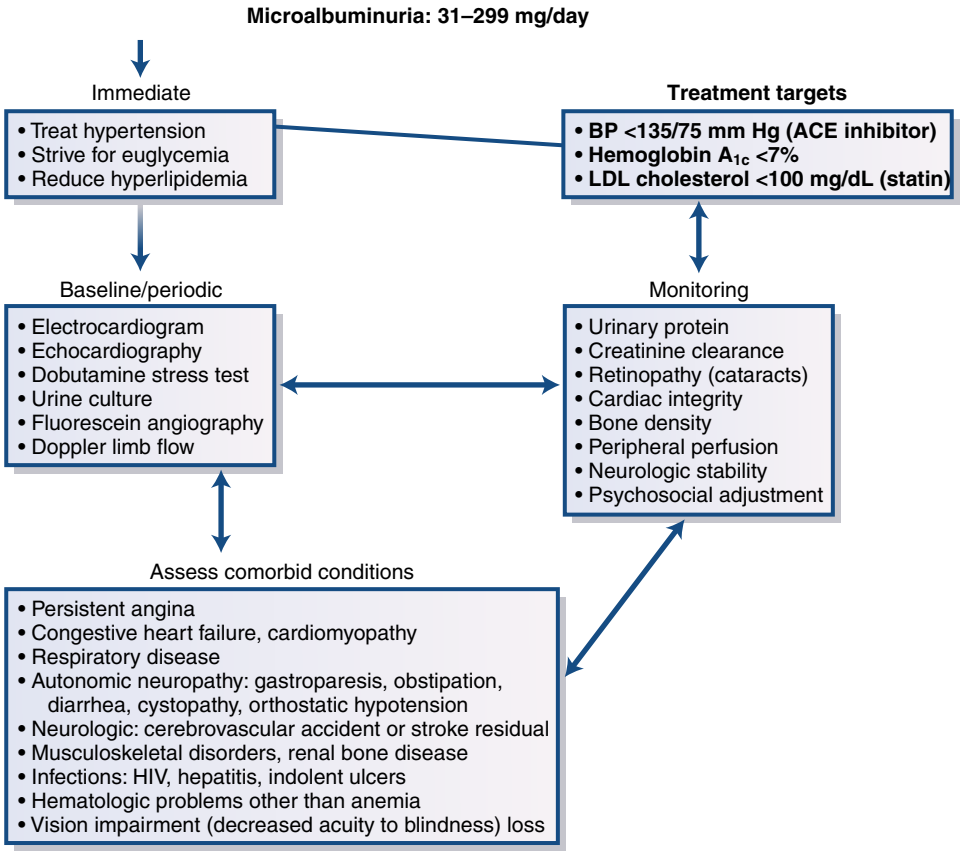
Other Renal Manifestations of Diabetes

Renal Artery Stenosis

Because diabetic patients have, in general, an increased burden of atherosclerosis, they appear to have a higher risk of renal artery stenosis. However, although angiographic studies have demonstrated a high prevalence of renal artery stenosis in diabetic patients, these lesions are often of no hemodynamic significance. Nevertheless, a small subgroup will have a hemodynamically significant stenosis, enhancing hypertension, increasing the risk of acute pulmonary edema, and inducing progressive renal impairment.[515] In such subjects, specific interventions such as surgery or angioplasty need to be considered.[516] Furthermore, some patients have bilateral renal artery stenosis that, on commencement of an agent such as an ACE inhibitor, can lead to acute renal failure.[517] Fortunately, in most patients, if the renal failure is diagnosed early, cessation of the ACE inhibitor leads to rapid restoration of renal function in this situation.

Renal Papillary Necrosis

Renal papillary necrosis involves a severe destructive process, presumably as a result of ischemia to the medulla and papilla.[518] Beethoven's final illness might have been papillary necrosis in the context of diabetes.[519] The papilla is very sensitive to these ischemic changes because even in the normal setting it is exposed to a relatively hypoxic environment. Concomitant exacerbating factors include urinary tract infection and analgesic abuse. The importance of ischemia and possibly angiotensin II in this disorder has been suggested in experimental studies in transgenic rats that overexpress renin and angiotensin II in their kidney after induction of diabetes.[520] In these rats,



• **Fig. 37.39** Flow chart illustrating the management of diabetic nephropathy before the onset of renal failure. *ACE,* Angiotensin-converting enzyme; *BP,* blood pressure; *HIV,* human immunodeficiency virus; *LDL,* low-density lipoprotein.

diabetes was associated with development of papillary necrosis, which was prevented by blockade of the renin-angiotensin system. Clinically, papillary necrosis often manifests as flank pain, hematuria, and fever. Urinalysis reveals red and white blood cells, bacteria, and papillary fragments. Ureteric obstruction can occur as a result of these fragments and must be addressed as an emergency.

Renal Tubular Acidosis

A well-known functional abnormality associated with diabetic tubulopathy is *renal tubular acidosis (type 4)*, manifesting as hyperkalemia and hyperchloremic metabolic acidosis.[521] This is thought to be a manifestation of hyporeninemic hypoaldosteronism associated with diabetes, resulting in proximal tubule ammonia production being reduced to levels inadequate to buffer acid in the distal nephron. The precise cause of this abnormality remains to be established. In some patients, there appears to be a defect in the conversion of prorenin to active renin.[522] It has also been suggested that damage to the tubular cells of the juxtaglomerular apparatus associated with diabetes can contribute to impaired renin release, possibly due to reduced renal prostaglandin production and elevated vasopressin levels.[523]

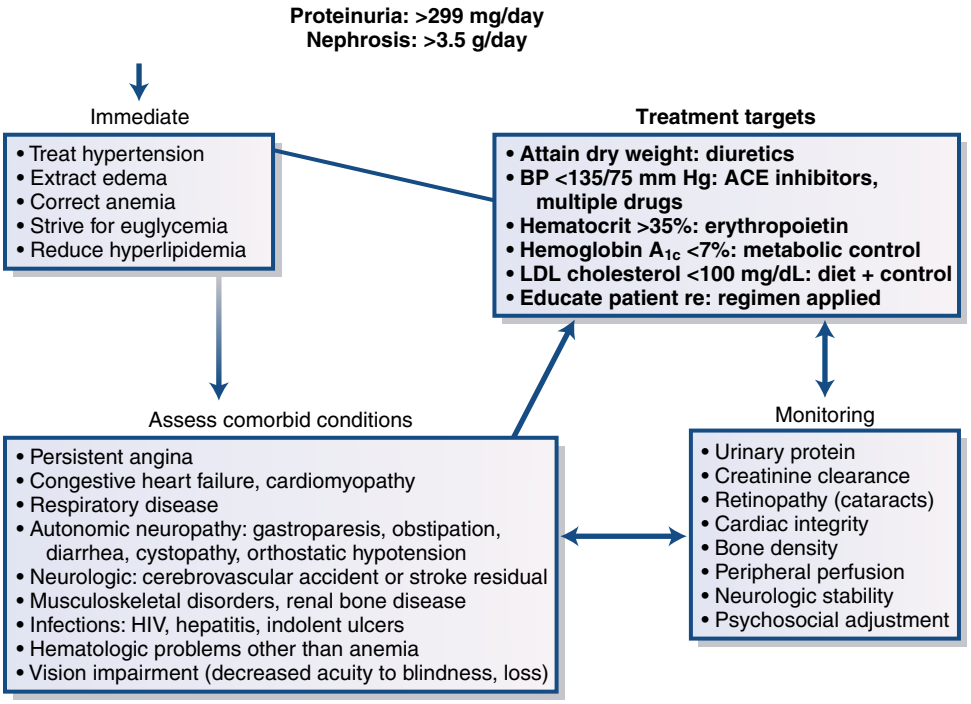
A major risk associated with hyporeninemic hypoaldosteronism is the development of life-threatening hyperkalemia. This is an increasingly important issue with the widespread use of ACE inhibitors and ARBs, often in combination, in this population. This is further exacerbated by the use of potassium-sparing diuretics (such as spironolactone) and beta blockers.

Contrast-Induced Nephropathy

Because many diabetic patients have impaired renal function, they are at high risk of increased renal impairment from certain nephrotoxic agents. One of the most important risks relates to radiocontrast dyes.[524] Where possible, patients with diabetes and renal impairment should avoid imaging studies that involve contrast and, in particular, multiple studies performed in rapid succession. Where intravenous contrast forms an indispensable tool to management, low-osmolality, nonionic, or gadolinium-based contrast media may be less nephrotoxic in patients with renal failure.[525,526] It has been suggested that patients who require such procedures should be well hydrated before, during, and after the procedure. However, a recent report suggests that this approach may not be as effective as previously presumed.[527] The role of *N*-acetylcysteine, a thiol-containing antioxidant, shows promise to protect against contrast-induced nephropathy.[528] The oral hypoglycemic drug metformin should also be discontinued before contrast procedures to prevent life-threatening lactic acidosis.

Management of Diabetic Kidney Disease

Blood pressure and glycemic control represent the major cornerstones for preventing and treating diabetic nephropathy (Figs. 37.39 and 37.40). In the early 1980s, a number of Scandinavian researchers found that aggressive blood pressure reduction reduces the rate of progression of diabetic nephropathy,[529,530] and in the 1990s other researchers found that intensified glycemic control has a similar benefit in both T1DM (DCCT)[9] and T2DM (UKPDS)



• **Fig. 37.40** Flow chart illustrating the management of diabetic nephropathy after the onset of clinical proteinuria. *ACE,* Angiotensin-converting enzyme; *BP,* blood pressure; *HIV,* human immunodeficiency virus; *LDL,* low-density lipoprotein.

diabetic subjects. These findings have led to the view that optimization of blood pressure and plasma glucose levels should be the mainstay of therapy for diabetic nephropathy.

Glycemic Control in Diabetic Kidney Disease

The importance of glucose as a factor in the progression of diabetic kidney disease, as initially suggested from epidemiologic and preclinical studies, was clearly demonstrated in the DCCT study in patients with T1DM.[9] In both the primary and secondary prevention arm of the study, any decrease in HbA_{1c} was strongly associated with a reduction in the risk of development of microalbuminuria as well as a decrease in the risk of progression to overt nephropathy. The follow-up EDIC study has confirmed long-lasting benefits of this therapeutic approach.[531] The UKPDS clearly demonstrated a role for intensified glycemic control in newly diagnosed T2DM subjects when treatment led to a reduction in HbA_{1c} from 7.9% to 7%. The Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) study has demonstrated that a further reduction of HbA_{1c} to an average of 6.5% was associated with a further reduction in renal events, as assessed by the development and progression of microalbuminuria.[532] A subsequent evaluation of this study[533] demonstrated intensified glycemic control that reduced the development of end-stage renal disease, emphasizing the fact that tighter glycemic control continues to confer renal benefits even in the setting of more advanced renal disease. This renal benefit persisted, as seen in the follow-up study known as ADVANCE-ON.[534] Thus despite the ongoing controversy as to the appropriate HbA_{1c} target to reduce macrovascular disease as a result of the findings from the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study,[535] no such controversy as to a possible deleterious effect of intensified glycemic control has been reported with respect to nephropathy.

It remains to be determined how useful the intensification of glycemic control is in the setting of overt nephropathy as a last-ditch strategy to delay the onset of end-stage renal disease. Aggressive management of hypertension and lipid lowering are clearly more important than glycemic control in reducing cardiovascular events and slowing renal disease progression at this stage of relatively advanced disease, although some studies suggest that poor glycemic control can accelerate the loss of renal function in diabetic nephropathy.[536] However, a number of large studies have failed to show any evidence that strict glycemic control per se retards renal progression once overt nephropathy is present.[537] In fact, in the Veterans Administration Diabetes Trial (VADT) tight glycemic control reduced albuminuria but failed to demonstrate any effect on GFR.[538] In addition, as renal function fails, tight glycemic control becomes more hazardous, with an increased risk of hypoglycemia. Nonetheless, because there is sufficient evidence that glycemic control can reduce both macrovascular events and microvascular complications of diabetes at other sites, it is reasonable to suggest that optimization of metabolic control in patients with overt nephropathy remains worthwhile.

The choice of agent, however, remains controversial. Certainly, several types of drugs are able to improve glycemic control in patients with T2DM[539]; however, the particular advantages of one class over another for preventing and treating diabetic nephropathy remain to be established. Nevertheless, this issue appears to have become more clinically relevant with the widespread use of newer classes of glucose-lowering drugs, including dipeptidyl peptidase 4 (DDP4) inhibitors, GLP1 analogs, and SGLT2 inhibitors.[539] With respect to DPP4 inhibitors, modest renal benefits have been suggested, particularly with saxagliptin in the Saxagliptin Assessment of Vascular Outcomes Recorded in Patients with Diabetes Mellitus (SAVOR) study[540] and in pooled analyses with linagliptin.[541] Pending results from studies such as the

Cardiovascular and Renal Microvascular Outcome Study With Linagliptin in Patients With Type 2 Diabetes Mellitus (CARMELINA)[542] will further clarify the potential renoprotective role of these agents. Recent studies have been performed with GLP1 analogues, including liraglutide and semaglutide.[543–545] Both agents, in addition to conferring cardiovascular protection, afforded renal benefits. In the Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial, liraglutide-treated patients had a 22% lower incidence of new onset of persistent macroalbuminuria and a slower decline in the eGFR over time, particularly in the subgroup of patients who had evidence of kidney damage at baseline.[545] In the Trial to Evaluate Cardiovascular and Other Long-term Outcomes with Semaglutide in Subjects with Type 2 Diabetes (SUSTAIN 6), semaglutide-treated patients had a similar reduction in renal outcomes. However, semaglutide-treated patients also had increased risk of serious diabetic retinopathy, including 1.91-fold increased risk of retinal photocoagulation and a 2.29-fold increased risk of vitreous hemorrhage,[543,544] which may be due to more severe retinal disease at baseline and rapid glycemic improvements. Finally, SGLT2 inhibitors have been shown to have strong renoprotective effects. For example, the EMPA-REG OUTCOME study demonstrated an approximately 50% decrease in composite renal outcomes, including benefits on reducing hard renal endpoints such as end-stage renal failure.[474] Similar benefits have also been reported in the CANVAS study using the SGLT2 inhibitor canagliflozin.[473] Of major interest is the finding that renoprotection is observed even in the absence of glucose lowering with these agents as seen in subjects with eGFR below 45 mL per minute.[546] This suggests that these agents confer renoprotection at least in part in a glucose-independent manner, but the mechanism(s) are unknown. Changes in sodium balance, intrarenal hemodynamics, plasma volume, decreased insulin resistance, and triglyceride-rich lipoprotein production and modest actions in reducing blood pressure, body weight, and uric acid have all been suggested as possible mechanisms.

A number of differences in the side effect profiles should influence prescribing habits. In patients with renal impairment, particular care must be exercised in selecting and dosing oral diabetic therapy because an accumulation of either the drug or active metabolites can lead to hypoglycemia (e.g., with glyburide) and other serious adverse effects such as lactic acidosis (with metformin). Thiazolidinediones (TZDs), such as pioglitazone and rosiglitazone, should be used with caution in patients with advanced nephropathy who have or are at risk of heart failure, although renal impairment per se is not a contraindication for this class of drugs.

Blood Pressure Control in Diabetic Kidney Disease

A sustained reduction in blood pressure appears to be one of the most important interventions to prevent progressive nephropathy in T1DM and T2DM. For example, in the UKPDS, a reduction in blood pressure from 154 to 144 mm Hg was associated with a 30% reduction in microalbuminuria. All national and international guidelines now emphasize the importance of blood pressure reduction in the diabetic patient. Although many guidelines suggest that specific targets should be achieved, no such threshold appears to exist for any renal endpoint in patients with diabetes. In particular, the risk of progressive diabetic nephropathy continues to decrease, with blood pressure reductions into the normal range and below, meaning that the lowest achievable blood pressure is associated with the best clinical outcomes. This is particularly important in those with the greatest risk of renal damage, patients with overt nephropathy. In these patients, it has been suggested that optimal blood pressure control is less than 125/75 mm Hg.[547] Indeed, in a subanalysis from the blood pressure arm of the ADVANCE study, no blood pressure threshold was detected. Specifically, in those subjects in whom achieved blood pressure was reduced to levels even lower than currently recommended in national and international guidelines, there was a further decrease in renal events.[548] Thus it is possible that if individuals can tolerate lower blood pressures without major side effects such as dizziness and syncope it may be worth considering treating some T2DM subjects to blood pressure levels below those currently recommended. However, syncope is often a side effect limiting the options to intensify blood pressure–lowering therapy, particularly in those diabetic subjects with systolic hypertension as a result of diabetes-associated vascular stiffness.

There is good evidence that tight blood pressure control, no matter how it was achieved, is associated with a significant reduction in the risk of microalbuminuria (primary prevention). Although blood pressure reduction appears paramount, there is also evidence that ACE inhibitors[549] have renoprotective actions beyond their antihypertensive effects for primary prevention.[550,551] However, if treatment should commence in the normoalbuminuric stage, such a strategy would involve treating the majority of patients who are not at risk of nephropathy. Ideally, it would be useful to be able to identify patients, still normoalbuminuric, whose likelihood of progression is increased. As of yet, no such markers of predisposition to renal disease are available, although serum prorenin[476] and modest elevations in urinary albumin excretion albeit still within the normal range (borderline microalbuminuria)[489] might ultimately be examples of such markers.

The issue of primary prevention has been readdressed in two studies in which subjects with normoalbuminuria were treated with agents that interrupt the RAS. In the first smaller trial, which included the performance of sequential renal biopsies, no benefit of early institution of either the ACE enalapril or the angiotensin II receptor antagonist losartan was observed, as defined not only as a lack of effect on albuminuria but also no significant retardation in progression of renal morphologic injury despite benefits on retinopathy.[552] In the second, much larger trial known as the Diabetic Retinopathy Candesartan Trials (DIRECT) study, the angiotensin II antagonist candesartan, despite some modest retinoprotective effects, had no major impact on reducing the new onset of microalbuminuria.[553]

In secondary prevention studies, the additional benefits achieved from blocking the renin-angiotensin system are clearer. A meta-analysis incorporating the findings of more than 10 studies in patients with microalbuminuria has demonstrated the ability of ACE inhibitors not only to retard the development of overt proteinuria but also to decrease urinary albumin excretion by more than 30%. In some patients with microalbuminuria, ACE inhibition can reduce urinary albumin excretion into the normoalbuminuric range.[550] In patients with T1DM and overt proteinuria, aggressive blood pressure reduction reduced proteinuria by up to 50% and retarded the rate of decline in renal function.[529,530]

Similar studies have been performed in T2DM patients. Two landmark trials, RENAAL and Irbesartan in Diabetic Nephropathy Trial (IDNT), examined the renoprotective effects of the ARBs losartan and irbesartan, respectively.[506,469] In both studies, when compared to various alternative antihypertensive agents such as calcium antagonists (but not ACE inhibitors), ARB treatment was associated with a reduction in end-stage renal failure, a greater than 30% decrease in proteinuria, and a major reduction

in hospitalization for heart failure. As a result of these studies, ARBs are recommended as first-line treatment for blood pressure reduction in T2DM patients with overt proteinuria.[554]

Although ACE inhibitors have not been as extensively studied in this population, the Diabetics Exposed to Telmisartan and Enalapril (DETAIL) trial suggested similar renoprotective actions for both drug classes.[555] Similar findings comparing the angiotensin II antagonist telmisartan to the ACE inhibitor, ramipril, are also reported in the much larger ONTARGET study, albeit that trial was not performed exclusively in diabetic subjects.[556] Thus from a clinical perspective no clear difference between these two drug classes has been identified. The one exception is cough, which occurs in 5% to 30% of patients taking ACE inhibitors, depending on ethnicity, which is higher in Asian subjects. In microalbuminuric T2DM subjects, ARBs have also been demonstrated to have a role. For example, in the Irbesartan Microalbuminuria Type 2 (IRMA2) trial, irbesartan dose-dependently reduced the risk of development of macroproteinuria,[557] confirming the findings seen predominantly with ACE inhibitors in microalbuminuric T1DM subjects.[550]

Another approach to inhibit the renin-angiotensin system has involved the use of the recently introduced renin inhibitors such as aliskiren. For example, in the Safety and Efficacy of Aliskiren When Added to Standardized Losartan and Optimal Antihypertensive Therapy in Patients With Hypertension, Type 2 Diabetes and Proteinuria (AVOID) study in T2DM subjects,[558] this agent appeared to have an additional effect on albuminuria when administered with the angiotensin II antagonist losartan. Unfortunately, as reported in the larger subsequent Aliskiren Trial in Type 2 Diabetes Using Cardiorenal Endpoints (ALTITUDE) study,[511] aliskiren has failed to demonstrate superior cardiovascular or renal protection, and thus this approach of add-on renin inhibition is not recommended. Other approaches focusing on blood pressure reduction continue to be examined in these populations. Pilot studies with various mineralocorticoid (MC) antagonists, albeit not studied extensively, have revealed that spironolactone and eplerenone reduce albuminuria.[559,560] Unfortunately, these agents are associated with hyperkalemia, particularly in subjects with renal impairment and/or type 4 renal tubular acidosis. However, the advent of a newer MC antagonist, finerenone, which has a lower risk of hyperkalemia, has led to renewed interest in this treatment approach. Indeed, in the mineralocorticoid Receptor Antagonist Tolerability Study—Diabetic Nephropathy (ARTS-DN) trial, a dose-dependent effect of finerenone was associated with a progressive decrease in albuminuria.[561] These positive findings have led to larger trials with this drug that are currently in progress.

Evaluation of Additional Approaches to the Management of Diabetic Kidney Disease

Low-protein diets (0.75 g/kg/day) have been shown to retard the progression of renal disease, although the data are not totally convincing for diabetic nephropathy, per se. A meta-analysis of five studies in T1DM subjects supported a minor renoprotective role for these diets,[562] but this has not been a universal finding.[563] There are even fewer data in T2DM subjects with overt nephropathy.[564] However, the expected benefits that can be achieved through protein restriction in patients with diabetic nephropathy are at best modest in comparison with adequate blood pressure control and blockade of the renin-angiotensin system. Moreover, the nutritional impact of such interventions must be carefully considered, particularly in patients with brittle glycemic control.

The role of lipid-lowering agents as renoprotective drugs remains controversial. Although in rodents a large body of evidence suggests that lipids promote renal injury and that various lipid-lowering drugs reduce nephropathy, even in the setting of no or minimal effect on lipids,[565] the data in humans are variable.[566] However, in a study of fenofibrate in T2DM, known as the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study, there was an impressive reduction in albuminuria.[567,568] Furthermore, in the Heart Protection Study, simvastatin appeared to retard the decline in renal function, although this analysis was not confined to the diabetic subgroup.[569] Another group has also reported a potential renoprotective effect of a statin,[570] although this effect has not been observed in all studies. Indeed, several meta-analyses have generally reported at best modest benefits of statins on renal disease.[571–573] Nevertheless, because cardiovascular disease is so prominent in diabetic patients, particularly those with incipient or overt renal disease, lipid-lowering treatment should be considered in most patients independent of its putative renoprotective actions.[574]

Other approaches to consider include correction of anemia with agents such as erythropoietin.[575] The role of these agents as renoprotective drugs remains to be clarified,[576] but the potential benefits on general patient well-being and in reducing left ventricular hypertrophy[577] provide a rationale for using such agents judiciously in diabetic patients. However, the Trial to Reduce Cardiovascular Events With Aranesp Therapy (TREAT) study, although focusing on cardiovascular events and mortality using the erythropoietin analogue darbepoetin, did not demonstrate that darbepoetin is renoprotective. Furthermore, the drug was unfortunately associated with a twofold increase in cerebrovascular events.[578] With the advent of new hemoglobin-raising drugs such as the hypoxia-inducible factor prolyl hydroxylase inhibitors,[579] there is likely to be a new approach for correcting anemia in diabetes-associated chronic kidney disease.

Over the past decade, several clinical trials targeting diabetic nephropathy with novel agents have yielded disappointing results. For example, PKCβ inhibition with ruboxistaurin, which had renal benefits in experimental diabetes, failed to show any major benefits on albuminuria in T2DM subjects.[580] Another promising agent, sulodexide, postulated to restore the glomerular charge by repleting the loss of glycosaminoglycans[581] and thereby act as an antiproteinuric and ultimately renoprotective drug, also failed to demonstrate any evidence of renoprotection in several large trials. An endothelin antagonist, avosentan, was assessed in the Assess the Effect of the Endothelin Receptor Antagonist Avosentan on Time to Doubling of Serum Creatinine, End Stage Renal Disease or Death in Patients With Type 2 Diabetes Mellitus and Diabetic Nephropathy (ASCEND) trial.[582] Although this drug was associated with impressive reductions in albuminuria, the associated side effect of fluid retention reduced the enthusiasm for this agent. However, another endothelin antagonist, atrasentan, with fewer side effects and being antiproteinuric,[583] was developed. However, this endothelin antagonist also unfortunately failed at a relatively advanced stage of clinical development. Finally, bardoxolone, an agonist of the transcription factor Nrf2, which appears to act as an antioxidant, has been investigated in T2DM subjects with impaired renal function. In the initial Bardoxolone Methyl Treatment: Renal Function in CKD/Type 2 Diabetes (BEAM) trial[584] an improvement in renal function was reported. However, a subsequent larger study in T2DM subjects with stage 4 chronic kidney disease known as the Bardoxolone Methyl Evaluation in Patients with Chronic Kidney Disease and Type 2 Diabetes Mellitus: the

Occurrence of Renal Events (BEACON) study was prematurely terminated because of increased cardiovascular events.[585] Nevertheless, this drug continues to be evaluated,[586] including in new studies, albeit with a lower dose, such as in the Phase II Study of Bardoxolone Methyl in Patients With Chronic Kidney Disease and Type 2 Diabetes (TSUBAKI) study where positive findings have been reported.

Treatment of the Diabetic Uremic Patient

Renal impairment in a patient with diabetes necessitates changes in therapy. Often, blood glucose control becomes more brittle because the half-life of insulin is prolonged and the renal response to hypoglycemia is impaired. High swinging blood glucose levels in a patient with nephropathy can often mistakenly lead to an increase in oral therapy. However, in patients with renal impairment, particular care must be exercised in the selection and dosing of oral hypoglycemic therapy. Fortunately, DPP4 inhibitors can be used safely in such individuals, albeit often the dose needs to be reduced in subjects with low GFR. Importantly, one DPP4 inhibitor, linagliptin, which is not excreted by the kidney, can be given without dose reduction, even in subjects on dialysis.[587] Nonsteroidal anti-inflammatory drugs (NSAIDs) and COX2 inhibitors should be avoided when possible because their use is associated with inadequate blood pressure control, often as a result of reduced efficacy of antihypertensive drug therapy. Patients at high risk for progressive deterioration in their renal function should be considered for an early referral to a nephrology service for management of renal failure (Fig. 37.41). This facilitates access to erythropoietin, control of calcium phosphate balance, and planning for renal replacement therapy with the preemptive placement of access catheters and lines. Delay in referral can result in a more precipitous start to renal replacement and usually a bad prognostic outcome.[588]

Many options are now available for the diabetic patient requiring renal replacement therapy.[589] These include home or facility hemodialysis, including overnight dialysis, peritoneal dialysis, renal transplantation (cadaveric or living related), or combined pancreas-kidney transplantation. Most patients choose hemodialysis rather than peritoneal dialysis, although data are conflicting regarding which approach leads to better survival (Table 37.6). Some patients opt for withdrawal of treatment because their quality of life, with advanced cardiovascular disease, visual impairment, and amputations, is poor.

The Burden of Nephropathy

One must never consider renal disease in a diabetic patient in isolation. Proteinuria, per se, is strongly associated with other complications such as macrovascular disease, heart failure, and retinopathy. Furthermore, treatments directed toward one complication may be useful for the other complications. Indeed, intensified glycemic control has been shown to be particularly useful for other microvascular complications.[9] In addition, the various antihypertensive regimens, particularly those using agents that interrupt the renin-angiotensin system as well as glucose and blood pressure lowering with SGLT2 inhibitors, also confer important cardiovascular benefits such as reducing heart failure.[469,506,590] Recent data also support use of angiotensin receptor neprilysin inhibitors (ARNi). A post hoc analysis of the Prospective Comparison of ARNI With ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) trial using

TABLE 37.6 Options in Therapy for End-Stage Renal Disease in Diabetic Patients

Variable	Peritoneal Dialysis	Hemodialysis	Kidney Transplantation
Extensive extrarenal disease	No limitation	No limitation except for hypotension	Excluded in cardiovascular insufficiency
Geriatric patients	Limited by frailty, cognitive dysfunction; patient treatment satisfaction greater with assisted peritoneal dialysis	No limitation	Arbitrary exclusion as determined by program
Complete rehabilitation	Rare, if ever	Very few patients	Common as long as graft functions
Death rate	Much higher than for nondiabetic patients	Much higher than for nondiabetic patients	About the same as for nondiabetic patients
First-year survival rate	~75%	~75%	>90%
Morbidity during first year	~15 days in hospital	~12 days in hospital	Weeks to months hospitalized
Survival to second decade	Almost never	<5%	~1 in 5
Progression of complications	Usual and unremitting; hyperglycemia and hyperlipidemia	Usual and unremitting; might benefit from metabolic control	Interdicted by functioning pancreas plus kidney; partially ameliorated by correction of azotemia
Special advantage	Can be self-performed; avoids swings in solute and level of intravascular volume	Can be self-performed; efficient extraction of solute and water in hours	Cures uremia; freedom to travel
Disadvantages	Peritonitis; hyperinsulinemia; hyperglycemia, hyperlipidemia; long hours of treatment; more days hospitalized than with either hemodialysis or transplantation	Blood access a hazard for clotting, hemorrhage, and infection; cyclic hypotension, weakness, aluminum toxicity, amyloidosis	Cosmetic disfigurement, hypertension, personal expense for cytotoxic drugs; induced malignancy; HIV (human immunodeficiency virus) transmission
Patient acceptance	Variable, usual compliance with passive tolerance for regimen	Variable; often noncompliant with dietary, metabolic, or antihypertensive components of regimen	Enthusiastic during periods of good renal allograft function; exalted when pancreas proffers euglycemia
Relative cost	Most expensive over long run	Less expensive than kidney transplantation in the first year; subsequent years more expensive	Pancreas plus kidney engraftment most expensive uremia therapy for diabetics; after first year, kidney transplantation alone is lowest cost option

sacubitril/valsartan, a combination of neprilysin inhibition and angiotensin II receptor blockade, was reported to slow the rate of reduction of eGFR in patients with stage 2 to 4 heart failure with reduced ejection fraction, a finding which was more prominent in the participants with T2DM at study entry.[591] Interestingly this agent is also associated with modest glucose-lowering effects.[592]

Thus as clearly expounded in the Intensified Multifactorial Intervention in Patients With Type 2 Diabetes and Microalbuminuria (Steno-2) study, the multifactorial approach in microalbuminuric subjects will not only lead to renal benefits as confirmed in a follow-up study,[593] but will also confer other advantages to the diabetic patient, including reducing all-cause mortality.[594] Because those with renal disease have the greatest risk for nonrenal complications, it stands to reason that they also are likely to have the greatest absolute benefit from risk-reduction strategies.

Diabetic Neuropathies

Diabetic neuropathies are a group of clinical syndromes with distinct presentations secondary to different underlying pathogenetic mechanisms. These syndromes are most commonly classified into two broad groups: diffuse versus focal neuropathies. Among the diffuse diabetic neuropathies, distal symmetric polyneuropathy (DSPN) is the most common, followed by the family of autonomic neuropathies, including cardiac autonomic neuropathy (CAN), and autonomic neuropathy of the gastrointenstinal, urogenital, and sudomotor systems. Focal neuropathies are much less common than diffuse neuropathies and include isolated mononeuropathies of one or more peripheral nerves; even rarer are focal neuropathies of one or more nerve roots, classified as radiculopathy or polyradiculopathy, respectively (Tables 37.7 and 37.8).

Epidemiology and Impact of Diabetic Neuropathies

Diabetic neuropathies are the most common complications of T1DM and T2DM. Distal symmetric polyneuropathy represents the most commonly diagnosed and highly morbid of the diabetic neuropathies. While prevalence estimates vary depending on how the diagnosis is made, DSPN occurs in at least half if not more of all diabetic patients over time.[595] Prevalence as determined by clinical examination was approximately 45% after 25 years of diabetes in the classic study by Pirat following a cohort of 4400 diabetic patients between 1947 and 1973.[596] However, when more contemporary quantitative sensory testing or nerve conduction studies are used as part of the diagnostic criteria, the prevalence of DSPN increases from 60%[597] to greater than 75%.[598] Multiple studies now confirm that DPSN also occurs in

TABLE 37.7 Classification for Diabetic Neuropathies

Diabetic Neuropathies

A. Diffuse neuropathy
DSPN
- Primarily small fiber neuropathy
- Primarily large fiber neuropathy
- Mixed small and large fiber neuropathy (most common)

Autonomic
Cardiovascular
- Reduced HRV
- Resting tachycardia
- Orthostatic hypotension
- Sudden death (malignant arrhythmia)

Gastrointestinal
- Diabetic gastroparesis (gastropathy)
- Diabetic enteropathy (diarrhea)
- Colonic hypomotility (constipation)

Urogenital
- Diabetic cystopathy (neurogenic bladder)
- Erectile dysfunction
- Female sexual dysfunction

Sudomotor dysfunction
- Distal hypohydrosis/anhidrosis
- Gustatory sweating

Hyoglycemia unawareness

Abnormal pupillary function

B. Mononeuropathy (mononeuritis multiplex) (atypical forms)
Isolated cranial or peripheral nerve (e.g., CN III, ulnar, median, femoral, peroneal)
Mononeuritis multiplex (if confluent may resemble polyneuropathy)

C. Radiculopathy or polyradiculopathy (atypical forms)
Radiculoplexus neuropathy (a.k.a. lumbosacral polyradiculopathy, proximal motor amyotrophy)
Thoracic radiculopathy
Nondiabetic neuropathies common in diabetes
Pressure palsies
Chronic inflammatory demyelinating polyneuropathy
Radiculoplexus neuropathy
Acute painful small-fiber neuropathies (treatment induced)

DSPN, Distal symmetric polyneuropathy.

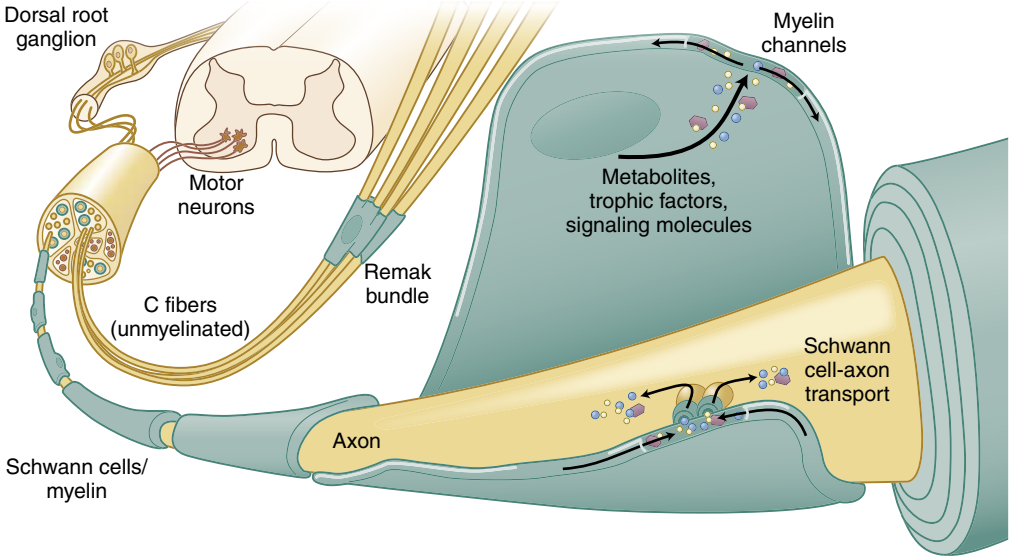
patients with prediabetes and the metabolic syndrome[599–601] and while higher in those metabolic syndrome patients with hyperglycemia, ranging from prediabetic to T2DM levels, DSPN can also occur independent of glycemic status.[601] With the alarming rise of prediabetes, T2DM, and the metabolic syndrome, estimates range from 15 million to 30 million individuals in the United States are living with DSPN.[602]

DSPN leads to a poor quality of life, limiting a patient's function, especially DSPN associated with pain. Up to 70% of DSPN patients experience some form of disrupted sleep, depression, anxiety, and poor work productivity.[603] Impairment of physical functioning in DSPN is associated with a 15-fold increase in the likelihood of falling and fractures, particularly in older diabetics.[604] Foot ulceration leading to amputation is one of the most serious and adverse effects of DSPN. Foot ulcers are a strong predictor of early mortality in diabetic patients[605] and precede nearly all amputations.[606] Of patients with new foot ulcers, 5% die within 1 year of their first ulcer and 42.2% of people with existing ulcers die within 5 years, as shown in a recent study of 414,523 patients with diabetes.[607] A 2017 systematic review reported that the global foot ulcer prevalence is 6.3%, with the highest prevalence, 13%, occurring in North America.[608] Worldwide DSPN accounts for more hospitalizations than all the other diabetic complications combined and is the root cause of 50% to 75% of nontraumatic amputations in North America.[609,610] Though rates of lower extremity amputation among Medicare-enrolled diabetics have decreased by 28.8% between 2000 and 2010,[611] the cost of caring for DSPN complications has not decreased because of delay in diagnosis.[612]

Like DSPN, autonomic neuropathies adversely affect function in patients with T1DM and T2DM, affecting a wide variety of organ systems, including cardiovascular, gastrointestinal, urogenital, and sudomotor/thermoregulatory systems. Of these, cardiac autonomic neuropathy is the best studied. Multiple studies confirm early mortality and sudden death in diabetic CAN patients, with mortality estimates up to 56% over a 10-year period.[613] One-third of patients with autonomic neuropathy have impaired quality of life,[614] with erectile dysfunction predicting not only poor quality of life in the affected patient[615] but also in the patient's sexual partner.[616]



• **Fig. 37.42** The peripheral nervous system. The peripheral nervous system (PNS) is comprised of both neurons and Schwann cells (SCs), and the structure, location, and interaction of these components have important implications for PNS function. Efferent axons of motor neurons, whose cell bodies are located in the ventral horn of the spinal cord, carry signals from the central nervous system (CNS) to muscles and glands, whereas afferent axons of sensory neurons, whose cell bodies are located in the dorsal root ganglia, relay information from peripheral sensory receptors to the CNS. Thin and unmyelinated sensory axons, also known as C fibers or small fibers, are associated with nonmyelinating Schwann cells and are grouped as Remak bundles. These represent a large portion of the PNS neurons. Myelinated sensory axons, on the other hand, are surrounded by myelin sheaths made by Schwann cells that form distinct nodal domains important for saltatory conduction. They also form a tubular network of myelinic channels that connect the SC cytoplasm with the periaxonal space, providing substrate for energy generation to the axonal compartment. (Redrawn from Feldman EL, Nave KA, Jensen TS, et al. New horizons in diabetic neuropathy: mechanisms, bioenergetics, and pain. *Neuron.* 2017;93:1296–1313.)

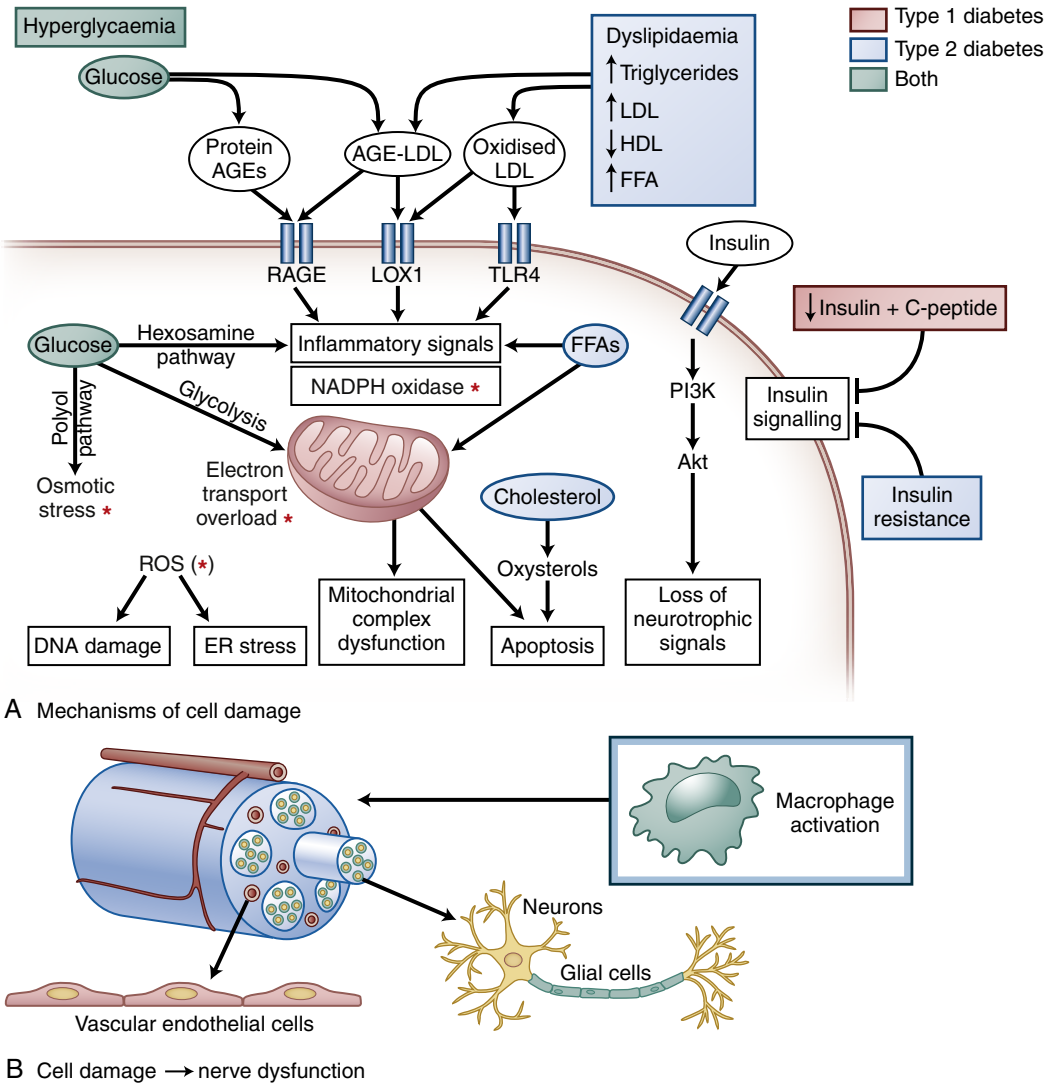
While cost estimates vary, the total annual cost of DSPN is estimated to be greater than $25 billion,[617] with total annual medical costs for a diabetic patient with painless DSPN estimated at $12,492 compared to $6632 for a diabetic patient without DSPN. Costs are even greater with painful DSPN, from $27,931 up to $30,755 per patient, depending on the severity of the pain[617] and the use of generic versus nongeneric medications.[618] Importantly, little money is spent in the United States on patient education or preventative foot care, an investment that has been proven to be effective in decreasing the incidence of DSPN complications.[619]

Pathophysiology of Diabetic Neuropathies

While the pathophysiology of diabetic neuropathy has been discussed earlier in this chapter, an understanding of nerve structure (Fig. 37.42) provides additional insight into neuropathy pathogenesis and clinical presentation. In the peripheral nervous system, afferent axons from sensory receptors send information to the dorsal root ganglia of the central nervous system (CNS), while efferent axons relay CNS signals to muscles and joints. Schwann cells envelope and myelinate large and midsize sensory axons, knowns as *large fibers*. In contrast, the cytoplasm from one Schwann cell can envelope 30 or more unmyelinated small axons, known as *small fibers*. These large and small fibers carry specific information: Large fibers relay vibratory, proprioception, and tactile sensation; small fibers relay thermal sensation and pain, and they also regulate microvascular blood flow. Small fiber damage usually precedes large fiber damage in diabetes[620] and frequently presents as burning pain, although patients also report tingling and prickly sensations.[621] With time, large fiber involvement occurs, with corresponding numbness and poor position sense.

How diabetes changes the interaction between Schwann cells and axons is not yet understood, and it remains unclear if the primary insult in DSPN lies in the sensory neuron, axon, or Schwann cell; logically, it is likely that all three components are adversely affected, in both distinct and overlapping ways. In the diabetic microenvironment, glycolytic intermediates are depleted in Schwann cells[622] while fatty acid oxidation is increased,[623] producing a state of cellular oxidative stress and excess cytosolic bioactive lipids.[624] Emerging evidence reveals that axon-Schwann cell communication, via myelinic channels between the two tissues, allows for the two-way transport of these glycolytic intermediates and bioactive lipids.[602,625] The concept of *crosstalk* between Schwann cells and axons is further supported by a recent finding that delivery of exosomes from Schwann cells cultured in high glucose to sciatic nerves of mice resulted in murine DSPN.[626] Finally, the idea of axon-Schwann cell crosstalk and reciprocal supply of critical intermediary metabolites is supported by Schwann cell–specific knockout experiments of a serine-threonine kinase required for Schwann cell energy regulation. This knockout caused degeneration of sensory greater than motor axons, especially in the small unmyelinated fibers.[627]

Clinical trials have yielded insights into potential differences underlying the pathogenesis of DSPN in T1DM and T2DM. Glucose control has a significant effect on DSPN onset and progression in T1DM but no effect or a modest 3% to 5% effect at



• **Fig. 37.43** Mechanisms of diabetic neuropathy. Factors linked to type 1 diabetes *(red),* type 2 diabetes *(blue),* and both *(green)* cause DNA damage, endoplasmic reticulum stress, mitochondrial complex dysfunction, apoptosis, and loss of neurotrophic signaling (A). These mechanisms can damage neurons, glial cells, and vascular endothelial cells and can trigger macrophage activation. Damage to each of these cell types can lead to nerve dysfunction and neuropathy (B). The relative importance of the pathways in this network will vary with cell type, disease profile, and time. *AGE,* Advanced glycation end products; *ER,* endoplasmic reticulum; *FFA,* free fatty acids; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein; *LOX1,* oxidized LDL receptor 1; *PI3K,* phosphatidylinositol-3-kinase; *RAGE,* receptor for advanced glycation end products; *ROS,* reactive oxygen species (red star); *TLR4,* toll-like receptor 4. best on DSPN in T2DM.[628] The idea that DSPN is actually two distinct disorders, DSPN T1DM and DSPN T2DM, is a source of active investigation,[11] with the emerging concept that neurons can develop insulin resistance[629] that contributes to DSPN in T2DM (Fig. 37.43).[630]

Clinical Features of Diabetic Distal Symmetrical Polyneuropathy

Clinical Symptoms

DSPN is the most common and widely recognized form of diabetic neuropathy. An international consensus meeting defined DSPN as "the presence of symptoms and/or signs of peripheral nerve dysfunction in people with diabetes after the exclusion of other causes."[631,632] Alternate causes of DSPN include vitamin B_{12} deficiency, multiple myeloma, and hereditary neuropathies. The onset of DSPN is usually insidious but can be acute, as discussed later. DSPN is primarily a sensory neuropathy and can involve small fibers, large fibers, or both.[633] Motor involvement is only seen late in the disease, if at all.

Symptoms of DSPN secondary to diabetes depend on the affected fiber types. Early in the course of the disease, small fibers are preferentially involved, leading to symptoms of pain, hyperalgesia and allodynia in the lower limbs, followed over time by a loss of thermal sensitivity and pain perception.[621] These same early symptoms of DSPN are also the main constellation of presenting

symptoms in prediabetic neuropathy.[600] Symptoms often are exacerbated at night and are manifested in the feet more than the hands. Spontaneous episodes of pain can be severely disabling. The pain varies in intensity and character and has been variably described by patients as lancinating, stabbing, or sharp. Paresthesias or episodes of distorted sensation, such as pins and needles, tingling, coldness, numbness, or burning, often accompany the pain.[633] As a whole, these multiple symptoms are classified as *positive* symptoms, as the affected diabetic patient actively experiences discomfort.

In contrast, the symptoms of large fiber neuropathy are most commonly denoted as *negative* symptoms, with the patient presenting with a numb, insensate foot. Diabetic patients with large fiber predominant DSPN are frequently unaware of their neuropathy, and are surprised when a physical examination reveals absent sensation in their feet. As large fibers mediate position sense, poor balance with frank falling is a common presenting symptom in diabetic patients with a large fiber predominant DSPN. While less common, these patients can also experience a deep-seated, dull, toothache-like sensation in their feet and, in very severe cases, will experience symptoms of distal weakness of the toes and ankles, secondary to late-onset large motor fiber involvement.

While the distinction is classically made between small and large fiber predominant DSPN, a common presentation of DSPN in diabetic patients is a combination of symptoms from both fiber types. A few clinical "pearls" can assist the clinician in identifying symptoms that are atypical for DSPN secondary to diabetes. These include motor greater than sensory symptoms and a reportable asymmetry. If the physical examination confirms these symptoms, an alternative diagnosis to DSPN must be pursued.

Clinical Signs of Diabetic Neuropathy

A simple examination can distinguish between small and large fiber impairment. Inspection of the skin is an essential first part of the clinical examination because small fibers also subserve sudomotor function. The foot is inspected for dry skin, fissures, and callouses. Small fiber function is then assessed using a simple disposable safety pin, a cotton wisp, or by assessing the ability of a patient to distinguish temperatures between a proximal location (the face) and a distal location (the dorsum of the great toe). A simple bedside approach is to determine if the patient can differentiate between the sharp and dull end of the safety pin on the dorsum of the toe, and if he or she can perceive a cotton wisp in the same anatomic location. To assess temperature in the most simple manner, a cool tuning fork is placed on the patient's cheek, then the same instrument is placed on the great toe, and the patient is asked to report on perceiving the same cool temperature in both anatomic locations or not. Large fiber function is initially assessed by measuring the time in seconds that a patient can perceive vibration sensation on the great toe after a health care provider places a 128-Hz vibrating tuning fork on the dorsum of the patient's great toe. Proprioception is assessed by minor movements of the first metatarsophalangeal joint of the great toe. Ankle reflexes are an essential part of assessing large fiber function and are best produced with the examiner mildly dorsiflexing the patient's foot and striking the Achilles tendon with a Tromner or Queens Square reflex hammer.

Given that the glove and stocking distribution of the DSPN reflects nerve fiber length, when sensory loss reaches the midcalves, patients begin to perceive symmetric sensory loss of the fingertips. Examination of the upper extremity is most commonly performed as outlined earlier for the lower extremity, except the dorsum of the index finger is used by the examiner.

The Semmes-Weinstein 10-g filament as an assessment of touch pressure, a large fiber function, can be used as a screening tool for DSPN.[634] The filament is bent to a C-shape applying pressure to the plantar surface of the great toe. Because of the variability in the sensitivity and specificity of the 10-g filament,[635] it is recommended that a three-site test be done involving the plantar aspects of the great toe, the third metatarsal, and the fifth metatarsal. The ability to sense the 10-gram filament on the soles of the feet is also frequently used by podiatrists as a screening tool for DSPN, although it is generally held that this is not sufficiently sensitive to diagnose DSPN.[634]

In advanced cases of DSPN, examination will reveal wasting of the small muscles of the feet, with hammertoes and weakness of toe extension; in extreme cases, there is weakness of the anterior tibialis and the intrinsic hand muscles.

Differential Diagnosis of Diabetic Neuropathy

The American Academy of Neurology suggests checking a serum protein electrophoresis with immunofixation, a B_{12} level, and thyroid function tests in all patients suspected of having DSPN. If these are normal, and there are no atypical signs, the most likely diagnosis is prediabetic neuropathy or DSPN.[631] The importance of performing these screening tests was confirmed in the Rochester Diabetic Neuropathy Study, in which up to 10% of peripheral neuropathy in diabetic patients was determined to not be secondary to diabetes.[636]

Importantly, the symptoms and signs of DSPN are sensory and symmetrical, and any convincing asymmetry evidence of motor greater than sensory involvement, or a rapid and aggressive clinical course, should lead the clinician to suspect an alternative etiology for the patient's clinical presentation. In these atypical cases, it is essential to exclude other causes of neuropathy in patients with diabetes (Table 37.9).[637]

Classification of Diabetic DSPN

The Toronto Consensus panel convened in 2009 and redefined the minimal criteria for diagnosis of typical diabetic neuropathy[638]:

1. Possible DSPN. The presence of symptoms or signs of DSPN may include the following: symptoms—decreased sensation, positive neuropathic sensory symptoms (e.g., "asleep numbness," prickling or stabbing, burning or aching pain) predominantly in the toes, feet, or legs; or signs—symmetric decrease of distal sensation or unequivocally decreased or absent ankle reflexes.
2. Probable DSPN. The presence of a combination of symptoms and signs of neuropathy, including any two or more of the following: neuropathic symptoms, decreased distal sensation, or unequivocally decreased or absent ankle reflexes.
3. Confirmed DSPN: The presence of an abnormality of nerve conduction and a symptom(s) or sign(s) of neuropathy confirm DSPN. If nerve conduction is normal, a validated measure of small fiber neuropathy (with Class 1 evidence) may be used. To assess for the severity of DSPN, several graded clinical scores can be used that include various continuous measures of sum scores of neurologic signs, symptoms, or composite clinical and electrophysiologic scores; scores of function of activities of daily living; or scores of predetermined tasks or of disability.
4. Subclinical DSPN. The presence of no signs or symptoms of neuropathy are confirmed with abnormal nerve conduction or a validated measure of small fiber neuropathy (with Class 1 evidence). Definitions 1, 2, or 3 can be used for clinical practice, and definitions 3 or 4 can be used for research studies.

TABLE 37.9 Common Causes of Rare Subtypes of Peripheral Neuropathy

Localization	Condition
Diffuse, nonlength-dependent neuropathy; demyelinating sensory motor	AIDP; CIDP; CIDP variants: POEMS syndrome, IgM anti-MAG neuropathy, Waldenstrom acroglobulinemia, and MGUS; diphtheria; and toxic exposures (hexane, arsenic, and amiodarone)
Demyelinating sensory	Sensory CIDP or AIDP; and DADS (IgM anti-MAG neuropathy)
Demyelinating motor	MMN
Axonal sensory motor	Toxic exposures; ASMAN; and AIP
Axonal sensory	Paraneoplastic (Hu, CRMP5, and amphyphisin); Sjögren syndrome; chemotherapy (platinum based, bortezomib); vitamin B_6 toxicity; idiopathic; HIV, HTLV; autoimmune hepatitis; celiac disease; HSAN; Friedrich ataxia; CANVAS; SANDO; and CANOMAD
Axonal motor	ALS; PMA; postpolio syndrome; HIV, HTLV, WNV, enterovirus D68; MMN without conduction block; radiation; monomelic amyotrophy; HMN; SMA (including Kennedy syndrome); and complicated HSP
Multiple mononeuropathies	Systemic vasculitic neuropathy: microscopic polyangiitis, Wegener granulomatosis, polyarteritis nodosa, Churg-Strauss syndrome, cryoglobulinemia, Sjögren syndrome, rheumatoid arthritis, and SLE; nonsystemic vasculitic neuropathy; neoplasm (malignant and benign); HNPP; sarcoidosis; amyloidosis; MMN; and MADSAM
Polyradiculopathy	Compressive: disc herniation/spondylosis, osteomyelitis, and neoplasm; noncompressive: infection (CMV, VZV, Lyme, and tuberculosis), inflammatory (sarcoidosis), neoplastic (leukemia and lymphoma), and radiation
Plexopathy	Compressive: neoplasm and hemorrhage; noncompressive: infection (VZV, HSV, CMV, and Lyme), inflammatory (sarcoidosis), neoplastic (leukemia, lymphoma), and radiation
Radiculoplexus neuropathy	Diabetic lumbar (diabetic amyotrophy); diabetic cervical; postsurgical inflammatory; nondiabetic lumbar or cervical; infection (VZV, HSV, CMV, and Lyme); inflammatory (sarcoidosis); neoplastic (leukemia and lymphoma); and radiation

AIDP, Acute inflammatory demyelinating polyneuropathy; *AIP,* acute intermittent porphyria; *ALS,* amyotrophic lateral sclerosis; *ASMAN,* acute sensory motor axonal neuropathy; *CANOMAD,* chronic ataxic neuropathy, ophthalmoplegia, monoclonal IgM protein, cold agglutinins, disialosyl antibodies; *CANVAS,* cerebellar ataxia neuropathy vestibular areflexia syndrome; *CIDP,* chronic inflammatory demyelinating polyneuropathy; *CMV,* cytomegalovirus; *CRMP5,* collapsing response mediator protein 5; *DADS,* distal-acquired demyelinating syndrome; *HIV,* human immunodeficiency virus; *HMN,* hereditary motor neuropathy; *HNPP,* hereditary neuropathy with liability to pressure palsies; *HSAN,* hereditary sensory autonomic neuropathy; *HSP,* hereditary spastic paraplegia; *HSV,* herpes simplex virus; *HTLV,* human T-lymphotrophic virus; *MADSAM,* multifocal acquired demyelinating sensory and motor neuropathy; *MGUS,* monoclonal gammopathy of unclear significance; *MMN,* multifocal motor neuropathy; *PMA,* progressive muscular atrophy; *POEMS,* polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes; *SANDO,* sensory ataxia neuropathy dysarthria ophthalmoplegia; *SLE,* systemic lupus erythematosus; *SMA,* spinal muscular atrophy; *VZV,* varicella zoster virus; *WNV,* West Nile virus.

5. Small fiber neuropathy (SFN). SFN should be graded as follows: (1) possible: the presence of length-dependent symptoms and/or clinical signs of small fiber damage; (2) probable: the presence of length-dependent symptoms, clinical signs of small fiber damage, and normal sural nerve conduction; and (3) definite: the presence of length-dependent symptoms, clinical signs of small fiber damage, normal sural nerve conduction, and altered intraepidermal nerve fiber (IENF) density at the ankle and/or abnormal thermal thresholds at the foot (both of the later provide Class 1 evidence).

Graded Scores for the Classification of DSPN

While DSPN is diagnosed at the bedside, as outlined earlier, there are several scores that provide structure to the bedside examination and range from simple assessments of large and small fibers to more complex assessments requiring quantitative thermal testing, electrophysiology, or skin biopsies. These scores include the Neuropathy Impairment Score of the lower limb (NIS-LL),[639] Michigan Diabetic Neuropathy Score (MDNS),[640] Modified Toronto Clinical Neuropathy Score (mTCNS),[641] Total Neuropathy Score–Clinical (TNS-C),[642] the Utah Early Neuropathy Score (UENS),[643] and the Neuropathy Disability Score (NDS).[644] The sensitivities and specificities are listed in Table 37.10. Electrophysiologic testing or nerve conduction studies along with a referral to a neurologist is normally not needed, unless the patient has either atypical symptoms or signs.

The importance of the skin biopsy as a diagnostic tool for DSPN is increasingly recognized when no clear objective evidence of small or large fiber dysfunction is present on examination.[621] This technique quantitates small IENFs through antibody staining of the neuronal antigen protein gene product (PGP) 9.5. It is minimally invasive (3-mm-diameter punch biopsies) but enables direct study of small fibers that cannot be evaluated by standard nerve conduction studies. Prediabetic neuropathy and DSPN are accompanied by loss of these small fibers in a distal-to-proximal gradient.

Treatment of DSPN

Treatment of DSPN is commonly divided into either direct disease-modifying therapies or treatment of pain, a common occurrence in patients with DSPN. Accumulating evidence supports the idea that disease-modifying therapies are distinct for DSPN, depending if the patient has T1DM or T2DM.[645] In contrast, treatment of pain is not personalized to the type of diabetes,

TABLE 37.10 Sensitivity and Specificity for Tested Neuropathy Scales

	Cutoff	Sensitivity	Specificity	PPV	NPV	LRP	LRN
Modified Toronto Clinical Neuropathy Score (mTCNS)	3.00	98.00	97.00	0.99	0.94	31.20	0.03
Total Neuropathy Score (Clinical) (TNSc)	5.00	81.00	97.00	0.99	0.66	25.90	0.20
Utah Early Neuropathy Scale (UENS)	3.00	85.00	97.00	0.99	0.72	27.20	0.15
Early Neuropathy Score (ENS)	5.00	83.00	97.00	0.99	0.67	26.67	0.17
Michigan Diabetic Neuropathy Score (MDNS)	5.00	80.00	100.00	1.00	0.65	—	0.20
Neuropathy Impairment Score of the Lower Limb (NISLL)	3.00	83.00	97.00	0.98	0.69	26.47	0.18
Neuropathy Disability Score (NDS)	4.00	89.00	100.00	1.00	0.78	—	0.11

LRN, Likelihood ratio negative; *LRP,* likelihood ratio positive; *NPV,* negative predictive value; *PPV,* positive predictive value.

although emerging research indicates there may be differences in the pain phenotypes among the different types of diabetes.[602]

Disease-Modifying Therapy in DSPN

There are no US Food and Drug Administration (FDA)–approved therapies that directly address DSPN as a disease entity. In the absence of pharmaceuticals, dietary and lifestyle interventions are recommended to modify the course of the illness. A 2012 Cochrane review reported that glucose control has only modest effects, if any at all, on DSPN in T2DM, while it is an important factor in determining the onset and progression of DSPN in T1DM.[645] In both prediabetes and T2DM, the components of the metabolic syndrome are collectively drivers of neuropathy. Multiple studies confirm that dyslipidemia, hypertension, obesity, and low hip:waist ratios are present in patients with prediabetic neuropathy and T2DM patients with DSPN. Modification of these factors, beyond glucose control alone, is required to effect a clinically meaningful change in neuropathy in both patient groups. Of interest, obese patients with the metabolic syndrome but normoglycemia also have neuropathy, further confirming that glucose control alone is insufficient to address neuropathy pathogenesis in the prediabetic or T2DM patient.[600]

The 2017 American Diabetes Association (ADA) recommendations are outlined in Table 37.11.[646]

Treatment of Painful Neuropathy

Pain is a common presentation of prediabetic neuropathy and present in approximately 20% of patients with DSPN.[647] There are no compelling studies that show glucose control is helpful in the treatment of pain. In contrast, aggressive glucose control over a short period of time can result in debilitating pain syndromes in both T1DM and T2DM patients.[648] These pain syndromes are known as treatment-induced neuropathies. It is now well established that the degree of a patient's impairment correlates with the rate of change of the HbA_{1c} (Fig. 37.44),[649] cautioning the clinician to achieve glycemic control at a rate of less than 1% per month HbA_{1c}.[649]

There are three FDA-approved drugs for the treatment of painful DSPN, with better evidence for duloxetine and pregabalin. The opioid tapentadol also is FDA approved, but with weaker evidence. In light of the current opioid epidemic in both North America and worldwide, opioid use is discouraged in the treatment of painful DSPN.

TABLE 37.11 American Diabetes Association Recommendations for Distal Symmetric Polyneuropathy (DSPN)

- Tight glucose control targeting near-normal glycemia in patients with type 1 diabetes dramatically reduces the incidence of distal symmetric polyneuropathy and is recommended for distal symmetric polyneuropathy prevention in type 1 diabetes. **A**
- In patients with type 2 diabetes with more advanced disease and multiple risk factors and comorbidities, intensive glucose control alone is modestly effective in preventing distal symmetric polyneuropathy, and patient-centered goals should be targeted. **B**
- Lifestyle interventions are recommended for distal symmetric polyneuropathy prevention in patients with prediabetes/metabolic syndrome and type 2 diabetes. **B**

ADA recommendations are assigned ratings of A, B, or C depending on the quality of evidence.

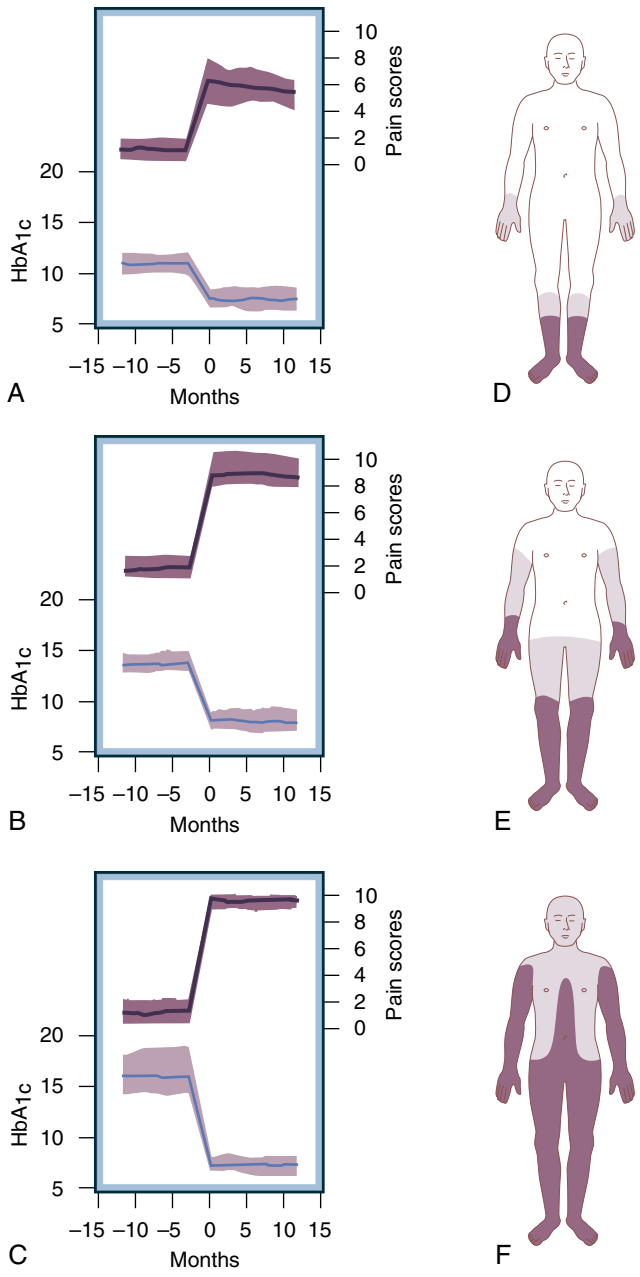
Both the American Academy of Neurology (AAN) and the European Federation of Neurological Societies (EFNS) have reviewed the Class 1 and 2 studies for the treatment of painful DSPN (Table 37.12). In general, three classes of therapies appear effective in the treatment of DSPN: the voltage-gated α2δ ligands (pregabalin, gabapentin), the serotonin-norepinephrine reuptake inhibitors (duloxetine, venlafaxine), and the secondary amine tricyclic antidepressants (amytriptyline, nortriptyline, desipramine). Fig. 37.45 provides a management algorithm for the patient with painful DSPN; Table 37.13 outlines the commonly used doses and range of side effects. A simple rule is to begin with one drug from one of the three classes, and maximize the dose of this drug to either side effects or known therapeutic dosage; if there is some clinical benefit, although not complete, then a second agent from a different drug class should be added for more symptom relief. This agent is again titrated slowly to either side effects or maximal known therapeutic dose. While figures vary, this approach generally provides relief for at least two-thirds, if not more, of patients[618]; there is also an emerging literature that coupling pain treatment with an exercise regimen provides even greater symptom



• **Fig. 37.44** Complications and risks associated with treatment-induced neuropathy of diabetes (TIND). (A–F) The 104 individuals with treatment-induced neuropathy of diabetes are grouped by change in glycosylated HbA_{1c} scores. (A) The 27 individuals with a decrease in HbA_{1c} of 2% to 3.9% are shown. (B) The 52 individuals with a decrease in HbA_{1c} of 4% to 7% are shown. (C) The 25 individuals with a decrease in HbA_{1c} of more than 7% are shown. (A–C) The lower portion of the graph *(left y-axis)* reveals the glycosylated haemoglobin (HbA_{1c}) scores over time. The mean value is shown in blue and the standard deviation in light purple. The upper portion of the graph *(right y-axis)* reveals neuropathic pain scores during the same time frame. The mean value is shown in black and the standard deviation in dark purple. The representative distribution of neuropathic is shown in (D–F), with the area in dark purple representing pain common to all individuals, and the area in light purple common to many individuals. (D) The least widespread pain distribution in the individuals with the smallest change in HbA_{1c} (corresponding to A). (E) The pain distribution in the individuals with moderate decreases in HbA_{1c} (B). (F) The group with the largest decrease in HbA_{1c}. (C) has widespread neuropathic pain. (Redrawn from Gibbons CH, Freeman R. Treatment-induced neuropathy of diabetes: an acute, iatrogenic complication of diabetes (part 1). *Brain.* 2015;138:43–52.)

relief.[650] This approach to pain is recommended in the 2011 AAN guidelines and the 2017 ADA position statement.

While not part of the ADA position statement, the AAN guidelines discuss the addition of selected therapies, which are briefly described later, for patients who do not achieve pain control with metabolic control, combination therapy, and exercise.[651] Alpha-lipoic acid is an antioxidant that is used in Europe at a dose of 600 mg per day as an adjunct to the treatment of painful DSPN.[652,653] Capsaicin is a natural substance that locally depletes substance P, resulting in a loss of small fibers. Capsaicin cream applied topically (0.075% four times/day) to the feet in patients with painful DSPN was reported to provide a modest improvement in pain.[654] Similarly local lidocaine applied to painful areas has been reported to improve pain in selected small studies,[655] although a Cochrane systematic review found no role for lidocaine in the treatment of painful neuropathy.[656] Studies on the use of transelectric stimulation (TENS) units are limited for painful DSPN, but do support its use as an adjuvant therapy in treatment-resistant patients.[657–659]

There is no role for opioids in the treatment of chronic painful DSPN, and limited use, if at all, in acute painful DSPN, possibly for the pain experienced with treatment-induced neuropathy. If pain management is not achieved without opioids, then referral to a pain clinic for the patient is the next suggested step.

Other Diabetic Somatic Neuropathies: Clinical Features and Treatment Paradigms

As presented in Table 37.7, there are other diabetic neuropathies. Cranial mononeuropathies occur primarily in the older population. Onset is usually acute and associated with pain, and the course is self-limited, resolving within 6 to 8 weeks. It is generally believed these neuropathies are secondary to vascular insufficiency.[660] The most common cranial mononeuropathy secondary to diabetes is a mononeuropathy of the third cranial nerve, presenting as a complete third nerve palsy with pupillary sparing. Less common are mononeuropathies of cranial nerves 4, 6, and 7. Because it is essential to distinguish these mononeuropathies from a more serious central etiology, including cranial aneurysms and stroke, neuroimaging is frequently required to confirm that the symptoms and signs are due soley to diabetes.

Mononeuropathies must be distinguished from entrapment syndromes, which start slowly, progress, and persist without intervention (see Table 37.8). The most common entrapment site in diabetic patients is the median nerve, although patients also experience ulnar, lateral cutaneous femoral, and peroneal nerve entrapment. Median nerve entrapment, commonly known as the carpal tunnel syndrome, occurs three times as often in persons with diabetes than in a normal, healthy population,[661,662] and its increased prevalence in diabetes may be related to diabetic cheiroarthropathy,[663] repeated undetected trauma (due to repetitious use of the hands), metabolic changes, or accumulation of fluid or edema within the confined space of the carpal tunnel.[664] Diagnosis can be confirmed by nerve conduction studies or ultrasound.[665] The mainstays of nonsurgical treatment are resting of the wrist, aided by the placement of a wrist splint in a neutral position for day and night use, and the addition of anti-inflammatory medications. Surgical treatment consists of sectioning the volar carpal ligament.[666] The decision to proceed with surgery should be based on several considerations,

TABLE 37.12 Class I and Class II Randomized Controlled Trials From the American Academy of Neurology and European Federation of Neurologic Societies Guidelines on the Treatment of Painful Diabetic Distal Symmetric Polyneuropathy

Source[c]	Treatment per Day	Evidence Class[a]	Study Duration (wk)	No. Receiving Treatment/ Total Sample[b]	Mean Pain Reduction on 0-10 Rating Scale vs. Placebo (95% CI)	PATIENTS WITH >50% PAIN REDUCTION		Common Adverse Effects
						Treatment Effect (%)	Placebo Effect (%)	
Lesser et al., 2004	Pregabalin, 300 mg		5	81/337	–1.26 (–1.86 to –0.65)	46	18	Dizziness, somnolence, peripheral edema, confusion, blurry vision

Pharmacokinetic profile, spectrum of AEs, drug interactions, comorbidities, and costs to be considered in selecting the agent of choice. **Duloxetine is FDA approved for painful DSPN, whereas venlafaxine is not. Pharmacokinetic profile, spectrum of AEs, drug interactions, comorbidities, and costs should be considered in selecting the agent of choice. #None is FDA approved for painful DSPN. Spectrum of AEs, drug interactions, and comorbidities need be considered if selecting these agents. (Modified from Pop-Busui R, Boulton AJ, Feldman EL, et al. Diabetic neuropathy: a position statement by the American Diabetes Association. *Diabetes Care.* 2017;40:136–154.)

including severity of symptoms, appearance of motor weakness, and failure of nonsurgical treatment.[667]

Another distinct class of diabetic neuropathies includes the diabetic polyradiculoneuropathies. This disorder is also known by many other names, including proximal motor neuropathy, diabetic amyotrophy, diabetic femoral neuropathy, and diabetic radiculoplexus neuropathy. It primarily affects older T2DM male patients. The onset of the disease can be gradual but is more commonly abrupt, presenting with excruciating pain in the thighs and hips or buttocks, followed by significant weakness of the proximal muscles of the lower limbs. The neuropathy begins unilaterally, but frequently spreads bilaterally, and coexists with DSPN. Electrophysiologic evaluation reveals lumbosacral plexopathy most commonly superimposed on DSPN.[668] Patients usually clinically resolve with time, and the general course of treatment is supportive. Use of intravenous gammaglobulin is reported to accelerate the resolution of symptoms,[669] but must be used with caution in diabetic patients because of the greater risk of inducing renal failure.[670]

Clinical Features of Diabetic Autonomic Neuropathy

Diabetic autonomic neuropathy is secondary to dysfunction in the sympathetic and parasympathetic nervous systems. The pathogenesis underlying diabetic autonomic neuropathy is generally considered to be similar to DSPN, with a distal-to-proximal dying back of axons due to multiple metabolic insults.[671] Because of the widespread innervation pattern of the autonomic nervous system to critical organs, the symptoms and signs of autonomic dysfunction are varied, dependent on the organ system. These are summarized in Table 37.14.[646]

Cardiac autonomic neuropathy is clinically the most important of the autonomic neuropathies because of its association with early cardiac arrhythmia, silent myocardial infarctions, and early mortality.[672] CAN may present as lightheadedness upon standing, palpitations, frank syncope, and a generalized sense of weakness. In very early stages, CAN may be asymptomatic and only

identified by abnormal heart rate variability, either with deep breathing or upon standing. Later signs include resting tachycardia with a heart rate above 100 beats per minute and orthostatic hypotension defined as a reduction of more than 20 mm Hg in systolic or 10 mm Hg in diastolic pressure when going from a lying to a standing position.

The 2017 ADA guidelines suggest screening for CAN in all diabetic patients with DSPN or other microvascular complications of diabetes (Table 37.15).[646] As with DSPN, there are no disease-modifying therapies, and T1DM patients are instructed to monitor glucose control, while T2DM patients are instructed to focus more on general lifestyle parameters and controlling all aspects of the metabolic syndrome. These recommendations are presented in Table 37.16 and parallel those for DSPN (see Table 37.11).

Diabetic autonomic neuropathy can involve the gastrointestinal tract, resulting in esophageal dysmotility, delayed gastric emptying, and both constipation and diarrhea with frank fecal incontinence. Among these disorders, the best studied is diabetic-mediated delayed gastric emptying, also known as gastroparesis. While estimates vary, the disorder is more prevalent in T1DM than T2DM and has a prevalence of approximately 5% in T2DM patients.[673] The 2017 ADA recommendations for the screening and diagnosis of gastroparesis is presented in Table 37.17.[646]

TABLE 37.13 Treatment for Pain Associated With Distal Symmetric Polyneuropathy

Drug Class	Agent[a]	DOSE		NNT Range 30–50% Improvement[c]	Common Adverse Events	Major Adverse Events

Treatment of gastroparesis is multifaceted. Patients are instructed to eat multiple small meals with lower fat and fiber content and to discontinue any drugs that decrease gastric motility, such as tricyclic antidepressants or opioids. If these interventions do not provide sufficient symptomatic relief, patients can begin metoclopramide, the only FDA-approved drug for the treatment of gastroparesis. Patients should not take the drug for more than 5 consecutive days, secondary to the risk of developing extrapyramidal symptoms, and even this short regimen should only be undertaken when all other interventions have failed.[646]

Sexual and bladder function are also under the control of the autonomic nervous system, and dysfunction occurs commonly in both with long-term diabetes. Erectile dysfunction is common in men and may occur in up to 50% of men over the age of 40. Men are more likely to experience erectile dysfunction if they have T1DM or T2DM, with an increase in dysfunction with a longer duration of diabetes. Erectile dysfunction is further exacerbated by obesity, smoking, and hypertension, along with excessive alcohol use and selected medications.[674] While there is likely a component of autonomic dysfunction in most affected individuals, it is essential to address the modifiable risks factors that are outlined earlier. The phosphodiesterase type 5 inhibitors provide a first line of therapy for erectile dysfunction; these drugs include sildenafil, tadalafil, and vardenafil.[675] Additional therapeutic approaches

TABLE 37.14 Symptoms and Signs Associated With Diabetic Autonomic Neuropathy

Cardiac Autonomic Neuropathy	Gastrointestinal	Urogenital	Sudomotor
Resting tachycardia Abnormal blood pressure regulation • Nondipping • Reverse dipping	Gastroparesis (Gastropathy) • Nausea • Bloating • Loss of appetite • Early satiety • Postprandial vomiting • Brittle diabetes	Bladder dysfunction • Frequency • Urgency • Nocturia • Hesitancy • Weak stream • Dribbling • Urinary incontinence • Urinary retention	Dry skin • Anhidrosis • Gustatory sweating
Orthostatic hypotension (all with standing) • Lightheadedness • Weakness • Faintness • Visual impairment • Syncope	Esophageal dysfunction • Heartburn • Dysphagia for solids	Male sexual dysfunction • Erectile dysfunction • Decreased libido • Abnormal ejaculation	
Orthostatic tachycardia or bradycardia and chronotropic incompetence (all with standing) • Lightheadedness • Weakness • Faintness • Dizziness • Visual impairment • Syncope	Diabetic diarrhea • Profuse and watery diarrhea • Fecal incontinence • May alternate with constipation	Female sexual dysfunction • Decreased sexual desire • Increased pain during intercourse • Decreased sexual arousal • Inadequate lubrication	
Exercise intolerance	Constipation • May alternate with explosive diarrhea

include intracavernosal injections, vacuum devices, psychosexual counseling, and cognitive behavioral therapy.[675] Generally, a combination of therapies provides the best therapeutic responses.

Bladder and lower urinary tract dysfunction can occur in men and women with diabetes. Symptoms include frequent urination with urinary urgency, nocturia, and a weak urinary stream. In older men, these symptoms can be attributed to benign prostatic hyperplasia (BPH), but are frequently exacerbated by diabetes. While estimates vary, studies suggest up to a twofold increase in lower urinary tract symptoms in men with diabetes.[676] Urinary incontinence occurs in 50% of middle-aged women with diabetes; in several studies, the presence of diabetes is reported to significantly increase the risk of female urinary incontinence.[676] This can be multifactorial, due to multiple pregnancies, obesity, and medications, in addition to diabetes. The studies that directly

TABLE 37.17 American Diabetes Association Recommendations for Gastrointestinal Neuropathies

- Evaluate for gastroparesis in people with diabetic neuropathy, retinopathy, and/or nephropathy by assessing for symptoms of unexpected glycemic variability, early satiety, bloating, nausea, and vomiting. **C**
- Exclusion of other causes documented to alter gastric emptying, such as use of opioids or glucagon-like peptide 1 receptor agonists and organic gastric outlet obstruction, is needed before performing specialized testing for gastroparesis. **C**
- To test for gastroparesis, either measure gastric emptying with scintigraphy of digestible solids at 15-min intervals for 4 h after food intake or use a ^{13}C-octanoic acid breath test. **B**

ADA recommendations are assigned ratings of A, B, or C depending on the quality of evidence.

link bladder and lower urinary tract dysfunction to autonomic neuropathy are listed in Table 37.18[676] and suggest an association with bladder and lower urinary tract dysfunction to both CAN and DSPN. In both men and women, bladder and lower urinary tract dysfunction increase the risk of urinary tract infections.[677] As with all forms of diabetic autonomic neuropathy, patients are counseled to achieve glucose control and address other comorbidities, including obesity, hypertension, and hyperlipidemia, that may contribute to the disorder.[678]

Hypoglycemic unawareness is another form of diabetic autonomic neuropathy with significant patient morbidity. Hypoglycemia is defined as a plasma glucose level of less than 70 mg/dL (3.9 mmol/L) without autonomic warning signs.[679,680] In most patients, two categories of symptoms occur with hypoglycemia: neuroglycopenic and autonomic symptoms. Neuroglycopenic symptoms are directly correlated with lack of available glucose for brain function, including hunger, altered mental status, confusion, perioral paresthesias, difficulty speaking, diffuse weakness, and syncope. In more severe cases, patients develop seizures, become comatose, and (in extreme cases) die. Autonomic symptoms

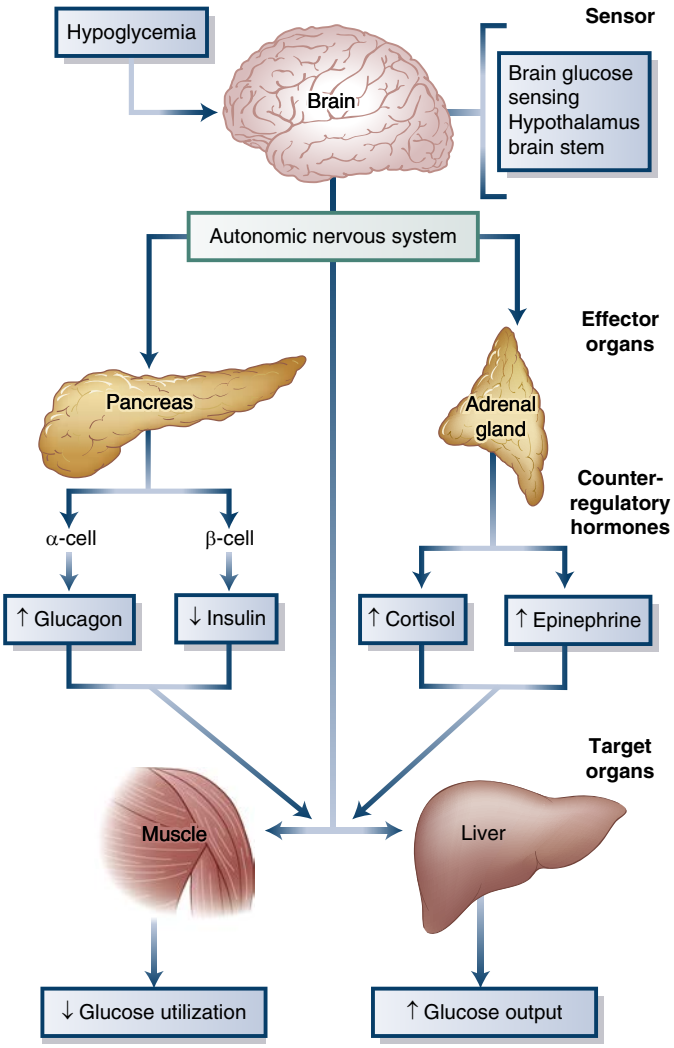
include diaphoresis, tremulousness, pallor, palpitations, and generalized anxiety. Hypoglycemic unawareness is defined as the presence of neuroglycopenic symptoms prior to or in the absence of autonomic warning symptoms.[681]

Counterregulatory responses under the control of the autonomic nervous system are required to restore normal glycemia in response to hypoglycemia. These essential responses include stimulation of catecholamines (both norepinephrine and epinephrine), glucagon, cortisol, and growth hormone, while inhibiting insulin secretion.[682] These counterregulatory responses stimulate hepatic glucose production while decreasing glucose utilization in the periphery, and collectively restore euglycemia (Fig. 37.46). Recurrent hypoglycemic episodes decrease the plasma glucose level that serves as the setpoint for activating the counterregulatory response in both T1DM and T2DM patients.[682] Severe hypoglycemia with life-threatening neuroglycopenic symptoms is more common in T1DM patients with hypoglycemic unawareness and correlates with longer duration of diabetes, intensive control, and advancing age.[683,684] While a commonly cited statistic is that 40% of T1DM patients experience one or more episodes of hypoglycemic unawareness,[682] a recent multinational study using a patient self-reported assessment tool, the global Hypoglycemia Assessment Tool (HAT), reported the global incidence of hypoglycemic unawareness in T1DM and T2DM patients on insulin therapy as 97.4% and 95.3%, respectively, with approximately 6.9 events per month in T1DM patients and 2.4 events in T2DM patients.[685]



• **Fig. 37.46** Counterregulatory response to hypoglycemia in type 2 diabetes. (From Martín-Timón I, del Cañizo-Gómez FJ. Mechanisms of hypoglycemia unawareness and implications in diabetic patients. *World J Diabetes.* 2015;6:912–926.)

Regardless of the exact percentages, it is clear that hypoglycemic unawareness is common and a source of significant patient morbidity. There is a strong association between recurrent hypoglycemia and an increase in fatal cardiac arrhythmias.[686] An analysis of unrecognized hypoglycemia in 10,096 participants from the ACCORD trial revealed a relationship between the number of episodes of hypoglycemic unawareness and death, leading to early discontinuation of the trial.[687] While hypoglycemic unawareness does not result in significant permanent cognitive impairment in adults,[688,689] it represents a major and potentially disabling event in children and adolescents.[690] Recurrent episodes in young children can result in behavioral problems and neurocognitive dysfunction[691,692] associated with changes in brain structure.[693] In adults who drive, it can result in potentially fatal automobile accidents.

Management of hypoglycemic unawareness begins with prevention, with careful blood glucose monitoring and reasonable blood glucose targets personalized to each patient,[694] in parallel with patient education.[695] This approach can be augmented with β_2-adrenergic agents, caffeine, and serotonin reuptake inhibitors, although the effects are small and use of these agents is controversial.[682] Most therapeutic efforts focus on glycemic control. Continuous glucose monitoring (CGM) to identify hypoglycemia can decrease the number and severity of adverse hypoglycemic events. In a group of T1DM patients with hypoglycemic unawareness, CGM reduced severe hypoglycemic events from 8.1 to 0.6 events per year.[696] Pharmacologic treatment options begin with optimizing insulin regimens; for example, rapid-acting insulin analogs afford more flexibility for patients with exercise regimens and varying mealtimes,[697] while long-acting insulin analogs provide a flatter, less variable glycemic profile that decreases the rate of overall and nocturnal hypoglycemia.[698] The use of continuous subcutaneous insulin infusion (insulin pump) is very effective in decreasing the number of hypoglycemic events,[699] with reported improvements in patient-reported quality of life assessments.[700] Regardless of the insulin regimen chosen by the patient, personalized insulin treatment with appropriate glycemic targets is the cornerstone of treatment.[682,701]

Diabetic Heart Disease

Coronary Artery Disease

In recent decades, cardiovascular disease mortality rates have declined substantially in the general population in the United States. However, improvement in cardiovascular mortality rates has been significantly less in people with diabetes.[8] Diabetes remains associated with excess morbidity and mortality rates even after adjustment for traditional risk factors. Most studies of cardiovascular risk in diabetes have been in the T2DM population, who represent more than 90% of all patients with diabetes.

Effect of Diabetes on Risk of Coronary Heart Disease (CHD)

The Framingham Heart Study showed a twofold to threefold elevation in risk of clinically evident atherosclerotic disease in patients with T2DM compared to those without diabetes.[702] Diabetic

men in the Multiple Risk Factor Intervention Trial (MRFIT) had an absolute risk of cardiovascular death more than three times higher than that of the nondiabetic cohort, even after adjustment for established risk factors.[703] Seminal work from Finland showed that patients with T2DM without a previous myocardial infarction have a risk of myocardial infarction over 7 years as high as that of nondiabetic patients with a history of a myocardial infarct.[704] In this study, the case fatality rate after myocardial infarction was also substantially higher in patients with diabetes. In women, diabetes eliminates the cardioprotective effects of the premenopausal period, and women with diabetes have a cardiovascular mortality rate as high as that of diabetic men. The follow-up of the Diabetes UK cohort, a group of 23,751 subjects with insulin-treated diabetes diagnosed before the age of 30 years, also showed similar mortality rates for men and women, and the size of this cohort permitted robust gender-specific estimates of standardized mortality ratios.[705] For example, among those aged 30 to 39 years, the standardized mortality ratios for ischemic heart disease mortality were 8 and 41.6, respectively. Other forms of cardiovascular diseases, such as hypertension, valvular disease, cardiomyopathy, heart failure, and stroke, are also increased.

The risks of cardiovascular events and death conferred by T2DM have been examined in several prospective and observational trials with various populations of patients. The adjusted relative risk is generally increased by 1.3 to 1.6 for total mortality, mortality attributed to cardiovascular events, nonfatal myocardial infarction or stroke, and congestive heart failure.[706–709] Many epidemiologic studies observe the hazard ratio for cardiovascular mortality risk in patients with diabetes is similar to that in nondiabetic patients who had experienced a previous myocardial infarction. Whether or not the diagnosis of diabetes itself is a risk equivalent to having a history of prior myocardial infarction remains controversial.[709,710] However, all studies demonstrate diabetes results in a significantly increased risk of cardiovascular disease. Thus the strategy of considering diabetes as a CHD risk equivalent is appropriate for purposes of assessing risk and defining an aggressive multirisk treatment regimen. With more intensive management of cholesterol, blood pressure, and decreased smoking, rates of myocardial infarction, stroke, amputation, and mortality are decreasing among people with diabetes, especially in high-income countries. Yet the global burden of cardiovascular disease attributable to diabetes is not declining due to major increases in the number of people developing diabetes.[711]

Coronary heart disease risk has also been evaluated in smaller numbers of patients with T1DM. In the Framingham study, the cumulative cardiovascular mortality rate in patients with T1DM was approximately four times that of nondiabetic patients by age 55 years.[710] Patients with T1DM and a HbA_{1c} level of 6.9% or lower, considered at goal by most management guidelines, had a risk of death from any cause or from cardiovascular causes that was twice as high as the risk for matched controls.[712] As in patients with T2DM, the early deaths related to coronary heart disease in patients with T1DM may occur by the fourth decade of life, and the cumulative mortality rate increases at a similar rate in both T1DM and T2DM in the subsequent decades. The increased cardiovascular mortality rate with age in patients with T1DM is substantially even higher in those patients who also have nephropathy, with gradations of cardiovascular risk evident across the spectrum from microalbuminuria to macroalbumuria to end-stage renal disease, with a 2.8-fold, 9.2-fold, and 18.3-fold increase in mortality compared to the general population across these groups.[451] Therefore persistent proteinuria is a strong predictor of the development of coronary heart disease in this population. Studies suggest that proteinuria is a marker of generalized vascular damage that predisposes to atherosclerosis and coronary events.

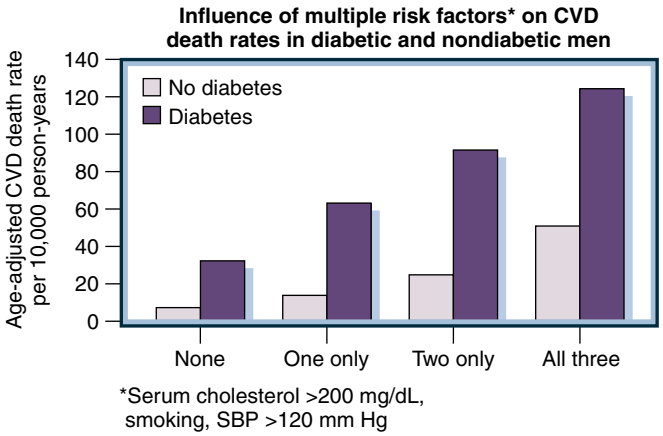
It is unclear whether there has been any recent decline in mortality or morbidity rates from coronary artery disease associated with T1DM. The Pittsburgh Epidemiology of Diabetes Complications (EDC) study reported no difference in the cumulative incidence of cardiovascular disease with 20, 25, or 30 years of disease duration according to year of diagnosis (1950 through 1980).[713] The benefits of improved treatment of hyperglycemia and concomitant hypertension and other comorbid conditions with standard care therefore do not appear to have reduced cardiovascular mortality rates associated with T1DM, in contrast to dramatic reductions realized for diabetic retinopathy and nephropathy.

Aggregation of Traditional CHD Risk Factors in Diabetes

Multiple traditional cardiovascular risk factors (e.g., hypertension, dyslipidemia, obesity, insulin resistance) occur together in patients with diabetes.[714] Approximately 50% of patients with T2DM have hypertension, and more than 30% have hypercholesterolemia at the time of diagnosis. As in nondiabetic patients, these risk factors independently predict cardiovascular mortality.[703] However, even in the presence of one or more concomitant risk factors, diabetes further increases the cardiovascular death rate (Fig. 37.47). It also appears that diabetes interacts synergistically with other risk factors to more sharply increase risk as the number of total risk factors increases.

The UKPDS further confirmed the importance of risk factor aggregation in T2DM as well as the relationship between specific risk factors and future cardiovascular events. In this large population of patients with newly diagnosed T2DM, higher LDL cholesterol levels, lower HDL cholesterol concentrations, higher HbA_{1c} levels and systolic blood pressure measurements, and a history of smoking measured at baseline were all associated with a risk of future cardiovascular disease.[10]

Cardiovascular risk associated with T2DM may be a consequence of insulin resistance and its associated abnormalities that are often present in the prediabetic state.[715] In patients spanning



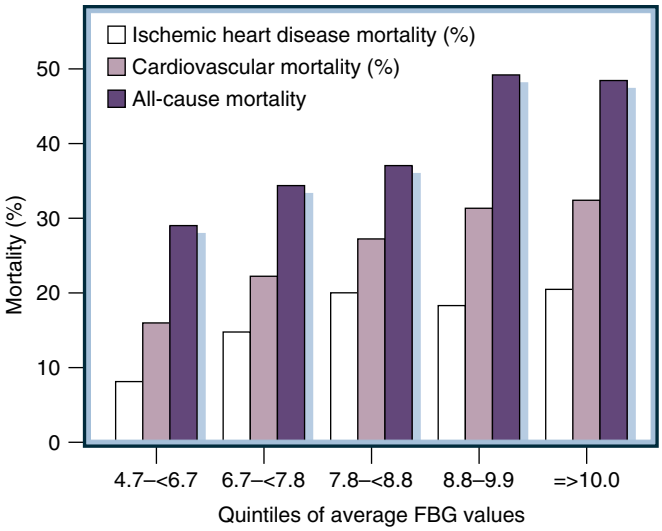
• **Fig. 37.47** Age-adjusted cardiovascular disease *(CVD)* death rates by number of risk factors for men with and without diabetes at baseline screened for the Multiple Risk Factor Intervention Trial. In the presence of diabetes, the cardiovascular death rate steeply rises at any level of concomitant risk factors. *SBP,* Systolic blood pressure. (From Stamler J, Vaccaro O, Neaton JD, et al. Diabetes, other risk factors, and 12-year cardiovascular mortality for men screened in the Multiple Risk Factor Intervention Trial. *Diabetes Care.* 1993;16:434–444.)

the spectrum of glucose tolerance, from normal to impaired glucose tolerance to frank diabetes, insulin resistance positively correlates with atherosclerosis as assessed by carotid intimal medial thickening.[716] The San Antonio Heart Study, a population-based study of diabetes and cardiovascular disease in Mexican Americans and non–Latin American whites, showed those who converted to diabetes from a prediabetic state and who were more insulin resistant had higher blood pressure, higher triglyceride levels, and lower HDL cholesterol levels.[17] Strikingly, individuals with normal glucose tolerance and high insulin resistance had twice the 8-year risk of adverse cardiovascular outcomes compared to those with low insulin resistance, even after adjustment for 11 risk factors. Although it is not possible to fully distinguish hyperinsulinemia from hyperglycemia, hyperinsulinemia has been hypothesized to contribute mechanistically to the relationship between hyperglycemia and coronary heart disease in patients with T2DM,[717] and a number of studies have shown hyperinsulinemia to independently predict cardiovascular risk. These results suggest treatment strategies that increase insulin sensitivity in these patients can reduce cardiovascular risk. However, no significant difference in the rates of death and major cardiovascular events were observed using insulin provisional compared to insulin sparing therapeutic strategies in patients with both T2DM and heart disease in the Bypass Angioplasty Revascularization Investigation 2 Diabetes Trial (BARI 2D).[718] Furthermore, when insulin therapies were used prospectively to lower HbA_{1C} in either patients with T2DM or prediabetes, they have not been shown to worsen cardiovascular outcomes. This suggests that hyperinsulinemia is a marker of insulin resistance but not a cause of the adverse cardiovascular effects of insulin resistance.

Given the multifactorial nature of atherogenic risk in patients with T2DM, it is reasonable to conclude that an aggressive multifactorial intervention could significantly reduce cardiovascular risk. The value of such a treatment regimen was tested in the Steno-2 study,[595] in which 160 patients with T2DM and microalbuminuria were randomized to receive either conventional treatment in accordance with national guidelines or intensive therapy that included behavior modification and targeted pharmacologic therapy for hyperglycemia, hypertension, dyslipidemia, and microalbuminuria along with secondary prevention of cardiovascular disease with aspirin. Over a mean follow-up period of 7.8 years, patients who received intensive treatment had greater improvements in HbA_{1c}, blood pressure, fasting serum cholesterol and triglyceride values, and urinary albumin excretion than did patients receiving conventional therapy. The greater degree of improvement in risk factors with intensive therapy was also reflected in outcomes. Patients receiving intensive therapy had an approximately 50% reduction in events comprising a multiple cardiovascular endpoint, and in retinopathy, nephropathy, and autonomic neuropathy.[594]

Insulin Resistance, Plasma Glucose, and Excess CHD Risk in Diabetes

Insulin resistance and its consequences increase cardiovascular risk in people with normal glucose tolerance. Yet diabetes confers increased risk that is not explained by the known risk factors associated with insulin resistance. Newer proatherogenic consequences of pathway-specific insulin resistance are discussed in the first section of this chapter. Although a meta-analysis of randomized controlled trials showed limited benefits of intensive glucose-lowering treatment on all-cause mortality and deaths from cardiovascular causes, using HbA_{1c} as an indicator,[13] effects of hyperglycemia not captured by HbA_{1c} may also explain excess cardiovascular risk in prediabetes as well as in diabetes. Hyperglycemia increases insulin resistance, and circadian variation in insulin resistance causes fasting hyperglycemia. One study showed that mortality rates from all causes, cardiovascular mortality, and ischemic heart disease increased progressively across quintiles of fasting blood glucose levels in patients with T2DM (Fig. 37.48).[719] Other data support a dose-response relationship between fasting hyperglycemia and cardiovascular mortality rate in diabetes, with patients with the highest levels of fasting blood glucose having a cardiovascular mortality rate almost five times higher than patients with the two lowest levels combined.[720]



• **Fig. 37.48** All-cause mortality, cardiovascular mortality, and ischemic heart disease mortality rates in patients with type 2 diabetes mellitus by quintiles of average fasting blood glucose (FBG) values. Cardiovascular mortality and all-cause mortality rates increase throughout the range of fasting plasma glucose in a graded fashion. (From Andersson DK, Svärdsudd K. Long-term glycemic control relates to mortality in type II diabetes. *Diabetes Care.* 1995;18:1534–1543.)

Prediabetes refers to the presence of *impaired fasting glucose* (≥100 mg/dL [≥5.5 mmol/L] and <120 mg/dL [<6.7 mmol/L]), and *impaired glucose tolerance,* defined as a 2-hour post–75-g oral glucose load value of 140 to 199 mg/dL (7.8–11 mmol/L) with the fasting level below 100 mg/dL (<5.5 mmol/L) and/or HbA_{1c} between 5.7% and 6.5%. Impaired glucose tolerance (IGT)—a prediabetic state associated with insulin resistance—is also a risk factor for mortality. In a large study of the relationship between 2-hour postload blood glucose and cardiovascular fatality, 17,869 male civil servants enrolled in the Whitehall Study from 1967 to 1969 were monitored, and outcomes were correlated with baseline measurements of the 2-hour postload blood glucose (2hBG) level after a 50-g oral glucose load.[721] The hazard ratio for cardiovascular mortality increased as a linear function of 2hBG for all values of 2hBG greater than 83 mg/dL (>4.6 mmol/L). With 2hBG values between 83 and 200 mg/dL (4.6 and 11.1 mmol/L), the age-adjusted hazard ratio for cardiovascular disease was 3.62 (95% CI, 2.3–5.6).

Tominaga and colleagues examined survival rates in a cohort of participants in a diabetes prevalence trial in Japan[722] and concluded the risk of cardiovascular fatality is associated with impaired glucose tolerance rather than impaired fasting glucose. Further substantiation of the role of impaired glucose tolerance in cardiovascular mortality risk was provided by an analysis of

data from the Diabetes Epidemiology: Collaborative Analysis of Diagnostic Criteria in Europe (DECODE) study.[723] In this study, more than 25,000 men and women were monitored for a mean of 7.3 years, and outcomes were correlated with measurements of fasting glucose and 2hBG after a 75-mg glucose load at baseline. The results indicated that the oral glucose tolerance test provides the best index of risk of mortality associated with impaired glucose tolerance.

The Nurses' Health Study also implicated the prediabetic state as a cardiovascular risk factor.[724] In this large cohort of women, 5894 developed diabetes over a 20-year follow-up. The age-adjusted relative rate for myocardial infarction was 3.75 (95% CI, 3.10–4.53) in the period before diagnosis of diabetes and 4.57 (95% CI, 3.87–5.39) after diagnosis, compared with women who did not develop diabetes, even after adjustment for other cardiovascular risk factors. The risk of stroke was also increased before onset of diabetes.

The continuum of cardiovascular risk with rising glucose levels has also been identified in patients with T1DM[725] and in people without clinically overt diabetes but with varying levels of glucose intolerance.

Cardiovascular Disease in Patients With Metabolic Syndrome

Definitions and Diagnosis

Metabolic syndrome is a term referring to the frequent clustering of the cardiovascular risk factors of hypertension, obesity, insulin resistance, dyslipidemia, and dysglycemia in a single patient. Separate diagnostic criteria for different risk components have been put forth by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III),[726] the World Health Organization (WHO),[727] and the International Diabetes Federation (IDF),[728] with clinical overlap among these definitions and the designation of prediabetes.[729]

According to prior NCEP guidelines,[729a] the metabolic syndrome is based on the presence of three of the following five risk factors[726]:

- Abdominal obesity (waist circumference >40 inches (>101.6 cm) in men and >35 inches (>88.9 cm) in women)
- Plasma triglycerides 150 mg/dL (1.7 mmol/L) or higher
- Plasma HDL cholesterol less than 40 mg/dL (<1.04 mmol/L) in men, less than 50 mg/dL (<1.30 mmol/L) in women
- Blood pressure 130/85 mm Hg or higher
- Fasting plasma glucose 110 mg/dL (6.1 mmol/L) or higher

The NCEP criteria give precedence to obesity as a contributor to the metabolic syndrome and apply cutoff points for triglycerides and HDL that are probably less stringent than would be used to identify a categoric risk factor, reflecting the fact that many marginal risk factors can result in a significant risk for CHD. The NCEP criteria do not require explicit demonstration of insulin resistance for diagnosis of the metabolic syndrome, and patients with diabetes are not excluded from the diagnosis.[727] There are modest differences between the NCEP criteria and those developed by the WHO[727] and the IDF.[728] One intriguing aspect of the IDF criteria is the recognition that individuals of Asian origin may have increased visceral adiposity with lower waist circumference than what is observed in Western countries and hence the difference in waist circumference criteria for such individuals.

Studies support the concept that insulin resistance during the prediabetic state contributes to atherogenic risk.[730] Prediabetic subjects who were insulin resistant had higher levels of inflammatory markers (C-reactive protein, PAI1, and fibrinogen) than converters to diabetes with predominantly low insulin secretion or nonconverters. Thus insulin resistance is associated with a proinflammatory state that can contribute to the atherogenic risk profile in prediabetic patients. Many aspects of insulin resistance and the proatherogenic and proinflammatory state of prediabetes are associated with increased visceral fat.[731]

By 2012, more than one-third of all US adults met the definition and criteria for metabolic syndrome agreed to jointly by several international organizations.[732] Although there continues to be debate about the validity and significance of identifying the metabolic syndrome or prediabetes in patients, clinicians, including primary care physicians, often find the construct of value in understanding the relevant underlying issues and explaining these to patients. Behind some of the reluctance to identify metabolic syndrome/prediabetic states in patients is the clinical question of what to do after such a diagnosis is made. Perhaps new data showing cardiovascular risk reduction with newer glucose-lowering therapies that do not cause hypoglycemia (discussed later) may shift this perspective. These new drug options, along with effective medications for reducing cholesterol and hypertension, support the clinical utility of continuing to identify prediabetes and the metabolic syndrome.

Cardiovascular Consequences of Metabolic Syndrome

Metabolic syndrome, prediabetes, and other overlapping definitions from the NCEP, WHO, and others have been evaluated in multiple studies regarding the incidence and mortality risk of CHD.[733–735] In general, age-adjusted cardiovascular mortality and all-cause mortality increase twofold to threefold in patients with metabolic syndrome, regardless of the diagnostic criteria used to define the syndrome. Increased risk is not seen in every study. Differences among these studies exist and involve when and how analyses were done and the metabolic syndrome definitions used, including key issues such as whether frank diabetes is included or excluded from metabolic syndrome definition and the hyperglycemia threshold used.

In a definitive meta-analysis of 87 studies involving 951,083 patients, the metabolic syndrome was found to be associated with an increased risk of cardiovascular disease (relative risk [RR]: 2.35; 95% CI: 2.02–2.73), cardiovascular mortality (RR: 2.40; 95% CI: 1.87–3.08), all-cause mortality (RR: 1.58; 95% CI: 1.39–1.78), myocardial infarction (RR: 1.99; 95% CI: 1.61–2.46), and stroke (RR: 2.27; 95% CI: 1.80–2.85); metabolic syndrome in the absence of diabetes was still associated with increased cardiovascular risk,[732] although it is based on fewer studies.

Another approach to assessing cardiovascular risk of metabolic syndrome involves consideration of this cohort in clinical trials. For example, in the West of Scotland Coronary Prevention Study,[735] those with the metabolic syndrome had an increased cardiovascular risk, along with elevated C-reactive protein levels versus the rest of the cohort, which added prognostic value for both cardiovascular disease and diabetes.

Controversies over metabolic syndrome and other prediabetic states exist.[736] One issue has been whether the cardiovascular risk associated with the metabolic syndrome differs from the additive risk conferred by the presence of each metabolic syndrome component. Another has been what therapeutic intervention should ensue once a diagnosis of metabolic syndrome is made. These and other issues have limited the extent to which this issue has been studied in trials or further considered by guidelines.[737] Evidence continues to emerge regarding the pathologic issues associated

with prediabetes, including intimal medial thickening and plaque in carotid arteries, and adverse functional cardiac parameters such as reduced diastolic filling (now referred to as *heart failure with preserved ejection fraction*).[738] For now, specific relatively subtle differences among diagnostic criteria of prediabetic states may be less relevant for the clinician than the recognition of the increased risk of cardiovascular disease and diabetes associated with metabolic syndrome, the commonly encountered clustering of these risk factors, and the impact lifestyle and modest weight reduction can have of many component risk factors. New data for cardiovascular event reduction in patients with diabetes with agents that do not cause hypoglycemia as well as weight loss agents may stimulate reexamination of these issues.

The Role of Glycemic Control in Improving Cardiovascular Outcomes

The UKPDS confirmed the positive association between plasma glucose levels and CHD risk for HbA_{1c} levels greater than 6.2% in patients with diabetes.[717] Each percentage point elevation in HbA_{1c} increased cardiovascular risk by 11%. Multiple other lines of evidence, as noted, confirm the relationship between hyperglycemia, diabetes, and increased cardiovascular risk. Despite this, it has been difficult to establish that glucose control in diabetes could decrease future macrovascular events, including trials investigating intensive versus standard diabetes treatment and different strategies of achieving glycemic control. Although meta-analyses of randomized controlled trials of diabetes treatments revealed improved glucose control was associated with reductions in nonfatal myocardial infarction rates, there has been no evidence for decreases in either cardiovascular death or all-cause mortality.[13] Given the clear increased cardiovascular risk with diabetes, the inability to reduce cardiovascular events in response to treating diabetes represented a clinical paradox, a contrast to contemporaneous studies showing the increased cardiovascular risk of hypercholesterolemia could be reversed by lowering LDL with statin therapy, including in patients with diabetes. Various hypotheses have been raised regarding this inability of diabetes treatment to show improved cardiovascular outcomes, including trial issues such as study design, sample size, duration, and poorly selected primary endpoints, and disease issues such as disease duration or treatment-specific factors (e.g., drugs used).

In 2008, the FDA mandated that novel glucose-lowering therapies seeking approval must demonstrate cardiovascular safety. The resulting data, involving over nine cardiovascular outcome trials reported to date involving 200,000 patients, have led to a striking pivot for the fields of both diabetes and cardiology with data demonstrating not only cardiovascular safety but also cardiovascular benefit for glucagon-like peptide 1 receptor agonists (GLP1RA) and sodium glucose transporter 2 inhibitors (SGLT2i). Other studies established cardiovascular safety but also identified potential concerns over an increased risk for inducing heart failure, as seen with some dipeptidyl-peptidase 4 inhibitors (DPP4i). Given the landmark nature of these trials, their impact on clinical management of diabetes, and the new questions posed by these findings, a review of the prior studies with older antidiabetic agents warrants review and provides context before the results with these newer agents are considered.

Earlier studies, such as the DCCT in T1DM and the smaller Veterans Affairs Diabetes Feasibility (VA) trial in T2DM, did not show a reduction in cardiovascular endpoints with intensive metabolic control. These well-conducted studies had inherent limitations. Although relatively large (N = 1441), the DCCT followed a relatively young (mean age 27 years) population of patients with T1DM for approximately 6 years. At the end of follow-up, few events had occurred.[9] Intensive therapy reduced the risk of coronary artery and peripheral vascular disease by 41% compared with conventional therapy, but the difference was not statistically significant. Similarly, in the VA trial, intensive blood glucose control in patients with T2DM trended to but did not significantly reduce cardiovascular endpoints.[739] Both studies lacked adequate power to detect a difference in macrovascular events between treatment groups because of the small number of events in each group, small patient populations, and relatively short follow-up.

In contrast, the 17-year follow-up of the 1441 patients from the DCCT trial (EDIC) demonstrated the benefit of early intensive glycemic control in T1DM on cardiovascular risk in the subsequent post-DCCT, EDIC observational setting.[740] This study and its findings are discussed in the sections on biochemistry and molecular cell biology and retinopathy earlier in the chapter. During follow-up, those who had previously been randomized to intensive treatment had an emergent reduction in cardiovascular risk of 42% (p = 0.02) and a reduction in the composite risk of nonfatal myocardial infarction, nonfatal stroke, or cardiovascular death of 57% (p = 0.02). Of note, this separation was evident even though after 11 years of follow-up, HbA_{1c}, as well as blood pressure and lipid risk factors, were essentially identical between the two arms. Patients in the conventional treatment group had more albuminuria and microalbuminuria than intensively treated patients, but the differences in risk remained significant after adjustment for these factors. These findings indicate early intensive glycemic control reduced the long-term risk of cardiovascular disease in patients with T1DM while also raising intriguing mechanistic questions regarding metabolic memory (discussed in the first section of this chapter).

For T2DM, the UKPDS was larger and adequately powered to detect differences between groups in terms of macrovascular events in regular versus intensive glycemic control.[379] Those receiving intensive glycemic control showed a trend toward lower myocardial infarction rates compared to conventional treatment, which was not statistically significant (p = 0.052).[379] Despite the lack of overall efficacy of intensive treatment for management of macrovascular complications of diabetes in the UKPDS, there were indications that metformin as a specific therapy may be effective in reducing cardiovascular events.[379,741] In a retrospective analysis of an overweight subset (n = 342) of the UKPDS cohort who were randomized to metformin, significant reductions in the occurrence of any diabetes-related endpoint (32%), diabetes-related death (42%), and all-cause mortality (36%) were seen compared with conventionally treated patients.[741] Although this is subset data in a limited number of patients, these results, along with registry data suggesting decreased mortality with metformin use,[742] promoted acceptance of metformin having potential cardiovascular benefit.

Subsequent trials examined whether lowering the target for glycemic control (to HbA_{1c} <7%) would reduce cardiovascular events. The ACCORD trial randomized patients with T2DM who had established cardiovascular disease or multiple risk factors to a treatment-directed HbA_{1c} value lower than 7% or to standard therapy with an HbA_{1c} target value between 7% and 7.9%. Over 3.5 years of follow-up, total mortality rate increased in the intensively treated group without any significant reduction in cardiovascular events.[535] The VADT, which randomized patients to either intensive treatment (median HbA_{1c} 6.9%) or standard therapy (median HbA_{1c} 8.4%) also failed to demonstrate cardiovascular benefit through tighter HbA_{1c} control.[538] The ADVANCE trial,

which randomly assigned patients to an intensively treated group, who attained HbA_{1c} of 6.5% versus a standard control group who had HbA_{1c} values of 7.3%, demonstrated a relative reduction of 10% in the combined outcome of major macrovascular and microvascular events that was not statistically significant.[532] Of note, this statistically insignificant 10% relative decrease in cardiovascular events was driven largely by a 21% reduction in nephropathy. Taken together, these three studies do not support HbA_{1c} reduction beyond 7%, improving cardiovascular outcomes in patients with established coronary heart disease and treated with these agents.

An additional perspective on the prior data showing limited if any cardiovascular benefit through older glucose-lowering treatments is that HbA_{1c} represents a flawed surrogate marker for identifying risk of future macrovascular outcomes responsive to therapy, contrasting with the ability of HbA_{1c} to track efficacy in predicting microvascular responses to glucose-lowering treatment. Given that HbA_{1c} is used to define the disease of diabetes, enrolling patients based on HbA_{1c} may not consistently enroll those more likely to benefit in terms of macrovascular outcomes in response to the treatment under study.

Overall, many studies provide strong epidemiologic data showing that diabetes is associated with a large increase in cardiovascular risk. In contrast to studies of microvascular disease, where the associated risk is high per unit change in HbA_{1c}, the associated cardiovascular risk per unit change in HbA_{1c} is lower, once corrected for triglycerides, LDL cholesterol, hypertension, and smoking.

While the benefit of glucose lowering with metformin to reduce myocardial infarction was shown in the substudy of the UKPDS,[741] as previously mentioned, little data was available to support other therapeutic approaches or specific agents.

Studies Using Insulin-Sensitizer Medications

The BARI 2D trial randomized 2368 patients with T2DM and coronary heart disease to either prompt revascularization or intensive medical therapy alone and to either insulin sensitization or insulin provision diabetes therapy. Randomization was stratified by the proposed revascularization method. The 5-year survival and major cardiovascular event rates were similar in all study subgroups except for those patients undergoing coronary artery bypass grafting who had fewer major cardiovascular events after revascularization. There was less hypoglycemia and weight gain and greater apparent benefit from coronary artery bypass grafting in the insulin sensitization group.

To evaluate insulin versus other therapies for lowering glucose as a strategy to decrease cardiovascular events, in the Outcome Reduction With Initial Glargine Intervention (ORIGIN) trial, insulin or noninsulin therapies were used in patients with either prediabetes or early T2DM to achieve a fasting plasma glucose of 95 mg/dL versus 123 mg/dL (5.3 mmol/L vs 6.8 mmol/L) with other therapies.[743] No difference in cardiovascular outcomes was evident in the more aggressively treated arm.

Thiazolidinediones are direct insulin sensitizers, improving insulin sensitivity rather than increasing insulin levels. TZDs bind to and activate the nuclear receptors known as peroxisomal proliferator-activated receptor gamma (PPARγ) and to mitoNEET, a mitochondrial protein-regulating energy metabolism.[744] TZD effects in vascular and inflammatory cells limit atherosclerosis and inflammatory responses. In the PROactive study (i.e., Prospective Pioglitazone Clinical Trial in Macrovascular Events), 5238 patients with T2DM and evidence of macrovascular disease were randomized to either pioglitazone or usual care with the objective of similar glucose control in both arms.[745] After a mean of 34.5 months, there was no significant difference in the two treatment groups in the study's primary endpoint—a seven-component composite of all-cause mortality, nonfatal myocardial infarction, stroke, acute coronary syndrome, surgical intervention in the leg or coronary arteries, and amputation above the ankle. This broad primary endpoint, which extended beyond the more standard objective cardiovascular primary endpoint used in cardiovascular trials, was used to increase the prospect of demonstrating cardiovascular benefit, under the assumption that peripheral arterial disease behaves like coronary disease. However, improvements in peripheral arterial disease endpoints have been difficult to demonstrate, even with potent cardiovascular risk-reducing agents such as statins. Patients treated with pioglitazone had significantly lower risk for the prespecified secondary endpoint in this trial, which was more consistent with the standard primary cardiovascular trial endpoint of combined all-cause mortality, nonfatal myocardial infarction, and nonfatal stroke (HR: 0.84; 95% CI: 0.80–1.02; $p = 0.027$).

Two issues have complicated the use of TZDs. A meta-analysis of rosiglitazone effects on cardiovascular outcomes examining short-term trials of glycemic control suggested rosiglitazone was associated with an increased risk of myocardial infarction. Total event rates were low in the included studies and they did not examine cardiovascular events as primary endpoints nor were the cardiovascular events adjudicated.[746] In contrast, other meta-analyses, including ones using only randomized clinical trials with prespecified cardiovascular endpoints and/or adjudication, found no increase in cardiovascular events or cardiovascular death with either rosiglitazone or pioglitazone.[747] This conclusion was also supported by other subsequent studies and an FDA consensus review panel.[748] Differences do exist between pioglitazone and rosiglitazone. A second factor limiting use of these agents has been their known side effects, including fluid retention that may increase heart failure (although without myocardial changes or increased mortality), increased bone fractures, significant increases in weight among a subset of patients, and increases in bladder cancer.[749] Whether these untoward effects are offset by clinical cardiovascular benefit may require further consideration, especially given more recent positive clinical trial data discussed later in the chapter.

Prior inability to conclusively demonstrate cardiovascular event reduction with specific diabetes approaches or therapies could have been due to not having the right agent or targeting the most impactful mechanism rather than other explanations such as patient characteristics or study design.[750,751]

As a result of the 2008 FDA-instituted guidance that new antidiabetic drugs must provide cardiovascular safety data in their approval process, a large amount of new data regarding cardiovascular effects of newer antidiabetic agents has emerged and continues to do so, including new data showing cardiovascular risk reduction for patients treated with GLP1RA or SGLT2 inhibitors. These results have focused thinking on specific agents and potential mechanisms that are likely more complex than simply lowering blood glucose concentration.

Studies Using Newer Antidiabetic Medications: A New Era?

Dipeptidyl Peptidase 4 Inhibitors and Cardiovascular Disease

DPP4i lower glucose by inhibiting degradation of the incretin GLP1. The SAVOR–Thrombolysis in Myocardial Infarction (TIMI) 53 (SAVOR-TIMI 53) trial established safety for this

agent with no difference in major adverse cardiovascular events (MACE) (the composite of nonfatal myocardial infarction, nonfatal stroke, or cardiovascular death); however, a 27% increase in hospital admissions for heart failure was seen.[752] The Examination of Cardiovascular Outcomes With Alogliptin Versus Standard of Care (EXAMINE) similarly established cardiovascular safety for the MACE outcome with this DPP4i.[753] Although EXAMINE investigators reported that alogliptin had no impact on heart failure,[754] differences in the design and endpoint measurements in this trial as compared to SAVOR-TIMI 53 may limit this conclusion.[755] In the Trial to Evaluate Cardiovascular Outcomes After Treatment With Sitagliptin (TECOS), sitagliptin showed no cardiovascular benefit but also no adverse effects, including no increased admissions for heart failure, all as compared to usual care. Other approaches to the issue of DPP4i and heart failure, like observational studies and meta-analyses, have varied in conclusion about whether specific agents differ in heart failure risk. The FDA has included heart failure warnings in DPP4i labeling. While none of these agents increase mortality, it is prudent to examine DPP4i-treated patients with diabetes for signs and symptoms of heart failure. Notably, prior to these outcome studies, less rigorous forms of data had suggested cardiovascular benefits with DPP4i, underscoring the primacy of randomized, prospective, blinded clinical trial data.

In the CARMELINA study,[756,756a] the effect of linagliptin (5 mg once daily) was compared to placebo (both added to standard of care) on cardiovascular outcomes in 6979 adults with T2DM and high cardiovascular risk, the majority of whom also had kidney disease. Linagliptin demonstrated a similar cardiovascular safety profile compared to placebo when added to standard of care. There was a similar kidney safety profile and no increase in heart failure compared to placebo.[756,756a] The companion Cardiovascular Outcome Study of Linagliptin Versus Glimepiride (CAROLINA)[757] is comparing linagliptin to the sulfonylurea glimepiride in patients with T2DM and higher cardiovascular risk (known cardiovascular disease or T2DM-associated end-organ damage or older age or two or more cardiovascular risk factors).

GLP1RAs and Cardiovascular Disease

In contrast to the DPP4 inhibitor data, studies with both GLP1RAs and SGLT2 inhibitors provided landmark data showing decreased cardiovascular events with glucose-lowering therapy. Not surprisingly, these positive findings have prompted intense scrutiny and further questioning regarding mechanisms explaining these results. Nevertheless, the findings stand. The fact that two different agents within each drug class have shown a positive cardiovascular primary endpoint reinforces the general validity of the data. Furthermore, both GLP1RAs and SGLT2 inhibitors improved renal outcomes (see "Glycemic Control in Diabetic Kidney Disease").

GLP1RAs have GLP1 receptor-dependent and receptor-independent effects on the cardiovascular system.[758,759] GLP1RAs can induce satiety, promote weight loss, lower blood pressure, and have other effects in preclinical and smaller translational studies that might promote cardiovascular benefit.[760] In the LEADER trial[543] (Table 37.19), 9340 patients with T2DM and increased cardiovascular risk received random assignment to either liraglutide (titrated to 1.8 mg once daily) or placebo, with median follow-up of 3.8 years. The primary time-to-event analysis, which was the combined results of first occurrence of cardiovascular death, nonfatal myocardial infarction, or nonfatal stroke, was significantly decreased among liraglutide (overall incidence 13%) versus placebo group (14.9%, $p < 0.001$ for noninferiority; $p = 0.01$ for superiority).[543]

Semaglutide, a GLP1RA administered once a week, was studied in the SUSTAIN 6 trial, which enrolled 3297 patients with T2D, of whom the majority had established cardiovascular disease, chronic kidney disease, or both. Participants received either semaglutide (0.5 or 1 mg) or placebo once weekly for 2 years. The primary composite outcome, which was the first occurrence of the same 3-point major adverse cardiovascular event, was significantly reduced in those on semaglutide ($p < 0.001$ for noninferiority), with nonsignificantly decreased nonfatal myocardial infarction and significantly decreased nonfatal stroke (see Table 37.19).[544] In further support of GLP1RAs having cardiovascular benefit, the Harmony Outcomes trial demonstrated that 9463 patients with T2DM and cardiovascular disease receiving albiglutide 30 to 50 mg based on glycemia and tolerability had a 22% reduction in cardiovascular events compared to those receiving placebo in conjunction with usual care[761] over a median follow-up of 1.5 years.

In contrast, other GLP1RAs have shown cardiovascular safety but no benefit in outcome trials. In the Evaluation of Lixisenatide in Acute Coronary Syndrome (ELIXA) trial, 6068 patients with T2DM with recent (<180 days) myocardial infarction or unstable angina hospitalization received lixisenatide 10 to 20 μg once daily or placebo[762] with usual care with median follow-up of 25 months. The primary composite endpoint of cardiovascular death,

TABLE 37.19 Key Findings From GLP1 Receptor Agonist Cardiovascular Outcome Trials

[a]CV death, myocardial infarction, or stroke.

CV, Cardiovascular; *GLP1RAs,* glucagon-like peptide-1 receptor agonists.

myocardial infarction, stroke, or unstable angina hospitalization showed no superiority, while also establishing safety given noninferiority versus placebo. The Exenatide Study of Cardiovascular Event Lowering (EXSCEL) trial, with extended-release exenatide also showed safety but no benefit when studied in 14,752 patients with T2DM treated with either extended-release exenatide 2 mg weekly or placebo over 3.2 years; no difference was seen versus placebo on the primary composite outcome of first occurrence of cardiovascular death, nonfatal myocardial infarction, or nonfatal stroke (HR: 0.91; 95% CI: 0.83–1.00; $p < 0.001$ for noninferiority; $p = 0.06$ for superiority).[763]

The basis for positive cardiovascular outcomes with liraglutide, semaglutide, and albiglutide but not lixisenatide or extended-release exenatide remains obscure. Differences between clinical trials such as enrollment criteria, subtle differences in patient populations, study locations, trial duration, and concomitant medication use may be underlying factors. It remains possible some members of the same drug class may have more potent effects on discrete cardiovascular risk parameters, such as blood pressure or weight loss. Given the prior literature, differences in glucose control itself seem unlikely to explain variable outcome benefits within drug classes or between older and newer agents. Pharmacologic differences among the agents is difficult to exclude (e.g., short-acting vs long-acting activity with long-acting exenatide nearly reaching statistical significance).

Initial concerns about increased risk of pancreatitis, pancreatic cancer, and thyroid cancer with GLP1RAs have not been borne out in clinical trials, although a prior history of such issues is viewed as a potential contraindication to use. Given that GLP1 provides a gut-derived satiety signal to the brain, the gastrointestinal side effects seen with these drugs, mainly nausea, are not surprising, may contribute to beneficial weight loss, and are not a barrier for most patients. GLP1RAs do not pose concerns for patients with chronic kidney disease, within the limits of the populations enrolled. A decrease in progression of chronic kidney disease has been noted. For some patients, the injectable nature of GLP1RAs may be an issue. These agents on their own do not cause hypoglycemia, although caution may be needed when combined with insulin provisional diabetes treatments (e.g., sulfonylureas or insulin).

SGLT2 Inhibitors and Cardiovascular Disease

By blocking glucose absorption in the proximal tubule, SGLT2 inhibitors lower glucose levels, while also wasting an energy substrate and having a diuretic effect, with resulting weight loss and blood pressure lowering.[764]

In the EMPA-REG OUTCOME trial[765] (Table 37.20), 7020 patients with T2DM and established cardiovascular disease received empagliflozin, 10 mg or 25 mg, or placebo once daily in addition to usual care. After a median duration of 3.1 years, the primary major cardiovascular event composite outcome among those receiving empagliflozin was significantly decreased. Especially impressive was that this positive outcome was driven primarily by a major decrease in death, which was seen in both cardiovascular (38%) and all-cause mortality (32%). Hospitalization for heart failure was significantly reduced in those on empagliflozin (–35%, $p = 0.002$), as evident in both those with and without a history of heart failure, as possibly expected for an agent with diuretic effects. An antihypertensive effect was also evident. However, a similar magnitude of reduction in hospitalization for heart failure has not been seen in clinical trials of diuretics or other antihypertensive drugs, making this explanation less likely. Given that most participants did not have a heart failure history, this effect highlights the extent to which subclinical heart failure as well as risk for heart failure is a major issue in T2DM while also suggesting new directions for SGLT2 inhibitor use now being investigated. The rapid separation of curves in terms of mortality and heart failure, both occurring after approximately 6 months, was also noteworthy.

Canagliflozin, another SGLT2 inhibitor, was studied in the CANVAS[473] program (see Table 37.20), which involved two cardiovascular trials, including CANVAS-R that focused on patients with renal disease. These studies involved 10,142 subjects with T2DM and either a history of cardiovascular disease (approximately two-thirds) or just an additional cardiovascular risk factor (one-third). After a mean of 3.6 years (median 2.4 years), the primary major adverse cardiovascular endpoint (myocardial infarction, stroke, cardiovascular mortality) was significantly reduced. Although each of these components trended toward benefit, none of them were significant on their own, including cardiovascular mortality or total mortality, in contrast to the EMPA-REG OUTCOME trial. A signal for an increased risk of amputations was seen in CANVAS, without clear evidence for similar issues in the EMPA-REG OUTCOME trial. Other analyses have also raised concerns regarding possible increased risk for amputations with canagliflozin. The extent to which this finding is valid involves other SGLT2 inhibitors, and the potential underlying mechanism for this putative issue remains unresolved and awaiting further data, although the significant reduction in cardiovascular events is evident. In Dapagliflozin Effect on Cardiovascular Events (DECLARE-TIMI 58), the effects of dapagliflozin in 17,150 patients with inadequately controlled diabetes and either known cardiovascular disease (secondary prevention cohort) or at least two risk factors for cardiovascular disease (primary prevention cohort) was studied. In announced but not yet published topline results, dapagliflozin demonstrated cardiovascular safety and a reduction in a composite of cardiovascular death or hospitalization for heart failure but without a significant difference in the major adverse composite outcome of combined cardiovascular death, nonfatal myocardial infarction, or ischemic stroke.

Other large cardiovascular outcome trials are being done with other SGLT2 inhibitors. Ertugliflozin is also being investigated in a large outcome cardiovascular trial. Future studies in other specific populations will provide additional insight into SGLT2 inhibitor effects. Other real-world data analyses, performed outside of a randomized clinical trial setting, have supported cardiovascular benefits with SGLT2 inhibitors. For example, CVD-REAL[766] (see Table 37.20), which reviewed medical claims, hospital records, and registries from 309,056 patients in six countries taking SGLT2 inhibitors, found SGLT2 inhibitor use was associated with a 39% lower risk of heart failure hospitalization ($p < 0.001$) and a 51% reduction in total death ($p < 0.001$) independent of country.

The mechanism for cardiovascular benefits with SGLT2 inhibitors remains to be defined. The multitude of prior negative trials with glucose-lowering argues against the modest improvement in HbA_{1c} as underlying the observed benefit. Reductions in blood pressure, weight and volume, with concomitant increases in hematocrit as well as unique aspects to tissue-based volume shifts, have been hypothesized to contribute to the decrease in cardiovascular risk. However, the relative small changes in these parameters and the lack of similar effects in trials with diuretics or other antihypertensives suggest the involvement of other factors. Serum uric acid levels, previously linked to cardiovascular risk, are decreased with SGLT2 inhibition, but the rapidity with which the curves

Lower risk of heart failure and death in patients initiated on sodium-glucose cotransporter-2 inhibitors versus other glucose-lowering drugs: the CVD-REAL study (comparative effectiveness of cardiovascular outcomes in new users of sodium-glucose cotransporter-2 inhibitors). *Circulation.* 2017;136:249–259.

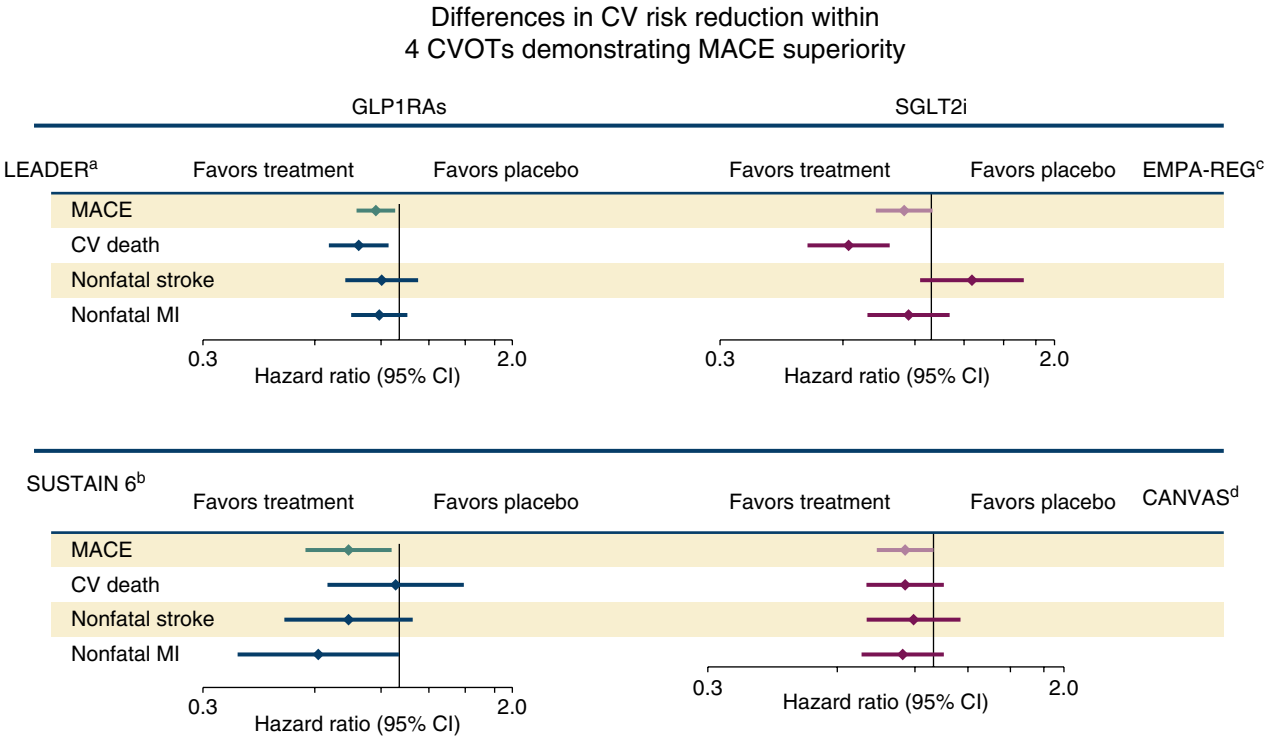
separate in the SGLT2 trials make this explanation less likely. Other proposed mechanisms include more efficient fuel switching in patients with T2DM and ischemia, through increased plasma β-hydroxybutyrate as a better energy substrate, changes in dysregulated neurohormonal signaling, and alterations in sodium-hydrogen exchange, among others.

Untoward effects with SGLT2 inhibition align in part with its known mechanism of action. Induced glucosuria can promote myocotic genital infections, which can be offset by good hygienic practices, with consideration of avoiding these agents in patients with a history of these issues. Increased diabetic ketoacidosis and euglycemic ketoacidosis have been reported with SGLT2 inhibitors although not seen in meta-analyses or the randomized trials discussed earlier. The question of increased amputation risk with canagliflozin was noted previously. Hypoglycemia is not an issue with this class of drugs, unless added to a regimen that includes insulin provisional therapies.

The positive cardiovascular outcome trials with both GLP1RAs and SGLT2 inhibitors (Fig. 37.49) raise fundamental questions regarding optimal T2DM management: How should these data be incorporated into guidelines, including the choice between GLP1RAs and SGLT2 inhibitors? Most guidelines have adopted an approach of recommending these agents in ways that align with the trials, for use mainly in patients with inadequately controlled HbA_{1c} and established or high risk for cardiovascular disease. This leaves unresolved the question of changing therapies for patients who have reasonable glycemic control but use antidiabetic drugs with no proven cardiovascular benefit. Separately, should cardiologists prescribe glucose-lowering agents, and how should previously encountered barriers to cardiologist engagement with diabetes treatment be overcome? Greater insight into the mechanisms underlying cardiovascular benefit from these newer agents may yield further refinement in their use, while also advancing continued drug development. Finally, the positive clinical trial data in T2DM patients with established cardiovascular disease or high cardiovascular risk have prompted further consideration of how the benefits seen with these therapies might be extended to other indications and patient groups, particularly T2DM patients without current cardiovascular disease. Clinical trials of these agents in people with T2DM and hypertension or heart failure are already under study. These agents, which do not cause hypoglycemia, may be especially appealing for reducing cardiovascular risk in those with prediabetes.

Characteristic Features and Treatment of Dyslipidemia in Diabetic Patients

Dyslipidemia has been well characterized as a risk factor that increases atherosclerosis in patients with T2DM. Various patterns of dyslipidemia are often encountered in diabetes and may



• **Fig. 37.49** Components of positive primary endpoint responses in landmark glucagon-like peptide 1 receptor agonist (GLP1RA) and sodium-glucose cotransporter-2 (SGLT2) inhibitor trials. Data shown for GLP1RAs (LEADER/liraglutide, SUSTAIN 6/semaglutide) and SGLT2 inhibitor (EMPA-REG/empagliflozin, CANVAS/canafliglozin) cardiovascular outcome trials (CVOT). *CI,* Confidence interval; *MACE,* major adverse cardiovascular events; *MI,* myocardial infarction. increase atherogenic risk (also see Chapter 41). Although patients with diabetes tend not to have marked elevations in plasma LDL cholesterol levels, their LDL cholesterol levels remain predictive of cardiovascular risk. LDL particles in diabetes are smaller and more dense than normal LDL. These small, dense triglyceride-rich LDL particles are especially pathologic. Small dense LDL particles are more susceptible to oxidation, particularly in the setting of poor glucose control. Other evidence suggests that glycation of LDL may be enhanced in diabetes, impairing recognition of the lipoprotein by its hepatic receptor and extending its half-life. Conversely, HDL cholesterol levels are decreased in patients with T2D.[767]

A key feature of diabetic dyslipidemia is an increase in hepatic very low-density lipoprotein (VLDL) production in response to elevations in FFA flux often seen in diabetes with insulin-resistant adipocytes. Although insulin and lipases such as lipoprotein lipase mediate the uptake of triglyceride-derived FFAs by striated muscle, reducing the levels presented to the liver, insulin resistance results in the opposite effect, increasing the levels of FFAs presented to the liver. The metabolic syndrome, with its characteristic abdominal obesity and insulin resistance, also increases FFA delivery to the liver. In addition, reduced lipoprotein lipase activity in T2DM leads to an accumulation of triglyceride-rich lipoproteins in the plasma of these patients and may also result in decreased physiologic delivery of lipolytically derived, biologically active molecules to cells. Such models align with genetic evidence in the general population. Gain-of-function variants with increased lipoprotein lipase activity, as well as those with genetic loss of function of inhibitors of the lipoprotein lipase pathway, appear to have less cardiovascular risk. Triglyceride-rich lipoproteins also play a role in the reduced levels of HDL cholesterol by increasing the transfer of cholesterol from these particles.

A number of landmark trials have established that lowering LDL cholesterol levels produces major clinical benefits in terms of reducing cardiovascular events in patients with and without a history of cardiovascular disease at baseline. These findings have now been extended to the population of subjects with T2DM and dyslipidemia. Although LDL levels are often within the average range in patients with diabetes, treatment with 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) has consistently shown improved outcomes among both those with and without diabetes, including those with and without a prior history of heart disease. Statins are now incorporated into current diabetes management guidelines, discussed further later in the chapter.

In the Cholesterol and Recurrent Events (CARE) trial, T2DM patients with a prior cardiovascular event receiving pravastatin had a 25% reduction in the incidence of cardiovascular death, nonfatal myocardial infarction, coronary artery bypass graft, and revascularization procedures compared to placebo.[768] In the Long-Term Intervention With Pravastatin in Ischemic Disease (LIPID) study, patients with diabetes had a 19% reduction in major coronary heart disease events (fatal cardiovascular disease and nonfatal myocardial infarction).[769] In a post hoc subgroup analysis of secondary prevention in a large cohort of patients with diabetes, impaired glucose tolerance, or normal glucose tolerance, simvastatin normalized associated elevations in total cholesterol and triglycerides across the range of glucose values.[770] Treatment also significantly reduced major coronary events and revascularizations in patients with diabetes and reduced major coronary events, revascularizations, and total and coronary mortality in patients with impaired glucose tolerance.

Several studies have further validated the use of statins in patients with diabetes and related conditions.[567,771–774] In the Heart Protection Study, a large (N = 20,536), randomized, placebo-controlled trial of the use of simvastatin 40 mg in high-risk patients, roughly 29% of the study participants had T2DM.[775] Over the 5-year course of the study, treatment with simvastatin resulted in a significant reduction in the occurrence of major vascular events in patients with T2DM who had established coronary heart disease (33.4% vs 37.8% in simvastatin-treated and placebo-treated patients, respectively), in T2DM with no prior coronary heart disease (13.8% vs 18.6%), and in both categories combined (20.2% vs 25.1%). Overall, the study also demonstrated a highly significant 12% relative risk reduction in all-cause mortality and an 18% reduction in coronary mortality among all subjects treated with simvastatin.

The Collaborative Atorvastatin Diabetes Study (CARDS) had a fundamental impact on the management of diabetes because of the magnitude of beneficial effects seen in the statin-treated group. CARDS was a randomized, placebo-controlled trial that tested the effect of starting low dose atorvastatin (10 mg/day) in T2DM patients with no prior history of heart disease, with plasma LDL levels lower than 160 mg/dL (<4.1 mmol/L) (N = 2838) on preventing acute coronary heart events, coronary revascularization, or stroke.[574] The trial was terminated 2 years early because the prespecified efficacy criteria were met. After a median of 3.9 years follow-up, patients treated with atorvastatin had a relative risk reduction for first cardiovascular event of 37% (95% CI: 52–17% reduction; p = 0.001), compared with placebo-treated patients. Assessed separately, acute coronary heart disease events, coronary revascularizations, and stroke were significantly reduced, by 36%, 31%, and 48%, respectively. The CARDS trial showed that in patients with T2DM, a threshold LDL cholesterol level should not be the sole determinant of whether a statin is prescribed. Of note, stroke was reduced in CARDS, addressing prior questions about whether LDL lowering with statins might or might not reduce stroke to the same extent as they lower coronary heart disease. Currently, it is generally accepted that statins are effective in reducing cerebrovascular disease.[776] As a result of CARDS and other studies discussed, most if not all guidelines have endorsed statin use in most appropriately aged individuals with diabetes.

The Treating to New Targets (TNT) study compared the effects of atorvastatin 10 mg or 80 mg daily for a median follow-up period of 4.9 years in patients with clinically evident coronary heart disease who also met the NCEP criteria for diagnosis of the metabolic syndrome.[772] The study included 778 patients with T2DM, who constituted 22% of the study population. Treatment with atorvastatin 80 mg reduced major cardiovascular events 29% more than atorvastatin 10 mg, presumably due to the greater reduction in LDL cholesterol seen with higher dosing of atorvastatin.

Pooling of data from the multiple statin trials further supports statin benefits in those with diabetes. In the Cholesterol Treatment Trialists' (CTT) Collaboration,[777] analysis of 18,646 patients with diabetes in 14 different studies revealed a 9% proportional reduction in all-cause mortality per mmol/L reduction in LDL cholesterol (RR: 0.91, 99% CI: 0.82–1.01; p = 0.02) as compared to a similar 13% reduction in those without diabetes (RR: 0.87, 99% CI: 0.82–0.92; p < 0.0001).[778] A clinically and statistically significant 21% proportional reduction in major vascular events per mmol/L reduction in LDL cholesterol was observed in people with diabetes (RR: 0.79, 99% CI: 0.72–0.86; p < 0.0001).

In 2013, revised cholesterol treatment guidelines were provided by the American College of Cardiology (ACC) and the American Heart Association (AHA).[779] These recommendations depart from prior guidelines by focusing initiation of lipid-lowering therapy on four clinically defined patient groups who warranted either high-intensity, moderate-intensity, or low-intensity statin intervention while also abandoning use of LDL targets as a means of guiding therapy. Patients with diabetes were one of these four treatment groups, as supported by the data from primary and secondary prevention trials noted previously. A controversial aspect of these guidelines was their abandonment of specific LDL targets. Both TNT and the subsequent Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT), which showed that adding the nonstatin LDL-lowering agent ezetimibe to stable statin therapy further decreased cardiovascular events in patients with coronary heart disease,[780,781] support the clinical utility of using specific LDL targets. The 2013 guidelines might be best viewed as a scientific statement given their precise focus on what had been proven in clinical trials, which explains the specific age cutoff points for statin treatment of patients with diabetes.

Clinical trials have also revealed statins are associated with an increase in new-onset diabetes among a small subset of patients at high risk for development of T2DM. In the Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) study, which investigated rosuvastatin 20 mg versus placebo in 17,603 patients with no history of atherosclerotic events, baseline mean LDL levels of 108 mg/dL, and an elevated C-reactive protein of 4.2 mg/L, physician-reported new-onset diabetes was found in 270 patients on rosuvastatin versus 216 on placebo.[782] In the JUPITER population 41% of participants had metabolic syndrome at study entry. New-onset diabetes was found in 28% in patients with one or more risk factors for developing diabetes, who at the same time benefited by a 39% reduction in cardiovascular events and a 17% reduction in total mortality. Among those with no risk factors for diabetes, there was no increase in new diagnoses of diabetes.[783] Thus the modest increase in diabetes in response to statin treatment is markedly offset by major decreases in cardiovascular events. For patients in whom statin treatment is appropriate, concerns over increased conversion to diabetes should not be a factor in the decision to use statins. While increases in new diabetes has been seen with multiple statins, the mechanism underlying this statin effect remains obscure.

Additional data are now available regarding LDL cholesterol levels and cardiovascular risk associated with using additional new LDL-lowering therapies. In population studies, individuals with lifelong low LDL cholesterol levels were found to have genetic loss of function in the Proprotein Convertase Subtilisin/Kexin Type 9 *(PCSK9)* gene, which was associated with decreased atherosclerosis and cardiovascular events but no other untoward effects. Further supporting PCSK9 as a drug target, genetic variants with increased PCSK9 function resulted in a lipid and clinical picture that replicated familial hypercholesterolemia (FH). PCSK9 action targets the LDL receptor for proteosomal degradation rather than allowing it to return to the cell surface for another cycle of LDL clearance. In an impressive glimpse into future drug development prospects, in less than 10 years, PCSK9 inhibitors in the form of monoclonal antibodies were being tested for their clinical efficacy in cardiovascular event reduction. In FOURIER, adding the PCSK9 inhibitor evolocumab (Repatha) to statin therapy versus statin alone in 27,546 patients with established coronary disease reduced LDL levels by 59% (92 mg/dL to 30 mg/dL [2.4 mmol/L to 0.78 mmol/L]) and was associated with a statistically significant reduction in cardiovascular events of 15%.[784] The ODYSSEY trial with alirocumab (Praluent) in patients with recent acute coronary syndrome also showed a statistically significant reduction in cardiovascular events, as presented but not yet published.[785] Patients with diabetes are receiving attention in terms of PCSK9 inhibitor use as a function of their increased risk for cardiovascular events. Post hoc studies on outcomes in those with diabetes was a prespecified analysis in FOURIER and demonstrated similar benefit and no adverse issues among these patients (40%) compared to those who did not have diabetes at baseline (60%). In ODYSSEY, 29% of subjects had diabetes, indicating that there should be forthcoming data about this group. Other studies indicate no issues with alirocumab use in those with diabetes, with presentations suggesting an augmented impact on event reduction in acute coronary syndrome patients. An ongoing scientific question is evidence suggesting PCSK9 loss of function may be associated with increased risk of hyperglycemia and perhaps diabetes,[786] although no increased signal for new diabetes has been seen in the clinical trials published to date.

Outcomes of treatment with other nonstatin therapies have been variable. With niacin, data have been disappointing, with no additional benefit seen when added to statins in several trials.[773,787,788] Although the lower HDL levels found in patients with diabetes might make niacin an appealing treatment option, niacin's lack of proven efficacy combined with its side effects of increasing insulin resistance and relatively poor tolerability have limited its use. Recent genetic studies using Mendelian randomization have demonstrated that variants associated with higher HDL levels often do not protect against CV events.[789] Current attention is focused on the concept that the key element in the inverse relationship between HDL and cardiovascular disease is HDL functionality, which may not be reflected in total HDL levels.[790]

Fibric acid derivatives, which lower high triglycerides and raise HDL, have also been proposed as a treatment in people with diabetes given the usual nature of diabetic dyslipidemia. In the VA High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT), men given gemfibrozil had a significant decrease in coronary events and strokes in the absence of statin use.[774] Post hoc analyses suggesting these benefits were driven by the diabetes subgroup focused further attention on fibrates. The FIELD study assessed the effect of long-term fenofibrate therapy on cardiovascular events in patients with T2DM.[567] Patients were randomized to receive either micronized fenofibrate 200 mg per day (n = 4895) or placebo (n = 4900). During 5-year follow-up, 5.9% of the placebo-treated patients versus 5.2% of the fenofibrate-treated patients had a major coronary event (coronary heart disease death or nonfatal myocardial infarction), the primary endpoint of the trial, a difference that was not statistically significant. Fenofibrate therapy significantly reduced some secondary endpoints, including total cardiovascular events (HR: 0.89, 95% CI: 0.75–1.05, p = 0.035), coronary revascularization, progression of albuminuria, and the need for laser treatment of retinopathy. Other secondary endpoints such as cardiovascular mortality were higher, although not statistically significant, with fenofibrate. Statistical significance for the primary endpoint of the study might have been missed because a greater percentage of patients in the placebo group began statin therapy during the study period compared to the fenofibrate group, thus modulating their risk and potentially masking the treatment effect.

The ACCORD trial addressed the use of fibrates in combination with statins in patients with T2DM. This trial investigated whether combination therapy with simvastatin plus fenofibrate, compared with simvastatin alone, would reduce cardiovascular events in diabetic patients at high risk for cardiovascular disease. In this randomized clinical trial comparing fenofibrate to placebo in statin-treated patients, combination therapy did not reduce the rate of cardiovascular mortality, nonfatal myocardial infarction, or nonfatal stroke, although other secondary parameters such as first myocardial infarction were improved. In a prespecified subgroup with a high triglyceride ratio (triglycerides ≥204 mg/dL [≥5.3 mmol/L] and HDL ≤34 mg/dL [≤0.88 mmol/L]), fenofibrate did reduce the primary outcome as compared to the placebo group. A pattern has emerged in fibrate trials of greater benefit in those with significantly elevated triglycerides and lower HDL—the population in which fibrates would be commonly used. At this time, no formal recommendation exists that patients with significant dyslipidemia receive combination statin-fibrate therapy for further risk reduction on the basis of T2DM alone.[791] In those with a significant history of CVD, elevated triglycerides, and low HDL, expert opinion might endorse fibrates as an adjunct to statin therapy once LDL levels are appropriately controlled as a reasonable if not definitively established option. Importantly, improved glycemic control and decreased insulin resistance, whether through drug therapy or improved lifestyle interventions and modest weight loss, can improve diabetic dyslipidemia. Topline results from the Reduction of Cardiovascular Events With EPA—Intervention Trial (REDUCE-IT),[792] using a specific eicosapentaenoic acid only from fish oil in patients with established cardiovascular disease or diabetes mellitus and at least one other cardiovascular risk factor indicate a 25% reduction in the primary endpoint composite of the first occurrence of major adverse cardiovascular events, including cardiovascular death, nonfatal myocardial infarction, nonfatal stroke, coronary revascularization, or unstable angina requiring hospitalization.

Genetic variants linked to low triglyceride levels, like apolipoprotein CIII (apoCIII) loss of function, have been reported to predict future cardiovascular events.[793] ApoCIII loss of function reduces plasma triglyceride, and the atherogenicity of chylomicrons, VLDL, LDL, and HDL particles. These findings provide a rationale for pursuing ApoCIII inhibition and genetic knockdown as a therapeutic strategy, which continues to be pursued despite initial FDA rejection of volanesorsen, an apoCIII antisense therapy, out of concerns for thrombocytopenia.[794]

Sources for cholesterol guidelines have transitioned from the prior NCEP Adult Treatment Panel recommendations, the last being the NCEP ATPIII, to joint guidance from the American College of Cardiology and the American Heart Association. Considering both the ATPIII recommendations and the most recent ACC/AHA approaches is valuable and provides additional perspective. The importance of dyslipidemia as a contributor to cardiovascular risk in patients with diabetes was incorporated in the NCEP ATPIII guidelines, which identified diabetes as being equal in cardiovascular risk to having had prior coronary heart events.[726] According to the NCEP ATPIII guidelines, patients with T2DM would receive cholesterol-lowering therapy if the LDL cholesterol level were higher than 130 mg/dL (>3.36 mmol/L), with the goal of reducing LDL cholesterol to less than 100 mg/dL (<2.57 mmol/L).[726] In practice, more aggressive approaches were often used, instituting drug treatment if LDL cholesterol level were higher than 100 mg/dL (>2.57 mmol/L). Subsequent guideline updates endorsed an LDL cholesterol goal of less than 70 mg/dL (<1.81 mg/dL) in higher risk patients even when the high-risk patient had a baseline LDL cholesterol level lower than 100 mg/dL (<2.57 mmol/L).[795] The most recent ACC/AHA cholesterol guidelines took a completely different approach. The guidelines abandon specific LDL targets, instead identifying four specific patient groups in whom clinical trial data supported statin use. Since clinical trials had not specifically targeted more-intensive versus less-intensive LDL goals with a single statin, the recommendations also focused on the appropriate statin dose intensity for given patient groups. The presence of diabetes was one of these four patient groups, with the recommendation that designated patients with diabetes (age 40–75 years), as defined by subjects enrolled in trials, receive a high-intensity statin (atorvastatin 40 or 80 mg, rosuvastatin 20 or 40 mg) if their 10-year calculated risk was greater than or equal to 7.5%, and a moderate-intensity statin (these same statins at their other lower doses and remaining other statins at their mid to highest doses) if calculated 10-year risk was less than 7.5%. This approach has been controversial, especially the abandonment of target LDL levels. However, data from multiple clinical trials, including those with ezetimibe, supported benefits from lower LDL levels. The subsequent PCSK9 inhibitor data has further strengthened evidence for additional cardiovascular benefit from achieving lower LDL levels as mentioned in further guideline updates and will likely be incorporated in an upcoming AHA/ACC guideline release.

Characteristic Features and Treatment of Hypertension in Diabetic Patients

Approximately 50% of patients with newly diagnosed diabetes also have hypertension. As with dyslipidemia, hypertension interacts with diabetes to amplify the risk of cardiac mortality (see Fig. 37.47). Although the cause of hypertension is multifactorial, the insulin-resistant state is one factor postulated to predispose patients to develop hypertension. In addition to its negative effects on the cardiovascular system, high blood pressure is a key contributor to the development of microvascular disease in diabetes. Based on the guidelines of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7), blood pressure should be reduced to less than 130/85 mm Hg in patients with diabetes.[547] A longer duration of diabetes has been linked to increased arterial stiffness, decreased vasomotor function, and changes in pulse pressure, which can contribute to patient symptoms in response to blood pressure treatment. Patients with diabetes may also lose the usual nocturnal blood pressure dip.

Results of the most recent clinical trials underscore the benefits of aggressive treatment of hypertension in patients with diabetes, although achieving mean blood pressure reductions to currently recommended targets is challenging both in clinical trials and in real-world settings. This may also help explain disconcordant trial results. Data have continued to support achieving a systolic blood pressure between 120 and 140 mm Hg in those with diabetes, while additional benefit is less clear with systolic blood pressure less than 120 mm Hg.[796]

Use of a long-acting dihydropyridine calcium channel blocker in the Systolic Hypertension in Europe (Syst-Eur) study resulted in substantial reductions in rates of total mortality (55%), cardiovascular mortality (76%), and cardiovascular events (69%) in the diabetic subgroup, greater benefits than were seen in the subgroup without diabetes. In the Heart Outcomes Prevention Evaluation (HOPE) study, in which almost 40% of patients had diabetes and one other cardiovascular risk factor, ramipril reduced the primary

outcome by 24% and total mortality risk by 25%.[797] Even in normotensive patients with diabetes, some benefit was seen with a drop in blood pressure (2–4 mm Hg) with ACE inhibitor therapy, raising questions about what mechanisms were responsible for the benefit seen with even modest blood pressure changes. Other rigorously designed studies, such as the UKPDS[798] and the Hypertension Optimal Treatment (HOT) study,[799] suggested that tight blood pressure control in patients with diabetes caused cardiovascular benefits of even greater magnitude. In the ADVANCE trial, over 11,000 type 2 diabetes patients received either a fixed-dose combination of perindopril and indapamide or placebo along with usual care.[800] Those on perindopril/indapamide had on average 5.6–mm Hg lower systolic blood pressures and 2.2–mm Hg diastolic blood pressures, with a 9% decrease in the relative risk of a major macrovascular or microvascular event as compared to 16.8% for those on placebo, with a hazard ratio 0.91. The macrovascular and microvascular events responded similarly but not independently, highlighting the pathogenic role of hypertension in both large and small vessel disease.

In the Losartan Intervention For Endpoint Reduction in Hypertension (LIFE) study, patients with diabetes, hypertension, and signs of left ventricular hypertrophy were randomly assigned to treatment with losartan-based (n = 586) or atenolol-based (n = 609) treatment for hypertension.[800a] Despite similar blood pressure reductions, losartan was more effective than atenolol for reducing rates of cardiovascular morbidity and mortality while also demonstrating fewer conversions to new diabetes. The ability of losartan to reduce events more effectively than atenolol may be related to the ability of angiotensin receptor blockers to reverse left ventricular hypertrophy more effectively than beta blockers.

Although beta blockers are thought to worsen glycemic control in patients with diabetes, it is not clear whether this is a property of all members of this drug class or whether this property persists if beta blockers are given in combination with renin-angiotensin system inhibitors that are known to increase insulin sensitivity. In the Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives (GENINI) trial, patients with documented T2DM and hypertension who were taking a stable dose of either an ARB or an ACE inhibitor were randomized to receive either carvedilol, a nonselective beta blocker, which also blocks α_1-adrenergic receptors, or metoprolol, a β_1-selective adrenergic blocker. Although the degree of blood pressure control was similar with both beta blockers, HbA_{1c} and insulin resistance increased significantly with metoprolol but not with carvedilol. Therefore carvedilol appears not to cause the adverse effects that metoprolol does on glucose levels when used in combination with RAS inhibitors, although this conclusion needs to be confirmed in a longer term outcome trial.

The investigators of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) compared outcomes during first-step treatment of hypertension in 31,512 patients with T2DM, impaired fasting glucose (IFG) levels, or normoglycemia with a calcium channel blocker (amlodipine 2.5–10 mg/day) or ACE inhibitor (lisinopril 10–40 mg/day) compared with a thiazide-type diuretic (chlorthalidone 12.5–25 mg/day).[801] There was no significant difference in the occurrence of the primary outcome (fatal cardiovascular disease or nonfatal myocardial infarction) in patients with T2DM treated with a calcium channel blocker or an ACE inhibitor compared with chlorthalidone. Patients with impaired fasting glucose treated with a calcium channel blocker had a significantly higher relative risk for the primary outcome than patients receiving chlorthalidone.

A major unresolved question has been whether treatment of hypertension to lower targets than currently recommended would further reduce cardiovascular risk in patients with type 2 diabetes. Most trials establishing the remarkable benefit of blood pressure lowering, regardless of the medications used, have studied people whose systolic blood pressure was higher than 140 mm Hg. In the ACCORD trial, the effect of lowering systolic blood pressure to two different levels on cardiovascular risk was assessed.[802] One group was randomized to a systolic blood pressure lower than 120 mm Hg (intensive therapy); the other group was treated to a systolic pressure lower than 140 mm Hg (standard therapy). Targeting the lower blood pressure level did not reduce the rate of fatal and nonfatal cardiovascular events. Based on this result, there is no recommendation to treat patients with T2DM and hypertension to a systolic blood pressure lower than the currently recommended target of 130 mm Hg to decrease cardiovascular events. However, further blood pressure reduction may reduce the incidence of diabetic nephropathy.[548,802] In contrast, in the Systolic Blood Pressure Intervention Trial (SPRINT), which did not enroll patients with diabetes, more aggressive blood pressure lowering was beneficial,[803] prompting subsequent discussions about potential discrepancies between SPRINT and these other studies, including differences in hypertension management in the presence or absence of diabetes.[804]

The HOT trial also studied intensive versus standard control in 18,790 participants, including 1501 subjects who had diabetes, with a focus on enrollment and targeted blood pressure based on diastolic measurements. While more intensive blood pressure control did not make a difference in the primary cardiovascular outcome in the study as a whole, the subgroup with diabetes experienced a 51% decrease in events, with optimal cardiovascular risk reduction found in those achieving a diastolic blood pressure of 82.6 mm Hg and systolic blood pressure of 138.5 mm Hg.[799]

Acute Coronary Syndromes in Diabetes Mellitus

The case fatality rate from myocardial infarction is almost twice as high in patients with diabetes as in nondiabetic patients. This excess risk is seen both during the acute phase and in the early and late postinfarction periods. A number of mechanisms have been hypothesized to be responsible for worse outcomes in patients with diabetes, including the following:

- Increased risk of heart failure due to maladaptive remodeling of the left ventricle[805–807]
- Increased risk of sudden death due to sympathovagal imbalance as a consequence of autonomic neuropathy[808–810]
- Increased likelihood of early reinfarction due to impaired fibrinolysis[811–813]
- Extensive underlying atherosclerosis[814,815]
- Changes in myocardial cell metabolism, including a shift from glucose oxidation to FFA oxidation, with less generation of ATP at any level of oxygen consumption[816,817]
- Associated cardiomyopathy[818]

Collective data provide strong evidence that a variety of treatment modalities can improve outcomes from myocardial infarction in patients with diabetes. In terms of interventions, patients with diabetes experiencing an acute infarct respond as favorably to fibrinolytic therapy as do nondiabetic patients.[814,815] Glycemic control is an essential component of overall management. Glucose levels at hospital admission have been independently correlated with early and late fatality after myocardial infarct in patients with and without diabetes mellitus.[820–823]

Studies such as the Diabetes and Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study have assessed the impact of intensive glycemic control in patients with diabetes during the acute phase of myocardial infarction. Patients in this study were randomized to either intensive insulin therapy (insulin-glucose infusion for 24 hours, followed by subcutaneous insulin injection for 3 months) or standard glycemic control.[824] The intensive insulin regimen lowered blood glucose level during the first hour after admission and at discharge compared with conventional therapy. The 1-year mortality rate was reduced with the insulin infusion group compared with the control group, a difference that was maintained after 3.4 years of follow-up.

Although the mechanisms responsible for the potential benefit shown in the original DIGAMI study are not entirely clear, experimental data suggest that strict glycemic control can improve myocardial cell metabolism by increasing the availability of glucose as a substrate for ATP generation and reducing the formation of FFAs, thereby shifting cardiac metabolism from FFA oxidation to glycolysis and glucose oxidation. Intensive glycemic control can also reverse the impaired fibrinolysis that is typically seen in patients with diabetes.

However, DIGAMI 2, a prospective, randomized, open-label trial that followed up the DIGAMI trial, comparing outcomes in patients with either T1DM or T2DM, failed to corroborate the earlier reported improvement in outcomes with intensive insulin treatment.[825] The lack of effect of long-term insulin treatment on outcomes may have been perhaps partially influenced by protocol violations, including the patient group assigned to standard metabolic management, without insulin or glucose infusions, having such interventions, with 14% receiving insulin-glucose infusions and as many as 41% receiving extra insulin injections. As a result, the blood glucose levels in all three groups were not significantly different after treatment.

Results from the CREATE-ECLA (Clinical Trial of Reviparin and Metabolic Modulation in Acute Myocardial Infarction Treatment Evaluation—Estudios Cardiologicos Latin America), a randomized, controlled trial of 20,201 patients who presented with ST-segment elevation myocardial infarction within 12 hours after onset of symptoms, are consistent with DIGAMI 2 findings. Patients were randomized to either high-dose glucose-insulin-potassium (GIK) infusion (i.e., 25% glucose, 50 U/L regular insulin, and 80 mEq KCl) administered over 24 hours or to usual care.[826] Roughly 18% of the patients in both treatment arms had T2DM. After 30 days, there were no differences in the rate of occurrence of mortality, cardiac arrest, cardiogenic shock, or reinfarction in the two treatment groups.

Sulfonylureas have been implicated as increasing cardiovascular mortality rate, particularly in patients undergoing revascularization for acute myocardial infarction.[827] The UKPDS did not show a deleterious effect of these agents on the incidence of sudden death or myocardial infarction[379] or over 10 years of follow-up.[24] The sulfonylureas act through the sulfonylurea receptor component of ATP-sensitive potassium channels in the pancreatic beta cell. In the heart, ATP-sensitive potassium channels are involved in ischemic preconditioning and coronary vasodilation.[828–830] It is not clear whether the sulfonylureas modulate these channels in the heart or vascular system or whether they significantly increase risk in patients with diabetes who are experiencing an acute myocardial infarct.

ACE inhibitors dramatically reduce the mortality rate after a myocardial infarction in patients with diabetes, ostensibly through their effects to reduce infarct size and limit ventricular remodeling. In addition to these hemodynamic benefits, ACE inhibitors can also improve outcomes in diabetes by improving endothelial function,[831] improving fibrinolysis,[832] and decreasing insulin resistance.[833]

In a retrospective analysis of the GISSI-3 (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico) study,[834] lisinopril administration within 24 hours after hospital admission for acute myocardial infarction reduced both 6-week and 6-month mortality rates more in patients with diabetes than in patients without diabetes.

Similarly, in the Trandolapril Cardiac Evaluation Study (TRACE), which investigated trandolapril use in patients with left ventricular dysfunction after prior anterior myocardial infarct, a subgroup analysis of diabetes patients revealed trandolapril treatment greatly improved outcomes, with a 36% decrease in mortality from any cause and a 62% reduction in progression to severe heart failure as compared to placebo in those with diabetes, benefits that were more pronounced than the effects seen in TRACE subjects without diabetes (18% reduction in mortality, no effect on progression to severe CHF).[834a]

Beta blockers are now widely accepted for the treatment of acute coronary syndrome in patients with diabetes. Older, noncardioselective beta blockers might have adversely affected the lipid profile and inhibited the metabolic response to hypoglycemia, but more recent data with cardioselective beta blockers suggest that these agents have less negative effect on metabolic indices, perhaps because they increase peripheral blood flow and improve glucose delivery.[835,836] Clinical trial data confirm that beta blockers reduce the rates of mortality and reinfarction in patients with myocardial infarction in the presence of diabetes. In fact, the magnitude of their effects in patients with diabetes appear to exceed those seen in nondiabetic patients. A large review of data from more than 45,000 patients, 26% of whom had diabetes, showed beta blocker therapy was associated with a lower 1-year mortality rate in patients with diabetes than in those without diabetes, with no evidence of an increase in diabetes-related complications.[837]

Postulated mechanisms for the benefit of beta blockers in patients with diabetes include dampening of the sympathetic nervous system overactivity that arises as a consequence of autonomic neuropathy. Beta blockers can also reduce FFA levels and thereby reduce myocardial oxygen requirements. Carvedilol, although not a cardioselective beta blocker, has unique α_1-adrenergic receptor blocking properties along with purported antioxidant effects. These actions may underlie the decreased insulin resistance and greater blood pressure effects of this agent, which may be of particular benefit in patients with type 2 diabetes.[838]

Aspirin has been a cornerstone of therapy for the primary or secondary prevention of acute coronary syndrome in patients with T1DM and T2DM who do not have contraindications to its use. Aspirin significantly lowers the risk of myocardial infarction without increasing the risk of vitreous or retinal bleeding, even in patients with retinopathy.[839] Use of aspirin therapy (75–162 mg/day) as a secondary prevention strategy in those with diabetes and a history of atherosclerotic cardiovascular is currently recommended by the ADA,[840] with presumed benefits through modulation of the enhanced platelet aggregation seen with both T1DM and T2DM.[841] Despite this, controversy has arisen about the ideal dose of aspirin, if enteric coating might interfere with aspirin's effects,[842] and more recently, if aspirin benefits in primary prevention are offset by the risk of bleeding. The Aspirin in Reducing Events in the Elderly (ASPREE) trial studied aspirin 100 mg versus placebo in 19,114 subjects 70 years of age or older

with no known cardiovascular disease, including about 10% of participants who had diabetes, and found no benefit on cardiovascular outcomes, including the diabetes subgroup, but a significant increase in bleeding.[843] In contrast, in ASCEND, in which 15,480 participants with diabetes received either aspirin 100 mg or placebo for a mean of 7.4 years, the aspirin group had fewer serious vascular events (658 participants [8.5%] vs 743 [9.6%]; RR: 0.88, 95% CI: 0.79–0.97, p = 0.01) than placebo, but at the expense of more major gastrointestinal or other extracranial bleeding (4.1% on aspirin group vs 3.2% on placebo group, RR: 1.29, p = 0.003).[844] Aspirin use in patients with diabetes must be tailored to their particular overall cardiovascular and bleeding risk.

Antiplatelet therapy with the antagonist of the $P2Y_{12}$ subclass of ADP receptor clopidogrel also benefits patients with diabetes. The Clopidogrel Versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) trial compared outcomes in patients with non–ST-segment elevation myocardial infarction treated with aspirin or with clopidogrel and included 3866 patients with diabetes.[845] Although the event rate was higher among the diabetic patients than in the overall study population, the response to treatment was also better. The event rate for the primary endpoint (vascular death, ischemic stroke, myocardial infarction, or rehospitalization for ischemia or bleeding) was 17.7% for diabetic patients treated with aspirin and 15.6% for those randomized to clopidogrel, a significant RR of 12.5%. Newer antiplatelet therapies are also now available, including $P2Y_{12}$ receptor antagonists with greater potency. In the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition With Prasugrel-Thrombolysis In Myocardial Infarction 38 (TRITON-TIMI 38) study, participants with diabetes had a 30% relative risk reduction in the primary endpoint (cardiovascular death, nonfatal myocardial infarct, or nonfatal stroke) without evidence for increases in major bleeding.[846] In the Platelet Inhibition and Patient Outcomes (PLATO) trial, ticagrelor equally reduced the rate of ischemic events in acute coronary syndrome patients both with and without diabetes; in the diabetes subgroup, reductions were seen in the primary composite endpoint (18%), all-cause mortality (18%), and stent thrombosis (35%) with no increase in major bleeding. Patients with diabetes are felt to have an increased risk for complications with percutaneous interventions like stent thrombosis, and may warrant more intensive oral antiplatelet therapy in appropriate patients.

Newer adjunct therapies, such as the platelet glycoprotein IIb/IIIa receptor antagonists that antagonize platelet action, have also been assessed in diabetic patients who present with unstable angina or non–Q-wave infarction. Overall, these agents appear to work equally well, or perhaps slightly better, in patients with diabetes compared with nondiabetic patients. In the Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) study, the addition of tirofiban to heparin therapy reduced the 7-day composite endpoint, compared with heparin alone. This effect was greater in patients with diabetes than in patients without diabetes.[847]

In one study of patients undergoing percutaneous transluminal coronary angioplasty, glycoprotein IIb/IIIa antagonist therapy was associated with fewer acute events but a higher rate of long-term target-vessel revascularization in the diabetic cohort compared with the nondiabetic cohort.[848] However, in another trial, in which stents were used, the rate of target vessel revascularization at 6 months was significantly decreased with the addition of a glycoprotein IIb/IIIa antagonist compared with placebo.[849]

Results of the BARI study showed that coronary artery bypass grafting provides better outcomes than percutaneous transluminal coronary angioplasty in patients with diabetes, possibly because it addresses the extensive coronary vascular disease in these patients.[850] This study did not employ stents or glycoprotein IIb/IIIa inhibitors, two modalities that, when used together, appear to improve outcomes after percutaneous transluminal coronary angioplasty in patients with diabetes.

In terms of revascularization strategies, the Future Revascularization Evaluation in Patients With Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) trial had a major impact on management decisions. This trial was an appropriately powered, randomized comparison of percutaneous coronary interventions (with drug-eluting stents) and coronary artery bypass graft (using arterial grafting) in patients with diabetes and multivessel coronary artery disease on concomitant optimal medical therapy. It provided strong evidence that that coronary bypass resulted in fewer major cardiovascular events, and reduced 5-year mortality compared to percutaneous coronary interventions.[851] Continued progress in stent technology and adjunctive therapies, as noted, continues to make this a challenging decision. Patients with diabetes with less extensive coronary disease for whom invasive intervention is warranted can certainly be managed with percutaneous interventions.

Cardiomyopathy in Patients With Diabetes Mellitus

Diabetes is associated with a fourfold increase in the risk of congestive heart failure, even after adjustment for other cardiovascular risk factors such as age, blood pressure, cholesterol level, obesity, and history of coronary heart disease.[852] Contributing factors include diabetes-induced cardiomyocyte dysfunction, impaired microvascular perfusion because of defective endothelial function, increased collagen deposition with fibrosis, and maladaptive remodeling after myocardial infarction, leading to both diastolic and systolic heart failure (also discussed in "Biochemistry and Molecular Cell Biology"). Current nomenclature[853] organizes heart failure into two broad categories: with preserved ejection fraction (HFpEF) and with reduction ejection fraction (HFrEF).[854] Patients with diabetes, who commonly present with either form, also experience higher rates of heart failure than do nondiabetic patients after an acute myocardial infarction, regardless of the size of the infarct zone.[806,855] These findings suggest that diabetes itself causes deleterious effects on the myocardium, leading to poorer outcomes.

A number of key structural, functional, and metabolic factors in diabetes have been implicated in the increased risk of maladaptive remodeling that leads to heart failure. For example, evidence of silent myocardial infarction is found in up to 40% of patients with diabetes who present with a clinically apparent infarct and can lead to unrecognized regional and global ventricular dysfunction.[834,856] As many as 50% of patients with diabetes and coronary heart disease have cardiac autonomic neuropathy, which is known to contribute to both systolic and diastolic dysfunction.[857] Like hypertension, diabetes can cause fibrosis of the myocardium and increased collagen deposition.[858,859] These effects are even more pronounced in patients with coexisting hypertension and diabetes and may contribute to the finding of diastolic dysfunction common in patients with diabetes.[860] Enhanced myocardial endothelial dysfunction in diabetes has also been described as a pathophysiologic pathway to impaired microvascular perfusion and ischemia.[861,862]

On a cellular level, both hyperglycemia and insulin resistance have direct negative effects on myocardial metabolism. Depression

of myocardial GLUT4 levels in the setting of diabetes inhibits glucose entry and glycolysis in the heart. As a result, intracellular metabolism shifts from glycolysis to FFA oxidation, thereby reducing glycolytic ATP generation, a major source of energy under anaerobic (i.e., ischemic) conditions.[816] The production of oxygen free radicals can also be enhanced in this situation, further depressing myocardial contractile function.[862] Mitochondrial dysfunction is a feature of ischemia-reperfusion injury, leading to generation of reactive oxygen species. In experimental models of ischemia-reperfusion, mitochondrial reactive oxygen species generation is mediated by reversal of succinate dehydrogenase, leading to succinate accumulation. On reperfusion, restoration of succinate dehydrogenase activity leads to rapid succinate oxidation, causing reactive oxygen species generation by reverse electron transport at mitochondrial complex I.[863] Increased myocardial production of succinate is a feature of acute ST-segment–elevation myocardial infarction in humans.[864]

A major advance in the heart failure field in general was the finding in PARADIGM-HF that the combination of an angiotensin receptor blocker (valsartan) and a neprilysin inhibitor (sacubitril) proved superior to the ACE inhibitor enalapril in patients with reduced ejection fraction (≤40%), significantly reducing cardiovascular death or hospitalization for heart failure, and doing so against a medicine previously shown to have a mortality benefit.[865] Progression of heart failure and renal dysfunction were also decreased. Of note, among the nearly 45% of patients in this study who had diabetes, there was evidence of greater decreases in HbA_{1c} and less progression to insulin use, raising intriguing mechanistic questions, while also potentially supporting the use of sacubitril/valsartan in patients with diabetes and reduced ejection fractions.[592]

Knowledge about the pathophysiology underlying increased coronary artery disease in people with prediabetes and type 2 diabetes has increased enormously in recent years. That knowledge has directed seminal clinical studies, which in turn have enlarged our understanding of pathophysiology. These seminal studies provide the rationale for an optimized multifactorial approach to the prevention and treatment of diabetic cardiovascular disease, including choice of drugs to manage hyperglycemia, dyslipidemia, and hypertension, and postinfarction sequelae. Data from ongoing clinical trials and new pharmaceutical developments will further improve the cardiovascular prognosis for people with diabetes.

The Diabetic Foot

Foot complications of ulceration and amputation are associated with high mortality, yet diabetic foot ulcers are the most preventable late adverse outcome of diabetes.[866–869] Elliott Joslin correctly noted in 1934 "diabetic gangrene is not heaven-sent, but earth-born." The neuropathic foot does not spontaneously ulcerate; insensitivity, deformity, and unperceived trauma (e.g., inappropriate footwear) promote skin breakdown. Most amputations are preceded by foot ulcers. Increased appreciation of the complex pathogenesis of foot ulcers permits design of screening programs for risk identification, preventive education, and design of multidisciplinary foot care programs. Much progress has been made, but suboptimal adherence to current professional guidelines has prevented translation of this into a universal decline in amputation rates.

Epidemiology of Diabetic Foot Ulceration

Foot ulceration is common and occurs in both T1DM and T2DM. The annual incidence of foot ulceration is about 2% to 2.5% in Western countries: Higher incident rates are found in select diabetic populations, including US Medicare recipients (6%), US veterans (5%), and the global diabetes population (6.3%).[870] Approximately 5% to 10% of diabetic patients have had past or present foot ulceration, and 1% have undergone amputation.[866] Although between 1990 and 2010, a significant reduction in certain diabetes-related complications was reported from the United States,[8] unfortunately there was no reduction in rates of amputations reported in this time frame. A large community-based study in the United Kingdom showed an annual incidence of ulceration of approximately 2%; this rose to 7% with known diabetic neuropathy and to as high as 50% with a past history of ulceration.[871] The lifetime risk for development of a foot ulcer in a diabetic patient is estimated to be as high as 25%.[868,872] Multiple factors likely contribute to different rates of foot ulceration, including diabetes duration, smoking, and other neurologic and cardiovascular risk factors. Foot ulceration is most common in patients with a history of similar problems. In experienced diabetic foot clinics, more than 50% of patients with new foot ulcers give a past ulcer history. Patients with other complications of diabetes, including retinopathy and renal dysfunction, are at increased risk for foot ulceration. Patients on dialysis are among those at the very highest risk for ulceration.[872a]

More than 80% of amputations are preceded by foot ulcers. Diabetes is the most frequent cause of nontraumatic lower limb amputation in the United States, and rates are 15 times greater than those in the nondiabetic population. Reduced amputation rates occur following implementation of foot screening and education programs.[873,874] Implementation of strategies to reduce ulceration and amputation are necessary and may benefit from additional education on behavioral aspects of diabetic foot care, including awareness of ulceration risk, compliance with daily foot inspection, and the importance of nonweightbearing with early foot infections.[875] Treatments to reduce cardiovascular and renal risk likely further reduce amputation rates, but this has been less clearly established.

Pathogenesis of Foot Ulceration

Foot ulceration results from multiple interacting component causes, none of which alone is sufficient to cause ulceration but when combined may lead to skin breakdown. A combination of two or more risk factors promotes diabetic foot ulceration, and the triad of component causes—neuropathy, deformity, and trauma—is present in 63% of incident ulcers. Edema and ischemia are also common component causes. These risk factors were demonstrated in a North American/United Kingdom collaborative study of more than 150 consecutive foot ulcer cases.[876]

Diabetic Neuropathy and the Foot Ulcer

All three components of neuropathy—sensory, motor, and autonomic—can contribute to foot ulceration. The risk of foot ulceration in patients with neuropathy is sevenfold higher than in those without this complication of diabetes.[871] Chronic sensorimotor neuropathy is common, affecting at least one-third of older diabetic patients in Western countries. Its onset is gradual and insidious, and symptoms may be so minimal that they go unnoticed. Although uncomfortable, painful, and paresthetic symptoms predominate in most patients, some never experience symptoms. Clinical examination usually reveals a sensory deficit

in a glove-and-stocking distribution, with signs of motor dysfunction such as small muscle wasting in the feet, and absent ankle reflexes. Although a history of typical symptoms strongly suggests a diagnosis of neuropathy, absence of symptoms does not exclude the diagnosis and must never be equated with a lack of foot ulcer risk. Therefore assessment of foot ulcer risk must always include a careful foot examination, including assessment of proprioception (i.e., pressure perception using a 10-g monofilament) regardless of history. Loss of sensation and proprioception reduce capillary perfusion and increase ischemia at sites of increased pressure load.

Sympathetic autonomic neuropathy affecting the lower limbs results in reduced sweating, dry skin, and development of cracks and fissures. In the absence of large-vessel arterial disease, there may be increased blood flow to the foot, with arteriovenous shunting leading to the warm but at-risk foot.

Callus, Deformity, and High Foot Pressures

Motor neuropathy, with imbalance of the flexor and extensor muscles in the foot, commonly results in foot deformity, with prominent metatarsal heads and clawing of the toes (Fig. 37.50). The combination of proprioceptive loss due to sensory neuropathy and the prominence of metatarsal heads lead to increased pressures and loads under the diabetic foot. Neuropathy is only one cause of high foot pressures. High pressures, together with dry skin, often result in the formation of callus under weightbearing areas of the metatarsal heads. Presence of plantar callus is a highly significant marker for foot ulcer risk. Conversely, removal of plantar callus is associated with reduced foot pressures and thereby a reduced foot ulcer risk.[877]

Peripheral Vascular Disease, Diabetic Foot Ulcers, and Amputation Risk

Peripheral vascular disease in isolation rarely causes ulceration. However, the common combination of vascular disease with minor trauma can lead to ulceration. Minor injury and subsequent infection increase the demand for blood supply beyond the circulatory capacity, and ischemic ulceration and risk of amputation develop. Early identification of patients at risk for peripheral vascular disease is essential, and appropriate investigation involving noninvasive Doppler studies, together with arteriography, often leads to revascularization procedures to improve lower extremity blood flow. Presence or absence of a dorsalis pedis or posterior tibial pulse may be the simplest and most reliable indicator of significant ischemia that can be elicited at the bedside.[878] However, Doppler-derived ankle pressure can be misleadingly high in patients with long-standing diabetes, so the use of the toe-brachial index together with Doppler waveforms of distal arteries can be useful in deciding which patients need further diagnostic intervention.[879]

Distal bypass surgery or endovascular interventions have good short-term but mixed long-term results in terms of limb salvage.[878,880] Advances in techniques and devices for both distal arterial bypass surgery and endovascular interventions have been made, and it is unclear which approach is preferred. A recent systematic review was unable to conclude any particular method was superior to any other.[881] However, a recent study in all patients with diabetic foot ulcers demonstrates that prompt vascular evaluation and revascularization within 2 weeks reduces the rate of amputations to the rate of nondiabetics with peripheral artery disease, supporting a change in clinical disease management.[882]

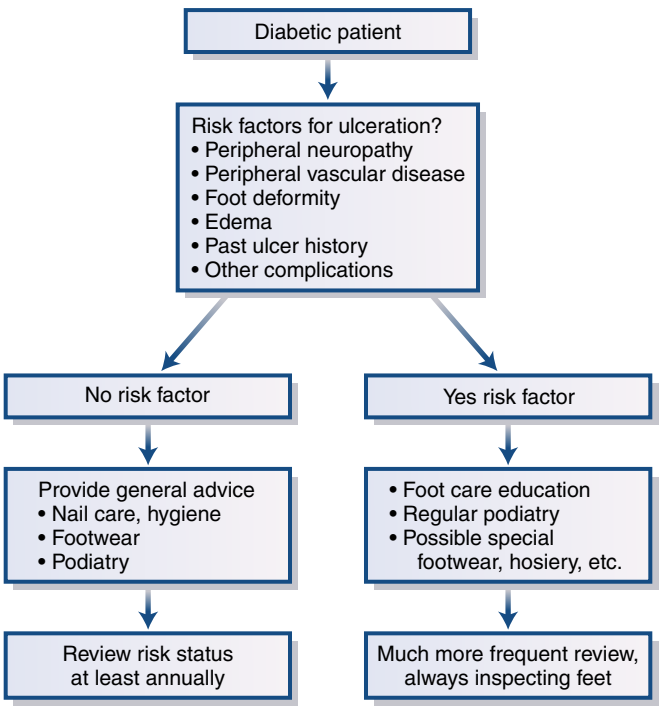
• **Fig. 37.50** The high-risk neuropathic foot. (A, B) Two lateral views of a patient with typical signs of a high-risk neuropathic foot. Notice the small-muscle wasting, clawing of the toes, and marked prominence of the metatarsal heads. At presentation with type 2 diabetes mellitus, this patient had severe neuropathy with foot ulceration on both the right foot *(shown here)* and the left foot. (From Andersson DK, Svärdsudd K. Long-term glycemic control relates to mortality in type II diabetes. *Diabetes Care.* 1995;18:1534–1543.)

Prevention of Foot Ulceration and Amputation

Relatively simple interventions can reduce amputations by up to 80%.[873,874] Therefore strategies for early identification of patients at potential risk for ulceration are required, and education programs that can be adapted for widespread application need to be developed. Because foot ulcers precede most amputations, are among the most common causes of hospital admission for patients with diabetes, and account for much morbidity and even fatality, the widespread application of preventive foot care strategies is urgently required.

Patients with any type of diabetes require regular foot examination for evidence of risk factors for ulceration, irrespective of disease duration. Neuropathy, vascular disease, and even foot ulceration may be the presenting feature of T2DM, so there can be no exception to the rule of screening (Fig. 37.51). At a minimum, such screening should be carried out annually. Of all the long-term complications of diabetes, foot problems and their risk factors are probably the easiest to detect. No expensive equipment is required, and feet can be examined for evidence of neuropathic and vascular deficits in the office setting using simple equipment.[871]

In 2008, a task force of the ADA published a report on the examination components that should be included in the annual Comprehensive Diabetic Foot Examination (CDFE) (Table 37.21).[884] The most important message is for practitioners to have patients remove shoes and socks to examine feet for the presence of callus, deformity, muscle wasting, and dry skin, all of which are clearly visible on inspection. A simple neurologic examination includes assessment of pressure perception using a 10-g monofilament. Sensory neuropathy with clinical evidence of peripheral arterial disease are the strongest predictors of future foot ulceration. Absence of the ability to perceive pressure from a 10-g monofilament, inability to perceive a vibrating 128-Hz tuning fork over the hallux, and absent ankle reflexes all have been shown to be predictors of foot ulceration.[868,869]



• **Fig. 37.51** Simple algorithm for risk screening in the diabetic foot.

The Diabetic Foot Care Team

Patients identified as being at high risk for foot ulceration should be managed by a team of specialists with expertise in the diabetic foot. The podiatrist usually takes responsibility for care of the skin and nails and, together with the specialist nurse or diabetes educator, provides foot care education. The orthotist, or shoe fitter, is invaluable to advise about and sometimes design footwear to protect high-risk feet. Team members should work closely with the diabetologist and the vascular and orthopedic surgeons. Patients with risk factors for ulceration require preventive foot care education, including self-foot care at home, frequent review by a foot surgeon or podiatrist, good foot wear with orthotics when indicated, and avoidance of potentially dangerous over-the-counter foot products.[874,877]

Classification of Foot Ulcers

Many different classification systems for grading diabetic foot ulcers have been reported.[868,877] One developed by Wagner[885] (Table 37.22) is widely used and accepted. More recently, the University of Texas (UT) group developed an alternative classification system that, in addition to ulcer depth (as in the Wagner system), accounts for presence or absence of infection and ischemia (Table 37.23). A prospective study from 2001 compared these two wound classification systems and concluded that the UT scheme is a better predictor of outcome than the older Wagner system.[885]

Management of Diabetic Foot Ulcers

Basic principles of wound healing apply equally to diabetic foot ulcers as to wounds in any other site or condition. In general, a

TABLE 37.21 Key Components of the Comprehensive Diabetic Foot Examination

Dermatologic

Skin status: color, thickness, dryness, cracking
Sweating
Infection: check between toes for fungal infection
Ulceration
Calluses/blistering: hemorrhage into callus?

Musculoskeletal

Deformity (e.g., claw toes, prominent metatarsal heads, Charcot joint)
Muscle wasting (guttering between metatarsals)
Assess whether shoes are appropriate for the feet (e.g., size, width)

Neurologic

Ability to perceive pressure from a 10-g monofilament plus one of the following:
- Vibration using 128-Hz tuning fork
- Pinprick sensation
- Ankle reflexes
- Vibratory perception threshold

Vascular

Foot pulses
Ankle-brachial index, if indicated

Adapted from Boulton AJ, Armstrong DG, Albert SF, et al. Comprehensive foot examination and risk assessment: a report of the Task Force of the Foot Care Interest Group of the American Diabetes Association, with endorsement by the American Association of Clinical Endocrinologists. *Diabetes Care.* 2008;31:1679–1685.

diabetic foot ulcer has high likelihood of healing if the following three conditions are satisfied:

- Arterial inflow is adequate.
- Infection is treated appropriately.
- Pressure is removed from the wound and the immediate surrounding area.

Although this approach appears simplistic, failure of diabetic foot ulcers to heal is usually a result of failure to pay sufficient attention to one or more contributing conditions, including pressure on the wound, infection, ischemia, and inadequate debridement.

The most common cause of nonhealing neuropathic foot ulcers is failure to remove pressure from the wound and immediate surrounding area. Patients who are advised not to put pressure over an ulcer find it especially difficult to adhere to such advice when peripheral sensation is lost or reduced. Pain results in protection of an injured area; the lack of pain permits pressure to be put directly onto the ulcer and results in nonhealing. A patient with normal sensation and a foot wound will limp to avoid putting pressure on the wound because doing so is painful. A patient who walks on a plantar wound without limping must have neuropathy.

The effect of pressure relief on the histopathologic features of neuropathic ulcers was assessed in a randomized study[886] with biopsy either at presentation or after 20 days of off-loading in a total-contact cast (TCC). Histologic features of chronic inflammation, with mononuclear infiltration, cellular debris, and scarce evidence of angiogenesis or granulation, were seen in patients who underwent biopsy at presentation; whereas granulation, neoangiogenesis, and a predominance of fibroblasts were seen in patients treated with TCC before biopsy. These important observations support that repetitive pressure on a neuropathic wound contributes to the chronicity of the wound, whereas pressure relief results in a reparative phase.

The next most common error is inappropriate management of infection. Topical applications are usually unhelpful, and if clinical infection is present, then it must be treated urgently with antibiotics. Most infections are polymicrobial, with gram-positive cocci, gram-negative rods, and anaerobes, with or without multidrug-resistant organisms (see later discussion).

Another common management error is failure to appreciate ischemic symptoms that are atypical due to altered pain sensation as a result of neuropathy. The most difficult ulcer to heal is the neuroischemic ulcer. Symptoms and even signs of ischemia may be altered in the diabetic state. Therefore appropriate noninvasive investigation and arteriography are indicated for patients with a nonhealing diabetic foot ulcer if there is any question about the vascular status.

Inappropriate wound debridement contributes to slow healing or nonhealing of a diabetic foot ulcer. Appropriate debridement and removal of all callus, dead, and macerated tissue is essential local treatment of a diabetic foot ulcer, which results in more rapid healing compared with inadequately debrided wounds.

The principles of management of neuropathic and neuroischemic foot ulcers are considered in the following sections referencing both the UT and the Wagner grading systems.

Neuropathic Foot Ulcer Without Osteomyelitis (Wagner Grades 1, 2; University of Texas Grades 1a, 1b, 2a, 2b)

Provision of adequate pressure relief is the most important feature in the management of neuropathic foot ulcers that occur under weightbearing areas such as the metatarsal heads and great toe. This is usually achieved by a TCC or a removable Scotch cast boot.[868,877]

The TCC has long been recognized as the gold standard for off-loading a foot wound. The TCC was associated with the shortest healing time in a randomized, controlled trial conducted by Anderson and colleagues comparing three off-loading techniques demonstrated.[887] When any cast device is used, regular removal of the cast is essential, because regular debridement of the wound by a specialist is essential, and any casting device could injure insensitive skin, especially over bony prominences. As the TCC requires a specially trained casting technician to apply it, and frequent removal is required for wound assessment, recent research has focused on alternative reusable devices that can only be removed in the specialist's office.

The removable cast walker (RCW) resulted in slower healing than the TCC, in the aforementioned trial by Armstrong

TABLE 37.22 Wagner Diabetic Foot Ulcer Classification System

Grade	Description
0	No ulcer, but high-risk foot (e.g., deformity, callus, insensitivity)
1	Superficial full-thickness ulcer
2	Deeper ulcer, penetrating tendons, no bone involvement
3	Deeper ulcer with bone involvement, osteitis
4	Partial gangrene (e.g., toes, forefoot)
5	Gangrene of whole foot

Modified from Oyibo S, Jude EB, Tarawneh I, et al. A comparison of two diabetic foot ulcer classification systems: the Wagner and the University of Texas wound classification systems. *Diabetes Care.* 2001;24:84–88.

TABLE 37.23 University of Texas Wound Classification System

Stage	Grade 0	Grade 1	Grade 2	Grade 3
A	Preulcer or postulcer lesion; no skin break	Superficial ulcer	Deep ulcer to tendon or capsule	Wound penetrating bone or joint
B	+ Infection	+ Infection	+ Infection	+ Infection
C	+ Ischemia	+ Ischemia	+ Ischemia	+ Ischemia
D	+ Infection and ischemia	+ Infection and ischemia	+ Infection and ischemia	+ Infection and ischemia

Modified from Armstrong DG, Lavery LA, Harkless LB. Validation of a diabetic wound classification system. The contribution of depth, infection, and ischemia to risk of amputation *Diabetes Care.* 1998;12:855–859.

et al,[887] even though prior gait laboratory studies suggested they are equally efficacious at off-loading. The reason for this disparity may be explained by the observation that although patients were instructed to wear the RCW at all times, patients used these devices for only 28% of all footsteps during a 24-hour period. To overcome this limitation the RCW, which can be applied by any clinic personnel and does not require specialist training, can be rendered irremovable by wrapping it in casting material. A controlled trial showed the irremovable RCW was as effective at healing neuropathic foot wounds as the TCC.[888]

Theoretically, complete healing of all superficial and neuropathic ulcers should be possible without the need for amputation. In the treatment of neuropathic ulcers with a good peripheral circulation, antibiotics are not indicated unless there are clear clinical signs of infection, including prominent discharge, local erythema, and cellulitis. The presence of any infective features in Wagner grade 1 or 2 ulcers would warrant reclassification in the UT system from 1a or 2a to 1b or 2b. In such cases, deep wound specimens should be taken and broad-spectrum oral antibiotic treatment should be started with, for example, either an amoxicillin–clavulanic acid combination (Augmentin) or clindamycin. The antibiotic may need to be altered after sensitivity results become available.[889]

Neuroischemic Ulcers (Wagner Grades 1, 2; University of Texas Grades 1c, 1d)

The principles of management of neuroischemic Wagner grade 1 and 2 ulcers are similar to those for neuropathic ulcers, with the following important differences. TCCs are not usually recommended for management of neuroischemic ulcers, although removable casts and pneumatic cast boots (Aircast) may be used in cases without infection. Antibiotic therapy is required for most neuroischemic ulcers. Investigation of the circulation is indicated, including noninvasive assessment and, if required, arteriography with appropriate subsequent surgical management or angioplasty.[878]

Osteomyelitis (Wagner Grade 3; University of Texas Grades 3b, 3d)

Wagner or UT grade 3 ulcers are deeper and involve underlying bone, often with abscess formation. Osteomyelitis is a serious complication of foot ulceration and may be present in as many as 50% of diabetic patients with moderate to severe foot infections.[868] If the physician can probe down to bone in a deep ulcer, the presence of osteomyelitis is strongly suggested. Plain radiographs are indicated for any nonhealing foot ulcer and are useful in the diagnosis of osteomyelitis in more than two-thirds of patients, although radiologic changes may be delayed. In difficult cases, further investigation, such as magnetic resonance imaging (MRI), bone scans, or an indium-111 (^{111}In)–labeled white blood cell scan can be useful in diagnosing bone infection.[890]

Although osteomyelitis treatment is traditionally surgical and involves resection of the infected bone, successful long-term treatment can occasionally be effective with antibiotics. *Staphylococcus aureus* is the most common infective bacteria. Therefore agents such as clindamycin (which penetrates bone well) or flucloxacillin are often used. Antibiotic therapy for 90 days was equally efficacious when compared to local surgery for diabetic foot osteomyelitis in a recent randomized trial.[891]

Gangrene (Wagner Grades 4, 5)

The presence of gangrene is always a serious sign in the diabetic foot. However, localized areas of gangrene, especially in the toes, that are without cellulitis, spreading infection, or discharge can occasionally be left to spontaneously auto-amputate. The presence of more extensive gangrene requires urgent hospital admission; treatment of infection, often with multiple antibiotics; glycemic control, usually with intravenous insulin; and detailed vascular assessment. It is in this situation that the team approach is most important, with close collaboration among the diabetes specialist, the vascular surgeon, and the radiologist.

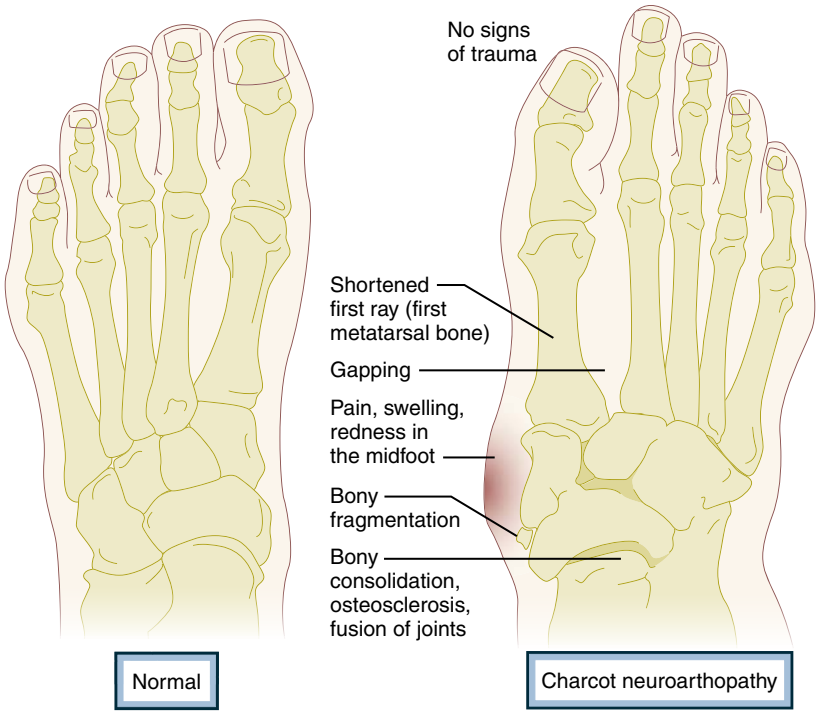
Charcot Neuroarthropathy

Charcot neuroarthropathy is a disabling condition affecting the joints and bones of the foot in the general diabetic population. It is much more frequent (10–13%) in high-risk diabetic patients. Permissive features for development of this condition include the presence of severe peripheral neuropathy and autonomic dysfunction with increased blood flow to the foot. The peripheral circulation is usually intact. In the Western world, diabetes is the most common cause of a Charcot foot, and increased awareness of this condition can enable earlier diagnosis and treatment to prevent severe deformity and disability.

The pathogenesis of the Charcot process remains poorly understood; however, the patient with peripheral insensitivity and autonomic dysfunction, with increased blood flow reflecting the autonomic dysfunction, to the foot is vulnerable to trauma, which the patient may not recall. Repetitive trauma results in increased blood flow through the bone, increased osteoclastic activity, and bone remodeling. In some cases, patients walk on a fracture, which leads to continuing bone and joint destruction in that area. Recent evidence suggests acute Charcot neuropathy may be triggered in the susceptible (i.e., neuropathic) individual by any event that leads to localized inflammation in the affected foot, triggering a vicious cycle in which there is increasing inflammation, increasing expression of receptor activator of nuclear factor-κB ligand (RANKL), a member of the tumor necrosis factor superfamily, and increasing bone breakdown.[892] Targeting activation of the RANKL/osteoprotegerin pathway might lead to novel, future treatments.

Charcot neuropathy can be difficult to distinguish from osteomyelitis or an inflammatory arthropathy.[890] A unilateral swollen, hot foot without an ulcer in a patient with neuropathy must be considered to be a Charcot foot until proved otherwise. Charcot arthropathy can be diagnosed in most patients by plain radiography and a high index of suspicion (Fig. 37.52). Radiographs reveal bone and joint destruction, fragmentation, and remodeling, although radiographic findings may be normal early in disease. In such cases, three-phase bisphosphonate bone scans show increased bone uptake, while ^{111}In-labeled bone scans will be negative in the absence of infection. In patients where osteomyelitis is suspected, ^{18}F-fluorodeoxyglucose–positron emission tomography–computed tomography (FDG-PET-CT) has the highest sensitivity for distinguishing Charcot arthropathy from osteomyelitis.

After diagnosis, management of the acute phase involves immobilization, usually in a TCC.[893] There is little evidence to support use of any pharmacologic treatment in the management of this condition. Although Charcot neuroarthropathy is rare, it should be suspected in any patient with unexplained swelling and heat in a neuropathic foot. Early intervention with immobilization may halt progression that, in the untreated state, can lead to marked foot deformity and require local or major amputations.



• **Fig. 37.52** Some of the key features of Charcot neuroarthropathy, an often overlooked complication of diabetes. (Redrawn from Botek G, Anderson MA, Taylor R. Charcot neuroarthropathy: an often overlooked complication of diabetes. *Cleve Clin J Med.* 2010;77:593–599.)

Adjunct Treatments for Foot Ulcers

Tissue-Engineered Skin and Platelet-Derived Growth Factors

Genetically derived growth factors and novel bioengineered skin substitutes have been developed as adjunctive treatments for diabetic foot ulcers, including Apligraf, a bilayered living human skin equivalent; Dermagraft, a human fibroblast-derived dermal substitute; and human platelet-derived growth factors. Although there are some benefits for each of these agents, they are costly[894] and should be reserved for ulcers that fail to respond to standard treatments. Any newer treatments should be considered an addition to good wound care, which must always include adequate off-loading and regular debridement. There is little objective evidence to date in support of routine use of these therapies, as well as others under study, including stem cell therapy and hyperbaric oxygen.[895]

Negative-Pressure Wound Therapy (NPWT)

NPWT, also known as vacuum-assisted closure, is increasingly used to treat large and complex diabetic foot wounds. The treatment may stimulate development of granulation tissue in previously nonhealing wounds and can also be helpful in the postoperative management of diabetic foot wounds, as supported by randomized, controlled trials in complex nonhealing diabetic foot ulcers[896] and postoperative cases.[895] Use of NPWT remains controversial, as discussed in a systematic review. The strongest evidence for efficacy is with postoperative diabetic foot wounds.[895]

Achilles Tendon Lengthening Procedures

Although some centers advocate and perform tendo-Achilles lengthening as an adjunct treatment to prevent recurrent diabetic foot ulcers posthealing, there are no adequate data supporting use of this procedure in the diabetic foot. Given the high risk of any foot surgery in the diabetic foot, the nonsurgical approach of prescribing footwear designed to reduce pressure on the metatarsal heads is preferable unless and until adequately powered prospective randomized clinical trials of Achilles tendon lengthening procedures demonstrate superior outcomes.

SGLT2 Inhibitors and Diabetic Foot Disease

An increased incidence of distal lower extremity amputations, mainly at the toe and metatarsal levels, was observed in the CANVAS trial[473] designed to evaluate the cardiovascular safety of canagliflozin. Numerous potential mechanisms have been suggested, but the cause of this finding remains enigmatic. However, a recent pharmacovigilance analysis confirmed that use of canagliflozin, but not dapagliflozin or empagliflozin, might be associated with an increased risk of amputations. The use of canagliflozin should probably be avoided in patients with distal neuropathy or peripheral arterial disease or with a history of foot disease. Although this does not appear to be a class effect,[897] use of other SGLT2 inhibitors should be used with caution in the abovementioned groups.

Hypoglycemia

PHILIP E. CRYER AND ANA MARIA ARBELÁEZ

CHAPTER OUTLINE

KEY POINTS

- Hypoglycemia—a plasma glucose concentration low enough to cause symptoms or signs—is a rare occurrence in individuals without diabetes but is common in sulfonylurea-, glinide-, or insulin-treated diabetes.
- The plasma glucose concentration is normally maintained in a relatively narrow range, 72 to 144 mg/dL (4.0–8.0 mmol/L), owing to a fine balance between glucose influx (exogenous glucose delivery and endogenous glucose production) and glucose efflux (glucose utilization by insulin-sensitive tissues, such as the skeletal muscle, and insulin-insensitive tissues, particularly the brain).
- Hypoglycemia results from an imbalance between glucose influx and glucose efflux due to either excessive glucose removal from the circulation, deficient glucose delivery into the circulation, or both.
- Hypoglycemia in diabetes is typically the result of the interplay of therapeutic hyperinsulinemia and compromised defenses against falling glucose levels resulting in hypoglycemia-associated autonomic failure (HAAF), including defective glucose counterregulation and impaired awareness of hypoglycemia.
- An attenuated sympathoadrenal response to falling glucose levels, the key feature of HAAF, is induced by recent antecedent hypoglycemia, sleep, or prior exercise, and reversible by short-term scrupulous avoidance of hypoglycemia.
- Iatrogenic hypoglycemia is associated with both morbidity and fatality in type 1 and type 2 diabetes mellitus.
- The practice of hypoglycemic risk reduction in persons with diabetes at risk of hypoglycemia includes addressing the issue, applying the principles of aggressive glycemic therapy, and considering the conventional risk factors and those indicative of HAAF.
- In the absence of diabetes, hypoglycemia in ill or medicated individuals can be caused by many drugs, critical illnesses, endocrine deficiencies, or non–islet cell tumors; in seemingly well individuals, it may be caused by endogenous hyperinsulinism or by various accidental, surreptitious, or malicious mechanisms. In children, it may also be the result of abnormalities in enzyme deficiencies that are key for the metabolism of fuel substrates that will contribute to abnormalities in glucose production and utilization.
- The decision to evaluate a given nondiabetic person systematically—seeking evidence of a metabolic disorder or an endogenous insulin excess during hypoglycemia—is recommended only for persons in whom Whipple triad (symptoms, signs, or both consistent with hypoglycemia; a low reliably measured plasma glucose; and resolution of those symptoms or signs after the glucose concentrations is raised) can be documented.
- Short-term treatment of hypoglycemia includes oral carbohydrates, or parenteral glucagon or glucose; long-term treatment requires correction of the hypoglycemic mechanism.

Iatrogenic hypoglycemia is the limiting factor in glycemic management of diabetes mellitus with insulin provisional therapies: insulin, a sulfonylurea, or a glinide.[1] Hypoglycemia is a distinctly uncommon clinical disorder in persons without diabetes.[2]

Glucose is an obligate metabolic fuel for the brain under physiologic conditions.[3] Because the brain cannot synthesize glucose, store more than a few minutes supply as glycogen, or utilize physiologic concentrations of other circulating fuels effectively, survival of the brain, and therefore the individual, requires a virtually continuous supply of glucose from the circulation. Blood-to-brain glucose transport is a direct function of the arterial plasma glucose concentration and requires the plasma glucose concentration be maintained within, or above, the physiologic range. Hypoglycemia causes functional brain failure, which is typically corrected after the plasma glucose concentration is raised (Table 38.1). Rarely, it causes a fatal cardiac arrhythmia or, if it is profound and prolonged, brain damage and death.

TABLE 38.1 Whipple Triad

Whipple triad is:
symptoms, signs, or both consistent with hypoglycemia, a low reliably measured plasma glucose concentration, and resolution of those symptoms or signs after the plasma glucose concentration is raised.[a]

Clinically, neuroglycopenic symptoms are more compelling than neurogenic symptoms.

The definition of "low" is judgmental, but a plasma glucose concentration of less than 55 mg/dL (3.0 mmol/L) is unequivocally low.

Documentation of Whipple triad is particularly important for the diagnosis of hypoglycemia in patients who do not have insulin-, sulfonylurea-, or glinide-treated diabetes because hypoglycemic disorders are uncommon in such individuals.

[a]Modified from Whipple AO. The surgical therapy of hyperinsulinism. *J Int Chir* 1938; 3:237–276.

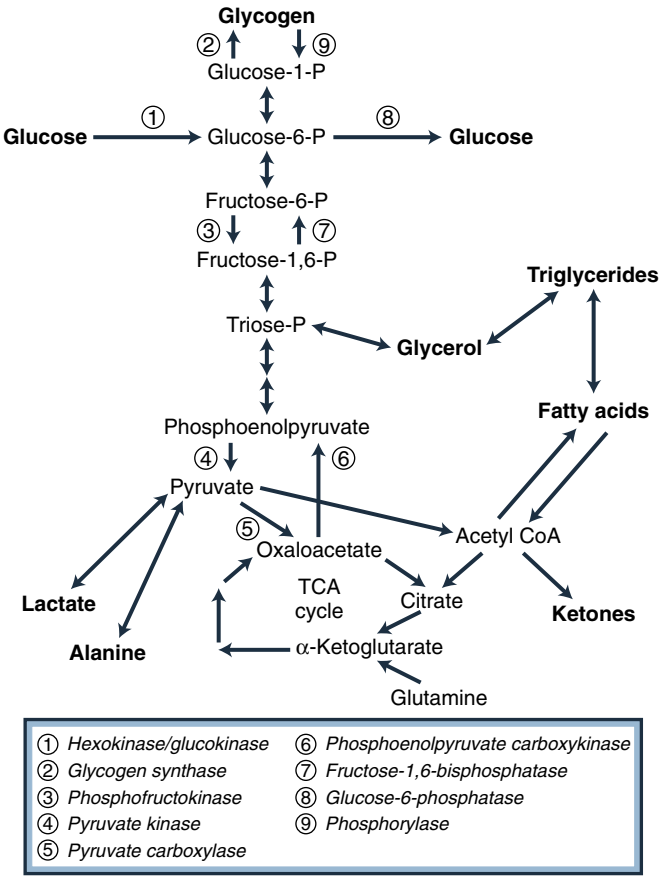
Given the survival requirement to maintain the plasma glucose concentration, it is not surprising that physiologic and behavioral mechanisms that prevent or rapidly correct hypoglycemia have evolved.[3] These mechanisms are so effective that hypoglycemia is an uncommon clinical event, except in persons who use drugs that lower the plasma glucose concentration, such as insulin, sulfonylureas, or alcohol.

Glucoregulatory failure resulting in hyperglycemia (diabetes mellitus) is discussed in Chapters 33 through 37; that resulting in hypoglycemia is discussed in the paragraphs that follow.

Physiology of Defense Against Hypoglycemia

Glucose Metabolism

Glucose is derived from three sources: intestinal absorption following digestion of dietary carbohydrates; *glycogenolysis*, which is the breakdown of glycogen, the polymerized storage form of glucose; and *gluconeogenesis*, which is the formation of glucose from precursors including lactate (and pyruvate), amino acids (especially alanine and glutamine), and, to a lesser extent, glycerol. There are multiple fates of glucose transported into cells (external losses are normally negligible) (Fig. 38.1). Glucose may be stored as glycogen, or may undergo glycolysis to pyruvate, which can be reduced to lactate, transaminated to form alanine, or converted to acetyl coenzyme A (CoA). Acetyl CoA, in turn, may be oxidized to carbon dioxide and water through the tricarboxylic acid cycle, converted to fatty acids that can be incorporated into triglycerides, oxidized, or utilized for synthesis of ketone bodies (acetoacetate, β-hydroxybutyrate) or cholesterol. Finally, glucose may be released into the circulation. Only liver and kidneys express glucose-6-phosphatase, the enzyme necessary for release of glucose into the circulation, at levels sufficient to permit substantial contributions to the systemic glucose pool. Many tissues express the enzymes required to synthesize and hydrolyze glycogen (glycogen synthase and phosphorylase, respectively). The liver and kidneys also express the enzymes necessary for gluconeogenesis, including the critical gluconeogenic enzymes pyruvate carboxylase, phosphoenolpyruvate carboxykinase, and fructose-1,6-bisphosphatase.



• **Fig. 38.1** Schematic representation of glucose metabolism. *CoA*, coenzyme A; *P*, phosphate; *TCA*, tricarboxylic acid.

The liver is the major source of net endogenous glucose production (through glycogenolysis and gluconeogenesis). Conversely, the liver can be an organ of net glucose uptake and glycogen synthesis. The kidneys also produce glucose (through gluconeogenesis) and utilize glucose.

Muscle can take up and store glucose as glycogen, or metabolize glucose (through glycolysis) to pyruvate, which, among other fates, can be reduced to lactate or transaminated to form alanine. Lactate (and pyruvate) released from muscle can be transported to the liver and the kidneys, to serve as a gluconeogenic precursor (the Cori or glucose-lactate cycle). Alanine, glutamine, and other amino acids can also flow from muscle to liver and kidneys, where they also serve as gluconeogenic precursors. These constitute the glucose-alanine and glucose-glutamine cycles, in which new glucose formation is from precursors (e.g., amino acids) where the carbons are not derived from glucose. Although quantitatively less important than muscle, fat can also take up and metabolize glucose.

Glucose is essentially the sole metabolic fuel for the brain under physiologic conditions.[3] Glucose largely undergoes terminal oxidation in the brain. Although the adult human brain constitutes only about 2.5% of body weight, its oxidative metabolism accounts for approximately 25% of the basal metabolic rate and more than 50% of whole-body glucose utilization. The brain can utilize alternative fuels if their circulating levels rise high enough for them to enter the brain in quantity. For example, during extended fasting, markedly elevated circulating ketone levels can support the majority of the energy needs of the brain and reduce its utilization of glucose. Notably, ketogenesis is suppressed during episodes of insulin-mediated hypoglycemia such that again, the

TABLE 38.2 Systemic Glucose Balance[a] and Effects of Circulating Hormones on Endogenous Production and Use of Glucose

Source of glucose influx or efflux	HORMONAL EFFECTS		
	Insulin	Glucagon	Epinephrine
Glucose Influx Into the Circulation			
Exogenous glucose delivery			
Endogenous glucose delivery			
In liver: glycogenolysis and gluconeogenesis	↓	↑	↑
In kidneys: gluconeogenesis	↓		↑
Glucose Efflux Out of the Circulation			
Ongoing brain glucose utilization			
Variable glucose utilization by other tissues (e.g., muscle fat, liver, kidneys)	↑		↓

[a]Total glucose influx = total glucose efflux.

brain is critically dependent on a virtually continuous supply of glucose from the circulation.[3]

Systemic Glucose Balance

Normally, rates of endogenous glucose influx into the circulation and those of glucose efflux out of the circulation into tissues other than the brain are coordinately regulated—largely by the plasma glucose–lowering (regulatory) hormone insulin and the plasma glucose–raising (counterregulatory) hormones glucagon and epinephrine—such that systemic glucose balance is maintained, hypoglycemia (as well as hyperglycemia) is prevented, and a continuous supply of glucose to the brain is ensured (Table 38.2). This is accomplished despite wide variations in exogenous glucose influx (e.g., after meals vs. during fasting) and in glucose efflux (e.g., during exercise vs. rest). Hypoglycemia occurs when rates of glucose appearance in the circulation (the sum of endogenous glucose production and exogenous glucose delivery from ingested carbohydrates) fail to keep pace with rates of glucose disappearance from the circulation (the sum of ongoing glucose metabolism largely by the brain and of variable glucose utilization by tissues including muscle, fat, liver, and kidneys).

In healthy adults, the physiologic postabsorptive (fasting) plasma glucose concentration ranges from approximately 70 mg/dL (3.9 mmol/L) to 110 mg/dL (6.1 mmol/L), with a mean of about 90 mg/dL (5.0 mmol/L).[3] In the postabsorptive steady state, rates of glucose production and utilization average approximately 2.2 mg/kg per minute (12 μmol/kg per minute), with a range of 1.8 to 2.6 mg/kg per minute (10–14 μmol/kg per minute). These rates are as much as threefold higher in infants, at least in part because of their greater brain mass relative to body weight.

The liver is the predominant source of endogenous glucose production in the postabsorptive state; the kidneys, which both utilize and produce glucose, contribute little to net glucose production. However, as in the liver, glucose production in the kidney is regulated; it is suppressed by insulin and stimulated by epinephrine but not by glucagon. As a result, net renal glucose production occurs under some conditions, including hypoglycemia.[4] Therefore, endogenous glucose production cannot be equated solely with hepatic glucose production.

Gluconeogenesis and glycogenolysis are important for maintenance of the plasma glucose concentration.[5] The glucose pool—namely, free glucose in the extracellular fluids and in the cells of certain tissues (primarily the liver)—is only about 15 to 20 g (83–111 mmol). Glycogen that can be mobilized to provide circulating glucose (e.g., hepatic glycogen) contains approximately 70 g (390 mmol) of glucose, with a range of about 25 to 130 g (135–722 mmol). Therefore, in an adult of average size, preformed glucose can provide less than an 8-hour supply of energy, even at the diminished rate of glucose utilization that occurs in the postabsorptive state.

If fasting is prolonged to 24 to 48 hours, the plasma glucose concentration declines and then stabilizes; hepatic glycogen content falls to less than 10 g (55 mmol), and gluconeogenesis becomes the sole source of glucose production. Because amino acids are the main gluconeogenic precursors that result in net glucose formation, muscle protein is degraded. Glucose utilization by muscle and fat virtually ceases. As lipolysis and ketogenesis accelerate and circulating ketone levels rise, ketones become a major fuel for the brain. Glucose utilization by the brain declines by about half, which reduces the rate of gluconeogenesis required to maintain the plasma glucose concentration and hence decreases protein wasting.

After a meal, glucose absorption into the circulation increases to more than twice the rate of postabsorptive endogenous glucose production, depending on the carbohydrate content of the meal, the rate of gastric transit, and the rate of digestion and absorption. As glucose is absorbed, endogenous glucose production is suppressed, and glucose utilization by muscle, fat, and liver accelerates. The exogenous glucose is assimilated and, after a small rise, the plasma glucose concentration returns to the postabsorptive level.

Exercise increases glucose utilization (by muscle) to rates that can be several times greater than those of the postabsorptive state. Endogenous glucose production normally accelerates to match use so that the plasma glucose concentration is maintained.

In summary, the plasma glucose concentration is normally maintained within a relatively narrow range despite wide variations in glucose flux and thus maintains the systemic glucose balance. This remarkable homeostatic feat is accomplished by an array of hormonal, neural, and substrate glucoregulatory factors.

Responses to Hypoglycemia

Falling plasma glucose concentrations cause a sequence of responses, with defined glycemic thresholds, in healthy individuals[1,6–9] (Table 38.3). The first response is a decrease in insulin secretion. This decrease occurs as glucose levels decline within the physiologic range. Increased secretion of glucose counterregulatory hormones, including glucagon and epinephrine, occurs as glucose levels fall just below the physiologic range. Lower plasma glucose concentrations cause a more intense sympathoadrenal (sympathetic neural as well as adrenomedullary) response and symptoms. Even lower glucose levels cause cognitive dysfunction and additional manifestations of functional brain failure including seizure or coma.

Clinical Manifestations of Hypoglycemia

The symptoms and signs of hypoglycemia are nonspecific.[9] Clinical hypoglycemia—that sufficient to cause symptoms and signs[2]—is most convincingly documented by Whipple triad (see Table 38.1).

TABLE 38.3 Physiologic Responses to Decreasing Plasma Glucose Concentrations

Response	Glycemic Threshold[a] (mmol/L [mg/dL])	Physiologic Effects	Role in Prevention or Correction of Hypoglycemia (Glucose Counterregulation)
↓ Insulin	4.4–4.7 (80–85)	↑ R_a (↓ R_d)	Primary glucose regulatory factor, first defense against hypoglycemia
↑ Glucagon	3.6–3.9 (65–70)	↑ R_a	Primary glucose counterregulatory factor, second defense against hypoglycemia
↑ Epinephrine	3.6–3.9 (65–70)	↑ R_a, ↓ R_c	Involved, critical when glucagon is deficient, third defense against hypoglycemia
↑ Cortisol and growth hormone	3.6–3.9 (65–70)	↑ R_a, ↓ R_c	Involved, not critical
Symptoms	2.8–3.1 (50–55)	↑ Exogenous glucose	Prompt behavioral defense (food ingestion)
↓ Cognition	<2.8 (50)	—	(Compromises behavioral defense)
↓ Brain glucose metabolism	<2.8 (50)	—	—

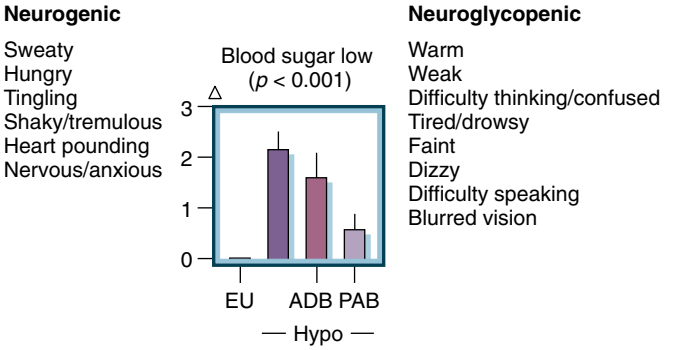
[a]Arterialized venous, not venous, plasma glucose concentrations.

R_a, Rate of glucose appearance, glucose production by the liver and kidneys; R_c, rate of glucose clearance by insulin-sensitive tissues; R_d, rate of glucose disappearance, glucose utilization by insulin-sensitive tissues such as skeletal muscle (no direct effect on central nervous system glucose utilization).

Neuroglycopenic symptoms are a direct result of brain glucose deprivation. They include cognitive impairments; behavioral changes; psychomotor abnormalities; and, at lower glucose levels, seizure and coma.[1,9] Neurogenic (or autonomic) symptoms are largely the result of the perception of physiologic changes caused by the sympathoadrenal (particularly the sympathetic neural[10]) discharge triggered by hypoglycemia. They include adrenergic (catecholamine-mediated) symptoms such as palpitations and tremor, and anxiety/arousal and cholinergic (acetylcholine-mediated) symptoms such as sweating, hunger, and paresthesias. Central mechanisms may also be involved in the generation of some of these symptoms (e.g., hunger).[11] Subjective awareness of hypoglycemia is largely the result of the perception of neurogenic symptoms[9] (Fig. 38.2).

The mechanism(s) of the signaling of the glucose regulatory and counterregulatory hormone and sympathetic responses to hypoglycemia are not known. However, those responses are not mediated by a decrease in brain glucose metabolism because the glycemic threshold for a decrease in the cerebral metabolic role of glucose, measured with [^{11}C]-glucose positron emission tomography, is at a lower plasma glucose concentration than the glycemic thresholds for the hormonal and sympathetic responses[12] (see Table 38.3).

Signs of hypoglycemia include pallor and diaphoresis, which result from adrenergic cutaneous vasoconstriction and cholinergic activation of sweat glands, respectively.[2,3] Heart rates and systolic blood pressures are raised, but often not greatly. Neuroglycopenic manifestations are often observable.



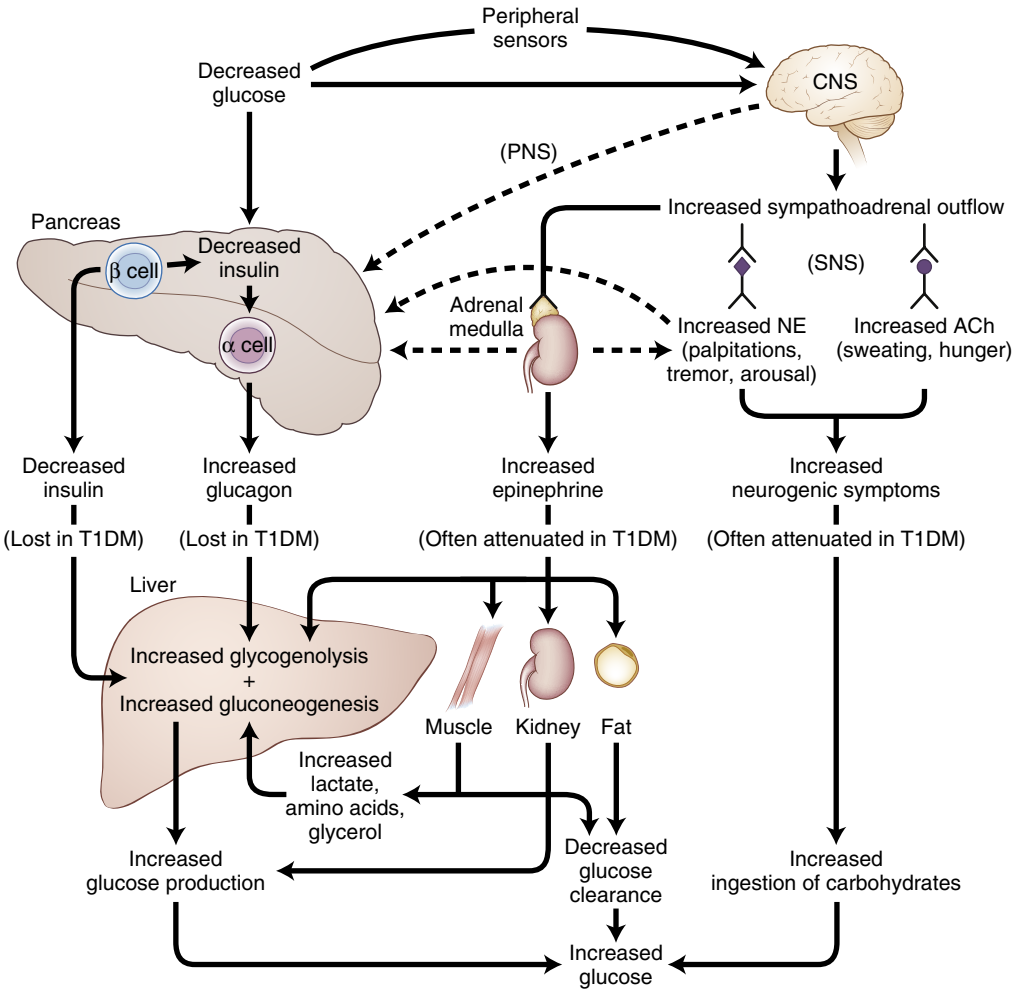
• **Fig. 38.2** Neurogenic (autonomic) and neuroglycopenic symptoms of hypoglycemia in healthy humans. Among the neurogenic symptoms, "sweaty," "hungry," and "tingling" are cholinergic, and "shaky/tremulous," "heart pounding," and "nervous/anxious" are adrenergic. See the text for discussion. Mean subject scores (± standard error) for awareness of hypoglycemia (low blood sugar) are shown during clamped euglycemia (EU) and during three conditions of hypoglycemia (Hypo): alone, with combined α- and β-adrenergic blockade by infused phentolamine and propranolol (ADB), and with combined α- and β-adrenergic blockade plus muscarinic cholinergic blockade by atropine (panautonomic blockade, PAB). (From Towler DA, Havlin CE, Craft S, Cryer P. Mechanism of awareness of hypoglycemia: perception of neurogenic [predominantly cholinergic] rather than neuroglycopenic symptoms. *Diabetes Care*. 1993;42:1791–1798, used with permission of the American Diabetes Association.)

Maintenance of Systemic Glucose Balance

Although obligatory glucose utilization, largely by the brain, is continuous, the delivery of exogenous glucose from dietary carbohydrates is intermittent. Systemic glucose balance (see Table 38.2) is normally maintained, and hypoglycemia and hyperglycemia are prevented, by dynamic, minute-to-minute regulation of endogenous glucose production from the liver and kidneys and of glucose utilization by tissues outside the central nervous system (CNS), such as muscle.[1,3] This regulation is exerted primarily by insulin, glucagon, and epinephrine[1–3] (Fig. 38.3; see also Table 38.3), although an array of hormones, neurotransmitters, and substrates is involved.[13]

The key physiologic defenses against falling plasma glucose concentrations are (1) a decrease in insulin, (2) an increase in glucagon, and, in the absence of the latter, (3) an increase in epinephrine.[3] The behavioral defense is carbohydrate ingestion prompted by symptoms that are largely sympathetic neural in origin[1,3,10] (see Table 38.3 and Fig. 38.3).

The first physiologic defense against hypoglycemia is a decrease in insulin secretion by the pancreatic islet beta cells. Signaled primarily by declining glucose levels at the beta cells, this response



• **Fig. 38.3** Physiologic and behavioral defenses against hypoglycemia in humans. *ACh,* acetylcholine; *α cell,* pancreatic islet alpha cell; *β cell,* pancreatic islet beta cell; *CNS,* central nervous system; *NE,* norepinephrine; *PNS,* parasympathetic nervous system; *SNS,* sympathetic nervous system; *T1DM,* type 1 diabetes mellitus. occurs as plasma glucose concentrations decline within the physiologic range[3] (see Table 38.3) and favors increased hepatic and renal glucose production with virtual cessation of glucose utilization by insulin-sensitive tissues such as muscle (see Fig. 38.3).

The second physiologic defense against hypoglycemia is an increase in glucagon secretion by pancreatic islet alpha cells. This increase occurs as plasma glucose concentrations fall just below the physiologic range (see Table 38.3) and stimulates hepatic glucose production, largely by stimulating glycogenolysis (see Fig. 38.3). This response is signaled primarily by a decrease in intraislet insulin, perhaps among other beta-cell secretory products, in the setting of low alpha-cell glucose concentrations[14–18] (see Fig. 38.3) and other signals that may include a decrease in somatostatin among others as yet to be determined mechanisms[14–18] and only secondarily by increased autonomic nervous system (sympathetic, parasympathetic, adrenomedullary) inputs.[19]

The third physiologic defense against hypoglycemia, which becomes critical when glucagon is deficient, is an increase in adrenomedullary epinephrine secretion. Signaled via the CNS, it also occurs as plasma glucose concentrations fall just below the physiologic range[1–3] (see Table 38.3) and raises plasma glucose concentrations largely by β_2-adrenergic stimulation of hepatic and renal glucose production (see Fig. 38.3). However, the plasma glucose–raising actions of epinephrine also involve limitation of glucose clearance by insulin-sensitive tissues, mobilization of gluconeogenic precursors such as lactate and amino acids from muscle and glycerol from fat, and α_2-adrenergic limitation of insulin secretion[20] (Fig. 38.4). Indeed, the adrenergic actions on beta-cell insulin secretion normally play an important role in the glycemic actions of epinephrine. α_2-Adrenergic limitation of insulin secretion permits the glycemic response; β_2-adrenergic stimulation alone has little effect because it also stimulates insulin secretion. However, some increase in insulin secretion—due to the rising glucose level, β_2-adrenergic stimulation, or both—limits the magnitude of the glycemic response to epinephrine. These physiologic interactions explain why glycemic sensitivity to epinephrine is increased in patients who cannot increase insulin secretion (e.g., those with type 1 diabetes mellitus [T1DM]).[20] Circulating epinephrine is derived almost exclusively from the adrenal medulla in adults.[10] Whereas circulating norepinephrine is derived largely from sympathetic nerve terminals under resting conditions and in many stimulated states (e.g., exercise), the plasma norepinephrine response to hypoglycemia is derived largely from the adrenal medulla.[10]

These physiologic defenses against hypoglycemia typically abort episodes of declining plasma glucose concentrations and prevent clinical (i.e., symptomatic) hypoglycemia. If they do not, the lower plasma glucose concentration causes a more intense sympathoadrenal response, resulting in symptoms[1,3] (see Table 38.3). These symptoms, particularly the neurogenic symptoms, cause awareness of hypoglycemia that prompts the behavioral defense against hypoglycemia—ingestion of carbohydrates[3] (see Fig. 38.3).

The integrated physiology of glucose counterregulation[1–3] is further illustrated in Fig. 38.5. Falling glucose levels within the pancreatic islet cells signal a decrease in insulin secretion and an increase in glucagon secretion. Falling glucose levels sensed in the periphery and in the CNS, acting through the hypothalamus, signal an increase in sympathoadrenal activity that results in an increase in adrenomedullary epinephrine secretion and in neurogenic symptoms, the latter largely resulting from increased sympathetic neural activity. Fig. 38.5 includes a putative cerebral network that may modulate the hypothalamic response.

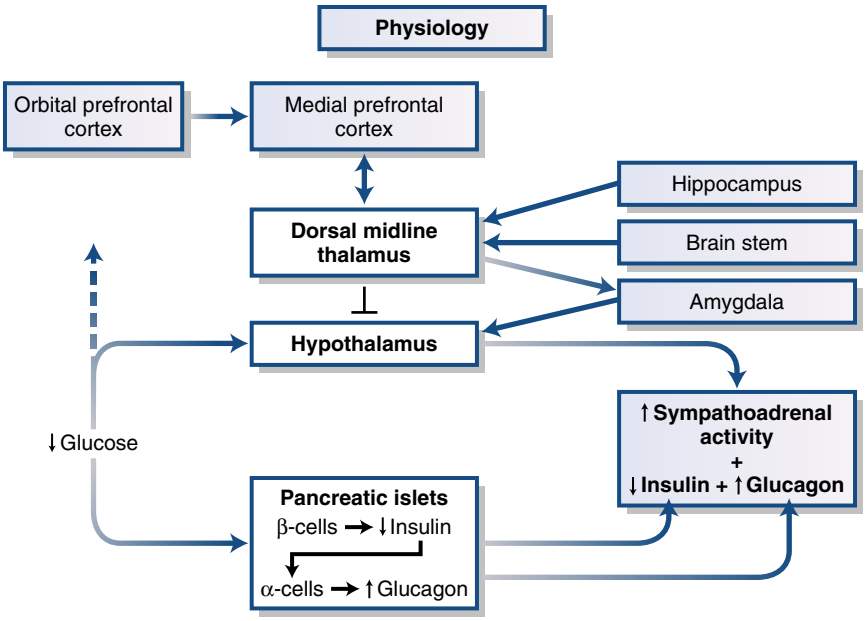
Catecholamines, pheochromocytoma and diabetes. *Diabetes Rev*. 1993;1:309–317, used with permission of the American Diabetes Association.)

Clinical Hypoglycemia

Definition and Diagnosis

Clinical hypoglycemia is, by definition, a plasma glucose concentration low enough to cause symptoms or signs, including impairment of brain function. The glycemic thresholds for symptoms and signs of hypoglycemia are dynamic; for example, they shift to lower plasma glucose concentrations in patients with recurrent hypoglycemia[21–23] and to higher concentrations in those with poorly controlled diabetes. Therefore, it is not possible to state a single plasma glucose concentration that categorically defines hypoglycemia. Furthermore, the symptoms and signs of hypoglycemia are nonspecific, and a low measured plasma glucose concentration can be artifactual. For all of these reasons, hypoglycemia is most convincingly documented by Whipple triad[1,2] (see Table 38.1).

Documentation of Whipple triad is particularly important when hypoglycemia is suspected in a person who does not have diabetes mellitus, because hypoglycemic disorders are rare. In the absence of diabetes, a thorough diagnostic evaluation is recommended only for patients in whom Whipple triad can be documented.[2] Ideally, patients with diabetes being treated with an insulin secretagogue or insulin should monitor their plasma glucose concentration whenever they suspect hypoglycemia. Nonetheless, the likelihood that a symptomatic episode is the result



• **Fig. 38.5** Schematic representation of the integrated mechanisms of the physiologic responses to hypoglycemia in humans: decrements in insulin secretion, increments in glucagon secretion, and increments in sympathoadrenal (adrenomedullary and sympathetic neural) activity. *α-cells*, pancreatic islet alpha cells; *β-cells*, pancreatic islet beta cells. (From Cryer PE. *Hypoglycemia in Diabetes: Pathophysiology, Prevalence and Prevention*. Alexandria, VA: American Diabetes Association; 2009, used with permission of the American Diabetes Association.)

of hypoglycemia is high, because hypoglycemia is common in patients treated with insulin, a sulfonylurea, or a glinide. It is also important to recognize that glucose concentrations measured in whole blood are approximately 15% lower than those in plasma and may be further reduced if the hematocrit is high.

Clinical Classification of Hypoglycemia

Causes of hypoglycemia[2] are outlined in Table 38.4. Drugs are, by far, the most common cause of hypoglycemia. Such drugs include insulin secretagogues and insulin used to treat diabetes. Although persons with diabetes can suffer from the same hypoglycemic disorders as those without diabetes, their hypoglycemic episodes are usually the result of treatment of their diabetes. Furthermore, the pathophysiology of hypoglycemia in diabetes is unique, and the diagnostic and management approaches are different from those for individuals without diabetes. Therefore, hypoglycemia in persons with diabetes and hypoglycemia in those without diabetes are discussed separately in this chapter.

Hypoglycemia in Persons With Diabetes

The Clinical Problem of Hypoglycemia in Diabetes

Iatrogenic hypoglycemia is the limiting factor in the glycemic management of diabetes with insulin, a sulfonylurea, or a glinide.[1]

It causes recurrent morbidity in most persons with T1DM and in many of those with advanced type 2 diabetes mellitus (T2DM), and it is sometimes fatal. The barrier of hypoglycemia generally precludes maintenance of euglycemia over a lifetime of diabetes and thus full realization of the vascular benefits of glycemic control. Furthermore, hypoglycemia compromises physiologic and behavioral defenses against subsequent falling plasma glucose concentrations, resulting in a vicious cycle of recurrent hypoglycemia.

Hypoglycemia in diabetes is caused by pharmacokinetically imperfect treatment with insulin or an insulin secretagogue (e.g., a sulfonylurea or a glinide) that results in episodes of therapeutic hyperinsulinemia. Thus, it is fundamentally iatrogenic. Episodes of substantial absolute therapeutic hyperinsulinemia can cause isolated episodes of hypoglycemia. However, as developed later in this chapter, recurrent hypoglycemia in diabetes is typically the result of the interplay of relative or mild to moderate absolute therapeutic hyperinsulinemia and compromised physiologic and behavioral defenses against falling plasma glucose concentrations.[1,2]

Frequency of Hypoglycemia in Diabetes

Hypoglycemia is unfortunately a fact of life for people with T1DM.[24–26] The average patient suffers untold numbers of episodes of asymptomatic hypoglycemia (which are not benign, because they impair defenses against subsequent hypoglycemia), approximately two episodes of symptomatic hypoglycemia per week (thousands of such episodes over a lifetime of diabetes), and roughly one episode per year of severe, at least temporarily disabling hypoglycemia, often with seizure or coma. This problem has not abated since it was highlighted by the report of the Diabetes Control and Complications Trial (DCCT) in 1993.[24] In 2007, the United Kingdom Hypoglycaemia Study Group reported an incidence of severe hypoglycemia twice that reported in the DCCT among patients who had had T1DM for less than 5 years and five times the DCCT incidence among those with T1DM for more than 15 years in their population-based study.[27]

The overall incidence of hypoglycemia during treatment of T2DM with an insulin secretagogue, or even with insulin, is lower than that in patients with T1DM.[26–34] However, for pathophysiologic reasons discussed later, the incidence of hypoglycemia increases progressively over time as patients approach the absolute endogenous insulin-deficient end of the spectrum of T2DM.[27,29,30] Indeed, the incidence of hypoglycemia has been reported to be similar in patients with T2DM and in those with T1DM matched for duration of insulin therapy.[30] The United Kingdom Hypoglycaemia Study Group found a prevalence of severe hypoglycemia of 7% and an incidence of 10 episodes per 100 patient-years among patients with T2DM treated with insulin for less than 2 years; among those treated for longer than 5 years, these figures rose to 25% prevalence and 70 episodes per 100 patient-years.[27] The patterns for self-treated hypoglycemia were similar. Therefore, at least with current, less than euglycemic treatment goals, the frequency of iatrogenic hypoglycemia is relatively low during the first few years of treatment of T2DM with insulin but increases substantially in advanced T2DM, approaching the frequency among patients with T1DM. As discussed later in this chapter, new technologies, particularly continuous glucose monitoring (CGM) and drugs for the treatment of T2DM that do not cause hypoglycemia, will reduce the frequency of hypoglycemia for those who are able to use them.

Estimates of the incidence and prevalence of hypoglycemia in diabetes are generally underestimates because of the challenge of ascertainment.[1,2] Asymptomatic episodes will be missed unless

they are incidentally detected by self-monitoring of blood glucose or by CGM. Symptomatic episodes may not be recognized to be the result of hypoglycemia, because the symptoms of hypoglycemia are nonspecific. Even if they are recognized, they may not be remembered[35,36] and reported at periodic patient contacts. Because they are dramatic events that are more likely to be reported (by the patient or an associate), estimates of the frequency of severe hypoglycemia (that requiring the assistance of another person) are more reliable, although they represent only a small fraction of the total hypoglycemic burden. Prospective, population-based studies with a focus on hypoglycemia should provide the most reliable data.

The prospective, population-based data of Donnelly and colleagues[26] indicate that the overall incidences of any episode of hypoglycemia and of severe hypoglycemia in insulin-treated T2DM are about one-third of those in T1DM. Two other population-based studies reported the incidence of severe hypoglycemia requiring emergency treatment in insulin-treated T2DM to be 40%[31] and 100%[32] of that in T1DM. Taken together, and considering that the prevalence of T2DM is approximately 20-fold greater than that of T1DM and that most patients with T2DM ultimately require treatment with insulin, these data suggest that most episodes of iatrogenic hypoglycemia, including severe hypoglycemia, occur in persons with T2DM.

Impact of Hypoglycemia in Diabetes

Iatrogenic hypoglycemia causes recurrent physical and psychosocial morbidity and impairs glycemic defenses against subsequent hypoglycemia in many patients with diabetes.[1] The barrier of hypoglycemia generally precludes maintenance of euglycemia over a lifetime of diabetes. Hypoglycemia often causes functional brain failure that is typically reversed after the plasma glucose concentration is raised. Rarely, it causes sudden death, presumably the result of cardiac arrhythmia, or, if it is profound and prolonged, permanent brain dysfunction and death.

At a minimum, an episode of symptomatic hypoglycemia is a nuisance and a distraction. It can impair judgment, behavior, and performance of physical tasks such as driving. It can cause a seizure or loss of consciousness. Transient neurologic deficits sometimes occur, but permanent neurologic damage is rare. Systematic long-term follow-up of the DCCT patients suggests that recurrent iatrogenic hypoglycemia does not cause chronic cognitive impairments in young adults,[37] but the possibility that it does so in young children[38,39] and the elderly[40] remains. Among other psychological disorders, fear of hypoglycemia can be a barrier to glycemic control.[41]

Iatrogenic hypoglycemia can be fatal.[42–53] That hypoglycemia can kill has been known since the discovery of insulin.[42] There are epidemiologic associations of hypoglycemia with death,[43] reports of excessive mortality rates during intensive glycemic therapy in randomized controlled trials of patients with T2DM[43,44] and intensive care unit patients,[45,46] and reports of hypoglycemia mortality rates in series of patients with diabetes.[47–51] Early reports indicated that 2% to 4% of patients with T1DM died of hypoglycemia.[47–49] More recent reports indicate that 4%,[49,50] 7%,[51] 8%,[52] and 10% or greater[53] of deaths of persons with T1DM were caused by hypoglycemia. Indeed, hypoglycemia at the time of death has been documented by CGM.[54] Death rates of up to 10% of patients who suffer severe sulfonylurea-induced hypoglycemia have been reported.[55]

The finding of Currie and colleagues[56] that lower glycosylated hemoglobin (HbA_{1c}) levels are associated with increased mortality in patients with T2DM at higher risk of hypoglycemia is entirely consistent with this body of evidence that iatrogenic hypoglycemia is a risk factor for death in diabetes. Thus, there are iatrogenic mortality rates in both T1DM and T2DM.

Although prolonged, profound hypoglycemia can cause brain death, most instances of sudden hypoglycemic death are thought to be the result of cardiac arrhythmias triggered by an intense sympathoadrenal response to hypoglycemia.[44,57,58] These are mediated through β-adrenergic receptors.[58] Sudden death has been associated with QT interval prolongation and reduced baroreflex sensitivity in patients with classic diabetic autonomic neuropathy.[59–61] Adler and colleagues[62] demonstrated, in studies of nondiabetic individuals, that recent antecedent hypoglycemia causes reduced baroreflex sensitivity the following day. The induction of functional sympathetic failure by recent antecedent hypoglycemia as an additional, potentially fatal, feature of the concept of hypoglycemia-associated autonomic failure (HAAF) in diabetes[1] is discussed later in this chapter.

Clinical Definition and Classification of Hypoglycemia in Diabetes

The American Diabetes Association/Endocrine Society Workgroup on Hypoglycemia[63] (ADA/ES Workgroup) defined hypoglycemia in diabetes as "all episodes of abnormally low plasma glucose concentration that expose the individual to potential harm." That is broader than the recommended definition of clinical hypoglycemia in persons without diabetes (i.e., a plasma glucose concentration low enough to cause symptoms or signs[1,2]), because it includes asymptomatic episodes. The latter are not benign in persons with diabetes; they compromise defenses against subsequent hypoglycemia,[1,2] and they identify increased risk of imminent severe iatrogenic hypoglycemia.[64] Again, it is not possible to define a plasma glucose concentration that categorically defines hypoglycemia, because the glycemic thresholds for responses to hypoglycemia are dynamic. They shift to lower plasma glucose concentrations in patients with recurrent hypoglycemia[21,22] and to higher plasma glucose concentrations in those with poorly controlled diabetes.[20,21]

The ADA/ES Workgroup recommends that people with diabetes (implicitly those treated with an insulin secretagogue or insulin) become concerned about the possibility of developing hypoglycemia at a self-monitored plasma glucose concentration of 70 mg/dL (3.9 mmol/L) or less.[63] Within the error of self-monitoring (or CGM), that conservative alert value approximates the lower limit of the nondiabetic postabsorptive plasma glucose range[1,2] and the normal glycemic thresholds for activation of physiologic glucose counterregulatory systems[1,2] (see Table 38.3); it is low enough to reduce glycemic defenses against subsequent hypoglycemia in nondiabetic persons. Therefore, the recommended glucose alert level of 70 mg/dL (3.9 mmol/L) or less is data driven; it usually gives the patient time to take action to prevent a clinical hypoglycemic episode, and it provides some margin for the limited accuracy of glucose monitoring devices at low plasma glucose concentrations. It has been implicitly endorsed by the US Food and Drug Administration and the European Medicines Agency.

The recommended alert value does not, of course, mean that persons with diabetes should always self-treat for hypoglycemia at an estimated plasma glucose concentration of 70 mg/dL (3.9 mmol/L) or less. Rather, they should consider actions ranging from repeating the measurement in the near term, through behavioral actions such as avoiding exercise or driving until the glucose level is raised, to carbohydrate ingestion and subsequent adjustments of the therapeutic regimen.

The ADA/ES Workgroup[63] also recommended a clinical classification of hypoglycemia in diabetes (Table 38.5).

TABLE 38.5 Classification of Hypoglycemia in Diabetes

Clinical Classification	Definition
Severe hypoglycemia	An event requiring the assistance of another person to actively administer carbohydrate, glucagon, or other resuscitative actions. Plasma glucose measurements may not be available during such an event, but neurologic recovery attributable to the restoration of plasma glucose to a normal level is considered sufficient evidence that the event was induced by a low plasma glucose concentration.
Documented symptomatic hypoglycemia	An event during which typical symptoms of hypoglycemia are accompanied by a measured plasma glucose concentration of ≤70 mg/dL (3.9 mmol/L).
Asymptomatic hypoglycemia	An event not accompanied by typical symptoms of hypoglycemia but with a measured plasma glucose concentration of ≤70 mg/dL (3.9 mmol/L).
Probable symptomatic hypoglycemia	An event during which symptoms typical of hypoglycemia are not accompanied by a plasma glucose determination but were presumably caused by a plasma glucose concentration of ≤70 mg/dL (3.9 mmol/L).
Pseudohypoglycemia	An event during which the person with diabetes reports any of the typical symptoms of hypoglycemia and interprets those as indicative of hypoglycemia, with a measured plasma glucose concentration that is >70 mg/dL (3.9 mmol/L) but is approaching that level.

The International Hypoglycaemia Study Group[65] proposed three levels of iatrogenic hypoglycemia in diabetes:

- *Level 1*: A glucose alert value of 70 mg/dL (3.9 mmol/L) or less
- *Level 2*: A glucose level less than 54 mg/dL (3.0 mmol/L), which is sufficiently low to indicate serious clinically important hypoglycemia
- *Level 3*: Severe hypoglycemia as defined by the American Diabetes Association.

These levels were endorsed by the American Diabetes Association and the European Association for the Study of Diabetes.[65]

Based on the fact that the HbA_{1c} level provides useful information about long-term glycemic control but no information about short-term glycemic control, it has been suggested[66] that the classification of severe hypoglycemia (see Table 38.5) should be expanded to include a distinctly low plasma glucose concentration, perhaps less than 50 mg/dL (2.8 mmol/L) or less than 54 mg/dL (3.0 mmol/L),[65] detected by self-monitoring of plasma glucose, CGM, or a laboratory determination. This would be particularly useful if there were no symptoms at the time of the detection of the distinctly low glucose concentration, because it would document impaired awareness of hypoglycemia, a treatable condition.

Pathophysiology of Glucose Counterregulation in Diabetes

The pathophysiology of glucose counterregulation and its relationship to clinical hypoglycemia in diabetes[1,2] are summarized in the paragraphs that follow (see earlier discussion and Figs. 38.3 and 38.5). Again, the key physiologic defenses against falling plasma glucose concentrations are a decrease in insulin, an increase in glucagon, and, in the absence of the latter, an increase in epinephrine. The behavioral defense is carbohydrate ingestion prompted by symptoms[9] that are largely sympathetic neural in origin.[10]

Insulin Excess

Episodes of therapeutic hyperinsulinemia, produced by treatment with an insulin secretagogue (a sulfonylurea or a glinide) or with insulin, are a prerequisite for the development of iatrogenic hypoglycemia. Marked absolute insulin excess can cause isolated episodes of hypoglycemia. However, iatrogenic hypoglycemia is typically the result of the interplay of relative or mild to moderate absolute therapeutic hyperinsulinemia and compromised physiologic and behavioral defenses against falling plasma glucose concentrations[1,2] (Fig. 38.6).

Defective Glucose Counterregulation and Hypoglycemia Unawareness

In established (absolute deficiency of endogenous insulin) T1DM, circulating (exogenous) insulin concentrations do not decrease as plasma glucose concentrations fall in response to therapeutic hyperinsulinemia. That is the result of absolute beta-cell failure with no regulated endogenous insulin secretion. Therefore, the first physiologic defense against hypoglycemia[3] is lost. Furthermore, despite the presence of functional alpha cells, there is no increase in glucagon secretion[1,2,18] (Fig. 38.7). That also is largely the result of beta-cell failure,[14–18] which causes loss of the decrement in insulin that normally signals an increase in alpha-cell glucagon secretion during hypoglycemia[1,18] (see Figs. 38.3 and 38.5). Therefore, the second physiologic defense against hypoglycemia[3] is lost as well.

In addition, the increase in epinephrine secretion, the third physiologic defense against hypoglycemia,[3] is typically attenuated[1,2,67] (see Fig. 38.7). In the setting of absent insulin and glucagon responses, the attenuated epinephrine response causes the clinical syndrome of defective glucose counterregulation[67–69] (see Fig. 38.6), which is associated with a 25-fold[69] or greater[70] increased risk of severe hypoglycemia in T1DM. The attenuated epinephrine response is a marker of attenuation of the sympathoadrenal response (including the sympathetic neural response) that normally causes neurogenic symptoms that largely prompt the behavioral response leading to carbohydrate ingestion (see Figs. 38.3 and 38.5). This attenuated response (largely the attenuated sympathetic neural response) causes the clinical syndrome of hypoglycemia unawareness[1,2] (see Fig. 38.6).

Although the term *hypoglycemia unawareness* is used widely, "impaired awareness of hypoglycemia"[71] is more precise because there is a spectrum ranging from partial to complete loss of symptoms. Attenuated sympathoadrenal responses to falling plasma glucose concentrations can be caused by recent antecedent hypoglycemia[72] (Figs. 38.8 and 38.9), prior exercise,[73] or sleep,[74,75] but the precise mechanism is not known. (See later discussion on HAAF.)

Impaired awareness of hypoglycemia is largely the result of reduced release of the sympathetic neurotransmitters norepinephrine and acetylcholine.[10] There is evidence of decreased β-adrenergic sensitivity, specifically reduced cardiac chronotropic sensitivity to isoproterenol, in affected patients.[76,77] However, vascular sensitivity to a β-adrenergic agonist was not found to be reduced in unaware patients.[78] Reduced sensitivity to β-adrenergic

signaling of neurogenic symptoms remains to be demonstrated in patients with unawareness, and it would be necessary to also postulate decreased cholinergic sensitivity to explain reduced cholinergic symptoms such as sweating.

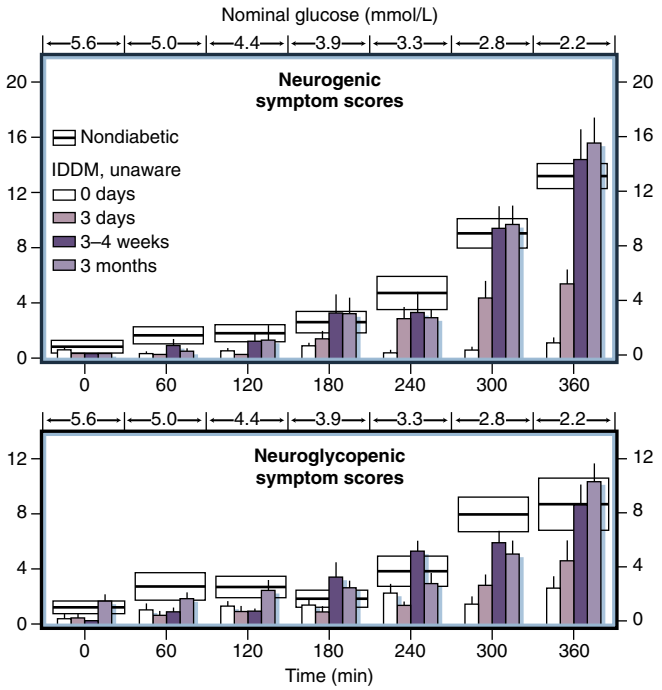
In contrast to these compromised defenses in T1DM, defenses against hypoglycemia are intact early in the course of T2DM. However, they become compromised over time.[1,79] In advanced T2DM (i.e., with absolutely deficient endogenous insulin), insulin and glucagon responses to falling plasma glucose concentrations are lost and sympathoadrenal responses to hypoglycemia are reduced by recent antecedent hypoglycemia, as is observed in T1DM.[79]

In summary, the pathophysiology of glucose counterregulation is the same in T1DM and T2DM but with different time courses.[67,79,80] The pathogenesis of an episode of iatrogenic hypoglycemia involves therapeutic hyperinsulinemia resulting in falling plasma glucose concentrations. With the absence of appropriate decrements in insulin and of increments in glucagon, hypoglycemia occurs. That, in turn, causes attenuated sympathoadrenal responses to subsequent falling glucose levels and recurrent episodes of hypoglycemia (see Fig. 38.6). Because beta-cell failure, which causes loss of both insulin and glucagon responses, occurs rapidly in T1DM but slowly in T2DM, the syndromes of defective glucose counterregulation and impaired awareness of hypoglycemia develop early in T1DM but later in T2DM. That temporal pattern of compromised glycemic defenses explains why iatrogenic hypoglycemia becomes progressively more frequent as patients approach the insulin-deficient end of the spectrum of T2DM.[27]

HAAF in Diabetes

The concept of HAAF[1,2,67,68,81] in diabetes developed in humans posits that in patients with absolute endogenous insulin deficient diabetes (T1DM or advanced T2DM), necessarily imperfect insulin replacement results in falling plasma glucose concentrations, but no decrease in insulin secretion and no increase in glucagon secretion, and thus recurrent episodes of hypoglycemia. Those episodes[72] (as well as sleep[74,75] or prior exercise[73]) attenuate adrenomedullary epinephrine secretion and sympathetic neural activation in response to subsequent hypoglycemia. In the setting of absent insulin and glucagon responses, the attenuated epinephrine responses cause the clinical syndrome of defective glucose counterregulation, which is associated with a 25-fold[69] or greater[70] increased risk of severe iatrogenic hypoglycemia during intensive glycemic therapy. The attenuated sympathetic neural responses cause the clinical syndrome of impaired awareness of hypoglycemia, which is associated with at least a sixfold increased risk of severe iatrogenic hypoglycemia during intensive glycemic therapy.[71] The resulting recurrent hypoglycemia further attenuates the sympathoadrenal response to falling plasma glucose concentrations (see Fig. 38.6). HAAF is a functional form of autonomic failure, distinct from classic diabetic autonomic neuropathy.[82] HAAF has cardiovascular implications because, like autonomic neuropathy, it reduces baroreflex sensitivity[62] and may predispose patients to cardiac arrhythmias.

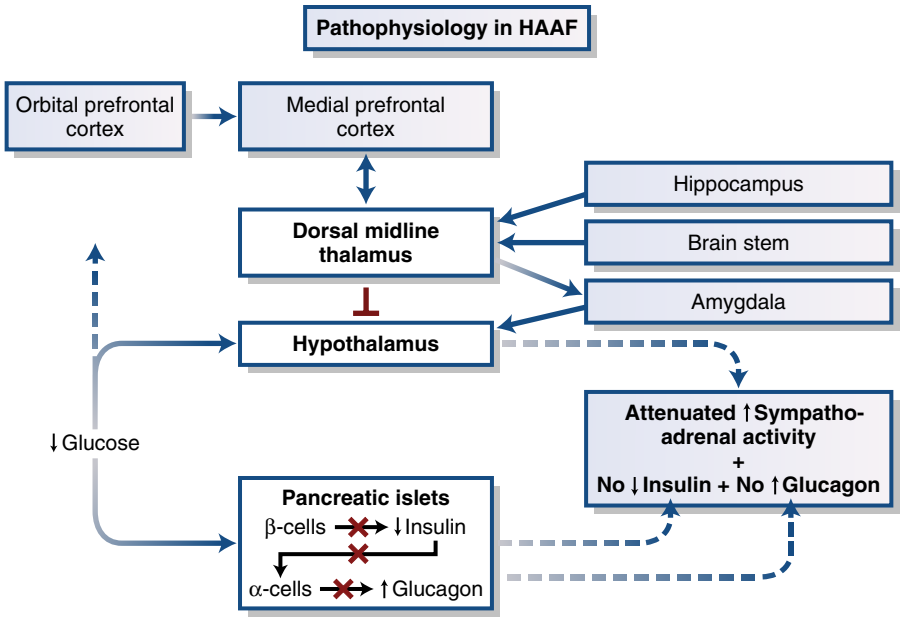
Recent antecedent hypoglycemia, even asymptomatic nocturnal hypoglycemia, reduces epinephrine and symptomatic responses to a given level of subsequent hypoglycemia,[83] reduces detection of hypoglycemia in the clinical setting,[84] and reduces glycemic defense against hyperinsulinemia[80] in T1DM. Perhaps the most compelling support for the clinical relevance of HAAF is the finding, originally from three independent laboratories,[85–88] that as little as 2 to 3 weeks of scrupulous avoidance of hypoglycemia reverses impaired awareness of hypoglycemia (Fig. 38.10) and improves the attenuated epinephrine component of defective glucose counterregulation in most affected patients. HAAF also occurs in advanced T2DM.[79]



• **Fig. 38.10** Mean (± standard error) neurogenic and neuroglycopenic symptom scores during hyperinsulinemic stepped hypoglycemic glucose clamps in nondiabetic subjects (*rectangles*) and in people with type 1 diabetes mellitus (IDDM) selected for clinical impaired awareness of hypoglycemia studied at various time points during scrupulous avoidance of iatrogenic hypoglycemia: at baseline (0 days), after 3 days, after 3 to 4 weeks, and after 3 months (see the key in the figure). *IDDM,* insulin-dependent diabetes mellitus. (From Dagogo-Jack S, Rattarasarn C, Cryer PE. Reversal of hypoglycemia unawareness, but not defective glucose counterregulation, in IDDM. *Diabetes*. 1994;43:1426–1434, used with permission of the American Diabetes Association.)

There are three recognized causes of a reversibly attenuated sympathoadrenal response to hypoglycemia and, therefore, three forms of HAAF.[1,2] Antecedent hypoglycemia–related HAAF led to the concept.[72,80] Exercise-related HAAF[73] is exemplified by late postexercise hypoglycemia, which typically occurs 6 to 15 hours after strenuous exercise and is often nocturnal.[89,90] Sleep-related HAAF[74,75] is the result of further attenuation of the sympathoadrenal response to hypoglycemia during sleep. Sleeping patients with T1DM are much less likely to be awakened by hypoglycemia than nondiabetic individuals,[75] probably because of their attenuated sympathoadrenal responses. There may well be additional, unrecognized causes of HAAF, and there may also be a structural (neuropathic) component.[1,2]

The integrated pathophysiologic mechanisms of HAAF are illustrated in Fig. 38.11. Loss of insulin and glucagon responses to falling plasma glucose concentrations caused by therapeutic hyperinsulinemia is the result of beta-cell failure in T1DM and advanced T2DM.[1,2,67] Neither can be attributed to loss of islet autonomic innervation, because low glucose concentrations decrease insulin secretion and increase glucagon secretion in patients with a transplanted (i.e., denervated) pancreas,[91] in dogs with a denervated pancreas,[92] and in isolated perfused pancreas and perifused islets. The mechanism of the attenuated sympathoadrenal response is



• **Fig. 38.11** Schematic representation of the integrated mechanisms of hypoglycemia-associated autonomic failure (HAAF) in diabetes. Alexandria, VA: American Diabetes Association; 2009, used with permission of the American Diabetes Association.)

not known, but it must involve the brain or the afferent or efferent components of the sympathoadrenal system.[67] The proposed mechanisms include the systemic mediator, brain fuel transport, brain metabolism, and cerebral network hypotheses.[93–97] There is considerable evidence against the first two of these proposed mechanisms.[67] Among many potential mechanisms, an effect of lactate on brain metabolism has been studied[98–100] and includes evidence of reduced glutamate release within the ventromedial nucleus of the rat hypothalamus.[101]

Much of the fundamental research into the mechanism of HAAF has focused on the hypothalamus, the central integrator of the sympathoadrenal response to hypoglycemia. It is conceivable, however, that the changes in the hypothalamic/sympathoadrenal response reflect modulation by higher brain centers.[67,95–97] For example, measurements of regional cerebral blood flow using oxygen-15–labeled water and positron emission tomography indicate that hypoglycemia increases synaptic activity in widespread but interconnected brain regions in humans[95] and that recent antecedent hypoglycemia both reduces sympathoadrenal and symptomatic responses (a model of HAAF) and increases synaptic activation in the dorsal midline thalamus (and only in that brain region) during subsequent hypoglycemia.[96,97] Therefore, it has been suggested that there may be a cerebral network that results in thalamic inhibition of hypothalamic activity in HAAF.[96,97] Such a putative cerebral network is included in Fig. 38.11, although it remains theoretical.

Risk Factors for Hypoglycemia in Diabetes

The risk factors for iatrogenic hypoglycemia[102] (Table 38.6) follow directly from the pathophysiology of glucose counterregulation in diabetes and are based on the tenet that iatrogenic hypoglycemia is typically the result of the interplay of relative or absolute therapeutic insulin excess and compromised physiologic and behavioral defenses against falling plasma glucose concentrations (i.e., HAAF) in T1DM and advanced T2DM, as discussed earlier.

TABLE 38.6 Risk Factors for Hypoglycemia in Diabetes

Conventional Risk Factors: Absolute or Relative Insulin Excess

- Insulin or insulin secretagogue doses are excessive, ill timed, or of the wrong type
- Exogenous glucose delivery is decreased (e.g., after missed meals, during the overnight fast)
- Glucose utilization is increased (e.g., during exercise)
- Endogenous glucose production is decreased (e.g., after alcohol ingestion)
- Sensitivity to insulin is increased (e.g., after weight loss, with improved fitness or improved glycemic control, in the middle of the night)
- Insulin clearance is decreased (e.g., with renal failure)

Risk Factors for Hypoglycemia-Associated Autonomic Failure

- Absolute endogenous insulin deficiency
- A history of severe hypoglycemia, impaired awareness of hypoglycemia, or both, and recent antecedent hypoglycemia, prior exercise, or sleep
- Aggressive glycemic therapy per se (lower HbA_{1c} levels, lower glycemic goals, or both)

HbA_{1c}, Glycosylated hemoglobin.

Absolute or Relative Insulin Excess

The conventional risk factors for hypoglycemia in diabetes[1,102] (see Table 38.6) are based on the premise that absolute or relative insulin excess is the sole determinant of risk. Absolute therapeutic insulin excess occurs when doses of insulin or insulin secretagogue are excessive, ill timed, or of the wrong type, or when the clearance

of insulin is decreased (as in renal failure). Relative insulin excess occurs when exogenous glucose delivery is reduced, glucose utilization is increased, endogenous glucose production is decreased, or sensitivity to insulin is increased. Persons with diabetes and their caregivers must consider these risk factors, including each of the examples listed in Table 38.6, when iatrogenic hypoglycemia is recognized to be a problem. However, these factors explain only a minority of episodes.[103]

Clinical risk factors for hypoglycemia include the presence of HAAF (including both defective glucose counterregulation and impaired awareness of hypoglycemia), a history of severe hypoglycemia, chronic kidney disease, a long duration of diabetes, and malnutrition.[1]

Risk Factors for HAAF

The risk factors for HAAF[102,104–109] (see Table 38-6) include the following:

1. Absolute endogenous insulin deficiency[1,102,104–108]
2. A history of severe iatrogenic hypoglycemia, impaired awareness of hypoglycemia, or both, and recent antecedent hypoglycemia, prior exercise, or sleep[102,105–107]
3. Aggressive glycemic therapy per se (i.e., lower HbA_{1c} levels, lower glycemic goals, or both).[102,105–109]

As discussed earlier, the degree of beta-cell failure determines the extent to which insulin levels will not decrease and glucagon levels will not increase as glucose levels fall in response to therapeutic hyperinsulinemia. The importance of loss of a decrease in insulin as glucose levels decline in response to therapeutic hyperinsulinemia is underscored by the fact that patients with T1DM and some degree of preserved insulin secretion have a lower incidence of hypoglycemia.[110] A history of severe hypoglycemia indicates (and that of impaired awareness of hypoglycemia implies) recent antecedent hypoglycemia. Like prior exercise or sleep, recent antecedent hypoglycemia causes attenuated sympathoadrenal and symptomatic responses to subsequent hypoglycemia, the key feature of HAAF. Aggressive glycemic therapy is a risk factor for hypoglycemia. That does not mean, however, that one cannot both improve glycemic control and minimize the risk of hypoglycemia in many patients[102] (see later discussion).

Prevention of Hypoglycemia in Diabetes

Hypoglycemia risk factor reduction[102,111] (Table 38.7) is an empiric approach to minimizing the risk of iatrogenic hypoglycemia while maintaining or improving glycemic control in persons with diabetes. It involves four steps: acknowledge the problem, apply the principles of aggressive glycemic therapy,[102] consider the conventional risk factors, and consider the risk factors for HAAF (see Table 38.6).

TABLE 38.7 Hypoglycemia Risk Factor Reduction[a]

1. Acknowledge the problem.
2. Apply the principles of aggressive glycemic therapy:
   - Diabetes self-management (patient education and empowerment)
   - Frequent self-monitoring of blood glucose (and in some instances, continuous glucose sensing)
   - Flexible and appropriate insulin (and other drug) regimens
   - Individualized glycemic goals
   - Ongoing professional guidance and support
3. Consider the conventional risk factors for hypoglycemia.[a]
4. Consider the risk factors for HAAF.[a]

[a]See Table 38.6.

HAAF, Hypoglycemia-associated autonomic failure in diabetes.

Acknowledge the Problem

The problem of hypoglycemia should be addressed, at least in persons treated with an insulin secretagogue or with insulin, in every patient contact. Acknowledging the issue allows the caregiver to move on if hypoglycemia is not a problem, or to deal with it and keep it in perspective if hypoglycemia is a problem. Some patients are reluctant to raise the issue, but their concerns about the reality, or even the possibility, of hypoglycemia can be a barrier to glycemic control.[112–114] If possible, close associates of the patient should be asked whether they have observed clues to episodes not recognized by the patient. Even if no concerns are expressed, review of the record of self-monitoring of blood glucose (or CGM data) may disclose that hypoglycemia is a problem.

Apply the Principles of Aggressive Glycemic Therapy

These principles[111] include diabetes self-management by a well-informed patient, frequent self-monitoring of blood glucose levels (and in some instances CGM), flexible and appropriate insulin and other drug regimens, individualized glycemic goals, and ongoing professional guidance and support (see Table 38.7).

As the therapeutic regimen becomes progressively more complex—early in T1DM and later in T2DM—successful glycemic management becomes progressively more dependent on the many decisions and the skills of a well-informed person with diabetes. Therefore, patient education and empowerment are fundamentally important. Patients treated with insulin secretagogues or insulin need to know the common symptoms of hypoglycemia, their individual most meaningful symptoms, and how to treat (and not overtreat) an episode. They need to know the relevant conventional risk factors for hypoglycemia, including the temporal patterns of the glucose-lowering actions of their individual secretagogue or insulin preparations and the effects of missed meals, the overnight fast, exercise, and alcohol ingestion. They also need to know that increasing episodes of hypoglycemia signal an increased likelihood of future, often more severe, hypoglycemia.[105–107] Close associates also need to know how to recognize hypoglycemia, to understand why a neuroglycopenic patient may become uncooperative, and to know when and how to administer glucagon. Finally, patients need to learn to apply the data from their self-monitoring of blood glucose concentrations (or from CGM) toward the goal of minimizing hypoglycemia (as well as hyperglycemia). Structured education focused on avoidance of hypoglycemia can restore awareness of hypoglycemia and reduce the incidence of severe hypoglycemia without deterioration of glycemic control.[115–117]

Frequent self-monitoring also becomes vital to diabetes self-management as the therapeutic regimen becomes more complex, early in T1DM and later in T2DM. Ideally, patients should monitor their glucose level whenever they suspect hypoglycemia. That would confirm or refute an episode and help the patients learn their individual key symptoms and might lead to regimen adjustments. It is important for patients with impaired awareness of hypoglycemia to monitor glucose levels before performing critical tasks such as driving. Unfortunately, conventional blood glucose monitoring, in which a measurement is obtained at one point in time, does not indicate whether the glucose level is falling, stable, or rising. That shortcoming is being addressed by evolving technologies for CGM.[118,119]

Despite considerable enthusiasm for continuous subcutaneous insulin infusion (CSII) over multiple daily injections (MDI) of insulin,[120] one meta-analysis[121] disclosed no significant difference in minor or severe hypoglycemia events with CSII or MDI, and a randomized trial[122] that specifically included structured patient education in both groups revealed no difference in severe hypoglycemia with CSII or MDI.

There is convincing evidence that insulin analogues reduce the incidence of severe hypoglycemia in patients with diabetes who are at high risk for hypoglycemia[123] that includes both rapid-acting prandial insulins (lispro, aspart) and the long-acting basal insulins degludec[124] and glargine U-300,[125] both compared with glargine U-100 once daily.

There is increasing evidence that hybrid closed-loop insulin replacement systems, specifically those that temporarily suspend insulin infusion when a low glucose concentration is predicted, reduce hypoglycemia in T1DM.[126] Pancreatic islet transplantation prevents hypoglycemia, as long as the transplant is functional, and improves glucose counterregulation.[127]

Therapeutic hyperinsulinemia, a prerequisite for iatrogenic hypoglycemia, can occur during treatment with an insulin secretagogue (e.g., a sulfonylurea or a glinide) or with insulin. Early in its course, T2DM may respond to drugs that do not raise insulin levels at normal or low plasma glucose concentrations and therefore should not, and probably do not,[1,128] cause hypoglycemia. Such drugs include the biguanide metformin, sodium-glucose cotransporter 2 inhibitors, thiazolidinediones, α-glucosidase inhibitors, glucagon-like peptide 1 (GLP1) receptor agonists, and dipeptidyl peptidase 4 inhibitors. All of these drugs require endogenous insulin secretion to lower plasma glucose concentrations, and insulin secretion declines appropriately as glucose levels fall into the normal range. That is true even for the GLP1 receptor agonists and dipeptidyl peptidase 4 inhibitors, which enhance glucose-stimulated insulin secretion (among other actions). Nonetheless, all six categories of drugs increase the risk of hypoglycemia if used with an insulin secretagogue or insulin.

Among the commonly prescribed sulfonylureas, hypoglycemia is more often associated with the longer-acting glyburide (glibenclamide) than with the shorter-acting glimepiride.[129] Despite some advantages,[123–125] insulin analogues can cause hypoglycemia.[130,131]

As reviewed in detail elsewhere,[132] there is compelling evidence from randomized controlled trials that tight glycemic control partially prevents or delays microvascular complications (retinopathy, nephropathy, neuropathy) in T1DM and T2DM. As reviewed there and developed earlier in this chapter, there is also compelling evidence that tight glycemic control increases hypoglycemic morbidity and mortality risks. Thus, it follows that the selection of a glycemic goal should be linked to the risk of hypoglycemia.[132]

Given the premise that glycemic goals in diabetes are a trade-off between glycemic control and iatrogenic hypoglycemia,[132] it has been suggested that a reasonable individualized glycemic goal is the lowest HbA_{1c} that does not cause severe hypoglycemia and preserves awareness of hypoglycemia, preferably with little or no symptomatic or even asymptomatic hypoglycemia, at a given stage in the evolution of the individual's diabetes. Parenthetically, the substantial relationship between a lower HbA_{1c} level and a higher incidence of severe hypoglycemia has been consistently documented in randomized control clinical trials in both T1DM[28,133] and T2DM.[13,43,52,134,135] In these trials, when patients with diabetes were randomly assigned to intensive glycemic therapy, largely with insulin, and shown to have lower HbA_{1c} levels or to more conventional glycemic goals and shown to have higher HbA_{1c} levels, the incidence of severe hypoglycemia was two- to threefold higher in each of the groups with the lower HbA_{1c} levels. The frequency of hypoglycemia was inversely related to the HbA_{1c} level in both the original DCCT and in the follow-up Epidemiology of Diabetes Intervention and Complications (EDIC) phase,[28,133] although the slope was less steep in the EDIC phase. The extent to which the latter is the result of insulin analogues, improved insulin delivery, glucose monitoring, patient education, patient or caregiver skill, or some other fact is not known.

There is increasing evidence that hypoglycemia is proarrhythmogenic.[136–138] Holter monitoring during CGM detected episodes of iatrogenic hypoglycemia has detected runs of cardiac arrhythmias ranging from ventricular tachycardia[136] to brachycardia,[137] and repolarization abnormalities have been identified in persons with diabetes.[138] Thus, fatal cardiac arrhythmias almost assuredly underlie hypoglycemic cardiovascular mortality in diabetes.

In an extensive review, with the exception of a 15% reduction of nonfatal myocardial infarction, Rodriguez-Gutierrez and Montori[139] found no significant impact of tight glycemic control of T2DM on outcomes important to patients—end stage renal disease/dialysis, renal death, blindness, clinical neuropathy, cardiovascular or all-cause mortality, stroke, amputation, or peripheral vascular disease. They did find a two- to threefold increase in severe hypoglycemia during intensive therapy. The authors concluded that the overwhelming consensus in favor of tight glycemic control to prevent complications needs to be recalibrated. There is evidence of an association between mortality and substantially elevated HbA_{1c} levels in T1DM.[140,141] In a 27-year follow-up of DCCT patients, a rise in mortality above that of the US general population began only with a HbA_{1c} level greater than 9% (75 mmol/mol).[140] Analysis of a much larger dataset[141] disclosed the same finding. Notably, 8% of all of the deaths of DCCT/EDIC patients attributed to hypoglycemia and hypoglycemia with seizure, coma, or both were associated with mortality.[52] At 30 years of follow-up, previous intensive glycemic therapy (i.e., that during the DCCT) did not reduce major cardiovascular events (nonfatal myocardial infarctions, stroke, or cardiovascular death) significantly, although the trend was in that direction.[142] Given these data,[52,139–142] it would seem that the overwhelming consensus in favor of tight glycemic control for the prevention of macrovascular complications,[143] like that for neurovascular complications,[139] is stronger than the evidence to support it. However, these trials antedated T2DM drugs that do not cause hypoglycemia, such as GLP1 receptor agonists and sodium-glucose cotransporter 2 inhibitors, and newer technologies, including CGM, which undoubtedly will reduce the risk of intensive glycemic therapy in patients who can use them.

Clearly, one should strive to balance benefits and harms in the selection of a glycemic goal for a person with diabetes. Many persons with diabetes—those with HAAF, a history of severe hypoglycemia, chronic kidney disease, a long duration of diabetes, or malnutrition—are at risk of harm from iatrogenic hypoglycemia. Those with chronic vascular complications, serious comorbidities, or a short life expectancy have little likelihood of benefit. In both of these groups, a less stringent glycemic goal is indicated,[144] perhaps an HbA_{1c} less than 8.5% (69 mmol/mol).[145]

Finally, because the glycemic management of diabetes is empiric, caregivers should work with each patient to find the most effective and safest regimen at a given point in the course of that patient's diabetes.

Consider the Conventional Risk Factors

The conventional risk factors are those that result in relative, as well as absolute, insulin excess (see Table 38.6). In addition to insulin secretagogue doses, timing, and type, they include conditions in which exogenous glucose delivery or endogenous glucose production is decreased, glucose utilization or sensitivity to insulin is increased, or insulin clearance is decreased.

Consider the Risk Factors for HAAF

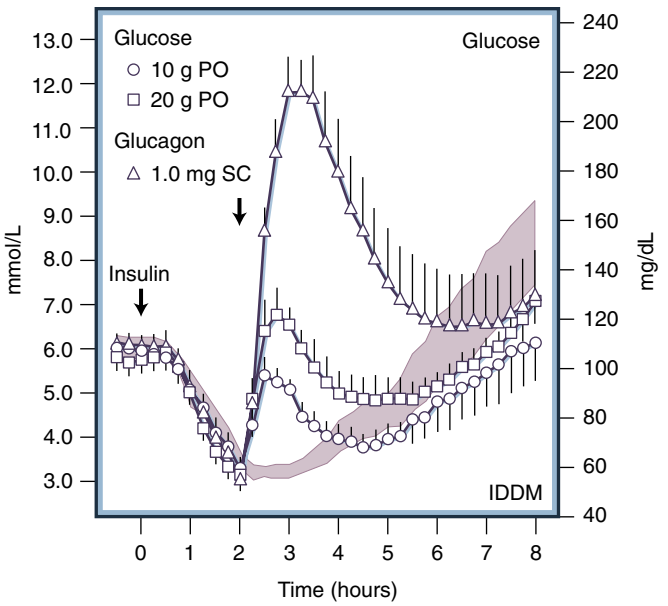
The risk factors indicative of HAAF (see Table 38.6) include the degree of endogenous insulin deficiency; a history of severe hypoglycemia, impaired awareness of hypoglycemia, or both, and recent antecedent hypoglycemia, prior exercise, or sleep; and aggressive glycemic therapy per se. An episode of severe hypoglycemia is a clinical red flag. Unless the cause is easily explainable, it should prompt consideration of a fundamental change in the therapeutic regimen. Without such a change, the risk of a subsequent episode of severe hypoglycemia is high.[105–107] In a patient with impaired awareness of hypoglycemia, patient reeducation[115–117] and a 2- to 3-week period of scrupulous avoidance of hypoglycemia is advisable and can be expected to restore awareness.[85–88] This approach usually requires somewhat higher glycemic goals in the short term. A history of late postexercise hypoglycemia, nocturnal hypoglycemia, or both should prompt appropriately timed regimen adjustments to provide more carbohydrate intake, less insulin action, or both.

Treatment of Hypoglycemia in Diabetes

Most episodes of symptomatic hypoglycemia or of asymptomatic hypoglycemia detected by self-monitoring or CGM are effectively self-treated by ingestion of glucose tablets or carbohydrates.[1] A reasonable dose is 20 g of glucose.[1] A meta-analysis indicated that glucose tablets result in a higher rate of relief of symptomatic hypoglycemia than dietary sugar.[146] Clinical improvement should occur in 15 to 20 minutes. The temptation to overtreat is understandable but should be avoided. With ongoing hyperinsulinemia, the glycemic response to oral glucose is transient, typically lasting less than 2 hours (Fig. 38.12). Therefore, ingestion of a snack or meal shortly after the glucose level is raised is usually advisable.

In a patient who is unable or unwilling (because of neuroglycopenia) to take carbohydrate orally, parenteral therapy is necessary. Glucagon, in a dose of 1.0 mg in adults, can be injected subcutaneously or intramuscularly by an associate of the patient. Administration of glucagon can be lifesaving, but it often causes substantial, albeit transient, hyperglycemia (see Fig. 38.12), and it can cause nausea and even vomiting. Smaller doses of glucagon (e.g., 150 µg), repeated if necessary, have been found to be effective without side effects.[147] For the prompt treatment of episodes of severe iatrogenic hypoglycemia and particularly for infusion, with insulin, in a bihormonal artificial pancreas, a glucagon analogue that is stable in solution and that retains the rapid plasma glucose–raising action has been developed. That preparation[147] and a nasal glucagon preparation[148] represent major improvement for the treatment of hypoglycemia with glucagon because they simplify treatment.

Because it acts by stimulating glycogenolysis, glucagon is ineffective in glycogen-depleted individuals (e.g., after a binge of alcohol ingestion). Although it is not an issue in T1DM or advanced T2DM, glucagon stimulates insulin secretion. Indeed, glucagon has been reported to cause hypoglycemia in nondiabetic individuals (see later discussion). Glucagon can be administered intravenously by medical personnel; however, in that setting, intravenous



• **Fig. 38.12** Mean (± standard error) plasma glucose concentrations during hypoglycemia produced by subcutaneous insulin injection in people with type 1 diabetes mellitus in response to 10 g (*circles*) or 20 g (*squares*) of oral (PO) glucose or 1.0 mg of subcutaneous (SC) glucagon (*triangles*) compared with placebo (*shaded area*). *IDDM,* insulin-dependent diabetes mellitus. (From Wiethop BV, Cryer PE. Alanine and terbutaline in treatment of hypoglycemia in IDDM. *Diabetes Care*. 1993;16:1131–1136, used with permission of the American Diabetes Association.)

(IV) glucose (dextrose) is the standard parenteral therapy. A common initial dose is 25 g, but lower doses are generally advisable to avoid posthypoglycemic hyperglycemia.[13]

The glycemic response to IV glucose is, of course, transient in the setting of ongoing hyperinsulinemia. Therefore, IV glucose administration often needs to be followed by glucose infusion and, once it is practical, by carbohydrate feeding.

The duration of an episode of severe hypoglycemia is a function of its cause. An episode caused by a rapid-acting insulin secretagogue or insulin analogue will be relatively brief. That caused by a long-acting insulin secretagogue or insulin analogue can result in prolonged hypoglycemia requiring hospitalization.

Finally, research on the development of glucose-responsive insulin formulations that would not cause hypoglycemia continues.[149]

Hypoglycemia in Persons Without Diabetes

The Decision to Evaluate for Hypoglycemia

Although hypoglycemia is common in persons with diabetes,[1] it is a distinctly uncommon clinical event in persons who do not have diabetes[2,150] because of the effectiveness of the normal physiologic and behavioral defenses against falling plasma glucose concentrations. Therefore, in the absence of diabetes, a thorough evaluation for hypoglycemia is recommended only for patients in whom Whipple triad (see Table 38.1) can be documented. In the absence of such documentation, evaluation for hypoglycemia may expose the patient to unnecessary evaluation, costs, and potential harm without expectation of benefit.[2]

Plasma glucose concentrations used to document Whipple triad must be measured with a reliable laboratory method and not with a blood glucose self-monitor. A reliably measured low plasma glucose concentration obtained in the absence of recognized

symptoms or signs should not be ignored. However, such a finding raises the possibility of "pseudohypoglycemia," an artifact of continued glucose metabolism by the formed elements of the blood after the blood sample is drawn.[2] This may occur if the sample is collected in a container that does not include an inhibitor of glycolysis, such as sodium fluoride or ethylenediaminetetraacetic acid-citrate (EDTA), and separation of the plasma or serum from the formed elements is delayed, particularly in the setting of erythrocytosis, leukocytosis, or thrombocytosis.

Venous sampling is standard in the clinical setting, but it is the arterial plasma glucose concentration that fuels the brain. Arteriovenous plasma glucose concentration differences are negligible in the postabsorptive state, but antecubital venous glucose levels are as much as one third lower than arterial glucose levels when insulin secretion is increased (e.g., after an oral glucose load) stimulating glucose extraction across the forearm.[151] Because of the provision of alternative fuels (specifically ketones) to the brain, plasma glucose concentrations lower than the overnight fasted physiologic range occur in healthy individuals, especially women and children, during extended fasting.[3] Finally, the glycemic thresholds of responses to hypoglycemia shift to lower plasma glucose concentrations in patients with recurrent hypoglycemia.[21,22] For all of these reasons, it is important to document Whipple triad before concluding that a hypoglycemic disorder exists in a person without diabetes.[2] However, a reliably measured, unequivocally normal plasma glucose concentration (e.g., >70 mg/dL [3.9 mmol/L]) during a symptomatic episode provides strong evidence that the symptoms were not the result of hypoglycemia.[2]

Clinical Classification of Hypoglycemic Disorders

The traditional classification of hypoglycemic disorders in nondiabetic persons, as either postabsorptive (fasting) or postprandial (reactive) hypoglycemias, has been supplanted by a clinical categorization. This distinguishes a patient who has a relevant disease or treatment from a patient who is otherwise seemingly well[2,152] (see Table 38.4). The presence of postprandial symptoms without Whipple triad (see Table 38.1), previously called *reactive hypoglycemia*, is now considered a functional disorder in which symptoms are not due to hypoglycemia and for which an oral glucose tolerance test is not indicated.[2]

Ill or Medicated Individual

Drugs are the most common cause of hypoglycemia.[153–159] In addition to insulin secretagogues and insulin (discussed earlier), offending drugs include alcohol, among many others[154–158] (Table 38.8). Drugs, often in the setting of critical illnesses including renal failure, are the most common cause of hypoglycemia in hospitals.[153] Again, insulin or insulin secretagogues are common offending drugs,[153,160] particularly if they are administered when enteral or parenteral nutrition is interrupted.

Ethanol inhibits gluconeogenesis. Clinical alcohol-induced hypoglycemia typically follows a binge of alcohol consumption during which the person eats little food (i.e., in the setting of glycogen depletion).[155] Alcohol-induced hypoglycemia can be fatal, but with restoration of euglycemia and supportive care, recovery is the rule. Ethanol is usually measurable in blood at the time of presentation.

Hypoglycemia sometimes occurs in patients with critical illnesses[2] (see Table 38.4). Hepatogenous hypoglycemia occurs most commonly when destruction of the liver is rapid and massive (e.g., in toxic hepatitis). It is unusual in common forms of cirrhosis or hepatitis, although glucose metabolism is measurably altered in uncomplicated viral hepatitis.[161] Hypoglycemia is also unusual in metastatic liver disease despite extensive hepatic replacement.[162] The pathogenesis of hypoglycemia in some patients with renal failure is unknown and likely multifactorial; it has been attributed to drugs, sepsis, or inanition.[153,163–165] Reduced renal clearance of insulin and reduced renal glucose production might be relevant factors. However, renal transplantation did not correct hypoglycemia in patients with glucose-6-phosphatase deficiency.[166]

The pathogenesis of the hypoglycemia occasionally seen in patients with severe cardiac failure is also not understood. The finding of elevated blood lactate levels associated with hypoglycemia[167] raises the possibility of inhibited gluconeogenesis. Sepsis is a relatively common cause of hypoglycemia.[153,154,168] Increased glucose utilization (by skeletal muscle and by macrophage-rich tissues, e.g., liver, spleen, and lung), which is thought to be cytokine mediated and is matched initially by increased glucose production, characterizes experimental sepsis.[169–171] The later decline in glucose production, which in the setting of persistently high glucose utilization results in hypoglycemia, is not the result of glucose counterregulatory failure; rather, it is caused by decreased responsiveness to appropriate glucose counterregulatory signals (i.e., low insulin and high glucagon and epinephrine levels).[172]

TABLE 38.8 Drugs, Other Than Antihyperglycemic Agents and Alcohol, Reported to Cause Hypoglycemia

Moderate Quality of Evidence

Cibenzoline
Gatifloxacin
Pentamidine
Quinine
Indomethacin
Glucagon (during endoscopy)

Low Quality of Evidence

Chloroquinoxaline sulfonamide
Artesunate/artemisinin/artemether
Insulin-like growth factor type 1
Lithium
Propoxyphene/dextropropoxyphene

Very Low Quality of Evidence

>25 Cases Identified

Angiotensin-converting enzyme inhibitors
Angiotensin receptor antagonists
β-Adrenergic receptor antagonists
Levofloxacin
Mifepristone
Disopyramide
Trimethoprim-sulfamethoxazole
Heparin
6-Mercaptopurine

<25 Cases Identified

From Cryer PE, Axelrod L, Grossman AB, et al. Evaluation and management of adult hypoglycemic disorders: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2009;94:709–728; based on Murad MH, Coto-Yglesias F, Wang AT, et al. Drug-induced hypoglycemia: a systematic review. *J Clin Endocrinol Metab.* 2009;94:741–745, with permission of the Endocrine Society.

Hypoglycemia can be caused by inanition.[173] A plausible suggestion is that glucose becomes the sole oxidative fuel in the setting of total body fat depletion, and the resulting high rates of glucose utilization exceed the capacity to produce glucose because of a limited supply of gluconeogenic precursors (e.g., amino acids). Postabsorptive hypoglycemia (with low circulating alanine concentrations) has been reported in patients with profound muscle atrophy[174,175]; hypoglycemia is presumably the result of substrate limitation of gluconeogenesis in such patients.

With the notable exception of HAAF in patients with T1DM and advanced T2DM (discussed earlier), hormone deficiencies resulting in hypoglycemia are not common. Postabsorptive hypoglycemia, typically after a period of caloric deprivation caused by an intercurrent illness, can occur in patients with deficient secretion of cortisol, growth hormone, or both, particularly infants and young children.[176–178] Glycemic intolerance of fasting is largely corrected by glucocorticoid replacement; growth hormone replacement has a lesser effect.[177,178] Because cortisol normally supports gluconeogenesis by increasing gluconeogenic enzyme activities and mobilizing gluconeogenic precursors,[177,179] the hypoglycemic mechanism is thought to be reduced glucose production in the setting of glycogen deficiency. Nonetheless, most adults with deficiencies of these hormones do not experience hypoglycemia. Indeed, plasma glucose concentrations and rates of endogenous glucose production after overnight fasting have been reported to be indistinguishable from normal values in short-term glucocorticoid-withdrawn patients with hypopituitarism never treated with growth hormone.[180] Hypoglycemia has been reported in adrenocorticotropic hormone–deficient adults when glucose utilization or loss was increased (as during exercise or pregnancy, respectively)[181] or when glucose production is impaired (as after alcohol ingestion).[182]

Non–islet cell tumor hypoglycemia (NICTH) is rare. The tumors are usually, but not invariably, large, clinically apparent, and mesenchymal in origin. NICTH is often the result of overproduction of incompletely processed pro–insulin-like growth factor 2 (pro-IGF2),[183–186] but hypoglycemia attributed to overproduction of insulin-like growth factor 1 (IGF1) has also been reported.[187] The pro-IGF2 binds poorly to its binding proteins and therefore more freely enters tissue spaces, where its insulin-like actions cause hypoglycemia. Concentrations of plasma free IGF2 (or IGF1[187]) are elevated.[184] Because of suppression of growth hormone secretion and the resulting low IGF1 levels, the ratio of plasma IGF2 to IGF1 is elevated in pro-IGF2–mediated hypoglycemia. Plasma total IGF2 levels may be within the normal range, but the ratio of pro-IGF2 to IGF2 may be elevated.[185] Endogenous insulin secretion is suppressed appropriately during hypoglycemia in NICTH. Treatment of the tumor is seldom curative but may alleviate hypoglycemia. Treatment with a glucocorticoid, growth hormone, or both is sometimes effective.

Seemingly Well Individual

In seemingly well individuals with no evidence of drug, critical illness, hormone deficiency, or non–islet cell tumor as a cause of their hypoglycemia, the differential diagnosis narrows to two categories: (1) accidental, surreptitious, or even malicious hypoglycemia and (2) endogenous hyperinsulinism[2,150,152,188–190] (see Table 38.4). Consideration of the former possibility should precede a systematic assessment of the latter. Medical, pharmacy, and hospital errors can result in hypoglycemia and do occur. Surreptitious hypoglycemia[188–192] is more common in people with knowledge of, and access to, glucose-lowering medications. Malicious hypoglycemia[188,189] can be accomplished by administration of an insulin secretagogue or insulin.

Insulinomas (insulin-secreting pancreatic beta-cell tumors) are the prototypical, but not the only, cause of endogenous hyperinsulinemic hypoglycemia.[2,150,193–197] Patients with an insulinoma typically present with a history of episodes of neuroglycopenia occurring in the postabsorptive (fasting) state. However, an appreciable subset of patients (6% in one series[193]) report symptoms exclusively in the postprandial state. Insulinomas are rare; an incidence of 1 in 250,000 patient-years has been reported. Less than 10% of the patients have malignant insulinomas, multiple insulinomas, or multiple endocrine neoplasia type 1 (MEN1) syndrome.[197] Long-term survival is the rule after successful surgical removal of an insulinoma.[197]

Some patients (4% of one series[197]) with fasting endogenous hyperinsulinemic hypoglycemia do not have an insulinoma but have diffuse islet involvement with islet hypertrophy, sometimes with hyperplasia, and enlarged and hyperchromatic beta-cell nuclei. This condition is often termed *nesidioblastosis*, although the histologic finding of islets budding from pancreatic ducts is not invariably present. Such patients are clinically indistinguishable from those with an insulinoma.[198–202] Other patients have noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS)[202–205] or post–gastric bypass hypoglycemia.[206–216]

NIPHS[202–205] is characterized by spells of neuroglycopenia caused by endogenous hyperinsulinemic hypoglycemia occurring typically, but not invariably, after a meal. NIPHS is less common than insulinoma.[2,150] Because the syndrome is diffuse, anatomic tumor imaging studies are uniformly negative. Given documented postprandial hyperinsulinemic hypoglycemia, documentation of diffuse beta-cell hyperfunction depends on a positive selective arterial calcium stimulation test. The findings from that test can be used to guide partial pancreatectomy if empiric medical therapy (e.g., diet, an α-glucosidase inhibitor, diazoxide, octreotide) fails. In one relatively large surgical series, most patients improved; however, recurrence of symptoms was the rule, and some patients were not helped after partial pancreatectomy.[204]

Some patients who have undergone Roux-en-Y gastric bypass develop postprandial endogenous hyperinsulinemic hypoglycemia several months to years after the surgery.[206–214,217,218] Affected patients have accelerated absorption of ingested glucose that triggers a large insulin secretory response that is mediated, at least in part, by a robust increase in GLP1.[209–213] Post–gastric bypass hypoglycemia is rare, reported to occur in 0.2% of operated patients.[214] GLP1 receptor blockade has reported to eliminate hypoglycemia,[215] although this remains experimental. Suggested treatments include a low-carbohydrate diet, acarbose, somatostatin analogues, diazoxide, and possibly feeding into the bypassed stomach.[208]

Autoimmune hypoglycemia caused by an antibody to insulin is rare.[216,219] Affected individuals often have a history of other autoimmune disorders. Hypoglycemia occurs in the late postprandial period as insulin, which is secreted in response to the meal and then bound to the circulating antibody, dissociates from the antibody in an unregulated fashion. A clue to the diagnosis is the finding of very high measured plasma insulin levels during hypoglycemia. The diagnosis is made by the finding of high-titer serum insulin antibodies. There is no consistently effective therapy. A similar disorder has been reported in patients with a high-capacity insulin-binding monoclonal paraprotein.[220]

Accidental or surreptitious ingestion of an insulin secretagogue causes endogenous hyperinsulinemic hypoglycemia indistinguishable from that caused by an insulinoma aside from the presence

of a measurable oral hypoglycemic agent in the circulation at the time of hypoglycemia.[2,150]

Very rare causes of insulin-related hypoglycemia have been linked to a mutation of the insulin receptor,[221] to exercise-induced hyperinsulinemia,[222] or to an agonist antibody to the insulin receptor.[223] In the latter case, endogenous insulin secretion is suppressed appropriately, and inappropriately high insulin levels are thought to result from blockade of receptor-mediated insulin clearance by the antibody. Finally, although seemingly convincing cases of ectopic insulin secretion have been reported (e.g., by Seckl and colleagues[224]), the condition must be extraordinarily rare.

Diagnostic Approach

Patients with a hypoglycemic disorder may present in several different ways, including with a history of symptomatic episodes compatible with hypoglycemia, a serendipitously measured low plasma glucose concentration, or a familial syndrome that includes a hypoglycemic disorder (e.g., MEN1).[2,152,188] A careful history of any spells—including the specific symptoms, their timing in relation to meals, their duration, and any factors that aggravate or alleviate them—is important for the formulation of a diagnostic plan. A history that includes neuroglycopenia is particularly compelling.[2] Again, documentation of Whipple triad establishes that a hypoglycemic disorder exists.[2] The diagnostic strategy recommended in the Endocrine Society clinical practice guideline[2] is described here.

First, review the history, physical findings, and all available laboratory data, seeking clues to specific disorders such as drugs, critical illnesses, hormone deficiencies, or non–islet cell tumors (see Table 38.4), then pursue those.[2] This approach will identify the cause of hypoglycemia in most instances. Again, drugs[2] are, by far, the most common cause of hypoglycemia (see Table 38.8).

If the cause of a hypoglycemic disorder is not evident (i.e., in a seemingly healthy individual), measure plasma glucose, insulin, C-peptide, proinsulin, and β-hydroxybutyrate concentrations and screen for oral hypoglycemic agents during an episode of spontaneous hypoglycemia, and observe the plasma glucose response to IV injection of 1.0 mg of glucagon.[2] In addition, measure insulin antibodies.[2]

Failure of insulin secretion to fall to very low rates as plasma glucose concentrations fall to hypoglycemic levels is the key pathophysiologic feature of endogenous hyperinsulinism. Hypoglycemia is the result of low rates of glucose production rather than high rates of glucose utilization.[225] Plasma insulin, C-peptide, and proinsulin concentrations may not always be high relative to normal values obtained under euglycemic conditions, but they are essentially always inappropriately high relative to the low plasma glucose concentrations.[2,152,188] The traditional critical diagnostic criteria (assuming Whipple triad is documented) are plasma insulin concentrations of 3 μU/mL (18 pmol/L) or higher, plasma C-peptide concentrations of 0.6 ng/mL (0.2 nmol/L) or higher, and plasma proinsulin concentrations of 5.0 pmol/L or higher when plasma glucose concentrations are less than 55 mg/dL (3.0 mmol/L) (Table 38.9). These data, first published in 1995,[152] reassessed in 2009,[193,196] and incorporated into the Endocrine Society clinical practice guideline on adult hypoglycemic disorders,[2] were independently reassessed in 2013.[196] Notably, however, the extent to which the unaffected subjects in the latter study had low plasma glucose concentrations at the time of insulin, C-peptide, and proinsulin sampling is not made clear.[196] The insulin criterion of 18 pmol/L (3 μU/mL) or higher was generally supported: 93% sensitivity with 95% to 100% specificity[193] and 98% sensitivity with 60% specificity.[196] The C-peptide criterion of 0.6 ng/mL (0.2 nmol/L) or higher was not supported: sensitivity at 100% or lower with specificity of 60% to 78%[193] versus sensitivity at

TABLE 38.9 Patterns of Findings During Fasting or After a Mixed Meal in Normal Individuals[a] and in Individuals With Hyperinsulinemic (or IGF-Mediated) Hypoglycemia or Hypoglycemia Caused by Other Mechanisms

Symptoms, Signs, or Both	Glucose (mg/dL)	Insulin (μU/mL)	C-Peptide (nmol/L)	Proinsulin (pmol/L)	β-Hydroxybutyrate (mmol/L)	Glucose Increase After Glucagon (mg/dL)	Circulating Oral Hypoglycemic Agent	Antibody to Insulin	Diagnostic Interpretation

Evaluation and management of adult hypoglycemic disorders: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2009;94:709–728, used with permission of the Endocrine Society. Data from Service[152] and Placzkowski and associates.[193] See discussion of Guettier and associates[196] for independent data.

100% but specificity only 10%[196]; raising the criterion to 2.3 ng/mL (0.8 nmol/L) or higher lowered sensitivity to 84% but raised specificity to 76%.[196] The proinsulin criterion of 5 pmol/L or higher provided 100% sensitivity in both series but with specificity of 68% to 78%[193] and 41%[196]; raising the criterion to 27 pmol/L or higher still provided 100% sensitivity but with 100% specificity.[196] Plasma β-hydroxybutyrate concentrations of 2.7 mmol/L or lower and an increase in the plasma glucose concentration of more than 25 mg/dL (1.4 mmol/L) over the low value over 30 minutes after glucagon injection provide evidence of biologic actions of inappropriately high insulin (or IGF) levels, with suppression of lipolysis and ketogenesis and preservation of hepatic glycogen stores, respectively. The patterns of findings in patients with a hypoglycemic disorder and in those with hyperinsulinemic (or IGF-mediated) hypoglycemia are summarized in Table 38.9. Occasionally, a patient with an insulinoma may not fulfill these criteria even during a 72-hour fast,[2,226] and a few have plasma insulin levels lower than 3 μU/mL (18 pmol/L) during hypoglycemia; however, at least in some series,[227] plasma C-peptide and proinsulin levels are elevated in such patients.

If Whipple triad has not been documented and the measurements described have not been obtained during an episode of spontaneous hypoglycemia, an attempt should be made to re-create the circumstances in which symptomatic hypoglycemia is likely to occur.[2] This can be accomplished by withholding food in a patient with a history suggestive of fasting hypoglycemia or by providing a mixed meal likely to cause a symptomatic episode in a patient with a history suggestive of postprandial hypoglycemia. Failing these relatively informal procedures, a patient with a history suggestive of fasting hypoglycemia should undergo a prolonged supervised fast.[2,226] The fast should be continued until Whipple triad is documented (or until a plasma glucose concentration of less than 55 mg/dL [<3.0 mmol/L] is reached if Whipple triad was unequivocally documented previously[226]) unless a progressive increase in plasma β-hydroxybutyrate levels signals a negative fast. Serial plasma glucose concentrations should be measured with a precise method, not with a point-of-care glucose monitor. About two thirds of patients with an insulinoma meet the diagnostic criteria during a fast of less than 24 hours; most, but not all, do so in less than 48 hours.[226] Therefore, the diagnostic fast can be initiated, and often completed, in the outpatient setting and continued in the inpatient setting if necessary. However, a patient with a history suggestive of postprandial hypoglycemia should undergo a mixed meal test conducted over 5 hours. Standards for interpretation of the findings of the mixed meal test have not been established; current usage[2] is to apply the criteria developed under fasting conditions.[152] Detailed suggestions for performance of a prolonged supervised fast and of a mixed meal test have been published.[2]

An insulinoma may well be present in a patient with documented Whipple triad; inappropriately high levels of insulin, C-peptide, and proinsulin along with no detectable circulating oral hypoglycemic agent; suppressed β-hydroxybutyrate levels; a brisk glycemic response to IV glucagon during fasting (or even postprandial[193]) hypoglycemia; and no circulating insulin antibody. However, as noted earlier, there are other causes of hyperinsulinemic hypoglycemia (see Tables 38.4 and 38.9). Therefore, the next step is to attempt to localize an insulinoma.[2]

Computed tomography, magnetic resonance imaging, and transabdominal ultrasonography detect approximately 75% of insulinomas.[193,228,229] They also detect metastases in the minority of patients who have a malignant insulinoma. Older somatostatin receptor scintigraphy is somewhat less sensitive.[230] Endoscopic pancreatic ultrasonography, with the option of fine-needle aspiration of a detected tumor, has a sensitivity greater than 90%.[230,231] With the combination of noninvasive imaging and, if necessary, endoscopic pancreatic ultrasonography, preoperative localization of insulinomas has become the rule.[193] Given the promise of positron emission tomography with radiotracers such as ^{68}Gallium DOTA-(Tyr3)-octreotate,[232] noninvasive localization of insulinomas may become the preferred approach. If anatomic localization of insulinoma is negative or equivocal, selective pancreatic arterial calcium injections, with an end point of at least a twofold[232,233] increase (or perhaps a greater than fivefold increase with contemporary assays[234]) in hepatic venous insulin levels over baseline, regionalize insulinomas with high sensitivity.[233,235] Although this invasive procedure is seldom necessary in patients with an insulinoma, it is the procedure of choice for confirming NIPHS[216,219] and hypoglycemia occurring after Roux-en-Y gastric bypass[206–214] (Table 38.10). Finally, intraoperative pancreatic ultrasonography almost invariably localizes tumors that are not apparent even to the experienced pancreatic surgeon.

TABLE 38.10 Causes of Hypoglycemia Unique to, or Typically With Onset in, Infancy and Childhood

Intolerance of Fasting

Preterm or small-for-gestational-age infants
Hypopituitarism, adrenal hypoplasia, congenital adrenal hyperplasia
Ketotic hypoglycemia of childhood

Hyperinsulinism

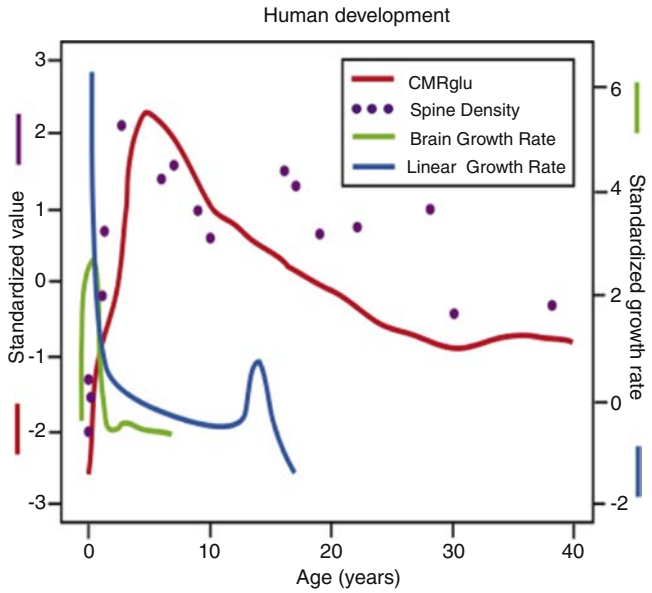
Infant of a diabetic mother
Maternal drugs (sulfonylurea, β_2-adrenergic agonist)
Congenital hyperinsulinism
Perinatal stress, small for gestational age
Others: Rh incompatibility, Beckwith-Wiedemann syndrome, exchange transfusions, perinatal stress, insulin-secreting tumors of pancreatic islet cells (insulinomas)

Inborn Errors of Metabolism (Enzyme Defects)

Carbohydrate metabolism: Glycogen storage disease types I, III, and VI; glycogen synthase deficiency; fructose-1,6-bisphosphatase deficiency; fructose-1-phosphate aldolase deficiency; galactose-1-phosphate uridyltransferase deficiency
Protein metabolism: Branched-chain α-keto acid dehydrogenase complex deficiency
Fat metabolism: Fatty acid oxidation defects including deficiencies in the carnitine cycle, the β-oxidation spiral, the electron transport system, and the ketogenesis sequence

Treatment of Hypoglycemia Disorders

Prevention of ongoing or recurrent hypoglycemia requires treatment that corrects or circumvents the hypoglycemic mechanism.[2] Obviously, treatment should be tailored to the specific hypoglycemic disorder identified. Offending drugs can be discontinued or their dosage reduced. Critical illnesses can often be treated. Deficient hormones, such as cortisol, can be replaced. Reduction of non–islet cell tumor mass with surgery, irradiation, or chemotherapy may alleviate hypoglycemia even if the tumor cannot be cured. Treatment with a glucocorticoid, growth hormone, or even octreotide may alleviate hypoglycemia in such patients. Surgical resection of a benign insulinoma typically is curative.



• **Fig. 38.13** Brain (*green*) and linear (*blue*) growth rates, dendritic spine density (*purple*), and cerebral metabolic rate of glucose (*red*) values across the life span during human development. *CMRglu*, cerebral metabolic rate of glucose. (Data from Goyal MS, Venkatesh S, Milbrandt J, et al. Feeding the brain and nurturing the mind: linking nutrition and the gut microbiota to brain development. *Proc Natl Acad Sci U S A.* 2015;112[46]:14105–14112.)

In unresectable disease, empirical treatments (diet, diazoxide, octreotide) can be tried; there has been progress with chemotherapy (e.g., everolimus).[236] Diet, including frequent feedings, an α-glucosidase inhibitor, diazoxide, or octreotide, can be tried in patients with NIPHS or post–gastric bypass hypoglycemia. Treatment of autoimmune hypoglycemia (with a glucocorticoid or another immunosuppressive medication) is problematic, but the disorder is sometimes self-limited. Failing these treatments, frequent feedings during the day and bedtime administration of large doses of uncooked cornstarch or even overnight intragastric glucose infusion may be necessary. Interestingly, a missense MAFA mutation leading to familial insulinomas or diabetes mellitus has been identified in two families.[237]

Hypoglycemia in Infancy and Childhood

The fetus receives a continuous supply of glucose from the maternal circulation across the placenta to meet a substantial proportion of its energy needs, and its glucose levels are mostly reflective of the maternal glycemic level. Hepatic glucose production and gluconeogenesis are absent during fetal life, due to the absence or very low activity of pyruvate carboxylase, phosphoenolpyruvate carboxykinase, glucose-6-phosphatase, and fructose 1,6 diphosphatase.[238] These rate-limiting enzymes of gluconeogenesis rapidly increase within the first few hours of life. Even though the enzymes needed for glycogen synthesis and glycogenolysis are present in the fetal liver, hepatic glycogen stores do not increase much until the third trimester, accounting for about 5% of the total liver weight at birth.[239]

Plasma glucose concentrations decline after birth as placental blood flow is interrupted, and they reach their nadir usually in the first 2 hours of life.[240] This is accompanied by a decrease in insulin and activation of glucose counterregulatory systems that favors not only mobilization of glycogen stores and gluconeogenesis but also lipolysis and eventually ketogenesis in the neonate. Because mobilizable glycogen stores are limited and quickly depleted, and feeding is intermittent, the newborn is forced to increase its endogenous glucose production and thus become largely dependent on gluconeogenesis initially. In most infants, the plasma glucose concentration is usually steady or is increasing by 4 to 6 hours of life. As feedings are spaced and the fasting period is prolonged, lipolysis and ketogenesis increase and ketones become a significant fuel source, particularly for the brain.

The brain relies almost exclusively on a constant supply of glucose to meet its metabolic demands and fuel brain growth and key maturational changes. The brain cannot do gluconeogenesis or use free fatty acids, because they are not transported across the blood-brain barrier. However, under special circumstances, it can use ketone bodies (beta-hydroxybutyric acid and acetoacetic acid) or lactate as transient surrogate fuels if levels rise significantly enough. In the first years of life, the human brain accounts for nearly 50% of the body's glucose consumption due to the proportionally larger brain to body mass ratio,[238,241] with the peak of cerebral glucose consumption occurring during middle childhood (~5–10 years of age).[242] Likewise, this metabolic peak is mirrored by increases in synaptic density and synaptic pruning, which occurs well beyond the periods of greatest linear brain growth and differs across brain regions[243] (Fig. 38.13). The rate of total-body and brain glucose metabolism then falls to normal adult rates. Overall, the rates of glucose flux (production and utilization) are nearly three times higher in infants and children than in adults. Throughout the lifespan, this glucose flux is finely regulated to maintain euglycemia by insulin, counterregulatory hormones (glucagon, catecholamines, cortisol, and growth hormone), incretins, other gut hormones (ghrelin and leptin), and neuronal inputs.[244] However, transient or persistent hypoglycemia may occur when glucose supplies are low and ketone body production is small or impaired, as in children with hyperinsulinism

or inborn errors of metabolism, or when there is impairment of the glucoregulatory mechanisms.[245,246] Hypoglycemia, if severe, may cause neurologic compromise or death. The extent of brain injury seems to be influenced by multiple factors, such as duration and degree of hypoglycemia.

It is key to recognize that transient low blood glucose concentrations are common in healthy infants in the first 24 to 48 hours of life as the glucose supply changes from a continuous transplacental supply to an intermittent supply from feeds, resulting in a quick depletion of the glycogen stores. Furthermore, newborns in these first hours of life are relatively hyperinsulinemic compared with older children due to a lower glycemic threshold for insulin secretion shortly after birth—55 to 65 mg/dL (3.0–3.6 mmol/L) compared with 80 to 85 mg/dL (4.4–4.7 mmol/L) in older infants, children, and adults.[247] Therefore, if the first feedings after birth are delayed, a considerable amount of normal term newborns cannot maintain a plasma glucose concentration above 40 mg/dL (2.2 mmol/L).[240] But as feeds are established, maintenance of plasma glucose concentrations is no longer primarily dependent on gluconeogenesis, and hypoglycemia becomes less common. Thus, it is important to distinguish this normal physiologic transitional response from disorders that result in persistent or recurrent hypoglycemia beyond the first 3 days of life. Because of potential difficulty in distinguishing a persistent hypoglycemia disorder from transitional neonatal glucose concentrations during the first 48 hours of life, the Pediatric Endocrine Society suggests delaying diagnostic evaluations for hypoglycemia until 2 to 3 days after birth. However, in infants who are at risk for hypoglycemia, glucose screening should be performed after the first feed, which should occur within 1 hour after birth. Plasma glucose concentrations should continue to be measured every 3 to 6 hours before feeds for the first 24 to 48 hours of life, because many at-risk newborns present with their first documented low glucose concentrations during this period.[247]

As in adults,[2] the diagnosis of clinical hypoglycemia should be considered in pediatric patients that have Whipple triad (see Table 38.1). Signs and symptoms of hypoglycemia are quite nonspecific in a neonate or children and may be difficult to recognize. Some of these may include jitteriness/tremors, hypotonia, changes in the level of consciousness, apnea/bradycardia, cyanosis, tachypnea, poor suck or feeding, hypothermia, and/or seizures. In addition, as in adults, it is not possible to state a single low plasma glucose concentration that categorically defines hypoglycemia in infants and children; its precise definition continues to be controversial. This is because (1) normal distributions of glucose values will vary depending on age; (2) glucose values will vary depending on conditions of feeding and fasting; (3) there are potential artifacts that may lead to inaccuracies in glucose determination; (4) the thresholds for specific responses to hypoglycemia can be altered by recent antecedent hypoglycemia; and (5) there is lack of outcome data, as there is not a single glucose value that has been associated with brain injury.[245–247] However, most clinical guidelines postulate arbitrary glucose thresholds to provide guidance on when to initiate a workup to identify children with an underlying disorder and when to initiate an intervention to reduce potential harm from hypoglycemia and minimize possible overtreatment.

The American Academy of Pediatrics in 2011, followed by the Pediatric Endocrine Society in 2015, wrote clinical reports and guidelines on screening and subsequent management of neonatal hypoglycemia.[247,248] Although these guidelines do not coincide on the glycemic thresholds for the diagnosis of hypoglycemia, they both endorse that hypoglycemia persisting beyond 48 hours is not likely to be transitional, and they emphasize the need for early identification of the infant at risk for severe hypoglycemia during the first 48 hours after delivery and for persistent hypoglycemia beyond 48 hours of life to determine the need for screening. These include not only the infant of a diabetic mother or the child with a family history of a genetic form of hypoglycemia or a congenital syndrome associated with hypoglycemia, such as congenital hyperinsulinism, Beckwith-Wiedemann syndrome, or hypopituitarism, but also those with relatively more common perinatal stress hyperinsulinism: birth asphyxia, intrauterine growth restriction, or toxemia, or infants receiving total parenteral nutrition.

The Pediatric Endocrine Society suggests a plasma glucose concentration of 50 mg/dL (2.8 mmol/L) or less as an appropriate threshold to trigger further diagnostic testing in a child less than 48 hours old and 60 mg/dL (3.3 mmol/L) or less after 48 hours of age.[247] Nevertheless, many will criticize that it is a relatively conservative threshold, whereas others will say that it may lead to overtreatment of many neonates, but the neonatal threshold is intended to avoid discharging newborns who may be at risk for recurrent and severe hypoglycemia.[247,249] The diagnostic evaluation for neonatal hypoglycemia should include a plasma confirmation of a low blood glucose value and simultaneous measure of carbon dioxide to determine if there is an associated acidosis, insulin level and ketone bodies to determine if there is evidence of hyperinsulinism and measure of the counterregulatory hormones (cortisol for cortisol deficiency and growth hormone for growth hormone deficiency), free fatty acids to see if there is a defect on fatty acid oxidation, and a lactate level. If outside of the newborn period, or if there are concerns for exogenous hyperinsulinism, C-peptide, which is a by-product of the metabolism of insulin, should also be also measured. In the case of a child with hypoglycemia of unknown cause, a glucagon stimulation test at the time of hypoglycemia can provide very useful diagnostic information about glycogen stores and possible hyperinsulinism. In such a test, 0.03 mg/kg of glucagon is given intravenously or by intramuscular injection when the child is hypoglycemic. Plasma glucose levels are measured prior to the injection and 10, 20, and 30 minutes after. If plasma glucose rises by more than 30 mg/dL (1.7 mmol/L) within the first 30 minutes after glucagon administration, it suggests that the child has hyperinsulinemia, because during hyperinsulinism there is inappropriate buildup of hepatic glycogen stores that are released in response to glucagon administration.

If the patient persists in being hypoglycemic or becomes hypoglycemic after obtaining the critical laboratory samples and doing the glucagon stimulation test, it is key to treat the low plasma glucose to prevent adverse outcomes. If the patient is conscious and able to drink and swallow safely, then he or she can be treated with administration of 10 to 20 g of rapidly absorbed carbohydrates by mouth or by a gastric tube, if available. This process may be repeated after 15 minutes, but if the hypoglycemia does not improve within 30 minutes, parenteral glucose is recommended. In infants and children with altered consciousness, IV dextrose should be given. A slow bolus of 2 mL/kg of 10% dextrose solution can be given, followed by a continuous infusion of dextrose at 6 to 9 mg/kg per minute. If IV access is not readily available and the patient has documented hyperinsulinism, then intramuscular glucagon (0.03 mg/kg up to a maximum of 1 mg) should be given.

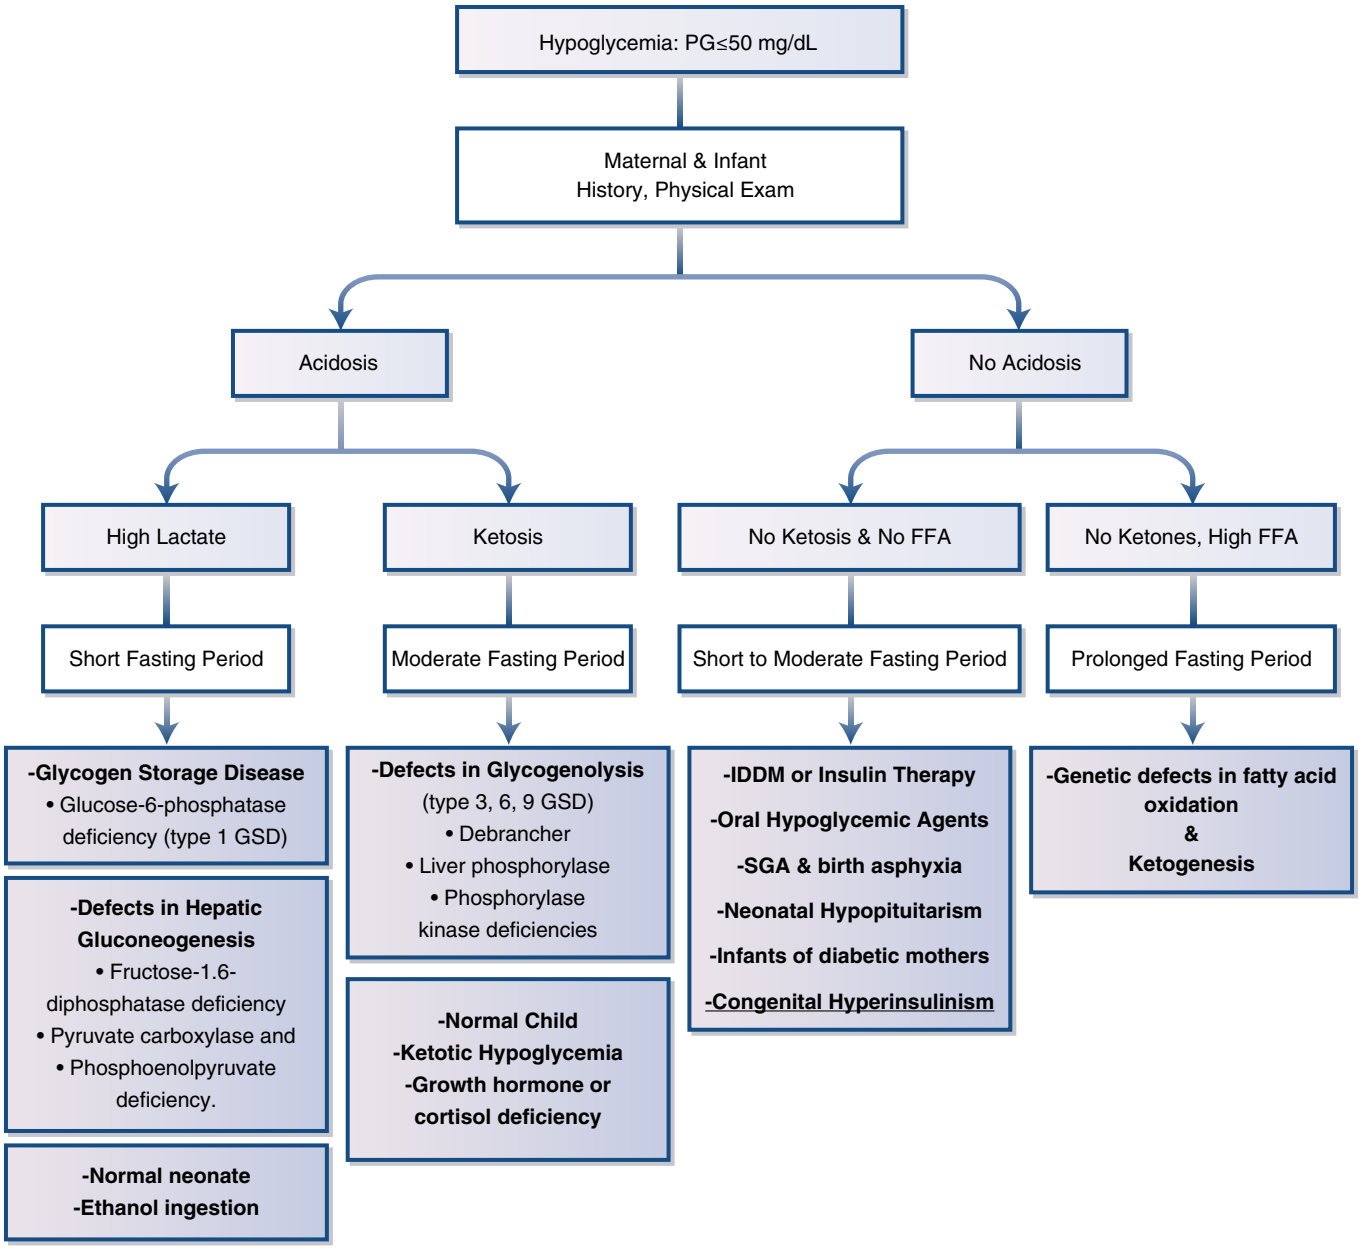
Close monitoring for further evaluation and treatment is needed in children found to have low plasma glucose. In neonates, monitoring should continue until plasma glucose concentrations

can be maintained with regular feedings at above 50 mg/dL (2.8 mmol/L) in newborns less than 48 hours old and above 60 mg/dL (3.3 mmol/L) in newborns more than 48 hours old. However, the mean plasma glucose concentration in the postabsorptive state of children and neonates after 48 hours of age does not differ from that in adults (70–100 mg/dL [3.9–5.5 mmol/L]). Thus, in children with the diagnosis of a disorder causing persistent hypoglycemia or a known risk of a persistent hypoglycemic disorder, the goal of treatment is to maintain a plasma glucose concentration above 70 mg/dL (3.89 mmol/L). Therefore, a safety fast (6-hour fast), in which a term neonate over 3 days of life is asked to skip a single feed, should always be done before discharge to ensure that plasma glucose concentrations can be maintained above that range.

Even though hypoglycemia in children can be caused by the same mechanisms as in adults[2] (see Table 38.4), including drugs and critical illnesses, there are several hypoglycemic disorders unique to infancy or childhood that can be classified as intolerance of fasting, hyperinsulinism, or are due to inborn errors of metabolism[245,246] (see Table 38.10). The presentation of these different conditions may vary, as well as the age of onset and the tolerance of the fasting period (Fig. 38.14). Thus, a good clinical history, physical examination, and critical laboratory samples are key to determine the diagnosis.

Intolerance of Fasting

Infants and toddlers may have a plasma glucose concentration less than 70 mg/dL (3.9 mmol/L) and hyperketonemia after overnight fasting because of limited fasting tolerance.[250–252] It is particularly common in preterm or small-for-gestational-age infants



• **Fig. 38.14** Diagnostic algorithm for determining the etiology of hypoglycemia in children. *FFA,* free fatty acid; *GSD,* glycogen storage disease; *PG,* plasma glucose. (Modified from Sprague JE, Arbeláez AM. Glucose counterregulatory responses to hypoglycemia. *Pediatr Endocrinol Rev.* 2011;9[1]:463–475.)

and is thought to result partially from incomplete development of gluconeogenic mechanisms.[2] When hypoglycemia occurs, glycogenolysis is the first mechanism that occurs, followed by gluconeogenesis, to try to raise systemic blood sugars. However, if fasting is prolonged or feeding is interrupted, as during an intercurrent illness in children who are least tolerant of fasting, there is lack of increased renal gluconeogenesis, and the endogenous substrate availability from muscles or liver is low[253,254] and ketotic hypoglycemia occurs. The syndrome of ketotic hypoglycemia of childhood typically occurs in 2- to 5-year-old children and remits spontaneously before age 10 years, when the ratio of brain to body weight changes. This should be a diagnosis of exclusion after other conditions that can present with ketosis, such as growth hormone deficiency, hypopituitarism, adrenocorticotropic hormone unresponsiveness, and glycogen synthase deficiency, are ruled out. Cortisol and growth hormone deficiency reduce gluconeogenesis and hepatic glucose production. Moreover, there are low plasma concentrations of gluconeogenic substrate, and there is a blunted glucagon response.[255]

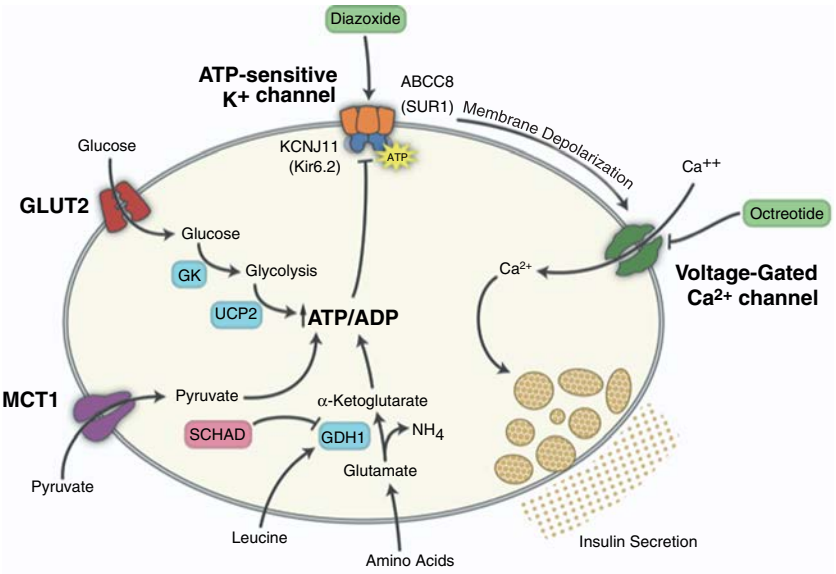
Hyperinsulinism

Hyperinsulinism can be suspected when the plasma insulin concentration is inappropriately normal or elevated for the level of hypoglycemia, and plasma or urine ketones levels, as well as free fatty acids, are low. In addition, this condition should also be suspected when there is a glycemic response to glucagon at the time of hypoglycemia. In the neonatal period, these children are typically large for gestational age, and hypoglycemia occurs after a short to moderate fasting period.

Maternal diabetes is a common cause of neonatal hypoglycemia due to transient hyperinsulinism in the offspring.[246] Infants of diabetic mothers have been hyperglycemic in utero due to the mother's hyperglycemia, which causes chronic stimulation of fetal insulin secretion in utero. Therefore, shortly after birth, there is failure of insulin to fall normally as glucose levels decline and transient neonatal hypoglycemia develops. Transient hyperinsulinemia also causes transient hypoglycemia and can occur due to other conditions listed in Table 38.10. Infants with perinatal stress, prematurity, or small for gestational age can develop transient hypoglycemia secondary to hyperinsulinism, which is usually responsive to diazoxide and resolves by 6 months of age. In children, postprandial hypoglycemia analogous to that occurring after gastric bypass can follow Nissen fundoplication. Insulin-secreting tumors of pancreatic islet cells are rare in children but have been reported in association with MEN1 and occur outside of the neonatal period. As in adults, hyperinsulinemic hypoglycemia can be accidental, surreptitious, or even malicious. When suspecting those cases, a C-peptide test can be very informative.

Congenital hyperinsulinism[256–258] is the most common cause of nontransient neonatal hypoglycemia, although it occurs in only 1 of every 30,000 to 50,000 live births. However, it can be as common as 1 in 2,500 live births in highly consanguineous communities.[259] Hypoglycemia may persist from the neonatal period or become apparent during the first year of life. These conditions usually have a significant associated risk of hypoglycemic seizures and developmental delays. The need for very high glucose infusion rates is a diagnostic clue.

Glucose-stimulated insulin secretion normally involves increased glucose transport into beta cells, glucokinase-mediated phosphorylation of glucose, and glucose metabolism via the glycolytic pathway, resulting in an increase in the ratio of adenosine triphosphate (ATP) to adenosine diphosphate. This leads to closure of membrane ATP-gated potassium (K_{ATP}) channels and their sulfonylurea receptor 1 (SUR1) and potassium inward rectifying channel (Kir6.2) subunits, membrane depolarization, calcium influx, and exocytosis of insulin. Insulin secretion is usually stimulated by glucose oxidation via glucokinase, but it can also occur due to leucine stimulation of glutamate oxidation via glutamate dehydrogenase. Several inherited abnormalities of these different cellular mechanisms (Fig. 38.15) are now known to cause congenital hyperinsulinism and hypoglycemia in neonates and infants.[256–258,260,261]



• **Fig. 38.15** Cellular mechanisms affecting beta-cell insulin secretion in congenital hyperinsulinism and therapeutic targets. Medications used to treat congenital hyperinsulinism are in *green*. *ADP,* adenosine diphosphate; *ATP,* adenosine triphosphate; *GDH1,* glutamate dehydrogenase 1; *GK,* glucokinase; *GLUT2,* glucose transporter 2; *MCT1,* monocarboxylate transporter 1; *SUR1;* sulfonylurea receptor 1; *UCP2,* uncoupling protein 2. (Courtesy Dr. Stephen Stone.)

Congenital hyperinsulinism has been associated with mutations of an increasing array of genes,[256–258,260,261] including SUR1 (encoded by *ABCC8*), Kir6.2 (encoded by *KCNJ11*), glucokinase (GK, encoded by *GCK*), glutamate dehydrogenase (GDH, encoded by *GLUD1*), short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD encoded by *HADH*), ectopic expression on beta-cell plasma membranes of *SLD16A1* (which encodes monocarboxylate transporter 1 [MCT1]), and mutations of *HNF4A* and *HNF1A*. Many patients with hyperinsulinemic hypoglycemia respond to the K_{ATP} channel opener diazoxide[262] and others to octreotide,[263] whereas some do not respond to medical management.

Identification of the genetic mutation in patients with congenital hyperinsulinism is key, as the management and prognosis will vary depending on the gene that is affected. Inactivating SUR1 or Kir6.2 mutations are the most common and most severe causes of congenital hyperinsulinism. They result in reduced K_{ATP} channel activity and, consequently, increased constitutive insulin secretion. Therefore, most affected patients do not respond to treatment with the K_{ATP} channel opener diazoxide, which normally suppresses insulin secretion. In contrast, patients with dominantly inherited mutations do retain responsiveness to diazoxide. Homozygous or compound heterozygous recessive mutations in either the *ABCC8* or *KCNJ11* gene typically result in diffuse congenital hyperinsulinism. However, patients with paternally recessively inherited mutations of the *ABCC8* or *KCNJ11* gene and a specific loss of maternal alleles of the imprinted chromosome region 11p15 develop focal congenital hyperinsulinism, in which only a small portion of the pancreas is affected with somatic loss of heterozygosity and paternal isodisomy of the chromosome 11p15 region that contains the *ABCC8* and *KCNJ11* genes in addition to several imprinted genes that increase beta-cell proliferation.[264] For those who do not have a sustained response to medical therapy (e.g., frequent feedings, diazoxide, octreotide), near-total pancreatectomy is required. Those with a focal lesion do not respond to diazoxide and are usually cured by surgical resection of the lesion. Focal lesions can be detected noninvasively with [^{18}F]-dihydroxyphenylalanine positron emission tomography[265] with a sensitivity of 85%, a specificity of 96%, and a 96% positive predictive value for diagnosis of focal hyperinsulinism.[266] These children should be evaluated by clinicians experienced with congenital hyperinsulinism and the multiple subspecialty services that are necessary for the management of the disorder.[267]

Activating, dominantly inherited mutations of the glutamate dehydrogenase gene cause hyperinsulinemia and hyperammonemia syndrome, the second most common form of congenital hyperinsulinism. Hypoglycemia typically develops after several months of life and is responsive to diazoxide. Activating, dominantly inherited mutations of the glucokinase gene cause varying degrees of hypoglycemia that may respond to diazoxide but may require pancreatectomy. Recessively inherited mutations of the SCHAD gene result in hypoglycemia that is generally responsive to diazoxide. In addition to hyperinsulinemic hypoglycemia, biochemical markers include increased levels of plasma 3-hydroxybutyrylcarnitine and increased urinary 3-hydroxyglutarate. Dominantly inherited mutations of the monocarboxylate transporter 1 gene (*SLC16A1*), resulting in increased pyruvate transport into beta cells and hyperinsulinism, have been associated with exercise-induced hypoglycemia.

Clinical manifestations, including low plasma glucose concentrations and inappropriately high levels of plasma insulin and C-peptide coupled with low plasma β-hydroxybutyrate levels and a brisk glycemic response to administered glucagon—all analogous to hyperinsulinemic hypoglycemia in adults[2]—characterize congenital hyperinsulinism in neonates and infants.[256–258,260,261] As in adults with endogenous hyperinsulinism,[2] plasma insulin concentrations are not invariably 3 μU/mL (18 pmol/L) or higher during hypoglycemia in patients with congenital hyperinsulinism,[257] although hyperinsulinism is often documented by serial insulin measurements and by inclusion of C-peptide measurements during hypoglycemia. Genetic testing for many mutations is available commercially. Finally, an association of hypertrophic cardiomyopathy and congenital hyperinsulinism has been recognized.[268]

Activating mutations in the postreceptor insulin signaling pathway (e.g., in the RAC-beta serine/threonine-protein kinase [*AKT2*] gene[269,270]) results in hypoinsulinemic hypoglycemia that resembles hyperinsulinemic hypoglycemia aside from evidence of reduced insulin secretion.

Given the array of potential causes of hypoglycemia in neonates and infants, the differential diagnosis is facilitated by an array of measurements during hypoglycemia when the precise hypoglycemic mechanism is obscure.[271] In addition to glucose, insulin, C-peptide, and β-hydroxybutyrate levels (and the glycemic response to glucagon), such measurements should include plasma bicarbonate, lactate, nonesterified fatty acid (NEFA), growth hormone, and cortisol levels. When laboratory findings are not consistent with hyperinsulinism, other causes of hypoglycemia should then be explored. In those instances, a plasma acylcarnitine profile and measurement of ammonia and urine organic acids are also needed, but they do not have to be obtained during hypoglycemia.

Inborn Errors of Metabolism (Enzyme Deficiencies)

Hypoglycemia that develops in infancy and persists into adult life with effective therapy can be caused by enzymatic defects in carbohydrate, protein, or fat metabolism[245] (see Table 38.10). Hypoglycemia usually becomes apparent later in infancy as the intervals between feedings become longer.

Abnormalities in the metabolism of carbohydrates are usually due to enzymatic deficiencies in the synthesis or metabolism of glycogen, gluconeogenesis, or metabolism of galactose or fructose. Glycogen storage diseases (GSDs) are due to different enzyme deficiencies that present early in childhood and are usually characterized by hypoglycemia after short fasting periods, that may have mild to moderate ketosis, and may present with or without hepatomegaly and have no response to glucagon stimulation. GSD type 0 is caused by glycogen synthase deficiency, which results from mutations in *GYS2* and does not cause hepatomegaly, but is characterized by preprandial ketotic hypoglycemia and postprandial hyperglycemia and lactic acidemia. GSD type Ia (von Gierke disease) is caused by mutations in *G6PC*, the gene that encodes glucose-6-phosphatase hydrolase activity. It occurs in approximately 1 of every 100,000 live births[272] and accounts for 80% of GSD type I cases. Given that glucose-6-phosphatase is the final enzyme in the hepatic release of glucose from gluconeogenic and glycogenolytic pathways, absence of its activity results in low rates of endogenous glucose production and severe fasting hypoglycemia[272] with no glycemic response to administered glucagon. Clinical findings include failure to thrive, hepatomegaly (due to both glycogen and fat accumulation), hypertriglyceridemia, accelerated lipolysis and ketogenesis, hyperuricemia, platelet dysfunction, and

marked lactic acidosis (from the metabolism of glucose-6-phosphate). With the exception of hepatomegaly, these abnormalities can be reversed by effective prevention of hypoglycemia with frequent feedings during waking hours and continuous intragastric glucose infusion during sleep or bedtime administration of large doses of uncooked cornstarch. Liver transplantation corrects hypoglycemia and the associated metabolic abnormalities. Late complications include progressive renal disease due to glycogen accumulation in the kidneys and hepatic adenomas. GSD type Ib is caused by mutations in *G6PT1*, the glucose-6-phosphate microsomal transporter. Their clinical presentation and biochemical findings are identical to GSD type Ia, but these patients also have chronic or intermittent neutropenia and neutrophil dysfunction, and are susceptible to recurrent infections. The diagnosis of GSD type Ia and type Ib is confirmed by mutation analysis of *G6PC* and *G6PT1*. Hypoglycemia is less prominent in GSD type III (hepatic amylo-1,6-glucosidase deficiency due to mutations in *AGL*), GSD type VI (hepatic glycogen phosphorylase deficiency due to mutations in *PYGL*), and GSD type IX (hepatic phosphorylase kinase deficiency due to mutations in *PHKA2*) because hepatic gluconeogenesis is preserved and these defects in glycogenolysis are rarely complete. These forms of GSD are rare and are treated with avoidance of hypoglycemia by frequent administration of frequent high-carbohydrate feedings and uncooked cornstarch, particularly at bedtime; in GSD type III, a high-protein diet can be of benefit.

Hypoglycemia can also be caused by enzymatic defects in gluconeogenesis including fructose-1,6-bisphosphatase, phosphoenolpyruvate carboxykinase, and pyruvate carboxylase deficiencies.[245] Glucose-6-phosphatase deficiency is considered by some as a gluconeogenesis defect; however, it was discussed earlier because it is also involved in glycogenolysis. The disorders of gluconeogenesis are characterized by hypoglycemia after moderate fasting periods that occur when hepatic glycogen stores are depleted. Thus, they present with lactic acidemia, ketosis, hyperlipidemia, and no response to glucagon stimulation, except in fructose-1,6-bisphosphatase deficiency, which may have a response in the fed state. Fructose-1,6, bisphosphatase deficiency presents similar to GSD type I, except hepatic glycogen accumulation does not occur, and hepatomegaly, which is the result of lipid accumulation instead of glycogen, is usually mild and liver function is normal. This condition is usually treated with a high-carbohydrate diet and frequent feeding. PEPCK deficiency and pyruvate carboxylase are quite rare. In patients with a mutation in the glucose transporter 1 (GLUT1) gene, plasma glucose concentrations are normal but brain glucose levels are low, causing neuroglycopenia. Hypoglycemia has been attributed to GLUT2 deficiency in Fanconi-Bickel syndrome. Postprandial, rather than postabsorptive, hypoglycemia occurs in galactosemia and in hereditary fructose intolerance (fructose-1-phosphate aldolase deficiency). Other disorders of gluconeogenesis may be due to lack of some gluconeogenic substrates such as galactose, fructose, or amino acids. In galactosemia, there is a deficiency of galactose-1-phosphate uridyl transferase (GALT), in which infants are unable to metabolize galactose to glucose, causing hepatic accumulation of galactose-1-phosphate, which inhibits enzymes of glycogenolysis. This can be a big issue in very young children considering that galactose is a by-product of lactose hydrolyzation and lactose is the major dietary carbohydrate for infants. These children may present with hypoglycemia, vomiting after ingestion of lactose or galactose, failure to thrive, or sepsis. Hypoglycemia in hereditary fructose intolerance, caused by a deficiency of the enzyme aldolase B, occurs after ingestion of fructose or sucrose (a disaccharide that is hydrolyzed to glucose and fructose). The main goal of long-term treatment of classic galactosemia is to minimize dietary galactose intake, and in patients with hereditary fructose intolerance, complete elimination of fructose and sucrose from the diet is an effective treatment for most people, although this can be challenging. Impaired gluconeogenesis may also occur due to alcohol intoxication and salicylate poisoning.

Deficiencies of enzymes involved in protein metabolism (see Table 38.10) that can cause fasting hypoglycemia include branched-chain ketoaciduria (maple syrup urine disease and tyrosinemia). They present with profound acidosis and failure to thrive. The pathogenesis of hypoglycemia is unclear but includes defective gluconeogenesis due to liver disease.

Several defects that ultimately impair fatty acid oxidation result in hypoglycemia with hypoketonemia during extended fasting.[269] Mitochondrial fatty acid oxidation and ketogenesis require transport of fatty acids across the plasma membrane, formation of fatty acyl-CoA derivatives, and transport of those derivatives into mitochondria. Because the inner mitochondrial membranes are not permeable to long-chain (as opposed to medium-chain and short-chain) fatty acyl-CoA esters, the long-chain fatty acyl-CoA esters are transesterified to fatty acylcarnitines at the outer surface of the membranes (by carnitine palmitoyltransferase 1, CPT1), transported across the membranes (by a translocase), and reconverted to the fatty acyl-CoA esters (by carnitine palmitoyltransferase 2, CPT2) at the inner surface of the membranes. Then, they can be oxidized or converted to ketones. Insulin decreases fat oxidation and ketogenesis by decreasing lipolysis and by increasing lipogenesis and the formation of malonyl CoA, which inhibits CPT1. Conversely, low insulin levels favor fatty acid oxidation and ketogenesis. High glucagon levels do so by decreasing malonyl CoA; catecholamines do so largely by stimulating lipolysis. Any defect in this complex sequence (see Table 38.10) decreases fatty acid oxidation (and ketogenesis) and reciprocally increases glucose oxidation, resulting in hypoketonemic postabsorptive hypoglycemia. Reduced plasma carnitine levels (20–50% of normal) are the rule in these disorders, but extremely low carnitine levels characterize the carnitine transport defect—a true carnitine deficiency state that is responsive to carnitine supplementation.[270] The diagnosis of specific fatty acid oxidation defects is typically accomplished by blood acylcarnitine profiling,[271] although molecular diagnosis is increasingly possible.

There are many fatty acid oxidation disorders that result in hypoketonemic hypoglycemia.[a] The most common is medium-chain acyl-CoA dehydrogenase deficiency. Because affected patients can become symptomatic—fatigue, vomiting, seizure, and coma—before becoming hypoglycemic, a normal acylcarnitine profile should be documented before a diagnostic fast is performed in such infants. Other fatty oxidation disorders include very long-, long-, and short-chain acyl-CoA dehydrogenase defects, as well as defects in electron transfer (glutaric acidemia type 2), 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) synthase deficiency, and HMG-CoA lyase deficiency. Defects in carnitine transport and in the carnitine cycle that cause hypoketonemic hypoglycemia include primary carnitine deficiency due to autosomal recessive mutations in the carnitine transporter (*OCTN2*). Others are CPT1 deficiency, carnitine acylcarnitine translocase (*CACT*) deficiency, and CPT2 deficiency. Treatment includes frequent feedings and a low-fat diet rich in medium-chain triglycerides in CPT1 deficiency[276] and carnitine supplementation in primary carnitine deficiency.

In summary, neonatal hypoglycemia may present with or without acidosis. If acidosis is present, this may be associated with lactic

[a]References 245, 246, 253, 256, 257, 260–263, 265, 268, 273–275.

acidemia or ketosis. If the patient has no acidosis and suppressed levels of NEFAs and β-hydroxybutyrate, it suggests hyperinsulinism; if the patient has high NEFA but low β-hydroxybutyrate, it suggests a defect in fatty acid oxidation or ketogenesis. Hypoglycemia with acidosis and high lactate levels suggests a defect in gluconeogenesis or glucose release. If the patient has high concentrations of both NEFA and β-hydroxybutyrate, it suggests a defect in glucose production or release including deficiency of cortisol, although NEFA and ketone levels need not be elevated in patients with hypopituitarism (see Fig. 38.14).

Acknowledgments

Neuroendocrine Control of Energy Stores

MARTIN G. MYERS, JR., AND DAVID P. OLSON

CHAPTER OUTLINE

KEY POINTS

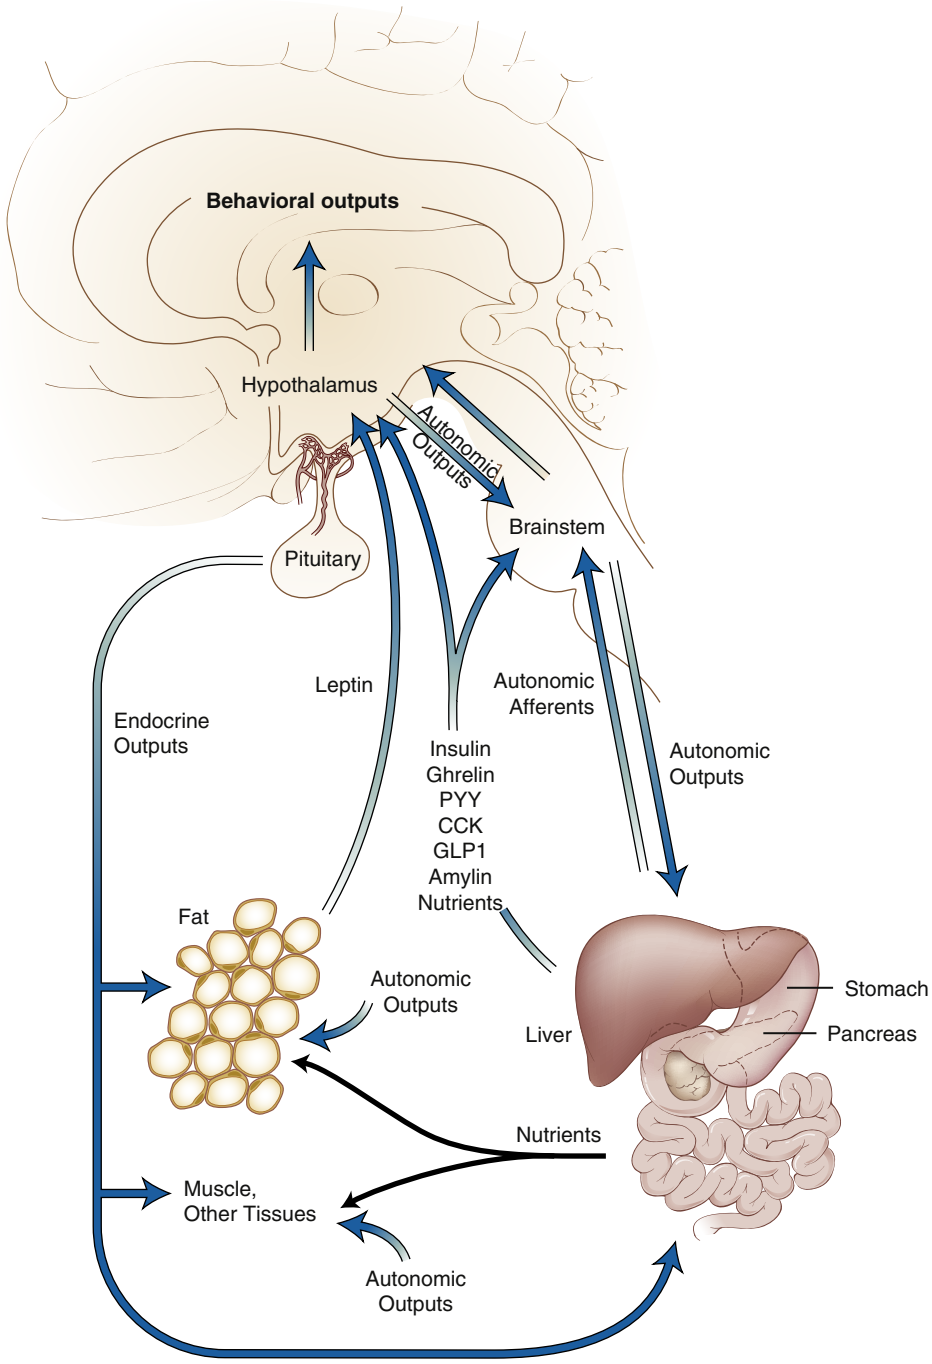
- The body's physiologic systems maintain stable energy stores and body weight by matching long-term food intake to energy expenditure.
- The study of monogenetic obesity syndromes in rodents and humans and the identification of human genetic variants that predispose to obesity have revealed key gene products and brain systems (such as the adipose-derived hormone, leptin, and the hypothalamic melanocortin system) that participate in the regulation of energy balance.
- Hypothalamic circuits mediate the long-term balance between energy intake and expenditure; hypothalamic nuclei that play important roles in energy homeostasis include the arcuate nucleus, the ventromedial nucleus, the dorsomedial nucleus, the paraventricular nucleus, and the lateral hypothalamic area.
- Brain regions such as the ventromedial nucleus, along with melanocortin circuits, also play a role in the central control of glucose homeostasis.
- Food and drug rewards share some common neural substrates, and the signals and systems that control food intake and body weight modulate the brain circuits that control reward. Understanding the molecular and neural mechanisms that modulate rewarding aspects of feeding may reveal sites for therapeutic intervention in obesity.
- The brainstem has traditionally been considered to control short-term feeding by mediating the effects of gut-derived satiety signals, but the brainstem represents the likely site of action for several antiobesity medications that decrease food intake and body weight over the long term. Brainstem nuclei that contribute to the control of food intake include the area postrema, the nucleus of the solitary tract, the dorsal motor nucleus of the vagus, and the lateral parabrachial nucleus.

The Biologic Control of Energy Balance

The law of conservation of energy dictates that body energy stores reflect the difference between energy taken in and energy expended. Consuming more calories than one expends leads to the storage of excess energy (generally, in adipose tissue); chronically, such positive energy balance causes obesity. Conversely, when expenditure exceeds intake, energy/fat stores decline.

While often thought of as a cosmetic problem, obesity represents a major health concern that contributes to the development of diabetes, cardiovascular disease, and cancer (among other illnesses).[1] In addition to their human toll, obesity and its complications cost $147 billion each year in the United States alone.[1] Furthermore, while common wisdom holds that voluntary behaviors (i.e., choosing to eat too much) dictate energy balance and underlie the development of obesity, several lines of evidence demonstrate the biologic (involuntary) basis for the regulation of body weight and adiposity.[2]

Humans and other animals exhibit a remarkable degree of weight stability over the long term because the depletion of body energy stores activates compensatory physiologic systems to counteract weight deviations and return energy stores to their previous levels or set-point.[2] Energy deficit causes hyperphagia and decreased energy expenditure, while forced overfeeding causes anorexia with increased energy expenditure, such that body weight ultimately returns to previous levels upon ad libitum feeding. Such observations prompted Gordon Kennedy[3] to propose a model of body weight regulation in which a signal proportional to energy



• **Fig. 39.1** Circuits and hormones that contribute to the control of food intake and energy homeostasis by the brain-gut-adipose axis. *CCK,* cholecystokinin; *GLP1,* glucagon-like peptide 1; *PYY,* peptide YY.

stores elicited compensatory changes in food intake and energy expenditure to maintain adipose mass at a presumed set-point.

It has long been understood that organic lesions within specific regions of the brain can cause obesity. For example, at the end of the 19th century clinicians, including Alfred Fröhlich, described a condition characterized by pituitary tumors associated with obesity and hypogonadism.[4,5] While several groups (including Harvey Cushing and his colleagues) argued that the syndrome was due to disruption of the pituitary gland,[6–8] removing the pituitary gland without damage to the overlying hypothalamus did not result in obesity in dogs.[9] Indeed, it was subsequently shown that destruction of the medial basal hypothalamus (which contains the arcuate and ventromedial nuclei) without damage to the pituitary gland caused morbid obesity and neuroendocrine derangements similar to those described by Frölich.[10] Conversely, lesions in other brain regions (such as the lateral hypothalamic area) suppressed feeding, resulting in leanness.[11] Thus the hypothalamus plays crucial roles in the control of energy balance and neuroendocrine function with early formulations suggesting that the lateral hypothalamic area contains a putative feeding center, while the medial basal hypothalamus contains a presumptive satiety center.[11]

The past several decades have expanded our understanding of the systems that contribute to the control of energy balance.[2] In addition to the originally described hypothalamic centers, we have

learned a great deal about brainstem systems that control feeding, the circuits that modulate the incentive value of food, and the peripheral signals that modulate them (Fig. 39.1).

Leptin Signals the Repletion of Adipose Stores

Parabiosis (joining the circulatory systems of two animals to permit the exchange of hormones) between obese rats with medial basal hypothalamus lesions and nonlesioned rats led to starvation and weight loss in the latter, while parabiosis between two medial basal hypothalamus-lesioned rats did not alter energy balance in either animal.[12–14] Thus medial basal hypothalamus-lesioned obese rats must produce a circulating factor that inhibits feeding in normal animals and acts via a medial basal hypothalamus satiety center.[11] An important series of experiments by Douglas Coleman almost 50 years ago provided the first insights into a potential mediator of this effect. Coleman used mice homozygous for *ob*, a recessive allele that causes hyperphagia, decreased energy expenditure, endocrine dysfunction, and obesity, and for *db*, which lies at a different locus but produces a phenotype similar to that of *ob*. Parabiosis of lean (wild-type) mice with *ob/ob* mice suppressed weight gain in the *ob/ob* mice, whereas parabiosis of wild-type and *db/db* mice caused profound hypophagia and weight loss in the wild-type mice.[15–17] Based upon these results, Coleman predicted that the *ob* locus produces a circulating satiety factor, while the *db* locus encodes a component required for the response to the presumptive *ob* hormone.

Cloning of the causative gene mutations in *ob* and *db* strains confirmed the predictions of these parabiosis studies: The gene mutated in *ob* encodes a hormone of the type 1 cytokine family (subsequently named leptin [from the Greek *leptos*, meaning "thin"]), while *db* affects the gene that encodes the leptin receptor (LepR), a member of the type 1 cytokine receptor family.[18–20] Treatment with leptin decreases feeding, adipose mass, and body weight in leptin-deficient *ob/ob* ($Lep^{ob/ob}$) mice and in lean normal mice, but fails to alter *db/db* ($Lepr^{db/db}$) mice.[21–23]

Adipose tissue produces leptin in approximate proportion to triglyceride stores, serving as a signal of the repletion of adipose energy stores to the central nervous system to control energy balance. Decreased leptin following caloric restriction initiates the neuroendocrine starvation response, increasing food-seeking and appetite and suppressing the expenditure of energy by neuroendocrine systems (resulting in infertility, decreased sympathetic nervous system tone, thyroid function, etc.).[24,25] Exogenous leptin reverses the neuroendocrine manifestations of starvation as well as the neuroendocrine dysfunction of $Lep^{ob/ob}$ mice. Leptin also reverses the hyperphagia, obesity, and neuroendocrine dysfunction of rare human patients with congenital leptin deficiency.[26–28]

Similarly, human patients and transgenic animals that lack adipose tissue (lipodystrophy) exhibit hyperphagia along with a predisposition to insulin resistance and other endocrine and metabolic abnormalities that are not corrected with caloric restriction.[29,30] Due to the dearth of adipose tissue in lipodystrophy, this syndrome causes low leptin concentrations, and leptin treatment improves hunger indices and endocrine/metabolic abnormalities. Indeed, leptin was recently approved for the treatment of lipodystrophy syndromes in humans.[31]

In contrast to the dramatic ability of leptin to reverse the hyperphagia and neuroendocrine abnormalities associated with congenital leptin deficiency and lipodystrophy, exogenous leptin modestly and briefly blunts food intake and body weight in normal-weight animals and minimally alters energy balance in obese humans or animals that have elevated endogenous leptin due to increased fat mass.[32] Indeed, serum leptin levels in humans are generally proportional to adipose mass,[33,34] thus the vast majority of obese humans are not leptin deficient, but rather fail to respond to elevated leptin concentrations with weight loss. Hence the absence of leptin sends a more powerful physiologic signal than does its excess. Indeed, while low leptin clearly represents the crucial signal of energy deficit, leptin does not mediate the anorexia that follows forced overfeeding,[35] suggesting the existence of a separate signal important for the suppression of food intake during nutritional surfeit.

The Hypothalamic Melanocortin System

In 1902, French geneticist Lucien Cuenot described the obese agouti mouse (A^y/a; also termed *lethal yellow* because homozygotes for the allele die prenatally) that had been bred for decades by European mouse fanciers.[36] The A^y/a strain is notable for the dominant inheritance of an obesity phenotype proportional to the intensity of its yellow coat color.[36] The increased body weight of A^y/a mice results mainly from hyperphagia and reflects both increased fat mass and lean body mass (with increased body length).[37]

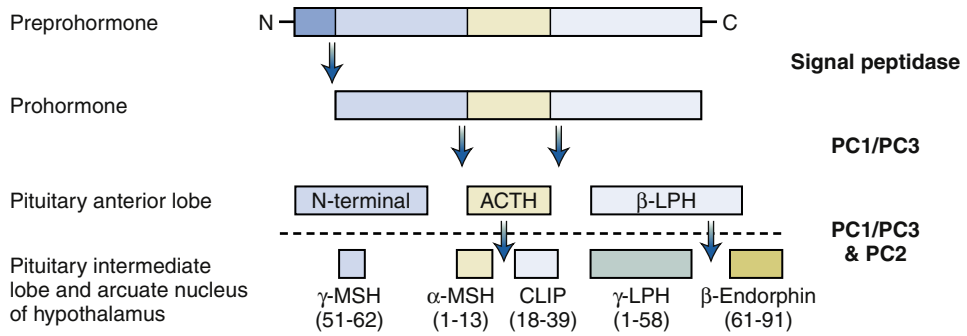
The A^y allele results from a genetic rearrangement that deletes the *Raly* gene and fuses the *Asip* gene to the *Raly* promoter, resulting in continuous expression of agouti signaling protein (ASIP) throughout the body.[38,39] ASIP is a secreted peptide that binds to and inhibits melanocortin receptors. The yellow coat color of the A^y/a mouse results from overexpression of ASIP in the skin, which blocks α-melanocyte stimulating hormone (αMSH) signaling at MC1 receptors (MC1R) in the hair follicle.[38] Since MC1R promotes the synthesis of eumelanin (black pigment) instead of pheomelanin (yellow pigment) in melanocytes, ASIP-mediated antagonism of hair follicle MC1R results in yellow coat color.

The brain contains two predominant melanocortin receptor isoforms: MC3R and MC4R,[40] both of which are activated by αMSH and inhibited by ASIP. Intracerebroventricular administration of αMSH or other melanocortin receptor agonists decreases food intake and body weight; overexpression of ASIP in the brain antagonizes the anorectic action of αMSH signaling and blunts endogenous melanocortin receptor activity resulting in hyperphagia. Thus the hypothalamic melanocortin system is crucial for the control of food intake and energy balance.

At its core, the hypothalamic melanocortin system includes arcuate nucleus neurons that express pro-opiomelanocortin (POMC), the precursor peptide for melanocortin receptor agonists. POMC in the arcuate nucleus is processed to produce αMSH (and at times, β-endorphin), although other POMC-expressing cells in the pituitary and elsewhere produce other POMC-derived peptides[41] (Fig. 39.2). Mice null for *Pomc* throughout the body or specifically in the arcuate nucleus are hyperphagic and weigh approximately twice as much as control animals in adulthood.[42] These animals also exhibit adrenal insufficiency due to the lack of POMC-derived adrenocorticotropic hormone (ACTH) in the anterior pituitary.

In addition to POMC neurons, the arcuate nucleus contains distinct neurons that express the ASIP homolog, agouti-related peptide (AgRP).[38] AgRP (like ASIP) binds and inhibits melanocortin receptors (especially MC3 and MC4 receptors, which are mainly expressed in the brain), and intracerebroventricular administration of AgRP elicits a long-lasting hyperphagic response in rodents.[38] These neurons also contain the inhibitory transmitters neuropeptide Y (NPY, which, like AgRP, promotes feeding when administered intracerebroventricularly) and gamma amino butyric acid (GABA). Negative energy balance (e.g., caloric restriction) activates these arcuate nucleus NPY/AgRP–containing neurons and increases the expression of *Agrp* and *Npy*.[43]

Mice null for *Mc4r* display substantial hyperphagia and increased adiposity body weight, and display increased linear growth, as is



• **Fig. 39.2** Organization of pro-opiomelanocortin (POMC), the precursor hormone of corticotropin (ACTH, adrenocorticotropic hormone), β-lipoprotein (βLPH), and related peptides. The precursor protein contains a leader sequence (signal peptide), followed by a long fragment that includes sequence 51-62, corresponding to γ-melanocyte-stimulating hormone (γMSH). This fragment is cleaved at Lys-Arg bonds to form corticotropin 1-39, which in turn includes the sequences for αMSH (corticotropin 1-13) and corticotropin-like intermediate lobe peptide (CLIP; corticotropin 18-39) and a sequence corresponding to βLPH (1-91) that includes γLPH (1-58) and β-endorphin (61-91). The β-endorphin sequence also includes a sequence corresponding to met-enkephalin. The precursor molecule in the anterior lobe of the pituitary is processed predominantly to corticotropin and βLPH. In the intermediate pituitary lobe (in the rat), corticotropin and βLPH are further processed to αMSH and a β-endorphin–like material. In all extrapituitary tissues, post-translational processing of the prohormone resembles that in the intermediate lobe. Hypothalamic processing is similar but not identical to that in the intermediate lobe. In the latter, β-endorphin and αMSH are present predominantly in their acetylated forms. *C,* carboxy-terminal; *PC,* prohormone-converting enzyme. (Courtesy Dr. Malcolm Low, University of Michigan, Ann Arbor, MI.)

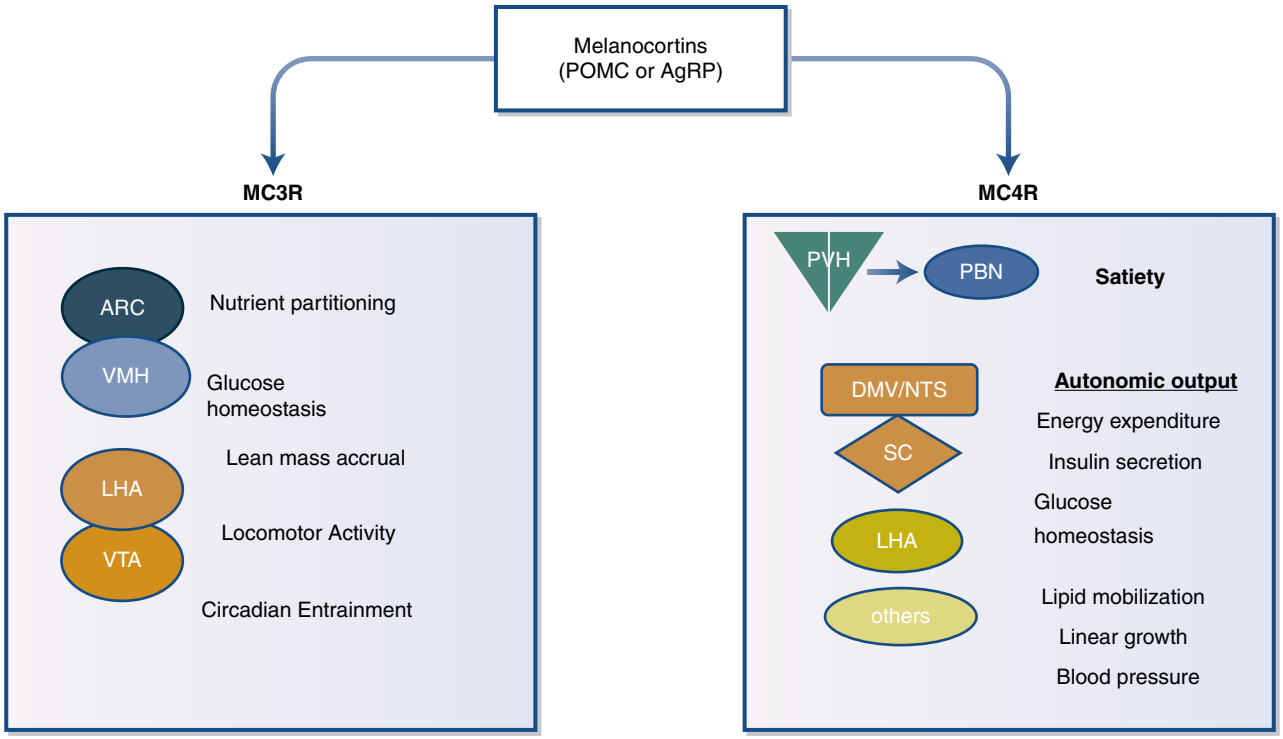
characteristic of *A^y/a* mice.[44] Mice null for *Mc3r* display a subtler obesity phenotype, as noted later in the chapter. Thus MC4R represents the major melanocortin receptor that mediates the control of food intake and body weight. MC4R is expressed in hypothalamic sites critical for feeding control, including the paraventricular nucleus, dorsomedial nucleus, ventromedial nucleus, and lateral hypothalamic area[39] as well as in the brainstem and other brain areas. While some other sites play roles in the control of energy balance, *Mc4r* expression in the paraventricular nucleus is necessary and sufficient for the control of feeding.[45,46] Thus the hypothalamic melanocortin system suppresses food intake by acting on *Mc4r*-expressing paraventricular nucleus neurons (Fig. 39.3).

Extrahypothalamic MC4Rs also contribute to melanocortin action on energy balance. For example, MC4R agonist injection into the fourth ventricle or the dorsal motor nucleus of the vagus decreases food intake, while injection of MC4R antagonists increases food intake.[47,48] Also, deleting MC4Rs in autonomic (cholinergic) neurons lowers energy expenditure and increases adiposity, especially in high-fat diet–fed animals.[49,50] Deleting MC4Rs in parasympathetic preganglionic neurons (vagal motor neurons) causes hyperinsulinemia and insulin resistance but does not significantly impact energy balance, suggesting an important role for MC4R in presympathetic cells for the control of energy expenditure.[49,50]

MC3R, which is distributed in central nervous system sites largely distinct from those that contain MC4R, also plays a role in energy homeostasis. In the mouse, this receptor is most highly expressed in arcuate nucleus POMC and NPY/AGRP neurons, the ventromedial nucleus, the ventral tegmental area, and the medial habenula.[51,52] Within the arcuate nucleus, MC3R is also expressed presynaptically on NPY/AGRP terminals and acts as an inhibitory autoreceptor on the POMC-MC4R circuitry.[53] Although *Mc3r* haploinsufficiency does not produce a phenotype, homozygous *Mc3r* deletion in mice causes increased adipose mass, decreased lean mass, reduced fast-induced refeeding,[54–56] elevated basal and fasting-induced corticosterone,[54] and defects in circadian rhythms and meal entrainment.[57]

The first evidence for a human melanocortin obesity syndrome resulted from the astute recognition of a rare agouti mouse–like syndrome in two families, resulting from null mutations in the *POMC* gene[58] (Fig. 39.4). These patients have ACTH insufficiency, red hair, and obesity, resulting from the lack of ACTH peptide in the serum and a lack of melanocortin peptides in skin and brain, respectively. This obesity syndrome demonstrated that the central melanocortin circuitry subserves energy homeostasis in humans as it does in the mouse. Shortly after the description of *POMC* mutations in humans, heterozygous frameshift mutations in the human *MC4R* locus associated with nonsyndromic obesity in two separate families were reported.[59,60] Additional reports[61–63] provide a clearer picture of the frequency and diversity of *MC4R* mutations and revealed that *MC4R* haploinsufficiency in humans represents the most common monogenic cause of severe obesity, accounting for up to 5% of cases. Remarkably, the associated physical findings are virtually identical to those reported for the mouse,[44] with increased adipose mass, increased linear growth and lean mass, hyperinsulinemia greater than that seen in matched obese control subjects, and severe hyperphagia. MC4R haploinsufficient adults also exhibit reduced sympathetic tone and mild hypotension.[64] Initial pharmacologic approaches to melanocortin obesity syndromes were complicated by blood pressure effects of MC4R agonist therapy. Recently, however, the MC4R agonist, setmelanotide (currently under clinical development), has been shown to promote significant weight loss without associated blood pressure problems in patients with either POMC deficiency or leptin receptor deficiency.[65,66] Thus central nervous system circuits that regulate energy balance may be targeted for therapeutic benefit.

While a syndrome resulting from MC3R mutations in humans has not yet been definitively identified, several other monogenetic obesity syndromes in mice and humans likely result from alterations in melanocortin signaling. The products of many of the affected genes play important roles in peptide processing. POMC is cleaved by prohormone convertase 1 (PC1, also called PCSK1 or PC1/3) and PC2 (PCSK2) to generate a precursor peptide that



• **Fig. 39.3** Distribution of melanocortin action in the central nervous system. Pro-opiomelanocortin neurons (POMC) in the arcuate nucleus (ARC) produce melanocortin-receptor agonists, whereas agouti-related peptide (AgRP)–producing neurons antagonize melanocortin action. MC3R and MC4R are the predominant melanocortin receptors in the brain and have relatively distinct physiologic roles. MC3R is expressed at high levels in the ARC and the ventromedial nucleus (VMN), where it mainly controls nutrient partitioning, conversion of food to fat, and lean mass accrual. MC3R in the lateral hypothalamic area (LHA) and ventral tegmental area (VTA) likely control motivation and activity. MC4R is expressed in many brain regions and plays a critical role in energy balance. MC4Rs in the paraventricular hypothalamic nucleus (PVH) profoundly affect food intake through projections to the parabrachial nucleus (PBN). MC4Rs in other brain regions, including the lateral hypothalamus (LHA), dorsal motor nucleus of the vagus (DMV), nucleus of the solitary tract (NTS), and spinal cord (SC) are involved in energy expenditure, autonomic output, and glucose regulation. MC4R action in the DMV regulates insulin secretion, and MC4Rs regulate sympathetic output (and energy expenditure) through the intermediolateral cell column of the spinal cord (IML). The sites mediating melanocortin action on linear growth, lipid handling, and blood pressure are not defined.

is further cleaved by carboxypeptidase E (CPE) to generate active αMSH[67] (see Fig. 39.2). Prolyl carboxypeptidase (PRCP) acts on substrate proteins (such as αMSH) where the penultimate amino acid is a proline residue, cleaving the COOH-terminal amino acid and inactivating the peptide.[68]

The *fat* mutation, which causes diabetes and obesity in mice, results from a point mutation in the *Cpe* gene[69]; miscleavage of POMC presumably underlies the obesity in Cpe^{fat} mice. Similarly, mice and humans null for *Pcsk1* are obese with adrenal insufficiency (in addition to displaying other endocrine defects) due to impaired processing of POMC and other peptides.[70,71] Mice null for *Pcsk2* are not obese, however,[72] presumably due to the partial activity of the POMC PC1 product on MC3/4R, even in the absence of PC2-mediated processing. Conversely, mice null for *Prcp* are lean due to prolonged activity of αMSH.[68]

Hypothalamic Systems and Signals That Regulate Energy Balance

The hypothalamus, a highly conserved brain region, plays crucial roles in the maintenance of homeostasis; destruction of the hypothalamus is not compatible with life.[73] The hypothalamus receives sensory inputs from the external environment and information regarding the internal environment. In addition, several hormones crucial for the regulation of food intake and metabolism (e.g., leptin, ghrelin, insulin, estrogen) directly act on neurons in the hypothalamus. The hypothalamus integrates these inputs to modulate key outputs (including the pituitary gland, the cerebral cortex, premotor and motor neurons in the brainstem and spinal cord, and autonomic [parasympathetic and sympathetic] preganglionic neurons) to coordinate endocrine, behavioral, and autonomic responses that maintain homeostasis in several physiologic systems, including energy balance (see Fig. 39.1). Several hypothalamic sites (including the arcuate nucleus, ventromedial nucleus, dorsomedial nucleus, paraventricular nucleus, and lateral hypothalamic area) play key roles in coordinating food intake and other parameters of energy homeostasis. Information flow for the hypothalamic circuits generally begins with the arcuate nucleus, the entry point for many hormonal signals (such as insulin and leptin) (Fig. 39.5). The paraventricular nucleus mediates important outflow from the hypothalamus to brainstem centers that control food intake. In between, the dorsomedial nucleus integrates other signals and relays information to and from the arcuate and paraventricular nuclei.

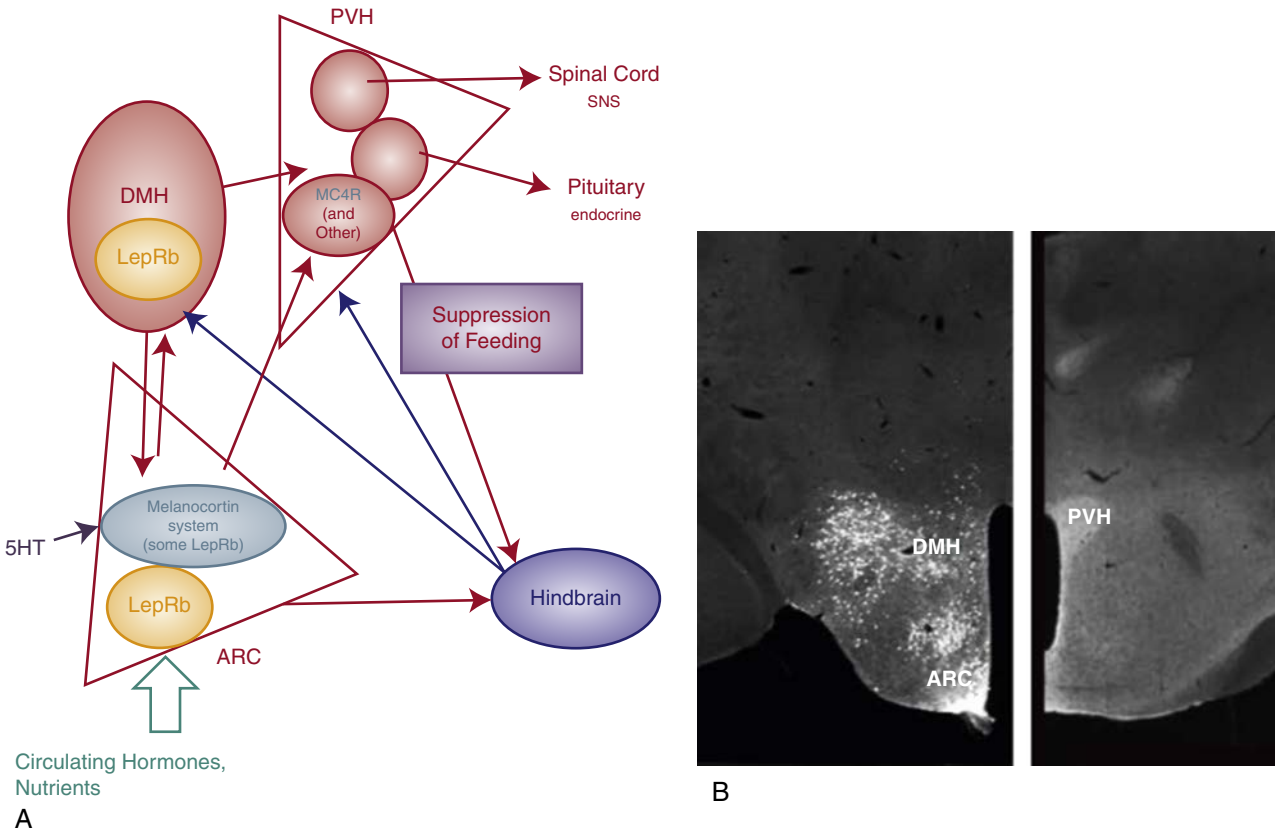
Orthologs of many of the genes that encode crucial mediators of energy balance and/or that underlie rodent obesity models also cause or contribute to obesity in humans. In the past several decades, causative mutations in multiple genes have been found in human obesity disorders, including *LEP, LEPR, POMC, MC4R, PCSK1, GNAS, SH2B1, BDNF, TRKB,* and *SIM1*.[74] These mendelian disease genes appear to act primarily in the hypothalamus. Furthermore, genome-wide association studies have identified over 100 single nucleotide polymorphisms significantly associated with body mass index, and these are predominantly located in or near genes thought to act primarily in the hypothalamus.[75,76]

Leptin-Regulated Hypothalamic Circuits

Alternative splicing of the *Lepr* transcript produces multiple LepR isoforms[77]; $Lepr^{db}$ produces an mRNA splicing error that inserts the final exon of one of the short LepR isoforms (LepRa) into the mRNA, replacing the long LepRb isoform (which uniquely contains all intracellular cytokine receptor signaling motifs) with LepRa throughout the body.[78] Because the $Lepr^{db}$ allele synthesizes all LepR isoforms except LepRb, this isoform plays a crucial role in energy homeostasis.[79]

Consistent with leptin's behavioral effects (e.g., on feeding) and its effects on the neuroendocrine and autonomic systems, most LepRb-expressing cells lie in the brain,[19,80,81] suggesting the potential importance of the central nervous system as a site of leptin action. Indeed, transgenic overexpression of LepRb in the central nervous system substantially corrects the obesity syndrome



• **Fig. 39.5** Flow of information into and out of the hypothalamus. Core "homeostatic" hypothalamic circuits are shown in *red,* brainstem circuits are in *dark blue,* peripheral signals are *green,* leptin receptor pathways are in *orange,* and melanocortin pathways are in *light blue*. (B) Images of hypothalamic regions in question, using LepRb-GFP *(left panel)* reporter mice showing LepRb neurons in areas, including the ARC and DMH and LepRb-enhanced green fluorescent protein (EGFP) *(right panel)* reporter mice, showing projections from LepRb neurons into regions, including the PVH.

of *Lepr*$^{db\text{-}3J}$ mice (which lack all LepR isoforms).[82] Similarly, ablation of LepRb specifically in the central nervous system promotes hyperphagia, neuroendocrine failure, and obesity.[83]

Within the brain, the majority of LepRb-expressing neurons reside within the hypothalamus and brainstem, consistent with the known roles for these structures in the control of feeding and endocrine and autonomic function.[80,81,84] In the brainstem, LepRb knockdown in the nucleus of the solitary tract and surrounding regions alters the control of meal size and slightly increases long-term food intake,[85] while lateral parabrachial nucleus LepRb ablation alters the response to hypoglycemia and other metabolic emergencies but does not impact energy balance.[86,87] In contrast, pan-hypothalamic ablation of LepRb promotes a phenotype very similar in quality and magnitude to that of whole-body null *Lepr*$^{db/db}$ animals, suggesting that hypothalamic LepRb neurons mediate the majority of leptin action on energy balance.[88]

Within the hypothalamus, multiple nuclei contain populations of LepRb neurons, including the arcuate nucleus, ventromedial nucleus, dorsomedial nucleus, lateral hypothalamic area, and ventral premammillary nucleus.[80,81] Substantial subpopulations of arcuate nucleus POMC and NPY/AGRP neurons contain LepRb, although additional LepRb-expressing arcuate nucleus populations also exist.[89–91] While it was initially assumed that the absence of LepRb from POMC and/or NPY/AGRP neurons would recapitulate the obesity phenotype of *Lepr*$^{db/db}$ mice (which results from defects that exist in the early embryo), the early embryonic ablation of LepRb from these cell populations only minimally alters energy balance, suggesting important roles for LepRb in distinct hypothalamic population(s).[92–94]

Importantly, however, undefined compensatory processes attenuate phenotypes that result from the early developmental alteration of NPY/AGRP cells, and ablating LepRb from NPY/AGRP cells in adult mice produces a dramatic hyperphagic obesity.[95] Thus while LepRb in NPY/AGRP neurons contributes only minimally to the *Lepr*$^{db/db}$ phenotype, the control of NPY/AGRP neurons by LepRb plays a crucial role in energy balance in adult animals.

Roles in leptin action have been examined for other circumscribed sets of hypothalamic LepRb neurons as well. Early embryonic ablation of LepRb in the ventromedial nucleus blunts energy expenditure and thereby increases adiposity,[96] while deletion of LepRb in neurotensin-expressing lateral hypothalamic area neurons diminishes motor activity to blunt energy expenditure and increase adiposity.[96,97] LepRb in the ventral premammillary nucleus contributes to the control of reproduction[98] but not energy balance; LepRb in arcuate nucleus growth hormone–releasing hormone *(Ghrh)*–expressing cells does not contribute detectably to the control of growth or energy balance.[94]

In contrast to the minimal phenotypes observed following the early embryonic ablation of LepRb in the circumscribed sets of hypothalamic LepRb neurons tested to date, ablation of LepRb from broadly distributed hypothalamic vesicular GABA transporter (vGat)–expressing or nitric oxide synthase-1 (NOS1)–expressing neurons promotes dramatic hyperphagia and obesity.[99,100] While this might suggest that the total number of LepRb neurons affected (rather than the specific cell types) matters most for the control of energy balance, deletion of LepRb across broad populations of hypothalamic serotonin 2c receptor *(Ht2cr)*–expressing neurons largely distinct from vGat and NOS1 cells minimally impacts energy balance,[94] suggesting that specific LepRb cell types do play specialized roles in energy balance. The dorsomedial nucleus contains substantial populations of both vGat and NOS1-expressing LepRb neurons, suggesting that important sets of food intake–controlling LepRb neurons may lie in the dorsomedial nucleus. Although a subpopulation of prolactin-releasing hormone *(Prlh)*–expressing dorsomedial nucleus LepRb neurons contributes only to the control of energy expenditure,[101] ablation of dorsomedial nucleus LepRb in adults increases food intake and promotes dramatic obesity,[102] suggesting an important role for non-*Prlh* dorsomedial nucleus LepRb neurons in the control of food intake and energy balance. The vGat-containing dorsomedial nucleus LepRb neurons that play important roles in the acute regulation of NPY/AGRP neurons[103] may represent at least some of these crucial energy balance–controlling LepRb neurons.

Roles for NPY/AGRP Neurons in Energy Balance

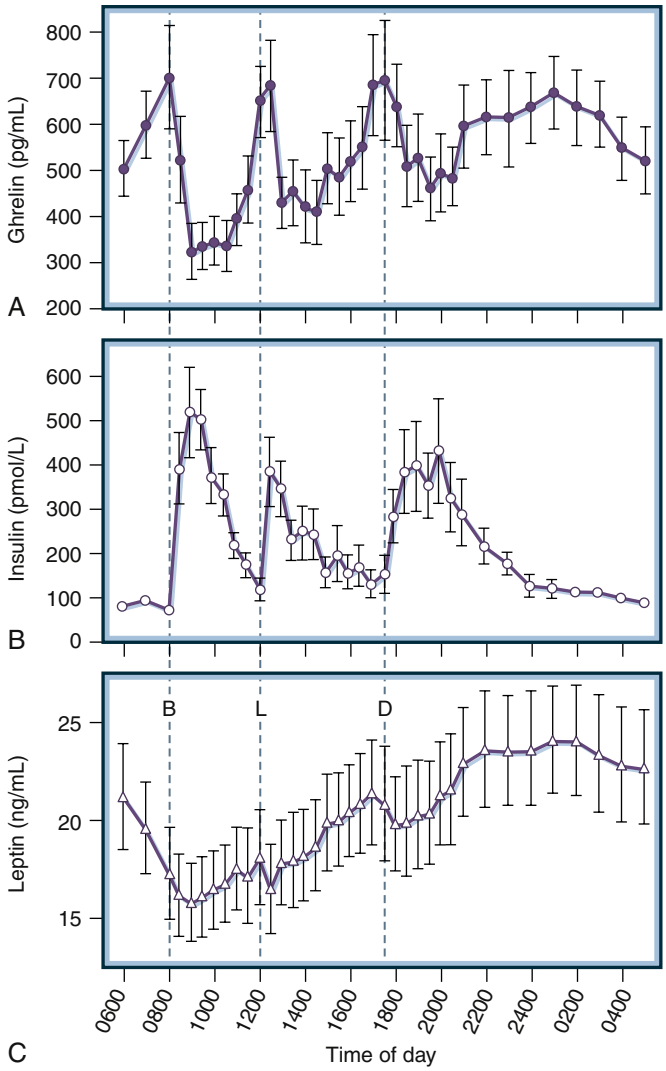
Not only does activating NPY/AGRP neurons increase food intake and body weight,[104] but ablating NPY/AGRP neurons in adult animals results in anorexia.[105–107] Thus NPY/AGRP neurons play important roles in the control of food intake and energy balance. Indeed, while leptin inhibits NPY/AGRP neurons, these cells also respond to other hormonal modulators of energy balance (including ghrelin, which activates NPY/AGRP cells to promote food intake [see upcoming discussion]), and nutrient signals (such as glucose, which inhibits NPY/AGRP cells).[108]

While early models proposed that the endogenous MC4R agonist/antagonist pair (αMSH and AgRP, respectively) might simply act competitively to determine the relative amount of activation of the MC4R, recent findings have demonstrated additional roles for AgRP.[109] AgRP not only acts via MC4R to control the activity of the G protein, GαS, but also alters membrane potential in target neurons by controlling potassium channels independently of G proteins.

Furthermore, NPY/AGRP neurons control feeding via several neuronal mechanisms. While NPY/AGRP cells contain the orexigenic peptides AgRP and NPY, early developmental ablation of these peptides minimally alters the ability of NPY/AGRP neurons to promote food intake or to control energy balance.[110] In contrast, ablation of GABA signaling by NPY/AGRP cells abrogates their orexigenic action.[111] GABA signaling by NPY/AGRP cells not only provides direct inhibitory input to arcuate nucleus POMC neurons but also is required to promote food intake by the paraventricular nucleus and to inhibit anorexigenic and aversive lateral parabrachial nucleus cells that express calcitonin gene–related peptide (CGRP) (see hindbrain section later in the chapter).[105,111,112]

Ghrelin

Ghrelin (an acylated 28–amino acid peptide that potently stimulates food intake) acts via the ghrelin receptor (known as the growth hormone secretagogue receptor [GHSR]).[113–117] Predominantly secreted by the stomach, ghrelin levels are markedly reduced with meal ingestion in both rodents and humans but rebound to baseline before the next meal or increase after an overnight fast[115–117] (Fig. 39.6). Ghrelin is unique in that it requires the addition of an eight-carbon fatty acid (octanoate) side chain to have agonist activity at the ghrelin receptor.[118] The enzyme ghrelin O-acyltransferase catalyzes the addition of the octanoyl group.[118] Unlike other signals involved with energy homeostasis, ghrelin secretion is inhibited in response to meals and stimulates appetite, leading to the notion that ghrelin participates in meal initiation.[117] Fasting ghrelin levels are inversely proportional to body weight[115] and are higher than normal in underweight subjects with anorexia nervosa and cardiac



• **Fig. 39.6** Average plasma ghrelin (A), insulin (B), and leptin (C) concentrations during a 24-hour period in 10 human subjects consuming breakfast (B), lunch (L), and dinner (D) at the times indicated (0800, 1200, and 1730 hours, respectively). (From Cummings DE, Purnell JQ, Frayo RS, et al. A preprandial rise in plasma ghrelin levels suggests a role in meal initiation in humans. *Diabetes.* 2001;50:1714–1719.)

cachexia compared to control subjects.[114,119] Both of these changes presumably reflect the regulation of ghrelin by nutritional status rather than any role for ghrelin in the pathogenesis of these diseases.

Peripheral administration of ghrelin activates arcuate nucleus NPY/AGRP neurons,[120] and ablation of the arcuate nucleus blocks the actions of the ghrelin administration on feeding.[121] Furthermore, re-expression of the ghrelin receptor only in NPY/AGRP neurons in ghrelin receptor-null mice suffices to restore the orexigenic effect of exogenous ghrelin.[122]

Despite the significant amount of data suggesting that ghrelin increases food intake, mice null for ghrelin or ghrelin receptor demonstrate little alteration of food intake or energy balance. Similarly, neither genetic deletion of ghrelin O-acyltransferase[123] nor the ablation of ghrelin-producing cells[124] results in major changes in food intake and body weight. These findings have brought into question the physiologic relevance of ghrelin. They may also reflect developmental compensation of NPY/AGRP neurons to the lack of ghrelin action.

Roles for the Paraventricular Nucleus in Energy Balance

The metabolic consequences that result from abnormal paraventricular nucleus development or the interference with paraventricular nucleus function underscore the importance of the paraventricular nucleus in energy balance and autonomic function. Destruction of the paraventricular nucleus by electrolytic lesion causes hyperphagia and obesity.[125] Similarly, loss of one copy of single-minded homolog-1 (Sim1), a key transcription factor regulating paraventricular nucleus development, disrupts paraventricular nucleus development and function, resulting in hyperphagic obesity with associated glucose dysregulation in both rodents and humans.[126–128] In addition, the paraventricular nucleus serves as an important regulatory output center for stimuli that modulate food intake, including leptin, melanocortins, and dehydration.[129,130] Melanocortin agonists engage and stimulate melanocortin receptor–bearing neurons in the paraventricular nucleus to activate effector pathways that inhibit food intake and stimulate energy expenditure (see Fig. 39.5). Melanocortin action in paraventricular nucleus neurons plays crucial roles in the control of food intake, energy balance, and glucose homeostasis.[45,131] While the role for the paraventricular nucleus in regulating energy balance is clear, much less is known about the identity of the neurons and specific circuitry mediating these effects, however.

The paraventricular nucleus is composed of a heterogeneous group of glutamatergic neurons that have been classically described as parvocellular or magnocellular based on cell size and axonal projection patterns. Paraventricular nucleus parvocellular cells are neurochemically diverse and send projections within the central nervous system to three main areas: (1) the median eminence, where secreted factors (e.g., thyroid-releasing hormone [TRH] and corticotrophin-releasing hormone [CRH]) enter the portal hypophyseal circulation and affect pituitary function; (2) the brainstem, including the dorsal vagal complex (comprised of the dorsal motor nucleus of the vagus and the nucleus of the solitary tract) and the lateral parabrachial nucleus, both of which have been implicated in feeding[105,132]; and (3) the preganglionic sympathetic output centers, such as the intermediolateral column of the spinal cord.[133,134] Hypothalamic parvocellular paraventricular nucleus neurons that respond to the satiety signals are thought to regulate feeding by modulating hindbrain responses to ascending signals from the gut and periphery.[135–137] Magnocellular neurons (expressing oxytocin or vasopressin [AVP]) send their axonal projections to the posterior pituitary to release their neuropeptides and transmitters directly into the systemic circulation. Paraventricular nucleus-mediated energy balance control is thought to be regulated predominantly by parvocellular paraventricular nucleus neurons.

Specific Roles of Paraventricular Nucleus Neuronal Subsets in Metabolic Homeostasis

Oxytocin and CRH neurons within the paraventricular nucleus have garnered significant attention as potential regulators of energy balance. Both oxytocin and CRH peptides alter feeding when delivered to the brain, and oxytocin and CRH paraventricular nucleus neurons project to other brain regions that regulate feeding. Rodents lacking oxytocin or CRH have near normal energy balance under basal conditions, however.[138,139]

Moreover, direct activation of paraventricular nucleus oxytocin neurons does not alter feeding, and ablation of paraventricular nucleus oxytocin has little effect on body weight unless animals are challenged with a high-fat diet.[140,141] In addition, mice lacking oxytocin neurons demonstrate normal anorectic responses to

melanocortin agonists. Thus oxytocin neurons (and their contents) are not required for anorectic melanocortin action, and other (non-oxytocin) paraventricular nucleus neurons play crucial roles in the control of feeding (including in response to melanocortin action).

Paraventricular nucleus MC4R neurons play a critical role in energy balance control. Deletion of paraventricular nucleus *Mc4r* results in hyperphagic obesity, whereas re-expression of *Mc4r* selectively in the paraventricular nucleus in an otherwise null *Mc4r* background normalizes feeding and dramatically attenuates the obesity phenotype of these mice.[45,131] Selective manipulation of paraventricular nucleus MC4R-expressing neurons revealed that these neurons directly regulate feeding but not energy expenditure.[45] Indeed, the paraventricular nucleus MC4R → lateral parabrachial nucleus projection pathway is critical for these feeding effects.[46] Other paraventricular nucleus cell types shown to be involved in energy balance regulation include brain-derived neurotrophic factor-expressing neurons,[142] Nos1-expressing neurons,[140] AVP neurons,[143] and nesfatin-expressing cells.[144] Whether these neurochemical markers identify unique cell populations, or target a common neural circuitry for anorexia, remains unclear.

Role for the Ventromedial Nucleus in Energy Balance

As noted earlier, medial basal hypothalamus lesion studies demonstrated that combined ablation of the arcuate nucleus and ventromedial nucleus produce obesity. In addition to the roles played by arcuate nucleus (including POMC and NPY/AGRP neurons), the ventromedial nucleus contributes to the control of energy balance as well. Indeed, animals null for the transcription factor steroidogenic factor-1 (SF1), which is expressed in most if not all ventromedial nucleus neurons,[145] exhibit ventromedial nucleus dysgenesis and adrenal agenesis and develop late-onset obesity.[97,146,147] Furthermore, deletion of LepRb from SF1 neurons produces obesity due to decreased energy expenditure (especially in animals exposed to high-fat diet),[96] but without increasing food intake, suggesting a role for ventromedial nucleus neurons in the control of energy expenditure. Indeed, the ventromedial nucleus represents an important site for the modulation of sympathetic nervous system outflow.

Serotonergic Control of Energy Balance

The central serotonin (5-hydroxytryptamine [5HT]) system represents another key regulator of energy balance. This system consists of 5HT containing cell bodies that lie in several midbrain raphe nuclei and that project widely through the central nervous system; 5HT acts via 14 different 5HT receptors (HTRs).[148,149] Note also that 5HT represents a widely used and important neurotransmitter in the enteric nervous system of the gut. A variety of compounds that promote HTR signaling, including fenfluramine, promote weight loss.[150] In combination with phentermine (Fen/Phen), the clinical use of fenfluramine successfully reduced food intake and body weight in humans, prior to its removal from the market as a result of heart valve disorders. Subsequent work identified central nervous system HT_{2C}Rs[151–153] as crucial mediators of 5HT-mediated weight loss: The anorexic properties of fenfluramine depend on the presence of *Htr2c*, and mice null for *Htr2c* demonstrate hyperphagic obesity,[154] demonstrating both a physiologic and pharmacologic role for 5HT and HT_{2C}R in the control of feeding and body weight. In 2012 the US Food and Drug Administration (FDA) approved the use of the HT_{2C}R agonist lorcaserin for the treatment of obesity.[150]

The hypothalamic melanocortin pathway mediates the suppression of feeding by 5HT and HT_{2C}R.[155,156] Arcuate nucleus POMC neurons express $5HT_{2C}$Rs,[155] and 5HT directly activates POMC neurons via HT_{2C}R-mediated mechanisms.[155,157,158] Indeed, mice in which expression of the HT_{2C}R is disrupted globally but the receptor is re-expressed only in POMC neurons do not develop the hyperphagia and obesity characteristic of global $5HT_{2C}$R deficiency and respond to HT_{2C}R agonists.[156,159]

Interestingly, while POMC neurons express LepRb and HT_{2C}R, the HT_{2C}R-expressing POMC neurons are distinct from those that express LepRb,[157] suggesting that the two populations of POMC cells may suppress feeding in response to distinct stimuli. Furthermore, the regulation of the central nervous system 5HT system by feeding-relevant stimuli has only recently begun to be explored,[160] and the specific physiologic role played by the 5HT system in the control of food intake remains unclear: While the 5HT system is well known for its role in responses to a variety of psychologic (e.g., restraint, social defeat) and physiologic stressors (e.g., fasting), whether this system mediates the anorectic response to stress has not been defined.

The Role of Insulin and Glucose in the Regulation of Energy Homeostasis

In addition to the well-known role for insulin action on peripheral tissues to control glucose homeostasis, insulin acts in the central nervous system to contribute to the control of energy balance.[161] Insulin injection into the brain can reduce food intake,[161,162] and pan-neuronal deletion of insulin receptors causes mild obesity.[163] Glucose may also act in the brain to contribute to the control of energy balance. Several distinct populations of neurons in the brain sense glucose[164]: some neurons are activated by rising concentrations of glucose (glucose-excited cells), while other classes of neurons are inhibited by rising glucose (glucose-inhibited cells). While the chemical identity of many glucose-sensing cells remain to be determined, glucose-inhibited neurons include arcuate nucleus NPY/AGRP cells, lateral hypothalamic area neurons that contain orexin (OX),[165,166] lateral parabrachial nucleus LepRb cells,[86] and other cell types in the hindbrain and thalamus that likely play roles in energy homeostasis.

Estrogen

In addition to their primary reproductive effects, gonadal steroids also play a key role in regulating energy balance and glucose homeostasis.[167,168] Estrogens exert antiobesity and antidiabetic effects, and lower levels of estrogens in postmenopausal women are associated with an increased risk for developing obesity.[169–171] Ovariectomy reduces estrogen, causing obesity.[172–174] Although ovariectomy increases food intake, hyperphagia does not account for all of the ovariectomy-associated obesity.[174] Indeed, ovariectomy causes rats to gain weight to a similar extent when they are pair-fed to estradiol-treated rats,[175,176] suggesting that endogenous estrogens regulate body weight homeostasis primarily by modulating energy expenditure. Estradiol replacement decreases food intake and increases energy expenditure in rodents, however,[177] indicating that exogenous estrogens may influence both energy intake and energy expenditure.

The alpha isoform of the estrogen receptor (ERα) mediates many of estrogen's effects on body weight homeostasis. For example, female mice with a targeted deletion (knockout [KO]) in the ERα gene (ERαKO) develop obesity and hyperadiposity primarily because of decreased energy expenditure.[178–180] ERα is clearly

required to mediate the normal satiation process because estradiol-induced hypophagia and cholecystokinin (CCK)–induced satiation in wild-type mice are blocked in ERαKO mice.[180]

ERα is expressed in brain regions implicated in the regulation of energy balance, including the arcuate nucleus, paraventricular nucleus, and ventromedial nucleus in the hypothalamus, as well as key brainstem sites such as the nucleus of the solitary tract.[181,182] Consistent with the role for the ventromedial nucleus in controlling sympathetic nervous system outflow and energy expenditure, knockdown or knockout of ERα in the ventromedial nucleus produces mice that are less sensitive to estradiol-induced weight loss and develop increased visceral adipose tissue[167,183,184] due to decreased physical activity and impaired diet-induced thermogenesis; food intake of these animals is not directly affected.[183] Collectively, these results support the hypothesis that ERα signaling in ventromedial nucleus neurons plays an important role in regulating energy expenditure rather than food intake.

Arcuate nucleus POMC neurons express ERα,[167,185,186] and estrogens regulate the excitability of POMC neurons. The number of excitatory inputs to arcuate POMC neurons rises as female mice enter proestrus, when estrogen levels are high.[177,187] Further, central estradiol administration rapidly increases excitatory inputs to POMC neurons.[177,187] The synaptic changes in POMC neurons are tightly paralleled with the effects of estradiol on food intake and body weight.[177] Consistently, female mice lacking ERα only in POMC neurons develop hyperphagia.[167] These observations suggest that estrogen signals in POMC neurons are physiologically relevant in the regulation of food intake.[167] In contrast, although estradiol inhibits the activity of NPY/AGRP neurons, NPY/AGRP cells do not express ERα, suggesting that these effects are mediated indirectly.[188]

Central Nervous System Control of Thermogenesis

The systems that coordinate energy homeostasis balance energy intake with energy expenditure. Energy expenditure is often grouped into three categories: energy required for basal metabolism, energy required for physical activity, and the thermic effect of food.[189] The latter, often referred to as diet-induced thermogenesis, is estimated at 8% to 10% of total expenditure and is defined as the increased energy expenditure in response to energy intake.[189] This process is under the control of the sympathetic nervous system, and energy expenditure is increased by stimulation of β-adrenergic receptors. The importance of sympathetic output in energy balance is revealed by the profound obesity of mice lacking all β-adrenergic receptors when exposed to a high-fat diet.[190] In rodents, the major tissue mediating the energetic response to sympathetic output is brown adipose tissue, which contains adipocytes with dense collections of mitochondria.[191] In addition, brown adipocytes express uncoupling protein 1 (UCP1), which uncouples mitochondrial respiration and thus induces energy expenditure and heat. In humans the key tissue mediating energy expenditure in response to changing energy intake is likely skeletal muscle, although brown adipose tissue has been identified in humans and may play a role in energy balance control.[191,192] It is clear that the sympathetic nervous system is required for coordinated control of energy expenditure and resistance to diet-induced obesity, however.

Key mediators of central nervous system autonomic output are the parasympathetic and sympathetic preganglionic neurons in the brainstem and spinal cord.[73,193] Sympathetic preganglionic neurons are found within the interomediolateral cell column of the spinal cord and extend from the upper thoracic to the upper lumbar cord segments. Different rostral-caudal levels of the intermediolateral column provide innervation to different target organs and thus mediate distinct autonomic responses. For example, sympathetic preganglionic neurons in the upper thoracic levels of the intermediolateral column are thought to be important for control of the heart and cardiovascular system. Additionally, sympathetic preganglionic neurons in thoracic levels T6 to T12 of the intermediolateral column provide innervation of the adrenal gland and endocrine pancreas.[194–196]

Descending central nervous system input to sympathetic preganglionic neurons from key regulatory groups in the hypothalamus and brainstem play a dominant role in autonomic control.[73,197,198] The largest projection to the sympathetic preganglionic neurons in the spinal cord is composed of inputs from the arcuate nucleus, the paraventricular nucleus, and the lateral hypothalamic area,[194,198,199] although other important projections also arise from the brainstem.[200–203]

As noted earlier, the hypothalamic melanocortin system regulates energy expenditure (in addition to controlling food intake). For example, MC4R blockade in mice prevents diet-induced thermogenesis[204] and blocks the upregulation of brown adipose tissue activity.[205] In addition, blocking MC4R signaling prevents the normal induction of thermogenic proteins by high-fat diet feeding.[206] Paraventricular nucleus MC4Rs do not mediate this affect, however, because although activation of the paraventricular nucleus neurons increases energy expenditure, selective activation of MC4R paraventricular nucleus neurons does not.[46]

Sympathetic preganglionic neurons express MC4Rs[207] and receive direct inputs from leptin-responsive POMC neurons, suggesting a potential role for melanocortin action on these cells.[208] Indeed, selective deletion or re-expression of MC4R expression in cholinergic neurons produces high-fat diet sensitivity, failure to increase adipose tissue UCP1, an impairment of diet-induced thermogenesis, and increased cold tolerance.[49,209,210] Thus direct melanocortin input to sympathetic preganglionic neurons mediates important aspects of diet-induced thermogenesis and energy expenditure.

Control of Glucose Homeostasis by the Brain

While peripheral hormones (e.g., insulin) are crucial for glucose homeostasis, autonomic outputs from the central nervous system control important aspects of metabolism.[211–213] The concept that the central nervous system plays a primary role in the control of insulin action and glucose homeostasis originates from physiologist Claude Bernard's 1849 observation that physical lesions to the floor of the fourth ventricle of rabbits dramatically increased blood glucose, resulting in glucose spillover into the urine.[7,214] Bernard concluded that this effect was mediated by the stimulation of autonomic drive to increase hepatic glucose output. While the neuroanatomy and neural mechanism(s) by which this early brainstem lesion altered blood glucose remain somewhat obscure, several hypothalamic systems clearly play important roles in the control of glucose homeostasis.

A variety of nutrient and hormonal cues (e.g., glucose and leptin) act in the hypothalamus to modulate glucose homeostasis.[213,215,216] For instance, as part of the counterregulatory response (CRR) to hypoglycemia, the central nervous system activates the sympathetic nervous system to alter hormone secretion and

promote hepatic glucose output to restore normoglycemia.[217,218] Conversely, other central nervous brain systems control glucose disposal and utilization.

Leptin plays a role in glucose homeostasis as well as energy balance. For instance, *Lep*$^{ob/ob}$ mice exhibit hyperglycemia despite constitutively elevated insulin production. Similarly, lipodystrophic mice and humans exhibit severe insulin resistance that is corrected by leptin replacement.[29,30,219] Leptin action in the arcuate nucleus mediates part of this effect, since restoration of arcuate nucleus LepRb expression in otherwise LepRb-null mice improves glucose homeostasis.[220–222] Leptin mediates at least part of its effects on glucose homeostasis by promoting glucose disposal and utilization: Direct central nervous system infusion of leptin increases glucose disposal and rapidly normalizes blood glucose in *Lep*$^{ob/ob}$ mice.[223,224] Central nervous system infusion of leptin also increases glucose disposal into muscle and brown adipose tissue and normalizes blood glucose in insulin-deficient rodents.[225–227]

Ventromedial Nucleus Control of Glucose and Energy Homeostasis

The ventromedial nucleus plays important roles in the regulation of the sympathetic nervous system and contributes to both hepatic glucose output and glucose disposal.[228–231] Low glucose activates glucose-inhibited ventromedial nucleus neurons that presumably participate in augmenting hepatic glucose output (e.g., to increase blood glucose during the CRR), while glucose-excited ventromedial nucleus neurons are postulated to promote glucose disposal. Since the ventromedial nucleus contains both glucose-inhibited and glucose-excited neurons, pan-ventromedial nucleus manipulations reveal the aggregate function of all cell types within the ventromedial nucleus. For instance, activating all ventromedial nucleus neurons mimics the CRR[232] because unrestrained hepatic glucose output overwhelms the ability of peripheral tissues to dispose of glucose. Conversely, under fed conditions the neurons that promote glucose utilization play a dominant role in glycemic control; thus disrupting overall ventromedial nucleus function causes glucose intolerance and blunts energy expenditure to promote weight gain.[233] Similarly, disruption of glutamatergic neurotransmission within the ventromedial nucleus (a predominantly glutamatergic nucleus) impairs glucose tolerance and increases body weight at baseline but blunts the CRR to glucoprivation.[234]

Ventromedial nucleus LepRb neurons likely contribute to the control of glucose disposal (as well as energy expenditure), since intraventromedial nucleus leptin increases glucose uptake into muscle and brown adipose tissue, and ablation of LepRb in the ventromedial nucleus decreases glucose tolerance.[96,227] Activation of ventromedial nucleus LepRb neurons (unlike the activation of all ventromedial nucleus neurons) does not mimic the CRR, however,[232] suggesting that non-LepRb ventromedial nucleus neurons mediate the CRR and other responses that increase hepatic glucose output. The ventromedial nucleus neurons that promote hepatic glucose output and mediate the CRR have yet to be definitively identified.

POMC Neurons Sense Changes in Glucose Concentration

The hypothalamic melanocortin system, including arcuate nucleus POMC neurons, also contributes to the control of glucose homeostasis.[215,220,221] For example, mice lacking MC4Rs are hyperinsulinemic prior to the onset of obesity,[44,235] while intracerebroventricular MC4R agonists decrease plasma insulin levels in lean and obese mice.[235] Moreover, MC4R-deficient humans display greater hyperinsulinemia than would be expected from their degree of obesity alone, and children as young as 12 months old are hyperinsulinemic.[236,237] Additionally, although ablation of LepRb from arcuate nucleus POMC cells minimally impacts body weight, it promotes glucose intolerance. Conversely, restoration of POMC neuron LepRb expression on a LepRb-null background improves glucose homeostasis without substantially altering body weight.

Glucose-Inhibited Neurons of the Arcuate Nucleus and Lateral Hypothalamic Area

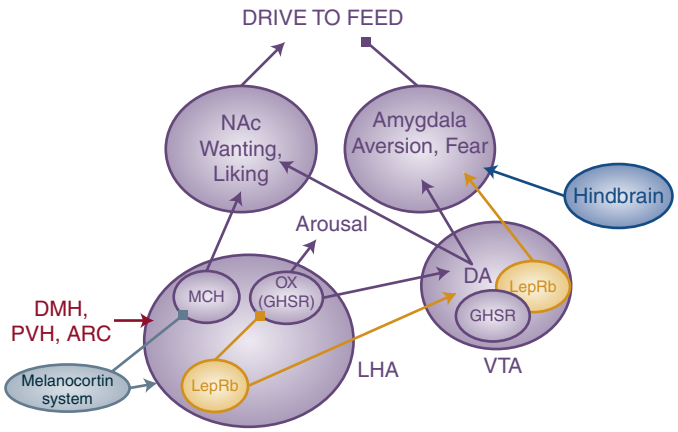
While independent effects of blood glucose, such as food intake and body weight, are less well established for arcuate nucleus NPY/AGRP cells than for POMC neurons, decreased glucose concentrations activate NPY/AGRP cells, suggesting a potential role for these cells in the response to low blood sugar (perhaps by promoting food intake during hypoglycemia). Furthermore, low glucose activates orexin-producing neurons in the lateral hypothalamic area.[165,166] Since orexin neurons play key roles in the control of arousal (see upcoming discussion), these cells could promote hypoglycemia awareness.

Intersection of Energy Balance and Reward Circuits

Behaviorally, two systems govern eating: the circuits that control the incentive and reward values (wanting and liking) of food and the satiety system, which promotes meal termination associated with the sensation of fullness.[238] Although physiologically integrated, they are often studied and described as distinct entities to reduce complexity.

Overlapping central nervous systems mediate motivation for natural and artificial rewards (e.g., food and drugs of abuse, respectively). The mesolimbic dopamine system, composed of dopaminergic neurons in the ventral tegmental area that project to the nucleus accumbens and other places, play important roles in motivation and reward.[239] For example, mice lacking the ability to produce dopamine normally die of starvation but will resume feeding after reintroduction of dopamine into the nucleus accumbens and nearby structures.[240,241] Also, lesions of the nucleus accumbens reduce food intake[242] and the desire to work for food.[243]

The neurohormonal systems that control food intake and metabolism also modulate the mesolimbic dopamine system and parameters of reward. Indeed, leptin suppresses the motivation of animals to perform rewarding brain self-stimulation,[244] and subpopulations of ventral tegmental area neurons express LepRb or ghrelin receptor.[245,246] Furthermore, ablating ventral tegmental area LepRb slightly increases the intake of rewarding foods. Ventral tegmental area LepRb neurons may also modulate anxiety-related behaviors.[247,248] Similarly, ghrelin administration increases the reward value of food, and ablation of ghrelin receptor in the ventral tegmental area increases food intake, while restoration of ventral tegmental area ghrelin receptor in ghrelin receptor-null mice increases feeding as well as partially restoring the orexigenic effects of ghrelin.[249] Taken together, these findings suggest that signals such as leptin and ghrelin not only affect hypothalamic pathways but also control reward behaviors—in part by direct action within the central nervous system reward circuitry.



• **Fig. 39.7** Reward circuits involved in feeding control. The Lateral Hypothalamic Area Links Food Intake Control and Arousal

Ablation of the lateral hypothalamic area abrogates the motivation to eat (as well as the motivation for other rewards),[250] and many types of lateral hypothalamic area neurons innervate components of the mesolimbic dopamine system. Melanin-concentrating hormone and the orexin peptides (orexin-A and orexin-B, also known as hypocretins) are uniquely expressed in distinct populations of lateral hypothalamic area neurons and contribute distinctly to the control of the mesolimbic dopamine system and feeding.[251–253] Both populations project widely throughout the brain[254,255]; the expression patterns of the receptors for these peptides are also widespread (Fig. 39.7).[256–258]

Injection of melanin-concentrating hormone into the brain increases food intake.[251] Mice lacking melanin-concentrating hormone are hypophagic and lean, while mice that overexpress melanin-concentrating hormone become obese.[259,260] In addition, mice lacking both melanin-concentrating hormone and leptin are leaner compared to mice that lack leptin but express melanin-concentrating hormone.[261] Melanin-concentrating hormone modulates the incentive value of food and drugs of abuse, at least in part via direct action in the nucleus accumbens.[262] Thus melanin-concentrating hormone contributes to the control of food intake and energy balance by modulating the reward-encoding systems of the brain.

Orexin contributes to the control of energy balance, but its role is more complex.[263,264] While initially thought to promote feeding based upon the finding that central injection of orexin peptides increases feeding and body weight,[252,265] orexin-null mice, dogs, and humans exhibit narcolepsy (a cataplectic sleep syndrome), and orexin promotes hypervigilance. Hence the control of wakefulness and vigilance represents a major function for orexin.[266,267] Indeed, mice null for orexin or its receptors exhibit obesity due to decreased activity and energy expenditure rather than changes in food intake. Thus the likely mechanism by which orexin injection promotes food intake is by the increase in wakefulness during the normal sleep cycle. Orexin neurons express ghrelin receptor, and ghrelin directly activates these cells.

While neither orexin nor melanin-concentrating hormone neurons express LepRb, leptin acts directly on a distinct set of lateral hypothalamic area LepRb neurons.[268] These lateral hypothalamic area LepRb neurons inhibit orexin neurons and also project directly to the ventral tegmental area and a few other midbrain sites and modulate the function of the mesolimbic dopamine system.[269–271] Disruption of LepRb in the neurotensin-expressing subpopulation of lateral hypothalamic area LepRb neurons alters mesolimbic dopamine function to decrease locomotor activity and promote obesity. Thus leptin action in the lateral hypothalamic area controls orexin cells and ventral tegmental area cells to modulate the mesolimbic dopamine system. Leptin likely controls melanin-concentrating hormone neurons via its action on the hypothalamic melanocortin system.[272]

Brainstem Circuits That Regulate Energy Balance

Circuits in the brainstem play important roles in the control of food intake, as well.[273–276] The brainstem represents a crucial entry point for a wide variety of signals from visceral organs, including the gastrointestinal tract, which mediate parasympathetic reflex arcs to control gut physiology and which convey signals further into the brain to promote meal termination and to modulate emotional valence relevant to gut status (e.g., nutrients in the gut promote positive valence, while toxins in the gut promote aversion) (Fig. 39.8). These gut signals converge in the dorsal vagal complex, which contains the nucleus of the solitary tract, the dorsal motor nucleus of the vagus, and the area postrema.

The area postrema is a circumventricular organ (and thus lies outside the blood-brain barrier, facilitating the sensing of circulating factors) that lies directly above the nucleus of the solitary tract.[277] Circulating signals of gut status (including a variety of gut-derived peptides) activate area postrema neurons, which relay those signals into the nucleus of the solitary tract and the lateral parabrachial nucleus.[275]

Sensory afferent signals carried by the glossopharyngeal and vagus nerves (e.g., taste, gastric stretch, nutrients in the gut and portal vein) innervate the nucleus of the solitary tract, which represents the primary site for innervation by vagal afferents from the gut.[278–280] The cell bodies of vagal afferent nerves lie in the nodose ganglia; those deriving input from the upper gastrointestinal tract respond to three basic stimuli: gastric and duodenal distention or contraction, chemical contents of the lumen, and gut peptides and neurotransmitters released from the stomach and duodenum in response to nutrients.[278] Recent work demonstrates vagal afferent neurons that express the receptor for glucagon-like peptide-1 (GLP1; GLP1R) and convey signals of stomach distension, while those that express G protein–coupled receptor 65 (GPR65) sense nutrients in the gut.[281]

The activation of nucleus of the solitary tract neurons that receive feeding-related information from the gut suppresses food intake, consistent with a role for certain nucleus of the solitary tract neurons in the control of meal termination.[282,283] While the nucleus of the solitary tract innervates a variety of hypothalamic structures (e.g., the paraventricular nucleus and dorsomedial nucleus), other important nucleus of the solitary tract targets include brainstem sites, including the dorsal motor nucleus of the vagus and the lateral parabrachial nucleus. The dorsal motor nucleus of the vagus contains parasympathetic preganglionic neurons, which innervate and provide parasympathetic input to the

entire gastrointestinal tract. Meal-activated nucleus of the solitary tract cells project to and modulate the activity of dorsal motor nucleus of the vagus neurons that alter parasympathetic tone to the stomach, decreasing the rate of gastric emptying as part of a meal-activated reflex arc.

Major projections of the lateral parabrachial nucleus, which receives input from the area postrema and the nucleus of the solitary tract, include the thalamus, the amygdala, and several hypothalamic sites.[284] Recent findings identified a set of calcitonin gene–related peptide (CGRP)–expressing lateral parabrachial nucleus neurons required for the suppression of food intake in response to aversive gut stimuli.[105,285,286] Stimuli that promote gut malaise (such as lithium chloride [LiCl] injection in rodents and some chemotherapeutic agents) activate these neurons. Furthermore, lateral parabrachial nucleus CGRP cells act via their projections to the amygdala to mediate both the suppression of food intake and the aversive response to such stimuli. Arcuate nucleus NPY/AGRP neurons also innervate lateral parabrachial nucleus CGRP neurons, inhibiting these cells to promote the consumption of disfavored foods when NPY/AGRP neuron activity is high (e.g., during prolonged fasting). The withdrawal of NPY/AGRP neuron-mediated inhibition of lateral parabrachial nucleus CGRP cells activates their amygdala projection to suppress food intake.[45,105,137,287–289] Other lateral parabrachial nucleus neurons appear to mediate the nonaversive suppression of food intake in response to distinct signals,[46] but the molecular identity of this putative second set of lateral parabrachial nucleus cells has yet to be determined.

Gut Peptides Involved in Satiety and Hunger

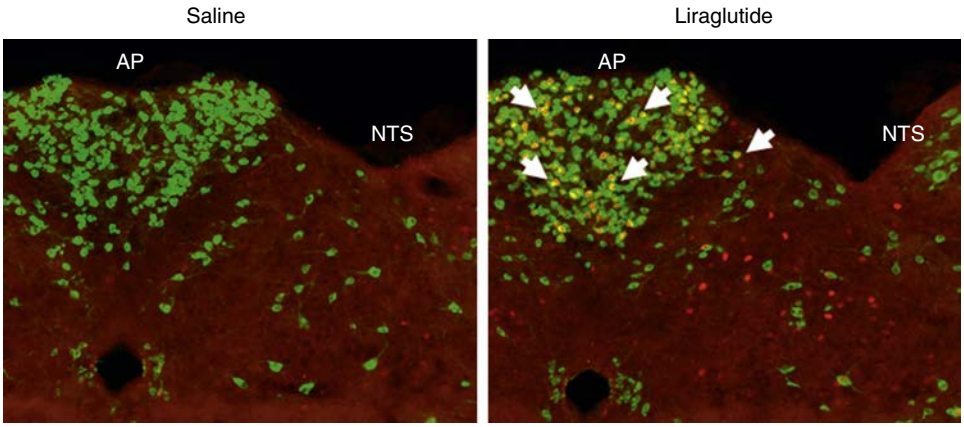
In addition to signals from gut distention, gut peptides stimulated by meal intake mediate satiety via centers in the brainstem. These gut peptide–derived brainstem signals can be modified by signals that mediate long-term energy balance, such as leptin, which acts in part via nucleus of the solitary tract LepRb neurons to increase the meal-terminating response to a number of gut peptides.[290–292] While gut-peptide signaling and brainstem signals (in general) are often considered to modulate short-term effects on feeding (e.g., decreasing meal size, which is compensated by increased meal frequency), gut peptides also interact with hypothalamic circuits that mediate long-term energy balance. Furthermore, pharmacologic agonists for many gut peptide receptors suppress food intake and can promote chronic weight loss in humans as well as in preclinical models.[293]

GLP1 Action in the Central Nervous System

Current strategies for the treatment of type 2 diabetes mellitus are not optimally effective, and even multiple drug combinations often fail to normalize glycemia in a sustained manner in many patients. Hence there remains intense interest in new therapies that safely and effectively lower blood glucose in diabetes. Over the past decade, drugs that enhance the action of incretins have seen increasing use for the treatment of type 2 diabetes and obesity.[294,295] Incretins are hormones released by the gut in response to oral ingestion of nutrients that act to increase insulin secretion. The prototypical incretin hormone is GLP1, which is derived from proglucagon; upon secretion, GLP1 undergoes rapid degradation by dipeptidyl peptidase-4 (DPP4) in the circulation.[296] While pancreatic alpha cells mainly generate glucagon from proglucagon in pancreatic alpha cells, the L cells of the intestine and the proglucagon-expressing cells in the brain mainly produce GLP1 and GLP2.[294,295]

GLP1 receptor (GLP1R) agonists induce multiple desirable antidiabetic and antiobesity actions, and protease-resistant long-acting GLP1 analogues are currently available for the treatment of type 2 diabetes and/or obesity.[294,295] In addition to enhancing glucose-dependent insulin secretion, slowing gastric emptying, and inhibiting gastric acid secretion, these compounds reduce food intake.

Given the increasing use of GLP1R analogues and DPP4 inhibitors (which block GLP1 degradation) for the treatment of diabetes and the FDA approval in 2014 of liraglutide for the treatment of obesity, understanding the central actions of GLP1 is important for predicting the biologic consequences of sustained GLP1R agonist administration. The effects of GLP1R agonists on



• **Fig. 39.9** Activation of area postrema/nucleus of the solitary tract glucagon-like peptide-1 receptor (GLP1R) neurons by peripheral administration of GLP1R agonist. *Glp1r*^{cre} mice on a green fluorescent protein (GFP) reporter background labels GLP1R expressing cells with GFP *(green)*. Neuron activation can be assayed by increased expression of the immediate early gene FOS. Treatment of fasted mice with the long-acting GLP1R agonist, liraglutide, stimulates FOS expression in GLP1R neurons *(green)* in the area postrema (AP) and nucleus of the solitary tract (NTS) 2 hours after administration. appetite may be mediated in part via inhibition of gastric emptying and may also reflect direct effects of GLP1R agonists on satiety, including the induction of nausea and other aversive gut symptoms.[297–299]

Initial interest in the central nervous system actions of GLP1 stemmed from the observation that GLP1 inhibits food intake.[300,301] In humans, peripheral GLP1 administration to normal and diabetic subjects induces satiety and reduces food intake in short-term studies.[302–305] Chronic continuous GLP1 administration to human diabetic subjects is associated with weight loss.[306,307] The central nervous system expression of GLP1 is restricted to a population of caudal nucleus of the solitary tract neurons that receive and process viscerosensory information from the gastrointestinal tract. Thus these nucleus of the solitary tract GLP1 neurons are in a prime position to rapidly modify ingestive behavior in direct response to gut signals; these cells also express LepRb and respond to leptin. Indeed, activation of GLP1 neurons in the nucleus of the solitary tract suppresses food intake and decreases metabolic rate, and chronic activation in the setting of high-fat diet–induced obesity leads to weight loss consistent with the antiobesity effects of chronic GLP1R agonist treatment.[308]

Numerous brain areas that participate in the control of food intake receive projections from nucleus of the solitary tract GLP1 neurons and express Glp1r mRNA, including the area postrema, lateral parabrachial nucleus, paraventricular nucleus, dorsomedial nucleus, and arcuate nucleus.[281,309,310] Infusion of GLP1R agonists directly into several of these brain regions suppresses feeding consistent with the idea that GLP1R agonists exert their beneficial effects through several brain regions. Deleting *Glp1r* from specific cell types in the mouse demonstrated that the feeding effects but not the glucose-lowering effects of GLP1R agonists are located in the central nervous system.[311] Several groups have ablated *Glp1r* from POMC, paraventricular nucleus, or ventromedial nucleus cells[312] without affecting anorexic response to GLP1R agonists. Broader deletion of GLP1Rs from glutamatergic neurons dramatically attenuates the response to GLP1R agonists, however, suggesting that a crucial population of GLP1R cells may lie in the hindbrain (e.g., in the area postrema [the main site where exogenous GLP1R agonists activate GLP1R-expressing neurons]) (Fig. 39.9).[310]

Peptide YY (PYY)

Endocrine cells in the ileum and colon[313] release both a full-length (i.e., 36–amino acid) and a 34–amino acid (PYY[3-36]) form of PYY following a meal.[314] PYY is a potent agonist of both Y1 and Y2 receptors, whereas PYY(3-36) is a Y2-specific agonist, with approximately a 1000 times greater affinity for the Y2 versus Y1 receptor.[315] Y1-preferring and Y2-preferring binding sites are located in the area postrema, nucleus of the solitary tract, and dorsal motor nucleus of the vagus. Peripheral administration of PYY in the rat activates neurons in the area postrema, as well as in the nucleus of the solitary tract.[316] Infusion of PYY within the physiologic range has numerous effects, including inhibition of gastric emptying,[317] gastric acid secretion,[318] and pancreatic exocrine secretion.[318] These actions of PYY appear to be mediated by PYY action directly on the nucleus of the solitary tract and dorsal motor nucleus of the vagus as well as on gastric mucosal enterochromaffin-like cells (for review see Yang[319]). Both Y1 and Y2 receptors are found within the nucleus of the solitary tract and dorsal motor nucleus of the vagus.[320] For example, PYY appears to inhibit gastric acid secretion primarily through vagal innervation of the gastric fundus.[321] The ability of low-dose PYY and PYY(3-36) to inhibit the activity of dorsal motor nucleus of the vagus efferents appears to be Y2 mediated, whereas Y1 agonists appear to stimulate these cells.[319]

Peripheral administration of PYY(3-36) in pharmacologic doses suppresses feeding in rodents as well as humans,[276,322,323] thus suggesting a potential function as a satiety factor. The mechanisms underlying the action of PYY(3-36) in reduction of food intake have not been fully elucidated. Intraperitoneal administration of PYY(3-36) activates a small number of arcuate POMC neurons.[322,324] However, vagotomy also blocks PYY(3-36)-induced inhibition of feeding,[325] and the inhibition of feeding by PYY(3-36) persists in the MC4R knockout mouse[326] and in obese *A^{y}/a* mice.[327] Thus the release of melanocortin peptides derived from POMC and their subsequent activation of the MC4R does not appear to be required for the inhibition of feeding by PYY(3-36). Furthermore, PYY appears to induce conditioned taste aversion in

rodents and nausea in some human studies, suggesting an aversive effect of the peptide likely to involve brainstem sites such as the area postrema. Interestingly, however, PYY also contributes to the inactivation of NPY/AgRP neurons during feeding.[328]

Despite the short-acting anorexic effects of the peptide in most experimental models, two knockout studies demonstrate that removal of the gene encoding PYY produces obese hyperinsulinemic mice,[329,330] suggesting that the peptide may also play an important role in the regulation of long-term energy stores. One study shows the peptide may be specifically involved in the satiating effects of protein in the diet.[329]

Cholecystokinin (CKK)

Produced by the gastrointestinal tract in response to meal ingestion, the diverse actions of CKK include stimulation of pancreatic enzyme secretion, inhibition of gastric motility, activation of intestinal motility, and the acute suppression of feeding. Early experiments administering CCK peripherally supported a role for increased CCK levels in the early termination of a meal.[331,332] The finding that repeated injections of CCK lead to reduced meal size without a change in body weight, due to a compensatory increase in meal frequency, argued against CCK acting as a signal regulating long-term energy stores.[333,334]

Two subtypes of the CCK receptor belonging to the G protein–coupled family of receptors have been described: CCKA and CCKB. Studies using CCK receptor–specific antagonists as well as surgical or chemical vagotomy demonstrated that the satiety effects of CCK are specifically mediated via CCKA receptors on afferent vagal nerves.[335–337]

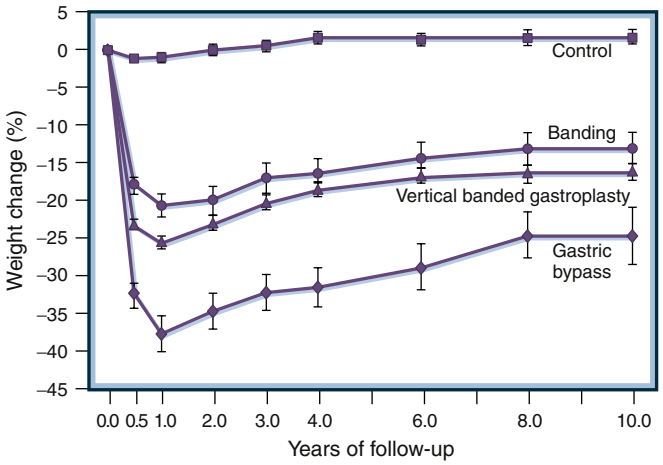
Amylin

Amylin, or islet amyloid polypeptide (IAPP), is a 37–amino acid polypeptide that is cosecreted with insulin from pancreatic beta cells in response to nutrient intake and insulin secretagogues.[338,339] In humans, pancreatic IAPP can form amyloid fibrils that are hypothesized by some to play a role in the decline in islet cell function that accompanies type 2 diabetes.[340,341] In addition, amylin has been shown to impair gastric motility and have effects independent of insulin on energy homeostasis.

Both peripheral and intracerebroventricular infusions of amylin inhibit food intake acutely and, during chronic infusion, lead to a sustained reduction in body weight.[342–344] Amylin readily enters the brain, and high-affinity amylin-binding sites have been found in several brain regions, including the hypothalamus and brainstem (including the area postrema and nucleus of the solitary tract).[342,345,346] The exact site(s) of anorectic amylin action remain unclear.

GDF15

Also known as MIC1, growth and differentiation factor-15 (GDF15) is a distant relative of the transforming growth factor-β family, most closely related to the glial-derived neurotrophic factors (GDNF).[347,348] While GDF15 is not technically a gut-derived peptide, it acts via the central nervous system to control food intake. Most tissues produce GDF15 at low levels, but a variety of cellular stressors (including hypoxia, ER stress, mitochondrial dysfunction, etc.) increase GDF15; GDF15 is not controlled by fasting, feeding, or most other nutritional interventions. Hence circulating GDF15 levels increase in disease processes that produce cellular stress, including in malignancies (most tumor cells produce GDF15), heart failure, kidney failure, and systemic infection. Exogenous GDF15 suppresses feeding (including at levels observed in the aforementioned disease states), and interference with GDF15 action provides protection from the anorexia and weight loss associated with these disease states.



• **Fig. 39.10** Apparent alteration of the adipostatic set-point after bariatric surgery. (Modified from Sjostrom L, Lindroos AK, Peltonen M, et al. Swedish obese subjects study scientific group. Lifestyle, diabetes, and cardiovascular risk factors 10 years after bariatric surgery. *N Engl J Med.* 2004;351:2683–2693.)

GDF15 acts via the GDNF receptor alpha-like receptor (GFRAL), which is expressed only in the area postrema (and to a lesser extent in the nearby nucleus of the solitary tract).[349–352] Mice null for *Gfral* (or *Gdf15*) display mildly increased body weight, especially on a high-fat diet, and GFRAL is required for the anorectic effects of GDF15 and (like GDF15) for weight loss in response to a variety of pathophysiologic insults. Thus GDF15 appears to act via area postrema GFRAL to limit food intake in response to pathologic conditions that cause cellular stress rather than in response to alterations in nutritional or metabolic status.

Bariatric Surgery

In contrast to most pharmacologic therapies, certain types of bariatric surgeries, such as the Roux-en-Y gastric bypass and vertical sleeve gastrectomy not only cause significant weight loss but also mediate the maintenance of reduced body weight for many years (Fig. 39.10). Furthermore, improvement in diabetes following these procedures often occurs before significant weight loss and is sustained in a significant percentage of patients. Both these findings imply that the procedures mediate a profound impact on the neuroendocrine control of long-term energy stores. That bariatric surgery appears capable of creating a new stable weight set-point suggests that hormonal or vagal and nutritional signals from the gut may indeed have a more profound impact on long-term energy homeostasis than previously thought.

Many researchers are attempting to identify the peripheral and central changes that produce weight loss and improve glucose control following these procedures, with the ultimate goal being to reproduce the response to surgery using a nonsurgical approach. Circulating GLP1 is elevated following sleeve gastrectomy[353] and gastric bypass,[353–355] as are bile acids. GLP1R deletion fails to modify weight loss or glucose responsiveness in a sleeve gastrectomy in the mouse however,[356] although alteration of the bile acid receptor (FXR) blunts the response to sleeve gastrectomy.[357] Presumably the alterations in feeding and body weight following sleeve gastrectomy result from increased activity of neurons within the area postrema and/or the dorsal vagal complex.

40 Obesity

ELEFTHERIA MARATOS-FLIER

CHAPTER OUTLINE

KEY POINTS

- Body mass index permits stratification of risk for obese individuals, but healthy ranges are specific to different ethnic groups.
- Body mass index is an imprecise measure of adiposity.
- Energy homeostasis involves complex molecular and physiologic processes that determine both food intake and energy expenditure.
- Both environmental and genetic factors contribute to energy homeostasis.
- Most human obesity is polygenic, and single gene mutations are responsible for a relatively small number of cases of obesity.
- Currently available weight-loss treatments include dietary intervention, increased physical activity, behavior modification, pharmacotherapy, and surgical approaches.

Obesity is a chronic disease and a significant risk factor for multiple serious medical problems. Obesity is also associated with impaired quality of life, and considerable economic and social burden due to increased health care costs and loss of productivity.[1,2] This chapter addresses key clinical and pathophysiologic issues in obesity.

Obesity is not a new phenomenon. It was described by Hippocrates, who made observations on the importance of diet in individuals with excess weight, also noting that the Scythians were obese because they were sedentary, and describing them as flabby and torpid.[3] Galen, writing in the second century of the common era, described obesity as an illness for which he prescribed diet and exercise and used the term *polysarkia* to refer to morbid obesity.[4] Obesity as a recognizable medical condition persists throughout history usually as a problem of the wealthy and sedentary, such as Henry VIII of England, who weighed more than 300 pounds (136 kg) and likely suffered from type 2 diabetes and gout at his death.

In the United States, rates of obesity became worrisome in the 1990s as overweight and obesity increased in the population. Until the past two decades, rates of both were higher in the United States than in other countries. Recently other nations have caught up, and prevalence is higher now in Mexico and countries in the Middle East than in the United States. Considering that the genetics of the population has not changed over the interval during which the dramatic rise in rates of obesity have occurred, the increase must result from a complex interplay of genes and environment. Many individuals have a predisposition toward eating and storing calories when they are available. The tendency to store excess fat is common in many mammals, as seen in the incidence of obesity in pets in developed countries. This may be a consequence of selection over time for effective storage, as starvation is an acute threat to survival, whereas the comorbidities of obesity take years to decades to become problematic.

Mammals have evolved to acquire food and store it as fat against times of food scarcity. Until the modern era, food scarcity had been a substantial threat to existence over excess calories. A pound of fat, containing 3500 calories, may provide 2 to 4 days of survival for an individual without any food supply. In a very calorie restricted environment, 50 pounds of extra fat would make a substantial survival difference. Lean persons will die after only approximately 60 days of starvation, when more than 35% of body weight is lost. Obese persons can tolerate longer fasts, even for more than 1 year, without major adverse effects. In the longest reported fast, a 456-pound (207-kg) man ingested only acaloric fluids, vitamins, and minerals for 382 days and lost 278 pounds (126 kg), or 61% of his initial weight.

Assuming genetic traits and a physiology favoring eating and storing excess calories dating back to antiquity, the modern obesity epidemic is more likely explained by changes in the food environment. As a consequence of modern agriculture and ease of transportation of food to the consumer, food is cheaper, more readily available, and more varied than ever before, and together with genetic predisposition much of the world population is now fighting obesity. Alternative explanations for obesity have also been proposed. For example, one posits that mammals can risk excess body weight when they are not subject to predation and that food uncertainty does not play a role in driving excess weight gain.[5]

Definition of Obesity

Body Mass Index

Obesity represents an unhealthy excess in body fat mass. The current practical definition of obesity is determined by calculating body mass index (BMI), by dividing an individual's weight in kilograms by the square of height in meters (BMI = weight [kg]/height [m^2]). Underweight, normal weight, overweight, and obesity are defined on the bases of increased risk for mortality and predisposition of comorbidity. Table 40.1 summarizes the classification of weight status by BMI proposed by the major national and international health organizations. However, BMI is an imperfect index of excess fat. BMI calculations do not factor muscle mass so that at any given weight, an individual with greater muscle mass will be less liable to comorbidities. Furthermore, individuals classified as obese may be healthy without any comorbidity. Other as yet unidentified factors predispose some individuals to metabolic consequences early in life, whereas in some, comorbidities evolve later, after decades of obesity. The relationship between BMI and comorbidity is visualized in Fig. 40.1. Increased mortality at lower BMI may represent the contribution of smoking; eating disorders; and chronic disease states such as heart failure, cancer or malabsorption. As BMI rises, mortality increases, as increased fat increases risk for diabetes, cardiovascular disease, liver disease, cancer, sleep apnea, arthritis, and other diseases.

The precise magnitude of excess weight associated with increased mortality risk remains somewhat unclear. Overweight and even class I obesity was not associated with increased mortality in a report on the National Health and Nutrition Examination Survey data collected between 1971 and 2000.[6] However, studies concur that risk is increased for class II (BMI >35 kg/m^2) or higher-magnitude obesity.

Body Fat Distribution

The relationship between BMI and health risk is not absolute but is influenced by body fat distribution, age, concomitant medical illness, weight gain, aerobic fitness, and ethnicity.

Excess body fat is not distributed equally in all people. Some obese persons develop excess visceral obesity and will be at higher risk of comorbidities than those with excess subcutaneous fat. Waist circumference correlates with abdominal fat mass and is a surrogate marker for visceral obesity, and thus is a predictor of health outcomes in adult men and women regardless of age or ethnicity. The relationship between waist circumference and comorbidities is strongest for diabetes risk, and waist circumference is an independent and better predictor of diabetes than BMI. Waist circumference thresholds for increased cardiometabolic risk are 40 inches (102 cm) in Caucasian men and 35 inches (88 cm) in women; these cutoff values were derived from waist circumference values that correlated with a BMI of 30 kg/m^2 or greater, based on populations of European origin.

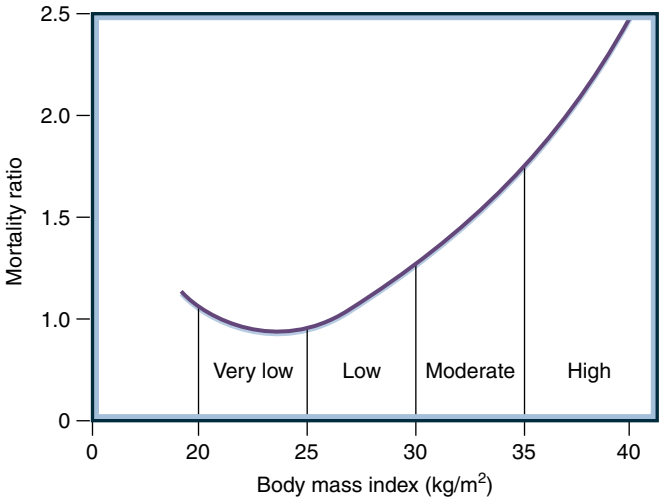
BMI-associated health risk is influenced by ethnicity. Asian-Pacific populations are at increased risk for the development of diabetes and cardiovascular disease at lower BMI ranges than other populations. Accordingly, in these populations, the World Health Organization proposed lower BMI cutoffs for public health action[7] (see Table 40.1). Asian populations also tend to have more visceral obesity at lower BMI compared with other ethnic groups, and, further, at any given waist circumference, the relative risk of mortality is higher. World Health Organization guidelines define waist circumference thresholds in the Asian population as 90 cm for men and 80 cm for women. Different levels have been suggested in Japan and China, with cutoff values of 85 cm for men and 80 cm for women, and slightly lower values have been suggested in India. Black individuals also appear to have increase disease risk at lower BMI thresholds than individuals of European descent—for example, the equivalent risk BMI for diabetes is 30 kg/m^2 in Caucasian women and 26 kg/m^2 in black women.[8] There is also a significant sex difference in comorbid disease risk, with men having higher risk than women across the range of ethnicities.[9]

The risk of developing obesity-associated diabetes or cardiovascular disease can be modified by aerobic fitness. The incidences of diabetes and cardiovascular fatality are lower in those who are physically fit, as defined by maximal ability to consume oxygen during exercise, compared with those who are unfit across a range of body adiposity. For example, in a population of middle-age men, low aerobic capacity was associated with increased mortality rates, independent of traditional risk factors, including smoking, blood pressure, and serum cholesterol, during more than 40 years of follow-up.[10]

TABLE 40.1 Weight Classification by BMI

Weight Classification	Obesity Class	BMI (kg/m^2) Europeans	BMI (kg/m^2) Asians	Risk of Obesity-Related Diseases
Underweight		<18.5	<17.5	Increased
Normal weight		18.5–24.9	17.5–22.9	Normal
Overweight		25.0–29.9	23.0–27.4	Increased
Obesity	I	30.0–34.9	27.5–32.4	High
	II	35.0–39.9	32.5–37.5	Very high
Extreme obesity (polysarkia)	III	≥40.0	≥37.5	Extremely high

BMI, Body mass index.



• **Fig. 40.1** Relative risk for morbidity and mortality in obese European populations. The thresholds for defining obesity are based on risk. Although risk rises even at fairly low body mass index, the inflection thresholds are seen in the body mass index range greater than 35 kg/m^2, especially in men.

Physiology of Energy Balance

Energy homeostasis, defined as the balance between energy intake and energy expenditure, is regulated by complex molecular and physiologic processes. Control of energy homeostasis requires physiologic integration of biologic signals from different organs including fat, muscle, liver, gut, and brain; nutrient-related signals; and postprandial neural and hormonal influences.

Regulation of energy intake is complicated because it includes both homeostatic and hedonic feeding. Homeostatic feeding is the component responding to signals aimed at maintaining weight, such as hunger occurring with long intermeal intervals, whereas hedonic feeding is defined as excess eating in the satiated state based on availability of highly palatable food or social cues that encourage eating. Eating can also be influenced by emotional moods including stress or depression, which lead to overeating in some individuals while decreasing food consumption in others.

Central Nervous System Regulation of Appetite

The hypothalamus is an important area for integrating complex signals that govern food ingestion. Pro-orexigenic neurons in the arcuate nucleus, which express neuropeptide Y (NPY) and agouti-related protein (AgRP), and appetite inhibiting neurons, which express the proopiomelanocortin (*POMC*) gene and process its product to α-melanocyte-stimulating hormone (αMSH), are two well-studied hypothalamic networks that inversely regulate weight. Key issues are summarized in the following (for additional details, see Chapter 39).

Administration of both NPY and AgRP peptides into rodent brain markedly increased food intake, even in satiated rats. Direct stimulation of these neurons also induces feeding. However, eliminating expression of NPY, AgRP, or both peptides in transgenic mice is associated with at best minimal feeding phenotypes. Full ablation of the neuronal population is required to observe decreased feeding, suggesting that the neurotransmitter expressed by theses neurons, γ-aminobutyric acid, is more important than either peptide in regulating appetite. POMC neurons, a discreet population localized to the arcuate nucleus, play a role to inhibit eating. The precursor protein POMC is processed to αMSH, which suppresses feeding. Elimination of POMC expression leads to obesity in both rodents and humans. Furthermore, a downstream receptor for αMSH in the brain, the melanocortin 4 receptor (MC4R) is critical for maintaining normal energy balance. MC4R is regulated by both αMSH and agouti, and the output of MC4R neurons in the paraventricular nucleus and other locations represents a balance of AgRP and MSH signaling. The finding that *MC4R* deletion in mice and mutations of *MC4R* in humans are associated with obesity confirms the central role of these neurons in energy balance. Indeed, in humans, *MC4R* mutations are the most common cause of monogenic obesity, accounting for about 5% of early-onset familial obesity.

Other areas in the hypothalamus contribute to feeding and weight. For example, the lateral hypothalamus contains populations of neurons expressing the neuropeptide melanin-concentrating hormone (MCH), and a distinct population expresses orexin. In rodents, MCH administration into the brain leads to an acute, robust increase in feeding, whereas genetic deletion of the neuropeptide leads to leanness.[11] MCH antagonists inhibit feeding in several species; however, they are frequently associated with undesirable side effects complicating the development of an effective therapeutic.[12] MCH neurons receive inputs from the arcuate nucleus, and MCH appears to be important in the action of leptin. However, human biology is complicated by the presence of two receptors (MCH-R1 and MCH-R2) in higher mammals. Orexin is another lateral hypothalamic peptide implicated in feeding but more important in generalized arousal, as rodents, dogs, and humans without orexin have narcolepsy.

The endocannabinoid system is also involved in the regulation of food intake, particularly the cannabinoid 1 (CB_1) receptors (encoded by *CNR1*) and their endogenous ligands, anandamide (*N*-arachidonoyl-ethanolamine) and 2-arachidonoylglycerol. Absence of CB_1 receptors in mice with a disrupted *CB_1* gene causes hypophagia and leanness. Administration of cannabinoids increases food intake and promotes body-weight gain, and treatment with selective CB_1 receptor antagonists decreases food intake and body weight in obese mice. Although randomized controlled trials in obese individuals with a CB_1 receptor antagonist found decreased body weight, administration of the antagonist was associated with depression and anhedonia,[13] which complicated attempts to target the system for weight loss.

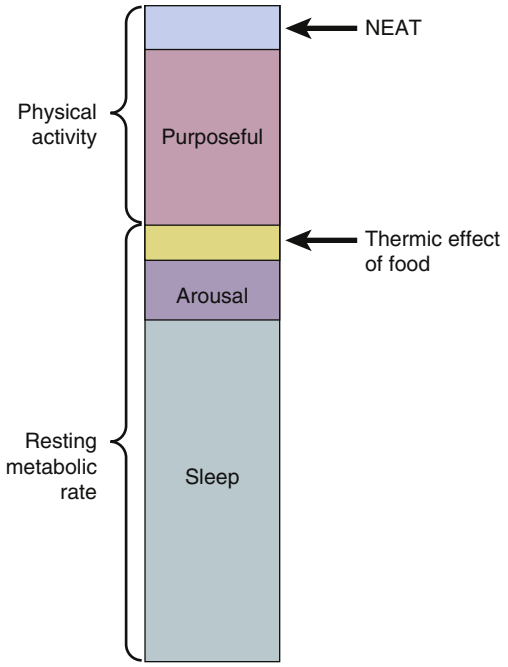
Signals From the Periphery Regulating Appetite

Multiple peripheral signals regulate energy homeostasis. Leptin, the product of the *ob* gene, is critically important for weight maintenance. Leptin absence, resulting from gene mutations, is associated with absent appetite control resulting in morbid obesity in mice, rats, and humans. Although leptin is necessary for weight maintenance, it is not sufficient. As rodents become obese, adipose tissue synthesizes increased leptin, causing increased levels in the circulation. However, the increased levels fail to decrease food intake. Likewise, most overweight and obese humans have high circulating leptin concentrations. Thus, most obesity is associated with resistance to leptin action.

Most other peripheral signals that participate in energy balance are derived from the gut. Of these, ghrelin is an orexigenic factor derived from the stomach that increases before meals and decreases after feeding. Most other gut peptides, secreted by enteroendocrine cells, inhibit appetite. Of these, glucagon-like peptide 1 (GLP1), derived from pre-proglucagon, is secreted by the L cells of the intestine that also secrete peptide YY. GLP1 and peptide YY are co-secreted after a meal and induce satiety,[14] and GLP1, when infused directly into the rat ventricle, opposes the actions of orexigenic peptides including MCH and NPY.[15] Cholecystokinin, another gut peptide, is distributed throughout the gastrointestinal tract. It stimulates bile release from the gallbladder after a meal but likely also contributes to satiety.

Energy Expenditure

Energy expenditure is a key component critical for weight homeostasis. Several factors contribute to total daily energy expenditure (Fig. 40.2). The largest component is basal or resting energy expenditure, defined as the energy required in the basal state for normal cellular and organ function; it has also been termed *basal metabolic rate*. Resting energy expenditure accounts for approximately 70% of total energy expenditure. A second significant contributor is the energy expended by physical activity, which represents a smaller contribution, about 20%, of the daily total. Voluntary activities such as exercise, and involuntary activities important in maintaining posture and fidgeting, contribute to this component of total energy expenditure. Digestion of ingested nutrients also contributes to energy expenditure and is termed the *thermic effect of food*,



• **Fig. 40.2** Components of energy expenditure. The largest component is heat generated by biochemical reactions and physiologic processes occurring at rest that are required for systemic homeostasis, including respiration, circulation, and excretion. The process of arousal increases resting energy expenditure as posture needs to be supported. Resting energy expenditure is regulated by hormones, output from the central nervous system, and sympathetic activity. Eating also requires energy, and postprandial processes involved in digestion and absorption and distribution of nutrients contribute to the thermic effect of food. Physical activity is a smaller component of energy expenditure and includes the energy expended toward purposeful activities and nonexercise activity thermogenesis (NEAT), such as fidgeting.

accounting for about 10% of the daily total and representing the energy expended in chewing, digestion, absorption, and sympathetic nervous system activation after a meal.

Resting energy expenditure is regulated by several mechanisms, particularly by thyroid hormone.[16] An excess of thyroid hormone as seen in thyrotoxicosis leads to increased resting energy expenditure that in many individuals will lead to significant weight loss, unless they experience compensatory hyperphagia. Indeed, weight loss can be a presenting symptom of hyperthyroidism. Given the effects of thyroid hormone to reduce weight, in the mid-20th century it was transiently used therapeutically in obesity. Although effective, serious side effects curtailed use.

In contrast to the clear effects of thyroid hormone to regulate resting energy expenditure, the role of the sympathetic nervous system is less clear. Epinephrine and norepinephrine are critical regulators of metabolism across multiple organs activating what is commonly referred to as the fight-or-flight response, but a precise role in regulating resting energy expenditure remains hard to define. Sympathetic activity increases after meals and contributes to the thermic effect of food. In addition, patients with tumors secreting epinephrine and norepinephrine (pheochromocytoma) manifest downstream effects of increased sympathetic activity, such as tachycardia and hypertension, but rarely present with weight loss. Although it is possible that individuals prone to obesity have lower sympathetic activity and therefore resting energy expenditure than those who maintain lower body weights, the role of sympathetic activity in energy homeostasis in humans is uncertain.

Effects of resting energy expenditure on weight gain also remain unclear. In a longitudinal study of 92 Pima Indians, the highest cumulative incidence of a 22-pound (10-kg) weight gain after 1 to 4 years was seen in those in the lowest tertile of resting energy expenditure at baseline.[17] In contrast, no relationship between initial resting energy expenditure and weight change was found in the Baltimore Longitudinal Study on Aging, which followed 775 men for 10 years.[18] However, currently available research technology is unable to detect small but chronic reductions in energy metabolism that may be clinically important over time. In addition, it is difficult to establish a causal relationship between energy expenditure and the development of obesity, because energy metabolism measurements capture only a brief point in time and therefore may not reveal abnormalities that emerge during specific life stages. Genetic or environmental differences may also impact the relationship between resting energy expenditure and weight change.

The two other components of energy expenditure—voluntary activity (exercise) and nonexercise activities—contribute to obesity. Increased food consumption is required for energy homeostasis in the setting of increased voluntary activity, as seen in athletes, people with regular exercise, or physically demanding jobs. When these activities end, as for young adults previously participating in college sports, resulting weight gain can be substantial. Likewise, nonexercise activity thermogenesis, such as fidgeting, may contribute to weight maintenance, as individuals with higher nonexercise activity thermogenesis tend to have some resistance to weight gain.

Body Weight Set-Point

Many individuals will maintain a constant weight over years and even decades, supporting the theory that there is a set-point regulating food intake and energy expenditure so that weight stays constant.[19] The set-point theory is that a complex set of physiologic adaptations maintains body weight. According to the set-point theory, body weight is predetermined such that weight loss promotes a decrease while weight gain promotes an increase in metabolic rate that acts to restore body weight to a preset level.[20] The effectiveness of the set-point has been called into question because many individuals will gain weight over time.[21]

Hypocaloric feeding reduces energy expenditure by an average of 8 kcal/kg of lean body mass in obese individuals but only 6 kcal/kg of lean body mass in normal-weight individuals, amounting to a 15% to 20% daily decrease.[22] This reduction cannot be completely accounted for by the accompanying decrease in body size, or lean or adipose body mass, and is considered a normal part of the physiologic adaptation to energy restriction.

The decrease in energy metabolism with weight loss is largely appropriate for concomitant changes in body composition, and a persistent decrease might promote weight regain. However, the reduction in resting energy expenditure that occurs during negative energy balance is transient and does not persist during maintenance of a lower body weight. Long-term maintenance of weight loss is not associated with an abnormal decrease in either resting or total energy expenditure when adjustments are made for changes in body composition,[23] although this remains controversial.[24]

When energy intake exceeds energy expenditure, weight gain occurs, but the amount of weight gained varies among individuals. Genetic factors can influence the amount of weight gained with overfeeding. Data from a study that fed monozygotic twins an extra 1000 kcal/day for 84 days found considerable variability

in weight gained among different twin pairs but that members of each twin pair gained similar amounts of weight while overfed and then lost similar amounts during the postoverfeeding recovery period.[25] The amount of weight gained may also reflect the extent of the increase in energy expenditure that is a consequence of overfeeding.[22] In another study, increase in body fat after 8 weeks of overfeeding was inversely related to changes in nonvolitional energy expenditure (e.g., fidgeting), aspects of which may be regulated.[26]

Pathogenesis of Obesity: Genes and Environment

It is challenging to identify causal factors of obesity because there are few monogenetic forms of obesity, and many single nucleotide polymorphisms (SNPs) associated with excess weight are in noncoding regions of the genome. In addition, there are substantial social and environmental determinants of weight. Food environments are complex and include not just food availability but food cost, cultural perspectives of weight, and an individual's social network.

Environmental Effects in High-Risk Populations

A striking example of the effects of modern diet on obesity is seen in Pima Indians living in Arizona. A combination of diet and lifestyle changes starting in the 1950s resulted in an epidemic of both obesity and diabetes. The modern diet is much higher in fat (50% of energy as fat) than the traditional Pima diet (15% of energy as fat). In addition, Pima Indians who became urbanized are more sedentary, especially when compared with the Pima Indian population still living in the Sierra Madre Mountains of northern Mexico. These rural Pima Indians eat a traditional diet and are physically active as farmers and sawmill workers; they have a much lower incidence of obesity and diabetes than their Arizona kindred.[27] Likewise, Aborigines of northern Australia are another high-risk population whose weight and health status has been compromised by exposure to a modern environment. Urbanized Aborigines are heavier than and have a high prevalence of type 2 diabetes mellitus compared with rural kindred, who are usually very lean (BMI <20 kg/m^2). The traditional Aboriginal diet included a low-fat, low-calorie diet of wild game, fish, and plants, as well as a high level of physical activity. Short-term (7 weeks) reexposure to the traditional lifestyle can result in weight loss and significant improvements or normalization of glucose tolerance and fasting glucose, insulin, and triglyceride concentrations in urbanized Aborigines with type 2 diabetes mellitus and hypertriglyceridemia.[28]

Influences of Childhood and Parental Obesity

Childhood obesity increases the risk of becoming an obese adult, as does having at least one obese parent. The risk of adult obesity increases with increasing age and with the severity of obesity in childhood. For example, the risk of being obese at 21 to 29 years of age ranged from 8% for persons who were obese at 1 to 2 years of age and had nonobese parents to 79% for persons who were obese at 10 to 14 years of age and had at least one obese parent, with multiple permutations between these extremes. It remains unclear how much of this is due to the genetic risk from parental obesity, including epigenetic factors, or the environmental and behavioral traits that may be shared between parent and offspring.

Genetics and Obesity

Monogenic Causes of Obesity

Only a small percentage of obese people have an identified single gene mutation that leads to obesity. The most common identified mutation associated with obesity involves MC4R, which is expressed in the central nervous system, in neurons downstream of those emanating in the arcuate nucleus. Action of αMSH from the arcuate nucleus on MC4R inhibits appetite, so a functioning MC4R is essential to maintain normal body weight. Frameshift mutations in MC4R in individuals with childhood obesity, reported by multiple groups,[29,30] may account for about 5% of early-onset obesity. These are usually heterozygous, and a gene dosage effect is seen; individuals homozygous for the same mutation or double heterozygotes for different mutations will have more severe obesity. The range of mutations is very diverse.[31] Individuals with *MC4R* mutations will respond to bariatric surgery, although the magnitude of response may vary depending on the specific mutation.[32,] In addition, MC4R agonists are currently in clinical development, as it may be possible to rescue melanocortin signaling using MC4R agonists, depending on the specific *MC4R* mutation involved.[33]

Other, much less common, mutations in the melanocortin signaling pathway involve those in the *POMC* gene, which leads to loss of all of the product peptides including adrenocorticotropic hormone and αMSH. The presentation of patients with *POMC* mutations is typically secondary to adrenal insufficiency, usually observed in early life. Consistent with absent melanocortin signaling, individuals also have red hair.

Although leptin is critical for the normal maintenance of energy balance, very few leptin-deficient humans have been identified, and leptin mutations are extremely rare.[34] The first humans with a leptin mutation,[35] which resulted in a protein that was not secreted, was found in a pair of consanguineous cousins. Shortly thereafter, three members in an obese family were reported with leptin receptor mutations.[36] There is remarkable consistency in the phenotype of mice and humans with absolute deficiency in leptin signaling, whether as a result of absent leptin or a mutation in the leptin receptor. Both mice and humans demonstrate massive early-onset obesity, hyperphagia, exaggerated food-seeking behavior, and infertility. Normal pubertal development does not occur in the absence of leptin. The handful of individuals with leptin deficiency can be treated with exogenous leptin, which normalizes weight and food intake, permits puberty,[37,38] and reestablishes insulin sensitivity.[39] As would be expected, leptin is of no use in individuals with leptin receptor deficiency.[40]

Prohormone Convertase 1 Gene Mutation

Prohormone convertase 1 (also known as proprotein convertase subtilisin/kexin type 1 [PCSK1]) cleaves POMC and is involved in processing of peptides in enteroendocrine cells in the gut. A few individuals with mutations in *PCSK1* and obesity have been identified.[41] Although the initial report involved a mutation in *PCSK1* in an adult obese woman with a history of severe childhood obesity, a significant number of individuals with this mutation present with diarrhea and failure to thrive. In some individuals, this then evolves into obesity, although the mechanisms promoting the transition remain poorly understood.

Mutation of the Neurotrophin Receptor TrkB

The neurotrophin brain-derived neurotrophic factor (BDNF) acts through a receptor kinase, TrkB, to potentiate synaptic

transmission. Heterozygous deletion of *BDNF* in mice leads to a syndrome of hyperphagia obesity and aggression. In humans, mutations in this system are very rare but include a report of a chromosomal deletion encompassing the *BDNF* gene in a mother and child pair.[42] At least one case of a mutation in the TrkB signaling pathway associated with developmental delays and obesity has been reported in an 8-year-old boy. The mutation was associated with impaired receptor autophosphorylation.[43]

Single-Minded Homolog 1 (*SIM1*) Gene Mutation

A de novo balanced translocation between chromosomes 1 and 6 was found in a severely obese girl who weighed 104 pounds (47 kg) at 5½ years of age.[44] The mutation caused a disruption in *SIM1*, the human homolog of the *Drosophila* single-minded (*sim*) gene that regulates neurogenesis. *SIM1* encodes a transcription factor involved in the formation of the paraventricular and supraoptic nuclei. It is likely that this mutation altered energy balance in this patient by stimulating food intake, because measured resting energy expenditure was normal. In addition, several chromosomal deletions involving 6q14-q21, a region that includes *SIM1*, have been identified in obese patients presenting with developmental delay and a Prader-Willi–like syndrome,[45] although the specific role of SIM1 haploinsufficiency has not been definitively established.

Src Homology 2B 1 (SH2B1) Deficiency

Src homology 2B adapter protein (SH2B1) interacts with several receptors to modulate signaling of ligands including leptin, insulin, and growth hormone. In mice, deletion of this gene results in obesity and insulin resistance when mice are exposed to a high-fat diet. In humans, this deletion is associated with a range of abnormalities including early-onset obesity and hyperphagia. Consistent with a role in insulin signaling, problems with insulin sensitivity appear disproportionate to the severity of obesity. Behavioral abnormalities have also been reported.[46] Interestingly, the result of deletions that include the *SH2B1* gene at the chromosomal 16p11.2 site may be pleiotropic and not include obesity.[47]

Obesity Syndromes

Prader-Willi Syndrome

Prader-Willi syndrome was initially described more than 60 years ago as an association of morbid obesity, short stature, hypogonadism, and cognitive deficiency.[48] Prader-Willi results from a chromosomal abnormality in which the paternal segment of chromosome 15q11.2-q12 is either deleted or absent. Interestingly, maternal deletion of the same segment is associated with a distinct phenotype known as Angelman syndrome, which is an autistic spectrum disorder.[49] Prader-Willi has a prevalence of 1 in 15,000 to 30,000 births. The molecular etiology has been linked to a deletion in the melanoma antigen gene (MAGE) family member L2 *(MAGEL2)*, a regulator of ubiquitin kinase.[50]

Bardet-Biedl Syndrome

Bardet-Biedl syndrome is rare, with a prevalence of less than 1 in 100,000, mostly seen in consanguineous populations. The disorder is clinically heterogeneous and includes obesity, hypogonadism, and abnormalities that include dysmorphic extremities, renal impairments, and retinopathies. Severe vision loss is not uncommon. Bardet-Biedl syndrome maps to multiple genes that lead to abnormal ciliary function[51,52]; how these cause obesity remains unknown.

Polygenic Causes of Obesity

Obesity results from a complex interaction of genetic predisposition and a nutrient-rich environment. More than 100 polymorphisms have been identified as potentially contributing to the predisposition to obesity.[53] However, most of these loci individually make only small weight contributions to obesity. Among hundreds of genes, the best association is with *FTO* (the fat mass and obesity associated gene).[54]

FTO was originally identified as a gene playing a role in programed cell death. In 2007, three studies demonstrated an association between variations in *FTO* and body mass. Several polymorphisms have been identified. The 16% of individuals homozygous for the risk allele SNP rs9939609 weigh about 3 kg more and have 1.67-fold increased odds of obesity when compared with those not inheriting a risk allele. This association reflects a specific increase in fat mass and can be seen in those 7 years and older.[55] A similar association with common *FTO* variants was reported in a population from Sardinia.[56] These reports were followed by numerous reports of *FTO* and excess body weight in multiple human populations. However, the mechanistic link between *FTO* and obesity has been difficult to make. The phenotype of the SNPs is difficult to identify, with some reporting increased caloric intake and some reporting decreased physical activity. Mouse studies point to a role of *FTO* in regulating body composition.[57] *FTO* has also been implicated in reward systems and methylation of proteins involved in synaptic transmission and cell signaling,[58] as *FTO* encodes a 2-oxoglutarate–dependent nucleic acid demethylase.[59] However, the causal link between *FTO* and obesity remains elusive and raises significant questions as to how to best investigate causality of human genetic variants in disease.[60]

Most individuals, perhaps up to BMIs in the high 30 range, are likely physiologically normal and become obese as they respond to the temptations of modern environments rich in high-calorie food. Given the polygenic nature of obesity, where many variants in the same or different genes contribute only modestly to body weight but may act synergistically to quantitatively affect weight, it is likely that polygenic risk scores may better estimate the overall genetic risk of obesity from common variants rather than individual risk variants considered alone.[61] Epigenetic factors may also contribute by regulating expression of obesity-associated genes. A better understanding of factors contributing to the pathogenesis of obesity might be obtained if we use the BMI range to identify the relative risk of comorbidities rather than as a guide for discovering pathology. The search for genetic variants of disease might be more fruitful if the comparisons focused on extreme leanness and extreme obesity.

Adipose Tissue as an Endocrine and Immune Organ

Until fairly recently, the traditional view of adipocytes was as a passive, efficient storage depot for triglycerides that would be released with fasting to provide fuel. This view changed as discoveries indicated adipocytes secrete multiple factors, termed *adipokines*, with both metabolic and immune functions[62] (Table 40.2). One of the first secreted factors was adipsin, a serine protease in the complement family[63] whose expression was impaired in both genetic and acquired obesity.[64] Although more than 30 years have elapsed since this initial observation, the role of adipsin in adipocyte and systemic biology remains relatively obscure and serves as an example of some of the difficulties encountered in understanding adipocyte

TABLE 40.2 Adipocyte-Secreted Factors

Category	Protein
Hormones	Leptin, resistin, angiotensinogen, adiponectin, estrogens, visfatin, glucocorticoids, angiopoietin 4, apelin
Cytokines	Interleukins 1, 6, 8, 10; monocyte chemoattractant protein 1; interferon-γ; tumor necrosis factor α
Extracellular matrix proteins	Various subtypes of collagen α1, various metalloproteinases, fibronectin, osteonectin, laminin, entactin, thrombospondin 1 and 2
Complement factors	Adipsin, complement C3, factor B
Enzymes	Cholesterol ester transfer protein, lipoprotein lipase
Acute phase response proteins	Alpha-1-acid glycoprotein, haptoglobin
Other	Fatty acids, plasminogen activator inhibitor 1, prostacyclin, vascular endothelial growth factor

biology. Understanding immune responses in obesity is further complicated by findings of increased infiltration of immune cells in fat. Initially considered pathologic, recent findings suggest that they may also play a positive role in adipose tissue metabolism by clearing lipids and senescent fat cells.[65] Different types of infiltrating immune cells may play different roles within the adipose tissue. Multiple hormones and cytokines are synthesized in fat, a selection of which are considered here.

Leptin

Potentially the most critical product of the adipocytes is the protein leptin, which is synthesized in the adipocyte and released into the circulation. Leptin is required for normal energy balance, as genetic deletion in both rodents and humans is associated with morbid obesity, as noted earlier.[66] Leptin synthesis is regulated, and levels fall dramatically with starvation, leading to many functional consequences including a decrease in fertility, which can be corrected by exogenous leptin in both mice and humans.[67,68] Leptin levels also rise with acute overfeeding.[69]

Although leptin deficiency leads to morbid obesity, most obese humans have high levels of leptin, and indeed adiposity correlates with circulating serum leptin levels in both rodents and humans, leading to the concept of leptin resistance,[70–72] which is supported by attenuated induction of downstream mediators of leptin action in obese rodents. The existence of leptin resistance, which has recently been linked to the stability of the leptin receptor,[73] also suggests that leptin does not serve as a biologic "adipostat" and that its primary function is to signal starvation.[74]

Resistin

Resistin is another signaling polypeptide secreted by adipocytes. Resistin concentrations are increased in mice with diet-induced and genetic forms of obesity and insulin resistance. Administration of recombinant resistin to normal mice leads to impaired glucose tolerance and attenuated insulin action. Based on these findings, it has been proposed that resistin is a hormone that links obesity to diabetes by inducing insulin resistance.[75]

Adiponectin

Adiponectin is a key signaling peptide produced by adipocytes; it is also the most abundant.[76] Plasma adiponectin concentrations are decreased in obesity and insulin resistance in both rodents and humans. Adiponectin acts to increase insulin sensitivity,[77] and expression increases with improved insulin sensitivity, such as when animals are treated with thiazolidinediones.[78] Weight loss[79] independent of the type of diet is also associated with increases in circulating adiponectin. However, adiponectin structure is quite complex, being composed of protein dimers and tetramers. The ratio of high-molecular-weight isoforms to low-molecular-weight isoforms is more important than total adiponectin in determining insulin sensitivity[80] and weight loss. Additionally, there are two receptors mediating its action. Administration of exogenous adiponectin lowers glucose in obese rodent models through suppression of hepatic gluconeogenesis, as well as promoting liver ceramide breakdown.[76] Unfortunately, it has not been possible to develop adiponectin-based therapies due to the complex structure. Several SNPs of adiponectin in human populations have been reported and may be linked to cardiovascular disease; however, the possible mechanism(s) remain uncertain.[81]

Estrogens

Adipose tissue contributes to total serum estrogen derived from androgens through the action of aromatase, which catalyzes formation of estrone from androstenedione. The conversion rate of androstenedione into estrone increases with age and obesity. In women, after menopause, adipose tissue becomes a significant source of estrogen biosynthesis. Increased estrogen has been implicated in the risk of breast cancer in obese women.[82] Adipose tissue also expresses estrogen receptors ERα and ERβ. Differential expression of estrogen receptors in different depots and gender differences in estrogen concentrations may explain, in part, differences in lipid accumulation in men and women.[83] Postmenopausal women who lose weight have lower breast cancer risk than those with stable weight or weight gain. It is possible that this effect is modulated through adipose estrogens, although this remains speculative.[84]

Selected Cytokines

Expansion of adipose tissue leads to a low-grade inflammatory state in fat.[65] Increased expression of cytokines from adipose tissue results in recruitment of macrophages, which may serve to aggravate inflammation and insulin resistance.[85] The precise consequences of macrophage recruitment are unclear, because while promoting inflammation, they may also have beneficial effects related to buffering of released lipids (efferocytosis) and clearance of necrotic cells.[86] Several dozen cytokines are synthesized in adipose tissue and have been reviewed extensively.[87] Two key examples are discussed here.

Tumor Necrosis Factor α

Tumor necrosis factor α (TNFα) is an inflammatory cytokine that plays a role in many disease processes. It is synthesized by multiple cell types, including adipocytes, macrophages, monocytes, and neutrophils. TNFα regulates expression of other cytokines, growth factors, and transcription factors. In adipocytes, TNFα expression increases with obesity and leads to localized inflammation that is associated with decreased insulin sensitivity. Likewise,

blocking TNFα action improves insulin sensitivity.[88] A positive correlation exists between circulating TNFα concentrations and obesity; however, it seems likely that the major effects of TNFα are local.[89] Notably, despite widespread use of anti-TNFα treatments for rheumatologic diseases,[90,91] improvements of insulin sensitivity and glycemia in patients with type 2 diabetes mellitus are not clinically evident.

Interleukin 6

Another proinflammatory cytokine increased in obesity is interleukin 6 (IL6), which may contribute to systemic inflammation and insulin resistance. Insulin sensitivity is inversely related to plasma IL6 concentrations, and IL6 directly impairs insulin signaling.[92] Administration of IL6 induces dose-dependent increases in fasting blood glucose in humans, probably by stimulating release of glucagon and other counterregulatory hormones, by inducing peripheral resistance to insulin action, or both. IL6 and other proinflammatory cytokines may also play a direct role in regulating adipocyte metabolism and vascular health.[93]

Brown Adipose Tissue

Brown adipose tissue (BAT) is a distinct fat depot that is structurally and functionally different from white adipose tissue; it contains multilocular fat vacuoles and large mitochondria and is intensively innervated by sympathetic nerves.[94] BAT contributes to energy homeostasis in rodents, where it is part of the adaptation to cold exposure[95] but also plays a role in the adaptation to very low carbohydrate diets.[96] Under these conditions, BAT is activated; as a result, there is an increase in the levels of the factor uncoupling protein 1 (UCP1), which generates a mitochondrial proton leak that results in less production of adenosine triphosphate and energy wastage through the generation of heat. Recently, BAT depots have been identified in humans, which increased interest in BAT biology. Human BAT can be activated by cold exposure[97] and increased adrenergic activity.[98] However, human BAT depots are relatively small, and it is unlikely that BAT plays a significant role in energy expenditure in otherwise healthy humans.

Metabolically Normal Obesity

Obesity is commonly associated with impaired metabolic function—namely, insulin resistance, diabetes, dyslipidemia (increased serum triglyceride and decreased serum high-density lipoprotein cholesterol), and increased blood pressure. Nevertheless, some individuals with increased weight remain metabolically normal based on measurements of lipids, blood pressure, and insulin resistance. Metabolically healthy obese individuals do not appear to have increased risk for cardiovascular mortality.[99] The concept of "metabolically healthy obese" is difficult to evaluate, and assessment of such individuals may be confounded by multiple factors, such as the presence of comorbidities, selection bias, or other factors.[100] For example, individuals most susceptible to cardiovascular disease may die earlier. It seems logical that obesity will have differential impact on individuals based on as yet undefined genetic or behavioral predispositions. It would be expected that some individuals with mild to moderate obesity would remain healthy.

Although, in general, increased BMI is associated with increased disease risk, in certain patient populations, being overweight or obese is associated with lower mortality rates than for similar patients with normal BMI values. This BMI paradox is associated with cardiovascular disease[101] (myocardial infarction, congestive heart failure, hypertension, and coronary heart disease), coronary artery bypass graft surgery, and end-stage renal disease.[102] Although this may represent an intrinsic paradox, it may also reflect that chronic disease is associated with sarcopenia, and individuals with higher BMI may be healthier as a consequence. It is also plausible that treatment of comorbidities with statins, angiotensin-converting enzyme inhibitors or angiotensin-receptor blockers, and others can provide some degree of protection when excess weight is not extreme, with differential use in the setting of excess weight compared with the same value in the normal-weight patient.

Adverse Consequences of Obesity

Obesity as a Disease Risk Factor

Metabolic Syndrome

Metabolic syndrome refers to the common co-occurrence of multiple diseases with obesity, particularly obesity with a visceral distribution. Most of these obesity-related disorders are associated with increased cardiovascular disease risk. Metabolic syndrome has multiple definitions. National Cholesterol Education Program Adult Treatment Panel III includes any three of the following five clinical measures: increased waist circumference defined on the basis of ethnic specific criteria, elevated triglyceride levels, low high-density lipoprotein cholesterol levels, increased blood pressure, or high fasting glucose. World Health Organization criteria for metabolic syndrome includes presence of insulin resistance along with the identification of at least two additional risk factors.[103] Based on meta-analysis of studies that included more than 900,000 people, metabolic syndrome led to a 2-fold increased risk of cardiovascular disease and a 1.5-fold risk of increased mortality from all causes.[104]

Obesity predisposes to cardiovascular disease through multiple mechanisms, as it increases the likelihood of type 2 diabetes mellitus, dyslipidemia, and hypertension, all of which are independent risk factors for cardiovascular morbidities. Factors secreted from the adipocyte can also promote a proinflammatory, prothrombotic state.

Type 2 Diabetes

Type 2 diabetes mellitus is a common consequence of excess adiposity.[105] Indeed, more than 90% of individuals with type 2 diabetes mellitus are obese.[106] Rising prevalence rates of type 2 diabetes mellitus coincide with rising rates of obesity. Rates of diabetes across the continental United States range from a low of 7% in Colorado to a high of 13.6% in Mississippi, and rates in the US territories of Guam and Puerto Rico are even higher.[107] Diabetes prevalence parallels the prevalence of obesity, which is lowest in Colorado, where rates range between 20% and 25%, and highest in the southeastern states, including Mississippi, with rates higher than 35%.

Risk of diabetes increases with earlier onset and more severe obesity. For example, the likelihood of developing diabetes is 70% for women with a BMI greater than 35 at age 18 years, with an expected diagnosis of diabetes by the sixth decade.[108] An increased waist to hip ratio, reflective of increased visceral obesity, is also associated with increased diabetes risk.[109]

Dyslipidemia

Primary dysfunction in the adipocyte is associated with abnormal lipid metabolism, increasing the risk of dyslipidemia. Abnormal lipid metabolism in association with genetic factors results in dyslipidemia including hypertriglyceridemia; reduced high-density

lipoprotein cholesterol levels; and an increased fraction of small, dense low-density lipoprotein particles. This association is especially strong in persons with abdominal obesity.[110]

Hypertension

There is a linear relationship between hypertension and BMI.[111] Prevalence rates are more than twice as high in obese men and women compared with lean men and women, and risk of hypertension increases with both age and weight gain. Approximately 70% of hypertension in adults is attributable to excess adiposity, especially visceral adiposity. Obesity-related hypertension has distinct genetic determinants compared with hypertension in the absence of obesity. Physiologic mechanisms of obesity-related hypertension include insulin resistance, sodium retention, increased sympathetic nervous system activity, activation of renin-angiotensin-aldosterone, and altered vascular function. Weight loss results in blood pressure reductions[112,113]; however, the effects may not be durable.

Cardiovascular Disease

Obesity is associated with a significantly increased lifetime risk of cardiovascular disease, including coronary artery disease, heart failure, and cerebrovascular disease. Risks are higher for men and for those with visceral obesity.[114] Absolute thresholds for weight-associated cardiovascular disease are hard to determine and can depend on the type of event being assessed, the subpopulation, and other confounding factors. In middle-age men, the risk of a cardiovascular event increases with increased BMI, and the risk of cardiovascular death is twofold for individuals with a BMI greater than 40 kg/m^2 compared with normal-range BMI. A similar increase in risk in cardiovascular events is seen in women, although risk of cardiovascular death does not significantly correlate with BMI. Overweight individuals have similar longevity to those with normal BMI; however, the increased risk in cardiovascular events leads to living with chronic cardiovascular morbidity.[115]

In a recent analysis of data from both the Nurses' Health Study and the Health Professionals study, no increased cardiovascular risk was seen in the overweight category. When this was adjusted for lifetime weight history, a small increase was noted in the overweight BMI range,[116] indicating that at lower excess weights, assessment of risk is complicated.

Increasing BMI also increases the risk of ischemic cerebrovascular events in both men and women. The risk of fatal and nonfatal ischemic stroke is approximately twice as great in individuals with a BMI greater than 35 kg/m^2. In intermediate BMI ranges of greater than 25 kg/m^2 and up to 32 kg/m^2, it is difficult to assess the relative increased risk in otherwise healthy individuals. At least one study reports similar survival following an ischemic event in normal-weight and overweight subjects.[117]

Obesity is also associated with an increased risk of thromboembolic disease, and risk increases with higher waist circumference.[118]

Liver Disease

As a result of the increasing prevalence of obesity, nonalcoholic fatty liver disease (NAFLD) is now the most common cause of chronic liver disease in both developed and developing countries. In the United States, NAFLD affects 30% of the obese population and 53% of obese children.[119] Risk increases with additional excess weight such that prevalence increases to 90% in morbidly obese populations.[120,121] Hepatosteatosis is diagnosed when 5% of all cells contain lipid droplets by histology or when magnetic resonance imaging reveals more than 5% fat in the liver. Diagnosis of NAFLD requires exclusion of other causes of liver pathology, including alcohol abuse, viral infections, and biliary or autoimmune disease. Although fatty liver itself is a relative benign state, it can progress unpredictably to steatosis, cirrhosis, and hepatocellular carcinoma. Progression to nonalcoholic steatohepatitis, characterized by hepatocyte apoptosis, inflammation, and fibrosis, is seen in 10% to 20% of NAFLD patients and poses a high risk for further progression to cirrhosis and hepatocellular carcinoma. Unfortunately, at present, it is not possible to identify individuals who will progress from NAFLD to nonalcoholic steatohepatitis and hepatocellular carcinoma. Effective treatments are limited to weight loss, which is problematic because few interventions lead to meaningful sustained weight loss. Thus, understanding the molecular mechanisms underlying the progression from hepatic steatosis to frank steatohepatitis is of critical importance for clinical assessments and for pharmacologic treatment.

Obstructive Sleep Apnea

Overall effects of obesity on lung function are relatively benign. However, respiratory function can be significantly affected by obstructive sleep apnea that can be severe. Obstructive sleep apnea occurs when there is either complete or partial upper airway obstruction due to mechanical pressure in the neck. Daytime sleepiness is common. Sleep apnea is also an independent risk factor for hypertension and may predispose to type 2 diabetes mellitus. Weight loss is effective in improving indices of apnea.[122]

Musculoskeletal Disease

Because overall body weight contributes to mechanical pressure at the hip and knee, obesity is a risk factor for osteoarthritis. Overweight increases the risk of knee osteoarthritis by almost twofold, whereas frank obesity is associated with additional risk. Overweight and obesity are more significant factors in new-onset knee pain than a previous knee injury. The increasing prevalence of overweight and obesity is also associated with increasing total knee and hip arthroplasty.[123] Hyperuricemia and gout are also associated with obesity.[124] The risk of gout also increases with body weight, and the relative risk in individuals with a BMI greater than 35 kg/m^2 is almost threefold higher compared with normal-weight persons.[125,126]

Cancer

Overweight and obesity increase the risk of certain cancers. Based on data from a prospective study in more than 900,000 adults in the United States, it was estimated that overweight and obesity could account for 14% of all deaths from cancer in men and 20% of such deaths in women. Obesity is associated with higher rates of death due to cancers of the gastrointestinal tract (liver, pancreas, stomach, esophagus, colon and rectum, and gallbladder) and kidney, multiple myeloma, and non-Hodgkin lymphoma, as well as prostate cancer in men and uterine, cervical, ovarian, and postmenopausal breast cancer in women. The risks of breast and endometrial cancer fatality increase with both obesity and weight gain after age 18 years. The risk of breast cancer increases with increasing BMI in postmenopausal women; in premenopausal women, increased BMI may actually protect against breast cancer. Genetic, hormonal, and metabolic factors associating adiposity to cancers remains incompletely understood.

Diagnostic and Therapeutic Approach

Height and weight measurements are intrinsic to the physical examination; most electronic medical records automatically calculate BMI, which can also be calculated manually by dividing the weight in kilograms by the height in meters squared or by using the online calculator provided by the Centers for Disease Control and Prevention. Once the current BMI is known, an essential part

of the medical history is to determine an individual's weight trend over time, often by obtaining weight at age 18 years. For normal-weight and modestly overweight individuals (i.e., BMI <27 kg/m^2 without comorbidities for those with European heritage or 25 kg/m^2 for Asian heritage), counseling with no additional intervention other than monitoring weight over time is warranted.

Beyond weight, little additional evaluation is warranted for obesity per se. In those reporting early obesity, presenting during childhood or adolescence, who also have a family history, genetic testing for a mutation in MC4R might be considered. This is the only commercially available test, and it may be helpful in a small number of individuals who test positive. However, at present, there are no specific therapies that would be more effective if the mutation were present, so pursuing the test is dependent on clinical suspicion of physician and patient preference.

Management of overweight and obesity can be difficult.[127] A conservative clinical approach is provided in Table 40.3. First, an individual must acknowledge a potential problem. At the time of annual physical examination, weight should be noted, BMI calculated, and a brief overview of BMI and risk provided. In general, mildly overweight patients need to be advised of the advantages of modest weight loss and warned against additional weight gain. For individuals with a BMI greater than 27 kg/m^2 (25 kg/m^2 for Asians) or those with comorbidities, the risk of excess weight should be addressed and patients should be encouraged to be attentive to their weight, offered access to a nutritionist, provided with dietary advice, and given an approach to behavioral modification. Using a home scale for scheduled weighing time and recording the result alone may be ineffective for achieving weight loss, but it may help an individual be attentive to risk and may prevent or slow down further weight gain.

Individuals with a BMI greater than 35 kg/m^2 should be advised of risks, encouraged to obtain a consultation from a nutritionist, and be counseled in behavioral modifications, and a repeat visit should be scheduled within 3 to 4 months of the initial visit. If the interval has passed without weight loss, pharmacotherapy should be considered. Although GLP1 receptor agonists (see later discussion) are highly effective, few individuals are willing to consider an injectable therapy at the outset; additionally, many insurance companies insist on a trial of available oral therapies to start. There is no reliable way of predicting a response to the various medications available; the initial choice needs to be individually tailored on the basis of the likelihood of compliance and risk of side effects. Metabolic surgery options should be discussed.

Once therapy is prescribed, it is critically important to evaluate weight loss within a short interval to determine effectiveness. An official weight, in a medical environment, should be recorded at 8 weeks. If no weight loss is observed, weight should be checked at 12 to 16 weeks. Weight gain should signal cessation of therapy. If weight loss is absent, or less than 5% or 3.3 pounds (1.5 kg), therapeutic dose adjustments may be considered up to maximal approved levels or therapy should be discontinued between 12 and 16 weeks. If weight loss exceeds 3.3 pounds (1.5 kg), individuals should be recalled for weight checks every 8 weeks. If weight loss is ongoing, the decision to continue medical therapy over the long term needs to be evaluated on an individualized basis that balances the risk of medication with the benefit of reduced body weight. Weight regain is common when pharmacotherapy is stopped.

TABLE 40.3 Suggested Weight-Loss Treatment Options Based on BMI and Risk Factors

BMI (kg/m^2)	Advice, Nutrition, Exercise	Pharmacotherapy[a]	Surgery[b]
25.0–26.9	Yes	No	No
27.0–29.9	Yes	Consider if there are risk factors and weight gain trajectory	No
30.0–34.9	Yes	Strongly consider with risk factors and weight gain trajectory	No
35.0–39.9	Yes	Yes	If drugs fail, with comorbidity
≥40	Yes	Yes	If drugs fail

Ethnic adjustments to BMI ranges should be considered.

[a]Pharmacotherapy should be considered in patients who are unable to achieve adequate weight loss with available conventional therapy and who do not have any absolute contraindications for drug therapy.

[b]Bariatric surgery should be considered in patients who are unable to lose weight with available conventional therapy and who do not have any absolute contraindications for surgery.

BMI, Body mass index.

Benefits of Intentional Weight Loss

Weight loss resulting from any therapeutic modality will lead to improvements in the complications of obesity and significantly lower the risk for diabetes and other comorbidities,[128] although there may be unintended risk associated with pharmacologic and surgical approaches. Diabetes remission with weight loss can be of several years duration but appears to depend on residual beta-cell function and additional potential for beta cells to recover.[129,130] However, it is interesting the lifestyle interventions promoting weight loss through decreased caloric intake and increased physical activity do not improve cardiovascular event rates in individuals with type 2 diabetes mellitus,[131] perhaps due to increased use of lipid-lowering and blood pressure medications in patients not engaged in the intervention.

Modalities that can be used to address obesity include lifestyle interventions such as diet and exercise, behavioral therapy, pharmacotherapy, bariatric surgery, and some various combinations.

Dietary Intervention

Caloric Restriction

Dietary intervention may involve decreasing food intake without making major changes in the composition of food consumed. A pound of fat contains 3500 calories, so an individual aiming to lose 1 pound per week needs a net daily calorie deficit of 500 calories. A 55-year-old, moderately active, woman weighing 300 pounds (136 kg), will need approximately 2600 calories for weight maintenance. For her, a net 500 calorie deficit will be approximately a 20% reduction in her daily food intake. If maintained, this would lead to about 50 pounds (22.5 kg) of weight loss in a year, which can seem discouragingly slow for someone aiming for ideal body weight. It is important to set realistic expectations to foster success and continued efforts.

To increase the rate of weight loss, many individuals consider restricting daily food intake by pursuing very low calorie diets using meal replacements. Very low calorie diets that limit to 800 calories per day can also be effective for weight loss, especially if coupled with either a commercial provider or physician or nutritionist support. Many commercial options providing 200 to 300 calories of meal substitutes replete with protein are available, such as Optifast, HMR, and Medifast. These are available over the counter

or may be prescribed and overseen by a physician, but they may be considered relatively expensive by the patient. Diets that limit calories to 800 calories daily are typically associated with 2 pounds of weight loss weekly. Some approaches involve a period of several weeks of meal replacements only, limiting food intake to 800 calories (3–4 meal supplements daily), whereas other approaches include a single meal of conventional food combined with two daily supplements. When initiated solely as meal replacements, very low calorie diets typically progress to modified fasts wherein a single relatively low calorie meal is consumed. A meta-analysis comparing commercial programs with simple nutritional counseling and calorie restriction reports that commercial programs fare better with more weight loss between 6 and 12 months. In general, weight loss is greater with these programs than with simple counseling, but long-term weight loss is only sustained in a relatively small number of individuals.[132]

Additional recent approaches involve limited fasting to 2 to 3 days each week. A current popular approach is the "5/2 diet," which involves limiting food intake to less than 400 calories 2 days a week and eating "normally" the other 5 days. Other approaches involve eating only during a limited number of hours daily and maintaining at least 16 hours per day without any food intake.

Macronutrient Composition

Significant attention has been given to macronutrient composition of diets in attempts to determine what proportion of nutrients might lead to greater and more sustainable weight loss. There is significant debate between those that favor low-fat diets in comparison to low-carbohydrate, Atkins-style diets. Most controlled studies show that weight loss is similar regardless of diet composition, although very low carbohydrate diets have a small early advantage.[127,133] For individuals who self-select Atkins-style diets and who also utilize a support system, weight loss can be dramatic and substantial improvements in glucose control have been observed.[134]

As there is little support for any specific type of diet, it is best to inform individuals regarding different options, recommend based on their preference, and follow closely to confirm efficacy and safety.[135] A potential exception is recommendation of Atkins-style diets in individuals with type 2 diabetes mellitus. Although still somewhat controversial, increasing evidence suggests that significant limitation of carbohydrates improves glucose control, decreases dependence on medications, and facilitates weight loss.[134]

Physical Activity

In the past half century, sedentary behavior has increased with physical labor progressively mechanized, both commercially, such as in farming operations, and in households where machines such as vacuum cleaners and dishwashers lead to less daily energy expended. Reduced energy expended on these activities is estimated to represent a 140 kcal/day decline and may contribute to population weight gain.[136] However, increasing physical activity through discretionary exercise is not particularly effective for weight loss. In a study of exercise alone, postmenopausal women were advised to exercise at moderate intensity for 45 minutes 5 days per week. Weight loss was minimal, averaging 2.8 pounds (1.3 kg) over the course of a year.[137] When coupled with diet, exercise has a modest effect to improve weight loss in men but only prevented weight gain in women.[138] The failure of exercise to have a significant impact on weight loss may reflect compensatory overeating.

Behavior Modification

Behavior modification is an unspecific term that covers approaches to weight loss and or limiting weight gain that include exercise, diet, food shopping habits, and food pantry stocking.[139] Behavioral modification strategies and guidelines should be sensitively discussed with obese and overweight individuals, especially those who are gaining weight over time. Raising awareness may slow down weight gain; prevent additional weight gain; and, under some circumstances, encourage weight loss. Recognizing and learning to avoid behaviors such as stressful eating and setting realistic and achievable goals are both important. Successful weight loss has been reported with combinations of exercise and intensive lifestyle modification that includes frequent monitoring and support. In the Look AHEAD study of individuals with type 2 diabetes mellitus and obesity, those randomized to the intensive lifestyle modification limb lost up to 17.6 pounds (8 kg) in the first year. Although, in general, individuals regained weight over time, weight loss of about 9 pounds (4 kg) persisted out to 4 years.[140]

Pharmacotherapy

Most medications currently available to treat obesity are associated with relatively modest weight loss (Table 40.4). Furthermore, nonresponder rates can be high so that for any agent, only a minority of individuals who initiate therapy in a standard outpatient setting will lose weight. It is uncertain if patients who fail one therapy are more likely to succeed with other class agents.

To date, the most tolerated and effective class of medications for weight loss are GLP1 receptor agonists. These were developed for the treatment of type 2 diabetes mellitus and fortuitously were found to have meaningful effects in reducing appetite and body weight. Effects on appetite with continuous infusion were reported early, and when the first agonist, exenetide, came to market for glucose control in type 2 diabetes mellitus, modest weight loss was noted in many patients. Subsequent studies found that weight loss effects could be extended to obese individuals without diabetes and, further, that it was possible to stratify subjects as responders or nonresponders based on weight loss after 8 weeks of treatment.[141] The GLP1-R agonist liraglutide, also used in type 2 diabetes mellitus (marketed as Victoza), and in a higher-dose formulation (Saxenda) has now been approved for obesity management in the United States, Europe, and Japan. Liraglutide provides benefit in terms of reduced rates of nonfatal myocardial infarction and stroke and cardiovascular death in patients with diabetes and established or at high risk for cardiovascular disease.[142] Semaglutide has also been recently approved for management of type 2 diabetes mellitus with once-weekly dosing. Semaglutide may also reduce the rate of nonfatal myocardial infarction or stroke or cardiovascular death in patients with type 2 diabetes mellitus at high cardiovascular risk.[143] Whether these agents will provide similar cardiovascular benefits in reducing cardiovascular risk in obese individuals is unclear. When administered at lower daily doses, it leads to weight loss in obese nondiabetic individuals. In a direct comparison of semaglutide and liraglutide, weight loss at 0.3 mg of semaglutide daily resulted in mean weight loss of 12.3% compared with mean weight loss of 8.3% in those randomized to 3.0 mg of liraglutide.[144] Currently, most GLP1 receptor agonists are administered by subcutaneous injection. Headache and gastrointestinal events such as nausea, vomiting, diarrhea, or constipation represent the major side effects that limit use of GLP1 receptor agonists.

Phentermine is a sympathomimetic that was approved for obesity treatment in 1959. It stimulates the release of norepinephrine, and to a lesser extent serotonin (5-hydroxytryptamine [5HT]) and dopamine. Weight loss with phentermine is approximately 5% at 8 to 12 weeks, and typically is administered at 15 mg to 37.5 mg orally three times daily with meals as a short-term adjunct (a few weeks) to behavioral weight loss approaches. A lower 8-mg

dose for longer-term use is available, but durability has not been reported. The clinical effect of phentermine is to diminish appetite, and it appears to work better in individuals who start with greater hunger and less cognitive restraint on their eating behavior.[145] Side effects of phentermine can include pulmonary hypertension, valvular heart disease, palpitations, increased heart rate or blood pressure, insomnia, restlessness, dry mouth, diarrhea, constipation, and changes in sexual drive.

Phentermine has been combined with topiramate into an extended-release (ER) formulation marketed as Qsymia, which is available in four doses ranging from combinations of 3.75/23 to 15/92 of phentermine to topiramate. Phentermine-topiramate ER has been evaluated in two large randomized clinical trials. Weight loss at 1 year demonstrated a dose-response relationship and was similar in both studies. In an intention-to-treat analysis after 1 year of therapy, the placebo-subtracted weight loss was approximately 9% for the top dose and approximately 6.5% for the recommended dose. Common adverse effects of phentermine-topiramate ER include dry mouth, dizziness, dysgeusia, constipation, insomnia, and paresthesia. Cognitive impairment (attention or memory deficits) is also reported and, when it occurs, leads to discontinuation of the drug.

Orlistat inhibits pancreatic lipase and thereby reduces enteric absorption of fatty acids. In turn, this leads to some degree of fat malabsorption. Excretion of about 30% of ingested triglycerides, which is near the maximum plateau value, occurs at a dose of 360 mg/day (120 mg three times daily with meals). A meta-analysis of multiple weight loss studies indicated that about 50% of individuals taking orlistat will lose weight,[146] although weight loss at 1 year is small, with an average loss of 11 pounds (5 kg).[147] Use of Orlistat is limited by the common side effect of fatty diarrhea, which leads to reduced compliance. Systemic side effects directly related to the drug are uncommon because orlistat is not absorbed.

Lorcaserin (marketed in the United States as Belviq) is a selective 5HT2c receptor agonist that decreases food intake leading to modest weight loss, which in a meta-analysis of several trials was just over 11 pounds (5 kg). In a high-risk population of overweight or obese patients, lorcaserin promoted sustained weight loss without increasing rates of major cardiovascular events.[148] Lorcaserin has greater binding affinity and activation of the 5HT2c receptor subtype over the 2a or 2b receptor subtypes, and given the tissue distribution of the receptor subtypes, it would be expected to have a reduced cardiac valve risk profile compared with earlier serotonergic agents, such as fenfluramine. Valvulopathy has not been reported. The most frequent adverse effects of lorcaserin in these studies were headache, dry mouth, dizziness, and nausea.

The naltrexone slow-release (SR)/bupropion SR combination, marketed as Contrave, is a μ-opioid receptor antagonist combined with a norepinephrine and dopamine receptor inhibitor. Bupropion has neuronal effects associated with reduced energy intake and increased energy expenditure, and naltrexone potentiates this effect such that the effects of the combination are greater than those with buproprion alone. The overall magnitude of weight loss is on the order of 5%, but in trials, more patients lose 5% of their body weight with treatment compared with placebo. There are improvements in lipid and glucose profiles and patient reported outcomes but small increases in heart rate and blood pressure.[152a]

Metformin is typically used to treat diabetes and is associated with weight loss. Data from most studies on the effect of metformin on body weight indicate that metformin does not cause weight gain, as single-agent therapy and concomitant treatment with other medications may limit the expected weight gain.[149,150] Metformin has also been reported to lead to an average net 11-pound (5-kg) weight loss after 6 months of treatment over control obese individuals without diabetes.[151] Although not approved for weight loss in nondiabetic individuals, metformin has been prescribed off label for weight loss, and because there are few side effects, therapy may be continued indefinitely if effective.

A summary of medications approved for weight loss, along with maximal placebo-adjusted maximum weight loss, is provided in Table 40.4.

Endoscopic Gastric Therapies

Endoscopic bariatric and metabolic therapies are more recently available for the treatment of obesity.[152] These include devices that are placed via flexible endoscopy and procedures that utilize flexible endoscopy instruments for weight loss indications. Currently, three intragastric balloon devices have been approved for use in the United States, including the ReShape Integrated Dual Balloon System, the ORBERA Intragastric Balloon System, and the Obalon Balloon System; others are under development. A small number of deaths have occurred in patients using these devices. Aspiration therapy using the AspireAssist device permits food to be removed from the stomach after a meal. Electrical stimulation systems place an electrical stimulator in the abdomen to block nerve activity between the brain and stomach, such as the Maestro System. Procedures include endoscopic sleeve gastrectomy, as well as POSE (Primary Obesity Surgery, Endoluminal), which is performed via endoscopy to reduce the size of the stomach and diminish hunger cravings. Currently, there are limited data to compare safety effectiveness and durability of these devices and procedures.

TABLE 40.4 Drugs Commonly Prescribed for Weight Loss[146]

Year Approved	Generic Name	Trade Name	Placebo-Corrected Anticipated Weight Loss (kg)
1959	Phentermine	Ionamin, Adipex-P, Fastin, Oby-Trim (approved only for short-term weight loss)	Approved for short-term use only
1999	Orlistat	Xenical, Ally (over the counter)	2.63
2010	Liraglutide	Victoza (approved for type 2 diabetes mellitus)	0 to 3.7[a]
2012	Phentermine-topiramate extended release	Qsymia	8.80
2013	Lorcaserin	Belviq	3.25
2014	Liraglutide	Saxenda (approved for obesity)	5.24
2014	Bupropion-naltrexone	Contrave	4.95

[a]Depending on comparator.

Note: Intensity of lifestyle interventions and maximum weight loss differs in studies. Represented values mean weight loss in excess of placebo.

Bariatric Surgery

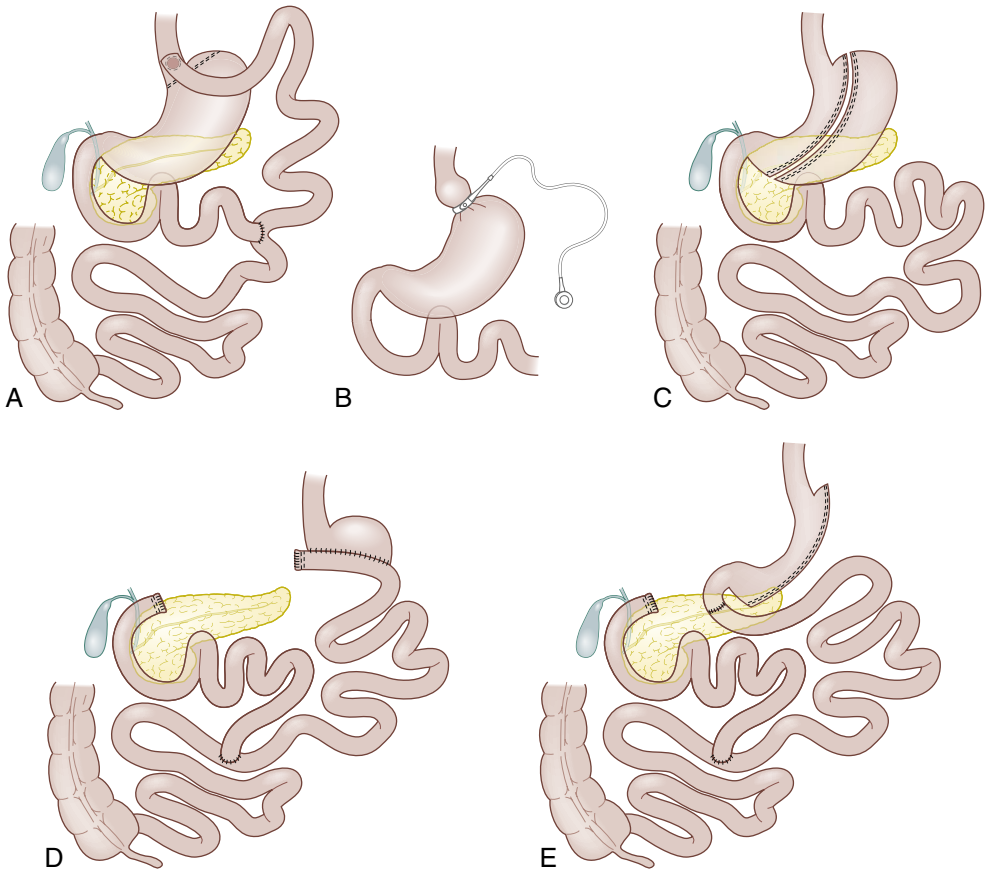
Attempts to treat obesity through surgical procedures were first attempted more than 60 years ago, with almost all initial procedures involving shunts between the jejunum and the colon. Jejunoileal bypass surgery was effective for weight loss but was associated with significant complications, including liver disease,[153] liver failure resulting in death,[154] and protein malnutrition.[155] Thus, this surgical approach was largely abandoned. A decade later, a report on the success of Roux-en-Y-gastrojejunostomy in more than 600 morbidly obese patients revealed that this surgical approach was effective with very little morbidity and mortality.[156]

Although many consider bariatric surgery as a draconian approach to obesity, weight loss is substantial and sustained, and associated with remission or improvement of type 2 diabetes mellitus, dyslipidemia, hypertension, and other weight-related comorbidities[157] that may occur early following surgery and persist for years. Not surprisingly, following the procedure, decreased levels of inflammatory markers have also been reported.[158] Surgical weight loss may reduce mortality by as much as 30% to 40% in the severely obese, although these studies were not randomized.[159,160] There is some controversy regarding whether the severity of obesity is the optimal characteristic to use when considering a patient for metabolic surgery; however, the accepted indications for surgery are a BMI greater than 40 kg/m^2 or a BMI between 35 and 40 kg/m^2 with an associated comorbidity.[161]

Four surgical procedures are offered for obesity therapy, including adjustable gastric banding, sleeve gastrectomy, Roux-en-Y gastric bypass, and biliopancreatic diversion (Fig. 40.3). Although biliopancreatic diversion is effective, few procedures are currently performed because of the higher rates of complication. Adjustable gastric banding has also become less common, with Roux-en-Y and gastric sleeve surgery now also routinely performed laparoscopically, providing more rapid recovery. In addition, gastric banding has significantly lower expected weight loss.

Roux-en-Y gastric bypass and sleeve gastrectomy are the two favored procedures. Similar weight loss is achieved, of almost 11 pounds (5 kg) per month for the first 4 months, with weight nadir between 6 and 24 months and effects that can persist over years. Perioperative mortality with bariatric surgery is low and reported as 0.04% to 0.3%, similar to that of a cholecystectomy. Potentially fatal risks include pulmonary emboli, sepsis, and bleeding. Because of the underlying increase in cardiovascular disease, the likelihood of cardiovascular risk is higher in the perioperative period. Of concern would be a leak at the anastomosis site, which can lead to sepsis and needs to be diagnosed and treated aggressively. Overall, the incidence of adverse events in the initial 28-day period was less than 5%.

Hypoglycemia can occur as a long-term complication of weight loss surgery, which may occur to some degree in up to 14% of individuals without a prior history. Severe hypoglycemia is only reported in a small number of patients[162]; it appears



• **Fig. 40.3** Schematic diagrams of Roux-en-Y gastric bypass (A), laparoscopic adjustable gastric banding (B), sleeve gastrectomy (C), biliopancreatic diversion (D), and biliopancreatic diversion with duodenal switch (E). (Modified from Bradley D, Magkos F, Klein S. Effects of bariatric surgery on glucose homeostasis and type 2 diabetes. *Gastroenterology.* 2012;143[4]:897–912.)

to be more common after the Roux-en-Y procedure[163] and may be managed by continuous blood glucose monitoring and carbohydrate support,[164] although, on occasion, somatostatin analogues or diazoxide are necessary to reduce insulin secretion following meals.

Patients having Roux-en-Y gastric bypass should be followed for development of anemia and deficiencies of fat-soluble vitamins, because the absorption of iron and fat-soluble vitamins can be impaired, leading to low levels even in the setting of standard replacement therapy with oral multivitamins. Iron infusion therapy may be needed in some patients. Bone health should be monitored. Bariatric surgery may also exacerbate depression and may increase the likelihood of this comorbidity after surgery. Rates of depression are high in individuals with morbid obesity, which is also associated with increased suicide risk.[165,166] A psychological evaluation for depression and emotional postsurgical support is an essential part of the care of individuals undergoing surgery.

Summary

Obesity results from complex interactions of individuals' risk and environmental influences. The first-order advice regarding diet and exercise is rarely successful. In the past decade, there have been some significant improvements in medical therapy, as GLP1 agonists have demonstrated effectiveness in at least 30% of individuals. Bariatric surgery has become safer and more acceptable. However, the demand for therapies persists.

Disorders of Lipid Metabolism

CLAY F. SEMENKOVICH AND IRA J. GOLDBERG

CHAPTER OUTLINE

KEY POINTS

- Abnormalities of lipid metabolism cause heart disease, pancreatitis, vitamin deficiencies, and gallstones.
- Endocrine disorders such as diabetes and obesity have protean effects on lipid metabolism.
- Lowering low-density lipoprotein decreases vascular disease, allows regression of established atherosclerotic lesions, and prolongs life.
- Substantial additional lowering of low-density lipoprotein beyond that seen with statins can be achieved by inhibiting proprotein convertase subtilisin/kexin type 9.
- Pharmacologic elevation of high-density lipoprotein has no apparent benefit.
- Extreme elevations of triglycerides should be treated to avoid pancreatitis.
- Moderate elevations of triglycerides may be associated with vascular disease, but evidence that treating this condition reduces cardiovascular events has not been established.

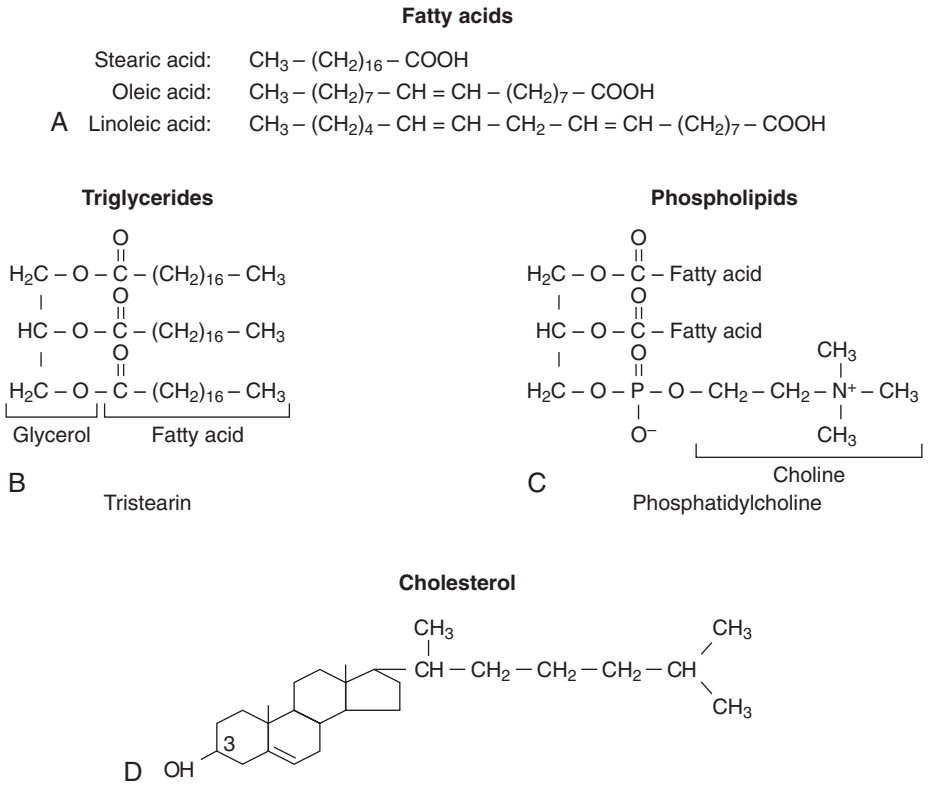
Lipid Biochemistry and Metabolism

There are multiple adverse health effects of abnormal serum or tissue lipids. Endocrine disorders impact lipids, making mechanisms underlying primary and secondary disorders of lipid metabolism relevant to both clinicians and basic scientists. Primary genetic disorders of lipid metabolism, such as familial hypercholesterolemia (FH), are relatively common, occurring in about 1 in 300 to 500 people. The low-density lipoprotein (LDL) receptor pathway is functionally impaired in FH, with higher LDL contributing to a genetic predisposition to atherosclerotic heart disease. This pathway underlies the mechanism of action of statin drugs, which decrease the risk of vascular events and prolong life,[1] and proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors, which lower lipid levels and reduce cardiovascular events even in the setting of statin treatment.[2] The quintessential secondary disorder of lipid metabolism is that seen in diabetes, a disease so frequently characterized by abnormalities of fat that lipids have been implicated in its pathogenesis.

Lipids are required for life, constituting the physical bilayer allowing formation of cell membranes, which compartmentalize specialized organelles inside cells and regulate transport between extracellular and intracellular environments. Lipids circulate in blood, with fatty acids and triglycerides providing an energy source to tissues such as heart and skeletal muscle, and nonnutritive sterols providing substrates for hormone production by gonads and adrenals. Specialized functions include development of surfactant in lung to maintain patency of alveoli, formation of bile to facilitate excretion of a variety of metabolites, and constitution of myelin throughout the nervous system to ensure the fidelity of nerve transmission. Lipids are also signaling molecules, serving as targets of lipid kinases that perpetuate signaling cascades, substrates for cyclooxygenases and related enzymes that generate prostaglandins, and ligands for nuclear receptors such as the peroxisome proliferator-activated receptors (PPARs). The broad spectrum of lipid functions results in part from their biophysical characteristics.

Simple and Complex Lipid Structure

The functional versatility of lipids is attributable to their hydrophobic structure. Due to the presence of fairly long carbon chains, lipids tend to associate with each other and have limited or no solubility in water. Fatty acids and cholesterol are simple lipids, whereas triglycerides and phospholipids are complex lipids (Fig. 41.1).



• **Fig. 41.1** Structures of common lipids, exemplified by the stearic, oleic, and linoleic fatty acids (A); the triglyceride tristearin (B); the phospholipid phosphatidylcholine (C); and cholesterol (D).

Fatty Acids

The chemical structure of fatty acids is determined by the number of carbon atoms and number of double bonds (see Fig. 41.1A). For example, stearic acid has 18 carbon atoms and is saturated, meaning that it has no double bonds; it is designated using the abbreviation C18:0. The 18-carbon monounsaturated fatty acid oleic acid (C18:1) has one double bond, and the polyunsaturated fatty acid linoleic acid (C18:2) has two double bonds.

Linoleic acid and arachidonic acid (C20:4) are omega-6 fatty acids, meaning that a double bond is present at the sixth carbon from the end of the molecule farthest from the carboxy (COOH)-terminus. Fish oils, which lower lipids, are omega-3 fatty acids, with a double bond present at the third carbon from the end opposite the COOH-terminus. Saturated fatty acids and some unsaturated fatty acids, such as oleic acid, are nonessential (i.e., they can be synthesized). Most omega-6 and omega-3 fatty acids are essential; they cannot be synthesized and are usually required for health, especially during development and in times of physiologic stress. Table 41.1 shows major food sources of fatty acids.

Triglycerides

The structure of tristearin, a triglyceride with three molecules of stearic acid connected to a glycerol molecule by means of ester linkages, is shown in Fig. 41.1B. Other triglycerides have a similar structure with alternative fatty acids esterified to the glycerol backbone.

Most adipose tissue mass is composed of triglycerides; triglycerides that circulate in the blood primarily reflect the fatty acid composition of adipose tissue triglycerides, and both sources reflect dietary fatty acid composition. Butter, common in Western

TABLE 41.1 Major Fatty Acids

Chemical Designation	Common Name	Common Food
Saturated Fatty Acids (No Double Bonds)		
C12:0	Lauric	Coconut oil
C14:0	Myristic	Coconut oil, butter fat
C16:0	Palmitic	Butter, cheese, meat
C18:0	Stearic	Beef, chocolate
Monounsaturated Fatty Acids (One Double Bond)		
C18:1	Oleic	Olive and canola oils
Polyunsaturated Fatty Acids (Two or More Double Bonds)		
Omega-6 Fatty Acids		
C18:2	Linoleic	Sunflower, corn, soybean, and safflower oils
C20:4	Arachidonic	Chicken, eggs
Omega-3 Fatty Acids		
C18:3	α-Linolenic	Canola, flaxseed, and soybean oils
C20:5	Eicosapentaenoic acid (EPA)	Salmon, cod, mackerel, tuna
C22:6	Docosahexaenoic acid (DHA)	Salmon, cod, mackerel, tuna

diets, consists of similar amounts of palmitate and oleate with a lesser amount of stearate; adipose tissue and circulating triglycerides in persons eating Western diets contain mostly palmitate and oleate. Olive oil, found in Mediterranean diets, is predominantly oleate with much less palmitate, so fat and circulating triglycerides in people eating a Mediterranean diet are enriched in oleic acid. Extremely high levels of triglycerides in the blood predispose to pancreatitis.

Phospholipids

The chemical structure for a generic phosphatidylcholine, a type of phospholipid, is shown in Fig. 41.1C. As with triglycerides, phospholipids have a glycerol backbone to which fatty acids are esterified at the first two alcohols. The characteristics of these fatty acids are important for determining cell membrane shape and function.[3,4] The third alcohol is esterified to a phosphate moiety linked to another molecule, such as choline, ethanolamine, or serine.

The presence of long-chain fatty acids comprising hydrophobic regions and the charged species at the end of the molecule make phospholipids ideal for generating cell membranes and lipoprotein surface components: the bilayer is oriented so that the hydrophobic regions point toward each other, and the hydrophilic regions interact with the aqueous environment. Phospholipids are distributed asymmetrically in cell membranes, with choline-containing lipids directed toward the outer surface and amine-containing lipids directed toward the cytoplasmic surface. Appearance of the aminophospholipid phosphatidylserine on the cell surface initiates blood clotting and marks apoptotic cells for phagocytosis. Several enzymes are involved in the dynamic process of remodeling cell membrane phospholipids, and some appear to be involved in metabolic disease, such as 1-acylglycerol-3-phosphate-O-acyltransferase 5 (AGPAT5), a membrane protein that converts lysophosphatidic acid to phosphatidic acid as the second step in de novo phospholipid biosynthesis, and which mediates insulin resistance in mice.[5]

Cholesterol

The structure of cholesterol is shown in Fig. 41.1D. Cholesterol in the plasma membrane is critical for maintaining membrane fluidity, probably by disrupting interactions between phosphatidylcholine and other molecules. It is also required for assembly of lipid rafts, which are ordered plasma membrane domains that mediate signal transduction.[6] The concentration of cholesterol is enriched in the plasma membrane, with much lower levels detected in the membranes of most intracellular organelles. Cholesterol is necessary for the synthesis of estrogen, progestins, androgens, aldosterone, vitamin D, glucocorticoids, and bile acids. Cholesterol deficiency is associated with severe developmental defects, as manifested in the rare Smith-Lemli-Opitz syndrome, which is likely caused by disruption of the Hedgehog signal transduction pathway.[7] Cholesterol excess is associated with gallstones and vascular disease.

Fatty Acid Metabolism

Fatty Acid Biosynthesis

In humans eating a typical Western diet, the overall contribution of de novo lipogenesis to lipid metabolism is small because the ingestion of exogenous fat is sufficient to suppress the energy-requiring process of synthesizing fats from carbohydrates. However, high-carbohydrate diets, especially those containing fructose,[8] substantially increase lipogenesis in liver and adipose tissue of humans.

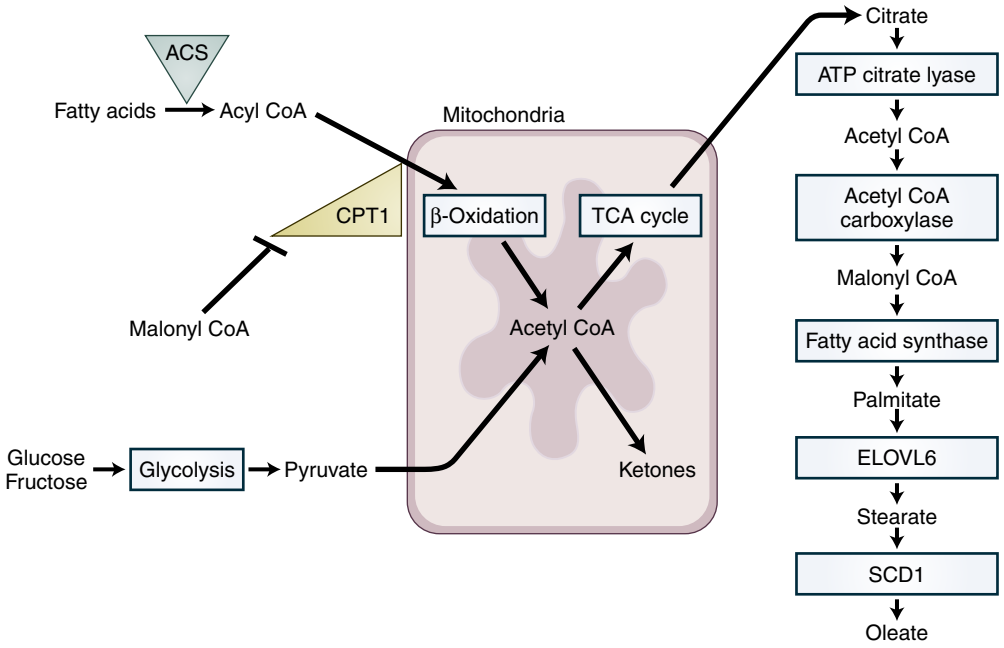
Fatty acid biosynthesis is carried out in most tissues at least minimally regardless of nutritional status. However, the liver is by far the major site of de novo fatty acid synthesis. Several key steps in fatty acid biosynthesis, presented in Fig. 41.2, also have major effects on systemic metabolism. Citrate derived from the tricarboxylic acid (TCA) cycle is converted to acetyl coenzyme A (acetyl CoA) in the cytoplasm by the action of adenosine triphosphate (ATP) citrate lyase. Acetyl CoA is then converted to malonyl CoA by acetyl CoA carboxylase (ACC), which exists in two isoforms: ACC1 (encoded by the gene *ACACA*) is cytosolic and important in liver and fat for de novo lipogenesis, and ACC2 (*ACACB*) is associated with mitochondria, also plays a role in liver metabolism, and is expressed at highest levels in muscle and heart. Antisense targeting of ACC isoforms has been shown to improve lipid metabolism and insulin sensitivity.[9]

Malonyl CoA inhibits carnitine palmitoyltransferase 1 (CPT1), which transports fatty acids into mitochondria, and thereby malonyl CoA prevents catabolism of fats under physiologic conditions in which energy is being stored as fat through fatty acid biosynthesis. Malonyl CoA also serves as substrate for fatty acid synthase, which sequentially connects two carbon fragments to generate saturated fatty acids such as palmitate. Inhibition of fatty acid synthase in the hypothalamus suppresses appetite by decreasing orexigenic peptides and increasing anorexigenic peptides in the arcuate nucleus, inducing weight loss and improving insulin sensitivity.[10] Pharmacologic inhibition of fatty acid synthase improves glucose metabolism in mice and primates,[11] and the mechanism may involve suppression of inflammatory pathways in macrophages.[12] Palmitate is converted to stearate through the action of a long-chain fatty acid elongase, which, when inactivated, promotes obesity but prevents insulin resistance.[13] Stearate is subsequently converted to oleate by stearoyl-CoA desaturase 1, which, when inactivated, increases fatty acid oxidation and protects against diet-induced obesity and insulin resistance.[14]

Fatty Acid Oxidation

Metabolism of fatty acids provides more energy per gram than metabolism of carbohydrates or proteins. Fatty acids undergo the process of β-oxidation in mitochondria (see Fig. 41.2). They are transported or diffuse across the plasma membrane, converted to acyl-CoA species by acyl-CoA synthase, then translocated to the mitochondrial matrix by CPT1 and CPT2. β-oxidation removes two carbon fragments through sequential actions of acyl-CoA dehydrogenases (e.g., medium-chain acyl-CoA dehydrogenase and very long chain acyl-CoA dehydrogenase), enoyl-CoA hydratase, hydroxy-CoA dehydrogenase, and thiolase. This process generates reduced nicotinamide adenine dinucleotide and reduced flavin adenine dinucleotide, which participate in electron transport to yield ATP. After multiple cycles, acetyl CoA is produced, which is a substrate for the tricarboxylic acid cycle and for ketogenesis.

Ketogenesis, a process restricted to the liver, is necessary for life during times of nutritional deprivation, as it can spare the use of glucose for ATP generation by the brain and other organs. Extreme production of ketones occurs in the setting of insulin deficiency usually due to autoimmune destruction of pancreatic beta cells and represents a threat to life. 3-Hydroxy-3-methylglutaryl (HMG)-CoA synthase (rate limiting in mitochondria) converts acetyl CoA to hydroxymethylglutaryl CoA, which is converted to acetoacetate by HMG-CoA lyase. Acetoacetate is either reduced to β-hydroxybutyrate or converted to acetone.



• **Fig. 41.2** Fatty acid metabolism. Fatty acids are substrates for ACS, which generates CoA moieties that are transported into mitochondria by CPT1. This process is inhibited by malonyl CoA. In mitochondria, β-oxidation generates acetyl CoA, which can also be generated from glycolysis (*bottom left*). Acetyl CoA can be used to produce ketones, or it may enter the TCA cycle, leading to production of citrate; in the cytoplasm, citrate is a substrate for ATP citrate lyase, which produces acetyl CoA. The acetyl CoA serves as a substrate for de novo synthesis of fatty acids, as depicted on the right side of the figure. *ACS,* acyl-CoA synthase; *ATP,* adenosine triphosphate; *CoA,* coenzyme A; *CPT1,* carnitine palmitoyltransferase 1; *ELOVL6,* elongation of very long chain fatty acid protein 6; *SCD1,* stearoyl-CoA desaturase 1; *TCA,* tricarboxylic acid.

Defects in fatty acid oxidation are among the most common inborn errors of metabolism. Presentations include nonketotic hypoglycemia, liver dysfunction, and cardiomyopathy.[15]

Triglyceride and Phospholipid Metabolism

Dietary fat, consisting of triglycerides and phospholipids, is digested in the stomach and proximal small intestine. Triglycerides are broken down into component fatty acids in part through the action of pancreatic lipase, which is activated by bile acids. Bile salts form micelles that acquire fatty acids and interact with the unstirred water layer of the intestine, where fatty acids are absorbed. Long-chain fatty acids are taken up by enterocytes, re-esterified into triglycerides, and exported into the lymph as lipoproteins. Medium-chain (≤C10) fatty acids directly enter the portal vein to access the liver.

Triglyceride Synthesis

Key steps in triglyceride synthesis have a major impact on systemic metabolism. Most triglycerides are synthesized through the glycerol phosphate pathway (Fig. 41.3, *top portion*) by a sequence of acylations. Another pathway, the monoacylglycerol pathway, is thought to be active only in the small intestine. Glycerol-3-phosphate is acted on by one of the glycerol-3-phosphate acyltransferases (GPATs) to generate lysophosphatidic acid. An important isoform is GPAT1, which competes with CPT1 for fatty acyl CoA molecules inside the cell, with GPAT1 prevailing when energy is to be stored and CPT1 dominant when energy is required. The next acylation is mediated by acylglycerol-3-phosphate acyltransferases (AGPATs) and generates phosphatidic acid. Human mutations in AGPAT2 are responsible for the disease called *congenital generalized lipodystrophy*.

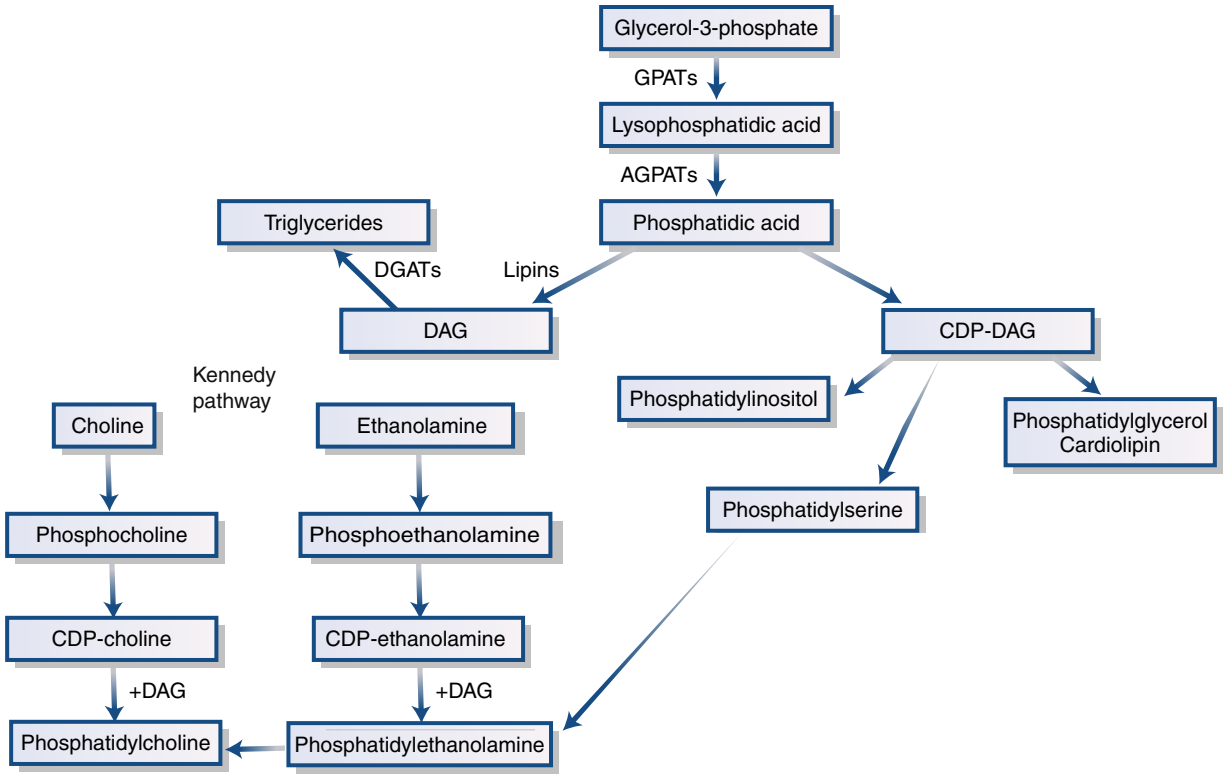
Phosphatidic acid represents an important branch point in lipid metabolism. It serves as substrate for synthesis of either cytidine diphosphate diacylglycerol (CDP-DAG, the precursor for molecules like phosphatidylinositol) or diacylglycerol (DAG). Synthesis of DAG requires a phosphatase activity provided by lipins.[16] DAG can serve as a signaling molecule and as substrate for synthesis of either triglycerides or common phospholipids. The acylation of DAG to form triglycerides is catalyzed by acyl-CoA:diacylglycerol acyltransferases (DGATs). Inactivation of DGAT1 in mice prevents diet-induced obesity,[17] but mutation of the gene in humans prevents normal fat absorption and causes steatorrhea in infants.[18]

Phospholipid Synthesis

As shown in the bottom left portion of Fig. 41.3, phospholipid synthesis is intimately related to triglyceride synthesis. Generation of the most common phospholipids, phosphatidylcholine and phosphatidylethanolamine, occurs mostly through the Kennedy pathway, which utilizes choline as an initial substrate and DAG at the final step. Mammalian liver can generate phosphatidylcholine from phosphatidylethanolamine through successive methylations. Phosphatidylserine can be converted to phosphatidylethanolamine, and other conversions between phospholipid species are possible.

Lipolysis of Triglyceride Stores in Adipose Tissue

Most of the body's triglyceride mass resides in adipose tissue, and turnover of energy stores from fat has important effects on lipid metabolism, normal physiology, and human health. Increased lipolysis in adipose tissue in obesity results in elevated circulating free fatty acids, which may cause dysfunction in pancreatic



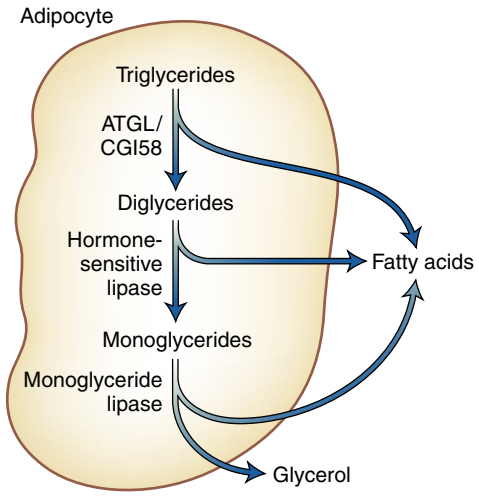
• **Fig. 41.3** Phospholipid and triglyceride synthesis. Glycerol-3-phosphate is converted by glycerol-3-phosphate acyltransferases (GPATs) to lysophosphatidic acid, which is converted to phosphatidic acid by acylglycerol-phosphate acyltransferases (AGPATs). Phosphatidic acid can be converted to cytidine diphosphate diacylglycerol (CDP-DAG), to fuel one arm of phospholipid synthesis, or to diacylglycerol (DAG), which is a substrate for another arm of phospholipid synthesis and for acyl-CoA:diacylglycerol acyltransferases (DGATs), which generate triglycerides. The Kennedy pathway, which utilizes DAG at its final steps, is depicted at the bottom left of the figure.

beta cells, liver, skeletal muscle, and heart. Healthy offspring with parents who have type 2 diabetes mellitus have impaired insulin-mediated suppression of circulating fatty acids,[19] suggesting that an early defect in adipose tissue fatty acid metabolism contributes to the evolution of diabetes.

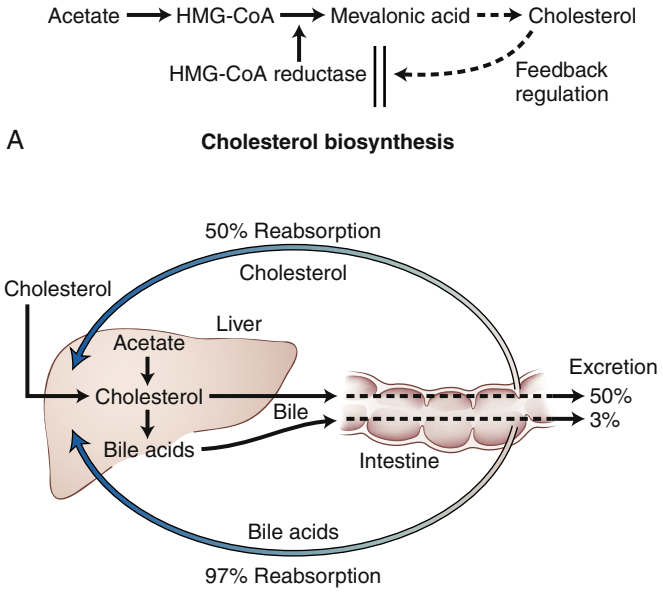
Release of free fatty acids and glycerol from adipose tissue is controlled by a variety of hormones, many of which act through G protein–coupled receptors. The most robust mediators of fatty acid release are catecholamines, which bind to β-adrenergic receptors, activating stimulatory G proteins (G_s) that prompt an increase in the activity of cyclic adenosine monophosphate and protein kinase A. Glucagon, adrenocorticotropic hormone, α-melanocyte-stimulating hormone, and thyroid-stimulating hormone also induce lipolysis through G_s proteins. Adenosine suppresses lipolysis by binding to receptors that activate inhibitory G proteins (G_i). Niacin, which also suppresses lipolysis, binds to the G protein receptor GPR109A, but this interaction does not mediate this vitamin's effects on lipid metabolism.[20] Insulin is a major lipolytic inhibitor, activating the insulin receptor–signaling cascade and suppressing lipolysis at many steps, one of which includes a decrease in protein kinase A activity. At least three enzymes and two accessory proteins are required for the normal process of hormone-induced lipolysis in adipose tissue.[21] Stored triglycerides are acted on by the enzyme, adipose triglyceride lipase (encoded by *PNPLA2*), which requires the coactivator protein comparative gene identification 58 (CGI58). Diglycerides are hydrolyzed by hormone-sensitive lipase, yielding monoglycerides that are metabolized by monoglyceride lipase. This process cannot occur unless perilipin 1, a protein that coats small lipid droplets, is phosphorylated by protein kinase A. Defects in *PLIN1*, the gene encoding perilipin 1, are associated with familial partial lipodystrophy.[22] Adipose tissue lipolysis is depicted schematically in Fig. 41.4. Human mutations in adipose triglyceride lipase or *CGI58* are responsible for two variants of neutral lipid storage disease that are characterized by hepatic steatosis; lipid accumulation in skeletal muscle; cardiomyopathy; neurologic problems; and, in one variant, skin defects.

Lipoprotein Lipase

Most lipids are delivered to peripheral tissues such as muscle and fat through the activity of lipoprotein lipase (LPL). LPL is rate limiting for clearance of plasma triglycerides and essential for generation of high-density lipoprotein (HDL) particles,[23] and hydrolyzes triglycerides (and, to a lesser extent, phospholipids) in circulating triglyceride-rich lipoproteins to allow peripheral sites access to preformed fatty acids. Much of this lipid flux is controlled by insulin, which increases LPL in fat and decreases LPL in muscle. Exercise tends to have the opposite effect,[24] ensuring appropriate energy supplies to meet metabolic demands. LPL activity requires the presence of a coenzyme, apoC-II, which primarily circulates as a component of very low density lipoprotein (VLDL) and HDL. In addition, the association of LPL with the luminal surface of endothelial cells requires the presence of its anchoring protein, glycosylphosphatidylinositol-anchored HDL-binding protein 1 (GPIHBP1).



• **Fig. 41.4** Lipolysis in adipocytes. Stored triglycerides are metabolized to yield the fatty acids that circulate in plasma through the action of three distinct lipases with separate substrate specificities. Triglycerides are acted on by adipose triglyceride lipase (ATGL) in complex with the coactivator protein CGI58 to yield diglycerides, which are acted on by hormone-sensitive lipase to yield monoglycerides. The monoglycerides, in turn, are acted on by monoglyceride lipase to yield glycerol. Lipid droplet proteins modulate this lipolytic process.



• **Fig. 41.5** (A) Cholesterol biosynthesis. 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase is the rate-limiting enzyme regulating cholesterol biosynthesis. The enzyme is downregulated by excess cholesterol in the cell. (B) Enterohepatic circulation of cholesterol and bile acids. Approximately 50% of cholesterol and 97% of bile acids are reabsorbed from the intestine and recirculated to the liver. (A, Modified from Brown MS, Goldstein JL. A receptor-mediated pathway for cholesterol homeostasis. *Science*. 1986;232:34–47.)

Free fatty acids released from lipoproteins by the action of LPL associated with the luminal surface of capillary endothelial cells must then cross the endothelial cell barrier to be captured by resident cells via conversion to acyl-CoA species. Tissue uptake of fatty acids at low concentrations appears mediated by cell surface transporters, whereas at high concentrations fatty acids may enter and transit the member in a nonregulated, nonsaturable process, sometimes referred to as flip-flop. Fatty acyl CoAs are then either stored as triglycerides or subjected to fatty acid oxidation. LPL is not synthesized in endothelial cells but is produced in adipocytes, cardiac myocytes, and skeletal myocytes and then secreted and targeted to the luminal surface of the endothelium. Both LPL and triglyceride-rich lipoproteins bind to endothelial GPIHBP1, which serves as a platform for lipolysis in the plasma.[25]

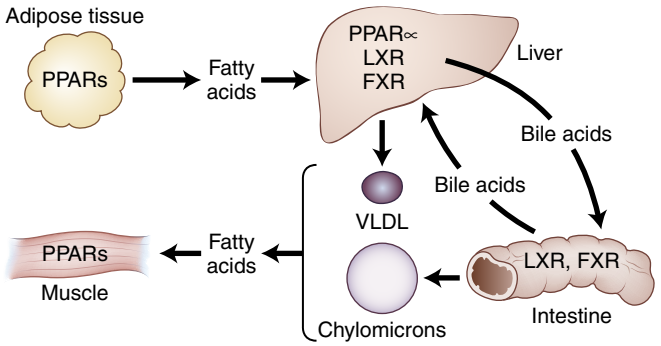
Cholesterol Metabolism

In adults, dietary cholesterol is not required because many tissues are capable of cholesterol synthesis. Most diets include animal products, the source of cholesterol. Plants do not have cholesterol, but their membranes contain phytosterols, which are structurally similar to cholesterol and are useful in the dietary treatment of hypercholesterolemia because they compete with cholesterol for absorption. The liver and intestine are quantitatively the most important sites for cholesterol metabolism in humans, although a very small amount of cholesterol is also lost through the normal turnover of skin.

Cholesterol Absorption, Synthesis, and Excretion

Cholesterol is absorbed through a process that requires formation of bile salt micelles. The efficiency of absorption varies widely in humans. There is a gradient of absorption through the intestine that is greatest in the proximal small intestine and least in the ileum. This gradient parallels the expression of Niemann-Pick C1–like 1 (NPC1L1), a transmembrane protein with a sterol-sensing domain that is involved in cholesterol absorption.[26] NPC1L1 is the target of ezetimibe, a drug that lowers cholesterol and has been shown to decrease heart disease. NPC1L1 also absorbs phytosterols such as sitosterol. The function of NPC1L1 in cholesterol absorption requires an interaction with LIM domain and actin binding 1 (LIMA1), which when mutated in humans is associated with low LDL cholesterol.[27] Sterols are pumped out of the enterocyte and into the intestinal lumen by two ATP-binding cassette (ABC) transporters: ABCG5 and ABCG8. Human mutations in these transporters cause the rare disorder sitosterolemia,[28] characterized by increased absorption and circulating levels of sitosterol and cholesterol, xanthomas, and heart disease (see later discussion).

Fig. 41.5A illustrates cholesterol synthesis. Acetate is converted to HMG-CoA. The latter is a substrate for HMG-CoA reductase, the enzyme that is rate limiting for cholesterol biosynthesis and is inhibited by statin drugs. Cells exquisitely regulate cholesterol acquisition.[29] When levels are low, the transcription factor sterol response element–binding protein (SREBP) translocates to the nucleus to activate genes that increase cholesterol biosynthesis and import cholesterol from the extracellular environment. Statins, by lowering cholesterol and preventing cholesterol biosynthesis, work predominantly by increasing liver uptake of cholesterol from the plasma through the LDL receptor (see later discussion) and promoting its excretion. Free cholesterol in cells is esterified to form cholesteryl esters for storage. This esterification reaction is carried out by acyl CoA:cholesterol acyltransferases (ACATs). These endoplasmic reticulum enzymes exist in two forms: ACAT1 is present in macrophages and has been implicated in atherosclerosis, and ACAT2 is present in the liver and intestine and is implicated in cholesterol absorption. Nonspecific ACAT inhibition in humans does not affect serum lipids and does not have beneficial effects on atherosclerosis.[30]



• **Fig. 41.6** Nuclear receptors in lipid metabolism. Peroxisome proliferator-activated receptors (PPARs) are active in adipose tissue, which is a source of fatty acids that are transported to liver, where PPARα, the liver X receptors (LXRs), and farnesoid X receptor (FXR) are active. Bile acids produced by the liver participate in an enterohepatic circulation with the intestine, another site of LXR and FXR expression. Very low density lipoprotein (VLDL), produced by the liver, and chylomicrons, from the intestine, are metabolized to release fatty acids that fuel muscle (another site of PPAR expression) and may be stored by adipose tissue.

Cholesterol, which is non-nutritive and cannot be catabolized to carbon dioxide and water, is either secreted into the bile as free cholesterol (about half of which is reabsorbed) or converted to bile acids for secretion into bile. Most bile acids are reabsorbed in the terminal ileum. This enterohepatic circulation of cholesterol and bile acids is shown in Fig. 41.5B. The rate-limiting enzyme for bile acid synthesis is cholesterol 7α-hydroxylase, which is under feedback regulation by bile acids. Interruption of the enterohepatic circulation of bile acids through the use of bile acid sequestrants reduces the farnesoid X receptor (FXR)-mediated inhibition of bile acid synthesis. The subsequent induction of bile acid synthesis is associated with a reduction in plasma cholesterol and an increase in triglyceride production, explaining triglyceride elevations seen with bile acid sequestrant therapies. At least in mice, evidence suggests that cholesterol can be excreted directly by enterocytes (independent of the biliary system) through an active metabolic process called *transintestinal cholesterol excretion*.[31]

Nuclear Receptors and Lipid Metabolism

Nuclear receptors, usually transcription factors with both ligand- and DNA-binding domains, affect lipid metabolism. Classic hormones that interact with nuclear receptors and have important lipid effects include thyroid hormone, glucocorticoids, estrogen, and testosterone.

SREBPs are a family of transcription factors that control the metabolism of both cholesterol and triglycerides.[32] In an inactive state such as occurs with excess cellular cholesterol, they are associated with the endoplasmic reticulum membrane. Reduced endoplasmic reticulum cholesterol allows proteolytic processing of SREBPs allowing translocation to the nucleus, where they regulate production of biosynthetic genes for cholesterol and the LDL receptor (SREBP2) and for triglyceride (SREBP1c) (both are discussed in more detail later).

Thyroid hormone reduces circulating cholesterol concentrations via modulation of LDL receptor expression, or through reduced hepatic synthesis of apoB lipoproteins and greater excretion of cholesterol into the bile.[33] Thus, lipid levels tend to be high in hypothyroid patients and low with hyperthyroidism. Glucocorticoids have robust effects on multiple aspects of lipid metabolism, inducing expression of HMG-CoA reductase to promote cholesterol synthesis, increasing expression of fatty acid synthase to promote fatty acid synthesis, and decreasing LPL to impair clearance of circulating lipids. Accordingly, hyperlipidemia is commonly seen in the setting of glucocorticoid treatment, and insulin resistance induced by glucocorticoids amplifies the hyperlipidemia. Estrogens and selective estrogen receptor modulators such as raloxifene lower cholesterol[34] by inducing LDL receptor activity; they tend to increase triglyceride levels, especially when higher oral doses are administered. Derivatives of cholesterol can serve as selective estrogen receptor modulators to affect the vasculature.[35] Androgens, by activating the androgen receptor, decrease HDL.[36] Changes in HDL with estrogens and androgens correlate with changes in hepatic triglyceride lipase, an enzyme that, like LPL, is released into the bloodstream after heparin injection.

Aside from classic hormones and their receptors, other nuclear receptors affect lipid metabolism after interacting with several types of metabolic by-products. These receptors include the PPARs, the liver X receptors (LXRs), and FXR. A schematic view of the roles of these receptors in lipid metabolism is presented in Fig. 41.6.

There are three known types of PPARs: α, γ, and δ. PPARα promotes fatty acid oxidation, as well as ketogenesis, and is induced by starvation. PPARα expression is highest in tissues adapted to metabolize fats, such as liver and skeletal muscle, but is also present in numerous other sites. In humans, pharmacologic activation of PPARα with fibrates lowers triglycerides and increases HDL. Fatty acids interact with the receptor, but a phosphatidylcholine species was identified as an endogenous ligand for PPARα.[37]

Whereas PPARα facilitates energy utilization, PPARγ activates genes that promote energy storage. It is expressed at the highest levels in adipose tissue and is also found in macrophages, where it may help coordinate the complex relationship between inflammation and metabolism. Ether lipids, which are phospholipids generated in peroxisomes, appear to be endogenous ligands for PPARγ.[38] Pharmacologic activation of PPARγ in humans with thiazolidinediones results in insulin sensitization and weight gain (see Chapter 35). The latter effect occurs because this nuclear receptor promotes both adipogenesis and fluid retention through effects on the kidney. Importantly, thiazolidinediones increase incident heart failure.[39] Thiazolidinedione treatment in humans tends to lower triglycerides and increase HDL, probably by modulating insulin signaling. In mice, these agents reduce atherosclerosis, and in people with metabolic syndrome with a recent stroke or transient ischemic attack, pioglitazone reduces risk of stroke and myocardial infarction.[40] Dual agonists for PPARα and PPARγ lower hemoglobin A_{1c} and serum lipids in humans but also increase the all-cause mortality rate.[41]

PPARδ promotes fatty acid oxidation in skeletal muscle, and activation of this receptor may mimic some aspects of exercise.

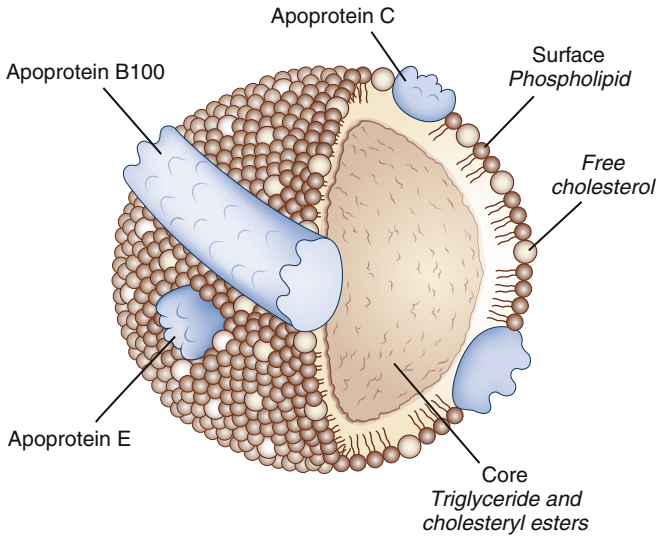
LXRs and FXR are also involved in lipid metabolism. LXRα and LXRβ are activated by oxysterols (derivatives of cholesterol) to increase conversion of cholesterol into bile acids, increase bile acid excretion, and decrease cholesterol absorption. LXR activation inhibits cholesterol uptake by inducing the degradation of the LDL receptor.[42] LXRs also induce fatty acid and triglyceride synthesis. FXR is activated by bile acids to stimulate both bile acid secretion and reabsorption. Administration of the bile acid sequestrant colesevelam to humans with diabetes lowers blood sugar, but the role of nuclear receptors in this effect is not defined.

Additional nuclear receptors also play important roles in lipogenesis—the process of converting carbohydrates to triglycerides rather than glycogen. Carbohydrate response element–binding

protein (ChREBP) may control as much as 50% of this process. It responds to carbohydrate excess by transactivating a series of glycolytic and lipogenic genes.[43] SREBP1c is also critical for this process.[44]

Plasma Lipoproteins, Apolipoproteins, Receptors, and Other Proteins

Lipoproteins, which are spherical particles that circulate in the blood, transport vital non–water-soluble nutrients, vitamins, structural components, and proteins with specialized functions from the gut through the plasma compartment to remote tissues. Appropriate concentrations of lipoproteins are essential for health, but increased circulating concentrations of certain lipoproteins are associated with increased risk for cardiovascular disease. Absent or low levels of other lipoproteins may lead to vitamin deficiency syndromes. The roles of the various lipoproteins are discussed in detail in the following sections.



• **Fig. 41.7** General structure of lipoproteins: schematic representation of a very low density lipoprotein particle.

Major Lipoproteins

A prototypical lipoprotein is shown in Fig. 41.7. The fundamental structure of a lipoprotein exploits biochemical characteristics of its components. The surface consists of charged molecules that interact with the aqueous environment, such as phospholipids and free cholesterol. Amphipathic proteins (with both hydrophilic and hydrophobic domains), called *apolipoproteins* (or simply *apoproteins*), are also present on the surface, with hydrophilic domains oriented toward the plasma and hydrophobic domains toward the core of the particle. Apolipoproteins regulate the lipoprotein interaction with metabolic enzymes and cellular receptors. The lipoprotein core consists of neutral (uncharged) lipids, such as triglycerides and cholesteryl esters.

Lipoprotein movement through the plasma compartment is dynamic. Humans spend most of their lives in the postprandial state. Eating is associated with generation of lipoproteins and the induction of enzymes that metabolize those lipoproteins. Within the circulation, lipolysis of triglyceride leads to rapid reduction in the size of chylomicrons. Along with loss of core triglyceride, excess surface components of shrinking particles are extruded, and both nonesterified fatty acids and fat-soluble vitamins are delivered into tissues.

The major classes of lipoproteins are listed in Table 41.2. They were identified based on migration in an ultracentrifuge, and classes were defined based on density assessed using salt-containing solutions. An alternative original classification scheme, which is no longer useful, involved electrophoretic mobility in agarose gels. Chylomicrons, chylomicron remnants, and VLDLs are rich in triglycerides. Intermediate-density lipoproteins (IDLs), LDLs, and lipoprotein(a) (Lp[a]), are rich in cholesterol. HDLs are enriched in phospholipids. Triglyceride-rich lipoproteins such as chylomicrons are large and generally insoluble, which accounts for the cloudy appearance of plasma when it is obtained in nonfasting subjects or in fasting subjects with some types of hyperlipidemias.

TABLE 41.2 Major Classes of Plasma Lipoproteins

Type	Density (g/mL)	Origin	Major lipids	Major Apolipoproteins	Size (nm)
Chylomicrons	<0.95	Intestine	85% Triglyceride	B48, AI, AIV, E, CI, CII, CIII	~100–500
Chylomicron remnants	<1.006	Derived from chylomicrons	60% Triglyceride 20% Cholesterol	B48, E	~80–125
VLDL	<1.006	Liver	55% Triglyceride 20% Cholesterol	B100, E, CI, CII, CIII	30–80
IDL	1.006–1.019	Derived from VLDL	35% Cholesterol 25% Triglyceride	B100, E	25–35
LDL	1.019–1.063	Derived from IDL	60% Cholesterol 5% Triglyceride	B100	18–25
HDL	1.063–1.21	Liver, intestine, plasma	25% Phospholipid 20% Cholesterol 5% Triglyceride	AI, AII, CI, CII, CIII, E	5–12
Lp(a)	1.05–1.09	Liver	60% Cholesterol 5% Triglyceride	B100, apo(a)	~30

apo, Apolipoprotein; *IDL,* intermediate-density lipoprotein; *LDL,* low-density lipoprotein; *Lp(a),* lipoprotein(a); *VLDL,* very low density lipoprotein.

Table 41.2 provides general ranges for particle size, which differ substantially among lipoproteins and within each class. The relative amount of protein versus less dense lipids correlates with the size and also the buoyancy of the lipoproteins—for example, large VLDLs contain much more lipid than the smaller HDLs. The subspecies of these particles similarly differ in size and protein/lipid content. One lipoprotein subtype, small dense LDL, is associated with cardiovascular disease, insulin resistance, and hypertriglyceridemia.

Chylomicrons originate in the gut. They are lighter than water and float to the top of a plasma sample. The particles are cleared rapidly (within minutes) after a meal and should be absent after an overnight fast. Their distinguishing apolipoprotein is apoB48, which is the only form of apolipoprotein B produced by intestinal cells in humans. B48 is so named because, as a splice variant, it is 48% of the entire B100 protein found in VLDL and LDL. Chylomicrons acquire apoC and apoE molecules by interacting with HDL particles, a process that promotes chylomicron metabolism and conversion to chylomicron remnants. Chylomicron remnants, also characterized by the presence of apoB48, are cleared rapidly from the plasma. Remnant particles, as well as LDL, promote arterial atherosclerosis.

VLDL particles are of hepatic origin. Smaller than chylomicrons, their distinguishing apolipoprotein is apoB100, the form of apoB produced by the liver. VLDLs also carry apoC molecules that modulate the conversion of VLDLs to IDLs, which are VLDL remnants and are also atherogenic. IDL particles contain apoB100 and apoE, and they are converted to LDL, which is characterized by carrying essentially only apoB100 as an apolipoprotein. LDL is the major carrier of cholesterol in most humans, and its measurement forms the basis for coronary heart disease risk stratification and treatment goals. For most clinical laboratories, LDL results represent both IDL and LDL particles.

HDL particles have a complex biology. They can be generated by the liver and intestine or assembled in the plasma as a consequence of the metabolism of other lipoproteins. They are arbitrarily divided into HDL_2 (less dense, at 1.063–1.125 g/mL), which typically contains both apoAI and apoCs, and HDL_3 (more dense, at 1.125–1.21 g/mL), which typically contains apoAI, apoAII, and apoCs. There is also a minor subclass known as HDL_1 that carries a large percentage of plasma apoE. High HDL levels are associated with low cardiovascular risk in population studies, but it is not known if HDL plays a direct role in atherosclerosis. HDL can be assessed by its cholesterol content or more recently by a functional assay of cholesterol efflux capacity. This activity, reflecting the movement of labeled cholesterol from a cultured macrophage cell line to apoB-depleted plasma, may be inversely associated with cardiovascular events (see later discussion).[45] In part, the disparity between HDL concentration and function might explain why genetic markers associated with HDL levels do not associate with cardiovascular disease risk.[46]

Lp(a), produced by the liver, consists of an LDL particle in which the apolipoprotein apo(a) has been covalently linked to apoB100. Apo(a) has substantial protein homology to plasminogen, which is required for the endogenous thrombolytic response, and it exists in isoforms based on Kringle repeats (named after a type of pastry). Isoforms with fewer repeats, and therefore lower mass, tend to circulate at higher concentrations. Higher levels increase the risk of myocardial infarction, aortic valve calcification, and aortic stenosis.[47,48]

Major Apolipoproteins

The chromosomal location, size, sites of synthesis, and major functions of important apolipoproteins are summarized in Table 41.3.

Apolipoproteins AI, AII, AIV, and AV

ApoAI is the most abundant apolipoprotein in HDL. It is synthesized by the liver and intestine and activates the enzyme lecithin:cholesterol acyltransferase (LCAT), which transfers a fatty acid from lecithin to the free hydroxyl group on cholesterol to generate cholesteryl ester. Maturation of HDL particles begins as lipid-poor discs containing apoAI which then acquire free cholesterol. Cholesterol within the nascent HDL is converted to cholesteryl ester through the activity of LCAT leading to expansion into spheres. ApoAI mediates efflux of cholesterol from peripheral tissues, an important step in the process of reverse cholesterol transport.[49] Human genetic mutations in apoAI cause low levels of HDL and corneal opacities. ApoAI is considered to be an antiatherogenic protein, but genetic defects leading to low levels of apoAI are not consistently associated with coronary artery disease.

ApoAII is present with apoAI in some HDL particles. Synthesized mostly in the liver, it has been implicated in the activation of hepatic lipase, an enzyme involved in HDL metabolism, and in the inhibition of LCAT. ApoAII disrupts the ability of HDL to promote reverse cholesterol transport, but the genetic absence of this protein in humans does not seem to be associated with a phenotype.[50]

ApoAIV originates in the gut, and its secretion is induced by consumption of a high-fat meal. It may affect food intake in mice, but information in humans is not available.

ApoAV is encoded by a locus near the apoAIV gene in the apoAI/CIII/AIV/AV gene cluster on chromosome 11. It is produced by liver and circulates at low concentrations in association with VLDL particles in humans. ApoAV is involved in the hydrolysis of triglyceride-rich lipoproteins by LPL, its expression is inversely related to triglyceride levels, and it promotes lipoprotein clearance by hepatic proteoglycans.[51] In humans, homozygous mutations in apoAV increase risk for hyperchylomicronemia and pancreatitis.[52]

Apolipoprotein B

There are two forms of this apolipoprotein, apoB100 and apoB48, which are encoded by a single gene. A unique mechanism that involves RNA editing allows translation into these two forms of apoB (Fig. 41.8). In both liver and intestinal cells, the same messenger RNA is transcribed, but an editing protein complex interacts with the message only in the intestine (in humans) to change the cytosine at nucleotide position 6666 to uracil leading to production of an intestinal protein that is approximately 48% of the length of apoB100.

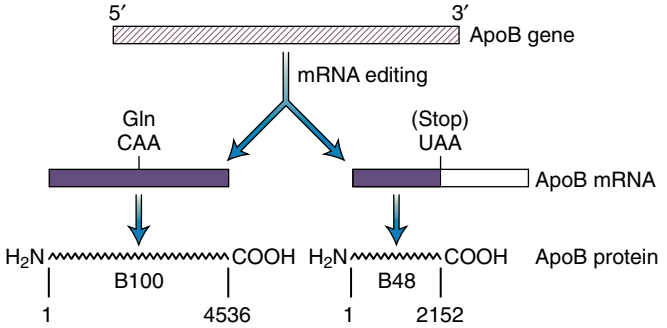
ApoB48 is important for the assembly of chylomicrons.[53] There are one or two apoB48 molecules on each chylomicron, where they provide structural support to the particle. The COOH-terminus of apoB100, missing in apoB48, determines interaction with the LDL receptor, so apoB48 does not appear to be involved in the clearance of gut-derived lipoproteins.

ApoB100 originates in the liver, where it is cotranslationally associated with lipids to coordinate the formation of VLDL particles. VLDL assembly and export, which affect the levels of circulating atherogenic lipoproteins, are determined not by transcriptional control of the apoB gene but by a mechanism involving stabilization of the apoB protein by lipid. VLDL production

TABLE 41.3 Major Apolipoproteins

Apolipoprotein (Chromosome No.)	Molecular Weight (kDa)	Synthesis	Functions
AI (11)	~29	Liver, intestine	Structural protein (HDL) Cofactor for LCAT Crucial role in reverse cholesterol transport Ligand for ABCA1 and SR-BI
AII (1)	~17 (dimer)	Liver	Inhibits apoE binding to receptors Activates hepatic lipase Inhibits LCAT
AIV (11)	~45	Intestine	Potential satiety factor Activator of LCAT Facilitates lipid secretion from intestine
AV (11)	39	Liver	Activator of LPL-mediated lipolysis Might inhibit hepatic VLDL synthesis
B100 (2)	~500	Liver	Structural protein (VLDL and LDL) Ligand for LDL receptor
B48 (2)	~200	Intestine	Structural protein (chylomicrons)
CI (19)	6.6	Liver	Modulates remnant binding to receptors Activates LCAT
CII (19)	8.9	Liver	Cofactor for LPL
CIII (11)	8.8	Liver	Modulates remnant binding to receptors Inhibitor of LPL
E (19)	~34	Liver, brain, skin, testes, spleen	Ligand for LDL and remnant receptors Local lipid redistribution Reverse cholesterol transport (HDL with apoE)
apo(a) (6)	~400–800	Liver	Modulates thrombosis/fibrinolysis

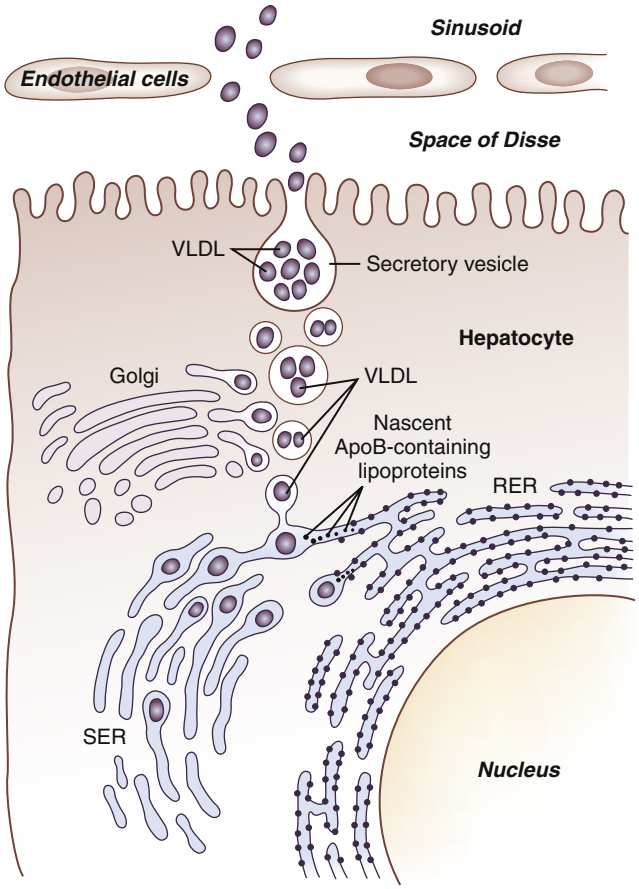
ABCA1, Adenosine triphosphate–binding cassette transporter A1; *apo,* apolipoprotein; *HDL,* high-density lipoprotein; *LCAT,* lecithin:cholesterol acyltransferase; *LDL,* low-density lipoprotein; *LPL,* lipoprotein lipase; *SR-B1,* scavenger receptor class B type 1; *VLDL,* very low density lipoprotein.



• **Fig. 41.8** Synthesis of apolipoprotein B100 and apoB48 by a messenger RNA (mRNA) editing mechanism. In the human intestine, a specific cytosine (C) is changed to a uracil (U) in the apoB mRNA. This change results in a stop codon and the formation of apoB48, which contains only the first 21^{52} amino acids of the full-length apoB100 (4536 amino acids). *COOH,* carboxy-terminus; *Gln,* glutamine; *H_2N,* amino-terminus.

is shown in Fig. 41.9. Assembly is thought to involve two distinct processes. First, as the apoB message is translated on the rough endoplasmic reticulum, it binds to lipids that are provided by microsomal triglyceride transfer protein (MTP; the target of a medication, see later discussion). This protein heterodimerizes with protein disulfide isomerase, which remodels the apoB protein by rearranging the positions of disulfide bonds in the molecule to accommodate incoming lipid. Most of this lipid originates in adipose tissue, where triglyceride lipolysis releases free fatty acids that are transported to the liver. Phospholipids and cholesterol also associate with apoB at this step. If sufficient lipids are not available in the liver, apoB (which is constitutively produced) is ubiquitinated and degraded in the proteasome. Second, maturing VLDL particles fuse with additional lipid droplets in the Golgi apparatus, a process facilitated by apoE. The triglyceride-rich particles are then secreted into the space of Disse. The discrete fates of these two potential sources of VLDL may be complex, but VLDL particles ultimately gain access to the circulation, where the transfer of apolipoproteins from other lipoproteins modifies VLDL structure to promote metabolism in the periphery.

Increased VLDL production, fueled by the increased availability of lipid, is predominantly responsible for the dyslipidemia seen with obesity and diabetes. There is one copy of apoB100 on each VLDL particle, and this relationship is retained as these lipoproteins are metabolized to IDL and then to LDL. Therefore, measurements of apoB100 in the plasma reflect the particle number, and higher levels of apoB are associated with cardiovascular disease. The complete absence of apoB, which occurs in the rare human disorder abetalipoproteinemia, is usually caused by mutations in MTP.[54] Patients with this disease can have severe neurologic deficits, probably reflecting vitamin E deficiency, because triglyceride-rich lipoproteins transport this lipid-soluble vitamin. Very low, but not absent, apoB, which occurs in the human



• **Fig. 41.9** Very low density lipoprotein (VLDL) biosynthesis by hepatocytes. The nascent apolipoprotein B (ApoB)-containing apolipoproteins synthesized by the rough endoplasmic reticulum (RER) are thought to combine with lipids in the smooth endoplasmic reticulum (SER). The VLDLs are processed in the Golgi apparatus and accumulate in large secretory vesicles. They are then released into the space of Disse and enter the plasma. (Modified from Alexander CA, Hamilton RL, Havel RJ. Subcellular localization of B apoprotein of plasma lipoproteins in rat liver. *J Cell Biol.* 1976;69:241–263; by copyright permission of the Rockefeller University Press.)

disorder hypobetalipoproteinemia, is usually caused by truncation mutations in apoB. These individuals present with low cholesterol and triglycerides and appear to be healthy. Another cause of hypobetalipoproteinemia is a defect in angiopoietin-like protein 3 (ANGPTL3), which leads to reduced hepatic secretion of lipoproteins and increased clearance without causing fatty liver.[55] A mutation at amino acid residue 3500 of the apoB100 protein, within the COOH-terminal region of the molecule that mediates binding to the LDL receptor, causes familial defective apoB100. These individuals have high LDL cholesterol, mimicking the presentation of FH.[56]

Apolipoproteins CI, CII, and CIII

These small apolipoproteins are encoded by loci residing at two different locations in the genome. ApoCI and apoCII are transcribed from a site on chromosome 19 near the apoE gene. The apoCIII gene is a component of the apoAI/CIII/AIV/AV cluster on chromosome 11. ApoCs, which can be exchanged freely among lipoprotein particles, are important for triglyceride metabolism because their presence either interferes with the recognition of apoE by lipoprotein receptors or displaces apoE from lipoproteins (both of which would increase triglycerides by impairing their clearance). The function of apoCII is more complex. High levels in mice cause elevated triglycerides by displacing apoE, but normal levels of apoCII are required for normal lipid clearance because this apolipoprotein is a cofactor for the enzyme LPL. Mutations of apoCII in humans cause severe hypertriglyceridemia, mimicking LPL deficiency.

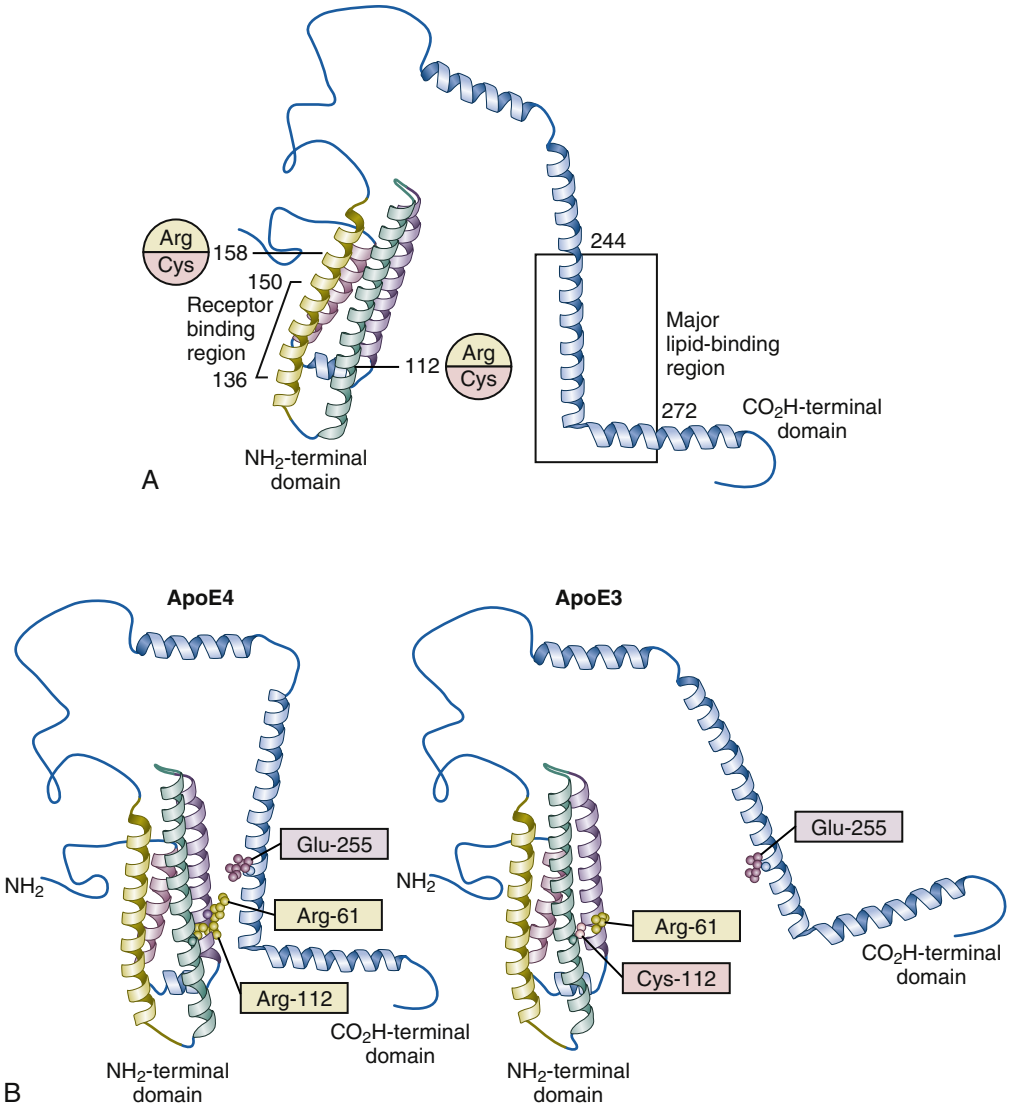
ApoCIII may be particularly relevant to human health. Levels are increased in the setting of many dyslipidemias, and most lipid-lowering medications lower apoCIII levels. A mutation in the apoCIII gene causing lower apoCIII levels is associated with an improved lipid profile and less atherosclerosis,[57] suggesting that therapies targeted at apoCIII might provide clinical benefit. In patients with extremely high triglycerides due to familial chylomicronemia syndrome (FCS; see later discussion), inhibiting the apoCIII mRNA results in substantial triglyceride lowering.[58]

Apolipoprotein E

ApoE biology is also complex. ApoE expression is highest in the liver, followed by the brain. In the brain, astrocytes and microglial cells synthesize apoE, which can also be produced by injured neurons. Many other cell types synthesize the protein, including macrophages. ApoE circulates in plasma within all lipoproteins, with the probable exception of LDL. Its principal function involves interactions with the two major receptors mediating the clearance of plasma lipoproteins: the LDL receptor and the LDL receptor–related protein (LRP1, also known as the chylomicron remnant receptor). Therefore, apoE is primarily responsible for clearance of intestinal-derived lipoproteins after a meal and for clearance of VLDL and IDL particles before they are converted to LDL.

There are three major apoE isoforms: E2, E3, and E4. They are encoded, respectively, by alleles referred to as ε2, ε3, and ε4, with charge differences caused by variations in amino acids at residues 112 and 158 in the protein. ApoE3 is considered the normal isoform; it has a cysteine at residue 112 and an arginine at 158. ApoE2 has cysteines at both 112 and 158, and apoE4 has an arginine at both 112 and 158. These variations have structural and functional consequences (Fig. 41.10). The protein has two domains: an amino (NH_2)-terminus interacts with lipoprotein receptors and a COOH-terminus interacts with lipids (see Fig. 41.10A). In apoE4, the isoform associated with disease, these domains interact, which does not occur with apoE3 (see Fig. 41.10B).

Comprehensive data (more than 86,000 individuals for lipids and more than 37,000 for coronary events) link apoE allele and genotype frequencies, lipid levels, and coronary risk.[59] Allele frequencies in healthy adults are 7% for ε2, 82% for ε3, and 11% for ε4. Genotype frequencies are 0.7% for ε2/ε2, 11.6% for ε2/ε3, 2.2% for ε2/ε4, 62.3% for ε3/ε3 (the most abundant genotype), 21.3% for ε3/ε4, and 1.9% for ε4/ε4. There is a linear relationship between the genotype and both LDL level and coronary risk, from least to most, as follows: ε2/ε2 < ε2/ε3 < ε2/ε4 < ε3/ε3 < ε3/ε4 < ε4/ε4. Compared with the reference group (ε3/ε3), the presence of the ε2 allele decreases coronary risk by about 20%, and the presence of the ε4 allele slightly increases risk. These observations are interesting for two reasons. First, ε2/ε2 individuals, although they are protected from coronary heart disease on a population basis, are at risk for dysbetalipoproteinemia, occurring in about 5% of ε2/ε2 individuals and which is associated with aggressive vascular disease. Second, the E2 protein binds less well to the LDL receptor than E3 and E4. This suggests that LDL cholesterol in patients with the E2 protein should be higher (because it is less



• **Fig. 41.10** (A) The amino (NH_2)-terminal domain of apoprotein E is composed of a four-helix bundle. A region of random structure encompassing residues 165 to 200 forms a connector or hinge region linked to the carboxy (CO_2H)-terminal domain. There are two major functional regions. Residues 136 to 150 (*yellow helix*) encompass the receptor-binding region; residues 240 to 260 in the carboxy-terminal domain encompass the lipid-binding region. (B) ApoE4 displays the unique property of domain interaction that distinguishes it from apoE3 (Arg-61 in the amino-terminal domain interacts with Glu-255 in the carboxy-terminal domain). *Arg,* arginine; *Cys,* cysteine; *Glu,* glutamic acid.

likely to be cleared by this receptor), yet the opposite is observed. These data suggest that other receptor-mediated processes, such as those mediated by heparan sulfate proteoglycans (HSPGs), may be critical for clearance of apoE-containing lipoproteins.[60]

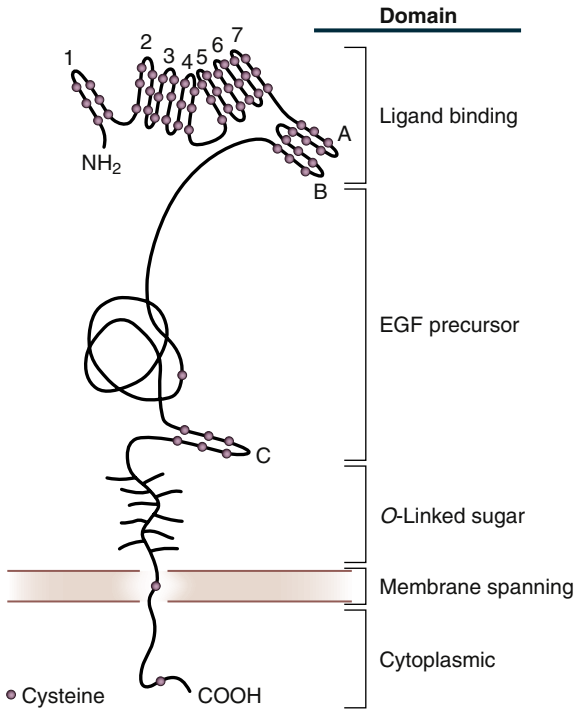
ApoE is a well-characterized genetic marker for Alzheimer disease. Risk increases approximately 3-fold in those with one ε4 allele and 12-fold in those with two ε4 alleles.[61] The presence of an ε2 allele is protective. These relationships hold for both early- and late-onset Alzheimer disease. There are HDL-like lipoproteins in the central nervous system, and apoE-mediated delivery of cholesterol is important for normal synaptic function. The relation of lipid metabolism to Alzheimer disease is incompletely understood, but evidence suggests that deposition of amyloid-β (the major constituent of the plaques that characterize the disease) begins sooner in the brains of those with the E4 protein. Because people with the ε4 allele are also more likely to have atherosclerosis, central nervous system vascular disease may help explain why this apoE variant is involved in neurodegeneration.

Major Receptors Involved in Lipid Metabolism

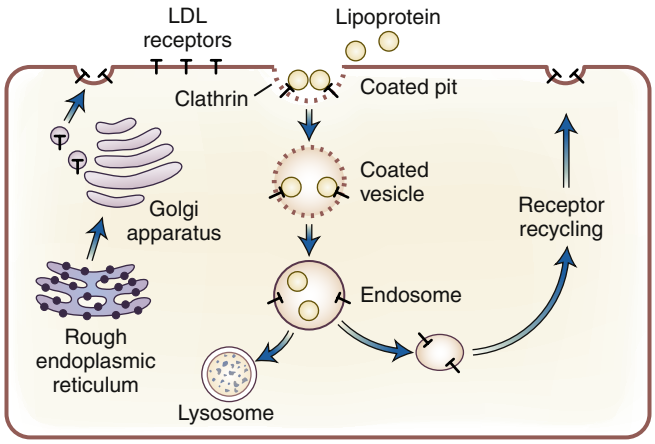
LDL Receptor Gene Family

There are at least 10 members of the LDL receptor family; LDL receptor and LRP1 are the two most important ones for systemic lipid metabolism. The LDL receptor recognizes apoB100 and apoE, whereas LRP1 recognizes only apoE. Other core family members (those that share considerable structural homology) include the VLDL receptor, the apolipoprotein E receptor 2 (apoER2 or LRP8), LRP4, LRP1B, and megalin (LRP2, also known as gp330 and as the major Heymann nephritis antigen).

Three family members lack some of the structural features of the others. They are sortilin-related receptor L1 (LR11/SORL1),



• **Fig. 41.11** Functional domains of the low-density lipoprotein receptor. Numbers 1 through 7 indicate repeats in the ligand-binding domain. A, B, and C are epidermal growth factor (EGF)-like repeats in the EGF precursor domain. See the text for a complete description. *COOH,* carboxy-terminus.



• **Fig. 41.12** Low-density lipoprotein (LDL) receptor pathway. LDL interacts with receptors on the cell surface. The complex enters the coated pit and is internalized. The coated vesicle loses its clathrin coat and becomes an endosome, the site of lipoprotein and receptor dissociation. The receptors recycle to the cell surface, and the lipoproteins are degraded. Alternatively, new receptors are synthesized in the rough endoplasmic reticulum and transported to the cell surface. (Modified from Brown MS, Goldstein JL. A receptor-mediated pathway for cholesterol homeostasis. *Science* 1986;232:34–47; and Myant NB. *Cholesterol Metabolism, LDL, and the LDL Receptor*. San Diego, CA: Academic Press; 1990.)

LRP5, and LRP6. Along with the LDL receptor and LRP1, sortilin receptors participate in brain development, synaptic function, and neuroprotection, making them relevant to Alzheimer disease.[62] LRP5 and LRP6 are both coreceptors for a family of G protein–coupled receptors known as frizzled receptors. Frizzled receptors bind the Wnt molecule to induce an important signaling cascade upstream of the transcription factor β-catenin. Genetic variants in LRP5 are associated with obesity,[63] and a human mutation in LRP6 results in metabolic syndrome and coronary artery disease.[64] Loss-of-function mutations in LRP5 or LRP6 cause osteoporosis in humans, whereas gain of function in LRP5 causes osteopetrosis. These observations suggest that insulin resistance, coronary disease, and osteoporosis, which are common comorbid conditions in patients, may be related to abnormal Wnt signaling.

LDL Receptor

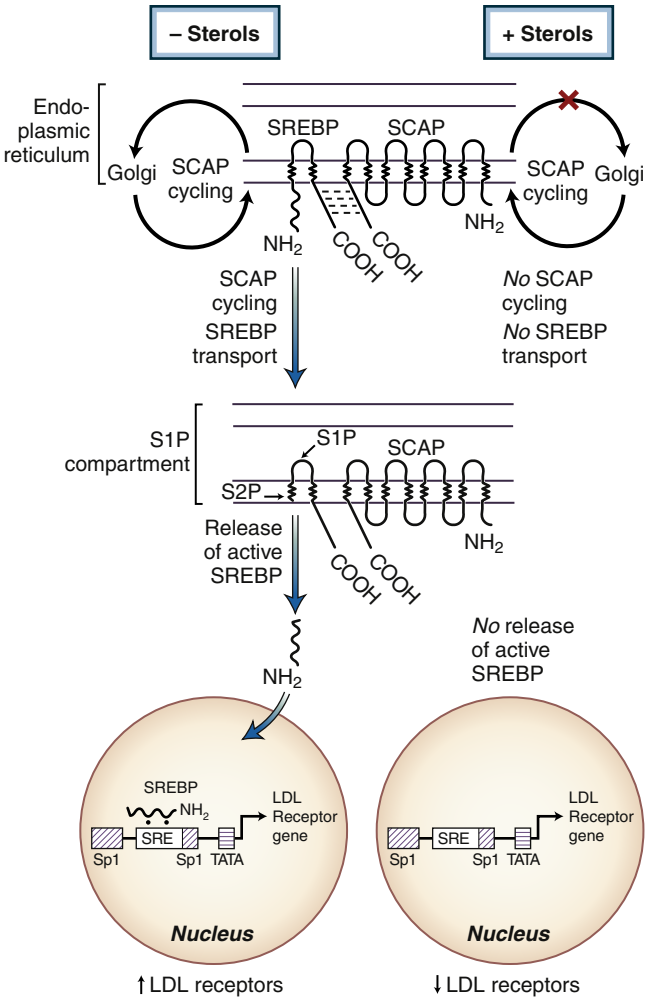
The LDL receptor is a large (160 kDa) glycoprotein expressed on most cells. Because it recognizes apoB100 as well as apoE, it is involved in the uptake of LDL, chylomicron remnants, VLDL, and IDL. Most HDL particles do not have apoE and therefore do not interact with this receptor or the LRP. The discovery of this receptor in the 1970s by Brown and Goldstein[65] explained a human disease (FH), the mechanism of action of drugs that lower cholesterol, and defined receptor-mediated endocytosis as a paradigm for providing cells with critical components from the external environment.

The LDL receptor shares functional domains with other members of this receptor family, including the ligand-binding domain, the epidermal growth factor (EGF) precursor domain, the *O*-linked sugar domain at the cell surface, the membrane-spanning domain, and the cytoplasmic domain at the COOH-terminus (Fig. 41.11). The ligand-binding domain includes seven repeats of approximately 40 amino acids, each containing six cysteines that form three disulfide bonds within the repeat to stabilize the structure. The repeat also includes negatively charged amino acids that interact with positively charged residues on the ligands apoB and apoE and with calcium ions. The EGF precursor domain consists of three EGF-like repeats (see Fig. 41.11) with a structure known as a β-propeller located between repeats B and C. The *O*-linked sugar domain is the site at which carbohydrate moieties attach to the molecule, and this is followed by a short membrane sequence. The cytoplasmic domain consists of 50 residues that include an NPXY (asparagine, proline, any amino acid, tyrosine) targeting sequence where adapter proteins dock, which leads to receptor clustering in coated pits.

Coated pits are specialized cell surface regions characterized by the presence of the protein complex clathrin. When LDL receptors bind lipoproteins, they migrate to coated pits, and clathrin directs the complex to a cell membrane region that folds inward, creating an intracellular vesicle or endosome (Fig. 41.12). Endosomes become acidic, causing the lipoprotein to be displaced from the LDL receptor by the β-propeller of the EGF precursor domain.[66] The unoccupied receptor recycles back to the cell surface. In the presence of PCSK9 (see later discussion and Fig. 41.18), the LDL receptor conformation is altered, promoting degradation and preventing recycling to the cell surface.[67]

Lipoproteins are degraded in lysosomes. Cholesterol is transported out of the lysosomes through the action of two proteins, Niemann-Pick C1 and C2 (NPC1 and NPC2), which are mutated in the human disease Niemann-Pick type C, which is characterized by intracellular accumulation of cholesterol. Intrathecal administration of cyclodextrin may confer clinical benefit.[68] NPC2, which is soluble, binds cholesterol after lipoprotein hydrolysis in the lysosome and moves this sterol to the membrane-associated NPC1 for subsequent release to the cell, where it serves structural and regulatory functions.

One key regulatory function of cholesterol is control of LDL receptor expression. Intracellular sterol concentrations are sensed



• **Fig. 41.13** Low-density lipoprotein (LDL) receptor gene regulation. *COOH,* carboxy-terminus; *S1P,* site-1 protease; *S2P,* site-2 protease; *SCAP,* SREBP cleavage–activating protein; *SRE,* sterol regulatory element; *SREBP,* sterol regulatory element–binding protein; *TATA,* the TATA box or core promoter sequence.

by SREBP cleavage–activating protein (SCAP), which binds to SREBPs in the endoplasmic reticulum. SREBP2 is most important for LDL receptor transcription; its NH_2-terminus contains a leucine zipper–type transcription factor structure that binds to a sterol regulatory element in the promoter of the LDL receptor gene. When cells are sterol depleted (Fig. 41.13, *left side*), SCAP migrates to the Golgi apparatus, where sugar moieties attached to the protein are modified. This allows SCAP to transport SREBPs to the site-1 protease (S1P) compartment. There, two proteases, S1P and site-2 protease (S2P), sequentially act on SREBPs to release their NH_2-terminus, which migrates to the nucleus and binds to the sterol regulatory element in the promoter region of lipid genes such as the LDL receptor and HMG-CoA reductase, increasing transcription and subsequent levels of functional proteins. In the presence of cholesterol (see Fig. 41.13, *right side*), SCAP does not cycle to the Golgi structure, it cannot move SREBPs to the S1P compartment, and SREBPs are not cleaved to allow their transcription factor to migrate to the nucleus. This disruption of SREBP activation in the presence of cholesterol protects cell from excessive accumulation of cholesterol.

LDL Receptor–Related Protein 1

LRP1 is also known as the apoE receptor or the chylomicron remnant receptor. LRP1 is large, containing components of four LDL receptors with a multiplicity of ligand-binding domains. Embryonic inactivation of LRP1 (but not of the LDL receptor) is lethal in mice. The major cell types expressing LRP1 include hepatocytes, neurons, and placental syncytiotrophoblasts. Multiple different ligands bind to LRP1 and participate in both nutrient flow and signaling. These ligands include amyloid precursor protein (processed to form the amyloid-β of plaques in Alzheimer disease), bacterial by-products, tissue plasminogen activator (which interacts with LRP1 to promote inflammation in the setting of brain ischemia), plasminogen activator inhibitors, and α_2-macroglobulin (which contributes to inflammation, in part by inactivating matrix metalloproteinases). LRP1 is associated with receptor-associated protein, a small protein that binds to several regions of LRP1 to chaperone this large protein during intracellular processing.

LRP1 binds apoE but not apoB100. Therefore, it mediates the metabolism of the major apoE-containing lipoproteins, including chylomicron remnants and IDL (VLDL remnants), but is not involved in LDL metabolism. The interaction between LRP1 and lipoproteins is more complex than that between LDL and the LDL receptor. Multiple apoE molecules are required for LRP1 binding, and this interaction requires an initial binding of the lipoprotein to proteoglycans on the cell surface. Other moieties on apoE-containing lipoproteins also facilitate the binding process. LPL, which metabolizes chylomicrons and VLDL particles, adheres to particles after mediating the release of fatty acids and other components at the endothelium. Lipoprotein-bound LPL molecules (as well as hepatic lipase) are thought to interact with LRP1 and to facilitate the uptake of remnants by the liver.

Pattern Recognition Receptors

The delivery of excess lipids to the blood vessel leads to atherosclerosis. The innate immune system and at least two broad types of receptors—scavenger receptors and toll-like receptors (TLRs)—that preferentially recognize ligand patterns (e.g., those associated with carbohydrates, lipids, or nucleic acids) instead of discrete features (e.g., specific amino acid sequences) are involved in the atherosclerotic process and thought to be activated by lipids.

Scavenger Receptors

The observation that macrophages can bind and internalize modified forms of LDL but not native LDL prompted the discovery of scavenger receptors. There are multiple classes of these receptors[69] that bind altered (e.g., oxidized, acetylated) LDL or other polyanionic ligands. Class A and class B receptors may be particularly important.

Class A receptors include scavenger receptor A (SR-A types 1 and 2, which consists of alternative splice variants), macrophage receptor with collagenous structure (MARCO), scavenger receptor A 5 (SCARA5), and scavenger receptor with C-type lectin domain (SRCL-I/II, also referred to as CL-P1). SR-A, the first to be discovered, binds a wide variety of ligands (including bacterial by-products), activates stress signaling pathways including mitogen-activated protein kinases, and is believed to be involved in atherosclerosis, the clearance of apoptotic cells, and Alzheimer disease.

Class B receptors include CD36 and scavenger receptor class B (SR-BI [called CLA1 in humans]). These receptors bind modified LDL, but unlike other scavenger receptors, they also bind VLDL, native LDL, and HDL. CD36 is expressed on a wide variety

of cell types, including monocytes, macrophages, adipocytes, platelets, endothelial cells, hepatocytes, microglial cells, and the tongue, where it detects dietary fat. In addition to lipoproteins, long-chain fatty acids are ligands for CD36.[70] The tissue distribution of SR-BI is more limited, with expression on hepatocytes, monocyte/macrophages, and steroidogenic tissues. A genetic deficiency of SR-BI in humans leads to increased circulating HDL but also increased risk for coronary heart disease.[71]

Toll-Like Receptors

The TLR family comprises key effectors of the innate immune system required for host defense mechanisms against pathogens. Their activation has been implicated in many chronic inflammatory diseases, including atherosclerosis, through signaling pathways that increase nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), activator protein 1 (AP1), and other transcription factors that control inflammation. Some scavenger receptors, such as CD36, may be coreceptors for TLRs. TLRs are found on myeloid cells such as monocyte/macrophages and on the gut epithelium. TRL ligands include lipopolysaccharide (TLR4) and glycolipids found in bacteria (TLR2). TLR2 mediates monocyte activation by apoCIII on triglyceride-rich lipoproteins.[72]

Other Enzymes and Transfer Proteins Mediating Lipid Metabolism

Hepatic Lipase

Heparin lipase primarily is a phospholipase with some triglyceride lipase activity. It is synthesized in hepatocytes but found mostly on endothelial cells in the liver and on HSPG in the space of Disse. It is also found in steroidogenic tissues but is not synthesized at those sites. Unlike LPL, which is mostly present at tissues remote from the liver, thereby ensuring the peripheral delivery of lipids and vitamins, hepatic lipase centrally coordinates lipoprotein metabolism. Functions include conversion of IDL to LDL, HDL_2 to HDL_3, and probably the final metabolism of chylomicron remnants to facilitate their uptake by LRP1. Unlike LPL, hepatic lipase does not require a cofactor such as apoCII, but both enzymes are displaced from their endothelial sites of activity by injection of heparin (postheparin lipase activity). High levels of hepatic lipase decrease HDL concentrations, whereas high levels of LPL increase HDL.

Endothelial Lipase

Evolutionarily related to hepatic lipase and LPL, endothelial lipase is a phospholipase with almost no triglyceride lipase activity. It is expressed at high levels in embryonic endothelial cells, with expression declining during maturation. In adults, expression is highest in endothelial cells, thyroid, lung, liver, placenta, and gonads. In mice, overexpression decreases HDL and inactivation increases HDL. Endothelial lipase is expressed in the aorta, where it may increase with atherosclerosis. Human loss-of-function mutations are associated with increased HDL.[73] Endothelial lipase does not appear to affect atherosclerotic risk.

Proprotein Convertase Subtilisin/Kexin Type 9

PCSK9 is a secreted protease that promotes the degradation of the LDL receptor by interacting with the receptor so that it is targeted to the lysosome. PCSK9 catalytic activity is not required for receptor degradation. Highest expression levels are seen in the liver, intestine, and kidney. The importance of PCSK9 in lipid metabolism was discovered when missense mutations within the gene (subsequently determined to be gain-of-function mutations) were associated with hypercholesterolemia and coronary artery disease.[74] Overexpression of PCSK9 in mice decreases LDL receptor protein. Human loss-of-function mutations in PCSK9 are associated with low LDL concentrations and decreased risk of vascular disease.[75,76] Some PCSK9 associates with circulating LDL,[77] which might assist with targeting this protein to LDL receptors. Antibodies to PCSK9 are useful for treatment in humans.

Lipoprotein-Associated Phospholipase A_2

Phospholipases hydrolyze the ester bond at the sn2 position of phospholipids, usually resulting in the release of a fatty acid and lysophosphatidylcholine, which can induce inflammation. Phospholipases were originally identified as a component of snake venom, and many distinct classes have since been characterized. Membrane phospholipids are the substrate for most phospholipases. Lipoprotein-associated phospholipase A_2 (Lp-PLA_2) is an exception because it can hydrolyze substrate in the aqueous phase. Lp-PLA_2 binds to both LDL and HDL lipoproteins and is a biomarker for coronary artery disease.[78] In humans, inhibition of this enzyme decreases the expansion of the lipid core of atherosclerotic plaques[79] but does not decrease cardiovascular end points.[80]

Cholesteryl Ester Transfer Protein

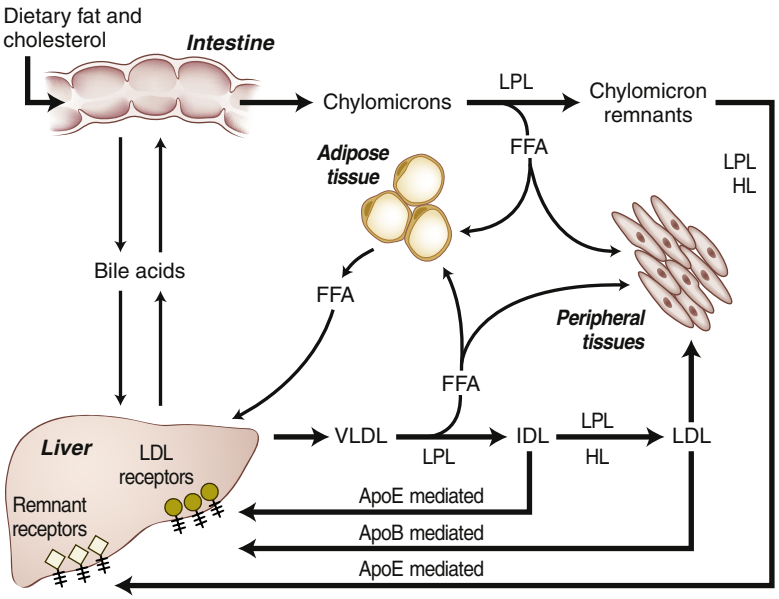
Cholesteryl ester transfer protein (CETP) promotes the exchange between lipoproteins of two classes of neutral lipids: cholesteryl esters and triglycerides. HDL cholesteryl esters are transferred to VLDL, IDL, and chylomicron remnants; in return, triglycerides from VLDL, IDL, and remnants are transferred to HDL. Humans and other primates have CETP activity; the transfer of cholesteryl ester from HDL to apoB-containing lipoproteins ultimately leads to most of their cholesterol burden being carried by LDL, and this is thought to result in atherosclerosis. Rodents and dogs do not have CETP. Most of their cholesterol is carried in HDL; LDL is low, and these animals are resistant to atherosclerosis. Such observations led to the notion of inhibiting CETP activity as a treatment for atherosclerosis in humans. In clinical trials, different inhibitors have increased HDL cholesterol and lowered LDL cholesterol but also increased mortality,[81] selectively increased HDL with no impact on cardiovascular events,[82] and reduced events perhaps due to lower LDL cholesterol.[83]

Lecithin:Cholesterol Acyltransferase

LCAT is an enzyme synthesized primarily in the liver; it circulates in the plasma associated with HDL particles and, to a lesser extent, with LDL particles. LCAT is activated by several apolipoproteins (apoAI and others) and uses the phospholipid lecithin (phosphatidylcholine) and free cholesterol as substrates to generate lysolecithin (lysophosphatidylcholine) and cholesteryl ester. Most of the cholesteryl esters in lipoproteins are derived from LCAT activity. Rare human mutations in LCAT result in low HDL levels. The role of LCAT in atherosclerosis is uncertain, and some reports suggest that humans with loss-of-function LCAT mutations do not appear to have increased risk for atherosclerosis,[84] perhaps because their residual HDL is functional in assays of reverse cholesterol transport. The other clinical manifestations of LCAT deficiency are described in the Lecithin:Cholesterol Acyltransferase Deficiency section.

Integrative Physiology of Lipid Metabolism

Lipid metabolism is characterized by a dynamic flux of multiple lipid species from the external environment to the liver, from the



• **Fig. 41.14** General scheme summarizing the major pathways involved in the metabolism of chylomicrons synthesized by the intestine and VLDL synthesized by the liver. *ApoB,* apolipoprotein B; *ApoE,* apolipoprotein E; *FFA,* free fatty acid; *HL,* hepatic lipase; *IDL,* intermediate-density lipoprotein; *LPL,* lipoprotein lipase; *VLDL,* very low density lipoprotein. Philadelphia, PA: JB Lippincott; 1995:1369–1378.)

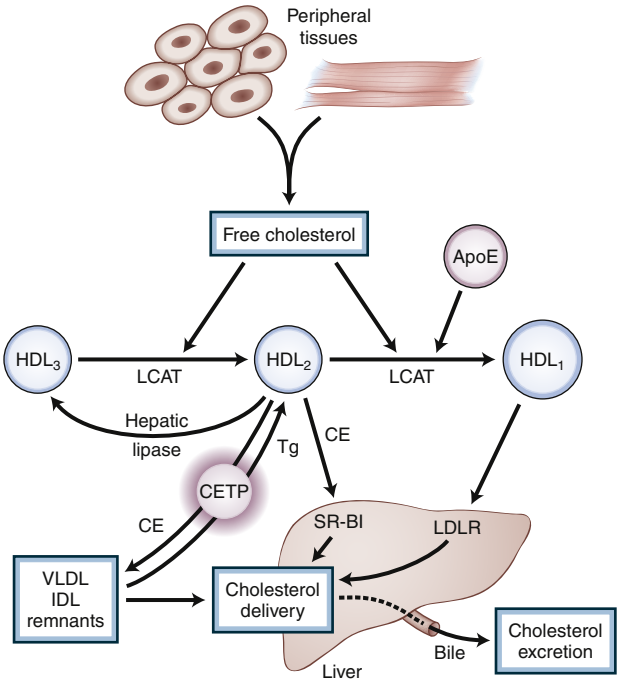
liver to peripheral tissues, from peripheral tissues back to the liver, and eventually back to the external environment through the excretion of bile acids. Integrated views of the major pathways involved are shown in Figs. 41.14 and 41.15.

Exogenous Lipid Transport

Dietary fat and cholesterol (see Fig. 41.14, *top left*) absorbed by the duodenum and proximal jejunum are used to generate chylomicrons that are secreted at the lateral borders of enterocytes and enter mesenteric lymphatics. They access the plasma via the thoracic duct and are rapidly metabolized by LPL to yield chylomicron remnants. These are taken up by remnant receptors (LRP1/HSPG) and by LDL receptors in the liver. Free fatty acids liberated by the action of LPL are available to adipose tissue for storage and to other tissues (e.g., skeletal muscle, heart) for use as energy substrates.

Endogenous Lipid Transport

Lipid derived from remnants and from lipolysis of adipose tissue is reassembled in the liver (see Fig. 41.14, *bottom left*) as VLDL particles, which are secreted into the plasma. Abnormal lipid metabolism in insulin resistance is mediated in large part by overproduction of VLDL, an event that occurs through disruption of signaling downstream of the insulin receptor and the insulin receptor substrate (IRS) adapter proteins. VLDL particles are metabolized by LPL to yield IDL particles, which are metabolized by LPL and hepatic lipase to yield LDL particles. Thus, LDL is derived from VLDL, which helps explain why treatments that increase LPL actions to lower triglycerides (carried by VLDL) are frequently associated with at least transient increases in LDL. IDL



• **Fig. 41.15** Role of HDL in the redistribution of lipids from cells with excess cholesterol to cells requiring cholesterol or to the liver for excretion. can be taken up by the liver through an apoE-dependent process, and LDL is taken up by the liver through the binding of apoB100 to LDL receptors. Small VLDL particles, IDL particles, and LDL particles may be taken up by peripheral tissues to deliver nutrients, cholesterol, and fat-soluble vitamins. When present in excess, each of these lipoproteins may be atherogenic.

Reverse Cholesterol Transport and Dysfunctional HDL

Cholesterol cannot be metabolized by peripheral tissues and must be returned to the liver for excretion. This process, called *reverse cholesterol transport*, is dependent on HDL and its precursors and is depicted in Fig. 41.15. Excess cholesterol in tissues can be effluxed either to lipid-poor apoAI, mediated by the protein transporter ABCA1 (ATP-binding cassette transporter 1), or to nascent HDL particles, mediated by ABCG1. Efflux from cultured cells to human plasma as a biomarker of cardiovascular risk is thought to mostly reflect the activity of ABCA1. There is also evidence that cholesterol can be acquired by HDL without the assistance of transporters by following a concentration gradient at the cell surface. LCAT esterifies HDL-associated cholesterol to form cholesteryl ester and induces the maturation of HDL. HDL particles have three pathways for transporting sterols to the liver. First, they can directly bind to SR-BI (CLA1) at the liver, which induces cholesteryl ester delivery through a mechanism involving lateral lipid transfer and not receptor internalization. Second, cholesteryl esters can be transferred to apoB-containing lipoproteins by CETP, and these particles can deliver cholesterol to the liver through the LDL receptor. Third, a small portion of HDL can acquire apoE and bind to the liver LDL receptor. Once in the liver, cholesterol is converted to bile acids for excretion.

Cholesterol is the principal component of atherosclerotic plaque, and thus atherosclerosis might be treated by promoting the efflux of cholesterol from lesions. HDL participates in this process, but static levels of HDL are poor predictors of reverse cholesterol transport. Dysfunctional HDL particles incapable of mediating cholesterol efflux could explain why some HDL-elevating interventions have not been associated with decreased cardiovascular disease. Measurements of the rate of flux of cholesterol from the periphery to the liver, which may be possible in humans, would represent a better predictor of beneficial therapies. In vitro cholesterol efflux capacity might be useful for assessing risk[45] but does not appear to be universally inversely associated with disease.[85,86]

In addition to participating in reverse cholesterol transport, HDL has other properties that could be impaired by a variety of processes leading to a dysfunctional particle. They include the induction of endothelial nitric oxide synthase, the transport of proteins involved in the acute phase response and inflammation, and the suppression of thrombosis through induction of prostacyclin (which decreases thrombin production via the protein C pathway and decreases platelet activation).

Overview of Hyperlipidemia, Dyslipidemia, and Atherogenesis

Abnormal lipids can present as elevated triglycerides, elevated cholesterol, elevations of both triglycerides and cholesterol, and low HDL. A summary of the primary and secondary causes of each condition is presented in Table 41.4.

Plasma lipid levels are highly dependent on lifestyle. For example, the high-fat, high-cholesterol diets of Western societies raise plasma cholesterol, and vigorous exercise lowers both atherogenic particles and triglycerides. For this reason, normal blood concentrations—those that are within 2 standard deviations of the mean—vary among countries and over time. The overriding influences of diet and lifestyle on plasma cholesterol were illustrated by studies of ethnic Japanese populations showing that cholesterol was markedly increased in Japanese-Americans consuming a Westernized diet.[87] Because total cholesterol levels correlate with the risk for coronary heart disease over a broad range (Fig. 41.16), normal levels are preferably defined as those associated with minimal cardiovascular risk rather than population averages, suggesting that most people in the developed world have lipid levels that put them at risk for atherosclerotic cardiovascular disease. Epidemiologic studies support that total cholesterol below 150 mg/dL (3.9 mmol/L) is associated with low risk of cardiovascular disease (see Fig. 41.16). Furthermore, atherosclerosis regression, such as the reduction of the size and presumably inflammatory status of established lesions, can be seen with LDL below 70 to 80 mg/dL (<2.0 mmol/L) in patients with established atherosclerotic cardiovascular disease.[88]

Population, genetic, and therapeutic data support that atherosclerosis is frequently caused by cholesterol deposition within the arterial wall. As described earlier, several genetic hyperlipidemic disorders are associated with premature atherosclerosis. Reductions of blood cholesterol by diet, statins, and other cholesterol-lowering therapies, and even surgical ileal bypass, have convincingly shown that cholesterol reduction will reduce the incidence of major cardiovascular events, especially myocardial infarction, need for revascularization, and stroke. Most striking is the observation that the majority of patients with coronary artery disease will have reduced disease (i.e., regression) with statin therapy.[88] The cholesterol hypothesis is further supported by a wealth of animal data: altering blood lipid levels by diet or genetic modification causes atherosclerosis-free animals to develop disease, and reduction of cholesterol leads to regression.

Atherosclerosis and its clinical presentations as coronary artery disease, stroke, and peripheral vascular disease are likely the product of several pathophysiologic changes. Depending on the patient and setting, arterial disease results from a varying reaction to lipid infiltration, arterial damage, and macrophage inflammation. More than 100 years ago, pathologists identified cholesterol as a major component of atherosclerosis. This poorly metabolized lipid is found to be associated with both collagen and proteoglycans (key components of connective tissue consisting of proteins attached to carbohydrates), and within arterial cells. Macrophages and smooth muscle cells are converted into foam cells, so called because of their intracellular foamy lipid. In addition, there are often acellular lipid-rich areas, a variable amount of overlying collagen-rich connective tissue, and regions where the atherosclerotic plaque has ruptured. The process begins with lipid infiltration into the arterial wall.[89] Unresolved pathogenic issues include (1) how lipid enters the artery, (2) determining which pathways lead to excess lipid uptake by foam cells, and (3) determining which processes cause rupture and thrombosis.

Lipoproteins cross the arterial barrier and infiltrate the artery wall. Larger particles, such as chylomicrons, are likely to be excluded by the endothelial barrier. LDL can leave the circulation via channels between cells, along the continuous transendothelial movement of cell-free plasma, or via interaction with specific receptors. Once in the subendothelial space, lipoproteins must

TABLE 41.4 Differential Diagnosis of Hyperlipidemia and Dyslipidemia

Hypertriglyceridemia	Hypercholesterolemia	Increased Cholesterol and Triglycerides	Low HDL
Primary Disorders			
LPL deficiency	Familial hypercholesterolemia	Familial combined hyperlipidemia	Familial hypoalphalipoproteinemia
ApoCII deficiency	Familial defective apoB100	Dysbetalipoproteinemia	ApoAI mutations
Familial hypertriglyceridemia	Polygenic hypercholesterolemia		LCAT deficiency
Dysbetalipoproteinemia	Sitosterolemia		ABCA1 deficiency
Secondary Disorders			
Diabetes mellitus	Hypothyroidism	Diabetes mellitus	Anabolic steroids
Hypothyroidism	Obstructive liver disease	Hypothyroidism	Retinoids
High-carbohydrate diets	Nephrotic syndrome	Glucocorticoids	HIV infection
Renal failure	Thiazides	Immunosuppressives	Hepatitis C infection
Obesity/insulin resistance		Protease inhibitors	
Estrogens		Nephrotic syndrome

• **Fig. 41.16** Relation between plasma cholesterol levels and coronary heart disease (CHD) mortality rate in the Multiple Risk Factor Intervention Trial. (Modified from Stamler J, Wentworth D, Neaton JD. Is relationship between serum cholesterol and risk of premature death from coronary heart disease continuous and graded? Findings in 356,222 primary screenees of the Multiple Risk Factor Intervention Trial [MRFIT]. *JAMA.* 1986;256:2823–2828; Copyright © 1986, by the American Medical Association.)

accumulate to cause disease. It is theorized that positive charges on apoB interact with negatively charged proteoglycans to promote lipoprotein retention. Both apoB100 in LDL and VLDL, apoB48 in chylomicron remnants, and apoE in several classes of lipoproteins have proteoglycan-binding sequences.[90] Another possibility is that within the artery, lipoproteins fuse to form large aggregates that are unable to disassociate and reenter the circulation. Lipoprotein uptake into cells is usually well controlled because excess cellular cholesterol downregulates LDL receptors. Therefore, aberrant lipoprotein receptor regulation may be a factor, or LDL (and remnants) may enter cells by non–cholesterol-regulated pattern recognition receptors (see earlier discussion).

Cholesterol-containing lipoproteins can become inflammatory. Enzymes within the artery might induce alterations in the protein and lipid content of LDL that convert these particles into more inflammatory oxidized LDL. Although low-dose aspirin has some anti-inflammatory properties, its reduction of cardiovascular events is most likely secondary to effects on platelet aggregation rather than direct effects on atherosclerosis. A recent clinical trial showed that blocking the interleukin 1β receptor reduced major coronary events in patients with high C-reactive protein and known vascular disease.[91] This finding supports that at least

some therapies directed to inflammation will be useful to prevent and treat residual risk for atherosclerosis even in the presence of lipid-lowering therapy.

Although the arterial lumen can be progressively narrowed by the accumulation of macrophages, the proliferation of smooth muscle cells, and the deposition of cholesterol, the truly dangerous lesion (the culprit lesion) may not cause marked luminal narrowing.[92] As atherosclerosis progresses, there is a compensatory expansion of the lumen that maintains an almost constant lumen size. As the lesion develops within the intima, the complication of rupture of the overlying intima or endothelial erosion leads to exposure of the lesional contents to platelets, initiating thrombosis. It is the acute thrombosis that is responsible for infarctions in most patients. Rupture or erosion occurs where the fibrous cap covering the underlying thrombogenic lipid is thin.

The surfaces of complicated lesions can become thrombogenic as endothelial cells are lost or the fibrous cap ruptures and the subendothelial space is exposed. Platelets can adhere to this exposed surface, promoting thrombus formation. In these unstable plaques, blood actually dissects into the artery wall, leading to the formation of a large thrombus. Calcification is also a feature of late lesions. Advanced lesions can weaken the elasticity and integrity of the artery wall, potentially creating an aneurysm of the vessel. Removal or reduction of the atherogenic stimulus can result in plaque regression and stabilization, leaving a remnant devoid of lipid that resembles a wound scar and is less likely to serve as a nidus for thrombus formation.

Observations first made in animals and now confirmed in humans indicate that the atherosclerotic process can be reversed if plasma cholesterol reduction is intensive.[93] LDL reduction to levels below 70 mg/dL (1.8 mmol/L) reduced lesions size in about two thirds of subjects studied by intravascular ultrasound.[88] Even greater regression was found with lower LDL achieved using PCSK9 inhibitors.[94]

In humans, vascular disease is not universal, even among those individuals with marked hypercholesterolemia. Similarly, patients with low cholesterol are not assured of being protected from the disease. Perhaps half of atherosclerosis is attributable to hyperlipidemia and other known cardiac risk factors.[95]

Despite the importance of lipids in atherosclerosis, there remains an unmet medical need to find additional approaches for residual risk in the lipid-lowering era. Several approaches to atherosclerosis treatment directed toward nonlipid causes have not been successful. Use of vitamin E and antibiotics has not altered cardiovascular event rates. Other inflammatory diseases (e.g., collagen vascular diseases) associated with cardiac events have not yet been shown to achieve lower cardiac event rates with cholesterol-lowering therapies. Statin-mediated cholesterol reduction appears to be ineffective in end-stage renal disease, although those patients usually do not have elevated LDL levels. In contrast, cardiovascular events in patients with less severe renal disease are reduced by treatment with statin/ezetimibe.[96]

Hypertriglyceridemia

Severe hypertriglyceridemia usually leads to pancreatitis if triglycerides exceed 2000 mg/dL (22.6 mmol/L). At approximately 500 mg/dL (5.6 mmol/L), LPL is saturated and a large bolus of fat during a dietary indiscretion may not be cleared from the bloodstream, thereby promoting severe hypertriglyceridemia and pancreatitis. Triglyceride guidelines have focused on prevention of pancreatitis and not cardiovascular disease, as there is no level 1 evidence to date that directed therapies to reduce triglyceride will affect cardiovascular events. Ongoing trials using fibrates and omega-3 fatty acids are likely to resolve this issue in the near future.

Fasting Hyperchylomicronemia

The most dramatic example of severe hypertriglyceridemia is that of fasting hyperchylomicronemia. This can result from a primary defect in chylomicron metabolism, or it can occur secondary to increased VLDL and saturation of LPL. LPL saturation occurs when triglyceride levels exceed about 500 mg/dL (5.6 mmol/L); this means that higher triglyceride levels exceed the capacity for the enzyme to act on its substrate, so dietary triglyceride is not metabolized and remains in the circulation. Therefore, familial hypertriglyceridemia, familial combined hyperlipidemia, and dysbetalipoproteinemia can be associated with fasting hyperchylomicronemia. One common cause of such exacerbations is poorly controlled diabetes leading to increased adipose intracellular lipolysis, return of fatty acids to the liver, greater secretion of VLDL triglyceride, and saturation of LPL. Several dietary and environmental factors also modulate triglyceride production. The most dramatic is alcohol, a major substrate for triglyceride production. In addition, diets that are rich in free carbohydrates, and especially simple sugars, induce triglyceride production. Fructose also increases de novo production of lipids in the liver but has less effect on circulating triglycerides.

Triglyceride levels above 500 mg/dL (5.6 mmol/L) and hypertriglyceridemic pancreatitis are relatively common; triglycerides above 1000 mg/dL (11.3 mmol/L) are found in 0.4% of a general medical population, and of these, 5.4% had a pancreatitis episode within 1 year.[97] Genetic defects leading to this condition, called *familial chylomicronemia syndrome* (or FCS), are relatively rare and estimated to occur in approximately 1 in 250,000 people.[98] Thus, the majority of patients are likely to be genetically predisposed to severe hypertriglyceridemia, with symptoms emerging due to environmental factors such as alcohol use or another underlying conditions such as diabetes. Defects in LPL most commonly cause genetic FCS; the lack of normal LPL prevents chylomicron clearance. LPL deficiency usually, but not always, manifests in childhood. The symptoms vary from difficulty feeding young infants to frank pancreatitis, which is sometimes mistaken as appendicitis. The plasma is often milky, and whole blood may have a pinkish, "cream of tomato soup" hue. The trigger level of triglyceride elevation leading to pancreatitis is variable; some patients have triglycerides in excess of 10,000 mg/dL (113 mmol/L) with no symptoms, whereas others develop pancreatitis at much lower triglyceride levels but usually in excess of 2000 mg/dL (22.6 mmol/L). However, patients presenting with pancreatitis have often avoided eating, and the first measured sample may not reflect the peak triglyceride. Several additional mutations in proteins required for normal LPL actions also cause FCS (see the LPL Deficiency section).

The pathophysiology of the relationship between hyperchylomicronemia and pancreatitis is unknown. Lipid-rich blood may sludge, leading to pancreatic ischemia. The small number of lipases that normally leak from the acinar cells may lead to exuberant local lipolysis; creation of toxic local concentrations of free fatty acids and lysolecithin, a toxic lipid produced from phosphatidylcholine; and further acinar cell damage to adjacent cells. Insults to the acinar cells such as those provided by alcohol can accelerate this process.

Although most patients with severe hyperchylomicronemia who do not develop pancreatitis are asymptomatic, a few with

extreme levels exceeding 10,000 mg/dL (113 mmol/L) develop the hyperchylomicronemia syndrome. These patients have dyspnea and confusion that may be indistinguishable from early dementia. Presumably, this is the result of reduced blood flow or defective oxygen delivery.

The marked increase in blood triglyceride concentration can lead to accumulation of triglycerides in several organs and can be observed in the blood. The latter is best appreciated by examining the blood directly, allowing the red blood cells to settle, and observing a creamy layer on the plasma, or by noting the pinkish discoloration of the blood on funduscopic examination, known as *lipemia retinalis* (Fig. 41.17B). Eruptive xanthomas, as shown in Fig. 41.17G, are 2- to 5-mm papules with a yellow center surrounded by erythema. They are caused by triglyceride-enriched skin macrophages. These lesions are sometimes confused with acne or folliculitis. For unclear reasons, eruptive xanthomas are most commonly found on the buttocks, extensor surfaces of the arms, and the back. Enlargement of the liver and spleen is not uncommon and is thought to be caused by triglyceride accumulation in these organs.

Aside from severe hypertriglyceridemia, other laboratory indices are sometimes abnormal. Plasma sodium is reduced; liver transaminases are sometimes elevated. Despite the presence of pancreatitis, amylase may be normal due to an assay artifact; serum lipase is a more reliable indicator in this setting. Often the clinical laboratory will note the severe lipemia and fail to report measurements of routine chemistries due to the turbidity of the serum. If these other measurements are required, plasma can be centrifuged, the chylomicron layer removed, and the remaining plasma examined.

LPL Deficiency

Almost every racial group has been reported to have patients with genetic defects in LPL, and a founder mutation makes the defect especially common among French Canadians. At least half of the cases of severe genetic primary hypertriglyceridemia are the result of LPL defects. Most LPL enzyme deficiencies are caused by inactive LPL protein. However, lack of protein production has also been reported, and because LPL might have receptor functions that do not require catalytic function, patients with these defects may have a more severe phenotype.

Although genetic LPL deficiency has been reported to manifest in adulthood, most cases of severe hyperchylomicronemia in adulthood are associated with partial LPL deficiency or other causes. In adults, the most important of these causes are type 2 diabetes mellitus and obesity, because insulin resistance is associated with defective clearance of lipoproteins. Postprandial lipemia is a prominent feature of diabetes. A thorough history of triglyceride-raising medications should be taken (see the Secondary Causes of Hypertriglyceridemia section).

Regulation of LPL is complicated, and defects in its actions are associated with genetic or acquired abnormalities that are exclusive of genetic defects in the LPL molecule. Defective apoCII, the obligate cofactor for LPL, leads to deficient LPL activity. Two molecular defects initially found in mice occasionally cause severe human hypertriglyceridemia. GPIHBP1 (discussed earlier) is a molecule expressed by endothelial cells whose deficiency leads to defective association of LPL with its binding site on the capillary lumen and defective intravascular lipolysis. In one report, 20% of patients with FCS had GPIHBP1 mutations.[99] Lipase maturation factor 1 (LMF1) is an intracellular protein required for correct intracellular folding and activation of LPL.[100] Mutations in LPL, GPIHBP1, and LMF1 all reduce postheparin LPL activity; mutated apoCII does not, but serum from these patients fails to maximally activate LPL. An additional genetic mutation associated with FCS involves glucokinase regulatory protein, which when dysfunctional allows excess de novo synthesis of fatty acids within the liver.[101]

Autoimmune conditions can be associated with defective triglyceride catabolism due to inhibition of LPL, apoCII, or heparin. Antibodies against heparin are thought to prevent normal LPL association with the endothelial surface. Antibodies against GPIHBP1 may be the most common causes of autoimmune chylomicronemia, as the tertiary structure of this protein appears to make it especially immunogenic.[102] Recognition of an autoimmune disorder such as concomitant presence of systemic lupus or rheumatoid arthritis is especially important because treatment with glucocorticoids, avoided in other hyperchylomicronemia syndromes, is often indicated. In addition, patients with vascular disease or generalized intravascular reactions to transfusions or chemotherapy can occasionally develop defects in LPL. Transient episodes of fasting hyperchylomicronemia have been attributed to viral infections and to excessive fat/calorie intake after fasting.

Postprandial Hyperlipidemia

Although plasma lipid levels are usually measured after an overnight fast, chylomicron remnants are associated with vascular disease in several animal models and with genetic or dietary causes of hyperlipidemia. This has led to a widely accepted hypothesis that remnant lipoproteins are an overlooked cause of human vascular disease. Postprandial lipidemia, measured as triglyceride increase, is associated with greater risk of atherosclerotic cardiovascular disease.[103] However, postprandial triglyceride elevations are also correlated with fasting triglycerides and reduced HDL, so the use of postprandial measurements in clinical practice is not currently recommended. Postprandial lipemia is a prominent feature of diabetes[104] but does not impair fasting glucose or impair glucose tolerance.[105]

Diagnostic Evaluation of Severe Hypertriglyceridemia

Assessment of underlying medical conditions and consideration of age at onset are required. If possible, biochemical and genetic evaluation of LPL and its regulating genes will refine the diagnosis. Conditions that cause fasting hypertriglyceridemia (discussed later) can lead to severe hypertriglyceridemia when exacerbated by diet, drugs, or other conditions such as diabetes or pregnancy. Genetic LPL deficiency is diagnosed by the clinical setting and either biochemical deficiency of LPL activity in postheparin blood or a genetic defect in LPL. LPL deficiency is more typically associated with younger age at onset, especially onset in childhood. A family history of low HDL is the most common lipid abnormality in heterozygous carriers. LPL variants are also a determinant of HDL levels within the general population. A family history of French Canadian ancestry is suggestive.

More than 100 mutations of the LPL gene have been described, and the diagnosis can be made through commercial DNA sequencing. Postheparin plasma can be collected for measurements of LPL activity in unusual presentations, but heparin administration is contraindicated in the setting of acute pancreatitis. This approach should be pursued in consultation with a research laboratory, because LPL activity is not measured in clinical laboratories. Deficiency of

apoCII, the LPL activator, and inhibitors of LPL such as antibodies can be detected in research assays by mixing the patient's serum with a standard human source of LPL and then assessing activity. Diagnosis in these rare cases can improve clinical management.[106]

Moderate Fasting Hypertriglyceridemia Due to Elevated VLDL

Triglyceride levels of 150 to 500 mg/dL (1.7–5.6 mmol/L) are considered to be abnormal. These more moderately increased levels may confer risk of pancreatitis in addition to cardiovascular disease. A study from Copenhagen of 116,550 individuals identified nonfasting triglycerides exceeding 177 mg/dL (2.0 mmol/L) as associated with a risk of acute pancreatitis that was greater than the risk for myocardial infarction.[107] Genome-wide association studies[108] and the observation that reduced triglycerides are associated with both lower atherosclerotic disease and genetic mutations in apoCIII,[57] a protein that might inhibit LPL actions and reduce uptake of triglyceride-rich lipoproteins by the liver, suggest an atherogenic role for triglycerides. Moreover, heterozygous LPL mutations also increase atherosclerosis risk,[109] even though hypertriglyceridemia is often manifested only when other conditions are present.

Several different clinical conditions lead to fasting hypertriglyceridemia. Familial combined hyperlipidemia is associated with increased apoB production, and at different times and in different family members, hypertriglyceridemia (increased VLDL), increased cholesterol (LDL), or both occur. This disorder is associated with increased risk of cardiovascular disease,[110] but its specific role is clouded by its presence in patients with other risk factors associated with metabolic syndrome. The concomitant insulin resistance, obesity, and/or overt diabetes in many hypertriglyceridemic patients make it difficult to isolate one specific cause of this metabolic disturbance. Although families with isolated triglyceride elevations and no vascular disease have been described, in the presence of metabolic syndrome, triglyceride elevations probably predispose to vascular disease through unclear mechanisms.

Some cases of isolated hypertriglyceridemia have been associated with hepatic overproduction of bile acids in the setting of impaired intestinal absorption of bile acids, analogous to the hypertriglyceridemia associated with use of bile acid–binding resins. There is uncertainty as to whether the large, triglyceride-rich VLDLs in this setting are atherogenic.

A homozygous mutation in apoE, apoE2/E2, leading to defective clearance of chylomicron and small VLDL remnants (see earlier discussion) underlies dysbetalipoproteinemia. These patients, with a prevalence of approximately 1 of every 10,000 people in the general population, present with elevated triglyceride and cholesterol due to defective clearance of remnant lipoproteins. Patients with dysbetalipoproteinemia sometimes have tuberous and palmar xanthomas and a propensity to peripheral vascular disease (see later discussion).

Genetic hypoalphalipoproteinemia syndromes are invariably associated with moderate hypertriglyceridemia. These syndromes include LCAT deficiency, Tangier disease, and apoAI Milano variant and are diagnosed as discussed later (see the Lecithin:Cholesterol Acyltransferase Deficiency, ABCA1 Deficiency, and Apolipoprotein AI Mutations sections). A reduced apoCII reservoir on HDL may be responsible.

Secondary Causes of Hypertriglyceridemia

Diabetes Mellitus

Diabetes mellitus is the most prominent cause of hypertriglyceridemia; in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, the average triglyceride was 162 mg/dL (1.8 mmol/L),[111] above the healthy ideal value. Insulin reduces fatty acid flux from adipose tissue, reduces liver apoB production, inhibits de novo triglyceride synthesis, and optimizes LPL production. Kinetic studies in humans show that both increased triglyceride secretion and reduced clearance of triglyceride from the bloodstream often occur in concert in patients with diabetes.[112] Diabetes is also associated with increased postprandial lipemia. The most common diabetic dyslipidemia is moderate hypertriglyceridemia and low HDL. Reduced HDL results from greater exchange of VLDL triglyceride for HDL cholesteryl ester, hydrolysis of the triglyceride-rich HDL by hepatic lipase, and more rapid clearance of the smaller HDL from the circulation. Defective lipolysis might also reduce the amount of cholesterol contributed to HDL from triglyceride-rich lipoproteins. CETP also enhances transfer of triglyceride to LDL, allowing these lipoproteins to be converted to smaller, denser forms that may be more atherogenic. This lipoprotein phenotype is also commonly referred to as diabetic dyslipidemia, although it is also found in nonhyperglycemic patients with metabolic syndrome. Although patients with diabetes do not have increased LDL compared with age- and sex-matched controls, improved diabetes control can be associated with reduced LDL. As stated earlier, diabetes is associated with severe fasting chylomicronemia. Many such patients also have an underlying dyslipidemia (e.g., due to heterozygous LPL deficiency), but others do not have a defined lipid disorder.

Patients with type 1 diabetes mellitus in poor control develop hypertriglyceridemia. However, because insulin stimulates HDL production, patients in good control sometimes develop high levels of HDL. Limited data suggest insulin-induced increases in HDL do not prevent cardiovascular disease.

Renal Failure

Renal failure is associated with hypertriglyceridemia and low HDL levels. The reasons for this are not clear but may reflect underlying insulin resistance and defects in lipolysis of plasma triglycerides. Hypertriglyceridemia in nephrotic syndrome has been linked to increased circulating levels of the LPL inhibitor angiopoietin-like protein 4.[113]

Drugs

Diabetes, obesity, and renal disease are common causes of fasting hypertriglyceridemia, but various drugs can also elevate triglycerides. The most common drugs associated with hypertriglyceridemia are estrogens, thiazides, beta blockers, protease inhibitors, glucocorticoids, immunosuppressives, retinoids (isotretinoin, Accutane), bile acid–binding resins, and newer antipsychotic medications.

Oral estrogen therapy increases plasma triglyceride levels as a result of greater liver production of VLDL, but combined estrogen-progestin therapy does not raise triglycerides and is sometimes associated with reduced LDL.[114] In the setting of an underlying hypertriglyceridemia, severe hyperchylomicronemia and pancreatitis can occur in patients taking oral estrogen alone or estrogen-containing birth control pills, or during oocyte induction for fertility. For this reason, triglyceride levels should be measured in women before estrogen therapy or estrogen-inducing therapy is initiated. Transdermal estrogen administration, which does not lead to high liver exposure, does not increase triglycerides.[115] Tamoxifen, a selective estrogen-receptor modulator, can cause severe hypertriglyceridemia and pancreatitis,[116] but raloxifene, another selective estrogen-receptor modulator, does not raise triglycerides.[117]

Diet and Alcohol

Diets can lead to marked changes in plasma triglyceride levels. Most lipoprotein profiles use fasting blood to avoid the postprandial increase in triglycerides that represent both dietary fat and hepatic de novo triglyceride production. Liver triglyceride production is especially robust after ingestion of simple sugars, such as those found in sweetened foods (especially beverages including high fructose corn syrup) and other carbohydrates (bread, pasta, rice, and potatoes). Excessive intake of simple carbohydrates usually leads to moderate hypertriglyceridemia but can also exacerbate underlying genetic hypertriglyceridemias. Fat intake, especially in the setting of triglyceride levels greater than 500 mg/dL (5.6 mmol/L), can cause severe hyperchylomicronemia.

Alcohol is a major clinical cause of hypertriglyceridemia. Sensitivity to the triglyceride-raising effects of alcohol is variable, but elimination of alcohol from the diet of hypertriglyceridemic patients is often curative. Alcohol has many effects on lipid metabolism, including inducing de novo fatty acid synthesis and inhibiting fatty acid oxidation in the liver. A common clinical conundrum is deciding whether hypertriglyceridemia alone is responsible for pancreatitis in an alcohol-using patient. Patients with dysbetalipoproteinemia are particularly sensitive to the effects of alcohol consumption because of alcohol-induced overproduction of VLDL and subsequent production of remnant particles in the setting of impaired remnant clearance. Because alcohol also raises HDL, the presence of elevated triglycerides without reduced HDL is a clinical clue that an alcohol effect may be contributing to the lipid disorder.

Diagnostic Evaluation of Moderate Hypertriglyceridemia

A search for associated disorders, review of medication use, and delineation of dietary choices are appropriate. If both triglycerides and cholesterol are elevated, a search for the underlying lipoprotein disorder is sometimes useful. By ultracentrifugation, dysbetalipoproteinemia due to the presence of cholesterol-enriched VLDL can be differentiated from that of familial combined hyperlipidemia: The usual ratio of VLDL triglyceride to cholesterol of approximately 5 is reduced to 3 or less in dysbetalipoproteinemia. ApoE genotyping will determine if the patient has the apoE2/E2 genotype, which can be associated with aggressive vascular disease. Cholesterol-enriched VLDL is also found in patients with hypothyroidism, renal failure, or hepatic lipase deficiency.

Hypercholesterolemia Without Hypertriglyceridemia

Because all lipoproteins contain cholesterol, dramatic increases in triglycerides will invariably also lead to elevated blood cholesterol values. However, the ratio of triglyceride to cholesterol will be greater than 5. Disorders associated with primarily increased cholesterol are discussed in this section. The clinical presentation of hypercholesterolemia is limited. Although patients with severe disease occasionally present with cosmetic concerns or orthopedic issues associated with tendon xanthomas, hypercholesterolemia is usually clinically occult and uncovered by blood testing during routine assessment or in the setting of vascular disease.

Polygenic Hypercholesterolemia

Most patients with elevated LDL cholesterol do not have FH, and even cholesterol levels above 300 mg/dL (7.8 mmol/L) are not usually associated with xanthomas or defects in the LDL receptor. If, as is conventional for other laboratory values, hypercholesterolemia is defined as a cholesterol value that exceeds the 95th percentile for the population, only 1 in 25 of these patients should have FH. Although diet and lifestyle influence LDL, the genetic and environmental factors associated with most elevated LDL levels are unknown, and therefore this type of hypercholesterolemia is referred to as polygenic. Nonetheless, the increased cholesterol is associated with a higher risk of coronary artery disease.

Increased LDL levels can be a result of defective LDL clearance with normal LDL receptors, a more subtle regulation of the receptor, or increased LDL production. This last type occurs in the setting of familial combined hyperlipoproteinemia (see later discussion), which can manifest as primary elevations of LDL. Greater LDL production due to greater absorption of gut cholesterol, abnormalities in the regulation of lipid-regulated nuclear transcription factors, or gain-of-function abnormalities in cholesterol and apoB lipoprotein assembly pathways are all possible but poorly defined.

Genetic FH

The centrality of the LDL receptor to the understanding of cholesterol metabolism was uncovered through investigations by Brown and Goldstein (see the LDL Receptor section) into the cause of heterozygous FH. This relatively common cause of severe hypercholesterolemia results from one of many defects in production of the LDL receptor leading to impaired function or production of the LDL receptor protein. Patients with FH (most with heterozygous forms of the disease) have cholesterol levels that exceed 300 mg/dL (7.8 mmol/L). Homozygous presentations of the disease include cholesterol levels that are approximately twice this value. In one health care system in the United States, the heterozygous form was detected with a prevalence of 1 in 256 in unselected participants and 1 in 118 in cardiac catheterization laboratory participants.[118] FH is a major cause of early-onset coronary artery disease. In addition, homozygous and some other severe forms of LDL receptor deficiency are associated with aortic valve calcification and stenosis. Humans can have LDL receptor defects without hypercholesterolemia, but these individuals are still at increased risk of cardiovascular disease.[119]

Patients with heterozygous FH have cholesterol deposition on tendons leading to tendon xanthomas like those seen in Fig. 41.17C and D. They are most common on the Achilles tendon. On inspection, a loss of the usual bow-like shape of the tendon occurs or a bump or generalized thickening of the tendon is apparent. The irregularity of the tendon can also be detected by palpation. This physical finding is sometimes similar to scarring that results from tendon rupture. If the tendon is abnormal, a history of athletic injury should be sought. Xanthomas also occur on extensor tendons of the hands, but less frequently, and are best appreciated on the knuckles of a clenched fist. Xanthomas of the Achilles tendon can cause recurrent episodes of Achilles tendinitis. Some xanthomas are subtle and are apparent only as a thickening of the tendon or a small bump at the insertion of the tendon into muscle. Patients with FH also have xanthelasmas (see Fig. 41.17A) and premature corneal arcus (i.e., in persons younger than 40 years), but these findings can also occur in patients without FH. Many affected subjects have no physical findings. Premature coronary artery disease is common but variable. Some FH patients develop coronary disease in the third or fourth decade of life, especially if they also have reduced HDL or associated risk due to cigarette smoking. Even before the introduction of statin therapy, some FH patients (especially women) never develop clinical vascular

disease. Incomplete penetrance or protective factors perhaps due to lifestyle may contribute to their normal life span.

Homozygosity for FH is not common but is likely to occur more frequently than previously appreciated.[120] These subjects come to clinical attention early in life because of the appearance of tendon and planar xanthomas, as well as tuberous xanthomas (see Fig. 41.17E), marked hypercholesterolemia apparent at birth, premature coronary disease, or aortic valve disease. Typical plasma cholesterol concentrations range from 600 mg/dL (15.5 mmol/L) to 1000 mg/dL (25.9 mmol/L), and LDL concentrations range from 500 to 950 mg/dL (13.0 to 24.6 mmol/L). Symptomatic coronary disease can occur before age 10 years. If not treated, these homozygous persons usually die from myocardial infarction by age 20 years. Aortic valve disease in homozygotes can be valvular or supravalvular. The diagnosis of homozygous FH should be suspected in any child with extremely high plasma cholesterol (typically >500 mg/dL [13.0 mmol/L]) or the xanthomas characteristic of FH. Both parents are obligate heterozygotes and should manifest the phenotype of heterozygous FH. These children are treated with repetitive LDL apheresis or liver transplantation.

Familial Defective Apolipoprotein B100

Population-based genotyping shows that defects in LDL binding to normal LDL receptors leads to elevated LDL cholesterol by 60 to 70 mg/dL (1.5–1.8 mmol/L).[121] Familial defective apoB100 has a phenotype that is indistinguishable from that of FH, including increased susceptibility to coronary heart disease. The substitution of glutamine for arginine at amino acid 3500, which reduces LDL binding to the LDL receptor, accounts for most cases of familial defective apoB100, although other defects have also been reported. Often the LDL elevations are less severe, such as with LDL below 200 mg/dL (5.2 mmol/L), a reflection of a partial defect in receptor binding attributed to the mutation or the continued ability of apoE to mediate lipoprotein uptake.

Rare Mutations Associated With Elevated LDL Levels

Several rare, isolated causes of hypercholesterolemia have been reported. Mutations in *LDLRAP1*, the gene encoding a putative adaptor protein (ARH) required for internalization of LDL bound by the LDL receptor on the surface of hepatocytes, cause autosomal recessive hypercholesterolemia. Mutations in ARH associated with autosomal recessive hypercholesterolemia have been reported mostly in Italians (Sardinia) and Lebanese.

Autosomal dominant hypercholesterolemia caused by a mutation in the gene encoding cholesterol 7α-hydroxylase has been reported.[122] The hypercholesterolemia is caused by defective cholesterol conversion to cholic acid.

Mutation of PCSK9 (see the LDL Receptor section) leads to alterations in LDL receptor expression because this enzyme modulates intracellular LDL degradation.[123] Gain-of-function mutations reduce LDL receptor numbers and lead to defective LDL clearance by the liver. Inhibitors of this protein are an effective therapy for hypercholesterolemia.[124] As noted earlier, loss-of-function mutations in PSCK9 are associated with low total cholesterol and LDL, and decreased risk of coronary artery disease.

Elevated Plasma Lp(a)

Apo(a), a protein of unknown function that shares high sequence homology with plasminogen, associates with apoB to produce an LDL called *Lp(a)*. Elevated levels of Lp(a) increase the risk of cardiovascular disease and calcific aortic valvular stenosis[125] and are found in approximately 20% of patients.[126] Patients with high Lp(a) are more likely to clot bypass grafts and stents. Unlike LDL, which confers risk as a continuous function of plasma level, risk is found only in individuals with the highest levels of Lp(a).

Plasma Lp(a) levels are largely determined genetically. Lp(a) particles contain a variable number of a protein repeat known as a Kringle. Smaller Lp(a) particles, with fewer Kringle repeats, are usually produced at higher levels. For this reason, some suggest Lp(a) size, rather than plasma level, that confers vascular risk. Renal failure leads to elevations of Lp(a). Niacin treatment, but not statin treatment, reduces Lp(a), whereas PCSK9 inhibitors decrease Lp(a) by increasing its plasma clearance.[127] Specific therapies to reduce Lp(a) using antisense and silencing RNA approaches are in development.

Lipoprotein(X)

Obstructive liver disease sometimes leads to a marked increase in plasma cholesterol. In part, this is the result of increased LDL, presumably due to a defect in LDL receptors. In addition, free cholesterol circulates in association with albumin, a particle referred to as Lp(X). This is caused by a deficiency in the cholesterol esterifying enzyme, LCAT. The clinical setting suggests the diagnosis. In addition, an abnormal ratio of free to total cholesterol (or cholesteryl ester) can be determined by the laboratory. The relationship of Lp(X) to vascular disease is unclear.

Sitosterolemia

In this rare disorder, dietary sitosterol and other plant sterols, which are not normally absorbed in significant quantities in the intestine, are absorbed in large amounts, resulting in their accumulation in the plasma and in peripheral tissues and causing premature atherosclerosis.[128] The molecular cause is a mutation in the genes encoding ABCG8 and ABCG5, which are responsible for resecretion of absorbed plant sterols. Patients develop tendon xanthomas in childhood and have normal to high plasma LDL; the differential diagnosis includes FH and cerebrotendinous xanthomatosis. The diagnosis can be confirmed by gas-liquid chromatography of plasma lipids, which demonstrates the high levels of plant sterols. Therapy consists of restriction of dietary plant sterols and treatment with ezetimibe (see later discussion), which inhibits absorption of dietary sterols.[129]

Cerebrotendinous Xanthomatosis

Cerebrotendinous xanthomatosis is a rare disorder of sterol metabolism associated with neurologic disease, tendon xanthomas, and cataracts in young adults. Neurologic manifestations include cerebellar ataxia, dementia, spinal cord paresis, and subnormal intelligence. Premature atherosclerosis is common. Osteoporosis has been reported and is presumably caused by alterations in vitamin D metabolism. The disorder results from mutations that cause deficiencies of 27-hydroxylase, a key enzyme in cholesterol oxidation and bile acid synthesis, leading to high plasma levels of cholesterol and cholestanol, with subsequent accumulation of these sterols in tendons and in tissues of the nervous system. Chenodeoxycholic acid is indicated for treatment.

Hypothyroidism and Elevated Cholesterol

All patients with significant hyperlipidemia should be screened for hypothyroidism, because thyroid hormone deficiency causes hypercholesterolemia, and low levels of thyroid hormone predispose to statin-induced myositis.[130] Although hypothyroidism usually increases LDL, it can also be associated with high plasma triglycerides. Levels of HDL are usually unchanged or slightly lower in hypothyroidism and may be reduced in hyperthyroidism. Subclinical hypothyroidism is a cause of hypercholesterolemia that sometimes responds to thyroid hormone replacement.[131]

Diagnostic Evaluation of Isolated Hypercholesterolemia

All adults and perhaps children should have a cholesterol level assessed at least every 5 years. In adults, cholesterol levels higher than 300 mg/dL (7.8 mmol/L) and LDL greater than 190 mg/dL (4.9 mmol/L) suggest FH. Heterozygous FH should be suspected in any person with premature atherosclerotic cardiovascular disease. The diagnosis of heterozygous FH can be confirmed clinically by the presence of tendon xanthomas and a family history of premature coronary disease. The diagnosis of FH is primarily clinical, but genetic testing is available and, although costly, may be helpful for assessing risk in family members and in genetic counseling. This is important because many patients with FH will not initially present with elevated LDL but have increased risk of cardiovascular disease, presumably due to a lifelong LDL that is higher than desirable.

Increased HDL

Occasionally, patients with hypercholesterolemia primarily have elevations of HDL with normal LDL. Usually, this pattern is found in families with little cardiovascular disease. However, genetic association studies fail to link genetic factors that elevate HDL with reduced vascular disease,[132] and no pharmacologic interventions that raise HDL in the statin era appear to provide benefit.

There are subgroups of patients with increased HDL and whose HDL does not confer a protection from cardiovascular disease. Isolation of HDL from such patients with cardiovascular disease and high levels of HDL led to the observation that these HDLs do not have anti-inflammatory properties.[133] Atherogenic HDL has been detected in patients with systemic lupus erythematosus.[134] Therefore, there are clinical circumstances in which HDL may be dysfunctional (see the Reverse Cholesterol Transport and Dysfunctional HDL section).

Genetic Disorders Causing Increased HDL

CETP deficiency is a hereditary syndrome in which plasma HDL levels are increased because of diminished activity of plasma CETP. The disorder is not uncommon in the Japanese population. Its features include marked elevations of plasma HDL in homozygotes (usually >100 mg/dL [2.6 mmol/L]). Despite the elevated HDL levels, the effect on coronary disease risk of CETP gene mutations is unclear. Heterozygotes have moderately elevated HDL. The lower activity of CETP results in diminished transfer of cholesteryl esters from HDL to apoB-containing lipoproteins. As a result, more cholesteryl esters are found in HDL, and the ratio of total cholesterol to HDL is markedly reduced. CETP is most active in the setting of hypertriglyceridemia, so, in addition to reducing HDL, it provides a mechanism for reduction of triglyceride through HDL metabolism. Perhaps for this reason, studies in mice, which normally do not have significant plasma CETP activity, have shown reduced apoB-containing lipoproteins and reduced atherosclerosis with addition of a CETP transgene. As noted, CETP inhibitors do not appear to have benefit that can be attributed to increased HDL.[83]

Several other pharmacologic agents are associated with increased plasma HDL. The antiatherogenic capacity of HDL produced in these circumstances is unknown. HDL induction occurs with the use of oral estrogens, alcohol intake, phenytoin (Dilantin), phenobarbital, and insulin therapy in some patients with type 1 diabetes mellitus.

Endothelial lipase deficiency is caused by defects in the third member of the lipase gene family—endothelial lipase. As described earlier, loss-of-function mutations in this lipase are associated with increased HDL levels but not reduced risk of coronary heart disease.

Elevated Triglycerides and Cholesterol

Elevated triglyceride and cholesterol levels can be caused by increased VLDL and LDL, combined hyperlipidemia, or the presence of increased circulating remnant lipoproteins (dysbetalipoproteinemia). Methods to diagnose dysbetalipoproteinemia are usually not fruitful unless patients present with premature vascular disease or palmar xanthomas.

Combined Hyperlipidemia

Combined hyperlipidemia is a common disorder associated with elevations of plasma cholesterol and triglyceride levels and increased susceptibility to coronary disease. Lipoprotein isolation reveals increased LDL and VLDL. Kinetic analysis has associated this pattern primarily with overproduction, rather than defective clearance, of apoB lipoproteins. When it occurs within families, it is termed *familial combined hyperlipidemia*. These individuals, who do not necessarily have other causes for lipid abnormalities, characteristically come from families with various hyperlipidemias that include increased isolated triglycerides or increased isolated LDL. Moreover, the abnormal lipoprotein pattern (increased triglycerides, cholesterol, or both) can vary over time in an individual.

Regulation of apoB production involves several steps (see the Apolipoprotein B section), and understanding this physiology explains some of the association of combined hyperlipidemia with other diseases. Increased fatty acid return to the liver and reduced insulin action prevent degradation of newly synthesized apoB. Therefore, it is not surprising that both metabolic syndrome and type 2 diabetes mellitus are commonly found with combined hyperlipidemias. Although the genetics of this disorder have been investigated, the coexistence of this lipoprotein pattern with insulin resistance and obesity syndromes has been a confounder. Therefore, although alterations in several genes associated with lipid metabolism, such as LPL and apoCIII, have been observed, a firm genetic marker is not currently available.

Familial Dysbetalipoproteinemia

Familial dysbetalipoproteinemia is an uncommon disorder of lipoprotein metabolism that is characterized by moderate to severe hypertriglyceridemia and hypercholesterolemia caused by the accumulation of cholesterol-rich remnant particles in the plasma.

Premature peripheral vascular disease and coronary artery disease are common. The cause is mutations in the apoE gene that result in defective binding of apoE to lipoprotein receptors. The disorder is associated with the apoE2 isoform and in most instances is inherited as an autosomal recessive trait. Because the phenotypic expression of the disorder is limited to approximately 5% of the patients with the apoE2/E2 phenotype, other genetic or environmental factors must also be operative. The hyperlipidemia is caused by a defect in clearance of remnant lipoproteins whose liver uptake requires apoE interaction with the LDL receptor, LRP1, and HSPG (see the Apolipoprotein E section). The remnants that accumulate have lost much of their triglyceride through LPL-mediated triglyceride hydrolysis and therefore are cholesterol rich. The predominant remnant particles, termed *β-VLDL*, can be identified by abnormal migration on gel electrophoresis or by abnormal lipid content.

Dysbetalipoproteinemia is usually diagnosed in adults and rarely detected in persons younger than 20 years. The disorder is more common in men than in women. Plasma triglyceride and cholesterol levels typically range from 300 to 400 mg/dL (3.4–45.2 mmol/L). Concentrations of HDL are normal. Xanthomas are present in more than half of affected subjects. Palmar xanthomas, which are planar xanthomas in the palmar creases (see Fig. 41.17F), are pathognomonic for this disorder. Tuberous or tuboeruptive xanthomas (see Fig. 41.17E) are also common but are less specific for this disorder. Tendon xanthomas and xanthelasma may occur. Unlike FH, in which peripheral vascular disease is uncommon, premature peripheral vascular disease occurs in addition to premature coronary artery disease in patients with dysbetalipoproteinemia. Coexisting metabolic conditions that exacerbate the phenotype of dysbetalipoproteinemia, such as obesity, alcohol consumption, diabetes mellitus, and hypothyroidism, are often present.

In addition to homozygosity for the apoE2 isoform, some mutations in the apoE gene are known to lead to the dysbetalipoproteinemia phenotype in an autosomal dominant fashion. The phenotype manifests at an early age without exacerbating factors.

Hepatic Lipase Deficiency

Hepatic lipase deficiency is a rare disorder associated with lack of heparin-releasable hepatic lipase activity in the plasma. Because this enzyme mediates the final step of conversion of IDL to LDL and is involved in chylomicron remnant clearance, its deficiency causes a phenotype that is similar to that found with dysbetalipoproteinemia—namely, elevated plasma cholesterol (250–1500 mg/dL [6.5–38.9 mmol/L]) and triglycerides (395–8200 mg/dL[4.5–92.7 mmol/L]). Patients also have palmar and tuboeruptive xanthomas, premature arcus corneae, and premature coronary artery disease. Because hepatic lipase also mediates HDL metabolism, HDL levels are not decreased. The demonstration of hepatic lipase deficiency requires in vitro assays of hepatic lipase activity in postheparin plasma or DNA analysis to identify mutations.

Nephrotic Syndrome

Hyperlipidemia almost always accompanies nephrotic syndrome. Total cholesterol, VLDL, LDL, total triglycerides, and plasma apoB may all be elevated. Nephrotic syndrome increases liver production of apoB-containing lipoproteins, leading to increased plasma LDL, VLDL, or both. This may be a response to hypoalbuminemia and an associated generalized increase in liver protein secretion.

Protease Inhibitor Use in Human Immunodeficiency Virus Infection

Treatments for human immunodeficiency virus infection often cause hyperlipidemia, lipodystrophy, and insulin resistance. Hypertriglyceridemia is the most common lipid abnormality, although increases in LDL are also found. These effects were initially thought to result from the use of protease inhibitors, but other agents, such as reverse transcriptase inhibitors, can also cause dyslipidemia. Metabolic syndrome is not uniformly induced by all drugs; older agents such as ritonavir are more likely to have metabolic side effects. The cause of this syndrome is unclear but may be related to greater liver production of apoB lipoproteins and triglycerides.

Immunosuppressive Regimens

Patients undergoing transplantation who require several medications commonly present with hypertriglyceridemia with or without hypercholesterolemia. Glucocorticoids more often raise triglycerides, cyclosporine raises cholesterol, and rapamycin increases both cholesterol and triglycerides.

Diagnostic Evaluation of Elevated Triglycerides and Cholesterol

Mixed elevations of triglycerides and cholesterol are common. Appropriate assessment usually requires that clinicians determine whether the hyperlipidemia is primarily a genetic disorder or is secondary to a systemic disorder or medications. Medications are perhaps the most common cause. Table 41.4 provides an overview of diagnostic considerations. In terms of lipid disorders, familial combined hyperlipidemia requires both medical history and fasting lipid panels for family members. This disorder is common and associated with premature vascular disease. In some situations, an evaluation for dysbetalipoproteinemia, a rare disorder, is useful. In other cases, empiric treatment is reasonable (see the Combination Therapy for Other Hyperlipidemias section).

Hypocholesterolemia

Secondary causes that can lead to very low levels of apoB-containing lipoproteins and low cholesterol levels include malabsorption, sepsis, liver failure, cachexia syndromes, and malnutrition. There are also genetic conditions that cause low cholesterol.

Familial Hypobetalipoproteinemia

Familial hypobetalipoproteinemia is defined as apoB and LDL levels below the 5th percentile. Hypobetalipoproteinemia is not associated with a phenotype and leads to a reduced risk for cardiovascular disease. Possible causes of this syndrome include mutations leading to truncation of apoB and mutations in PCSK9 presumably leading to increased numbers of LDL receptors. PCSK9 loss-of-function mutations occur in as many as 2% of African Americans but are rare in persons of European descent. Other patients have a defect in angiopoietin-like protein 3.[55] Patients with hypobetalipoproteinemia, except those due to the angiopoietin-like protein 3 defect, have an increased risk of hepatic steatosis.

Abetalipoproteinemia

Abetalipoproteinemia is a rare autosomal recessive disorder caused by a deficiency in MTP (see the Apolipoprotein B section), which results in a virtual absence of apoB-containing lipoproteins in the plasma. Abetalipoproteinemia occurs in fewer than 1 in a million persons and has the same phenotype as homozygous hypobetalipoproteinemia, including malabsorption of fat and fat-soluble vitamins from the intestine, which can lead to neurologic disease related to vitamin E deficiency. The disorder is usually detected in infancy because of fat malabsorption associated with marked decreases in plasma cholesterol and triglyceride levels.

Chylomicron Retention Syndrome

Anderson disease, or chylomicron retention syndrome, is a rare condition that is phenotypically similar to abetalipoproteinemia. Subjects with Anderson disease cannot secrete chylomicrons from the intestine. Mutations in the *SAR1B* gene (formerly *SARA2*) have been linked to Anderson disease. This gene encodes SAR1B, a protein that is important in the transport of chylomicrons through the secretory pathway in enterocytes.

Familial Hypoalphalipoproteinemia

Although low HDL in the general population is correlated with greater coronary artery disease, genetic disorders leading to very low plasma HDL have variable and sometimes undefined coronary risk. In part, this might result from the rarity of some of these diseases. For this reason, the approach to the disorders is often unclear.

Apolipoprotein AI Mutations

Mutations in the apoAI gene can decrease HDL formation and result in low plasma HDL levels. ApoAI deficiency can be caused by point mutations in the apoAI gene or by deletions or gene rearrangements at the apoAI/CIII/AIV/AV gene locus. ApoAI deficiency typically results in plasma HDL lower than 10 mg/dL (0.26 mmol/L). Some apoAI variants activate LCAT (see the next section) poorly. The molecular diagnosis is made by protein analysis showing an altered apoAI size or by genetic sequencing. Some apoAI variants are associated with amyloidosis, but there are no defined specific clinical effects of these variants.

The apoAI Milano variant ($apoAI_{Milano}$) is caused by a substitution of cysteine for arginine at amino acid 173. This results in low plasma HDL levels without premature coronary heart disease. This HDL is hypothesized to be antiatherogenic, but administration of recombinant $apoAI_{Milano}$ does not appear to induce plaque regression in acute coronary syndrome in the setting of contemporary statin therapy.[135]

Lecithin: Cholesterol Acyltransferase Deficiency

LCAT deficiency[136] leads to low HDL as a consequence of defective conversion of cholesterol to cholesteryl ester. LCAT deficiency leads to striking corneal arcus (sometimes leading to marked visual impairment), normochromic anemia, and, occasionally, renal failure in young adults. Renal biopsies show characteristic foam cells. In a phenotypically appropriate patient, measurement of the ratio of free cholesterol to cholesteryl ester is diagnostic; normally, free cholesterol is approximately 30% of the total, but this percentage increases to more than 90% in LCAT deficiency. LCAT activity measurements and sequencing can also be performed. Despite very low HDL levels, risk for coronary disease in patients with LCAT deficiency is not pronounced, which may reflect the low levels of LDL also found in many of these patients.

A rare variant of LCAT deficiency, called *fish-eye disease*, is also caused by mutations of the LCAT gene. The phenotype is less severe than that seen in complete LCAT deficiency. Fish-eye disease is characterized by low plasma HDL and corneal opacities; anemia and renal disease do not occur. The phenotypic differences between LCAT deficiency and fish-eye disease have been attributed to whether mutations in the LCAT gene encode variants that fail to esterify cholesterol of both HDL and apoB-containing lipoproteins (LCAT deficiency) or of HDL only (fish-eye disease).

ABCA1 Deficiency

The ABCA1 transporter is essential to complete synthesis of mature HDL by the liver and the small intestine. Several mutations in this receptor are associated with hypoalphalipoproteinemia. Because the number of genetic mutations is great, assays often study fibroblast "unloading" of cholesterol to apoAI to show the defect.

Tangier disease is the most flagrant example of a defect in ABCA1. These patients, originally from Tangier Island in the Chesapeake Bay, had hypocholesterolemia resulting from a marked decrease in plasma HDL, as well as low LDL and the striking physical finding of orange tonsils. The orange tonsils likely result from defective reverse cholesterol transport from macrophages of the reticuloendothelial system, with the color from carotenoids. The risk of cardiovascular disease with this syndrome is uncertain.

Treatment of Lipid Disorders

Evidence Supporting Treatment of Lipid Disorders: Cholesterol and Cardiovascular Disease

Despite a very significant decrease in the incidence of vascular disease, cardiovascular diseases, including coronary heart disease and cerebrovascular disease, remain the major causes of death in the United States for both men and women.[137] The major risk factors are age, elevated LDL, reduced HDL, smoking, hypertension, insulin resistance with or without overt diabetes mellitus, and a family history of premature cardiovascular disease. Modifiable risk factors account for most of the excess cardiovascular disease risk. Although several new risk factors have been proposed to increase the accuracy of predicting risk of cardiovascular events, four conditions—dyslipidemia, hypertension, cigarette smoking, and diabetes mellitus—account for increased cardiovascular disease risk in most patients.

Statins reduce the chances of recurrent events (secondary prevention) in patients with previous cardiovascular events.[1,138] Meta-analyses of clinical trials demonstrate that statins reduce risk of initial cardiovascular events (primary prevention) in most groups of patients, including men and women. They also reduce cardiovascular events in high risk patients with diabetes, with hypertension, and regardless of baseline LDL cholesterol.

Evidence for the benefit of lowering triglycerides or raising HDL levels, or both, is not strong. Data are most significant in studies of the fibric acid gemfibrozil. The Helsinki Heart Study[139] and the Veterans Affairs–High-Density Lipoprotein Cholesterol Intervention Trial[140] both used gemfibrozil, the former for primary prevention and the latter for secondary prevention, and in

both studies the greatest benefit was in men with high triglycerides and low HDL. Studies with other fibrates, such as fenofibrate, have yielded equivocal results.[141] In the lipid treatment arm of the ACCORD trial in type 2 diabetes, fenofibrate was added to statin therapy in patients with an average triglyceride of 162 mg/dL (1.8 mmol/L). There was no overall benefit, although a subgroup of patients with higher triglycerides and reduced HDL had reduced cardiovascular events,[142] and these observations persisted with extended follow-up.[143]

Although decreasing LDL reduces cardiovascular event rates by 30% to 50% in statin studies, there is still significant residual risk, especially in patients with established vascular disease, many of whom have events despite achieving LDL levels of 70 to 80 mg/dL (1.8–2.1 mmol/L), raising the issue of how to decrease this residual risk. Other questions include the following: How early in life should therapy be started for primary prevention? Will longer duration of therapy lead to better outcomes? What is the benefit of lowering triglycerides or raising HDL? What biomarkers are best to screen and monitor in at-risk patients? Can other mediators of atherosclerosis be manipulated? How can lifestyle changes be accomplished?

Measurement of Plasma Lipids

A complete plasma lipid profile (total cholesterol, calculated LDL, HDL, and triglycerides) should be measured in all adults 20 years of age and older at least once every 5 years. Triglycerides should be measured in all patients with pancreatitis. Ideally, plasma lipids should be measured at least twice under fasting steady-state conditions before therapeutic decisions are made. Plasma lipids are usually measured after a 12-hour fast to preclude detection of significant elevations in atherogenic remnant lipoproteins. Because cholesterol is a minor component of chylomicrons, total plasma cholesterol can be measured in either a fasting or a nonfasting state. Plasma lipid measurements are usually reliable if done within the first 24 hours after an acute myocardial infarction.[144]

Most clinical laboratories measure plasma total cholesterol, total triglycerides, and HDL; the last analysis is performed after apoB-containing lipoproteins are removed from the plasma. For many years, the plasma LDL concentration has been calculated from these measurements using the Friedewald formula:

$$\text{LDL} = \text{total cholesterol} - \text{HDL} - \text{VLDL}$$

where VLDL is calculated as triglycerides divided by 5. This formula assumes the cholesterol content of VLDL is about 20% of the plasma triglyceride level. It is reliable only when triglycerides are 400 mg/dL (4.5 mmol/L) or less. LDL concentrations calculated by this formula may be inaccurate in the presence of severe hypertriglyceridemia or when the triglyceride-to-cholesterol ratio of VLDL is altered as occurs in dysbetalipoproteinemia. Notably, the Friedewald formula may underestimate LDL levels in the low range that is now encountered with intensive statin and PCSK9 therapy.

A novel formula is now being used by commercial laboratories. The Martin-Hopkins calculation uses an adjustable factor for the triglyceride-to-cholesterol ratio of VLDL based on an array of triglyceride and non-HDL cholesterol levels from more than 1.3 million lipid samples in the United States.[145] This approach is more accurate than the Friedewald formula at determining LDL levels in certain patients, especially those with triglycerides between 100 and 400 mg/dL (0.11–4.5 mmol/L).

TABLE 41.5 Criteria for Diagnosis of Metabolic Syndrome

Measure[a]	Categorical Threshold
Waist circumference	*Whites, African Americans, Latin Americans*: Men, ≥40 in.; women, ≥35 in. *Asians*: Men, ≥35 in.; women, ≥32 in.
Elevated triglycerides	≥150 mg/dL *or* On drug treatment for elevated triglycerides
Reduced HDL	Men, <40 mg/dL; women, <50 mg/dL *or* On drug treatment for reduced HDL
Elevated blood pressure	≥130 mm Hg systolic or ≥85 mm Hg diastolic *or* On antihypertensive drug treatment
Elevated fasting glucose	≥100 mg/dL *or* On drug treatment for elevated glucose

[a]Three of the five measures are required for diagnosis.

HDL, High-density lipoprotein.

Adapted from Grundy SM, Cleeman JI, Daniels SR, et al. Diagnosis and management of the metabolic syndrome: an American Heart Association/National Heart, Lung, and Blood Institute scientific statement. *Circulation*. 2005;112:2735–2752.

Specialized laboratories can directly assay different lipoproteins by ultracentrifugation or nuclear magnetic resonance techniques. Direct measurement of LDL is also now available in many clinical laboratories. Value for direct measurements in clinical practice is uncertain, as they were not utilized in large clinical trials and are not incorporated into most guidelines.

Treatment of High LDL

As noted, clinical trials clearly demonstrate the benefit of LDL reduction. Optimal risk factor management reduces clinical atherosclerotic event rates. However, in the United States, the 5-year incidence of myocardial infarction or cardiac death after a first event remains high, depending on age, race, and gender and risk factor control.[137]

The initial evaluation for all patients consists of a history and physical examination, including assessment of diet, exercise, cardiovascular risk factors, and measurement of plasma lipids. Exclusion of secondary causes of lipid disorders (see Table 41.4) is important. Obesity is an independent risk factor for cardiovascular disease, reflected in the waist circumference measurement that is used to define metabolic syndrome (see Table 41.5). Obesity aggravates dyslipidemia, hypertension, and insulin resistance, and is a target of therapy regardless of the severity of traditional cardiovascular risk factors (see Table 41.6). Particular emphasis should be placed on obtaining a detailed history of all first-degree relatives to identify cholesterol disorders or premature cardiovascular disease. In primary care, a child-parent screening strategy is effective at identifying FH with high cardiovascular risk.[146] The examination should emphasize the cardiovascular system, manifestations of hyperlipidemia, and disorders causing secondary lipid abnormalities.

Hyperchylomicronemia-Induced Pancreatitis

Markedly increased triglyceride levels are most often diagnosed by laboratory detection, including the observation of lipemia. A triglyceride higher than 1000 mg/dL (11.3 mmol/L) usually signifies

HDL, High-density lipoprotein.

Data from Goff DC Jr, Lloyd-Jones DM, Bennett G, et al. 2013 ACC/AHA guideline on the assessment of cardiovascular risk: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;63:2935–2959.

the presence of two or more abnormalities of lipid metabolism (e.g., estrogen therapy in the presence of underlying familial hypertriglyceridemia). Elevated plasma triglyceride levels can fluctuate markedly within an individual over short periods. Fluctuation occurs because the LPL-mediated clearance mechanisms for triglyceride-rich particles becomes saturated at plasma triglyceride concentrations of approximately 500 mg/dL (5.6 mmol/L). Therefore, triglyceride levels can rise precipitously as dietary fat intake increases and can fall rapidly with dietary fat restriction. Very high carbohydrate diets, unless composed of primarily complex carbohydrate, may lead to poor glycemic control and increased triglyceride levels. Patients with the chylomicronemia syndrome may initially require a diet with less than 10% of calories from fat to decrease chylomicron production.

Visual inspection of plasma after it has been refrigerated overnight can be helpful. A cream-like layer on the top signifies chylomicrons. A turbid infranatant signifies high levels of VLDL. A cream-like top layer and turbid plasma indicates the presence of both chylomicrons and VLDL.

A history of diabetes, alcohol use, or triglyceride-elevating medications is common. Physical examination might be useful. Lipemia retinalis (see Fig. 41.17B), a condition in which lipemic blood causes opalescence of retinal arterioles, can be observed during funduscopic examination. It is typically seen only when triglycerides are 2000 mg/dL (22.6 mmol/L) or higher.

Eruptive xanthomas (see Fig. 41.17G) appear as small, yellowish, round papules that contain a pale center and an erythematous base. Their distribution includes the abdominal wall, back, buttocks, and other pressure contact areas. They are caused by accumulation of triglyceride in dermal histiocytes and typically occur when the plasma triglyceride level is 1000 to 2000 mg/mL (11.3–22.6 mmol/L) or higher. They can disappear rapidly with lowering of the plasma triglyceride concentration.

Severe hypertriglyceridemia (1000 mg/dL [>11.3 mmol/L]) should be treated aggressively because pancreatitis associated with these levels can be fatal. Lifestyle intervention includes exercise, diet (avoid high fat, simple sugars, and noncomplex carbohydrates), diabetes control, and elimination of triglyceride-raising medications if possible. Initial drug treatments are fibrates, fish oils, and/or niacin. Patients have also been treated with newer therapies that inhibit apoB production (mipomersen) or MTP (lomitapide), but increased liver accumulation of triglyceride is a concern. Antisense reduction of liver production of apoCIII effectively reduces triglyceride levels in patients with and without LPL mutations.[58] Additional approaches under development target the LPL inhibitory protein ANGPTL3.[147]

In the setting of acute pancreatitis, the approach to treatment is based on clinical impression and our understanding of the pathophysiology rather than randomized clinical trials. In the setting of diabetes, insulin therapy is essential. In nonhyperglycemic patients, low-dose insulin (1–2 units per hour) is usually sufficient to block adipose tissue lipolysis, reduce circulating free fatty acids levels, and theoretically reduce triglyceride production by the liver. LPL activity is also induced by insulin. Higher doses of insulin, such as those used to treat diabetic ketoacidosis, require large amounts of glucose infusion to prevent hypoglycemia and are likely to increase de novo triglyceride production in the liver. In most patients, triglycerides will decrease approximately 50% within 24 hours, so evidence for the lack of response requires accurate initial levels that should be obtained by plasma dilution. Plasmapheresis is rarely indicated and has not been proven to be effective,[148] despite a marked reduction in circulating triglyceride levels. For this reason, it might be most reasonable to consider this therapy only in patients not responding to conventional methods, with associated organ dysfunction, with plasma levels that are extraordinarily elevated (more than 10,000 mg/dL [259 mmol/L]), or during pregnancy when triglyceride increases are driven by estrogen induction of liver triglyceride production.

Screening for Secondary Disorders

The history and physical examination should be directed toward uncovering secondary disorders of lipid metabolism and identifying agents including medications that could cause hyperlipidemia (see Table 41.4). Minimal studies should include fasting blood glucose, glycosylated hemoglobin, renal and hepatic function tests, urinary protein, and thyroid-stimulating hormone.

Patient Selection and Treatment Goals

Many professional groups have issued and updated guidelines for management of hyperlipidemia over decades. As guidelines for treatment of lipoprotein disorders and approaches to reduce cardiovascular risk have evolved, they have engendered controversy. Early recommendations based on epidemiology, preclinical data, and limited randomized clinical data were shown to be prescient by subsequent clinical trials. Although it is widely accepted that LDL cholesterol reduction prevents atherosclerotic cardiovascular disease and reduces clinically important cardiovascular events in patients with established disease or at increased risk, who should be treated and to what lipid target has been disputed. The National Cholesterol Education Program, established by the National Institutes of Health in the late 1980s, created a standard for cholesterol levels and pioneered a practical approach to treatment by dividing the population according to cardiac risk based on lipid and other cardiac risk factors. This approach has persisted. More recent clinical trials have shown greater reductions of plaque with aggressive and safe LDL reduction. Although, in general, desirable levels of LDL for primary prevention of disease are less than 100 mg/dL (0.26 mmol/L) and for secondary prevention of disease are less than 70 mg/dL (1.8 mmol/L), others have recommended even lower targets (<55 mg/dL [1.4 mmol/L]) in the setting of documented atherosclerosis, very high risk, or evidence of continued disease progression despite LDL less than 70 mg/dL (1.8 mmol/L).[149]

The American College of Cardiology and American Heart Association (ACC/AHA) guidelines from 2013[150] (Table 41.7) were controversial because they focused not on LDL goals but on the use of high- versus low-dose statin therapies, as well as the percentage of LDL reduction achieved. Others, including the

TABLE 41.7 American College of Cardiology/American Heart Association 2013 Statin Benefit Groups

Benefit Group	Management
Clinical ASCVD	Age <75 years without contraindications: high-intensity statin Age >75 years or with contraindications: moderate-intensity statin
LDL >190 mg/dL, age >21 years	High-intensity statin Can consider nonstatin drug if further LDL reduction is desirable
Primary prevention—diabetes: age 40–75 years, LDL 70–189 mg/dL	Moderate-intensity statin If 10-year ASCVD risk is ≥7.5%, consider high-intensity statin
Primary prevention—no diabetes[a]: ≥7.5% 10-year ASCVD risk,[b] age 40–75 years, LDL 70–189 mg/dL	Moderate- to high-intensity statin

[a]Requires risk discussion between clinician and patient before statin initiation.

[b]Statin therapy may be considered if risk decision is uncertain after use of the ASCVD risk calculator.

ASCVD, Atherosclerotic cardiovascular disease; *LDL*, low-density lipoprotein.

Data from Stone NJ, Robinson JG, Lichtenstein AH, et al. 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol.* 2014;63:2889–2934.

Canadian Cardiovascular Society and European groups have continued to include goals for treatment (Table 41.8). With evidence that all approaches to LDL reduction lead to a similar reduction in cardiovascular events and the advent of new potent therapies, such as PCSK9 inhibitors, recommended therapeutic goals will likely become more aggressive.

Risk calculators based on current ACC/AHA guidelines are available on the ACC and AHA websites. The Framingham risk calculator remains frequently used and includes age, total cholesterol, HDL, systolic blood pressure, and smoking status, and many others are available and include additional well-known risk factors such as Lp(a), C-reactive protein, and coronary calcium scores. Different risk scoring systems may be appropriate for diverse populations and regions.[151–153] In acknowledgement that lipoproteins other than LDL are also atherogenic, some guidelines use non-HDL cholesterol (total cholesterol minus the HDL) as a secondary goal that is 30 mg/dL (0.8 mmol/L) higher, accounting for the likely atherogenic risk due to triglyceride-rich lipoproteins.

Most guidelines recommend treatment for any patient with LDL greater than 190 mg/dL (4.9 mmol/L). When lipid-lowering therapy for primary prevention should be initiated is unclear. Biomarkers such as C-reactive protein, Lp(a), and imaging techniques such as coronary calcium scores are sometimes added to more precisely estimate individual risk. Guidelines for treatment of patients with type 2 diabetes mellitus consider their increased risk of cardiovascular events. Patients with established vascular disease and diabetes mellitus are considered to be at very high risk.[154] Cardiovascular disease accounts for a high percentage of deaths in the geriatric population, and there are survival benefits of treatment in elderly patients up to the age of 85 years who have known coronary heart disease.

Some patients with LDL levels below previous treatment thresholds benefit from greater LDL cholesterol reduction.[155] Therefore, treat-to-target approaches may underestimate benefits that could accrue with greater LDL reduction.[156,157] Cardiovascular outcome trials using PCSK9 antibodies, which can reduce LDL to very low levels, may lead to recommendations for LDL levels below current goals.

Specific Therapies

Specific therapies include lifestyle changes (diet, exercise, and weight management) and drug therapy.

Lifestyle Treatment

Lifestyle changes including dietary intervention, moderate exercise, and weight loss are first-line therapies for hyperlipidemia (Table 41.9) and may be sufficient for mild dyslipidemias in low-risk patients. All other treatments should build on therapeutic lifestyle changes.[158] Hypertriglyceridemia often responds to decreased intake of fat, simple sugars, alcohol, and calories. Most patients will have a 10% to 15% decrease in LDL levels with diet, which may be adequate for primary prevention in low-risk patients. In patients with established coronary heart disease, drug therapy should be instituted along with diet therapy. Response to lipid-lowering drugs may be disappointing in patients who do not follow dietary recommendations.

Daily moderate exercise, such as walking, may help reduce triglyceride levels. Exercise may be particularly useful in obese, insulin-resistant patients with high triglycerides, low HDL, and moderately elevated LDL. An exercise program combined with a moderately hypocaloric diet leading to modest weight loss may improve dyslipidemia, as well as glucose tolerance and blood pressure, especially in patients with metabolic syndrome. Team management that includes nutritionists and dietitians is likely to enhance dietary therapies. Dietary changes are best when individualized and instituted gradually. Involvement of family members is important. The DASH (Dietary Approaches to Stop Hypertension) or Mediterranean diets are appropriate. Patients with the chylomicronemia syndrome may initially require a diet with less than 10% of calories from fat to decrease chylomicron production. The response to very low fat diets may be disappointing in patients with impaired glucose tolerance unless the diet is hypocaloric.

Effects of various types of dietary fats have been studied extensively.[159] Current recommendations[160] are to restrict saturated fats and trans fats and substitute with complex carbohydrates, polyunsaturated fats, and monounsaturated fats. High cholesterol and saturated fat intake elevate plasma cholesterol by decreasing receptor-mediated clearance of LDL. High dietary cholesterol also promotes increased LDL synthesis. Trans fats are unsaturated fatty acids with at least one *trans* double bond; they are produced when liquid vegetable oils are partially hydrogenated to produce semisolid fats used in margarines and shortening. Trans fats raise LDL and reduce HDL, and they have been implicated in cardiovascular disease.

Fish oils are rich in eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA) (see Table 41.1). Daily doses of 4 g of EPA plus DHA lower VLDL and treat elevated triglycerides. Observational data support that fish intake is associated with decreased cardiovascular risk in those with and without known cardiovascular disease. Many experts recommend eating two servings of oily fish weekly or taking fish oil capsules that provide 1 g/day of EPA plus DHA daily as reasonable for those not interested in consuming fish.

TABLE 41.8 Comparison of Dyslipidemia Guidelines

Risk Category	TREATMENT INTENSITY OR GOALS		
	ACC/AHA[a]	CCS[b]	Eur Soc Card+[c]
Secondary prevention/high or very high risk	Clinical ASCVD: Lifestyle + high-intensity statin (LDL reduction ≥50%)	Clinical ASCVD, most DM (age ≥40 years, age ≥30 with 15-year duration, microvascular disease), abdominal aortic aneurysm, chronic kidney disease Lifestyle + statin to goal of LDL <77 mg/dL (2.0 mmol/L) or >50% reduction or non-HDL <100 mg/dL (2.6 mmol/L)	Very high risk (documented CVD, DM with target organ damage, CKD with GFR <30 mL/min/1.73 m^2, calculated SCORE ≥10%) Lifestyle advice and concomitant drug treatment Goal of LDL <70 mg/dL (1.8 mmol/L)
Primary prevention	LDL ≥190 mg/dL (rule out secondary causes): lifestyle + high-intensity statin (add non-statin if insufficient response)	Framingham Risk Score 10% to 19% and LDL ≥135 mg/dL (3.5 mmol/L) or non-HDL ≥166 mg/dL (4.3 mmol/L) or one additional risk factor Lifestyle + statin to goal of LDL <77 mg/dL (2.0 mmol/L) or >50% reduction or non-HDL <100 mg/dL (2.6 mmol/L)	High risk: Cholesterol >310, most DM, moderate CKD with GFR 30 to 59 mL/min/1.73 m^2, calculated SCORE ≥5% to <10% Lifestyle advice with drug treatment if LDL >100 Goal of LDL <100 mg/dL (2.5 mmol/L)
	DM without ASCVD, LDL <190 mg/dL: perform risk calculation Moderate- to high-intensity statin		Moderate risk calculated SCORE level 1% to 5% Lifestyle advice, consider drug if LDL uncontrolled Goal of LDL <115 mg/dL (3.0 mmol/L)
	ASCVD risk ≥7.5% Risk discussion with patient Moderate- to high-intensity statin		
Other considerations	Evaluate triglycerides >500 mg/dL	Ezetimibe first-line add-on and PCSK9 inhibitors as second line; apoB levels for risk stratification	Triglycerides <150 desirable, physical activity and other lifestyle changes to increase HDL

It is not clear whether fish oil supplementation is effective for prevention or treatment of atherosclerotic vascular disease,[161,162] and Cochrane analysis of published reports suggests that increasing EPA and DHA has little or no effect on mortality or cardiovascular health.[163] However, a recent study using 4 grams of icosapent ethyl in hypertriglyceridemic subjects with known atherosclerosis or high risk (such as diabetes) reduced coronary events.[164]

Other dietary components can influence plasma lipids. For example, soluble fibers such as psyllium or oat bran, which can bind bile acids in the gut and promote net cholesterol excretion, decrease LDL modestly (about 5–10%). Margarines made with sitostanol or sitosterol, which are plant sterols that inhibit cholesterol absorption, reduce serum cholesterol by about 10%. Together, the combination of plant sterols, soluble fiber, and restriction of saturated fat and cholesterol can reduce LDL levels by about 30%.

Drug Treatment

Table 41.10 lists drugs that inhibit cholesterol synthesis in cells (HMG-CoA reductase inhibitors), interfere with the degradation of the LDL receptor by inducing LDL receptor expression in hepatocytes (PCSK9 inhibitors), block cholesterol absorption from the gut (ezetimibe), or interfere with bile acid absorption from the gut (bile acid sequestrants). Fibrates, and omega-3 fatty acids, and niacin either inhibit VLDL production or enhance clearance of triglyceride-rich particles. Drugs that decrease hepatic VLDL production include the apolipoprotein B antisense oligonucleotide, mipomersen, and the MTP inhibitor lomitapide.

HMG-CoA Reductase Inhibitors (Statins)

Statins inhibit cholesterol biosynthesis, upregulate LDL receptors, enhance LDL clearance, reduce lipoprotein release from the liver, and may decrease triglycerides by enhancing VLDL clearance and decreasing lipoprotein production.

Statins are useful in all types of hyperlipidemias in which LDL is elevated. They are particularly useful for patients with vascular disease and those with very high LDL (e.g., FH, combined hyperlipidemia), and they are the drugs of choice for lowering LDL as primary or secondary prevention but are less effective in homozygous LDL receptor deficiency. Several statins are approved for use in children and adolescents with FH, high LDL, or a significant family history of premature coronary artery disease.

TABLE 41.9 Lifestyle Recommendations to Reduce Cardiovascular Risk

Modality	Intervention
Diet	Follow a dietary pattern high in vegetables, fruits, whole grains, poultry, fish, low-fat dairy products, legumes, nontropical vegetable oils, and nuts Limit red meat, sweets, and sugar-sweetened beverages Limit saturated fat to 5–6% of total calories Limit calories from trans fats
Physical activity	Engage in aerobic physical activity 3–4 sessions per week of moderate- to vigorous-intensity physical activity averaging 40 minutes per session
Weight management	For obese patients (BMI ≥30) or overweight patients (BMI ≥25) who have additional risk factors, sustained weight loss of 3–5% or greater reduces ASCVD risk Consultation with a registered dietitian may be helpful to plan, start, and maintain a diet that promotes weight loss and restricts intake of saturated fats

ASCVD, Atherosclerotic cardiovascular disease; *BMI,* body mass index.

Data from Eckel RH, Jakicic JM, Ard JD, et al. 2013 AHA/ACC guideline on lifestyle management to reduce cardiovascular risk: a report of the American College of Cardiology American/Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol.* 2014;63:2960–2984; Jensen MD, Ryan DH, Apovian CM, et al. 2013 AHA/ACC/TOS guideline for the management of overweight and obesity in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the Obesity Society. *J Am Coll Cardiol.* 2014;63:2985–3023.

Table 41.11 provides the relative potency of various statins when used at different dosages, and Table 41.12 lists expected effects of various statins on LDL. They reduce LDL by 20% to 60%, increase HDL by 2% to 16%, and reduce triglycerides by 7% to 37%, depending on the drug; the dosage; and, in the case of triglycerides, baseline levels. Effects also vary among patients, with greater or lesser degrees of LDL reduction even at the same dose. For each statin, doubling of the dose typically produces an additional 6% reduction of LDL.[165] LDL lowering is seen within 1 to 2 weeks after the start of therapy and is stable in about 4 to 6 weeks. Pitavastatin, atorvastatin, and rosuvastatin have long half-lives, about 12 hours, 14 hours, and 21 hours, respectively. The other statins have half-lives of about 2 to 3 hours. First-generation statins with short half-lives should be taken in the evening. Atorvastatin and fluvastatin have minimal renal clearance and may be more suitable for patients with renal insufficiency. Several statins are available as generic drugs in the United States. Table 41.13 shows specific features of available statins.

The most common side effects of statins are abdominal pain, constipation, flatulence, nausea, headache, fatigue, diarrhea, and muscle complaints. Except for musculoskeletal symptoms, most side effects are infrequent.

Liver toxicity is not common with statin use. Hepatic aminotransferase elevation is usually mild and does not require discontinuation of the statin. It may be dose dependent, as demonstrated in clinical trials that showed rates of persistent elevations of liver aminotransferase greater than three times the upper limit of normal occurring in 0.1% to 1.9% of patients, depending on the statin and the dose. The requirement for routine monitoring of hepatic transaminases was removed from statin labeling by the US Food and Drug Administration in 2012. Hepatic transaminases should be obtained at baseline and during treatment only if there is a clinical indication for their measurement. Only about 1% of statin-using patients have aminotransferase increases to greater than three times the upper limit of normal, and the elevation often decreases even if patients continue on the statin.[166] Statins can be used cautiously in the presence of liver disease that is not decompensated, and nonalcoholic hepatic steatosis is not a contraindication.[167] If aminotransferases remain greater than three times the upper limit of normal, consider lowering the dose or changing to a different statin and identify other contributing conditions or drugs. Irreversible liver damage resulting from statins is extremely rare, with a liver failure rate of 1 case per 1 million person-years of use.[167]

About 5% of patients complain of muscle side effects, but recent randomized placebo-based trials have suggested that many of these issues are due to a nocebo effect, which is the anticipation of a side effect leading to altered perception.[168] The adverse effects associated with statin use correlate with drug dose,[169] but many large randomized, placebo-controlled clinical trials have not shown differences in rates of myalgias and creatine kinase elevations between statin-treated and placebo groups. Regardless, muscle complaints are a common reason for statin discontinuation by patients, perhaps related to misinformation about the risks of statin therapy promulgated through the internet.[170] In the proper context, it is possible to carefully reintroduce statins after a presumed myalgia.

In patients with muscle complaints after statin administration, disorders that might influence skeletal muscle or present with muscle symptoms must be excluded, such as hypothyroidism, vitamin D deficiency, rheumatologic conditions, and perhaps depression. Inhibition of statin catabolism is associated with increased myopathy risk. Drugs metabolized through the cytochrome P450 (CYP) system, such as ketoconazole, itraconazole, clarithromycin, and erythromycin, increase statin plasma levels especially with use of older statins that have a more limited hepatic disposal. Other drugs that increase the risk of statin myopathy include gemfibrozil, cyclosporine, digoxin, verapamil, diltiazem, amiodarone, colchicine, and protease inhibitors.

The most serious potential side effect of statins is rhabdomyolysis leading to myoglobinuria and renal failure. Rhabdomyolysis is rare and is more likely in patients with renal insufficiency, advanced age, other comorbid conditions, or polypharmacy and during perioperative periods. Routine surveillance of creatine kinase is not useful in most patients. Management of dyslipidemia in patients with muscle-related complaints is challenging and may include using a different statin, decreasing the dose, giving the medication less frequently, or considering other LDL-lowering drugs. Higher doses of simvastatin should be avoided. The US Food and Drug Administration recommends that simvastatin 80 mg not be used, and simvastatin should be limited to 10 mg in patients taking amiodarone, verapamil, and diltiazem, and to 20 mg in those taking amlodipine and ranolazine.

Statin therapy is associated with increased incidence of type 2 diabetes mellitus in patients with a predisposition to developing this disorder. This association was most evident with the use of the highest doses of atorvastatin (80 mg) and rosuvastatin

TABLE 41.10 Drugs used to Treat Hyperlipidemia

Class and Drugs Available	Dosage	Major Lipoprotein Decreased	Mechanism
HMG-CoA Reductase Inhibitors			
Rosuvastatin	5–40 mg qd	LDL	Decrease cholesterol synthesis; increase LDL receptor–mediated removal of LDL
Atorvastatin	10–80 mg qd		
Simvastatin	5–40 mg qd		
Lovastatin	10–80 mg qd		
Pravastatin	10–40 mg qd		
Fluvastatin	20–80 mg qd		
Pitavastatin	1–4 mg qd		
PCSK9 Inhibitors			
Evolocumab	140 mg sc q 2 weeks or 420 mg sc q month	LDL	Prevent degradation of the LDL receptor
Alirocumab	75–150 mg sc q 2 weeks		
Intestinal Cholesterol Absorption Inhibitor			
Ezetimibe	10 mg qd	LDL	Inhibits cholesterol absorption
Bile Acid Sequestrants			
Cholestyramine	4–12 g bid	LDL	Increase sterol excretion and LDL clearance
Colestipol	5–15 g bid		
Colesevelam	3.75–4.375 g qd		
Fibric Acid Derivatives			
Gemfibrozil	600 mg bid	VLDL (LDL)	Decrease VLDL production; enhance LPL action
Fenofibrate[a]	30–200 mg qd		
Omega-3 Fatty Acids			
Lovaza (1-g capsule contains EPA and DHA)	4 g qd	VLDL	Inhibit VLDL production
Vascepa (1-g capsule contains EPA)	4 g qd		
Epanova (1-g capsule contains EPA and DHA free fatty acids)	2–4 g qd		
Nicotinic Acid			
Niacin (crystalline)	1–3 g qd	VLDL (LDL)	Decrease VLDL production; enhance LPL action
Niaspan (extended-release niacin)	500–2000 mg qd		
ApoB Antisense Oligonucleotide			
Mipomersen	200 mg once a week sc injection	VLDL, LDL, Lp(a)	Inhibits synthesis of apolipoprotein B
Microsomal Triglyceride Transfer Protein Inhibitor			
Lomitapide	5–60 mg qd	VLDL, LDL, Lp(a)	Inhibits microsomal triglyceride transfer protein

[a]There are several different preparations of fenofibrate with different doses.

bid, Twice a day; *EPA*, highly concentrated ethyl esters of eicosapentaenoic acid; *DHA*, docosahexaenoic acid; *HMG-CoA*, 3-hydroxy-3-methylglutaryl coenzyme A; *LDL*, low-density lipoproteins; *Lp(a)*, lipoprotein(a); *LPL*, lipoprotein lipase; *PCSK9*, proprotein convertase subtilisin/kexin type 9; q, every; *qd*, every day; *sc*, subcutaneously; *VLDL*, very low density lipoprotein.

(40 mg).[171] Genetic studies[172,173] indicate that that variants in the LDL receptor, PCSK9, and HMG-CoA reductase (the target of statins) are associated with type 2 diabetes mellitus risk, suggesting that promoting uptake of LDL might affect diabetes pathogenesis. Nonetheless, the major adverse cardiovascular event reduction benefits of lowering LDL markedly outweigh the risks of increased glucose in all but those at lowest atherosclerotic risk. Attention to diet, exercise, and weight can mitigate the diabetes risk.

Patients have many complaints that might or might not be due to statins. Complaints about confusion or memory loss should be appropriately evaluated for causes of these symptoms. There is no evidence that statins cause direct adverse effects on renal function beyond that due to rhabdomyolysis. Statins are contraindicated during pregnancy and nursing and in patients with significant hepatic dysfunction.

Proprotein Convertase Subtilisin/Kexin Type 9 Inhibitors

This newer class of medications is fully humanized monoclonal antibodies to PCSK9 that lower LDL levels by preventing degradation of the LDL receptor, increasing recirculation of the receptor to the surface of hepatocytes, and consequent

• **Fig. 41.18** Role of PCSK9 and its inhibition in low-density lipoprotein (LDL) metabolism. Both the LDL receptor and proprotein convertase subtilisin/kexin type 9 (PCSK9) are processed by the Golgi apparatus with PCSK9 being secreted. In the absence of PCSK9 inhibition, this protein interacts with the LDL receptor and promotes its retention in pathways that lead to lysosomal degradation of the LDL receptor protein. In the presence of PCSK9 inhibition, more of the LDL receptor recycles to the cell surface, where it clears LDL particles from the circulation to lower LDL cholesterol and decrease cardiovascular risk.

lowering of circulating LDL (Fig. 41.18). Alone or in conjunction with statins, they increase removal of LDL from the circulation, leading to nearly 60% further reduction in circulating LDL; a reduction in coronary heart disease events[2]; and, as noted earlier, atheroma regression in patients with known atherosclerosis.

Clinical trials with both PCSK9 inhibitors marketed in the United States, alirocumab and evolocumab, demonstrate reductions in atherosclerotic cardiovascular disease events, particularly in patients with recent acute coronary syndrome, multivessel coronary artery disease, or peripheral arterial disease. Reductions in LDL to levels less than 25 mg/dL (0.65 mmol/L), which occurred in more than a quarter of the patients in the clinical trials, are associated with even lower cardiovascular disease event rates, establishing no lower limit for LDL when using PCSK9 alone or in combination with a statin. PCSK9 inhibitors are recommended for high-risk patients with LDL levels of 70 mg/dL (1.8 mmol/L) or higher on maximally tolerated oral therapies including statins and/or ezetimibe. PCSK9 inhibitors are useful in homozygous FH, where carriers have a high prevalence of premature death and which can otherwise be challenging to treat. Unlike statins, PCSK9 inhibitors decrease Lp(a), although modestly. These drugs are injected every 2 to 4 weeks. As with many new biologics, insurance restrictions and expense limit clinical availability. Aside from injection site reactions, side effects of this therapy thus far appear minimal.

Ezetimibe

Ezetimibe inhibits cholesterol absorption by binding to NPCL1, the intestinal cholesterol absorption transporter. Ezetimibe lowers LDL by 14% to 25% when used alone or in combination with statins. Ezetimibe has been shown to further reduce cardiovascular events when added to statin therapy; in this study, LDL was reduced from nearly 70 to 54 mg/dL (1.8–1.4 mmol/L).[155] Ezetimibe can be useful in patients who are intolerant of statins. Ezetimibe undergoes glucuronidation, leading to extensive enterohepatic circulation. Absorption is not affected by food.

Side effects are relatively uncommon but may include diarrhea and abnormal liver functions. Myopathy is rare and, like myalgias, is not clearly related to the medication.[174] Ezetimibe can increase

cyclosporine levels. Fibrates can increase the levels of ezetimibe, a finding with unknown clinical significance.[175] Ezetimibe is contraindicated in pregnancy and in severe liver dysfunction.

Bile Acid Sequestrants

The bile acid sequestrants have been used since the 1970s but now are primarily reserved for patients unable to take statins or who require additional cholesterol reduction. Clinical trials conducted prior to widespread use of statins showed that bile acid sequestrants reduce cardiovascular events.[176,177] They work by binding negatively charged bile acids and bile salts in the small intestine to interrupt the enterohepatic circulation of bile acids and increase the conversion of cholesterol into bile. Decreased hepatocyte cholesterol content increases LDL receptors, leading to reduced circulating LDL levels. Cholesterol synthesis also increases, which promotes VLDL secretion; for this reason, these drugs are contraindicated in patients with hypertriglyceridemia.

As monotherapy, sequestrants lower LDL by 5% to 30% in a dose-dependent manner. Cholestyramine, colestipol, and colesevelam are available in the United States. Colesevelam has greater bile acid–binding capacity and affinity than cholestyramine or colestipol and is used at lower doses. LDL reduction is typically 15% at 3.8 g/day (six 625-mg tablets) and 18% at 4.3 g/day (seven 625-mg tablets).[178,179] Bile acid sequestrants lower fasting blood glucose and hemoglobin A_{1c} levels in patients with diabetes mellitus.[180] The mechanism underlying this effect is unclear but might relate to activation of a bile sensitivity receptor (TGR5) in the colon.

Gastrointestinal disturbances are common and include constipation, nausea, bloating, abdominal pain, flatulence, and aggravation of hemorrhoids. Initiation with low doses, patient education, and use of stool softeners or psyllium can increase compliance. These drugs are not absorbed, so they can be used in pregnancy. Bile acid sequestrants affect absorption of a wide variety of drugs; other medications should be taken either 1 to 2 hours before or 4 to 6 hours after the sequestrant.

Fibrates

In the Helsinki Heart Study (primary prevention) and the Veterans Affairs–High-Density Lipoprotein Cholesterol Intervention Trial (secondary prevention), the use of the fibrate gemfibrozil reduced fatal and nonfatal cardiovascular events and did not increase mortality from noncardiac causes.[139,140] In the Fenofibrate Intervention and Event Lowering in Diabetes study, although fenofibrate did not reduce the composite cardiovascular outcome of cardiovascular death, nonfatal myocardial infarction, and stroke in patients with type 2 diabetes mellitus, fewer nonfatal events were observed.[141] The addition of fenofibrate to a statin may provide benefit to diabetes patients with high triglycerides and low HDL.[142,143] Fenofibrate decreased the progression of retinopathy in patients with diabetes in the Fenofibrate Intervention and Event Lowering in Diabetes and ACCORD trials and is approved by the Australian Health Authorities for diabetic retinopathy.[181,182] The underlying mechanism is unknown and does not appear to be related to effects on circulating lipids.

Fibrates activate PPARα (see earlier discussion), which increases fatty acid oxidation, increases LPL, and increases apoAI, as well as apoAII, while lowering triglycerides (by 30–50%), decreasing apoCIII, and raising HDL (by 10–20% in those with elevated triglycerides). Fibrates may lower LDL modestly, but they are most commonly used for severe hypertriglyceridemia and combined hyperlipidemia. Fenofibrate may be taken once daily. Gemfibrozil is given twice a day with meals but is used less often due to a less favorable drug interaction profile.

Fibrates are contraindicated in patients with liver or gallbladder disease. The risk of gallstones may be increased. Liver transaminases may increase, particularly with fenofibrate. Side effects may include gastrointestinal discomfort, rash, and pruritus. Fenofibrate should be avoided in patients with renal insufficiency, which predisposes to myopathy. The combination of gemfibrozil and most statins is associated with an increased risk of myopathy due to increased statin blood levels, whereas fenofibrate does not interfere with statin metabolism and is preferred in fibrate/statin combination regimens.[183] Because of the effects on protein binding, warfarin doses may need to be adjusted when fibrate therapy is started. Gemfibrozil may be used beginning in the second trimester in pregnant women with severely elevated triglycerides who are at risk for pancreatitis.

Omega-3 Fatty Acids

Fish-derived omega-3 fatty acids (EPA and DHA) reduce circulating triglycerides, but their effects on cardiovascular events are less clear. The Japan EPA Lipid Intervention Study showed that combined treatment with a statin plus EPA (1.8 g/day) in patients with coronary heart disease reduced major coronary events by 19% compared with a statin alone.[184] This effect was similar to that found in the recent REDUCE-IT trial.[164] Other clinical outcome studies with fish oils and meta-analysis of trials with EPA and DPA do not show mortality or cardiovascular health benefits.[162,163,185] Whether the positive outcome of REDUCE-IT was due to its specific omega 3 formulation, subject selection, or dose is unclear.

Omega-3 fatty acids decrease triglyceride secretion from the liver through unclear mechanisms and are indicated for triglycerides higher than 500 mg/dL (5.6 mmol/L). EPA and DHA lower triglycerides by 20% to 50% depending on the baseline levels. There is minimal effect on HDL. LDL may increase as VLDL is converted to LDL.

Approximately 3 to 4 g/day of EPA plus DHA is used to lower triglycerides. Over-the-counter preparations have variable quantities of EPA and DHA. Prescription formulations usually contain twice the content of omega-3 fatty acids than nonprescription preparations. Preparations contain EPA and DHA, unesterified EPA and DHA, or only EPA. Unlike fibrates, EPA and DHA do not affect statin metabolism and do not increase the risk of myopathy. Side effects with omega-3 fatty acids include eructation, diarrhea, and abdominal discomfort. There is potential for increased bleeding, but this has not been seen in clinical trials.

Niacin

Nicotinic acid, or niacin, is a B-complex vitamin that was found to lower plasma cholesterol in humans in 1955. The mechanism underlying the effects of niacin are not understood beyond the physiologic observation of decreased VLDL secretion. Niacin lowers triglycerides by 10% to 30% and increases HDL by 10% to 40%. Niacin also lowers Lp(a) by up to 25%. The niacin arm of the Coronary Drug Project showed a decrease in nonfatal myocardial infarctions in men with coronary artery disease during the 6-year trial and a decrease in total mortality rate in the 9 years after the study.[186] However, more recent trials of slow-release niacin in subjects whose LDL was already markedly reduced by statins, the AIM-HIGH (Atherothrombosis Intervention in Metabolic Syndrome With Low HDL/High Triglycerides: Impact on Global Health Outcomes) and HPS2-THRIVE (Heart Protection Study 2–Treatment of HDL to Reduce the Incidence of Vascular Events) studies, failed to show additional clinical benefit with niacin[187,188]

despite improvements in HDL and triglycerides. This lack of proven efficacy and the introduction of new agents (ezetimibe and PCSK9 inhibitors) have reduced niacin use except in refractory hypercholesterolemia or hypertriglyceridemia.

Cutaneous flushing, most notable with the first doses, is the most common side effect. Tolerance can occur with repeated and consistent dosing. Flushing occurs 15 to 60 minutes after ingestion, lasts 15 to 30 minutes, and may be related to release of dermal prostaglandin D_2. Ingestion with food and taking aspirin (preferably 325 mg) 30 to 60 minutes in advance of niacin minimizes flushing,[189] whereas alcoholic beverages and spicy foods potentiate it. Prescription extended-release niacin (Niaspan) may be better tolerated than crystalline niacin. Starting low and gradually increasing the dose improves tolerability.

Niacin has additional adverse effects. Hepatotoxicity is the most serious and is seen more with crystalline niacin compared with prescription slow-release forms. Worsening of glucose tolerance and hyperuricemia may occur. Niacin is contraindicated in active peptic ulcer disease. Rare side effects include blurred vision and a reversible condition known as cystoid macular edema. Myopathy is rare with niacin alone or in combination with statins. Niacin is contraindicated during pregnancy.

Combination Therapies

Combination therapy is indicated for patients with severe lipid elevations and those who have an insufficient response to monotherapy. Patients with FH or familial combined hyperlipidemia are at particularly increased risk and may require LDL reductions that cannot be achieved with a single agent. LDL levels lower than 70 mg/dL (1.8 mmol/L) can be difficult to achieve with a single drug. Higher statin doses may be associated with increased side effects. If the highest tolerated statin dose does not produce adequate LDL reduction, adding an agent from a different class may produce the desired result. Statins, ezetimibe, PCSK9 inhibitors, and sequestrants work through different mechanisms and can be more effective in combination than when used alone. Data on clinical outcomes with combination therapy are limited. Table 41.14 presents combination therapies for LDL.

Combination Therapy for Other Hyperlipidemias

Statin Plus Fibrate

The combination of a statin plus a fibrate can be used in patients requiring treatment for elevated triglycerides and elevated LDL, which may be useful for patients with metabolic syndrome, diabetes, or other forms of mixed dyslipidemia. Risk of myopathy, including rhabdomyolysis, is increased with the combination of most statins with gemfibrozil, because the latter drug interferes with the glucuronidation of statins, leading to higher serum levels of the statin drug.[190] Rhabdomyolysis is about 15 times less likely with fenofibrate combined with statins (0.58 per 1 million prescriptions) than with gemfibrozil plus statins (8.6 per 1 million prescriptions).[183]

Statin-fibrate combinations should be avoided in patients with renal insufficiency, congestive heart failure, severe debility, or other conditions that affect medication clearance. Side effects include mild gastrointestinal discomfort, rash, and pruritus.

Other Combinations

Triple-drug therapy with a statin, ezetimibe, and fenofibrate may help to obtain adequate reductions of both triglycerides and LDL without using very high statin doses or when PCSK9 inhibitors are not covered by patient insurance. When triglycerides are decreased with a fibrate, LDL may increase. If statins are not tolerated and triglycerides well controlled, a bile acid sequestrant could be added. Ezetimibe may lower LDL in combination with a fibrate when triglyceride levels are not optimal. Adding omega-3 fatty acids can be helpful if triglycerides are not well controlled. For markedly elevated triglyceride levels, it may be necessary to combine a fibrate with niacin or with omega-3 fatty acids, or both.

TABLE 41.14 Combination Therapies for LDL

Statin plus ezetimibe	• Ezetimibe added to a statin may further reduce LDL by 20% or more and reduce triglycerides by 7–13%. • The combination provides equivalent LDL reduction to a fourfold increase in statin dose. • Daily ezetimibe added to a low-dose statin given 2–3 times per week can improve tolerance. Combination pills containing statin and ezetimibe are available. • Most common side effects reflect those of the individual drugs. • Combination ezetimibe and simvastatin has been shown to decrease cardiovascular events in patients with renal disease[96] and acute coronary syndrome.[155]
Statin and PCSK9 inhibitors	• This combination is the most effective known treatment for hypercholesterolemia. • There are no known negative interactions between these two therapies. • This combination reduces CHD events more than statin alone.
Statin plus bile acid sequestrants	• Bile acid sequestrants in combination with statins further decrease LDL from 24% to 60%. • Cholestyramine and colestipol can interfere with the absorption of statins. Colesevelam does not affect statin absorption. • The statin-colesevelam combination is not ideal for patients with high triglycerides but may be useful in type 2 diabetes mellitus because colesevelam reduces glycemia.
Statin plus niacin	• Adding niacin to a statin can lower LDL by 10% to 20% in addition to beneficial effects on triglycerides. • When used in combination with a statin, the maximum dose of niacin should be 2000 mg/day. • This combination in subjects with already low LDL levels did not reduce CHD events.
Bile acid sequestrants plus niacin	• Before the availability of statins, bile acid sequestrants plus niacin were used to lower LDL in high-risk patients. • The availability of colesevelam and extended-release niacin has made this combination tolerable for many patients who are unable to use statins.
Ezetimibe plus bile acid sequestrants	• Ezetimibe inhibits cholesterol absorption, and sequestrants enhance cholesterol excretion through conversion to bile acids. The combination can have additive effects. • This combination is useful for patients who cannot take statins.

CHD, Coronary heart disease; *LDL,* low-density lipoprotein; *PCSK9,* proprotein convertase subtilisin/kexin type 9.

Treatment for Chylomicronemia Syndrome

Patients with chylomicronemia syndrome should be treated with total fat restriction and other measures mentioned previously until the triglycerides fall to less than 1000 mg/dL (11.3 mmol/L), after which a fat-restricted diet (e.g., <10% of calories) can be instituted. The goal is to maintain triglycerides under 1000 mg/dL (11.3 mmol/L) and preferably lower if possible. Diet and modification of glycemia, alcohol consumption, or offending medications are useful. Medium-chain triglyceride oils can be provided for cooking. A fibrate or niacin is usually required to control triglycerides. Therapy with orlistat to block fat absorption may be beneficial, because it mimics a low-fat diet.[191] In the setting of pancreatitis risk, a low-fat/low-carbohydrate liquid formula diet may be indicated.

Several novel therapies for hyperchylomicronemia and recurrent pancreatitis are on the horizon. A gene therapy treatment for LPL deficiency had been available in Europe using an adeno-associated virus expressing LPL^{S447X}, an active truncated LPL. Effects were transient following multiple intramuscular injections. Additional therapies using methods to inhibit production of apoC-III or ANGPLT3 are in development.

Treatment of FH

Guidelines for FH patients are available.[192] Treatment of heterozygous FH includes a diet low in total and saturated fats and cholesterol, but effects on cholesterol are modest (5–15%). Adequate cholesterol lowering can occasionally be achieved with a single potent statin, but combinations of drugs are often needed. Many patients will achieve LDL levels below 100 mg/dL (2.59 mmol/L) with a high-intensity statin and ezetimibe. Addition of a PCSK9 inhibitor to a statin or statin plus ezetimibe can lead to even greater LDL reduction.[193] PCSK9 inhibitors have some effect in patients with mutated, but not absent, receptors.[194] LDL apheresis or liver transplantation are other options in these patients.[195]

The age at which drug treatment should begin in heterozygous FH is controversial, but starting treatment at younger ages may have a favorable impact during early stages of lesion development. Statins are approved for the treatment of children with heterozygous FH who are 8 years of age (pravastatin) or 10 years (other agents) or older. Factors such as the age at onset of coronary disease in parents and grandparents and the presence of other risk factors should be considered.

Several medical approaches for treatment of homozygous FH have been developed. Mipomersen is an apoB antisense oligonucleotide that was approved but rarely used in the United States for the treatment of homozygous FH. It prevents apoB translation, which decreases apoB levels and LDL.[196] It lowers LDL in patients with homozygous and heterozygous FH.[197,198] Pyrexia, body aches, and reactions at the injection site are the most common side effects, but potential hepatotoxicity and adverse cardiovascular effects are the most serious. Lomitapide is an inhibitor of MTP and approved in the United States and European Union for the treatment of homozygous FH. MTP (see earlier discussion) is required for VLDL assembly. Its inhibition may decrease LDL by 50% in homozygous FH.[199] Side effects include diarrhea, elevated hepatic transaminases, and increased hepatic fat. In a long-term study in homozygous FH, lomitapide decreased LDL by 50% during the initial phase of the study and by 31% at 78 weeks of treatment.[200]

Treatment of familial defective apoB100 is similar to that of heterozygous FH and consists of a low-fat, low-cholesterol diet and a combination drug regimen. Family members at risk should also be screened for the dominant mutation.

Treatment of Familial Combined Hyperlipidemia

Weight reduction and dietary treatment can help correct metabolic abnormalities such as obesity and insulin resistance that contribute to the hyperlipidemia. Drug therapy should be directed at the predominant lipid abnormality. Statins are most appropriate for most patients. Fibrates can lower triglycerides and raise HDL, and they reduce the incidence of coronary events in insulin-resistant hypertriglyceridemic patients with low HDL. Patients with low HDL should be treated with statins. Because familial combined hyperlipidemia is associated with premature coronary heart disease, affected family members should be identified.

Treatment of Metabolic Syndrome

Metabolic syndrome is an extremely common condition defined by the presence of at least three of the five features presented in Table 41.5: increased abdominal girth, hypertriglyceridemia, low HDL, hypertension, and elevated fasting glucose. Metabolic syndrome is clearly associated with increased risk of vascular disease and development of type 2 diabetes mellitus, and it is equivalent to what was previously referred to as prediabetes. Because obesity is a risk for coronary disease, as well as diabetes mellitus and dyslipidemia, a body mass index less than 25 kg/m^2 in patients of European ancestry (lower for those from southern and eastern Asia) is a goal that may require combinations of dietary, exercise, pharmacologic, and surgical therapies (see Chapter 40). Because this goal is often not achievable, these patients may also need therapies directed at hypertension, smoking, diabetes, and dyslipidemia. All patients should be assessed according to existing guidelines for treatment of high triglycerides, low HDL, hypertension, and hyperglycemia.

Treatment of Dysbetalipoproteinemia

Because dysbetalipoproteinemia is influenced by coexisting metabolic conditions, a vigorous effort should be made to identify and treat obesity, diabetes mellitus, and hypothyroidism, and to reduce alcohol consumption. Lipid abnormalities can often be resolved without the use of drug therapies. Dysbetalipoproteinemia is associated with hypothyroidism in particular and responds dramatically to thyroid hormone replacement therapy. Dietary therapy should be aimed at restricting total fat; saturated fat; cholesterol; and, if appropriate, calories. If diet and treatment of coexisting metabolic conditions are unsatisfactory, drug therapy should be initiated using statins. Combination therapy may be required. Because the disorder is associated with premature vascular disease, first-degree relatives should be screened for the presence of apoE2 (see earlier discussion).

Treatment for Elevated Plasma Lp(a)

There are no outcome trials of lowering Lp(a). Newer antisense and silencing RNA approaches are being studied in clinical trials.[201] Apheresis lowers Lp(a) and has been used in those with elevated Lp(a) and progressive coronary heart disease.[202] Evolocumab, alirocumab, niacin, mipomersen, and lomitapide each lower Lp(a), although modestly, in addition to lowering LDL.

Treatment for Low Levels of HDL

Patients with familial hypoalphalipoproteinemia can have normal or modestly increased plasma cholesterol but very low HDL, resulting in a predisposition to coronary heart disease. Such patients can have high ratios of total cholesterol to HDL (e.g., >10) despite having normal plasma cholesterol levels. Statins lower total cholesterol and represent the most efficacious way to

lower the ratio of total cholesterol to HDL. Statins decrease clinical events in patients with low HDL.[203] Fibrates do not increase HDL in patients with normal triglycerides. As noted earlier, pharmacologic therapies for raising HDL levels do not provide clinical benefits.

Summary of Treatment of Lipid Disorders

In the absence of clear demonstration of serious adverse effects, statins should be considered for most common lipid disorders. Inappropriate false claims about harms associated with statins likely contribute to discontinuation and underuse of these agents. Abundant evidence indicates that any future findings about the effects of statins will not fundamentally alter the favorable balance of benefits over risks for this class of drugs.[204]

Multiple Endocrine Neoplasia

PAUL J. NEWEY AND RAJESH V. THAKKER

CHAPTER OUTLINE

KEY POINTS

- Multiple endocrine neoplasia (MEN) syndromes, which may be inherited as autosomal dominant traits, are characterized by the occurrence of two or more tumors in a patient, and four major types (MEN1–4) are recognized.
- MEN1 is characterized by occurrence of parathyroid, anterior pituitary, and duodenopancreatic neuroendocrine tumors, and occasionally also foregut carcinoid and adrenal tumors. MEN1 is caused by mutations of the *MEN1* gene, which encodes the tumor suppressor protein menin.
- MEN2 (also referred to as MEN2A) is characterized by occurrence of medullary thyroid carcinoma (MTC), pheochromocytomas, and parathyroid tumors. MEN2 includes the variants MEN2A with Hirschsprung disease, MEN2A with cutaneous lichen amyloidosis, and familial MTC-only.
- MEN3 (also referred to as MEN2B) is characterized by occurrence of MTC and pheochromocytomas in association with a marfanoid habitus, mucosal neuromas, medullated corneal fibers, and intestinal ganglioneuromatosis.
- MEN2 and MEN3 are due to *rearranged during transfection (RET)* proto-oncogene mutations that lead to constitutive activation of the encoded receptor tyrosine kinase.
- MEN4 patients may develop parathyroid, anterior pituitary, and pancreatic neuroendocrine tumors with gonadal, adrenal, renal, and thyroid tumors due to mutations of the cyclin-dependent kinase inhibitor p27Kip1 (*CDKN1B*) gene.
- Genetic testing should be offered to MEN patients and their first-degree relatives, and individuals with a mutation, who are at risk of developing tumors, should have periodic clinical, biochemical, and radiologic screening for the early detection and treatment of tumors.
- Treatment of MEN patients, which aims to minimize the disease-associated morbidity and mortality, while maintaining quality of life, requires a multidisciplinary approach.

Introduction to Multiple Endocrine Neoplasia Syndromes

Multiple endocrine neoplasia (MEN) is characterized by the occurrence of tumors involving two or more endocrine glands within a single patient.[1–3] The disorder has previously been referred to as multiple endocrine adenopathy or pluriglandular syndrome. However, glandular hyperplasia and malignancy may also occur in some patients, and the term *multiple endocrine neoplasia* is now preferred. Four major forms of MEN—MEN types 1 through 4—are recognized, and each form is characterized by the development of tumors within specific endocrine glands[1,4] (Table 42.1). All of these forms of MEN may be inherited as autosomal dominant disorders or may occur sporadically in the absence of a family history.[1,3] However, this distinction between sporadic and familial cases may sometimes be difficult, because in some sporadic cases, a familial history may be absent because the patient with the disease may have died before symptoms developed. In addition to MEN types 1 through 4, six other syndromes, which are associated with tumors involving one or more of the endocrine glands as well as nonendocrine organs, have been reported.[5–10] These include the hyperparathyroidism-jaw tumor syndrome, von Hippel–Lindau disease, Carney complex, neurofibromatosis type 1, Cowden syndrome, and McCune-Albright syndrome; all of these may be inherited as autosomal dominant disorders, except McCune-Albright syndrome, which is due to a mosaic expression of a postzygotic somatic cell mutation. This chapter will focus on describing the major clinical and molecular aspects of MEN type 1 through 4 syndromes.

TABLE 42.1 MEN Syndromes and Their Characteristic Tumors and Associated Genetic Abnormalities

Type (Chromosome Location)	Tumors (Estimated Penetrance)	Gene; Most Frequently Mutated Codons
MEN1 (11q13)	Parathyroid adenoma (90%) Enteropancreatic tumor (30–70%) — Gastrinoma (40%) — Insulinoma (10%) — Nonfunctioning (20–55%) — Glucagonoma (<1%) — VIPoma (<1%) Pituitary adenoma (30–40%) — Prolactinoma (20%) — Somatotropinoma (10%) — Corticotropinoma (<5%) — Nonfunctioning (<5%) Associated tumors — Adrenal cortical tumor (20–40%) — Pheochromocytoma (<1%) — Bronchopulmonary NET (2%) — Thymic NET (2%) — Gastric NET (10%) — Lipomas (30%) — Angiofibromas (85%) — Collagenomas (70%) — Meningiomas (8%)	*MEN1* 83/84, 4-bp del (≈4%) 119, 3-bp del (≈3%) 209-211, 4-bp del (≈8%) 418, 3-bp del (≈4%) 514-516, del or ins (≈7%) Intron 4 ss (≈10%)
MEN2[b], also known as MEN2A (10 cen-10q11.2)	MTC (90%) Pheochromocytoma (50%) Parathyroid adenoma (20–30%)	*RET* 634, missense (e.g., Cys→Arg)
MEN3, also known as MEN2B (10 cen-10q11.2)	MTC (>90%) Pheochromocytoma (40–50%) Associated abnormalities (40–50%) Mucosal neuromas Marfanoid habitus Medullated corneal nerve fibers Megacolon	*RET* 918, Met→Thr
MEN4 (12p13)	Parathyroid adenoma[a] Pituitary adenoma[a] Reproduction organ tumors[a] (e.g., testicular cancer, neuroendocrine cervical carcinoma) ?Adrenal + renal tumors[a]	*CDKN1B*, no common mutations identified

[a]Insufficient numbers reported to provide prevalence information.

[b]MEN2 comprises variants that include familial MTC-only, MEN2A with cutaneous lichen amyloidosis, and MEN2A with Hirschsprung disease.

Autosomal-dominant inheritance of MEN1 syndrome has been established.

del, Deletion; *ins,* insertion; *MEN,* multiple endocrine neoplasia; *MEN1,* MEN type 1; *MEN2,* MEN type 2; *MEN3,* MEN type 3; *MEN4,* MEN type 4; *NET,* neuroendocrine tumor; *PPoma,* pancreatic polypeptide–secreting tumor; *VIPoma,* vasoactive intestinal polypeptide–secreting tumor; *MTC,* medullary thyroid cancer.

MEN Type 1

MEN1, which has been referred to as Wermer syndrome, is an autosomal dominant disorder with an estimated prevalence of 1 in 30,000 of the population. MEN1 is characterized by the combined occurrence of parathyroid, pituitary, and duodenopancreatic neuroendocrine tumors (NETs). In addition, patients may also develop other endocrine tumors (e.g., adrenal cortical tumors, carcinoids of the thymus and bronchus) and nonendocrine tumors (e.g., meningiomas, facial angiofibromas, collagenomas, and cutaneous lipomas) (see Table 42.1). The first description of MEN1 was reported by Erdheim[11] in 1903, at autopsy in a patient with an anterior pituitary tumor and enlarged parathyroid glands. In the 1920s, the occurrence of pancreatic islet cell tumors in association with parathyroid and pituitary tumors was reported,[12,13] and throughout 1930 and 1960, the triad of parathyroid, pancreatic islet cell, and anterior pituitary tumors became recognized as characteristic of MEN1, together with the familial basis and autosomal dominant inheritance of the syndrome.[14–16] Studies throughout the 1980s and 1990s of MEN1 families and

MEN tumors led to the identification of the *MEN1* gene, which is located on chromosome 11q13.[17,18] Since then, the implementation of germline *MEN1* genetic testing of affected individuals (and their relatives) has transformed the diagnosis and management of the disorder. In addition, somatic *MEN1* mutations have been identified as major drivers of sporadic parathyroid and pancreatic NETS, and this has widened the biologic and clinical significance of the *MEN1* gene and its encoded protein, menin, which consists of 610 amino acids and is a nuclear protein that acts as a tumor suppressor by interacting with other proteins in transcription regulation, genome stability, cell division, proliferation, and epigenetic regulation.

Clinical Features and Management

The clinical manifestations of MEN1 are related to the sites of tumor development and/or consequences of hormone hypersecretion. MEN1 is highly penetrant; virtually all patients develop clinical or biochemical evidence of tumor development by age 50 years. MEN1 tumors are unusual in early childhood (i.e., ≤5 years of age) but thereafter demonstrate an increasing age-related penetrance—approximately 75% of patients will have one or more tumors by age 20 years.[19] Parathyroid tumors are typically the first manifestation of disease in 75% to 90% of MEN1 patients (see Table 42.1), although childhood presentations with pancreatic NETs (e.g., insulinoma) or pituitary tumors are not infrequent, whereas some patients may present with gastrinoma, thymic carcinoid, or adrenal tumors. Overall, clinically relevant duodenopancreatic NETs, including both hormone-secreting and nonsecreting tumors (Fig. 42.1), occur in 40% to 70% of patients, whereas anterior pituitary tumors occur in 30% to 40% of patients. The frequency of other endocrine tumors is variable: 20% to 55% of MEN1 patients have adrenal tumors, whereas fewer than 10% manifest thymic or bronchial tumors. The recognition and appropriate management of the MEN1-associated tumors is important because they are associated with high morbidity and mortality—approximately 30% to 70% of MEN1 patients will die of causes directly related to MEN1, with malignant duodenopancreatic NETs and thymic carcinoid tumors accounting for the greatest risk of premature death.[20]

A diagnosis of MEN1 may be established in an individual by one of three criteria[1,21,22]: on the basis of the occurrence of two or more primary MEN1-associated endocrine tumors (i.e., parathyroid adenoma, enteropancreatic tumor, and pituitary adenoma); the occurrence of one of the MEN1-associated tumors in a first-degree relative of a patient with a clinical diagnosis of MEN; and identification of a germline *MEN1* mutation in an individual, who may be asymptomatic and has not yet developed serum biochemical or radiologic abnormalities indicative of tumor development.

The management of each of the respective MEN1-associated tumors is broadly similar to that of their sporadic counterparts, although there are several MEN1-specific factors that require consideration. Most importantly, MEN1-associated tumors are frequently multiple, resulting in a reduced likelihood of surgical cure. For example, MEN1 patients often develop multiple small submucosal duodenal gastrinomas, and achieving biochemical remission is difficult without extensive surgical resections. In this setting, disease control with proton pump inhibitor (PPI) therapy may be considered a suitable alternative and has been associated with improved long-term outcomes. Similarly, the occurrence of synchronous pancreatic NETs may make planning of therapeutic interventions challenging (e.g., localizing functioning tumors for resection), and it is important to consider that any remnant pancreatic tissue post tumor resection will remain at risk of further tumor development. Thus, the goal of treatment in MEN1 should be to balance the potential risks and benefits of any intervention with the ultimate aim of minimizing disease-associated morbidity and mortality while preserving the patient's quality of life. In this regard, it is important that MEN1 is managed by a multidisciplinary team, and that patients play an active role in the decision-making process.

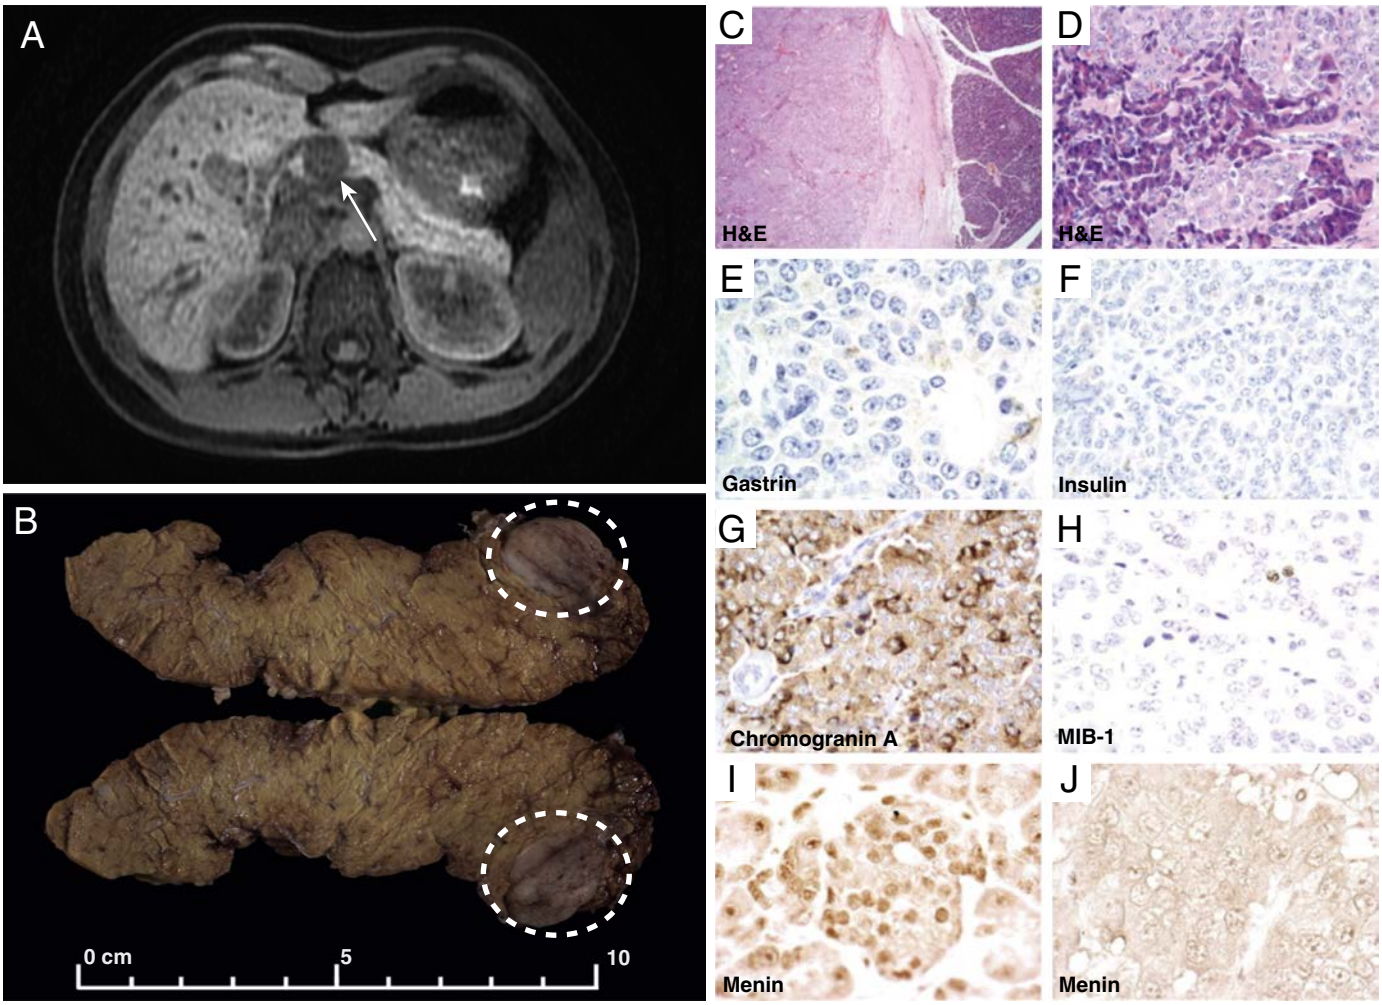
Parathyroid Tumors

Clinical Features

Primary hyperparathyroidism (PHPT) is the most common feature of MEN1. PHPT occurs in approximately 95% of all patients[1,23–25] and is the first manifestation of MEN1 in 75% to 90% of patients.[19,23] Patients are frequently asymptomatic with only biochemical evidence of disease, although symptomatic presentations due to hypercalcemia (i.e., polyuria, polydipsia, constipation, malaise) or other manifestations, including nephrolithiasis, osteitis fibrosa cystica, or peptic ulceration, may occur.[1,26] The diagnosis of PHPT is made by the demonstration of hypercalcemia in the presence of raised or inappropriately normal circulating parathyroid hormone (PTH) concentrations. The degree of hypercalcemia is usually mild, and severe hypercalcemia or parathyroid carcinoma is rare.[1] PHPT in MEN1 patients usually occurs in those older than 15 years, although the earliest symptomatic and asymptomatic presentations are reported in children of 8 and 4 years of age, respectively.[19] Biochemical evidence of PHPT has been reported in up to 75% of children and young adults with MEN1 (<21 years of age), although only a minority of these patients will have clinical features (e.g., nephrolithiasis).[19] In addition to the early age of onset, MEN1-associated PHPT has other important differences when compared with non-MEN1 PHPT, and these include an equal sex distribution (male to female, 1:1 vs. 1:3, respectively) and the synchronous or asynchronous involvement of all four parathyroid glands with tumors,[1,19,25,27] resulting from the monoclonal expansion of one or more population of cells within individuals glands due to biallelic inactivation of the *MEN1* gene.[24,28,29] MEN1-associated PHPT is reported to be associated with a greater reduction in bone mineral density than that occurring in non-MEN1 PHPT, and therefore osteoporosis and osteopenia are common in MEN1 patients.[30,31] The reduction in bone mineral density and bone demineralization in MEN1 patients is particularly evident at the lumbar spine, femoral neck, and distal radius when compared with those with equivalent sporadic PHPT.[31,32] These observations may be due to earlier age of onset and chronicity of MEN1-associated PHPT or differences in disease pathogenesis.

Treatment

Surgical removal of the overactive parathyroid glands is the treatment of choice for MEN1-associated PHPT. However, several aspects of management remain controversial, including the indications for and timing of surgery and the extent of surgery.[1] These uncertainties reflect a paucity of high-quality evidence to guide clinical recommendations.[1] Currently, surgery is recommended for MEN1-associated PHPT in those with symptomatic disease,



• **Fig. 42.1** Nonfunctioning pancreatic NET in a 14-year-old MEN1 patient. The abdominal magnetic resonance imaging scan demonstrates a low-intensity, larger than 2.0 cm (anteroposterior maximal diameter) tumor within the neck of pancreas (indicated by the *arrow*) (A). There was no evidence of invasion of adjacent structures or metastases. The pancreatic NET was removed by surgery, and macroscopic examination confirmed the location of the tumor in the neck of the pancreas (*white interrupted circles*) (B). H&E examination demonstrated a tumor that was largely well circumscribed (C), but focally the margin between tumor (paler cells) and normal pancreas was poorly defined (D). Immunostaining supported the clinical and biochemical diagnosis of a nonfunctioning pancreatic NET because the tumor did not have significant expression of gastrointestinal peptides (result for gastrin and insulin shown [E and F]) but did contain chromogranin A (G). The proliferative index measured by MIB-1 (Ki-67) was low, consistent with a low-grade tumor (H). Loss of menin expression was demonstrated in the tumor; in the adjacent nontumorous pancreatic tissue, nuclear menin expression is evident within pancreatic islets (I), whereas nuclear menin expression is lost within the tumor (J), consistent with biallelic inactivation of the *MEN1* gene. *H&E*, hematoxylin and eosin; *MEN1*, multiple endocrine neoplasia type 1; *NET*, neuroendocrine tumor. (A and C to J, modified from Newey PJ, Jeyabalan J, Walls GV, et al. Asymptomatic children with multiple endocrine neoplasia type 1 mutations may harbor nonfunctioning pancreatic neuroendocrine tumors. *J Clin Endocrinol Metab.* 2009;94[10]:3640–3646.)

severe hypercalcemia (i.e., >3.00 mmol/L), and/or evidence of end-organ damage (e.g., nephrolithiasis, hypercalciuria [>9 mmol/L per 24 hours or 400 mg per 24 hours], creatinine clearance <60 mL/minute, reduced bone mineral density [i.e., T-score <–2.5] and/or previous fragility fracture).[1] Most centers will recommend subtotal parathyroidectomy (removal of 3–3.5 glands) or total parathyroidectomy with or without autotransplantation of cryopreserved parathyroid tissue.[1,33–40] Concurrent transcervical thymectomy is also suggested at the time of neck surgery to remove parathyroid tumors that may be embedded in the thymus.[1] Minimally invasive selective parathyroidectomy, unilateral clearance, and less than subtotal parathyroidectomy (i.e., removal of <3–3.5 glands) are not recommended because all four parathyroid glands are usually affected with multiple adenomas or hyperplasia, although this histologic distinction may be difficult. The aims of parathyroid surgery in MEN1 are to maintain normocalcemia for as long as possible and to avoid iatrogenic complications of surgery, including laryngeal nerve damage and permanent

hypoparathyroidism. The lowest risk of persistent or recurrent PHPT occurs with subtotal and total parathyroidectomy, with higher rates of recurrence occurring in those with less than subtotal parathyroidectomy.[36–39] Long-term outcome data for unilateral or minimally invasive parathyroidectomy has not been reported, although recurrent disease is inevitable in this setting.[41,42] Total parathyroidectomy is reported to be associated with the highest risk of permanent hypoparathyroidism, which may occur in 13% to 67% of cases.[37,39] The development of permanent hypoparathyroidism requires lifelong therapy with active vitamin D metabolites (i.e., calcitriol or alfacalcidol), and this may be associated with significant morbidity (e.g., due to development of inadvertent significant hypo- or hypercalcemia). Total parathyroidectomy with autotransplantation of either fresh or cryopreserved parathyroid tissue into the forearm has therefore been considered as an alternate approach.[1,35,43] The use of cryopreserved tissue allows confirmation of hypoparathyroidism postoperatively but is associated with a higher graft failure rate due to reduced cell viability, as well as a higher rate of permanent hypoparathyroidism. Moreover, recurrent disease is frequently observed in the transplanted tissue,[36] which may necessitate surgical removal,[37] and the reported finding in a MEN1 patient of a metastatic thymic carcinoma within the parathyroid autotransplanted tissue highlights the need for caution with this surgical approach.[44] Thus, the majority of centers recommend either subtotal parathyroidectomy (of at least 3.5 glands) or total parathyroidectomy with long-term oral calcitriol or alfacalcidol treatment. It is recommended that the timing and extent of surgical intervention should be taken by a multidisciplinary team, which takes into account the local surgical expertise, the availability of vitamin D analogues for subsequent treatment of long-term hypoparathyroidism, and the preferences of the patient. Cinacalcet, a calcimimetic that is an allosteric modulator of the calcium-sensing receptor, has been used to reduce or normalize plasma calcium and PTH levels in MEN1 patients with PHPT in whom surgery is contraindicated because of comorbidities or where surgery has failed to cure the PHPT.[45]

Preoperative imaging (e.g., ultrasound, technetium-99m sestamibi, computed tomography [CT], magnetic resonance imaging (MRI), and fluorine-18 fluorocholine positron emission tomography [PET]-CT) is of limited value because all parathyroid glands may be affected, thereby necessitating an open bilateral neck exploration, and reducing the rationale for such preoperative localization studies. Indeed, preoperative imaging in MEN1 patients has been reported to not alter the surgical approach in more than 90% of patients; to have limited value in identifying ectopic parathyroid glands, which were correctly identified in only approximately 38% of cases; and to only correctly localize the largest parathyroid gland subsequently identified at surgery in 69% of cases while failing to identify enlarged contralateral glands in 86% of these cases.[34,46] However, the use of an intraoperative PTH assay may help identify hyperfunctioning parathyroid tissue.[34,47] For example, a reduction in PTH concentration greater than 75% is associated with a high biochemical cure rate, although it does not exclude the development of recurrent hyperparathyroidism at a later time.[47] Bilateral neck exploration, together with the use of intraoperative PTH measurement, may also indicate the likely presence of ectopic and/or supernumerary hyperfunctioning parathyroid glands, which occur predominantly within the thymus, with other locations being the mediastinum or carotid sheath. Indeed, the potential for supernumerary glands within the thymus has led to the recommendation for bilateral transcervical thymectomy at the time of parathyroid surgery.[1,34,37]

The optimal management of asymptomatic MEN1 patients, including children and young adults who manifest only mild biochemical features, remains to be defined; at present, some centers advocate early treatment to minimize impacts on bone health, whereas others favor conservative treatment involving the regular assessment of patients for the onset of symptoms and/or associated complications.[1,19]

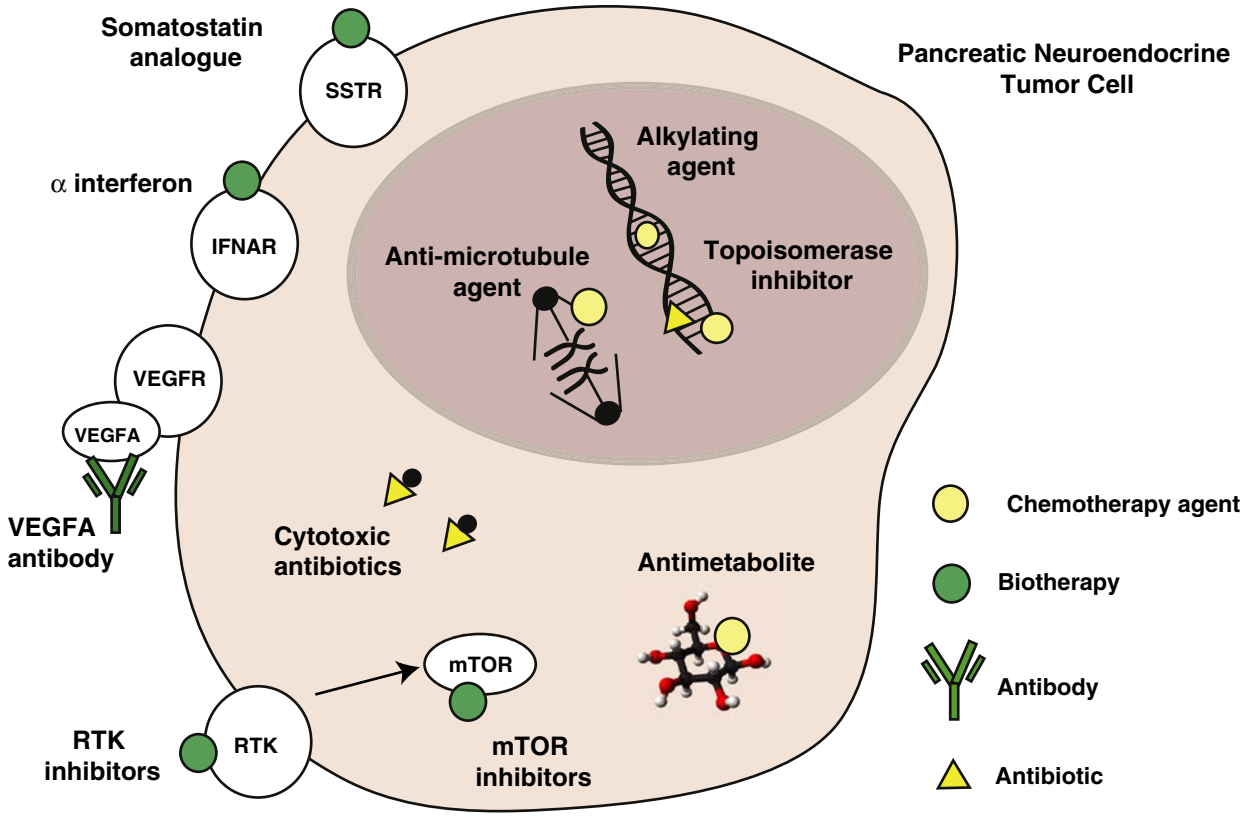
Pancreatic NETs

Pancreatic NETs remain the leading cause of premature death in MEN1 patients. Clinically apparent pancreatic NETs are reported in 30% to 80% of MEN1 patients,[1,19,48–51] although microscopic islet tumors are found in almost all MEN1 patients when evaluated histopathologically.[52] Pancreatic NETs (e.g., gastrinoma, insulinoma, and glucagonoma) may secrete excess hormones and result in relevant clinical features or may be nonsecreting (also referred to as nonfunctioning [NF]) tumors (see Fig. 42.1), and these include those producing pancreatic polypeptide (PP) that is not associated with manifestations of hormonal excess.[1] A MEN1 patient may have more than one pancreatic NET—for example, 10% of patients may have gastrinomas and insulinomas, which may arise co-temporarily or at different times.[23] The main goals of treatment for these MEN1-associated pancreatic NETs are to reduce the morbidity and mortality associated with their occurrence (i.e., relief of symptoms and risk of malignancy). However, there are many different treatments available (Fig. 42.2), and the absence of high-quality evidence for their efficacy makes it challenging to decide on correct therapy. For example, the ideal treatment of a nonmetastatic, single pancreatic NET is surgical removal, as this offers the only potentially curative treatment. However, this situation rarely arises in MEN1 patients, who will have multiple pancreatic NETs—for example, gastrinomas and insulinomas are multiple in more than 95% and approximately 40% of MEN1 patients, respectively, with sizes varying from microadenomas to larger than 4 cm. The clinical behavior of these pancreatic NETs also varies, and generally all macroscopic pancreatic NETs are potentially malignant, although the aggressiveness of an individual pancreatic NET cannot be accurately predicted by tumor size, radiologic features, or hormone production.[53] However, studies have shown that most microadenomas are stable and infrequently increase in size, 30% to 40% of macroadenomas smaller than 2 cm will increase in size over 10 years,[49] approximately 50% to 70% of pancreatic NETs between 2 and 3 cm will be associated with lymph node metastases, and approximately 25% to 40% of pancreatic NETs larger than 4 cm will be associated with hepatic metastases.[53] Survival in MEN1 patients correlates with nonmetastatic disease—for example, survival at 15 years in MEN1 patients with gastrinomas smaller than 2.5 cm in size that were associated with nonmetastatic or metastatic disease has been reported to be 100% and 50%, respectively. Thus, the occurrence of multiple pancreatic NETs and their varied and unpredictable malignant potential in MEN1 patients pose major challenges in their management.[1,53] The diagnosis and treatments for these MEN1-associated pancreatic NETs will be reviewed.

Gastrinoma

Clinical Features

Gastrin-secreting tumors are associated with a marked overproduction of gastric acid, which results in recurrent peptic ulceration, a combination referred to as Zollinger-Ellison syndrome



• **Fig. 42.2** Current and emerging medical therapies for pancreatic neuroendocrine tumors (NETs). Medical therapies for pancreatic NETs include drugs, biotherapies, and antibodies that target different pathways in cancer cells. Somatostatin analogues (e.g., octreotide and lanreotide) are used widely in the treatment of pancreatic NETs. Somatostatin analogues target members of the somatostatin receptor family on the tumor cell surface to control excess hormone secretion and inhibit growth (i.e., antiproliferative effects). Additional medical therapies include mammalian target of rapamycin (mTOR) inhibitors (e.g., everolimus) and receptor tyrosine kinase (RTK) inhibitors (e.g., sunitinib and pazopanib), which have been shown to delay pancreatic NET tumor progression. Current clinical trials are investigating the use of these agents in combination or with other therapies including monoclonal antibodies targeting the vascular endothelial growth factor receptor (VEGFR) (e.g., bevacizumab). Interferon-α (IFNα), which targets the IFNα/β-receptor (IFNAR) may also be effective in symptom and tumor control. Chemotherapeutic agents may also be effective in the treatment of metastatic pancreatic NETs and include alkylating agents (e.g., streptozocin, temozolomide, cisplatin, cyclophosphamide, procarbazine, dacarbazine, and oxabiplatin), antimicrotubule agents (e.g., docetaxel and etoposide), antimetabolites (e.g., 5-fluorouracil, capecitabine, and gemcitabine), topoisomerase inhibitors (e.g., doxorubicin, etoposide, and irinotexan), and cytotoxic antibiotics (e.g., actinomycin D, doxorubicin, mitomycin C, mitoxantrone). Combinations of chemopreventative agents that target different cellular pathways are more frequently used rather than as a monotherapy. *VEGFA,* vascular endothelial growth factor A. (Modified from Frost M, Lines KE, Thakker RV. Current and emerging therapies for PNETs in patients with or without MEN1. *Nat Rev Endocrinol.* 2018;14[4];216–227.)

(ZES).[54,55] Symptoms of ZES include those associated with peptic ulceration (i.e., abdominal pain, heartburn), as well as weight loss, diarrhea, and steatorrhea.[1] In addition, esophageal stricture and/or Barrett esophagus are also more common in patients with ZES, and acute presentations with small bowel perforation and/or hemorrhage secondary to peptic ulceration contribute to the high morbidity associated with ZES.[56] Symptomatic presentations are rare in childhood, although they have been reported in children younger than 10 years.[19] Gastrinomas occur in approximately 20% to 60% of MEN1 patients[53,57–59] and are found more frequently in adult males.[27] Approximately 20% of patients with sporadic gastrinoma will have MEN1.[1] MEN1-associated gastrinomas frequently occur as small (<5 mm in diameter), multiple nodular lesions deep within the duodenal mucosa and are only rarely observed in the pancreas,[57,60] in contrast to sporadic gastrinomas, which typically occur as solitary tumors within the pancreas or duodenum. In addition, MEN1-associated gastrinomas often occur as microscopic tumors (i.e., <1 mm), which despite their small size frequently metastasize to local lymph nodes at an early stage in the disease course.[57,60] Indeed, local lymph node metastases are found in 30% to 70% of cases at diagnosis,[53,61–63] although advanced presentations with hepatic metastases are rare in MEN1; however, when present, they are associated with a poor prognosis.[64,65] Additional poor prognostic indicators include markedly elevated gastrin levels, ectopic Cushing syndrome, and occurrence of primary pancreatic tumors.[66] Gastrinoma in MEN1

patients appears to occur rarely in the absence of PHPT,[58,67] and successful treatment of PHPT with restoration of normocalcemia is reported to result in symptomatic and biochemical improvements in approximately 20% of MEN1 patients with hypergastrinemia and ZES.[68]

The diagnosis of gastrinoma is made by demonstrating an increased fasting serum gastrin in association with increased basal gastric acid secretion.[1,61,69–71] A raised fasting serum gastrin alone is insufficient to make the diagnosis, as this may occur in achlorhydria, antral G-cell hyperplasia, *Helicobacter pylori* infection, renal failure, hypercalcemia, and PPI therapy.[69–71] An intravenous provocation test with secretin or calcium, which in patients with gastrinoma will be associated with a marked increase in gastrin, may help in the diagnosis.[1] MEN1 gastrinomas in the duodenum may be localized by endoscopic ultrasound. CT, MRI, selective angiography, and/or somatostatin receptor scintigraphy combined with selective arterial secretagogue injection (e.g., calcium) and hepatic venous gastrin measurements may help localize the tumor.[1]

Treatment

The lack of results from prospective randomized controlled trials of treatments in MEN1 patients with gastrinomas makes their management challenging and reliant on expert opinion.[1,53] The aims of treatment should be to ameliorate the symptoms and/or sequelae of the associated hypergastrinemia while reducing the likelihood of developing advanced metastatic disease. The medical treatment of gastrinoma has been transformed following the introduction of PPI therapies (e.g., omeprazole and lansoprazole), which are highly efficacious at reducing basal acid secretion to less than 10 mmol/L and reducing symptoms associated with gastrinoma.[1] H2-receptor antagonists (e.g., ranitidine) may be added if symptoms remain uncontrolled on high-dose PPI therapy. These therapies represent the mainstay of treatment for controlling symptoms and have resulted in a marked reduction in the morbidity and mortality previously associated with ZES in MEN1 patients. However, the effects on tumor growth and/or risk of developing advanced disease with this treatment are not established. In addition, the role of somatostatin analogue therapy in MEN1 gastrinomas, which may express somatostatin receptors, remains to be established.

The role of surgery in MEN1-associated gastrinoma remains controversial, which in part is due to not knowing the long-term natural course of disease in MEN1 patients.[53,72] Overall, the prognosis of gastrinoma in MEN1 patients is excellent with 5-, 10-, and 20-year survival rates of 90% to 96%, 75% to 96%, and 58% to 90%, respectively,[73] with the higher survival estimates observed following the introduction of acid-suppressive therapies. However, a minority of patients develop aggressive disease, and identifying these patients remains challenging. Poor prognostic features in MEN1-associated gastrinoma include large tumor size, a pancreatic location of the primary tumor, presence of liver metastases, early age of onset, and male gender.[65,73] The risk of hepatic metastases is higher for a pancreatic gastrinoma and correlates with tumor size, and surgery is therefore recommended for all gastrinomas larger than 2 cm in MEN1 patients.[1,73] In all other settings, the role of surgery remains controversial, with some centers advocating an initial medical approach and others pursuing an earlier surgical intervention. Centers advocating a nonsurgical approach point to the excellent long-term prognosis associated with smaller tumors, even in the presence of lymph node metastases; the low surgical cure rates in the presence of multiple small duodenal tumors; the potential high morbidity associated with pancreaticoduodenal resections; the excellent symptom control achieved with PPI therapy; and the lack of evidence demonstrating improved survival in those undergoing surgical resections.[1,53,73] In contrast, centers advocating early surgical intervention in all patients with MEN1-associated gastrinoma point to results that have achieved eugastrinemia in 30% to 75% of patients for 3 to 5 years.[74,75] Surgical approaches in these studies have included duodenotomy with excision of gastrinomas in the duodenal mucosa coupled with enucleation (if feasible) or resection of tumors in the pancreatic head, peripancreatic and lymph node removal, and corporacaudal pancreatic resection; partial pancreaticoduodenectomy; pancreas-preserving total duodenectomy; and total pancreaticoduodenectomy.[1,53,74–77] Total pancreaticoduodenectomy (i.e., Whipple procedure), which is associated with a substantially greater risk of diabetes mellitus and malabsorption, is rarely performed and is typically reserved for patients with diffuse large pancreatic tumors.[1] However, long-term remission and survival data are not known, and currently the benefits of medical therapies over such surgery have resulted in many centers and guidelines recommending nonsurgical management for gastrinomas in MEN1 patients, with surgery being reserved for patients in whom medical therapy has failed.[1,53]

The management of advanced/disseminated gastrinomas is difficult and does not differ from that of sporadic disease. Chemotherapy with streptozotocin and 5-fluorouracil, capecitabine and temozolomide, cisplatin and etoposide, hormonal therapy with octreotide or lanreotide (which are human somatostatin analogues) (see Fig. 42.2), selected internal radiation therapy, radio-frequency ablation, peptide receptor radionuclide therapy, hepatic artery embolization, administration of human leukocyte interferon, and removal of all resectable tumor and hepatic transplantation have each been employed with occasional benefit.[53,74]

Insulinoma

Clinical Features

Insulinomas, which arise from pancreatic islet beta cells, occur in approximately 10% to 30% of patients with MEN1, whereas 5% to 10% of patients presenting with insulinoma will have MEN1.[1,19,23,25] Insulinomas in MEN1 patients frequently occur, in contrast to non-MEN1 patients, before the age of 40 years and may be the first manifestation of MEN1 in approximately 10% of cases. Indeed, a recent study of 160 MEN1 patients younger than 21 years observed insulinomas to occur in 12% of the cohort, with the earliest presentation at 5 years of age.[19]

MEN1 patients with insulinomas typically present with symptoms of hypoglycemia (e.g., weakness, headaches, sweating, faintness, anxiety, altered behavior, seizures, and loss of consciousness) that develop after fasting or exercise and improve after glucose (food) intake.[19] The diagnosis is most reliably made by a supervised 72-hour fast,[1,69,78] in which hypoglycemia (i.e., glucose <2.2 mmol/L [40 mg/dL]) is documented in the presence of inappropriate elevated concentrations of insulin (together with proinsulin and C-peptide).[1] It is also important to demonstrate the absence of sulfonylureas in the plasma and urine samples obtained during the investigation of hypoglycemia. Medical therapy, which consists of frequent carbohydrate meals, diazoxide, and somatostatin analogues, is not always successful, and removal of the insulinoma by surgery is the optimal treatment. Surgical success

is improved by preoperative localization of the tumor. The majority of insulinomas are single lesions, occurring in the body or tail of the pancreas, although multiple or multicentric insulinomas may be observed in approximately 40% of MEN1 patients.[79] Furthermore, concurrent pancreatic NETs (e.g., NF tumors) are frequently present in MEN1 patients, thereby posing a challenge for the correct localization of the insulinoma. Imaging modalities routinely employed for preoperative localization include endoscopic ultrasound, CT, and MRI, whereas more specialized methods, including celiac axis angiography and selective intra-arterial calcium stimulation combined with hepatic venous insulin measurements may also be required.[80–82] Somatostatin receptor scintigraphy (SRS) with ^{111}In-octreotide has been reported to be associated with low sensitivity in insulinoma (20–60%), although ^{68}Ga-DOTATATE PET-CT may have a higher sensitivity.[83] More recently, scintigraphy based on glucagon-like peptide 1 has been reported to be highly sensitive in localizing insulinomas when compared with conventional imaging modalities and may provide a useful diagnostic modality.[83–85] The utility of ^{18}F-fluorodeoxyglucose (FDG)-PET/CT for insulinoma detection is typically limited to high-grade metastatic disease.[83] Finally, direct intraoperative pancreatic ultrasound may be used at the time of surgery to identify the likely tumor.[80,86,87]

Treatment

Surgery is the treatment of choice for those with nonmetastatic disease. Several surgical procedures have been reported to provide long-term curative outcomes, including enucleation or excision of single or multiple tumors, distal or partial pancreatectomy, and pancreatoduodenectomy.[79,88,89] In one large series of MEN1 patients undergoing surgery for insulinoma, distal pancreatectomy was associated with a lower risk of hypoglycemia recurrence than enucleation but a higher risk of surgery-related morbidity.[90] Minimally invasive approaches (e.g., laparoscopic, robot assisted) may be appropriate in selected MEN1 cases.[88,91] The surgical approach adopted will depend on the location and size of insulinoma, as well as the presence or absence of additional pancreatic tumors. In MEN1 patients, insulinomas typically occur as benign tumors, and surgical outcomes and long-term prognosis are excellent.[90] For advanced and metastatic disease, chemotherapy (using streptozotocin, 5-fluorouracil, and doxorubicin), and locoregional approaches, including hepatic artery embolization, may be employed for disease and symptom control[1,53,92] (see Fig. 42.2).

Glucagonoma

Clinical Features

Glucagonomas, which arise from the pancreatic islet α-cells and lead to excess glucagon secretion, occur in 1% to 2% of MEN1 patients.[93] However, the characteristic clinical features of skin rash (necrolytic migratory erythema), stomatitis, weight loss, venous thrombosis, and anemia may be absent.[93] Instead, glucagonomas may be detected in asymptomatic MEN1 patients following surveillance pancreatic imaging or the finding of marked hyperglucagonemia (i.e., greater than two times the upper limit of normal) with or without glucose intolerance. It should be noted that a significant proportion of NF pancreatic NETs immunostain for glucagon (either in insolation or together with additional pancreatic hormones) in the absence of hyperglucagonemia,[52,94] whereas a proportion of NF tumors will be associated with modest elevations in plasma glucagon (i.e., less than two times the upper limit of normal).

Treatment

Glucagonomas most frequently present in the tail of the pancreas, where possible surgical resection, which can be curative, is the treatment of choice. However, curative surgery may not be feasible considering that 50% to 80% of patients may have large tumors with metastases.[1] Medical treatment with somatostatin analogues (e.g., octreotide or lanreotide) or chemotherapy (with streptozotocin and 5-fluorouracil or dimethyltriazeno-imidazole carboxamide) (see Fig. 42.2) has been successful in some patients, and hepatic artery embolization has been used to treat metastatic disease.[1,53,92]

VIPoma

Clinical Features

Patients with vasoactive intestinal peptide (VIP)omas, which are VIP-secreting pancreatic tumors, develop watery diarrhea, hypokalemia, and achlorhydria.[1,93] This clinical syndrome has been referred to as Verner-Morrison syndrome, WDHA (watery diarrhea, hypokalemia, achlorhydria) syndrome, or VIPoma syndrome.[1] Only a few patients with MEN1 have been reported to have VIPomas.[93] The diagnosis is established by excluding laxative and diuretic abuse and confirming a stool volume in excess of 0.5 to 1.0 L/day during a fast, together with a markedly increased plasma VIP concentration.

Treatment

Surgical management of VIPomas, which are mostly located in the tail of the pancreas, has been curative, although approximately 50% of patients have metastases at diagnosis.[95,96] In patients with unresectable disease, treatment with somatostatin analogues such as octreotide and lanreotide, streptozotocin with 5-fluorouracil, corticosteroids, indomethacin, metoclopramide, and lithium carbonate has proved beneficial, and hepatic artery embolization has been useful for the treatment of metastases[1] (see Fig. 42.2).

NF Pancreatic NETs

Clinical Features

NF pancreatic NETs are islet-derived tumors that do not give rise to a clinical syndrome associated with excess hormone production, and hence these tumors may have presentations with symptoms related to local mass effects (i.e., pain and/or compression of adjacent structures) or metastatic disease (e.g., cachexia, jaundice, hepatomegaly, and hepatic and bone pains). However, some NF pancreatic NETs may be associated with elevations in PP and/or glucagon,[1,97] although plasma PP and glucagon, together with chromogranin A, are reported to have low sensitivity and specificity for pancreatic NET detection in MEN1 patients,[98,99] and circulating biomarkers for detection of NF pancreatic NETs are not available at this time. As a consequence, pancreatic imaging remains the mainstay of diagnosis, although the optimal modality for detection has not been established and frequently depends on local availability and expertise related to different modalities. NF pancreatic NETs in MEN1 are typically considered as a single entity (see Fig. 42.1), although they likely represent a heterogeneous group of tumors with distinct pathologic and/or molecular subtypes. The implementation of surveillance imaging programs for patients with MEN1 has shown that NF pancreatic NETs are the most prevalent pancreatic NET in MEN1, with clinically apparent tumors occurring in 15% to 55% of patients.[49,51,53,97,100] For example, a prospective endoscopic ultrasound study (EUS) demonstrated that approximately 55% of MEN1 patients had one or more NF NETs,[48] and a histopathologic study reported that almost

all MEN1 patients have small microadenoma NF tumors.[52,53] In addition, NF pancreatic NETs have been reported to occur in more than 5% to 40% of children and young adults, 12 to 20 years of age, with MEN1.[19,97,101] The current guidelines therefore recommend surveillance imaging for NF pancreatic NETs from age 10 years,[1] with the aims of detecting and monitoring clinically relevant tumors yet minimizing exposure to ionizing radiation and/or iatrogenic complications relating to the procedure. EUS has been reported to be the most sensitive method for detection of tumors smaller than 1 cm, and to provide accurate estimates of tumor growth rates, and also provides the potential opportunity to assess the mitotic count and/or Ki67 index of tumors obtained from EUS-guided fine-needle aspirates.[53,102] However, EUS is an invasive and time-consuming procedure that is dependent on user expertise, and it has been reported to overestimate the size of NF pancreatic NETs in MEN1, which has important implications considering that decisions regarding surgery are frequently based on size criteria.[103] Alternate methods of imaging include MRI, CT, SRS (i.e., based on octreotide/^{68}Gallium-DOTATATE PET), and FDG-PET, and each has been associated with high sensitivity and specificity in different series such that combinations of these modalities are often used to fully characterize tumors and for assessing the likelihood of metastatic risk.[53,104,105]

NF pancreatic NETs are the leading cause of premature mortality in patients with MEN1, and they are associated with a worse prognosis than other MEN1-associated pancreatic NETs (e.g., insulinoma, gastrinoma).[20,53,61,106] Premature morbidity and mortality typically results from the development of metastatic disease but may also arise due to complications of surgical intervention.[20,49,51,106,107] The risk of developing liver metastases correlates with primary tumor size, and synchronous liver metastases have been reported in approximately 43% of patients with NF NETs larger than 3 cm, 18% of patients with NF NETS 2 to 3 cm, 10% in those with NF NETS 1 to 2 cm, and only 4% of those with NF NETS smaller than 1 cm.[100] However, tumor size is not universally correct at predicting metastatic risk in NF NETs, as a small percentage of patients with small tumors are reported to develop advanced disease.[108] In addition, currently circulating biomarkers are not available for predicting metastatic risk in NF pancreatic NETs, and circulating biomarkers based on microRNA, circulating tumor cells, multigene signatures, and tumor DNA, which are being evaluated, may hold future promise in predicting tumor behavior.[104,109,110]

Treatment

The aims of treatment for MEN1-associated NF NETs are to minimize the risk of developing metastatic disease while avoiding unnecessary surgical interventions that are known to result in significant early and late complications.[1,53,107] However, surgical removal of NF pancreatic NETs is of benefit, as illustrated by a recent study in which only 6 of 16 (~40%) MEN1 patients with NF pancreatic NETs larger than 3 cm and who had surgery, developed hepatic metastases, or died compared with 5 of 6 (~80%) patients who did not have surgery.[51] However, the same study reported that rates of metastasis in patients undergoing surgery for NF pancreatic NETs smaller than 2 cm were not significantly different from those managed without surgery.[51] Thus, the majority of centers recommend surgery for NF pancreatic NETS larger than 2 cm, especially because smaller NF pancreatic NETS (<2 cm) have been reported to have stable appearances over an average of 10 years.[49,111] For example, in one study, 60% (28 of 46) of patients with NF pancreatic NETs smaller than 2 cm had stable disease, whereas in the remaining 40% of patients who had an increase in size or number of tumors, or developed hypersecretion syndromes, only 15% (7 of 46) required surgery and only 2% (1 of 46) of patients died from metastatic disease.[49] Moreover, another study reported that surgery in MEN1 patients with NF NETs smaller than 2 cm does not affect progression-free survival (PFS) when compared with those patients managed conservatively, as the majority of tumors displayed indolent behavior.[111] However, surgery is recommended when there is rapid tumor growth (i.e., doubling of tumor size over a 3–6 month interval) (see Fig. 42.1), and some centers will consider surgery if pancreatic NETs are 1 cm or larger in size. The decision to undertake surgery for NF pancreatic NETs in MEN1 should consider the potential presence of additional tumors within the pancreas (and elsewhere), the presence of occult metastatic disease either related to the tumor undergoing resection or from another source, and the fact that any remnant pancreatic tissue will remain a risk for the development of further tumors. Thus, all of these considerations highlight the importance of multidisciplinary working and the involvement of the patient in the decision-making process.[106]

Medical treatments for small (i.e., <2 cm) NF pancreatic NETs in MEN1 include long-acting octreotide, which has been reported to be associated with a tumor response in 10% of patients, stable disease in 80% of patients, and disease progression in 10% of patients over 12 to 15 months of treatment,[112] with reductions in PP and glucagon in those with stable tumor size.[113] For patients with advanced disease, treatments include locoregional and systemic approaches (see Fig. 42.2) and are similar to those employed for the other pancreatic NETs. However, the evidence for the use of such treatments arose from study of non-MEN1 patients, and extrapolation of this to MEN1 patients requires some caution.[53] Somatostatin analogue therapy is reported to be associated with a approximately 50% reduction in the risk of disease progression in non-MEN1 patients with well-differentiated advanced pancreatic NETs.[114,115] The receptor tyrosine kinase (RTK) inhibitor sunitinib is associated with an increase in PFS from 5.5 to 11.4 months in non-MEN1 patients with advanced well-differentiated pancreatic NETs,[116] and the mammalian target of rapamycin inhibitor everolimus increases PFS from 6 to 11 months in non-MEN1 patients with low- or intermediate-grade advanced pancreatic NETs.[117] Additional therapies for advanced NF pancreatic NETs include chemotherapy, peptide receptor radionuclide therapy, and locoregional therapies (e.g., radio-frequency ablation, transarterial chemoembolization, and selective internal radiation therapy).[53,92]

Somatostatinoma

Pancreatic tumors secreting somatostatin are associated with somatostatinoma syndrome, characterized by hyperglycemia, cholelithiasis, low acid output, steatorrhea, diarrhea, abdominal pain, anemia, and weight loss. Although elevations in somatostatin are observed in a significant proportion of MEN1-associated pancreatic NETs, somatostatinoma syndrome has not been reported.[20,93] Thus, this group of tumors is frequently considered part of the NF category.

GHRHoma

Pancreatic islet tumors secreting growth hormone–releasing hormone (GHRH) have been reported in some patients with MEN1.[1,118] Patients may present with features of acromegaly and are diagnosed by demonstrating elevations in serum growth hormone (GH), GHRH, and insulin-like growth factor 1. In the

context of MEN1, GHRHomas occur predominantly within the pancreas, although sporadic GHRHomas may arise in the lung or small intestine.[118] Surgical removal is the treatment of choice for MEN1-associated pancreatic GHRHomas.[118]

Pituitary Tumors

Clinical Features

Anterior pituitary tumors occur in 30% to 50% of patients with MEN1, although the frequency of detection has increased with the introduction of routine surveillance of MEN1 patients together with the improved sensitivity of imaging modalities.[1,23,119–121] Women are reported to be affected more frequently than men,[27,121] and one study reported an intrafamilial correlation and suggested occurrence of potential genetic modifying influences that are independent of the *MEN1* mutation.[122] Pituitary tumors typically present in early adulthood at a mean age of 30 to 40 years.[119,121] However, pituitary tumors may occur earlier; one study reported a prevalence of approximately 35% before 21 years of age, with the majority of cases presenting between 15 and 20 years of age,[19] whereas the youngest presentation reported was in a 5-year-old boy.[123] Pituitary tumors are the first manifestation of MEN1 in 10% to 20% of cases.[19,124] Initial studies reported a high prevalence (>80%) of pituitary macroadenomas (i.e., >1 cm) in MEN1 patients,[121] although more recent series indicate that microadenomas (i.e., <1 cm) occur frequently, and these differences are likely explained by the introduction of sensitive surveillance imaging.[119,124] Pituitary tumor subtypes are observed in MEN1 patients, with prolactinomas representing the most common type, accounting for 40% to 75% of MEN1-associated pituitary tumors.[19,119,120,124] Other functioning pituitary tumors include GH-secreting tumors (5–15%) and adrenocorticotropic hormone (ACTH)-secreting tumors (3–7%), whereas plurihormonal secretion (i.e., prolactin/GH and prolactin/ACTH) may be observed in a minority of tumors. The remaining tumors predominantly comprise NF pituitary tumors (15–40%),[20,119,121,124] although some of these are associated with secretion of glycoprotein subunits.[1] One recent study reported that approximately 50% of pituitary tumors detected by screening in MEN1 patients (i.e., as opposed to clinical presentations) represented NF tumors, of which the majority were microadenomas.[119] The clinical manifestations associated with MEN1-associated pituitary tumors are similar to those in patients with sporadic pituitary tumors. For example, patients with prolactinomas will have features associated with hyperprolactinemia (e.g., amenorrhea, galactorrhea, and infertility in females, and erectile dysfunction and loss of libido in males), whereas those with GH- and ACTH-secreting tumors will manifest symptoms and signs associated with acromegaly and Cushing disease, respectively. Pituitary macroadenomas typically present with local mass effects (e.g., headache, visual field defects) or features of hypopituitarism. Diagnosis and clinical investigations are similar to those for sporadic pituitary tumors and will include dynamic biochemical testing and imaging to characterize the nature of the tumor and to assess any compromise of pituitary function (e.g., hypopituitarism). Given the high risk of tumor development, *MEN1* mutation carriers are recommended to undergo periodic biochemical evaluation for prolactin and insulin-like growth factor 1, together with MRI of the pituitary fossa.

Treatment

Overall, the prognosis for patients with MEN1 pituitary tumors, the majority of which are benign neoplasms, is favorable.[20] Pituitary carcinoma is extremely rare in MEN1, with only a few cases reported.[1,125] The treatment of pituitary tumors in patients with MEN1 is similar to that employed for their sporadic counterparts and comprises appropriate medical therapy (e.g., cabergoline for prolactinoma; somatostatin analogues and/or pegvisomant for somatotropinoma) or selective transsphenoidal adenomectomy, if feasible, with radiotherapy reserved for those patients with residual and/or unresectable tumor tissue.[125] However, pituitary tumors in MEN1 patients have been reported in some studies to be larger and more invasive than their sporadic counterparts, as well as less responsive to medical treatments.[120,121,125] One study reported that pituitary tumors in young male MEN1 patients were larger than those occurring in their female counterparts, with the majority occurring as macroadenomas with invasive imaging characteristics (i.e., Hardy grade 3 or 4).[19] However, other studies of predominantly adult MEN1 patients have reported that the majority of pituitary tumors respond well to medical therapies and have a similar behavior to sporadic tumors (e.g., the response rate for prolactinomas is >90%), whereas NF tumors were frequently small and stable, not requiring surgical intervention.[72,119]

Adrenal Tumors

Clinical Features

The incidence of adrenocortical tumors in patients with MEN1 is reported to be 20% to 55%,[1,126] although a higher frequency of adrenal involvement (~75%) has been reported when highly sensitive imaging modalities have been employed, including endoscopic ultrasound.[127] Most affected patients are asymptomatic, as the majority of tumors, which may include cortical adenomas, hyperplasia, multiple adenomas, nodular hyperplasia, cysts, or carcinomas, are NF.[1,126] Indeed, fewer than 10% of patients with enlarged adrenal glands have biochemical evidence of hormonal hypersecretion, and among these, primary hyperaldosteronism and ACTH-independent Cushing syndrome are the most commonly encountered.[126] Occasionally, hyperandrogenemia may occur in association with adrenocortical carcinoma, whereas the occurrence of pheochromocytoma in MEN1 patients is rare. Although adrenal involvement is most commonly observed in adults with MEN1 (with equal sex distribution), occasional presentations in childhood are reported. For example, adrenal carcinoma has been reported in a 4-year-old boy and 16-year-old girl, each having clinical and biochemical evidence of androgen excess.[19] It is also reported that adrenal tumors demonstrate heritability in MEN1 kindreds, highlighting a need for increased vigilance in those with other affected family members.[122] Biochemical investigation (e.g., plasma renin and aldosterone concentrations, the low-dose dexamethasone suppression test, urinary catecholamines and/or metanephrines) should be undertaken for those with symptoms or signs suggestive of functioning adrenal tumors, or for those with tumors larger than 1 cm. The incidence of adrenocortical carcinoma is reported to be approximately 1% in MEN1 patients but is higher (at approximately 13%) in MEN1 patients with adrenal tumors larger than 1 cm.[126] Thus, it is important that MEN1 patients with adrenal tumors are offered annual imaging and that those displaying atypical radiologic characteristics, significant growth, or are larger than 4 cm are considered for surgical removal.[1,126]

Treatment

Consensus has not been reached about the management of MEN1-associated NF adrenal tumors, because the majority of these neoplasms are benign. However, the risk of malignancy is increased if the tumor has a diameter larger than 4 cm, although adrenocortical carcinomas have been identified in tumors smaller

than 4 cm in patients with MEN1.[1,126] Surgery is recommended for adrenal tumors that are larger than 4 cm in diameter, have atypical or suspicious radiologic features (e.g., increased Hounsfield units on an unenhanced CT scan) and are 1 to 4 cm in diameter, or show significant measurable growth over a 6-month interval.[1,127] The treatment of functioning (i.e., secreting) adrenal tumors in MEN1 patients is similar to that for tumors occurring in non-MEN1 patients.

Carcinoid Tumors

Carcinoid tumors arising in the thymus, bronchi, or gastrointestinal tract occur at varying frequencies in patients with MEN1. Thymic carcinoid tumors, although rare, present the most significant clinical challenge because they are associated with an aggressive disease course and are one of the leading causes of premature death in MEN1 patients.

Thymic Carcinoids

Thymic carcinoid tumors occur in 2% to 8% of MEN1 patients[1,128–131] and are observed predominantly in adult male patients, although gender differences appear specific to individual ethnic populations (e.g., European populations, 20 male to 1 female; Japanese populations, 2 male to 1 female; Chinese populations, 1 male to 1 female).[27,129,132] In MEN1 populations of European descent, smoking is an independent risk factor for tumor development.[129] The median age at diagnosis is 40 to 45 years,[129] although much earlier presentations have been reported, including a 16-year-old boy who died 49 months after diagnosis from local and distant metastatic disease.[19] Although the overall frequency of thymic carcinoid tumors is low in MEN1 patients, several reports highlight clustering of cases within individual families, thereby suggesting a high heritability independent of the *MEN1* mutation.[122,129] Thymic carcinoids are responsible for approximately 20% of premature deaths in MEN1 patients,[20,61,129] with the highest hazard ratio for increased mortality of all the MEN1-associated tumors (hazard ratio, 4.64; 95% confidence interval, 1.73–12.41).[20] Once diagnosed, MEN1 patients with thymic carcinoid tumors have a median survival of 8 to 10 years.[129,131] Symptomatic presentations may include pain (e.g., arising from chest, shoulder, breast) or features of vena caval obstruction,[131] whereas the features of carcinoid syndrome (i.e., flushing, diarrhea) are not typically observed.[129,131] Indeed, the majority of patients are asymptomatic at diagnosis, and most tumors are detected by radiology.[131] Biochemical markers (e.g., raised chromogranin A, urinary 5-hydroxyindoleacetic acid) are not sufficiently sensitive for tumor detection; as a consequence, diagnosis is reliant on radiologic imaging, although the optimal screening methods have not been established. CT is considered to be sensitive for tumor detection, but there is concern over the repeated exposure to ionizing radiation, particularly as the natural history of thymic carcinoid tumors in MEN1 is one of rapid development such that a frequent scanning interval (i.e., every 1–2 years) would be required.[1,130] "Low-dose" CT or MRI may be optimized for tumor detection, but further studies are required to assess their utility in MEN1. Similarly, SRS is frequently positive in thymic carcinoids, although insufficient evidence is available to recommend its use as a screening modality. FDG-PET may also be useful in the evaluation of patients with thoracic lesions in MEN1.[133] The treatment of thymic carcinoids depends on the stage of presentation. Surgical removal is recommended because it may be curative, although recurrence rates following surgery are high.[129,131] Older age of presentation, larger tumor diameter, and presence of metastases are each associated with worse clinical outcomes.[129] For those with advanced disease, chemotherapy (e.g., etoposide and cisplatin) and radiotherapy may be used.[129,131] The value of somatostatin analogue therapy in this context is not known but may improve symptoms and/or result in tumor response. It should be noted that cervical thymectomy is recommended in MEN1 patients undergoing parathyroidectomy, although there is little evidence that such prophylactic thymus removal reliably prevents thymic carcinoid development, and several cases of thymic carcinoid have been reported in patients who have undergone this procedure.[131] Similarly, although current guidelines recommend regular screening for thymic carcinoid, there is no evidence that this approach, aimed at early tumor detection, results in improved outcomes.[130]

Bronchial Carcinoids

Bronchial carcinoids, which are observed in 4% to 13% of adult patients with MEN1, are not typically associated with increased mortality,[20,128,130,134] as they frequently run a benign course, although occasional patients have developed malignant disease.[134] The incidence of bronchial carcinoids appears to be approximately equal between sexes,[128] although they were initially reported to occur predominantly in women. Bronchial carcinoids present in adulthood at a median age of approximately 40 years, and childhood presentations do not appear to be reported.[19,128,130] The majority of patients with bronchial carcinoids are asymptomatic, and features of carcinoid syndrome are typically absent.[59,128] Diagnosis is made on imaging, most frequently with CT. However, it should be noted that pulmonary lesions in MEN1 patients require careful evaluation because they may represent metastatic lesions from other tumor sites.[128,133] Surgery is typically performed for bronchial NETs, and although there is no direct evidence of improved outcomes employing this approach in MEN1 patients, in sporadic cases surgery is reported to be beneficial.[130,134,135]

Gastric Carcinoids

Type II gastric carcinoids (also referred to as enterochromaffin-like cell carcinoids [ECLomas]) are observed in approximately 15% to 70% of MEN1 patients with coexistent hypergastrinemia and are frequently detected incidentally at the time of upper gastrointestinal endoscopy.[1,136,137] The tumors are usually multiple and small (e.g., <1.5 cm), and SRS may demonstrate increased uptake in the stomach. The malignant potential of these tumors is uncertain, and, where feasible, surgical resection may be appropriate.[136,137] However, treatment with somatostatin analogue therapy has also been reported to result in regression of these tumors.[136–138]

Other Tumors

Central Nervous System Tumors

Central nervous system tumors including ependymomas, schwannomas, and meningiomas have been reported in MEN1 patients.[1] Meningiomas are reported in approximately 8% of MEN1 patients. The majority of meningiomas were not associated with symptoms, and 60% did not enlarge.[1] The treatment of MEN1-associated meningiomas is similar to that occurring in non-MEN1 patients.

Lipomas

Subcutaneous lipomas may occur in 15% to 33% of patients with MEN1, and frequently they are multiple.[1,23] In addition, visceral, pleural, or retroperitoneal lipomas may occur in patients with MEN1. Management is conservative. However, when surgically removed for cosmetic reasons, they typically do not recur.

Facial Angiofibromas and Collagenomas

Studies have revealed that multiple facial angiofibromas occur in 22% to 88% and collagenomas in 0% to 72% of patients with MEN1[1] (Fig. 42.3). MEN1 angiofibromas are clinically and histologically identical to those observed in patients with tuberous sclerosis, with the exception that in patients with MEN1, angiofibromas were also present on the upper lip and vermilion border of the lip, which are areas not involved in tuberous sclerosis. These cutaneous findings, which occur with a higher frequency in patients with MEN1, may provide a useful means for possible presymptomatic diagnosis of MEN1 in the relatives of a patient with MEN1. Treatment for these cutaneous lesions is usually not required.

Thyroid Tumors

Thyroid tumors consisting of adenomas, colloid goiters, and carcinomas have been reported to occur in more than 25% of patients with MEN1.[1,23] However, the prevalence of thyroid disorders in the general population is high, and it has been suggested that the association of thyroid abnormalities in patients with MEN1 may be incidental.[1]

Breast Cancer

Female MEN1 patients have been reported to have an increased relative risk between 2.3 and 2.8 of developing breast cancer. The majority of breast tumors are of ductal type with mixed hormone receptor status (estrogen receptor [ER], progesterone receptor, and human epidermal growth factor receptor).[139] Some of the breast cancers had reduced menin expression and loss of heterozygosity of the *MEN1* locus, although further studies are required to confirm the association.[140] Based on these initial observations, together with subsequent studies reporting that the increased breast cancer is not related to other known risk factors,[141] some centers have advocated the introduction of screening for breast cancer in female MEN1 patients over the age of 40 years.[141] However, further evidence is required to support both the association of breast cancer with MEN1 and the value of undertaking such screening.[85]

• **Fig. 42.3** Multiple angiofibromas in a patient with multiple endocrine neoplasia type 1.

Molecular Genetics

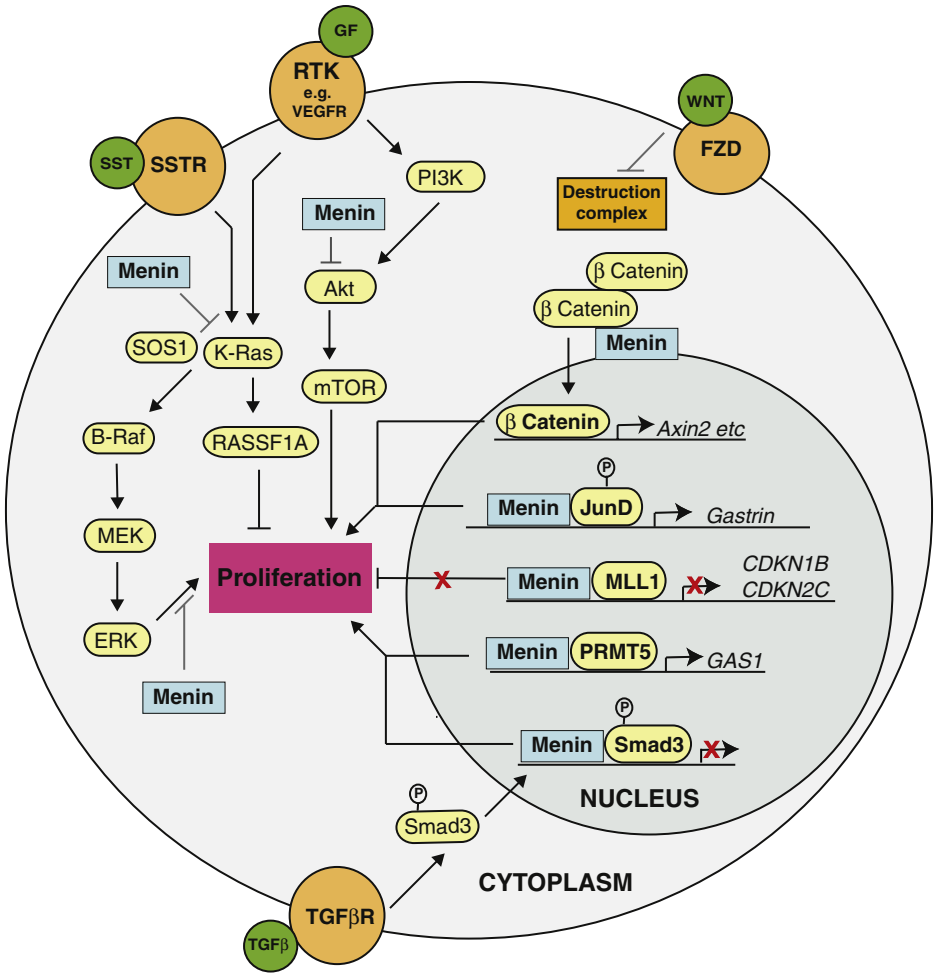
MEN1 *Gene*

The *MEN1* gene is located on chromosome 11q13 and consists of 10 exons, which encode a 610 amino acid protein, menin, that regulates transcription, chromatin structure, genome stability, and cellular proliferation through direct associations with interacting protein partners, or via the modulation of key cellular signaling pathways[18,92,142–144] (Fig. 42.4). Patients with MEN1 harbor germline heterozygous mutations of the *MEN1* gene, which predisposes them to tumor development; however, tumorigenesis requires somatic inactivation of the wild-type *MEN1* allele such that MEN1 tumors demonstrate biallelic inactivation of the *MEN1* gene. Most commonly, the inactivation of the wild-type allele occurs through a large somatic deletion (i.e., at the 11q13 locus), which manifests as loss of heterozygosity (LOH) of the tumor DNA, consistent with Knudson's "two-hit" model of inherited tumorigenesis and a tumor suppressor function for menin in endocrine tissues. However, alternate mechanisms leading to inactivation of the wild-type *MEN1* allele include point mutations (i.e., resulting in nonsense or missense amino acid substitutions) or small insertions or deletions (indels), and in such cases LOH will not be apparent.[1]

The *MEN1* gene spans 7.7 kb of genomic DNA, and at least 16 different *MEN1* transcripts have been identified. The main *MEN1* transcript is a 2.76-kb mRNA, which encodes the 610 amino acid isoform of menin, although the canonical transcript, which appears to be rare, is longer at 3.16 kb and is predicted to elongate the reading frame by 5 amino acids at the exon2/intron2 junction, giving a protein isoform of 615 amino acids. The approximately 1400-bp region upstream of exon 2 is reported to display strong promoter activity, containing both the minimal promoter region and several regulatory regions. Expression of the *MEN1* transcript is observed in all human tissues examined, although menin protein expression may not necessarily correlate with transcript levels. The *MEN1* gene and menin protein are highly conserved in mammalian species (e.g., ~89% and ~97% DNA and protein identity, respectively, with mouse and rat). Orthologues of menin are observed in evolutionary distant specifies, including zebrafish and *Drosophila*, although they are not present in yeast (e.g., *Saccharomyces cerevisiae*) or nematodes (e.g., *Caenorhabditis elegans*). Recent population-level genetic studies indicate that the coding region of *MEN1* demonstrates high levels of constraint against missense and nonsense variation, suggesting that it remains under strong evolutionary selection pressure.[145] Transcription of the *MEN1* gene is reported to be, in part, regulated by its own protein product, menin, whereby reductions in menin expression activate the *MEN1* promoter activity, and menin overexpression downregulates promoter activity.[146] More recently, the *MEN1* 3′ untranslated region has been observed to bind microRNA 24-1, which is reported to suppress menin expression.[147]

Germline MEN1 *Mutations*

To date, more than 1200 germline *MEN1* mutations have been reported in patients with MEN1 or individuals with associated tumors, and of these, approximately 600 different germline mutations are observed.[148–150] *MEN1* mutations are most frequently inherited from an affected parent, although they arise de novo in approximately 10% of cases. The majority of mutations (~70%) are predicted to result in a loss of function through premature truncation of the menin protein (i.e., frameshift deletions or insertions [40–45%], nonsense mutations [14–20%], splice-site mutations [~10%]), whereas the remainder occur as missense mutations (20–25%), in-frame deletions or insertions (~5%), or as gross deletions involving all or part of the



• **Fig. 42.4** Menin has nuclear and cytoplasmic roles. Loss of menin expression (*blue boxes*) in endocrine tissues may result in increased cell proliferation by multiple pathways. In the nucleus, the loss of menin results in disruption of its interaction with transcription factors JUND and PRMT5 that lifts the transcriptional repression of target genes *Gastrin* and *GAS1*, respectively; binding to MLL1, MLL2, and SMAD3 (a TGFβ signaling component) to promote transcription of target genes; and ability to regulate the WNT pathway because β-catenin is no longer prevented from entering the nucleus by menin, thereby enabling transcription of WNT pathway target genes. Interactions with additional transcription factors and chromatin-modifying protein complexes may further modulate oncogenic signaling pathways. In the cytoplasm, loss of menin reduces its inhibitory actions on the mammalian target of rapamycin (mTOR) pathway by binding to AKT (downstream of PI3K, part of the RTK signaling pathway) and preventing its translocation to the plasma membrane, and KRAS-induced proliferation (by possible inhibition of ERK-dependent phosphorylation (P) and prevention of the interaction between SOS1 and KRAS). All pathways affect proliferation, which involves both nuclear and cytoplasmic mechanisms (shown in the cytoplasm only). Ligands are shown as *green circles*, and receptors are *orange circles*. *Akt*, protein kinase B; *B-Raf;* serine/threonine-protein kinase B-Raf; *CDKN,* cyclin-dependent kinase inhibitor; *ERK,* extra signal-related kinase; *FZD,* frizzled; *GAS1,* growth arrest specific 1; *GF,* growth factor; *MEK,* mitogen-activated protein kinase kinase; *MLL,* mixed lineage leukemia; *PI3K,* phosphoinositide 3-kinase; *PRMT5,* protein arginine N-methytransferase 5; *RASSF1A,* Ras-associated domain family member 1 isoform A; *Smad3,* mothers against decapentaplegic hormone 3; *SOS1,* sons of sevenless 1; *SST,* somatostatin; *SSTR,* SST receptor;*TGFβ,* transforming growth factor β; *TGFβR*, TGFβ receptor; *WNT,* wingless-related integration site. (Modified from Frost M, Lines KE, Thakker RV. Current and emerging therapies for PNETs in patients with or without MEN1. *Nat Rev Endocrinol.* 2018;14[4];216–227.)

MEN1 gene (1–2.5%).[148,150] The mutations are observed throughout the entire coding region of the *MEN1* gene, although nine individual mutations have been reported to account for more than 20% of all germline *MEN1* mutations (e.g., c.249_252delGTCT, c.292C>T, c.358_360delAAG, c.628_631delACAG, c.784-9G>A, c.1243C>T, c.1378C>T, c.1546delC, c.1546_1547insC).[148] In addition, 11 individual codons (i.e., 45, 69, 70, 139, 156, 183, 220, 253, 418, 436, and 516) are reported to be affected by five or more different *MEN1* mutations.[150] Together, these studies indicate that specific regions of the *MEN1* gene may be more susceptible to mutation, and it is notable that some of these mutations occur within repetitive DNA sequences, consistent with a replication-slippage model of mutagenesis. For example, the delC and insC (c.1546-1547) in codon 516 involve a poly(C)7 tract, and a slipped-strand mispairing model has been proposed to explain the high number of insertions or deletions at this site.[148,151] An alternative proposed explanation for the occurrence of these recurrent mutations in unrelated kindreds is the presence of population-specific founder mutations, whose presence may be established by haplotype analysis.[143,152,153]

Correlations between *MEN1* mutations and clinical manifestations of the disorder appear to be absent.[4,148,151] For example, studies of several large MEN1 kindreds, each harboring the same *MEN1* mutation, have shown that members of the respective families can develop a different range of tumors.[4,154] However, it has been reported that mutations of codons 428 through 610, which disrupt menin interaction with the checkpoint kinase 1 (CHES1) protein, are associated with a higher frequency of aggressive pancreatic NETs and a higher mortality than other *MEN1* mutations,[155] and that mutations of the three menin domains (codons 1–40, 139–242, and 323–428) that affect the interaction with JunD had a higher risk of premature death when compared with other *MEN1* mutations.[156] Further studies are required to validate these findings. In addition, some kindreds with germline *MEN1* mutations have been reported to not develop the full clinical phenotype of MEN1. For example, families with the Burin or prolactinoma variant of MEN1, who harbor specific nonsense mutations (i.e., Tyr312Ter, Arg460Ter), are reported to be characterized by a high occurrence of prolactinomas but a low occurrence of gastrinoma.[157,158] Similarly, somatotropinomas were not observed in a large kindred from Tasmania carrying a splice site *MEN1* mutation (c.446-3C>G).[159] Other families with germline *MEN1* mutations only develop parathyroid tumors, a condition referred to as familial isolated hyperparathyroidism (FIHP).[148,150,160] These phenotypic variants may be due to the specific *MEN1* mutation or genetic modifiers. For example, FIHP, when compared with MEN1, is associated with a high occurrence of missense *MEN1* mutations (~38% vs. 23%, $p < .01$), and several of the FIHP missense mutations, when compared with MEN1-associated mutations, have been reported to retain menin protein stability and biologic activity, consistent with the milder phenotype.[161] However, some FIHP kindreds have the same protein-truncating mutations that occur in MEN1 families, thereby implicating a role for genetic modifiers. Germline *MEN1* mutations have also been reported in patients with apparently sporadic pancreatic NETs, although it is unclear whether all such patients were systematically evaluated for the presence of other MEN1 manifestations.[162] Independent of *MEN1* genotype, one study reported that the type O blood group was associated with an increased risk of NETs in MEN1 patients,[163] although a subsequent study found no such relationship.[164]

Finally, it should be noted that approximately 10% of patients with a clinical diagnosis of MEN1 do not harbor mutations in the *MEN1* coding region,[165] and these individuals may harbor mutations in the promoter or untranslated regions of the gene, or represent phenocopies with mutations in other genes (see later discussion).[1] In addition, some of these patients, when compared with patients with *MEN1* mutations, have been reported to present with the first endocrine tumor at a later age, to very rarely develop a third MEN1 manifestation,[165] and to have a greater life expectancy.[72,165] Thus, it seems likely that such individuals may have two coincidental sporadic endocrine tumors rather than the hereditary MEN1 syndrome.[165]

MEN1 *Polymorphisms*

At least 35 different common germline variants (i.e., polymorphisms with minor allele frequency [MAF] >0.5%) are observed in the coding and nonregions of the *MEN1* gene, comprising 5 in the coding region (3 synonymous and 2 nonsynonymous [i.e., p.Arg176Gln and p.Ala546Thr in the canonical transcript]), 20 in the intronic regions, and 10 in the untranslated regions (http://phase3browser.1000genomes.org/ and http://gnomad.broadinstitute.org/). It is important to recognize the occurrence of these polymorphisms, and especially the nonsynonymous coding region variants, as their finding in an apparently affected index case does not necessarily equate to pathogenicity, and careful evaluation of any potential novel *MEN1* mutation is required. For example, approximately 200 rare (MAF <0.5%) missense variants are observed in the GnomAD dataset (http://gnomad.broadinstitute.org/), and most of these will not be of clinical significance. The recognition of such variants as benign is becoming easier owing to the availability of large population-based databases.[145]

MEN1 Phenocopies and Mutations in Other Genes

Phenocopy refers to the development of disease manifestations, which are usually associated with a particular gene but have instead been caused by mutations in another gene or environmental factors. Phenocopies are reported in 5% to 10% of MEN1 kindreds and may occur in different clinical settings.[21,22,159,166] For example, phenocopies have been reported in the context of familial MEN1, in which patients manifesting a MEN1-associated tumor (e.g., pituitary or parathyroid tumor) do not harbor the familial *MEN1* mutation.[21,22] Phenocopies may also occur in the context of patients or kindreds presenting with an apparent clinical diagnosis of MEN1 (i.e., ≥2 MEN1-associated endocrine tumors) who do not harbor a *MEN1* mutation but instead have mutations in another gene, which is more typically associated with a different disease.[21,22] Such genes include *CDC73*, which encodes the tumor suppressor parafibromin, mutations of which result in hyperparathyroidism-jaw tumor syndrome[167]; *CASR*, which encodes the calcium-sensing receptor, mutations of which result in familial benign hypocalciuric hypercalcemia type 1 and/or FIHP[168,169]; and *AIP*, which encodes the aryl hydrocarbon receptor interacting protein, mutations of which are associated with familial isolated pituitary adenoma.[170] Finally, a small percentage of patients manifesting clinical features of MEN1 in the absence of a *MEN1* mutations may have a mutation in *CDKN1B*, which results in the associated disorder of MEN4[171,172] (see Table 42.1). Thus, the possibility of a phenocopy or an alternate genetic diagnosis should be considered in those presenting with typical or atypical manifestations of MEN1 in whom a *MEN1* mutation is not found. In addition, genetic testing should be undertaken in all kindred members where a familial *MEN1* mutation is present, irrespective of the clinical disease status of the individual.

Somatic MEN1 *Mutations*

More than 90% of tumors from MEN1 patients have LOH involving loci on chromosome 11q13, and this has generally been taken as evidence that the *MEN1* gene acts as a tumor suppressor (i.e., as a result of biallelic *MEN1* inactivation).[24,29,173] The identification of the *MEN1* gene and its encoded protein menin as a key determinant of

endocrine neoplasia has led to the investigation of its role in the development of sporadic endocrine tumors, which have been shown to have somatic inactivation of both *MEN1* alleles, which most commonly results from an inactivating point mutation or small indel affecting one allele and a large-scale deletion of the other.[148] Overall, somatic *MEN1* mutations are observed in approximately 35% of parathyroid tumors,[174,175] 40% to 45% of NF pancreatic NETs,[162,176] approximately 40% of gastrinomas,[148] 0% to 15% of insulinomas,[177] 3% to 5% of pituitary tumors,[148,178] approximately 15% to 20% of pulmonary carcinoids,[179,180] less than 3% of small intestinal NETs,[181,182] less than 3% of adrenocortical tumors, 10% of angiofibromas, and approximately 30% of lipomas.[148] The somatic mutations observed in these sporadic tumors are reported to occur throughout the *MEN1* coding region and comprise loss-of-function and missense mutations, similar to the germline mutations.[148] The identification of somatic *MEN1* mutations in sporadic tumors currently has little clinical utility, although it is possible that tumor genotyping may contribute to future personalized treatment approaches. In addition, such mutation profiling of tumors may provide prognostic information, and it has been reported that the presence of a somatic *MEN1* mutation in sporadic pancreatic NETs is associated with an improved survival when compared with those without a *MEN1* mutation.[176]

Functions of the Menin Protein and Insights Into Mechanisms of Tumorigenesis

Menin is a ubiquitously expressed protein that is located predominantly in the nucleus, and it is reported to have at least three nuclear localization signals within its C-terminus.[143,144,183] Menin is also reported to be found in the cytoplasm, where it is regulates key signaling pathways.[184] Menin, which functions as a scaffold protein, has been reported to interact with more than 20 proteins and molecules that facilitate its role in transcriptional and epigenetic regulation, genome stability, DNA repair, cell division, cell signaling, and cell motility[143,144,183] (see Fig. 42.4). The roles of menin in transcription, in which it can act as an activator and repressor, and as a component in some canonical signaling pathways, will be briefly reviewed, as these illustrate menin's ability in behaving as a tumor suppressor and oncogenic cofactor, depending on the cellular context.[183] Thus, in the majority of endocrine tissues, menin acts as a tumor suppressor, whereas in other neoplasms including leukemia, pediatric glioma, and prostate, hepatocellular, and breast cancer, it acts as an oncogene.[143,144,183,185,186]

Menin activates transcription by interacting with the mixed-lineage leukemia proteins 1 and 2 (MLL1 and MLL2) histone methyltransferase complexes,[187,188] which are responsible for histone H3 lysine 4 residue trimethylation (H3K4Me3), which causes chromatin modification and is associated with activation of transcription[187–189] (see Fig. 42.4). Menin/MLL1 occupancy has been reported to occur at the promoter regions of thousands of genes, and to generally correlate with active transcription, although menin loss is associated with changes in transcription of only a small subset of genes.[190] The menin-MLL complex is a key activator of *Hox* gene expression[187] and the p27 and p18 cyclin-dependent kinase inhibitors,[191,192] and menin physically links MLL with the lens epithelium–derived growth factor (LEDGF), which is a chromatin-associated protein required for MLL-dependent transcription that has been implicated in leukemic transformation.[193] Analysis of the crystal structure of menin in complex with MLL1 and LEDGF has demonstrated the key interacting domains, in which menin adopts a "curved left hand" structure, with the N-terminus resembling the thumb (a long β-hairpin), the central portion the palm, and the C-terminus the curved fingers.[144,194] A deep pocket within the central "palm" region forms the MLL1-binding site, whereas LEDGF is observed to simultaneously bind both menin and MLL1. Thus, menin acts as a molecular adaptor to link such proteins, and disruption to these interacting domains abrogates downstream transcriptional activity.[144,194] However, the intact menin-MLL complex enhances transcriptional activation of genes (e.g., *HOX* genes, *EZH2*) involved in leukemogenesis,[187,195,196] and small molecule inhibitors targeting this protumorigenic function of the menin-MLL interaction have been developed and are shown to be effective for the treatment of MLL-dependent leukemia in preclinical in vitro and in vivo models.[197,198] The menin-MLL complex is also reported to act as an oncogenic coactivator of androgen receptor (AR) signaling in prostate cancer, which is effectively inhibited in vivo using small molecule menin-MLL inhibitors[185]; ESR1 signaling in breast cancer, in which it recruits the transcriptional enhancers FOXA1 and GATA3 to support expression of cancer-relevant genes[183]; and platelet-derived growth factor receptor A signaling in pediatric glioma.[186] Transcriptional activation, independent of H3K4Me3 activity, has been reported to occur by a direct interaction between menin and the oncogene MYC in fibrosarcoma and hepatocellular carcinoma (HCC) cell lines.[199]

Menin regulates transcriptional repression through several direct and indirect mechanisms. Thus, menin directly interacts with JunD (see Fig. 42.4), a member of the activating protein 1 (AP1) transcription factor family,[143,144] and JunD utilizes the same menin binding pocket employed by MLL1 such that JunD and MLL1 likely compete for menin binding.[194] The binding of menin to JunD facilitates the recruitment of the Sin3 transcription regulator homolog (mSin3A) histone deacetylase (HDAC) complex to inhibit JunD-dependent transcription, and the forkhead transcription factor CHES1 associates with the menin-mSin3A transcriptional repressor complex, to regulate an S-phase checkpoint pathway related to DNA damage.[143,144,183] Menin binding to JunD blocks c-Jun N-terminal kinase (JNK)-mediated phosphorylation, thereby inhibiting post-translational modification (and subsequent activation) of JunD.[194] In addition, menin represses expression of the *PTN* gene, which encodes the pleiotrophin pro-proliferative receptor, and this increases the Polycomb gene enhancer of zeste homolog 2 (EZH2)-mediated histone H3 lysine 27 trimethylation (H3K27M3), which is a negative mark for gene transcription. Studies of HCC have revealed that elevated levels of menin, EZH2, and H3K27Me3 are associated with a poor prognosis, whereas inhibiting H3K27Me3 effectively blocked the aggressive phenotype of HCC cells.[200] Menin also recruits the transcription factor PRMT5 (see Fig. 42.4) to the promoter of the growth arrest–specific protein 1 (*GAS1*) gene, which is an important cofactor required for the binding of the Sonic Hedgehog (Shh) ligand to its cell surface receptor, and thereby acts as a negative regulator of Hedgehog signaling.[201] Menin also represses transcription mediated by members of the NFκB family, and other menin regulatory functions include modulation of gene expression through regulation of microRNA biosynthesis,[147,202] regulation of expression of nuclear receptor target genes (e.g., direct interaction with ERα), and participation in the DNA damage response in which menin undergoes phosphorylation and influences the transcriptional response through an altered affinity for RNA polymerase II.[203]

Menin modulates several canonical signaling pathways involved in endocrine and nonendocrine tumorigenesis,[92,144] which are cell- and tissue specific. For example, menin has been reported to act as a negative regulator of the Wnt/β-catenin signaling pathway (see Fig. 42.4) by regulating the phosphorylation and export of β-catenin out of the nucleus and into the cytoplasm, thereby diminishing Wnt target gene expression,[184] and loss of menin expression in human and murine pancreatic NETs has been reported to result in activation of the Wnt signaling pathway. This has provided

support for the rationale of using small molecule Wnt inhibitors for the treatment of MEN1-associated pancreatic NETs in mutant mice.[204] However, another study has reported that menin acts as a positive regulator of Wnt signaling in pancreatic endocrine cells, thereby highlighting apparent paradoxical activities dependent on the cellular environment.[205] A similar complex interplay is observed between menin and RAS signaling pathways, in which menin has been reported to determine the outcome of K-RAS signaling (see Fig. 42.4) in a cell-context specific manner within the pancreas.[206] K-RAS activation typically enhances cell proliferation, but in pancreatic endocrine cells, it suppresses proliferation; this activity is due to menin-dependent preferential activation of the antiproliferative RAS effector RASSF1A, with simultaneous suppression of the pro-proliferative RAF/MAPK pathway (see Fig. 42.4). Downregulation of menin in pancreatic endocrine cells then releases this inhibition and results in greater RAF/MAPK signaling and endocrine cell proliferation.[206] Other signaling pathways also reported to be modulated by menin expression include transforming growth factor β (TGFβ), bone morphogenetic protein (BMP), Hedgehog, AKT, and MYC pathways[92,144,189,199] (see Fig. 42.4). The better understanding of these complexities of menin function, together with the identification of key interacting proteins and alterations in major signaling pathways, has facilitated the identification of several potential novel therapeutic targets, which have been evaluated in preclinical models for both MEN1- and non–MEN1-related tumors, and these include menin-MLL inhibitors, other epigenetic-modifying agents, and Wnt inhibitors (see Fig. 42.4).

Animal Models

Menin is highly evolutionary conserved in mammalian species (i.e., 90% and 97% DNA and protein identity, respectively, between and human and mouse), whereas more evolutionary distant organisms harbor orthologues with lower degrees of similarity (e.g., zebrafish [*Danio rerio*], fly [*Drosophila melanogaster*]). Although some studies of menin function have employed these more distant model organisms (i.e., homozygote deletion of the *MEN1* orthologue *Mnn1* in *D. melanogaster* results in viable offspring but increased sensitivity to DNA damage and other environmental stressors [e.g., heat shock, hypoxia]),[207] the major insights into the in vivo function of menin have arisen from studies of conventional and conditional *Men1* mouse knockout models.[207]

Conventional Men1 *Mouse Knockout Models*

Several conventional *Men1* knockout models have been established by the targeted deletion of different exonic regions of the *Men1* gene including deletion of exons 1-2,[208] exon 2 alone,[209] exon 3,[210] and exons 3-8,[211] resulting in either the absence of *Men1* transcription (i.e., through the loss of the transcription start site) or the generation of severely truncated *Men1* transcripts.[207] Despite some subtle differences in tumor spectrum, each of these models recapitulates major features of the clinical MEN1 syndrome; thus, heterozygous ($Men1^{+/-}$) mice are observed to develop multiple tumors affecting the pancreatic islets, anterior pituitary, parathyroid, and adrenal glands.[208–211] $Men1^{+/-}$ mice also develop gonadal, thyroid, and prostate tumors that are not typically associated with MEN1 in patients.[207,208,210,211] In several instances, biochemical and/or immunohistochemical analysis have confirmed features consistent with the respective human tumors, including raised plasma insulin levels and pancreatic NETs consistent with insulinoma, raised PTH and/or hypercalcemia and parathyroid hyperplasia consistent with PHPT, plurihormonal expressing pancreatic NETs, and somatostatin receptor type 2 (SSTR2) and vascular endothelial growth factor A (VEGF-A) expression in pancreatic NETs and pituitary tumors.[208,210,211] In each of the $Men1^{+/-}$ models, the various tumors emerged in a time-dependent fashion, typically commencing at approximately 9 months, and molecular analysis of the tumors confirmed LOH at the *Men1* locus and loss of menin expression, consistent with biallelic *Men1* inactivation for tumor development, and its role as a tumor suppressor.

In each of the conventional mouse models, homozygous *Men1* ablation ($Men1^{-/-}$) is reported to result in embryonic lethality between embryonic day (E) 10.5 and 14.5 with craniofacial defects, hemorrhages, edema, and neural tube defects, as well as abnormalities of early pancreatic endocrine development.[212,213] Thus, in contrast to the situation in *D. melanogaster*, menin appears essential for viable mammalian development. However, the timing of embryonic death and the specific observed phenotypes are dependent on the background strain of mouse, indicating a possible role for genetic modifiers.[212] Furthermore, it is possible that the differences in tumor phenotype observed in each of the conventional $Men1^{+/-}$ models may also reflect similar differences in genetic background and/or influences of genetic modifiers. The potential synergy between menin and other key tumor suppressor genes has also been investigated using $Men1^{+/-}$ mice. For example, an acceleration or augmentation of tumor development was not observed in $Men1^{+/-}$ mice that also had deletion of one allele of the retinoblastoma gene ($Men1^{+/-}/Rb^{+/-}$), thereby indicating that menin and the retinoblastoma protein (pRB) act in common tumorigenic pathways.[214] This is supported by the observation that genetic ablation of the retinoblastoma binding protein 2 (RBP2; also called *JARID1A* or *KDM5A*), which is a histone demethylase that contributes to the tumor suppressor activity of pRB, decreases tumor formation, and prolongs survival of a beta-cell specific *Men1* knockout mouse model.[215] In contrast, the combined mutation of *Men1* and the cyclin-dependent kinases (CDK) inhibitor *Cdkn1b* ($Men1^{+/-}/Cdkn1b^{-/-}$) was not observed to significantly influence tumor expression, whereas disruption to *Cdkn2c* (encoding the p18 protein) accelerated endocrine tumor development in *Men1* mice ($Men1^{+/-}/Cdkn2c^{-/-}$).[216]

Conditional Men1 *Mouse Knockout Models*

The conventional *Men1* mouse models have several potential limitations to study tumor biology, and these include the incomplete penetrance of organ-specific tumor formation and the latency period required for tumorigenesis (i.e., due to the need for a somatic "second hit") such that it is difficult to study early events in tumor development. To address these deficiencies, several tissue-specific conditional knockout models have been generated, including those under temporal control, thereby enabling the consequences of controlled biallelic *Men1* inactivation to be evaluated in endocrine and nonendocrine tissues.[207] For example, a parathyroid-specific conditional mouse model, which was generated using a Cre-recombinase under the control of the PTH promoter, was found to develop hyperparathyroidism at a higher penetrance than the respective conventional $Men1^{+/-}$ model.[217] Pancreatic beta-cell specific $Men1^{-/-}$ mice, which have been generated exploiting different rat insulin promoter (RIP) Cre mouse lines, have been reported to have early-onset islet hyperplasia, followed by highly penetrant insulinoma formation, although some models also developed prolactinomas because of Rip-Cre expression in the pituitary.[207] The targeted deletion of *Men1* in both endocrine and exocrine pancreatic cells, achieved by using a Pdx1-Cre promoter, resulted in increased endocrine cell proliferation and pancreatic NET formation, but no exocrine tumor

manifestations.[218] Pancreatic α-cell-specific *Men1* knockout models surprisingly did not develop glucagonoma but instead had insulinomas, thereby suggesting the possibility of transdifferentiation of α-cells to β-cells, or the presence of modulatory paracrine effects.[219,220] Temporal regulation of beta-cell *Men1* inactivation has been achieved through the use of inducible conditional knockouts (i.e., combining established Rip-Cre *Men1* models with transgenic mice harboring an ER-Cre, thereby facilitating *Men1* ablation on exposure to tamoxifen)[207,221]; studies of these mice have revealed a rapid onset of islet cell proliferation, following *Men1* inactivation, and this mutant mouse may provide a model for investigation of early events in tumorigenesis and for assessing the effects of novel therapies on tumor development.[221]

Nonendocrine Phenotypes in Men1 *Mouse Knockout Models*

Tissue-specific inactivation of *Men1* in Pax3 or Wnt1 expressing neural crest cells resulted in mutant mice with cranial bone defects, cleft palate, and perinatal death,[222] and menin inactivation in mature osteoblasts (using an osteocalcin-cre) resulted in reduced bone mineral density, trabecular bone volume, and cortical bone thickness,[223] thereby demonstrating a critical role for menin in bone development. Hepatocyte-specific *Men1* deletion is reported to result in a high-fat diet-induced liver steatosis through a mechanism involving histone deacetylation.[224] Moreover, induction of hepatic cancers by a chemical carcinogen has been reported to be reduced in *Men1*$^{-/-}$ female mice, and studies of this model have indicated that menin plays an important epigenetic role involving H3K4Me3 in promoting liver tumorigenesis,[225]

Preclinical Evaluation of Drug Therapies in Men1 *Mouse Models*

The *Men1* knockout mouse models have been used to study several treatments, including gene therapy, new somatostatin analogues, epigenetic modulators, β-catenin antagonist, and MEK1/2 inhibitors.[92] These will be reviewed briefly.

In MEN1-associated tumors, biallelic inactivation of the *MEN1* gene is typically observed and consistent with a proposed tumor suppressor function for menin. Thus, *MEN1* gene replacement therapy offers a potential therapeutic strategy to restore menin function. To establish proof of concept, a replication-incompetent adenoviral vector containing the mouse *Men1* cDNA under a cytomegalovirus promoter was injected into the pituitary tumors of conventional *Men1*$^{+/-}$ female mice, resulting in restoration of menin expression and decreased tumor proliferation, thereby indicating the potential utility of such an approach.[226]

The efficacy of somatostatin analogue therapy has been assessed in different mouse models. Thus, pasireotide, a multiple-receptor-ligand somatostatin analogue targeting SSTR1 through SSTR3 and SSTR5, was observed to reduce proliferation and increase apoptosis of pancreatic NETs and pituitary tumors in conventional *Men1*$^{+/-}$ mice and pancreatic NETs in *Pdx1-Cre- Men1* conditional knockout mice.[227,228] Systemic pasireotide therapy was also found to reduce pancreatic NET formation in *Men1*$^{+/-}$ mice,[92,227] thereby indicating that it has chemopreventive actions. Use of a hybrid adeno-associated virus and phage displaying biologically active octreotide for targeted delivery of a tumor necrosis factor transgene to pancreatic NETs in the *Pdx1-Cre-Men1* model has shown that this can reduce tumor volume and improve survival.[229]

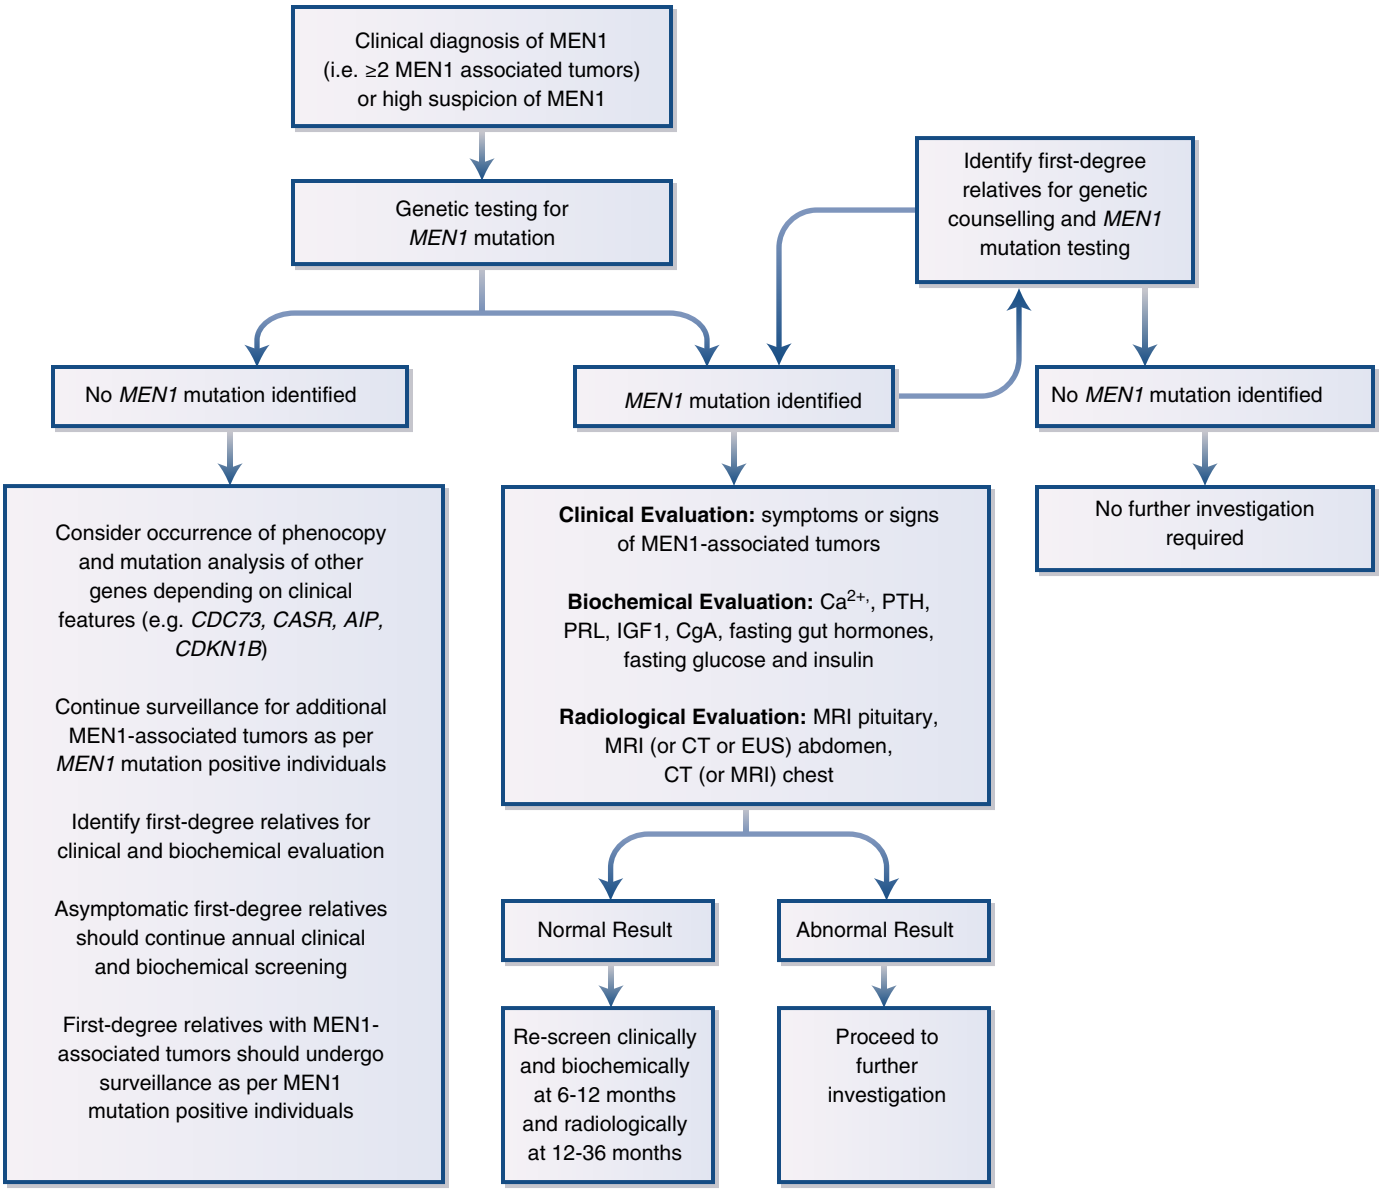
MEN1-associated tumors are reported to have alterations in epigenetic mechanisms such as histone modifications and DNA methylation, and menin interacts with several histone modifying proteins, including MLL1 and PRMT5 (see Fig. 42.4), and deacetylase complexes (e.g., histone deacetylase complex subunit MSin3A). The use of epigenetic modulators to treat pancreatic NETs, in *Men1*$^{+/-}$ mice was assessed using JQ1, an inhibitor of the bromo and extraterminal domain (BET) family of proteins that bind to acetylene residues to promote gene transcription. JQ1 reduced proliferation and increased apoptosis of pancreatic and bronchial NET cell lines in vitro, and also in pancreatic NETs, in vivo, that developed in beta-cell–specific menin knockout (*RIP-Cre-Men1*$^{-/-}$) mice.[230] Thus, inhibitors that target epigenetic mechanisms may represent a novel class of anticancer drugs in MEN1.

Other drugs that have been effective in treating pancreatic NETs in *Men1* knockout mice include WNT and K-RAS signaling modulators (see Fig. 42.4). Thus, a small molecule β-catenin antagonist (PKF115-584) reduced proliferation of the pancreatic NETs in *RIP-Cre-Men1*$^{-/-}$ mice and ameliorated the excess in insulin secretion.[204] In addition, studies of pancreatic islet cells and NETs obtained from *Ins2-Cre Men1*$^{-/-}$ mice have demonstrated that in pancreatic endocrine beta cells, K-RAS activates opposing growth pathways, but the antiproliferative pathways dominate due to menin activity, which prevents the MAPK pathway from driving growth, while leaving the RASSF1A intact (see Fig. 42.4). Thus, loss of menin in the pancreatic NETs increases proliferation due to removal of the blockage of MAPK-driven proliferation downstream of K-RAS, whereas K-RAS signaling increases proliferation by decreasing unopposed RASSF1A activity.[206] The importance of the RAF/MEK/ERK pathway in driving inappropriate growth and survival of pancreatic beta cells with reduced menin activity was further demonstrated by the use of MEK1/2 inhibitors (i.e., PD0325901 or GSK1120212) that modulate the KRAS pathway, and which revealed these inhibitors to have antiproliferative and cytotoxic actions. Thus, these may provide novel therapeutic approaches for menin-deficient tumors.

Genetic Testing, Tumor Surveillance, and Organization of Care

Clinical Utility of MEN1 *Mutational Analysis*

MEN1 mutational analysis is helpful in clinical practice in several ways that include (1) confirmation of the clinical diagnosis, (2) identification of family members who harbor the *MEN1* mutation and require screening for tumor detection and early treatment, and (3) identification of family members who do not harbor the familial germline *MEN1* mutation and can therefore be reassured[1,21] (Fig. 42.5). Current guidelines recommend that *MEN1* mutational analysis should be undertaken in (1) an index case with two or more MEN1-associated tumors (i.e., parathyroid, pancreatic islet, or pituitary tumors); (2) all first-degree relatives of a known *MEN1* mutation carrier irrespective of whether they are asymptomatic or manifest associated clinical features (i.e., having symptoms, signs, or biochemical and/or radiologic evidence of one or more MEN1-associated tumors); and (3) in patients with suspicion of MEN1 or atypical manifestations, which include those with a parathyroid adenoma below the age of 30 years and/or multigland parathyroid disease, gastrinoma, or multiple pancreatic NETs presenting at any age, or individuals who have two or more MEN1-associated tumors that are not exclusively limited to the classic triad of parathyroid, pancreatic islet, and parathyroid tumors (i.e., parathyroid plus adrenal tumor).[1,21] These recommendations are supported by results from several studies. Thus, a



• **Fig. 42.5** An approach to genetic testing and tumor screening in MEN1. Index cases, or individuals in whom there is a high suspicion of clinical MEN1, should be offered genetic counseling and *MEN1* mutation testing. The identification of a germline MEN1 mutation should prompt entry into a periodic clinical, biochemical, and radiologic screening program. At the same time, all first-degree relatives should be identified and offered genetic counseling and *MEN1* mutation testing irrespective of whether they express clinical features of MEN1 or are asymptomatic. Individuals who have inherited the *MEN1* mutation should enter periodic screening. First-degree relatives who have not inherited the *MEN1* mutation require no further follow-up and may be alleviated of the anxiety associated with the development of MEN1-associated tumors. For index cases in whom no *MEN1* mutation is identified (including the exclusion of partial or whole gene deletions [e.g., by multiplex ligation-dependent probe amplification analysis]), additional genetic testing may be indicated depending on the specific clinical features. This may include examination for mutations in genes associated with familial parathyroid syndromes including *CDC73* associated with the hyperparathyroidism-jaw tumor syndrome (HPT-JT) and the calcium-sensing receptor (*CASR*) associated with familial benign hypercalciuric hypercalcemia (FBHH), or cyclin-dependent kinase 1B (*CDKN1B*) and aryl hydrocarbon receptor interacting protein (*AIP*), which are rarely identified in those with clinical MEN1. Up to 10% of kindreds with clinical MEN1 may harbor phenocopies emphasizing the importance of accurate genetic evaluation. For MEN1 kindreds in whom no *MEN1* mutation is identified, a pragmatic approach is to offer clinical, biochemical, and radiologic screening to those with clinical manifestations of disease and to offer annual clinical and biochemical screening to asymptomatic first-degree relatives. Ca^{2+}, calcium; *CgA,* chromogranin A; *CT,* computed tomography; *EUS,* endoscopic ultrasound; *IGF1*, insulin-like growth factor 1; *MEN1,* multiple endocrine neoplasia type 1; *MRI,* magnetic resonance imaging; *PRL,* prolactin; *PTH,* parathyroid hormone. (Redrawn from Thakker RV, Newey PJ, Walls GV, et al. Clinical practice guidelines for multiple endocrine neoplasia type 1 (MEN1). *J Clin Endocrinol Metab.* 2012;97[9]:2990–3011.)

study of 200 patients with endocrine tumors reported that *MEN1* mutations occurred in more than 70% of individuals with two or more of the major MEN1-associated endocrine tumors (e.g., parathyroid, pancreatic pituitary tumors) and a family history of these tumors; approximately 60% of individuals with at least one of the major endocrine tumors and a first-degree relative with a major endocrine tumor; and 6% of patients with sporadic (i.e., nonfamilial) MEN1-associated endocrine tumors referred for testing, although the *MEN1* mutations were only observed in patients who had multiple endocrine tumors and/or were younger than 30 years of age.[231] In addition, another study has reported that the likelihood of finding a *MEN1* mutation correlates with the presence of clinical features, with 80% of index cases presenting with three MEN1-related tumors having a germline MEN1 mutation, which increased to more than 90% if family history revealed the presence of affected relatives, whereas only 15% of patients presenting with a single MEN1-associated tumor had a *MEN1* mutation, and this decreased to 0% when the family history revealed the absence of affected relatives.[232] A study of 205 patients with PHPT and a family history of PHPT revealed that approximately 45% had a *MEN1* mutation, and that multigland disease, male sex, and age younger than 45 years were independent predictors for an associated germline mutation, with odds ratios of 14, 1.7, and 8, respectively.[233] Finally, a study of 39 patients with atypical presentation (i.e., pituitary adenomas with pheochromocytoma/paraganglioma) identified two patients with germline *MEN1* mutations.[234] All of these studies indicate that failure to undertake genetic testing may result in a missed opportunity for early diagnosis.[1,235]

Following the genetic diagnosis of MEN1, predictive genetic testing should be offered to all first-degree relatives (see Fig. 42.5), and current guidelines recommend that this should be undertaken at the earliest opportunity.[1] Indeed, delays in the genetic diagnosis of first-degree relatives of an affected index case are reported to result in increased morbidity, highlighting the need for proactive cascade testing within MEN1 kindreds.[236] However, there are several ethical issues to consider, and pretest counseling and transparency are essential. Thus, patients may be concerned by the implications of finding a causative mutation on other family members, future reproductive decision making, and the potential for financial or societal discrimination. Indeed, a frequent concern of patients undergoing genetic testing is the potential implications on future employment or ability to get insurance, although many countries have legislation in place to protect individuals from such genetic discrimination. For example, in the United States, the Federal Genetic Information Nondiscrimination Act prohibits health insurance companies or employers from using genetic information to determine eligibility for health insurance coverage, or decisions in employment-related matters (i.e., hiring, promotion), respectively. With appropriate genetic counseling, most patients conclude that the potential benefits of genetic testing outweigh the potential harms. A further consideration involves the genetic testing of children, which is frequently undertaken with parental consent. Indeed, in view of the high penetrance of early-onset MEN1-associated tumors,[19] it is recommended that at-risk asymptomatic children (i.e., offspring of an affected parent) undergo genetic testing in the first decade of life and ideally before 5 years of age.[21,174]

Preconception genetic counseling, where appropriate, should be provided to individuals at risk of transmitting *MEN1* to their future offspring (i.e., symptomatic or asymptomatic *MEN1* mutation carriers), and advances in genetic testing combined with in vitro fertilization can now offer potential parents the opportunity to have preimplantation genetic diagnosis. This may be achieved by the direct sequencing of DNA from a small number of cells obtained from the early blastocyst, with subsequent implantation of only those embryos identified to not carry the mutation, thereby markedly reducing the risk of transmitting the genetic disease to the child.

Finally, it is important to emphasize that all MEN1 genetic testing should be undertaken in accredited genetics laboratories using validated testing strategies that adequately sequence all exonic and splice-site regions of the *MEN1* gene, thereby facilitating the reliable detection of all single nucleotide variants or small insertions or deletions (indels). In the absence of such mutations, multiplex ligation-dependent probe amplification should be employed to detect partial or whole gene deletions.

Surveillance of "At-Risk" Individuals

Current guidelines recommend that all individuals at high risk for MEN1 (i.e., mutant gene carriers) undergo periodic clinical, biochemical, and radiologic screening to facilitate the early detection and treatment of tumors with the aim of reducing their associated morbidity and mortality[1] (Table 42.2; see Fig. 42.5). Although it seems logical that such screening programs are likely to be beneficial, high-quality evidence supporting their effectiveness has not been established. However, most clinicians recommend the implementation of interval surveillance, although the frequency and scope of investigation is debated.[19,72,85] Two particularly controversial areas involve the detection of NF pancreatic NETs and thymic carcinoid tumors, which represent the two leading causes of premature MEN1-related death. In particular, the age to begin screening, the use of biochemical tumor markers, and the optimal radiologic approach are areas that are controversial and under debate.[19,85,98,99,237] For example, current guidelines recommend commencing pancreatic imaging from the age of 10 years, and this is supported by several reports that indicate a high penetrance of NF-NETs in the second decade of life.[19,97,101] However, some centers recommend that imaging should be delayed until at least 16 years. Similarly, for thymic carcinoid tumors, the rapid growth rates and aggressive disease course would favor at least annual screening with thoracic CT, but the high cumulative ionizing radiation dose associated with such a schedule is considered unacceptable, particularly as such tumors occur in only a minority of MEN1 patients. Another controversial topic relates to breast screening in women with MEN1, with some groups advocating screening from age 40 years because of the reported increased relative risk of breast cancer.[139,141] Thus, several uncertainties exist, and it is important to individualize these current recommendations to the patient, and to adapt them for the local availability of resources and wishes of the patient, who should be involved in the decision-making process. For example, a recent study highlights that the majority of MEN1 patients are highly fearful of disease occurrence, both for themselves and their relatives, which may be compounded by regular surveillance screening.[238] Furthermore, this psychological distress is reported to be associated with a lower health-related quality of life, and these factors should be considered.[238]

MEN Types 2 and 3

MEN2, which has been referred to as MEN2A and Sipple syndrome, is an autosomal dominant disorder with a reported incidence of 1 in 80,000 to 200,000 live births, which is characterized by the occurrence of medullary thyroid carcinoma

TABLE 42.2 Suggested Screening Guidelines for Individuals at Risk of MEN1

MEN1-Associated Tumor	Age to Begin Screening (Years)	Biochemical Screening Test (Annually)	Imaging Screening Test (Time Interval)
Parathyroid	8	Calcium, PTH	None
Pancreatic			
Gastrinoma	20	Fasting gastrin	None
Insulinoma	5	Fasting glucose (± insulin)	None
Other pancreatic NET (e.g., nonfunctioning)	10	Chromogranin A, gastrointestinal hormone profile[a] (e.g., glucagon, pancreatic polypeptide, vasoactive intestinal peptide)	MRI abdomen, EUS (annually)
Pituitary			
Prolactinoma	5	Prolactin	None
Somatotropinoma	5	Insulin-like growth factor 1	None
Other pituitary adenoma (e.g., nonfunctioning NET)	10[b]	None, unless signs or symptoms of functioning tumor (e.g., corticotroph adenoma)	MRI pituitary (every 3 years)
Adrenocortical	<10	None, unless signs or symptoms of functioning tumor or tumor >1 cm on imaging	MRI abdomen (annually)
Thymic/bronchial carcinoid	15	None	CT or MRI chest (every 1–2 years)

[a]Although chromogranin A, pancreatic polypeptide, and glucagon concentrations can be elevated with nonfunctioning PNETs, they have low sensitivity and specificity such that their value is debated.

[b]Although pituitary tumors are reported in MEN1 patients as young as 5 years of age, in the absence of symptoms, signs, or biochemical evidence of a pituitary adenoma, pituitary imaging may be delayed until after 10 years of age to coincide with pancreatic imaging.

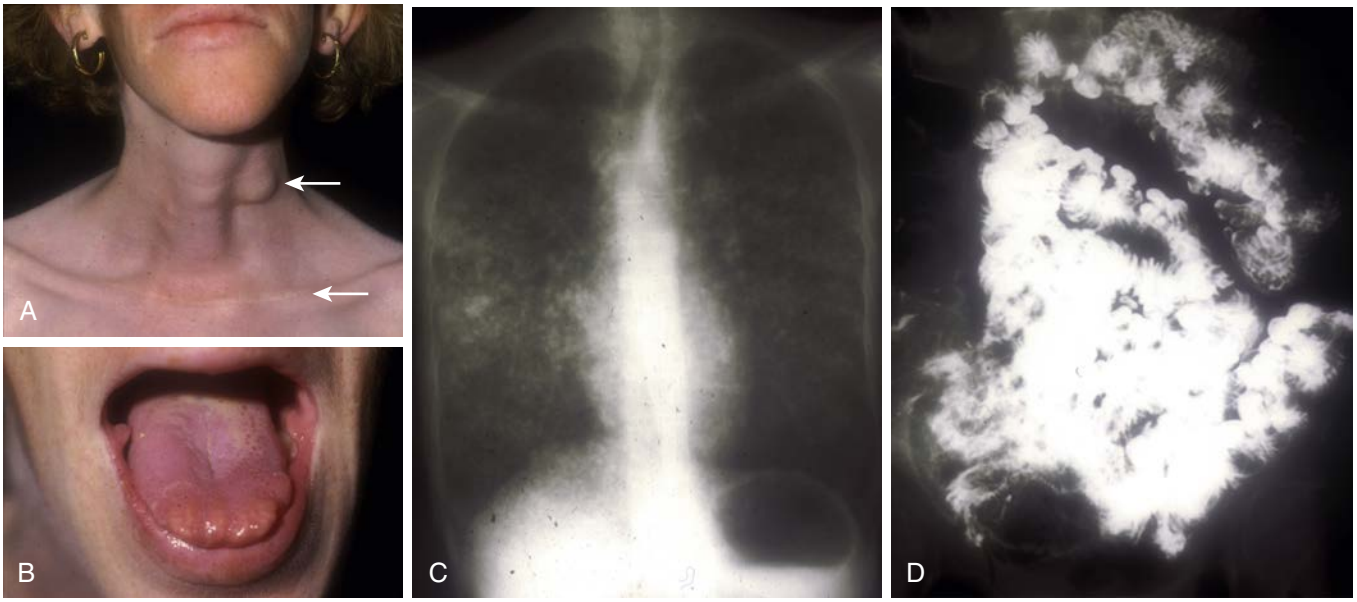
(MTC) in association with pheochromocytoma and parathyroid tumors.[3,239,240] MEN2 also includes three variants, which are MEN2A with Hirschsprung disease (HSCR), MEN2A with cutaneous lichen amyloidosis (CLA), and familial MTC-only (FMTC),[3] in which MTC is the sole manifestation of the syndrome. MEN3, also referred to as MEN2B, is characterized by the occurrence of MTC and pheochromocytoma, without PHPT, but in association with a marfanoid habitus, mucosal neuromas, medullated corneal fibers, and intestinal autonomic ganglion dysfunction leading to megacolon[3] (Fig. 42.6). MEN2 is more common than MEN3, with MEN2 accounting for greater than 90% and MEN3 between 5% and 10% of patients, although MTC in MEN3 usually arises in infancy and has a more aggressive course.[3]

Historically, the association between thyroid carcinoma and pheochromocytoma was first reported by Sipple[241] in 1961, with Cushman and Rochester reporting a family with autosomal dominant inheritance of pheochromocytomas, MTC, and parathyroid adenoma,[242] and Steiner and colleagues[243] in 1968 proposing the term *MEN2* to describe a family with MTC, pheochromocytoma, PHPT, and Cushing syndrome. The association of multiple neuromas, pheochromocytoma, and MTC was reported by Williams and Pollock[244] in 1966, and Schimke and colleagues[245] in 1968, and Chong and colleagues[246] in 1975, used the term *MEN2B* to describe this disorder. Interestingly, the first descriptions of MEN2A and pheochromocytoma, in 1886, were in an 18-year-old woman who had bilateral adrenal tumors, and whose relatives, in the Black Forest in Germany, have subsequently been reported to have pheochromocytoma and MTC due to a rearranged during transfection (*RET*) mutation (Cys634Trp), indicating that this patient and family have MEN2A.[247] The first descriptions of patients with likely MEN3 were in 1922 and 1923 by Wagenmann[248] and Froboese,[249] respectively.

Genetic studies of MEN2 and MEN3 families throughout the 1980s and 1990s led to the demonstration that mutations of the RET proto-oncogene, which is located on chromosome 10q11.21 and encodes an RTK, caused the MEN2 and MEN3 syndromes. Approximately 95% of MEN2 *RET* mutations involve the cysteine-rich extracellular domain (ECD), with mutations of Cys634 accounting for approximately 85% of all MEN2 mutations, whereas approximately 95% of MEN3 *RET* mutations are of Met918, which is located in the intracellular tyrosine kinase (TK) domain (Table 42.3 and Fig. 42.7; see Table 42.1). Moreover, the identification of these *RET* mutations, which reliably predict the risk of MTC with regard to its clinical expression and age of onset, have transformed the management of patients, as it has helped to determine the timing of prophylactic thyroid surgery that is highly effective in avoiding the morbidity and mortality associated with MTC. Indeed, prophylactic thyroidectomy, with lifelong thyroxine replacement, has dramatically improved outcomes in the patients with MEN2 and MEN3 such that 90% of young patients with *RET* mutations who had a prophylactic thyroidectomy had no evidence of persistent or recurrent MTC at 7 years after surgery.[250] To facilitate management of MTC in MEN2 and MEN3 patients, the American Thyroid Association (ATA) has defined three categories for germline *RET* mutations that are based on their correlations between genotype and phenotype (e.g., aggressiveness of MTC), and these comprise highest risk (MEN3-associated Met918Thr mutation), high risk (Cys634 and Ala883Phe mutations associated with MEN2 and MEN3, respectively), and moderate risk (all other MEN2 *RET* mutations)[3] (Table 42.4; see Table 42.3). For asymptomatic individuals identified to harbor *RET* mutations, current recommendations for tumor surveillance and treatment are based on these risk categories, with the aim of identifying *RET* mutations at a sufficiently early age



• **Fig. 42.6** Clinical features in a patient with multiple endocrine neoplasia type 3. The patient has evidence of a nodule in the left side of the neck representing metastases from medullary thyroid carcinoma (indicated by the *upper arrow*). Note the thyroidectomy scar (*lower arrow*) (A). Mucosal neuromas are evident on the tongue and lips (B). Chest x-ray demonstrating bilateral lung metastases of medullary thyroid carcinoma (C). Radiograph of barium meal and follow through demonstrating multiple intestinal diverticula, which are secondary to autonomic ganglion dysfunction (D). The patient had a history of diarrhea and malabsorption. (Modified from Thakker RV. Multiple endocrine neoplasia. *Medicine.* 2013;41[10];562–565.)

• **Fig. 42.7** RET receptor structure highlighting the main functional domains and locations of common multiple endocrine neoplasia type 2 (MEN2)-associated *RET* mutations (A). MEN2-associated mutations arise most frequently in the cysteine-rich region of the extracellular (EC) domain, or in the intracellular (IC) tyrosine kinase domain, which are linked by the transmembrane domain (TM). The mutations shown represent those most commonly observed in MEN2 and MEN type 3 (MEN3), although additional *RET* mutations

Continued

Fig. 42.7, cont'd have been described in small numbers of kindreds. The American Thyroid Association risk category of *RET* mutation is also indicated: "highest" risk, *red*; "high" risk, *blue*; "moderate" risk, *green*. Mutations associated with MEN3 are noted in parentheses. All other mutations are associated with MEN2. RET receptor activation occurs following binding of members of the glial cell–line derived neurotropic factor (GDNF) family of ligands (GFLs), which comprise GDNF (shown), neurturin, persephin, and artemin (B). However, binding is mediated by a coreceptor, represented by members of the GDNF family receptor α group of proteins (GFRα1 shown). Thus, once formed, the GFL-GFRα complex engages RET, facilitating receptor dimerization and receptor activation, resulting in autophosphorylation of specific tyrosine residues within the tyrosine kinase domain, and subsequent recruitment and activation of downstream signaling complexes. Mutations associated with MEN2 are associated with ligand-independent receptor activation but achieve this by different mechanisms (C). MEN2 mutations in the extracellular (EC) cysteine-rich domain result in ligand-independent receptor dimerization mediated by disulphide-bond (S) formation between unpaired cysteine residues, resulting in constitutive receptor activation. In contrast, MEN2-associated mutations affecting the intracellular (IC) tyrosine kinase domain result in receptor activation in monomeric form. The MEN3 Met918Thr mutation also results in monomeric ligand-independent receptor activation but potentially may be further enhanced by the presence of RET ligand, thereby facilitating receptor dimerization and even higher levels of receptor signaling. However, the in vivo role of such ligand-enhanced activity in association with the Met918Thr mutation remains uncertain (represented by double question marks [??]). (A, modified from Newey PJ. Multiple endocrine neoplasia. *Medicine.* 2017;45[9]:538–542.)

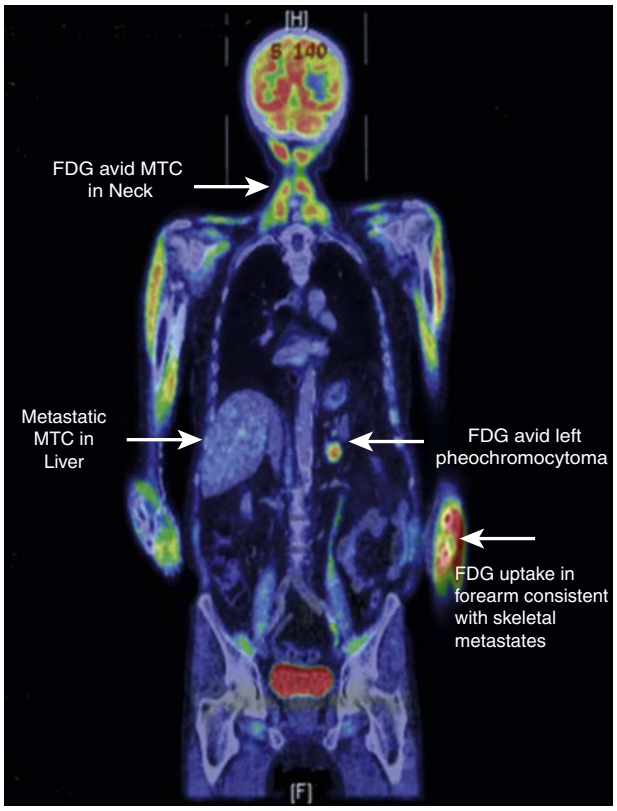
(i.e., often in the first months or years of life) to provide a window of opportunity for "prophylactic" thyroidectomy. In addition, the identification of a MEN2-associated *RET* mutation in an affected patient should prompt screening of all first-degree relatives, and the possibility of MEN2 or MEN3 should be considered in all patients presenting with MTC or pheochromocytoma, and germline *RET* genetic testing undertaken. However, it is important to note that de novo *RET* mutations are observed in 5% to 10% and approximately 75% of individuals with MEN2 and MEN3, respectively. These advances in our understanding of RET and RTKs have also resulted in the use of RTK inhibitors for the treatment of advanced and metastatic MTC. The treatment of patients presenting with one or more of the clinical manifestations of MEN2 and MEN3 require a multidisciplinary approach involving surgeons, oncologists, endocrinologists, and geneticists to ensure the optimal therapeutic approach.

Clinical Features and Management

Medullary Thyroid Carcinoma

Clinical Features

MTC is the most common and often the first manifestation of MEN2 and MEN3, and it occurs in almost all affected individuals (Fig. 42.8; see Fig. 42.6). MTC, which also represents the major cause of premature morbidity and mortality, frequently presents in children. Thus, early detection and treatment of MTC is important, and widespread implementation of *RET* mutation testing has transformed the management of patients from MEN2 and MEN3 families in whom the causative *RET* mutation is known. Indeed, the identification of *RET* as the causative gene for MEN2 and the subsequent ability to undertake genetic testing of "at-risk" first-degree relatives has resulted in a shift in clinical presentation from those presenting with a neck mass and advanced disease to



• **Fig. 42.8** ^{18}FDG-PET scan showing MTC with liver and skeletal metastasis and PET-avid uptake by the left adrenal pheochromocytoma in a patient with MEN2 due to a Cys634Arg *RET* mutation. *FDG*, fluorodeoxyglucose; *MEN2*, multiple endocrine neoplasia type 2; *MTC*, medullary thyroid carcinoma; *PET*, positron emission tomography (From Naziat A, Karavitaki N, Thakker R, et al. otherwise asymptomatic *RET* mutation carriers, who are recommended to have prophylactic thyroidectomy that substantially reduces their likelihood of developing advanced MTC.[250,251] Furthermore, widespread availability of *RET* genetic testing that identifies presymptomatic individuals who then undergo a prophylactic thyroidectomy has resulted in a significant fall in the proportion of MEN2 cases who present as index cases with MTC.[252] However, in the absence of a relevant family history (and/or prior knowledge of *RET* genetic status), the presentation of MTC is typically with a palpable neck mass, which may be asymptomatic or associated with symptoms of pressure or dysphagia in more than 15% of patients, although it should be noted that only a small minority (0.3–1.4%) of the population presenting with thyroid nodules harbor an underlying MTC.[3] For such index cases presenting with MTC (i.e., with a neck lump), regional and/or distant metastases are frequently evident at the point of diagnosis, and surgical cure is rarely achieved. MTC and pheochromocytoma may be present synchronously, and this possibility should be considered prior to any thyroid surgical intervention, particularly if the results of *RET* genetic testing are unavailable. Additional symptoms associated with MTC include diarrhea, which is reported in approximately 30% of patients, and/or flushing, each reflecting high circulating concentrations of calcitonin or other tumor-secreted hormones (e.g., serotonin, prostaglandins). Diarrhea occurs most frequently in those with advanced disease and most often in the presence of liver metastases.[3] The ectopic production of ACTH or corticotropin-releasing hormone from MTC may give rise to Cushing syndrome, and 1% to 3% of all cases of ectopic Cushing syndrome are due to MTC.[253] In those presenting with a neck mass, lymph node and distant metastases are frequently present at the time of diagnosis, and the extent of lymph node involvement provides important prognostic information.[3,254] The cervical and mediastinal nodes are the most common sites of local metastases, whereas distant spread typically involves bone, liver, lung, or brain.

MTC occurs following the malignant transformation of parafollicular C cells, which are concentrated in the middle and upper regions of the thyroid gland. The embryologic origins of the parafollicular C cells are considered to be of neuroectodermal origin, although there may be species-specific differences.[255] In mammalian species, C cells are reported to be derived from a subpopulation of ectodermal-derived neural crest cells that migrate to the most inferior pharyngeal arch (i.e., fourth arch), whereby they merge with a pair of endoderm-derived ultimobranchial bodies and become part of the developing thyroid gland.[255] C cells secrete several biogenic amines and peptides, including calcitonin, an evolutionary conserved hormone that is involved in calcium homeostasis. However, the physiologic function of calcitonin in mammalian species is unknown, as an absence of the hormone either by genetic knockout of the calcitonin gene in mice, or thyroid dysgenesis in humans, does not affect viability or bone development and indeed is associated with a normal development and a normal phenotype.[255] The transformation of C cells to MTC occurs along a multistep pathway, which initially involves C-cell hyperplasia (CCH), followed by noninvasive microscopic MTC (i.e., <1 cm), that progresses to invasive carcinoma with lymph node and distant metastases.[239] The molecular basis of each of these stages remains ill defined, although aberrant *RET* signaling almost certainly represents the key initiating event in tumor formation. In the context of MEN2, MTC is frequently multifocal and bilateral, occurring in the upper two thirds of the thyroid corresponding to the highest concentration of C cells, and it is likely that the CCH observed early in the disease course represents monoclonal proliferation of transformed progenitor cells rather than hyperplasia per se.[3] The secretory capacity for calcitonin is usually retained throughout each stage of tumor development, thereby providing a valuable tumor marker, with clinical utility for both MTC diagnosis and subsequent tumor surveillance (i.e., detecting residual, recurrent, or progressive disease).[3] Thus, the diagnosis of MTC relies on the demonstration of high basal serum calcitonin concentrations together with supporting cytologic/histopathologic evidence.[3]

Neck ultrasound with fine-needle aspiration (FNA) is the initial investigation of choice for individuals presenting with a solitary thyroid nodule, whereas radionuclide thyroid scans may reveal MTC tumors as "cold" nodules. MTC may display variable cytologic appearances and on occasion may be misdiagnosed as other tumor types.[3] Typical cytologic appearances include the presence of discohesive or weakly cohesive cells, which may be spindle shaped or have plasmacytoid or epithelioid appearances.[3] Important cytologic criteria for MTC are reported to include a dispersed pattern of polygonal or triangular cells, azurophilic cytoplasmic granules, extremely eccentrically placed nuclei with coarse granular chromatin, and amyloid.[3] Some studies have reported a high diagnostic accuracy of FNA in MTC (i.e., >80%), but a meta-analysis of 15 studies and 641 MTC cases reported a detection rate of approximately 55%, with several specimens that were initially classified as indeterminate or benign being subsequently found to be MTC; however, many specimens that were not identified as MTC were found to be malignancies, thereby indicating a need for surgery.[3,256] For aspirate

results that are suspicious for MTC or indeterminate, the diagnostic accuracy may be improved by measuring calcitonin levels in the FNA washout fluid and/or undertaking additional immunohistochemical evaluation for neuroendocrine markers including calcitonin, chromogranin, and carcinoembryonic antigen (CEA).[3,257]

Once MTC is suspected, the measurement of basal serum calcitonin levels should be undertaken. Modern commercial immunochemiluminometric assays are highly sensitive and specific for monomeric calcitonin and do not typically display cross reactivity for procalcitonin or other calcitonin-related peptides. However, elevated serum calcitonin concentrations may be observed in other conditions, such as chronic renal failure, parathyroid disease, thyroiditis, lung and prostate cancers, and other NETs, thereby diminishing the specificity of basal calcitonin levels for diagnosis of MTC.[3] Elevated (or occasionally inappropriately low) calcitonin levels may also occur in the presence of heterophile antibodies, whereas false-negative or inappropriately low calcitonin levels may occasionally be observed due to the "Hook effect," in which very high levels of serum calcitonin saturate the binding capacity of the antibody in the immunoassay, although the likelihood of this is reduced with modern immunochemiluminometric assays. Inappropriately low serum calcitonin concentrations (i.e., relative to disease stage) may also rarely occur in the setting of advanced MTC, in which tumor dedifferentiation results in reduced calcitonin secretion.[3] Finally, occasional case reports of calcitonin-negative MTC presenting with a solitary thyroid nodule have been reported.[258] Reference ranges for basal serum calcitonin levels are assay specific, which must also take into account age-related and sex-dependent factors. For example, serum calcitonin concentrations are typically higher in males than females, reflecting a higher total C-cell mass. In addition, serum calcitonin levels are elevated in infants and young children, and age-specific reference ranges are required until 2 to 3 years of age, after which serum calcitonin concentrations are indistinguishable from those of adults.[3,259] Establishing a serum calcitonin concentration below which the diagnosis of MTC can be confidently excluded in a patient presenting with a thyroid nodule remains challenging, as false positives occur frequently.[260] Thus, routine measurement of basal serum calcitonin concentrations in all patients presenting with thyroid nodules and before an FNA is controversial. Advocates of calcitonin measurement pre-FNA cite the need for early diagnosis given the low cure rates observed once MTC spreads beyond the thyroid. However, the very low overall frequency of MTC in this setting (i.e., <1%) raises concerns over cost effectiveness, whereas the potential for iatrogenic morbidity in those with raised basal serum calcitonin levels, but no subsequent MTC, has not been fully evaluated.[261] Thus, current guidelines recognize differences in clinical practice and do not make any clear recommendation.[3] Previously, provocation tests with potent secretogogues including calcium and pentagastrin, which were commonly used to improve the diagnostic value of serum calcitonin measurements, are now employed less frequently.[3] In addition to calcitonin, other biomarkers that may be associated with MTC include CEA, although this is not specific for MTC and has little role in establishing the diagnosis but may be useful for monitoring disease progression,[3] and others such as serum carbohydrate antigen 19.9, which may be associated with MTC but is not routinely employed for diagnosis.[262]

Once the diagnosis of MTC has been made by FNA of a thyroid nodule and demonstration of an elevated basal serum calcitonin concentration, further investigations are required to determine the likely extent of disease. Thus, preoperative staging with neck ultrasound is mandatory, whereas cross-sectional imaging, using CT or MRI, should be undertaken in those in whom metastatic disease is suspected, which is usually based on extensive neck disease and/or very high serum calcitonin levels (e.g., >500 pg/mL). CT is used widely to detect lung and mediastinal lymph node involvement, whereas complementary additional modalities (e.g., MRI, bone scintigraphy) are employed to detect metastases at other locations. FDG-PET/CT or F-DOPA-PET/CT, which may be helpful (see Fig. 42.8), is not readily available in many centers. Finally, for the investigation of MTC, it is important to undertake *RET* germline genetic testing in all patients, and for those who have a mutation (or for those in whom there is likely to be a significant delay in testing), the presence of pheochromocytoma and PHPT should be excluded prior to surgery.[3]

MTC is highly penetrant in MEN2, with 70% to 100% of affected individuals developing disease by the age of 70 years. There is a strong genotype-phenotype correlation such that the timing of MTC is predicted (at least in part) by the specific *RET* mutation, and the current ATA risk categorizations of germline *RET* mutations are based on the potential "aggressiveness" of MTC, which in turn is based on the age of onset rather than tumor behavior[3,263] (see Table 42.4). Thus, the ATA highest risk category, represented by the Met918Thr mutation in association with MEN3, is invariably associated with MTC initiation during the first few years of life, and macroscopic disease may occur before the age of 1 year. Indeed, the earliest reported case of MTC in MEN3 is 9 weeks of age, and lymph node metastases have been identified in the first year of life.[264,265] However, the high frequency of de novo mutations in MEN3 patients frequently results in a delayed diagnosis of the associated MTC until the second decade of life (i.e., mean age of diagnosis ~14 years), by which time spread beyond the thyroid is invariably present and the opportunity for curative treatment missed.[264–266] Indeed, MTC is the leading cause of death in MEN3 and is associated with an apparent aggressive disease course such that it has a worse 10-year survival than the MTC occurring in MEN2, although this may, in part, reflect the earlier age of onset and typical later stage of diagnosis.[265]

MTC occurs in MEN2 and MEN3 patients with ATA high-risk *RET* mutations (i.e., codon Cys634 mutations and the Ala883Phe mutation, respectively), with a median age of diagnosis of 20 to 25 years, although it has been reported in those younger than 5 years of age.[263,267] However, in these high-risk *RET* mutation carriers, lymph node metastases are unusual in those younger than 10 years of age,[3,268] and different codon 634 mutations may be associated with subtle differences in MTC expression. For example, the penetrance of MTC is reported to be higher in carriers of the Cys634Arg mutation when compared with other codon 634 substitutions.[269,270] MEN2 patients with ATA moderate-risk *RET* mutations (i.e., all other *RET* mutations excluding Met918Thr, those of Cys634 and Ala883Phe) have a median age of MTC onset that is typically later than those with higher-risk mutations, but this may be highly variable. For example, in a series of 127 patients with moderate-risk *RET* mutations, the median age of MTC diagnosis was 42 years, with a range of 6 to 86 years.[263] Furthermore, despite the later age of MTC diagnosis in moderate-risk compared with high-risk mutation carriers, no difference in clinical course was observed, suggesting that the *RET* mutations predominantly influence age of onset rather disease aggressiveness per se.[263] In addition, recent studies indicate that it may be possible to further subdivide the ATA moderate-risk category to include moderate-high risk groups, such as mutations affecting codons Cys611, Cys618, and Cys620, and moderate-low risk groups, such as mutations affecting codons Leu790, Val804,

and Ser891, according to the age-related progression of MTC.[267] The penetrance of MTC associated with certain moderate-risk *RET* mutations (e.g., Val804Met) is also likely to be significantly reduced, as indicated by a higher than anticipated frequency of individuals harboring the variant in the background population.[145,271] Thus, the risk and age-related penetrance of MTC is strongly determined by codon-specific *RET* mutations, although additional genetic and/or environmental modifying factors are likely to influence disease expression. For example, the risk of MTC (and other MEN2 clinical features) in individuals with a specific *RET* mutation may also be influenced by additional *RET* coding variants and/or the background *RET* haplotype.[272,273]

Treatment

Surgery, comprising total thyroidectomy with dissection of cervical lymph node compartments, is the recommended treatment for sporadic and hereditary MTC, as it offers the best chance of achieving cure. For recurrent or metastatic MTC, several different treatment strategies (e.g., locoregional cytoreductive surgery, external beam radiotherapy, radio-frequency ablation, chemoembolization, and systemic targeted therapies such as RTK inhibitors) are available.

The majority of patients presenting with MTC in the context of a thyroid nodule will have evidence of lymph node metastases at diagnosis, and the extent of surgery remains controversial. In addition, index cases with MEN2 may have multifocal and/or bilateral disease, and the degree of cervical lymph node involvement and/or presence of distant metastases will influence the extent of surgery. Preoperative basal serum calcitonin concentrations have been reported to be associated with the degree of cervical lymph node involvement and are used in some centers to make decisions on the extent of lymph node resection. For example, a study of 300 treatment-naive MTC patients reported that the presence of lymph node metastases in the ipsilateral central and lateral neck, contralateral central neck, contralateral lateral neck, and upper mediastinum were associated with basal serum calcitonin concentrations above 20, 50, 200, and 500 pg/mL, respectively,[274] and that bilateral compartment-oriented neck surgery could achieve biochemical cure in more than 50% of patients with pretreatment calcitonin levels of 1000 pg/mL or higher, whereas such outcomes were not achieved in patients with preoperative calcitonin levels of 10,000 pg/mL or higher.[274] Postoperative biochemical remission or cure is important, as it is associated with low recurrence rates and excellent long-term survival rates of 98% at 10 years.[275,276] Prognostic information on lymph node involvement and surgical cure rates has also been reported for CEA.[277] For example, preoperative serum CEA concentrations greater than 30 ng/mL are reported to indicate central and ipsilateral lateral lymph node metastases, whereas serum CEA concentrations greater than 100 ng/mL are reported to signify the presence of contralateral lateral lymph node involvement and/or distant metastases.[277] However, consensus has not been reached on the optimal surgical approach for MTC with regard to the extent of lymph node resection, and the current guidelines suggest total thyroidectomy and central compartment lymph node clearance in patients with MTC and no evidence of cervical lymph node metastases on ultrasound, whereas removal of lymph nodes in the lateral compartments may be considered based on calcitonin levels.[3] If there is cervical lymph node involvement, then dissection of the central and involved lateral compartment is recommended, although if the lateral compartment on the opposite side to that of the MTC is observed to be free of disease, then decisions on lymph node removal in this area may be based on calcitonin levels.[3]

In patients with regional lymph node involvement, total thyroidectomy and bilateral lymph node dissection frequently fails to achieve biochemical cure. For example, in those with involvement of 1 to 10 cervical lymph nodes involved, immediate postoperative normalization of serum calcitonin is achieved in only 31% to 57% of patients, whereas in those with involvement of more than 10 cervical nodes, biochemical remission is observed in 0% to 4%.[278,279] Thus, the presence of lymph node metastases is a poor prognostic factor, and the number of involved lymph nodes has also been reported to provide prognostic information on the likelihood of developing distant metastases.[254,280] In addition, it has been reported that in patients undergoing thyroidectomy and lymphadenectomy for MTC that a higher number of lymph nodes harvested at surgery (i.e., lymph node yield)—a surrogate for adequate staging—and the metastatic lymph node ratio (i.e., number of metastatic lymph nodes/lymph node yield) correlated with a poorer survival.[280] The American Joint Committee for Cancer tumor, node, metastasis staging system also provides prognostic utility, and increased recurrence rates are reported for a primary tumor that extends beyond the thyroid capsule to invade local structures (i.e., pT4 tumors).[3] However, the American Joint Committee for Cancer system does not incorporate age, pre- and postoperative serum calcitonin levels, or quantification of the number of affected lymph nodes, which each also provide additional prognostic information.

Thyroidectomy together with lymph node clearance may be associated with several postoperative complications, including lymphatic leakage, transient (and occasionally permanent) hypoparathyroidism, and transient or longer-term damage to the recurrent laryngeal nerves and/or spinal accessory nerve. Following surgery, basal or stimulated calcitonin levels should be ascertained to assess disease status, although typically this is delayed by approximately 3 months to allow sufficient time for levels to reach a nadir.[3,281] Following total thyroidectomy, all patents require lifelong thyroid hormone replacement and will also require monitoring of plasma calcium concentrations with appropriate treatment, where necessary. In patients with known advanced disease (i.e., extensive regional or metastatic disease), less aggressive surgery may be appropriate because cure will not be achieved and the aims in these patients will be to maintain the voice and swallowing, preserve the quality of life, and avoid local complications.[3]

Prophylactic Thyroidectomy in MEN2

The ability to identify individuals at high-risk of developing hereditary MTC through germline *RET* mutation testing provides a window of opportunity to undertake preventative or curative surgery in otherwise asymptomatic individuals.[3,239,268] Indeed, "prophylactic" thyroidectomy has become the mainstay of treatment for children at risk of hereditary MTC, and when undertaken at a sufficiently early stage, it has the potential to avoid the morbidity and mortality associated with MTC development.[3,239,250–252,268,282,283] For example, in 2005, a study reported that prophylactic thyroidectomy in 50 patients who were younger than 19 years of age with MEN2-associated *RET* mutations resulted in no evidence of residual or recurrent disease in approximately 90% of cases at a mean follow-up period of 7 years. More recently, a study reporting the outcomes of prophylactic thyroidectomy in 167 children with MEN2- and MEN3-associated *RET* mutations reported no instances of recurrent or residual disease after a mean of 7 years in any of the 149 patients for whom follow-up data were available. In addition, normalization of postoperative serum calcitonin was observed in 99% of patients who had

raised preoperative calcitonin levels.[251] However, it is important to note that the aim of such preventative surgery is not necessarily to remove the thyroid before any abnormality develops but rather to do so before there is a significant risk of metastatic disease. In this regard, the advent of highly sensitive serum calcitonin assays now provides additional information that may help inform surgical decisions, although it should be noted that serum calcitonin concentrations in young children, and especially in the first few months of life, are frequently high and do not accurately reflect disease status. Thus, although prior recommendations on the timing of prophylactic thyroidectomy were based on the risk category of the *RET* mutation alone,[2] more recent guidelines suggest that in some instances it is reasonable to take into account basal or stimulated serum calcitonin levels, which provide a reliable indicator of MTC status and disease risk.[3] This represents an important change and recognizes that there remains considerable heterogeneity in the age of MTC onset in those carrying the same *RET* mutation who may be even from the same kindred. Furthermore, it suggests that although the risk category of *RET* mutation is the major determinant of the age of onset of CCH and subsequent transformation to MTC, additional genetic and/or environmental factors may influence disease expression.

Thyroidectomy in early childhood is associated with a higher complication rate than that observed in older children or adults. Such surgery should only be undertaken at a center with appropriate experience. Complications associated with surgery include a higher likelihood of developing hypoparathyroidism, as frequently the parathyroid glands are hard to identify in very young children. Complications in early childhood are also increased if central lymph node dissection is performed, and this includes the higher risks of transient and permanent hypoparathyroidism, as well as the likelihood of transient recurrent laryngeal nerve palsy.[268,284] As a consequence, the timing of prophylactic surgery aims to strike an important balance between the risks associated with early surgery and those associated with more extensive surgical procedures, which may be necessary when intervention is delayed. Current guidelines attempt to address this balance, offering some flexibility in the timing of prophylactic thyroidectomy in children with germline *RET* mutations associated with a later age of MTC onset while recommending early surgery in those deemed to be at highest risk (see Table 42.4). Thus, children identified to harbor the ATA highest-risk *RET* mutations (i.e., Met918Thr) are recommended to undergo total thyroidectomy in the first year of life, and the higher potential complication rate of hypoparathyroidism in this age group is considered acceptable given the potential for metastatic disease by delaying treatment. In children with ATA high-risk mutations (i.e., codon Cys634 and Ala883Phe mutations), prophylactic thyroidectomy is typically recommended before 5 years of age, with the exact timing based on annual clinical examination, neck ultrasound, and serum calcitonin levels starting from the age of 3 years. For those children with ATA moderate-risk *RET* mutations, the timing of prophylactic thyroidectomy should be based on the findings of clinical examination, neck ultrasound, and serum calcitonin concentrations commencing at age 5 years.[3] Thyroidectomy is indicated once serum calcitonin concentrations are elevated, although it may also be appropriate in children with normal calcitonin levels in whom such long-term monitoring is not feasible or desired. The window of "safe" serum calcitonin concentrations in which curative surgery is feasible has not been precisely defined, although once basal serum calcitonin levels exceed the upper end of the normal range (e.g., ~10 pg/mL), this may herald the early stages of MTC development and a suitable time for surgical intervention. Serum calcitonin concentrations between 10 and 30 pg/mL may represent an optimal window for intervention, as nodal metastases were not observed to occur in children with *RET* mutations who had serum calcitonin concentrations of 30 pg/mL or less.[268,283] Once calcitonin levels are greater than 30 pg/mL, the likelihood of nodal metastases increases, and this will often necessitate central node dissection, which is associated with increased operative morbidity and a reduction in duration of long-term remission.[268,285]

Postoperative Evaluation and Management of Patients With MTC

Following surgery, the normalization of serum calcitonin levels is associated with very favorable long-term outcomes, although a small proportion of these patients may develop recurrent disease. For example, patients with postoperative basal serum calcitonin concentrations less than 10 pg/mL are reported to have 3- and 5-year relapse-free survival of 95% and 90%, respectively,[276] with only approximately 4% of patients with recurrent disease found to have had normal postoperative serum calcitonin levels.[286] Thus, postoperative normalization of serum calcitonin levels cannot be considered curative in all patients and highlights the need for long-term clinical and biochemical follow-up. Patients who have postoperative basal serum calcitonin levels above the reference range will require further investigation, and this will depend on the severity the hypercalcitonemia. Thus, serum calcitonin levels that are greater than 10 pg/mL but less than 150 pg/mL indicate localized residual disease within the neck that should be evaluated by ultrasound, whereas serum calcitonin concentrations greater than 150 pg/mL indicate the possibility of more extensive disease that will require additional imaging (e.g., CT, MRI, bone scintigraphy). The extent and location of the residual/recurrent disease with the rate of tumor progression determined both by imaging and calcitonin and/or CEA doubling time will determine which of the different local or systemic treatment options (see the following discussion) should be pursued. Calcitonin doubling time is an important guide of prognosis,[281] and calcitonin doubling times of less than 6 months and 6 to 24 months have been reported by one study to be associated with 10-year survivals of approximately 10% and approximately 40%, respectively, whereas all patients with a doubling time of greater than 24 months were alive at the end of the study.[287] In another study, both calcitonin and CEA doubling times were also strongly related to disease progression, with approximately 95% of those with doubling times of 2 years or less observed to have progressive disease, whereas approximately 85% of those with doubling times greater than 2 years had stable disease.[288]

Management of Advanced Disease

The management of advanced MTC in patients with MEN2 or MEN3 does not differ from that in patients with sporadic MTC.[3] In MEN2 and MEN3 patients with significant elevations of serum calcitonin preoperatively (e.g., >500 pg/mL), postoperatively (e.g., >150 pg/mL), or during the subsequent follow-up periods, the possibility of locally advanced and/or metastatic disease should be investigated, as this will influence the choice of downstream therapeutic approach.[3]

In patients with residual or recurrent disease that is limited to the neck, reoperation with compartmental dissection of central and/or lateral regions based on preoperative investigation (i.e., imaging and/or biopsy) may be appropriate, with the aim of normalizing or reducing serum calcitonin levels, although these potential benefits must be balanced against the increased

morbidity that may be associated with further neck surgery. Postoperative radioiodine is not recommended for patients with MTC unless there is evidence that the recurrent MTC contains elements of papillary or follicular thyroid cancer. External beam radiotherapy (EBRT) to the neck has been used widely for locoregional disease control, although there is little evidence of survival benefit when other prognostic factors are taken into account.[289] Current guidelines suggest considering EBRT in those patients at high risk for local disease recurrence and those at risk of airway obstruction. However, the decision to use EBRT in these situations should take into account the potential acute and chronic toxicities associated with the treatment.[3]

Once distant metastases have developed, treatments are aimed at disease control and/or symptomatic benefit, as curative therapies are not available. Determining the optimal therapy will depend on several factors, including the site(s) and extent of metastases, the rate of tumor progression, the performance status of the patient, the treatment modalities available to the patient, and the wishes of the patient. MTC most commonly metastasizes to the liver and axial skeleton (see Fig. 42.8), and to a lesser extent the lungs (see Fig. 42.6), brain, and skin, and in these settings, several treatment approaches may be employed to achieve symptom and/or disease control.[3] Treatments for metastatic disease are broadly categorized into local and systemic therapies. Local treatments, which are typically used for disease or symptom control at specific sites related to tumor spread, include surgical resection/debulking, chemoembolization, radio-frequency ablation, and EBRT.[3] Symptoms related to aberrant hormonal secretion may also require treatment. For example, antimotility agents (e.g., loperamide) and/or somatostatin analogues may improve diarrhea in those with hormonally active hepatic metastases and may be used prior to surgical debulking and/or selective arterial chemoembolization.[3] Similarly, biochemical control of Cushing syndrome (i.e., due to the ectopic production of corticotropin-releasing hormone or ACTH) may be required to minimize the associated morbidity (e.g., hyperglycemia, osteoporosis, hypertension, hypokalemia, gastritis), and this may be achieved by several approaches, including medical therapies (e.g., ketoconazole, metyrapone, mitotane), bilateral adrenalectomy, or debulking of hepatic metastases. Remission of ectopic Cushing syndrome due to MTC has also been observed in case reports of patients receiving the RTK inhibitor vandetanib (see the following discussion).[290]

Systemic antitumor therapies are typically reserved for patients with metastatic MTC in whom there is evidence of significant disease burden and/or evidence of disease progression. The advent of targeted therapy with RTK inhibitors has provided a significant advance in the field, and these drugs now represent first-line treatment for the majority of patients with advanced progressive disease (see the following discussion). In contrast, conventional cytotoxic chemotherapeutic regimens, either as single agents or in combination, have been associated with low response rates and are not routinely recommended. Alternate systemic therapies, including radionuclide therapies (e.g., [^{90}Y-DOTA]-TOC), have also been employed in early-phase clinical trials, but these treatments require further evaluation to support their wider clinical use.[3]

Targeted Therapies for MEN2-Associated MTC

Currently, two RTK inhibitors are approved for use in advanced progressive MTC: vandetanib, which targets RET, endothelial growth factor receptor (EGFR), and vascular EGFR (VEGFR) kinases, and cabozantinib, which targets RET, c-Met, and VEGFR kinases.[3,266,291–293] The anti-RET activity of these drugs is considered to be the determinant of their clinical efficacy in MTC, but it is important to note that the targeting of alternate TKs, including VEGFR, by these drugs may also contribute substantially to their antitumor activity.

The safety and efficacy of vandetanib in advanced MTC was initially evaluated in clinical trials of MEN2 and MEN3 patients, which demonstrated partial response rates of 15% to 20% and stable disease persisting for 24 weeks or more in an additional approximately 50% of patients.[294,295] In a subsequent phase III trial of patients with advanced MTC due to sporadic of hereditary disease, vandetanib demonstrated increased PFS when compared with placebo (median PFS 30.5 months vs. 19.5 months, respectively), whereas approximately 45% of patients in the treatment group demonstrated a partial tumor response.[291] Vandetanib treatment in 28 patients with germline *RET* mutations revealed approximately 45% to have an objective tumor response,[291] and tumors harboring a somatic Met918Thr *RET* mutation also had an enhanced response.[291] A subsequent study of vandetanib in children and adolescents with MEN3 and locally advanced or metastatic MTC reported an objective partial response rate of 47%, whereas all 15 MEN3 patients harboring the germline Met918Thr mutation experienced some reduction in tumor size.[296]

Cabozantinib, in a phase III clinical trial, resulted in a partial tumor response in 28% of patients with locally advanced or metastatic MTC compared with 0% in the placebo group, whereas PFS was increased in those receiving treatment compared with placebo (11.2 vs. 4.0 months, respectively).[297] However, no overall survival benefit was demonstrated between treatment and placebo arms.[297] Subsequent analysis of this trial reported an increased median PFS in patients with a *RET* or *RAS* mutation receiving cabozantinib compared with placebo (13.8 months vs. 4.6 months, and 10.8 months vs. 1.8 months, respectively). In contrast, no such benefit was observed in patients without *RET* or *RAS* mutations (median PFS in treatment and placebo groups of 5.6 months vs. 5.3 months, respectively).[298] In addition, patients with tumors harboring the Met918Thr *RET* mutation were also found to have the greatest median PFS benefit with cabozantinib treatment (14.1 months), and, importantly, these patients were the only group to have increased overall survival.[298–300] Moreover, objective response rates of 32% and 22% were observed in patients with and without *RET* mutations, respectively, indicating some antitumor activity in patients without *RET* mutations.[298,299]

These studies reveal that treatment with RTK inhibitors of patients with advanced MTC resulted in objective tumor responses in more than 50% of patients. In addition, the majority of patients developed drug resistance, thereby resulting in only short- to medium-term improvements in disease control, and long-term disease remission and major survival benefits were not demonstrated.[266,299,300] Furthermore, the adverse effects associated with these drugs, which included diarrhea, rash, fatigue, hypertension, abdominal pain, photosensitivity, prolonged QT interval, and gastrointestinal fistulas, resulted in either drug discontinuation or the requirement for a dose reduction in 12% to 16% and 35% to 79%, respectively.[3] There was also marked heterogeneity in drug response even between individuals harboring similar *RET* mutations, and improved molecular understanding of these agents is required to establish their optimal use.[266,296] For example, determining the clinical activities in the presence of different *RET* mutations and establishing the relative contribution of their different anti-TK activities, such as anti-VEGFR, would be important, especially because cabozantinib was demonstrated by using in vitro and in vivo tumor models to be active against several

mutated forms of *RET*, such as Met918Thr and Tyr791Phe, whereas other mutated forms of RET, including those harboring substitutions at Val804, appeared to be resistant to certain RTK inhibitors, including vandetanib.[301,302]

Other multi-TK and RET inhibitors have also been evaluated in early-phase clinical trials for advanced MTC, including sorafenib, which demonstrated partial responses in 6% to 25% of patients[303,304]; lenvatinib, which demonstrated objective tumor responses in approximately 35% of MTC patients[305]; and sunitinib, which demonstrated an objective response rate of 38%.[306] However, these and several additional TK inhibitors are not currently approved for use, and larger studies are required to determine the effectiveness of these treatments in MEN2 and MEN3 patients with MTC. Preclinical studies have evaluated other RTK and RET inhibitors with activity against specific TK receptor mutations. For example, alectinib and ponatinib demonstrated significant anti-RET activity, including effective targeting of the Val804 "gatekeeper" mutants (e.g., Val804Met and Val804Leu),[292,299,307] and several RET-specific inhibitors are in development.[292]

Finally, it is likely that either sequential or combination systemic therapy will be required to achieve longer-term treatment responses, and early phase studies are in progress.[292] Furthermore, an improved understanding of the mechanisms of acquired resistance is required to determine the optimal use of emerging agents.

Pheochromocytoma

Clinical Features

Pheochromocytomas are the second most frequent neoplasms in MEN2 and MEN3, with an overall penetrance of 40% to 50%. Pheochromocytoma may be the first manifestation in a minority (<10%) of cases and may also occur synchronously with MTC in approximately 35% of cases[308–310] (see Fig. 42.8). Childhood presentations of pheochromocytoma are rare in MEN2, although the earliest ages of onset related to codon Cys634 and Met918Thr mutations are 8 and 12 years, respectively.[3,311] A key characteristic of MEN2-associated pheochromocytoma is that in 50% of patients, it occurs as a bilateral disease, which can occur synchronously or metachronously.[308,312–315] Such bilateral disease has a higher frequency in individuals with specific genotypes including the Cys634Arg *RET* mutation.[269,270,315] The majority (>95%) of MEN2- and MEN3-associated pheochromocytomas arise within the adrenal gland and occur on the background of adrenal medullary hyperplasia.[239,316] However, more recent studies indicate that regions of adrenal medullary hyperplasia share molecular characteristics with pheochromocytoma and should be more appropriately considered as micropheochromocytomas.[317] The overwhelming majority (>95%) of MEN2- and MEN3-associated pheochromocytomas are benign, and only 0% to 4% are reported to progress to malignancy in large series, although individual cases reports highlight occasional instances of metastatic spread.[308,315,318–320] Extra-adrenal pheochromocytoma/paraganglioma is extremely rare in MEN2 and MEN3.[321]

The clinical signs and symptoms of pheochromocytoma in MEN2 and MEN3 do not differ from those occurring in patients with nonsyndromic and nonfamilial pheochromocytomas. Thus, MEN2 and MEN3 patients with pheochromocytoma may present with features associated with excess catecholamine secretion, and these include episodic headaches, sweating, palpitations, anxiety, and hypertension. However, 30% to 50% of MEN2 and MEN3 patients are asymptomatic, and the pheochromocytoma is diagnosed during a screening program.[315,322] Thus, the possibility of pheochromocytoma due to MEN2 should be considered in all patients diagnosed with MTC prior to surgery (irrespective of signs or symptoms), as failure to diagnose and treat a concurrent pheochromocytoma may result in catastrophic outcomes due to an intraoperative adrenergic crisis.[3] Furthermore, it is important to exclude pheochromocytoma in all "at-risk" MEN2 and MEN3 patients prior to pregnancy.[3]

The diagnosis of pheochromocytoma is confirmed by demonstrating elevated concentrations of plasma and/or urinary free fractionated metanephrines. MEN2-associated pheochromocytomas are typically adrenergic and are reported to secrete disproportionate amounts of epinephrine,[239,315] and elevated epinephrine (and associated metanephrine) concentrations may help distinguish MEN2 from other hereditary pheochromocytoma/paraganglioma syndromes, such as von Hippel–Lindau disease and familial paraganglioma syndromes, in which norepinephrine or other metabolites predominate. Preoperative tumor localization studies are essential because there is a high probability of bilateral disease, and the imaging should evaluate both adrenal glands. Cross-sectional imaging with CT or MRI is recommended, and some centers will prefer CT because it provides a higher resolution with the pheochromocytoma appearing as a dense, hypervascular mass.[312,323] Several functional imaging modalities (e.g., ^{123}I-metaiodobenzylguanidine [^{123}I-MIBG], ^{18}F-FDOPA PET/CT, ^{18}F-FDG PET, 68Ga-DOTA) are also associated with high sensitivity and specificity for disease localization and detection of metastatic and extra-adrenal disease, although their usefulness in MEN2 and MEN3 may not be great considering that the majority of patients have benign disease limited to the adrenal medulla.[324,325]

The occurrence of pheochromocytomas in patients with MEN2 and MEN3 is dependent on genotype.[239,268,270,312,314,322] Thus, the highest prevalence of pheochromocytoma is observed in those with ATA high (codon Cys634 and Ala883Phe)- and highest (Met918Thr)-risk *RET* mutations, whereas a lower disease frequency is observed in those with moderate-risk *RET* mutations (see Table 42.3 and Fig. 42.7). To date, most estimates of pheochromocytoma penetrance are age related, and the absolute lifetime risk for several *RET* mutations is unknown. For example, 30% and 100% of patients with the Met918Thr mutation developed pheochromocytoma by the age of 27 and 56 years, respectively; 25%, 30% to 60%, 52%, and 88% of codon Cys634 *RET* mutation carriers developed disease by age 30, 35, 50, and 77 years, respectively; and fewer than 20% of patients carrying moderate-risk exon 10 mutations (e.g., those affecting codons 609–620) had pheochromocytomas by 35 years of age.[268,270,309,312,314,322] Different mutations affecting the same Cys634 residue have been reported to give rise to different tumor penetrances, with the Cys634Arg mutation being associated with the highest incidence of pheochromocytoma in MEN2 patients.[269,270,310] In addition, recent studies also indicate the presence of potential genetic or environmental disease modifiers, and a different natural history of pheochromocytoma in MEN2 is reported in individuals with the same *RET* mutations from different geographic regions. For example, MEN2 patients from South America with exon 11 mutations (e.g., affecting codon Cys634) appear to have a lower disease penetrance and/or later age of onset than those from European locations (i.e., Southern, Central, Western Europe).[326] Further support for the influence of genetic modifiers is provided by the observation that even within the same kindred, the penetrance and expression of pheochromocytoma varies. Potential insights into such modifying influences include the observation that certain haplotypes containing *RET* mutations alongside additional

RET rare variants (e.g., Tyr791Phe) or polymorphisms (e.g., Leu769Leu, Ser836Ser, and Gly691Ser/Ser904Ser) result in an increased age-related risk of pheochromocytoma.[273,327]

Treatment

Surgical removal of the pheochromocytoma(s) is the treatment of choice. However, pre- and perioperative α- and β-blockade must be instituted, and in patients having bilateral adrenalectomy, who are at risk of postoperative steroid and mineralocorticoid deficiency, perioperative steroids should be administered. For unilateral or bilateral adrenalectomy, open (i.e., retroperitoneoscopic) and laparoscopic approaches are appropriate and reported to be associated with similar outcomes.[3] However, several additional factors should be considered specifically in MEN2 and MEN3 patients when compared with patients with nonsyndromic and nonfamilial pheochromocytomas in planning the surgical strategy. For example, in patients with synchronous bilateral pheochromocytomas, the simultaneous removal of both adrenal glands results in postoperative adrenal insufficiency, with all patients requiring lifelong glucocorticoid and mineralocorticoid replacement.[268,322] For this reason, bilateral adrenalectomy is not recommended in those with unilateral disease despite the potential for tumor development in the contralateral gland.[3] To reduce the risk of adrenal insufficiency in patients requiring bilateral adrenalectomy, some centers have advocated adrenal-sparing surgery (i.e., subtotal adrenalectomy) despite the potential risk for tumor recurrence in the remnant tissue.[268,312,322,328] Adrenal-sparing surgery involves removal of the pheochromocytoma while aiming to leave 10% to 30% residual adrenal cortical tissue to provide sufficient adrenal reserve for glucocorticoid and mineralocorticoid function. Supporters of this approach cite the low risk of malignancy, a relatively low tumor recurrence rate with substantial disease-free intervals, and a low frequency of adrenal insufficiency associated with adrenal-sparing surgery. Several retrospective series have compared clinical outcomes between conventional and adrenal-sparing adrenalectomy. For example, in one series of 552 MEN2 patients undergoing surgery for pheochromocytoma, approximately 20% were treated by adrenal-sparing surgery and approximately 60% of those undergoing bilateral tumor resections were demonstrated to have preserved glucocorticoid production.[322,328] Furthermore, following either unilateral or bilateral adrenal-sparing surgery, a low tumor recurrence rate of approximately 3% was observed in the remnant operated gland after 10 years of follow-up.[312,322] Although higher recurrence rates are reported in other series, and are likely to rise with increasingly lengths of follow-up, current guidelines suggest adrenal-sparing surgery as an alternative to adrenalectomy, although this approach may not be technically feasible in MEN2 and MEN3 patients with multifocal disease.[3,268,312,314,328–330] Finally, in patients who have pheochromocytoma concurrently with MTC, the usual practice is to remove the adrenal tumor(s) prior to thyroidectomy.[3] The decisions regarding surgical strategy should balance the relative risks and benefits of the planned approach, as well as take into account the wishes of the patient. In addition, it is important to note that the improvements in the screening programs and treatment approaches have reduced the morbidity and mortality associated with MEN2- and MEN3-associated pheochromocytoma, which have a very low frequency of malignant disease; thus, current outcomes generally are very favorable.[312,322] Following surgery, lifelong follow-up is required for all patients to ensure appropriate compliance and monitoring of glucocorticoid and mineralocorticoid replacement therapy in those with adrenal insufficiency, and to monitor for development of additional pheochromocytoma in the contralateral adrenal gland following unilateral resections, or in remnant adrenal tissue following adrenal-sparing surgery, so that appropriate surgery (i.e., adrenalectomy) can be planned and provided.

Primary Hyperparathyroidism

Clinical Features

PHPT, which occurs in approximately 30% of patients with MEN2, typically presents in the third to fourth decade of life.[3,268,270,312,314,331] The risk of PHPT is related to *RET* genotype, and patients with the Met918Thr *RET* mutation do not develop PHPT, whereas approximately 10% to 20% of patients with codon Cys634 mutations will develop PHPT by 35 to 40 years of age[268,269,314]; among these, carriers of the Cys634Arg *RET* mutation are reported to be at the highest risk of having PHPT.[269,270] Patients with other *RET* mutations (e.g., of exon 10 involving codons Cys609, Cys611, Cys618, and Cys620) have less than 5% risk of having PHPT.[3,332] However, in some MEN2 patients with codon Cys634 mutations, PHPT has been reported to occur as early as 2 years of age.[3,333,334] In MEN2 patients with PHPT, multiple parathyroid glands may be affected with hyperplasia and/or adenoma formation, and frequently this is asynchronous such that a dominant single-gland parathyroid tumor is often observed.[312]

The diagnosis of PHPT in MEN2 does not differ from patients with nonsyndromic and nonfamilial presentations and is reliant on demonstrating hypercalcemia with elevated or inappropriately normal plasma PTH concentrations. However, MEN2 patients with PHPT are frequently asymptomatic and only have mild hypercalcemia[3,268] such that the diagnosis is often made following routine biochemical testing or during screening for other MEN2 manifestations. Preoperative imaging using sestamibi, ultrasound, and four-dimensional CT scans to localize the parathyroids is useful only in patients who have had prior neck surgery (i.e., thyroidectomy and/or central node neck dissection) for MTC, as this may help to guide the surgical approach. However, in patients in whom the diagnosis of PHPT is made concurrently with that of MTC, neck ultrasound or MRI for MTC staging may help identify enlarged parathyroid glands, but there is little added value of further parathyroid imaging because surgical exploration will allow evaluation of all four parathyroid glands.

Treatment

The current recommendations for treatment of PHPT in MEN2 favor the removal of only enlarged/diseased parathyroid glands rather than the more substantial operations recommended for MEN1.[3,268] However, the surgical approach will depend on the timing of the diagnosis relative to MTC. Thus, in patients who have synchronous MTC and PHPT and are undergoing thyroidectomy for the MTC, the recommendation is to remove only the enlarged parathyroid glands, with the success of parathyroidectomy being monitored by intraoperative PTH assays.[268] However, in patients with four-gland involvement, it is recommended that subtotal parathyroidectomy that leaves a remnant in situ on a vascular pedicle or total parathyroidectomy with autotransplantation should be undertaken.[3] In patients who have development of PHPT subsequent to thyroidectomy, the goals of parathyroid surgery should be tailored to the removal of only enlarged parathyroid glands, which may have been identified by preoperative imaging studies,[3] and intra-operative PTH assays used to monitor for successful removal of the enlarged glands, with the normal parathyroid glands being left in situ. Finally, in patients undergoing thyroidectomy for MTC with normal calcium and PTH, it

recommended that prophylactic parathyroidectomy is not undertaken, but that normal-appearing and viable parathyroid glands should be left in situ.[331]

Additional Clinical Features Associated With MEN2A Variant Disorders

Familial MTC-Only

FMTC is characterized by MTC being the sole manifestation of MEN2. However, distinction between FMTC and MEN2A is difficult because of the low penetrance of pheochromocytoma in some patients, and FMTC should be considered only if there are at least four family members older than 50 years who are affected by MTC but not pheochromocytomas or PHPT.[3,335,336] FMTC, when strict diagnostic criteria are applied, is found to be very rare.

MEN2 With CLA

CLA has been reported to occur in up to 35% of MEN2 patients harboring codon Cys634 mutations[337] (Fig. 42.9) but is very rarely observed in MEN2 patients with other *RET* mutations. CLA typically presents with intense pruritus and a rash in the interscapular area of the T2-6 dermatome region[3] (see Fig. 42.9). The lesions improve with sunlight and may worsen at times of stress. CLA may predate the other clinical manifestations of MEN2. Treatment includes the use of topical creams including corticosteroids, systemic antihistamines, and/or phototherapy, which may provide partial symptom relief.[3]

MEN2 With HSCR

Approximately 7% of patients with MEN2 manifest features of HSCR and typically present shortly after birth with the inability to pass stool and the development of megacolon, resulting from an absence of enteric ganglia along a variable length of the intestine. The phenotype is only observed in MEN2 patients harboring activating *RET* mutations in exon 10 that affect cysteine residues at positions 609, 611, 618, and 620. Heterozygous loss-of-function *RET* mutations are observed in approximately 50% of patients with sporadic HSCR, and thus the co-occurrence of MEN2 with HSCR appears paradoxical (i.e., HSCR occurring in the context of both activating and loss-of-function *RET* mutations).[338,339] Knowledge of receptor structure/function (see the following discussion) has provided potential insights into the molecular basis of these paradoxical observations, with the hypothesis that these specific exon 10 mutations result in constitutive receptor activation sufficient for oncogenic signaling (i.e., resulting in the MEN2 phenotype), but diminishing cell surface receptor expression (e.g., through reduced stability), thereby resulting in inadequate ligand-dependent RET signaling during enteric nervous system development.[340]

Very occasionally, dermatologic features more typical of MEN3 have been reported in patients with MEN2 including dermal hyperneury (i.e., hypertrophic myelinated and unmyelinated nerve fibers in the skin). In addition, multiple sclerotic fibromas have also been reported, more reminiscent of changes observed in the PTEN hamartoma tumor syndrome.[341]

• **Fig. 42.9** Cutaneous lichen amyloidosis in a patient with multiple endocrine neoplasia type 2 harboring a codon Cys634 mutation. (From Birla S, Singla R, Sharma A, Tandon N. Rare manifestation of multiple endocrine neoplasia type 2A & cutaneous lichen amyloidosis in a family with *RET* gene mutation. *Indian J Med Res.* 2014;139[5];779–781.)

Additional Clinical Manifestations Associated With MEN3

Extraendocrine features occur in virtually all MEN3 patients, who typically have the endocrine manifestations of early-onset aggressive MTC together with pheochromocytoma[265]. However, the penetrance and/or severity of these extraendocrine features may be variable, although some may be evident very early in life; when recognized, they may facilitate early diagnosis. However, such features frequently are overlooked, resulting in delays in treatment.[342] These extra- (or non)endocrine features include a skeletal phenotype giving rise to a marfanoid habitus with tall stature, long limbs, narrow elongated face, high arched palate, chest wall abnormalities (e.g., pes excavatum, pes cavus), scoliosis, arachnodactyly, and increased risk of slipped capital femoral epiphyses[3,265]; multiple mucosal neuromas, typically presenting as soft papules in and around the oral cavity (e.g., affecting tongue, lips), as well as in the nasal and laryngeal mucosa (see Fig. 42.6); ocular manifestations such as alacrima, mild ptosis, conjunctival neuromas, and prominent corneal nerve fibers[265]; upper gastrointestinal symptoms such as swallowing difficulties and vomiting, likely due to esophageal abnormalities; lower gastrointestinal symptoms such as altered bowel habit (most commonly constipation) and early feeding intolerance due to diffuse intestinal ganglioneuromatosis (see Fig. 42.6) and impaired colonic motility resulting in megacolon[265,343]; tooth malposition; and dermal hyperneury.

Molecular Genetics

The RET Proto-Oncogene

The human *RET* proto-oncogene, which encodes a single-pass transmembrane receptor of the TK family, is located in the pericentromeric region of chromosome 10q11.2 and comprises 21 coding exons that span approximately 55 kb of genomic DNA.[293,307,344–348] The RET receptor, which is an RTK, consists of an ECD containing four cadherin-like repeats and a cysteine-rich region, a transmembrane domain, and an intracellular domain (ICD) that comprises the TK domain and an isoform specific C-terminal (see Fig. 42.7). *RET* transcription is regulated by several DNA-binding factors that act on upstream promoter and enhancer elements, and the transcript levels are further controlled by regulatory elements within intronic and 3′ untranslated regions.[307] Alternate splicing

of *RET* results in several highly conserved protein isoforms, and the two predominant isoforms are RET9 ("short") and RET51 ("long"), which differ only by 9 and 51 C-terminal amino acids, respectively, in their extreme C-terminal regions[307] (see Fig. 42.7).

Germline RET *Mutations*

More than 50 different germline heterozygous *RET* mutations, which result in receptor activation, have been reported in association with MEN2 and MEN3.[240,340] The majority of MEN2-associated *RET* mutations involve heterozygous nonsynonymous amino acid substitutions of cysteine residues within the cysteine-rich ECD of the receptor, or of noncysteine residues within the intracellular TK domain (see Fig. 42.7). However, several additional MEN2-associated *RET* mutations, the majority of which affect a relatively small number of codons, are reported and include either nonsynonymous amino acid substitutions outside of these regions or small duplications, insertions, and deletions (see Table 42.3). Thus, MEN2 is most frequently associated with amino acid substitutions of codon Cys634 in the cysteine-rich ECD (see Fig. 42.7), with mutations of cysteine residues at codons 609, 611, 618, or 620 in this domain also accounting for a significant proportion of the remaining MEN2 mutations.[240,270,340] MEN2 mutations also occur in the intracellular TK domain, and these involve substitutions of Leucine 790 (i.e., Leu790Phe), Valine 804 (i.e., Val804Met, Val804Leu), and Serine 891 (i.e., Ser891Ala). Additional variants in the cysteine-rich and the TK domains have also been reported in some patients. However, some variants previously reported as pathogenic (i.e., mutations) may have been misclassified due to ascertainment and/or reporting biases, and these likely represent benign variants (e.g., Ser649Leu, Tyr791Phe, and Ile852Met).[267,340,349] Approximately 95% of MEN3 mutations involve a methionine to threonine substitution of codon 918 (Met918Thr) of the intracellular TK domain, and fewer than 5% are represented by the Ala883Phe mutation, which is typically associated with a less aggressive disease course.[350]

A paradigmatic feature of MEN2 and MEN3, which has transformed the clinical management of patients, is the strong genotype-phenotype correlation that predicts the potential disease spectrum and age of MTC onset associated with a specific *RET* mutation. However, the disease phenotype and its severity may vary between individuals harboring the same mutation, and even within the same kindred, thereby implicating a role for genetic modifiers, which may include the co-occurrence of *cis*-acting *RET* coding region variants alongside the pathogenic mutations.[307,340] For example, several *RET* variants (e.g., Glu805Lys, Tyr806Cys, and Ser904Phe) have been reported in individuals harboring the Val804Met mutation, and these are associated with enhanced receptor signaling, which results in a more severe disease phenotype that resembles MEN3.[351,352] In addition, several noncoding and synonymous *RET* polymorphisms, identified by haplotype analysis, have been reported to modify disease expression and clinical course.[272]

The overall prevalence of MEN2-associated germline *RET* mutations in European populations has been estimated to be approximately 1 in 80 to 100,000,[240] although recent evaluation of the Exome Aggregation Consortium cohort revealed a much higher frequency at approximately 1 in 2000.[145] In particular, a high frequency of the ATA moderate-risk Val804Met *RET* variant was observed, indicating that this mutation is likely associated with a lower disease penetrance than reported previously.[145] This observation is supported by a further bioinformatic study in which the Val804Met was estimated to have a disease penetrance for MTC of less than 5%.[271] Together, these studies highlight the need for further unbiased population-based studies to refine current estimates of disease prevalence in *RET* variant carriers, as has been performed for other hereditary endocrine tumor genes.[353] However, it is also important to note that the incidence and spectrum of *RET* mutations may vary by geographic area, reflecting possible population-specific factors and the presence of potential founder mutations. For example, a study of approximately 500 MEN2 families from Germany, Italy, and France demonstrated that approximately 34% of kindreds harbored codon Cys634 *RET* mutations, with approximately 17%, approximately 10%, and 7.6% having codon Val804, Met918, and Leu790 mutations, respectively.[240] In contrast, another study from Denmark reported that codon Cys611 *RET* mutations were the most prevalent, likely reflecting a founder mutation (e.g., Cys611Tyr) in this population.[354]

More than 50% of patients with FMTC have *RET* mutations of Cys618, with Cys618Arg being the most common. However, a small number of families with FMTC do not have *RET* mutations, and recently a germline *ESR2* mutation was reported to cosegregate with MTC in one family,[355] thereby indicating the occurrence of genetic heterogeneity and roles for other genes in the etiology of MTC.

Germline loss of function *RET* mutations are the most common cause of isolated HSCR,[356] and more than 200 different heterozygous *RET* mutations, which are predicted to result in diminished RET receptor signaling and a failure to transmit key developmental signals required for enteric nervous system development, have been reported in HSCR patients.

Somatic RET *Mutations and Rearrangements*

Somatic *RET* mutations are the most common recurrent mutation in sporadic MTC.[357] Overall, 40% to 50% of sporadic MTCs are reported to harbor somatic *RET* mutations, although this frequency varies by tumor size and stage of disease.[340,357,358] Thus, the frequency of *RET* mutations is increased in tumors larger than 2 cm and may exceed 80% in those with advanced or metastatic presentations.[358,359] The somatic *RET* mutations occurring in sporadic MTC typically affect the same residues as those disrupted in MEN2 and MEN3, and 60% to 80% are represented by the MEN3-associated Met918Thr substitution.[358,359] In MTC without *RET* mutations, somatic *RAS* mutations (predominantly of *HRAS* and *KRAS*) represent the second most common genetic abnormality and occur in approximately 10% to 30% of sporadic MTCs, thereby supporting the role for activation of the RET-RAS-MAPK kinase pathway as a central feature of MTC development.[357] Testing for somatic *RET* mutations may be of future clinical use, as a recent meta-analysis has reported that patients with somatic *RET* mutations have an increased risk of lymph node metastases, distant metastases, tumor recurrence, and higher mortality,[360] and another study has reported that advanced MTCs harboring double somatic *RET* mutations were associated with unfavorable outcomes.[359]

Somatic rearrangements of the *RET* locus, giving rise to chimeric fusion proteins with constitutive TK activity, have been reported in approximately 20% to 40% of sporadic papillary thyroid carcinomas (PTCs), and these different RET fusion partners are collectively referred to as RET/PTC rearrangements. Each RET/PTC rearrangement is characterized by the placement of the *RET* TK domain genetic locus adjacent to a ubiquitously expressed donor gene containing a coiled-coil dimerization domain that facilitates constitutive receptor function and

activation of downstream oncogenic signaling pathways.[340] For example, the RET/PTC1 and RET/PTC3 rearrangements, which are most commonly observed, are the result of intrachromosomal inversions on the long arm of chromosome 10 that bring the RET TK domain adjacent to the coiled-coil domain containing 6 (*CCDC6*) or nuclear receptor coactivator 4 (*NCOA4*) genes, respectively. The RET/PTC chimeric proteins have a higher prevalence in radiation-induced PTC, indicating that ionizing radiation likely is a risk factor for their occurrence, although they may also occur without exposure to radiation and are often observed in children with PTC.[345] In addition, RET/PTC fusions have been reported in benign thyroid nodules and in patients with Hashimoto thyroiditis.[340] Somatic RET rearrangements resulting in chimeric proteins have also been reported in approximately 1% of lung adenocarcinomas (e.g., predominantly involving fusions with *KIF5B*) and in case reports of hematopoietic malignancies including chronic myelomonocytic leukemia.[345]

RET *Polymorphisms*

Common polymorphisms and nonpathogenic rare sequence variants within the *RET* gene need to be distinguished from pathogenic *RET* mutations. Common polymorphisms (global MAF >0.5%) within the coding region include 2 missense (p.Gly691Ser, p.Arg982Cys) and 6 synonymous variants. However, many additional missense variants are observed at MAF ≥0.5% in specific ethnic groups (e.g., p.Leu56Met in the European population; p.Tyr791Phe in the Finnish European and Ashkenazi Jewish populations; p.Asp489Asn, pThr278Asn, p.Arg67His, p.Arg114His in East Asian populations; and p.Gly446Arg in African populations), although many of these are also observed at lower frequencies in other ethnic populations. At least 15 common noncoding variants are observed in the *RET* untranslated regions, whereas the large *RET* intronic regions harbor more than 300 additional noncoding common polymorphisms (http://phase3browser.1000genomes.org/ and http://gnomad.broadinstitute.org/). Thus, it is important to recognize the occurrence of these polymorphisms, and caution is required when *RET* sequence variants are identified during genetic testing. This is particularly important for novel missense variants occurring in proximity to known functional RET domains, where ascribing pathogenicity may not be possible until there is clear evidence of variant segregation with the disease phenotype and/or abnormalities in cellular function established. The potential challenge of variant interpretation is highlighted by the observation that approximately 600 different rare (MAF <0.5%) missense *RET* variants have been reported in the GnomAD dataset (http://gnomad.broadinstitute.org/), whereas a recent study evaluating the Exome Aggregation Consortium cohort estimated that approximately 1 in every 35 individuals in the background population will harbor a rare (MAF <0.5%) nonsynonymous *RET* variant.[145] In each setting, most individual *RET* coding variants will not be of clinical significance.

RET Structure and Function

The RET receptor comprises several specific regions: a large ECD containing four cadherin-like repeats and a cysteine-rich region, a hydrophobic single-pass transmembrane domain, a juxtamembrane segment, an intracellular TK domain, and an isoform-specific C-terminal tail[2,307,344–346,348] (see Fig. 42.7). RET signaling is activated by the binding of members of the glial cell–line derived neurotropic factor (GDNF) family of ligands (GFLs), which comprise GDNF, neurturin, persephin, and artemin[344] (see Fig. 42.7). However, for receptor engagement, each of these ligands requires the presence of a ligand-binding coreceptor, which comprises members of the GDNF family receptor α (GFRα) group of proteins.[307,344,347] Four different GDFα coreceptors are described (GFRα1–4), with apparent preferential selectivity for each of the four GFLs. Although the precise sequence of events leading to receptor activation is debated, the formation of the GFL-GFRα complex allows RET recruitment and the formation of heterodimers in which the RET-GFL-GFRα complex has a 2:2:2 stoichiometry.[344] The formation of this ternary complex results in activation of the TK domain and autophosphorylation of multiple intracellular tyrosine residues, which in turn form docking sites for signaling proteins such as those with SRC homology 2 (SH2) or phosphotyrosine-binding domains that ultimately facilitate downstream transmission of signals within the cell via a large number of effector pathways.[293,344] Several conserved residues have been found to have key functions in catalytic activation and subsequent signal transduction.[293,344] For example, autophosphorylated tyrosine residues at Tyr1062 and Tyr1096 in the RET51 isoform appear to form key signaling hubs that facilitate activation of multiple distinct signaling pathways (e.g., RAS-MAPK and PI3K-AKT),[307,346] and autophosphorylation of the juxtamembrane residue Tyr687 has been shown to increase RET catalytic activity. Receptor function is also reported to be dependent on a phosphoserine residue (Ser909) within the activation loop indicating that RET acts as a dual-specific kinase.[361]

The activation of multiple downstream pathways (e.g., Ras/MAPK, PI3K/Akt, phospholipase C-γ, JNK, JAK-STAT, FAK, and β-catenin/Wnt) modulates cellular processes that include differentiation, proliferation, migration, and cytokine production.[348] The ability of RET to direct specific cellular effects is likely to be achieved by several mechanisms. For example, the binding of different RET ligands (i.e., GFLs) may result in differences in receptor activation,[348] whereas the expression of different RET isoforms (e.g., RET9 and RET51) may result in the differential deployment of individual intracellular signaling pathways.[362] Furthermore, the availability of each of the various intracellular signaling partner complexes in different cells may also contribute to RET signaling specificity.

Under physiologic conditions, the RET protein is expressed at its highest levels during embryonic development, where it plays an essential role in the development of multiple tissues. For example, RET is essential for the normal development of the kidneys and urogenital tract, where it plays a key role in modulating wolffian duct patterning and branching morphogenesis of the ureteric bud.[307,363,364] In addition, RET is predominantly expressed in cell lineages derived from the neural crest, including neuroendocrine and neuronal lineages, and it is therefore not surprising that several of these relate to the diseases observed in patients with *RET* mutations. Thus, RET is expressed in the thyroid parafollicular cells, adrenal chromaffin cells, and neurons, where it plays an essential role in the migration and establishment of the enteric nervous system.[293,365] RET expression also occurs in neural crest–derived peripheral and central neuronal populations, where it regulates axonal growth and cell survival.[307] For example, RET is expressed in spinal cord motor neurons during early development, where it mediates potent prosurvival activities, and similar protective effects have been reported in adult ventral midbrain dopaminergic neurons.[347] Finally, RET is expressed at low levels in hematopoietic and immune cell precursors, and it is reported to be required for the formation of gut-associated lymphoid tissue and Peyer patches.[366]

RET *Mutations and Receptor Function*

Mechanistic molecular insights into RET receptor function have been provided by studies of disease-associated *RET* mutations or translocations that result in abnormalities of receptor signaling. Thus, studies of heterozygous *RET* mutations, which cause loss of function and are associated with HSCR or gain of function (i.e., enhanced receptor signaling and are associated with MEN2 and MEN3), have increased our understanding of the structure-function relationships of this RTK. For example, MEN2 mutations involving substitutions of cysteine residues in the ECD (e.g., Cys609, Cys611, Cys18, Cys620, Cys630, Cys634) result in an unpaired cysteine residue that can form a disulfide bond with a similarly unpaired residue on a neighboring mutant RET receptor, thereby resulting in ligand-independent dimerization and constitutive receptor activation (see Fig. 42.7). Interestingly, some of these mutations (e.g., affecting Cys611, Cys18, Cys620) can result in RET receptors with apparent paradoxical gain- and loss-of-function activity. This occurs because the mutant RET receptors, although having constitutive activity, have poor maturation that results in their decreased cell surface expression, which will have detrimental effects on the development of tissues dependent on GFLs. Thus, the mutant RET receptors, although activated, will be fewer, and this provides an explanation for the coexistence of MEN2 due to enhanced RET signaling, and HSCR, which is associated with RET haploinsufficiency and loss-of-function mutations.[293,307,338] The RET receptor mutations of the ECD may also alter downstream receptor signaling. For example, the ligand-independent dimerization associated with cysteine-rich domain mutations may be associated with different cellular localizations and result in altered access to downstream signaling complexes and preferential activation of individual pathways such as the PI3K/AKT pathway[307,348] or otherwise altered ICD function that results in different patterns of receptor autophosphorylation and recruitment of adaptor proteins. These different effects on RET signaling may, in turn, contribute to the observed differences in phenotypes in patients.

The MEN2-associated *RET* mutations of the ICD (e.g., affecting Leu790, Tyr791, Val804, Ser891) result in mutant receptors that are active as monomers in the absence of ligand, and this autonomous signaling is not further enhanced in the presence of ligand. This contrasts to the MEN3-associated *RET* mutation, Met918Thr, which also resides in the ICD TK domain but results in a receptor conformation change that increases affinity for adenosine triphosphate and ligand-independent kinase activity in both monomeric and dimeric forms, which is enhanced further by the presence of ligand.[293,344] This enhanced function is more pronounced for the RET9 isoform when compared with RET51, and this greater signaling activity may contribute to the aggressive clinical phenotype observed in MEN3 patients. In addition, mutations in the RET ICD are reported to result in phosphorylation of substrates more commonly associated with cytoplasmic TKs (e.g., SRC and FAK), and this may also contribute to enhanced tumorigenic activity and more aggressive tumor manifestations in patients.[344]

Animal Models

The *RET* gene is highly evolutionary and conserved in mammalian and vertebrate species, with all higher organisms having a single copy of a RET orthologue. Furthermore, all vertebrates have been observed to harbor GDNF family ligands and respective GFRα proteins. RET orthologues are also observed in more evolutionary distant organisms, including *D. melanogaster* and *Amphioxus*.[347] Although some insight into RET function has come from the study of nonmammalian models, including zebrafish (*D. rerio*) and *Drosophila*, the predominant model organism for evaluating *RET* mutations that are relevant to MEN2 and MEN3 has been the mouse. Several mouse models have been generated by the transgenic expression of mutant RET proteins, or knock-in methods in which specific mutations have been introduced into the *Ret* gene.[367,368] Mice that are homozygous for an inactivating *Ret* mutation die soon after birth and have renal agenesis and a lack of enteric neurons in the gastrointestinal tract.[340,363]

For MEN2, two transgenic models have been established in which the human Cys634Arg mutation is expressed in a tissue-restricted manner. In one model, expression of the human mutant RET9 isoform under the control of the rat calcitonin-gene related peptide/calcitonin promoter was reported to result in overt CCH followed by bilateral MTC with morphologic features similar to human MTC.[369] In the other model, expression of the human mutant RET51 isoform under control of the human calcitonin promoter resulted in mice with early-onset CCH and subsequent bilateral MTC, and one founder line also developed tumors resembling papillary thyroid cancer, pancreatic cystadenomas, and cystoadenocarcinomas.[368,370] In addition, a transgenic mouse expressing the human *RET* gene with the Cys634Arg mutation in multiple tissues (e.g., thyroid, heart, liver, colon, brain) developed CCH and/or MTC that was accompanied by high serum calcitonin concentrations, and the tumors, but not normal tissues, from these mice had RET dimerization and complex formation with Shc and Grb2 adaptor proteins.[371] A knock-in mouse model with the Cys620Arg mutation has also been established for MEN2, and aged heterozygous ($Ret^{+/620R}$) mice were found to develop CCH and adrenal gland hyperplasia, although no overt MTC or pheochromocytoma developed. However, homozygote mice ($Ret^{620R/620R}$) were observed to die on the first postnatal day with renal agenesis and intestinal aganglionosis, consistent with the phenotype observed in conventional *Ret* knockout mice, and these observations further demonstrate the apparent paradoxical activity of certain *RET* mutations that exhibit both loss- and gain-of-function activity.[372]

For MEN3, transgenic and knock-in mouse models have been generated. Transgenic expression of the MEN3-associated Met918Thr mutation under the human calcitonin promoter in one mouse model resulted in the development of nodular CCH from 8 months of age and progression to MTC in 13% of mice after 11 months.[373] Transgenic expression of the same mutation in another mouse model using the dopamine β-hydroxylase promoter that facilitated expression in the developing sympathetic nervous system, enteric nervous system, and adrenal medulla resulted in neuroglial tumors, which were histologically indistinct from human ganglioneuromas, in the adrenals and sympathetic nervous system.[374] A knock-in mouse model harboring the murine equivalent of the Met918Thr mutation (i.e., Met919Thr) has been generated in which heterozygous ($Ret^{+/MEN3}$) and homozygous ($Ret^{MEN3/MEN3}$) mice develop CCH and adrenal chromaffin cell hyperplasia.[375] Progression to pheochromocytoma and a more severe thyroid phenotype were observed in homozygote mice only, thereby indicating a potential dosage effect of the activating mutation on disease expression. However, none of the mouse models developed mucosal neuromas or gastrointestinal ganglioneuromas, which are found in MEN3 patients.[367,368,375]

Genetic Testing, Tumor Surveillance, and Organization of Care

Clinical Utility of Genetic Testing for MEN2 and MEN3

The widespread implementation of *RET* genetic testing has transformed the management of patients with MEN2 and MEN3, as it enables the identification of those individuals who are at a higher risk of developing the disease, and very often this is now in early childhood and before the onset of clinical features (i.e., presymptomatic diagnosis), and therefore appropriate monitoring and early treatment can be implemented. Indeed, the effectiveness of *RET* genetic testing in MEN2 has been demonstrated in studies from Germany, which reveal a fall in the percentage of index cases in the population, owing to the increased detection of at-risk individuals through cascade genetic testing, together with a marked fall in MTC occurrence in nonindex *RET* mutation carriers, owing to prophylactic thyroidectomy.[252] The situation for MEN3 is more difficult due to the high percentage (~75%) of cases presenting with de novo mutations, and thus opportunities for early detection and prophylactic treatment are often missed.[342]

The potential for improved clinical outcomes within kindreds following a genetic diagnosis of MEN2 highlights the need to identify potential index cases harboring germline *RET* mutations. Thus, genetic testing should be considered in several settings to maximize the likelihood of successfully establishing the diagnosis in an index case. Thus, currently, *RET* genetic testing is indicated in all patients presenting with a clinical diagnosis of MEN2 (e.g., MTC and pheochromocytoma), as well as those with clinical features of an associated MEN2 syndrome (e.g., FMTC, CLA, HSCR) or phenotypic manifestations of MEN3. Similarly, those presenting with MEN2-associated clinical features and a relevant family history require testing. In addition, all patients presenting with apparently sporadic MTC, or unilateral or bilateral adrenal pheochromocytoma, should undergo *RET* mutational analysis.[3,340] For patients in whom the *RET* mutation status is unknown, either a prioritized DNA sequencing approach of the *RET* gene that incorporates recurrently affected exons (e.g., exons 10, 11, 13–16) or sequencing of the entire *RET* coding region should be undertaken. In patients in whom the clinical phenotype is highly suggestive of a specific genotype (e.g., typical MEN3 extraendocrine features with Met918Thr mutations), a more limited testing of the *RET* gene sequence may be appropriate. However, if *RET* testing is limited to specific exons, it is possible that additional sequence variants may be overlooked, and this may have clinical implications for the patient.[3] *RET* sequence variants that have not been reported previously in MEN2 and MEN3 patients will need careful evaluation by the clinical genetics team for the likely pathogenicity of the variant, and decisions on the role of cascade genetic testing of family members will have to be taken based on the clinical picture.

Once an established pathogenic *RET* mutation has been identified in an index case, genetic counseling and appropriate genetic testing for the specific sequence variant should be offered to all at-risk first-degree relatives. Cooperation of the patient will be required to contact the relatives, and occasionally complex ethical issues may arise (e.g., if the patient is reluctant to disclose their health status to family members). In the management of children, similar ethical challenges may arise if an affected parent refuses to allow appropriate investigation and testing of an at-risk child. However, such situations are rare. *RET* genetic testing of at-risk individuals should be performed at an early time point, and in children who may harbor the ATA highest- and high-risk categories of *RET* mutations, this should be in the first months or years of life, respectively, due to the early onset of disease in these groups. *RET* gene testing of the first-degree relatives of a presumed affected index case whose mutational status is unknown or unavailable is also indicated. Preconception genetic counseling, where appropriate, should be provided to all individuals at risk of transmitting *RET* mutations to their future offspring. Prenatal genetic testing using invasive (e.g., amniocentesis) or noninvasive approaches (e.g., by evaluating cell-free fetal DNA from maternal blood) may inform prospective parents regarding the disease status of the developing fetus. Recent advances in genetic testing combined with in vitro fertilization also offer prospective parents the opportunity to have a preimplantation genetic diagnosis.

Screening and Intervention in RET *Mutation Carriers*

The ability to make a genetic diagnosis of MEN2 or MEN3 in at-risk individuals, often in early childhood and before the onset of clinical features, enables the appropriate monitoring and treatment of asymptomatic individuals. Recommendations for the respective schedule of tumor surveillance and timing of potential prophylactic thyroidectomy is determined by the ATA risk category of *RET* mutation (see Table 42.4). Thus, for those with the highest- and high-risk categories of *RET* mutations, prophylactic thyroidectomy is typically recommended by the ages of 1 and 5 years, respectively (although earlier in some instances based on clinical, biochemical, and/or radiologic features). The timing of prophylactic surgery in those with moderate-risk *RET* mutations is now based on the serial measurement of basal serum calcitonin levels in combination with neck imaging studies.[3] Appropriate annual screening for pheochromocytoma and PHPT, based on genotype-phenotype correlations, is also recommended and should commence at an age commensurate with the risk profile of *RET* mutation (see Table 42.4). In adult patients identified to harbor MEN2-associated *RET* mutations through cascade genetic testing, serum calcitonin concentrations and plasma/urinary free fractionated metanephrines should be determined immediately. In individuals with normal serum calcitonin concentrations and/or normal metanephrines, annual monitoring of serum calcitonin and plasma/urinary metanephrines should commence. This situation is most frequently observed for moderate-risk *RET* mutations that may result in late-onset disease or reduced tumor penetrance. In those identified to have elevated serum calcitonin concentrations or elevated plasma or urinary metanephrines, full evaluations to determine the stages of the MTC and/or pheochromocytoma should be performed prior to appropriate treatment. Furthermore, it is imperative that coexistent pathologies such as pheochromocytoma should be excluded prior to any intervention in all patients with a *RET* mutation or who has MTC, MEN2, or MEN3.

MEN Type 4

MEN4, an autosomal dominant disorder due to mutation of the *CDKN1B* gene located on chromosome 12p13, has been reported in fewer than 20 index cases,[172,376,377] and patients had clinical features that are similar to those patients with MEN1. Indeed, among the 5% to 10% of patients with a clinical diagnosis of MEN1 who do not have *MEN1* gene mutations, approximately 3% will have *CDKN1B* mutations.

Clinical Features and Management

MEN4 patients predominantly have parathyroid, pituitary, and pancreatic tumors in association with other tumors, which

include gastrointestinal, bronchial, and cervical NETs; NF adrenal tumors; PTC; lipoma; and breast cancer.[5,172,376–379] Parathyroid tumors associated with PHPT have been reported in approximately 80% of MEN4 cases, although PHPT is observed to occur at a later age than MEN1. Pituitary tumors (including somatotropinoma, corticotropinoma, prolactinoma, and NF adenoma) occur in approximately 40% of cases,[172] and duodenopancreatic NETs occur in approximately 35% of cases. The investigation and treatments for these MEN4-associated tumors are similar to those for MEN1 and non-MEN1 tumors.

Molecular Genetics and Animal Models

The identification of the gene responsible for MEN4 resulted from observations in a rat model of endocrine neoplasia (termed *MENX*),[380] in which the disease locus was mapped to the distal part of chromosome 4,[381] a region that contained the *Cdkn1b* gene. *Cdkn1b* encodes the CDKI $p27^{kip1}$, also referred to as p27.[171,172,377,379] A homozygous frameshifting insertion of 8 bp in the rat *Cdkn1b* gene at codon 179, which resulted in a missense peptide and termination at codon 218 and a highly unstable mutant $p27^{kip1}$ protein, was identified in the MENX rats.[171,172] Subsequent studies of a patient with a MEN1 phenotype (pituitary and parathyroid disease) but absence of the *MEN1* mutation identified a nonsense *CDKN1B* mutation.[171] The identification of further patients harboring *CDKN1B* mutations followed, and MENX was renamed *MEN4*.[172,382,383] To date, fewer than 20 MEN4 index cases with *CDKN1B* mutations have been reported, and the majority of these mutations are associated with reduced levels of $p27^{Kip1}$ or altered protein function, consistent with a tumor suppressor role. The mutations reported include nonsense, frameshift, splice-site, and missense mutations.[171,172,376,377,382–385] Germline *CDNK1B* mutations have also been reported in patients with apparently sporadic (i.e., nonfamilial) PHPT, although further studies are required to confirm the clinical significance of the variants and whether such individuals develop additional MEN-associated tumors.[386,387] It is notable that that some rare missense variants in *CDKN1B* and other CDK inhibitor genes are observed at relative high frequency in the background population,[145] thereby suggesting that some *CDKN1B* variants that are benign polymorphisms may have been misclassified as mutations.

$p27^{kip1}$ participates in cell cycle regulation through its interaction with several cyclins and their respective CDKs. These include interactions with cyclin E/cdk2, cyclin A/cdk2, and cyclin D/cdk4.[388–390] The major function of the $p27^{kip1}$ protein appears to be the control of G1 to S phase during cell replication, where the binding of $p27^{kip1}$ to cyclin E/cdk2 arrests cell cycle progression.[388] The cellular $p27^{kip1}$ levels are tightly regulated at transcriptional, translational, and post-translational levels, and the transcription of *CDKN1B* is under the regulation of menin through its interaction with MLL.[191,192] However, post-translational regulation facilitates rapid changes in $p27^{kip1}$ expression. For example, on receipt of a mitogenic signal, at least two pathways in the cytoplasm and nucleus are activated, which result in phosphorylation of specific residues on $p27^{kip1}$ leading to proteosomal-mediated degradation and a derepression of cell cycle progression.[388,391,392] Furthermore, downregulation of $p27^{kip1}$ is observed in many cancers, including those of the colon, breast, stomach, and prostate.[388] The reported mechanisms for reduced levels of $p27^{kip1}$ protein may include decreased transcription, reduced translation, increased protein degradation, reduced binding to key interacting partners, or cellular mislocalization.[376,382–384,388]

Genetic Testing, Tumor Surveillance, and Organization of Care

Genetic analysis for *CDKN1B* mutations is indicated in individuals who have clinical evidence of typical or atypical MEN1 but without *MEN1* mutations or those who are first-degree relatives of patients with a known *CDKN1B* mutation.[1,172,376] The few numbers of patients reported with MEN4 make it difficult to provide guidelines specifically for the management of MEN4, and currently it would appear reasonable to follow a similar protocol of surveillance to that of MEN1.[1,172,376,377]

Future Directions and Concluding Remarks

Significant progress has been made in the diagnosis and management of the MEN syndromes. In particular, the widespread implementation of *MEN1*, *RET*, and *CDKN1B* genetic testing has facilitated the identification of individuals at risk of developing MEN1, MEN2 and MEN3, and MEN4, respectively. This approach has facilitated the periodic screening of mutation carriers, thereby enabling the early and/or presymptomatic detection of tumors, as well as leading to treatments that aim to reduce disease-associated morbidity and mortality. For example, the implementation of "prophylactic" thyroidectomy in MEN2 has resulted in significant improvements in clinical outcomes. Furthermore, an improved understanding of the natural history of the MEN syndromes has led to the formulation of clinical guidelines, but these are often based on a consensus among experts rather than evidence from clinical trials, which are required to address key issues such as the optimal treatment of MEN1-associated pancreatic NETs and parathyroid tumors. Reliable biomarkers and diagnostic tools that accurately predict the behavior of MEN1-associated pancreatic NETs and thymic carcinoids are also required, as is the evaluation of novel therapeutic approaches that have emerged from an understanding of menin biology, which have been demonstrated to be effective in preclinical models. In addition, the genetic and environmental factors that influence MEN2 disease expression and penetrance remain to be elucidated, and improved screening programs that enable the detection of de novo mutations associated with MEN3 are needed to reduce the number of children presenting with advanced MTC. More effective targeted treatments for advanced MTC are also required, as well as establishing the optimal use of existing therapies, including RTK inhibitors. This is likely to be aided by further mechanistic insights into RET receptor structure/function and the development of personalized therapies targeting individual *RET* mutations. Finally, the natural history of MEN4 and its clinical expression needs to be characterized by the continued identification and careful clinical evaluation of individuals and kindreds with *CDKN1B* mutations.

The Immunoendocrinopathy Syndromes

JENNIFER M. BARKER, PETER A. GOTTLIEB, AND MARK S. ANDERSON

CHAPTER OUTLINE

KEY POINTS

- Endocrine diseases may occur together, and understanding of these associations can lead to earlier diagnosis of additional disorders.
- Many autoimmune endocrine diseases have genetic risk at overlapping genetic loci, explaining, in part, their concurrence in individuals.
- Elucidation of the causes of these rare disorders has led to fundamental insights into the functioning of the immune system in autoimmunity.
- Studies of these disorders have uncovered the genetic basis for these rare syndromes and have helped to define important immune pathways.
- The search for means to define endocrine autoimmunity and disease states has led to the development of new assays that have become the cornerstone of endocrine autoimmune testing.
- Recommended testing for these related disorders is discussed in this chapter.

Since Addison's initial description of primary adrenal insufficiency in a patient with two autoimmune disorders (vitiligo and the hyperpigmentation of Addison disease), the immunoendocrinopathy syndromes have contributed to the understanding of both endocrinology and immunology (Fig. 43.1). Understanding the pathogenesis of the polyendocrine syndromes continues to expand. In particular, shared genetic loci underlying disease susceptibility, potential environmental factors, and organ-specific autoantigens targeted by the immune system are being defined. Recent advances include the development of more reliable T-cell and other immunologic assays, further refinement in predictive models of disease, and continued unraveling of the genetic factors underlying disease susceptibility.

Most autoimmune endocrine disorders (e.g., type 1 diabetes, autoimmune thyroid disease) occur in isolation. Two distinct autoimmune polyendocrine syndromes with characteristic groupings of manifestations are readily recognized. *Autoimmune polyendocrine syndrome type I* (APS-I) is a rare disorder with autosomal recessive inheritance that is caused by defects in the *autoimmune regulator* (*AIRE*) gene. In contrast, *autoimmune polyendocrine syndrome type II* (APS-II) is more common but less well defined and includes overlapping groups of disorders. A unifying characteristic within APS-II is the strong association with polymorphic genes of the human leukocyte antigen (HLA) region located on the short arm of chromosome 6 (band 6p21.3). In addition to HLA, many other genetic loci are likely to contribute to susceptibility to APS-II. For purposes of simplicity in this chapter, APS-II encompasses what some clinicians divide into APS-II (Addison disease plus type 1 diabetes or thyroid autoimmunity), APS-III (thyroid autoimmunity plus other autoimmune diseases, not Addison disease or type 1 diabetes), and APS-IV (two or more other organ-specific autoimmune disorders).

APS-II has also been known by various other names, including Schmidt syndrome, polyglandular autoimmune disease, polyglandular failure syndrome, organ-specific autoimmune disease, and polyendocrinopathy diabetes. Such diverse names reflect the large number of studies and case reports of this syndrome and its historical importance. Each of these other names has some shortcomings, such as failure to include the fact that both hyperfunction and hypofunction of endocrine glands can occur, or failure to recognize that nonendocrine disorders such as pernicious anemia and celiac disease are parts of the syndrome. Studies of patients with APS-II were instrumental in identifying the autoimmune bases of several diseases and developing autoantibody assays such as those for type 1 diabetes and cytoplasmic islet cell antibodies.

Other rare autoimmune endocrine disorders have contributed to an understanding of the development of autoimmunity. For example, the rare disorder called *immunodysregulation polyendocrinopathy enteropathy X-linked syndrome* (IPEX) is caused by a mutation of the *forkhead box P3* (*FOXP3*) gene. *FOXP3* plays a central role in the development and function of regulatory $CD4^+$ T cells that function to maintain tolerance to self. It has become increasingly

• **Fig. 43.1** This illustration accompanied Addison's initial description of primary adrenal insufficiency (Addison disease). (From Addison T. *On the Constitutional and Local Effects of Disease of the Supra-renal Capsules*. London, UK: Samuel Highley; 1855.)

recognized that these T cells play a key role in the pathogenesis of many autoimmune diseases, and therapies targeting these cells will likely be developed and tested. A thorough understanding of these rare and often genetically simple disorders provides insight into the development of syndromes that are characterized by polygenic inheritance and that affect a larger group of patients.

Autoimmunity Primer

An understanding of the pathophysiology of autoimmune disease requires a basic knowledge of the immunologic mechanisms that underlie tolerance (the ability to differentiate self from nonself). Autoimmunity develops when the mechanisms of immune tolerance break down. It can occur centrally at the level of the generative organs (e.g., thymus, bone marrow) or peripherally in the target organs or lymphoid tissues. T lymphocytes and autoantibodies produced by B cells are two arms of the immune system that differ fundamentally in their recognition of target antigens. Autoantibodies react with intact molecules (including both soluble and cell surface molecules) and usually interact with conformational determinants of the autoantigen. In contrast, T lymphocytes recognize peptide fragments of autoantigens, often 8 to 12 amino acids in length, that are presented on the surface of another cell by molecules of the major histocompatibility complex (MHC).

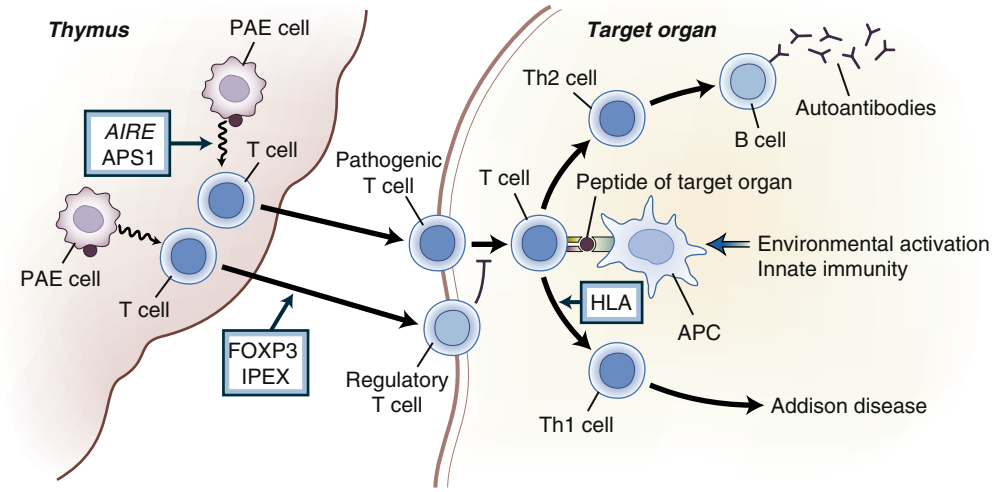
Histocompatibility molecules interact with T-cell receptors when bound with an antigenic peptide. These molecules resemble a hot dog in a bun, with the antigenic peptide (the hot dog) bound in the groove of the histocompatibility molecule (the bun). Histocompatibility molecules are extremely polymorphic, with different amino acids lining the peptide-binding groove. These variable amino acids determine which peptides are bound and presented to T lymphocytes.

T cells differ based on multiple cell surface molecules, and these molecules determine their function in the immune system. T cells interact with other cells within and outside the immune system. $CD4^+$ T cells typically react with peptides that are derived from proteins in extracellular compartments that are bound and acquired by class II histocompatibility molecules (HLA-DP, HLA-DQ, or HLA-DR in humans), expressed on antigen-presenting cells (APCs) such as macrophages, dendritic cells, and B lymphocytes. $CD8^+$ T cells react with peptides bound by class I histocompatibility molecules (HLA-A, HLA-B, and HLA-C). Class I molecules are present on the surface of almost all nucleated cells. The antigen peptide in this case is derived from proteins expressed endogenously and is presented in a complex by class I HLA by the target cell itself. Recognition of the antigenic peptide by $CD8^+$ T cells typically leads to the release of cytotoxic chemicals that kill the target cell.

The T-cell response depends on the context in which the antigen is presented. The simple expression of histocompatibility molecules and recognition of antigen by a T cell are not sufficient for T-cell activation. This context is at least partially determined by the interaction of cell surface molecules on both the T cell and the APC. Interaction among the MHC, the peptide, and the T-cell receptor (*signal one*) is critical to the activation process; other co-stimulatory molecules then help to define the nature of the immune response (*signal two*). The context in which the antigens are presented is critical for the determination of this response. Cell surface molecules and receptors, cytokines, and chemokines form the context in which the antigen is presented. Based on this context, the cell can become activated, tolerized, or anergic (immune unresponsive). For example, the APC cell surface molecule CD80 or CD86 engages the CD28 receptor on the T cell and amplifies signal one, which leads to T-cell activation. When a T cell recognizes an antigen in the context of the MHC and does not receive the appropriate second signal, anergy results.

Tolerance induction is a staged process that begins in the thymus during T-cell maturation. This process depends in part on the presence of *peripheral antigens* in the thymus. Peripheral antigens are self-antigens (e.g., insulin) normally expressed in tissues outside the immune system that are expressed at low levels in the thymus. Developing T cells that react strongly to these peripheral molecules in the context of the MHC are deleted in the thymus and are thus removed from the T-cell repertoire in a process known as negative selection. Study of *AIRE* gene knockout mice has supported the importance of these phenomena in the development of autoimmunity. These mice have low levels of expression of peripheral antigens in the thymus and develop lymphocytic infiltrates in multiple organs (see later discussion).

Peripheral tolerance is an important mechanism for tolerance induction after T cells have matured in the thymus. Anergic and regulatory T cells are integral in the development of tolerance for naive T cells. A major population of T-regulatory cells carry the cell surface markers CD4 and CD25 and express FOXP3. The function of the population of $CD4^+/CD25^{high}$ cells involves an active suppressive activity and relies on the transcription factor FOXP3. Deletion of this transcription factor leads to fulminant autoimmunity in neonates (e.g., neonatal type 1 diabetes and enteropathy), often resulting in death within the first year of life (IPEX syndrome; see later discussion). Another set of key molecules that help control peripheral T-cell tolerance are cytotoxic T-lymphocyte antigen 4 (CTLA4) and programmed death 1 (PD1).[1] CTLA4 is expressed in T cells and acts as a negative regulator of T-cell signaling by competing with the T-cell activator CD28 (described earlier). CTLA4 outcompetes CD28 for binding to its ligands CD80 and CD86 due to its higher affinity for ligand. In addition, CTLA4 is broadly expressed on the surface of FOXP3-expressing CD4-positive T-regulatory cells, where it likely plays a role in blocking CD28 interactions with CD80 and CD86. PD1 is yet another co-stimulatory molecule that becomes upregulated on T cells that have been chronically activated, and it confers negative signals through inhibitory signaling domains in its intracytoplasmic tail. The importance of both PD1 and CTLA4 in peripheral tolerance is underscored in knockout mouse models that develop spontaneous multiorgan autoimmunity and in cancer patients treated with antibodies that block their activity where many of these patients develop autoimmune complications (see later discussion).



• **Fig. 43.2** Model of the pathogenesis of autoimmunity in polyendocrine disorders. The development of autoimmune disease is determined by a group of T cells that recognize one or more organ-specific epitomes. Peptides are presented in the human leukocyte antigen (HLA) molecule and are recognized by the T-cell receptor. Recognition of self molecules depends on the maturation of the T cell, a process that begins in the thymus and continues in the periphery. The transcription factor FOXP3 stimulates the development of $CD4^+/CD25^+$ regulatory T cells. B cells produce autoantibodies under the stimulation of T cells. *AIRE*, autoimmune regulator; *APC*, antigen-presenting cell; *APS1*, autoimmune polyendocrine syndrome 1; *IPEX*, immunodysregulation polyendocrinopathy enteropathy X-linked; *PAE*, peripheral antigen-expressing cell; *Th1*, type 1 helper T cell; *Th2*, type 2 helper T cell. (From Eisenbarth GS, Gottlieb PA. Autoimmune polyendocrine syndromes. *N Engl J Med*. 2004;350:2068–2079.)

Cognate help is the process by which B cells are activated by $CD4^+$ T cells that are responding to the same antigen. $CD4^+$ T cells activate B cells to produce the humoral immune response. This occurs after the $CD4^+$ T cell engages an antigen in the context of the MHC on the cell surface of a B cell. The cytokines (interleukin [IL] 4, IL5, and IL6) produced by the $CD4^+$ T cells induce the maturation of a B cell. Depending on the cytokine milieu, the B cell will switch from producing immunoglobulin M (IgM) to IgG, IgE, or IgA. The development of B-cell tolerance is partially dependent on this linked recognition: autoreactive B-cell clones that do not have a $CD4^+$ T cell that can bind with the antigen in its MHC groove will not normally be activated. Thus, in most cases, the generation of autoantibodies by B cells is also linked to an autoreactive T cell specific for the same self-antigen. Growing evidence supports the role of autoreactive B cells as critical APCs to autoreactive T cells, creating a positive feedback loop in the expansion and maintenance of the autoimmune process.

Natural History of Autoimmune Disorders

The natural history of autoimmune disorders can be divided into a series of stages beginning with genetic susceptibility, followed by triggering of autoimmunity (e.g., dietary gliadin exposure in celiac disease) and active autoimmunity preceding clinical manifestations (e.g., progressive glandular destruction), and, finally, overt disease. This is a theoretical construct that may be useful for understanding factors involved with the development of autoimmunity and disease, but of necessity it is simplified and does not reflect the potential relapsing-remitting nature of autoimmunity (Fig. 43.2).

Genetic Associations

Although there is familial aggregation of APS-II and its component disorders, there is no simple pattern of inheritance (Table 43.1). Susceptibility is probably determined by multiple genetic loci (with HLA having the strongest effect) interacting with environmental factors. Autoimmune diseases share common genetic risk factors, including HLA, the MHC class I–related gene A (*MICA*), the gene for lymphoid tyrosine phosphatase (*PTPN22*), the cytotoxic T lymphocyte–associated antigen 4 (CTLA4), and the gene for NACHT leucine-rich repeat protein 1 (NLRP1, or NALP1).[2] In addition, genetic susceptibility for some autoimmune diseases has been linked to polymorphisms that are organ specific—for example, polymorphisms in the variable nucleotide tandem repeat upstream from the insulin gene have been associated with risk for type 1 diabetes.[3]

Genes located on the MHC found on chromosome 6 have been implicated in the pathogenesis of organ-specific autoimmune diseases. These genes are in strong linkage disequilibrium with each other and encode proteins that are important in the function of the immune system. Foremost in importance for the genetics of organ-specific autoimmune diseases are class I and class II HLA genes. Molecular HLA genotyping has revealed many subtypes of the older, serologically defined alleles, and the unique genetic sequence encoding each polymorphic chain of the histocompatibility molecules is now given a unique identifying number. A case in point is the DQ molecule, which is the histocompatibility molecule most strongly associated with endocrine autoimmunity. A number is assigned for each unique α- and β-chain sequence. Examples are DQA1*0501 for the α chain and DQB1*0201 for the β chain of the DQ molecule (also termed *DQ2*) commonly encoded on DR3 (DRB1*0301) haplotypes. A haplotype consists of a series of alleles of different genes on a contiguous region of a chromosome (e.g., DQA1 and DQB1 alleles) that are inherited together. A genotype is the combination of the haplotypes of both chromosomes. Fine mapping of the HLA has shown remarkable conservation of the HLA-A1/B8/DR3 haplotype such that a region of approximately 2.9 megabases is invariable. Conservation of large areas

TABLE 43.1 Genetic Associations With Autoimmune Disease

Gene	Proposed Mechanism of Action	Polymorphism/Mutation	Disease	Inheritance
HLA	Antigen presentation	DR3-DQ2/DR4-DQ8 DR3-DQ2 DR3-DQ2/DRB1*0404-DQ8 DR3-DQ2/DR4-DQ8 DR3 DR5	Type 1 diabetes Celiac disease Addison disease Graves disease Hypothyroidism	Multigenic
MICA	Priming of naive T cells	5, 5.1 4, 5.1 5.1	Type 1 diabetes Celiac disease Addison disease	Multigenic
PTPN22	T-cell receptor signaling pathway through interaction with regulatory kinases	Tryptophan substitution for arginine at position 620	Type 1 diabetes SLE RA Graves disease Hypothyroidism Vitiligo	Multigenic
CTLA4	Receptor on activated $CD4^+$ and $CD8^+$ T cells; decreases T-cell activation	CT60 CT60; +49A/G CT60; +49A/G ++49A/G ++49A/G	Type 1 diabetes Graves disease Hypothyroidism Celiac disease Addison disease	Multigenic
AIRE	"Peripheral" antigen presentation in the thymus	Multiple reported mutations	APS-I	Autosomal recessive
FOXP3	Transcription factor important for maturation of $CD4^+$/$CD25^+$ regulatory T cells	Multiple reported mutations	IPEX	X-linked

AIRE, Autoimmune regulator; *APS-I*, autoimmune polyendocrine syndrome type I; *CTLA4*, cytotoxic T lymphocyte–associated antigen 4; *FOXP3*, forkhead box protein 3; *HLA*, human leukocyte antigen; *IPEX*, immunodysregulation polyendocrinopathy enteropathy X-linked; *MICA*, major histocompatibility complex class I–related gene A; *PTPN22*, the gene for lymphoid tyrosine phosphatase; *RA*, rheumatoid arthritis; *SLE*, systemic lupus erythematosus.

suggests that these areas of the genome have been inherited without recombination and are in very tight linkage disequilibrium. This greatly complicates the ability to identify which, if any, of the genes within the area of conservation are associated with disease and must be accounted for when assessing susceptibility to disease in this region.

Part of the overlapping risk for autoimmune disease is related to shared genetic susceptibility, especially within the HLA. For example, the highest-risk HLA genotype for type 1 diabetes is DR3-DQ2, DR4-DQ8 (DQ8 = DQA1*0301-DQB1*0302). The importance of this HLA genotype in the development of type 1 diabetes is highlighted by the observation that children who inherited the same DR3-DQ2, DR4-DQ8 as a sibling with type 1 diabetes are at greater than 75% risk for development of autoimmunity by age 12 years and at greater than 50% risk of developing diabetes by 12 years.[4] A specific DR4 subtype of this gene, DRB1*0404, shows a strong association with Addison disease.[5,6] The DR3-DQ2 haplotype is associated with celiac disease both in the presence[7] and absence[8] of type 1 diabetes. This haplotype has been associated with autoimmune thyroid disease,[9] although conflicting reports exist.[10]

Whereas some HLA alleles increase disease risk, others are associated with protection from disease. For example, the DQ alleles DQA1*0102-DQB1*0602 (usually associated with DR2) not only confer strong protection from type 1A diabetes in a dominant fashion[11] but also confer susceptibility to another autoimmune disorder—multiple sclerosis. Furthermore, this protection is not general to endocrine autoimmunity, because no protection from Addison disease is afforded by DQB1*0602. DP is another gene within the MHC, and its 0402 polymorphism has been shown to be associated with a decreased risk for type 1 diabetes in subjects with the highest-risk HLA genotype for type 1 diabetes (DR3/DR4).[12] Observations such as these suggest that as more is learned about the genetic influence of disease, researchers will be able to combine different genotypes and refine prediction of autoimmune disease.

MICA produces a protein that is expressed in the thymus and in naive $CD8^+$ T cells. Polymorphisms of *MICA* have been associated with type 1 diabetes,[13] celiac disease,[14] and Addison disease.[15] A particular polymorphism of *MICA*, denoted 5.1, results from the insertion of a single base pair. This insertion produces a premature stop codon and a truncated protein. This particular polymorphism has been shown to influence the risk for Addison disease in subjects with autoimmunity associated with Addison disease.

Genes outside the MHC have also been implicated in the pathogenesis of autoimmune disease. For example, the *PTPN22* gene encodes lymphoid tyrosine phosphatase (LYP) protein. LYP, through interactions with regulatory kinases such as CSK, appears to act as an inhibitor of the signal cascade downstream from the T-cell receptor. A specific polymorphism associated with a tryptophan substitution for arginine at position 620 (R620W) blocks LYP's interaction with CSK.[16] Recent work has suggested that this allele may increase the development of autoreactive B cells[16,17] and affect intracellular signaling pathways in both T and B cells.[18] This polymorphism has been associated

with type 1 diabetes,[19] rheumatoid arthritis,[20] systemic lupus erythematosus (SLE),[21] Graves disease,[22] and vitiligo,[23] and is weakly associated with Addison disease.[24] Furthermore, this disease-associated allele has also been associated with SLE, rheumatoid arthritis, type 1 diabetes, and autoimmune hypothyroidism in families with several members affected by more than one autoimmune disease.[24]

CTLA4 is expressed on activated $CD4^+$ and $CD8^+$ T cells, where it is hypothesized to act as a negative regulator as outlined earlier.[25] Several polymorphisms within the CTLA4 gene have been associated with autoimmune diseases. One polymorphism associated with AT repeats has been shown to reduce the inhibitory function of CTLA4 in subjects with Graves disease.[26] A single nucleotide polymorphism in the 3′ untranslated region, denoted CT60, has been associated with Graves disease[27] and autoimmune hypothyroidism.[28] An additional polymorphism, denoted +49A/G, has been associated with celiac disease in the Dutch population,[29] with autoimmune thyroid disease,[30] and with Addison disease.[31]

NALP1 regulates the innate immune system. After the initial observation that this gene was associated with the risk of vitiligo[32] and other related autoimmune diseases, it was associated with Addison disease and type 1 diabetes.[33]

Organ-specific genetic polymorphisms have been associated with the development of specific autoimmune diseases. For example, polymorphisms of the variable number of tandem repeats upstream of the insulin gene have been associated with the development of type 1 diabetes. Higher numbers of tandem repeats are associated with increased production of insulin in the thymus and protection from type 1 diabetes presumably due to improved negative selection of insulin-reactive T cells.[3] Similarly, polymorphisms of the thyroglobulin gene are associated with autoimmune thyroid disease.[34]

Single-gene defects such as *AIRE* and *FOXP3* cause multiorgan autoimmunity and are discussed in sections devoted to those topics. Analysis of mutations of the *AIRE* gene indicates that it generally does not play a role in APS-II or sporadic Addison disease, with 1 (1.1%) in 90 patients with Addison disease (non–APS-I) and 1 (0.2%) in 576 control subjects having *AIRE* mutations.[31]

Environmental Triggers

Although genetics is known to play an important role in the development of autoimmunity, it does not tell the whole story. For example, the highest-risk HLA genotype for type 1 diabetes (DR3-DQ2, DR4-DQ8) is associated with a risk of 1 in 20 for the development of diabetes.[35] Although this is greater than the general population prevalence rate of 1 in 200 by the age of 20 years, it is certainly not a 100% risk. Therefore, other factors (genetic and environmental) must be involved in the initiation of autoimmunity. Some theorize that these factors may be environmental triggers.

For one disease, celiac disease, the underlying environmental trigger has been identified: gluten. Through studies such as DAISY (the Diabetes Autoimmunity Study in the Young), BabyDiab, and CEDAR (Celiac Disease Autoimmunity Research), the timing of first exposure to cereal has been identified as a risk factor for the development of diabetes and celiac disease autoimmunity. Infants exposed at a very young age to cereal developed diabetes and celiac-associated autoimmunity at a greater rate than those who had cereal introduced at a later date.[36–38] In epidemiologic studies, cod liver oil consumption has been associated with a decreased risk for type 1 diabetes. Cod liver oil contains omega-3 polyunsaturated fats and vitamin D. In prospective studies, there is some suggestion that lower consumption of omega-3 polyunsaturated fats is associated with an increased risk for autoimmunity associated with type 1 diabetes.[39] Further investigation may identify additional environmental associations. Changes in our diet, our food composition, and use of medicines such as antibiotics have the potential to change our gut flora and microbiome. Animal studies suggest that changes in the gut microbiome can affect disease in these models of autoimmunity.[40,41] Human evidence is being sought to determine whether the interaction between the microbiome and innate immunity is leading to increased inflammation and setting the stage for increased frequencies of all autoimmune disorders that have recently been observed.[42,43]

Virus and other infections have been considered as a cause of autoimmunity and have been shown to cause the development of type 1 diabetes when infection occurs in utero for rubella, for example. Examination of pancreata from individuals with prediabetes (autoantibodies) or those with diabetes has provided evidence consistent with viral infection of the organ.[44,45] Association is not causality, and further experiments are needed to determine whether this finding is an important component of how either autoimmunity is initiated or propagated.

Targeted immunologic therapies are also associated with the induction of autoimmunity. A remarkable example is the treatment of patients with multiple sclerosis with an anti-CD52 monoclonal antibody. One-third of 27 patients given the monoclonal antibody developed antithyrotropin receptor autoantibodies and hyperthyroidism.[46] Interferon-α (IFNα) therapy for hepatitis has been associated with thyroid autoimmunity[47] and type 1 diabetes.[48] Severe hypoglycemia associated with insulin autoantibodies in the absence of insulin administration, termed *Hirata disease*, is associated with methimazole treatment of Graves disease. The development of Hirata disease in these patients is associated with HLA-Bw62/Cw4/DR4 with a specific DRB1 allele (DRB1*0406).[49] Immune checkpoint blockade is now an approved treatment approach for several cancers, and these antibodies that block CTLA4 or PD1 on T cells have both been associated with the induction of autoimmune complications in a subset of patients. These autoimmune complications are broad but now include the induction of endocrine-related autoimmunity including thyroiditis, type 1 diabetes, lymphocytic hypophysitis, and adrenalitis.[50]

Development of Organ-Specific Autoimmunity

Autoantibodies highly specific for a given disorder are present before disease onset. Each specific autoantibody reacts with only a single autoantigen, although autoantigens may be present in multiple tissues. The targets of autoantibodies appear to be unrelated; however, for organ-specific autoimmunity, they are usually expressed in specific cells and cellular sites. Anti-islet antibodies include antibodies to glutamic acid decarboxylase (GAD); islet cell antibody (ICA) 512 (also termed *insulinoma antigen 2* [IA2]); insulin; and, the most recently discovered, ZnT8.[51] Celiac disease is associated with antibodies against tissue transglutaminase (tTG). Addison disease is associated with antibodies against 21-hydroxylase.

Given that the antibodies can be identified before the development of organ dysfunction, they can be used to screen subjects who are at high risk for development of autoimmune disease to identify risk for additional autoimmune diseases. This approach has been employed in studies such as TrialNet for type 1 diabetes to screen first-degree relatives of patients with type 1 diabetes for diabetes-related autoantibodies. In this and other cohorts, risk for development of diabetes increases with the number of autoantibodies and their persistence.

Organ-specific autoantibodies (identified with appropriate assays) are rarely present (approximately 1 in 100) in the general population and identify a subset of people who are at greater risk for clinical disease. These autoantibodies may be expressed for years before the disease develops, and additional autoantibodies can develop over time. The pace at which disease develops is highly variable. For example, children as young as 1 year can present with type 1 diabetes. In contrast, a subset of subjects (5–10%) with type 2 diabetes diagnosed in adulthood have autoimmunity as the underlying cause. This may be due in part to genetics, because subjects who develop autoimmune diabetes at an older age have a higher proportion of the protective diabetes allele DQB1*0602, although even in adults, DQB1*0602 provides dramatic protection.[52]

In contrast, less is known concerning the specificity of pathogenic T cells. Given the observation that cross-reactive recognition by pathogenic T-cell clones may be determined by as few as four properly spaced amino acids of a nonapeptide and the estimate that each T-cell receptor might react with a million different peptides, there is considerable potential for patterns of autoimmunity to be determined by cross-reactive T cells. An important development has been the discovery in the thymus and other lymphoid tissues of peripheral antigen-expressing cells that express autoantigens such as insulin. Minute quantities of such molecules in the thymus can contribute to tolerance. Insulin messenger RNA in the thymus is regulated by genetic polymorphisms of the insulin gene associated with diabetes risk.[3] There is also evidence that stromal and lymphoid cells ($CD11c^+$) in the spleen, lymph nodes, and circulation express multiple similar antigens.[53]

Failure of Gland

Organ dysfunction develops over time and can include a period of intermediate function that may be characterized by increased levels of the stimulatory hormones (e.g., thyroid-stimulating hormone, corticotropin [ACTH]) with normal levels of certain hormones (triiodothyronine, thyroxine, and cortisol). Once a significant portion of the gland has been destroyed, overt disease is then present.

Autoimmune Polyendocrine Syndrome Type I

Clinical Features

Table 43.2 compares the features of APS-I with those of APS-II. Table 43.3 shows the clinical features and recommended follow-up for patients with APS-I. Note some of the distinctions in the pattern of disease features of the two syndromes, particularly the propensity for hypoparathyroidism and candidiasis in APS-I, which is virtually absent in APS-II. Likewise, celiac disease is frequently observed in APS-II but is not seen in APS-I.

APS-I (Mendelian Inheritance in Man [MIM] 240300), also known as *autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy*, or APECED, is characterized by the classic triad of mucocutaneous candidiasis, autoimmune hypoparathyroidism, and Addison disease, which form three of the most common components of the disorder. Patients with APS-I are at risk for the development of autoimmune diseases affecting almost every organ. Multiple patient series have been reported, including subjects in two large series from both Finland[54–56] and the United States.[57,58]

TABLE 43.2 Contrasting Features of Autoimmune Polyendocrine Syndrome

Feature	APS-I	APS-II
Inheritance pattern	Autosomal recessive (only siblings affected)	Polygenic (multiple generations affected)
Associated gene	*AIRE* gene mutation	*HLA-DR3* and *DR4* associated
Gender association	Equal gender incidence	Female preponderance
Age at onset	Onset in infancy	Peak onset 20–60 years
Clinical features	Mucocutaneous candidiasis Hypoparathyroidism Addison disease	Type 1 diabetes Autoimmune thyroid disease Addison disease
Diagnostic antibodies	Anti-interferon	

APS, Autoimmune polyendocrine syndrome.

In a series of 89 Finnish patients described by Perheentupa,[54] all had chronic candidiasis at some time, 86% had hypoparathyroidism, and 79% had Addison disease. Gonadal failure (72% in women, 26% in men) and hypoplasia of the dental enamel (77% of patients) were also frequent findings. Other manifestations that occurred less often included alopecia (40%), vitiligo (26%), intestinal malabsorption (18%), type 1 diabetes (23%), pernicious anemia (31%), chronic active hepatitis (17%), and hypothyroidism (18%). The incidence rates for many of these disorders peak in the first or second decade of life, and the disease continues to develop over decades (Fig. 43.3). Therefore, reported prevalence rates of component disorders are highly dependent on the age at which follow-up ended.

APS-I is characteristically recognized in early childhood. Infants can present with chronic or recurrent mucocutaneous candidiasis in the first year of life, followed by hypoparathyroidism and Addison disease, but new components can develop at any age. Decades can elapse between the diagnosis of one disorder and the onset of another in the same patient. Consequently, lifelong follow-up is important to allow early detection of additional components.

Recurrent candidiasis commonly affects the mouth and nails and, less frequently, the skin and esophagus.[54] Chronic oral candidiasis can result in atrophic disease with areas suggestive of leukoplakia. If this develops, the patient is at significant risk for carcinoma of the oral mucosa (with its high mortality rate).

Ectodermal dystrophy is another component of the syndrome (manifested by pitted nails, keratopathy, and enamel hypoplasia) and cannot be attributed to hypoparathyroidism. Enamel hypoplasia can precede the onset of hypoparathyroidism and, despite adequate replacement therapy, can also affect teeth forming after the onset of hypoparathyroidism.[59]

TABLE 43.3 Clinical Features and Recommended Follow-Up for APS-I and APS-II

Component Disease	Frequency at Age 40 Years (%)	Recommended Evaluation
Autoimmune Polyendocrine Syndrome Type I		
Addison disease	79	Sodium, potassium, ACTH, cortisol, plasma renin activity, 21-hydroxylase autoantibodies
Diarrhea	18	History
Ectodermal dysplasia	50-75	Physical examination
Hypoparathyroidism	86	Serum calcium, phosphate, PTH
Hepatitis	17	Liver function test
Hypothyroidism	18	TSH; thyroid peroxidase and/or thyroglobulin autoantibodies
Male hypogonadism	26	FSH/LH
Mucocutaneous candidiasis	100	Physical examination
Obstipation	21	History
Ovarian failure	72	FSH/LH
Pernicious anemia	31	CBC, vitamin B_{12} levels
Splenic atrophy	15	Blood smear for Howell-Jolly bodies; platelet count; ultrasound if positive
Type 1 diabetes	23	Glucose, hemoglobin A_{1c}, diabetes-associated autoantibodies (insulin, GAD65, IA2)
Autoimmune Polyendocrine Syndrome Type II[a]		
Addison disease	0.5	21-Hydroxylase autoantibodies ACTH stimulation testing if positive
Alopecia		Physical examination
Autoimmune hypothyroidism	15–30	TSH; thyroid peroxidase and/or thyroglobulin autoantibodies
Celiac disease	5–10	Transglutaminase autoantibodies; small intestine biopsy if positive
Cerebellar ataxia	Rare[b]	Dictated by signs and symptoms of disease
Chronic inflammatory demyelinating polyneuropathy	Rare[b]	Dictated by signs and symptoms of disease
Hypophysitis	Rare[b]	Dictated by signs and symptoms of disease
Idiopathic heart block	Rare[b]	Dictated by signs and symptoms of disease
IgA deficiency	0.5	IgA level
Myasthenia gravis	Rare[b]	Dictated by signs and symptoms of disease
Myocarditis	Rare[b]	Dictated by signs and symptoms of disease
Pernicious anemia	0.5–5	Anti–parietal cell autoantibodies CBC, vitamin B_{12} levels if positive
Serositis	Rare[b]	Dictated by signs and symptoms of disease
Stiff-man syndrome	Rare[b]	Dictated by signs and symptoms of disease
Vitiligo	1–9	Physical examination

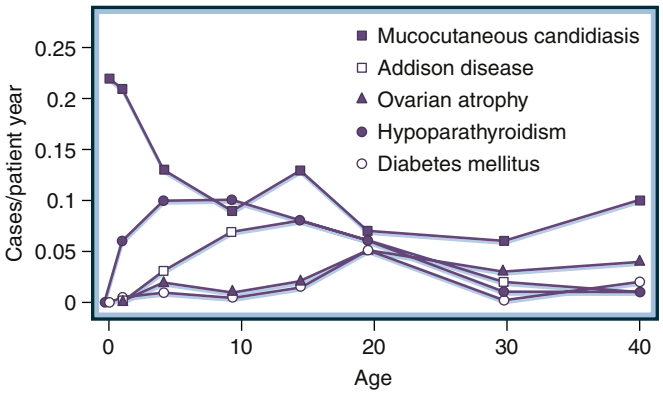
[a]In the population with type 1 diabetes.

[b]Rare reported disorders in subjects with APS-II.

ACTH, Adrenocorticotropic hormone; *APS*, autoimmune polyendocrine syndrome; *CBC*, complete blood count; *FSH*, follicle-stimulating hormone; *GAD*, glutamic acid decarboxylase; *IA2*, insulinoma antigen 2; *IgA*, immunoglobulin A; *LH*, luteinizing hormone; *PTH*, parathyroid hormone; *TSH*, thyroid-stimulating hormone.

Friedman and colleagues[60] reported the frequent occurrence of asplenism and cholelithiasis as additional features of APS-I. Splenic atrophy may also cause immune deficiency. Although the cause of this part of the disorder is unknown, it is relatively common: up to 15% of patients are asplenic.[54] The presence of Howell-Jolly bodies on peripheral blood smear is suggestive of asplenia. If asplenia is identified, immunization with polyvalent pneumococcal vaccine should be administered, and follow-up antibody titers should be obtained. If an adequate response is not produced, daily prophylactic antibiotics may be necessary.

Malabsorption with steatorrhea is of uncertain origin, is usually intermittent, and may be exacerbated by hypocalcemia. Bereket and associates[61] reported a case in which patchy intestinal lymphangiectasia was discovered by endoscopically directed biopsy. Pancreatic insufficiency has been treated with cyclosporine.[62] Autoantibodies (e.g., tryptophan hydroxylase, histidine decarboxylase) reacting with intestinal endocrine cells (enterochromaffin, cholecystokinin, and enterochromaffin like) occur and are associated with loss of endocrine cells on biopsy and with gastrointestinal dysfunction.[63,64]



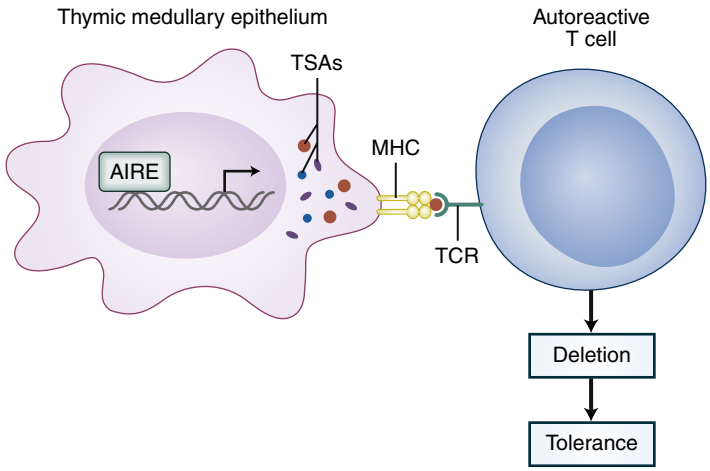
• **Fig. 43.3** Incidence of disease development by age in patients with autoimmune polyendocrine syndrome type I (APS-I). (From Perheentupa J. APS-I/APECED: the clinical disease and therapy. *Endocrinol Metab Clin North Am*. 2002;31:295–320.)

Genetics

APS-I is inherited in a classic mendelian autosomal recessive fashion and is caused by mutations in the *AIRE* gene, located on the short arm of chromosome 21 (near markers D21s49 and D21s171 on 21p22.3).[65] The gene encodes a transcriptional regulator protein that is highly expressed in antigen-presenting epithelial cells in the thymus and in a small subset of cells in lymphoid tissues.[66,67] It has been localized to the nucleus, and mutations have been demonstrated to be associated with decreased transcription of reporter products.[68,69] A mouse model of APS-I has been generated, and *Aire* knockout mice also spontaneously develop autoimmune features. Detailed analyses of antigen-presenting epithelial cells in the thymus of *Aire* knockout mice has shown that these cells have decreased expression of peripheral *tissue-specific self-antigens* (TSAs) and that Aire promotes the expression of thousands of such self-antigens in these cells.[66] Furthermore, autoreactive T cells with specificity to these TSAs can escape thymic deletion when Aire is defective and promote autoimmunity.[70–72] Thus, Aire appears to act as a transcriptional activator that promotes the expression of a wide array of TSAs in the thymus to promote central tolerance (Fig. 43.4).

Multiple mutations of *AIRE* have been identified in subjects with APS-I. The frequency of specific mutations varies in different populations. For example, in Sardinia, a deletion of amino acid 257 is present in 90% of mutated alleles. A 136–base pair deletion in exon 8 is present in 71% of British alleles and in 56% of alleles in the United States. Analysis of haplotypes indicates that this deletion has arisen on many occasions.

Most cases of APS-I are associated with autosomal recessive inheritance patterns; however, there are now reports of autosomal dominant inheritance. A rare kindred of patients from Italy have a mutation in the SAND domain of the AIRE protein (G228W)



• **Fig. 43.4** The autoimmune regulator (AIRE) gene functions to maintain tolerance by promoting the display of self-antigens in the thymus. An AIRE-expressing thymic medullary epithelial cell is shown (*left*). AIRE operates in the nucleus to promote the expression of thousands of different tissue-specific self-antigens (TSAs) that include many endocrine organ-specific proteins such as insulin. Peptide fragments of these TSAs are displayed on major histocompatibility complex (MHC) molecules to help promote the deletion of autoreactive T cells (*right*) that can be generated in the thymus from random gene rearrangement of the T-cell receptor (TCR). Such T cells are deleted when they encounter their antigen-MHC in the thymus, and thus immune tolerance is maintained.

that when present in the heterozygous state is associated with autoimmunity, thus fitting an autosomal dominant inheritance pattern.[73] In a mouse model of this mutation, the expression of TSAs in the thymus was decreased compared with that inthe control model, suggesting a mechanism for this observed inheritance pattern.[74] In addition, point mutations in the PHD1 domain of AIRE have now been associated with a dominant inheritance pattern.[75] In all cases, the molecular explanation could be related to the observation that AIRE forms multimers through its N-terminal domain, and thus mutations in other domains could still allow for multimerization with a wild-type copy of AIRE and a dominant-negative effect in AIRE activity. The autoimmune phenotype in this group of patients appears to be milder with the development of fewer autoimmune features or even a single disease feature that likely reflects partial AIRE activity in these patients.

Diagnosis

The diagnosis of APS-I is highly likely when two or more of the primary component disorders (i.e., mucocutaneous candidiasis, hypoparathyroidism, and Addison disease) are present. Siblings of an affected patient should be considered affected even if only one of these disorders is present. Sequence analysis of *AIRE* for mutations may be helpful in identifying subjects with APS-I. Any patient with any of the component disorders deserves careful follow-up to watch for the development of additional disease.

Autoantibodies against IFNα and IFNω have been identified in almost 100% of subjects with APS-I, regardless of age at screening.[76] The autoantibody has been found in subjects with many different mutations of the *AIRE* gene; it is not present in other autoimmune diseases, and it has been proposed to use this autoantibody to screen subjects with multiple autoimmune diseases for APS-I. It is unclear if antibodies to these type 1 IFNs are of any clinical consequence, as APS-I subjects do not have an increased propensity for viral infections.[54] In contrast, it has also been shown that many APS-I subjects also harbor autoantibodies to IL17A, IL17F, and IL22.[77,78] These are key cytokines for the function of the Th17 T-cell subset, and recent work has demonstrated that loss of function of these cytokines, as in patients with mutations in the IL17 receptor, is associated with increased susceptibility to *Candida albicans* infections.[79] Thus, it appears that the *Candida* susceptibility in APS-I may be due to an autoimmune response against this effector cytokine family.

Therapy and Follow-Up

The treatment of adrenal insufficiency and hypoparathyroidism is the same as that discussed in other chapters with the caveat that malabsorption can complicate treatment. The therapy for mucocutaneous candidiasis has been improved with the use of orally active antifungal drugs such as fluconazole and ketoconazole. Infection often recurs when the drug is discontinued or the dosage is decreased. Patients must be monitored carefully, because ketoconazole can inhibit adrenal and gonadal steroid synthesis and can precipitate adrenal failure. It is also associated with transient elevation of liver enzyme levels and, occasionally, with hepatitis. Fluconazole is associated with a lower frequency of hepatitis and does not inhibit steroidogenesis when given in the recommended doses.

Autoantibodies associated with multiple autoimmune diseases have been reported. Antiparathyroid and antiadrenal antibodies have been reported. Whereas 21-hydroxylase appears to be the major autoantigen in isolated Addison disease and in Addison disease associated with APS-II, autoantibodies against 17α-hydroxylase and cytochrome P450 side-chain cleavage enzyme (CYP11A1) have also been reported in Addison disease associated with APS-I.[80] There have been reports of antibodies to tryptophan hydroxylase in intestinal disease, tyrosine hydroxylase in alopecia areata, L-amino acid decarboxylase in hepatitis and vitiligo, and phenylalanine hydroxylase,[81,82] and antibodies reacting with hair follicles.[83] Tuomi and coworkers[84] originally observed that many more APS-I patients (41%) express anti-GAD65 autoantibodies than become diabetic, suggesting that reactivity to this single autoantigen has low predictive value in this population. Recently, antibodies against NALP5 were identified in 49% of patients with APS-I and hypoparathyroidism compared with none of those with APS-I but no hypoparathyroidism.[85] Screening for autoantibodies associated with additional autoimmune diseases may be useful in patients with APS-I.

Screening to allow the early detection of new disorders before overt symptoms and signs develop is recommended, including autoantibody studies, electrolytes, calcium and phosphorus levels, thyroid and liver function tests, blood smear, and plasma vitamin B_{12}. Patients at risk for adrenal failure can be screened by measurement of basal ACTH and supine plasma renin activity, followed by dynamic testing as appropriate. Evaluation for asplenism[60] with abdominal ultrasonography and blood smear examination for Howell-Jolly bodies is warranted, with pneumococcal vaccination and appropriate antibiotic coverage for affected patients.

There are case reports of severely affected patients who have benefited from immunosuppressive therapy. For example, Ward and colleagues[62] treated a 13-year-old patient who had keratoconjunctivitis, hepatitis, and severe pancreatic insufficiency. Treatment with cyclosporine was associated with normalization of stool fat (from 31.5 to 2.5 g/day).

Autoimmune Polyendocrine Syndrome Type II

Clinical Features

APS-II (MIM 269200) is defined by the occurrence in the same patient of two or more of the following: primary adrenal insufficiency (Addison disease), Graves disease, autoimmune thyroiditis, type 1A diabetes, primary hypogonadism, myasthenia gravis, and celiac disease. Vitiligo, alopecia, serositis, and pernicious anemia also occur with increased frequency in patients with this syndrome and in their family members (see Table 43.3). APS-II is more common than APS-I. It occurs more often in female than in male patients, often has its onset in adulthood, and exhibits familial aggregation (see Table 43.2).

When one of the component disorders is present, an associated disorder occurs more commonly than in the general population. Furthermore, circulating organ-specific autoantibodies are often present even in the absence of overt clinical disease. For example, in subjects with type 1 diabetes, there is a 15% to 20% risk of hypothyroidism, a 5% to 10% risk of celiac-related autoimmunity, and a 1.5% risk of adrenal autoimmunity. The risk of autoimmunity is greater in relatives of patients with APS-II. In our assessment of APS-II families with Addison disease, up to 15% of relatives were found to have 21-hydroxylase autoantibodies (Addison disease–associated autoantibodies), anti-islet autoantibodies, or tTG autoantibodies (celiac disease–associated autoantibodies). The initial lesion and precipitating events that result in the syndrome are unknown, but immunogenetic and immunologic similarities are present with regard to both the time course and the pathogenesis of each of the component disorders.

Because of the chronic development of organ-specific autoimmunity, patients with the syndrome and their families should have repeated endocrinologic evaluations over time. In a family in which the syndrome has been documented, relatives should be advised of the early symptoms and signs of the principal component diseases (a list is available from the Barbara Davis Center for Diabetes website[86]). Relatives of patients with multiple disorders should have a medical history, physical examination, and screening every 3 to 5 years, with measurement of anti-islet autoantibodies, a sensitive thyrotropin assay, and measurement of serum vitamin B_{12} levels. If there are any symptoms or signs, or if 21-hydroxylase autoantibodies are present, the patient should have annual assays of basal ACTH levels with Cortrosyn stimulation testing.

Among 224 patients with Addison disease and APS-II reported by Neufeld and colleagues,[57] type 1 diabetes and autoimmune thyroid disease were the most common coexisting conditions (52% and 69% of patients, respectively). Other components were less common, including vitiligo (5%) and gonadal failure (4%). In an Italian cohort of more than 600 patients, the majority of patients with Addison disease (86.7%, after exclusion of subjects with APS-I) had additional autoimmunity diseases, most frequently thyroid disease (56%) and diabetes (12%). A significant proportion of subjects exhibited thyroid- (16%) and diabetes- (8.8%) related autoimmunity without yet developing disease over average follow-up of 10 years.[87] Therefore, careful monitoring of patients with Addison disease for additional autoimmune diseases including thyroid, type 1A diabetes, and premature ovarian insufficiency is warranted.

Among patients with type 1A diabetes, thyroid autoimmunity and celiac disease coexist with sufficient frequency to justify screening. Thyroid peroxidase autoantibodies are present in 10% to 20% of children with type 1 diabetes; this incidence is higher in female patients and increases in all patients with age and with diabetes duration. A significant fraction of patients with type 1 diabetes and thyroid peroxidase autoantibodies develop thyroid disease. One study showed that after follow-up for more than 15 years, 80% of patients with thyroid peroxidase autoantibodies and type 1 diabetes became hypothyroid.[88] However, several studies have shown that a subset of patients with negative autoantibodies develop thyroid disease. Therefore, patients with type 1 diabetes should be screened annually for thyrotropin levels, which is a cost-effective approach.

With the identification of tTG as the major endomysial autoantigen of celiac disease, radioimmunoassays were developed and demonstrated that 10% to 12% of patients with type 1 diabetes have tTG autoantibodies.[7] The prevalence of tTG autoantibodies was higher in diabetic patients with HLA-DQ2; one-third of DQ2-homozygous subjects were found to express anti-tTG antibody, reflective of the influence of HLA-DQ2 in the development of both type 1 diabetes and celiac disease. Seventy percent of those with high-titer antibody who underwent biopsy were subsequently found to have the disease.[89] Celiac disease may be identified at onset of type 1 diabetes. However, it can develop in patients with long-standing diabetes as well and in at least one cohort has been shown to be increased in patients with adult-onset type 1 diabetes compared with childhood onset.[90] If left untreated, symptomatic celiac disease is also associated with an increased risk of gastrointestinal malignancy, especially lymphoma. Survival analysis in patients with type 1 diabetes and celiac disease shows an increase in mortality rate in patients with type 1 diabetes and celiac disease duration of greater than 15 years.[91] Frequency and method of screening remain areas of debate. At the very least, providers should be aware of the association and have a low threshold for screening with tTG antibodies. If the results are positive and are confirmed on repeat assay, small bowel biopsy to document celiac disease is warranted, with institution of a gluten-free diet if the disease is present. Many patients have asymptomatic celiac disease that is nevertheless associated with osteopenia and impaired growth.

Diagnosis

The diagnosis of APS-II requires an understanding of the risk for additional autoimmune diseases in patients with a single autoimmune endocrine disorder. A thorough history and physical examination may identify symptoms or signs of an additional autoimmune disorder. Screening for disease can include screening for markers of the autoimmune diseases (organ-specific autoantibodies) and assays of glandular function (e.g., thyrotropin levels).

Improved assays for several organ-specific autoantibodies have been developed since the cloning of specific autoantigens and the development of assays that use recombinant antigens. These radioimmunoassays are superior to assays based on immunofluorescence with tissue sections, such as ICA testing. The most notable finding is the identification of multiple autoantigens targeted even in single autoimmune disorders. Most of the endocrine autoantigens are hormones (e.g., insulin) or enzymes associated with differentiated endocrine function: thyroid peroxidase in thyroiditis; GAD, carboxypeptidase H, and ICA 512/IA2 in type 1 diabetes; 17α-hydroxylase and 21-hydroxylase in Addison disease; and the parietal cell enzyme H^+/K^+-adenosine triphosphatase in pernicious anemia.

In type 1 diabetes, the four most informative assays identify autoantibodies reacting with insulin, GAD65, ICA512/IA2, and ZnT8.[51] Similarly, a radioassay for autoantibodies against the enzyme 21-hydroxylase in Addison disease has been developed and provides excellent disease specificity and sensitivity. Adrenal autoantibodies reacting with recombinant 21-hydroxylase usually precede the development of Addison disease. Screening with 21-hydroxylase autoantibodies may identify patients with antibodies but have normal production of cortisol in response to ACTH. Annual screening with a basal level of corticotropin with follow-up cosyntropin stimulation testing is an effective strategy for identifying adrenal insufficiency in patients with 21-hydroxylase autoantibodies.

Typically, autoantibodies mark the presence of or risk for autoimmune disease caused by T-cell–mediated glandular destruction. However, autoantibodies may also be pathogenic. A hallmark of pathogenic autoantibodies is the existence of a neonatal form of the disorder, secondary to transplacental passage of the autoantibody. Examples include neonatal Graves disease (anti–thyrotropin-receptor autoantibodies) and neonatal myasthenia gravis (anti–acetylcholine-receptor autoantibodies).

Therapy

Treatment of the individual diseases of the polyendocrine autoimmune syndrome is discussed in other chapters. Therapeutic considerations related specifically to APS-II are discussed here.

Many of the component disorders of the syndrome have a long prodromal phase and are associated with the expression of autoantibodies before the manifestation of overt disease. Therefore, people at risk for autoimmune diseases can be identified prior to the clinical onset of disease, and if the right treatment were

identified, disease may be preventable. This is particularly important for type 1A diabetes but is also likely to apply to Addison disease and hypogonadism.

Prevention strategies have been extensively evaluated in patients with type 1 diabetes. Prevention of disease can occur at multiple time points along the natural history of evolving beta-cell dysfunction. Treatments targeted at patients with genetic risk without evidence for autoimmunity will expose people who will never get disease to an intervention (primary prevention). Therefore, any intervention must be safe and easily administered. Prevention trials in patients with diabetes-related autoantibodies prior to abnormalities of glucose metabolism (secondary prevention) can employ agents with higher risks of adverse events. Tertiary prevention of diabetes employs immune-modulating agents for the preservation of the beta-cell mass with the hopes of inducing a prolonged C-peptide production.

Primary prevention of type 1 diabetes targets infants at the highest risk for the development of type 1 diabetes on the basis of family history or specific HLA genotypes. Infants must be negative for diabetes-related autoantibodies. Interventions have focused on dietary manipulations including gluten-free diets, docosahexaenoic acid (DHA) supplementation, and elemental formulas lacking bovine insulin. To date, the interventions have not prevented the development of diabetes-related autoantibodies or diabetes in large-scale clinical trials.[92]

Secondary prevention of type 1 diabetes has been antigen specific (insulin and GAD65) and antigen nonspecific (nicotinamide). These studies have targeted subjects with positive diabetes-related autoantibodies prior to the development of diabetes. Some studies have included patients with abnormalities of glucose metabolism such as impaired first-phase insulin response and impaired glucose tolerance.

A large National Institutes of Health trial—the Diabetes Prevention Trial–Type 1 (DPT-1)—directly tested oral and parenteral insulin for prevention of diabetes. DPT-1 had two arms: intravenous-subcutaneous for those at high risk (risk of diabetes >50% within 5 years) and oral insulin for those at moderate risk (risk of diabetes 25–50% within 5 years). Neither parenteral[93] nor oral[94] insulin slowed progression to diabetes. However, in a subgroup analysis of subjects in the DPT-1 oral trial, a treatment effect was noted for those who had the higher insulin autoantibody levels at diagnosis,[94] and further trials are under way. In preclinical Addison disease, a short course of glucocorticoids appeared to suppress the expression of adrenal autoantibodies and prevent progressive adrenal destruction.[95] Studies of immune-modulating agents (abatacept and teplizumab) in patients with diabetes-related autoantibodies and abnormalities of glucose metabolism are currently under way.

Because of the autoimmune nature of these disorders, several studies have evaluated the use of immunosuppressive and immune-modulating drugs. Drugs such as cyclosporine have preserved some residual insulin secretion. However, because cyclosporine is nephrotoxic and potentially oncogenic, more generalized use is precluded. Newer immunosuppressive agents (e.g., sirolimus) are being studied, and biologics such as anti-CD20 antibody (rituximab), abatacept, and nonmitogenic CD3 antibodies have been shown to prolong C-peptide production and to result in a decreased insulin dose through the first year of diabetes when compared with control subjects.[96–100]

Thyroxine therapy can precipitate a life-threatening addisonian crisis in a patient with untreated adrenal insufficiency and hypothyroidism. Therefore, it is necessary to evaluate adrenal function in all hypothyroid patients in whom the syndrome is suspected before instituting such therapy. A decreasing insulin requirement in a patient with insulin-dependent diabetes can be one of the earliest indications of adrenal insufficiency, occurring before the development of hyperpigmentation or electrolyte abnormalities.

Other Polyendocrine Deficiency Autoimmune Syndromes

Rare polyendocrine syndromes are listed in Table 43.4.

Immunodysregulation Polyendocrinopathy Enteropathy X-Linked Syndrome

IPEX (MIM 340790, MIM 300292), first described in 1982, is a rare, X-linked recessive disorder that is characterized by immune dysregulation and results in multiple autoimmune diseases and early death (see Fig. 43.4). It is caused by mutations of the *FOXP3* gene. Clinical characteristics include very early onset type 1A diabetes, severe enteropathy resulting in failure to thrive, and dermatitis, generally resulting in death within the first couple of years of life unless definitive treatment is pursued. Other reported abnormalities include atopy, thrombocytopenia, hemolytic anemia, hypothyroidism, lymphadenopathy, nephropathy, and alopecia (2012 review).[101] Immunologic evaluation shows elevated IgE and eosinophilia in addition to the abnormalities associated with the component disorders.

The identification of *FOXP3* as the gene associated with IPEX was aided by the scurfy mouse model. The scurfy mouse exhibits characteristics similar to those seen in children affected with IPEX. The gene associated with this disorder in the scurfy mouse was found to be a DNA-binding protein with characteristics of a transcription factor.[102] Clues about the function of this gene included the observations that implantation of thymus from a scurfy mouse into immune-incompetent mice transfers the disease, but transplantation of thymus into immune-competent mice does not transfer disease, and injections of normal T cells can rescue the phenotype, suggesting that a regulatory cell is involved in the pathogenesis of this disorder. Linkage analysis demonstrated that a 17-centimorgan stretch of the X chromosome (Xp11.1-q13.3) is associated with IPEX, and mutations within the *FOXP3* gene have been identified in most of the families studied thus far.[103] *FOXP3* encodes a protein that is a member of the forkhead class of winged helix transcription factors (forkhead box protein 3). *FOXP3* has been shown to be expressed in $CD4^+/CD25^+$ regulatory T cells.[104] These T cells can suppress activation of other T cells.[104] Therefore, mutations in *FOXP3* result in inability to generate regulatory T cells and the development of IPEX. Patients with mutations throughout the *FOXP3* gene have been described. In general, milder phenotypes are associated with point mutations or small deletions that do not result in a total lack of *FOXP3*. However, significant variability in phenotype within a single mutation suggests that other genes or environmental exposures may play an important role in the development of the disorder.

Treatment options are targeted to the underlying disorders. At the time of diagnosis, infants may be so affected by the enteropathy that they require bowel rest and parenteral nutrition. Diabetes is managed with insulin therapy. Immunosuppression with calcineurin inhibitors has been used in the initial,

TABLE 43.4 Rare Polyendocrine Disorders

Disorder	Clinical Features	Cause
Hirata disease (insulin resistance syndrome)	Hypoglycemia	Insulin autoantibodies Associated with methimazole
IPEX or CD25 deficiency	Type 1 diabetes Enteropathy	Mutations of FOXP3 for IPEX Mutations of IL2RA for CD25-deficiency
Autoimmune lymphoproliferative syndrome type V	Autoimmune thyroiditis Autoimmune cytopenias Hypogammaglobulinemia	Mutations of CTLA4 resulting in haploinsufficiency
Infantile-onset autoimmune disease 1	Autoimmune cytopenias Autoimmune thyroiditis Type 1 diabetes Short stature	Dominant activating mutations of STAT3 in heterozygosity
Kearns-Sayre syndrome	Hypoparathyroidism Primary gonadal failure Nonautoimmune diabetes Hypopituitarism	Deletions of mitochondrial DNA
POEMS	Polyneuropathy Organomegaly Diabetes Primary gonadal failure	Plasma cell dyscrasia with production of M protein and cytokines
Thymic tumors	Myasthenia gravis Red blood cell hypoglobulinemia Autoimmune thyroid disease Adrenal insufficiency	Thymomas
Type B insulin resistance	Severe insulin resistance	Insulin receptor autoantibodies
Wolfram syndrome	Diabetes insipidus Nonautoimmune diabetes Bilateral optic atrophy Sensorineural deafness	Mutations of WSF1, which encodes wolframin

IPEX, Immunodysregulation polyendocrinopathy enteropathy X-linked; *POEMS,* plasma cell dyscrasia with *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m* protein, and *s*kin changes.

stabilization phase of treatment. Definitive treatment is with hematopoietic stem cell transplantation (HSCT). HSCT results in reversal of the enteropathy and other autoimmune components.[105] Generally, established type 1 diabetes and thyroid disease do not resolve. However, some reports document reversal of type 1 diabetes in patients who have received the conditioning immunotherapy and HSCT.[106] An additional case report shows that reconstitution of the gut immune system may occur later than reconstitution of the bone marrow.[107] Novel approaches to insert a functional *FOXP3* gene into lymphocytes as gene therapy in addition to or eventually in place of HSCT are being developed as well.[108,109]

Over the past several years, disorders with similar clinical characteristics as IPEX but without mutations in *FOXP3* have been identified. In these disorders, mutations in *IL2RA*,[110,111] *STAT5b*,[112] *STAT-1*,[113] and *ITCH*[114] result in abnormalities of regulatory T-cell function, emphasizing the important role of these cell populations in the maintenance of immune tolerance.

CTLA4, STAT3, and LRBA Mutations

With recent advances in whole genome sequencing, there has been rapid progress in associating rare genetic variants in isolated patients or kindreds with multiorgan autoimmunity that often involves endocrinopathy. Loss of function mutations in heterozygosity in the CTLA4 gene have now been associated with autoimmunity in a few isolated kindreds and appears to be associated with a defect in T-regulatory cell function.[115,116] However, it should be noted that the autoimmunity associated with these mutations is much milder than IPEX. A similar syndrome has also been recently described in patients with heterozygous mutations in the LRBA gene.[117] Here, the mechanism is less clear but may involve proper intracellular trafficking of CTLA4 in T cells. Finally, dominant activating mutations in the STAT3 gene have now been associated with an autoimmune syndrome in isolated cases and several families.[118,119] Here, patients frequently develop thyroiditis, cytopenias, and type 1 diabetes, along with other unusual features including short stature. The exact

mechanism of how these mutations lead to autoimmunity in these subjects is not clear but could involve improper activation of T cells, as STAT3 is a known transducer of effector cytokines.

Anti–Insulin Receptor Autoantibodies

In this rarely reported disorder (<100 patients), also called *type B insulin resistance* or *acanthosis nigricans*, insulin resistance is caused by the presence of anti–insulin receptor antibodies and anti-insulin antibodies.[120] Approximately one-third of patients with these antibodies have an associated autoimmune illness such as SLE or Sjögren syndrome. Arthralgia, vitiligo, alopecia, autoimmune thyroid disease, secondary amenorrhea, and family history of autoimmunity have also been reported. Autoimmune thyroid disease has been described in two such patients, one with hypothyroidism and the other with antithyroid antibodies. Antinuclear antibodies, an elevated erythrocyte sedimentation rate, hyperglobulinemia, leukopenia, and hypocomplementemia are common.[121]

The major clinical manifestations are related to the anti–insulin receptor antibodies. Insulin resistance is profound, and up to 175,000 U of insulin given intravenously per day may be ineffective in lowering the elevated glucose. Despite hyperglycemia and marked insulin resistance, ketoacidosis is uncommon. The course of the diabetes is variable, and several patients have had spontaneous remissions. Other patients have had severe hypoglycemia (perhaps related to the insulin-like effects of anti–insulin receptor antibodies demonstrable in vitro).[122] The acanthosis nigricans, which is caused by hypertrophy and folding of otherwise histologically normal skin, appears to be related to the insulin-resistant state. Other forms of marked insulin resistance in the absence of antireceptor antibodies are also associated with acanthosis nigricans. A treatment regimen developed at the National Institutes of Health that includes rituximab that targets B lymphocytes with cyclophosphamide and pulse corticosteroids has been used successfully to treat this rare disorder.[122,123]

POEMS Syndrome

The components of the multisystem disorder POEMS (*p*lasma cell dyscrasia with polyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal plasma cell disorder, and *s*kin changes), also known as Crow-Fukase syndrome (MIM 192240), consist of diabetes mellitus (3–36% of patients), primary gonadal failure (55–89% of patients), plasma cell dyscrasia, sclerotic bone lesions, and neuropathy.[124] Patients usually present with severe progressive sensorimotor polyneuropathy, hepatosplenomegaly, lymphadenopathy, and hyperpigmentation. On evaluation, they are found to have plasma cell dyscrasia and sclerotic bone lesions. Patients present in the fifth to sixth decades of life and have a median survival time after diagnosis of 14 years.[124,125]

The pathophysiology of POEMS is poorly understood. There is evidence implicating cytokines such as IL1A, IL6, and TNFα in addition to the M protein in the pathogenesis of this disorder. In several studies, elevated levels of vascular endothelial growth factor (VEGF) correlated with the disease state, and treatment with immunosuppressive agents reduced the symptoms of the disease and the levels of VEGF, suggesting that this growth factor plays a role in the disease.[126,127] A therapeutic trial of an anti-VEGF antibody would provide more definitive evidence for this hypothesis.

Algorithms have been proposed for the treatment of POEMS.[125] Important features of treatment include extensive baseline evaluation, ongoing monitoring for component disorders, systemic therapy for the plasma cell disorder, and radiation at the site of identified bone lesions. The diabetes mellitus responds to small, subcutaneous doses of insulin.

Kearns-Sayre Syndrome

The rare Kearns-Sayre syndrome (MIM 530000), also known as oculocraniosomatic disease or oculocraniosomatic neuromuscular disease with ragged red fibers, is characterized by myopathic abnormalities leading to ophthalmoplegia and progressive weakness in association with several endocrine abnormalities, including hypoparathyroidism, primary gonadal failure, diabetes mellitus, and hypopituitarism.[128] Crystalline mitochondrial inclusions are found in muscle biopsy specimens, and such inclusions have also been observed in the cerebellum. The relation between the mitochondrial disorders and endocrinologic abnormalities is not known. Antiparathyroid antibodies have not been described; however, antibodies to the anterior pituitary gland and striated muscle have been found, and the disease may have autoimmune components. Other abnormalities include retinitis pigmentosa and heart block. Deletions in mitochondrial DNA have been associated with Kearns-Sayre syndrome.[129] These mutations usually occur sporadically and are not associated with a familial syndrome.

Thymic Tumors

The thymus is a complex tissue with a specialized endocrine epithelium that synthesizes a variety of biologically active peptides involved in the control of T-cell maturation. This epithelium is derived from the neural crest and contains complex gangliosides that react with monoclonal antibody (A2B5) and tetanus toxin in a manner similar to that of pancreatic islets.

The illnesses associated with thymomas are similar to those seen in APS-II,[130] although the incidence of specific disorders is different. In one review of patients with thymoma, myasthenia gravis was found to occur in 44% of the patients, red blood cell aplasia in approximately 20%, hypoglobulinemia in 6%, autoimmune thyroid disease in 2%, and adrenal insufficiency in 1 of 423 patients (0.24%). The incidence of autoimmune thyroid disease reported in patients with thymoma is probably an underestimate, given the incidence of unsuspected thyroid disease in patients with myasthenia gravis. Mucocutaneous candidiasis in adults is also associated with thymomas. Interestingly, recent work suggests that an alteration in the proper expression of AIRE and peripheral antigens may be part of the explanation of the autoimmunity that arises in these patients.[131]

Wolfram Syndrome

Wolfram syndrome (MIM 222300, chromosome 4; MIM 598500, mitochondrial) is a rare autosomal recessive disease that is also called *DIDMOAD* (*d*iabetes *i*nsipidus, *d*iabetes *m*ellitus, progressive bilateral *o*ptic *a*trophy, and sensorineural *d*eafness). In addition, neurologic and psychiatric disturbances are prominent in most patients and can cause severe disability. Atrophic changes in the brain have been found on magnetic resonance imaging.[132] Segregation analysis of the mutations found in familial and sporadic cases of Wolfram syndrome led to the identification of wolframin, a 100-kDa transmembrane protein encoded by *WFS1*, a gene located at 4p16.1.116. Genotype and phenotype analyses have identified the severe phenotype (defined as the development of neurologic disease within the

first decade) in patients with truncated proteins and mutations in the carboxy-terminus of the protein.[133]

Wolframin has been localized to the endoplasmic reticulum[134] and is found in neuronal and neuroendocrine tissue.[135] Its expression induces ion channel activity with a resultant increase in intracellular calcium and may play an important role in intracellular calcium homeostasis.[136] Functional studies have shown that reported *WFS1* mutations lead to decreased stability of the protein wolframin.[137] Linkage to other loci in addition to *WFS1* may explain the variability in phenotype seen in this disorder.

Wolfram syndrome appears to be a slowly progressive neurodegenerative process, and there is also (nonautoimmune) selective destruction of the pancreatic beta cells, recently associated in a stem cell model with increased endoplasmic reticulum stress in the pancreatic beta cell.[138] This association is probably a result of the expression pattern of *WFS1.* Diabetes mellitus with an onset in childhood is usually the first manifestation. Diabetes mellitus and optic atrophy are present in all reported cases, but expression of the other features is variable. Duration of diabetes is linked to the development of microvascular complications.[137] Additional endocrinologic diseases, such as ACTH deficiency and growth hormone deficiency, have been reported.[137] In one case report, two related children with Wolfram syndrome had megaloblastic and sideroblastic anemia that responded to treatment with thiamine. Furthermore, thiamine treatment was associated with a marked decrease in insulin requirements.[139]

Omenn Syndrome

Omenn syndrome (MIM 603554) is a primary immunodeficiency syndrome with autoimmune manifestations affecting mainly the skin and gastrointestinal tract. Mutations associated with decreased recombination of the T-cell receptor have been described. One study showed that the levels of *AIRE* gene expression were decreased in the thymus of two affected patients and that this was associated with decreased expression of peripheral antigens compared with control subjects.[125]

Chromosomal Disorders

Down syndrome, or trisomy 21 (MIM 190685), is associated with the development of type 1 diabetes, thyroiditis, and celiac disease. Patients with Turner syndrome are at increased risk for the development of thyroid disease and celiac disease. It is recommended to screen patients with trisomy 21 and Turner syndrome for associated autoimmune diseases on a regular basis.

Conclusion

Through the study of rare disorders such as APS-I and IPEX, the processes of thymic expression of peripheral antigens and development of regulatory T cells are beginning to be defined. This understanding provides invaluable insight into the development of the normal immune system and the mistakes that can occur and lead to autoimmunity. Lessons learned from these rare diseases will help to better define the pathophysiology of more common autoimmune endocrine disorders, possibly leading to the development of immunologic methods for the prevention and treatment of these disorders.

Endocrinology of HIV/AIDS

TODD T. BROWN AND STEVEN K. GRINSPOON

CHAPTER OUTLINE

KEY POINTS

- In patients infected with human immunodeficiency virus (HIV) adrenal dysfunction is common. Specific protease inhibitors, including ritonavir, and the P450CYP3A4 inhibitor cobicistat may reduce metabolism of inhaled and injected steroids and increase systemic exposure.
- Hypogonadism is often seen among HIV-infected patients, is frequently associated with low or normal gonadotropins, and should be assessed using a specific free testosterone assay, given increases in sex hormone–binding globulin in this population.
- Fracture incidence is increased among HIV-infected patients and is multifactorial in nature, potentially related to increases in bone turnover, certain antiretroviral medications, immune activation, vitamin D deficiency, and gonadal dysfunction.
- Cardiovascular disease is increased among HIV-infected patients and relates to increases in traditional risk factors and nontraditional risk factors including immunologic and inflammatory factors.
- Endocrine management of insulin resistance, diabetes mellitus, and dyslipidemia, common among HIV-infected patients, may reduce cardiovascular disease risk in this population.
- Acquired immunodeficiency syndrome wasting, characterized by sarcopenia, should be distinguished from HIV lipodystrophy, characterized by subcutaneous fat loss.
- Endocrine strategies may be used to treat sarcopenia in acquired immunodeficiency syndrome wasting (testosterone and growth hormone) or to reduce visceral fat (growth hormone–releasing hormone) in HIV lipodystrophy.
- Medications used in the treatment of HIV disease have numerous endocrine and metabolic effects, including effects on steroid metabolism, gonadal function, vitamin D synthesis, renal phosphate excretion, glucose uptake, and very low density lipoprotein metabolism.

Human immunodeficiency virus (HIV) disease affects up to 36.7 million patients worldwide and more than 1.1 million in the United States. In many parts of the world, such as in sub-Saharan Africa, HIV remains epidemic, with an estimated 25.6 million people infected.[1] In addition, the number of HIV-infected patients is growing rapidly in Asia and other parts of the world. Endocrine dysfunction is common among HIV-infected patients. Adrenal, gonadal, thyroid, bone, and metabolic abnormalities have all been reported. HIV itself, related infectious organisms, immune activation, cytokines, and antiretroviral medications may all affect endocrine function. Endocrine disorders in HIV disease, such as hypogonadism, adrenal insufficiency, diabetes mellitus (DM), and bone loss, may cause significant morbidity and are thus important to diagnose. Interactions between antiretroviral therapy (ART) and specific medication may also contribute to endocrine disturbances. Endocrine strategies may improve quality of life and long-term survival through effects on critical metabolic and body composition parameters, including loss of muscle mass (sarcopenia) in acquired immunodeficiency syndrome (AIDS) wasting, fat redistribution with loss of peripheral and abdominal subcutaneous fat, and relative or absolute gains in central (visceral) adiposity among some patients. However, diagnosis and treatment may be difficult because of varying nutritional conditions and effects of the varied medications used to treat HIV disease. As HIV patients live longer as a result of the success of antiretroviral medications, adverse effects resulting from these very medications and HIV-related immune dysfunction have resulted in increased cardiovascular risk and metabolic changes that require intervention and long-term management by the endocrine specialist. This chapter will review the prevalence,

mechanisms, and optimal treatment strategies for endocrine abnormalities in HIV-infected patients.

Adrenal Function

Adrenal dysfunction may be suspected in the patient with advanced HIV disease because of fatigue, hyponatremia, and other features of adrenal insufficiency. Although clinical adrenal dysfunction is relatively rare among patients with AIDS, subtle impairments in adrenal reserve may be seen in this population. Adrenal dysfunction most often is caused by destruction of adrenal tissue by cytomegalovirus (CMV) in patients with advanced HIV disease but may also be caused by medications, hypothalamic/pituitary disease from opportunistic infection; idiopathic inflammation or tissue destruction; or, in rare cases, by cortisol resistance. In addition, some features of Cushing syndrome may be seen among HIV-infected patients with fat redistribution, but true Cushing disease is rare.

Adrenal Insufficiency

Biochemical evidence of adrenal insufficiency is relatively common among hospitalized AIDS patients, with 17% of 74 hospitalized AIDS patients screened by a cosyntropin test demonstrating inadequate adrenal stimulation (1-hour cortisol <18 μg/dL) in an early study. In contrast, fewer patients, 4%, demonstrate clinical symptoms of adrenal insufficiency.[2] Among patients with clinical symptoms and signs of adrenal insufficiency, including hyponatremia, a higher percentage, up to 30%, may demonstrate inadequate reserve using cosyntropin testing.[3]

Adrenal insufficiency occurring in the context of advanced HIV disease is most often caused by tissue destruction of the adrenal glands from opportunistic infections. CMV adrenalitis is the most common cause, seen in approximately 40% to 90% of patients with CMV infections at autopsy. However, adrenocortical destruction caused by CMV is usually less than 50% and therefore unlikely to cause adrenal insufficiency,[4] and CMV disease is rare with well-preserved immune function in patients on newer potent ARTs. Other organisms and processes that have been associated with adrenal destruction in HIV disease include *Mycobacterium tuberculosis*, *Mycobacterium avium-intracellulare* (MAI), *Cryptococcus*, and hemorrhage. Additionally, pituitary/hypothalamic destruction resulting in secondary adrenal insufficiency may be caused in rare instances by opportunistic infection (e.g., toxoplasmosis, *Cryptococcus*, and CMV). Idiopathic adenohypophyseal necrosis is also observed in a minority of patients, approximately 10% at autopsy, and may be related to a direct effect of HIV.[5]

Glucocorticoid Excess: Adrenal Shunting and Cortisol Resistance

Increased cortisol levels may also be seen in HIV-infected patients. More commonly, increased cortisol levels are seen as a stress response, in association with low weight or increasing degree of illness. Intra-adrenal shunting toward cortisol synthesis, potentially as a result of 17,20-lyase dysfunction, has been suggested by studies demonstrating a reduced dehydroepiandrosterone (DHEA) to cortisol ratio on cosyntropin testing.[6] Cytokine modulation of the hypothalamic-pituitary-adrenal (HPA) axis may also contribute to increased cortisol levels. Interleukin 1 (IL1), produced in the median eminence, has been shown to increase corticotropin-releasing hormone and adrenocorticotropic hormone (ACTH) secretion in vitro and in animal studies. Increased IL1 secretion from infected monocytes in the median eminence is thus another possible cause of increased cortisol secretion in HIV-infected patients. In turn, higher cortisol levels and greater diurnal variation may reduce T-cell immune activation.[7] Glucocorticoid resistance has also been shown in rare patients with advanced HIV disease, who demonstrate addisonian symptoms, including hyperpigmentation, in the setting of hypercortisolism and increased ACTH.

Medication Effects

Medications may contribute to adrenal insufficiency in HIV patients (Table 44.1). Ketoconazole, an antifungal agent, inhibits side-chain cleavage enzyme and 11β-hydroxylase. These effects are not generally seen with fluconazole, itraconazole, and more recently introduced imidazole derivatives. Phenytoin, opiates, and rifampin, among other drugs, affect cortisol metabolism. For example, adrenal insufficiency may be precipitated by the use of rifampin for treatment of tuberculosis in patients with reduced adrenal reserve. Megestrol acetate, a potent synthetic progestational derivative used as an appetite stimulant, has glucocorticoid properties and decreases ACTH. Abrupt withdrawal of megestrol acetate may precipitate adrenal insufficiency, and such patients should be tested for adrenal insufficiency and receive physiologic glucocorticoid administration as needed after megestrol withdrawal. In addition, megestrol acetate can decrease gonadal function, which should also be monitored during and after therapy. Cases of Cushing syndrome have been described with the concomitant use of fluticasone and ritonavir, via inhibition of CYP3A4 by ritonavir and resultant reduction in metabolism of fluticasone. This combination of medications can result in symptoms of severe cortisol excess and potential severe adrenal insufficiency with discontinuation of fluticasone.[8] Such patients demonstrate very low measured cortisol and ACTH levels, despite symptoms of hypercortisolemia, due to suppression of the endogenous HPA axis by increased concentrations of circulating fluticasone. After discontinuation of the fluticasone, long-term physiologic steroid replacement is necessary until the HPA axis recovers. In addition, adrenal insufficiency has been reported in approximately 5% of patients receiving intra-articular steroids while on protease inhibitors (PIs), particularly ritonavir, with increasing risk seen among those with more than two injections within the prior 6 months.[9] Similar interactions with intra-articular steroids have been seen with cobicistat, another potent CYP3A4 inhibitor used in combination with certain antiretroviral medications.[10]

Clinical Assessment

HIV-infected patients with symptoms of adrenal insufficiency, and particularly those with hyponatremia and risk factors for adrenal insufficiency, such as known disseminated CMV or recent use of megestrol acetate, should be evaluated. Evaluation of the cortisol axis should proceed as in other patients with suspected adrenal dysfunction. Cosyntropin testing is usually an adequate first step, except in those patients in whom hypothalamic or pituitary insufficiency of recent onset is suspected. In such patients, use of morning cortisol levels, metyrapone, or insulin tolerance testing may be necessary, if there are no contraindications. After adrenal insufficiency is documented, ACTH testing and appropriate imaging are used to localize the defect. In patients with clinical symptoms of adrenal insufficiency and elevated cortisol

TABLE 44.1 Major Endocrine and Metabolic Effects of Medications Used in the Treatment of HIV

Endocrine/Metabolic System	Interacting Medication	Mechanism	Effect
Adrenal	Ritonavir Cobicistat	CYP3A4 inhibitor that decreases metabolism of fluticasone and potentially other steroids	Cushing stigmata with reduced ACTH/cortisol
	Ketoconazole	11β-Hydroxylase inhibition	Adrenal insufficiency
	Megestrol acetate	Synthetic progestational agent with glucocorticoid properties	Adrenal insufficiency
	Rifampin	Increased cortisol metabolism	Adrenal insufficiency
Gonadal	Megestrol acetate	Decreased gonadotropins	Hypogonadism
	Ketoconazole	Inhibits side-chain cleavage enzyme	Hypogonadism
	Protease inhibitors	Variable effects to cause hyperprolactinemia directly or via dopamine antagonism	Potential hypogonadism
	Anabolic steroids	Decreased gonadotropins	Hypogonadism
Thyroid	Rifampin	Increased hepatic clearance of thyroid hormone	Reduced thyroxine levels
	Interferon	Autoimmune thyroiditis	Variable effects on thyroid function
Fluid and electrolytes	Trimethoprim	Structural similarities to amiloride with inhibition of tubular potassium secretion	Hyperkalemia
	Tenofovir disoproxil fumarate	Fanconi-like syndrome, phosphate wasting	Hypokalemia Hypophosphatemia
Calcium	Protease inhibitors	Variable effects to inhibit 1α-hydroxylation of 25-hydroxyvitamin D	Hypocalcemia
	Efavirenz	Increased catabolism of 25-hydroxyvitamin D through induction of CYP24A	Vitamin D deficiency
	Rifabutin	Induces cytochrome P450 and alters vitamin D metabolism	Vitamin D deficiency
	Foscarnet	Complexes with calcium	Decreased ionized calcium, magnesium
	Pentamidine	Renal magnesium wasting	Hypocalcemia
	Ketoconazole	Inhibits 1,25-dihydroxyvitamin D synthesis	Hypocalcemia
Bone	Tenofovir	Phosphate wasting and tubulopathy, possible direct effect on osteoclast function	Bone loss
	Protease inhibitors	Unclear	Bone loss
Glucose	Protease inhibitors	Variable effects to inhibit GLUT4-mediated glucose transport	Hyperglycemia
	NRTIs	Variable effects to inhibit mitochondrial DNA polymerase gamma	Hyperglycemia
	Pentamidine	Islet cell inflammation and insulin release	Hypoglycemia and subsequent hyperglycemia
Body composition	Protease inhibitors	Variable effects to inhibit SREBP1 and PPARγ signaling in subcutaneous fat	Subcutaneous fat loss
	NRTIs	Variable effects to inhibit mitochondrial DNA polymerase gamma in subcutaneous fat	Subcutaneous fat loss
Lipids	Protease inhibitors	Variable effects to decrease lipoprotein lipase-mediated clearance of VLDL and TG	Hypertriglyceridemia
	Anabolic steroids	Possible effects on hepatic lipase and LCAT	Low HDL

ACTH, Adrenocorticotropic hormone (corticotropin); *GLUT4,* glucose transporter type 4; *HDL,* high-density lipoprotein; *HIV,* human immunodeficiency virus; *LCAT,* lecithin:cholesterol acyltransferase; *NRTIs,* nucleoside reverse transcriptase inhibitors; *PPAR,* peroxisome proliferator-activated receptor; *SREB1,* sterol regulatory element–binding protein 1; *TG,* triglyceride; *VLDL,* very low density lipoprotein.

levels, cortisol resistance may be present and the diagnosis may be made by glucocorticoid receptor studies in blood monocytes. Conversely, in patients with symptoms of adrenal excess and low cortisol and ACTH levels, exogenous steroid use or interactions with ART should be suspected.

Gonadal Function

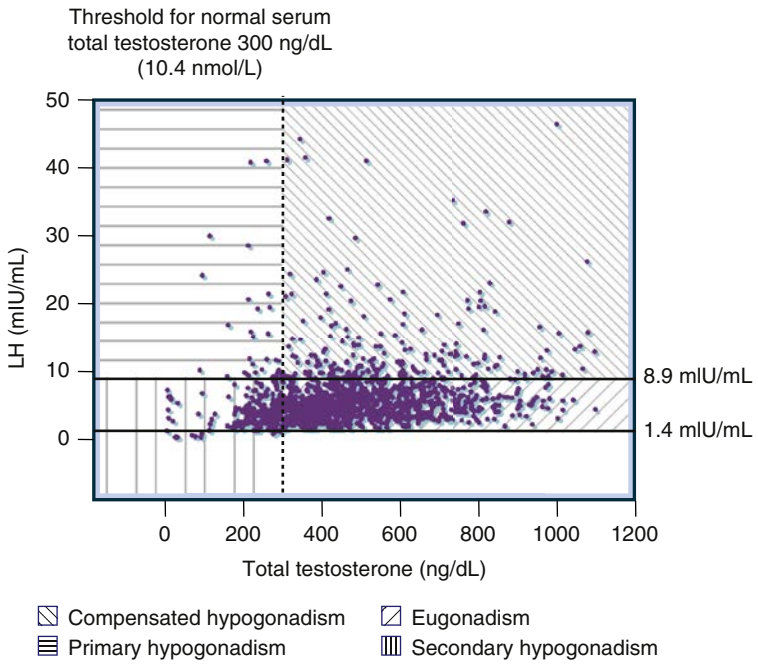
Male Gonadal Dysfunction

Gonadal dysfunction is common among HIV-infected men with weight loss and advanced illness. Initial studies indicated biochemical hypogonadism in approximately 50% of men with AIDS, in association with increased disease severity. Among HIV-infected men with low weight, hypogonadism was seen in 20%.[11] More recent studies suggest a lower prevalence of hypogonadism of approximately 9% to 16%.[12–15] The mechanisms of hypogonadism in HIV-infected patients may relate to severe illness or effects of undernutrition on gonadotropin secretion; medication effects; or, more rarely, tissue destruction from opportunistic infections. Most often, hypogonadism is secondary in nature, with low or inappropriately normal gonadotropin levels, as seen in 91% of patients with reduced free testosterone levels during initiation of highly active antiretroviral therapy (HAART) in the Swiss HIV cohort.[16] Primary hypogonadism is seen less often and may be caused by cytokine effects on the testes, including effects of tumor necrosis factor (TNF) to inhibit steroidogenesis via effects on the side-chain cleavage enzyme and of IL1 to inhibit Leydig cell steroidogenesis and luteinizing hormone binding to the Leydig cell. Indeed, among young men, median age 45 years, using an early morning total testosterone as a test to define hypogonadism in a large Italian cohort, Rochira and associates[13] demonstrated that gonadotropins were elevated in 16% of patients studied (Fig. 44.1). In addition, opportunistic infections of the testes have rarely been reported, and up to 25% of HIV-infected patients with AIDS will demonstrate testicular involvement of widespread opportunistic infection or systemic neoplasms, including CMV, toxoplasmosis, Kaposi sarcoma (KS), and testicular lymphoma, although there are few data to suggest that primary hypogonadism develops in all such cases.

In addition, several medications may affect the hypothalamic-pituitary-gonadal axis. Ketoconazole inhibits side-chain cleavage enzyme and other critical enzymes in testicular steroidogenesis. Megestrol acetate is used to increase appetite, but as a synthetic progestational agent it suppresses gonadotropin secretion and results in hypogonadism. Opiate therapy affects gonadotropin-releasing hormone secretion and may result in hypogonadotropic hypogonadism.

More recently, increased prolactin levels and gynecomastia have been demonstrated among HIV-infected patients. In a case-control study, gynecomastia was seen in 1.8% of 2275 consecutively screened HIV-infected patients and was associated with hypogonadism, hepatitis C, and degree of lipoatrophy (subcutaneous fat loss associated with potent ART). Thyroid-stimulating hormone (TSH, thyrotropin) levels were increased, although the proportion with hypothyroidism was not different.[17] Of ART medications, efavirenz is most closely associated with gynecomastia,[18] which is due to direct activation of the estrogen receptor.[19] Hyperprolactinemia has been reported in 21% of HIV-infected men with stable HIV disease and was significantly associated with opioid use and increased CD4 count but not with changes in body composition or gynecomastia.[20] Increased prolactin levels in association with galactorrhea have also been described among patients treated with PIs. The mechanism of this effect is unclear and may relate to a direct stimulation of prolactin secretion by specific PIs or effects on the P450 system to potentiate the dopamine antagonistic effect of other drugs.[21] Dopamine agonists should be used cautiously among HIV-infected men receiving PIs because of the potential for interactions.

Sex hormone–binding globulin levels are increased in 30% to 55% of HIV-infected patients. Therefore, use of bioavailable



• **Fig. 44.1** Gonadal status according to serum total testosterone threshold of 300 ng/dL and luteinizing hormone (LH) normal range. (From Rochira V, Zirilli L, Orlando G, et al. Premature decline of serum total testosterone in HIV-infected men in the HAART-era. *PLoS One.* 2011;6:e28512, Fig. 2.)

or free testosterone is recommended to diagnose hypogonadism, because use of total testosterone assays may underestimate the prevalence of true hypogonadism in this population. As a caveat, analogue assays of free testosterone may not be independent of sex hormone–binding globulin and should not be used. In contrast, determination of free testosterone by equilibrium dialysis or calculation by an accepted equation are more useful strategies to detect hypogonadism among the HIV population. For example, Monroe and colleagues[12] conducted a large study in the Multicenter AIDS Cohort Study, comparing normal-weight HIV-infected and well-matched uninfected patients in the current era of ART. In this study, total testosterone levels were similar in those who were HIV infected versus those who were not HIV infected, but free testosterone calculated using the Vermeulen equation was significantly lower in the HIV-infected patients. Reliance on total testosterone alone would have missed 33% of patients with hypogonadism.[12] Use of total testosterone or free testosterone analogue radioimmunoassay to diagnose hypogonadism among HIV-infected patients is associated with poor sensitivities of 25% and 33%, respectively.[14]

In patients in whom acute and chronic illness may contribute to hypogonadism, retesting of gonadal function by measuring an early morning free testosterone level is recommended on resolution of the illness, as endogenous function may return with improved health. In patients who remain hypogonadal, administration of physiologic testosterone replacement after appropriate diagnostic workup for the cause of hypogonadism is appropriate. In contrast to the potential utility of specific anabolic steroids in the treatment of weight loss in AIDS wasting (see the Treatment of AIDS Wasting and Loss of Lean Body Mass section), no role has been demonstrated for the use of anabolic steroids alone or in combination with testosterone for the treatment of hypogonadism per se in HIV-infected men.

Female Gonadal Dysfunction

Amenorrhea is seen in approximately 25% of HIV-infected women and may be caused by the reduction of gonadotropin production associated with the stress of illness. In contrast, anovulation may be seen in up to 50% of HIV-infected women in association with reduced CD4 counts. Among anovulatory HIV-infected women, changes in menstrual function are three times as likely compared with normally ovulating patients. Early menopause has been reported in up to 8% of HIV-infected women.[22]

Androgen levels are often reduced in HIV-infected women. In one study, androgen levels, assessed with the use of a free testosterone assay, were reduced below the level seen in age-matched healthy women in more than 50% of HIV-infected women with significant weight loss and in more than one third of HIV-infected women without weight loss.[23] The mechanisms of androgen deficiency in HIV disease may be caused in part by intra-adrenal shunting toward cortisol production and away from androgen production, particularly in women with significant weight loss[6] (see the Adrenal Function section).

Thyroid Function

Altered thyroid function tests are common in HIV-infected patients. Thyroid-binding globulin (TBG) levels are increased in HIV-infected patients and correlate inversely with CD4 counts.[24] Abnormal thyroid function test results may be caused by the stress of illness in patients with advanced disease or concomitant disorders, as found in other patients with euthyroid sick syndrome. However, among adults, some studies have shown that reverse triiodothyronine (rT_3) levels do not rise in association with decreasing T_3 levels, as one would expect in nonthyroidal illness.[3] Patients with progressive HIV disease therefore exhibit decreased T_3 levels, increased TBG, and decreased rT_3 levels with increasing illness.

In addition to the euthyroid sick syndrome, large screening studies have demonstrated an increased prevalence of primary hypothyroidism in HIV-infected patients. Recent studies have investigated the prevalence of thyroid dysfunction in the current era of HAART. In one study of 1565 HIV-infected patients, the prevalence of overt hypothyroidism was 2.5% and of overt hyperthyroidism 1%. A higher percentage of patients demonstrated subclinical hypothyroidism (4%) and abnormal thyroid test results associated with nonthyroidal illness (17%). Conversely, 76% of patients demonstrated normal thyroid function tests. HIV therapy and specific antiretroviral medications were not associated with thyroid dysfunction.[25] Among 2437 HIV-infected patients, Nelson and coworkers[26] demonstrated prevalence rates of hyperthyroidism and hypothyroidism each to be 1%. Use of specific antiretroviral agents, including PIs and efavirenz, were associated with thyroid dysfunction, but this has not been a consistent finding among studies.

Increased TSH has been demonstrated in young children with an average age of 1.5 years and failure to thrive. Thyroxine (T_4) levels were normal, but thyrotropin-releasing hormone testing showed exaggerated TSH responses, and growth rates increased in response to thyroid hormone.[27] Fundaro and associates[28] demonstrated increased antithyroglobulin antibodies in 34% of symptomatic HIV-infected children. Increased TSH levels were found in 28% of HIV-infected children, particularly those with severe immunosuppression. In contrast, a larger study in perinatally infected children demonstrated reduced total T_3, total T_4, and free T_4 and increased rT_3, TBG, and TSH, with negative autoantibodies, suggesting a euthyroid sick pattern, particularly in those with severe immunosuppression. HIV-infected children with failure to thrive should be screened for true hypothyroidism, but more often the thyroid function tests will reflect nonthyroidal illness and the severity of immune compromise.[29]

Recently, thyroid dysfunction has been described with an immune reconstitution syndrome in which autoimmune thyroid disease occurs in association with use of potent ART and improved immune function, typically 12 to 36 months after ART is initiated.[30] Graves disease is most often reported in this context. The estimated prevalence for immune reconstitution thyroid disease with initiation of HAART was 3% for women and 0.2% for men.[31] Graves disease has also been described after IL2 therapy in HIV-infected patients.[32]

In addition to autoimmune causes, thyroid disease related to anatomic replacement and infection of the thyroid has been reported in HIV-infected patients. *Pneumocystis* thyroiditis has been reported to cause a painful thyroiditis-like picture, with hyperthyroidism followed by hypothyroidism, decreased uptake on scanning, and a firm but tender gland. *Pneumocystis* thyroiditis may result from the use of inhaled pentamidine, which is associated with extrapulmonary *Pneumocystis* infections.

CMV, MAI, *Cryptococcus*, and KS have been demonstrated in the thyroid on autopsy but have not been related to clinical thyroid disease among patients with AIDS. Clinically apparent thyroidal abscesses from *Aspergillus* and *Rhodococcus equi* have been reported. Hypothalamic/pituitary replacement from

opportunistic infections, such as toxoplasmosis and CMV, has also been reported to cause secondary hypothyroidism.

Medications may affect thyroid function. Rifampin influences hepatic clearance of T_4, and interferon is associated with an increased incidence of autoimmune hypothyroidism.

Fluid Balance and Electrolytes

Disorders of fluid balance and electrolytes are common among patients with AIDS. Hyponatremia may be seen in upward of 50% of patients and is most often related to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Hyperkalemia is also frequently reported and may be seen in association with various drugs, such as trimethoprim. More rarely, hyperkalemia may be associated with adrenal insufficiency.

Sodium

Hyponatremia (sodium <130 mmol/L) is seen in 40% to 60% of hospitalized patients with AIDS and 20% of outpatients. SIADH (volume-replete patients with low levels of serum sodium, and inappropriately elevated levels of urine osmolarity) is seen in 23% to 47% of hyponatremic patients. SIADH may be caused by various infections and tumors and is treated with fluid restriction and hypertonic saline if severe. The vasopressin receptor 2 antagonist, tolvaptan, has also been used in the treatment of hyponatremia in patients with advanced HIV disease.[33]

Adrenal insufficiency is documented in 30% of volume-depleted, hyponatremic HIV-infected patients.[34] Volume depletion (diarrhea, vomiting) with excessive free water and impaired water clearance (HIV nephropathy) may cause hyponatremia among ill HIV-infected patients, especially those in the hospital. Volume repletion is the treatment. Hyporeninemic hypoaldosteronism,[35] more typically associated with hyperkalemia, may be another cause of hyponatremia and is treated with mineralocorticoids. The use of medications such as vidarabine, miconazole, and pentamidine is associated with hyponatremia of unknown cause. Hypernatremia may be caused by foscarnet-induced nephrogenic diabetes insipidus.

Potassium

Hyperkalemia occurs in 20% to 53% of AIDS patients on trimethoprim because of structural similarities to amiloride and inhibition of tubular potassium excretion.[36] Other potential causes include pentamidine-associated tubular nephropathy; HIV nephropathy (glomerular sclerosis); primary adrenal insufficiency; and, rarely, hyporeninemic hypoaldosteronism. Physiologic studies investigating potassium balance in HIV-infected patients also suggest an inadequate aldosterone response to hyperkalemia in HIV-infected patients. A Fanconi-like syndrome with tubular dysfunction, phosphate wasting, and hypokalemia has been described with the use of tenofovir disoproxil fumarate (TDF) and more rarely with adefovir, cidofovir, and didanosine.[37]

Calcium Homeostasis and Bone Changes

Calcium Homeostasis

Hypocalcemia is common in advanced HIV disease. Hypocalcemia, based on albumin-adjusted total calcium levels, was demonstrated in 6.5% of a large cohort of HIV-infected patients with AIDS. Calcium levels decreased progressively with stage of disease. Among patients with hypocalcemia, 48% were vitamin D deficient, and the expected increase in parathyroid hormone (PTH) levels was lacking in the majority.[38] Jaeger and colleagues[39] also demonstrated decreased PTH secretion in severely immunocompromised patients with AIDS, but the mechanism is unknown. In addition, decreased PTH levels may occur in the setting of hypomagnesemia during severe illness or in association with renal magnesium wasting. Vitamin D deficiency may be caused by malabsorption from AIDS enteropathy or by specific effects of antiretroviral drugs (e.g., inhibition of 1 α-hydroxylation of 25-hydroxyvitamin D by PIs or increased conversion of 25-hydroxyvitamin D to 24,25-dihydroxyvitamin D by efavirenz).[40–42]

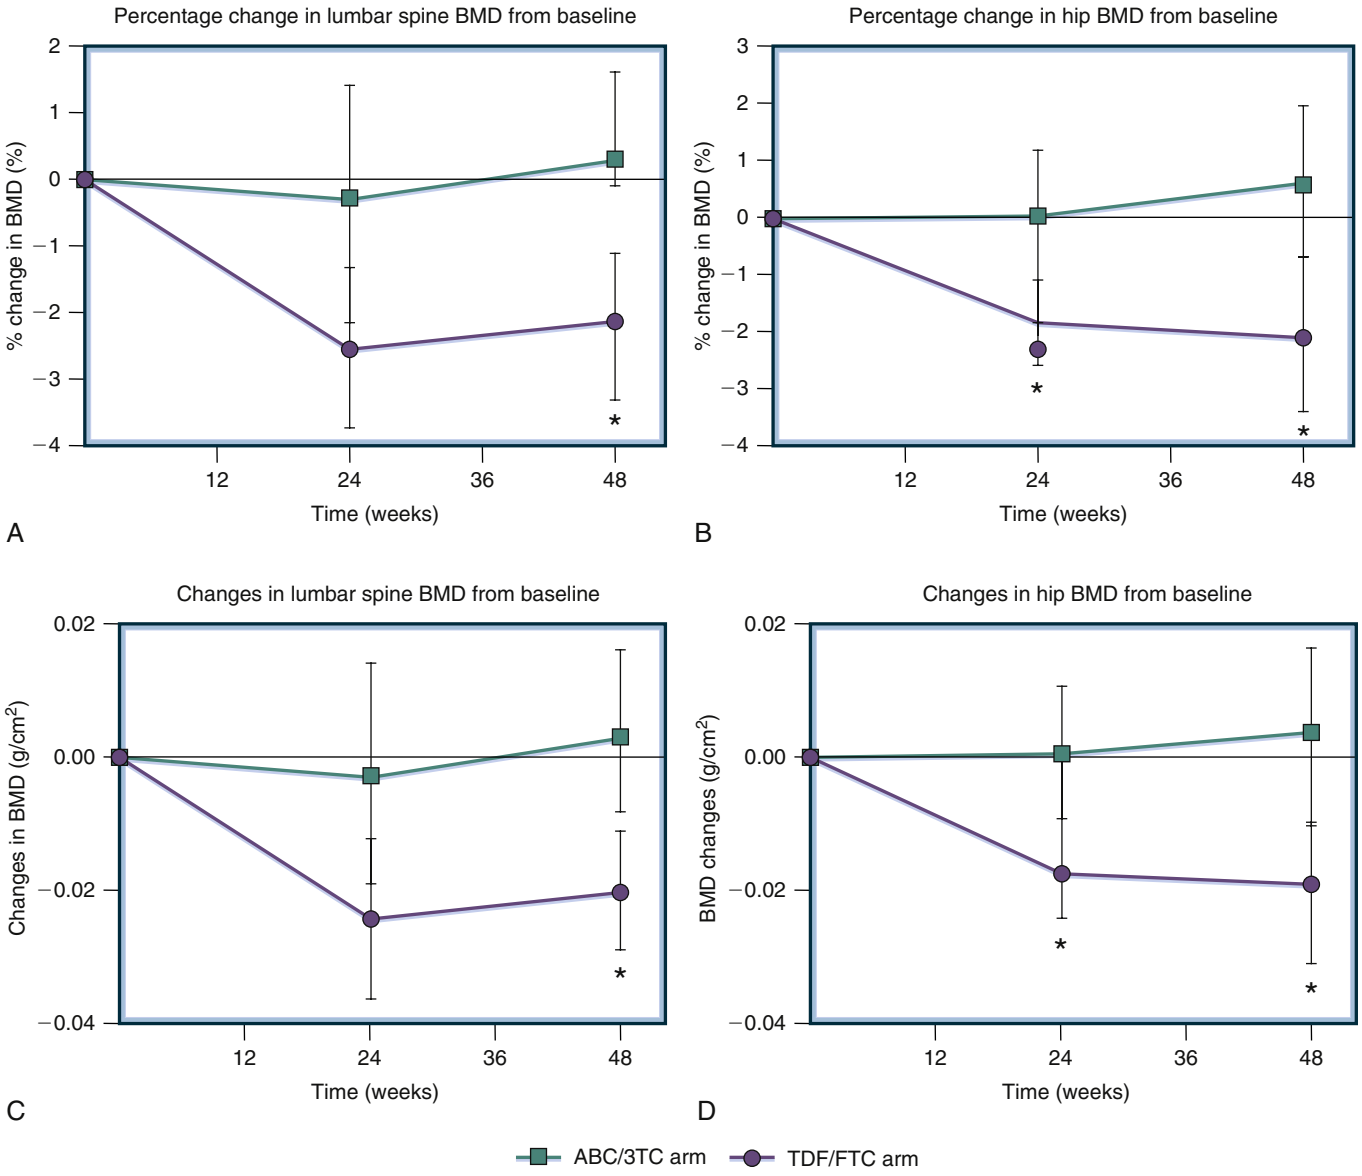
Severe vitamin D deficiency of nutritional origin has also been described in HIV-infected children. Osteomalacia has been associated with use of rifabutin for MAI in an HIV-infected patient. Rifabutin induces cytochrome P450, which may affect vitamin D metabolism. Other drugs that induce P450 could have a similar effect. Several drugs may affect calcium homeostasis (see Table 44.1). Foscarnet complexes with calcium to decrease ionized calcium levels and may also induce severe hypomagnesemia. Pentamidine therapy has been associated with renal magnesium wasting and severe hypomagnesemia, which may, in turn, cause hypocalcemia, through decreased PTH release and resistance to circulating PTH. Ketoconazole inhibits 1,25-dihydroxyvitamin D synthesis.

Among patients with HIV disease, hypercalcemia can be caused by excessive 1,25-dihydroxyvitamin D production in the setting of granulomatous disease (tuberculosis) or lymphoma, by local osteoclastic bone resorption from disseminated CMV, or by human T-cell lymphotropic virus 1–related activation of PTH-related protein. Immune reconstitution–associated hypercalcemia has been described in the setting of ART initiation among patients with known tuberculosis, in whom immune reconstitution results in increased granulomatous activity and 1,25-dihydroxyvitamin D production.[43]

Bone Loss: Prevalence, Etiologic Factors, and Treatment Strategies

Studies performed recently in the current era of ART give an estimate of the prevalence and risk factors for progression of bone loss among HIV-infected patients. Bonjoch and associates[44] investigated 671 HIV-infected patients and demonstrated osteopenia in 47.5% and osteoporosis in 23%. Progression rates to osteopenia and osteoporosis were 12.5% and 15.6% over 2.5 years of follow-up and 18% and 29% over 5 years of follow-up. In this large cohort, factors associated with progression of bone loss were age, male sex, lower body mass index (BMI), PI use, and TDF use.[44] Significant bone loss has also been shown among postmenopausal HIV-infected women, with time since menopause and traditional risk factors most significantly associated with bone loss. In a longitudinal analysis of postmenopausal HIV-infected women, Yin and coworkers[45] demonstrated increased markers of bone resorption and annualized bone loss in HIV-infected women versus non–HIV-infected control subjects.

Specific antiretroviral strategies may affect bone in the HIV population. Studies demonstrate that switching to a TDF-based regimen is associated with bone loss and increased bone turnover[46,47] (Fig. 44.2). Strong evidence for an effect of TDF is shown in studies in which patients at risk for HIV are given single-agent



• **Fig. 44.2** Changes from baseline in hip and lumbar spine BMD. Percentage and absolute mean changes from baseline in lumbar spine (A, C) and hip (B, D) bone mass density as measured by dual-energy x-ray absorptiometry. *ABC/3TC,* abacavir/lamivudine; *BMD,* bone mineral density; *TDF/FTC,* tenofovir/emtricitabine. Error bars show 95% confidence intervals. (From Rasmussen TA, Jensen D, Tolstrup M, et al. Comparison of bone and renal effects in HIV-infected adults switching to abacavir or tenofovir based therapy in a randomized trial. *PLoS One.* 2012;7:e32445, Fig. 2.)

tenofovir for preexposure prophylaxis. In these patients, bone loss averaged approximately 1% compared with control subjects over 2 years of follow-up. Larger effects might be seen in less healthy HIV-infected patients with other comorbid contributors.[48]

Current recommendations suggest that TDF should be avoided for the initial or continued treatment of HIV-infected persons at risk for fracture.[49] ART switching from TDF to abacavir, raltegravir, or the tenofovir prodrug, tenofovir alafenamide are associated with improvements in bone mineral density (BMD) in HIV-infected persons on effective ART.[50–52] In addition, because of their negative effects on BMD, PIs should be avoided in HIV-infected persons at risk for fracture.

Recent data suggest that immunologic factors including T-cell activation,[53] low CD4 cell count,[54] and coinfection with hepatitis B and C are strongly related to reduced bone density, particularly among women.[55] These data suggest the need to assess and follow bone density in HIV-infected patients with specific risk factors, such as older age, long-term ART use, low BMI, hypogonadism, hepatitis, low CD4 count, and TDF use.

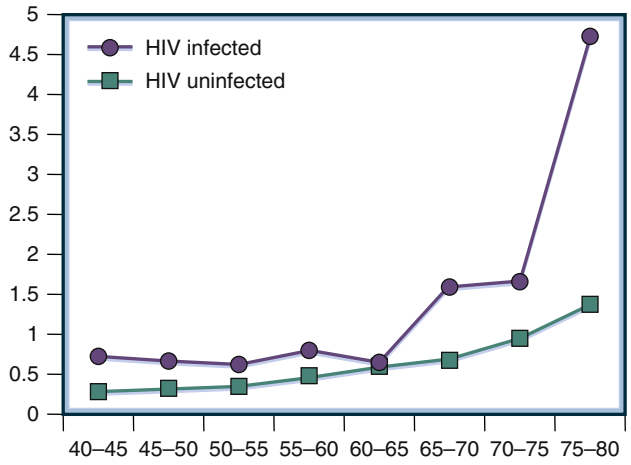
Endocrine factors may contribute to reduced bone density in HIV-infected patients, including hypogonadism, relative growth hormone (GH) deficiency, and vitamin D deficiency. In one study, GH pulse area determined from overnight frequent sampling was reduced in patients with central fat accumulation and correlated significantly with vertebral bone density.[56] This relationship may explain, in part, the inverse association between increased visceral fat and reduced bone density in HIV-infected patients.[57] Vitamin D deficiency is common among HIV-infected patients.

In a study of ambulatory clinic patients in London, the prevalence of 25-hydroxyvitamin D deficiency (<20 ng/mL) and severe 25-hydroxyvitamin D deficiency (<10 ng/mL) was 58.5% and 12.6%, respectively.[58] In a large cohort of 2044 consecutively followed HIV patients in Brussels, the prevalence of severe vitamin D deficiency using the 10-ng/mL cutoff was 32.4%.[59] Among HIV-infected patients in the study, advanced disease (CD4 <200 cells/mm^3) and current use of efavirenz were significantly associated with severe vitamin D deficiency.[59] In carefully conducted case matching studies, the odds ratio for vitamin D deficiency in HIV versus non–HIV-infected patients tended to be increased at 1.46, although this did not reach statistical significance.[60] TDF may increase PTH and bone turnover, potentially related to effects on proximal tubule phosphate reabsorption or other effects. PIs may also inhibit 1α-hydroxylase and result in vitamin D deficiency.[40]

Studies in HIV-infected patients receiving HAART have investigated markers of bone resorption and formation and found evidence of increased bone turnover.[61] Tebas and colleagues[62] evaluated serum and urine bone markers in 73 HIV-positive patients receiving PI therapy. Increased serum bone alkaline phosphatase and urine *N*-telopeptide were found to be inversely correlated with BMD T- and Z-scores measured by dual-energy x-ray absorptiometry, suggesting an increased rate of bone turnover among HIV-infected patients receiving PI therapy.[62] Recent data investigating the receptor activator for nuclear factor κB ligand (RANKL) system demonstrate reduced soluble RANKL in HIV-infected patients,[63,64] arguing against activation of this system as a mechanism for increased bone turnover in HIV-infected patients. In contrast, increased osteoprotegerin was shown among HIV-infected women with low bone density, suggesting a compensatory increase in the context of low bone density and high bone resorption rates.[65]

Several recent studies have examined fracture rates among HIV-infected patients. In a US-based data registry study, the overall fracture prevalence was 2.87 versus 1.77 per 100 persons for HIV versus non–HIV-infected patients.[66] In a large cohort study performed in Europe, significantly increased adjusted hazard ratios for hip and major fracture were 4.7 and 1.8, with an increased relative risk (RR) of fracture among older HIV-infected patients in the study[67] (Fig. 44.3). In a Veterans Administration cohort of men, Womack and coworkers[68] demonstrated that increased fragility fractures were strongly associated with a higher frailty score, low BMI, alcohol-related diagnoses, white race, proton pump inhibitor use, and PI use. In a study limited to women, lifetime fragility fractures were significantly more common in HIV-infected versus non–HIV-infected women (odds ratio, 1.7; 95% confidence interval, 1.1–2.6).[69] Use of the FRAX (Fracture Risk Assessment Tool) score to predict fragility fracture has shown relative poor sensitivity but good specificity among HIV-infected patients.[70] In partial contrast to the data on bone density, data from nonrandomized longitudinal cohorts demonstrate that overall use of PIs, nucleoside reverse transcriptase inhibitors (NRTIs), and non-NRTIs (NNRTIs) is associated with reduced fracture rates, whereas the effects of individual drugs vary. Low CD4 count, hepatitis, and DM are independently related to increased fracture risk.[71] These data suggest that overall effects of ART may be to improve bone through effects on improving immune function and virologic factors, but adverse effects of specific ART agents on bone may also be important.[72]

Limited data are available on treatment strategies for bone loss in HIV-infected patients. Among patients with idiopathic bone loss and high bone turnover, recent studies suggest that alendronate is effective in increasing bone density among HIV-infected patients, with studies demonstrating increases in lumbar spine bone density from 3.4% to 5.2% over 42 weeks and good safety tolerability, albeit in relatively small numbers of patients.[73,74] Use of longer acting bisphosphonates (e.g., zoledronate) showed even greater changes in spinal bone density of 8.9% over 2 years in a randomized, placebo-controlled study.[75] Importantly, significant differences persisted for bone density and bone turnover between groups 5 years after the final dose, suggesting potent, persistent effects after short-term dosing.[76] To date, there have been no studies examining the effect of teriparatide, abaloparatide, or denosumab in the HIV-infected population. Among men with AIDS wasting, testosterone at high doses (200 mg/week) has been shown to increase bone density.[77]

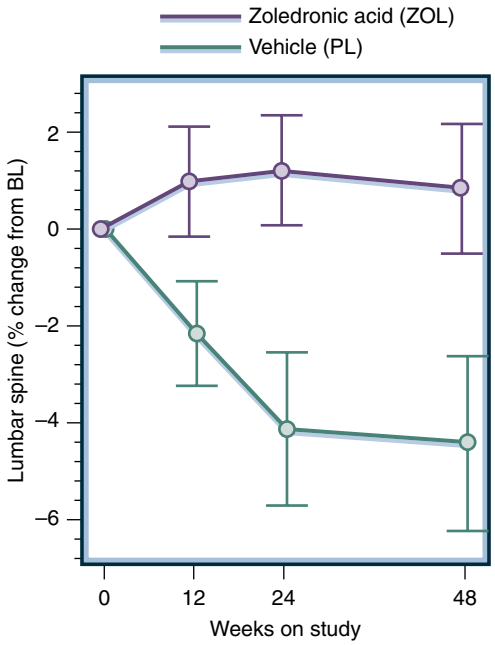


• **Fig. 44.3** Age-specific fracture incidence rates (per 100 person-years) in human immunodeficiency virus–infected versus uninfected patients. (From Guerri-Fernandez R, Vestergaard P, Carbonell C, et al. HIV infection is strongly associated with hip fracture risk, independently of age, gender, and comorbidities: a population-based cohort study. *J Bone Miner Res.* 2013;28:1259–1263, Fig. 1, used with permission.)

The first 2 years after the initiation of ART are associated with a 2% to 6% decrease in BMD, with the larger decreases in this range observed in those receiving TDF or PIs.[78–81] Advanced HIV disease at the time of ART initiation has also been associated with greater loss of BMD in this period.[82] In addition to avoiding TDF and PIs, as well as starting ART at a higher CD4 cell count, several strategies have been tested to mitigate bone loss during ART initiation. In a randomized controlled trial, high-dose vitamin D_3 (4000 IU/day) and calcium (1000 mg/day) at the time of ART initiation with TDF/emtricitabine/efavirenz was shown to attenuate ART-initiation–associated bone loss by 50%.[83] In another randomized trial, a single dose of zoledronic acid (5 mg) prior to ART initiation prevented bone loss over 96 weeks[84]; this may be an important strategy to maintain bone health in those HIV-infected patients initiating ART who are at risk for fracture because of older age, lower BMD, or the presence of other fracture risk factors (Fig. 44.4).

Bone Metabolism in HIV-Infected Children

Reduced bone density has also been reported in HIV-infected children. O'Brien and associates[85] demonstrated reduced total-body bone density in perinatally infected girls at age 9 years in association with increased *N*-telopeptide and PTH levels. In a 2013 study, HIV-infected children ages 12 to 13 years had a greater



• **Fig. 44.4** Longitudinal percentage change over 48 weeks in lumbar spine bone mineral density (BMD) with initiation of antiretroviral therapy (ART) with concomitant zoledronic acid (5 mg intravenous; ZOL) or placebo (PL). *BL,* baseline. (Redrawn from Ofotokun I, Titanji K, Lahiri CD, et al. A single-dose zoledronic acid infusion prevents antiretroviral therapy-induced bone loss in treatment-naive HIV-infected patients: a phase IIb trial. *Clin Infect Dis.* 2016;63[5]:663–671; Fig. 3B.)

prevalence of low bone density than HIV-exposed but uninfected children, although these differences were attenuated after height and weight adjustment, suggesting that delays in growth may account for differences in bone density.[86] Among young HIV-infected adults ages 20 to 25 years, Tanner stage 5, infected either perinatally or during adolescence, both volumetric bone density and cortical and trabecular thickness on high-resolution peripheral quantitative computed tomography was reduced, suggesting lower peak bone mass among HIV-infected patients.[87] In contrast to increased markers of resorption, reduced osteocalcin levels have been reported in HIV-infected children, suggesting reduced bone formation and a relative discrepancy between increased resorption and reduced formation in this group.[88] Similar to data in adults, bone density is related to insulin-like growth factor 1 (IGF1) in HIV-infected children, suggesting a potential effect of low GH on bone.[89] Mora and colleagues[90] followed bone density longitudinally over 1 year to compare changes in HIV-infected children and control subjects and demonstrated relative reductions in total-body but not spinal bone density accrual and relative increases in bone turnover. ART initiation with TDF has been associated with small decreases in BMD in children but does not appear to affect accrual of bone over 10 years in small studies.[91,92] There is conflicting evidence whether TDF exposure affects bone health or linear growth in HIV-exposed uninfected infants.[93,94]

Vitamin D supplementation has been tested as a strategy to improve BMD in HIV-infected children and adolescents. Among children, supplementation with vitamin D (100,000 IU of cholecalciferol every 2 months and calcium [1 g/day]) did not increase bone density over 2 years.[95] In another study of adolescents taking ART containing TDF, vitamin D_3 (50,000 IU/monthly) was associated with modest increases in lumbar spine BMD, which was not observed in the placebo comparison group.[96] Another randomized, placebo-controlled study over 24 months showed no differences in BMD change between vitamin D_3 dosing of 18,000 IU/month, 60,000 IU/month, and 120,000 IU/month.[97] Taken together, these finding suggest that the effect of vitamin D supplementation on BMD in children and adolescents may be minimal.

Avascular Necrosis of Bone

Miller and coworkers[98] demonstrated a 4.4% prevalence of avascular necrosis (AVN) among 339 asymptomatic HIV-infected individuals. A significant relationship was reported between AVN and prior use of systemic corticosteroids. Other potential factors significantly associated with an increased risk of AVN included the presence of anticardiolipin antibodies, as well as routine bodybuilding and its associated mechanical stress. Alcohol use may also be a factor associated with AVN among HIV-infected patients.[99] In an analysis among HIV-infected patients, osteonecrosis of the bone was associated with exposure to one or more ART drugs and high triglyceride and cholesterol levels, as well as high serum immunoglobulin E.[100] A role for altered coagulation and inflammation was also suggested by the observation of increased D-dimer among patients with osteonecrosis[101] and that past history of immunosuppression was a major risk factor for AVN incidence.[102]

The GH/IGF1 Axis

Significant abnormalities in the GH/IGF1 axis occur in HIV-infected patients. Among patients with AIDS wasting and significant weight loss, GH levels are increased in association with reduced IGF1 levels, a pattern typical of GH resistance seen with malnutrition. In contrast, in the setting of visceral fat accumulation, frequent sampling of GH levels over 24 hours has suggested a different pattern.[103] Mean overnight GH and GH pulse amplitude were decreased in this setting, whereas pulse frequency was not different compared with age-matched and BMI-matched non-lipodystrophic HIV- and non–HIV-infected patients. Reduced GH levels were strongly predicted by increased visceral fat in the patients. A role for suppression of GH release by free fatty acids (FFAs) was suggested by experiments in which acipimox, a nicotinic acid derivative that blocks peripheral tissue lipolysis and lowers FFA levels, was administered. Peak GH response to GH–releasing hormone (GHRH) was increased in response to acipimox, in inverse association to the change in FFA.[104] Physiologic studies of GH in HIV-infected patients suggest a schema whereby increased somatostatin tone, reduced ghrelin, and increased lipolysis contribute to reduced GH secretion in viscerally obese HIV-infected patients with lipodystrophic changes in fat distribution.[104]

GH deficiency is a potential cause of growth failure in HIV-infected children, and treatment with GH results in improved auxologic parameters in such children.[105] Increased IGF-binding protein 3 (IGFBP3) proteolysis and reduced IGF1, IGFBP3, and acid-labile subunit of the IGFBP3 ternary complex are demonstrated among HIV-infected children with failure to thrive.[106] IGF1 and IGFBP3 responses to GH may be impaired in HIV-infected children, suggesting a degree of GH insensitivity in this population. These responses may improve with weight gain and improved immune function in response to HAART.[107] GH deficiency may also disrupt normal thymic development in

HIV-infected children. GH has been used to increase height in HIV-infected children with normal GH responses to stimulatory testing.[105] Among HIV-infected children, reduced GH secretion is associated with excess visceral adiposity. Among adults, GH is approved by the US Food and Drug Administration (FDA) for the treatment of AIDS wasting. In addition, a GHRH analogue, tesamorelin, is FDA approved to reduce excess visceral fat accumulation in HIV lipodystrophy (see the discussion in the Treatment of Metabolic and Body Composition Changes in HIV-Infected Patients section).

Glucose Homeostasis and Pancreatic Function

Disorders of glucose homeostasis were relatively infrequent prior to the institution of potent ART but may result from use of specific antiretroviral agents and are commonly seen in association with dyslipidemia and fat redistribution in the current era of HAART (see the Metabolic and Body Composition Changes in HIV-Infected Patients section). The pancreas is a frequent target of opportunistic infections and malignancies in patients with advanced HIV disease. However, clinical endocrine dysfunction rarely results, except in cases of massive pancreatic replacement from lymphoma or KS. For example, opportunistic infections of the pancreas are seen on postmortem examination but are rarely clinically relevant. More commonly, pancreatitis and hypoglycemia follow use of certain drugs, such as pentamidine, didanosine, or zalcitabine. Hypoglycemia can result from pentamidine administration secondary to islet cell inflammation and insulin release, especially in the context of high-dose therapy and azotemia. Subsequently, chronic hyperglycemia from pancreatic B-cell destruction may follow pentamidine use. Megestrol acetate use has been associated with new-onset DM because of its potent glucocorticoid action. Pancreatitis is common among patients with HIV and most often related to a drug effect (i.e., pentamidine, trimethoprim-sulfamethoxazole, didanosine, and zalcitabine). In a large study of almost 6000 patients followed for 23,460 person-years at the Johns Hopkins HIV Clinic, the incidence of acute pancreatitis was 5.1 in 1000 person-years between 2001 and 2006. Low CD4 count, aerosolized pentamidine, and female gender were associated with pancreatitis. In contrast, specific antiretroviral medications were not.[108] In the EuroSIDA study, a lower incidence of pancreatitis was seen since 2001—1.27 in 1000 person-years—and, again, low CD4 count was predictive. Similar to the data from the Hopkins cohort, no association was seen between cumulative exposure to ART and exposure to didanosine and stavudine—NRTIs that have been associated with pancreatitis.[109] Amylase levels may also be elevated in HIV-infected patients secondary to macroamylasemia and salivary amylase.

Metabolic and Body Composition Changes in HIV-Infected Patients

HIV-infected patients demonstrate several changes in body composition and metabolism. These changes are present to varying degrees among HIV-infected patients and are multifactorial in nature, related, in part, to the HIV virus itself, inflammation, and specific antiretroviral drugs, as well as the interplay of these factors.[110,111] Of importance, some of these changes may contribute to increased cardiovascular disease (CVD) and respond to changes in ART, lifestyle modification (LSM), and specific pharmacologic strategies (e.g., to improve lipids or insulin sensitivity).

The AIDS Wasting Syndrome and Loss of Lean Body Mass

Wasting was initially a common feature of progressive HIV disease, which was known originally as "slim disease." The AIDS wasting syndrome is currently defined by weight less than 90% ideal body weight or weight loss greater than 10% over 3 months. It is characterized by a disproportionate loss of lean body mass, with a relative sparing of body fat, particularly in men. In women, fat mass may be lost disproportionately with disease progression. The loss of lean body mass occurs early and may antedate weight loss. Muscle wasting, weakness, and increased resting energy expenditure of 8% to 9% are also features of this disease. Macallan and associates[112] demonstrated that energy expenditure fell during periods of rapid weight loss but less than the decrease in caloric intake. Cytokines associated with severe illness may increase energy expenditure and decrease appetite. In addition, chronic weight loss may be associated with gastrointestinal disease, including malabsorption. Weight loss is a significant predictor of mortality rate in HIV infection, with BMI less than 18.4 kg/m^2 associated with a 2.2-fold increase in mortality rate and BMI less than 16.0 kg/m^2 associated with a 4.4-fold increase in mortality rate.[113] Hypogonadism is observed in 30% to 50% of men with AIDS wasting and may contribute to loss of lean body mass[114] (see the Gonadal Function section).

In contrast to the traditional paradigm of wasting, HIV disease may be associated with overweight and obesity, particularly in developed countries with emerging obesity epidemics. In one study, performed at a large urban clinic for HIV-infected patients located in the southern United States, the prevalence of underweight was less than 10% and the prevalence of overweight and obesity was 44% despite high viral load at ART initiation.[115] With ART, 20% of patients increased from normal to overweight or overweight to obese[115] (Fig. 44.5). Subjects with more severe

immune dysfunction and using boosted PIs tended to gain the most weight with ART.

Changes in Fat Mass and Distribution

The most commonly seen change in body composition among HIV-infected patients is loss of abdominal and peripheral subcutaneous fat, including loss of subcutaneous fat in the face.[116] Other changes that may also be seen include relative preservation of central fat, with relative and absolute accumulation of excess visceral fat and excess upper trunk fat.[116,117] In addition, ectopic fat collections can be seen, including in the dorsocervical area. Increased fat deposition in the liver and muscle is also seen and is associated with insulin resistance. In prospective studies of antiretroviral-naive patients beginning treatment in the early 2000s, including an NRTI and PI, initial gains in both peripheral subcutaneous and central fat depots are seen with reversal of the catabolic wasting state in association with control of viral infection. These changes are followed by subsequent decreases in peripheral fat and relative preservation and even absolute gains in central fat. More recent data of ART-naive persons initiating treatment with more modern regimens suggest increase in both subcutaneous and visceral fat over 96 weeks.[118] Data from the Study of Fat Redistribution and Metabolic Change in HIV Infection (FRAM study) demonstrate that increases in visceral fat and reductions in limb fat are independently associated with increased mortality rate in HIV-infected patients[119] (Fig. 44.6).

The cause of relative central fat accumulation remains unknown. For example, it remains unknown whether this is a direct effect of specific antiretroviral drugs and whether abnormal nutrient partitioning to relatively preserved central adipose stores, less affected by NRTI administration and mitochondrial toxicity, may contribute. In contrast, several mechanisms have been shown to contribute to the fat loss seen peripherally. NRTIs can inhibit mitochondrial DNA polymerase gamma and contribute to mitochondrial dysfunction. Use of specific NRTIs, including older NRTIs such as stavudine, has been associated with apoptosis of fat and reduced mitochondrial DNA in vitro and in vivo, as well as reduced expression of lipid metabolism genes, and clinically with reduced subcutaneous fat and lipoatrophy.[120,121] PIs may have direct effects on adipogenesis (via inhibition of nuclear localization of sterol regulatory element–binding protein 1 [SREBP1] and reduction in peroxisome proliferator-activated receptor γ [PPARγ] expression).[122] NRTIs and PIs have been associated with increased lipolysis in vivo and in vitro.

Genetic polymorphisms may predispose to changes in body composition and metabolic alterations in HIV-infected patients receiving ART. Such findings could indicate a gene-environment interaction contributing to such changes. For example, single-nucleotide polymorphisms in the resistin gene were seen to predict the development of dyslipidemia, insulin resistance, and limb fat loss in response to a specific antiretroviral regimen.[123] In the same study, polymorphisms in the hemochromatosis gene and specific mitochondrial gene haplotypes were also associated with increased limb fat loss.[124] Specific haplotypes of the Fas gene (*APOC3*), PPAR gene, and adrenergic receptor have also been associated with the development of lipoatrophy.[125]

Other studies suggest early molecular changes in the fat of patients with subsequent peripheral adipose tissue loss. Kratz and colleagues[126] showed that reduced expression of messenger RNA (mRNA) encoding lipoprotein lipase and the transcription factors SREBP1, PPARγ, and CCAAT/enhancer binding protein C/EBPα in thigh subcutaneous fat were associated with the loss of fat, before it became evident clinically, whereas increased levels of mRNA encoding hydroxysteroid 11β-dehydrogenase 1 and the transcription factor C/EBPβ were found in adipose tissue from patients with preservation of subcutaneous fat mass. The expression of endoribonuclease Dicer, which modulates brown and white adipocyte differentiation, was found to be reduced in subcutaneous fat of HIV-infected persons with lipodystrophy, providing a

Decreased limb muscle and increased central adiposity are associated with 5-year all-cause mortality in HIV infection. *AIDS.* 2011;25[11]:1405–1414, Fig. 1, used with permission.)

novel mechanisms for adipose dysfunction in HIV.[127] In addition, studies suggest increased activation of the renin-angiotensin-aldosterone system associated with visceral adipose accumulation in HIV. Recent data suggest that use of the mineralocorticoid receptor antagonist eplerenone in HIV-infected patients may reduce immune activation and improve select metabolic indices.[128]

Changes in fat distribution have been most widely recognized since the introduction of HAART, but abnormal fat distribution can be seen in antiretroviral-naive patients, suggesting that viral factors also may contribute. In this regard, recent data suggest that adipose tissue dysfunction may be related to a viral accessory protein, Vpr, which may simultaneously coactivate the glucocorticoid receptor and repress PPARγ.[129]

The changes in fat distribution seen among HIV-infected patients bear some similarities to those in Cushing syndrome, with dorsocervical fat accumulation and centripetal fat distribution. However, more specific stigmata of true Cushing syndrome, including proximal muscle weakness, facial plethora, thin skin, bruising, and violaceous striae, have not been seen, and thus these changes constitute a pseudo-Cushing syndrome.[130] Miller and coworkers[130] observed normal cortisol levels and adequate suppression in response to dexamethasone among HIV-infected patients with cushingoid features. Yanovski and associates[131] compared HIV-infected patients with PI-associated lipodystrophic changes in fat to control patients and those with true Cushing syndrome. In contrast to patients with true Cushing syndrome, patients with PI-associated lipodystrophy demonstrated normal diurnal variation in cortisol levels. The 24-hour urine free cortisol levels were reduced and 17-hydroxysteroid levels were increased compared with levels in control subjects. Among HIV-infected patients with changes in fat distribution, increased 11β-hydroxysteroid dehydrogenase expression in subcutaneous adipose tissue (SAT) has been demonstrated in association with an increased ratio of urinary cortisol to cortisone metabolites and may also contribute to increased cortisol production.[132] In addition, as noted earlier, viral proteins may activate the glucocorticoid receptor in specific fat depots.[129]

Other abnormalities of steroid metabolism have been noted in association with changes in fat distribution. In a longitudinal evaluation, the development of lipodystrophy was associated with reduced DHEA, increased cortisol/DHEA ratio, and increased interferon α.[133] Increased cortisol regeneration from affected fat depots may contribute to insulin resistance and further fat redistribution.

Lipid Abnormalities

Lipid abnormalities are highly prevalent among HIV-infected patients, particularly those with changes in fat distribution and increased visceral fat and upper trunk fat. Hypertriglyceridemia has long been associated with HIV infection; was observed prior to the introduction of potent ART; and is related, in part, to increased very low density lipoprotein (VLDL) secretion and decreased clearance.[134] The cause of these changes is not known but may relate to the effects of viral infection itself, microbial translocation via lipopolysaccharide,[135] altered cytokines including interferon α,[136] or increased apolipoprotein E.[137] In longitudinal studies, reduction in high-density lipoprotein (HDL), total cholesterol, and LDL cholesterol has been observed with seroconversion. With antiretroviral treatment, cholesterol and LDL rise to preinfection levels but low HDL levels persist.[138]

Among HIV-infected patients receiving combination ART including a PI, hypercholesterolemia (>240 mg/dL), hypertriglyceridemia (>200 mg/dL), and low HDL (<35 mg/dL) were reported in 27%, 40%, and 27%, respectively, compared with corresponding percentages of 8%, 15%, and 26% in previously untreated patients.[139] Among patients with changes in fat distribution, 57% demonstrated hypertriglyceridemia and 46% low HDL in comparison to an age- and BMI-matched cohort from the Framingham Offspring Study.[140] A phenotype of atherogenic small, dense LDL particles among HIV-infected patients with lipodystrophy has been described.[141] In addition, investigators have demonstrated increased triglyceride enrichment of LDL and impaired hepatic lipase, suggesting impaired lipoprotein processing, further contributing to atherogenic dyslipidemia.[142]

Dyslipidemia among HIV-infected patients may result from the effects of antiretroviral drugs, including specific PIs, which have been shown to increase triglyceride levels. Use of PIs may also be associated with an atherogenic dyslipidemia and an increase in small, dense LDL[143]; increased apolipoprotein C-III and apolipoprotein E; and decreased proteasomal degradation of apolipoprotein B.[144,145] Mulligan and colleagues[146] demonstrated that changes in lipid levels occur within 3 months of PI therapy. Hypertriglyceridemia is most severe among patients treated with ritonavir or the ritonavir/saquinavir combination. Among the currently approved PIs, atazanavir is least often associated with hyperlipidemia.[147] Lipid changes appear to be less and improve with use of atazanavir in contrast to other PIs.[148] Some NNRTIs, such as efavirenz, may raise total cholesterol and non-HDL cholesterol but also raise HDL cholesterol.[149] Newer NNRTIs, such as rilpivirine and etravirine, have less pronounced effects on the lipid profile than efavirenz.[150–152] Integrase strand transfer inhibitors, such as raltegravir, dolutegravir, elvitegravir, and bictegravir, have a more favorable lipid profile than PIs.[153–155] These agents are preferred as initial management of HIV infection in combination with NRTIs.[156]

Hyperglycemia and Insulin Resistance

Insulin resistance and DM are relatively common among HIV-infected patients. In an early longitudinal study, DM was 3.1 times more likely to develop in HIV-infected patients receiving combination ART than in control subjects.[157] More recent studies confirm increased risk of DM prior to 2000 but found equivalent rates among HIV-infected and non–HIV-infected patients in the era of modern ART, with agents less likely to contribute to glucose abnormalities.[158] These estimates suggest a peak incidence of 23.2 in 1000 patient-years immediately prior to 2000 that has decreased to less than 10 in 1000 patient-years, with no difference between subjects naive to and those using ART[159] (Fig. 44.7). However, a recent analysis comparing a large nationally representative population of HIV-infected persons had an adjusted DM prevalence of 11.8%, which was significantly higher than 8.0% DM prevalence in the National Health and Nutrition Examination Survey.[160] BMI, lipodystrophy, low CD4 counts, and exposure to specific, older ART medications including stavudine and indinavir are predictive of DM in the HIV population.[158] HIV-infected patients with impaired glucose tolerance demonstrate hyperinsulinemia, suggesting that insulin resistance contributes to the development of impaired glucose homeostasis in this population.

Hemoglobin A_{1c} has been shown to underestimate levels of blood glucose in HIV-infected patients, particularly those with increased mean corpuscular volume resulting from specific ART agents. In one study, use of an A_{1c} cutoff of 5.8% optimized the area under the curve for the diagnosis of DM and increased

sensitivity from 40.9% to 88.8% while simultaneously decreasing specificity from 97.5% to 77.5% compared with use of a cutoff of 6.5%.[161]

Insulin resistance among HIV-infected patients may be caused by the abnormal fat distribution itself (e.g., increased central adiposity, loss of peripheral subcutaneous fat, and associated molecular changes). These changes include altered cytokines (e.g., low adiponectin, increased resistin, or elevated TNF) or changes in other processes such as mitochondrial dysfunction, increased lipolysis, increased proteolysis, increased expression of suppressor of cytokine signaling 1 (SOCS1),[162] and increased accumulation of fat in the muscle and liver. Increased inflammation after initiation of ART is associated with development of DM among HIV-infected patients,[163] and metabolic changes may result from persistent microbial translocation across the gastrointestinal barrier, resulting in increased levels of lipopolysaccharide in the blood despite viral suppression.[164] Metabolic abnormalities in HIV have been shown to be associated with increased levels of retinol-binding protein 4 (RB4), which may further contribute to insulin resistance.[165] Rarely, insulin receptor autoantibodies may develop among HIV-infected patients experiencing an immune reconstitution syndrome during ART initiation.[166] In addition, significant evidence suggests direct effects of specific antiretrovirals to reduce insulin sensitivity. PIs have been shown to decrease glucose uptake by inhibiting the transport function of glucose transporter type 4 (GLUT4) in vitro[167] and have been shown to reduce insulin sensitivity in vivo.[168] Effects to decrease beta-cell apoptosis and compromise insulin secretion have also been postulated.[169] NRTIs are associated with insulin resistance, which may be a direct effect, potentially related to mitochondrial toxicity[170] or through effects on subcutaneous fat.[121] For more details on the metabolic effects of specific ART agents, see Table 44.1. The specific manifestations and course of DM in HIV patients have not been well studied, but initial studies suggest an increased risk of albuminuria in HIV-infected patients, particularly those with increased viral load, independent of blood pressure.[171]

Treatment of Metabolic and Body Composition Changes in HIV-Infected Patients

There are several options available for the treatment of body composition and metabolic abnormalities in HIV-infected patients.

Treatment of AIDS Wasting and Loss of Lean Body Mass

Testosterone has been used successfully to increase lean body mass in men with AIDS wasting. Randomized studies of intramuscular testosterone for hypogonadal men with AIDS wasting suggest a beneficial effect of testosterone administration on lean body mass (2.0 kg over 6 months) and improved quality of life.[172] Although a limited number of studies have shown a benefit of anabolic steroids in HIV-infected patients with wasting, these agents potently suppress endogenous gonadal function and may

thus cause hypogonadism. Methyltestosterone and anabolic steroids may cause problems with the liver, including peliosis hepatis, worsening liver function, and potentially malignancy. In addition, high-dose oxandrolone suppresses endogenous testosterone levels, significantly increases transaminase levels, and increases LDLs.[173] Nandrolone (100 mg intramuscularly every other week) was shown to be effective in increasing weight and lean body mass in HIV-infected women with weight loss.[174] Anabolic steroids are associated with decreased HDL and other side effects, including effects on the liver, and hold no advantage over natural testosterone in the treatment of hypogonadism associated with AIDS-related weight loss. Short-term use of anabolic steroids may be considered in eugonadal patients with severe wasting, but they may be associated with adverse effects and should generally be avoided. DHEA may be used to improve mood and depression among HIV-infected patients with subsyndromal depression and dysthymia,[175] but the use of DHEA has not been standardized particularly with respect to dose, duration of treatment, and clinical end points, and thus it remains investigational.

Several studies have investigated androgen administration to HIV-infected women with low weight. These studies have investigated testosterone using a transdermal patch designed to deliver low physiologic doses of 150 to 300 μg/day. Among studies using the 150-μg/day dose, functional capacity and strength significantly improved with a trend toward increased lean body mass over 6 months. Hirsutism was not seen, and virilization did not occur. An 18-month randomized, placebo-controlled study conducted among relatively androgen-deficient HIV-infected women demonstrated that 300 μg/day increased lean body mass and bone density at the hip and improved depression indices without aggravation of lipid or glucose parameters.[176] Preliminary studies have investigated the effects of DHEA on androgen levels in HIV-infected premenopausal women, but the clinical utility of this strategy in HIV-infected women remains unknown.

Megestrol acetate is a synthetic progestational agent with glucocorticoid-like properties. Randomized studies in the literature show that megestrol acetate increases weight 3 to 4 kg over 12 weeks with an increase in caloric intake.[177,178] However, the change in weight is almost entirely fat mass without an increase in lean body mass. In addition, megestrol acetate, because of its glucocorticoid-like properties, is associated with several side effects, including hypogonadism and hyperglycemia, and abrupt withdrawal can precipitate adrenal crisis. In children, megestrol acetate promotes weight gain without improving linear growth.[179]

Several other agents have been used in the setting of AIDS wasting. Thalidomide blocks the action of TNFα and decreases esophageal ulcers in AIDS patients. Clinical studies demonstrate a modest beneficial short-term effect of thalidomide on weight indices but significant associated adverse effects, including rash and fever. Human chorionic gonadotropin results in increased testosterone levels and may have independent effects to inhibit KS. No data are available from randomized controlled studies to determine effects on wasting in humans.

In addition, patients with AIDS wasting may demonstrate a typical pattern of nutrition-related GH resistance (see The GH/IGF1 Axis section). These patients exhibit elevated GH levels but decreased IGF1, the primary hormone mediating the action of GH on muscle, suggesting GH resistance.[180,181] GH has been used in HIV-infected patients to increase lean body mass in sarcopenic patients with AIDS wasting. Among patients with AIDS wasting, high-dose, supraphysiologic GH (0.1 mg/kg per day) has been investigated. Relatively small but significant effects on weight (1.6 kg) were seen over 3 months in a placebo-controlled study.[182] GH administration at 0.1 mg/kg has also been shown to increase work output during treadmill exercise[182] and quality of life, as well as peripheral muscle oxygen extraction and utilization, in patients with AIDS wasting.[183] These studies suggest that large doses of GH may be necessary to significantly increase lean mass in patients with AIDS wasting and nutritionally mediated resistance to GH. However, high-dose GH is associated with side effects including hyperglycemia and fluid retention[184] and is not well tolerated in the long term. For these reasons, caution should be used with respect to long-term high doses of GH for treatment of AIDS wasting, because this treatment may cause acute and chronic side effects of GH excess. At high doses, GH was shown to increase thymic mass and circulating CD4 cells in one study[185] and to induce HIV1-specific T-cell responses at low doses (0.7 mg/day) in patients on effective ART,[186] but further studies are needed to investigate the effects of GH on the immune axis.

A multidisciplinary approach to AIDS wasting syndrome is most useful. Optimization of ART is paramount in conjunction with provision of adequate nutrition and protein intake. However, even in this context, weight and muscle loss may occur because of the highly catabolic nature of the disease. In such cases, endocrine evaluation should include assessment of gonadal function, which will often be reduced. GH levels are increased in AIDS wasting, but supraphysiologic administration, as approved by the FDA, can further increase lean body mass. This strategy is best reserved for severe wasting refractory to other treatments. Other therapeutic strategies that increase weight by stimulating appetite, including megestrol acetate, are not associated with gain in lean body mass and may be associated with side effects. In the current era of HAART, lipoatrophy, usually associated with antiretroviral use, should be distinguished from traditional wasting. Whereas true AIDS wasting involves sarcopenia and requires anabolic strategies to increase muscle mass, the presence of severe lipoatrophy suggests the need for strategies to spare fat loss.

Strategies for Treating Lipoatrophy and Subcutaneous Fat Loss

Antiretroviral switching to less toxic NRTIs or PIs may be useful for improving changes in fat distribution and hyperlipidemia.[187] For example, one study demonstrated that switching off lopinavir/ritonavir to atazanavir/ritonavir improved glucose trafficking into muscle, reduced triglyceride levels (by 182 mg/dL on average), and decreased visceral fat by 25%.[148] Other studies have demonstrated significant increases in SAT and reductions in visceral adipose tissue (VAT) after switching to a non-thymidine analogue–based ART strategy.[188] LSM and resistance training are unlikely to reverse the loss of subcutaneous fat often seen in HIV-infected patients receiving ART.

Treatments for Visceral Fat Accumulation

LSM, in combination with exercise, may improve lipid levels and visceral adiposity among HIV-infected patients.[189] Progressive resistance training (PRT) may also significantly improve glucose homeostasis in HIV-infected patients through a reduction in muscle adiposity.[190] Studies of LSM in HIV-infected patients modeled after the Diabetes Prevention Program demonstrate effects of LSM to improve cardiorespiratory fitness and raise levels of HDL and C-reactive protein (CRP)[191] but do not show significant effects on body composition.

Limited data are available on the use of testosterone among relatively androgen-deficient HIV-infected men with abdominal

fat accumulation (waist-to-hip ratio >0.95 or waist circumference >100 cm).[192] Ten grams of topical testosterone daily did not improve visceral fat mass but reduced overall trunk fat by 15% relative to placebo over 24 weeks. Significant effects on glucose and insulin were not seen. Effects of high-dose testosterone and anabolic steroids on lipid parameters may limit utility of this class of drugs to reduce visceral fat in HIV-infected patients. Moreover, studies among older, male, non–HIV-infected patients suggest that testosterone use may be associated with increased CVD events.[193,194] Use of testosterone among HIV-infected men should be limited to those with documented hypogonadism, among whom treatment may improve lean body mass and bone.

GH has also been used to reduce visceral fat in HIV-infected patients with central fat accumulation. Lo and coworkers[195] investigated low-dose, long-term GH over 18 months in HIV-infected patients with central fat accumulation and deficient responses to GHRH-arginine testing. Low-dose GH was shown to reduce VAT by 9% over 18 months, simultaneously lowering blood pressure and triglyceride level. Even with low-dose GH, however, 2-hour glucose increased, demonstrating that GH is potentially useful in decreasing central fat accumulation but is hard to titrate in a population with significant insulin resistance. Largely because of its ability to aggravate glucose, GH was not approved by the FDA for HIV lipodystrophy.

In contrast, GH secretagogues have been used successfully to increase lean body mass and reduce visceral and truncal fat, without significant effects on glucose. In the combined analysis of two large, randomized, placebo-controlled phase III trials of more than 800 patients, GHRH(1-44) (tesamorelin) reduced VAT by 15.4% relative to placebo in HIV-infected patients with central fat accumulation. Improvements were noted in triglyceride level (equal to 43 mg/dL), total cholesterol, and cholesterol-to-HDL ratio. Further improvements in body composition were seen over 12 months[196] (Fig. 44.8). Interestingly, no clinically significant effect to reduce SAT was seen, and thus GHRH(1-44) was selective for VAT. Use of GHRH(1-44) was associated with physiologic increases in IGF1 levels and was not associated with increased glucose or insulin levels, in contrast to low-dose GH. Larger reductions in visceral fat were associated with improvements in lipid and glucose levels, as well as adiponectin, suggesting metabolic improvements with VAT reduction.[197] Recently, GHRH(1-44) was also shown to improve liver fat in association with visceral fat, suggesting beneficial effects on other ectopic fat depots.[198] Discontinuation of both GH and GHRH resulted in reaccumulation of visceral fat back to baseline levels, demonstrating that the effects of these agents do not outlast the treatment period.[199–201] GHRH(1-44) was approved by the FDA for the treatment of central fat accumulation in HIV-infected patients in 2010.

Insulin-Sensitizing Strategies

Significant insulin resistance occurs among HIV-infected patients, in association with use of specific antiretroviral agents, changes in fat distribution, and other factors. Metformin is particularly appropriate for use in patients with significant truncal adiposity and increased FFA concentrations, in whom insulin resistance is, in part, attributable to increased hepatic glucose production. In addition, metformin has a modestly favorable effect on lipids. In patients with hyperlipidemia, metformin has been demonstrated to decrease triglyceride and LDL levels without adversely affecting other parameters. The modest 10% to 20% reduction in plasma triglyceride levels is thought to be caused by decreased hepatic VLDL production.

The effects of metformin have been investigated in HIV-infected patients with central fat accumulation and insulin resistance. Using a dose of 500 mg orally twice a day in a randomized, placebo-controlled 12-week study,[202] Hadigan and associates[202,203]

(From Falutz J, Mamputu JC, Potvin D, et al. Effects of tesamorelin (TH9507), a growth hormone-releasing factor analog, in human immunodeficiency virus-infected patients with excess abdominal fat: a pooled analysis of two multicenter, double-blind placebo-controlled phase 3 trials with safety extension data. *J Clin Endocrinol Metab.* 2010;95:4291–4304, Fig. 2, used with permission.)

demonstrated that administration of low-dose metformin over 12 weeks significantly reduced insulin resistance, diastolic blood pressure, tissue plasminogen activator, and plasminogen activator inhibitor concentrations and tended to reduce abdominal visceral fat, thus improving the CVD risk profile of such patients. The effects of metformin were sustained over 9 months.[204] Other studies of metformin in HIV-infected patients also demonstrate general improvements in markers of insulin sensitivity but less consistent effects on abdominal fat.[205] In a randomized trial, the effects of metformin and PRT were compared with metformin alone, and the addition of PRT to metformin further improved central adiposity, blood pressure, and insulin resistance.[206] Compared with LSM, metformin was shown to significantly reduce coronary artery calcium in HIV-infected patients.[191]

The loss of subcutaneous fat in HIV-infected patients may further contribute to insulin resistance by limiting peripheral glucose and triglyceride uptake. Therefore, attention has focused on insulin-sensitizing strategies that may act to increase subcutaneous adipogenesis. The thiazolidinediones (TZDs) have been shown to promote adipogenesis, primarily through activation of PPARγ. Although the TZDs have effects on both hepatic and peripheral insulin resistance, the dominant effect is to improve peripheral glucose uptake. The therapeutic efficacy of the TZDs has been questioned among non–HIV-infected patients, in whom rosiglitazone, but not pioglitazone, has been associated with an increased mortality rate.[207] Weight has reported to increase in response to TZDs, in contrast to metformin, which is associated with weight loss. Nonetheless, based on the known effects of TZDs to stimulate insulin sensitivity through PPARγ and promote adipogenesis, this strategy has been investigated in HIV-infected patients with subcutaneous fat loss and insulin resistance.

In a 3-month randomized, placebo-controlled study involving 28 patients selected based on insulin resistance, rosiglitazone was shown to improve insulin sensitivity, adiponectin, FFA, and subcutaneous fat mass.[208] In contrast, an effect of rosiglitazone on subcutaneous fat was not shown over 48 weeks in patients with lipoatrophy, selected for fat loss but not for insulin resistance.[209] Adiponectin levels significantly increased and resisting levels decreased in response to rosiglitazone among HIV-infected patients. Rosiglitazone may be effective in increasing subcutaneous fat in selected subpopulations of HIV-infected patients, particularly those with insulin resistance,[210] but significant adverse effects on lipid levels, particularly LDL, suggest that pioglitazone may be better in this regard. Slama and colleagues[211] investigated pioglitazone among HIV-infected patients with confirmed lipoatrophy in a large, randomized, placebo-controlled trial. Pioglitazone increased peripheral fat and improved HDL levels, suggesting the potential utility among HIV-infected patients with insulin resistance and fat atrophy. Overall, the TZDs contrast with metformin in terms of effects on lipid and body composition but demonstrate similar effects to improve glucose in HIV-infected patients.[212]

Mitochondrial function is significantly affected by NRTI therapy in HIV-infected patients. Mallon and associates[213] have shown that simultaneous use of NRTIs may reduce effects of TZD agents to promote subcutaneous adipogenesis in HIV-infected patients with lipoatrophy by limiting effects of rosiglitazone to increase adipose expression of PPARγ. In addition, therapies for mitochondrial dysfunction, including increasing glutathione with cysteine and glycine supplementation, have been shown to improve mitochondrial fat and carbohydrate oxidation and insulin sensitivity in small studies among HIV-infected patients.[214] L-Acetylcarnitine was shown to decrease intramyocellular lipid accumulation and to increase percentage of leg fat while decreasing FFA in an open label study[215] and then was shown to increase T-cell mitochondrial DNA but to have no effect on body composition and metabolic indices in a second randomized study.[216] Studies to date using strategies to improve mitochondrial function are small, and further research is needed in this area.

Leptin Treatment for Metabolic Dysregulation Among HIV-Infected Patients With Lipoatrophy

Leptin levels are low in association with fat loss and lipoatrophy in HIV-infected patients. Initial small studies of leptin administration to HIV-infected patients with lipoatrophy and reduced leptin levels demonstrated significant improvements in insulin sensitivity, HDL, and triglyceride, as well as reduced truncal and visceral fat.[217,218] Among patients with mixed lipoatrophy and lipohypertrophy but low leptin levels, leptin administration improved total cholesterol and non-HDL cholesterol, as well as glucose parameters, but not HDL or triglyceride or lipid kinetics.[219] Because leptin reduces appetite, administration may be associated with weight loss. Metreleptin is FDA approved for treatment of complications related to congenital and acquired lipodystrophy, not related to HIV infection or its treatment. Further studies are needed to understand the clinical potential of leptin to improve metabolic parameters and fat redistribution among HIV-infected patients.

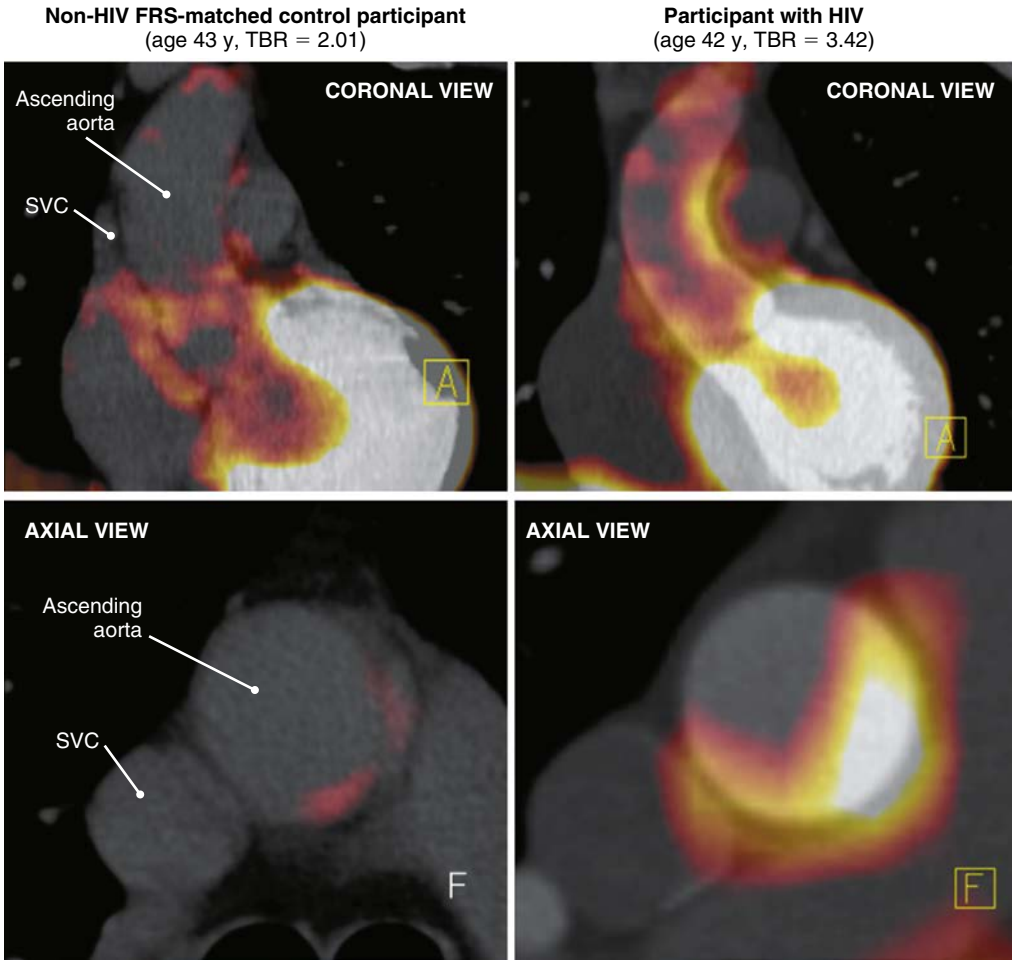
Lipid Management

See the Strategies for Hyperlipidemia Among HIV-Infected Patients section.

CVD in HIV-Infected Patients

CVD is increased among HIV-infected patients. Traditional risk factors for CVD in HIV-infected patients include increased smoking rates, insulin resistance, atherogenic dyslipidemia, truncal adiposity, hypertension (HTN), impaired fibrinolysis, and increased plasminogen activator inhibitor I and tissue plasminogen activator levels, as well as reduced adiponectin and increased CRP levels. DM is a risk equivalent in HIV-infected patients, conferring an increase in the RR of coronary heart disease equivalent to 2.41.[220] More than 40% of HIV-infected subjects meet the definition of the metabolic syndrome, and predicted myocardial infarction (MI) rates are increased in this subgroup.[221]

Abnormalities in surrogate markers, including carotid intima-media thickness and endothelial function, suggest increased CVD in HIV-infected patients. Abnormal endothelial function correlates with dyslipidemia, including increased chylomicrons, VLDLs, and intermediate-density lipoproteins and reduced HDL. Evidence for subclinical atherosclerosis has been demonstrated using coronary computed tomography in HIV-infected patients. Lo and coworkers[222] demonstrated an increased prevalence of coronary plaque among asymptomatic HIV-infected patients compared with well-matched non–HIV-infected patients (59% vs. 34%). Follow-up studies confirmed that the plaque in HIV-infected patients is more often noncalcified,[223] with vulnerable plaque features, including low-attenuation fatty lesions and eccentric positive remodeling.[224] Using fluorodeoxyglucose positron emission tomography to assess the degree of inflammation at the vascular surface, Subramanian and associates[225] demonstrated increased arterial inflammation (Fig. 44.9), even among those with minimal traditional cardiovascular risk indices. Increased immune activation indices correlated with the arterial inflammation, independent of traditional risk factors,

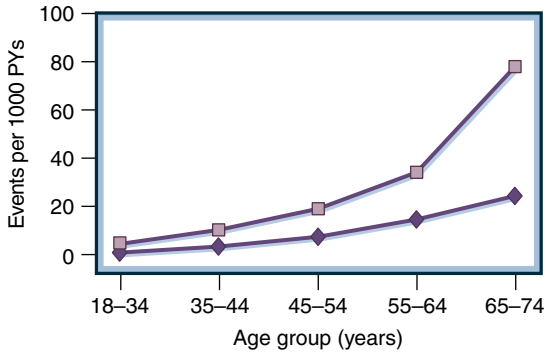


• **Fig. 44.9** Representative ^{18}F-FDG-PET/CT imaging of the aorta. There is increased aortic PET-FDG uptake (*red coloration*) in a participant infected with HIV compared with a non-HIV FRS-matched control participant. Neither participant had known heart disease. For each participant, the FRS was low with a score of 2, and calcium was not present on the cardiac CT scan. Neither participant was receiving a statin. *A* indicates anterior-posterior orientation, and *F* indicates foot-head orientation. *CT,* computed tomography; *^{18}F-FDG-PET,* [^{18}F]fluoro-2-deoxy-D-glucose positron emission tomography; *FRS,* Framingham risk score; *HIV,* human immunodeficiency virus; *SVC,* superior vena cava; *TBR,* target-to-background ratio. (From Subramanian S, Tawakol A, Burdo TH, et al. Arterial inflammation in patients with HIV. *JAMA.* 2012;308:379–386, Fig. 2, used with permission.)

suggesting an important role for nontraditional risk factors, including immune activation, in the accelerated atherogenesis observed in HIV-infected patients. In particular, markers of monocyte activation, including soluble CD163 and CD14,[226,227] and bacterial translocation[228] have been associated with atherosclerotic indices, including intima-media thickness and noncalcified coronary plaque among HIV-infected patients. In contrast, traditional risk factors cluster with coronary calcium among such patients[226] and may underestimate atherosclerotic burden.[229] Genetic polymorphisms and mRNA expression of chemokine receptor type 5 (CCR5) and oxidative stress markers may also be associated with increased atherosclerosis among HIV-infected patients.[230,231] Immune activation may contribute to the increased prevalence of inflamed vulnerable plaque with high-risk morphologic findings, which in turn may contribute to the increased risk of sudden cardiac death among HIV-infected patients.[232]

Several studies suggest increased MI rates in HIV patients. Initial studies suggested dyslipidemia from ART was a major factor contributing to increased CVD risk in HIV-infected patients. In a large prospective study of 23,468 patients, the covariate-adjusted risk was 1.26 per each additional year of antiretroviral exposure. Other risk factors included male sex, DM, older age, previous MI, HTN, and dyslipidemia.[233] Controlling for dyslipidemia significantly reduced the effects of HAART exposure, suggesting that dyslipidemia may contribute to excess CVD in HIV-infected patients.

In contrast, more contemporary studies suggest that other factors beyond traditional risks may contribute to increased CVD rates in HIV. In a large study of patients in a major US health care center, Triant and colleagues[234] demonstrated an RR of 1.75 (95% confidence interval, 1.51–2.02; $p < .0001$) for increased MI in HIV versus non–HIV-infected patients in a model accounting for age, gender, and race (Fig. 44.10). Increased rates of traditional risk factors, including DM (11.5% vs. 6.6%, HIV infected vs. non–HIV infected), HTN (21.2% vs. 15.9%), and dyslipidemia (23.3% vs. 17.6%) were seen, and each contributed to the increase in MI rates (RRs of 1.62, 1.98, and 3.03, respectively, for each risk factor). However, regression modeling, accounting for HTN, DM, and dyslipidemia, demonstrated that these three risk factors contributed to only 25% of the excess risk in HIV- versus non–HIV-infected patients, suggesting that other factors might contribute. Freiberg and associates[235] demonstrated an increased hazard ratio of 1.48 for MI among a large cohort of HIV-infected



• **Fig. 44.10** Myocardial infarction rates by age group. *Top line* (*squares*) indicates patients diagnosed with human immunodeficiency virus disease. *Bottom line* (*diamonds*) indicates patients not diagnosed with human immunodeficiency virus disease. men in the Veterans Administration system, controlling for Framingham risk factors. Smoking rates are increased and contribute to increased CVD risk in HIV patients.

Inflammation may play an important role in increased CVD risk among HIV-infected patients. Increased CRP levels are observed among HIV-infected patients and predict increased MI rates.[236] The SMART (Strategies for Management of Antiretroviral Therapy) Study Group demonstrated an increased rate of cardiovascular events among patients randomized to interrupted therapy with less strict goals for control of immune function.[237] Indeed, a 2014 study suggests that low CD4 and nadir CD4 are important contributing factors to CVD among HIV-infected patients, suggesting an important role for immune dysfunction.[238]

HIV-infected women are also at risk for increased CVD. In large cohort studies, the RR of MI and stroke is more increased in HIV-infected women compared with non–HIV-infected female control subjects (RR 2.98 for acute MI) than among HIV-infected men compared with non–HIV-infected male control subjects (RR 1.40 for acute MI).[234] Increased waist-to-hip ratio, visceral adiposity, CRP, IL6, triglyceride, and LDL, as well as reduced HDL and adiponectin, have been demonstrated in HIV-infected women compared with age- and BMI-matched control subjects. Central adiposity was significantly predictive of abnormal CVD risk indices, including newer inflammatory indices.[239] In addition, studies suggest a marked increase in immune activation indices among HIV-infected female patients, including markers of monocyte activation, in association with noncalcified plaque.[240]

Strategies for Hyperlipidemia Among HIV-Infected Patients

Treatment for hyperlipidemia among HIV-infected patients is indicated to reduce cardiovascular risk and should proceed according to current guidelines. It should be noted that CVD risk prediction equations established in the general population, such as Framingham coronary heart disease or American College of Cardiology/American Heart Association scores, perform poorly in HIV-infected persons and tend to underestimate true risk.[241] (Fig. 44.11). An HIV-specific risk prediction equation established in the Data Collection on Adverse Effects of Anti-HIV Drugs Study, which includes HIV-specific variables, may improve risk prediction compared with the Framingham CHD score[242] although this has not been seen in all populations.[243]

Severe hypertriglyceridemia should be treated to reduce the risk of pancreatitis. An initial option in patients with severe elevations in triglyceride levels is to switch treatment to a PI less likely to cause dyslipidemia. Triglyceride levels are reduced approximately 20% by diet[244] and 30% by exercise[245] in HIV-infected patients. Neither diet nor exercise is likely to normalize triglyceride levels in the HIV population with severe dyslipidemia. Fenofibrate resulted in a 40% reduction in triglyceride levels and a 14% reduction in total cholesterol levels over 3 months in HIV-infected patients with hypertriglyceridemia.[246] Lesser, but nonetheless beneficial, effects may be seen with gemfibrozil or other fibrate derivatives. Niacin also significantly reduces the triglyceride level but may worsen glucose tolerance in HIV-infected patients, although such changes in glucose may only be transient.[247] In addition, niacin may be difficult to use because of its associated flushing and potential liver abnormalities. In a large randomized 24-week controlled trial of diet and exercise with either fenofibrate, niacin, or both, maximal reduction in triglyceride (–52%) was seen with combination drug therapy plus diet and exercise, whereas HDL increased most with niacin and diet and exercise. Flushing was reported by 35% to 40% of niacin-treated subjects.[248] Recent studies also suggest the efficacy of omega-3 polyunsaturated fatty acids, which were shown to reduce triglyceride levels by 25.5% and to be well tolerated in a randomized, placebo-controlled study.[249] In a study investigating combined therapy, triglyceride levels were reduced by 65.5% among hypertriglyceridemic HIV-infected patients receiving simultaneous fenofibrate and fish oil.[250] Comparing fish oil with gemfibrozil, fibrates, and atorvastatin in hypertriglyceridemic HIV-infected patients, fish oil was shown to decrease triglyceride by 45 mg/dL, whereas fibrates (–66 mg/dL), but not atorvastatin (–39 mg/dL), were more effective in this regard.[251]

The 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors are most useful for lowering cholesterol levels in HIV-infected patients but are less effective in lowering triglyceride levels. For example, pravastatin combined with dietary advice

reduced total cholesterol levels by 17% over 24 weeks without effects on triglyceride levels.[252] The combination of gemfibrozil and atorvastatin resulted in a 30% reduction in cholesterol and 60% reduction in triglyceride in HIV-infected patients[244] and may be useful in HIV-infected patients with combined hyperlipidemia. When using the combination of HMG-CoA reductase inhibitors and fibric acid derivatives, the risk of rhabdomyolysis increases. In addition, PIs can themselves affect metabolism of the HMG-CoA reductase inhibitors. In this regard, ritonavir was shown to increase simvastatin levels by 3059% and atorvastatin levels by 79%.[253] Use of simvastatin should be avoided in patients receiving PI therapy. In an analysis of almost 900 HIV-infected patients in the Kaiser Permanente system, use of statins was shown to lower LDL by 25.6% versus 28.3% in HIV-versus non–HIV-infected patients, whereas use of gemfibrozil lowered triglyceride by 44.2% versus 59.3% in HIV- and non–HIV-infected patients. Effects of statins on LDL did not vary by antiretroviral treatment class, whereas effects of gemfibrozil were less in HIV-infected patients receiving PIs and best among those patients receiving therapy with NNRTIs. Safety of the statins, including atorvastatin, pravastatin, and lovastatin, were good, with few cases of myositis. The relative potency of each statin on LDL was generally similar, with reductions ranging from nearly 26.4% with atorvastatin to nearly 23.6% with pravastatin.[254] Rosuvastatin must be used at lower doses due to potential interaction with darunavir but has been shown to lower LDL by 28% at 10 mg/day in placebo-controlled trials.[255] New drugs, such as pitavastatin, may have the fewest interactions with ART, because they are glucuronidated and do not affect CYP3A metabolism. Ezetimibe is well tolerated in combination with statins in patients with HIV and further lowers LDL (additional 14% reduction).[256] Effects of statins on clinical events have not yet been reported in large randomized controlled trials, but cohort studies suggest a potential benefit on overall mortality rate among HIV-infected patients treated with ART with virologic suppression,[257] and preliminary studies suggest effects to improve atherosclerotic indices, such as carotid intima-media thickness and coronary plaque.[258,259] A large, placebo-controlled randomized trial examining the effect of pitavastatin on clinical events, called *REPRIEVE*, is under way in HIV-infected persons who do not have an indication for statin therapy.[260] Inhibition of proprotein convertase subtilisin kexin 9 (PCSK9) offers an additional treatment strategy for HIV-infected persons at high CVD risk.[261] PCSK9 levels were found to be higher in HIV-infected persons compared with matched HIV-uninfected controls and were related to markers of monocyte activation.[262]

Anti-Inflammatory Strategies for CVD in HIV

Initial studies are now investigating effects of anti-inflammatory strategies to improve endothelial function and reduce arterial inflammation. Such strategies include use of pentoxifylline, canakinumab, and methotrexate, but safety and efficacy of these agents in the HIV population remain unclear. Use of statins may also be beneficial as an anti-inflammatory strategy, as they may lower CRP and have pleiotropic effects on monocyte activation.

Neuroendocrine Tumors and Related Disorders

KJELL ÖBERG

CHAPTER OUTLINE

KEY POINTS

- The World Health Organization (WHO) classification system (2017) in neuroendocrine tumors (NET-G1, NET-G2, NET-G3) and neuroendocrine carcinoma (NEC-G3) is informative for the clinical management of neuroendocrine intestinal tumors (carcinoids).
- The most important circulating biomarkers are chromogranin A (general), urinary 5-hydroxyindoleacetic acid (5HIAA), and neuron-specific enolase (NSE) for lung tumors.
- The carcinoid syndrome includes flushing, diarrhea, right-sided heart fibrosis, and bronchial wheezing.
- Molecular imaging ^{111}In-DTPA-Phe octreotide (Octreoscan) and more recently ^{68}Ga-DOTA-octreotate positron emission tomography (PET) scanning are important procedures for staging of the disease as well determining possible therapy with peptide receptor radiotherapy (PRRT).
- First-line therapy for low proliferating small intestinal neuroendocrine tumors (e.g., NET-G1) are somatostatin analogues.
- Chemotherapy is reserved for NET-G2 mostly in the lung (atypical carcinoids).
- Peptide receptor radiotherapy could be considered for both NET-G1 and NET-G2.

The first clinical and histopathologic description of carcinoid tumor was made by Otto Lubarsch in 1888.[1] He was impressed by the multicentric origin of carcinoid tumors of the gastrointestinal (GI) tract, their lack of gland formation, and their lack of similarity with the usual adenocarcinoma of the alimentary system.

The term *Karzinoide* was introduced in 1907 by pathologist Siegfried Oberndorfer[2] as a descriptive name for what he considered to be a benign type of neoplasm of the ileum, which could nevertheless behave like a carcinoma. This myth of benignity has survived to the present, even though in 1949 Pearson and Fitzgerald[3] described a large series of metastasizing carcinoid tumors. The term *carcinoid* is nowadays less used and the preferred recommended term is *neuroendocrine tumor*. The typical midgut carcinoid is called *small intestinal neuroendocrine tumor* (SI-NET). Lung-neuroendocrine tumors are still usually called carcinoids. In this chapter, the term *carcinoid* will be used also for the gastrointestinal NETs.

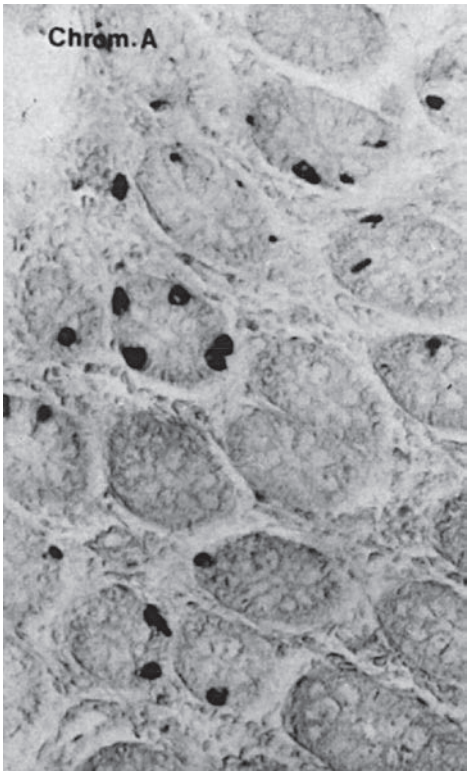
Neuroendocrine tumors have subsequently been reported in a wide range of organs, but they most commonly involve the lungs and GI tract. Carcinoid tumors of the thymus, ovaries, testes, heart, and middle ear have also been described. The clinically well-known *carcinoid syndrome* was described by Thorson and associates[4] in 1954; 1 year earlier, Lembeck[5] had extracted serotonin from a carcinoid tumor.

Phylogenesis and Embryology

Carcinoid tumors are derived from neuroendocrine cells, and Gosset and Masson[6] in 1914 were the first to point out the neuroendocrine properties of carcinoid tumors. Masson[7] later described the remarkable affinity for silver salts displayed by intracytoplasmic granules in tumor cells and noted that carcinoid tumors originate from enterochromaffin cells, the Kulchitsky cells in the crypts of Lieberkühn in the intestinal epithelium. Furthermore, he suggested that the tumors were of endocrine origin (Fig. 45.1).

The mammalian GI tract and pancreas contain 14 endocrine cell types, which initially were believed to originate from the neuroectoderm. This observation gave rise to the APUD (*a*mine *p*recursor *u*ptake and *d*ecarboxylation) concept because of the ability of these cells to take up and decarboxylate amino acid precursors of biogenic amines such as serotonin and catecholamines.[8] The APUD concept was later revised by others, who postulated that these endocrine cells might also be derived from mesoderm and endoderm.[9] The neuronal phenotype is clearly seen when culturing carcinoid tumor cells in vitro. The enterochromaffin cells, from which many carcinoid tumors derive, have the property of producing and secreting amines (such as serotonin) and polypeptides (such as neurokinin A and substance P) (Fig. 45.2).

Carcinoid tumors might also originate from other neuroendocrine cells, such as the enterochromaffin-like (ECL) cells of the gut and endocrine cells in the bronchi. The tumors derived from these cells can produce a wide range of hormones, such as gastrin, gastrin-releasing peptide (GRP), ghrelin, calcitonin, pancreatic polypeptide, adrenocorticotropic hormone (ACTH), corticotropin-releasing hormone (CRH), and growth hormone–releasing hormone (GHRH), as well as somatostatin, glucagon, and calcitonin gene–related peptide (CGRP).[10] A common secretory product from all types of carcinoid tumors is the glycoprotein chromogranin A (CgA)—the most important general tumor marker in these patients (see later discussion).



• **Fig. 45.1** Normal human intestine stained with chromogranin A (Chrom. A) to delineate neuroendocrine cells. The cells are scattered in the intestinal mucosa.

Molecular Genetics

Despite advances in the diagnosis, localization, and treatment of carcinoid tumors, no etiologic factor associated with the development of these tumors has been identified. Little is known about molecular genetic changes underlying tumorigenesis. Sporadic foregut carcinoids as well as the familial-type multiple endocrine neoplasia type 1 (MEN1) often display allelic losses at chromosome 11q13, and somatic *MEN1* gene mutations have been reported in one-third of sporadic foregut tumors.[11] In contrast with foregut carcinoids, molecular and cytogenetic data for midgut carcinoids are quite limited, and these tumors are not included in MEN1 syndrome. Deletions of chromosomes 18q and 18p have been reported in 38% and 33%, respectively, of GI carcinoids.[12]

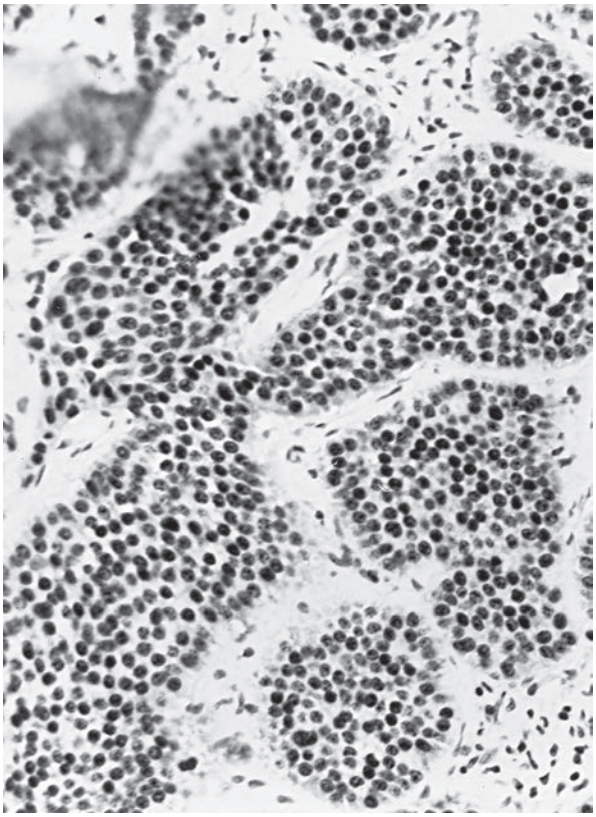
In one publication, deletions on chromosome 18 were found in 88% of midgut carcinoid tumors, but the *SMAD4/DPC4* locus was not deleted.[13] In addition to the consistent finding of deletions on chromosome 18, multiple deletions on other chromosomes (4, 5, 7, 9, 14, 20) were noticed in single tumors. The region telomeric to *SMAD4/DPC4/DCC* loci must be further explored for possible losses of a tumor suppressor gene in this area. Gene expression arrays in carcinoid tumors have demonstrated upregulation of the *RET* proto-oncogene, but no mutations have been detected so far. Reports indicate that the Notch signaling pathway is a significant regulator of neuroendocrine differentiation and serotonin production in GI carcinoid tumors.[14,15] The Wnt signaling pathway as well as transforming growth factor-β (TGFβ) signaling are upregulated in carcinoid tumors.[16] CDKN1B, a tumor suppressor in small intestinal nets, encodes a cyclin-dependent kinase inhibitor p27Kip1.[17] Mutations in the *MUTYH* gene involved in DNA repair have recently been reported.[18]

Classification

In 1963, Williams and Sandler reported a relationship between the embryonic origin of carcinoid tumors and the histologic, biochemical, and (to some extent) clinical features of the tumors.[19] Three distinct groups were formed (Table 45.1): foregut carcinoids (i.e., intrathoracic, gastric, and duodenal carcinoids), midgut carcinoids (carcinoids of the small intestine, appendix, and proximal colon), and hindgut carcinoids (carcinoid tumors of the distal colon and rectum).

Although this original classification has been useful in the clinical assessment of patients with carcinoid tumors, it has demonstrated significant shortcomings. As a result, a new classification system (World Health Organization [WHO] classification of 2010) has emerged that takes into account not only the site of origin but also variations in the histopathologic characteristics of carcinoid tumors.[20] In this revised system, typical tumors are classified as NET-G1 tumors, which show a characteristic growth pattern. Most recently, the WHO classification system has been updated (2017). This includes a new group NET-G3, which are well-differentiated tumors with higher proliferation (Ki67 >20%) but not as aggressive as NEC-G3.[21] Typical carcinoid tumors are usually slow growing, with low proliferation capacity (proliferation index <2%). They are usually confined to the mucosa and submucosa and are less than 1 to 2 cm in diameter (classical

midgut carcinoid). NET-G2 tumors show widely invasive growth and a high proliferation index (PI 2–20%). Poorly differentiated carcinomas (NEC-G3) are large tumors with metastases and a proliferation index greater than 20% (Fig. 45.3). The European Neuroendocrine Tumor Society (ENETS) has proposed a new tumor-node-metastasis (TNM) classification and grading system, which is widely used in the clinic.[22]



• **Fig. 45.2** Histopathology of a classic well-differentiated midgut carcinoid tumor.

The neuroendocrine lung tumors are divided into typical carcinoids, atypical carcinoids, large cell neuroendocrine carcinomas, and small cell lung carcinomas. The difference between the typical and atypical carcinoid is based on histopathologic features, with higher proliferation and necrosis found in the atypical carcinoid[23] (Fig. 45.4). The incidence of carcinoid tumors is similar in Western countries and is estimated to be 2.8 to 4.5 per 100,000 people (Surveillance, Epidemiology, and End Results [SEER] database).[24] Because many carcinoid tumors are indolent, the true incidence may be higher. In particular, appendiceal carcinoids have not been included in many studies, but a higher incidence of 8.2 per 100,000 was found in an autopsy study when appendiceal carcinoids were included.[25] The incidence of patients with a carcinoid syndrome is about 0.5 per 100,000.[26] Data from the United States, based on results from the End Results Group and the Third National Cancer Survey, 1950 to 1969 and 1969 to 1971, respectively, found that the stomach was the most common site of carcinoid tumors, followed by the rectum, ileum, lungs, and bronchi.[27]

An analysis done in the SEER program of the National Cancer Institute between 1973 and 2000 reported an increase in the percentage of pulmonary and gastric carcinoids and a decrease in the percentage of appendiceal carcinoids.[24] Age-specific incidence rates showed a peak between 65 and 75 years (7.5–9.5/100,000), with a male predominance. In persons younger than 50 years, a female predominance has been observed both for appendiceal and lung carcinoids.[28] Analyses of the SEER database (SEER 18) show an incidence of 6.98/100,000 in 2012 and a prevalence of 48/100,000 indicating a significant increase since 1993[24,27,29] (Fig. 45.5).

Biochemistry

The production of hormones is a highly organized function of carcinoid cells. In 1953, Lembeck isolated serotonin from a carcinoid tumor; since then, the carcinoid syndrome has been related to serotonin overproduction.[5] The biosynthesis of serotonin and its metabolic degradation are outlined in Fig. 45.6.

TABLE 45.1 Classification of Carcinoid Tumors

Foregut	Midgut	Hindgut
Histopathology		
Argyrophilic	Argentaffin positive	Argyrophilic
CgA positive	CgA positive	SVP2 positive
NSE positive	NSE positive	CgA positive, NSE positive
Molecular Genetics		
Chromosome 11q13 deletion	Chromosome 18q, 18p deletion	Unknown
Secretory Products		
CgA, 5HT, 5HTP, histamine, ACTH, GHRH, CGRP, somatostatin, AVP, glucagon, gastrin, NKA, substance P, neurotensin, GRP	CgA, 5HT, NKA, substance P, prostaglandin E_1 and F_2, bradykinin	PP, YY, somatostatin
Carcinoid Syndrome		
Present (30%)	Present (70%)	Absent

ACTH, Adrenocorticotropic hormone; *AVP,* arginine vasopressin; *CgA,* chromogranin A; *CGRP,* calcitonin gene–releasing peptide; *GHRH,* growth hormone–releasing hormone; *GRP,* gastrin-releasing peptide; *5HT,* 5-hydroxytryptamine; *5HTP,* 5-hydroxytryptophan; *NKA,* neurokinin; *NSE,* neuron-specific enolase; *PP,* pancreatic peptide; *YY,* peptide YY; *SVP2,* synaptic vesicle protein 2.

Trends in the incidence, prevalence, and survival outcomes in patients with neuroendocrine tumors in the United States. *JAMA Oncol*. 2017;3:1335–1342.)

Neuroendocrine tumors of the midgut and foregut regions with metastatic disease secrete serotonin and show elevated urinary excretion of 5-hydroxyindoleacetic acid (5HIAA) in 76% and 30%, respectively.[30] Carcinoid tumors arising from the foregut, however, commonly have low levels of L-amino acid decarboxylase, which converts 5-hydroxytryptophan (5HTP) to serotonin. Thus these tumors secrete primarily 5HTP.[31,32]

For many years, it was believed that the entire carcinoid syndrome could be explained by the secretion of these biologically active amines. However, further studies have indicated that serotonin is mainly involved in the pathogenesis of diarrhea and that other biologically active substances play a more important part in the carcinoid flush and bronchoconstriction.

Oates and associates[33] proposed that kallikrein, an enzyme found in carcinoid tumors, is released in association with flush and stimulates plasma kininogen to liberate lysyl-bradykinin and bradykinin. These biologically active substances cause vasodilation, hypotension, tachycardia, and edema.[33–35] Furthermore, prostaglandins (E_1, E_2, F_1, F_2) might also play a role in the carcinoid syndrome.[36] Gastric carcinoids and lung carcinoids have been found to contain and secrete histamine, which might be responsible for the characteristic bright red flush seen in these patients.[37–39] Metabolites of histamine are often present in high concentration in the urine from these patients. Dopamine and norepinephrine have also been found in carcinoid tumors.[40]

The occurrence of substance P in carcinoid tumors was first demonstrated by Håkansson and coworkers in 1977.[41] Substance P belongs to a family of polypeptides that share the same carboxy-terminus and are called *tachykinins* (Fig. 45.7). A number of tachykinin-related peptides have been isolated from carcinoid tumors, such as neurokinin A, neuropeptide K, and eledoisin. During stimulation of flush in patients with midgut carcinoids, multiple forms of tachykinins are released to the circulation (Fig. 45.8).[42–44]

Many different polypeptides (e.g., insulin, gastrin, somatostatin, S100 protein, polypeptide YY, pancreatic polypeptide, human chorionic gonadotropin α-subunit [hCGα], motilin, calcitonin, vasoactive intestinal polypeptide [VIP], and endorphins) have been demonstrated in carcinoid tumors by immunohistochemical staining and sometimes in tumor extracts.[10] Ectopic ACTH or CRH production may be found in foregut carcinoids; in particular, patients with bronchial or thymic carcinoids seem susceptible to Cushing syndrome.[45] Patients with carcinoid tumors of the foregut type might also present with acromegaly due to ectopic secretion of GHRH from the tumor.[46] Duodenal carcinoids as part of von Recklinghausen disease can secrete somatostatin.[47]

The chromogranin/secretogranin family consists of CgA, CgB (sometimes called *secretogranin I*), secretogranin II (sometimes called *CgC*), and some other members. CgA was first isolated in 1965 as a water-soluble protein present in chromaffin cells from bovine adrenal medulla.[48] Its immunoreactivity has been found in all parts of the GI tract and pancreas and has also been isolated from all endocrine glands.[49]

CgA is an acidic glycoprotein of 439 amino acids with a molecular weight of 48 kDa. It can be spliced into smaller fragments at dibasic cleavage sites, generating multiple bioactive fragments such as vasostatins, chromostatins, and pancreastatins[49–53] (Fig. 45.9).

Amines and hormones are stored intracellularly in two types of vesicles: large dense-core vesicles and small synaptic-like vesicles.

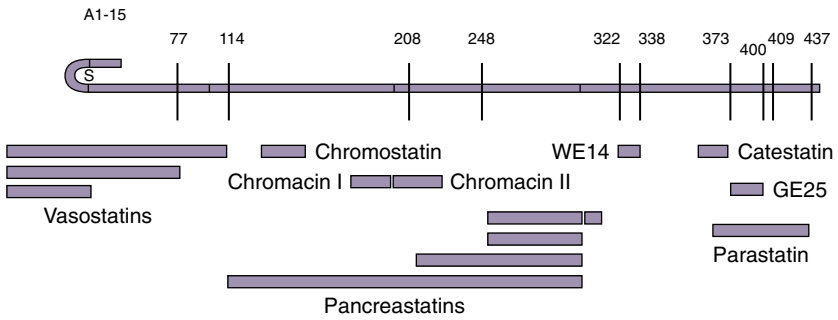
These vesicles release amines and hormones on stimulation. Large dense-core vesicles contain the hormones and one or more members of the chromogranin/secretogranin family of proteins.[50,54] Both amines and peptides are co-released (Fig. 45.10).

The physiologic function of CgA is not fully elucidated. Its ubiquitous presence in neuroendocrine tissues and its co-secretion with peptide hormones and amines indicate a storage role of the peptide within the secretory granule.[49,50,54] It also acts as a prohormone that can generate bioactive smaller fragments. CgA is an important tissue and serum marker for different types of neuroendocrine tumors, including those of the foregut, midgut, and hindgut (see Table 45.1 and later discussion).

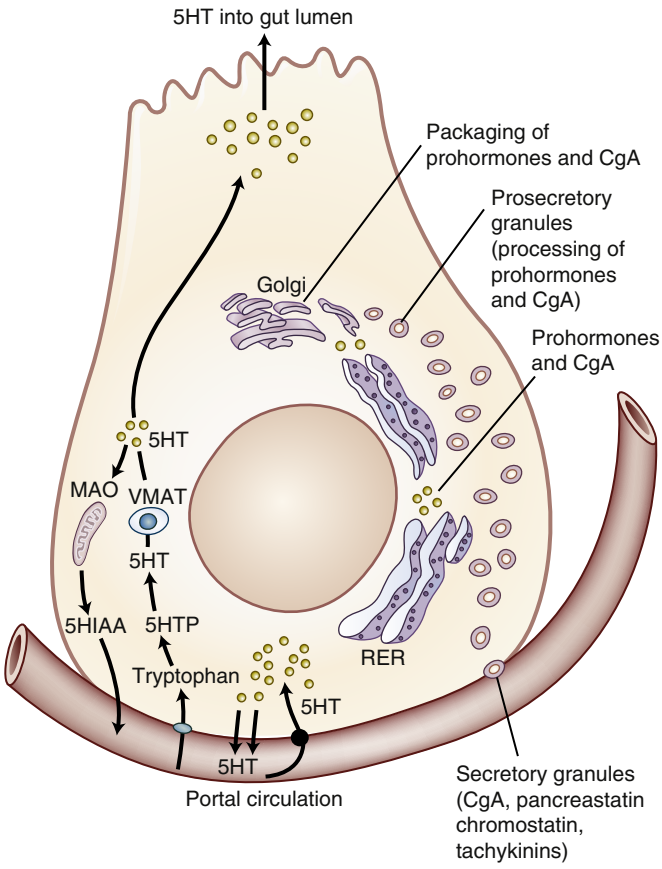
Clinical Presentation

The clinical presentation of neuroendocrine tumors depends on localization, hormone production, and extent of the disease. Usually a lung carcinoid is diagnosed incidentally on routine pulmonary radiography, whereas a midgut carcinoid may be identified as a bowel obstruction or as a cause of abdominal discomfort or pain. Rectal carcinoids might cause bleeding or obstruction. However, lung carcinoids can also manifest clinically with Cushing syndrome, due to secretion of CRH or ACTH, or with the carcinoid syndrome, due to production of serotonin, 5HTP, or histamine.[55] A midgut carcinoid often manifests with the carcinoid syndrome due to production of serotonin and tachykinins.

The clinical manifestations at referral depend on the type of referral center. At our institution, which cares for patients with malignant tumors, 74% of the patients present with the carcinoid syndrome, 13% with abdominal pain, 12% with carcinoid heart disease, and 2% with bronchial constriction.[27] When unbiased material is analyzed, bowel obstruction is the most common problem leading to the diagnosis of ileal carcinoid tumor. The second most common symptom is abdominal pain. Flushing and diarrhea, which are components of the carcinoid



• **Fig. 45.9** The glycoprotein chromogranin A and related peptides, including GE25 and WE14.



• **Fig. 45.10** Schematic of an enterochromaffin cell. The initial step in 5-hydroxytryptamine (5HT) synthesis is carrier transport of the amino acid tryptophan from blood into the cell across the cell membrane. Intracellular tryptophan is first converted to 5-hydroxytryptophan (5HTP), which in turn is converted to 5HT and stored in secretory granules. The transport of 5HT into granules requires vesicular monoamine transporters (VMATs). Via the basal lateral membrane, 5HT can be released into the circulation. There is also a membrane pump mechanism in the cell membrane responsible for amine reuptake. A minor part of 5HT can also be released into the gut lumen. Monoamine oxidase (MAO) degrades 5HT to 5-hydroxyindoleacetic acid (5HIAA). Peptide prohormones are synthesized in the rough endoplasmic reticulum (RER) together with chromogranin A (CgA) and other granule proteins. The products are transported to the Golgi apparatus for packaging into prosecretory granules. On stimulation, the secretory products are released from the granules by exocytosis.

syndrome, constitute only the third most common presentation.[56–58] Because many patients have vague symptoms, however, diagnosis of the tumor may be delayed by approximately 2 to 3 years.[26]

The Carcinoid Syndrome

In 1954, Thorson and coworkers for the first time described the carcinoid syndrome as having the following features: malignant carcinoid of the small intestine with metastases to the liver, valvular disease of the right side of the heart (pulmonary stenosis and tricuspid insufficiency without septal defect), peripheral vasomotor symptoms, bronchial constriction, and an unusual type of cyanosis.[4] One year later, Dr. William Bean[59] gave this colorful description of the carcinoid syndrome: "This witch's brew of unlikely signs and symptoms, intriguing to the most fastidious connoisseur of clinical esoterica—the skin underwent rapid and extreme changes—resembling in clinical miniature the fecal phantasmagoria of the aurora borealis."

The syndrome is thus well characterized and includes flushing, diarrhea, right-sided heart failure, and sometimes bronchial constriction and increased urinary levels of 5HIAA.[60,61] This is the classic carcinoid syndrome, but some patients display only one or two of the features. Other symptoms related to the syndrome are weight loss, sweating, and pellagra-like skin lesions.

Development of the carcinoid syndrome is a function of tumor mass, extent and localization of metastases, and localization of the primary tumor. The syndrome is most common in tumors originating in the small intestine and proximal colon; 40% to 60% of patients with these tumors experience the syndrome.[27,57,60,61] The disorders are less common in patients with bronchial carcinoids and do not occur in patients with rectal carcinoids.[55,62,63] The syndrome rarely occurs in patients with midgut carcinoids and a small tumor burden, such as only regional lymph node metastases.[58] Patients with the full syndrome usually have multiple liver metastases. The association with hepatic metastases is due to efficient inactivation by the liver of amines and peptides released into the portal circulation. The venous drainage of liver metastases is directly into the systemic circulation and bypasses hepatic inactivation.[64]

Other carcinoid tumors likely to be associated with the carcinoid syndrome in the absence of liver metastases are ovarian carcinoids and bronchial carcinoids, which release mediators directly into the systemic rather than the portal circulation. Retroperitoneal metastases from classic midgut carcinoids also release mediators directly into the circulation and might cause the carcinoid syndrome without any liver metastases.[60,61]

Flushing

Four types of flushing have been described in the literature: erythematous, violaceous, prolonged, and bright red.[60,61]

The first and best known type is the sudden, diffuse, erythematous flush, usually affecting the face, neck, and upper chest (i.e., the normal flushing area) (Fig. 45.11). This type of flush is

• **Fig. 45.11** Carcinoid syndrome before and after provocation. (A) Before flush provocation. (B) The same patient after pentagastrin-stimulated flush.

commonly of short duration, lasting from 1 to 5 minutes, and is related to early-stage midgut carcinoids. Patients usually experience a sensation of warmth during flushing and sometimes heart palpitations. This type of flushing is reported in 20% to 70% of patients with midgut carcinoid at onset of the disease.[26,60,62]

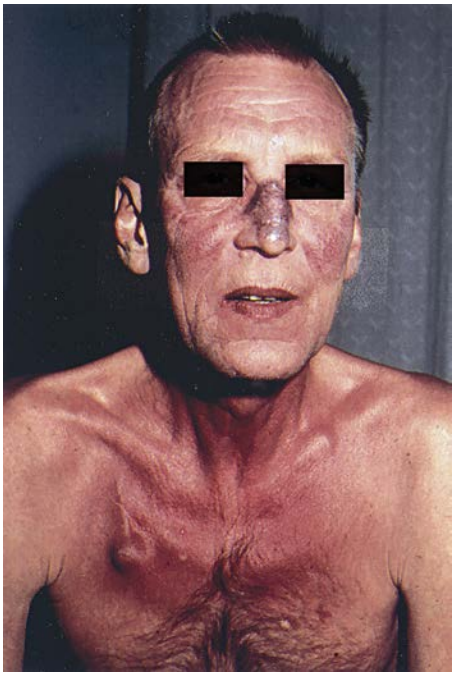
The second type is the violaceous flush, which affects the same area of the body. It has roughly the same time course or sometimes lasts a little longer. Patients may also have facial telangiectasia. This flush occurs during the later stages of midgut carcinoid (Fig. 45.12) and is normally not felt by patients because they have become accustomed to the flushing reaction.

The third type is prolonged flushing that usually lasts a couple of hours but can last up to several days. This flush sometimes involves the whole body and is associated with profuse lacrimation, swelling of the salivary gland, hypotension, and facial edema (Fig. 45.13). These symptoms are usually associated with malignant bronchial carcinoids.

The fourth type of flushing is a bright red, patchy flush seen in patients with chronic atrophic gastritis and ECL cell hyperplasia, or ECLoma (derived from ECL cells). This type of flushing is related to an increased release of histamine and histamine metabolites.

Flushes may be spontaneous or may be precipitated by stress (physical and mental); infection; alcohol; certain foods (spicy); or drugs, such as by injections of catecholamines, calcium, or pentagastrin (see later discussion). The pathophysiology of flushing in the carcinoid syndrome is not yet elucidated.[65–67] It was previously believed to be totally related to excess production of serotonin or serotonin metabolites.[66] However, several patients with high levels of plasma serotonin did not have any flushing, nor did a serotonin antagonist (e.g., methysergide, cyproheptadine, or ketanserin) have any effect on the flushing.[65,68]

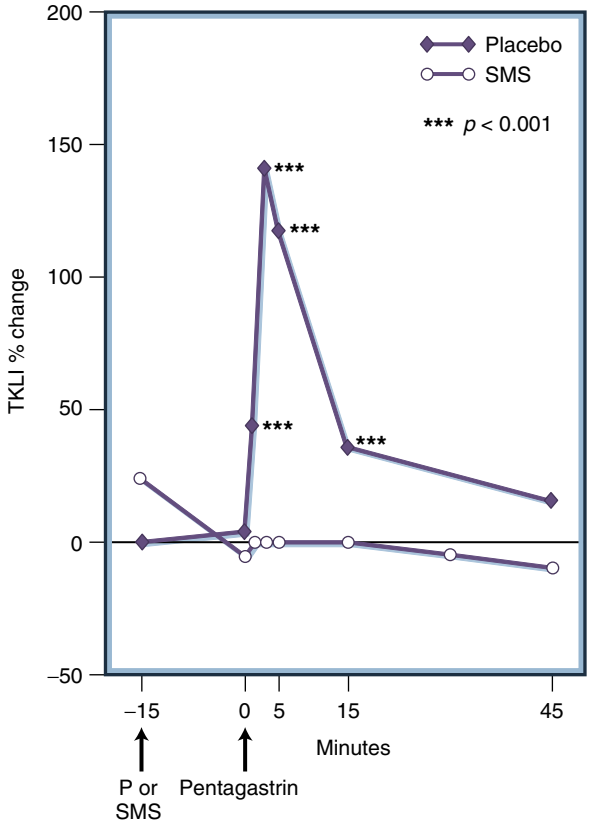
In a study from our own group in which we measured the release of tachykinins, neuropeptide K, and substance P during flushing provoked by pentagastrin or alcohol, a clear correlation was found between the onset and intensity of the flushing reaction and the release of tachykinins (see Fig. 45.6). Furthermore, when the release of tachykinins was blocked by prestimulatory administration of octreotide, little or no flushing was observed in the same patient (Fig. 45.14).[42–44] Other mediators of the flushing reaction may be kallikrein and bradykinins, which are released during provoked flushing.[33–35]



• **Fig. 45.12** Long-lasting chronic flushing in a patient with long-standing carcinoid disease. Note the telangiectases.

Histamine may be a mediator of the flushes seen in lung carcinoids and in gastric carcinoids (ECLomas).[37–39] Tachykinins, bradykinins, and histamines are well-known vasodilators, and somatostatin analogues might alleviate flushing by reducing circulating levels of these agents (see later discussion).[42–44,67–72] Furschgott and Zawadski have suggested that flushing is caused by an indirect vasodilation mediated by endothelium-derived relaxing factor (EDRF) or by nitric oxide released by 5HTP during platelet activation.[73]

• **Fig. 45.13** This patient has lung carcinoid and carcinoid syndrome with severe, long-standing flushing, lacrimation, and a swollen face.



• **Fig. 45.14** Tachykinin levels (TKLI) after stimulation with pentagastrin in patients with classic midgut carcinoids. Pretreatment for 15 minutes with somatostatin (SMS) causes inhibition of tachykinin release and inhibition of the flush reaction (*open circles*). *P,* placebo.

The facial flushing associated with carcinoid tumors should be distinguished from idiopathic flushing and menopausal hot flushes. Patients with idiopathic flushes usually have a long history of flushing starting early in life and sometimes with a family history without occurrence of a tumor. Menopausal hot flushes usually involve the whole body and are accompanied by intense sweating. Postmenopausal women in whom a true carcinoid syndrome is developing can differentiate between the two types of flushes.

Diarrhea

Diarrhea occurs in 30% to 80% of patients with the carcinoid syndrome.[26,27,60,61] Its pathophysiology is poorly understood but is probably multifactorial. The diarrhea is often accompanied by abdominal cramping, and endocrine, paracrine, and mechanical factors contribute to this condition. A variety of tumor products, including serotonin, tachykinins, histamines, kallikrein, and prostaglandins, can stimulate peristalsis, electromechanical activity, and tone in the intestine.[67,74–76] Secretory diarrhea can occur with fluid and electrolyte imbalance. Malabsorption can result from intestinal resections, from lymphangiectasia, secondary to mesenteric fibrosis, from bacterial overgrowth, and secondary to a tumor partially obstructing the small bowel or rapid intestinal transit. Increased secretion by the small bowel, malabsorption, or accelerated transit can overwhelm the normal storage and absorptive capacity of proximal colon and result in diarrhea, which may be aggravated if the reabsorptive function of the colon is impaired.

In a study of patients with elevated serotonin levels and the carcinoid syndrome, transit time in the small bowel and colon was significantly decreased in comparison with that of normal subjects.[77] The volume of the ascending colon was significantly smaller than that in normal subjects, and the postprandial colonic tone was markedly increased. This indicates that in patients in whom the carcinoid syndrome is associated with diarrhea, major alterations in gut motor function occur that affect both the small intestine and the colon. Many patients with carcinoid tumors have undergone wide resection of the small intestine, and they may be affected by the symptoms of short-bowel syndrome.

Serotonin is believed to be responsible for the diarrhea in the carcinoid syndrome by its effects on gut motility and intestinal electrolyte and fluid secretion.[61,74–76] Serotonin receptor antagonists, such as ondansetron and ketanserin, relieve the diarrhea to a certain degree.[74,78–80] Recently an inhibitor of the enzyme tryptophan-hydroxylase, telotristat ethyl, was shown to reduce serotonin levels and concomitantly the number of bowel movements.[81]

Carcinoid Heart Disease

A unique endocrine effect of carcinoid tumors is the development of plaque-like thickenings of the endocardium, valve leaflets, atria, and ventricles in 10% to 20% of the patients.[82,83] This fibrotic involvement causes stenosis and regurgitation of the blood flow. Findings of new collagen beneath the endothelium of the endocardium is almost pathognomonic for carcinoid heart disease.[82–84] The incidence of these lesions depends on the diagnostic methodology. Echocardiography can demonstrate early lesions in about 70% of patients with the carcinoid syndrome, whereas routine clinical examinations detect them in only 30% to 40%.[82,83,85] These figures have significantly dropped to 5% to 10%, probably because of earlier diagnosis and the use of biologic antitumor treatments such as somatostatin analogues and α-interferons. Both of these agents control the hormonal release and excess that are thought to be involved in the fibrotic process.

In a study performed in 1987,[26] 40% of patients with carcinoid tumors died of cardiac complications related to the carcinoid disease. Data from 2008 reveal that this complication is a rare event and that patients usually die of the effects of a progressive tumor.[27]

The precise mechanism behind the fibrosis in the right side of the heart has not been determined yet, but it occurs mainly

in patients with liver metastases who usually also have the carcinoid syndrome.[82,83] Substances inducing fibrosis are believed to be released directly into the right side of the heart and are then neutralized or degraded as they pass through the pulmonary circulation, because few patients present with similar lesions of the left side of the heart.[82,83] However, patients with lung carcinoids occasionally display the same fibrotic changes in the left side of the heart. Histologically, the plaque-like thickenings in the endocardium consist of myofibroblasts and fibroblasts embedded in a stroma that is rich in mucopolysaccharides and collagen.[82]

We have previously shown that the TGFβ family of growth factors is upregulated in carcinoid fibrous plaques on the right side of the heart.[86] The TGFβ family of growth factors is known to stimulate matrix formation and collagen deposition. The substances that induce TGFβ locally in the heart are not known, but serotonin, tachykinins, and insulin-like growth factor-1 (IGF1) may be mediators.[82,87]

A correlation has been found between circulating levels of serotonin and tachykinins and the degree and frequency of carcinoid heart lesions. The weight-reducing drugs fenfluramine and dexfenfluramine appear to interfere with normal serotonin metabolism and have been associated with valvular lesions identical to those seen in carcinoid heart disease.[88,89] However, treatment resulting in decreased urinary 5HIAA excretion does not result in regression of cardiac lesions.[90] Two animal studies indicate that serotonin might play a significant role in the development of carcinoid heart disease. Serotonin is also known to induce $TGF\beta_1$ in in vitro experiments.[91–93] Connective tissue growth factor (CTGF) is produced by carcinoid tumor cells, and increased expression is found in patients with advanced fibrosis. CTGF is known to stimulate TGFβ.[94] For early detection of carcinoid heart disease, measurement of NT-proBNP is the best diagnostic and prognostic marker.[95]

Bronchial Constriction

A true asthma episode is rare in patients with the carcinoid syndrome.[26,60,61] The causative agents of bronchial constriction are not known, but tachykinins and bradykinins have been suggested as mediators.[96,97] These agents can constrict smooth muscle in the respiratory tract and can also cause local edema in the airways.

Other Manifestations of the Carcinoid Syndrome

Fibrotic complications other than heart lesions may be found in patients with carcinoid tumors. They include intra-abdominal and retroperitoneal fibroses, occlusion of the mesenteric arteries and veins, Peyronie disease, and carcinoid arthropathy.[60,61]

Intra-abdominal fibrosis can lead to intestinal adhesions and bowel obstruction and is a more common cause of bowel obstruction than is the primary carcinoid tumor itself.[58,98,99] Retroperitoneal fibrosis can result in obstruction of the ureter that impairs kidney function, which sometimes requires treatment with ureteral stents.

Narrowing and occlusion of arteries and veins by fibrosis are potentially life threatening. Ischemic loops of the bowel might have to be removed, and this procedure ultimately causes short-bowel syndrome.[58,99]

Other rare features of the syndrome are pellagra-like skin lesions with hyperkeratosis and pigmentation, myopathy, and sexual dysfunction.[61]

Carcinoid Crisis

Carcinoid crisis has become rare since the introduction of treatment with somatostatin analogues.[100] It might occur spontaneously or during induction of anesthesia, embolization procedures, chemotherapy, or infection. Carcinoid crisis is a clinical condition characterized by severe flushing, diarrhea, hypotension, hyperthermia, and tachycardia. Without treatment, patients might die during the crisis.[100–102]

Intravenous (IV) or subcutaneous somatostatin analogues (or both) are given before, during, and after surgery to prevent the development of carcinoid crisis.[100,102–104] Patients with metastatic lung carcinoids are particularly difficult to treat during crisis. IV infusions of octreotide at doses of 50 to 100 μg/hour, supplemented with histamine H_1-receptor and H_2-receptor blockers and IV sodium chloride, are recommended.[105]

Other Clinical Manifestations of Carcinoid Tumors

Ectopic secretion of CRH and ACTH from pulmonary carcinoid tumors and thymic carcinoids accounts for 1% of all cases of Cushing syndrome.[45,106] Acromegaly due to ectopic secretion of GHRH has also been reported in foregut carcinoids.[46,107] Gastric carcinoid tumors make up less than 1% of gastric neoplasms. They can be separated into three distinct groups or types on the basis of clinical and histologic characteristics and originate from gastric ECL cells.[108] Type 1 is associated with chronic atrophic gastritis type A (80%). Type 2 is associated with Zollinger-Ellison syndrome as part of MEN1 syndrome (6%). Type 3 represents sporadic gastric carcinoids occurring without hypergastrinemia and pursue a more malignant course, with 50% to 60% developing metastases.[108,109]

About 80% of gastric carcinoids are associated with chronic atrophic gastritis type A, and more than 50% of patients with these carcinoids also have pernicious anemia. These tumors are more common in women than in men and are usually identified endoscopically during diagnostic evaluation for anemia or abdominal pain.[108,110] They are often multifocal and localized in the gastric fundus area, and they are derived from ECL cells. Patients have hypochlorhydria and hypergastrinemia. Gastrin hypersecretion has been postulated to result in hyperplasia of the ECL cells, which might later develop into carcinoid tumors.[111,112] Hyperplasia of ECL cells has been noticed in patients on long-standing proton-pump inhibitor therapy.[113,114]

Diagnosis

The diagnosis of a suspected carcinoid tumor must take into consideration molecular genetics, tumor biology, histopathology, biochemistry, and localization. The diagnosis of a carcinoid tumor may be suspected from clinical symptoms suggesting the carcinoid syndrome or from the presence of other clinical symptoms, or it can be made in relatively asymptomatic patients from the histopathologic findings at surgery or after liver biopsy for unknown hepatic lesions.

In one study involving 154 consecutive patients with GI carcinoids found at surgery, 60% were asymptomatic.[115] In patients with symptomatic tumors, the time from onset of symptoms until diagnosis is often delayed 1 to 2 years.[26] The current tumor biology program includes growth factors (platelet-derived growth factor, epidermal growth factor, IGF1, TGF)[116] and proliferation factors (measurements of the nuclear antigen Ki67) as a proliferation index. Such an index correlates with tumor aggressiveness and survival.[117,118] Adhesion molecules such as CD44, particularly exon-V6 and exon-V9, have been related to improved survival.[119] Determination of the expression of angiogenic factors basic fibroblast growth factor (bFGF) and vascular endothelial growth factor

(VEGF) should also be included in a tumor biology program. Somatostatin analogues are cornerstones in the treatment of the carcinoid syndrome; therefore determination of the different subtypes of somatostatin receptors (SSTR1–SSTR5) with specific antibodies is warranted.[120,121] Rare cases with familial carcinoids should be analyzed with respect to loss of heterozygosity on chromosome 11q13 and chromosome 18. Integrated genome-wide analysis, including exome and whole-genome sequencing, gene expression, DNA methylation, and copy number analysis, has identified three novel molecular subtypes of small intestinal NETs (carcinoids) with different clinical outcome. Epigenetic dysregulation is common in small intestinal NET.[17] Recently we identified mutations in the *MUTYH* gene involved in protein of DNA from oxidative stress.[18]

Histopathologic Diagnosis

The histopathologic diagnosis of carcinoids is based on immunohistochemistry using antibodies against CgA, synaptophysin, and neuron-specific enolase. These immunohistochemical stains have replaced the old silver stains, the argyrophil stains by Grimelius and Sevier-Munger. The argentaffin stain by Masson to demonstrate content of serotonin has also been replaced by immunocytochemistry with serotonin antibodies.[10] These neuroendocrine markers can be supplemented by specific immunocytochemistry to different hormones such as substance P, gastrin, and ACTH. The WHO classification forms the basis for therapeutic decisions (see earlier discussion) and therefore determination of Ki67 (MIB1) for analysis of cell proliferation is mandatory. Antibodies to TTF1 and CDX2 give good information on the localization of the primary tumor in patients with unknown primary tumors.[122]

Biochemical Diagnosis

In patients with flushing and other manifestations of the carcinoid syndrome, the diagnosis can be established by measuring the urinary excretion of 5HIAA because levels are invariably elevated under these circumstances.[123] Patients with carcinoid tumors usually have urinary 5HIAA levels of 100 to 3000 µmol/24 hours (15–60 mg/24 hours) (reference range: <50 µmol/24 hours [10 mg/24 hours]). Assays for urinary 5HIAA include high-pressure liquid chromatography (HPLC) with electrochemical detection and colorimetric and fluorescence methods.[124] Various foods and drugs can interfere with the measurement of urinary 5HIAA, and patients should avoid these agents during the 24-hour sampling (Table 45.2).[125] Normally two 24-hour urine collections are recommended. In a study of patients with malignant midgut carcinoid tumors, 60% to 73% presented with increased urinary 5HIAA levels,[27,60,61] with a specificity of almost 100%.

Today, measurement of urinary 5HIAA for diagnosis of carcinoid tumor is the predominant biochemical analytic procedure. However, urinary and platelet measurements of serotonin itself can give additional information. In some studies, platelet serotonin levels were more sensitive than urinary 5HIAA and urinary serotonin levels and were not affected by the patient's diet, as are 5HIAA levels.

In a comparative study of 44 consecutive patients with carcinoid tumor, the platelet serotonin, urinary 5HIAA, and urinary serotonin levels were measured. In foregut carcinoids the sensitivities were 50%, 29%, and 55%, respectively. For midgut carcinoids, the sensitivities were 100%, 92%, and 82%, respectively, and for hindgut carcinoids they were 20%, 0%, and 60%, respectively.[126]

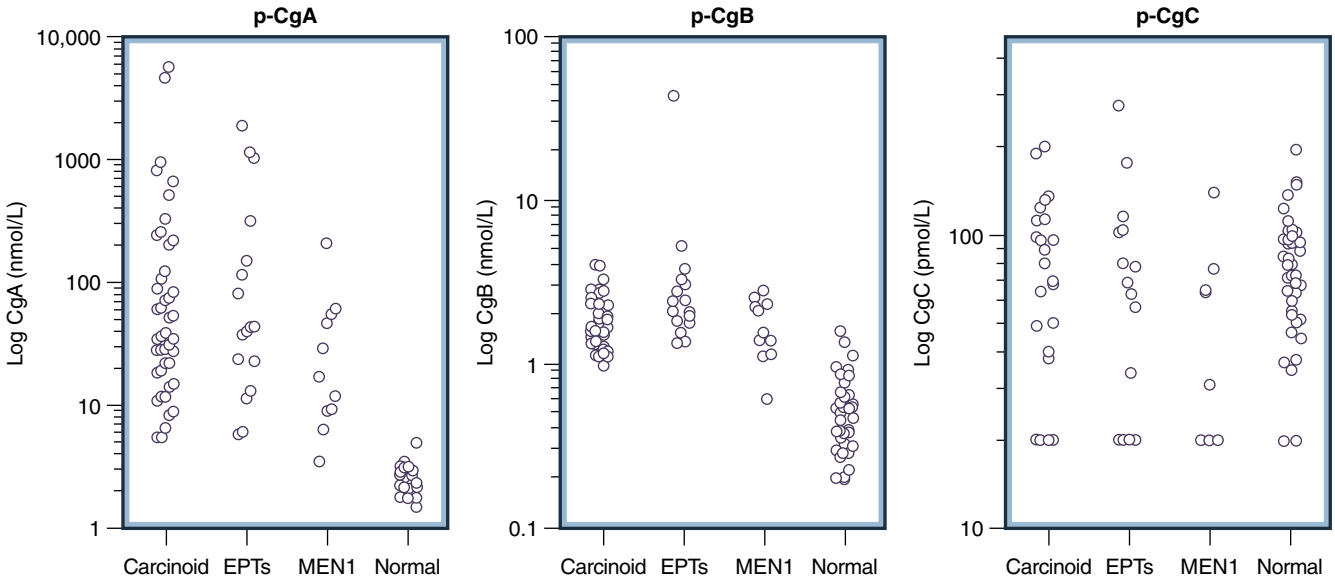
A method to determine 5HIAA in serum has been developed and will replace the urine 5HIAA.[127] Elevations of 5HIAA can occur in malabsorption states and a number of other conditions. Foregut carcinoids tend to produce an atypical carcinoid syndrome with increased plasma 5HTP, but not serotonin, because they lack the appropriate decarboxylase that results in normal urinary 5HIAA.[31,40] However, some of the 5HTP is decarboxylated in the intestine and other tissues, and many of these patients have slightly elevated urinary 5HT or 5HIAA levels.

Attempts have been made to identify more specific and sensitive serum markers for carcinoid tumors that might allow earlier diagnosis. One such marker is CgA. It has been shown that CgA and CgB are more abundant than CgC in human neuroendocrine tissues.[49,50,128] In 44 patients with carcinoid tumors, CgA was increased in 99%, CgB in 88%, and CgC in only 6% (Fig. 45.15).[129] It has been proposed that CgA levels in plasma might reflect tumor size. In a study of 75 patients with midgut carcinoids and the carcinoid syndrome,

TABLE 45.2 Factors That Interfere With Urinary 5HIAA Measurement

Foods	Drugs
Factors That Produce False-Positive Results	
Avocado	Acetaminophen
Banana	Acetanilide
Chocolate	Caffeine
Coffee	Fluorouracil
Eggplant	Guaifenesin
Pecan	L-Dopa
Pineapple	Melphalan
Plum	Mephenesin
Tea	Methamphetamine
Walnuts	Methocarbamol
	Methysergide maleate
	Phenmetrazine
	Reserpine
	Salicylates
Factors That Cause False-Negative Results	
None	Corticotropin
	p-Chlorophenylalanine
	Chlorpromazine
	Heparin
	Imipramine
	Isoniazid
	Methenamine mandelate
	Methyldopa
	Monoamine oxidase inhibitors
	Phenothiazine
	Promethazine

5HIAA, 5-Hydroxyindoleacetic acid.



• **Fig. 45.15** Plasma (*p*) levels of chromogranin A (CgA), CgB, and CgC in patients with various neuroendocrine tumors. *EPTs,* endocrine pancreatic tumors; *MEN1,* multiple endocrine neoplasia type 1.

CgA was elevated in 87% of carcinoid patients. Furthermore, a correlation between levels of plasma chromogranin and extent of disease was found ($p < 0.0001$).[27] In the same study, urinary 5HIAA was elevated in 76% of midgut carcinoids, and there were no correlations with tumor size or extent of disease.

CgA is a more sensitive marker than urinary 5HIAA in detecting carcinoid tumors, but because CgA is released and secreted from various types of neuroendocrine tumors, the specificity is lower.[129–132] Therefore in a workup of patients with the carcinoid syndrome, one should combine the determination of plasma CgA with urinary 5HIAA or serotonin. Importantly, plasma CgA might be elevated in other conditions such as chronic atrophic gastritis, treatment with proton-pump inhibitors, or impaired kidney function.[133] Plasma neuron-specific enolase (NSE) shows a lower sensitivity and specificity than does plasma CgA.[129] Plasma NSE is particularly helpful in patients with lung NETs and other NETs with higher proliferation.[134] Serum hCGα has been reported to be increased in 60% of patients with foregut carcinoid tumors and in 50% of those with hindgut carcinoids but only 11% in those patients with midgut carcinoids and the carcinoid syndrome. Plasma neuropeptide K levels have been reported to be elevated in 46% of patients with midgut carcinoids, whereas only 9% of patients with foregut carcinoids displayed elevated levels.[130,135] Plasma substance P has a sensitivity of 32% and a specificity of 85%.[27,42–44] Neurokinin A is reported to be a sensitive marker for carcinoids of the small intestine both for diagnosis and prognostication.[136] Pancreatic polypeptide levels are also elevated in about one-third of patients with midgut carcinoids and in as many with foregut carcinoids.[137] Recently a gene transcript test (51 genes) analyzing circulating mRNA presented a sensitivity/specificity of 98/97% to detect neuroendocrine tumors and predicted outcome of therapy.[137,138]

During therapy with somatostatin analogues, neither plasma CgA nor urinary 5HIAA is a reliable marker of tumor size because somatostatin inhibits the synthesis and release of the hormones without changes in tumor size.

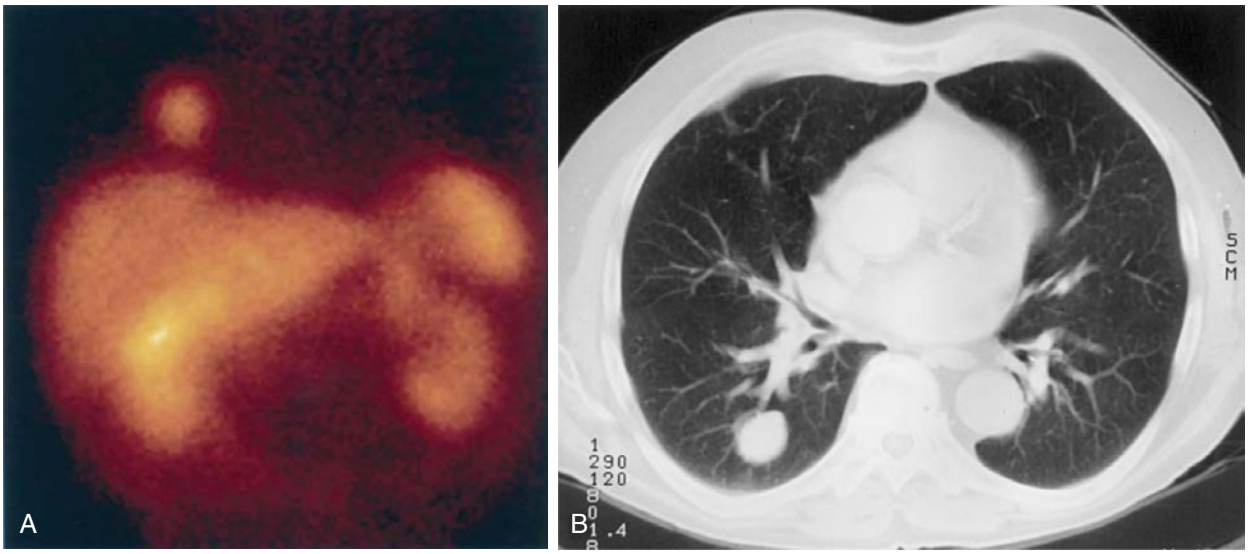
Localization Procedures

Numerous imaging techniques, including endoscopy, barium enema, chest radiography, ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and angiography, have been used to determine the location of the primary tumor as well as the metastases in patients with carcinoid tumors. In more recent years, somatostatin-receptor scintigraphy (SRS) and iodinated meta-iodobenzylguanidine (^{131}I-MIBG) scanning have been used to localize and stage the disease.[139–142] Bronchial carcinoids are usually detected by chest radiography, CT, or (occasionally) bronchoscopy.[143] The primary midgut tumor is usually small and difficult to localize with traditional diagnostic methods such as barium enema, CT scan, or MRI. Some of these tumors can be localized by angiography, capsule endoscopy, or SRS. Liver metastases are usually detected by CT or MRI. At present, CT or MRI and SRS are the primary diagnostic modalities for tumor staging (Fig. 45.16). SRS is nowadays replaced by ^{68}Ga-DOTATATE/TOC positron emission tomography (PET), which shows significantly higher sensitivity and specificity.[144,145]

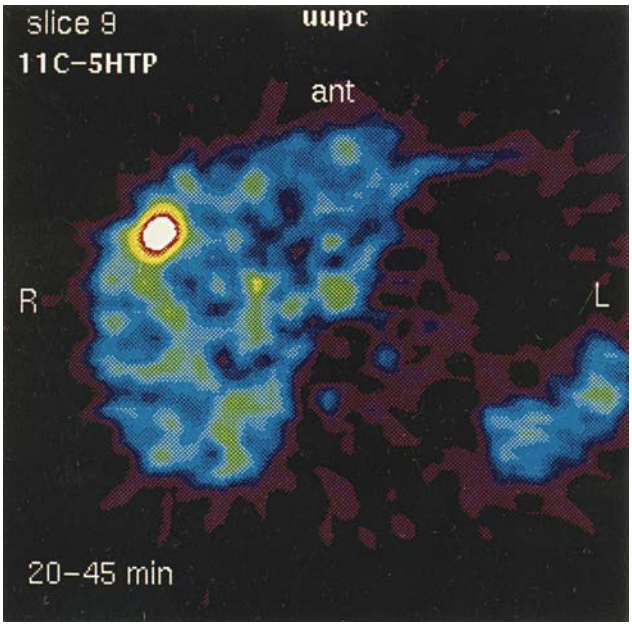
Other sensitive methods are PET or ^{18}F-DOPA-PET scanning[146] using ^{11}C5HTP, the precursor of serotonin synthesis (Fig. 45.17).[147,148] These isotopes accumulate in carcinoid tumors (APUD mechanism); with the development of PET cameras, tumors as small as 0.5 cm in diameter can be detected.[147] During treatment, a close relation has been found among changes in the PET scan, transport rate constant, and urinary 5HIAA, suggesting that PET scanning may be useful in monitoring the results of therapy. PET scanning using ^{18}F-fluorodeoxyglucose (FDG-PET) has been considered not useful in detecting low-proliferating neuroendocrine tumors, but recent data indicate it to be beneficial in identifying poorly differentiated anaplastic tumors but also well-differentiated tumors.[149]

Carcinoid tumors contain high-affinity receptors for somatostatin in 80% to 100% of cases.[120,121,150] The receptors are present in both the primary tumor and metastases. Five subtypes of somatostatin receptors have been cloned (SSTR1–SSTR5), and somatostatin receptor type 2 is the predominant subtype expressed in carcinoid tumors.

The most commonly available somatostatin analogue, octreotide, binds with high affinity to SSTR2 and with lower affinity to SSTR3 and SSTR5.[151–153] SRS with ^{111}In-DTPA-Phe-octreotide (Octreoscan) has been reported to detect carcinoids with a



• **Fig. 45.16** Bronchial carcinoid. (A) Somatostatin-receptor scintigraphy in a patient with a bronchial carcinoid. (B) Computed tomography scan in the same patient.



• **Fig. 45.17** Positron emission tomography (PET) scan with ^{11}C-5-hydroxytryptophan. Note the metastasis in the liver.

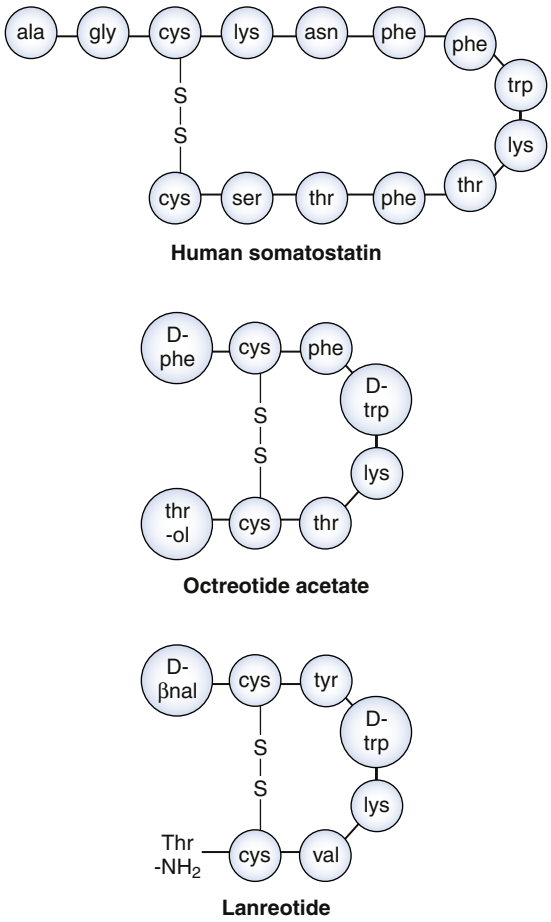
sensitivity of 80% to 90% in patients.[153,154] Many studies have demonstrated that SRS has greater sensitivity for localizing carcinoids compared with conventional imaging studies.[154–157] False-positive scans can be encountered in patients with granulomas (e.g., sarcoidosis, tuberculosis), activated lymphocytes (lymphomas, chronic infection), thyroid diseases (goiter, thyroiditis), endocrine pancreatic tumors, and other endocrine tumors. Because of its high sensitivity and ability to image, whole-body SRS should be the initial imaging procedure to localize and establish the stage of the disease. Bone metastases, which are common with carcinoid tumors, are efficiently detected by SRS, which is as sensitive as traditional bone scanning with technetium.[144,158–161] ^{68}Ga-DOTATATE/TOC-PET scanning has now been developed, showing higher sensitivity than Octreoscan and replacing it worldwide (Fig. 45.18).

Scintigraphy with ^{123}I-MIBG has been applied in patients with midgut carcinoids with a sensitivity of about 50%, which is lower than that for SRS (80–90%). However, it can pick up carcinoids in patients who are sensitive to therapy with ^{123}I-MIBG.[162] The current imaging workup is summarized by Van Essen and coworkers.[163]

A diagnostic algorithm is outlined in Fig. 45.19.

Treatment

Treatment of carcinoid tumors with the carcinoid syndrome requires a multimodal approach, including symptomatic control



• **Fig. 45.19** Molecular structure of human somatostatin-14, octreotide acetate, and lanreotide.

as well as tumor reduction. Most patients with the carcinoid syndrome have metastatic disease. The therapeutic goals are to ameliorate and improve clinical symptoms, abrogate the tumor growth, improve quality of life, and (if possible) prolong overall survival.

Symptomatic control of the carcinoid syndrome includes lifestyle changes, diet supplementation, and specific medical treatment that reduces the clinical symptoms related to the different components of the carcinoid syndrome. Avoiding stress, both psychologic and physical, as well as substances such as alcohol, spicy foods, and medications that precipitate a flushing reaction might be sufficient in early cases.[61]

Production of serotonin by the tumor consumes tryptophan. Normally, about 1% of body tryptophan is used for production of serotonin; in carcinoid tumors, however, as much as 60% of the available tryptophan may be consumed for the synthesis of serotonin, and this can result in tryptophan and niacin deficiencies. Therefore supplemental niacin to prevent the development of pellagra has been recommended over the years. Many patients have undergone resection of the terminal ileum, which can result in vitamin B_{12} and folic acid deficiencies. Supplementation is needed in these patients.

Heart failure due to carcinoid heart disease can require diuretics or angiotensin-converting enzyme (ACE) inhibitors. A few patients need bronchodilators such as salbutamol, which interacts with α-adrenergic receptors and does not induce flushing. The diarrhea seen in the carcinoid syndrome might be controlled by loperamide or diphenoxylate.[164] If patients still have the carcinoid syndrome, they receive somatostatin analogue treatment, which has replaced most of the earlier types of serotonin and serotonin receptor inhibitors. Serotonin inhibitors (e.g., parachlorophenylalanine and α-methyldopa), which inhibit serotonin synthesis, and serotonin receptor antagonists (e.g., cyproheptadine, methysergide, and ketanserin) are not used routinely clinically.[164]

These earlier treatments had limited efficacy in terms of inhibiting flushing and diarrhea and were accompanied by significant side effects. Telotristat ethyl, an inhibitor of the enzyme tryptophan hydroxylase, reduces the serotonin levels. In one study the compound reduced bowel movements by 44% and urinary 5HIAA levels by 75%. The patients experienced a significant improvement.[165] A combination of histamine H_1 and H_2 receptor antagonists is effective in the carcinoid syndrome that is caused by foregut carcinoids due to concomitant secretion of histamine and serotonin. Prednisolone in doses of 15 to 30 mg/day gives occasional relief in some cases with severe flushing and diarrhea.[164]

Somatostatin Analogues

Although natural somatostatin-14 reduces symptoms in patients with the carcinoid syndrome,[166] its use is limited by its short half-life (~2.5 minutes). During the past 30 years, synthetic somatostatin analogues (octapeptides) have been developed for clinical use. Octreotide is the most commonly available drug; other analogues are lanreotide and vapreotide.[167–172]

The somatostatin analogues used in clinical practice (octreotide, lanreotide) (Fig. 45.20) bind to receptors SSTR1 and SSTR5 and, with lower affinity, to SSTR3. They exert their cellular action through interaction with specific cell and transmembrane receptors belonging to the superfamily of G protein–coupled membrane receptors. They inhibit adenylate cyclase activity, activate phosphotyrosine phosphatases (PTPs), and modulate mitogen-activated protein kinases (MAPKs).[153,155,173–175] Receptor subtypes 2 and 5 modulate K^+ and Ca^{2+} fluxes in the cell.[173] Activation of all these pathways results in inhibition of known growth factor production and release and has antiproliferative effects.[154,155,168–171,173,174]

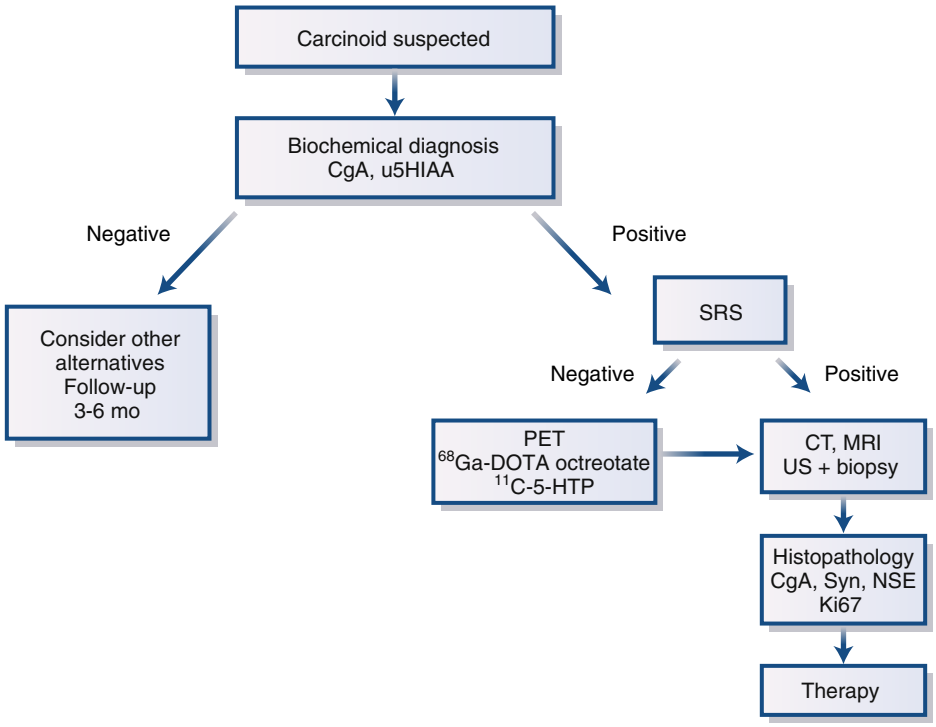
SSTR3 is known to mediate PTP-dependent apoptosis accompanied by activation of TP53 and BAX.[175] Four of the five somatostatin receptor subtypes (SSTR2–SSTR5) undergo rapid internalization after ligand binding, which has been explored by tumor-targeted radioactive somatostatin analogue therapy.[176–179]

An antiproliferative effect has been reported, probably through a combination of SSTR2 and SSTR5 activities, which inhibits MAPK and K^+ and Ca^{2+} fluxes leading to cell cycle arrest[173–175]; the precise antitumor mechanism, however, is not known.

It is now known that different subtypes of somatostatin receptors (SSTR1 and SSTR5) form heterodimers with dopamine receptor D_2. This cross-talk modulates the intracellular signal and gives a fine tuning of the mediated effects.[177]

All five subtypes of somatostatin receptors are expressed in carcinoid tumors; they are expressed in various combinations, although some tumors express all five subtypes.[177–179] The receptors are expressed not only on tumor cells but also in peritumoral veins.[180] Antiangiogenesis might be another antitumor mechanism of somatostatin analogues.[181]

Subcutaneous administration of octreotide and lanreotide every 8 to 12 hours can control the clinical symptoms in about 60% to 70% of patients with the carcinoid syndrome; these agents are considered the drugs of choice.[182–187] Octreotide and lanreotide decrease serotonin and urinary 5HIAA levels as well as plasma tachykinin and CgA



• **Fig. 45.20** Diagnostic algorithm for small intestinal neuroendocrine tumors (carcinoids). *CgA,* chromogranin A; *^{11}C-5-HTP,* ^{11}C-5-hydroxytryptophan; *CT,* computed tomography; *5HIAA,* 5-hydroxyindoleacetic acid; *MRI,* magnetic resonance imaging; *NSE,* neuron-specific enolase; *PET,* positron emission tomography; *SRS,* somatostatin-receptor scintigraphy; *Syn,* synaptophysin; *US,* ultrasound.

levels. The recommended dose for octreotide is 100 to 150 µg two or three times a day, a standard treatment for controlling clinical symptoms.[186] However, some patients require higher doses, up to a total of 3000 µg/day, to control the clinical symptoms and tumor growth, particularly during long-term therapy.[188]

Tachyphylaxis (reduced sensitivity) to somatostatin analogues can develop during long-term therapy.[189] Long-acting, slow-release formulations of octreotide acetate and lanreotide have been developed, and doses of octreotide LAR of 20 to 30 mg given once a month or lanreotide Autogel 90 to 120 mg once a month control clinical symptoms and hormone levels in 50% to 60% of patients with the carcinoid syndrome.[189,190] The long-acting formulations of somatostatin analogues have clearly improved the quality of life of patients by reducing the number of injections and provide more stable control of clinical symptoms.[189] A newer somatostatin analogue, pasireotide, binding to SSTR1, SSTR2, SSTR3, and SSTR5, has come into some clinical trials in carcinoid tumors. In a phase II study of carcinoid patients refractory to octreotide, the number of bowel movements and flushing episodes was reduced in one-third of the patients.[190,191] However, the drug did not exhibit superiority to standard octreotide in a randomized trial in small intestinal NETs.[189]

High-dose therapy with lanreotide (12 mg/day) and octreotide (3 mg/day) has increased the percentage of patients demonstrating a significant reduction in tumor size (12% vs. 5% for the standard dose).[192–195] Induction of apoptosis has been reported during high-dose therapy,[196] possibly mediated through activation of SSTR3. Ultrahigh-dose octreotide has generated significant antitumor responses in patients resistant to standard dose therapy.[195,196] A prospective randomized study in midgut carcinoids (PROMID) demonstrated a significantly longer time to progression for octreotide LAR compared to placebo.[197] These data have changed the US National Comprehensive Cancer Network (NCCN) guidelines for treatment of carcinoid tumors. All types of carcinoid tumors, irrespective of functionality, can now be treated with octreotide. The early results indicating an antitumor effect of somatostatin analogues is further supported by a 2014 study (CLARINET).[198] Lanreotide significantly prolongs progression-free survival time in nonfunctioning neuroendocrine tumors.[198]

For patients at risk for carcinoid crisis, somatostatin analogue therapy is the treatment of choice. Carcinoid crisis is a life-threatening complication of the carcinoid syndrome and can occur spontaneously or may be associated with stress and anesthesia, chemotherapy, and infections (see earlier discussion). Patients usually experience severe flushing, diarrhea, abdominal pain, and hypotension. Continuous infusion with somatostatin analogues, 50 to 100 µg/hour, is recommended and usually alters the life-threatening condition. It is also recommended that patients be given subcutaneous somatostatin analogues before surgery or other stressful situations.

Side effects of somatostatin analogue therapy have generally not been serious and occur in 20% to 40% of patients. They include pain at the injection site, gas formation, diarrhea, and abdominal cramping. Significant long-term side effects include gallstone formation, sludge in the gallbladder, steatorrhea, deterioration of glucose tolerance, and hypocalcemia.[103,184,185,188,189,195] The incidence of gallstones in patients treated over the long term has varied from 5% to 70%, and the incidence of symptomatic gallstones requiring surgical treatment is less than 10%.[189]

Interferons

Interferon-α (IFNα)—alone or in combination with a somatostatin analogue—is effective in the treatment of the carcinoid

syndrome. Symptomatic and biochemical control may be obtained in 40% to 50% of patients with the recommended doses of 3 to 5 million units of recombinant interferon alfa-2a or interferon alfa-2b three to five times per week subcutaneously.[184,199,200–204] Significant tumor reduction is reported in 10% to 20% of the patients.[204–206]

IFNα exerts a direct effect on the tumor cells by blocking cell division in the G_1/S phase, by inhibiting protein and hormone synthesis, and by reducing angiogenesis through inhibition of angiogenic factors bFGF and VEGF. It has also an indirect effect through stimulation of the immune system, particularly T cells and natural killer cells.[207,208] Response to IFNα can be predicted by analyzing induction of 2′,5′-oligoadenylate synthetase or protein kinase p68 (PKR), enzymes involved in cell cycle regulation and protein synthesis.[208–212] Long-acting formulations of IFNα are now available (pegylated interferons) that can be applied at doses of 80 to 150 μg/week subcutaneously.

Treatment with IFNα induces an intratumoral fibrosis that is not picked up by regular CT scanning or ultrasonography; therefore tumor size may remain unchanged.[213] The side effects of α-interferons are more pronounced than with somatostatin analogues and include chronic fatigue syndrome, anemia, leukopenia, and thrombocytopenia as well as the development of autoimmune reactions in 10% to 15% of the patients.[208,214] Most of the side effects are dose dependent and can be managed by individualizing the dose.

Patients with the carcinoid syndrome who have not responded to octreotide or IFNα alone may be given a combination of both agents. Such combinations have generated symptomatic control in 70% of patients and stabilization of tumor growth in 40% to 50% of patients.[215–217] The combination also offers better tolerance of α-interferons when somatostatin analogues are added. Moreover, somatostatin analogue treatment is hampered by development of tachyphylaxis with time, which means less sensitivity to the somatostatin analogue, necessitating escalating doses and, finally, withdrawal of the compound for several months, when IFNα therapy can continue. Conversely, IFNα can be withdrawn and the somatostatin analogue can be continued if severe side effects to IFNα (mainly chronic fatigue syndrome or mental depression) develop.[215–217] Recently, a prospective randomized phase III study between IFNα2b and bevacizumab showed similar antitumor activity.[218]

Chemotherapy

Most agree that patients with classic midgut carcinoids and the carcinoid syndrome, in which tumors show low proliferation capacity, should not receive chemotherapy. The results in various studies have been disappointing: Response rates are not more than 5% to 10%, are short lived, and are accompanied by considerable side effects.[219,220] The combination of streptozotocin and 5-fluorouracil, which has demonstrated antitumor effect in endocrine pancreatic tumors, has not shown similar effects in classic midgut carcinoids.[220] In foregut carcinoids, which usually manifest a more malignant behavior, however, cytotoxic treatment may be attempted. Such combinations include streptozotocin plus 5-fluorouracil, doxorubicin, cisplatin plus etoposide, and dacarbazine plus 5-fluorouracil.[221–223] Temozolomide has significant efficacy in foregut carcinoids.[224] All of these cytotoxic treatments can be combined with a somatostatin analogue.

Other Agents

Tyrosine kinase receptors (platelet-derived growth factor receptor [PDGFR] α/β, epidermal growth factor receptor [EGFR], VEGFR) are expressed in carcinoid tumor cells as well as in the stroma cells. Therefore treatment with tyrosine kinase receptor inhibitors has been attempted with objective response rates of about 10% to 15%.[225] Mammalian target of rapamycin (mTOR) inhibitors are new drugs that block the mTOR signaling pathway, which is activated in many tumors. Everolimus alone or in combination with octreotide has generated 15% to 20% objective responses.[226–228] Everolimus was evaluated in a randomized placebo-controlled study in nonfunctional lung or gastrointestinal NETs (RADIANT4). Treatment with everolimus was associated with significant improvement in progression-free survival.[225] However, in another trial in patients with carcinoid syndrome, no difference in overall survival was noted in patients receiving everolimus versus placebo (RADIANT2).[228]

Surgery

Because most tumors in patients with the carcinoid syndrome are malignant at the time of clinical presentation, surgical cure is seldom obtained. Resection of local disease or regional nodular metastatic disease can cure some patients; however, even if radical surgery cannot be performed, debulking procedures and bypass should always be considered and can be performed at any time during the course of treatment.[58,99,229]

A more proactive attitude among surgeons has emerged, and currently wider resections and debulking procedures are being performed.[229,230] Resection of primary tumor and locoregional metastases in patients has recently been debated. The final decision needs a prospective randomized trial.[231] In contrast to other metastatic tumors to the liver, in which liver transplantation has generally given poor results, an interest in liver transplantation is increasing for patients with metastatic carcinoids.[232–234] In a review of 103 patients with malignant neuroendocrine tumors, including both carcinoids and pancreatic endocrine tumors, 5-year and 2-year survival rates were 16% and 47%, respectively; however, recurrence-free survival rate was less than 24%.[234] Liver transplantation might be considered in younger patients (<50 years of age) with a life-threatening uncontrolled carcinoid syndrome during medical therapy or tumor-targeted radioactive treatment without known metastatic spread outside the liver (Milan criteria). However, a study from our group challenges the results of liver transplantation, with a 5-year survival time in patients younger than 55 years without surgery of 92 ± 9 months compared with transplanted patients fulfilling the Milan criteria showing a 5-year survival time of 97 ± 6 months.[232]

Another means of tumor reduction is hepatic artery embolization, which not only improves the carcinoid syndrome in about 50% of the patients but also reduces the tumor size in as many. The therapeutic effect may last for 9 to 12 months, and the procedure can be repeated.[235,236] Chemoembolization, simultaneous embolization with surgical gel (Gelfoam), and chemotherapy (doxorubicin, mitomycin C, cisplatin, 5-fluorouracil), or IFNα has resulted in symptomatic improvement in a significant number of patients with the carcinoid syndrome.[237,238] However, hepatic artery occlusion or embolization can result in serious side effects (nausea, vomiting, liver pain, fever) and major complications (hepatorenal syndrome, sepsis, gallbladder perforation, and intestinal necrosis). Complications are seen in 5% to 7% of patients.[236–238]

Other cytoreductive treatments include cryotherapy and radiofrequency ablation.[239] However, these procedures are limited to patients with smaller tumor burden, tumors less than 5 cm in diameter, and a limited number of metastases.

Irradiation

External irradiation has demonstrated limited efficacy and is used mainly to palliate symptoms related to bone and brain metastases.[240,241] MIBG is taken up by carcinoids and is concentrated. The possibility of radiolabeled MIBG therapy has been evaluated in a limited number of patients. The response rate has been reported to be about 30% with ^{125}I-MIBG or ^{131}I-MIBG.[242,243]

Somatostatin analogue–based tumor-targeted radioactive treatment has been applied using ^{111}In-DTPA-octreotide. Symptomatic improvement is reported in about 40% of the patients and tumor stabilization in about 30%.[244] Indium-111 (^{111}In) is a weak irradiator (Auger electrons) and has been replaced by yttrium-90 (^{90}Y) and lutetium-177 (^{177}Lu) (β-emitters).[245,247]

Studies with ^{90}Y-DOTA-octreotide have been reported with promising results.[245] The relatively new isotope, ^{177}Lu-DOTA-octreotate, has come into clinical use with further improved results. Significant tumor reduction occurs in 30% to 40% of patients with advanced disease. However, it is more effective for small tumors. It is an attractive mode of treatment because the radioactive ligand, after binding to the receptor, is internalized and transported to the cell nucleus, causing DNA damage.[245] Because tumor cells usually have higher-density somatostatin receptors (SSTR2 and SSTR5) than do surrounding normal tissues, the treatment might be better tolerated. A pivotal trial was recently published where small intestinal NETs were treated with either four cycles of ^{177}Lu-DOTATATE or 60 mg octreotide LAR every 4 weeks (NETTER1). Patients undergoing radioactive treatment showed a significant longer progression-free survival.[248] This trial has now been the basis for registration by EMA and FDA for treatment of patients with nonsurgical metastatic gastrointestinal NETs. Most recently, a genomic signature in blood was shown to predict response of PRRT with ^{177}Lu octreotide.[249]

In liver-dominant disease, radioembolization might be a valid alternative using ^{90}Y microspheres in the form of glass or resin beads injected into the hepatic artery.[250] The current treatment of metastatic carcinoid tumor is summarized in an algorithm (Fig. 45.21).

Prognosis

Clinically, the carcinoid syndrome is generally a manifestation of advanced disease. Carcinoids from various sites differ not only in the percentage developing the carcinoid syndrome but also in their aggressiveness. Survival rates for patients with various carcinoids depend on the site, the extent of the tumor, and tumor biology. In patients with only localized disease, the 5-year survival rate for midgut carcinoids is about 65%, not essentially higher than that for patients with regional metastases. In patients with distant metastases, the 5-year survival rate is reduced to 39%.[26–28,251,252] The relative 5-year, 10-year, and 15-year survival rates for midgut carcinoids were 67%, 54%, and 44%, respectively.[251] The 5-year and 10-year survival rates for typical bronchial carcinoid are 95% and 80%. Atypical lung carcinoids have significantly shorter survival, only 50% 5-year survival rate.[23]

One of the main determinants of survival in carcinoid patients is the presence of metastases. Female gender and a younger age are associated with a better prognosis. Other factors that correlate with lower survival rates are high CgA level at diagnosis and high proliferation index (Ki67).[38,117] During the 1990s there was a reduced incidence of death from carcinoid heart disease, possibly a result of earlier diagnosis, active surgery, and the introduction of somatostatin analogues and α-interferons. In an earlier study performed by our group, 30% of the patients died of carcinoid heart complications.[25] In a more recent 2008 study, this rate was reduced to less than 10%.[27] Clinically significant carcinoid heart disease is now rare. Between 5% and 10% of patients with

carcinoids are at an increased risk for developing simultaneous adenocarcinoma of the large intestine. The occurrence of a second malignancy is associated with a worse prognosis.[23,26] In two studies (in 2011 and 2014) comparing almost 900 patients with midgut or hindgut tumors, survival correlated with the WHO grading system as well with the TNM staging. For grade 1 (G1) the 10-year survival rate was 80%, for G2 tumor 50% to 66%, and for G3 tumor 35%; for stage I and II tumors survival rate was 100%, stage III 85%, and stage IV 35%.[251]

Significant negative prognostic factors for overall survival were old age at diagnosis, carcinoid heart disease, liver tumor load, high WHO grade, and peritoneal carcinomatosis.[250,252] Locoregional surgery had a positive impact on survival.[252]

Other Flushing Disorders

Medullary Thyroid Carcinoma and VIPoma

Other neuroendocrine tumors, such as medullary thyroid carcinoma (MTC) and VIP-producing tumors (ganglioneuroma, endocrine pancreatic tumors), can manifest with flushing syndromes (Fig. 45.22).[253,254] Patients might also have diarrhea, particularly those with VIP-producing tumors, which are accompanied by a severe secretory diarrhea. In patients with MTC, flushing and diarrhea are infrequent symptoms and are seen mainly in patients with high circulating levels of calcitonin and CGRP.

The mechanism behind the flushing and diarrhea is unknown, but it has been postulated to be mediated through prostaglandins stimulated by calcitonin. The frequency of flushing and diarrhea is usually less than 5% in patients with advanced metastatic MTC.[253,255] Treatment is directed against tumor growth and can consist of surgical resection, embolization of liver metastases, and cytotoxic treatment (doxorubicin-based combination therapies). Somatostatin analogue therapy can alleviate the diarrhea. Therapy with tyrosine kinase inhibitor vandetanib can reduce these symptoms and present an antitumor effect.[255]

VIPoma or WDHA (*w*atery *d*iarrhea, *h*ypokalemia, and *a*chlorhydria) syndrome (Verner-Morrison syndrome) is associated with severe secretory diarrhea (up to 15 L/day), and some patients also display a continuous whole-body violaceous flushing and hypotension.[254,256,257] The syndrome also includes achlorhydria, hypokalemia, and metabolic acidosis and is related to overproduction of VIP and a related peptide-peptide histidine methionine. These patients have tumors in the pancreas, lung, or sympathetic ganglia.[256,257]

The diagnosis is confirmed by measuring plasma VIP, which usually exceeds 70 pmol/L.[257]

Treatment is directed against the tumor and hormone excess. Administration of somatostatin analogues by either subcutaneous or IV infusion in the worst cases can control clinical symptoms.[258] Cytotoxic treatment with streptozotocin-based combinations, 5-fluorouracil, or doxorubicin is recommended for malignant cases.[256] Inhibitors, such as mTOR (everolimus), demonstrate an antitumor effect in VIPomas with reduction of clinical symptoms.[225]

Mastocytosis and Related Disorders

Mastocytosis, as well as other systemic mast cell activation, is clinically related to flushing disorders. Most patients with mastocytosis have an indolent course, but some forms of mastocytosis are aggressive. Symptoms are attributed primarily to paroxysmal mast cell activation.[259,260]

Most patients with mastocytosis have evidence of cutaneous involvement, the most common being multiple, small pigmented lesions that produce urticaria on stroking with a blunt object (Darier sign); this condition is called *urticaria pigmentosa*.[261,262] Another form of cutaneous mastocytosis is a more telangiectatic form called *telangiectasia macularis eruptiva persistans.* Hepatomegaly and splenomegaly can be due to infiltration of mast cells, and hepatic fibrosis is also common.[262,263]

Bone involvement can be manifested by either osteoporosis or osteosclerosis.[264] Systemic mastocytosis can also involve the GI tract with mucosal nodules in the ileum, stomach, and large bowel.[265]

Hematologic abnormalities are nonspecific, with marked mast cell infiltration of the bone, anemia, leukocytosis, sometimes lymphadenopathy, and eosinophilia.[266] In a subgroup of patients, the mastocytosis is secondary to primary hematologic disorders, usually myeloproliferative or myelodysplastic disease.[266–268] Mast cell leukemia has been reported in rare cases.[269] Some cases with FIP1-like 1/PDGFRα *(FIP1L1-PDGFRA)* gene arrangement overlap to chronic eosinophilic leukemia. They also manifest elevated serum tryptase levels.[270] A majority (>80%) of patients with systemic mastocytosis have an activating c-kit mutation in codon 816 in the mast cell.[270]

Clinical signs of systemic mastocytosis include flushing, tachycardia, hypotension, and sometimes nausea, vomiting, and diarrhea. This syndrome resembles the carcinoid syndrome. Histamine is a potent vasodilator and is released from mast cells. Other mediators of the syndrome are the release of prostaglandin D_2, tryptase, and heparin.[270–273] Prostaglandin D_2 is a more potent mediator than is histamine.

The diagnosis is made by measurement of histamine and histamine metabolites in the urine.[272] Quantification of histamine metabolites (*N*-methylhistamine and methylimidazole acetic acid) appears to be more sensitive for overproduction of histamine in patients with mastocytosis.[273] Measurement of endogenous production of prostaglandin D_2 can be assessed by quantifying the major urinary metabolite (9α-hydroxy-11,15-dioxo-2,3,18,19-tet-ranorprost-5-ene-1,20-dioic acid).[273] However, these measurements can be done only in specialized laboratories. Measurement of the tryptase release is easier to perform, and increased quantities

of this granule-associated enzyme tryptase (>20 ng/mL) can be detected by immunoassay.[274] Bone marrow analysis of CD25 cells might support the diagnosis of mast cell disease.[275]

Treatment depends on the severity of the disease. As in the treatment of allergic anaphylaxis, epinephrine is effective in reversing the hypotension associated with mast cell mediator release[275]; thus these patients should have constant access to epinephrine in the form of subcutaneous injection or inhalation. Chronic therapy to prevent acute attacks includes antihistamine therapy combined with inhibition of prostaglandin biosynthesis. Blockade of both histamine H_1 and H_2 receptors is required to prevent the vasodilator effect of histamine.[246,275,276]

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit the cyclooxygenase enzyme that catalyzes the formation of prostaglandins. Aspirin has been used, but some patients cannot tolerate it because of side effects in the gut and allergic reactions.[277] In patients resistant to both antihistamines and NSAIDs, IFNα has been attempted with a reduction in mast cell numbers as well as excretion of mast cell mediators. Treatment with IFNα is still considered experimental.[278] A subset of patients who carry the *FIP1L1-PDGFRA* oncogene will achieve complete clinical, histologic, and molecular remission with imatinib mesylate therapy, in contrast to those with c-kit D816V mutation.[277]

Managing Reproductive Disorders in Cancer

MAHMOUD SALAMA, VICTORIA SANDLER, AND TERESA K. WOODRUFF

CHAPTER OUTLINE

KEY POINTS

- With increasing cancer survival the adverse sequelae of the tumor, and treatment thereof, on multiple organ systems have increasingly been recognized. The endocrine system is one of the most frequent organ systems to be affected, with greater than 40% of childhood cancer survivors showing abnormalities.
- Oncofertility is a relatively new interdisciplinary field at the intersection of oncology and reproductive medicine that expands fertility options for young cancer patients.
- Aggressive gonadotoxic anticancer regimens including alkylating chemotherapy and total-body irradiation are used often in treating young cancer patients. The risks of gonadotoxicity and subsequent iatrogenic fertility loss depend mainly on the type and stage of the disease, dose and dosage of anticancer therapy, and the age of the patient at the beginning of treatment.
- If the risk of gonadotoxicity and subsequent iatrogenic fertility loss is greater than 50% and the patient desires to have children in the future, a fertility preservation and restoration strategy should be initiated before, during, and after chemotherapy and radiotherapy.
- Fertility preservation and restoration strategy should be individualized and tailored to the patient's circumstances after obtaining patient informed consent or that of the legal guardians for children.
- Fertility preservation and restoration options include gamete and gonadal tissue freezing and further autotransplantation, gonadal protection, gonadal tissue bioengineering, stem cells reproductive technology, and neoadjuvant cytoprotective pharmacotherapy.
- A multidisciplinary oncofertility approach involving strong coordination among oncologists, gynecologists, endocrinologists, surgeons, reproductive biologists, research scientists, and patient navigators is essential to ensure a high standard of care.

What Is Oncofertility, and Why Is It Important?

Scope of the Problem

Cancer affects more than 14 million individuals annually worldwide, of whom 10% are of reproductive age.[1] Among children and adolescents, cancer survival rates range from 71% to 86%, mostly due to successful early detection and effective cancer therapies. However, up to 80% of children, adolescents, and adults with cancer receive treatment that may temporarily or permanently affect their reproductive health, including fertility, gonadal function, and psychosexual well-being.[2] At the heart of the field of oncofertility is the consideration of a patient's reproductive health at the same time that decisions are being made about life-preserving but fertility-threatening cancer therapy. Thus, a comprehensive discussion of the endocrine consequences of cancer treatment, including fertility loss, dysfunction of steroid hormone–dependent tissues (e.g., bone and heart), and impaired psychosexual health, as well as a discussion of fertility preservation and contraception options, is critical for optimizing the future quality of life (QoL) of cancer survivors.[3]

Current oncology clinical practice guidelines recommend that health care providers engage in an active discussion about the potential effects of cancer therapy on future reproductive health prior to, during, and after treatment.[4] Although there is growing awareness of the impact of cancer treatment on reproductive health among health care providers, up to 50% of patients with cancer are not offered counseling on reproductive health prior to starting cancer treatment.[2,5,6] Cancer patients are deeply

interested in engaging in a discussion with their health care providers about reproductive health throughout the course of their cancer diagnosis, treatment, and follow-up. Among young women with cancer, 62% express having had plans for children before receiving their cancer diagnosis.[4,7] In fact, concern about future fertility is a source of distress among women of reproductive age who are undergoing cancer therapy, with one-third reporting symptoms of depression and/or anxiety that interfere with daily functioning and 15% requiring psychotropic medications.[8] Even among those cancer patients who do receive counseling regarding reproductive health prior to initiation of cancer therapy, many report dissatisfaction with the quantity and quality of the information provided.[4] For example, adult women with breast cancer report overall satisfaction with the fact that fertility preservation was mentioned prior to initiation of treatment, but many also note frustration with the focus on infertility as opposed to the variety of fertility preservation options and success rates, the cost of fertility preservation procedures, and experimental protocols. Importantly, adult women who felt they had received adequate and high-quality information about fertility preservation prior to initiation of cancer therapy were five times more likely to pursue fertility preservation than women who did not receive counseling. These women also report less regret and better QoL even if they chose not to pursue fertility preservation prior to starting treatment.[4,7] Among adult men with cancer, counseling regarding fertility preservation prior to cancer therapy is felt to be particularly important, as fertility status is interwoven with their sense of masculinity and their intimate relationships.[9] Men pursuing fertility preservation report reassurance about the prospect of biologic fatherhood as a reaffirmation of their masculine identity.[9] However, male cancer patients are less likely to be informed about potentially compromised fertility than their female counterparts.[5]

Furthermore, adolescent cancer patients face unique additional challenges in navigating issues related to personal body image, intimacy, relationships, and sexuality during and after cancer treatment. Both adolescents with cancer and their parents, who frequently serve as primary decision makers, express concern about future fertility. However, parents of adolescents with cancer prioritize initiation of therapy over fertility preservation and underestimate their children's concerns about future fertility.[10] Parents of pediatric cancer patients sometimes regulate the information presented to younger cancer patients (12–15 years of age) to reduce distress during a particularly emotional time. Consequently, some adults with a history of cancer in childhood and adolescence convey dissatisfaction about having been fully or partially excluded from conversations regarding the impact of cancer treatment on their fertility by both their parents and their health care providers.[11] Furthermore, many of these adults report having received insufficient information about reassessing fertility potential after completion of cancer treatment, including counseling regarding safe sex practices and contraception, family planning, and nonbiologic parenthood options.[11] In fact, both adult survivors of pediatric cancer and their parents retrospectively express regret over inadequate allotment of time and attention to discussions about fertility prior to initiation of cancer therapy and attribute responsibility to the health care providers for insufficient counseling.[12] Parents of adult survivors of pediatric cancer also retrospectively report that their children should have been involved in discussions regarding future fertility, regardless of their age at cancer diagnosis. For many adult survivors and their parents, discussion of future fertility prior to cancer therapy signifies hope for the future.[12]

Reproductive health counseling should also include discussion of chronic comorbidities associated with cancer treatment and subsequent endocrine dysfunction, including osteoporosis, cardiovascular disease, cognitive dysfunction, and mental health issues.[13] Not only are certain cancer treatments (anthracyclines, trastuzumab, chest irradiation) associated with cardiac toxicity,[14,15] but specific chemotherapeutic and immunologic agents, cranial irradiation, surgical tumor removal, and antihormone therapies are also linked with adverse metabolic parameters such as obesity, glucose intolerance, insulin resistance, hypertension, atherosclerosis, and dyslipidemia that increase the risk of cardiovascular disease.[16,17] In addition, many cancer treatments result in estrogen and testosterone deficiency by damaging the organs that produce these hormones, thereby inhibiting estrogen receptor–mediated signaling and aromatization of testosterone to estrogen and downregulating the hypothalamic-pituitary-gonadal axis. Considering that these steroid hormones are essential for bone health, cancer treatments that deplete estrogen and testosterone are associated with altered bone physiology, a rapid decline in bone mineral density, and a twofold increased risk of fracture in both men and women with cancer. In fact, more than 80% of men with prostate cancer experience a decline in bone mineral density after medical or surgical castration, and women with breast cancer experience an accelerated decline in bone density after onset of therapy-induced ovarian insufficiency. Cancer therapy is also associated with chronic nutritional deficiencies that impede normal bone building and with chronic deconditioning and treatment-related neuropathies that increase the risk of falls and subsequent fractures.[18] Last, cancer survivors also experience greater mental health morbidity than the general population,[19] with greater reported emotional and social distress among older, single, unemployed female cancer survivors of bone and central nervous system (CNS) tumors.[20] Sexuality, fertility, and parenthood are particularly important factors in psychosocial well-being among adult cancer survivors and are major contributors to the long-term psychological sequelae of cancer diagnosis and treatment.[21]

Reproductive Health Concerns During Cancer Treatment

Fertility

Fertility is a critical component of reproductive health and plays a significant role in health-related QoL among cancer patients, especially women. In fact, 60% of women and more than 50% of men with cancer report a desire for parenthood.[22] Temporary or permanent infertility after cancer treatment may affect up to 60% of cancer survivors. The impact of cancer treatment on fertility is often unpredictable and is influenced by the type of chemotherapy agent, dose of radiation, patient age, and gonadal reserve prior to therapy. For women with cancer, alkylating agents and pelvic irradiation are particularly toxic to primordial follicles, and these therapies deplete the ovarian reserve and shorten the reproductive window.[23] For men with cancer, chemotherapy and pelvic irradiation are associated with azoospermia within 3 months of the start of treatment, and almost a quarter of male cancer survivors experience persistent azoospermia or oligospermia. Chemotherapy and radiation may also result in unrepaired DNA damage in spermatogonia, which compromises fertility and/or increases the risk of congenital abnormalities in offspring.[24]

Biologic parenthood is central to cancer patients' sense of adult and gender identity, existential purpose, and perception of social acceptance. Female cancer survivors view gestation as a marker

of femininity, whereas male cancer survivors are more focused on biologic fatherhood as a marker of masculinity. Unknown fertility status further augments reproductive health-related anxiety among cancer survivors, especially those who are young and single and may fear that potential infertility will adversely affect their ability to find a partner. Thus, reassessment of reproductive function after completion of cancer therapy is an important aspect of the comprehensive care of cancer patients. Notably, cancer survivors who are fertile may choose not to pursue conception due to concerns about cancer recurrence, transmission of cancer to offspring, and the effect of their own morbidity and mortality on their future child.[22] Thus, health care providers involved in the care of cancer patients must not only address the logistics of fertility preservation and initiation of cancer treatment but also provide compassionate support related to the emotional aspects of oncofertility that are important for patients' overall and long-term well-being.

Contraception During Cancer Therapy

Despite the gonadotoxic effects of cancer therapy, many cancer patients remain fertile during treatment. Up to 10% of women undergoing cancer treatment do not consistently use a reliable contraceptive method,[25] and 3% of women with cancer experience an unplanned pregnancy.[26] Selection of an appropriate method of female contraception is guided by the type of cancer (e.g., a nonhormonal copper intrauterine device in women with breast cancer vs. a contraceptive implant in women with cervical cancer), functional status and comorbidities (e.g., immunocompetence, thromboembolic risk, liver dysfunction), and personal preference.[27] Barrier contraception provides protection against sexually transmitted infections[22] but is not as effective as intrauterine devices and contraceptive implants in preventing pregnancy due to high user failure rates. Emergency contraception, including a short course of oral agents, is considered safe for women with cancer. Options for male contraception are being expanded rapidly, and many have been shown to be acceptable among men. Methods that induce azoospermia include androgens alone or in combination with progestins, gonadotropin-releasing hormone (GnRH) agonists, GnRH antagonists, and vasectomy. Reversible inhibition of sperm under guidance using a polymer gel causes reversible sperm damage, whereas vaso-occlusive devices prevent transmission of sperm through the vas deferens.[28] However, use of these male contraceptive methods is limited by the discomfort of administration, cost, stigma against male contraception, concerns regarding effects on libido and sexual function, and ease of reversibility.[29] Selective androgen receptor modulators and nonhormonal agents are currently being investigated as contraceptive options in men.[29] Among women with cancer, contraceptive use is discordant with the desire for pregnancy. Many women with cancer indicate that they would opt for abortion if they became pregnant during cancer treatment, although abortion rates among pregnant women with cancer are not well reported. Cancer patients prioritize contraception as an important aspect of their care, but only a few studies have adequately documented the quantity and quality of contraception counseling in cancer patients. Notably, 65% of women who participate in contraception counseling report using an effective method of contraception.[25]

Appropriate timing of conception after completion of cancer treatment is also an important aspect of reproductive health in cancer survivors. Conception should not be attempted sooner than 6 months after the completion of chemotherapy and 12 months after completion of radiation therapy in women with cancer,[23] and no sooner than 12 to 24 months after completion of therapy in men given the risk of unrepaired DNA damage in ejaculated spermatozoa.[24] Additionally, the risk of cancer recurrence must also be considered prior to attempting conception. Appropriately planned contraception allows cancer patients to time pregnancy to a stage of better maternal health and to optimize fertilization, embryonic development, and early pregnancy outcomes.[24,30]

Gonadal Dysfunction

Women With Cancer

Women undergoing surgery, chemotherapy, or radiation therapy for the treatment of cancer are at an increased risk of premature ovarian insufficiency (POI). POI is characterized by amenorrhea and gonadal steroid hormone deficiency with concurrent elevation in serum follicle-stimulating hormone on at least two occasions at least 1 month apart in women younger than 40 years. The prevalence of POI among young female cancer survivors ranges widely at between 2% and 82%. Age at diagnosis, type of chemotherapy (e.g., alkylating agents and alkylating-like agents), dose and target area of radiation, and a diagnosis of Hodgkin lymphoma are risk factors for POI. Additionally, oophorectomy is associated with a rapid decline in estrogens and androgens that precipitates symptoms of POI, including hot flashes, night sweats, vaginal dryness, and decreased sexual desire. Vulvectomy and radical hysterectomy add to scarring and pain of the perineum, further augmenting sexual dysfunction. Importantly, ovarian hormone deficiency is associated with increased morbidity (e.g., osteoporosis and fracture risk, cardiovascular disease, mental illness, and cognitive decline) and mortality. Recovery of ovarian function is variable, somewhat unpredictable, and dependent on baseline ovarian reserve. Methods for better predicting ovarian reserve in female cancer survivors, including measurement of serum antimüllerian hormone, antral follicle count, and ovarian volume and surface area, are still being optimized. Standardized methods for assessing ovarian reserve (rather than or in addition to symptoms of POI) among female cancer survivors could be used to direct counseling on contraception and guide screening for long-term complications of POI.[31,32]

Several strategies have been developed to address the symptoms of POI. Hot flashes may be managed with lifestyle changes such as weight management and avoidance of triggers; cognitive behavioral therapy and hypnosis; and specific, nonhormonal medications.[14] Incontinence, vaginal dryness, and dyspareunia associated with estrogen deficiency may be improved with pelvic floor physical therapy, clitoral therapy devices, avoidance of irritants, lubricants/moisturizers, topical anesthetics, topical and intravaginal estrogen, testosterone, or dehydroepiandrosterone, and psychotherapy.[14] Although hormone replacement therapy is sometimes unfavorable in women with hormone-sensitive cancers, such as breast, endometrial, cervical, and some ovarian cancers, a few studies have demonstrated that hormone replacement therapy in female survivors of early gynecologic cancer is not associated with an increased risk of cancer recurrence.[14,33] However, alleviation of menopausal symptoms in female cancer survivors is not always associated with better QoL; thus, the psychosocial aspects of cancer survivorship must also be addressed.[32]

Men With Cancer

Hypogonadism in men with cancer can result from direct damage to the testes, such as a consequence of surgical resection of gonadal tumors or exposure to pelvic irradiation or systemic chemotherapy. Testicular dysfunction can also occur secondary to pituitary or hypothalamic damage, as in the case of cranial radiotherapy

or resection of tumors of the CNS. Men with hypogonadism due to cancer therapy may present with ambiguous symptoms of decreased sexual desire or function, hot flashes, fatigue, slowed mental processing, and dysthymia (persistent depressive disorder), which may be difficult to distinguish from the common side effects of cancer treatment. They may also present with objective changes in body habitus (e.g., decreased muscle tone, gynecomastia, weight gain, redistribution of fat, loss of body hair), reduced testicular size, and normochromic normocytic anemia. Men undergoing bilateral orchidectomy, hypophysectomy, or pelvic or cranial radiotherapy may develop symptoms of hypogonadism soon after treatment, whereas those undergoing systemic chemotherapy may experience a slower onset of hypogonadal symptoms. Many men treated with chemotherapy or radiation to the retroperitoneum will experience some manifestations of testosterone deficiency over the long term, with a higher risk among men older than 45 years.[34] The effect of chemotherapy on testicular function is agent specific, even within the same chemotherapeutic category.[31] Baseline testicular volume is inversely associated with risk of hypogonadism after cancer treatment.[34]

Testosterone deficiency is linked to decreased sexual desire, erectile dysfunction, and orgasmic disorders that develop across the spectrum of subnormal and low testosterone concentrations. Symptoms of hypogonadism are associated with worse health-related QoL. Testosterone deficiency is also associated with osteoporosis, depression, metabolic dysfunction, cardiovascular disease, and mortality. Thus, it is important to assess for hypogonadism in men undergoing cancer treatment.[34] Testosterone replacement is readily available but may not be an option for men with advanced prostate cancer or breast cancer.[34]

Physical Changes Related to Cancer Therapy

Anatomic changes after mastectomy for the treatment of breast cancer or hysterectomy for the treatment of cervical or endometrial cancer adversely affect self-esteem, decrease sexual desire, and negatively affect a woman's sense of sexuality and intimacy.[22,35,36] Nipple-sparing mastectomy has evolved as a surgical alternative that is associated with better cosmetic outcome, greater patient satisfaction, psychosocial and sexual well-being, and higher health-related QoL.[37,38] Considering that few surgical alternatives are available for women with gynecologic cancer, the impact of gynecologic surgery on psychosocial well-being must be identified and addressed in this cohort of cancer patients. Men with prostate and testicular cancer also suffer from changes to body image, self-perceived masculinity, and QoL after surgery.[39] Among testicular cancer survivors who undergo surgical removal of testis (orchiectomy) for cancer treatment, 7% report problems with ejaculation and erection, 17% report negative body image, 25% report decreased sexual interest, and 40% report reduced sexual activity 3 years after completion of therapy. Sexual dysfunction is particularly prevalent among men who undergo retroperitoneal lymph node dissection. Men who experience these unfavorable outcomes after cancer surgery also report lower marital satisfaction and compromised long-term relationships.[40] More than a quarter of men who undergo orchiectomy for unilateral testicular cancer opt for a testicular prosthesis, noting reasons related to regaining accepted male appearance, and more than 80% note long-term satisfaction with the prosthesis.[41] It is clear that anatomic changes related to cancer therapy have significant implications for self-image, sexual health, and QoL among men and women with cancer and must be appropriately addressed in the comprehensive care of cancer survivors.

Logistics of Fertility Preservation

Importance of Fertility Preservation and Restoration

When aggressive chemotherapy and radiotherapy are used, gonadotoxicity may occur as a side effect, leading to impairment of reproductive function, impairment of gonadal steroid hormone–dependent tissues (e.g., bone and heart), and fertility loss. To avoid or at least mitigate these devastating complications, effective strategies for preserving and restoring fertility in young patients with cancer should be offered before, during, and after chemotherapy and radiotherapy.[42–46]

As the numbers of young cancer patients surviving into adulthood have increased due to advances in early diagnosis and treatment, long-term health issues such as fertility have gained growing attention. To date, assisted reproduction technologies (ARTs), cryobiology, and experimental translational medicine protocols have been utilized to prevent or overcome chemotherapy- and radiotherapy-induced gonadotoxicity in patients with cancer to preserve and restore fertility. Each fertility preservation option has advantages and disadvantages and may not be feasible for all patients. A growing recognition of the importance of fertility preservation for patients with cancer is underscored by the numerous international fertility preservation and restoration guidelines that have been published in the past years by the American Society of Clinical Oncology (ASCO),[47–49] the American Society for Reproductive Medicine (ASRM),[50,51] the European Society for Medical Oncology (ESMO),[52,53] the American Oncofertility Consortium,[54,55] the International Society for Fertility Preservation,[56–59] the National Comprehensive Cancer Network,[60] the American Academy of Pediatrics,[61] the Association of Pediatric Hematology/Oncology Nurses,[62] and FertiPROTEKT (the German fertility preservation network).[63–65]

Fertility Loss, Preservation, and Restoration in Female Cancer Patients

Epidemiology of Cancer in Young Female Patients

According to statistics from the United Kingdom (2013–2015), the most common cancers in prepubertal girls (age 0–14 years) are leukemias (29%), CNS malignancies (28%), lymphomas (7%), and renal (6%) cancers. The most common cancers in female adolescents and young adults (AYA) (age 15–24 years) are lymphomas (20%), melanoma (16%), CNS (14%), and leukemias (7%). The most common cancers in adult females (age 25–49 years) are breast (44%), melanoma (9%), cervical (8%), CNS (6%), and ovarian (5%). The most common cancers that occur during the female reproductive years and may require aggressive gonadotoxic chemotherapy and radiotherapy are breast, cervical, leukemia, lymphoma, CNS, renal, and bone[64] (Table 46.1).

Risks of Gonadotoxicity and Fertility Loss in Young Female Patients

In young female patients undergoing cancer treatment, gonadotoxicity, POI, premature ovarian failure (POF), and fertility loss are more likely to occur when the ovaries are exposed to alkylating chemotherapies such as cyclophosphamide, ifosfamide, and busulfan; after ionizing radiotherapy to the pelvis and abdomen; or following cranial or total-body irradiation. The degree of gonadotoxicity depends mainly on the type, dose, and duration of cancer therapy, as well as the age of the patient and the type and

TABLE 46.1 Common Cancers Across the Life Span According to Reproductive Age in the United Kingdom (2013–2015)

	Female	Male
Prepubertal (0–14 years)	Leukemias (29%), central nervous system (28%), lymphoma (7%), and renal (6%)	Leukemias (31%), central nervous system (26%), and lymphoma (13%)
Adolescents and young adults (15–24 years)	Lymphomas (20%), melanoma (16%), central nervous system (14%), and leukemias (7%)	Germ cell tumors (27%), lymphomas (22%), central nervous system (13%), and leukemias (10%)
Adults (25–49 years)	Breast (44%), melanoma (9%), cervix (8%), central nervous system (6%), and ovary (5%)	Testis (14%), melanoma (11%), central nervous system (10%), bowel (10%), and head and neck (8%)
Most common types of cancer that may require aggressive (gonadotoxic) anticancer chemotherapy and radiotherapy and necessitate prior fertility preservation measures	Breast, cervical, leukemia, lymphoma, central nervous system	Testicular, germ cell tumor, leukemia, lymphoma, central nervous system

Data from Cancer Research UK. Cancer incidence by age. Available at http://www.cancerresearchuk.org/health-professional/cancer-statistics/incidence/age. Accessed February 8, 2019.

stage of cancer. Some guidelines have attempted to classify cancer treatments according to their gonadotoxicity and associated risks of POF and fertility loss in women[47–49,66,67] (Table 46.2).

Fertility Preservation and Restoration Options for Young Female Patients

When the estimated risk of gonadotoxicity from cancer therapy is greater than 50%, fertility preservation strategies should be offered to young patients (<40 years of age) prior to starting treatment. Several established, debatable, and experimental options are available for fertility preservation for young women and girls with cancer. Established options include embryo freezing and egg freezing. Debatable options include ovarian protection techniques such as treatment with GnRH analogues and hormonal suppression, surgical ovarian transposition (oophoropexy), gonadal shielding, and the use of fractionated chemotherapy and radiotherapy. Experimental options include ovarian tissue freezing for use in future autotransplantation, oocyte in vitro maturation (IVM), artificial ovary systems, stem cell transplantations, and neoadjuvant cytoprotective pharmacotherapy, among others[68–74] (Table 46.3 and Fig. 46.1).

Established Options for Fertility Preservation in Women and Girls

Embryo Freezing

Embryo freezing was the first established method for preserving female fertility and is still considered the gold standard. It involves cryopreservation of in vitro–fertilized mature oocytes via slow freezing or vitrification; the latter is now preferred due to a better post-thaw survival rate.[75–77] Embryo freezing requires prior ovarian stimulation, mature oocyte retrieval, and sperm for in vitro fertilization (IVF).[78–83] Therefore, it is not suitable for prepubertal girls who have an inactive hypothalamic-pituitary-ovarian axis and for single women who do not wish to use donated sperm for personal, ethical, or religious reasons. It is also not suitable for women with estrogen-sensitive cancers, such as breast and endometrial cancers, as conventional ovarian stimulation may lead to high serum estrogen levels. Alternative ovarian stimulation protocols to minimize the effects of elevated estrogen use either tamoxifen (a selective estrogen receptor modulator)[84,85] or letrozole (an aromatase inhibitor).[86–91] In addition, conventional ovarian stimulation may take up to several weeks and carries a risk of ovarian hyperstimulation syndrome); thus, it may not be a suitable option for women with highly aggressive malignancies (e.g., hematologic) that require immediate cancer treatment. For these women, random-start ovarian stimulation for emergency fertility preservation may be an option.[92–99] The standard storage period for frozen embryos, eggs, and sperm is 10 years, although longer storage periods may be possible. In healthy women, the live birth rate per frozen embryo transfer is nearly 30%.[100–102] However, in women with cancer, the live birth rate per frozen embryo transfer is reduced to approximately 15%, without any increased risk for congenital abnormalities.[103]

Egg Freezing

In 2012, the ASRM approved egg freezing as an established option for female fertility preservation.[104] Egg freezing involves cryopreservation of mature oocytes via slow freezing or vitrification.[105–108] Like embryo freezing, egg freezing requires prior ovarian stimulation for mature oocyte retrieval but does not involve IVF. Thus, egg freezing is not suitable for prepubertal girls; however, it is an option for single women who do not want to use donor sperm. Egg freezing carries the same disadvantages related to ovarian stimulation mentioned earlier for embryo freezing. In healthy women, the live birth rate per frozen oocyte is approximately 6% but continues to improve steadily due to advances in vitrification protocols and egg donation programs.[109–113] However, in women with cancer, there is not enough data on egg freezing outcomes to estimate the live birth rate per frozen oocyte. To date, only a few live births have been reported after oocyte vitrification in women with cancer.[113–115] Until more data become available, extrapolating the outcomes of egg freezing to female cancer patients should be done with caution during oncofertility counseling.

Debatable Options for Fertility Preservation in Women and Girls

GnRH Analogues and Hormonal Suppression

GnRH analogues are commonly prescribed in the fields of gynecologic endocrinology and reproductive medicine; however, the role of GnRH analogue treatment before and during chemotherapy to protect the ovaries from damage is widely debated.[116–120] Some randomized trials, systematic reviews, and meta-analyses

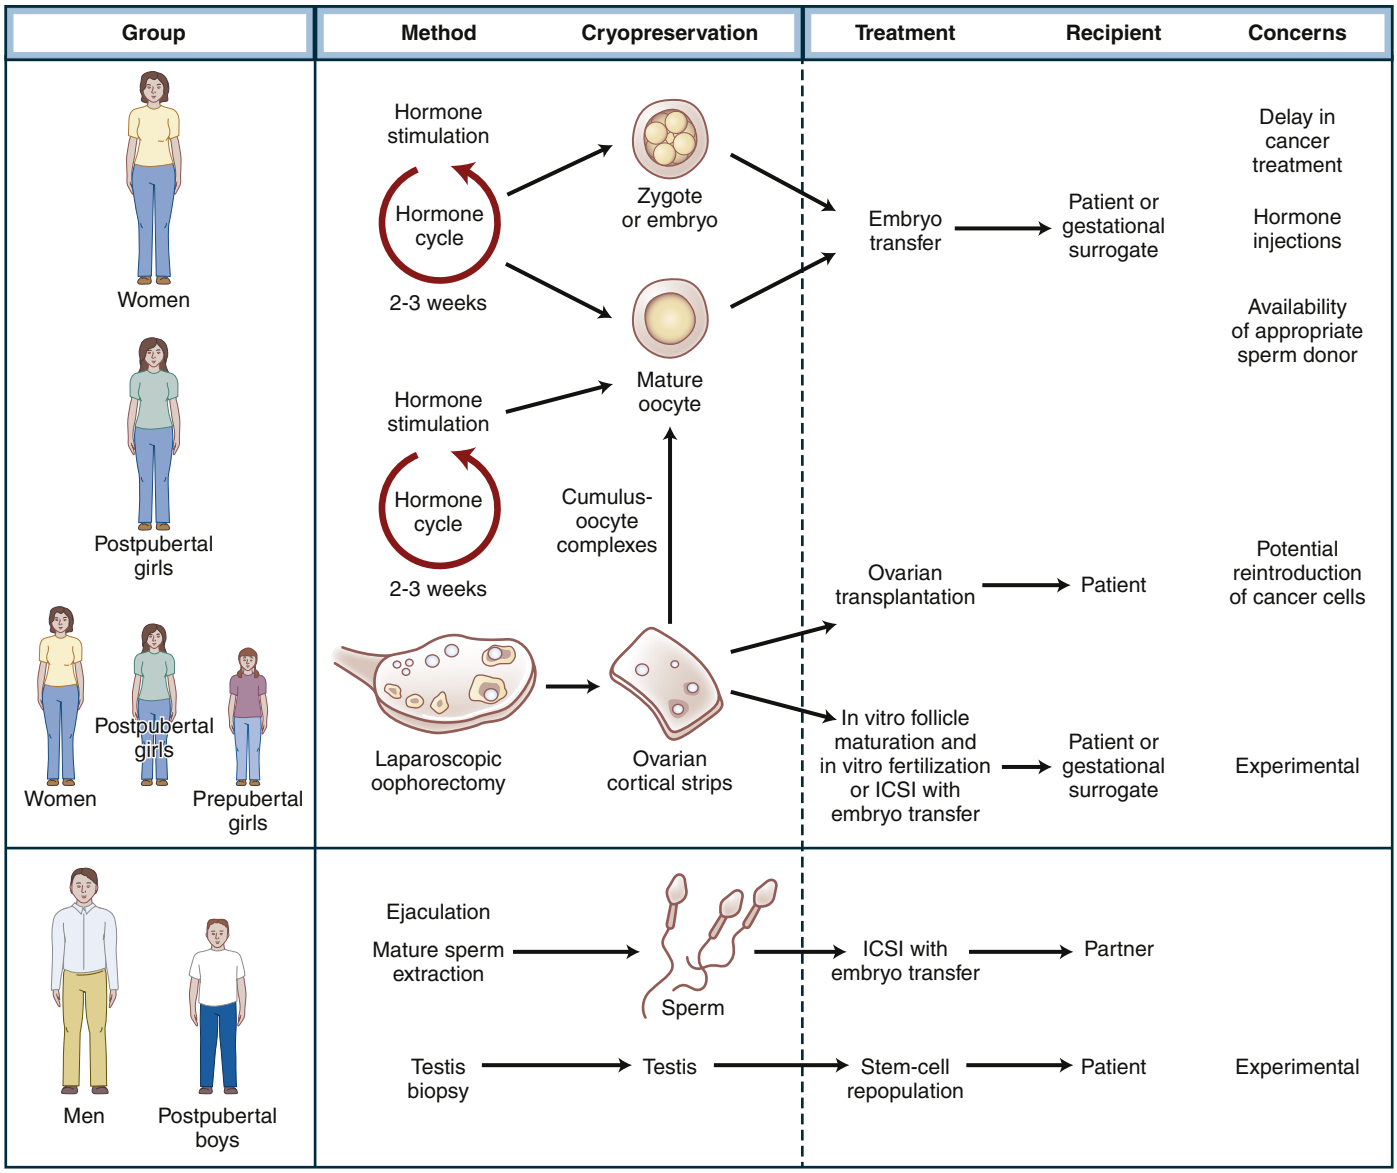
TABLE 46.2 Anticancer Therapy and Related Risks of Gonadotoxicity and Fertility Loss

Risk Level	Risk in Females	Risk in Males
High	• Hematopoietic stem cell transplantation with cyclophosphamide/total-body irradiation (TBI) or cyclophosphamide/busulfan • External beam radiation to a field that includes the ovaries. • CMF, CEF, CAF × 6 cycles in women 40 years and older (adjuvant breast cancer therapy) • Surgical removal of one or both ovaries or the pituitary gland	• TBI • Testicular radiation dose >2.5 Gy in men • Testicular radiation dose >6 Gy in boys • Cranial radiation >40 Gy • Protocols containing procarbazine: COPP, MOPP, MVPP, ChlVPP, ChlVPP/EVA, MOPP/ABVD, COPP/ABVD • Alkylating chemotherapy for transplant conditioning (cyclophosphamide, busulfan, melphalan) • Any alkylating agent (e.g., procarbazine, nitrogen mustard, cyclophosphamide) + TBI, pelvic radiation, or testicular radiation • Total cyclophosphamide dose >7.5 g/m^2 • Surgical removal of one or both testicles or the pituitary gland
Intermediate	• CMF, CEF, CAF × 6 cycles in women age 30–39 years (adjuvant breast cancer therapy) • AC × 4 cycles in women 40 years and older (adjuvant breast cancer therapy)	• Testicular radiation dose 1–6 Gy (due to scatter from abdominal/pelvic radiation) • BEP x 2–4 cycles • Cumulative cisplatin dose >400 mg/m^2 • Cumulative carboplatin dose ≥2 g/m^2 • Hormone treatments (prostate cancer) • Surgical procedures within in the pelvis (prostate, bladder, lower large intestine, rectum) • CHOP/COP
Low	• ABVD • CHOP × 4–6 cycles • CVP • Acute myeloid leukemia therapy (anthracycline/cytarabine) • Acute lymphoblastic leukemia therapy (multiagent) • CMF, CEF, CAF × 6 cycles in women younger than 30 years (adjuvant breast cancer therapy) • AC × 4 cycles in women younger than 40 years (adjuvant breast cancer therapy)	• Testicular radiation dose 0.2–0.7 Gy • Nonalkylating agents: ABVD, multiagent therapies for leukemia • Anthracycline + cytarabine • Bevacizumab (Avastin)
Very low or none	• Methotrexate, fluorouracil, vincristine, bleomycin, dactinomycin.	• Testicular radiation dose <0.2 Gy • Radioactive iodine • Multiagent therapies using vincristine
Unknown	• Taxanes, oxaliplatin, irinotecan, monoclonal antibodies, tyrosine kinase inhibitors.	• Irinotecan • Monoclonal antibodies such as cetuximab (Erbitux) • Tyrosine kinase inhibitors such as erlotinib (Tarceva), imatinib (Gleevec)

ABVD, Doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine; *AC,* doxorubicin (Adriamycin), cyclophosphamide; *BEP,* bleomycin, etoposide, cisplatin; *CAF,* cyclophosphamide, doxorubicin (Adriamycin), fluorouracil; *CEF,* cyclophosphamide, epirubicin, fluorouracil; *ChlVPP,* chlorambucil, vinblastine, procarbazine, prednisolone; *CHOP,* cyclophosphamide, hydroxydaunomycin, Oncovin, prednisone; *CMF,* cyclophosphamide, methotrexate, fluorouracil; *COP,* cyclophosphamide, Oncovin, prednisone; *COPP,* cyclophosphamide, Oncovin, procarbazine, prednisone; *CVP,* cyclophosphamide, vincristine, prednisone; *EVA,* etoposide, vinblastine, Adriamycin (doxorubicin); *MOPP,* mechlorethamine, Oncovin (vincristine), procarbazine, prednisone; *MVPP,* mechlorethamine, vinblastine, procarbazine, prednisolone; *NOVP,* Novantrone (mitoxantrone), Oncovin, vinblastine, prednisone; *OEPA,* Oncovin, etoposide, prednisone, Adriamycin (doxorubicin).

TABLE 46.3 Fertility Preservation Options for Patients Undergoing Gonadotoxic Anticancer Therapy

Option	Females	Males
Established	• Embryo freezing • Egg freezing	• Sperm freezing
Debatable	• Gonadotropin-releasing hormone (GnRH) analogues and hormonal suppression • Oophoropexy • Gonadal shielding • Fractionated chemotherapy and radiotherapy	• GnRH analogues and hormonal suppression • Gonadal shielding • Fractionated chemotherapy and radiotherapy
Experimental	• Ovarian tissue freezing and autotransplantation • In vitro maturation of oocytes and vitrification • Artificial ovary • Stem cells • Neoadjuvant cytoprotective pharmacotherapy • Others	• Testicular tissue freezing • Stem cells • Neoadjuvant cytoprotective pharmacotherapy • Others



• **Fig. 46.1** Options for fertility preservation in patients with cancer. ICSI, intracytoplasmic sperm injection. (Redrawn from Jeruss JS, Woodruff TK. Preservation of fertility in patients with cancer. *N Engl J Med*. 2009;360[9]:902–911.)

have shown a correlation between administration of GnRH analogues before and during chemotherapy and lower rates of POF in female cancer survivors.[119,121–126] The mechanism of action of GnRH analogues and their direct and indirect effects on ovaries are not fully understood. It is known that GnRH analogues suppress gonadotropin secretion from the pituitary gland and hence suppress ovarian function indirectly.[127,128] Some theories suggest that administration of GnRH analogues before and during chemotherapy suppresses the ovaries, decreasing the number of primordial follicles entering the growing pool; these dormant follicles are thought to be less sensitive to the gonadotoxic effects of chemotherapeutic agents. Other theories suggest a direct protective effect of GnRH analogues on the ovaries, including via upregulation of intraovarian antiapoptotic molecules and protection of ovarian germline stem cells.[129,130] In most patients, GnRH analogues have not been shown to protect ovaries from radiotherapy-induced gonadotoxicity. For this reason, GnRH analogues are not recommended for fertility preservation in female patients with cancer scheduled to undergo pelvic irradiation. According to ASCO, European Society for Medical Oncology, and ASRM guidelines,[47–53] GnRH analogues and other hormonal suppression methods (e.g., oral contraceptives) should not be relied on as female fertility preservation methods. Nevertheless, several recent publications have encouraged the use of GnRH analogues to preserve female fertility during chemotherapy.[128,131–139]

Oophoropexy

Oophoropexy is the surgical transposition of ovaries away from the field of pelvic irradiation, which is often used to treat pelvic malignancies such as Hodgkin lymphoma, cervical carcinoma, vaginal carcinoma, and pelvic sarcoma. During oophoropexy, ovaries can be transposed either laterally toward the pelvic wall or medially behind the uterus. Although underutilized, oophoropexy can be carried out via mini-laparotomy, laparoscopy, or even robotic surgery. The simplest and most successful technique is laparoscopic lateral oophoropexy. Oophoropexy has been

performed on one ovary while the other ovary is excised for ovarian tissue freezing.[140–146] According to ASCO guidelines, the success of oophoropexy in protecting ovaries and preserving fertility is debatable and varies according to the dose, site, and type of pelvic irradiation; the age of the patient; and whether radiation is combined with chemotherapy. There is also the probability of remigration of the transposed ovaries to their original positions during the course of radiotherapy. Following successful oophoropexy, spontaneous pregnancy may be possible without the need for ART. Oophoropexy does not protect ovaries from chemotherapy induced-gonadotoxicity. For this reason, it is not recommended for female patients with cancer scheduled to receive concomitant chemotherapeutic treatments.[47,48]

Gonadal Shielding

Gonadal shielding should be routinely used during pelvic irradiation to provide some ovarian protection, especially in young patients. Similar to oophoropexy, gonadal shielding does not protect ovaries from chemotherapy induced-gonadotoxicity and therefore has a limited role when chemotherapy is combined with radiation therapy.[47–63]

Fractionated Chemotherapy and Radiotherapy

Fractionation of chemotherapy and radiotherapy doses may reduce gonadotoxicity and gonadal damage and should be attempted whenever possible.[47–63,65]

Experimental Options for Fertility Preservation in Women and Girls

Ovarian Tissue Freezing and Autotransplantation

Ovarian tissue freezing is still considered an experimental method for female fertility preservation. It involves cryopreservation of surgically excised cortical ovarian tissues for later use in autotransplantation or in vitro oocyte maturation.[147–151] Additionally, immature oocytes could be retrieved directly from the extracted ovarian tissue for IVM and vitrification.[152–157] At least half of one ovary is excised via laparoscopy or laparotomy before the initiation of cancer treatment. The extracted ovarian tissue is transported within 24 hours under special conditions to central cryobanks to be processed by experienced oncofertility teams.[158–160] Ovarian tissue freezing is performed via slow freezing[161–163]; however, vitrification protocols have been attempted in numerous research trials with promising results.[164–168]

After recovery from cancer and when pregnancy is desired, the frozen ovarian tissue can be thawed and transplanted back into the same patient (autotransplantation), typically onto the remaining ovary or ovarian fossa. In the case of severe pelvic adhesions or poor pelvic vasculature due to previous irradiation, frozen-thawed ovarian tissue can be autotransplanted heterotopically to other sites, such as the subcutaneous space of abdominal wall or forearm. Following successful ovarian tissue freezing and autotransplantation, ovarian function may resume between 2 and 9 months postoperatively and may last for several years. After orthotopic autotransplantation, spontaneous pregnancy can be expected or patients with either orthotopic or heterotopic transplants can undergo ovarian stimulation, oocyte retrieval, and IVF. Although an international registry is still needed, at least 120 healthy babies have been born worldwide after ovarian tissue slow freezing and orthotopic autotransplantation, without any increased risk for miscarriage or congenital abnormalities. In such cases, the live birth rate per transplant was roughly estimated to be 25%. Ovarian tissue vitrification and heterotopic autotransplantation have resulted in few reported live births.[169–173]

Ovarian tissue freezing followed by autotransplantation may be the only suitable fertility preservation option for prepubertal girls, although few babies have been born in women whose ovarian tissue was frozen before puberty.[174,175] Compared with the established female fertility preservation options (embryo and egg freezing), ovarian tissue freezing and autotransplantation does not need prior ovarian stimulation and therefore does not delay cancer treatments. Moreover, this option can also restore both endocrine and reproductive ovarian function for several years.[147–151]

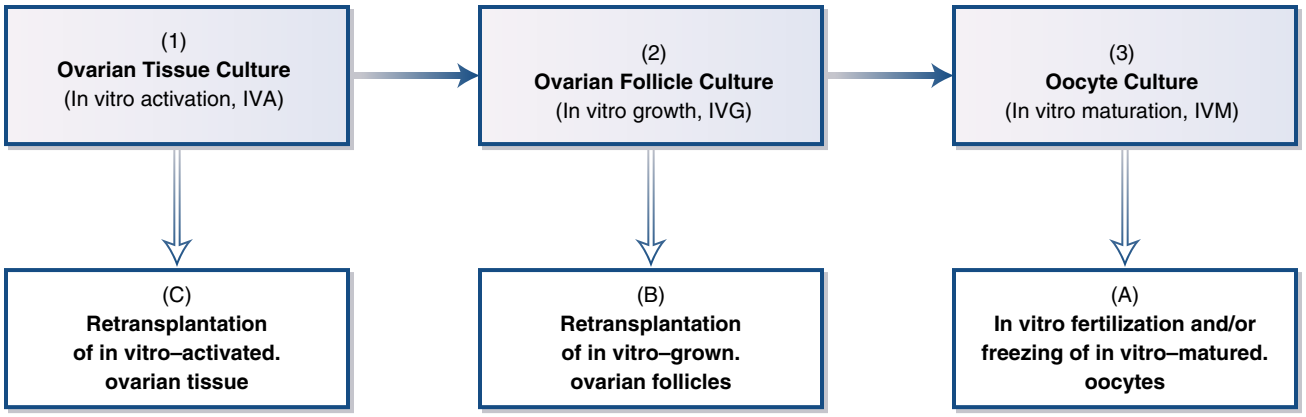
Transplantation of fresh and frozen-thawed ovarian tissue between monozygotic twin sisters has been successful, resulting in healthy live births.[176–178] Whole ovary cryopreservation via slow freezing or vitrification has been studied in human and several animal species.[179–182] However, the major challenges associated with cryopreservation and autotransplantation of the whole ovary are the very high follicular loss due to related cryoinjury and post-transplantation vascular complications and ischemia.[183–187]

Although promising, the use of autotransplantation of frozen-thawed ovarian tissue for fertility preservation in patients with cancer presents a significant and serious concern of possible contamination of ovarian tissue with malignant cells, or the presence of minimal residual disease in the case of ovarian carcinomas or in malignancies that may metastasize in ovaries. According to several studies, systematic reviews, and meta-analyses assessing the risk of reintroducing malignant cells, autotransplantation of frozen-thawed ovarian tissue should be absolutely contraindicated for women with any type of ovarian carcinoma or leukemia (high risk). It may be an option in women with Hodgkin lymphoma, and breast, bone, and connective tissue malignancies (mild risk), or with non-Hodgkin lymphoma and gastrointestinal cancers (moderate risk).[150,188–191] To assess the risk of reintroducing malignant cells, several tests can be performed on the excised tissue prior to autotransplantation, including histologic examination, in vitro culture, immunohistochemistry, polymerase chain reaction, multicolor flow cytometry, and long-term xenografting of ovarian tissue into immunodeficient mice.[159,192–200] The first delivery in a leukemia survivor after autotransplantation of cryopreserved ovarian tissue evaluated for leukemia cells contamination prior to reimplantation has recently been reported.[201] Although remarkable, it is not clear whether the risk of contamination is the same for all patients with leukemia; rather, it appears to be case dependent, and the results should therefore be extrapolated to oncofertility care with caution.

IVM of Oocytes

Considering that autotransplantation of frozen-thawed ovarian tissue should be absolutely contraindicated in some patients due to a high risk of ovarian tissue contamination with malignant cells or because of the presence of minimal residual disease, the safest way to restore fertility may be IVM of oocytes and artificial ovary technology.

In vitro, immature oocytes can be retrieved directly from extracted ovarian tissue and from unstimulated ovaries through a routine ultrasound-guided transvaginal approach. The retrieved immature oocytes are cultured in vitro for 24 to 48 hours to mature into metaphase II oocytes ready for either IVF or vitrification.[202–205] Although IVM is technically challenging, it is feasible for all patients, including prepubertal girls. Recently, the success rates of oocyte IVM have improved,[206–209] and a few new reports have shown comparable results to traditional IVF.[210,211]



• **Fig. 46.2** Artificial human ovary: the concept (*blue boxes*) and the applications (*white boxes*). (Redrawn from Salama M, Isachenko V, Isachenko E, Rahimi G, Mallmann P. Advances in fertility preservation of female patients with hematological malignancies. *Expert Rev Hematol*. 2017;10[11]:951–960.)

Artificial Ovary

The ovarian bioprosthetic, or artificial ovary, is a novel experimental technology that aims to produce mature oocytes ready for IVF through an ex vivo multistep strategy that includes sequential in vitro culture of ovarian tissue, follicles, and oocytes.[212–214] Although successful only in mice,[215,216] research is under way to improve artificial ovary methodology and outcomes and help to establish this technology for translation to clinical care[217] (Fig. 46.2).

Ovarian tissue culture (encapsulated in vitro follicle growth) involves in vitro culture of fresh or frozen-thawed human cortical ovarian tissue pieces from 6 to 10 days to activate the growth of primordial follicles within the tissue to reach preantral stages.[218,219] Preantral follicles are then isolated enzymatically and/or mechanically from the cultured ovarian tissue and cultured individually for up to 4 weeks in a biodegradable three-dimensional (3D) microenvironment made of alginate, matrigel, fibrin, or other biomaterials.[220] The 3D in vitro follicle culture supports preantral follicle growth to the early antral stage.[221–225] These in vitro–grown early antral follicles are then released enzymatically and/or mechanically from the surrounding 3D microenvironment and punctured to release the enclosed oocytes.[226] Finally, the released immature oocytes are cultured in vitro for 24 to 48 hours to mature into metaphase II oocytes ready for IVF or vitrification.[152–157]

Additional applications of the artificial ovary have included (1) IVF and/or vitrification of in vitro–matured oocytes,[152–157] (2) retransplantation of in vitro–grown ovarian follicles within a 3D biodegradable microenvironment with potential success in a xenotransplantation mouse model,[227–231] and (3) retransplantation of in vitro–activated ovarian tissue with reported live births in patients with POF[232–234] (see Fig. 46.2). Additional emerging technologies with potential applications in the field of female fertility preservation and restoration include tissue engineering[235] and 3D-printed organs.[236] The 3D-printed bioprosthetic ovary is a novel experimental technology in which isolated ovarian follicles are embedded in 3D-printed microporous hydrogel scaffolds to support follicle growth after transplantation in vivo. Full restoration of ovarian function after transplantation of a bioprosthetic ovary in surgically sterilized mice has been accomplished. After natural mating, mice with 3D-printed ovaries produced healthy pups.[236] These findings open a new horizon for creating a 3D-printed artificial human ovary to restore fertility in cancer patients.

Stem Cells

Due to recent advances in stem cell research over the past decades, many studies have examined potential applications in the field of female reproductive endocrinology and infertility. The recent discovery of ovarian (oogonial) stem cells and the creation of induced pluripotent stem cells has revealed new opportunities to maintain ovarian follicle and oocyte production, which normally halts just after birth. Stem cell–based therapies could potentially treat various conditions leading to infertility, including POF following aggressive gonadotoxic chemotherapy and radiotherapy.[237–245] Although promising, there is still a long way to go to translate stem cell science into routine clinical practice.

Neoadjuvant Cytoprotective Pharmacotherapy

The development of mitigation strategies to reduce chemotherapy- and radiotherapy-induced gonadotoxicity is another approach being taken in fertility preservation research. Recently, several strategies have been attempted to reduce the gonadotoxic effects of specific chemotherapeutic agents in animal models, with promising results. Examples of such strategies include the use of nanoencapsulated arsenic trioxide,[246] c-Abl-TAp63 pathway inactivation by imatinib,[247,248] and use of the GnRH analogue triptorelin.[123,249,250] S1P,[251] AS101,[252] and FTY720[253] treatments have also been investigated as approaches to reduce radiotherapy-induced gonadotoxicity.

Fertility Loss, Preservation, and Restoration in Male Patients With Cancer

Epidemiology of Cancer in Young Male Patients

According to statistics from the United Kingdom (2013–2015), the most common cancers in prepubertal boys (age 0–14 years) are leukemias (31%), CNS cancers (26%), and lymphomas (13%). The most common cancers in AYA males (age 15–24 years) are germ cell tumors (27%), lymphomas (22%), CNS cancers (13%), and leukemias (10%). The most common cancers in adult males (age 25–49 years) are testicular (14%), melanoma (11%), CNS (10%), bowel (10%), and head and neck cancers (8%). The most common cancers that arise during the male reproductive years that may require aggressive gonadotoxic chemotherapy and radiotherapy are testicular cancer, germ cell tumors, leukemia, lymphoma, and CNS cancer[64] (see Table 46.1).

Risks of Gonadotoxicity and Fertility Loss in Young Male Patients

In young male patients undergoing cancer treatment, gonadotoxicity, azoospermia, and subsequent fertility loss usually occur when the testes are exposed to alkylating chemotherapies such as chlorambucil, nitrogen mustard, and cyclophosphamide, or to ionizing radiotherapy to the pelvis and abdomen or cranial or total-body irradiation. The degree of gonadotoxicity depends mainly on the type, dose, and dosage of cancer therapy, as well as the age of the patient and the type and stage of cancer. Cancer treatments have been classified according to their risk of gonadotoxicity, azoospermia, and subsequent fertility loss in men[24,254–259] (see Table 46.2).

Fertility Preservation and Restoration Options in Young Male Patients

As in female patients with cancer, when the estimated risk of gonadotoxicity is greater than 50%, fertility preservation strategies should be offered to young male patients (<40 years of age) prior to cancer treatment. To preserve the fertility of young men and boys with cancer, a few established, debatable, and experimental options can be offered. The established option is sperm freezing. Debatable options include the use of GnRH analogues and hormonal suppression, gonadal shielding, and fractionated chemotherapy and radiotherapy. Experimental options include testicular tissue freezing, stem cells, neoadjuvant cytoprotective pharmacotherapy, and others[260–263] (see Table 46.3 and Fig. 46.1).

Established Options for Fertility Preservation in Men and Boys

Sperm Freezing

Sperm freezing is the first and the only established method for male fertility cryopreservation; since the 1950s, sperm freezing has been considered the gold standard option.[264,265] It involves sperm retrieval and cryopreservation of spermatozoa via slow freezing or vitrification; the latter approach is now preferred due to a better post-thaw survival rate.[266,267] Recently, cryoprotectant-free vitrification of human spermatozoa has been attempted and resulted in healthy live births.[268–270] Under normal conditions, sperm samples are obtained from adults and adolescents males by masturbation. However, in case of ejaculation disorders, vibratory or electrical stimulation can be used to obtain sperm. In patients with retrograde ejaculation, spermatozoa can be isolated from urine. When obstructive or nonobstructive azoospermia is diagnosed, testicular sperm aspiration or extraction can be performed to obtain sperm.[271–273] In clinical practice, frozen and fresh sperm have comparable live birth rates, and according to some reports, frozen sperm can be stored for more than 20 years without negative side effects. Healthy live births have been reported from IVF with semen stored for 21 years,[274] from intrauterine insemination with semen stored for 28 years,[275] and from intracytoplasmic sperm injection with semen stored for 40 years.[276]

Debatable Options for Fertility Preservation in Men and Boys

GnRH Analogues and Hormonal Suppression

The use of GnRH analogues before and during chemotherapy in males has been shown to have a gonadoprotective effect in mouse and rat models, but it does not appear to have the same effect in human and nonhuman primates.[277,278] In most cases, GnRH analogues do not protect the testes from radiotherapy-induced gonadotoxicity. Other hormonal methods to suppress testes with androgens and antiandrogens have not shown promising gonadoprotective effects in adult men. For these reasons, ASCO does not recommend the use of GnRH analogues and other hormonal suppression methods for male fertility preservation.[47–49]

Gonadal Shielding

Gonadal shielding should be routinely used during pelvic irradiation to provide some testicular protection, especially in young patients. However, gonadal shielding does not protect testes from chemotherapy-induced gonadotoxicity and therefore has a limited role when chemotherapy is combined with radiation.[47–63,65]

Fractionated Chemotherapy and Radiotherapy

As in women and girls with cancer, fractionation of chemotherapy and radiotherapy doses may reduce gonadotoxicity and gonadal damage and should be attempted whenever possible.[47–63,65]

Experimental Options for Fertility Preservation in Men and Boys

Testicular Tissue Freezing

Testicular tissue freezing is an experimental option that may be offered when sperm production is not possible, such as in prepubertal boys or in adults with azoospermia. In this technique, spermatogonial stem cells, either within the testicular tissue or as a cell suspension, are frozen via slow freezing or vitrification and stored for future autotransplantation, in vitro culture, or in vitro spermatogenesis.[279] As with ovarian tissue, autotransplantation of frozen-thawed testicular tissue may carry the risk of reintroducing malignant cells back into the patient, especially in patients with testicular cancer or malignancies that metastasize to the testes, such as leukemia. To date, testicular tissue freezing and spermatogonial stem cell autotransplantation, xenografting, in vitro culture, and in vitro spermatogenesis have proven more promising in mice than in other animal species and humans.[271,279–285]

Stem Cells

The recent discovery of spermatogonial stem cells and creation of induced pluripotent stem cells have opened new horizons for the recovery and maintenance of spermatogenesis after aggressive gonadotoxic chemotherapy and radiotherapy.[286–292] Although promising, much work still needs to be done to realize the promise of stem cell research for the clinical practice of fertility preservation.

Neoadjuvant Cytoprotective Pharmacotherapy

Although the development of neoadjuvant cytoprotective pharmacotherapy strategies to reduce chemotherapy- and radiotherapy-induced gonadotoxicity is an important topic of interest in fertility preservation research, few studies have examined the use of these strategies in men. Partial success has been observed with the immunomodulatory AS101 and carnitine in rodents.[293,294]

Other Experimental Options

Recently, several research technologies have emerged with potential applications in the field of male fertility preservation and restoration. Examples of such technologies include testicular tissue culture, in vitro spermatogenesis, and gene therapy.[295–302]

TABLE 46.4 Plausible Fertility Preservation and Restoration Strategies for Female Patients With Cancer

Age	Before Anticancer Therapy (Fertility Preservation)	During Anticancer Therapy (Fertility Preservation)	After Anticancer Therapy (Fertility Restoration)
Prepubertal (0–14 years)	• Ovarian tissue freezing • IVM of oocytes and vitrification • Oophoropexy	• Gonadal shielding • Fractionation of chemotherapy and radiotherapy • Neoadjuvant cytoprotective pharmacotherapy	• IVF/ICSI of frozen oocytes • Autotransplantation of frozen ovarian tissue • Artificial ovary • Stem cells
Adolescent & young adult (15–24 years)	• Egg freezing • Embryo freezing • Ovarian tissue freezing • IVM of oocytes and vitrification • Oophoropexy	• GnRH analogues and hormonal suppression • Gonadal shielding • Fractionation of chemotherapy and radiotherapy • Neoadjuvant cytoprotective pharmacotherapy	• IVF/ICSI of frozen oocytes • Intrauterine transfer of frozen embryo • Autotransplantation of frozen ovarian tissue • Artificial ovary • Stem cells
Adult (25–40 years)	• Embryo freezing • Egg freezing • Ovarian tissue freezing • IVM of oocytes and vitrification • Oophoropexy	• GnRH analogues and hormonal suppression • Gonadal shielding • Fractionation of chemotherapy and radiotherapy • Neoadjuvant cytoprotective pharmacotherapy	• Intrauterine transfer of frozen embryo • IVF/ICSI of frozen oocytes • Autotransplantation of frozen ovarian tissue • Artificial ovary • Stem cells

GnRH, Gonadotropin-releasing hormone; *ICSI,* intracytoplasmic sperm injection; *IVF,* in vitro fertilization; *IVM,* in vitro maturation.

Decision-Making Strategies for Young Female and Male Patients With Cancer

To provide fertility preservation and restoration strategies to young patients with cancer, the treating center should be properly equipped, with a highly skilled team of oncologists, gynecologists, andrologists, reproductive biologists, transplantation surgeons, and research scientists. Referring patients from oncology clinics, small medical centers, or general hospitals to highly specialized oncofertility centers is strongly encouraged to guarantee a high standard of care.[1,303,304]

For young patients with cancer, it is recommended that oncofertility counseling starts immediately after diagnosis. If the patient is younger than 40 years and has a reasonable chance of survival, is in good health, and has satisfactory reproductive function, the cancer treatment plan should be reviewed by the oncofertility team and the risk of gonadotoxicity and subsequent fertility loss should be assessed. If the risk is greater than 50% and the patient wishes to have children in the future, a fertility preservation strategy should be pursued before and during chemotherapy and radiotherapy. After the patient completes cancer therapy and crosses into the realm of survivorship, a new assessment of endocrine and reproductive function should be performed. If it is determined that the patient suffers from cancer therapy–induced fertility loss, the frozen gametes, gonadal tissue, or stem cells can be used to restore fertility. From a clinical perspective, fertility preservation and restoration strategies should be tailored to each patient's circumstances and wishes, and may involve a combination of established, debatable, and experimental options (after obtaining informed consent from the patient or legal guardians in case of a child).[1,305–309] As shown in Tables 46.4 and 46.5, plausible strategies according to patient's gender and age can be attempted—when feasible and not contraindicated—before, during, and after cancer therapy.

If fertility preservation options are rejected, contraindicated, or unavailable, adoption and third-party reproduction (gamete donation and surrogacy) can be offered as alternatives when possible.[310,311] If third-party reproduction services are not available or not legally allowed, patients may consider traveling abroad to pursue these options. This growing phenomenon has been called *cross-border reproductive care* or *fertility tourism* in the media.[312–319]

Challenges of Fertility Preservation

Factors That Prohibit Oncofertility Support

Only about one third of AYA cancer survivors pursue fertility preservation.[21] Barriers to oncofertility support include both patient- and provider-related factors.[25] Female sex, age, ethnicity, relationship status and current parenthood, religious beliefs, economic concerns, self-perceived lack of time, and emotional distress, as well as functional status, type of malignancy, and prognosis at the time of diagnosis, are important contributors to the provision of and participation in adequate counseling on reproductive health.[25,26,320] Some cancer patients hesitate to initiate conversations about reproductive health with their health care team due to the assumption that the topic should first be introduced by their providers.[321] Furthermore, many patients making fertility preservation decisions are in the early stages of coping with their cancer diagnosis and are overwhelmed by considerations of personal mortality, cancer recurrence, and comorbidities related to cancer therapy, in addition to evaluating the financial and ethical implications of fertility preservation.[29]

Although more than 80% of cancer health care providers believe that reproductive health is important for cancer patients, more than 70% of providers feel unprepared to formally assess and address these concerns.[321] Provider age, practice setting, perception

TABLE 46.5 Plausible Fertility Preservation and Restoration Strategies for Male Patients With Cancer

Age	Before Anticancer Therapy (Fertility Preservation)	During Anticancer Therapy (Fertility Preservation)	After Anticancer Therapy (Fertility Restoration)

of inadequate training, time, and resources, and personal view of the patient's desire and comfort with discussing reproductive health also influence whether oncofertility is included in comprehensive cancer care.[25,321] Among providers caring for pediatric and adolescent cancer patients, discomfort with discussing reproductive health with sexually immature patients and their parents influences the extent to which reproductive health is addressed. In particular, providers express concerns regarding patients' decision-making capacity on issues pertaining to their future fertility.[322]

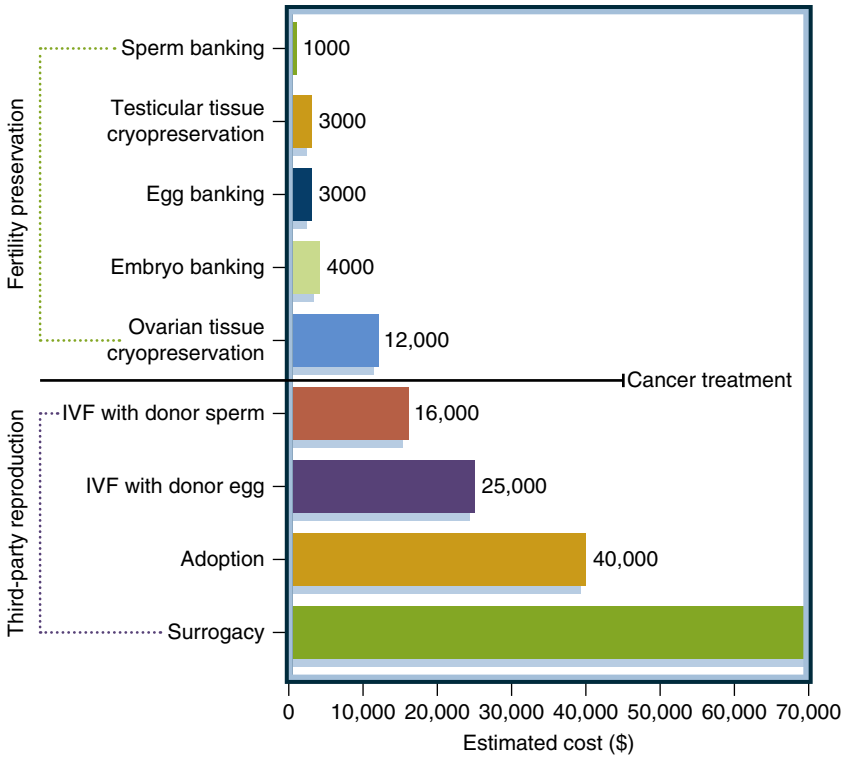
Both male and female cancer patients identify fertility as a high-priority element of their psychological and social well-being. Although an increasing number of cancer patients are receiving information about fertility preservation prior to treatment, fertility preservation options are highly underutilized,[21] partly due to insufficient referral to reproductive specialists after initial counseling.[323] Patients who undergo evaluation by a reproductive specialist are more likely to report better understanding of fertility preservation options prior to starting treatment, regardless of whether they pursue these options in the future.[323] Thus, effective execution of fertility preservation counseling requires an intricate level of communication and coordination and a shared sense of responsibility among those treating the cancer (oncologists, surgeons, radiologists) and fertility specialists and scientists.[324]

Special Patient Populations

The relationship between reproductive health and cancer diagnosis and treatment is particularly multifaceted for ethnic, cultural, and sexual minorities. Provision of oncofertility counseling varies by ethnicity.[320] Culturally specific beliefs about illness, spirituality, and mortality,[325] trust in the medical system[326] and medical decision making,[327] sexuality,[328,329] self-identity and autonomy,[330] and QoL[331] impact cancer patients' perspectives on the role that reproductive health plays in their overall well-being. Furthermore, patients' religious and cultural beliefs, specifically regarding gamete collection and storage, fertilization, procreation, and surrogacy, guide their selection among different fertility preservation options.[332] Thus, culturally competent oncofertility care is important, as it can improve patient-provider communication, reduce decision regret, and improve health-related QoL.[326]

Sexual minorities encounter distinct challenges relating to intimacy, fertility, and parenthood prior to, during, and after cancer therapy. On the one hand, members of the lesbian, gay, bisexual, transgender, or queer (LGBTQ) community who have cancer experience similar concerns regarding relationships, fertility, and body image as their heterosexual counterparts. On the other hand, LGBTQ cancer patients also uniquely express beliefs in the "chosen family," which is a family founded on love and kinship and not necessarily blood or biologic relation; they are more open to alternative parenting options, such as adoption, gamete donation, and surrogacy, and report less impact of fertility on their relationships compared with heterosexual cancer patients. Because many providers may not appropriately address these unique aspects of intimacy, relationships, and family building, almost one-third of LGBTQ cancer patients report unsatisfactory counseling about reproductive health prior to cancer treatment.[333]

Decisions regarding fertility and family building are also challenging for pregnant women with cancer, who comprise about 0.1% of the population of all pregnant women.[334] Although rare, the common cancers diagnosed during pregnancy include breast (the most common) and cervical cancers, Hodgkin lymphoma, non-Hodgkin lymphoma, ovarian cancer, malignant melanoma, leukemia, and thyroid and colorectal cancers.[335,336] Pregnant women with cancer may struggle with distinguishing between cancer- and pregnancy-related symptoms, are hesitant to undergo certain imaging or other diagnostic procedures, and are concerned about the possibility of missing clinically obscure cancers in the setting of pregnancy-related changes to their bodies. As such, they are at higher risk of pregnancy termination.[337] Because of the complexity of cancer during pregnancy, guidelines for the prenatal care for women with cancer during pregnancy have been established.[338] Treatment requiring surgery, radiotherapy, or chemotherapy necessitates close monitoring by a multidisciplinary team of oncologists, obstetricians, neonatologists, cardiologists, pharmacologists, surgeons, radiation oncologists, ethicists, and mental health providers. Live birth rates as high as 86% have been reported among pregnant women with cancer, whereas the rates of preterm delivery, small for gestational age birth weight, and neonatal intensive care unit admission are 48%, 21%, and 41%, respectively. Maternal age, type of cancer, extent of disease (systemic vs. localized), and type of chemotherapeutic agent (e.g.,



• **Fig. 46.3** Cost of fertility preservation versus third-party reproduction. Potential costs vary by state, institution, and insurance status. Fertility preservation costs do not include annual storage fees of reproductive tissues (approximately $250/year) or cost of in vitro fertilization (IVF; approximately $12,000). (Courtesy the Oncofertility Consortium and Teresa K. Woodruff.)

platinum based, taxanes) are risk factors for certain adverse obstetric and neonatal outcomes in pregnant women with cancer. Thus, changes to administration standards for chemotherapy (e.g., after the first trimester and no later than the 35th week of gestation) have been implemented to decrease the risk of congenital malformations and myelosuppression, respectively.[339] Appropriate timing and perioperative care prior to surgery for cancer treatment have reduced the risk of preterm delivery among women with cancer.[340] Nonetheless, women who undergo radiation therapy as part of their cancer treatment experience a dose-dependent increase in the risk of miscarriage, preterm delivery, abnormal placentation, fetal malposition, and low fetal birth weight in subsequent pregnancies.[31,341] The ultimate long-term impact of concurrent pregnancy and cancer treatment on cancer recurrence and overall maternal health is still unknown.[342] Notably, growth, cardiac function, neuropsychological capacity, and overall health in kids of mothers who had cancer during pregnancy are comparable to controls.[343]

Financial and Ethical Considerations

About 50% of cancer survivors experience financial hardship 1 year after diagnosis.[344] In fact, cancer patients are more than 2.6 times more likely to file for bankruptcy within 5 years of diagnosis, with patients 21 to 44 years of age bearing the greatest risk compared with matched controls.[345] "Financial toxicity" encompasses all of the financial considerations that patients with cancer experience throughout the course of their diagnosis, treatment, and follow-up. Financial toxicity is particularly burdensome for younger cancer patients and plays a significant role in personal choice about pursuing fertility preservation.[345] Out-of-pocket costs of fertility preservation are shown in Fig. 46.3. Many health insurance plans do not cover costs associated with fertility preservation, and only two states mandate insurance coverage for costs associated with iatrogenic infertility. Furthermore, some plans selectively cover the cost of ovarian stimulation but do not cover egg/embryo storage fees. Thus, fertility preservation may be an untenable option for many cancer patients of reproductive age.[346] In fact, more than 20% of cancer patients cite cost as the primary reason for not pursuing fertility preservation.[320] Disparities in financial hardship contribute to decreased health care–related QoL after cancer treatment, especially among certain ethnic minorities.[344,347] As such, patient financial literacy and navigation programs are making strides toward attenuating the financial burden of fertility preservation.[348]

The provision of adequate counseling on reproductive health prior to cancer treatment and the timely implementation of cancer treatment are commonly at odds at the time of cancer diagnosis, calling forth complex ethical questions. Specific ethical concerns include purposeful disclosure of fertility preservation options despite the potential delay to initiation of cancer therapy; ongoing awareness of patient confidentiality and privacy; procurement of assent and consent for fertility preservation in pediatric and adolescent patients; allocation of rights for future use, disposal, and donation of preserved tissue (including posthumous reproduction); utilization of preimplantation genetic diagnosis in future reproduction; provision of the costs associated with fertility preservation between the patient and involved partners; potential impact on QoL of subsequent offspring of cancer survivors; and avoidance of false hope in discussions of future fertility in patients with poor prognosis.[349] In prepubertal cancer patients, conversations about reproductive health, including

current contraception, sexuality, and future fertility, as well as the logistics of acquiring semen from boys and ovarian tissue from girls, are largely shaped by parents' and providers' beliefs about the child's sexual maturity.[332] Adult survivors of cancer who underwent fertility preservation counseling at a young age may disagree with decisions made by their parents at the time of cancer diagnosis.[350] Many cancer survivors experience social and emotional pressure to use previously stored gonadal tissue or gametes for achievement of genetic parenthood, especially in the context of socially constructed ideals of femininity, masculinity, and parenthood.[351] Furthermore, bioethical, legal, and regulatory concerns are particularly pertinent for young cancer patients considering experimental fertility preservation options and for cancer survivors considering reproductive tissue allografting or isografting or gestational surrogacy as ways to achieve parenthood.[352] Thus, many institutions have implemented task forces to help navigate the ethical issues that individual cancer patients face throughout the course of their cancer diagnosis, treatment, and follow-up.

Methods for Addressing Challenges

Providing Personalized Risk Assessment

The availability of information about the infertility risk posed by cancer or a particular cancer treatment is of the utmost importance for making an informed decision to undergo fertility preservation treatment. This is especially true for women, as the available fertility preservation techniques are costly and require several days or weeks to be completed. Several cohort studies have demonstrated the reduction of female and male fertility after cancer treatment; the probability of having children was found to be reduced by half in the Scandinavian Cohort Study and the Childhood Cancer Survivor Study.[353–355] However, prospective studies are still lacking or are of inadequate size, and randomized controlled trials are difficult to implement in this population of patients due to the amount of time required to assess fertility status after treatment. The sample size in particular is a difficult hurdle to overcome due to the heterogeneity of patient age, tumor stage, and treatment. Prospective or observational studies must last several years or decades to evaluate whether a particular cancer type or a cancer treatment prematurely reduces the ovarian reserve and fertility potential. Patient selection may also be biased, as the patients who enroll in these studies are highly interested in fertility. Despite these challenges, efforts have been made to identify individual predictors of infertility risk among patients with cancer, the most important of which are age in women and the type of cancer treatment in both men and women. Pretreatment evaluation of the ovarian reserve or sperm production is an important first step in estimating infertility risk, as reproductive function may already be compromised in patients with cancer. After cancer treatment, the recovery of ovarian or testicular function may occur months to years after radiation or chemotherapy. In men, semen analysis should be performed repeatedly to evaluate the recovery of sperm production, which can be delayed years after treatment because stem cells of the testicle reinitiate spermatogenesis. Although most studies have used amenorrhea as a surrogate marker for fertility loss in women, it is not accurate; in fact, resumption of regular menses does not always signal fertility. New and more accurate markers of ovarian function are needed to counsel patients about infertility risk and fertility status before and after cancer treatment.

Practice Management, Knowledge, and Access Barriers to Clinical Care

Oncofertility is a field that bridges reproductive science and oncology in an effort to preserve reproductive function for patients diagnosed with cancer. Achieving this goal requires a close collaboration of specialists involved in the treatment of cancer and infertility, who often have competing priorities. Discussions with patients about the possible risks posed by cancer and its treatment on fertility and the options for fertility preservation are necessarily complex—not only because multiple perspectives are in play but also because timing is crucial, particularly for patients with aggressive forms of cancer. This task can be particularly difficult in children with cancer, requiring practitioners to evaluate long-term infertility risks and offer appropriate fertility preservation techniques as soon as the urgent need for gonadotoxic treatment is established. Fertility preservation options for the youngest patients (immature gamete retrieval and cryopreservation) remain largely experimental, and the availability of this procedure is limited to only a few centers. Indeed, one of the major threats to this field is the need to have professional societies in many disciplines embrace fertility in their clinical setting—oncology, urology, allied health professionals, and reproductive endocrinologists (adult and pediatric) all need to be part of the equation.

Although the need for oncofertility and the collaboration between oncology and reproductive endocrinology is becoming globally recognized, with several scientific societies around the world establishing guidelines for fertility preservation in cancer patients,[50,356] there is still a gap in access—to knowledge, to the procedures themselves, and to support. To more fully address the issue of iatrogenic infertility after cancer treatment, it is essential to share information about oncofertility with individual cancer treatment centers, reproductive endocrinology and infertility practices, and infertility clinics. Updates in the field should be sent regularly to each of these stakeholders. Social media and traditional media must be engaged. Cross-platform resources should be widely distributed and made available online. Mobile applications linking practitioners and patients to oncofertility care must be advertised extensively.

Inclusion of Psychological Support Is Critical to Oncofertility Clinical Care Models

Psychological support during the oncofertility decision-making process is essential, especially for pediatric oncologic patients, who are presented with very specific challenges.[357] They (or their parents) may be overwhelmed by the cancer diagnosis and focused on what is necessary to survive cancer rather than a discussion of possible future infertility. Even when a patient decides to undergo fertility preservation, they are more likely to select a quick "one-stop" strategy, such as ovarian tissue cryopreservation, that does not delay the initiation of cancer treatment and does not require the patient to be actively engaged in the fertility preservation treatment, as would be necessary for embryo or oocyte cryopreservation. This raises some concern, because in many cases patients may be choosing to undergo an experimental, but quicker, procedure when an established but slower one could be at least as effective and certainly less invasive. It is important that practices understand the value of specialized oncofertility support personnel and models that train psychologists in oncofertility navigation and counseling who can provide psychological and decision-making support to patients at single centers or between centers. Building this capacity into oncofertility care is an important strategy that could be implemented on a macro (state, region, or country) scale.

Access and Affordability

The cost of fertility preservation is well beyond the reach of most people; in the United States, the average upfront cost of ART to cryopreserve oocytes is $9200, plus annual storage fees of approximately $300, and $4400 for thawing, fertilizing, and implanting the frozen eggs.[358] Although insurance, reimbursement, and specific cost issues vary in Europe, Asia, and North America, the primary reason for the underuse of ART, which has been available for the past 35 years around the world, is the cost of the procedures and medications, both inside and outside the cancer setting. In many places in the world, including in countries in the global north (like the United States), infertility treatments are frequently not covered by health insurance.[359] In the global south, infertility treatments are commonly seen as luxury items, given the lack of resources and the need to prioritize basic, lifesaving health care.[360] In Portugal, considerable effort has been made to improve financial support programs for ART, and today, public ART centers offer fertility preservation for men and women, with 69% of medication costs covered by social security.[361] Country-by-country assessments of the costs of oncofertility are ongoing and will provide insight into future approaches to reduce cost as a barrier to access for patients with cancer. The ability to have genetic children is important to many women and men throughout the world,[360] and the World Health Organization considers infertility to be a global health issue.[362] The significance of genetic parenthood and the public health perspective are important to factor into the arguments for pursuing fertility preservation, particularly in resource-limited environments. Ultimately, costs and priorities are intertwined and should be considered in equal measure.

Public Awareness

Although public awareness about oncofertility has increased dramatically in the past decade, there is still an overall lack of knowledge and understanding of the importance of fertility preservation in the cancer setting. The media is a powerful tool for disseminating health-related news and has played an important role in educating the public about oncofertility. However, awareness remains low among individuals who are less likely to be reached via the news media, those who are less educated, those who have lower health literacy, and those who are from lower socioeconomic backgrounds. Public awareness is the first step in creating public support for a given cause. Without widespread public support, it is difficult for a movement to gain momentum and engender real change. One of the barriers preventing oncofertility from accumulating more public support is the perception that ART is an elective procedure that is not medically necessary. Yet several professional medical organizations categorize infertility as a disease, and there is substantial evidence demonstrating the physical, psychological, social, and economic impact of infertility and its treatment. Correcting this misperception and illustrating the health benefits of oncofertility, beyond fertility preservation, for patients with cancer is a major focus in the field.

Distinguishing Between Oncofertility, Infertility, and Social Egg Freezing

Although oncofertility involves the same ART procedures used for infertility treatment, oncofertility is specifically focused on the needs young patients with cancer whose future fertility is threatened by the cancer or its treatment. It is important to recognize the differences between oncofertility patients and patients with traditional infertility. Unlike patients who seek treatment for infertility, oncofertility patients have *anticipated* iatrogenic infertility that is directly related to their lifesaving cancer treatment. Unfortunately, these two categories are often conflated, leading to a similar exclusion of oncofertility procedures from insurance coverage as a form of infertility treatment.[363] Clearly classifying oncofertility as part of the cancer treatment plan would help establish the difference between oncofertility and infertility treatments, as well as improve access to and insurance coverage for ART procedures specifically in the oncofertility setting.[364]

Many in the public also have difficulty distinguishing between the use of ART for fertility preservation in cancer patients and the use of ART for fertility preservation to avoid age-related infertility—what has been called *social egg freezing*.[365] In the past few years, social egg freezing by women who want to delay childbearing has received a great deal of news media attention.[366] Given low health and science literacy rates among the public, people may not be able to immediately understand the different reasons for fertility preservation in cancer patients versus healthy women who are concerned about age-related infertility, especially since the same technologies are used in each setting. With the increasing demand for social egg freezing, there is the concern that the cost of fertility preservation will increase for all patients, including oncofertility patients. More work must be done to more clearly illustrate in plain language the differences in the use of ART in the oncofertility setting (e.g., for infertility) versus social egg freezing.

Summary and Next Steps

Oncofertility sits at the fulcrum of disciplines and requires an integration of medical specialties—oncology, urology, and reproductive endocrinology—both with each other and with the emerging technologies that will be tomorrow's breakthroughs. The loss of reproductive function due to cancer has a profound impact on endocrine health, fertility, and psychosocial well-being, and attention to this rapidly moving field is crucial for ensuring a high QoL among cancer survivors.
