Thyroid hormone receptors: lessons from knockout and knockin mutant mice. *Trends Endocrinol Metab.* 2005;14:85–90; Ortiga-Carvalho TM, Sidhaye AR, Wondisford FE. Thyroid hormone receptors and resistance to thyroid hormone disorders. *Nat Rev Endocrinol.* 2014;10:582–591.

TRα, and *THRB* on chromosome 3 encodes TRβ.[243] These genes code for four classic receptor isoforms (TRα1, TRα2, TRβ1, and TRβ2), three of which bind thyroid hormones (T_3/T_4 affinity 10:1) and bind to DNA to effect gene transcription. The TRα2 isoform does not bind thyroid hormone but binds to DNA and can inhibit binding of other TRs. The TRs exist as monomers, homodimers, and heterodimers with other nuclear receptor family members such as retinoid X (RXR). Other TR transcripts, including TRΔα1 and TRΔα2, have been characterized; they do not bind DNA or T_3 but can inhibit TR and retinoid receptor activities.[244]

The TRs are expressed developmentally and differentially in various fetal and adult tissues. TRα proteins are present in most tissues. TRβ1 is expressed in liver, kidney, and lung and in developing brain, cochlea, and pituitary. TRβ2 expression is restricted largely to the pituitary gland, retina, and cochlea.[21,243] The receptors function redundantly, as indicated by knockout studies in mice, but predominant effects of one or another TR have been characterized (Table 23.4). Knockout of both the TRα and TRβ genes in mice is not lethal but results in elevated TSH concentrations, deafness, bradycardia, and decreased postnatal growth with delayed bone maturation.[21,243] Lethality occurs because of improper intestinal development associated with persistent TRΔα isoforms in TRα or combined TRα and TRβ knockout mice.[244] In the fetal rat brain, TRα1 mRNA and receptor binding are detectable by 12 to 14 days of gestation (term is 21 days), increasing to maximal levels at birth. The TRβ1 isoform is detected at birth and increases approximately 40-fold in the early postnatal period.[20,21] In human fetal brain, TRα1 and TRβ1 isoforms and receptor binding are present by 8 to 10 weeks' gestation; TRα1 transcripts and receptor occupancy increase 8-fold to 10-fold by 16 to 18 weeks.[21,245,246] Liver, heart, and lung receptor binding can be identified by 13 to 18 weeks.[21,246,247]

Heterozygous missense mutations in *THRA,* coding for the TRα1, have recently been described in association with short stature, developmental delay, and chronic constipation. The mutations act in a dominant negative fashion. The clinical phenotype is in line with the TRα1 being the predominant subtype receptor in bone, the gastrointestinal tract, cardiac and skeletal muscle, and the CNS.[248,249]

Ontogeny of Thyroid Hormone Secretion

The role of maternal thyroid hormone during fetal development remains controversial. The high placental concentration of D3 inactivates most of the thyroid hormone presented from the maternal circulation. The iodide released in this manner is used for fetal thyroid hormone synthesis. Despite the limited maternal-fetal placental transfer of T_4 and the predominant production of inactive thyroid hormone metabolites in the human fetus, significant levels of free T_4 are present in fetal fluids, from placental transfer early in gestation and from fetal thyroid production during later gestation.[20,21] Early in gestation, placental transfer is the only source of T_4 in fetal fluids and is essential for normal fetal neurodevelopment. T_4 is detectable in human coelomic fluid at levels of 0.5 to 2 nmol/L between 6 and 11 weeks' gestation, before the onset of fetal thyroid function.[19] Low concentrations of T_4 are detectable in the fetal brain at about 10 weeks of gestation. Significant placental transfer continues to term, when serum T_4 levels in the athyroid fetus range from 30 to 70 nmol/L (2.3–5.4 μg/dL).[250] Isotopic equilibrium studies with pregnant rats at term suggest that 15% to 20% of the T_4 in fetal tissues is of maternal origin.[251] As indicated, thyroid hormones cross the placenta early in gestation, supplying the low levels of free T_4 that are essential for brain development between 12 and 20 weeks, before the onset of fetal thyroid hormone production.[20] Most thyroid hormone in the fetal compartment is inactivated to sulfated and deiodinated analogues until the perinatal period.[219,232] This neutralization of active circulating thyroid hormone maintains the low T_3 metabolic state, facilitating fetal growth and programmed tissue maturation.

Thyroid hormone–programmed development of selective fetal tissues requires the interaction of local tissue D1, D2, thyroid receptors, receptor coactivators, and thyroid-responsive genes. In most responsive tissues, the timing of maturation events is controlled by the state of the thyroid receptors acting as a molecular switch.[244,252] In the absence of T_3, the unliganded receptor (aporeceptor) recruits corepressors, repressing gene transcription. Non–T_3-binding receptors also can repress transcription by inhibiting receptor DNA binding. Local tissue maturation events are initiated by the coincident availability of T_3, liganded T_3 receptor, T_3-mediated receptor exchange of corepressor with coactivators for creation of an active holoreceptor, and activation of responsive gene transcription.

These programming events have been investigated in studies of transgenic mice, including brain, liver, heart, intestine, and bone tissues; thermogenesis; and spleen erythropoiesis.[239,240,252–256] The timing of these events in the mouse ranges from early midbrain neuronal development at gestational day 15; through perinatal activation of hepatic enzymes, cardiac ion channels, and spleen erythropoiesis; to postnatal brain, intestinal, and bone maturation and thermogenesis. Parturition occurs at a gestational age equivalent to human midgestation. In hypothyroid mice, repressive effects of aporeceptors have been shown to delay tissue maturation in brain, bone, intestine, spleen, and heart.[240] The increase in circulating T_3 levels associated with parturition in mice and humans

normally triggers development of tissue functions essential to postnatal metabolism and homeostasis (e.g., hepatic, intestinal, and cardiac functions and brown fat thermogenesis). Thyroid hormone–stimulated maturation of vision and hearing appear to be triggered by the local expression of D2, mediating local T_3 production, postnatally in the mouse and probably toward the end of the second midtrimester in the human fetus.

In humans, T_3-mediated maturation of fetal tissues, including liver, heart, brown adipose tissue, and bone, allows them to become thyroid hormone responsive during late gestation and in the perinatal period. Paracrine actions of thyroid hormone are critical for normal fetal development (e.g., in the cochlea, where D2 is expressed in connective tissue immediately adjacent to the sensory epithelium, and in spiral ganglion, where thyroid hormone receptors are located). This implies that D2-containing cells in the connective tissue take up T_4 from the circulation, convert it to T_3, and then release D3 to adjacent responsive cells. Similarly, in the brain, D2 is expressed predominantly in glial cells, whereas TRs are expressed in adjacent neurons and oligodendrocytes. In other areas of the brain, such as the pituitary gland, hippocampus, and caudate nucleus, there is coexpression of D2 and TRs. On the other hand, D3 is coexpressed with TRs in neurons, thereby protecting sensitive tissues from the effects of excess thyroid hormone.

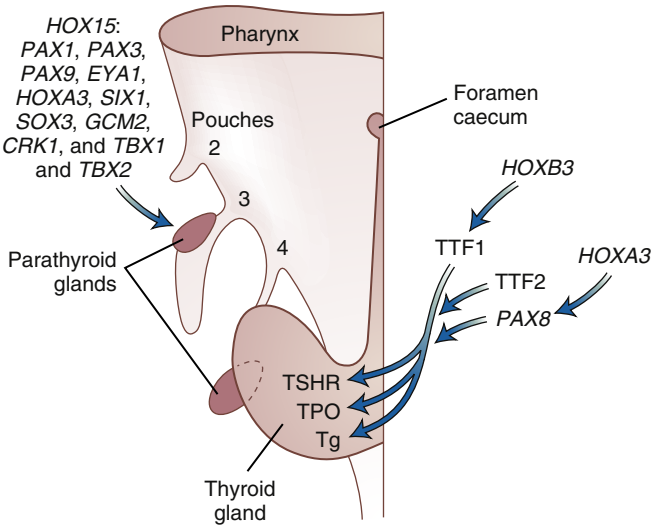
The actions of thyroid hormones and their developmental regulation in the brain are complex. Functionally, thyroid hormones are critical for the establishment of neural circuits during a critical window of brain development. They provide inductive cues for the differentiation and maturation of a number of processes such as neurogenesis and neural cell migration (occurring between 5 and 24 weeks of gestation), neuronal differentiation, dendritic and axonal growth, synaptogenesis, gliogenesis (late fetal period to 6 months postpartum), myelination (second trimester to 24 months postpartum), and neurotransmitter enzyme synthesis. TRs are found in highest concentration in developing neurons and in multiple areas of the fetal brain, including the cerebrum, the cerebellum, and the auditory and visual cortices. The hormones bind to receptors and stimulate a number of genes such as myelin, neurotropins and their receptors, cytoskeletal components, transcription factors, extracellular matrix proteins and adhesion molecules, intracellular signaling molecules, and mitochondrial and cerebellar genes.

Thyroid hormone is also important for normal bone growth. T_3 regulates endochondral ossification and controls chondrocyte differentiation in the growth plate both in vivo and in vitro. TRs are expressed on osteoblasts and growth plate chondrocytes, and T_3 target genes have been identified in bone. T_3 stimulates skull suture closure in vivo.[257]

In the perinatal period, thyroid hormone stimulates the transcription of thermogenin (also known as uncoupling protein 1 [UCP1]), a protein that uncouples nucleotide phosphorylation and the storage of energy as adenosine triphosphate (ATP), actions that are important for nonshivering thermogenesis by brown adipose tissue.

Genetic Regulation of Thyroid Development

At least five developmental genes are involved in thyroid and parathyroid gland embryogenesis. These include the genes for thyroid transcription factors *Pax8* (paired box 8), *Nkx2-1* (NK2 homeobox 1, previously known as TTF1), *Hhex* (hemopoetically expressed homeobox), *Foxe1* (forkhead box E1, previously known as TTF2), and *Nkx2-5* (NK2 homeobox 5) (Fig. 23.9).



• **Fig. 23.9** Homeobox genes that program development of the thyroid and parathyroid glands. *HEX* is involved early in the integrated cascade that programs thyroid gland embryogenesis. *HOXB3* and *HOXA3* may be responsible for activation of thyroid transcription factors TTF1 and TTF2, respectively, during early embryogenesis. *PAX8* is essential in the cascade. These factors are also involved in thyroid follicular cell function, promoting thyroglobulin (Tg), thyroid peroxidase (TPO), and thyroid-stimulating hormone receptor (TSHR) gene transcription. *HOX15* gene knockout in mice causes parathyroid gland aplasia. See text for details.

As well as mediating the formation of the thyroid bud, these transcription factors drive functional differentiation, regulate the expression of genes involved in thyroid hormone biosynthesis, and play a role in the maintenance of the mature thyroid gland (see Chapter 11). Mutations in *NKX2-1, PAX8,* and *FOXE1* are all associated with thyroid dysgenesis in humans.[215,217,258–260]

Putative Contributing Mechanisms to Thyroid Morphogenesis

Animal studies in mouse and zebrafish suggest that extrinsic factors such as permissive signals from blood vessels provide guidance cues in thyroid morphogenesis.[261] Genes known to contribute to thyroid morphogenesis in animal models include the Notch ligand *JAG1,* the thyroid and cardiac transcription factor *Nkx2-5,* and *NTN1,* which is implicated in zebrafish aortic arch artery formation and thyroid morphogenesis.[262–265] Other autonomous factors that may play a role include *Tbx,*[266] a member of the T-box family of transcription factors and the prime candidate gene missing in DiGeorge syndrome. In mice, *Tbx1* is expressed in both the pharyngeal endoderm and subpharyngeal mesoderm but only its mesodermal activity promotes the generation of *Nkx2-1*+ progenitors in the thyroid placode.[267] The effect of *Tbx1* on the embryonic thyroid is mediated by *Fgf8* that is also produced in the mesoderm.[267] It is known that signaling molecules such as those in the Shh pathway are also implicated in murine thyroid development.[261] In late organogenesis, *Shh* appears to have an important role in the symmetric bilocation of the thyroid; it also suppresses the ectopic expression of thyroid follicular cells.[268]

Thyroid Function in Preterm Infants

Compared to infants born at term, neonatal free T_4 increments are reduced in premature infants born at 31 to 34 weeks of gestation, attenuated at 28 to 30 weeks, and absent in infants 23 to 27 weeks.[269] This reflects hypothalamic-pituitary-thyroid system

immaturity inversely related to gestational age.[220] Age-specific changes in thyroid function in children with small for gestational age (SGA) and normal birth weight from birth to adulthood are available.[270] Premature birth interrupts the changes in thyroid hormone metabolism that occur over the third trimester resulting in low T_4 and T_3 concentrations that increase in proportion to increasing gestational age at delivery in preterm infants.[269] The thyroid hormone concentrations appear to be even lower than those expected in utero[271]; the reasons for this are multifactorial, including loss of maternal fT_4 in association with an immature TSH-T_4 axis, low iodide stores, and reduced deiodinase 1 (DIO1) activity.

A natural postnatal nadir in thyroxine concentration occurs at 7 days of life with a subsequent rise thereafter.[220,269,272] Several patterns of thyroid dysfunction can occur in preterm neonates[226,269,273]:

1. Transient hypothyroxinemia of prematurity—identified by a low free T_4 and normal TSH and seen in 50% of preterms born less than 28 weeks—does not require treatment. Maturation of the hypothalamic pituitary axis is likely to be delayed in prematurity and, although the postnatal TSH surge is seen at all gestational ages, it appears to be attenuated in the most premature infants.
2. Primary hypothyroidism—very low birth weight (VLBW) infants have a higher risk of primary hypothyroidism and can exhibit a pattern of delayed TSH rise, although in a considerable number of these infants the hypothyroidism is transient. Thyroid hormone treatment should be initiated and continue at least until thyroid hormone–dependent brain maturation has completed at approximately 3 years of age. At this stage thyroid function can be reassessed.
3. Hypothyroidism due to iodine excess—preterm infants are at risk from iodine-containing antiseptics and contrast agents.
4. Hypothyroidism due to iodine deficiency—preterm infants are at risk of iodine deficiency as they have low iodine stores (usually established in the third trimester), and enteral and parenteral nutrition contain little iodine.
5. Thyroid dysfunction due to nonthyroidal illness—often with low T_4, T_3, and TSH. Treatment is not indicated, but repeat testing every 1 to 2 weeks is recommended.

Congenital Hypothyroidism

Classic signs of congenital hypothyroidism (jaundice, lethargy, feeding difficulties, macroglossia, myxedema, hypothermia, growth retardation and progressive developmental delay, and intelligence quotient [IQ] deterioration) appear during the initial critical weeks and months of extrauterine life as maternal T_4 becomes unavailable and the non-CNS tissues become responsive to thyroid hormone.[21,219] Rarely, hypothyroidism is associated with respiratory distress in the neonatal period. The period of brain dependency for thyroid hormone extends up to 3 years of age, and most countries have a rigorous screening program to ensure early diagnosis and treatment.[280] Most cases of permanent primary congenital hypothyroidism are due to thyroid dysgenesis. Mutations in known genes account for less than 5% of patients with congenital hypothyroidism and thyroid dysgenesis. Carré and colleagues recently described the impact of *BOREALIN* mutations as a genetic cause of thyroid dysgenesis in humans. *BOREALIN* expression in human embryonic thyrocytes was shown before and after the onset of thyroid hormone synthesis, and *BOREALIN* is involved in the adhesion and migration of the thyrocytes, in keeping with a phenotype of thyroid ectopy.[281]

Lower neonatal screening thresholds have increased the incidence of congenital hypothyroidism with a normally located gland in situ, and recent studies reveal that a significant proportion of patients have multiple gene mutations in more than one thyroid-specific gene, supporting the hypothesis of an oligogenic etiology of congenital hypothyroidism.[282] Known causative genes in congenital hypothyroidism with gland in situ include *TG, TPO, DUOX2, DUOXA2, SLC5A5, SLC26A4, IYD,* and *TSHR,* and the molecular spectrum is increasing.

In congenital hypothyroidism there is an increased net flux of maternal thyroid hormone to the fetus, resulting in cord T_4 concentrations that are 25% to 50% of normal. There is increasing evidence of maternal-fetal T_4 transfer in the first half of pregnancy, when fetal thyroid hormone levels are low.[283] The transplacental passage of thyroid hormone, in conjunction with adjustments in brain deiodinase activity, has a critical role in minimizing the adverse effects of fetal hypothyroidism and helps explain the normal or near-normal outcome of hypothyroid fetuses (provided that prompt and adequate treatment of hypothyroidism ensues postnatally) as well as the relatively normal clinical appearance of the majority of babies with congenital hypothyroidism at birth. On the other hand, in the presence of both maternal and fetal hypothyroidism—such as that observed in the presence of potent TSHR-blocking antibodies, maternal and fetal POU1F1 deficiency, and severe iodine deficiency—there is severe neurocognitive impairment despite early and adequate commencement of thyroid replacement. Importantly, the presence of maternal hypothyroxinemia or inadequately controlled hypothyroidism is also associated with significant neurocognitive deficit in the offspring that is not reversible by early postnatal therapy.[284] Table 23.5 shows mechanisms resulting in congenital hypothyroidism due to abnormal thyroid development, dyshormonogenesis, abnormal thyroid hormone transport or action, and genes involved in these mechanisms.[285] International guidelines for treatment of congenital hypothyroidism are available.[286]

Gonadal Development

Sex determination is the result of a series of molecular events that direct the undifferentiated bipotential gonad to become a testis or ovary. Sex differentiation takes place once sex determination has occurred via factors produced by the gonads that determine the development of the phenotypic sex. The work of Alfred Jost, elucidating the pathophysiology of an experiment of nature, the freemartin calf, was seminal in the field of fetal sex development.[287]

The freemartin phenotype appears in a dizygotic twin pregnancy, where a genetically female fetus is masculinized in the presence of a male twin. The phenomenon of freemartinism is a disorder of sex development, explained by the endocrine effects of testosterone and antimüllerian factor from the male calf on the genital development of the female, made possible by the placental vascular anastomoses in cattle resulting in conjoined circulations of the twin calves. Subsequent advances in uncovering the genetic control and the pathophysiology of sex development have revealed that there is potential for disruption of the sex differentiation process at different stages, and clinical phenotype will depend on the nature of the disruption

Embryology

The mammalian gonad originates from the intermediate mesoderm, from which the bipotential urogenital ridge differentiates. Several genes (including those encoding SF1, WT1, EMX2,

TABLE 23.5 Mechanisms Involved in Congenital Hypothyroidism

Thyroid Dysgenesis (1 in 4500)

Isolated thyroid aplasia, hemiagenesis, hypoplasia, or ectopy
- Transcription factor defect *(PAX8)*
- Unknown[a]

Associated with other developmental abnormalities
- Transcription factor defect (TTF1, FOXE1 [TTF2], NKX2-5, SHH, Tbx1)

Inborn Errors of Thyroid Hormonogenesis (1 in 35,000)

- Abnormal iodide uptake via Na-I transporter *(NIS, SLC5A5)*
- Abnormal concentration of iodine
- Abnormal organification of iodine
- Abnormal iodination of thyroglobulin catalyzed by thyroid peroxidase *(TPO)*
- Abnormal H_2O_2 generation *(THOX, DUOX2, DUOXA2)*
- Efflux of iodide into colloid via apical anion channel (Pendred syndrome, *SLC26A4)*
- Defective thyroglobulin synthesis or transport
- Abnormal iodotyrosine deiodinase *(DEHAL1)*
- Abnormal thyroid hormone transport in the brain *(MCT8)*
- Abnormal selenium incorporation *(SECISBP2)*

Secondary and Tertiary Hypothyroidism (1 in 50,000–100,000)

Hypothalamic abnormality
- Isolated TRH deficiency
- Multiple hypothalamic hormone deficiencies
- Isolated hypothalamic defect
- Associated with other midline facial/brain dysmorphic features (e.g., *SOD*, cleft lip/palate)

Pituitary abnormality
- Isolated TSH deficiency *(IGSF1)*
- TRH resistance
- Abnormal TSHβ molecule
- Multiple pituitary hormone deficiencies
- Posterior pituitary eutopic (transcription factor defect, e.g., *POU1F1, PROP1, LHX3)*
- Posterior pituitary ectopic (idiopathic, transcription factor defect, e.g., *HESX1, SOX3, LHX4, OTX2)*

- TSH resistance
- TSH receptor gene mutation *(TSHR)*
- Postreceptor defect?
- Thyroid hormone resistance (1 in 100,000)
- $G\alpha_s$ gene mutation *(GNAS)*

[a]Most common.

CBX2, and PBX1) are required for formation of the bipotential gonadal ridge.[288] The gonad is derived from two tissue anlagen, the primordial germ cells of the yolk sac wall and the somatic, stromal cells that migrate from the primitive mesonephros.[289,290]

By 2 to 3 wpc, the germ cells have begun their migration from the yolk sac, and the gonadal ridge has appeared as a derivative of the mesonephros. The germ cells are incorporated into the developing urogonadal ridge during the fourth week postconception in the human embryo as a thickening of the mesothermic mesonephros covered by coelomic epithelium. The primitive gonad is composed of a surface epithelium, primitive gonadal cords continuous with the epithelium, and a dense cellular mass referred to as the adrenogonadal primordium, which includes the steroidogenic cell precursors.[290] As this primordium grows, the cells delaminate from the coelomic epithelium and invade the underlying mesenchyme, with the cells adjacent to the mesonephros migrating dorsolaterally to form the gonadal primordium.

Until the appearance of testicular cords made up of pre-Sertoli cells at 6 wpc, the fetal testis and ovary are indistinguishable. The development of a specific sex phenotype requires the action of networks of transcription factors and a complex signaling cascade that regulates differentiation of the bipotential gonad into a testis or ovary from 6 wpc.

Embryogenesis of the gonads is programmed by genes encoding the male sexual determinant SRY, as well as SF1, SOX9, and DAX1.[291,292] SRY, thought to have evolved from SOX3, is a critical regulator of male gonadal differentiation. The X chromosomal *SOX3* gene is not normally expressed in the developing gonad. Therefore, when ectopically expressed, it might substitute for *SRY* in driving testicular development. Loss-of-function mutations of *SOX3* do not affect sex determination, but *SOX3* overexpression in murine XX gonads leads to testis differentiation; in humans, *SOX3* duplication or rearrangements of the *SOX3* regulatory region have been found in 46,XX individuals with dysgenetic testes.[293]

SF1 is required for testicular and ovarian development and mediates müllerian-inhibiting hormone (i.e., antimüllerian hormone [AMH]) gene expression and gonadotropin production. Both SF1 and DAX1 are required for normal gonadal development.

By 7 wpc, in the XY gonad, *SRY* is expressed in pre-Sertoli cells resulting in the upregulation of *SOX9* expression that is further augmented by the synergistic action of SRY and SF1, leading to the initiation of definitive Sertoli cell differentiation. The transcriptional activation by *SRY* and *SF1* is mediated by the binding of these two proteins to the testis-specific enhancer of *SOX9* core (TESCO) region, which lies approximately 13 kb upstream of *SOX9.* Genomic rearrangements (such as duplication and triplication) affecting *SOX9* regulatory elements, located significantly further upstream (500 kb) than the TESCO enhancer region, have been found in patients with 46,XX sex reversal.[288]

Once SOX9 levels reach a critical threshold, several positive regulatory loops are initiated, including autoregulation of *SOX9* expression and formation of feed-forward loops via FGF9 or PGD2 signaling. During testicular development, *SOX9* functions by regulating the production of AMH from Sertoli cells and possibly by repressing genes involved in ovarian development such as *WNT4* and *FOXL2.* The DMRT1 transcription factor may also be involved in this process.[288]

WT1, the Wilms tumor suppressor gene, is also expressed in the bipotential gonadal ridge during its differentiation from the intermediate mesoderm and is critical for normal male sexual differentiation. Located at 11p13, it is expressed in both the primitive kidney and the genital ridge. WT1 isoforms associate and synergize with SF1 to promote expression of AMH. *WT1* missense mutations associated with 46XY disorders of sexual development (DSD) in Denys-Drash syndrome fail to synergize with SF1.[294] In addition, WT1 binds to and activates the SRY promoter.

The expression of SRY is transcriptionally regulated by WT1, SF1, GATA-4 and its cofactor zinc finger protein FOG2 (also called ZFPM2), and chromobox protein homologue 2 (CBX2).[295] In the presence of SRY, male gonadal differentiation begins with organization of the gonadal blastema into interstitium and germ cell–containing testicular cords. The primitive cords lose their connections with the epithelium, primitive Sertoli cells and spermatogonia become visible within the cords, and the epithelium differentiates to form the tunica albuginea.[296] Sertoli cells induce the development of fetal Leydig cells via a hedgehog-signaling pathway, which produces androgens and INSL3, a member of the insulin-like family, at 8 to 9 wpc.[297] INSL3 is required for

testicular descent.[288] Rare mutations have been described in cryptorchidism.[298,299] Testosterone and AMH cause regression of müllerian structures and differentiation of the wolffian duct into the epididymis, vas deferens, and seminal vesicles. In 46,XY males, testosterone is converted to 5-dihydrotestosterone (DHT) by the enzyme 5α reductase, resulting in the development of male external genitalia. The activity of DHT is mediated by the nuclear transcription factor, androgen receptor (AR), which has high affinity for DHT.

The fetal testes grow from approximately 20 mg at 12 wpc to 800 mg at birth; at 5 to 6 months they descend into the inguinal canal in association with the epididymis and the vas deferens.[296] The gonad, adrenal, and kidney all initially develop in close proximity, and as the testes descend they may carry rests of adrenocortical cells with them. These adrenal rests may become hyperplastic with resulting testicular enlargement if subjected to prolonged ACTH stimulation (e.g., in patients with poorly controlled congenital adrenal hyperplasia).

SF1 mutations result in a number of phenotypes related to gonadal development and function. A recurrent specific heterozygous mutation of SF1 accessory DNA-binding region was recently reported in XX individuals with varying degrees of testis development.[300] One individual, raised as female, was found to have a 46,XY karyotype and partial testicular dysgenesis. These findings highlight how a specific variant in a developmental transcription factor can switch organ fate from ovary to testis in mammals, which represents the first missense mutation causing isolated nonsyndromic 46,XX ovotesticular DSD in humans.

In human females, differentiation of ovaries begins during week 5 of conception, in the absence of *SRY*. In the XX gonad, the absence of SRY results in the inability of *SOX9* expression to reach a critical threshold, and together with the expression of factors such as RSPO1/WNT4 signaling, FST and FOXL2 lead to formation of the ovary, at least in part through suppression of the activity of "testis" genes. In the 46,XX female, the absence of androgens leads to the development of female genitalia; the wolffian duct regresses and the müllerian duct is maintained and forms the oviduct, uterus, cervix, and upper part of the vagina.[288] The gonadal blastema differentiates into interstitium and medullary cords containing the primitive germ cells, referred to as *oogonia*. The cords degenerate and cortical layers of surface epithelium, containing individual small oogonia, appear. By 9 to 10 wpc, clusters of dividing oogonia are surrounded by cord cells within the cortex; the medulla at this time consists largely of connective tissue.[301] At 10 wpc, primitive granulosa cells begin to replicate, and many of the large oogonia in the deepest layers of the cortex enter their first meiotic division.

Primordial follicles are first observed at about 16 wpc, and the number increases rapidly thereafter.[302] However, the number of oocytes progressively declines from a peak of 3 to 6 million at 5 months of gestation to approximately 2 million at term.[25,302] Germ cell proliferation and apoptosis occur simultaneously. Proliferating oocytes cluster, but the clusters break down with the development of follicles because only those oocytes enfolded by developing granulosa cells as primordial follicles survive.[25,302] By 5 months of gestation and during the seventh month, stroma-derived thecal cells develop around the primordial follicles as they mature to primary follicles. This process continues after birth progressing toward the superficial layers.

Each fetal ovary weighs about 15 mg at 12 wpc and 300 to 350 mg at term.[301] The number of surviving primary follicles at birth correlates with the duration of subsequent postpubertal ovulation. Interstitial cells with characteristics of steroid-producing cells are present after 12 weeks and, during the third trimester, theca cells with steroidogenic capacity surround the developing follicles.[25] Significant aromatase activity also is present but few if any steroids are produced by the ovary during development.[25,301]

The specific genetic mechanisms dictating ovarian development are being unraveled; some of the most powerful regulators include the WNT/FZD/β-catenin, FOXO/FOXL2, and TGFβ/SMAD pathways.[295,303] *FOXL2*, encoding a forkhead transcription factor, is required for ovarian development.[304] DMRT1, expressed in testis, prevents expression of FOXL2 and hence female programming in the postnatal testis.[305] In the XX gonad, *RSPO1, WNT4, CTNNB1, FOXL2,* and *FST* are also expressed in a female-specific manner to promote ovarian development and repress testicular development. In humans and mice, R-spondin-1 (encoded by *RSPO1*) augments β-catenin signaling, possibly via WNT4.[306] Homozygous mutations in *RSPO1* result in a syndrome with palmoplantar hyperkeratosis and 46,XX DSD with sex reversal and dysgenetic testes or ovotestes.[307] Aberrations of *WNT4* cause Mayer-Rokitansky syndrome or SERKAL syndrome (*s*ex *r*eversal, dysgenetic *k*idneys, *a*drenals, and *l*ung).[302,308]

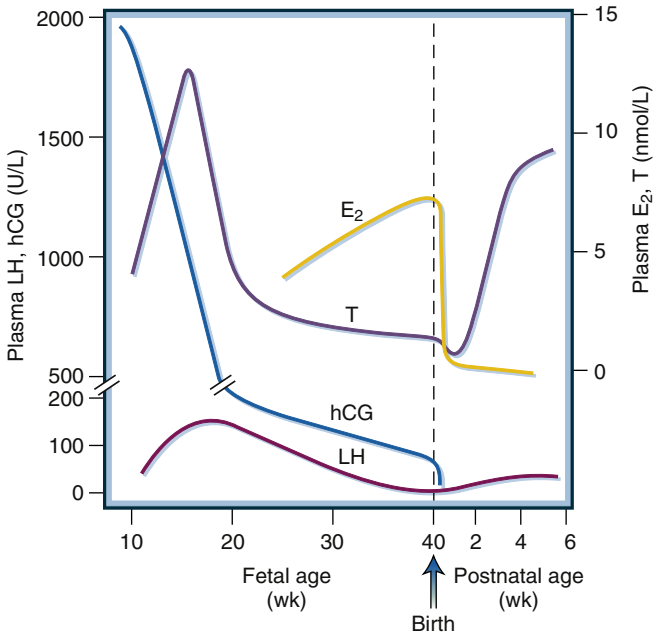
Fetal Sex Steroid Production

In the male fetus, the development of Leydig cells leads to an increase in fetal testosterone production between 8 and 18 wpc (Fig. 23.10).[296] Androgen receptors appear in the epithelium during development at 7 to 10 wpc[308] with no difference in expression between sexes.

In vitro studies in rat tissue have shown that hCG binding to fetal testis cells does not downregulate LH receptors. Fetal LH may contribute to fetal Leydig cell function, but quantitatively hCG is the predominant gonadotropin. Testosterone itself, acting through the androgen receptor, stimulates differentiation of the primitive mesonephric ducts into bilateral vas deferens, epididymides, seminal vesicles, and ejaculatory ducts. DHT stimulates male differentiation of the urogenital sinus and external genitalia, including differentiation of the prostate, growth of the genital tubercle to form a phallus, and fusion of the urogenital folds to form the penile urethra. DHT mediates the action of testosterone in the wolffian ducts.

The fetal testis also produces AMH, which causes dedifferentiation of the müllerian duct system in the male fetus.[309,310] AMH is a glycoprotein with a monomer that has a molecular size of approximately 72 kDa and multimer sizes ranging from 145 to 235 kDa. It is a member of the transforming growth factor β (TGFβ) family. It is produced by testicular Sertoli cells and reaches the müllerian ducts largely by diffusion; duct regression in vitro requires an exposure to AMH of 24 to 36 hours. AMH is synthesized early in gestation, with production peaking at the time of müllerian duct regression; biosynthesis continues throughout gestation and decreases after birth. *AMH* gene expression is activated by the *SRY* and *SF1* genes.[309] AMH also has autocrine and paracrine effects on testicular steroidogenic function during fetal life.[310] Male phenotypic differentiation is mediated by testicular testosterone and AMH and occurs between 6 and 12 wpc.

In the female fetus, the müllerian duct system differentiates in the absence of AMH, the mesonephric ducts fail to develop in the absence of testosterone, and the undifferentiated urogenital sinus and external genitalia mature into female structures. Mutation of the *AMH* gene results in a persistent müllerian duct syndrome in the XY fetus.[309]



• **Fig. 23.10** Patterns of change of plasma concentrations of human chorionic gonadotropin (hCG), luteinizing hormone (LH), testosterone (T), and estradiol (E_2) in a male fetus during gestation and in the neonatal period. (Data from Mann DR, Gould KG, Collins DC, et al. Estrogen effects are mediated by cognate receptors, members of the large family of steroid and thyroid hormone, vitamin D, and retinoid receptors.[311,312] Two receptors, ERα (encoded by *ESR1* on chromosome 6) and ERβ (encoded by *ESR2* on chromosome 14), have been identified, with 96% and 58% homology in the DNA-binding and ligand-binding domains, respectively. Expression profiles of mRNAs of both receptors have been characterized in the human fetus at 16 to 23 weeks. One or both receptor mRNAs are present in most tissues. The ERβ message is predominant, particularly in testis, ovary, spleen, thymus, adrenal, brain, kidney, and skin. The ERα message is prominent in the uterus, with relatively low levels in most other tissues.[311,312]

The significance of ERs in fetal development is unclear. Knockout of the *ERα* gene in mice does not impair fetal development of any tissue, but adult females are infertile with hypoplastic uteri and polycystic ovaries while adult males manifest decreased fertility.[312] ERβ knockout mice develop normally, and female adults are fertile with normal sexual behavior; adult males reproduce normally but have prostate and bladder hyperplasia.[311] It is known that estrogens regulate DHEA production in the baboon and human fetal adrenal.[311]

Knockout of both *ERα (ESR1)* and *ERβ (ESR2)* genes has little impact on fetal development, but after birth, the uterus, fallopian tubes, vagina, and cervix in females are hypoplastic and unresponsive to estrogen.[312] In humans, *ESR1* mutations in males are associated with tall stature, osteoporosis, and insulin insensitivity.[313]

Androgens and estrogens are both involved in the structural development of the rat brain.[314] Gonadal hormones also control gonadotropin production in the brain that results in cyclic ovarian function and normal function of the testes.[315,316] Testosterone administration to neonatal female rats produces permanent inhibition of cyclic hypothalamic control through local aromatization to estradiol and ER binding. In primates and humans, estrogens seem to be more effective in this regard, but there is no evidence for permanent programming in the primate nor does there appear to be major tissue biochemical differences between the sexes in utero to account for sexual dimorphic behavioral or gonadotropic programming.[315] The mechanisms for these effects are not yet clear in the primate and human fetus.

A current view of the pathways for genes programming gonadal differentiation is shown in Fig. 23.11. The full menu of downstream gene targets remains to be defined, but the net result is the highly organized pattern of gonadal development and phenotypic sexual differentiation. Fetal pituitary gonadotropins

are not required for gonadal development or sexual differentiation; *LH or FSH receptor* knockout mice are born phenotypically normal.[317]

Disorders of Sex Development

The increasing knowledge about sex determination and differentiation and society's increasing fluidity about the nature of sexual identity and gender roles have led to a reappraisal of former management practice in DSD. Optimal care for infants with DSD requires an experienced multidisciplinary team that transitions into adulthood, and there is a need for greater data sharing and formal research and clinical expertise networks at several levels, as highlighted by the Chicago Consensus in 2005. Human mutations in several genes programming gonadal differentiation have been described, and it is likely that future innovation in "omic" technologies (e.g., transcriptomics) will lead to improved understanding of the underlying abnormality as well as explain the variability in the phenotype.

Fetal Autonomic Nervous System

The activity of the autonomic nervous system may be regarded as a landmark brain function reflecting overall ability to regulate the fetal central nervous system. The interplay between the sympathetic and parasympathetic nervous systems is effected via the cerebral cortex, the medulla oblongata, the sympathetic ganglia, and the vagus nerve. There is an increasing realization that neural function in the fetus serves specialized needs particular to development and that the onset of maturity represents the loss of these unique patterns of neural activity. Nowhere is this more evident than in the sympathetic nervous system and its endocrine counterpart, the adrenal medulla.

Embryology

As early as 4 to 5 wpc the primordia of the sympathetic trunk ganglia are visible in the human fetus. The sympathoadrenal (SA) cell lineage is a derivative of the neuroectodermal crest (NC), which gives rise to sympathetic neurons and neuroendocrine chromaffin cells of the adrenal medulla and extra-adrenal chromaffin cells. Signals that are important for specification of these two types of cells are largely unknown. The SA progenitor cells that migrate in a dorsolateral direction form numerous extramedullary sympathetic paraganglia,[318] which are scattered throughout the abdominal and pelvic sympathetic plexuses.[319] Each of the paraganglia may reach a maximal diameter of 2 to 3 mm by 28 wpc; the largest of these, the organs of Zuckerkandl near the origin of the inferior mesenteric arteries, enlarge to 10 to 15 mm in length at term. After birth, the paraganglia gradually atrophy and disappear by 3 years of age.

The SA cells that migrate ventrally through the anterior sclerotome to reach the dorsal aorta[320] give rise to tyrosine hydroxylase-expressing, catecholaminergic neuronal progenitor cells in response to bone morphogenetic protein cues from cells of the wall of the dorsal aorta and the surrounding mesenchyme.[321] Some cells then migrate from the dorsal aorta along nerves and blood vessels to enter the adrenal primordium at the cranial end from 6 wpc[322,323] and acquire the phenotype of chromaffin cells. It was thought that these were SA cells that lost expression of neuronal genes, but more recently it has been shown that at least some of the presumptive chromaffin cell population enter the adrenal primordium still expressing neural crest markers and then gain tyrosine hydroxylase and dopamine β-hydroxylase expression but not neuronal markers.[324] A variety of transcription factors have been identified in the development of the SA cell lineage, including PHOX2B (paired-like homeobox 2b), MASH1 (mammalian achaete-scute homolog 1), PHOX2A (paired-like homeobox 2a), and HAND2 (heart and neural crest derivatives-expressed protein 2).[318] The *PHOX2B* gene is pivotal in the development of the autonomic nervous system. Phox2b$^{-/-}$ mice die in utero since autonomic nervous system neurons either fail to develop or degenerate. Mutations in human *PHOX2B* cause a rare syndrome of dysautonomia (congenital central hypoventilation syndrome) and a predisposition to neuroblastoma.[325]

Nerve growth factor (NGF) is required for the survival of developing sympathetic neurons. In the rodent, NGF antiserum injected into neonatal rats resulted in degeneration of immature chromaffin cells, sympathetic cells, and pheochromoblasts.[326] It is unclear whether NGF and other growth factors are involved in maturation of the human fetal autonomic nervous system.

Functional Development of the Sympathoadrenal System

Chromaffin cells are initially scattered within the adrenal cortex and are mostly noradrenergic. At around 10 wpc, small islets of chromaffin cells express phenylethanolamine *N*-methyltransferase (PNMT), the enzyme required to convert noradrenaline into adrenaline, to become adrenergic.[327] With increasing gestational age, there is progressive growth of the adrenal medullae, increasing catecholamine content and progressive maturation of medullary functional capacity. Histologically the adrenal medullae are somewhat immature at birth, but by 1 year they resemble the adult glands.

Catecholamines are present in the para-aortic chromaffin tissue by 8 to 13 wpc, and concentrations increase until term. The predominant catecholamine is norepinephrine (NE), presumably because of low activity of PNMT in para-aortic chromaffin tissue. In contrast, the adrenal medulla has high levels of PNMT activity. This enzyme catalyzes the methylation of NE to epinephrine and is activated by the high levels of cortisol that diffuse into the adrenal medulla from the adrenal cortex.[319,328]

How the fetus withstands an in utero environment of relative hypoxia has been a vibrant area of research for over a century. The ovine model provides a comparative system for physiologic and developmental research in the fetus that is applicable to human medicine. Basal plasma epinephrine, NE, and dopamine concentrations decrease during the last trimester in sheep[329,330] due to maturation of clearance mechanisms.[330] This model has been used to study fetal adaptive responses to chronic oxygen and nutrient deprivation during placental insufficiency. The fetal sheep responds to hypoxia with increased catecholamine concentrations.[331] This response is also present in human fetuses during the third trimester of gestation.[332] Central and adrenal enkephalins are also involved in fetal autonomic nervous system function; pretreatment with naloxone potentiates and methadone inhibits the catecholamine response to hypoxia.[319,333]

Catecholamines are critical for fetal cardiovascular function and fetal survival. Gene knockout studies in mice, targeting either tyrosine hydroxylase or dopamine β-hydroxylase, produced fetal catecholamine deficiency and midgestation fetal death in 90% of the mutant embryos.[334,335] In addition, fetal catecholamines are the major stress hormones in the fetus.[328,332] The fetal adrenal and the para-aortic chromaffin masses discharge large amounts of catecholamines directly into the circulation in response to fetal hypoxia.[328] Moreover, the defense against fetal hypoxia involves catecholamine actions mediated

through cardiac α-receptors that are unique to immature animals. α-Adrenergic receptors predominate in immature cardiac tissue and gradually decline in number as β-adrenergic receptors increase with maturation. Chromaffin tissue in the fetus is also innervated by opiate receptors and contains relatively large amounts of opiate peptides that appear to be co-secreted with the catecholamines.[328] The extent to which these peptides or pituitary endorphins are involved in modulating fetal catecholamine secretion remains unclear.

The human neonate responds to parturition with an increase in plasma epinephrine and NE concentrations, and these responses are augmented by hypoxia and acidosis.[331,334,335] In the newborn, catecholamine secretion also increases after cold exposure and hypoglycemia.[328,332] Labor-induced catecholamine release may provide an important mechanism underlying the neonate's process of adapting to extrauterine conditions and the recruitment of vital postnatal adaptations.

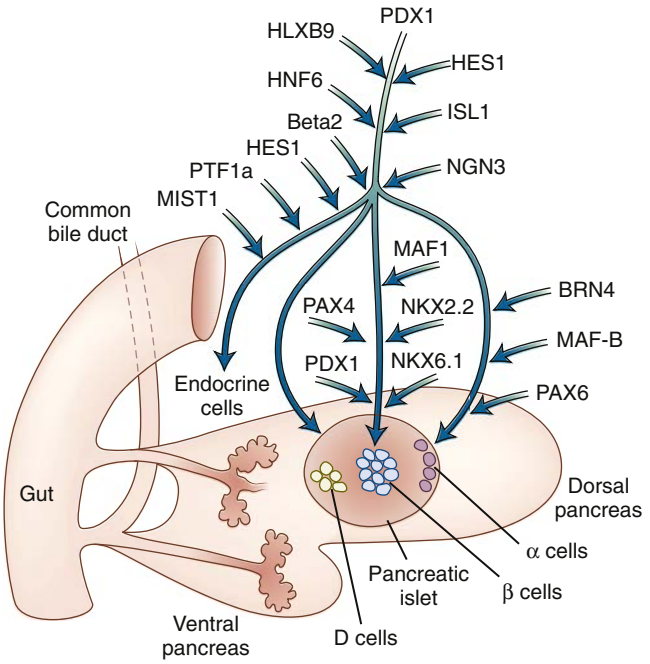
Endocrine Pancreas: Insulin and Glucagon

Embryology

Pancreatic development represents a fascinating process in which two morphologically distinct tissue types must derive from one simple epithelium. These two tissue types, exocrine (including acinar cells, centroacinar cells, and ducts) and endocrine (alpha cells secrete glucagon, beta cells secrete insulin, delta cells secrete somatostatin, and PP or gamma cells secrete pancreatic polypeptide), serve disparate functions. Pancreatic development is a multistep process defined by three major periods (primary and secondary transition and the postnatal period).

Embryogenesis of the pancreas is mediated by a series of homeobox genes and transcription factors that program pancreatic budding from the gut tube, development of branching ducts and undifferentiated epithelium, differentiation of exocrine and endocrine cell lineages that originate from endodermal tissue, and organization of the endocrine cells into islets of Langerhans.[336] Members of the EGF family of growth factors, laminin, and perhaps other growth factors, including the IGFs, also contribute to pancreatic growth and differentiation.[337,338]

Cell lineage determination during pancreatic development involves regulation by many transcription factors. The process has been well studied in the mouse and begins at day 8 of the 21-day gestation, extending to 2 to 3 weeks after birth (Fig. 23.12). An outgrowth of dorsal and ventral pancreatic buds from the dorsal foregut endoderm occurs at around embryonic day 8.5 (e8.5).[339] These cells express pancreatic and duodenal homeobox 1 (Pdx1) without which the pancreas is unable to form.[339] This phenotype in mice is mimicked in humans with homozygous loss of *PDX1* that is responsible for pancreatic agenesis. Pdx1 expression is quickly followed by expression of the basic helix-loop-helix protein pancreas-specific transcription factor 1a (Ptf1a), necessary for further development of both the endocrine and exocrine pancreas in mice as well as humans, forkhead box O1 (FOXO1), NK2 homeobox 2 (NKX2.2), and NK6 homeobox 1 and 2 (NKX6.1 and NKX6.2, respectively).[339,340] While regulatory factor X 6 (Rfx6) is also expressed during these early time points in mice, it appears only to be required for endocrine pancreatic development, a phenotype shared in humans with mutations in *RFX6*.[339] Motor neuron and pancreas homeobox 1 (Mnx1), formerly known as Hlbx9 or Hb9, is expressed early but, unlike the previously mentioned transcription factors, *Mnx1*-null mice fail to develop a dorsal pancreas, and the resulting pancreas has fewer and dysfunctional islets.[336,339,341] Similar phenotypic results were observed in humans with mutations in *MNX1*.



• **Fig. 23.12** Expression of main transcription factors during pancreatic embryogenesis. Knockout of *PDX1, MNX1* (previously called *HLXB9*), or *ISL1* is associated with early arrest of pancreatic development. *MNX1* knockout leads to failure of the pancreatic dorsal bud to develop with decreased β-cell number in the remnant pancreas. *HES1, PTF1A,* or neurogenin 3 *(NGN3)* disruption leads to aplasia or hypoplasia of the islets of Langerhans. Disruption of the downstream transcription factors impairs formation of the β cells or α cells. *SOX9* and *HNF3B* (not shown) are required for early foregut formation and pancreas specification. (Data from Habener JF, Kemp DM, Thomas MK. Minireview: transcriptional regulation in pancreatic development. *Endocrinology*. 2005;146:1025–1034.)

Hes family BHLH transcription factor 1 (Hes1) is a Notch signaling pathway component, and its loss in mice disrupts normal development of the pancreas but still allows formation of exocrine and endocrine cells.[340] During this period, the only hormone-positive endocrine cells produced are a small number of glucagon-positive cells. Whether these cells play a role in development and postnatal function and what that role might be is not understood.[336]

Starting at around e13.5 in the mouse, expression of the basic helix-loop-helix transcription factor neurogenin 3 (Ngn3) marks endocrine progenitor cells that will differentiate into the mature, hormone-producing cells of the islets of Langerhans.[336,339,340] Ngn3 is only highly expressed before hormone expression, and loss of *Ngn3* prevents the development of endocrine progenitor cells and consequently pancreatic islets. *Ngn3* knockout in the mouse leads to marked β-cell dysplasia and hypoplasia.[341] Ngn3 initiates a new set of developmental programs for endocrine cell lineage differentiation and maintenance. These include the LIM homeobox protein islet 1 (Isl1), paired box 4 and 6 (Pax4 and Pax6), aristaless related homeobox (Arx), and neuronal differentiation 1 (Neurod1), which are all lost in Ngn3-deficient mice. In mice, *Ngn3* knockout leads to complete absence of endocrine cells, whereas knockout of the lower pathway genes shown in Fig. 23.12 impairs specific islet cell differentiation.[341] *Nkx2.2, Nkx6.1, Pax4*, or *Pax6* loss of function results in endocrine cell agenesis or hypogenesis.[342–344] The competency of progenitors changes with time such that Ngn3$^+$ cells that arise early in development preferentially

differentiate into glucagon-positive cells while later $Ngn3^+$ cells give rise to insulin-positive or somatostatin-positive cells.[339]

During the later stages of β-cell differentiation, the MafB and MafA (V-maf musculoaponeurotic fibrosarcoma oncogene homologs B and A) transcription factors play a prominent role. Upon β-cell specification, the transcription of insulin is initiated and maintained by MafB, Pdx1, Neurod1, Pax6, and MafA. Additionally, Pax4, NKX6.1, and Pdx1 inhibit glucagon expression thereby preventing the expression of glucagon by β cells.[339]

Arx is one of the first known transcription factors to specifically mark the glucagon-producing α-cell lineage, and its loss prevents development of α cells with a concomitant increase in β and δ cells.[339] Indeed, a competitive reciprocal interaction between Arx and Pax4 is involved in the decision of cell fate between α and β cells. While Arx is necessary for the early specification of the α cell and directly maintains α-cell mass, it is not directly involved in glucagon expression. The Pax4-related factor Pax6 is expressed by both α and β cells. Pax6-deficient mice lack α cells. In addition to its role in insulin transcription in the β cell, Pax6 also coordinates glucagon transcription in the α cell directly by binding to the glucagon promoter and indirectly by inducing expression of other transcription factors such as c-Maf, MafB, and Neurod1, which also activate glucagon expression. A third factor that is crucial for later α-cell development is forkhead box A2 (Foxa2), which plays a role downstream of Arx and Pax6.[339]

A de novo heterozygous mutation in FOXA2 has been described in a child with congenital hyperinsulinism and congenital hypopituitarism with craniofacial dysmorphic features, choroidal coloboma, and endoderm-derived organ malformations in liver, lung, and gastrointestinal tract.[345,346] Expression profiling in human embryos by immunohistochemistry showed strong expression of hFOXA2 in endoderm-derived organs, including the pancreas, and transfection studies and Western blot assays demonstrated the causative role of FOXA2 in this syndrome. Upon successful specification of the α-cell lineage, pre-proglucagon expression is further promoted by forkhead box A1 (Foxa1), brain 4 (Brn4), and Isl1. Of all the transcription factors that can promote glucagon expression, expression of only two, Brn4 and MafB, is enriched in adult mouse α cells compared to β cells.[339]

More recent studies have compiled gene regulatory networks for pancreas development integrating data from multiple studies, including mutation analysis, gene expression, cell lineage tracing, and biochemical gene regulation. These networks include all the previously mentioned genes but also others such as *Tle2, Dll, Onecut1, BMP7,* and *SOX9.*[340] The transcription factor Glis-similar 3 (Glis3) has been implicated in the development of neonatal type 1 and type 2 diabetes.[347] Loss of functional *Glis3* leads to a severe reduction in both β-cell and pancreatic polypeptide cell numbers postnatally, as well as formation of cystic pancreatic ducts. Ngn3, glis-, and Glis3 represent the relatively "late actors" as their expression is restricted to the establishment of defined endocrine progenitor cells (or endocrine and ductal cells in the case of Glis3).

In humans, mutations in *GLIS3, NeuroD1, PDX1, PTF1A,* and *GATA6* are associated with neonatal diabetes mellitus due to pancreatic agenesis; mutations in *EIF2AK3* (encoding translation initiation factor 2-alpha kinase 3), *HNF1B* (hepatocyte nuclear factor-1β), *MNX1*, *NKX2.2,* and *RFX6* lead to neonatal diabetes due to pancreatic hypoplasia.[348–351] Recessive mutations in a distal enhancer of *PTF1A* also cause pancreatic agenesis.[352]

Functional Development of the Endocrine Pancreas

The human fetal pancreas is identifiable by 4 weeks of gestation and α and β cells can be recognized by 8 to 9 weeks. Insulin, glucagon, somatostatin, and pancreatic polypeptide are measurable by 8 to 10 weeks of gestation.[353] α Cells are more numerous than β cells in the early fetal pancreas and reach a relative peak at midgestation; β cells continue to increase throughout the second half of gestation so that, by term, the ratio of α to β cells is approximately 1:1. Both α and β cells have opposing roles in glucose homeostasis, although they derive from a common progenitor and share many proteins important for glucose sensing and hormone secretion. Mouse models have underlined the similarities between the two cell types by showing that β-to-α as well as α-to-β transdifferentiation can take place under certain experimental circumstances, revealing a remarkable degree of plasticity among the different pancreatic endocrine cells.[339]

The β cell is functional by 14 weeks of human gestation, and fetal pancreatic insulin content exceeds that of the adult throughout most of pregnancy. The insulin content of the pancreas increases from less than 3.6 pmol/g (0.5 U/g) at 7 to 10 weeks to 30 pmol/g (4 U/g) at 16 to 25 weeks of gestation and 93 pmol/g (13 U/g) near term; the concentration in the adult pancreas is approximately 14 pmol/g (2 U/g).[354] Endocrine cells are dispersed throughout the exocrine tissues by 20 weeks and the islets of Langerhans are clearly differentiated by 31 weeks.

Fetal glucose metabolism is largely independent of insulin and glucagon.[355–357] In physiologic doses, glucagon does not increase hepatic glucose production, probably because of a paucity of fetal hepatic glucagon receptors.[357] Insulin receptors are present in a variety of fetal tissues at levels generally exceeding those of the adult, but downregulation of insulin receptor binding does not occur during fetal hyperinsulinemia, in contrast with observations in adult animals. Acute hypoglycemia or hyperglycemia is not associated with significant alterations in either insulin or glucagon concentrations.

Although the fetal β cell is functional by 14 to 24 weeks of gestation, secretion of insulin into the bloodstream by the fetal pancreas is low. Insulin release from the fetal rat pancreas in vitro in response to glucose or pyruvate is minimal but can be stimulated by leucine, arginine, tolbutamide, or potassium chloride, indicating that parts of the secretory mechanism are functional in the fetus.[354,355,358] Insulin secretion in adult islets is mediated by two or more mechanisms, including stimulation of the adenylate cyclase system with production of cAMP and inhibition of potassium efflux, which leads to depolarization of the cell membrane and opening of voltage-dependent calcium channels. Calcium channel activation does not occur in fetal islets in response to initiators of insulin release that cause depolarization of adult islet cells.[358] Infusion of glucose or arginine to pregnant women fails to provoke fetal insulin secretion at midgestation or near term, and plasma insulin concentrations in the late human fetus are relatively unresponsive to high glucose concentrations before the onset of labor.[354] Similar observations have been made in the monkey: Neither glucose nor arginine stimulated fetal insulin release near term, but glucagon evoked prompt insulin production.[354] Late in gestation in the ovine fetus, epinephrine inhibits insulin release through a receptor pathway.[354]

In the anencephalic human fetus, the endocrine pancreas develops normally if maternal carbohydrate metabolism is not impaired; β-cell hypertrophy and hyperplasia do not occur in the anencephalic fetus or in decapitated fetal rabbits exposed to chronic hyperglycemia. This lack of β-cell response to hyperglycemia may be the result of deficiency of GH or IGF1, or both, because GH stimulates insulin gene expression and may play a permissive role in β-cell hyperplasia and hypertrophy.[338] Chronic

fetal hyperglycemia does evoke hyperinsulinemia and glucagon suppression, and chronic hypoglycemia may inhibit fetal insulin and promote fetal glucagon release.[343]

Pancreatic glucagon concentrations are relatively high in fetal plasma and increase progressively with fetal age.[354,355] The fetal pancreatic glucagon content at midgestation is approximately 6 μg/g, compared with an adult level of 2 μg/g. As is true for insulin, the capacity for glucagon secretion is blunted in the fetus. Hyperglycemia does not suppress fetal plasma glucagon concentrations in rats, monkeys, or sheep, and acute hypoglycemia does not evoke glucagon secretion in the rat fetus. Amino acids, which are important secretagogues for insulin and glucagon in the adult, probably have little role in modulating insulin and glucagon secretion in the preterm fetus, but infusion of alanine into women at term increases both maternal and cord blood glucagon concentrations, indicating a fetal glucagon response to amino acids in the term fetus. Catecholamines also evoke glucagon release in the near-term ovine fetus.[354]

Thus fetal pancreatic islet cells, although histologically mature and capable of hormone synthesis and hyperplasia, are relatively immature functionally at birth with regard to their capacity to secrete insulin and glucagon. The rapid maturation of responsiveness to glucose in the neonatal period in both premature and mature infants suggests that this blunted state may be a secondary result of the relatively stable fetal serum glucose concentrations maintained by placental transfer of maternal glucose rather than a primary, temporally fixed, maturation process. Alternatively, the lack of any enteric signal to the pancreas from feeding via release of incretins may also account for this stability. The blunted capacity for insulin and glucagon secretion has been related to a deficient capacity of the fetal pancreatic islet cells to generate cAMP or to rapid destruction of cAMP by phosphodiesterase, or both.[354]

In rodents, a period of a rapid increase in β-cell mass at the time of birth and shortly thereafter has been observed; this rapid change is attenuated by a period of apoptosis before adult mass is achieved. β-cell mass is more difficult to determine from a developmental standpoint in humans. At birth in the human, there are some 200 to 300 × 10^6 β cells, which is approximately one-third of the population present in adulthood. However, most of the actual mass change takes place in the newborn period and is associated with changes in β-cell size rather than number.[359] Thereafter, there is rapid further expansion in terms of cell numbers, but the waxing and waning of the β-cell mass, particularly with pregnancy, is poorly understood. How much β-cell mass is a determinant of progression to type 2 diabetes mellitus is unclear.

Insulin and glucagon are normally not necessary for substrate metabolism in the fetus.[355] Fetal energy needs are met by a continuous intravenous supply of glucose across the placenta, fetal glucose uptake being directly related to both the maternal blood glucose concentration and the transplacental gradient. There is little endogenous glucose production. The fetal respiratory quotient is approximately 1, which suggests that glucose is the primary energy substrate for the fetus. Other substrates, such as amino acids and lactate, may also be used in the human as in the sheep fetus and these, together with glucose, are stored as fat and glycogen in preparation for birth. Early in gestation, hepatic metabolism and substrate utilization appear to be independent of insulin and to be modulated in an autoregulatory fashion by glucose.[354] In addition, the constant supply of glucose normally precludes the necessity for endogenous gluconeogenesis, and gluconeogenic enzyme activities are low in the fetal liver.

Glycogen storage in the fetus is modulated by fetal glucocorticoids and probably by placental lactogen (hPL). Fetal insulin plays a role near term, when insulin also has the capacity to increase fetal glucose uptake and lipogenesis.[354,355] Insulin receptors are present on most fetal cells in higher numbers than on adult cells; moreover, hyperinsulinemia fails to downregulate fetal insulin receptors.[354] Fetal hepatic glucagon receptors, in contrast, are reduced in number, and fetal liver is relatively resistant to the glycemic effect of glucagon. These conditions tend to potentiate the fetal anabolic milieu during the period of rapid growth in the last trimester of gestation.

Pancreatic Regulation of Blood Glucose

During the neonatal period, the placental source of glucose is lost. A normal term infant has an immediate postnatal fall in blood glucose concentration during the first 2 to 4 hours from values close to maternal concentrations to around 2.5 mmol/L (45 g/dL) postpartum.[360,361] Low concentrations are usually transient, asymptomatic, and part of the normal adaptation to extrauterine life. Counterregulatory hormones rapidly become active, and these changes result in stabilization of blood glucose concentrations, although adult concentrations are not reached until approximately 72 hours of life.[360] Plasma glucagon concentrations rise in association with a rapid increase in functionally coupled glucagon receptors. The increase in plasma catecholamines coincident with parturition may be responsible for some of these changes; catecholamines stimulate glucagon and inhibit insulin release.[344,357,362] Phosphoenolpyruvate carboxykinase (PEPCK) activity also increases during this period. Thus gluconeogenesis is readily demonstrable in the newborn, where nearly 10% of glucose utilization is accounted for by gluconeogenesis from alanine.

Plasma free fatty acid concentrations increase postnatally because of the effects of catecholamines and chemical thermogenesis. Oxidation of fatty acids probably provides cofactors (acetyl coenzyme A and the reduced form of nicotinamide adenine dinucleotide) required for gluconeogenesis, as well as sparing glucose for utilization by crucially dependent tissues such as the brain.[344] Failure of this sequence of physiologic changes can lead to hypoglycemia, which is most common in the first few hours after birth. It has been reported that lactate may be neuroprotective in at-risk babies with hypoglycemia within the first 48 hours after birth, a time period when ketone bodies are unlikely to provide protection.[363] Neonatal hypoglycemia is common and is treated with supplemental feeds or intravenous glucose. Early feeding for prevention of hypoglycemia in at-risk babies (including infants of mothers with diabetes, small and large for gestational age, and preterm) is the mainstay of management. Dextrose gel is effective in treating neonatal hypoglycemia without affecting breastfeeding. The Pre-hPOD Study (*h*ypoglycemia *p*revention with *o*ral *d*extrose) reports the first randomized controlled trial (RCT) of prophylactic oral dextrose in at-risk babies, showing reduced incidence of neonatal hypoglycemia.[364]

Neonatal Diabetes

The neonatal diabetes phenotype encapsulates numerous subtypes, which involve severe disruption in β-cell function. Neonatal diabetes can be permanent and require lifelong treatment or may be transient, in which case the diabetes may spontaneously remit before 18 months of age (60% of cases) (or be so mild as not to require treatment) but will often relapse, usually during adolescence. Both have an incidence of approximately 1 in 200,000 to 250,000.[365]

Transient neonatal diabetes mellitus (TNDM) may be due to overexpression of an imprinted gene on chromosome 6q24 in the majority of cases, whereas activating mutations of *KCNJ11* and *ABCC8*, encoding for the two subunits (Kir6.2 and sulfonylurea receptor 1 [SUR1]) of the pancreatic β-cell ATP-sensitive inward rectifier potassium (K-ATP) channel account for 25% of cases. Mutations in the *INS* gene, encoding pre-proinsulin, are rarer, as are mutations in *ZPF57*, which regulates gene methylation. A genetic cause can be identified in approximately half of patients with NDM. Intrauterine growth retardation (IUGR) is another feature of TNDM, although not in TNDM due to K-ATP channelopathies. After remission, diabetes mellitus recurs in approximately 50% of cases.

Permanent neonatal diabetes mellitus (PNDM) is most often due to activating mutations in *KCNJ11* or *ABCC8*, resulting in overactivation of potassium channels and thus impaired insulin secretion. These patients are responsive to sulfonylurea therapy and do not require insulin treatment. Other causes of PNDM include *INS* and *GCK* mutations. Mutations in *EIF2AK3* (eukaryotic translation initiation factor 2-alpha kinase 3) lead to Wolcott-Rallison syndrome of which other features include skeletal abnormalities, liver dysfunction, cardiac and renal abnormalities, developmental delay, epilepsy, and neutropenia. *FOXP3* mutations result in IPEX (immune dysregulation, polyendocrinopathy, on X chromosome), which can lead to PNDM. Other monogenic causes of PNDM include mutations in genes encoding for zinc finger protein GLIS3, PAX6, the thiamine transporter SLC19A2, glucose transporter GLUT2 (encoded by *SLC2A2*),[366] NeuroG3, and NeuroD1, and genes important for pancreas development: *PTF1A* (hypoplasia of pancreas and cerebellum), *PDX1* (pancreas agenesis, endocrine and exocrine hormone deficiency),[367] *RFX6*, acting downstream of NeuroG3 (hypoplasia of pancreas, gallbladder, intestinal atresia, intractable diarrhea),[368,369] GATA4,[370] and GATA6.[367] Recently, mutations in *MNX1* (previously called HLXB9) and *NKX2-2*, coding for key transcription factors for pancreas development, were identified as monogenic causes for PNDM in humans.[350] Neonatal diabetes that does not respond to sulfonylurea therapy is best treated with continuous subcutaneous insulin infusion via a pump using rapid-acting insulin analogues. Dilution of insulin to fill the pump is often required for neonates and infants. Demand of insulin is so small, and feeding so frequent, that treatment with multiple daily injections is difficult.[371,372]

Although most cases of neonatal diabetes involve isolated diabetes, many of the known monogenic causes are characterized by a variety of syndromic features. Increased attention to the primarily genetic nature of early-onset diabetes has resulted in an expanding list of causal genes and an expansion of phenotypic characteristics in syndromic forms.

Hyperinsulinemic Hypoglycemia of Infancy

Hyperinsulinemic hypoglycemia (HH) is the most frequent cause of persistent and recurrent hypoglycemia in neonates and infants. It is due to unregulated secretion of insulin and can be transient or permanent.[373,374] Transient forms lasting for days are associated with maternal diabetes mellitus, maternal sulfonylurea treatment, and glucose infusions during labor. Poorly controlled maternal diabetes mellitus is associated with fetal macrosomia, an increased risk of spontaneous abortion, and fetal malformation. Maternal hyperglycemia also leads to hyperinsulinism and β-cell hyperplasia in the infant. Infants of diabetic mothers are prone to polycythemia, renal vein thrombosis, hypocalcemia, respiratory distress syndrome, jaundice, persistent fetal circulation, cardiomyopathy, congenital heart disease, and malformations of other organs.

Transient hyperinsulinism due to intrauterine growth retardation, perinatal asphyxia, and BWS can last for days to months and may require treatment.[375] Permanent hyperinsulinism can histologically be divided into focal and diffuse forms, which are inherited in, respectively, a sporadic and autosomal manner. To date, causative mutations in 12 different genes involved in β-cell insulin release have been described in congenital hyperinsulinism (CHI), for example, *ABCC8, KCNJ11, GLUD1, GCK, HADH, SLC16A1, HNF4A,* and *UCP2*.[374–376] *ABCC8* and *KCNJ11* encode for the subunits (Kir6.2 and SUR1) of the pancreatic β-cell ATP-sensitive K^+ channel.[377] However, the molecular basis of HH is unclear in up to 60% of patients.[375,376,378] Owing to their sensitivity to ATP, K^+ channels convert intracellular metabolic signals into membrane excitability in the following cascade. Glucose is transported into the cell by glucose transporters; intracellular glucokinase catalyzes an essential irreversible step for glycolysis. Intracellular glucose metabolism raises the cytosol ATP/adenosine diphosphate (ADP) ratio, which inhibits the SUR1 component of the K^+ channel, resulting in K^+ channel closure, which subsequently results in membrane depolarization, opening of voltage-gated calcium channels, and calcium influx, which then triggers the release of insulin from stored granules. Mutations in *ABCC8* and *KCNJ11* can thus result in oversecretion of insulin. The hyperinsulinism/hyperammonemia (HI/HA) syndrome is due to gain-of-function mutations in glutamate dehydrogenase (GDH) and is characterized by both fasting hypoglycemia and hyperinsulinemic hypoglycemia due to protein ingestion.[379] Certain syndromes have been associated with hyperinsulinism: overgrowth syndromes (BWS, Sotos, Simpson-Golabi-Behmel), chromosomal abnormalities (trisomy 13, mosaic Turner syndrome), growth failure syndromes (Kabuki syndrome, Costello syndrome), syndromes with abnormal calcium homeostasis (Timothy syndrome), congenital disorders of glycosylation, congenital hypoventilation syndrome, and a contiguous gene deletion, including *ABCC8* (Usher syndrome).[375]

The rarest forms of CHI have recently been associated with inactivating mutations in the uncoupling protein 2 gene *(UCP2),* a mitochondrial inner membrane protein,[380] and recently the spectrum of genetic causes for HH has been extended with the reported co-occurrence of congenital hyperinsulinism and congenital polycystic kidney disease, caused by a promoter mutation in the phosphomannomutase 2 gene *(PMM2)*.[381]

At the time of hypoglycemia, a hypoglycemia screen, including glucose, insulin, C-peptide, acetoacetate, and β-hydroxybutyrate, will easily identify congenital hyperinsulinism.

Diagnostic criteria are a glucose infusion rate more than 8 mg/kg/minute, a laboratory blood glucose less than 3 mmol/L with detectable serum insulin or C-peptide, low serum ketone bodies, and low serum fatty acids.

First-line treatment is diazoxide and chlorothiazide, and second-line treatment is octreotide and glucagon. Patients who are diazoxide insensitive need further investigation with a combined computed tomography (CT)/^{18}F-DOPA positron emission tomography (PET) scan to assess for focal or diffuse lesions. Focal lesions can be cured with surgery, whereas diffuse lesions require near-total pancreatectomy, which usually does not result in a cure and may lead to diabetes mellitus.[377]

Tremendous advances are being made in the field of hyperinsulinemic hypoglycemia, for example, use of rapid molecular genetic testing, application of novel imaging techniques (6-[fluoride-18]

fluoro-levodopa [^{18}F-DOPA] PET-CT, glucagon-like peptide 1 [GLP1] receptor imaging), and development of new medical therapies (e.g., long-acting octreotide formulations, mammalian target of rapamycin [mTOR] inhibitors, GLP1 receptor antagonists) and laparoscopic surgical techniques.[373,374]

Parathyroid/Calcitonin System

Embryology

During the fifth to sixth week of intrauterine development, the embryonic pharynx is marked externally by four branchial clefts of ectoderm origin and internally by five branchial pouches of endoderm origin. The branchial arches of mesoderm origin are in between them. Together these structures comprise the branchial apparatus, which normally undergoes involution leaving behind derivatives, including the thyroid gland, parathyroid glands, thymus, ultimobranchial body, eustachian tube, middle ear, and external auditory canal.[382]

The parathyroid glands develop as epithelial thickenings of the dorsal endoderm of the third and fourth branchial pouches. The superior parathyroid glands are derived from the fourth branchial pouch, which also gives rise to the thyroid gland. The third branchial pouch gives rise to the inferior parathyroid glands and the thymus. The parathyroid glands remain intimately connected with their respective branchial pouch derivatives, and parathyroid gland development from the third and fourth pharyngeal pouches proceeds in synchrony with thyroid embryogenesis.[21,383]

The third pouches encounter the migrating thyroid anlage, and the parathyroid anlagen are carried caudally with the thyroid gland, finally coming to rest at the lower poles of the thyroid lobes as the inferior parathyroid glands.[21,383] The fourth pouches encounter the thyroid anlage later and come to rest at the upper poles of the thyroid lobes as the superior parathyroid glands.[21,383] The individual parathyroid glands increase in diameter from less than 0.1 mm at 14 weeks of gestation to 1 to 2 mm at birth. Most of the parathyroid gland parenchyma is composed of chief cells (also known as the parathyroid gland principal cells). These play a critical role in calcium homeostasis by sensing changes in extracellular calcium concentration and releasing the appropriate amount of PTH to correct or maintain normal blood calcium concentrations. The chief cells spend most of their time inactive due to normal calcium homeostasis. Near term, fetal parathyroid cells are largely composed of inactive chief cells, with only a few intermediate chief cells containing occasional secretory granules. The fifth pouches contribute paired ultimobranchial bodies that are incorporated into the developing thyroid gland as the parafollicular or C cells that secrete calcitonin. The calcitonin content of C cells in the neonatal thyroid gland is as high as 540 to 2100 mU/g of tissue, values as much as 10 times those observed in the normal adult gland.[384] Both endocrine systems are functional during the second and third trimesters.

Transcription Factors Involved in Development of Parathyroid Glands

The molecular signaling pathways that are involved in determining the differentiation of the pharyngeal pouch endoderm into parathyroid cells are being elucidated by studies of patients with hypoparathyroidism and appropriate mouse models. These studies have revealed important roles for several transcription factors, which include members of the homeobox (Hox) and paired box (Pax) families. Disruption of the *Hox15* gene in mice results in parathyroid gland aplasia, indicating that this gene functions as part of the genetic cascade programming normal thyroid-parathyroid gland development. Deletions of genes encoding several transcription factors in mice result in developmental anomalies that include parathyroid defects, although such abnormalities have not yet been reported in man. The transcription factors include members of the Hox (Hoxa3, which results in parathyroid agenesis, and Pbx1, a protein that acts as a cofactor of HOX transcription factors) and Pax (Pax 1,3,9) families, the eyes absent homologue (Eya1) and sine oculis homeobox homologue (Six1).[385]

Human disorders with congenital hypoparathyroidism have been found in association with mutations and deletions in *GATA3* (hypoparathyroidism, deafness, renal dysplasia [HDR] syndrome), *AIRE1* (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED] syndrome or autoimmune polyglandular syndrome type 1 [APS1]), and tubulin folding cofactor E *(TBCE)* gene (Kenny-Caffey syndrome). *TBX1* (a DNA-binding transcriptional factor of the T-box family that is known to have an important role in vertebrate and invertebrate organogenesis and pattern formation) and *CRK1* mutations have been associated with 22q11 deletion syndrome.[386]

Isolated hypoparathyroidism can be found in association with mutations in *PTH*, *GCMB* (the human homologue of the mouse glial cells missing 2 *[Gcm2]* gene, which is expressed exclusively in the parathyroid glands) and the SRY-related HMG-box gene 3 *(SOX3)*.[385] X-linked recessive hypoparathyroidism has been reported in two multigenerational, related kindreds with a deletion-insertion downstream of *SOX3* likely to exert a position effect on *SOX3* expression. These findings point to a potential role for the *SOX3* gene in the embryologic development of the parathyroid glands from the pharyngeal pouches.

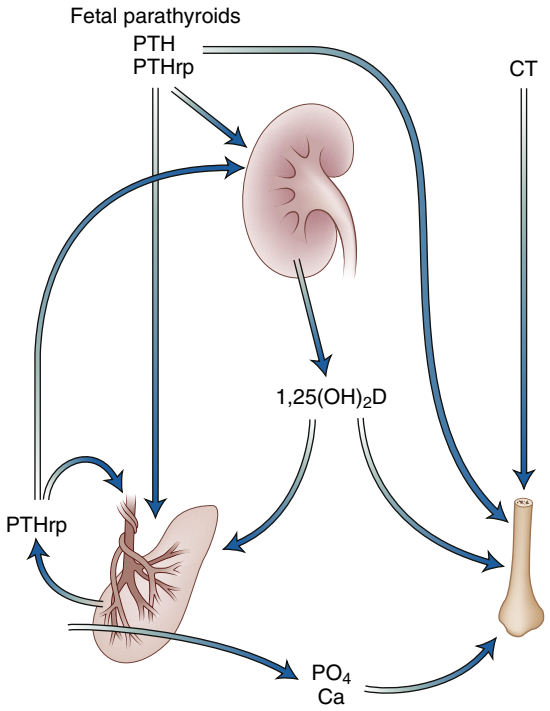
Fetal and Neonatal Calcium Metabolism

Parathyroid hormone produced by the parathyroid glands is an 84–amino acid sequence that stimulates bone resorption, renal tubular absorption, and synthesis of calcitriol in the kidneys. There is a negative feedback loop with ionized calcium and calcitriol. PTH-related protein (PTHrp) binds to and activates PTH receptors. This is expressed in the uterus, placenta, amnion, umbilic cord, lactating breast, and fetal parathyroid glands. In animal models, despite maternal hypocalcemia induced by a calcium-restricted diet, vitamin D deficiency, parathyroidectomy, or a vitamin D receptor deletion model, fetuses were reported to be normocalcemic. The calcium concentration in the fetus is therefore independent of the maternal calcium concentration (Fig. 23.13).

Studies in fetal sheep and monkeys and measurements in human preterm and term infants indicate that the majority of calcium is transported in the third trimester. Concentrations of total calcium (averaging 2.75–3 mmol/L in the third trimester) and ionized calcium, as well as phosphate and magnesium, are higher in the fetal circulation compared to maternal, demonstrating active transport of calcium across the placenta against a concentration gradient.[387,388] Nearly all the calcium transferred to the fetus is involved in mineralization of the fetal skeleton.[389]

Calcium enters the placental trophoblast at the brush-border membrane primarily via the TRPV6 channel. Transport is facilitated by calbindin D9K, and calcium is released to the fetal circulation through the calcium pump PMCA3. Inorganic phosphate enters the trophoblast probably via the sodium-phosphate cotransporter NaPiIIb.[387] A three-step model of transcellular placental calcium transport has been proposed[387,390]:

1. Influx of calcium ions from the maternal circulation involving voltage-dependent calcium channels (primarily transient



• **Fig. 23.13** Proposed actions of parathyroid hormone (PTH), PTH-related protein (PTHrp), and calcitonin (CT) in the fetus. PTHrp and perhaps PTH from the parathyroid glands and PTHrp from the placenta act on the placenta to promote calcium (Ca) and phosphate (PO_4) transport from the maternal to the fetal circulation to maintain the relative fetal hypercalcemia and the high rate of fetal bone formation during the last half of gestation. PTHrp also acts on the kidney to promote 1-hydroxylation of 25-hydroxycholecalciferol to $1,25(OH)_2D$ (1,25-dihydroxyvitamin D, calcitriol), which augments placental calcium transport and promotes fetal bone growth. High fetal CT levels tend to promote bone accretion. See text for details. (From Kovacs CS. Bone metabolism in the fetus and neonate. *Pediatr Nephrol*. 2014;29:793–803.)

receptor potential cation channel, subfamily V, member 6 [TRPV6], which is a calcium channel that opens in the maternal-facing basement membrane of the syncytiotrophoblast to enable calcium entry into cells) at the apical brush-border membrane of the trophoblast cells at the maternal-placental interface.

2. Movement of calcium through trophoblastic cytosol, involving intracellular calcium-binding proteins (mainly calbindin D9K), which transport calcium to the basal membrane.
3. Efflux of calcium ions from cytosol across the basolateral placental membrane involving a membrane ATP-dependent calcium pump (PMCA3, at the placental-fetal interface), which transports calcium into the fetal circulation.

Calcium and phosphate are maintained at a higher set-point in the fetus than in the pregnant mother, especially in the third trimester, to meet the demands of fetal bone mineralization. In late gestation, fetal serum concentrations of calcium and phosphate are maintained above the maternal concentrations by approximately 1.2 to 2 mg/dL and 1.5 mg/dL, respectively.[388] Although the fetal concentration of Mg is also increased compared with the maternal value, the gradient is less (~0.12 mg/dL)[388] than those of calcium and phosphate. Although the molecular mechanism of transplacental calcium transport has been well studied, little is known about the transport mechanism of phosphate and magnesium.

Fetal serum phosphate is also higher than maternal serum concentrations. The type IIb sodium-dependent inorganic phosphate transporter (NaPiIIb) is expressed in embryonic visceral and parietal endoderm as well as in labyrinthine cells of the placenta and likely has a role in fetal phosphate homeostasis.[387] Little is known of the mechanism of placental magnesium transport.

The placenta is impermeable to PTH, PTHrp, and calcitonin, but 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D (calcitriol) are transported across the placenta, and free vitamin D concentrations in fetal blood are similar to or higher than maternal values.[391,392]

The fetal sheep has low circulating concentrations of PTH but can increase serum PTH concentrations in response to a fall in serum calcium concentration induced by ethylenediaminetetraacetic acid (EDTA) and can respond promptly to infused calcium with increased serum calcitonin concentrations. In this model, fetal parathyroidectomy decreases placental calcium transport and lowers fetal serum calcium.

Although PTH has no effect on placental calcium transport, PTHrp is present in fetal tissues and placenta and stimulates calcium transport. The principal PTH receptor is PTHR1, which has equal affinity for PTH and PTHrp. A second receptor, PTHR2, is present in CNS and binds PTH but not PTHrp, whereas PTHrp action in the placenta occurs likely through a distinct receptor that binds PTHrp but not PTH.[387,393]

The PTH concentration in the fetus near the end of gestation is lower (<4.72 pg/mL) than maternal or nonpregnant adult concentrations. In cord blood, the concentration of PTHrp is 15-fold higher than that of PTH at term and plays a critical role in perinatal calcium homeostasis and maintenance of the higher fetal calcium set-point.[390,394] In the fetus, PTHrp is produced in many tissues, including the placenta. PTH plays an essential role in regulating calcium and bone homeostasis in the adult, but whether PTH is required at all for regulating fetal-placental mineral homeostasis and skeletal development is uncertain. It is unknown whether the human placenta produces PTH. Since maternal PTH concentrations are suppressed during pregnancy compared with those in the nonpregnant adult, fetal PTH concentrations appear to be strongly suppressed. Little PTH is detectable in fetal plasma using immunoassays, whereas bioassays showed significant bioactivity.[395] Parathyroid glands are active in the human fetus from about 12 weeks of gestation, and thyroparathyroidectomy in the fetal sheep causes a rapid decrease in fetal plasma calcium concentration and a loss of the placental calcium gradient.[391] Although the fetal PTH concentrations are very low, fetal PTH is thought to be important because fetal mice lacking parathyroid glands, PTH, or the PTH/PTHrp receptor are hypocalcemic and have undermineralized skeletons.[389,396,397] The principal factor responsible for this bioactivity would therefore appear to be PTHrp rather than PTH itself.

Other factors are involved in maintenance of fetal serum calcium concentrations because knockout of the mouse gene for PTH-PTHrp also results in hypocalcemia in the presence of normal or increased placental calcium transport.[390,398] PTH and PTHrp through the PTH/PTHrp receptor presumably modulate fetal skeletal calcium flux, calcium excretion through the fetal kidney, and perhaps reabsorption of calcium from amniotic fluid. PTHrp has a major role in fetal bone development and metabolism as well as fetal calcium homeostasis. PTHrp knockout mice display increased ossification of the basal portion of the skull, long bones, vertebral bodies and pelvic bones, and mineralization of the normally cartilaginous portions of the ribs and sternum; as

a result of the cartilaginous mineralization, the animals die of asphyxiation in the early neonatal period.[390,394,399,400]

The skeletal chondrodysplasia is more severe in combined PTH plus PTHrp or PTH/PTHrp receptor gene–ablated animals.[397,401] In the mouse, knockout of the calcitonin gene or the vitamin D receptor gene leads to postnatal osteosclerosis or osteomalacia, respectively; the pups appear normal at birth.[402] Studies have demonstrated that *Pthrp*-null fetuses had hypocalcemia (equal to maternal blood concentration), hypomagnesemia, hyperphosphatemia, reduced fetal-placental calcium transfer, normal amniotic fluid calcium content, and normal skeletal mineral content,[389] but the absence of parathyroids caused a more substantial reduction in serum calcium and skeletal mineral content than absence of PTHrp despite the fact that PTH normally circulates at low concentrations in the fetus.

PTH-null mice have enlarged parathyroids that are incapable of making PTH, whereas *Gcm2*-null mice lack parathyroids but have PTH that arises from the thymus. *PTH*-nulls served as a model of complete absence of PTH, whereas *Gcm2*-nulls are a model of severe hypoparathyroidism. Simmonds and colleagues demonstrated that PTH contributes to fetal mineral homeostasis because a fetal hypoparathyroid phenotype results with hypocalcemia, hypomagnesemia, hyperphosphatemia, low amniotic fluid mineral content, and reduced skeletal mineral content in its absence.[389] PTH regulates the placental expression of genes involved in calcium and other solute transfer and may contribute to the regulation of placental calcium transfer. PTH may contribute to placental gene expression and function through both endocrine/systemic (parathyroid-derived) and paracrine (placental-derived) pathways. Although parathyroid hormone–related protein (PTHrP) acts in concert with PTH to regulate fetal mineral homeostasis and placental calcium transfer, unlike PTH, it does not upregulate in response to fetal hypocalcemia.

The fetal parathyroid-placental axis promotes maternal-fetal transfer of bone mineral and accretion of fetal bone mineral. It seems likely that fetal PTH and presumably PTHrP act on the fetal kidney to stimulate 1α-hydroxylation of 25-hydroxyvitamin D and that 1,25-dihydroxyvitamin D participates in modulating placental calcium transport. $1,25(OH)_2D$ or $24,25(OH)_2D$ also play a role in fetal cartilage growth and bone mineral accretion.[403] Thus PTHrP and to a lesser extent PTH in the ovine fetus appear to augment maternal-to-fetal calcium transport across the placenta and thus provide for the high rate of bone mineral accretion in the latter half of pregnancy.

During pregnancy, maternal 25(OH)D crosses the placenta, so the fetal concentrations of 25(OH)D reach 75% to 100% of the maternal concentration at term.[404] Fetal $1,25(OH)_2D$ concentrations, however, are lower than that in the mother (<50%).[405] The maternal concentration of $1,25(OH)_2D$ during pregnancy is twofold to threefold higher than that in the nonpregnant adult. It is suggested that the maternal kidneys contribute to the abundance of $1,25(OH)_2D$ in the pregnant mother.[406] Nephrectomy in the fetal sheep reduces fetal serum calcium concentrations, and this can be prevented by prior administration of 1,25-dihydroxyvitamin D. Moreover, infusion into the sheep fetus of antibody to $1,25(OH)_2D$ reduced the placental calcium gradient.[391] The fetal kidney can produce $1,25(OH)_2D$ and the placenta contains $1,25(OH)_2D$ receptors, as well as a vitamin D–dependent calcium-binding protein.[400] It is thought that the synthesis of $1,25(OH)_2D$ in the fetus is suppressed by the high concentrations of calcium and phosphate and low concentrations of PTH.

The high blood concentrations of calcitonin in the fetus, probably resulting from the chronic stimulation by fetal hypercalcemia, are thought to contribute to the fetal bone mineral accretion.[391,397] The predominant effect of calcitonin is to inhibit bone resorption, and the high fetal serum calcium concentrations coupled with high circulating calcitonin promote bone mineral anabolism.[397] Placental calcitonin production may contribute to the calcitonin in fetal plasma, but the persistence of high plasma concentrations in neonatal plasma argues for predominant fetal production. Thyroid C cells begin to differentiate at around week 12 of gestation,[407] and calcitonin is detectable at around week 15 of gestation. Fetal circulating calcitonin concentrations are approximately twofold higher than those in the mother.[388,408,409] The trophoblasts of the placenta also produce calcitonin and supply it to the fetus.[410] Since calcitonin does not cross the placenta in the mouse or rat,[411] fetal circulating calcitonin is derived from fetal sources. The major source of fetal circulating calcitonin has not been determined.

Calcium-Sensing Receptor (CaSR) and FGF23

The calcium-sensing receptor plays a pivotal role in systemic calcium metabolism by modulating production and secretion of calcium-regulating hormones such as PTH, calcitonin, FGF23 and vitamin D, and urinary calcium excretion.[412,413] The CaSR is present in parathyroid glands, renal tubules, bone and cartilage, and many other tissues. Magnesium binds to the CaSR and influences PTH secretion. Mutations within the *CaSR* result in either inactivation or overactivation of the receptor resulting in hypercalcemia or hypocalcemia, respectively.[414] Inactivating mutations lead to switching off of PTH secretion at a lower calcium concentration than usual and hypercalcemia ensues. Renal calcium secretion is reduced.

Hypercalcemia disorders related to inactivating mutations of the *CASR* gene are either heterozygous (autosomal dominant familial benign hypercalcemia [FBH], still named hypocalciuric hypercalcemia syndrome type 1) or homozygous (severe neonatal hyperparathyroidism). The differential diagnosis consists of the hypocalciuric hypercalcemia syndrome, types 2 (involving *GNA11*) and 3 (involving *AP2S1*), hyperparathyroidism, abnormalities of vitamin D metabolism involving *CYP24A1* and *SLC34A1* genes, and reduced GFR.

Hypocalcemia disorders, which are rarer, are related to heterozygous activating mutations of the *CASR* gene (type 1), consisting of autosomal dominant hypocalcemia (ADH), sometimes with a presentation of pseudo-Bartter syndrome. The differential diagnosis consists of the hypercalciuric hypocalcemia syndrome type 2, involving *GNA11* and other hypoparathyroidism etiologies. An online database to keep track of described mutations is available at http://www.casrdb.mcgill.ca.

Some conditions are particularly important in the neonatal period. When a neonate presents with abnormal calcium concentrations, assessment of calcium, albumin, phosphate, creatinine, alkaline phosphatase, vitamin D and urine Ca-creatinine ratio, and phosphate reabsorption in both the child and parents will help formulate the underlying diagnosis. Hypocalcemia resulting from fetal and maternal vitamin D deficiency is relatively common. Occasionally, severe neonatal vitamin D deficiency can be associated with a dilated cardiomyopathy, which is reversible.[415,416] Asphyxia can result in subcutaneous fat necrosis, which is due to release of 1,25(OH)D from macrophages and leads to hypercalcemia. Hyperhydration, steroid therapy, low calcium milk, and occasionally bisphosphonate treatment may be needed to reduce calcium concentrations.

FBH and familial hypocalciuric hypercalcemia (FHH) can present in neonates with mild to moderately elevated calcium concentrations, high normal (nonsuppressed) PTH, and a low urine Ca-creatinine ratio.[417] FHH may also present as neonatal hyperparathyroidism leading to bone disease and variable symptoms of hypercalcemia. This occurs especially if an affected infant has inherited the inactivating *CaSR* mutation from the father while the mother is normal. The fetus will consider the mother as hypocalcemic and therefore overproduce PTH. Cinacalcet therapy may help bind calcium and settle the hyperparathyroidism but parathyroidectomy is occasionally necessary. Hypocalcemic and hypercalcemic disorders may also be due to mutations in G protein subunit alpha 11 (*GNA11*), *AP2S1* (involved in G protein internalization), and calcium channels *TRPV5* and *TRPV6*.[418,419]

FGF23 is the principal hormone that regulates phosphate transport. It is primarily produced and secreted into the circulation by osteocytes and, after its activation through glycosylation by GALNT3, acts through FGFR1c and FGFR4 on renal tubules to increase phosphate excretion through the sodium-phosphate exchanger (NaPiIIC, SLC34A3).[420] α-Klotho acts as a cofactor for FGF23 to bind to FGFR1c, increasing specificity of FGFR1c for FGF23. FGF23 is inactivated by cleavage by subtilisin/furin-like enzyme. PHEX (phosphate regulating gene with homologies to endopeptidases on the X chromosome) regulates cleavage of FGF23 and *PHEX* mutations, and therefore renders FGF23 constitutively active. Besides increasing renal tubular phosphate excretion, FGF23 inhibits 1α hydroxylase, thus reducing 1,25 vitamin D activity. Loss of FGF23 or components of the FGF23 network (*GALNT3*, *FGF23, α-Klotho*) cause hyperphosphatemia, extraskeletal calcifications, and early mortality; excess FGF23 or pathway components (*FGF23, PHEX, SLC34A3,* subtilisins *[PCSKs],* phosphate transporters *NPT2a* and *NPT2c*) cause hypophosphatemia with rickets or osteomalacia.[421] However, FGF23 may not be important during fetal development. In a study by Ma and colleagues, FGF23 deficiency (*Fgf23*-null) and FGF23 excess (*Phex*-null) did not alter fetal phosphorous or skeletal parameters.[422] Although FGF23 is present in the fetal circulation at concentrations that may equal adult values, and there is robust expression of FGF23 target genes in placenta and fetal kidneys, FGF23 itself may not be an important regulator of fetal phosphorous metabolism.

Fetal Growth

The hormones most important for postnatal growth, T_4, GH, and gonadal steroids have a limited role in fetal growth, even though TR and GHR are expressed in many embryonic tissues, including the growth plates.[1] Placental hormones, including the human GH variant and placental lactogens (hPL), play a limited role; hPL may promote early embryonic growth and may stimulate IGF and insulin production.[1] IGF1 and IGF2 are produced by the placenta and may exert autocrine-paracrine actions on placental growth. IGF1, IGF2, and the IGF1 and IGF2 receptors are widely expressed in fetal tissues of mesenchymal, ectodermal, and endodermal origin and play critical roles in modulating normal fetal growth, including the nervous system.[423,424]

Insulin-Like Growth Factors

IGFs are involved in regulation of uterine and placental growth during pregnancy. In early embryonic and fetal development, IGF1, EGF, and estrogens are mitogens for endometrial stromal cells, and the endometrial contents of *IGF1* and *IGF1 mRNA* are high at implantation and during early embryogenesis in the sow.[425] Uterine *IGF1* and *IGF1 mRNA* levels decrease progressively with advancing gestation.[425] Placental tissue also contains *IGF1* and *IGF2 mRNAs,* significant concentrations of the respective proteins, and IGF1 receptors.[25] Autocrine and paracrine roles for the IGFs in uterine and placental tissues are postulated. IGF1 and insulin are produced by embryonic tissues during the prepancreatic stage of mouse development; both factors stimulate growth of embryonic mouse cells.[426]

IGF2 is genomically imprinted and paternally expressed in the fetus and placenta. The mature IGF2 protein is generated from the biologically inactive pro-IGF2 peptide by the action of proprotein convertase 4. Previous studies have shown a role of IGF2 in determining placental nutrient supply and hence fetal growth.[427] In mutant mice lacking the imprinted placental-specific *IGF2* transcript, growth of the placenta is altered from early gestation, but fetal growth is normal until late gestation, suggesting functional adaptation of the placenta to meet the fetal demands. It is believed that this adaptation may be mediated by the altered expression of placental transporters GLUT3 and Slc38a4.[428]

Studies of transgenic mice with null mutations of the genes encoding *IGF1, IGF2,* or the *IGF1 receptor* have defined the role of these somatomedins; the birth weight of embryos lacking IGF1 or IGF2 is only 60% that of control mice. When both genes are inactive, birth weight is reduced by another 30%, and mice lacking the IGF1 receptor have birth weights averaging 45% of control values.[157] IGF2-deficient mice also manifest intrauterine growth retardation in association with a small placenta. They have near-normal postnatal growth but delayed bone development.[157] *IGF2-receptor* knockout fetal mice are 30% overweight, suggesting a negative growth-modulating effect of this receptor.

The normal growth in fetuses with both IGF1 receptor and *IGF2 receptor* knockout is caused by IGF1 signaling via the insulin receptor; combined IGF1, IGF2, and insulin receptor knockout results in severe intrauterine growth retardation and fetal death. Knockout of individual IGF-binding proteins (IGFBP) has little effect on fetal or placental growth.[157] In humans, mutations in *IGF1* or *IGF1R* are associated with intrauterine growth retardation,[429,430] suggesting that IGF1 signaling contributes significantly to fetal growth. Apart from growth retardation, these children also suffer from developmental delay, microcephaly, hypoglycemia, and sensorineural hearing loss.[428,429] Indeed, there is a relation between umbilic IGF1 concentration and birth weight in humans; maternal smoking reduces both umbilic IGF1 and birth weight.[431,432]

Recent work in mice suggests that IGF1 and IGF1R are required for late gestational lung maturation.[433] Hypomethylation of the 11p15 imprinted region has been associated with the phenotype of Silver-Russell syndrome (SRS).[434] This results in the relaxation of imprinting and biallelic expression of *H19* and downregulation of *IGF2*. Additionally, abnormal processing of IGF2 by proprotein convertase 4 in the placenta has been implicated in the etiology of fetal growth restriction.[435] Pregnant women carrying fetuses with intrauterine growth retardation (IUGR, low birth weight for gestational age) had higher concentrations of pro-IGF2 compared with controls. Recently, a genomic mutation of the human *IGF2* gene was described in four individuals from one family who exhibited severe intrauterine and postnatal growth retardation and signs of SRS.[436] The defect was a nonsense mutation with a predicted severe truncation of the prepro-IGF2; the disorder was paternally inherited and affected children had diminished IGF2 serum concentrations.

Murphy and colleagues reported severe intrauterine growth retardation and atypical diabetes mellitus secondary to insulin resistance in association with disruption of regulation of the *IGF2* gene.[437] On the other hand, overexpression of IGF2 as a result of loss of imprinting associated with uniparental disomy, *CDKN1C* gene loss of function, alteration in the KvLQT1 differentially methylated region (DMR), or microdeletions in the human H19 DMR are associated with overgrowth in the form of BWS.[438] As highlighted previously, activating mutations in the proliferating cell nuclear antigen (PCNA)–binding domain of *CDKN1C* have been shown to cause IMAGe syndrome.[181] Arboleda and colleagues demonstrated that missense mutations in the PCNA-binding domain have an inhibitory effect on growth and differentiation in vivo, via loss of binding of PCNA to CDKN1C.[181] The contrast between BWS and IMAGe mutations in *CDKN1C* highlights the dual and opposing effects of specific *CDKN1C* mutations.

IGF-binding proteins (BPs) are present as early as 5 weeks of gestation; prenatally as postnatally, the IGFs circulate in association with binding proteins.[157] High concentrations of circulating IGFBP1 are associated with fetal growth restriction in the mouse, as is overexpression of fetal IGFBP1 in the human.[439,440] IGFBP4, expressed in the maternal decidua and cleaved by its protease PAPP-A (pregnancy-associated plasma protein-A), inhibits IGF action. High maternal concentrations of IGFBP4 were recently shown to be related to fetal growth restriction.[435] During fetal and postnatal life, plasma concentrations of IGFs are relatively high compared with tissue concentrations.

In the fetus, IGF2 concentrations are five to six times higher than those of IGF1 in contrast to these concentrations in children and adults; concentrations of both increase progressively throughout gestation,[441] and fetal concentrations at term are 30% to 50% of the adult concentrations. The metalloproteinase pregnancy-associated plasma protein-A2 (PAPP-A2) regulates IGFBPs and is hypothesized to increase IGF1 bioactivity by specific proteolytic cleavage of IGFBP3 and 5. Mutations in *PAPPA-A2* have recently been shown to cause short stature due to low IGF1 availability as part of a novel syndrome of growth failure.[442] The two mutations described by Dauber and colleagues were shown to cause a complete absence of PAPP-A2 proteolytic activity, a significant increase in bound IGF1 and decreased IGF1 concentrations, highlighting the critical role of PAPP-A2 in releasing IGF1 from its BPs.[442]

In most studies, cord blood IGF1 concentrations correlate with birth size. Despite the fetal growth–enhancing effects of IGF2, blood concentrations are only weakly related to size at birth, largely because of the inhibiting effect of soluble IGF2 receptor (IGF2R)[424] but also because IGF2 appears to exert most of its growth effects in the earlier part of gestation. Soluble IGF2R is derived through proteolytic cleavage of the transmembrane region of the receptor in many tissues. IGF receptors have been identified as early as 5 weeks of gestation and are widespread in fetal tissues.[443] IGF1 stimulates glycogenesis in cultured fetal rat hepatocytes and induces formation of myotubes in cultured myoblasts. IGF2 is active in cultured muscle and neonatal rat astroglial cells. Insulin receptors are increased in fetal cells and are resistant to downregulation.

The control of IGF production differs in fetal and postnatal life. GH receptors are present, but receptors for hPL predominate in fetal tissue[61]; GH, which stimulates IGF1 production after birth, has a limited role in fetal IGF production.[423] GH does play a minor role in fetal growth, as reflected in the low IGF concentrations and slight reduction in birth weight and length in infants with GH resistance (Laron dwarfism) and growth hormone deficiency.[444] hPL stimulates IGF1 production and augments amino acid transport and DNA synthesis in human fetal fibroblasts and muscle cells.[61] IGF1 and IGF2 concentrations are reduced in fetuses of protein-starved pregnant rats, and the low IGF2 concentrations are reversed by hPL.[445]

Thyroidectomy of the third-trimester sheep fetus impairs skeletal muscle growth in association with a decrease in muscle *GH receptor mRNA* and *IGF1 mRNA* without an effect on IGF2 concentrations.[446] Glucocorticoids can inhibit fetal growth, presumably by inhibiting *IGF* gene transcription, but may also affect growth plate chondrocytes directly.[446] Indeed, nutrition is the major factor modulating IGF production in the fetus. IGF concentrations fall in suckling rats deprived of milk, and IGF1 and IGF2 concentrations are reduced in fetuses of protein-starved pregnant rats and placentally restricted sheep.[156,157] Recent work suggests that light stimuli alter circulating and brain IGF1 concentrations and control neuronal migration through increased IGF1 signaling.[447] Weekly intra-amniotic injections increase fetal growth of intrauterine growth–restricted sheep.[448] These data support the view that IGFs are important in embryonic and fetal growth and that in the fetus they are regulated, at least in part, by hPL and by nutritional substrate derived transplacentally. The high concentrations of IGF2 in fetal rat serum, the high concentrations of *IGF2* mRNA in fetal tissues, and the presence of a truncated form of IGF1 in human fetal brain tissue suggest unique developmental actions of these peptides.

Insulin

Insulin has been proposed to act as a fetal growth factor. Infants born to women with diabetes mellitus may have hyperinsulinemia associated with increased birth weight.[449] Most of this increased weight is accounted for by body fat; there is little increase in body length, but some organomegaly may occur. Infants with hyperinsulinemia caused by congenital hyperinsulinism or the BWS may also have increased somatic growth in utero; the human neonate is born large for gestational age, primarily due to increased lipogenesis mediated by insulin or IGF1 receptors. Conversely, the human fetus with pancreatic agenesis is small and has decreased muscle bulk and little or no adipose tissue.[449]

Mice with insulin or insulin receptor gene mutations have a 10% decrease in birth weight and early neonatal death with hyperglycemia and ketonemia.[157] Insulin receptor mutations in humans lead to severe intrauterine growth retardation and limited postnatal weight gain.[157] In contrast to mice, the human fetus during the latter half of gestation has a significant increase in adipose mass, and adipose tissue is highly sensitive to insulin. Treatment with IGF1 improves the clinical condition to some extent.[450]

Epidermal Growth Factor/Transforming Growth Factor

The EGF/TGFα system has been characterized in considerable detail.[451,452] EGF is a 6-kDa peptide product of a large, 1207–amino acid precursor molecule and acts through a 170-kDa membrane receptor glycoprotein. This has intrinsic tyrosine kinase activity like the IGF receptor, and tyrosine kinase–mediated autophosphorylation is a critical event in EGF signal transduction. TGFα, which has 35% amino acid homology with murine EGF and 44% homology with human EGF, also acts through the EGF receptor system.[453,454] Several additional family members have

been characterized, including amphiregulin, heparin-binding EGF, betacellulin, and neuregulins.[452] Three additional receptors are referred to as ErbB2, ErbB3, and ErbB4 in animals; the human receptors are called human EGF receptor 2 (HER2), HER3, and HER4.[452]

EGF, pre-pro-EGF mRNA, and EGF receptors are present in most tissues in the postnatal rodent, but mRNA levels are highest in salivary glands and kidneys. EGF and pre-pro-EGF mRNA levels are absent or low in the fetal mouse and remain low in mouse tissues during the early neonatal period.[453] Nonetheless, the EGF receptor knockout mouse exhibits epithelial immaturity and multiorgan failure with early death.[453] Tissue concentrations of EGF mRNA increase in the mouse during the first 2 months of postnatal life; indeed, concentrations of EGF in the salivary glands increase 1000s-fold between 3 weeks and 3 months of age. Mouse urinary levels increase 200-fold and kidney concentrations increase 10-fold between 1 week and 2 months of age. EGF concentrations in mouse ocular tissues increase 100-fold during the first week of life.[452] Liver EGF concentrations increase more slowly, as do serum concentrations, and there is a high degree of correlation between serum and liver EGF concentrations in the developing mouse.[452] Therefore the production of EGF in the rodent is accelerated during the early neonatal period, and it is during this time that most hormone-stimulated growth and development occur.

Fetal mouse and human tissues have high concentrations of TGFα.[451,454,455] Immunoreactive TGFα concentrations in mice are measurable at relatively high levels in lung, brain, liver, and kidney tissues in the fetal/neonatal rat, and the ontogenic pattern of TGFα is tissue specific; most late fetal tissues studied contained TGFα, and levels persisted or increased in most tissues through the period of growth and development.[454]

In rodents and sheep, EGF provokes precocious eyelid opening and tooth eruption in neonatal animals, stimulates lung maturation, promotes palatal development in organ culture, stimulates gastrointestinal maturation, evokes secretion of pituitary hormones (including GH, PRL, and corticotropin), and stimulates secretion of chorionic gonadotropin and placental lactogen by the placenta.[452,453]

Both EGF and TGFα compete for binding to the EGF receptor, and both factors accelerate eye opening and tooth eruption in the neonatal rodent, presumably through interaction with the same EGF receptor.[452] Considerable evidence suggests a role for the EGF family of growth factors in mammalian CNS development.[456] EGF, TGFα, neuregulins, and the EGF receptors are widely distributed in the nervous system.[452,457–460] EGF promotes proliferation of astroglial cells, acts as an astroglial differentiation factor, and enhances survival and outgrowth of selected neuronal cells.[457,458] Transgenic mice with a deficiency of neuregulin, ErbB2, ErbB3, or ErbB4 die in utero with cardiac anomalies and developmental anomalies of the hindbrain, midbrain, and ventral forebrain.[459,460]

EGF also plays an important role in rodent pregnancy. Maternal salivary gland and plasma EGF concentrations in the mouse increase fourfold to fivefold during pregnancy.[461] Removal of the salivary glands prevents the increase in plasma EGF and reduces the number of mice completing term pregnancy by 50%, decreases the percentage of live pups, and decreases the crown-rump length of fetuses delivered.[461] Administration of EGF antiserum to pregnant mice without salivary glands further increases the abortion rate, whereas administration of EGF improves pregnancy outcome.[461] Because maternal EGF is too large a molecule to traverse the placental barrier, an effect on maternal metabolism or on the placenta is likely.[461] The placenta is richly endowed with EGF receptors, and placental tissue binds and degrades EGF to constituent amino acids.[452] TGFα is also produced by the maternal decidua in rodents and stimulates proliferation of decidual tissue and decidual PRL production.

Other Factors

Additional growth factors involved in fetal growth and development include hematopoietic growth factors, platelet-derived growth factors (PDGFs), fibroblast growth factors, vascular endothelial growth factor (VEGF), and members of the TGFβ family.[157,462] The TGFβ superfamily of extracellular growth factors comprises more than 35 members, including TGFβ, the bone morphogenetic proteins (BMPs), growth and differentiation factors, activins, inhibins, müllerian-inhibiting substance, Nodal, and Lefty.[463] These ligands activate 12 transmembrane serine/threonine kinase receptors expressed in a variety of tissues. The family is critical for early embryonic development, left-right asymmetry, heart and vascular system development, craniofacial development, nervous system development, and skeletal morphogenesis and plays an important role in body composition and growth.

Hematopoietic growth factors are also active in the fetus during development; erythropoietin in fetal sheep is produced by the liver rather than the kidney, and erythropoietin gene expression in fetal sheep is regulated by glucocorticoids.[464] A switch to kidney production occurs after parturition.[465] Postnatally, thyroid hormones, testosterone, and hypoxia modulate erythropoietin production. PDGF represents a family of homodimers and heterodimers of PDGFA and PDGFB chains derived from two gene loci.[466] Two PDGF receptors have been characterized, PDGFα and PDGFβ. The genes for PDGF and its receptors are expressed in many tissues. *PDGFA* gene inactivation in mice leads to defects in lung, skin, intestine, testes, and brain resulting in early postnatal death.[466] *PDGFB* gene inactivation leads to microvessel disruption and leakage with hemorrhage, edema, and intrauterine death.

The FGF family of heparin-binding growth factors now includes 17 members with diverse effects on development, angiogenesis, wound healing, and other biologic systems.[467,468] These effects are mediated by ligand-activated tyrosine protein kinase receptors (FGFRs) transcribed from four related genes. Several receptor isoforms are products of alternative RNA splicing.[157,451] Targeted disruptions of *FGF* and *FGFR* genes in mice have defined critical roles in development.[157,467] FGF3-deficient mice show tail and inner ear defects. Knockout of the *FGF4* gene is lethal, leading to early death. Knockout of the *FGFR1* gene also leads to early fetal death. *FGF10* knockout mice die at birth because of pulmonary agenesis. Deficiency of FGF4, FGF8, FGF9, FGF10, or FGF17 is associated with limb deformities. FGF8 deficiency leads to abnormal left-right axis patterning. In mice, *FGFR3* knockout results in chondrocyte hypertrophy and increased bone length.[451] In humans, a variety of gain-of-function *FGFR* mutations are associated with chondrodysplasias and craniosynostosis syndromes.[451] On the other hand, loss-of-function mutations in both *FGFR1* and *FGF8* are associated with Kallmann syndrome or hypogonadotrophic hypogonadism; *FGF8* mutations are also associated with holoprosencephaly.[62,469,470] FGF, like EGF, stimulates the production of hCG from a choriocarcinoma cell line.[465] FGF21 is mainly produced by the liver but is also expressed in adipocytes and pancreas, and regulates glucose and lipid metabolism through pleotropic actions in these tissues and the brain.

During calorie restriction in mice, increased FGF21 causes growth attenuation and GH insensitivity. Additionally high concentrations of FGF21 may directly suppress growth plate chondrocyte proliferation and differentiation. A negative correlation between FGF21 concentration and linear growth has been reported, and high levels of FGF21 were associated with growth failure in preterm infants.[471] The mechanisms might involve GH resistance by GH-induced SOCS2 expression (which negatively regulates GH signaling) and inhibiting GH-induced signal STAT5 phosphorylation. These observations and the fact that the placenta contains FGF, NGF, TGFα, TGFβ, IGF1, and IGF2 suggest that the placenta plays an important role in modulating fetal growth.

Lastly, Wnt signaling, Notch signaling, BMP signaling, and hedgehog signaling play major roles in embryogenesis and fetal organ growth and development. These signaling pathways are also involved in bone development and growth and thus have a major effect on fetal size.[472]

Neutralization of Hormone Actions in the Fetus

After the period of embryogenesis, the fetal milieu is programmed to optimize body growth and organ development through an array of generalized and specialized growth factors with substrate supply maintained by the placenta. The endocrine and metabolic systems characterizing the extrauterine environment are programmed to maintain metabolic stability in a changing external environment. Hormonal systems in the fetus are programmed to maintain anabolism with minimal hormonal perturbation. Therefore production of catabolic and thermogenic hormones is limited, and the effects of the hormones altering metabolic substrate supply and distribution pathways are muted (Table 23.6).

Limitation of Hormone Secretion

The human fetal pancreas is functional during the second trimester, but secretion of insulin in response to glucose or pyruvate is minimal until the neonatal period.[354,355] Glucagon secretion is also blunted, although fetal blood glucagon concentrations are relatively high. Fetal islet hyperplasia and increased insulin secretion occur in response to chronic hyperglycemia (e.g., in the infant of a diabetic mother), and insulin release can be stimulated by acute fetal infusions of leucine, arginine, or tolbutamide.[355,358] Moreover, responsiveness of both insulin and glucagon secretion to glucose develops rapidly in the neonatal period. It is not clear whether the limited fetal islet cell responsiveness results from the relatively stable fetal serum glucose concentrations or from a temporally fixed maturation process.

Production of Inactive Hormone Metabolites

Throughout the second half of gestation, cortisol is metabolized in fetal tissues to inactive cortisone through the activity of 11βHSD2. The placenta is permeable to steroid hormones, including cortisol. During midgestation, placental 11βHSD2 activity is low, and some cortisol is transferred to the fetus. Placental 11βHSD2 activity increases during the second half of pregnancy under the control of placental estrogens, and enzyme activity near term is high.[25,194] Maternal-fetal cortisol transfer decreases progressively. In addition, although many adult tissues can convert cortisone to cortisol, conversion is limited during most of fetal life. Consequently, most of the cortisol that crosses the placenta or is produced by the fetus is inactivated to cortisone by the placenta or by fetal tissues.

Concentrations of cortisone in fetal plasma exceed those of cortisol by threefold to fourfold until after 30 weeks' gestation (see Fig. 23.5). Teleologically, this would help preserve the anabolic and growth-promoting milieu of the fetus and minimize premature maturational and parturitional effects of cortisol. After 30 weeks, the ratio of cortisol to cortisone in fetal tissues and plasma increases as a result of increased fetal secretion and decreased conversion of cortisol to cortisone within the placenta and fetal tissues.[194] Cortisol has an important maturational action on several fetal tissues near term.

Fetal thyroid hormone metabolism is characterized by conversion of active thyroid hormones to inactive rT_3 and inactive sulfated iodothyronines and by limited receptor and postreceptor responsiveness to thyroid hormone in selected tissues.[219,232] The placenta contains an iodothyronine inner-ring monodeiodinase that catalyzes conversion of maternal T_4 to rT_3. The fetal sheep liver and kidney, in contrast to the adult liver and kidney, manifest low concentrations of D1 outer-ring monodeiodinase activity, so conversion of T_4 to active T_3 is limited, and large amounts of inactive iodothyronine sulfoconjugates accumulate.[219,233] Consequently plasma T_3 concentrations in the fetus remain low until the last few weeks of gestation (see Fig. 23.8). Selected fetal tissues (brain, brown adipose tissue) have active D2 outer-ring monodeiodinase activities that contribute to local tissue T_3 concentrations; local T_3 is important in development, particularly in the hypothyroid fetus.[219,473] Near term and in the neonatal period in the human fetus, the dramatic increase in plasma T_3 concentrations, and presumably in T_3 production,

TABLE 23.6 Neutralization of Hormone Actions in the Fetus

PRODUCTION OF INACTIVE METABOLITES	
Active Hormone	**Inactive Metabolites**
Cortisol	Cortisone
Thyroxine (T_4)	rT_3, T_4S, rT_3S
Triiodothyronine (T_3)	T_3S, T_2

DELAYED EXPRESSION OR NEUTRALIZATION OF RECEPTORS	
Active Hormone	**Receptor**
Growth hormone (GH)	GHR
Thyroid hormone	TRα, TRβ
Catecholamines	βAR
Estrogens	ERα, ERβ
Glucagon	GR

LIMITED HORMONE SECRETION	
Active Hormone	**Secretory Cell**
Insulin	Islet cell β
Glucagon	Islet cell α

AR, Adrenergic receptor; *T_2*, diiodothyronine; *rT_3*, reverse T_3; *T_4S*, T_4 sulfate.

heralds the onset of thyroid hormone actions on growth and development and on metabolism (see Fig. 23.8).

Neutralization of Receptor Response

Selected ovine fetal tissues seem relatively unresponsive to thyroid hormones. Fetal ovine liver and kidney thermogenesis as evidenced by oxygen consumption, sodium-potassium pump (Na^+, K^+-ATPase) activity, and mitochondrial α-glycerophosphate activity is unresponsive to exogenous T_3 during the third trimester, and thyroid hormone responsiveness in a number of tissues (cardiac, hepatic, renal, and skin) develops only during the perinatal period.[474] β-Adrenergic receptor binding in heart and lung of the ovine fetus is unresponsive to T_3 late in the third trimester but increases in response to T_3 in the neonatal period.[21,474] In rodent species, in which development at birth is comparable to human fetal development at midgestation, pituitary GH concentrations become responsive to thyroid hormone only during the first weeks of extrauterine life.[475] Mouse submandibular gland EGF and NGF concentrations become responsive to thyroid hormone during the second week of life, as do urine and kidney EGF concentrations and hepatic EGF receptor levels.[476,477] Mouse skin EGF levels and EGF receptors are responsive during the first neonatal week.[478,479] Therefore, despite the presence of nuclear T_3 receptors in significant concentrations in developing rat and sheep fetuses, many thyroid hormone actions in these species are delayed.[480] The mechanism of this delayed thyroid hormone responsiveness is not clear; developmental programming of iodothyronine monodeiodinase expression and gene expression programming via unliganded TRs or TR-interacting corepressors probably all play a role.

The effect of high circulating concentrations of GH in the fetus is also limited. Fetal somatic growth is only partially GH dependent; indeed, the GH-deficient fetus has little or no growth retardation.[61,444] The paucity of fetal GH effects is due to delayed maturation of GH receptors or postreceptor mechanisms. In animals such as sheep, hepatic GH receptor binding appears only during the neonatal period.[61] Receptor deficiency may also be a factor in the limited PRL bioactivity in the fetus near term.[61]

There is less information on fetal hormone responsiveness in other systems. β-Adrenergic receptor binding in heart and lung of the sheep fetus is relatively low near term and increases in the neonatal period in response to thyroid hormones.[474] Premature lambs have an augmented plasma catecholamine surge at birth but have a relatively mild increase in plasma free fatty acid concentrations, which suggests reduced catecholamine responsiveness.[481] The high concentrations of progesterone and estrogens in fetal blood also seem to have limited effects in the fetus. Progesterone receptors are present in low concentration in fetal guinea pig kidney, lung, and uterus at midgestation and increase progressively until term.[482] ERs appear in neonatal rat uterus, oviduct, cervix, and vagina during the first 10 days of extrauterine life, and both *ERα* and *ERβ* mRNAs are present in human fetal tissues during the second trimester.[312,483] The human neonate often manifests mild breast enlargement at birth, and vaginal estrogenization may be evident in female infants at birth. Estrogen effects otherwise appear to be limited (see Table 23.6).

Programming of Fetal Endocrine Systems

It is becoming increasingly evident that the early environment can have a significant impact on the health of an individual throughout a lifetime. During the past several decades, the concept of the plasticity of fetal endocrine systems has evolved from experiments in several mammalian species indicating that hormonal programming occurs during a critical fetal or perinatal period of development. Our understanding of the mechanisms of programming is expanding with epigenetic processes clearly being implicated.

There is a growing list of examples. In the female rodent, transient neonatal androgen administration masculinizes the pattern of hypothalamic control of GnRH secretion and pituitary gonadotropin secretion. Furthermore, masculinization of adult behavior and sexual activity is seen, and the pattern of GH secretion is permanently altered with an increase in longitudinal bone growth and body weight.[484,485] Prenatal androgens program the timing of neuroendocrine puberty in sheep: The higher the dose of prenatal testosterone, the earlier the initiation of the pubertal LH rise.[486] Estrogen administration to pregnant rats during the last third of gestation produces cryptorchid male offspring and may permanently suppress spermatogenesis in adult males.[487] Transient levothyroxine administration to neonatal rodents leads to growth retardation, delayed puberty, decreased adult pituitary weight, decreased pituitary TRH concentrations, low serum thyrotropin levels, and decreased thyrotropin responsiveness to propylthiouracil challenge.[488,489] Administration of insulin or alloxan to neonatal rats produces permanent alteration of glucose tolerance.[490] A single dose of vasopressin to the neonatal rat permanently enhances the adult response to vasopressin.[5,32] Fetal exposure to high maternal glucocorticoid concentrations in the rat inhibits fetal growth and leads to subsequent hypertension in the offspring.[9] Moreover, it has been observed that the permanent programming can be transmitted to later generations, leading to the concept of epigenetic effects.[490,491]

The concept of fetal programming was extended with the observation of ecologic associations between fetal and early-life health indicators (e.g., birth size, infant mortality) and adult diseases. The concept advanced in the 1980s that adult diseases have fetal and perinatal genesis has been referred to as the Barker hypothesis.[492] There is now extensive documentation of the association of IUGR with an increased risk of later hypertension, insulin resistance, diabetes, and cardiovascular and coronary heart disease.[493–500] The programming involves epigenetic, neuroendocrine, hormonal receptor, and metabolic alterations involving the placenta and fetus.

Growth of the fetus involves complex interactions between epigenetic and genetic factors. Furthermore the impact of the environment is being increasingly recognized. It has been shown that airborne pollutants such as cadmium and cigarette smoke may alter thyroid hormone function, which is crucial for growth. A recent study examining the role of fine particle air pollution reported that fine particles with a diameter under 2.5 μm ($PM_{2.5}$) during the third trimester impacted on fetal thyroid function.[501] In cord blood, TSH and FT_4:T_3 ratio decreased with increasing exposure to $PM_{2.5}$ possibly via modulation of the hypothalamic-pituitary-thyroid axis indirectly via glucocorticoid activity as previously shown.[502]

An increasing range of epigenetic effects and corresponding clinical syndromes have been identified over recent years. Epigenetic effects include genetic imprinting. Imprinted genes are a class of genes in placental mammals and marsupials whose expression depends on the parental origin; they are expressed only from the paternal or the maternal gene copy but not biparentally. To date, more than 150 human genes have been shown to be imprinted,[503] but there are likely to be more.

Four classes of molecular changes are described in most imprinted disorders: uniparental disomy, chromosomal imbalances, aberrant methylation (epigenetic mutation), and genomic mutations in imprinted genes. These all alter expression of imprinted genes, but it is the parental allele affected by the mutation that determines phenotype. So far, genomic point mutations in imprinted genes have been reported only for Beckwith-Wiedemann, Silver-Russell, and Angelman syndromes, precocious puberty, and pseudohypoparathyroidism (PHP). Imprinting is controlled epigenetically (by factors such as nutrition) via DNA methylation, post-translational histone modification, chromatin structure, and noncoding RNAs. Imprinted loci often comprise several genes under epigenetic regulation leading to stage-specific and tissue-specific transcriptional activity in cells with identical DNA sequences. In the majority of imprinted disorders only the disease-specific loci are affected, but an increasing number have been reported to exhibit multilocus methylation imprinting disturbance (MLID),[504] the mechanism of which is at present unknown.

Many of the imprinted genes are involved in the control of fetal growth.[505] Paternally expressed imprinted genes tend to enhance fetal growth, and maternally expressed genes tend to suppress it. Knockout of paternally expressed genes for *IGF2, PEG1, PEG2,* and insulin results in IUGR, whereas knockout of the maternal genes *H19, IGF2R,* or overexpression of *IGF2* results in fetal overgrowth.[505] More recently, the identification of an *IGF2* mutation in patients with growth restriction indicates that IGF2 not only mediates prenatal growth but also contributes to postnatal growth and has pleiotropic effects.[436] A role of *IGF2* mutations in both overgrowth and growth restriction phenotypes is conceivable, as has been shown for functionally opposing mutations in *CDKN1C* in 11p15.5.[506] A loss of DNA methylation (LOM) at the *H19/IGF2* domain has been identified in over 50% of patients with SRS.[507] In contrast, gain of methylation at this domain is found in 10% of patients with BWS. Other genetic alterations, including modification of tandem repeats in the insulin gene, have been described.[508]

Hormones in the fetus are derived from the placenta, from the mother, from fetal endocrine glands, and from circulating precursors in fetal or placental tissues. These extensive networks linking maternal-placental-fetal endocrine interactions and the apparent plasticity of developing endocrine and metabolic systems facilitate endocrine system programming. As discussed earlier, the programming may be relatively system limited. Other examples include the observation many years ago that diethylstilbestrol administration to pregnant women increased the prevalence of vaginal adenocarcinoma in female offspring during the second and third decades of life.[498] More recently, it was shown that prenatal or neonatal diethylstilbestrol exposure in hamsters and mice perturbs normal uterine development by affecting the genetic pathways programming uterine differentiation and results in hyperplastic and neoplastic uterine lesions with increased levels of cJun, cFos, Myc, Bax, and Bclx.[509,510]

Excessive androgen exposure during fetal life has been associated with later polycystic ovary syndrome.[498] Hormonal programming is also demonstrable in cell lines and in unicellular organisms, in which a single exposure to a hormone can produce persistent alteration of the hormonal response characteristics or of prohormone processing.[511,512] Undernutrition during pregnancy in the rat results in the development of obesity, hyperinsulinemia, and hyperleptinemia during adult life; this phenotype is potentiated when the offspring are fed a high-fat diet. Neonatal leptin treatment normalized the programmed phenotype, indicating that metabolic programming may be reversible during the period of developmental plasticity.[513]

The effects of maternal undernutrition and fetal IUGR extend to several systems, and it is hypothesized that excessive maternal-fetal glucocorticoids play a significant programming role. Glucocorticoids have wide-ranging effects in the fetus, altering receptors, enzymes, ion channels, and transporters in a variety of cells and tissues in the late-gestation fetus, and they can induce programming of other endocrine systems. Throughout gestation, they modify *GLUT* gene expression in placenta and fetus, influence IGF and glucocorticoid receptor gene expression in various tissues, affect expression of several transcription factors, and affect a wide variety of enzymes in placenta, liver, kidney, intestine, and lung.[514] Intrauterine exposure to stress or high levels of endogenous or exogenous glucocorticoids has been shown to have molecular and structural impact on brain development, particularly limbic regions, impairing cognition and increasing anxiety and reactivity to stress.[515] Furthermore, recent studies have begun to show transgenerational effects in the rat model where in utero exposure to glucocorticoids resulted in two generations of offspring exhibiting decreased weight at birth compared to controls as well as abnormal glucose tolerance and behavior modifications.[491,516] These programming effects were transmitted by either maternal or paternal lines implying an epigenetic mechanism. The HPA axis seems to play an important role in the fetal programming of adult disease, but the pathologic mechanisms are largely unknown. In very preterm babies less than 32 weeks of gestation, a relative adrenal insufficiency is observed after birth, while adverse effects of chronic glucocorticoid excess are observed in adult life.[517,518] Maternal undernutrition, stress, and placental dysfunction are associated with increased maternal and fetal glucocorticoid concentrations, which contribute importantly to IUGR and programmed alterations in adult endocrine systems and metabolism.[496,514,519] Preweaning growth hormone treatment during a critical developmental window has been shown to prevent maternal undernutrition changes in postnatal growth pattern and related adiposity, normalizing body growth trajectory and reversing metabolic dysregulation in adult offspring.[520] These findings suggest that early intervention on the GH-IGF1 axis may attenuate or prevent long-term consequences of fetal programming.

Transition to Extrauterine Life

The transition to extrauterine life involves abrupt delivery from the protected intrauterine environment and succor by the placenta into the relatively hostile extrauterine environment. The neonate must initiate air breathing and defend against hypothermia, hypoglycemia, and hypocalcemia as the placental supply of energy and nutritional substrate is removed. Both the adrenal cortex and the autonomic nervous system, including the para-aortic chromaffin system, are essential for extrauterine adaptation. Longer term transition requires adaptation to an environment of intermittent nutrient supply and transient substrate deficiency and requires maturation of the secretory control mechanisms for the PTH-calcitonin system and the endocrine pancreas.

Cortisol Surge

In most mammals, a cortisol surge occurs near term and is mediated by increased cortisol production by the fetal adrenal and a decreased rate of conversion of cortisol to cortisone. Pepe and

Albrecht have proposed that the preterm fetal cortisol surge is due to the progressive stimulation by estrogens of placental 11βHSD2 activity and the subsequent increase in placental conversion of cortisol to cortisone.[194] The resulting decrease in maternal-to-fetal cortisol transfer results in stimulation of fetal CRH and corticotropin secretion through the negative-feedback control loop. The concomitant estrogen-stimulated increase in 11βHSD2 activity in fetal tissues potentiates the relative fetal cortisol deficiency and the CRH-corticotropin response.[194] Placental CRH may also potentiate fetal adrenal activation. Recent data suggest an increase in 11βHSD1 expression and activity in placenta and intrauterine fetal membranes during late gestation, with a consequent increase in local cortisol production in preparation for parturition.[521] The cortisol surge results in a number of actions (Fig. 23.14)[522–524]:

- Augments surfactant synthesis in lung tissue
- Increases lung liquid reabsorption
- Increases adrenomedullary PNMT activity, which in turn increases methylation of NE to epinephrine
- Increases hepatic iodothyronine outer-ring monodeiodinase activity and hence conversion of T_4 to T_3
- Decreases sensitivity of the ductus arteriosus to prostaglandins, facilitating ductus closure
- Induces maturation of several enzymes and transport processes of the small intestine
- Stimulates maturation of hepatic enzymes

In some cases, these events involve increased synthesis of specific proteins or enzymes. In other instances, such as the action on the ductus arteriosus, the mechanism remains obscure.

Secondary effects of cortisol also promote extrauterine adaptations. The increased T_3 concentrations stimulate β-adrenergic receptor binding, potentiate surfactant synthesis in lung tissue, and increase the sensitivity of brown adipose tissue to NE. The significance of prenatal cortisol is demonstrated by the effects of gene-targeted CRH or glucocorticoid receptor deficiency in mice; the progeny of homozygous CRH-deficient or glucocorticoid receptor–deficient animals die in the first 12 hours with lung dysplasia and surfactant deficiency.[525,526]

The adaptational effects of the prenatal cortisol surge have led to the current recommendation for prenatal corticosteroid therapy in pregnancies threatened by the risk of preterm delivery. Generally, preterm infants prenatally exposed to augmented glucocorticoid concentrations have lower overall morbidity and mortality than untreated infants.

Catecholamine Surge

Parturition also evokes a dramatic catecholamine surge in the newborn, resulting in extraordinarily high concentrations of NE, epinephrine, and dopamine in cord blood.[319] As discussed earlier, plasma NE concentrations exceed epinephrine concentrations because of peripheral and adrenomedullary and para-aortic catecholamine release. Cord blood NE concentrations of 15 nmol/L (2500 pg/mL) and epinephrine concentrations of 2 nmol/L (370 pg/mL) are common after spontaneous delivery of term infants.[319] Concentrations of 25 nmol/L (4200 pg/mL) of NE and 35 nmol/L (640 pg/mL) of epinephrine are common in cord blood of premature infants. These changes evoke critical cardiovascular adaptations, including increased blood pressure and cardiac inotropic effects and glucagon secretion, decreased insulin secretion, increased thermogenesis in brown adipose tissue, plasma free fatty acid concentrations, and pulmonary adaptation, including mobilization of pulmonary fluid and increased surfactant release.[319,521]

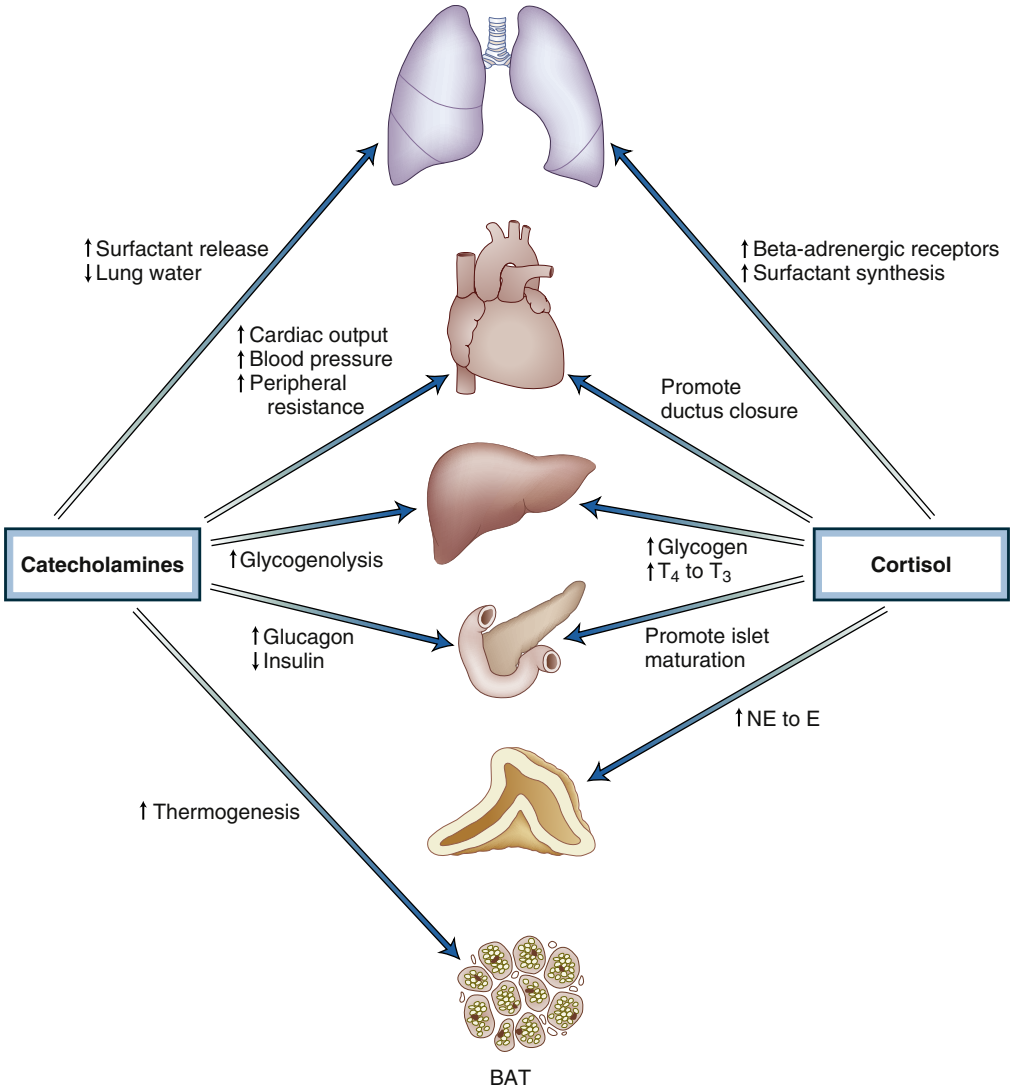
Thermogenesis in Neonatal Brown Adipose Tissue

Brown adipose tissue is the major site of thermogenesis in the newborn and is especially prominent in the mammalian fetus. The largest accumulations of brown adipose tissue envelop the kidneys and adrenal glands, and smaller amounts surround the blood vessels of the mediastinum and neck.[234] The mass of brown adipose tissue peaks at the time of birth and gradually decreases during the early weeks of life. Surgical removal of this tissue leads to neonatal hypothermia. NE, through β-adrenergic receptors, stimulates thermogenesis by brown adipose tissue, and optimal responsiveness of this tissue to NE is dependent on thyroid hormone.[527] Brown adipose tissue is rich in mitochondria containing a unique 32-kDa protein (thermogenin) that uncouples oxidation and phosphorylation of adenosine diphosphate, reduces ATP production, and consequently enhances thermogenesis.[234] Thermogenin is T_3 dependent, and brown adipose tissue contains a 5′-monoiodothyronine deiodinase that deiodinates T_4 locally to T_3.[234] Full maturation of catecholamine-stimulated cellular respiration in brown adipose tissue occurs before delivery in the ovine fetus and requires thyroid hormone.[234] Fetal thyroidectomy in this species leads to marked hypothermia, with low plasma free fatty acid concentrations and increased plasma epinephrine concentrations.[528] Basal brown adipose tissue thermogenesis and NE-stimulated and dibutyryl cAMP-stimulated thermogenesis are decreased by fetal thyroidectomy.

The rapid onset of thermogenesis in brown adipose tissue is essential for survival in newborn infants. Catecholamine release is the stimulus for brown adipose tissue thermogenesis in the early neonatal period, and responsiveness to catecholamines is markedly increased by cutting of the umbilical cord.[527] Fetal hypoxia and placental inhibitors, including prostaglandin E_2 and adenosine, appear to inhibit brown adipose tissue thermogenesis in utero.[527] Cord cutting, neonatal cooling, catecholamine stimulation, and augmented conversion of T_4 to T_3 in brown adipose tissue in the neonatal period are the essential features that mediate and condition newborn thermogenesis. It was previously thought that brown adipose tissue involuted soon after birth, but combined ^{18}F-fluorodeoxyglucose positron emission tomography (^{18}F-FDG-PET) and CT scans have identified active brown adipose tissue in adults and shown a strong positive correlation between brown adipose tissue activity and the basal metabolic rate.[529–531]

Calcium Homeostasis

In utero, active calcium transport from the mother to the fetus takes place through the placenta, responsible for approximately 20% to 30% of calcium stores in the fetus. The neonate must adjust rapidly from a high-calcium environment regulated by PTHrp and calcitonin to a low-calcium environment that requires regulation by PTH and vitamin D. With removal of the placenta in term infants, plasma total calcium concentration falls, reaching a nadir of approximately 2.3 mmol/L (9 mg/dL),[390] and the ionized calcium concentration reaches a low level of about 1.2 mmol/L (4.8 mg/dL) by 24 hours of life.[532] Plasma PTH concentrations are relatively low in the neonatal period and are minimally responsive to hypocalcemia during the first 2 to 3 days of life. Calcitonin concentrations are high in cord blood (~2000 ng/L), increase further during the early neonatal period, and remain high for several days after birth.[390,533] The relatively obtunded PTH response and the high calcitonin concentrations lead to a period of 2 to 3 days of transient neonatal hypocalcemia.[533,534]



• **Fig. 23.14** Actions of cortisol and catecholamines during fetal adaptation to the extrauterine environment. The prenatal cortisol surge promotes functional maturation of several organ systems. The neonatal catecholamine surge triggers or potentiates many of the extrauterine cardiopulmonary and metabolic functional adaptations that are critical to extrauterine survival. *BAT,* brown adipose tissue; *E,* epinephrine; *NE*, norepinephrine; T_3, triiodothyronine; T_4, thyroxine.

Inhibition of calcitonin secretion and stimulation of PTH secretion gradually result in increased serum calcium concentrations in the neonate. The disappearance of PTHrp in the neonatal lamb is approximately coincident with the time of restoration of calcium concentrations to the adult range.[390] The mechanism of transition from PTHrp to PTH secretion by the neonatal parathyroid glands is not clear.

Calcium homeostasis is also affected in the human newborn by the low level of glomerular filtration that persists for several days.[533,534] In addition, renal responsiveness to PTH is reduced in the first few days of life. These factors limit phosphate excretion and predispose the neonate to hyperphosphatemia, particularly if the diet includes high-phosphate milk such as unmodified cow's milk. Premature infants compared with term infants tend to have lower PTH and higher calcitonin concentrations and more immature kidney function; in these infants, neonatal hypocalcemia may be more marked and prolonged, and the incidence of symptomatic hypocalcemia is higher. Birth asphyxia also predisposes the neonate to hypocalcemia.[534] Infants born to mothers with hypercalcemia related to hyperparathyroidism have a high incidence of symptomatic hypocalcemia. These infants have a more marked suppression of parathyroid function and a longer period of transient hypoparathyroidism in the neonatal period. PTH secretion and calcium homeostasis usually return to normal in 1 to 2 weeks in full-term infants and within 2 to 3 weeks in the small premature infant.

Glucose Homeostasis

Fetal energy needs are met by a continuous intravenous supply of glucose across the placenta, fetal glucose uptake being directly related to both the maternal blood glucose concentration and the transplacental gradient. There is little endogenous glucose production. Glucose and other substrates are stored as fat and glycogen in preparation for birth. During labor and delivery, the secretion of stress hormones such as glucocorticoids and catecholamines

causes a rise in fetal blood glucose concentrations, so that cord blood glucose concentrations are often high.

At delivery following clamping of the cord, the maternal supply of glucose ceases. A normal term infant has an immediate postnatal fall in blood glucose concentration during the first 2 to 4 hours from values close to maternal levels to around 2.5 mmol/L (45g/dL) in the initial hours postpartum.[354,355] Low concentrations are usually transient, asymptomatic, and part of the normal adaptation to extrauterine life. In term infants metabolic adaptation is compensated for by producing alternative fuels, and the transition to intermittent feeding and fasting with the introduction of milk feeds into the gut is accomplished with little external evidence of the magnitude of changes taking place. Counterregulatory hormones rapidly become active with high catecholamine, glucagon, GH, and glucocorticoid concentrations and a fall in insulin.[354,355] Insulin concentrations are low at birth and tend to fall further with hypoglycemia. The early glucagon response is short lived, but concentrations remain at about 100 ng/L for the first 12 to 24 hours; the glucagon/insulin ratio is high enough to stabilize glucose concentrations in the range of 2.8 to 4 mmol/L (50–70 mg/dL) during this period. The early glucagon and catecholamine surges deplete hepatic glycogen stores, so the return of plasma glucose concentrations to normal after 12 to 18 hours requires maturation of hepatic gluconeogenesis under the stimulus of a high plasma glucagon to insulin ratio.[355] Glucagon secretion gradually increases during the early hours after birth, especially with protein feeding, which stimulates gut glucagon release and pancreatic glucagon secretion.[354,355] Together these changes result in stabilization of blood glucose concentrations, although adult concentrations are not reached until approximately 72 hours of life.

Failure of this sequence of physiologic changes can lead to hypoglycemia, which is most common in the first few hours after birth. Severe hypoglycemia occurs if the normal relationship of these hormones is disturbed but the net effect of the changes is to stabilize the blood glucose concentration at a lower level during the first few hours while milk feeding is initiated. The availability of ketone bodies allows a sparing effect of glucose for brain utilization. The process of adaptation is, however, incomplete and is compromised when an infant is born prematurely or following intrauterine growth retardation.

Premature infants have more severe and more prolonged hypoglycemia because of reduced glycogen stores and impaired hepatic gluconeogenesis. Infants born to diabetic mothers have more severe neonatal hypoglycemia because of relative hyperinsulinism. In the healthy term infant, glucose homeostasis is achieved within 5 to 7 days of life; in premature infants, 1 to 2 weeks may be required.

Other Hormonal Adaptations

Delivery of the placenta results in decreases in fetal blood concentrations of estrogens, progesterone, hCG, and hPL. The fall in estrogen concentrations presumably removes the major stimulus to fetal pituitary PRL release, and PRL concentrations decrease within several weeks. The relatively delayed fall may be due to lactotrope hyperplasia in the fetal pituitary or to delayed maturation of hypothalamic dopamine secretion. The gradual fall of GH concentrations during the early weeks of life is due to delayed maturation of hypothalamic-pituitary feedback control of GH release.[57] In the neonatal primate, there are concomitant decreases in plasma GH concentrations and GH responsiveness to exogenous GHRH.[535] The mechanisms remain unclear; changes in secretion or in pituitary sensitivity to GHRH or somatostatin, or both, may be involved. IGF1 and IGF2 concentrations fall to infantile values within a few days, presumably because of the removal of placental hPL and placental IGF production (see Fig. 23.5).

In male infants (see Fig. 23.10), after a transient fall in testosterone concentrations as the hCG stimulus abates, pituitary LH secretion rebounds modestly, and there is a secondary surge of plasma testosterone that persists at significant levels for several weeks.[57,536] This surge is mediated by hypothalamic GnRH; blockade of neonatal activation of the pituitary-testicular axis with a GnRH agonist in neonatal monkeys ablates the neonatal increments in LH and testosterone.[537] Such a blockade also results in subnormal increments in plasma LH and testosterone concentrations and subnormal testicular enlargement at puberty in these animals, suggesting that neonatal GnRH release with pituitary-testicular activation may be critical for normal sexual maturation of male primates.[537] In females, a transient, secondary surge in FSH may transiently elevate estrogen concentrations.

Delivery results in a reversal of the high fetal cortisone/cortisol ratio, and plasma cortisol concentrations are higher in the neonate despite relatively lower plasma corticotropin concentrations (see Fig. 23.7). Presumably this increase is due to decreased inhibition of adrenal 3βHSD by estrogen and perhaps to removal of a placental CRH action on fetal pituitary corticotropin release. Plasma DHEAS and DHEA concentrations fall as the fetal adrenal atrophies.

The increase in serum thyrotropin concentrations during the early minutes after birth is due to cooling of the neonate in the extrauterine environment.[21,219] In term infants, the thyrotropin surge peaks at 30 minutes at a concentration of about 70 mU/L (see Fig. 23.7). This peak evokes increased secretion of T_4 and T_3 by the thyroid gland. In addition, increased conversion of T_4 to T_3 by liver and other tissues maintains the T_3 concentration in the extrauterine range of 1.6 to 3.4 nmol/L (105–220 ng/dL). The re-equilibration of thyrotropin concentrations to the normal extrauterine range is probably a result of the readjustment of prevailing serum T_3 concentrations and maturation of feedback control of thyrotropin by thyroid hormones during the early weeks of life.[21,538] Production of rT_3 by fetal and neonatal tissues abates by 3 to 4 weeks of age, at which time serum rT_3 reaches adult concentrations.

Maternal and Fetal Medicine

Advances in fetal imaging, genomics, and minimally invasive techniques, as well as a better understanding of the intrauterine endocrine milieu and natural history of many endocrine diseases, have revolutionized the management of fetal and neonatal endocrine conditions. This progress has set the stage for disease diagnosis, therapy for fetal endocrine and metabolic disorders, management of disorders of fetal growth, and diagnosis and management of perinatal or neonatal endocrine dysfunction. In addition, understanding of developmental endocrinology is increasingly relevant to management strategies for premature infants, and infants and children with fetal growth retardation, and for understanding of the pathogenesis of adult endocrine and metabolic diseases. Up to 18% of babies are born preterm, and over the last decades survival has increased. Understanding the endocrine physiology in the extreme preterm and establishment of normal reference ranges has significant clinical value. To that effect, a biobank for blood samples of infants 24 to 32 weeks has recently been established.[539]

We are now entering an era of direct access to and management of the intrauterine environment with provision of medical and surgical fetal therapy, entailing both potential advantages and adverse effects.[540] With expansion of the application and scope of amniotic fluid fetal cell sampling, maternal plasma DNA analysis, and the advent of fetal visualization and intrauterine fetal blood sampling, direct access for fetal diagnosis is now possible.[541] Noninvasive technologies for fetal evaluation are realizing the promise of lower risk yet robust diagnostics; examples include sampling and analysis of free fetal DNA from maternal blood and analysis of fetal products accessible at maternal sites. After birth, definitive assessment of prenatal environmental and/or drug exposures to the fetus can be retrospectively assessed by analysis of meconium, hair, and other alternative matrices.[542] Intrauterine diagnosis of fetal adrenal and thyroid disorders has become the standard of care,[543,544] followed by the prospect of in utero treatment, although this is often controversial. Management of hypothyroid fetal goiter, for example, poses significant risks (including miscarriage) associated with both diagnostic amniocentesis/cordocentesis and intra-amniotic thyroid hormone therapy.[545] These risks often preclude large-scale studies of optimal antenatal treatment.

Intravenous nutritional supplementation of fetal sheep can prevent some forms of growth retardation, and chronic fetal therapy through indwelling pumps is feasible in animal fetuses.[546] These approaches, coupled with increasing availability of synthetic hormones and growth factor agonists and antagonists, facilitate direct fetal endocrine therapy. In addition, intrauterine stem cell transplantation has been successful in the correction of congenital hematologic diseases. The fetus in early gestation is a favorable recipient of cellular therapy, and fetal cell transplantation may be applicable to therapy for selected endocrine and metabolic disease.[547] Studies involving the endocrine pancreas, for example, have demonstrated long-term circulating human insulin following intrauterine stem cell transplantation in sheep, with potential translation as diabetic cellular therapy.[548]

Finally, there is a growing experience with fetal and neonatal gene therapy in animals,[549] although this field remains a challenging frontier of medicine. Intraplacental gene therapy, for example, is a novel strategy that takes advantage of an organ that will be discarded at birth. The results of preliminary studies in the rabbit recently have demonstrated that placental gene therapy may be an effective therapy for intrauterine growth restriction, for which no treatment is currently available.[550]

The rapid evolution of maternal-fetal medicine raises complex ethical and medicolegal challenges related to what constitutes innovative treatment versus human experimentation, with or without the umbrella of "medical research." There inevitably exists a grey zone between these black and white classifications, highlighting the need for clear, responsible guidelines and thoughtful, safe practice delivering excellence in care.[551]

24 Disorders of Sex Development

YEE-MING CHAN, SABINE E. HANNEMA, JOHN C. ACHERMANN, AND IEUAN A. HUGHES

CHAPTER OUTLINE

KEY POINTS

- Disorders of sex development (DSDs) can present to different health professionals at different ages, but pediatric and adult endocrinologists play a central role in diagnosis, support, and management.
- DSDs represent a broad range of conditions with many underlying causes; understanding the basic biology of sex development and steroidogenesis can help in elucidating the causes of these conditions.
- Achieving a diagnosis is important for predicting the natural history of specific conditions, identifying associated features, monitoring endocrine function and tumor risk, advising about fertility potential, and counseling families about inheritance patterns. In some situations, a diagnosis might influence sex designation.
- A range of special biochemical tests and genetic analyses can help reach a specific diagnosis in most steroidogenesis disorders. Currently, a genetic diagnosis is reached in less than half of children with gonadal dysgenesis.
- A multidisciplinary team approach is key in providing coordinated management from diagnosis through later life. An experienced psychologist or allied professional can help support families and young people in the early years, as well as following transition to adult services. Support groups also play an important role.
- Some DSDs present in teenage years or even in adulthood. Adult endocrinologists have a crucial role to play in managing young people who present in adulthood, as well as for long-term follow-up of individuals with DSDs diagnosed in childhood. A supportive and sensitive approach is essential.

Defined as "conditions in which chromosomal, gonadal, or anatomical sex is atypical,"[1] disorders of sex development (or differences in sex development [DSDs]) represent a broad range of conditions that can present to many different health professionals at different stages of life.

In the newborn period, approximately 1 in every 4500 babies has atypical (ambiguous) genitalia and cannot be immediately designated as male or female without further expert evaluation. However, DSDs can present in many other ways, such as discordance between prenatal karyotype and appearance of the external genitalia at birth; bilateral inguinal hernias; during evaluation for associated syndromic features (e.g., renal) in childhood; virilization, absence of pubertal development, or primary amenorrhea in teenage years; or even later in life with infertility. Therefore many different health professionals may be involved in DSDs, and all should be aware of the range of conditions, how they might present, and the principles of their management.[1,2]

The investigation and management of DSDs require a multidisciplinary team with experience in these conditions.[2,3] The pediatric endocrinologist plays a key role within this team in the childhood and teenage years, whereas adult endocrinologists need to be involved in transitioning care and in the management of long-term issues such as hormone replacement and bone health. In addition to input from urologists, gynecologists, biochemists, clinical pathologists, radiologists, and geneticists, it is becoming increasingly clear that experienced psychological support is essential for individuals with DSDs and their families at key points in their lives. The past decade has seen changing terminology and attitudes (Table 24.1), but DSD still has significant stigma, and engagement with support groups and the DSD community is increasingly important to define the best pathways of care at local and national levels.

In keeping with previous editions of this textbook, this chapter will first describe the development of the reproductive systems, then present an overview of the range of conditions that can be classified as DSDs, and finally consider approaches to investigation and management of DSDs at different ages.[4]

Development of the Reproductive Systems

Reproductive system development begins at 4 to 5 weeks after conception in humans and is complete with the achievement of secondary sex characteristics and fertility (i.e., production of viable gametes) after puberty. Sex development is a dynamic process that requires the interaction of many genes, proteins, signaling molecules, paracrine factors, and endocrine stimuli.[5–9] Marked differences in the basic mechanisms of sex determination, differentiation, and reproductive strategy have evolved in different species, with variability in sex chromosome complement, gonad development, and gametogenesis throughout the animal kingdom.[10,11] In this chapter, we focus on the basic mechanisms of reproductive development in humans. We also include some important insights obtained from studies of normal and transgenic mice, although these are reviewed extensively elsewhere. More detailed explanation of pituitary gonadotrope development is provided in Chapter 23 and of normal and disordered puberty in Chapter 26.

TABLE 24.1 Proposed Revised Nomenclature

Previous Terms	Proposed Terms
Intersex	Disorders of sex development (DSDs)
Male pseudohermaphrodite Undervirilization of an XY male Undermasculinization of an XY male	46,XY DSD
Female pseudohermaphrodite Overvirilization of an XX female Masculinization of an XX female	46,XX DSD
True hermaphrodite	Ovotesticular DSD
XX male or XX sex reversal	46,XX testicular DSD
XY sex reversal	46,XY complete gonadal dysgenesis

Reproduced with permission from Hughes IA, Houk C, Ahmed SF, et al. Consensus statement on management of intersex disorders. *Arch Dis Child.* 2006;91:554–562.

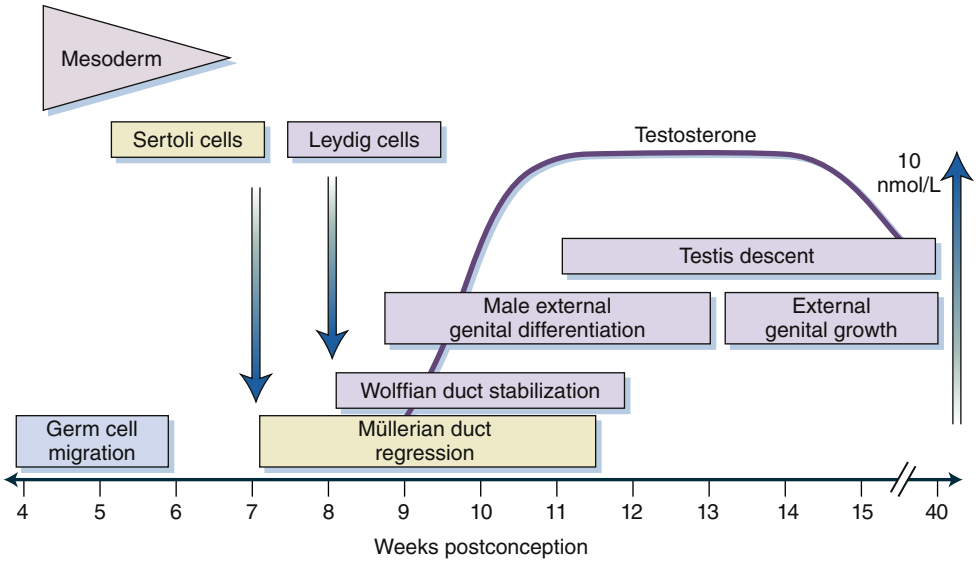
Sex Determination and Sex Differentiation

Sex determination is the process whereby the bipotential gonad develops into a testis or an ovary. Sex differentiation refers to the development of the internal and external genitalia, as directed by the production of peptide hormones and sex steroids by the developing gonad.

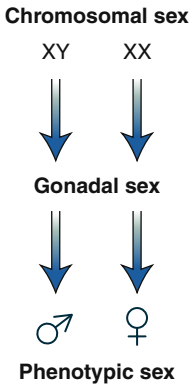
In the typical male, the process of sex differentiation involves androgenization of the external genitalia (leading to formation of the penis and scrotum), regression of müllerian structures (leading to absence of the uterus, fallopian tubes, and the upper two-thirds of the vagina), stabilization of wolffian structures (leading to development of seminal vesicles, vasa deferentia, and epididymides), and descent of the testes from their origin in the urogenital ridge to their final position in the scrotum (Fig. 24.1).

Ovarian hormonal secretion in fetal life has little if any effect on sex differentiation. At the time of puberty, estrogen synthesis stimulates breast and uterine development, and eventually coordinated activity of the reproductive endocrine axis results in regular menstrual cycles. Defects in ovarian development therefore usually manifest in adolescence with absent puberty. Ovarian development and differentiation have been viewed in the past as a "default" or passive process, but ovarian development in fact involves many active processes. Studies of gene expression show that a specific complement of genes is implicated in ovarian development and integrity, some of which (e.g., *RSPO1, NR2F2*) may actively antagonize testis differentiation.[6,12–14] Even the concepts of a fixed and quiescent population of ovarian germ cells at birth and of absent ovarian steroidogenesis have been challenged.[15,16]

In typical sex development, sex determination and sex differentiation can be divided into three major components: chromosomal sex (i.e., the complement of X and Y chromosomes), gonadal sex (i.e., presence of testes, ovaries, or both), and phenotypic or anatomic sex (i.e., presence of male and/or female external



• **Fig. 24.1** Events temporally related to sex differentiation in the male fetus. Mesoderm refers to the tissue source for Sertoli and Leydig cell formation. The continuous line depicts the rise in fetal serum testosterone, with a peak concentration of about 10 nmol/L (300 ng/dL).



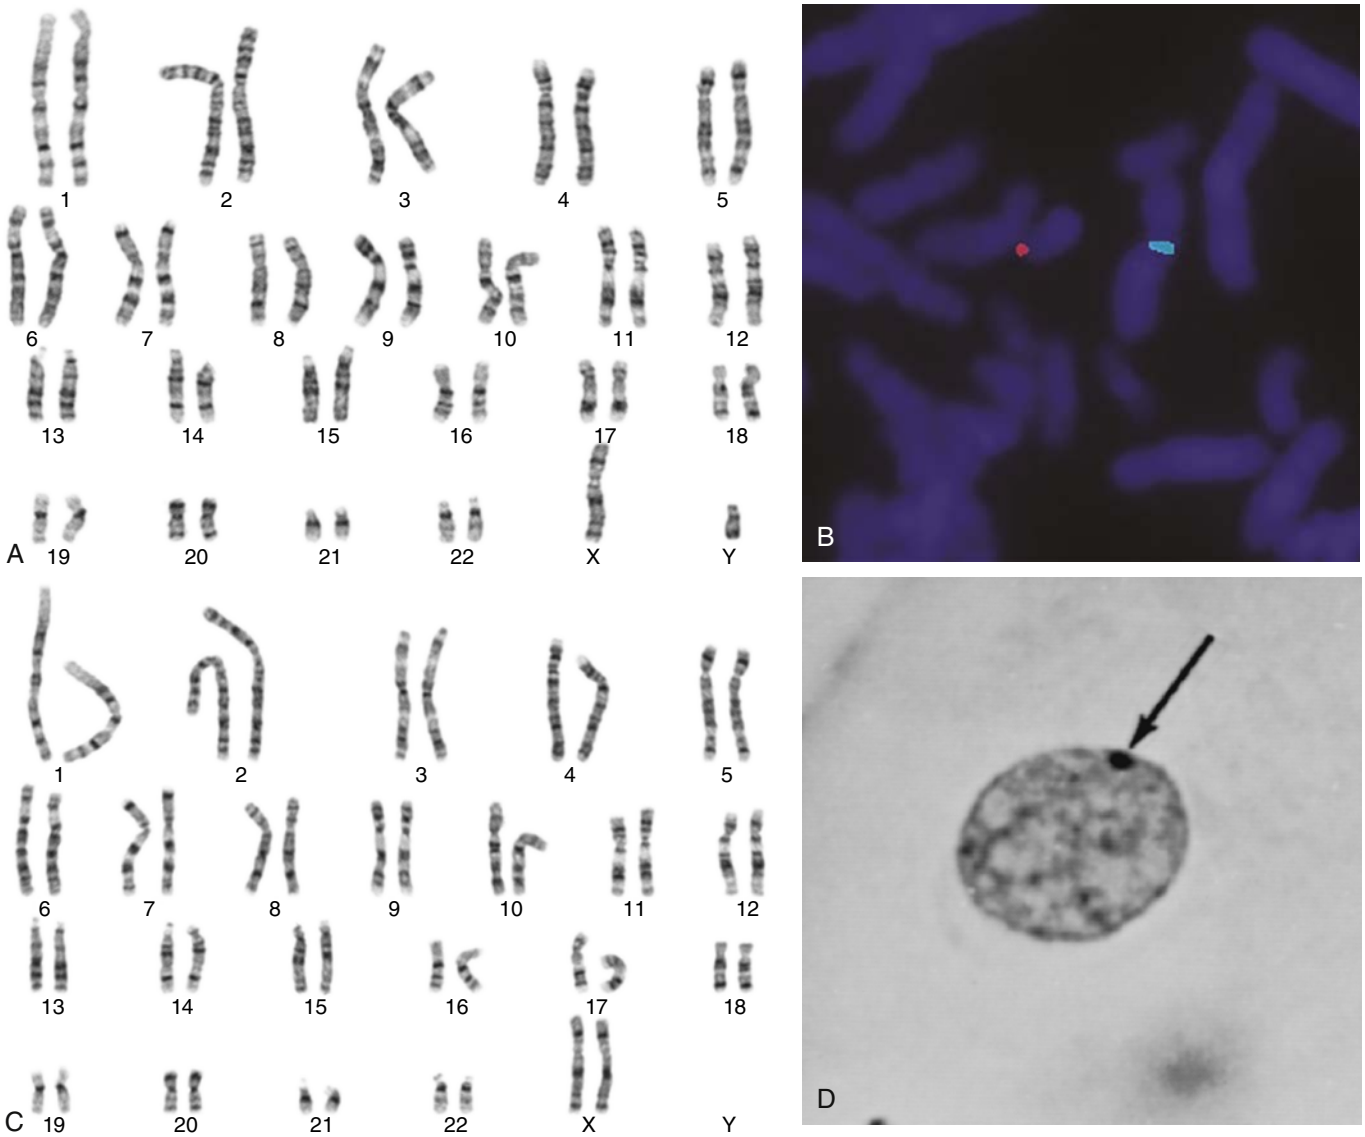
• **Fig. 24.2** Division of typical sex development into three major components provides a useful framework for diagnosis and classification. Chromosomal sex refers to the sex-chromosome complement. Gonadal sex refers to the presence of a testis or ovary after the process of sex determination. Phenotypic (anatomic) sex refers to the appearance of the external genitalia and internal structures after the process of sex differentiation.

and internal genitalia) (Fig. 24.2). Though consideration of sex development in terms of chromosomal sex, gonadal sex, and phenotypic (anatomic) sex can be a useful way of understanding the processes involved in reproductive development, none of these processes absolutely defines a person's sex, and gender and psychosexual development are influenced by several biologic factors as well as by environmental and social influences.

Chromosomal Sex

Chromosomal sex describes the complement of sex chromosomes present in an individual (e.g., 46,XY or 46,XX). In humans, the usual complement of 46 chromosomes consists of 22 pairs of autosomes (identified numerically from 1 to 22 based on decreasing size) and a pair of sex chromosomes (XX or XY) (Fig. 24.3). Other species have different numbers of chromosomes, and they may have different types of sex chromosomes or sexually dimorphic autosomes.[10,11]

In humans, chromosomal sex is usually determined at the time of fertilization, when two haploid gametes (an ovum and a sperm,



• **Fig. 24.3** Cytogenetic and fluorescence in situ hybridization (FISH) studies. (A) Typical male (46,XY) G-banded karyotype. (B) FISH analysis of a male (46,XY) using fluorescent probes directed against SRY (sex-determining region on the Y chromosome, spectrum red) and against the X centromere (spectrum green). (C) Typical female (46,XX) G-banded karyotype. (D) Photomicrograph shows the X chromatin body (Barr body, *arrow*) in the nucleus of buccal mucosa cells from a 46,XX female (thionine stain; original magnification, ×2000). (A–C, courtesy Lee Grimsley and Jonathan Waters, MD, North East London Regional Cytogenetics Laboratory, Great Ormond Street Hospital NHS Trust, London, UK.)

with 23 chromosomes each) fuse to generate a diploid zygote (with 46 chromosomes). Gametes are derived from germ cells, which initially replicate their chromosome complement and then undergo a series of two meiotic divisions (meiosis I and meiosis II) to produce haploid ova or sperm. Normal ova have a single X chromosome. Normal sperm contain a single Y chromosome or a single X chromosome, resulting in a 46,XY or 46,XX zygote, respectively, after fertilization.

Nondisjunction is the failure of a pair of sister chromatids to separate during anaphase.[17,18] Meiotic nondisjunction during gametogenesis can result in ova or sperm with gain or loss of sex chromosomal material. Fertilization by such gametes can give rise to a zygote with an imbalance in sex chromosome number, called *sex chromosome aneuploidy*. For example, a zygote with a single X chromosome (i.e., 45,X) has Turner syndrome, and the presence of an extra X causes Klinefelter syndrome (47,XXY) or triple X syndrome (47,XXX, trisomy X).[18] Zygotes with no X chromosomal material (e.g., 45,Y) are nonviable.

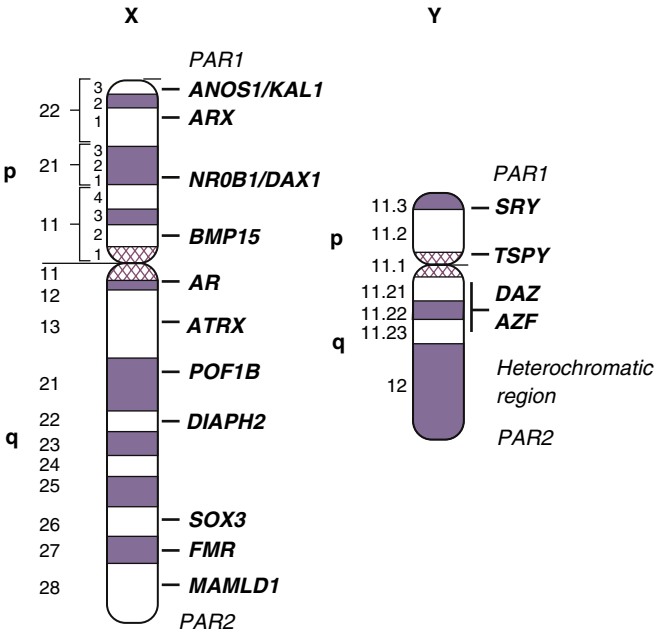
Mitotic nondisjunction can occur in the zygote (i.e., after fertilization), resulting in an imbalance in sex chromosome number in a subset of somatic cells, and this is called *sex chromosome mosaicism* (e.g., 45,X/46,XY). In such cases, the two (or more) cell lines originate from a single zygote. This situation differs from *chimerism*, which is the existence of two or more cell lines with different genetic origins in one individual. Chimerism can occur through several mechanisms, including double fertilization (dispermy) of a binucleate ovum, fusion of two complete zygotes or morulae before implantation, or fertilization by separate sperm of an ovum and its polar body. If the different cell lines have different sex chromosomes, a 46,XX/46,XY karyotype occurs. This form of true *sex chromosome chimerism* is very rare in humans. The consequences of some of these events in humans are discussed later (see "Sex Chromosome Disorders of Sex Development").

The Y Chromosome

Although the Y chromosome was initially thought to be inert, detection of a 46,XY karyotype in males and a 47,XXY karyotype in men with Klinefelter syndrome provided evidence that the Y chromosome is responsible for male sex determination.

The human Y chromosome is approximately 60 megabases (Mb) long and represents only 2% of the human genome (Fig. 24.4).[19,20] The Y chromosome consists of a heterochromatic region that is highly variable and largely genetically inactive, a conserved male-specific region, and autosomally derived regions that are estimated to have been added approximately 80 to 130 million years ago. The male-specific regions have undergone rapid evolution, with marked differences even between humans and chimpanzees.[21] It is thought that Y-chromosome genes encode around 57 proteins. Although some of these genes have putative roles in growth, cognition, and tooth development, several genes in the male-specific region are involved in reproductive development, function, and pathology. For example, a cluster of genes at Yq11.22 (e.g., the *AZFc* region) is essential for spermatogenesis, and genes within the gonadoblastoma locus (e.g., *TSPY*) increase the risk of malignancy when present in dysgenetic gonads (see Fig. 24.4).[22,23]

The euchromatic portion of the Y chromosome consists of a Y-specific segment and regions at the distal ends of the short and long arms, called the *pseudoautosomal regions* (PARs) (see Fig. 24.4).[19,24] These PARs are homologous to the distal ends of the short and long arms of the X chromosome and are the only regions involved in pairing and recombination during meiosis.

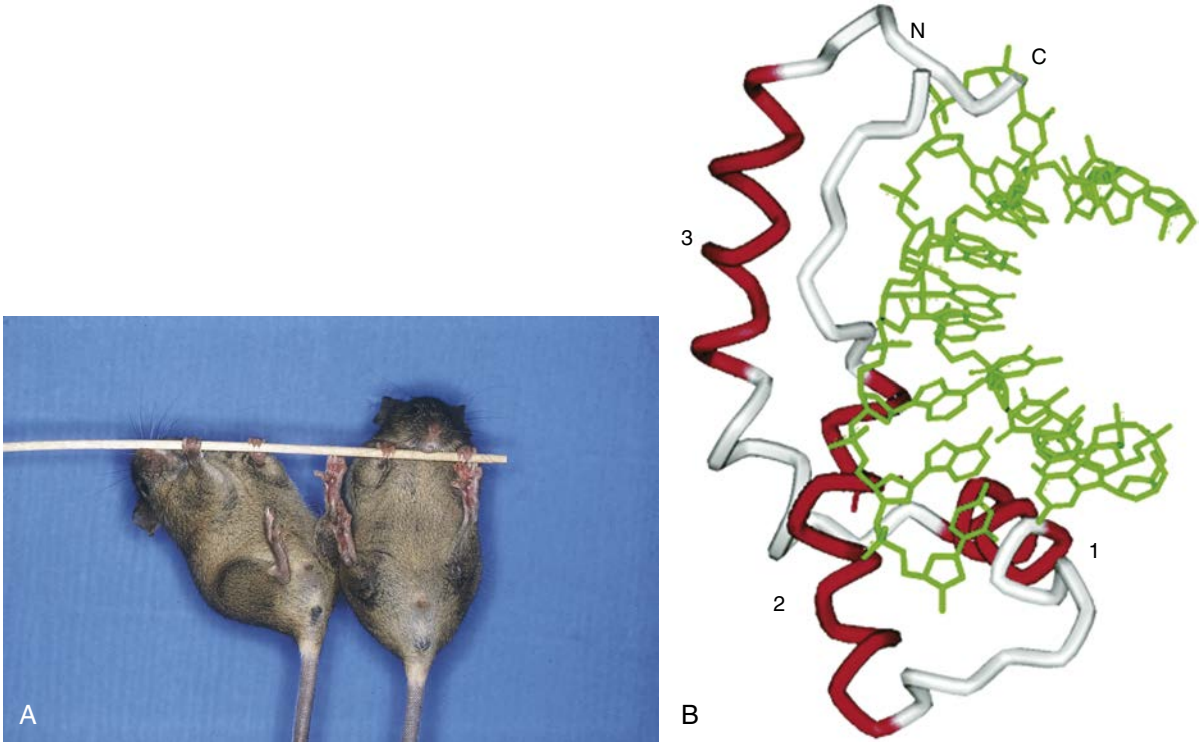


• **Fig. 24.4** Schematic diagrams of the X chromosome *(left)* and Y chromosome *(right)* show key regions and genes involved in sex development and reproduction. *ANOS1/KAL1,* Kallmann syndrome type 1; *AR,* Androgen receptor; *ARX,* aristaless-related homeobox, X-linked; *ATRX,* α-thalassemia, X-linked mental retardation; *AZF,* azoospermia factor; *BMP15,* bone morphogenetic protein 15; *DAZ,* deleted in azoospermia; *DIAPH2,* human homolog of the Drosophila diaphanous gene; *FMR,* fragile X, mental retardation; *MAMLD1,* mastermind-like domain containing 1 (CXorf6); p, short arm; *NR0B1/DAX1,* dosage-sensitive sex reversal congenital adrenal hypoplasia critical region on the X chromosome type 1; *PAR,* pseudoautosomal region; *POF1B,* actin-binding protein, 34 kDa; *q,* long arm; *SOX3,* SRY-related HMG box 3; *SRY,* sex-determining region Y; *TSPY,* testis-specific protein Y.

This process is essential for proper distribution of recombined sex chromosomal material to daughter cells as well as for maintaining dosage sensitivity of X-Y pairs, as these regions are not subject to dosage compensation (i.e., gene inactivation). PAR1 (distal short arm, Yp and Xp) contains at least 15 genes, including the homeobox gene *SHOX*. *SHOX* haploinsufficiency contributes to the short stature associated with Turner syndrome, Xp– or Yp– deletions, and Léri-Weill syndrome (i.e., dyschondrosteosis).

The search for a testis-determining factor on the Y chromosome began more than 50 years ago. In 1987, Mardon and Page proposed that the sex-determining function of the Y chromosome is located within a 140-kb segment of the short arm, within the Y-specific euchromatic portion.[25] The *ZFY* gene was the initial candidate in this region. However, in 1989, Palmer and colleagues described several 46,XX males who had Y-to-X translocations of Y-chromosomal material that was distal (telomeric) to the *ZFY* locus; this focused attention on a 35-kb region of the Y chromosome close to the pseudoautosomal boundary.[26] This region contained a gene encoding a putative transcription factor subsequently called *sex-determining region Y (SRY)* (see Fig. 24.4).

A series of elegant studies in mice and humans established *SRY* as the primary Y-chromosomal testis-determining gene.[27–29] The first definitive proof came with the generation of transgenic XX mice specifically expressing the *SRY* locus (14 kb); some of these mice had a male phenotype, developed testes (without spermatogenesis), and showed male sexual mating behavior (Fig. 24.5).[30] This work was supported by reports of deletions



• **Fig. 24.5** (A) The XXSRY+ mouse *(right)* has testis development and a male phenotype, providing convincing evidence that SRY (sex-determining region on the Y chromosome) is a testis-determining gene. and loss-of-function mutations in *SRY* in humans with 46,XY complete gonadal dysgenesis (Swyer syndrome) (see later discussion).[28,31,32] The structure and function of the *SRY* gene and SRY gene product are discussed later.

The X Chromosome

The X chromosome is a relatively large and gene-rich chromosome compared with the Y chromosome, and it consists of about 160 Mb of genomic deoxyribonucleic acid (DNA) (see Fig. 24.4).[19,33,34] This DNA contains 5% of the haploid genome and approximately 850 protein-encoding genes. Several genes on the X chromosome play an important role in sex development in males and females, gametogenesis, and hypothalamic-pituitary (gonadotrope) function (e.g., androgen receptor *[AR]*, *ANOS1* [also called *KAL1*], DAX1 *[NR0B1]*, *MAMLD1*, *SOX3*). However, most X-linked genes are unrelated to reproductive function and have a diverse range of cellular functions.

The X chromosome contains PARs at the distal end of each arm, similar to the Y chromosome (see Fig. 24.4).[19] These regions and several genes in their boundaries function with their homologs on the Y-chromosome PARs in an autosomal fashion. However, as large numbers of genes on the X chromosome are located outside the PARs and do not have homologs on the Y chromosome, a process must exist to maintain the balance in copy number (i.e., gene dosage) of these genes between males with a single X chromosome and females with two X chromosomes. This process is called *X inactivation*.

The first insight into X inactivation came after the identification in 1949 of the X chromatin body (i.e., Barr body) in a proportion of cells in females (see Fig. 24.3). This X chromatin is derived from one of the two X chromosomes in interphase nuclei of these somatic cells. Grumbach and colleagues showed that the X chromosome giving rise to X chromatin completes DNA synthesis later than any other chromosome.[35] These findings led to the concept that only one X chromosome is genetically active during interphase, whereas the other X chromosome is heterochromatinized and relatively inactive. This change in activation state occurs in early gestation in humans (12–18 days, late blastocyte stage) and is a multistep process, regulated by the gene *XIST* and the *TSIX* antisense transcript, leading to stable and epigenetic silencing of genes on all but one X chromosome (Lyon hypothesis).[36] However, female germ cells beyond the stage of oogonia are exempt from X inactivation, demonstrating a need for a second X chromosome for oocyte development.

X inactivation occurs randomly in different cells.[37] After inactivation has occurred, the inactive state of that particular X chromosome is transmitted to all descendants of that cell so that XX individuals effectively function as genetic mosaics for X-linked traits. If the initial population of cells is small, skewed X inactivation can occur as a chance event despite random inactivation.

In these situations, heterozygous female carriers of an X-linked disorder may manifest symptoms of the condition. A subset of genes on the X chromosome may also be imprinted and only expressed from one allele. Furthermore, recent data suggest that several other X-chromosome genes (especially on the short arm) may escape X inactivation, potentially in a tissue-specific manner, and that sex chromosome gene dosage may regulate autosomal gene networks.[38,39] All these phenomena might influence phenotype variability of X-linked conditions or sex chromosome aneuploidy.

Gonadal Sex

Gonadal sex refers to whether the gonadal tissue developed as a testis or an ovary. The principal embryologic and morphologic changes involved in gonadal development are shown in Fig. 24.6 and have been described in detail elsewhere.[6–8,40]

The Bipotential Gonad

The primitive gonad arises together with the adrenal gland from a condensation of the medioventral region of the urogenital ridge at approximately 4 to 5 weeks after conception in humans (see Fig. 24.6). The primitive gonad separates from the adrenal primordium at about 5 weeks but remains bipotential (indifferent) until about 42 days after conception.

Several important genes are expressed in the developing urogenital ridge in mice that facilitate formation of the bipotential gonad; they include *Emx2*, *Lim1*, *Lhx9*, *M33/Cbx2*, *Pod1*, *Six1/4*, *Map3k4*, *Wt1*, and *Nr5a1/Sf1*.[41–47] Deletion of these genes causes gonadal dysgenesis in mice and can be associated with abnormalities in other organs (e.g., kidney, brain). Only some of them have been associated with human DSDs to date (e.g., *WT1*, *CBX2*, *NR5A1/SF1*) (see "46,XY Disorders of Sex Development") (Fig. 24.7).[48] These factors may affect gonad/testis development at multiple stages (Fig. 24.8).

WT1 (11p13) is a gene that encodes a four–zinc finger transcription factor expressed in the developing genital ridge, kidney, gonads, and mesothelium.[49] Homozygous deletion of *Wt1* in mice prevents gonad and kidney development.[50] It is thought that at least 24 WT1 isoforms exist due to mRNA splicing variants and complex post-translational modifications.[51] The two most common variants are an isoform with alternative splicing of exon 5, resulting in insertion of an additional 17 amino acids in the middle of the protein, and an isoform that uses an alternative splice donor site for exon 9, resulting in the addition of three amino acids (lysine, threonine, and serine; called +KTS) between zinc fingers 3 and 4. It is thought that +KTS and –KTS isoforms have different cellular functions and differential effects on gonad and renal development.[52] The ratio of +KTS to –KTS isoforms may be important in testis development, with the +KTS isoform having a cell-autonomous role in regulating SRY expression and influencing cellular proliferation and Sertoli cell differentiation.[53] Wt1 also regulates expression of *Sf1* and *Sox9* in mice and may oppose β-catenin (Ctnnb1) pathways.

In humans, *WT1* transcripts can be detected in the indifferent gonadal ridge when it first forms at 32 days after ovulation.[54] Deletions or mutations of *WT1* cause well-defined syndromes. Haploinsufficiency of *WT1* due to deletion of the chromosomal locus containing *WT1* and *PAX6* (11p13) causes WAGR syndrome (Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation).[55] Dominant-negative point mutations in *WT1* cause Denys-Drash syndrome (gonadal dysgenesis, early-onset nephropathy, and predisposition to Wilms tumor),[56] whereas mutations in the exon 9 splice site of *WT1*, causing an altered ratio of +KTS to –KTS isoforms of WT1, result in Frasier syndrome (gonadal dysgenesis, late-onset nephropathy, and predisposition to gonadoblastoma) (see "46,XY Disorders of Sex Development" and Fig.

24.21 later).[57,58] Some phenotypic overlap in the latter two conditions exists.

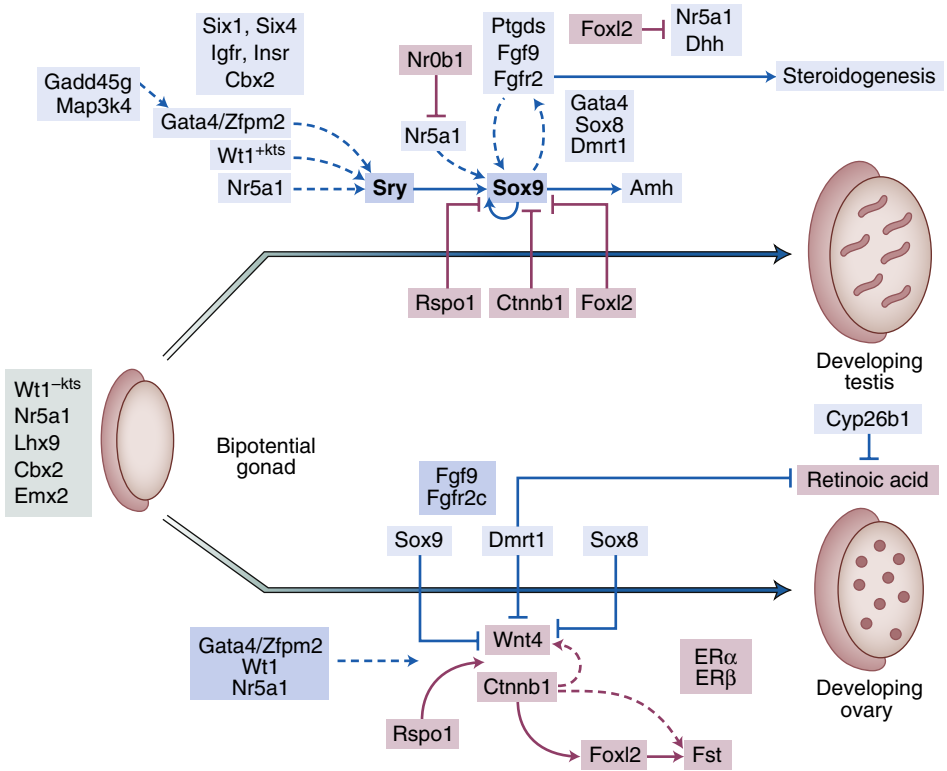
Another key transcription factor expressed in the urogenital ridge is steroidogenic factor 1 (SF1, encoded by *NR5A1*).[59] SF1 is a member of the nuclear receptor superfamily and regulates the transcription of at least 30 genes known to be involved in gonadal development, adrenal development, steroidogenesis, and reproduction. In mice, complete deletion of the gene encoding Sf1 results in apoptosis of the developing gonad and adrenal gland during early embryonic development, resulting in impaired androgenization and persistence of müllerian structures in XY animals.[60] Other features of these homozygous-deleted animals include hypogonadotropic hypogonadism, abnormalities of the ventromedial hypothalamus, and late-onset obesity in adult animals rescued by adrenal transplantation.[61] Heterozygous animals have reduced gonadal size and impaired adrenal stress responses.[62] Data for mice suggest that Sf1 plays a critical role in the generation of a population of Sf1+ progenitor cells in the gonad before sex determination occurs, as well as in promoting testis development by facilitating SRY regulation of *SOX9* expression (discussion to come).[63,64]

SF1 is expressed during the early stages of urogenital ridge formation in humans (32 days after ovulation).[54] Consistent with the mouse phenotype, heterozygous and homozygous loss-of-function mutations affecting key DNA-binding motives have rarely been described in patients with primary adrenal failure and severe 46,XY gonadal dysgenesis (see later discussion).[65,66] In contrast, haploinsufficiency of *NR5A1* due to heterozygous disruptive variants is now established as a relatively frequent cause of 46,XY DSD with normal adrenal function.[67]

Although SF1 was originally thought to play a less significant role in the ovary compared with the testis, studies in mice show that SF1 is also an important regulator of ovarian integrity and function as well as in the development of early progenitor cell populations in the ovary.[68–70] Loss of function or haploinsufficiency of *NR5A1* is associated with primary ovarian insufficiency (POI), whereas recurrent heterozygous variants affecting the same codon in SF1 (p.Arg92) are associated with 46,XX testicular and ovotesticular DSD,[71–76] suggesting that SF1 can also act as a switch between testis-development and ovary-development pathways.

Primordial Germ Cell Migration

Primordial germ cells (PGCs) are the embryonic precursors of gametes (spermatocytes or ova). Surprisingly, in all species, PGCs arise some distance from the developing gonad and undergo a process of migration during the early stages of embryogenesis.[77,78] In humans, PGCs arise from pluripotent epiblast cells and are initially located in the 24-day embryo in a region of the dorsal endoderm of the yolk sac, close to the allantoic evagination (see Fig. 24.6). After mitotic division, PGCs migrate into the primitive gonad (between 4 and 5 weeks postconception [wpc]) under the influence of signaling molecules, receptors, and extracellular matrix proteins such as KIT, the KIT ligand KITLG (formerly called Steel), β_1-integrin, E-cadherin, WNT5A/ROR2, KIF13B, interferon-induced transmembrane protein 1 (IFITM1), and IFITM3.[79,80] Hindgut expansion may also regulate or facilitate this process. Gonadal colonization is mediated by CXCL12 (previously called SDF1) and its receptor CXCR4 and influenced by CXCR7.



• **Fig. 24.8** Overview of some of the molecular events thought to be involved in the development of the bipotential gonad, as well as in testis determination and ovary development. These data are based mostly on studies in mice. Sry is the principal testis-determining factor, but many other factors interact downstream to support testis development and repress ovary development, or vice versa.

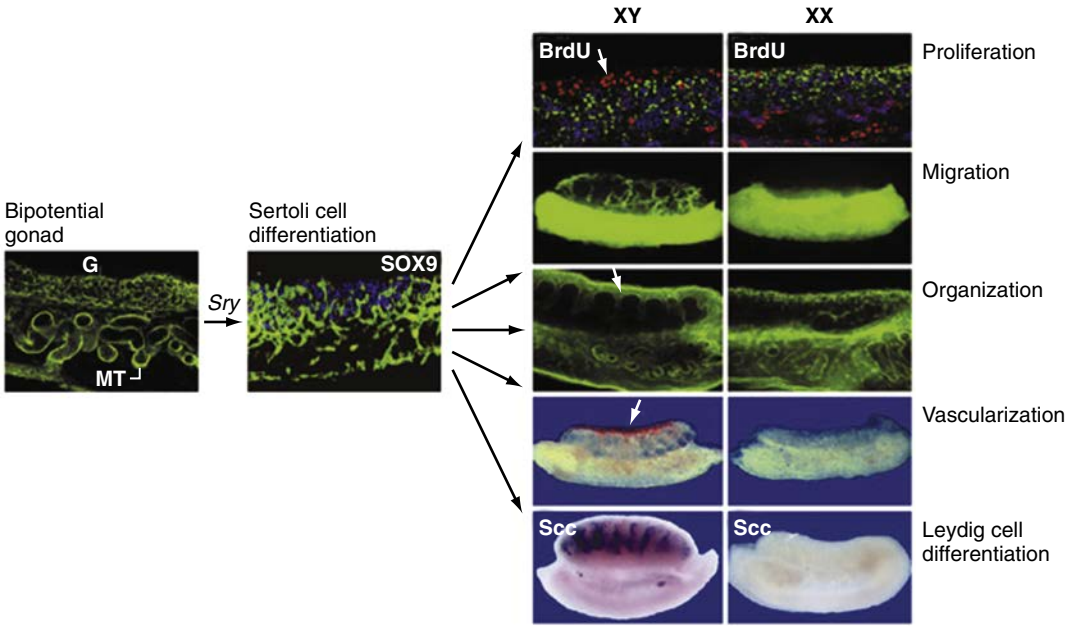
In the first few months of gestation, PGCs undergo multiple cycles of mitotic division. In the testis, a self-renewing population of germ cells exists. These undifferentiated PGCs are maintained by factors such as POU5F1 (also called OCT4), but they commit to differentiation in response to the expression of specific signaling molecules and transcription factors. After several cycles of mitotic division, these cells enter mitotic arrest.[81] Subsequent testicular development can occur in the absence of this germ cell population.[82] Meiosis does not occur until the onset of spermatogenesis in puberty (see Chapter 19).

In the developing ovary, primordial ova (oogonia) undergo mitotic expansion in the first few months of gestation (5–24 weeks), followed by meiotic division (8–36 weeks) and a process of meiotic arrest (oocytes). Although it was originally thought that entry into meiosis occurred autonomously, data suggest that retinoic acid signaling from the mesonephros stimulates this process.[83,84] Male germ cells may be protected from this signal by their location within the testis cord and by Sertoli cell expression of the cytochrome P450 isoenzyme 26B1 (CYP26B1), which breaks down retinoic acid. Meiotic arrest occurs in the first prophase, when the chromatids of homologous pairs have begun to separate but are fixed by chiasmata (diplotene stage). The presence of these PGCs and subsequent meiotic oocytes is critical for the differentiation of prefollicular cells into follicular cells and for the maintenance of ovarian development (see Chapter 17). More detailed insight into the stages of human PGC development is emerging from single-cell transcriptomic studies.[85]

More than 6 million oogonia and prophase oocytes exist in the developing ovary at about 16 weeks of gestation, and formation of oogonia from PGCs ceases by the seventh month. At that stage, some oocytes remain in undifferentiated nests, whereas others associate with somatic pregranulosa cells to form primitive or primordial follicles. However, approximately 80% of oogonia fail to form follicles and undergo apoptosis, so that only 1 million germ cells are present in the ovary at the time of birth. The resting primordial follicles can remain in that stage of development throughout the woman's reproductive life, and meiosis progresses only in response to ovulation of the graafian follicle, which occurs approximately 400 times in a woman's reproductive lifetime.

Testis Determination

Testis determination begins about 6 wpc in humans and consists of several distinct genetic and morphologic events.[5–7] One of the first and most significant events in testis determination is a transient wave of SRY expression through the hitherto undifferentiated gonad at approximately 42 days postconception (dpc) (Fig. 24.9; also see Fig. 24.8).[12,86] Initially, this occurs in the center of the gonad, followed by expression in cells located at the cranial and caudal poles. SRY expression must reach a certain threshold within a definite time window for testis development to occur.[87,88]



• **Fig. 24.9** Key morphologic changes in the developing testis in mice. No morphologic differences between the XY and XX gonad are seen during the bipotential gonad stage at 10.5 to 11.5 days postconception (dpc) *(far left)*. In XY gonads, *SRY* expression is followed by expression and nuclear localization of SOX9 *(blue)* in pre-Sertoli cells *(middle)*, resulting in Sertoli cell differentiation by 11.5 dpc (vasculature and germ cells are labeled with platelet endothelial cell adhesion molecule [PECAM] and appear *green*). Between 11.5 and 12.5 dpc, distinct changes occur in the XY gonad *(near right column)*, which are not seen in the XX gonad *(far right)*. These changes include proliferation of coelomic epithelial cells (measured by BrdU incorporation; *red, arrow*); migration of cells from the mesonephros (shown by recombinant culture of a wild-type gonad and a mesonephros in which the cells express green fluorescent protein); structural organization of testis cords (detected by laminin deposition, *green*); male-specific vascularization (by light microscopy with blood cells indicated by an *arrow*); and Leydig cell differentiation (detected by mRNA in situ hybridization for the steroidogenic enzyme P450scc). *BrdU,* bromodeoxyuridine; *MT,* basal lamina of mesonephric tubules; *G,* gonad. (From Brennan J, Capel B. One tissue, two fates: molecular genetic events that underlie testis versus ovary development. *Nat Rev Genet.* 2004;5:509–521. Used with permission of Macmillan Publishers, Ltd.)

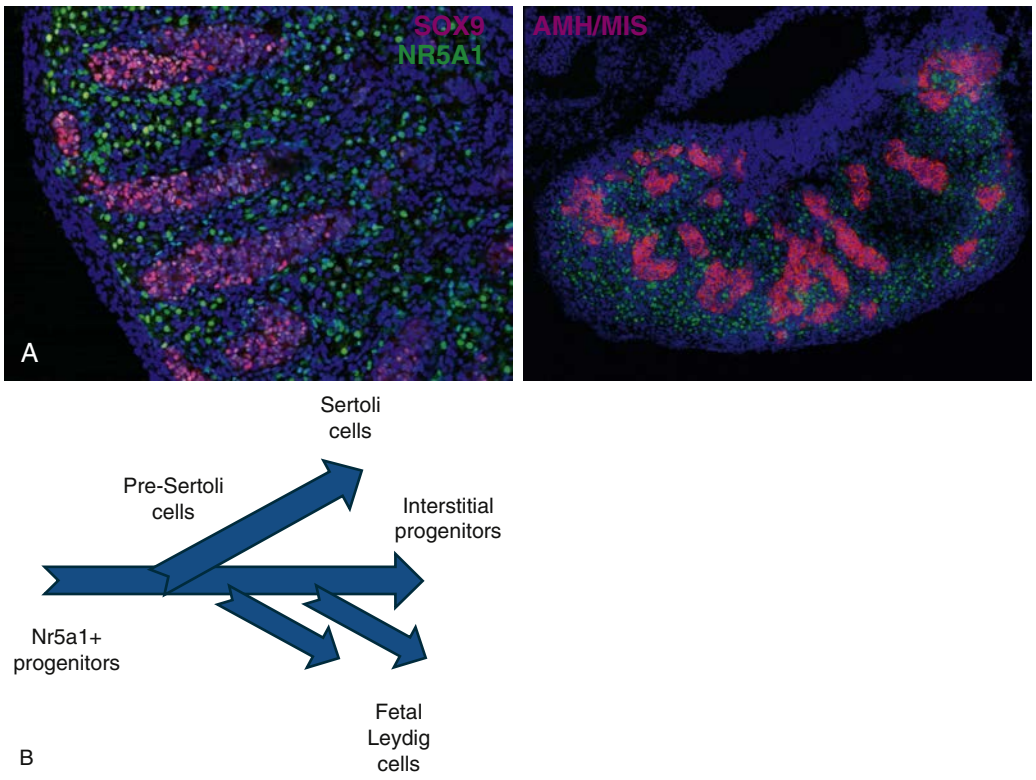
Expression levels peak from approximately day 44, when testicular cords are first visible. Thereafter, low-level SRY expression in humans is confined to Sertoli cells (day 52), where it persists into adulthood.

In humans, *SRY* is a single-exon gene (Yp11.3) that encodes a 204–amino acid, high-mobility group (HMG)–box transcription factor.[87] Mutations in *SRY* have been reported in approximately 10% to 15% of patients with sporadic or familial 46,XY gonadal dysgenesis (see "46,XY Disorders of Sex Development" and Fig. 24.22 in later discussion). As described earlier, the presence of *SRY* (due to translocation of *SRY* to the X chromosome or an autosome) or transgenic expression of *SRY* is sufficient to induce testis development in XX humans and mice (see "The Y Chromosome" and Fig. 24.5).

Mutations and deletions in *SRY* tend to cluster within the region encoding the HMG box. The HMG box is a 79–amino acid structure that has moderate homology with SRY in other species (~70%) and with the HMG box of related SOX (SRY-like HMG box) proteins (60%) (see "46,XY Disorders of Sex Development" and Fig. 24.22 later).[87] The HMG box consists of three α-helices, which are able to adopt an L-shaped or boomerang-shaped configuration (see Fig. 24.5). The HMG box binds to specific response elements (AACAAT/A and variants) in the minor groove of DNA and induces a 40-degree to 85-degree structural bend in its target, depending on the sequence. The precise function of protein-directed DNA bending is not known, although this interaction results in minor groove expansion, DNA unwinding, and altered base stacking. These effects likely alter DNA architecture in chromatin and may permit the interaction of other protein complexes with the DNA, resulting in activation or repression. Other important domains in SRY are two nuclear localization signals that can interact with calmodulin and importin-β to regulate cellular localization; several serine residues in the amino (N)-terminal of SRY that can undergo phosphorylation and influence DNA binding; and a carboxy (C)-terminal, 7–amino acid motif that interacts with PDZ domains of SRY-interacting protein 1 (SIP1).[89–93]

Although *SRY* was convincingly shown to be the primary testis-determining gene more than 20 years ago, relatively little is known about the regulation of *SRY* expression. Some studies have shown that SF1, WT1, GATA4, and ZFPM2 (FOG2) can all regulate *SRY* promoter activity in vitro, and MAP3K4 and insulin-related signaling pathways may be important, but the exact mechanisms that activate *SRY* in vivo remain relatively poorly understood (see Fig. 24.8).[47,94–98]

The downstream targets of *SRY* are also not entirely elucidated, but it seems likely that the most significant actions of SRY occur through upregulation of SOX9.[12] SOX9 is an SRY-related HMG box factor comprising three exons (509 amino acids).[99–102] In humans, SOX9 becomes strongly localized to the developing sex cords at 44 to 52 days after ovulation and is expressed in Sertoli cells thereafter (Fig. 24.10; also see Fig. 24.9).[86] SOX9 is also expressed in developing cartilage under the regulation of parathyroid hormone–related protein (PTHrP)/Indian hedgehog signaling pathways. Heterozygous mutations or deletions in *SOX9* cause campomelic dysplasia, a severe skeletal dysplasia that is



• **Fig. 24.10** (A) Expression of SOX9 *(left panel)* and AMH/MIS *(right panel)* in primitive seminiferous tubules of human fetal testis at 9 weeks postconception. NR5A1 (SF1) is shown in *green*. (B) Model for fetal testis lineage development based on single cell transcriptomic studies in the mouse. (A, modified from Del Valle I, Buonocore F, Duncan AJ, et al. A genomic atlas of human adrenal and gonad development. *Wellcome Open Res*. 2017;2:25; B, modified from Stévant I, Neirijnck Y, Borel C, et al. Deciphering cell lineage specification during male sex determination with single-cell RNA sequencing. *Cell Rep*. 2018;22:1589–1599.)

associated with variable gonadal dysgenesis in approximately 75% of patients.[99,100] Mutations have been found in the HMG box of SOX9, in the C-terminal transactivation domain, and in a region that interacts with heat shock proteins (e.g., HSP70) (see "46,XY Disorders of Sex Development" and Fig. 24.22 later).[101,102]

The regulatory region of the *SOX9* promoter is very large. Breakpoints have been reported up to 350 kb from the start of the *SOX9* gene in patients with campomelic dysplasia and gonadal dysgenesis. Studies have shown that Sry and Sf1 can synergistically regulate *Sox9* expression in mice and in vitro through a testis-specific enhancer region (TESCO).[64,103] Recently, several additional SOX9 enhancer regions have been characterized that are regulated by SRY/SF1 or through SOX9 autoregulation (e.g., Enh13)[104] and which may be involved in maintaining SOX9 expression at critical stages over time.

SOX9 can direct testicular development independently of SRY and function as a testis determination gene in its own right. Transgenic expression of *Sox9* in mice results in testis development in XX animals, and the XX *odsex (Ods)* mouse develops as a male owing to disruption of a regulatory element 1 Mb upstream of *Sox9* that causes testis-specific overexpression of Sox9 during development.[105,106] Similar disruption of an upstream *cis*-regulatory region resulting in SOX9 overexpression causes 46,XX testicular DSD,[107] and overexpression of SOX9 due to duplication of 17q24.3-q25.1 or duplications in the SOX9 promoter region have also been reported in 46,XX individuals with testicular or ovotesticular DSD.[108–110] In mice, *Sox9* may mediate its effects through direct interactions with other target genes (e.g., *Fgf9, Ptgds, Amh*) to promote testis development pathways and through the degradation of β-catenin to suppress inhibitors of testis development (see Fig. 24.8). Autoregulatory loops with the abovementioned target genes may also be important in maintaining SOX9 expression.

Around the time of SRY and SOX9 expression, the developing testis undergoes a series of distinct cellular and morphologic changes (see Fig. 24.9). Understanding of these processes has resulted largely from studies in mice, although data are also emerging from humans at a global level as well as from single-cell transcriptomic studies.[5,12,85,111] As outlined earlier, the first stage of testis development in mice involves a proliferation of Nr5a1/Sf1-positive somatic cells that results in an increase in pre-Sertoli cell precursors and, ultimately, Sertoli cell differentiation. This process is influenced by growth factors such as fibroblast growth factor 9 (Fgf9) and the receptor Fgfr2, as well as *DMRT1* (double sex, Mab3–related transcription factor 1; 9p24.3), a 373–amino acid protein that is homologous to the sex development *doublesex* gene of *Drosophila* and the *Mab3* gene of *Caenorhabditis elegans*, and SOX8.[112] These primitive Sertoli cells coalesce with peritubular myoid cells (i.e., flat, smooth muscle–like cells) to form primary sex cords, which then condense to form primitive seminiferous cords at about 7 wpc in humans.

Sex cord development is supported by a striking reorganization of the gonadal vasculature that occurs in the developing testis but not in the ovary (see Fig. 24.9).[5,113] These changes include the development of a discrete coelomic vessel, restriction of endothelial cells to the interstitial space between the sex cords, and increased branching of blood vessels. The development of these vascular systems is influenced by growth factor signaling systems, such as platelet-derived growth factor receptor-α (PDGFRα)/prostaglandin D_2 synthase (PTGDS), and can be repressed by the Wnt4/β-catenin/follistatin (Fst) systems in mice.[113] These changes in vascular architecture play an important role in determining cellular patterning and organization in the developing testis, in supporting paracrine interactions, and in the export of androgens from the developing fetal Leydig cells to the perineal and systemic circulation.

A fetal Leydig cell population also differentiates around this time from in the developing testis, supported by Nr5a1/Sf1 and following the loss of Tcf21 and Nr2f2/Coup-TFII from interstitial progenitors. Other key factors involved in this process that have been associated with human phenotypes include *DHH* (desert hedgehog), *ARX* (aristaless-related homeobox, X-linked gene), and *MAMLD1* (mastermind-like domain–containing 1, previously called *CXORF6*).[114–118]

Our understanding of the genetic events underlying cell fate is being advanced by newer techniques such as single-cell transcriptomics. These events have been reviewed recently and new data are emerging rapidly in this field.[40,63,111] These approaches are showing that the early Nr5a1+ common progenitor lineage first gives rise to a Sertoli cell lineage, followed by fetal Leydig cell lines, with a progenitor cell lineage maintained in the interstitium that has capacity for steroidogenic fate. A summary of these events is shown in Fig. 24.10.

Ovary Development

For many years, ovary development was thought to be a constitutive (default) process because the gonad differentiates as an ovary in the absence of a Y chromosome (and specifically lack of *SRY*). However, several studies in mice and humans have now shown that a similar number of genes are differentially expressed in the developing ovary at critical early stages of development compared to the testis.[12,13] Therefore ovarian development can be viewed as an active process that requires expression of a set of specific genes and factors to promote this process as well as to prevent testicular development. Considerable mutual antagonism between these pathways exists (see Fig. 24.8).

The initial stages of ovary development require establishment of the bipotential gonad. As in the testis, several key genes are required for supporting the early granulosa-cell lineage *(Gata4/Zfpm2*, *Wt1*, *Nr5a1)* (see Fig. 24.8). Subsequently, WNT signaling pathways play a key role in promoting ovarian development as well as in repressing testis development, mostly through antagonism of SOX9. RSPO1/R-spondin 1 and WNT4 stabilize β-catenin. Loss of either *RSPO1* or *WNT4* has been reported in association with XX ovotesticular DSD or hyperandrogenism in humans.[119,120]

Other key factors involved in ovary development in the mouse are Foxl2 and follistatin. Foxl2 is involved in maintaining or enforcing the ovary program and granulosa-cell fate, and loss of *Foxl2* in mice is associated with postnatal transdifferentiation of ovary into testis.[121] In humans, loss of *FOXL2* is associated with blepharophimosis-ptosis-epicanthus inversus syndrome (BPES). Women with BPES can have variable POI, but ovotesticular DSD has not been reported. The role of follistatin in human ovary development is not well established.

Recent reports of ovotesticular DSD associated with specific variants in *NR5A1*/*SF1* and *NR2F2* suggest that both these transcription factors play a role in maintaining the balance between ovarian and testicular differentiation, but more data regarding the specific mechanisms are needed,[71,122] as well as the role of related estrogen receptors (see Fig. 24.8). It has been proposed that *NR2F2* and *NR5A1* may be involved in supporting theca cell fate in the ovary by maintaining a stromal progenitor lineage (similar to that in the testis that gives rise to Leydig cells), but data from patients suggest that the ovotestis has more profound development of testicular structures beyond just Leydig cells.

As with testis development, single-cell transcriptomics data and lineage-tracing studies are starting to map out the genetic events underlying development of germ cells and pregranulosa cells, as well as theca cell origins in the mouse and human ovary. Current knowledge has been reviewed extensively recently, but it is likely major new insights will emerge in the future in this area.[40]

Phenotypic or Anatomic Sex

The developing gonad produces several steroid and peptide hormones that mediate sexual differentiation and result in the phenotypic sex seen at birth. Alfred Jost first showed the importance of fetal testicular androgens in this process in 1947.[123] In his classic experiments, Jost demonstrated that surgical removal of the gonads during embryonic development of the rabbit resulted in development of female reproductive characteristics, regardless of the chromosomal sex of the embryo.

Male Sex Differentiation

Sertoli Cells and Müllerian Regression. Sertoli cells play a key role in supporting germ cell survival, and they produce two important peptide hormones: antimüllerian hormone (AMH also known as müllerian-inhibiting substance [MIS]) and inhibin B. AMH, a glycoprotein homodimer, is a member of the transforming growth factor-β (TGFβ) superfamily and is first secreted in humans from about 7 to 8 wpc under the regulation of key transcription factors such as SOX9, SF1, WT1, and GATA4 (see Figs. 24.1, 24.6, and 24.10).[124,125] AMH causes regression of müllerian structures (i.e., fallopian tubes, uterus, upper two-thirds of the vagina) by its paracrine action on the AMH type 2 receptor (AMHR2).

Müllerian structures appear to be maximally sensitive to AMH between 9 and 12 weeks after conception, a time when the developing testis is producing peak concentrations of AMH but before the onset of significant AMH production by the developing ovary. Boys with mutations in the *AMH* or *AMHR2* genes can present with persistent müllerian duct syndrome (PMDS), which can present with undescended testes but otherwise typical male external genitalia. Severe forms of 46,XY gonadal dysgenesis can also result in persistent müllerian structures due to impaired Sertoli cell development and AMH release. In some cases, a hemiuterus is present if AMH release is affected on only one side (the same side as the hemiuterus); but in these cases, androgenization of the external genitalia is usually also impaired so that these children present with atypical genitalia. In contrast, defects confined to Leydig cell steroidogenesis in 46,XY DSD are not associated with persistent müllerian structures because Sertoli cell production of AMH is unaffected. In boys, a small müllerian remnant sometimes persists as a testicular appendage or as a prostatic utriculus or utricular remnant.

Inhibin B is also a member of the TGFβ superfamily and exerts negative feedback on pituitary follicle-stimulating hormone (FSH) secretion (but not secretion of luteinizing hormone [LH]), but it is unclear whether inhibin B has any local role during testis development.

Fetal Leydig Cells and Steroidogenesis. Fetal Leydig cells develop within the interstitium of the developing testis from common precursor cells. There is a marked upregulation of steroidogenic genes at around 53 to 57 dpc, followed by androgen synthesis and secretion (see Fig. 24.1).[12,126] An expansion in fetal Leydig cells occurs between 14 and 18 weeks of gestation, resulting in increased testosterone secretion at about 16 weeks.[126,127] Fetal Leydig cell steroidogenesis is stimulated by placental human chorionic gonadotropin (hCG) during the first trimester of pregnancy, but the developing hypothalamic-gonadotrope system produces significant amounts of LH from about 16 to 20 weeks of gestation.[128,129]

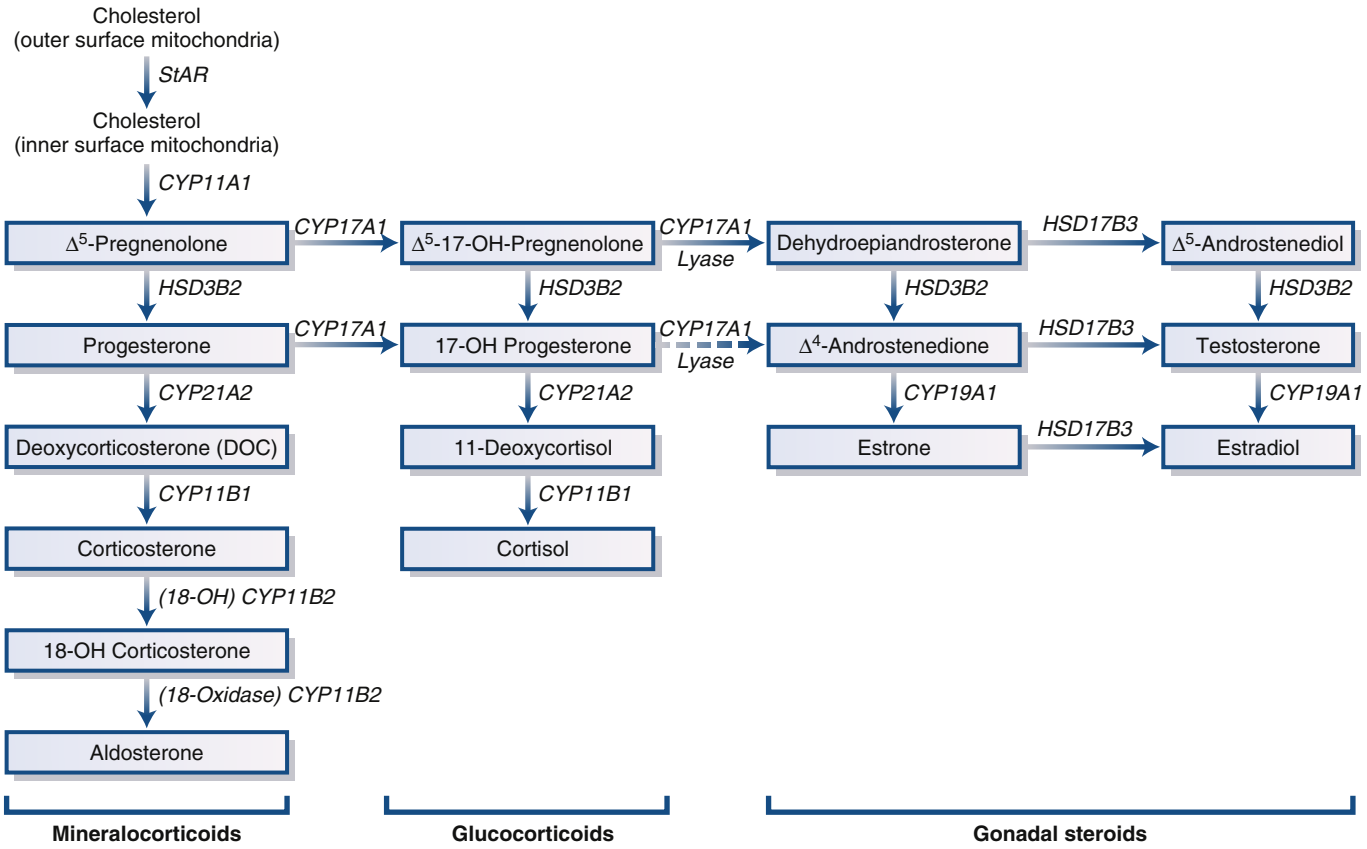
The pathways of testicular steroidogenesis are shown in Fig. 24.11 and overlap extensively with adrenal steroidogenesis pathways (see Chapter 15). The role of individual enzymes is discussed in relation to individual steroidogenic defects later in this chapter and in several excellent reviews.[130] In brief, cholesterol is taken up into Leydig cells by low-density lipoprotein or high-density lipoprotein receptors or is generated de novo by cholesterol synthesis pathways or from cholesterol ester. Stimulation of the LH/hCG receptor increases the ability of steroidogenic acute regulatory protein (StAR) to facilitate movement of cholesterol from the outer to the inner mitochondrial membrane.[131] The first and rate-limiting step in steroid hormone synthesis involves three distinct reactions: 20α-hydroxylation, 22-hydroxylation, and cleavage of the cholesterol side chain to generate pregnenolone and isocaproic acid. These steps are catalyzed by a single enzyme, P450scc (CYP11A1).

Pregnenolone is converted to progesterone by the microsomal enzyme 3β-hydroxysteroid dehydrogenase type 2 (3βHSD2), or it can undergo 17α-hydroxylation by P450c17 (CYP17) to yield 17-hydroxypregnenolone. CYP17 also has 17,20-lyase activity, which can cleave the C17,20 carbon bond of 17-hydroxypregnenolone to generate dehydroepiandrosterone (DHEA). This 17,20-lyase activity is favored by the presence of Δ^5-substrates (e.g., 17-hydroxypregnenolone), redox partners such as P450 oxidoreductase (POR) and cytochrome b_5, and serine phosphorylation of CYP17. These reactions are facilitated by the relative abundance of these factors in Leydig cells in humans, and the main pathway to androgen production is through conversion of 17-hydroxypregnenolone to DHEA rather than through conversion of 17-hydroxyprogesterone (17-OHP) to androstenedione.[132] Subsequent testosterone production can occur through conversion of DHEA to androstenedione by 3βHSD2, followed by the 17β-hydroxysteroid dehydrogenase action of 17βHSD3 to generate testosterone, or through the intermediate metabolite androstenediol (see Fig. 24.11).

Testosterone undergoes conversion to dihydrotestosterone (DHT) by 5α-reductase type 2 in peripheral tissues. DHT's high-affinity action on the androgen receptor results in androgenization of the external genitalia. Studies based on the phenotype of patients with POR deficiency and the fetal tammar wallaby have proposed that an alternative pathway to DHT production may exist in the human fetal testis (see "P450 Oxidoreductase Deficiency"): the so-called backdoor pathway (Fig. 24.12).[133,134]

Local production of testosterone stabilizes wolffian structures such as the epididymis, vas deferens, and seminal vesicle, whereas the potent metabolite DHT induces androgenization of the external genitalia and urogenital sinus (Fig. 24.13). In the male, the urogenital sinus gives rise to the prostate and prostatic urethra, the genital tubercle develops into the glans penis, the urogenital (urethral) folds fuse to form the shaft of the penis, and the urogenital (labioscrotal) swellings fuse to form the scrotum (Figs. 24.14 and 24.15).[135]

Testosterone and DHT mediate their effects through the androgen receptor (AR). The AR is a member of the superfamily of ligand-dependent nuclear receptor transcription factors encoded by a gene (*AR*, also known as *NR3C4*) on the X chromosome (Xq11-q12).[136] Like other nuclear receptors, it contains a highly conserved central DNA-binding domain (DBD) and a C-terminal ligand-binding domain (LBD) (Fig. 24.16). In addition, the AR uniquely contains an extended N-terminal domain (NTD) that



• **Fig. 24.11** Schematic diagram shows the steroid biosynthetic pathways leading to androgen production in the testis. In humans, the main pathway to androgen production is through conversion of 17-hydroxypregnenolone to dehydroepiandrosterone (DHEA) rather than through conversion of 17-hydroxyprogesterone to androstenedione. Subsequent testosterone biosynthesis can occur through conversion of DHEA to androstenedione (by 3β-hydroxysteroid dehydrogenase type 2 [3βHSD2]), followed by the actions of 17α-hydroxysteroid dehydrogenase type 3 (17βHSD3) to generate testosterone, or through the intermediate metabolite androstenediol. During male sex development, testosterone undergoes local conversion to dihydrotestosterone by 5α-reductase type 2 *(not shown)*. The high-affinity action of dihydrotestosterone on the androgen receptor results in androgenization of the external genitalia. The pathways responsible for mineralocorticoid and glucocorticoid synthesis are present in the adrenal gland. Additional or alternative pathways to dihydrotestosterone production may exist in the fetal testis.

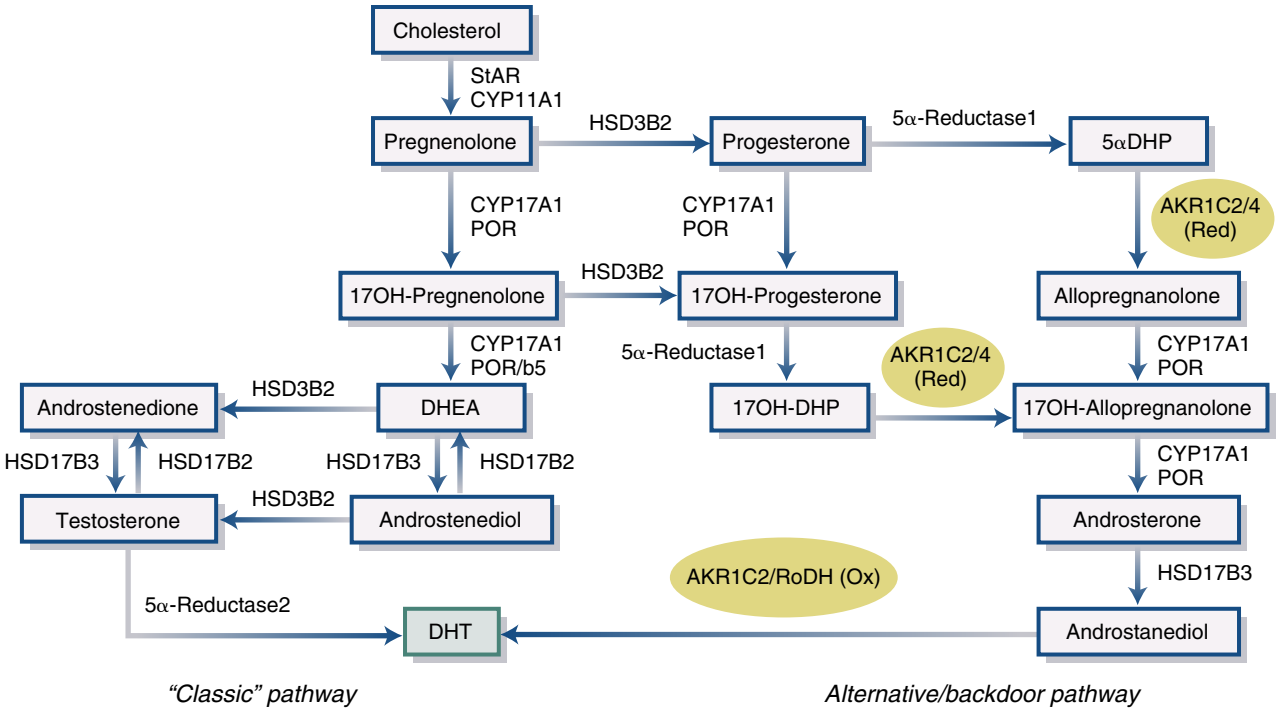
includes polyglutamine (CAG) and polyglycine (GGN) repeats that can vary in number; the length of these repeats can modulate AR activity, with a longer stretch of repeats associated with decreased AR activity.

The DBD contains cysteine residues that coordinate zinc atoms to form two zinc fingers, the first of which contains a P-box that enters the major groove of DNA to form specific base-pair contacts that are identical for all classic steroid receptors. The second zinc finger containing the D-box is involved in protein-protein interactions and stabilizes the unit for receptor dimerization. This binding requires preferential recognition of androgen response elements (AREs) composed of an inverted repeat of DNA sequences related to 5′-AGAACA-3′.[137]

The AR in the unliganded state is located in the cytoplasm and is complexed to heat shock proteins such as HSP70 and HSP90 and to co-chaperone proteins such as FKBP4 (also called FKBP52). Binding of ligand to its receptor results in dissociation from these complexes to allow translocation of the AR into the nucleus, where it binds to DNA target sequences as a homodimer.

The crystal structure of the AR LBD bound to natural and synthetic androgens is shown in Fig. 24.16C. Helix 12, in the presence of ligand, undergoes a conformational change to fold back on top of the ligand hydrophobic pocket to capture the ligand, thus slowing the rate of ligand-receptor dissociation. This trapping effect by helix 12 enables recruitment of transcriptional coactivators.

Activation of transcription involves motif activation function 1 (AF1) in the NTD and motif activation function 2 (AF2) in the LBD. AF1 is ligand independent, whereas AF2 is ligand dependent and interacts with p160 steroid receptor coactivators such as NCOA1, NCOA2, and NCOA3.[138] A relatively unique feature of the AR is interaction between the N-terminal and C-terminal domains (N-C interaction). In the presence of its primary physiologic ligands, testosterone and DHT, the AR recruits diverse coregulators that cooperate in the activation of transcription of androgen-regulated genes (see Fig. 24.16). N-terminal sequences comprising amino acid residues 23 to 27 (FQNLF) and residues 435 to 439 (WHTLF) participate in the AR N-C interaction to stabilize the AR and slow dissociation of the ligand. Further modulation of AR function occurs post-translationally by processes such as phosphorylation and sumoylation.



• **Fig. 24.12** The classic and alternative (backdoor) pathways of dihydrotestosterone (DHT) synthesis. The classic pathway leading to synthesis of DHT is *shown on the left*. The alternative pathway potentially involved in DHT synthesis is *shown on the right*. The alternative pathway involves the actions of additional enzymes: 5α-reductase, type 1 (5α-reductase 1, encoded by *SRD5A1*), AKR1C2 (3α-reductase, type 3) and possibly AKR1C4 (3α-reductase, type 1), and RoDH (3-hydroxyepimerase, encoded by *HSD17B6*). *DHEA,* dehydroepiandrosterone; *DHP,* dihydroprogesterone; *HSD,* hydroxysteroid dehydrogenase; *POR,* P450 oxidoreductase; *StAR,* steroidogenic acute regulatory protein. (From Flück CE, Meyer-Böni M, Pandey AV, et al. Why boys will be boys: two pathways of fetal testicular androgen biosynthesis are needed for male sexual differentiation. *Am J Hum Genet*. 2011;89:201–218.)

The action of the AR is further modulated by interaction with coregulatory proteins that function as coactivators or corepressors.[138] Agonist-induced changes in LBD organization enable coactivator recruitment through their LXXLL motifs.[139] The AR exhibits a selective preference for the ARA70, ARA55, and ARA54 coregulators, which contain FXXLF motifs related to the aforementioned amino acid residues in the N-terminus.

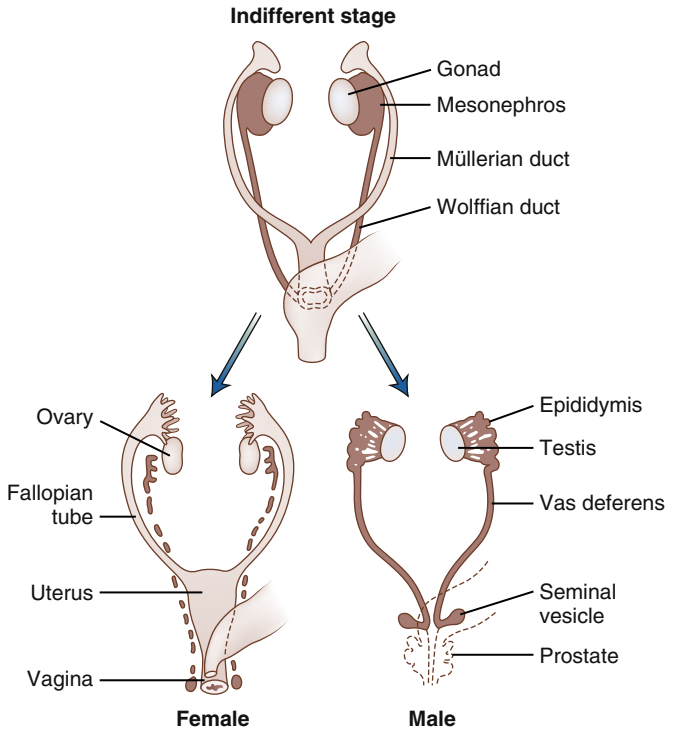
Relatively little is known about AR targets in the developing wolffian structures (which are testosterone responsive) and in the key target tissues such as the developing external genitalia (which are DHT responsive). Studies in mice have revealed a number of factors that are necessary for development of the wolffian ducts (e.g., Gdf7, Bmps4, Bmps7, Bmps8a, Bmps8b, Hoxa10, Hoxa11) and for growth of the genital tubercle (e.g., Fgfs, Shh, Wnts, Hoxa13, Hoxd13, Bmp/noggin, ephrin signaling). Impaired androgen action occurs in several syndromic conditions and may reflect defects in genes that mediate target-tissue responsiveness and genital tubercle growth (e.g., *HOXA10*, *HOXA13*).

Testicular Descent. Testicular descent is a two-stage process that starts at about 8 weeks of gestation and is usually complete by the middle of the third trimester.[140] The initial transabdominal stage of testicular descent (8–15 weeks) involves contraction and thickening of the gubernacular ligament and degeneration of the craniosuspensory ligament. This stage is mediated by the testis itself after secretion of factors such as insulin-like 3 (INSL3, a relaxin-like factor) and its G protein–coupled receptor, GREAT (also called LGR8 or RXFP2).[141] The subsequent transinguinal (or inguinoscrotal) phase of testicular descent (25–35 weeks) is primarily driven by androgens. The genitofemoral nerve and its neurotransmitter, calcitonin gene–related peptide (CGRP), have also been implicated in this process.

Subsequent Testicular Development. During the second and third trimesters, the testes show several distinct morphologic changes, including a reduction in fetal Leydig cell mass and elongation and coiling of seminiferous cords. There is no further significant development of germ cells during this time, and seminiferous cords do not canalize until later in childhood. Nevertheless, certain developmental insults can affect the testis at this stage. For example, testicular regression syndrome (also called vanishing or absent testis syndrome) is most likely a late fetal event, because boys with this condition have adequate androgenization and no müllerian structures, indicating normal testicular function in early gestation (see "Anorchia and Cryptorchidism").

Female Sex Differentiation

The processes of female sex differentiation do not involve significant morphologic changes in the external genitalia. Müllerian structures persist to form the fallopian tubes, uterus, and upper portion of the vagina (see Fig. 24.13). Normal uterine development in mice occurs even in the absence of the ovary and requires a host of factors for uterine development (e.g., Pax2, Lim1, Emx2, Wnt4/Lp, Hoxa13) and differentiation (e.g., Wnt7a, Hoxa10, Hoxa11, Hoxa13, progesterone and estrogen receptors).[142] The lack of local testosterone production leads to degeneration of wolffian structures. The urogenital sinus develops into the urethra and lower portion of the vagina, which in the absence of testosterone



• **Fig. 24.13** Embryonic differentiation of female and male genital ducts from wolffian and müllerian primordial tissue before descent of the testes into the scrotum. In females, müllerian structures persist to form the fallopian tubes, uterus, and upper portion of the vagina. The lower portion of the vagina and urethra are derived from the urogenital sinus. In males, wolffian structures develop into the epididymides, vasa deferentia, and seminal vesicles, whereas the prostate and prostatic urethra are derived from the urogenital sinus. In some cases, a small müllerian remnant can persist in males as a testicular appendage.

become separated by the vaginal plate, resulting in two separate orifices for these structures. The genital tubercle develops into the clitoris, the urogenital (urethral) folds form the labia minora, and the urogenital (labioscrotal) swellings form the labia majora (see Figs. 24.13 and 24.14).

In contrast to the testis, the developing ovary does not express FSH or LH/hCG receptors until after 16 weeks of gestation. At about 20 weeks of gestation, plasma concentrations of FSH reach a peak and the first primary follicles are formed.[129] By 25 weeks of gestation, the ovary has developed definitive morphologic characteristics. Folliculogenesis can proceed, and a few graafian follicles have developed by the third trimester.[8] Although some studies have suggested that the early fetal ovary can produce steroids and express aromatase, the amount of estrogen secreted by the developing ovary is likely to be insignificant compared with placental estrogen synthesis, and ovarian estrogen production does not seem to have significant effects on sex development until the time of puberty.[16]

Several conditions can affect 46,XX sex development in utero. Exposure of the fetus to androgens results in androgenization of the external genitalia. The local testosterone concentration typically is not sufficient to stabilize wolffian structures because the androgens are usually adrenal in origin. Most frequently, androgenization of the 46,XX fetus results from disorders of adrenal steroidogenesis (e.g., deficiency of 21-hydroxylase [CYP21], 11β-hydroxylase, POR, or 3β-hydroxysteroid dehydrogenase). Rare causes of androgenization include (placental) aromatase deficiency, glucocorticoid resistance, testicular and ovotesticular DSD, and maternal virilizing tumors (e.g., luteoma of pregnancy). With the exception of testicular/ovotesticular DSD, these conditions result in exposure to androgens but not AMH, so a uterus is usually present. Exposure to certain chemical agents in pregnancy has been proposed as a cause of fetal androgenization, but data are limited. For other developmental abnormalities of the female genital tract (e.g., Mayer-Rokitansky-Küster-Hauser [MRKH] syndrome) see "46,XX Disorders of Sex Development."

Psychosexual Development

Psychosexual development is traditionally viewed as having several distinct components (Table 24.2). *Gender identity* refers to a person's self-identification as male, female, or a nonbinary gender (e.g., intermediate to male and female, combined male and female, agender). For some individuals, gender identity may be fluid. *Gender role* (sex-typical behaviors) describes the expression or portrayal of psychological characteristics and behaviors that are sexually dimorphic within the general population, such as toy preferences, physical aggression, and choices of activities and occupation. *Gender expression* refers to whether outward appearance conforms more closely to male or female societal norms. *Sexual orientation* refers to romantic and erotic interests (e.g., heterosexual, bisexual, homosexual) and includes behavior, fantasies, and attractions and may or may not correspond to actual sexual activity.

The past 50 years have seen a number of opposing theories about the origins of psychosexual development and debate about the relative contributions of chromosomes, hormones, brain structure, and societal and family influences on the various components. Much of this work has focused on the study of rodents and nonhuman primate species. For example, Young and colleagues first showed in 1959 that exposure of guinea pigs to testosterone during pregnancy resulted in altered mating behavior of female offspring.[143] These effects may be most pronounced during a critical window of exposure and, in rodents and some primates, may depend in part on aromatization of the androgens to estrogens, receptor availability, and social environment.[144] More recently, interest has focused on the role of genes and chromosomes in sex behavior. For example, studies of differential gene expression patterns in the developing mouse brain have shown upregulation of different X and Y chromosomal genes in early embryonic life, even before the onset of significant androgen secretion by the developing testis in males.[145] Studies of mice in which *Sry* was deleted ($XYSRY^{-}$) or transgenically expressed (XXSRY) showed certain neuroanatomic differences between XY and XX mice independent of gonad development and endocrine status.[146] These findings suggest that factors related to chromosome complement have at least the potential to affect psychosexual development independent of sex hormone action, and a model integrating both factors may be more appropriate.[147]

Understanding the complex issues related to psychosexual development in humans is even more challenging, especially because gender identity cannot readily be assessed in nonhuman species. For many years, it was thought that gender identity would be concordant with the sex designated at birth, provided that the child was raised unambiguously, and appropriate surgical procedures and hormone therapies were instituted concordant with the gender chosen. This theory assumed psychosexual neutrality at birth, but it has been challenged by a refocusing on the potential importance of prenatal (e.g., endocrine) and innate (e.g., chromosomal) influences on psychosexual development.[148,149] Direct data to assess such effects

TABLE 24.2 Components of Psychosexual Development

Term	Explanation
Gender identity	Self-identification of gender as male, female, or other
Gender expression/role	Expression of gender-stereotypical behavior Aggression Parenting rehearsal Peer and group interactions Labeling (e.g., "tomboy") Grooming behavior
Sexual orientation	Pattern of sexual and romantic attraction

in humans are limited, but studies in women with complete androgen insensitivity syndrome (CAIS), in whom the karyotype is 46,XY but psychosexual development is almost always female, argue for a major role for androgens and a lesser role for Y chromosome genes alone in human psychosexual development.[150] However, the gender characteristics of individuals with a Y chromosome and a partial degree of androgen exposure or responsiveness (e.g., partial androgen insensitivity syndrome [PAIS], 17β-hydroxysteroid dehydrogenase deficiency, 5α-reductase deficiency) can vary, and long-term gender identity can be difficult to predict.[151,152] It has been suggested that the degree of androgenization of the external genitalia may serve as a marker of in utero testosterone exposure for not only the genitals but also the brain. Indeed, in a study of 46,XY individuals with PAIS, a greater degree of genital

androgenization generally correlated with increased scores on a composite gender index that incorporated assessments of both gender identity and gender-stereotypical behaviors, but there was wide variability for the most ambiguous phenotypes.[153]

Prenatal exposure to androgens can also influence psychosexual development in 46,XX individuals.[149,154] Girls with congenital adrenal hyperplasia (CAH) who have more marked genital androgenization are more likely to play more with boys' toys, with long-term effects evident into adulthood.[155] Prenatal androgen exposure can also be associated with other psychological characteristics, such as sexual orientation.[156] However, the association between high prenatal androgen exposure and gender identity is generally less marked, except perhaps in some cases of (ovo)testicular DSD and potentially severe deficiencies of aromatase or 11β-hydroxylase.[157] Although gender dissatisfaction (i.e., unhappiness with sex designated at birth) is more common in individuals with DSD, more than 90% of 46,XX individuals with CAH who are raised as girls later identify as female.[149,158] The small number of 46,XX men with CAH were usually raised male and diagnosed late. However, more 46,XX individuals with CAH and raised as girls may later identify as male than originally thought.[159,160]

Social environment and gender of rearing may also play a role in psychosexual development. Evidence for this comes from case series of 46,XY individuals with genital anatomy that was disrupted either developmentally (e.g., due to pelvic wall anomalies such as cloacal exstrophy) or iatrogenically (e.g., penile ablation) but who otherwise had normal testosterone production and responsiveness.[161,162] Historically, many of these individuals were raised as girls. Long-term follow-up of these patients has shown that many continued to identify as female, though a significant proportion identified as male gender or were uncomfortable with a female gender identity. Of note, of those raised as boys, all continued to identify with the male gender in late adolescence and adulthood, and current practice favors raising 46,XY patients as boys.

Collectively, these studies show that karyotype, prenatal androgen exposure, and designated gender may all influence gender identity. However, gender identity cannot be reliably predicted from any of these factors. Furthermore, because gender identity, sex-typical behavior, and sexual orientation are separate components of psychosexual development, it is important to appreciate that an interest in same-sex relationships (relative to sex of rearing) or strong cross-sex interest in an individual with DSD is not necessarily an indication of incorrect gender designation.[3]

Challenges in assessing gender identity in young children make it difficult to know when this is established, although it is thought to begin between 18 and 36 months and possibly younger.[163] Many of the sex differences in brain structures reported at late childhood, puberty, or adulthood are not seen in early childhood and are therefore not useful for guiding sex designation.[164,165] There may be some plasticity in psychosexual development, as is evident from studies of some patients with conditions such as 5α-reductase deficiency and 17β-hydroxysteroid dehydrogenase deficiency who may change their gender role in adolescence. Furthermore, some individuals with DSD do not fit into a binary model of gender. In several countries, important legal changes have taken place to acknowledge this, such as the option not to define gender as male or female on passports. Nevertheless, many societies and individuals still have a very binary view of gender, and freedom of expression remains difficult for many people who do not feel they fit a binary model.

Development of the Hypothalamic-Pituitary-Gonadal Axis in the Fetus

Development of the hypothalamic-pituitary-gonadal (HPG) axis is described in detail in Chapter 23; points that are particularly relevant to DSD are reviewed here.

Fetal hypothalamic-gonadotrope development occurs from 6 wpc in humans and occurs in parallel with the processes of sex determination and differentiation. This involves migration of gonadotropin-releasing hormone (GnRH)–producing neurons from the olfactory placode through the cribriform plate to the fetal hypothalamus, development of the hypothalamic nuclei, formation of the anterior pituitary from Rathke pouch, and specification and maturation of pituitary gonadotropes that are capable of releasing LH and FSH as part of a functional HPG axis. Defects in these systems can result in a range of clinical conditions, such as Kallmann syndrome, congenital isolated hypogonadotropic hypogonadism, and gonadotropin insufficiency as part of a multiple pituitary hormone deficiency, which are reviewed elsewhere (Chapters 8, 23, and 26).

It is generally thought that pulsatile release of LH and FSH does not occur and therefore does not influence the gonad until about 16 to 20 wpc, at which stage fusion of the penis is complete.[129] In male fetuses, the main effects of gonadotropins are to support the latter stages of testicular steroidogenesis involved in elongation of the penis and to support the transinguinal aspects of testicular descent. Consequently, boys with congenital gonadotropin insufficiency may have a small penis (micropenis) and/or bilaterally undescended testes. These children might need monitoring for important associated features such as renal agenesis in Kallmann syndrome or growth hormone or adrenocorticotropic hormone (ACTH) insufficiency (causing hypoglycemia) in panhypopituitarism. Classically, boys with hypothalamic or pituitary gonadotropin insufficiency do not have hypospadias, as fusion of urethral folds has occurred before 20 weeks. Rarely, hypospadias occurs with HPG disorders, potentially reflecting loss of factors that influence the HPG axis at multiple levels.[166,167]

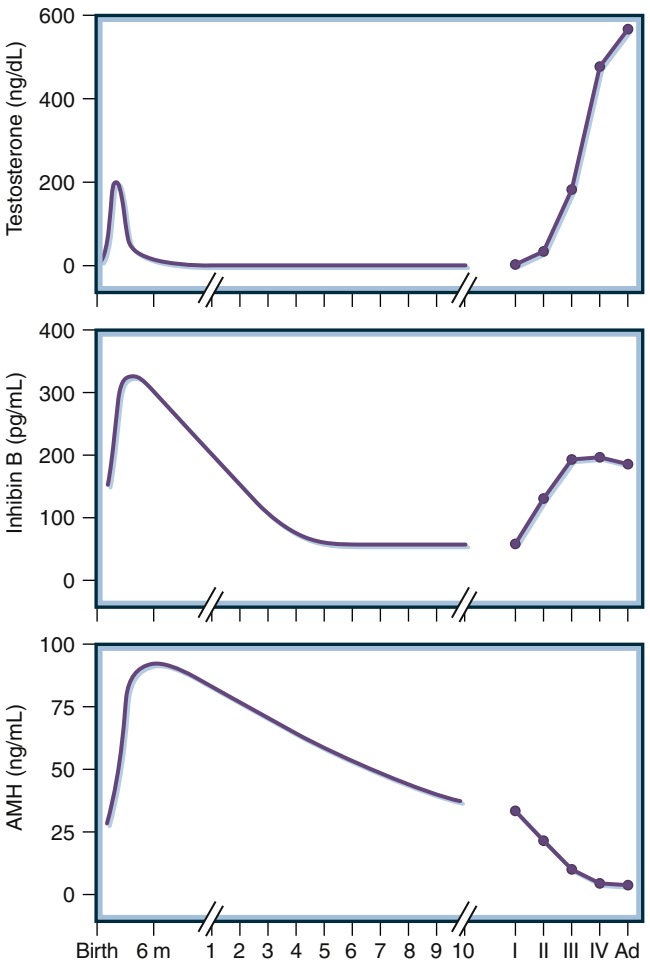
The Hypothalamic-Pituitary-Gonadal Axis in Infancy and Childhood

At birth, the infant is removed from the influence of maternal and placental hormones and undergoes a series of distinct endocrine changes.

Postnatal Endocrine Changes in Boys

Testosterone can be detected at birth, with levels falling during the first few days of life. Thereafter, a reactivation of the HPG axis occurs and results in serum testosterone that is typically measurable by 1 to 2 weeks of life and peaks at midpubertal levels between 2 and 3 months after birth (Fig. 24.17).[168,169] This peak of testosterone is associated with an acceleration in penile growth and may be linked in part to early postnatal maturation of gonocytes in the testis.[169] The HPG axis then becomes relatively quiescent from around 6 months of age until the onset of puberty, and serum concentrations of LH, FSH, and testosterone are low during this time.

Inhibin B concentrations are similarly high at birth and in infancy, fall during the first 2 years of life to low but still detectable levels, then rise again with the onset of puberty (see Fig. 24.17).[170,171] In contrast, AMH concentrations remain high from birth through childhood and only decline with the onset



• **Fig. 24.17** Typical postnatal changes are shown for testosterone, antimüllerian hormone (AMH), and inhibin B in normal males from birth to adulthood. Pubertal stages (I–IV) are indicated. Conversions: testosterone, ng/dL × 0.0347 for nmol/L; AMH, ng/mL × 7.14 for pmol/L; ranges may vary with the assay, so only indicative values are provided to show trends over time.

of puberty (see Fig. 24.17).[124,125] Inhibin B and especially AMH can therefore be useful markers of active testicular tissue (specifically, Sertoli cells) in boys with cryptorchidism, anorchia, and 46,XY DSD even when assessed between the periods of robust HPG activity in infancy and at puberty. INSL3 assays may provide a useful additional marker of Leydig cell function in the future.[172,173]

Postnatal Endocrine Changes in Girls

The early postnatal endocrine events in girls are less well characterized. Placental estrogen exposure can result in breast development before birth, and a small episode of menstrual bleeding can occur several days after birth from withdrawal of estrogen and progesterone. Girls also have a discrete activation of the HPG axis in infancy that declines by 1 to 3 years of age. Detectable concentrations of estradiol (5–20 pg/mL [20–80 pmol/L]) and inhibin B (50–200 pg/mL) can be measured in the first few months of life, and surprisingly high concentrations of FSH with marked interindividual variability can be found during infancy and early childhood (median, 3.8 IU/L; range, 1.2–18.8 IU/L [2.5–97.5%] at 3 months of age in healthy term girls).[174] Throughout childhood, FSH remains detectable, but LH is low. AMH is very low until puberty. Inhibin A, which is made exclusively by the ovary, has been proposed as a test of ovarian tissue in the newborn period in children with possible ovotesticular DSD, but this hormone is below the limits of detection in many normal term newborn girls, and FSH stimulation may be needed to detect it.[175]

Disorders (Differences) of Sex Development

DSDs can have a wide range of presenting phenotypes, depending on the underlying condition and its severity. Individuals with these conditions can present to many different health care professions, including neonatologists, geneticists, urologists, gynecologists, and internists. The classic presentation is an infant born with ambiguous genitalia, but not all conditions are apparent at birth. For example, 46,XY individuals with complete 17α-hydroxylase/17,20-lyase deficiency may first present in early adolescence with hypertension and delayed puberty, or a young woman with CAIS (46,XY) may first present to a gynecologist with amenorrhea.

Significant progress in understanding the molecular basis of gonadal development has occurred during the past 30 years. Several single-gene disorders causing gonadal dysgenesis in humans have been described, and many more candidate genes are emerging from studies in mice. The percentage of patients with disorders of gonadal development who can be diagnosed at the molecular level is increasing with the use of next-generation sequencing (NGS) of gene panels or whole exomes (currently around 25–40%),[166,176–179] and molecular diagnosis of classic disorders of steroidogenesis can be reached in most situations. Defining the exact basis of a patient's DSD can have important implications for sex designation, predicting response to treatment (e.g., androgen supplementation), screening for associated features (e.g., adrenal dysfunction), assessing the risk of tumorigenesis, determining likely fertility options, and providing long-term counseling for the individual and family. However, long-term outcome studies are often inadequate, and an evidence-based approach to management is not possible in many cases.

Nomenclature and Classification of Disorders of Sex Development

DSD has been defined as "congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical."[1] This definition is wide ranging enough to cover nonendocrine conditions such as cloacal exstrophy but sufficiently specific not to embrace, for example, disorders of puberty. The consensus statement that introduced the term DSD further suggested classification of DSD by karyotype (Table 24.3): sex chromosome variations (sex chromosome DSD), disorders of testis development and of androgen synthesis and action (46,XY DSD), and androgen excess and disorders of ovary development (46,XX DSD). Although karyotype does not define a person's gender, rapid assessment of karyotype can be a very useful stepping stone for focusing investigations and to start to counsel the family about likely causes and outcomes.

Sex Chromosome Disorders of Sex Development

Differences in the number of sex chromosomes (i.e., sex chromosome aneuploidy) can be considered *sex chromosome DSDs.*

TABLE 24.3 Example of a DSD Classification System

Sex Chromosome DSD	46,XY DSD	46,XX DSD
A: 47,XXY (Klinefelter syndrome) and variants B: 45,X (Turner syndrome) and variants C: 45,X/46,XY (mosaicism) and variants D: 46,XX/46,XY (chimerism)	A: Disorders of gonadal (testis) development Complete or partial gonadal dysgenesis (e.g., *SF1/NR5A1, WT1, GATA4, FOG2/ZFPM2, CBX2, SRY, SOX9, SOX8, MAP3K1, ESR2/NR3A2, DMRT1, TSPYL1, DHH, SAMD9, ARX, MAMLD1/CXorf6*) Ovotesticular DSD Testis regression	A: Disorders of gonadal (ovary) development Gonadal dysgenesis Ovotesticular DSD (e.g. *NR5A1, NR2F2, RSPO1*) Testicular DSD (e.g., *SRY*+, dup *SOX9,* dup *SOX3, NR5A1, NR2F2, RSPO1, WNT4*)
	B: Disorders in androgen synthesis or action Disorders of androgen synthesis Luteinizing hormone (LH) receptor mutations Smith-Lemli-Opitz syndrome StAR protein mutations Cholesterol side-chain cleavage *(CYP11A1)* 3β-hydroxysteroid dehydrogenase 2 *(HSD3B2)* 17α-hydroxylase/17,20-lyase *(CYP17)* P450 oxidoreductase *(POR)* Cytochrome b_5 *(CYB5A)* Aldo-keto reductase 1C2 *(AKR1C2)* 17β-hydroxysteroid dehydrogenase *(HSD17B3)* 5α-reductase 2 *(SRD5A2)* Disorders of androgen action Androgen insensitivity syndrome Drugs and environmental modulators	B: Androgen excess Fetal 3β-hydroxysteroid dehydrogenase 2 *(HSD3B2)* 21-hydroxylase *(CYP21A2)* P450 oxidoreductase *(POR)* 11β-hydroxylase *(CYP11B1)* Glucocorticoid receptor mutations Fetoplacental Aromatase (CYP19) deficiency Oxidoreductase (POR) deficiency Maternal Maternal virilizing tumors (e.g., luteomas) Androgenic drugs
	C: Other Syndromic associations of male genital development (e.g., cloacal anomalies, Robinow, Aarskog, hand-foot-genital, popliteal pterygium) Persistent müllerian duct syndrome Vanishing testis syndrome Isolated hypospadias Cryptorchidism *(INSL3, GREAT)* Environmental influences	C: Other Syndromic associations (e.g., cloacal anomalies) Müllerian agenesis/hypoplasia (e.g., MKRH) Uterine abnormalities (e.g., MODY5) Vaginal atresias (e.g., McKusick-Kaufman) Labial adhesions

CYP, Cytochrome P450 isoenzyme; *DSD,* disorders of sex development; *MODY5,* maturity-onset diabetes of the young type 5; *MRKH,* Mayer-Rokitansky-Küster-Hauser; *StAR,* steroidogenic acute regulatory (protein).

These conditions include Klinefelter syndrome (47,XXY and variants), Turner syndrome (45,X and variants), trisomy X (47,XXX and variants), XYY syndrome (47,XYY and variants), 45,X/46,XY mosaicism and its variants, and true sex chromosome chimerism (46,XY/46,XX) (Table 24.4). A 45,Y cell line is nonviable.

There can be ambiguous genitalia at birth if a Y chromosome or Y chromosome fragment is present in some but not all cells due to sex chromosome chimerism or mosaicism, but Klinefelter syndrome (unless four or more X chromosomes are present) and classic Turner syndrome in which there is no Y chromosomal material do not typically cause ambiguous genitalia. In many cases of classic sex chromosome aneuploidy, the diagnosis is made in adolescence or adult life during evaluation of characteristic features, impaired pubertal development, or infertility. More detailed descriptions of the features and long-term management of some of these conditions are provided in the relevant chapters (e.g., Turner syndrome in Chapter 26, Klinefelter syndrome in Chapters 19 and 26).

Klinefelter Syndrome and Its Variants

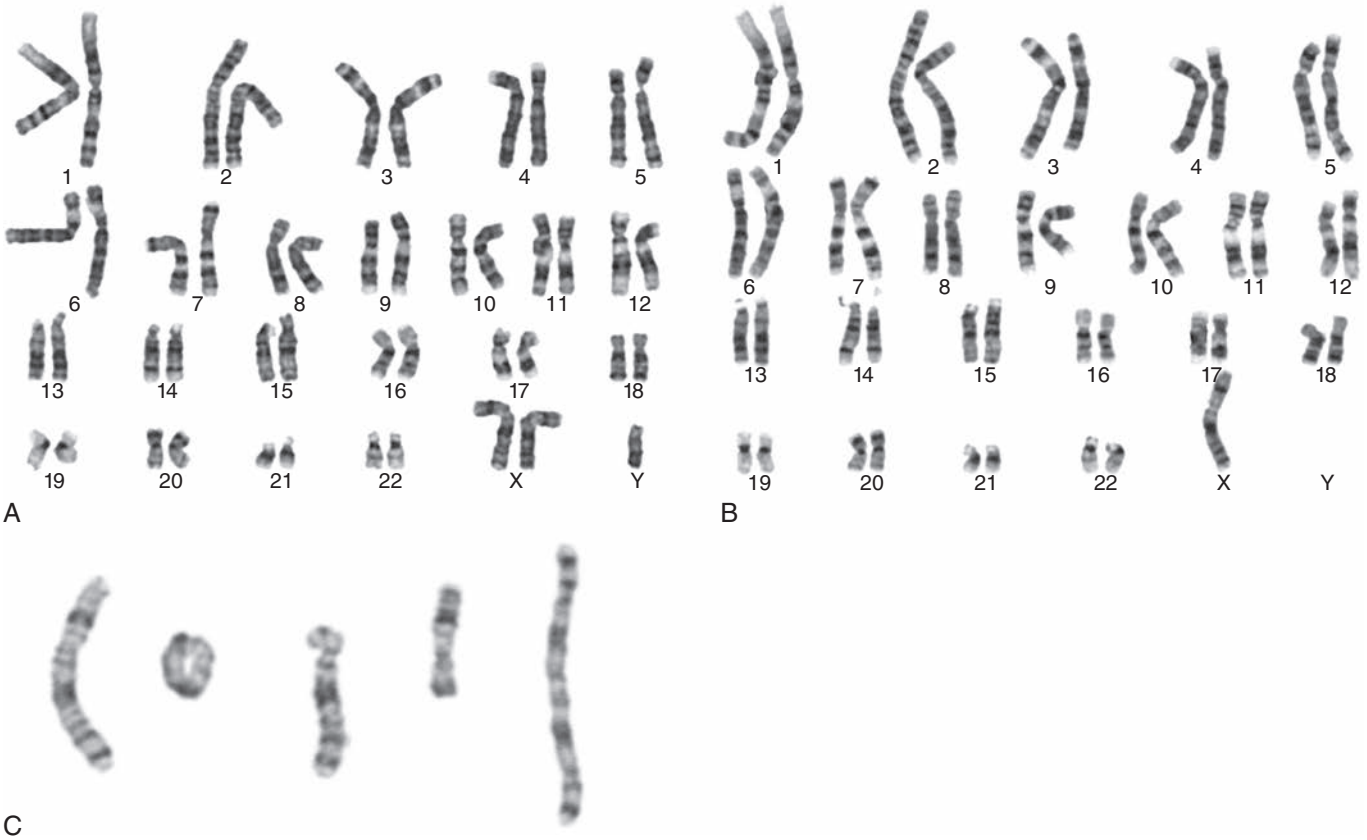
Klinefelter syndrome and its variants are the most common forms of sex chromosome aneuploidy, with a reported incidence of 1 in 500 to 1 in 1000 live male births.[180] This incidence may be increasing.[181] The classic form of Klinefelter syndrome is associated with a 47,XXY karyotype and is caused by meiotic nondisjunction of the sex chromosomes during gametogenesis (Fig. 24.18).[18] This abnormality occurs during spermatogenesis in approximately 50% of patients and during oogenesis or postzygotic division in approximately 50%.[180] Mosaic forms of Klinefelter syndrome (46,XY/47,XXY) likely represent mitotic nondisjunction within the developing zygote and are thought to occur in approximately 10% of individuals with Klinefelter syndrome. Other chromosomal variants of Klinefelter syndrome (e.g., 48,XXXY) can be seen.

The clinical features of Klinefelter syndrome and its variants are summarized in Table 24.4.[180] In the most obvious situations, a young man may be diagnosed because of small testes, gynecomastia, poor androgenization at puberty, eunuchoid proportions,

TABLE 24.4 Clinical Features of Sex Chromosome DSDs

Condition	Karyotype	Gonad	Internal Genitalia	Features
Klinefelter syndrome	47,XXY and variants	Hyalinized testes	No uterus	Small testis, azoospermia, hypoandrogenemia; tall stature and increased leg length; increased incidence of learning difficulties, language delay, obesity, breast tumors, varicose veins, impaired glucose tolerance
Turner syndrome	45,X and variants	Streak gonad or immature ovary	Uterus	*Childhood:* Lymphedema, shield chest, web neck, low hairline; cardiac defects and coarctation of the aorta; renal and urinary abnormalities; short stature, cubitus valgus, hypoplastic nails, scoliosis; otitis media and hearing loss; ptosis and amblyopia; nevi; autoimmune thyroid disease; visuospatial learning difficulties *Adulthood:* Pubertal failure, primary amenorrhea; hypertension; aortic root dilatation and dissection; sensorineural hearing loss; increased risk of CVD, IBD, colon cancer, thyroid disease, glucose intolerance and diabetes mellitus, osteoporosis (note that some of these may be related to estrogen deficiency)
Mixed gonadal dysgenesis	45,X/46,XY and variants	Testis or dysgenetic gonad	Variable	Increased risk of gonadal tumors; short stature; features of Turner syndrome may be present
Ovotesticular DSD	46,XX/46,XY chimerism	Testis, ovary, or ovotestis	Variable	Possible increased risk of gonadal tumors

CVD, Cardiovascular disease; *DSDs,* disorders of sex development; *IBD,* inflammatory bowel disease.



• **Fig. 24.18** G-banded karyotypes of Klinefelter syndrome (47,XXY) (A) and Turner syndrome (45,X) (B). (C) Structural changes of the X chromosome seen in variants of Turner syndrome *(from left to right):* normal X; ring chromosome (r[X][p22.3q22]); short-arm deletion (del[X][p21]); long-arm deletion (del[X][q21.31]); isochromosome (I[X][q10]). or infertility. Other features, such as learning difficulties, speech and language delay, behavioral issues, and altered motor development, may occur, and early educational support focusing on any specific areas of difficulty is important.[182,183] It is likely that the clinical detection of Klinefelter syndrome based on postnatal karyotyping is biased toward detection of those individuals with a more severe phenotype, and it is estimated that as few as 25% of men with Klinefelter syndrome may be diagnosed throughout their life span. However, this pattern may change as diagnosis of Klinefelter syndrome on prenatal genetic testing becomes increasingly common.

The development of testes and a male phenotype in individuals with Klinefelter syndrome provides important evidence for the key role of the presence of the Y chromosome (rather than X chromosome number) in testis determination and subsequent prenatal androgen production. However, testicular function may not be completely intact; micropenis and hypospadias may be presenting features in some cases, and some studies report mildly elevated FSH concentrations during the postnatal "mini-puberty" together with testosterone levels in the lower half of the normal range.[184]

A more predictable elevation in gonadotropin concentrations (e.g., FSH, LH) occurs in the periadolescent period in patients with Klinefelter syndrome, after activation of the HPG axis.[185,186] By midadolescence, plasma concentrations of FSH are increased in 90% of patients with Klinefelter syndrome, and plasma concentrations of LH are increased in 80%. Other serum markers of testicular function (e.g., peripubertal inhibin B, midpubertal INSL3) are often below the normal ranges.[173,186] Although puberty usually starts at a normal age with an appropriate rise in testosterone in classic Klinefelter syndrome, serum testosterone levels off around midpuberty with an increase of gonadotropins. In the majority of young adults, serum testosterone is in the lower half of the reference range.[185,187] Testes usually remain small and firm; the median length and volume are 2.5 cm and 3 mL, but most are smaller than 3.5 cm (range 1–7 mL).[185] Testes typically appear inappropriately small for the degree of androgenization. The serum estradiol concentration is often elevated, which contributes to the gynecomastia observed during the adolescent period.

Testicular biopsy is not warranted clinically because the diagnosis can usually be made on karyotyping from peripheral blood cells. However, studies in which testicular histologic examination has been obtained report germ cell depletion, progressive hyalinization of seminiferous tubules, and Leydig cell hyperplasia after chronic LH stimulation.[185] Testosterone levels need careful surveillance during puberty.[186] A significant proportion of individuals with Klinefelter syndrome receive testosterone supplementation to fully induce puberty and to support sex characteristics, libido, and bone mineralization into adult life. Psychological support and educational support may be needed, as well as attention to potential long-term issues such as diabetes. Management of Klinefelter syndrome in adolescence and adulthood is discussed in Chapter 19.

Although some cases of spontaneous fertility have been reported for mosaic forms of Klinefelter syndrome (46,XY/47,XXY), the prospects for fertility in classic Klinefelter syndrome have historically been poor. Occasionally, sperm can be obtained from ejaculate, and this should always be assessed, but most men have azoospermia. However, in the past decade, testicular sperm extraction (TESE, or micro-TESE) has allowed successful sperm retrieval for approximately 40% to 50% of men with classic Klinefelter syndrome (47,XXY) in specialist centers, independent of age, testicular volume, or hormonal profile.[188] Sperm retrieval rates also seem to be similar in those with and without previous testosterone treatment.[189] Subsequent intracytoplasmic sperm injection (ICSI) has led to successful pregnancy and live birth in approximately 40% to 50%.[185,188] The risk of transmission of the sex chromosome aneuploidy seems to be low, although an increase in some other chromosomal changes is seen, and preimplantation genetic diagnosis is often offered.

Turner Syndrome and Its Variants

Turner syndrome is the second most frequent form of sex chromosome aneuploidy, with an incidence of approximately 1 in 2500 live female births.[190] The classic form of Turner syndrome is associated with a 45,X karyotype, which occurs in approximately one-half of individuals with this condition (see Fig. 24.18). Mosaic forms of Turner syndrome (45,X/46,XX) account for approximately one-fourth of the patients, and the remainder have structural abnormalities of the X chromosome such as long-arm or short-arm deletions, isochromosomes, or ring chromosomes (see Fig. 24.18).[190]

A 45,X chromosomal constitution may be the consequence of nondisjunction or chromosome loss during gametogenesis in either parent that results in a sperm or ovum that lacks a sex chromosome. Although errors in mitosis in normal zygotes often lead to mosaicism, a purely 45,X constitution may arise at the first cleavage division from anaphase lag with loss of a sex chromosome or, less often, from mitotic nondisjunction with failure of the complementary 47,XXX or 47,XYY cell line to survive.[17] An estimated 2% of all zygotes have a 45,X karyotype, and approximately 7% of spontaneous abortuses have a 45,X karyotype, making this the most frequent chromosomal anomaly in humans.

The clinical features of Turner syndrome are highly variable, and the age at diagnosis can be similarly variable. For example, a prenatal diagnosis of Turner syndrome may be made incidentally on prenatal genetic testing or after the detection of increased nuchal translucency on fetal ultrasound scanning.[190] In early infancy, the diagnosis should be considered in females with lymphedema, nuchal folds, low hair line, and/or left-sided cardiac defects. Unexplained growth failure or characteristic somatic features (e.g., abnormal nails, shield chest, abnormal carrying angle, recurrent ear infections) may point to the diagnosis during childhood, and Turner syndrome should be considered in all girls with pubertal delay or pubertal failure associated with hypergonadotropic hypogonadism. The clinical features of Turner syndrome are summarized in Table 24.4, and diagnosis and management are discussed in Chapters 25 and 26. Growth hormone treatment can reduce the severity of short stature. Timely and appropriate introduction of estrogens is necessary in adolescence to ensure optimal growth, bone health, and psychosocial development as well as adequate breast and uterine development, thereby optimizing the opportunity to potentially carry a pregnancy by ovum donation in the future.[190–192] However, careful assessment of cardiovascular risk before and during pregnancy is essential.[193] Women with Turner syndrome benefit from dedicated transition in adolescence and long-term follow-up with a focus on issues such as cardiovascular, bone, and reproductive health and hearing.[190,194–198]

Girls with classic Turner syndrome show ovarian dysgenesis. Studies of Turner syndrome embryos have shown normal germ

cell migration and normal ovarian development until the third month of gestation.[199] Then, accelerated germ cell apoptosis and subsequent oocyte atresia occur, resulting in progressive degeneration of the ovary in the prenatal or postnatal period. With these gonadal changes, LH and FSH tend to rise in late childhood, after activation of the hypothalamic pulse generator, and sometimes even earlier. Nevertheless, sufficient estrogen synthesis for puberty to commence in adolescence occurs in approximately 25% of girls with Turner syndrome (10% of those with 45,X; 30–40% of those with 45,X/46,XX mosaicism), and menstruation occurs in about 2% of cases.[194,200] AMH may be a useful marker of ovarian reserve and a predictor of ovarian insufficiency.[201] Gonadectomy is not usually required except when a Y fragment containing the *TSPY* locus is present; in such patients, the risk of gonadoblastoma is increased.[202]

Oocyte cryopreservation has been used successfully in several women with Turner mosaicism and is a fertility preservation option for young women with persistent ovarian function.[190,203] Ovarian cortical tissue preservation is feasible but requires surgery and is currently considered experimental. Routine fertility preservation in girls under 12 years of age is not recommended.[190]

Risk from pregnancy is high in women with Turner syndrome due to cardiovascular defects and other comorbidities, and detailed assessment and counseling prior to and during any potential pregnancy are mandatory.[190,203]

45,X/46,XY Mosaicism and Variants

A mosaic 45,X/46,XY karyotype probably arises through anaphase lag during mitosis in the zygote, although Y chromosomal abnormalities are sometimes seen, and interchromosomal rearrangements with loss of structural abnormal Y material may be a common mechanism for variants of this condition. Although the classic form of this condition is associated with 45,X/46,XY mosaicism, 45,X/47,XYY, 45,X/46,XY/47,XYY, and other mosaic karyotypes can occur.

The true prevalence of this condition is unknown (see Table 24.4). Because individuals with 45,X/46,XY mosaicism are more likely to be referred for further assessment if they have atypical genitalia, most series of patients reported in the literature have probably reflected this bias; studies based on nonselected prenatal karyotyping have shown that most children with 45,X/46,XY mosaicism appear male.[204–206]

The phenotypes associated with 45,X/46,XY mosaicism are highly variable. The gonads can develop as dysgenetic ovaries (ovarian-like stroma with sparse primordial follicles) or streak gonads (similar to those seen in Turner syndrome), normal or dysgenetic testes, or very rarely as ovotestes (with testicular and dysgenetic ovarian components within a single gonad).

Depending on the degree of Leydig cell activity (if any), the gonads may be positioned anywhere along the pathway of testicular descent, with streak gonads more likely to be intraabdominal and well-formed testes more likely to be in the inguinoscrotal region. Marked differences in gonadal development and histologic appearance can sometimes be seen between the right and the left sides (referred to as *mixed gonadal dysgenesis*) or even within a single gonad.[207]

All possible genital phenotypes have been reported, ranging from typical female external genitalia or mild clitoromegaly through all stages of ambiguous genitalia to hypospadias or typical male external genitalia.[204,207–210] Asymmetry of the external genitalia strongly suggests asymmetric gonadal development (i.e., mixed gonadal dysgenesis).

Müllerian structures may be present if there is absent or impaired AMH production by Sertoli cells, and these structures are also often asymmetric. The presence of a hemiuterus and fallopian tube on the side of the more dysgenetic gonad in some cases of mixed gonadal dysgenesis provides important evidence for the paracrine actions of AMH on developing müllerian structures.

Somatic features associated with a 45,X/46,XY karyotype are also highly variable and do not always correlate well with the gonadal phenotype.[204,207,209,210] Approximately 40% of children have clinical features reminiscent of Turner syndrome, such as short stature, nuchal folds, low-set hairline, and cardiac and renal abnormalities.[207] In other cases, short stature may be the only somatic manifestation. Ongoing monitoring for features associated with Turner syndrome (e.g., thyroid function, hearing, and cardiac anomalies; see Chapter 26) is therefore applicable for this group of individuals.[190] Furthermore, many families benefit from the psychological support and education that can be linked to specialist services.

Sex designation can be difficult in individuals with 45,X/46,XY, and several factors should be considered, including probable gender identity, genital appearance and urogenital anatomy, fertility and reproductive options, risk of gonadal malignancy, and potential need for hormone replacement. Recommendation for sex designation should be handled like any other intervention, with a careful discussion of risks, benefits, and potential outcomes. Most infants with female or minimally androgenized genitalia are raised as female, and the presence of a uterus or hemiuterus may allow the potential for pregnancy by ovum donation in the future, though predicting future function can be difficult. Furthermore, as with girls with classic Turner syndrome, there may be risks associated with pregnancy (by ovum donation) due to cardiovascular anomalies. Intraabdominal streak-like (i.e., flat, scar-like gonads) and dysgenetic gonads are thought to pose a significant risk of germ cell malignancy and should be removed.[208,210,211] The risk of germ cell tumors in individuals with 45,X/46,XY DSD is estimated to be 15% to 40%.[212] Estrogen replacement is required to induce breast and uterine development in adolescence, and the addition of progestins allows menstruation if a uterus is present. Growth hormone treatment has been used when short stature is present, but no large trials have been performed to assess this group of patients. Usually there is a significantly reduced growth spurt during puberty, and some studies have suggested use of GH from earlier in childhood may optimize growth.[209,213] Similarly, limited long-term outcome data on gender identity or psychosexual functioning are available.

Infants with hypospadias are usually raised as male. Testosterone can sometimes be given to promote phallic growth in infancy, and hypospadias repair is usually offered as a one-stage or two-stage procedure, depending on the severity of the hypospadias. Attempts should be made to perform orchidopexy as a one-stage or two-stage procedure because there may be a significant risk of malignancy in these gonads. Gonadectomy should be considered for gonads that cannot be placed in a palpable position; some have advocated for close monitoring, but imaging is not able to detect early neoplastic changes in abdominal gonads.[208,210,214] Gonads that can be secured within the scrotum need careful monitoring by palpation/self-examination and imaging to detect changes such as microlithiasis.[214] At the time of orchidopexy, and in adolescence, biopsy can be used to assess for premalignant changes and estimate the risk of germ cell cancer. Puberty should be carefully monitored to ensure adequate endogenous testosterone production. Most boys enter puberty spontaneously, but some then

develop androgen insufficiency requiring testosterone supplementation.[210] Reduced final height is invariable, but there is a beneficial response to growth hormone in some boys.[215]

Designation of sex and management of a 45,X/46,XY child with *highly ambiguous genitalia* is a difficult situation for families and physicians, and long-term outcome data for this group are scant. Individuals raised female are infertile, usually have no uterus, require gonadectomy because of tumor risk, and are likely to undergo urogenital surgery. Those raised as male often undergo multiple hypospadias operations, may have poor corporal tissue, are infertile if dysgenetic gonads are present that need to be removed and often infertile even if the gonads are intact, and may have a significantly reduced height potential. There is limited data on gender identity outcomes; in one series of 11 children with mixed gonadal dysgenesis raised as girls, 6 later declared a male gender identity.[216] Detailed assessment of each child is important, and an individualized approach by an experienced multidisciplinary team is important for long-term monitoring, management, and support. Long-term outcome data from larger studies may provide better guidance on the management of this group of individuals in the future.

A 45,X/46,XY mosaic karyotype can also be associated with a male phenotype and apparently normal testis development. Initial cases of typical-appearing males with a 45,X/46,XY karyotype were described after screening of family members as potential bone marrow transplant donors, but later studies of amniocentesis showed that 90% of infants with a 45,X/46,XY karyotype have normal male genitalia and apparently normal testes, and postnatally these individuals may be diagnosed because of short stature or infertility.[205,206,217,218] There seems to be variable correlation between the degree of mosaicism on peripheral blood sampling and gonadal or somatic phenotype. Monitoring of gonadal function and growth, assessment for premalignant changes of the gonads, and cardiac and renal screening are advised in individuals with a typical male phenotype or minor genital anomalies because they are at risk for abnormal growth, Sertoli cell dysfunction, gonadal germ cell cancer, and cardiac and renal malformations.[217]

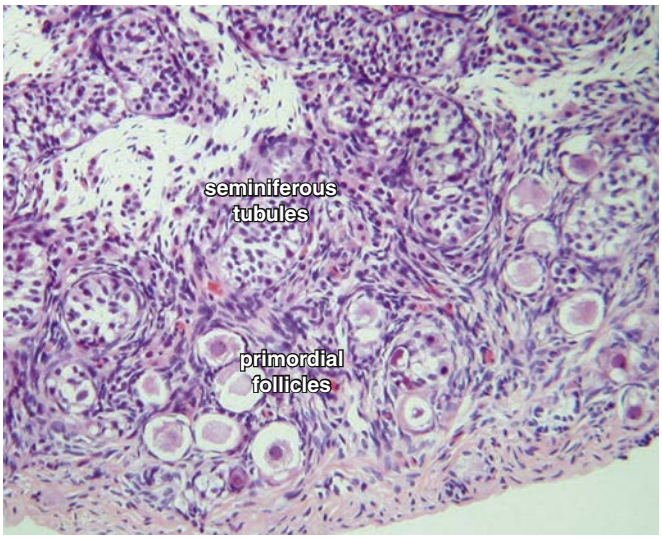
Ovotesticular Disorders of Sex Development: 46,XX/46,XY Chimerism and Variants

The diagnosis of ovotesticular DSD (previously referred to as true hermaphroditism) requires the presence of ovarian tissue (containing follicles) and testicular tissue in the same or the opposite gonad (Fig. 24.19; see Table 24.4). Gonadal stroma arranged in whorls, similar to what is found in a typical ovary but lacking oocytes, is a common finding in a dysgenetic or streak gonad and is not considered sufficient evidence to designate the rudimentary gonad as an ovotestis.

Ovotesticular DSD is an uncommon condition in the United States and Europe, occurring in less than 5% of babies referred because of atypical genitalia, but is a common cause of atypical genitalia in South Africa.[218a] Ovotesticular DSD can occur in several different scenarios. The classic diagnosis is 46,XX/46,XY chimerism (sometimes caused by double fertilization or ovum fusion; see "Chromosomal Sex"), which is found in approximately 20% to 30% of children with ovotestes in our center and occurs in all ancestral backgrounds (Table 24.5).[219,220] Somewhat more prevalent is ovotesticular DSD associated with a 46,XX karyotype. In a proportion of cases this can occur due to p.Arg92 variants in NR5A1/SF1, loss of function of RSPO1 or NR2F2/COUP-TFII, or upregulation of expression of SRY, SOX9, or SOX3.[71,72,122,221,222] Of note, 46,XX ovotesticular DSD is much more prevalent in children from sub-Saharan Africa; the molecular etiology for this is not currently known (see Table 24.5). The molecular basis of these conditions will be discussed later in the relevant section (see "46,XX Ovotesticular and 46,XX Testicular Disorders of Sex Development"). Finally, ovotestes have rarely been reported in several conditions associated with 46,XY gonadal dysgenesis (e.g., MAP3K1, SOX9), and fertile 46,XY women have been described.[223–225]

Here we will discuss basic principles of management of ovotesticular DSD based on 46,XX/46,XY chimerism, which are applicable to the other forms of the condition. However, it is important to remember that a Y chromosome (containing the spermatogenic locus) is necessary for potential sperm production, so 46,XX children with ovotestes will not be fertile males.

Patients with ovotesticular DSD often have asymmetric gonadal development and sometimes may be subclassified according to the type and location of the gonads.[4] Three forms are possible: *lateral* (20%) with a testis on one side and an ovary on the other, *bilateral* (30%) with testicular and ovarian tissue present bilaterally, and *unilateral* cases (50%) with an ovotestis present on one side and an ovary or testis on the other. It has been suggested that the left gonad is more likely to develop as an ovary, whereas the right gonad is more likely to develop as a testis. An ovary is



• **Fig. 24.19** Ovotestis, showing immature seminiferous tubules lined with Sertoli cells and germ cells *(upper left)* and ovarian tissue with primordial follicles *(lower right)* (hematoxylin-eosin stain; original magnification, ×400). DSD, Disorders of sex development.

Adapted from Krob G, Braun A, Kuhnle U. True hermaphroditism: geographical distribution, clinical findings, chromosomes and gonadal histology. *Eur J Pediatr*. 1994;153:2–10.

likely to be in its normal anatomic position, whereas a testis or ovotestis can be anywhere along the pathway of testicular descent and is often found in the inguinal region.

Differentiation of the genital tract and development of secondary sex characteristics vary in ovotesticular DSD.[226,227] Most patients who present early have ambiguous genitalia or significant hypospadias. Cryptorchidism is common, but often at least one gonad is palpable, usually in the labioscrotal fold or inguinal region, and is often associated with an inguinal hernia. The differentiation of the genital ducts usually follows that of the gonad, and a hemiuterus or rudimentary uterus is often present on the side of the ovary or ovotestis.

Breast development at the time of puberty is common in ovotesticular DSD.[227] Menses occur in a significant proportion of cases when a uterus is present, and ovulation and pregnancy have been reported in a number of patients with a 46,XX karyotype when an ovary is present. However, progressive androgenization can occur in girls with testicular tissue, which can result in voice changes and clitoral enlargement during adolescence if left untreated. Individuals reared as male often present with hypospadias and undescended testes, although bilateral scrotal ovotestes have been reported. These individuals can experience significant estrogenization at the time of puberty and may have cyclic hematuria if a uterus is present. Spermatogenesis is rare, and interstitial fibrosis of the testis is common. As noted, fertility requires Y chromosomal genes other than *SRY*, so boys with 46,XX ovotesticular DSD will be infertile.

Although ovotesticular DSD is rare, the diagnosis should be considered in all patients with ambiguous genitalia. A 46,XX/46,XY karyotype strongly suggests the diagnosis, but the detection of a 46,XX or 46,XY karyotype does not exclude the diagnosis, especially if a 46,XX baby has genital asymmetry. Pelvic imaging with ultrasound or magnetic resonance imaging (MRI) is useful for visualizing internal genitalia. The presence of testicular tissue may be detected by measurement of basal testosterone, AMH, and inhibin B in the first months of life and by measuring basal AMH thereafter. Ovarian tissue is more difficult to detect in early childhood, although estradiol, inhibin A, and follicular response to repeated injection of recombinant human FSH can provide useful information.[175] Examination under anesthesia and laparoscopy may provide the most detailed information about internal structures and allow a biopsy to confirm the diagnosis of ovotesticular DSD when other forms of DSD have been excluded.[228,229] However, the biopsy sometimes does not sample all the tissues present in a gonad.[229]

The management of ovotesticular DSD depends on the age at diagnosis, genital development, internal structures, and reproductive capacity. Either male or female designation may be appropriate for the young infant. Individuals with a 46,XX karyotype, little virilization, and a uterus are likely to have functional ovarian tissue, and female designation is likely to be appropriate. If androgenization is not desired by the individual, functional testicular tissue could potentially be removed before puberty and monitored postoperatively by measuring serum AMH and testosterone levels. Although still experimental, options for cryopreserving gonadal tissue are being explored. Potentially, GnRH agonists could be used to temporarily delay puberty if the young person needs more time to understand the condition and be involved in decisions about gonadectomy (whether complete or partial). The risk of malignant transformation in ovarian tissue of 46,XX patients is not known but is likely to be low given the absence of Y chromosomal material.

A male sex designation may be more appropriate if there is significant clitorophallic development and testicular tissue, and müllerian structures are absent or very poorly formed. Appropriate counseling should be provided and evidence of a likely male gender seen before considering prepubertal removal of ovarian tissue within an ovotestis. Again, cryopreservation of gonadal tissue may emerge as an option but is currently experimental. GnRH agonists or aromatase inhibitors might be considered on a trial basis if more time is needed to make decisions. Remnant müllerian structures can be removed by an experienced surgeon if there are problems with hematuria or urinary retention, although extreme care is needed not to disrupt the blood supply to any testis/testes being preserved, and often there is no harm in leaving müllerian structures intact. The testicular tissue is usually well differentiated in 46,XX ovotesticular DSD so that the risk of germ cell tumors is estimated to be low.[22]

Gender identity is also an important consideration in patients with ovotesticular DSD who first present in late childhood or adolescence due to androgenization in girls or estrogenization in boys. In most cases, gender identity is consistent with gender of rearing. After appropriate counseling, the discordant gonad and dysgenetic tissue can be removed to prevent unwanted androgenization in girls and estrogenization in boys. Sex hormone supplementation may be required for complete pubertal development and in adult life.

46,XY Disorders of Sex Development

The 46,XY DSDs can be categorized as disorders of testis development, disorders of androgen synthesis, disorders of androgen action, and other conditions affecting sex development (Table 24.6; see also Fig. 24.7).

Disorders of Testis Development

Disorders of testis development can have a spectrum of phenotypes and presentations. *Complete testicular dysgenesis*, a condition sometimes called *Swyer syndrome*, is associated with a complete lack of androgenization of the external genitalia and persistent müllerian structures due to insufficient AMH production. In contrast, *partial gonadal dysgenesis* may be associated with a range of phenotypes, ranging from clitoromegaly to ambiguous or atypical genitalia to isolated hypospadias. A uterus or uterine remnant and vagina may be present. Subtle forms of testicular dysgenesis can present with testicular regression, a small penis, or male infertility in the absence of an external genital phenotype.

Several single-gene disorders have been described in patients with various degrees of testicular dysgenesis. Table 24.6 summarizes these factors, and the role of many of these factors in development has already been discussed (see "Testis Determination"). Although associated features can sometimes help to direct genetic analysis, often there are no other findings, and a genetic diagnosis is currently reached in only about 20% to 40% of individuals with 46,XY testicular dysgenesis.

Single-Gene Disorders

Steroidogenic Factor 1: NR5A1. SF1 (encoded by *NR5A1*) is a member of the nuclear receptor superfamily that regulates the transcription of at least 30 genes involved in gonadal development, adrenal development, spleen development, steroidogenesis, and reproduction.[59,230] *NR5A1* mutations were first reported in two 46,XY individuals with female external genitalia, persistent müllerian structures, and primary adrenal failure.[65,66] The first variant was a de novo heterozygous p.Gly35Glu change in the P-box primary DNA-binding region of SF1; the second was a recessively inherited homozygous p.Arg92Gln mutation in the A-box secondary DNA-binding region (Fig. 24.20). These changes resulted

TABLE 24.6 Overview of Important Genes Involved in DSDs

Gene	Protein	OMIM	Locus	Inheritance	Gonad	Müllerian Structures	External Genitalia	Associated Features/Variants
A. Causes of 46,XY DSD								
Disorders of Gonadal (Testicular) Development: Single-Gene Disorders								
WT1	TF	607102	11p13	AD	Dysgenetic testis	±	Female, ambiguous or hypospadias	Wilms tumor, renal abnormalities, gonadal tumors (WAGR, Denys-Drash, and Frasier syndromes)
NR5A1 (SF1)	Nuclear receptor TF	184757	9q33.3	AD/AR (SLD)	Dysgenetic testis (variable)	±	Female, ambiguous, or hypospadias	More severe phenotypes include primary adrenal failure; milder phenotypes have isolated partial gonadal dysgenesis or impaired androgenization or both
GATA4	TF	600576	8p23.1	AD (SLD)	Dysgenetic testis (variable)	–	Female, ambiguous, or hypospadias/micropenis	Cardiac defects (e.g., septal defects, tetralogy of Fallot)
ZFPM2 (FOG2)	Coregulator	603693	8q23.1	AD	Dysgenetic testis (variable)	±	Female or ambiguous	Congenital heart defects. Learning and language difficulties, autism spectrum disorder in one individual.
CBX2	Polycomb protein	602770	17q25.3	AR	Ovary (one case)	+	Female	
SRY	TF	480000	Yp11.3	Y	Dysgenetic testis or ovotestis	±	Female or ambiguous	
SOX9	TF	608160	17q24-q25	AD	Dysgenetic testis or ovotestis	±	Female or ambiguous	Campomelic dysplasia (17q24 rearrangements have a milder phenotype than point mutations)
SOX8	TF	605923	16p13.3	AD, de novo	Dysgenetic testis (variable)	±	Female or ambiguous	16p deletion can have additional features
MAP3K1	Signaling molecule	600982	5q11.2	AD	Dysgenetic testis (variable)	±	Female, ambiguous, or hypospadias/micropenis	
NR3A2 (ESR2)	Nuclear receptor TF	601663	14q23.2	AD/AR	Dysgenetic testis	±	Female or ambiguous	Variable (anal atresia, blepharophimosis, dysmorphic features)
DMRT1	TF	602424	9p24.3	AD	Dysgenetic testis	+	Female	
TSPYL1	? Chromatin remodeling	604714	6q22.1	AR	Dysgenetic testis	–	Female or ambiguous	Sudden infant death
DHH	Signaling molecule	605423	12q13.1	AR	Dysgenetic testis, testis (Leydig)	–	Female or ambiguous	Minifascicular neuropathy in several patients
SAMD9	Growth repressor	617053	7q21.2	AD, de novo	Dysgenetic testis, testis (Leydig)	-	Female, ambiguous or hypospadias	MIRAGE syndrome (myelodysplasia, infections, restriction of growth, adrenal hypoplasia, genital phenotypes, enteropathy)
ARX	TF	300382	Xp22.13	X	Dysgenetic testis (Leydig)	–	Ambiguous	X-linked lissencephaly, epilepsy, temperature instability
MAMLD1 (CXORF6)	Unknown	300120	Xq28	X	Normal (Leydig cell dysfunction)	–	Hypospadias

Gene	Protein	OMIM	Locus	Inheritance	Gonad	Müllerian Structures	External Genitalia	Associated Features/Variants
Disorders of Gonadal (Testicular) Development: Chromosomal Changes Involving Key Candidate Genes[a]								
DMRT1	TF	602424	9p24.3	Monosomic deletion	Dysgenetic testis	±	Female or ambiguous	Mental retardation
ATRX	Helicase (? chromatin remodeling)	300032	Xq13.3	X	Dysgenetic testis	–	Female, ambiguous, or male	α-thalassemia, mental retardation
NR0B1 (DAX1)	Nuclear receptor TF	300018	Xp21.3	dupXp21	Dysgenetic testis or ovary	±	Female or ambiguous	
WNT4	Signaling molecule	603490	1p36.12	dup1p35	Dysgenetic testis	+	Ambiguous	Mental retardation
Disorders in Hormone Synthesis or Action								
DHCR7	Enzyme	602858	11q13.4	AR	Testis	–	Variable	Smith-Lemli-Opitz syndrome: coarse facies, second-third toe syndactyly, failure to thrive, developmental delay, cardiac and visceral abnormalities
LHCGR	G protein receptor	152790	2p16.3	AR	Testis	–	Female, ambiguous, or micropenis	Leydig cell hypoplasia
STAR	Mitochondrial associated protein	600617	8p11.2	AR	Testis	–	Female, ambiguous, or micropenis	Lipoid CAH (primary adrenal failure), pubertal failure
CYP11A1	Enzyme	118485	15q24.1	AR	Testis	–	Female or ambiguous	CAH (primary adrenal failure), pubertal failure
HSD3B2	Enzyme	201810	1p13.1	AR	Testis	–	Ambiguous	CAH, primary adrenal failure, ↑ Δ^5:Δ^4 ratio
CYP17A1	Enzyme	202110	10q24.3	AR	Testis	–	Female, ambiguous, or micropenis	CAH, hypertension due to DOC (except in isolated 17,20-lyase deficiency)
POR (P450 oxidoreductase)	CYP enzyme electron donor	124015	7q11.2	AR	Testis	–	Male or ambiguous	Mixed features of 21-hydroxylase deficiency, 17α-hydroxylase/17,20-lyase deficiency, and aromatase deficiency; sometimes associated with Antley-Bixler craniosynostosis
CYB5A	Cofactor	613218	18q22.3	AR	Testis	–	Ambiguous or hypospadiac	Methemoglobinemia
AKR1C2 (AKR1C4)	Enzyme	600450	10p15.1	AR (? digenic)	Testis	–	Variable	
HSD17B3	Enzyme	605573	9q22.23	AR	Testis	–	Female or ambiguous	Partial androgenization at puberty, ↑ ratio of androstenedione to testosterone
SRD5A2	Enzyme	607306	2p23.1	AR	Testis	–	Ambiguous or micropenis	Partial androgenization at puberty, ↑ ratio of testosterone to DHT

Androgen receptor (NR3C4)	Nuclear receptor TF	313700	Xq12	X	Testis	–	Female, ambiguous, micropenis, or normal male	Phenotypic spectrum from complete AIS (female external genitalia) to partial AIS (ambiguous) to normal male genitalia/infertility
AMH	Signaling molecule	600957	19p13.3	AR	Testis	+	Normal male	Persistent müllerian duct syndrome (PMDS)
AMH receptor	Serine/threonine kinase transmembrane receptor	600956	12q13.13	AR	Testis	+	Normal male	Male external genitalia, bilateral cryptorchidism
B. Causes of 46,XX DSD								
Disorders of Gonadal (Ovarian) Development								
SRY	TF	480000	Yp11.3	Translocation	Testis or ovotestis	–	Male or ambiguous	
SOX9	TF	608160	17q24	dup17q24 or deletion of regulatory region	Not determined	–	Male or ambiguous	
SOX3	TF	313430	Xq27.1	dup Xq27 or del of regulatory region	Testis (variable)	–	Male	Additional features if large duplication
NR5A1 (SF1)	Nuclear receptor TF	184757	9q33.3	AD or de novo (affecting codon 92)	Testis or ovotestis	-	Male or ambiguous	
NR2F2 (COUP-TFII)	Nuclear receptor TF	107773	15q26.2	AD or de novo	Testis or ovotestis	-	Male or ambiguous	Cardiac defects, diaphragmatic hernia, BPES
RSPO1	Thrombospondin (Wnt signaling)	609595	1p34.3	AR	Testis or ovotestis	–	Male	Palmar-plantar hyperkeratosis, squamous cell carcinoma
WNT4	Wnt signaling	611812	1p36.12	AR	Testis or ovotestis	–	Male or ambiguous	SERKAL syndrome
Androgen Excess								
HSD3B2	Enzyme	201810	1p13.1	AR	Ovary	+	Clitoromegaly (mild)	CAH, primary adrenal failure, partial androgenization due to ↑ conversion of DHEA

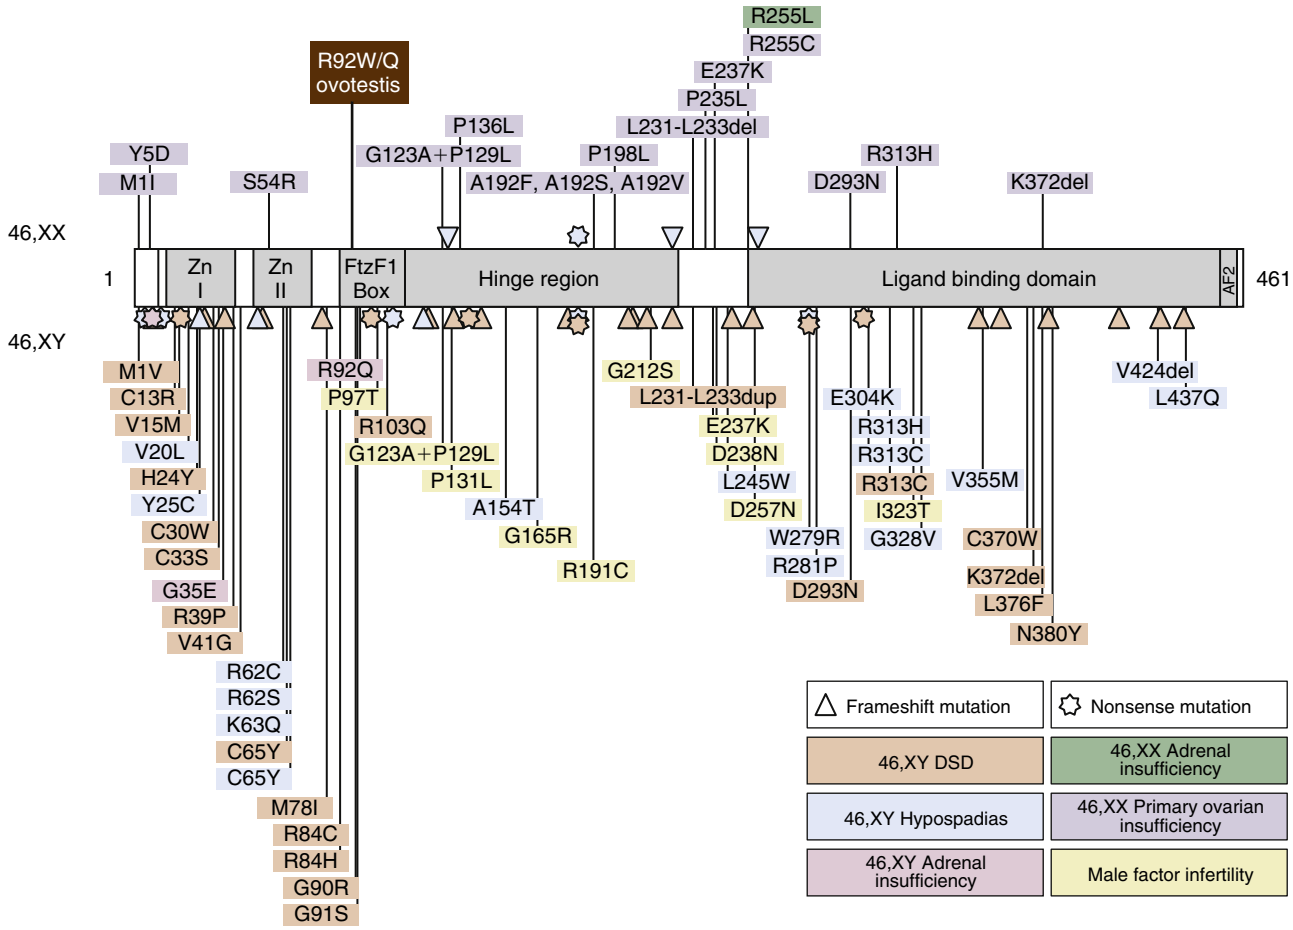
TABLE 24.6 Overview of Important Genes Involved in DSDs—cont'd

Gene	Protein	OMIM	Locus	Inheritance	Gonad	Müllerian Structures	External Genitalia	Associated Features/Variants
CYP21A2	Enzyme	201910	6p21.33	AR	Ovary	+	Ambiguous; rarely Prader V	CAH, phenotypic spectrum from severe salt-losing forms associated with adrenal failure to simple virilizing forms with compensated adrenal function, ↑ 17-OHP
CYP11B1	Enzyme	202010	8q24.3	AR	Ovary	+	Ambiguous; rarely Prader V	CAH, hypertension due to ↑ 11-deoxycorticosterone
POR (P450 oxidoreductase)	CYP enzyme electron donor	124015	7q11.23	AR	Ovary	+	Normal or ambiguous	Mixed features of 21-hydroxylase deficiency, 17α-hydroxylase/17,20-lyase deficiency and aromatase deficiency; associated with Antley-Bixler craniosynostosis
CYP19A1	Enzyme	107910	15q21.2	AR	Ovary	+	Ambiguous	Maternal androgenization during pregnancy, absent breast development at puberty except in partial cases
Glucocorticoid receptor[b] (NR3C1)	Nuclear receptor TF	138040	5q31.3	AR	Ovary	+	Normal or ambiguous	↑ ACTH, 17-OHP, cortisol, mineralocorticoids, and androgens; failure of dexamethasone suppression

[a]Chromosomal rearrangements likely to include key genes are included.

[b]Note: Patient heterozygous for a mutation in *CYP21*.

–, Absent; +, present; *ACTH,* adrenocorticotropic hormone; *AD,* autosomal dominant (often de novo mutation); *AIS,* androgen insensitivity syndrome; *AR,* autosomal recessive; *BPES,* blepharophimosis-ptosis-epicanthus inversus syndrome; *CAH,* congenital adrenal hyperplasia; *CYP,* cytochrome P450 enzyme; *DHEA,* dehydroepiandrosterone; *DHT,* dihydrotestosterone; *DOC,* 11-deoxycorticosterone; *DSDs,* disorders of sex development; *17-OHP,* 17-hydroxyprogesterone; *LHCGR,* luteinizing hormone (LH) or human chorionic gonadotropin (hCG) receptor; *OMIM, Online Mendelian Inheritance in Man*; *SERKAL,* sex-reversal with kidney, adrenal, and lung dysgenesis; *SLD,* sex-limited dominant; *TF,* transcription factor; *WAGR,* Wilms tumor, aniridia, genitourinary anomalies, and mental retardation.



• **Fig. 24.20** Schematic diagram of steroidogenic factor 1 (SF1) shows key domains and mutations associated with a gonadal phenotype. The Gly35Glu (heterozygous) and Arg92Gln (homozygous) changes affect DNA-binding regions of the protein and are associated with marked underandrogenization, dysgenetic gonads, müllerian structures, and primary adrenal failure. Heterozygous frameshift *(triangles)* and nonsense mutations *(stars)*, as well as missense mutations, have been described in 46,XY individuals with a spectrum of disorders of sex development (DSD) phenotypes *(below the structure drawing)* and in women with primary ovarian insufficiency *(above the structure drawing)*. (From Suntharalingham JP, Buonocore F, Duncan A, et al. DAX-1 (NR0B1) and steroidogenic factor-1 (SF-1, NR5A1) in human disease. *Best Pract Res Clin Endocrinol Metab*. 2015;29:607–619. Based on Lin L, Philibert P, Ferraz-de-Souza B, et al. Heterozygous missense mutations in steroidogenic factor-1 [SF1/Ad4BP, NR5A1] are associated with 46,XY disorders of sex development with normal adrenal function. *J Clin Endocrinol Metab*. 2007;92:991–999, used with permission of The Endocrine Society, Copyright 2007.)

in impaired DNA binding. The combination of gonadal and adrenal phenotype is uncommon, and it initially seemed that disruption of SF1 would be a rare cause of DSD in humans.

However, the past decade has seen a different picture emerging as an ever-increasing number of monoallelic (heterozygous) nonsense, frameshift, and missense mutations in *NR5A1* have been associated with a spectrum of 46,XY DSD conditions in individuals with normal adrenal function (see Fig. 24.20).[59,67,231,232] These changes usually result in haploinsufficiency of SF1. A range of phenotypes is seen, most commonly mild gonadal dysgenesis and significantly impaired androgenization, where alterations in SF1 are found in approximately 15% of cases.[59] These variations usually arise de novo but may be inherited from the mother in a sex-limited dominant fashion (i.e., the mother carries the mutation but is unaffected) or even from the father and occasionally may be autosomal recessive.[66] In some situations, there is a family history of ovarian insufficiency, and females in the family may be at risk of developing ovarian insufficiency in the future.[68] Loss of SF1 function is also reported in some boys with severe hypospadias and undescended testes (~5%), bilateral anorchia, and a small penis and in men with infertility (~2%).[233–235] Oligogenic effects of other genes have also been proposed to influence phenotype.[236,237] Therefore variable loss of SF1 activity is associated primarily with different degrees of testicular or ovarian dysfunction in humans. Adrenal function may need to be monitored over time, but at present, adrenal insufficiency does not seem prevalent. In addition, splenic abnormalities have been described, ranging from asplenia to polysplenia.[230,238] Although their prevalence among patients with *NR5A1* mutations is currently unclear, assessment of spleen anatomy and function by ultrasound and search for Howell-Jolly bodies in blood has been recommended given the serious consequences that (functional) asplenia may have.[238] Defining the molecular basis in different families can be important for counseling, especially about the potential risk of ovarian insufficiency,

and for identifying those males who might need surveillance for potential androgen insufficiency or a decline in fertility with age. *NR5A1* mutations can also result in ovotesticular DSD (see "Ovotesticular Disorders of Sex Development").

Wilms Tumor 1 Gene: *WT1*. *WT1* (11p13) is a four–zinc finger transcription factor expressed in the developing genital ridge, kidney, gonads, and mesothelium.[49] The WT1 protein has several different isoforms that have complex roles in sex development, as outlined previously and shown in Fig. 24.21. The important role of WT1 in human testis development has been confirmed through the description of various WT1 mutations in patients with WAGR syndrome, Denys-Drash syndrome, and Frasier syndrome.

WAGR syndrome is caused by deletion of a region of chromosome 11p13.[239] The resultant phenotype is likely to be the consequence of haploinsufficiency of *WT1* together with loss of developmental genes such as *PAX6*, which is involved in eye development.[55] Renal abnormalities include childhood Wilms tumor in about half of children; renal agenesis has been reported, and renal dysfunction often occurs after adolescence. Genitourinary abnormalities are usually relatively mild and include bilateral cryptorchidism, micropenis, and occasionally hypospadias. Careful ophthalmic support is needed for the aniridia or iridic hypoplasia, and cataracts or corneal clouding can occur. Developmental delay can occur with larger chromosomal deletions, and obesity may be a feature if the deletion is large and includes the *BDNF* gene (WAGRO syndrome).

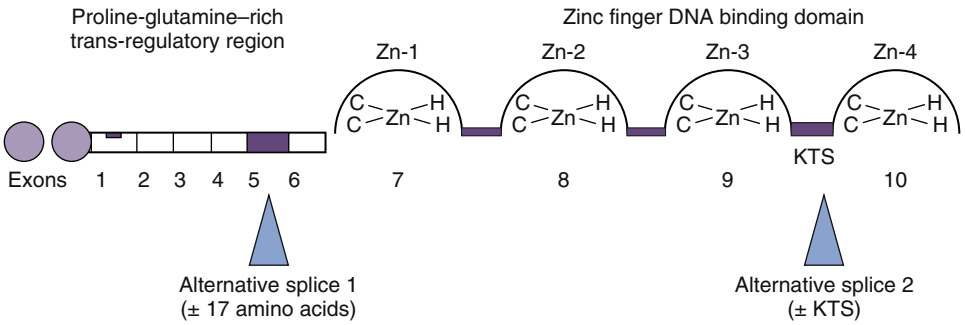
Denys-Drash syndrome is characterized by gonadal dysgenesis, severe congenital or early-onset nephropathy (i.e., diffuse mesangial sclerosis), and predisposition to Wilms tumor.[56] Most 46,XY patients with Denys-Drash syndrome present with genital ambiguity or severe penoscrotal hypospadias in the newborn period, although typical male or female genital appearance has been described. The presence or absence of müllerian structures depends on the degree of Sertoli cell dysfunction. Denys-Drash syndrome usually results from heterozygous de novo point mutations in *WT1* that have a dominant negative effect on the function of the wild-type protein. These point mutations usually affect the DNA-binding region (zinc fingers) of WT1. The risk of early-onset renal failure is high, and Wilms tumor usually develops in the first few years of life. There is an increased risk of germ cell tumors.[212] The prevalence of *WT1* mutations in boys with penoscrotal hypospadias and undescended testes has been reported to be as high as 7%.[240]

Frasier syndrome usually results from heterozygous mutations in the donor splice site of exon 9 of *WT1*.[57,58] These changes are predicted to result in an imbalance in the ratio of +KTS to –KTS isoforms of WT1. Frasier syndrome is typically characterized by streak gonads, a 46,XY female phenotype with müllerian structures, and later-onset nephropathy (i.e., focal segmental glomerulosclerosis) that usually progresses to renal failure in the second decade of life. There is a high risk of gonadal tumors (gonadoblastoma and dysgerminoma) in patients with Frasier syndrome.[241] In practice, Denys-Drash syndrome and Frasier syndrome may represent a continuum of phenotypes rather than distinct conditions.[242] Severe forms of these conditions can present with congenital nephrotic syndrome, whereas milder variants have been reported, for example, in a man with hypospadias and late-onset nephropathy.[243] Taken together, these cases highlight the importance of considering this diagnosis in 46,XY DSD and of performing urinalysis for proteinuria in children with 46,XY DSD. Meacham syndrome (i.e., DSD, cardiac defects, and diaphragmatic hernia) may also result from changes in *WT1*.[244]

Management of patients with *WT1* mutations includes monitoring and treatment of renal function and assessment for Wilms tumor, as well as gonadectomy in individuals with Frasier syndrome and in patients with Denys-Drash syndrome who have a Y chromosome if the gonads cannot be monitored.[22]

Gata-Binding Protein 4: GATA4. GATA4 is a four–zinc finger transcription factor involved in early testis development and heart development. Haploinsufficiency of *GATA4* or heterozygous loss-of-function changes are well established in a range of cardiac defects such as atrial and ventricular septal defects. More recently, heterozygous *GATA4* mutations have been shown to cause testicular dysgenesis with or without cardiac anomalies.[245] These mutations can be transmitted by a mother in a sex-limited dominant manner. Reported changes may disrupt interactions between GATA4 and its cofactor, friend of GATA 2 (FOG2, also known as ZFPM2).

Friend of GATA2 (FOG2): ZFPM2. FOG2 is a key coregulator of GATA4, and missense mutations in the gene encoding FOG2 *(ZFPM2)* have been described in individuals with 46,XY gonadal dysgenesis.[166,246,247] The point mutations affect interactions with GATA4, and some have been described previously in patients with cardiac defects, highlighting the variable penetrance of gonadal and cardiac phenotypes following disruption of the GATA4/FOG2 complex.



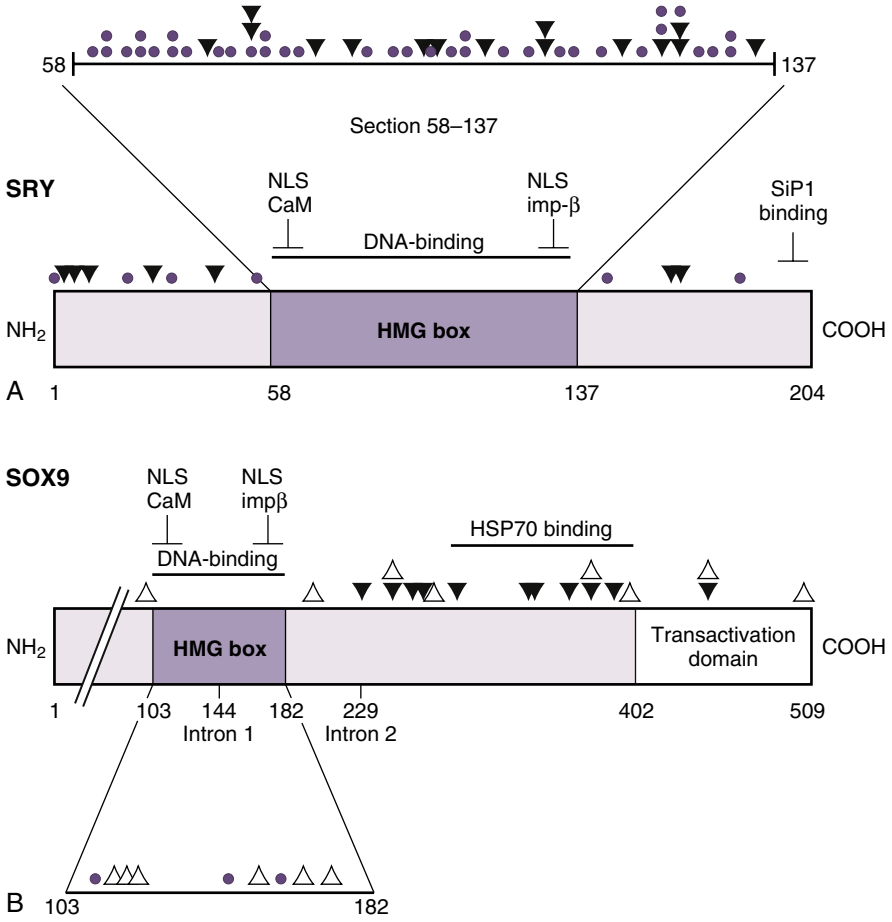
• **Fig. 24.21** Schematic diagram shows the structure of WT1 and the changes associated with exon 5 and exon 9 (addition of lysine, threonine, and serine) in +KTS isoforms. Many point mutations associated with Denys-Drash syndrome are located within zinc fingers 2 and 3 (especially Arg394). Mutations affecting the exon 9 splice site are associated with Frasier syndrome. (Modified from Koziell A, Grundy R. Frasier and Denys-Drash syndromes: different disorders or part of a spectrum? *Arch Dis Child*. 1999;81:365–369, used with permission of the BMJ Publishing Group, Copyright 1999.)

Chromobox Homolog 2: CBX2. Chromobox homolog 2 *(CBX2)* is a human homolog of the polycomb protein M33. Deletion of its gene causes XY sex reversal in mice. Loss-of-function mutations in *CBX2* were described in a 46,XY girl with a uterus and ovaries who was diagnosed by prenatal karyotyping, but at present, *CBX2* variants in humans are rare.[48]

Sex-Determining Region of the Y Chromosome: SRY. The sequence of events leading to the identification of *SRY* as the primary testis-determining gene and the actions of SRY in testis development were described earlier. SRY is a 204–amino acid HMG box transcription factor that is encoded by a single exon on the Y chromosome (Yp11.3) (see Fig. 24.5).[87] The discovery of inactivating mutations in SRY in patients with 46,XY gonadal dysgenesis confirmed the key role played by this factor in testis determination in humans.[31]

Approximately 10% of individuals with the complete form of 46,XY gonadal dysgenesis have inactivating mutations in *SRY*.[87] Most of the mutations occur in the HMG box DNA-binding domain of the SRY protein (Fig. 24.22), a region that is involved in binding and bending of DNA.[87] Rare mutations in the 5′ and 3′ flanking regions occur.[248] The HMG box contains at least two nuclear localization signals that bind calmodulin/exportin 4 and importin B. Mutations in these nuclear localization signal domains in the HMG box of SRY result in failure to transport the SRY protein into the nucleus, and subtle alterations in nuclear import and export can lead to XY gonadal dysgenesis.[90] Most individuals with *SRY* mutations are girls who have no pubertal development (Swyer syndrome). Testicular tumor risk in this group is high.

SRY Box 9: SOX9. Heterozygous mutations of the autosomal *SOX9* gene (17q24-q25) cause campomelic dysplasia.[99,100] Features of this condition include bowed long bones, hypoplastic scapulae, a deformed pelvis, 11 pairs of ribs, a small thoracic cage, cleft palate, macrocephaly, micrognathia, hypertelorism, and a variety of cardiac and renal defects. Death from respiratory distress often occurs in the neonatal period, but long-term survival has been reported.



• **Fig. 24.22** Structure of human SRY and SOX9 proteins and a selection of reported mutations. (A) Diagram of SRY. The high-mobility group (HMG) box is an 80–amino acid, DNA-binding domain with nuclear localization signals *(NLS)* at either end, one of which binds calmodulin (CaM) or exportin-4 and the other importin-β (imp-β). The last seven amino acids of SRY can bind to either of the PDZ domains found in SRY-interacting protein 1 (SiP1). The *solid circles* indicate missense mutations reported in the SRY protein that affect testicular development and cluster within the HMG box. Nonsense and frameshift mutations in SRY are indicated by *solid triangles*. (B) Diagram of SOX9. SOX9 has an HMG box with two NLSs, similar to SRY. However, SOX9 is encoded by three exons, binds to heat shock protein 70 (HSP70), and has a transactivation domain at the carboxy-terminal end, unlike SRY. Selected mutations causing 46,XY DSD and campomelic dysplasia are indicated by the *solid circles* (missense) and *solid triangles* (nonsense and frameshift). Mutations that cause only campomelia or a bony phenotype in 46,XY males or affect 46,XX females are indicated by *open triangles*.

SOX9 is an important testis-determining gene, and it is the key regulator of testis determination downstream of *SRY* (see "Testis Determination"). Consistent with this hypothesis, three-fourths of 46,XY patients with heterozygous *SOX9* mutations have dysgenetic gonads, but a wide range of genital phenotypes can be seen, from typically male to typically female appearance.[87] Histologic examination of the gonads from 46,XY patients with ambiguous or female external genitalia shows a similarly wide range of gonadal phenotypes, including streak gonads, dysgenetic testes, ovotestes, or even ovaries.[223] Müllerian structures may or may not be present, depending on the degree of gonadal dysgenesis. 46,XX females with *SOX9* mutations have normal external genitalia and apparently normal ovaries.

The locus for campomelic dysplasia with 46,XY DSD was mapped to 17q24.3-q25.1 after studies of three patients with balanced de novo reciprocal translocations, and *SOX9* was proposed as a candidate gene based on expression studies in the mouse. Subsequently, missense, nonsense, frameshift, and splice junction mutations have been detected in *SOX9* in patients with campomelic dysplasia with or without gonadal dysgenesis.[87] These mutations are usually heterozygous de novo changes. In one kindred, multiple siblings were affected due to germline mosaicism for a *SOX9* mutation in a parent.[223] The gonadal phenotype in this kindred varied in the two affected 46,XY siblings: One of them had dysgenetic gonads; the other was reported to have normal ovaries.

The *SOX9* gene has three exons and two introns; it encodes a 509-residue protein that contains an HMG box with 71% homology to that of the SRY protein and a C-terminal, *trans*-activation domain (see Fig. 24.22). Unlike SRY, in which most mutations are located within the HMG box, SOX9 mutations are located throughout the protein, with little relation between functional domains and phenotype. Chromosomal translocations that disrupt regulatory elements upstream of the *SOX9* promoter can be associated with a less severe phenotype or campomelic dysplasia without gonadal abnormalities, or 46,XY DSD without a skeletal phenotype. Heterozygous changes that allow residual DNA binding and transactivation may also be associated with the acampomelic variant and variable or absent DSD.

SRY Box 8: SOX8. *SOX8* (16p13.3) is closely related to *SRY* and *SOX9* and is coexpressed with *NR5A1* and *SOX9* in Sertoli and Leydig cells during the early stages of human testis determination.[249] Deletions and point mutations in *SOX8* have recently been described in individuals with testicular dysgenesis, sometimes as part of a chromosome 16p-deletion syndrome. An enrichment of rare variants in *SOX8* has also been found in individuals with a spectrum of reproductive phenotypes, including oligozoospermia and primary ovarian insufficiency.[249]

Mitogen-Activated Protein Kinase Kinase Kinase-1: MAP3K1. MAP3K1 is one of several kinase signaling pathways involved in organogenesis, and heterozygous splice site or point mutations in *MAP3K1* have been described in several families and individuals with impaired testis development.[97] MAP3K1 is expressed in early testis cords and Sertoli cells in mice, and disruption of *MAP3K1* has been described in diverse phenotypes ranging from 46,XY complete testicular dysgenesis to hypospadias and micropenis with cryptorchidism. Familial cases have a clear autosomal dominant inheritance. *MAP3K1* mutations may be one of the more common causes of 46,XY DSD, and routine screening has been recommended in all patients with 46,XY complete or partial gonadal dysgenesis.[225]

Estrogen Receptor β: ESR2/NR3A2. A homozygous *ESR2* mutation has been reported in an individual with 46,XY DSD characterized by absence of gonads, uterus, and vagina, as well as dysmorphic features, eye abnormalities, and anal atresia; heterozygous mutations were identified in two individuals with 46,XY complete and partial gonadal dysgenesis without syndromic features.[250] It was hypothesized that the *ESR2* variants may lead to increased activity of the MAPK pathway through nonclassic signaling, thereby altering gonadal fate.

Doublesex-Related and Mab3-Related Transcription Factor 1: DMRT1. *DMRT1*, a gene with sex-specific homologs in *Drosophila* (*doublesex* gene) and *Caenorhabditis elegans (Mab3)* that is expressed in early gonad development, plays an important role in supporting testis development.[112,251] Deletions of the region of chromosome 9p24-pter containing *DMRT1* are associated with 46,XY gonadal dysgenesis.[252] More recently, a partial deletion of *DMRT1* and a dominant-negative point mutation in *DMRT1* have been seen in patients with 46,XY DSD.[253,254]

Testis-Specific Protein, Y-Linked–Like 1 Gene: TSPYL1. An association between 46,XY gonadal dysgenesis and sudden infant death syndrome was characterized in a large Amish kindred and named *sudden infant death, dysgenetic testes* (SIDDT).[255] The gene responsible for this autosomal recessive condition, *TSPYL1*, encodes a protein of unknown function that may be involved in chromatin remodeling. Additional variants of *TSPYL1* have been described in patients with 46,XY DSD.[256]

Desert Hedgehog: DHH. The hedgehog signaling pathways play an important role in many aspects of neuronal, skeletal, and endocrine development. A homozygous mutation in the desert hedgehog gene *(DHH)* was originally reported in a patient with partial gonadal dysgenesis and minifascicular neuropathy.[116] Subsequently, a number of *DHH* changes have been found in patients with complete 46,XY gonadal dysgenesis or more often Leydig cell defects, with or without apparent neurologic features.[117,166]

Sterile α-Motif Domain-Containing Protein 9: SAMD9. SAMD9 is an endosomal protein that negatively regulates growth and development. Gain-of-function variants in SAMD9 have been reported to cause impaired testicular function and 46,XY DSD as part of a complex multisystem growth restriction disorder, MIRAGE syndrome (myelodysplasia, infections, restriction of growth, adrenal hypoplasia, genital phenotypes, enteropathy).[257,258] Children are often born preterm and have high mortality. Somatic rescue due to monosomy 7 or secondary somatic loss-of-function changes in SAMD9 itself can modify the phenotype, but monosomy can be associated with the development of myelodysplastic syndrome. The testicular phenotype most likely represents a Leydig cell defect.[258]

Aristaless-Related Homeobox, X-Linked Gene: ARX. ARX is a transcription factor that plays a central role in neuronal migration, and the *Arx* knockout mouse has a profound myelination defect. Mutations in *ARX* have been found in X-linked lissencephaly ambiguous genitalia (XLAG) syndrome.[114] This unusual form of lissencephaly is associated with severe epilepsy and thermal instability. The genital abnormality most likely represents a defect in Leydig cell function. Additional *ARX* mutations have been described in patients with neurologic defects (e.g., infantile spasms) without significant DSDs.

Mastermind-Like Domain-Containing 1: MAMLD1. *MAMLD1* (formerly called *CXORF6*) is a gene on the X chromosome that encodes a protein expressed in the developing testes. Hemizygous mutations in *MAMLD1* were originally described in boys with isolated severe hypospadias, but a range of phenotypes has since been described, although it is unclear whether the reported *MAMLD1* mutations suffice to explain the phenotype in

all individuals.[118,259,260] *MAMLD1* disruption results in a defect in fetal Leydig cell development and function.

Chromosomal Rearrangements Associated With Gonadal Dysgenesis

Abnormalities of genital development are associated with a number of chromosomal deletions, duplications, and rearrangements. The most frequently seen changes are deletions of 9p24-pter (affecting *DMRT1*, described earlier), 10q25-qter, and Xq13 and duplications of Xp21.

Terminal deletions of chromosome 10 (10q25-qter) are frequently associated with urogenital abnormalities and sometimes with complete gonadal dysgenesis.[261] The gene in this locus has not been identified; *FGFR2* is a candidate. Deletions of Xq13.3 and of the tip of chromosome 16p cause α-thalassemia mental retardation (ATR) syndromes that may have gonadal dysgenesis as part of the phenotype.[262] The Xq13.3 locus contains the transcription factor gene *ATRX* (also known as *XH2* or *XNP*). The *SOX8* gene is located on 16p, and rearrangements of this locus have been implicated in a variety of conditions with impaired gonadal development and/or function (see previous discussion).[249,263]

Duplications of the Xp21.3 region that contains the *DAX1 (NR0B1)* gene can cause 46,XY partial or complete gonadal dysgenesis.[264] The role of *DAX1* and the *WNT4* pathway (duplication 1p35) in opposing testis development was discussed previously (see "Development of Reproductive Systems").[264,265]

Several other studies using array comparative genomic hybridization or single-nucleotide polymorphism (SNP) analysis have been reported and have proposed other candidate regions for testicular dysgenesis.[266,267]

Syndromic Causes of 46,XY Disorders of Sex Development

In addition to the specific syndromes outlined earlier, various degrees of testicular dysgenesis and impaired genital development (e.g., hypospadias, cryptorchidism, scrotal transposition) are seen in many discrete syndromes.[268,269] In some situations, a genetic basis has been identified, but in many cases the cause is unknown. Syndromic associations of 46,XY DSD may be more prevalent than originally thought and have been reviewed in detail elsewhere.[268,269]

46,XY DSD is often associated with intrauterine growth restriction (IUGR).[270] Monozygotic twins can show disparate genital development, with the growth-restricted twin having ambiguous genitalia and the larger twin appearing as a normal male. The mechanism of this association is unclear and may represent a shared genetic cause or a common epigenetic or somatic developmental event affecting fetal growth, placental function, and reproductive development. More common genetic causes of 46,XY DSD (e.g., mutations of SRY, SF1, androgen receptor, and steroidogenic enzymes) are rarely found in this group of IUGR patients (personal observation).

Genes Involved in Central Hypogonadism

Central causes of hypogonadism resulting in LH and FSH insufficiency do not typically cause hypospadias, as the early stages of fetal testis steroidogenesis are autonomous or driven by hCG. However, boys can have combined central defects together with hypospadias or DSD, and potential disease-causing variants in several genes have been reported, which may affect the HPG axis at multiple levels (e.g., *CHD7*, *ANOS1*/*KAL1*, *WDR11*, *PROK2*, *PROKR2*, *FGF8*, and *FGFR1).*[166,167]

Potential Novel Genes and Oligogenic Effects

Whole-exome array and next-generation sequencing approaches have identified potential pathogenic variants in genes related to testis development (e.g., *WWOX*), but the significance of some of these findings is not yet clear. Furthermore, data emerging from these approaches suggest that oligogenic effects involving changes in more than one gene may also be associated with gonadal dysgenesis or may influence the severity of the phenotype in some situations.[166,236,237]

Disorders of Androgen Synthesis

Defects anywhere along the pathway of androgen synthesis and target organ action can result in impaired androgenization and 46,XY DSD (formerly referred to as male pseudohermaphroditism) (see Table 24.6 and Fig. 24.11). Because many of the steps of androgen synthesis overlap with those of glucocorticoid synthesis, some of the enzymatic deficiencies that cause androgen deficiency also cause congenital adrenal hyperplasia. In all of these conditions, because Sertoli cell secretion of AMH is intact, müllerian structures are absent.

Cholesterol Synthesis Defects: Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome is caused by a deficiency of 7-dehydrocholesterol reductase (3β-hydroxysterol Δ7-reductase [DHCR7]), the phylogenetically conserved sterol-sensing domain–containing enzyme required for the last step in the biosynthetic pathway from acetate to cholesterol. Cholesterol is necessary as a substrate for steroid-hormone synthesis, and intermediates of cholesterol synthesis may also have important interactions with hedgehog signaling pathways.

Smith-Lemli-Opitz syndrome has a broad phenotypic spectrum that typically includes microcephaly, developmental delay, cardiac defects, ptosis, upturned nose, micrognathia, cleft palate, polydactyly, syndactyly of toes (especially the second and third toes), severe hypospadias, micropenis, and growth failure.[271] Abnormalities of the external genitalia occur in approximately 65% of 46,XY patients and vary from micropenis and hypospadias to complete absence of androgenization, resulting in a female phenotype.

The syndrome is diagnosed by finding elevated plasma levels of 7-dehydrocholesterol (7-DHC) and low levels of cholesterol. The *DHCR7* gene maps to 11q12-q13, and more than 150 mutations have been described.[272] Measurement of serum 7-DHC should be considered in all underandrogenized males with relevant phenotypic features, however mild. Testis development is apparently normal, and normal, elevated, or low concentrations of plasma testosterone have been described in affected male infants with intact HPG function. Compromised adrenal function can sometimes occur.

Luteinizing Hormone Receptor Mutations

Mutations in the LH/hCG receptor cause impaired responsiveness to hCG and LH, resulting in Leydig cell agenesis or hypoplasia.[273] Phenotypically, the external genitalia vary from a female appearance to a male with micropenis (Table 24.7). Rudimentary wolffian derivatives may be present, even in some patients with severely underandrogenized external genitalia. This finding may reflect some early hCG-independent mechanisms of testosterone synthesis between 8 and 10 weeks of gestation. Small, undescended testes are usually found in the inguinal region in the most severe forms of this Leydig cell hypoplasia. Patients with milder phenotypes may have appropriately descended testes of relatively normal

TABLE 24.7 Clinical Features of Leydig Cell Hypoplasia in 46,XY Individuals

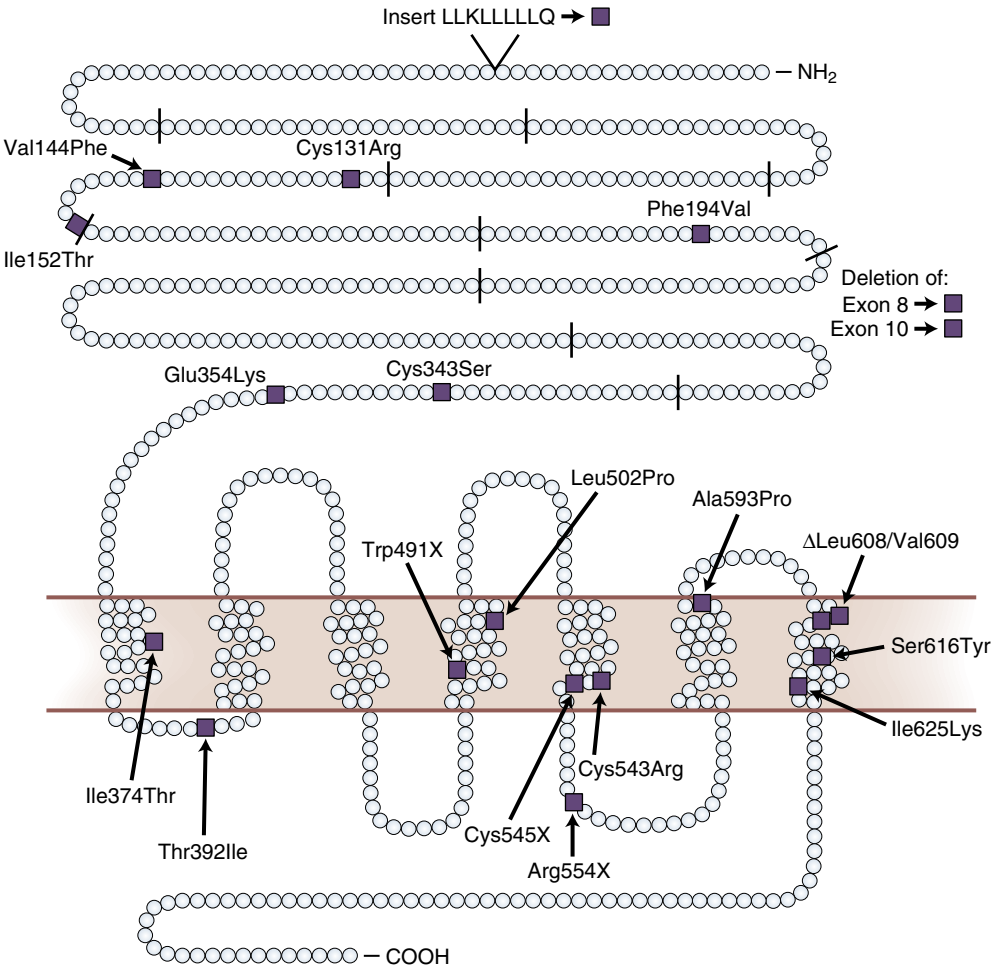
Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in *LHCGR* gene
Genitalia	Female, hypospadias, or micropenis
Wolffian duct derivatives	Hypoplastic
Müllerian duct derivatives	Absent
Gonads	Testes
Biochemical and physiologic features	Underandrogenization with variable insufficiency of sex hormone production at puberty
Hormone profile	Low T and DHT; elevated LH (and FSH); exaggerated LH response to LHRH stimulation; poor T and DHT response to hCG stimulation

DHT, Dihydrotestosterone; *FSH,* follicle-stimulating hormone; *hCG,* human chorionic gonadotropin; *LH,* luteinizing hormone; *LHCGR,* LH or hCG receptor; *LHRH,* luteinizing hormone–releasing hormone; *T,* testosterone.

size because the Leydig cell population contributes to only about 10% of testicular volume. On histologic examination, the testes lack distinct Leydig cells in prepubertal patients, though Leydig cells may be difficult to visualize even in normal prepubertal testes. Postpubertal patients have absent or decreased numbers of Leydig cells without Reinke crystalloids, normal-appearing Sertoli cells, and discrete seminiferous tubules with spermatogenic arrest. This observation highlights the important role of intratesticular testosterone in the final stages of sperm maturation.

The typical biochemical profile of patients with Leydig cell hypoplasia includes elevated basal and GnRH-stimulated LH (and FSH) levels in early infancy or at puberty due to loss of sex steroid negative feedback. In childhood, when the GnRH pulse generator is relatively quiescent, basal LH levels may still sometimes be detected above the normal range. Plasma levels of androstenedione and testosterone are low, with little or no response to prolonged hCG stimulation. Plasma LH falls after testosterone administration. Less marked biochemical changes can occur with milder forms of this condition.

More than 30 different homozygous or compound heterozygous mutations have been reported in the LH/hCG receptor gene *(LHCGR)* in individuals with various forms of this condition (Fig. 24.23).[274,275] The original reports of Kremer and colleagues[274] and Latronico and associates[275] described homozygous



• **Fig. 24.23** Diagram of the luteinizing hormone/human chorionic gonadotropin (LH/hCG) receptor with selected inactivating missense mutations shown by *squares*. Most of these changes are associated with marked underandrogenization. However, the changes at residues 616 and 625 in the seventh transmembrane domain are associated with a milder phenotype of micropenis.

Ala593Pro and Arg554Ter mutations, respectively, in 46,XY phenotypic females with Leydig cell hypoplasia, hypergonadotropic hypogonadism, and no testosterone response to hCG stimulation. An affected 46,XX sister showed normal sexual maturation at puberty but an elevated LH level and amenorrhea, demonstrating that the LH receptor is not necessary for estrogen synthesis but is necessary for normal ovulation in females. These mutations impair hCG stimulation of intracellular cyclic adenosine monophosphate (cAMP) in vitro through disturbances in hCG binding, intracellular signaling, and/or receptor stability and trafficking, depending on the nature of the change. Defects in a cryptic exon of the LH receptor (exon 6A) have also been described as a cause of 46,XY DSD.[276] Partial loss-of-function mutations in the LH/hCG receptor causing milder phenotypes such as micropenis have tended to localize within the seventh transmembrane domain (Ser616Tyr, Ile625Lys) (see Fig. 24.23).[275,277] Individuals with complete Leydig cell hypoplasia are usually reared as females and require estrogens at puberty. Gonadectomy is usually performed, though the risk of gonadal malignancy is unknown. If a male sex designation is chosen, testosterone supplements may be given in early infancy and to support puberty.

Steroidogenic Acute Regulatory Protein Defects

Steroidogenic acute regulatory protein is a 30-kDa mitochondrial protein that is present in the adrenal gland and gonads. It plays a key role in facilitating the rapid movement of cholesterol from the outer to the inner mitochondrial membrane.[131,278] This process is necessary to allow de novo steroid biosynthesis in response to ACTH or angiotensin II in the adrenal gland or an LH pulse in the gonad. Although a limited amount of cholesterol transfer is StAR independent (14%), this protein plays a central role in the acute regulation of adrenal and gonadal steroidogenesis. StAR is not necessary for placental progesterone production, unlike P450scc (CYP11A1, discussed next).

Consistent with these actions, patients with recessively inherited defects in StAR develop a severe form of primary adrenal failure called *lipoid congenital adrenal hyperplasia* (lipoid CAH).[279,280] Patients with this condition tend to present with severe glucocorticoid deficiency (e.g., hypoglycemia, hyperpigmentation) early in life and progressive mineralocorticoid insufficiency resulting in hyponatremia, hyperkalemia, dehydration, acidosis, and collapse (Table 24.8). Presentation is often between 3 weeks and 3 months of age. Little or no C18, C19, and C21 steroids (which include estrogens, androgens, and progesterone/glucocorticoids/mineralocorticoids, respectively) are detectable in plasma or urine, even after corticotropin or hCG stimulation. Females (46,XX) with lipoid CAH have typical female genitalia. In 46,XY individuals, mutations in *STAR* typically cause a marked deficiency in testosterone synthesis by fetal Leydig cells so that typical female genitalia are seen. Testes may be abdominal, inguinal, or labial. Müllerian structures have regressed, and there is a blind vaginal pouch. A karyotype should be performed in all apparent girls presenting with early-onset adrenal failure.

The typical histologic finding in lipoid CAH is lipid accumulation within steroidogenic cells. In the steroid-deficient state, the tropic drive by ACTH, angiotensin II, and LH causes increased cholesterol uptake and synthesis by steroidogenic cells. Coupled with the inability of StAR to facilitate cholesterol movement into mitochondria, this leads to marked accumulation of cholesterol in cells and results in the appearance of enlarged, lipid-laden adrenal glands sometimes seen on MRI or computed tomography (CT). Eventually, cholesterol accumulation causes engorgement and results in structural disruption superimposed on the functional disruption—the "two-hit" hypothesis (Fig. 24.24).[280]

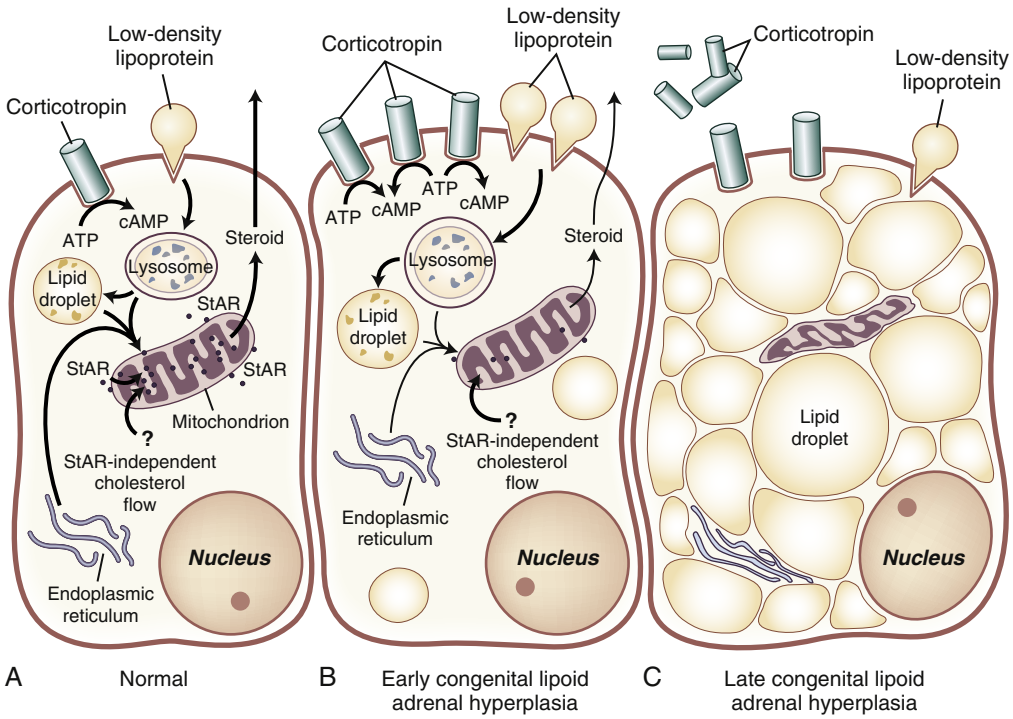
TABLE 24.8 Clinical Features of Lipoid CAH in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in *STAR* gene
Genitalia	Female; sometimes ambiguous, hypospadias, or male
Wolffian duct derivatives	Hypoplastic or normal
Müllerian duct derivatives	Absent
Gonads	Testes
Biochemical and physiologic features	Severe adrenal insufficiency in infancy with salt loss; lack of pubertal development; rare nonclassic cases associated with isolated glucocorticoid deficiency
Hormone profile	Usually deficiency of glucocorticoids, mineralocorticoids, and sex steroids except in nonclassic cases in which a predominant defect in glucocorticoid production is seen (similar to familial glucocorticoid deficiency)

CAH, Congenital adrenal hyperplasia; *StAR*, steroidogenic acute regulatory (protein).

The two-hit hypothesis explains why 46,XX girls with lipoid CAH show evidence of estrogenization and breast development at puberty but have progressive hypergonadotropic hypogonadism.[280,281] Follicular cells are relatively quiescent in utero and before puberty and are therefore undamaged. They are recruited at the beginning of each cycle, and a small amount of estradiol can be produced as a result of StAR-independent mechanisms. This can occur until the follicular cells are engorged and rendered nonfunctional. Puberty can occur, but any cycles are anovulatory. Without treatment, polycystic ovaries and progressive ovarian insufficiency failure usually ensue.

Although more than 40 different StAR mutations have been described in patients from around the world, lipoid CAH is especially prevalent in Japan and Korea, where it is the second-most common steroidogenic disorder after CYP21 deficiency (Fig. 24.25). Most Japanese patients and virtually all Korean patients harbor the Gln258Stop mutation, which is estimated to be carried by 1 in 300 Japanese people.[282] Other geographic clusters include the Leu260Pro mutation in patients of Swiss ancestry, Arg182His in Eastern Saudi Arabia, and Arg182Leu in Palestinians. Most of these mutations result in complete loss of function. However, a nonclassic form of lipoid CAH has been described that is caused by point mutations in StAR; in this form, StAR retains approximately 20% function.[283] These patients present with progressive glucocorticoid deficiency between 2 and 4 years of age; affected males have normal androgenization of the external genitalia but may be at risk of hypoandrogenism or reduced fertility later in life. StAR mutations with intermediate function may also be associated with hypospadias and milder adrenal failure.[284] These partial loss-of-function changes tend to affect amino acids (codons 187, 188, 192, 221) that lie around the cholesterol-binding pocket.[285]



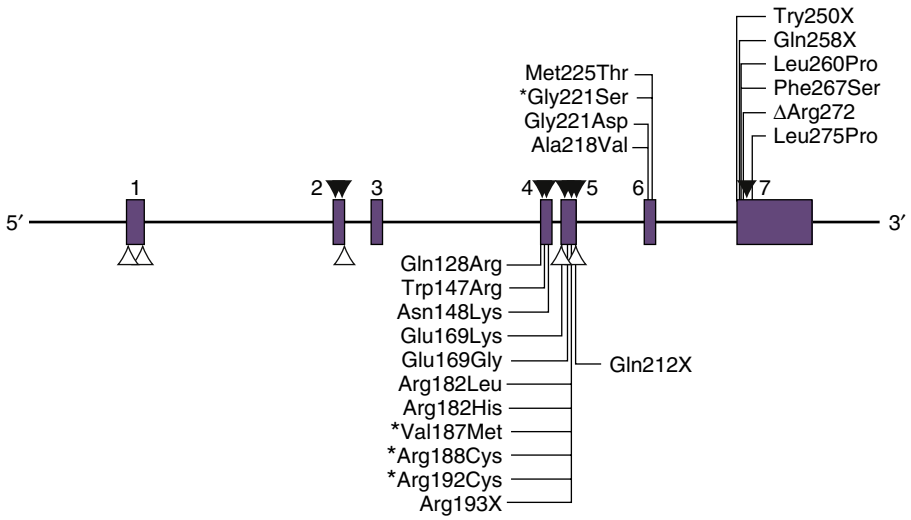
• **Fig. 24.24** Model of the steroid-synthesizing cell (adrenal/gonadal) showing conversion of cholesterol to steroids. (A) Cholesterol from low-density lipoprotein, from cholesterol esters stored in lipid droplets, and from endogenous synthesis in the endoplasmic reticulum is transported from the outer mitochondrial membrane to the inner membrane. This transport is facilitated by the steroidogenic acute regulatory protein (StAR) and by other StAR-independent mechanisms. In the mitochondria, steroid synthesis begins with the conversion of cholesterol to Δ^5 pregnenolone by the enzyme CYP11A1 (P450scc). (B) In patients with lipoid congenital adrenal hyperplasia, a mutation in the gene encoding StAR results in little or no activity of the mutant StAR, greatly reducing cholesterol transport into the mitochondria. Low levels of steroidogenesis by mechanisms independent of StAR can occur; however, increased secretion of corticotropin (or luteinizing hormone or follicle-stimulating hormone) results in cholesterol accumulation in the cells as lipid droplets. (C) Continued stimulation and resultant accumulation of cholesterol cause engorgement of these cells, with mechanical and chemical perturbation of cell function. This results in primary adrenal insufficiency and impaired androgen biosynthesis by fetal Leydig cells. Females with lipoid congenital adrenal hyperplasia feminize at puberty and menstruate but have progressive hypergonadotropic hypogonadism. This may occur because the follicular cells are relatively quiescent in utero and before puberty and therefore are undamaged. At the beginning of each cycle, follicles are recruited, and a small amount of estradiol can be produced as a result of StAR-independent mechanisms. This can occur until the follicular cells are engorged and rendered nonfunctional. *ATP,* Adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate. (From Bose HS, Sujiwara T, Strauss JF III, et al. The pathophysiology and genetics of congenital lipoid adrenal hyperplasia. *N Engl J Med*. 1996;335:1870–1878, used with permission of the Massachusetts Medical Society, Copyright 1996.)

Management of classic lipoid CAH includes glucocorticoid and mineralocorticoid replacement and salt supplementation in early life. Gonadectomy is usually performed in individuals with a 46,XY karyotype; although limited data are available, neoplastic germ cell changes have been reported.[286,287] Males with nonclassic lipoid CAH need careful follow-up to ensure adequate testosterone production in puberty and adulthood. Estrogen treatment is given to induce puberty and is administered to 46,XX females when gonadal insufficiency occurs.

P450 Side-Chain Cleavage Enzyme Deficiency

P450scc (CYP11A1) is the mitochondrial enzyme that converts cholesterol to pregnenolone by three distinct enzymatic reactions: 20α-hydroxylation, 22-hydroxylation, and cleavage of the cholesterol side chain. P450scc is therefore responsible for the first and rate-limiting step in steroid synthesis, which is necessary for pregnenolone and progesterone production by the placenta, for mineralocorticoid, glucocorticoid, and androgen production by the adrenal glands, and for sex steroid production by the gonads.

Although a natural model of lipoid CAH due to P450scc deficiency exists in the rabbit, it was thought that severe loss of P450scc activity in humans would be incompatible with survival. Placental progesterone production is necessary to support pregnancy after the second trimester in higher primates (due to the so-called luteoplacental shift) but not in rodents. However, complete disruption of P450 activity due to a homozygous frameshift mutation in *CYP11A1* has been reported in a 46,XY infant with female external genitalia and severe early-onset, salt-losing adrenal failure.[288] An increasing number of other mutations in P450scc have also been described, initially in 46,XY phenotypic females with severe salt-losing adrenal failure (Table 24.9).[289,290] More recently,



• **Fig. 24.25** Diagram of selected mutations identified in the *STAR* gene associated with lipoid congenital adrenal hyperplasia. Numbered *solid boxes* depict the exons. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; *X* indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift mutations *(solid triangles)* and splice site mutations *(open triangles)* are shown. Although *STAR* mutations are common in Japan, Korea, and regions of the Middle East, an increasing number of sporadic changes in the steroidogenic acute regulatory (StAR) protein are being detected in other countries. Missense mutations at residues 187, 188, 192, and 221 *(asterisks)* have been associated with a nonclassic late-onset phenotype of glucocorticoid insufficiency.

TABLE 24.9 Clinical Features of CYP11A1 Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in *CYP11A1* gene
Genitalia	Female; rarely ambiguous or hypospadias
Wolffian duct derivatives	Hypoplastic or normal
Müllerian duct derivatives	Absent
Gonads	Testes (or absent)
Biochemical and physiologic features	Severe adrenal insufficiency in infancy with salt loss ranging to milder adrenal insufficiency with onset in childhood; prematurity associated in one case
Hormone profile	Usually deficiency of glucocorticoids, mineralocorticoids, and sex steroids

CYP11A1, Cytochrome P450 side-chain cleavage enzyme.

partial loss-of-function defects in P450scc have been described in boys with hypospadias who developed adrenal failure in late childhood, and milder changes in *CYP11A1* have been reported in children with primary adrenal insufficiency without DSD.[291–293] This condition is now well established as a cause of combined adrenal and gonadal failure as well as isolated adrenal insufficiency. Long-term follow-up of patients with hypospadias or isolated adrenal insufficiency may be needed to monitor testicular function and fertility. Molecular analysis is needed to differentiate this P450scc deficiency from StAR deficiency, though it seems that patients with P450scc deficiency rarely have significant lipoid enlargement of the adrenal glands.[290]

3β-Hydroxysteroid Dehydrogenase/$\Delta^{4,5}$-Isomerase Type 2 Deficiency

3βHSD type 2 deficiency is a rare, autosomal recessive cause of CAH that affects both adrenal and gonadal steroid production. It is one of the few conditions that can cause atypical genitalia in both 46,XX and 46,XY individuals. This autosomal recessive disorder is a consequence of mutations in *HSD3B2*, the gene encoding the 3βHSD/$\Delta^{4,5}$-isomerase type 2 isozyme, which is expressed mainly in the adrenals and gonads. This enzyme catalyzes a crucial step in the biosynthesis of all steroid hormones, the conversion of Δ^5 steroids to Δ^4 steroids (see Fig. 24.11).[294] The other 3βHSD isoenzyme in humans, 3βHSD1, is expressed in the placenta and in peripheral tissues such as the skin (mainly sebaceous glands), breast, and prostate; it is not associated with CAH.

Classic 3βHSD2 deficiency is subdivided into salt-losing and non–salt-losing forms (Table 24.10). Severely disruptive changes in 3βHSD2 cause salt-losing adrenal insufficiency soon after birth. In 46,XY patients, the external genitalia are usually atypical, with small penis, severe hypospadias, partial labioscrotal fusion, and urogenital sinus. Mutations that severely disrupt enzymatic activity usually present with salt loss (Fig. 24.26).[295–297] In contrast, mutations such as Ala245Pro retain considerable enzyme activity (2–10%) and have been found in males with penoscrotal hypospadias and no salt loss. A late-onset form of 3βHSD2 deficiency usually manifests as premature pubarche and idiopathic hirsutism in females. The biochemical profile of classic 3βHSD2 deficiency is an elevated 17-hydroxypregnenolone, which is present at levels greater than 100 nmol/L at baseline or after ACTH stimulation.[298] An elevated ratio of Δ^5 to Δ^4 steroids is sometimes but not always seen; adrenal production of Δ^4 steroids such as

17-OHP and androstenedione is decreased, but serum concentrations may be elevated in 3βHSD2 deficiency. This apparent paradox arises because of peripheral conversion of Δ^5 to Δ^4 steroids by 3βHSD1 activity. In a neonatal screening program, an elevated 17-OHP level in a salt-losing person with 3βHSD2 deficiency may be potentially misdiagnosed as 21-hydroxylase CYP21A2 deficiency.[299,300] As the ratio of Δ^5 to Δ^4 steroids is not always elevated in 3βHSD2 deficiency, the ratio of 17-hydroxypregnenolone to cortisol has been proposed as a more sensitive screen for this condition.[301] However, a 17-hydroxypregnenolone assay is not always readily available, and early genetic testing may be an alternative.

TABLE 24.10 Clinical Features of HSD3B2 Deficiency in 46,XY Individuals

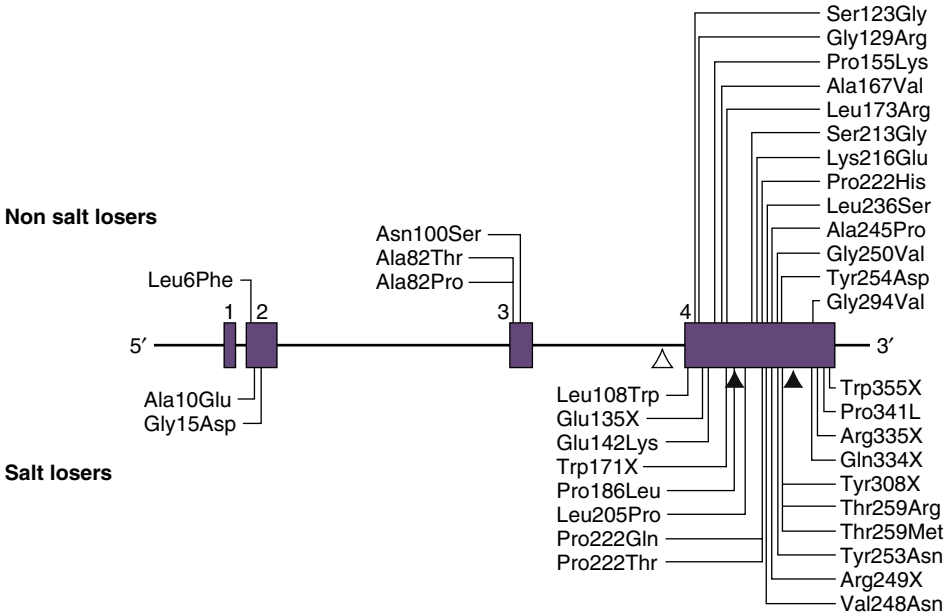
Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in *HSD3B2* gene
Genitalia	Ambiguous; hypospadias
Wolffian duct derivatives	Normal
Müllerian duct derivatives	Absent
Gonads	Testes
Biochemical and physiologic features	Severe adrenal insufficiency in infancy; poor virilization at puberty with gynecomastia *Mild form:* no mineralocorticoid deficiency, premature adrenarche → mild virilization
Hormone profile	Increased concentrations of Δ^5C21 and C19 steroids (e.g., 17-hydroxypregnenolone/cortisol ratio response to corticotropin, 17-hydroxypregnenolone, DHEA suppressible by dexamethasone)

DHEA, Dehydroepiandrosterone; *HSD3B2,* 3β-hydroxysteroid dehydrogenase type 2.

Children with 3βHSD deficiency need glucocorticoid and sometimes mineralocorticoid replacement. A recent study of the Amish population, in which the c.35G>A founder effect is seen, has suggested that some children need only physiologic doses of glucocorticoids to suppress ACTH and, in turn, adrenal androgen production, whereas others need higher, supraphysiologic doses.[300] Undertreatment can be associated with advanced skeletal maturation and early puberty due to sex steroid excess in childhood, whereas overtreatment can cause iatrogenic complications.[300] Gynecomastia can occur at puberty in affected males. This is presumably the result of 3βHSD1-mediated peripheral conversion of Δ^5C19 steroids to Δ^4C19 steroids and aromatization to estrogens.[302] Normal puberty has been reported in males with a null mutation in the *HSD3B2* gene, but puberty needs close monitoring to ensure adequate androgens are produced, and data on fertility are still limited.[302]

17α-Hydroxylase/17,20-Lyase Deficiency

P450c17 (CYP17) is a microsomal enzyme with 17α-hydroxylase and 17,20-lyase activity that is expressed in the adrenals and gonads but not in the placenta or in ovarian granulosa cells.[303,304] The 17α-hydroxylase action of P450c17 catalyzes the conversion of pregnenolone (Δ^5) to 17-hydroxypregnenolone and the conversion of progesterone (Δ^4) to 17-OHP (see Fig. 24.11). The 17,20-lyase action of P450c17 can convert 17-hydroxypregnenolone



• **Fig. 24.26** Diagram of the 3β-hydroxysteroid dehydrogenase type 2 gene *(HSD3B2)* shows the mutations that result in deficiency of the enzyme. Changes associated with salt loss are shown below and non–salt loss above. The numbered *solid boxes* depict the exons. Mutations are subdivided according to their association with salt-losing and non–salt-losing states. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; *X* indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift mutations *(solid triangles)* and splice site mutations *(open triangles)* are shown.

(Δ^5) to DHEA and 17-OHP (Δ^4) to androstenedione (see Fig. 24.11). P450c17 is bound to the smooth endoplasmic reticulum, where it accepts electrons from a specific flavoprotein, reduced nicotinamide adenine dinucleotide phosphate (NADPH)–P450 oxidoreductase (POR). The 17,20-lyase activity of P450c17 is favored by the presence of Δ^5 substrates, redox partners such as POR and cytochrome b_5, and serine phosphorylation. Unlike in rodents, the 17,20-lyase activity of human P450c17 on Δ^5 substrates is 50 times more efficient than its activity on Δ^4 substrates; therefore very little androstenedione is formed directly from 17-OHP, and the principal pathway to androgen production is through DHEA.[132] P450c17 also has 16α-hydroxylase activity.

Defects in P450c17 action can result in two different forms of CAH. Most often, combined 17α-hydroxylase/17,20-lyase deficiency is seen, but rare cases of isolated 17,20-lyase deficiency have been reported (Tables 24.11 and 24.12).[305]

Combined 17α-hydroxylase/17,20-lyase deficiency is a rare, autosomal recessive form of CAH, although an increasing number of cases are being reported from many different countries.[306] A prevalence of approximately 1 case per 50,000 individuals is reported in some areas, but in general, the prevalence is lower than this. The classic phenotype of complete combined 17α-hydroxylase/17,20-lyase deficiency is that of a phenotypic female (46,XX, or underandrogenized 46,XY) who presents with an absence of secondary sex characteristics and hypergonadotropic hypogonadism at puberty and is found to have low-renin hypertension and hypokalemic alkalosis (see Table 24.11).

The classic phenotype and underlying biochemistry can be explained by the enzyme deficiency (see Fig. 24.11).[305] A defect in 17α-hydroxylation in the adrenal cortex and gonads results in impaired synthesis of 17-OHP and 17-hydroxypregnenolone and therefore of cortisol, androgens, and estrogens. Decreased cortisol synthesis causes increased ACTH secretion, which results in excessive secretion of 17-deoxysteroids by the adrenal cortex, including the mineralocorticoids 11-deoxycorticosterone (DOC), corticosterone, and 18-hydroxycorticosterone. Excess DOC secretion eventually leads to hypertension, hypokalemic alkalosis, and suppression of the renin-angiotensin system. Diminished aldosterone synthesis and secretion are sometimes reported. Corticosterone is a weak glucocorticoid; the high plasma concentrations in this disorder prevent the signs and symptoms of cortisol deficiency (e.g., hypoglycemia) and moderate the secretion of ACTH.

Affected 46,XX females have normal typical female internal and external genital tracts, but the ovaries cannot secrete estrogens at puberty, resulting in absent breast development and hypogonadism with elevated plasma FSH and LH levels. The lack of adrenal and ovarian androgens can result in little or no growth of pubic and axillary hair. In affected 46,XX individuals, the ovaries have a high proportion of atretic follicles, and some ovaries contain enlarged follicular cysts.

Affected 46,XY individuals with complete combined 17α-hydroxylase/17,20-lyase deficiency who are diagnosed in adolescence usually have female external genitalia and a blind vaginal pouch (see Table 24.11). Testes may be intraabdominal, in the inguinal canal, or in the labioscrotal folds. Inguinal hernias are common, müllerian structures are absent, and wolffian derivatives are hypoplastic. Bone age is frequently delayed because of decreased sex steroid production, and prolonged linear growth can lead to tall stature. Pubic and axillary hair is absent or sparse, and hypergonadotropic hypogonadism results in a failure to develop secondary sex characteristics at puberty. Excessive secretion of DOC and corticosterone usually leads to low-renin hypertension and hypokalemic alkalosis, as in 46,XX girls with this condition.

Complete 17α-hydroxylase/17,20-lyase deficiency is associated with a variety of pathogenic variants in the *CYP17* gene that cause complete loss of function in assays of enzyme activity. These changes include a range of missense, frameshift, and nonsense mutations (Fig. 24.27). A common mutation is the 4-bp

TABLE 24.11 Clinical Features of Combined CYP17 Deficiency in 46,XY Individuals

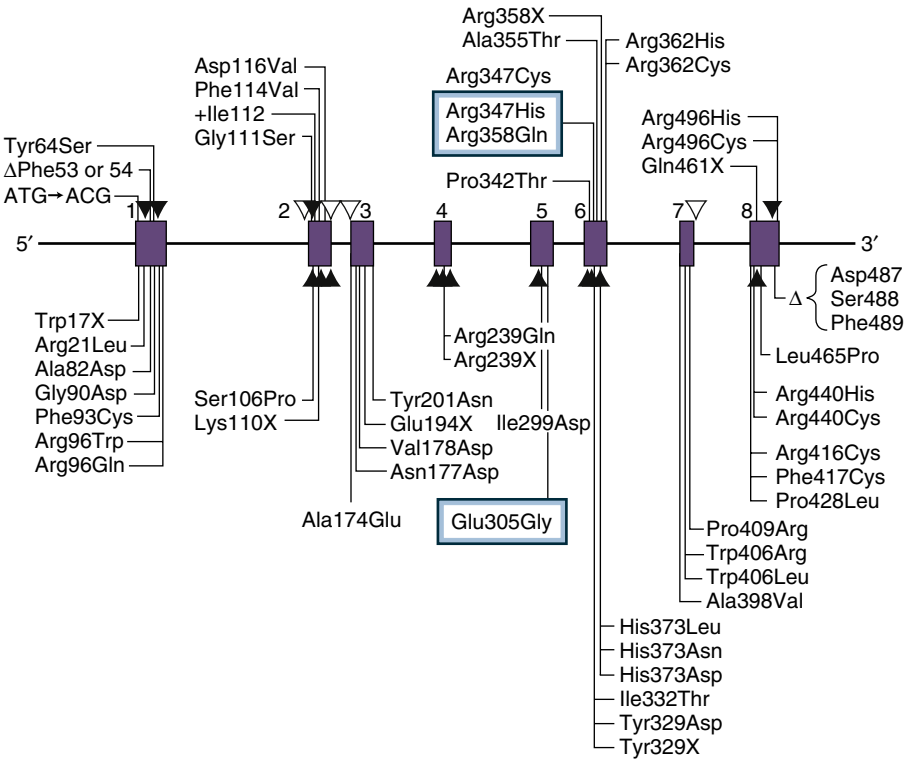
Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in *CYP17* gene
Genitalia	Female, ambiguous, or hypospadias
Wolffian duct derivatives	Absent or hypoplastic
Müllerian duct derivatives	Absent
Gonads	Testes
Physiologic features	Absent or poor virilization at puberty, gynecomastia, hypertension
Hormone profile	Decreased T; increased LH and FSH; increased plasma deoxycorticosterone, corticosterone, and progesterone; decreased plasma renin activity Low renin hypertension with hypokalemic alkalosis

CYP17, 17α-Hydroxylase/17,20-lyase; *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *T,* testosterone.

TABLE 24.12 Clinical Features of Isolated 17,20-Lyase Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in *CYP17* gene, usually affecting key redox domains
Genitalia	Female, ambiguous, or hypospadias
Wolffian duct derivatives	Absent or hypoplastic
Müllerian duct derivatives	Absent
Gonads	Testes
Physiologic features	Absent or poor virilization at puberty; gynecomastia
Hormone profile	Decreased plasma T, DHEA, androstenedione, and estradiol; abnormal increase in plasma 17-hydroxyprogesterone and 17-hydroxypregnenolone; increased LH and FSH; increased ratio of C21 deoxysteroids to C19 steroids (DHEA, androstenedione) after hCG stimulation

CYP17, 17α-Hydroxylase/17,20-lyase; *DHEA,* dehydroepiandrosterone; *FSH,* follicle-stimulating hormone; *hCG,* human chorionic gonadotropin; *LH,* luteinizing hormone; *T,* testosterone.



• **Fig. 24.27** Diagram of selected mutations in the *CYP17* gene causing 17α-hydroxylase/17,20-lyase deficiency. The numbered *solid boxes* depict the exons. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; *X* indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift and splice site mutations are shown by *solid triangles* and *open triangles*, respectively. All of these mutations cause 17α-hydroxylase deficiency. Several missense mutations, such as those at codons 305, 347, and 358 *(boxes)*, have been associated with isolated 17,20-lyase deficiency.

duplication in exon 8, which is shared by Mennonites and individuals in the Friesland region of the Netherlands and is attributed to a founder effect originating in Friesland. Other geographic clusters include an in-frame deletion of residues 487 to 489 in Southeast Asia and the Arg362Cys and Trp406Arg missense mutations found among Brazilians of Portuguese and Spanish ancestry, respectively.[306] However, many different changes occur in other populations and are located throughout the enzyme.[307]

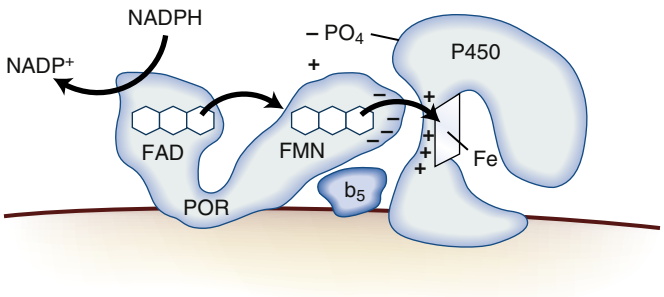
Partial forms of combined 17α-hydroxylase/17,20-lyase deficiency have been described. This condition most frequently manifests in a 46,XY infant with ambiguous genitalia or severe hypospadias for whom the steroid profile is consistent with the diagnosis of P450c17 deficiency. Hypertension may or may not be present in partial forms of combined 17α-hydroxylase/17,20-lyase deficiency, and aldosterone secretion may be normal or even elevated. Corticosterone levels, which are usually 50-fold to 100-fold higher than normal, provide adequate glucocorticoid effects and prevent symptoms of cortisol deficiency. The development of male secondary sex characteristics at puberty may be incomplete, and gynecomastia is often seen. This rare condition has been associated with a phenylalanine deletion at codon 53 or 54 and several missense changes.[305,308]

Isolated 17,20-lyase deficiency has been reported in a small number of patients.[305,309,310] These 46,XY individuals usually have genital ambiguity, normal secretion of glucocorticoids and mineralocorticoids, and marked reduction in sex steroid synthesis (see Table 24.12). The first two patients shown to have a molecular defect in P450c17 harbored homozygous point mutations (Arg347His, Arg358Gln) that specifically interfered with 17,20-lyase activity by changing the distribution of surface charges in the redox-partner binding site.[311] Other patients have been reported with similar mutations or with a point mutation (Glu305Gly) that alters the conformation of the substrate-binding site.[312]

The diagnosis of 17α-hydroxylase deficiency is strongly supported by the discovery of low-renin hypertension and hypokalemic alkalosis and by a lack of secondary sex characteristics at puberty. Plasma concentrations of corticotropin, DOC, corticosterone, and progesterone are high, and those of 17α-OHP, cortisol, and gonadal steroids are low. Replacement therapy with physiologic doses of glucocorticoids suppresses DOC and corticosterone secretion and normalizes serum potassium levels, blood pressure, and plasma renin and aldosterone levels. The hypokalemia can be associated with life-threatening cardiac arrhythmia, so careful monitoring and treatment in the acute phase are needed. Gonadectomy is usually performed in 46,XY patients who have a female gender identity and can consent. A gonadoblastoma and an invasive mixed germ cell tumor have been reported in the gonads of two 46,XX females with this condition.[306,313] Appropriate gonadal steroid replacement therapy is indicated at puberty.

Cytochrome b_5 Deficiency

A splice site mutation in the 17,20-lyase redox partner cytochrome b_5 was first reported in a 46,XY child with ambiguous genitalia and methemoglobinemia, although extensive hormone data were not reported.[314] Homozygous nonsense and missense mutations in this gene *(CYB5A)* have now been described in 46,XY children with severe hypospadias and a biochemical profile consistent



• **Fig. 24.28** Role of P450 oxidoreductase (POR) in electron transfer to microsomal (type II) P450 enzymes. Reduced nicotinamide adenine dinucleotide phosphate (NADPH) interacts with POR, which is bound to the endoplasmic reticulum, and transfers a pair of electrons to the FAD moiety. This change in charge results in altered conformation, which allows the electrons to pass from the FAD to the FMN moiety. After further realignment, the FMN domain can interact with the redox partner binding site of the P450 enzyme (e.g., P450c17, P450c21, P450c19), permitting electron transfer to the active heme group of the enzyme, which results in substrate catalysis. The interaction of POR and the P450 enzymes is coordinated by negatively charged acidic residues on the surface of the FMN domain of POR and positively charged basic residues in the redox partner binding site of the P450 enzyme. In the case of human P450c17, this interaction is facilitated by the allosteric action of cytochrome b_5 and by serine phosphorylation of P450c17. *FAD,* flavin adenine dinucleotide; *FMN,* flavin mononucleotide. (From Miller WL. Minireview: regulation of steroidogenesis by electron transfer. *Endocrinology*. 2005;146:2544–2550, used with permission of The Endocrine Society, Copyright 2005.)

TABLE 24.13 Clinical Features of P450 Oxidoreductase Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in *POR* gene
Genitalia	Ambiguous; hypospadias or male
Wolffian duct derivatives	Absent or hypoplastic
Müllerian duct derivatives	Absent
Gonads	Testes
Biochemical and physiologic features	Variable androgenization at birth; variable virilization at puberty, especially in girls; glucocorticoid deficiency; no severe mineralocorticoid deficiency; features of Antley-Bixler syndrome (craniosynostosis, skeletal dysplasia) in some cases
Hormone profile	Evidence of combined CYP17 and CYP21 insufficiency; normal or low cortisol with poor response to ACTH stimulation; elevated 17-OHP; T low

ACTH, Adrenocorticotropic hormone; *CYP,* cytochrome P450 enzyme; *17-OHP,* 17-hydroxyprogesterone; *POR,* P450 oxidoreductase; *T,* testosterone.

with isolated 17,20-lyase deficiency and in a family with multiple affected members and a range of genital phenotypes.[315,316] Methemoglobin was elevated above the normal range in all these cases, but it did not result in clinical signs.

P450 Oxidoreductase Deficiency

POR is a membrane-bound flavoprotein that plays a central role in electron transfer from NADPH to P450 enzymes (Fig. 24.28).[317] POR is crucial in the 17,20-lyase reaction of P450c17, and it interacts with all 57 microsomal P450 enzymes, including P450c21 (21-hydroxylase) and P450c19 (aromatase), and with many others involved in hepatic drug metabolism.

A potential role for POR in human steroidogenesis emerged after the description of several patients with apparent combined deficiencies of CYP17 and CYP21,[318] who presented not only with ambiguous genitalia and unusual patterns of combined steroidogenic defects but also with Antley-Bixler syndrome, a form of skeletal dysplasia that is characterized by craniosynostosis, brachycephaly, midface hypoplasia, proptosis, choanal stenosis, radioulnar or radiohumeral synostosis, femoral bowing, and arachnodactyly.

The first recessively inherited human mutations in *POR* were described in 2004, and a wide range of phenotypes has been described in patients (Table 24.13).[133,319,320] At the most severe end of the spectrum is ambiguous genitalia due to apparent combined CYP17 and CYP21 deficiency, with or without Antley-Bixler syndrome. Milder defects in POR have also been seen in women with a phenotype resembling polycystic ovary syndrome and in men with mild gonadal insufficiency, sometimes with subtle skeletal features. Two common mutations are emerging: Arg287Pro is the most prevalent mutation in patients of European ancestry, whereas the Arg457His mutation is common in Japan.[320,321] Activating mutations in fibroblast growth factor receptor 2 (FGFR2) have also been reported in association with Antley-Bixler syndrome; these patients do not have ambiguous genitalia or steroidogenic defects.

Most patients with POR deficiency have normal electrolytes and mineralocorticoid function (see Table 24.13). Cortisol insufficiency may be present, or if basal levels are adequate, the response to ACTH stimulation is reduced.[321] The serum 17-OHP concentration is usually elevated, with a variable response to ACTH stimulation, and levels of sex steroids tend to be low. POR deficiency can be associated with ambiguous genitalia in both 46,XY and 46,XX individuals. Underandrogenization of 46,XY males can occur due to disturbed 17,20-lyase activity during fetal Leydig cell steroidogenesis. The partial androgenization of 46,XX infants is more prevalent and may be the result of a disturbance in aromatase activity, because POR is an electron donor for this enzyme and aromatase deficiency causes prenatal androgenization of the developing 46,XX fetus (see "Aromatase Deficiency"). Alternatively or additionally, a "backdoor" pathway of androgen biosynthesis has been described in certain species, such as the tammar wallaby.[133,134] In this model system, 17-OHP can be converted to DHT without the use of androstenedione or testosterone as an intermediate. Emerging data indicate that this pathway may also be functional during human development. Puberty can be variable in children with POR deficiency, with delayed or disordered puberty that is especially common in girls. This diagnosis should be considered in any child with skeletal features and hypospadias (46,XY) or clitoromegaly (46,XX) or who does not progress through puberty.[322]

3α-Reductase Type 3 and 3α-Reductase Type 1: AKR1C2 and AKR1C4

The "backdoor" pathway from 17-OHP to DHT involves the activity of AKR1C2 (aldo-keto reductase family 1 member C2) (see Fig. 24.12). Variants in *AKR1C2*, sometimes in combination

with changes in *AKR1C4*, have been described in several members of a family with various degrees of 46,XY underandrogenization who were originally thought to have 17,20-lyase deficiency.[323] Compound heterozygous variants or rearrangements in *AKR1C2* were found in another unrelated child with 46,XY DSD. These variants were inherited in a sex-limited recessive manner.[134,323] These findings were taken as evidence that the "backdoor" pathway plays a role in fetal androgen synthesis in humans as well as in wallabies. These studies also highlight that biochemical 17,20-lyase deficiency can have several molecular causes: CYP17A1, CYB5A, POR, and possibly AKR1C2/4.[310]

17β-Hydroxysteroid Dehydrogenase Type 3 Deficiency

The 17β-hydroxysteroid dehydrogenase reaction (also called the 17-ketosteroid reductase reaction) is mediated by isozymes that catalyze the reduction of androstenedione, DHEA, and estrone to testosterone, Δ^5 androstenediol, and estradiol, respectively, as well as the reverse reaction (see Fig. 24.11). The family of 17βHSD comprises at least 14 isoenzymes that have physiologic relevance in a range of human tissues and disorders such as breast cancer, prostate cancer, and endometriosis. The *HSD17B3* gene on chromosome 9q22 contains 11 exons and encodes the type 3 isoenzyme, which is expressed primarily in the testes, where it favors the conversion of the weak androgen androstenedione to the more biologically active testosterone (see Fig. 24.11). 17βHSD isoenzymes other than 17βHSD3 play a role in estrogen synthesis in the ovary.

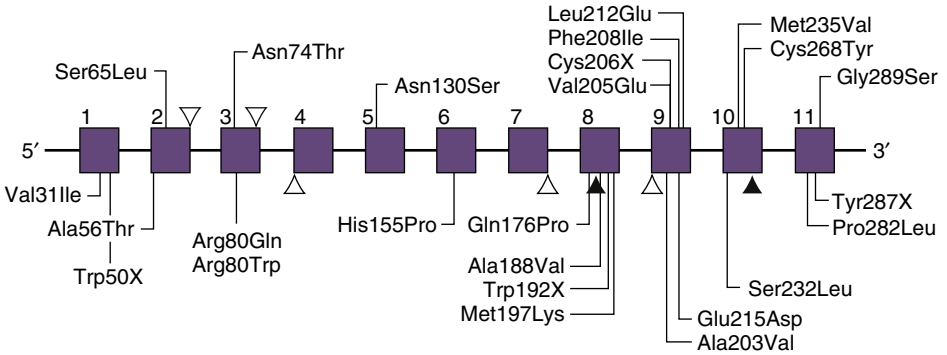
Deficiency of 17βHSD3, which was originally called 17-ketosteroid reductase, was first reported as an autosomal recessive cause of 46,XY DSD by Saez and colleagues (Fig. 24.29).[324] Many cases have been reported, and the phenotype is well characterized (Table 24.14).[325,326] Most affected 46,XY children have female-typical external genitalia at birth, although a few infants present with clitoromegaly or ambiguous genitalia. The testes are usually located in the inguinal canal. Müllerian structures are absent, and there is a blind vaginal pouch. The wolffian ducts are often stabilized to form epididymides, vasa deferentia, seminal vesicles, and ejaculatory ducts, likely due to paracrine androgenic effects of high concentrations of androstenedione.[327,328] Affected infants are usually designated female and may mistakenly be assumed to have CAIS. The phenotype of 17βHSD3 deficiency is limited to 46,XY individuals; 46,XX individuals with biallelic *HSD17B3* mutations are asymptomatic and fertile. The chances of having an affected child are twice as high if the mother has biallelic changes, which is why affected 46,XY siblings with 17βHSD3 deficiency are more common than might be expected.

Significant virilization usually occurs at puberty in 46,XY 17βHSD3 deficiency in the form of clitoral enlargement, hirsutism, deepening of the voice, and muscle development. These symptoms and signs may be the presenting features of this condition if it was not diagnosed earlier in life.[329] These changes are largely due to a pubertal increase in androstenedione production by the gonad and subsequent extraglandular conversion of androstenedione to testosterone. It has been speculated that this is mediated by genetic or environmental induction of enzyme activities of other 17βHSD isoenzymes, such as the type 5 isoenzyme (also known as 17βHSD5 and AKR1C3).[330] The testes may also have partial 17βHSD3 activity in some cases. In a large cohort of patients from a consanguineous population in the Gaza

TABLE 24.14 Clinical Features of HSD17B3 Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in *HSD17B3* gene
Genitalia	Female → ambiguous; blind vaginal pouch
Wolffian duct derivatives	Present
Müllerian duct derivatives	Absent
Gonads	Testes (usually undescended)
Physiologic features	Virilization at puberty (phallus enlargement, deepening of voice, and development of facial and body hair); gynecomastia variable
Hormone profile	Increased plasma estrone and androstenedione; decreased ratio of plasma testosterone/androstenedione after hCG stimulation test; increased plasma FSH and LH levels

FSH, Follicle-stimulating hormone; *hCG,* human chorionic gonadotropin; *HSD17B3,* 17β-hydroxysteroid dehydrogenase 3; *LH,* luteinizing hormone.



• **Fig. 24.29** Diagram of the 17β-hydroxysteroid dehydrogenase type 3 gene *(HSD17B3)* shows the mutations that result in deficiency of the enzyme. The numbered *solid boxes* depict the exons. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; *X* indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift mutations *(solid triangles)* and splice site mutations *(open triangles)* are shown.

Strip, the phallic lengths were described as reaching 4 to 8 cm.[331] The 17βHSD3 mutation reported in this population (Arg80Gln) is associated with 15% to 20% retention of normal 17βHSD3 activity (see Fig. 24.29). Gynecomastia occurs at puberty because of estrogens derived from the conversion of androstenedione to estrone by aromatase in extraglandular tissue and the subsequent conversion of estrone to estradiol by the action of the 17βHSD1 or 17βHSD2 isoenzymes.

The typical biochemical profile in 17βHSD3 deficiency is an elevated androstenedione level relative to testosterone (see Table 24.14). Expressed as a ratio of testosterone to androstenedione (after an hCG stimulation test before puberty), values less than 0.8 are typically found in these patients; however, this is not a universal finding presumably because of the extratesticular action of other 17βHSD isoenzymes, and diagnosis based on hormone measurements alone can be challenging.[326,332,333] Testicular vein sampling at the time of gonadectomy shows a markedly increased androstenedione gradient relative to testosterone, though this test is not routinely performed. Early genetic analysis can be useful and can avoid the need for hCG stimulation in some children.[334,335]

The range of mutations reported in patients with 17βHSD3 deficiency is shown in Fig. 24.29. Most are missense mutations. Expression studies of the mutant enzymes in heterologous cells usually show complete absence of activity in the conversion of androstenedione to testosterone compared with the normal enzyme. One recent study from a single center specializing in adult DSD found that approximately one-fourth of a cohort of women with partially virilized 46,XY DSD had mutations in *HSD17B3*.[336] The degree of androgenization was less than that typically seen in 5α-reductase deficiency, and many had been labeled as having PAIS. The diagnosis could only be made by genetic analysis.

Sex designation can be particularly difficult in children with 17βHSD3 deficiency because the external genital appearance correlates even less well with future gender identity than in other DSDs. Some babies have had early gonadectomy and been brought up as girls. In other settings (e.g., in Gaza), where affected patients typically adopted a male identity at puberty, some patients were designated male at diagnosis and were treated early with testosterone.[337] An alternative approach would be to raise the child as a girl initially and delay any interventions until late childhood or early adolescence so that the family and child have more time to consider the options and the child's gender is clearer. Careful monitoring is needed for the onset of puberty and androgen production if the child identifies as female, and gonadectomy may be considered to prevent undesired androgenization.

Those children who first present with virilization at puberty may declare a male gender identity in some cases. Gender changes at puberty have been reported in 39% to 64% of patients reared as girls in one study, but in our experience the rates are lower.[151,152,336] Other young people may identify as having a nonbinary gender. If androgenization is undesired, gonadectomy offers a definitive treatment; another potential option is short-term, reversible blockade of androgenization with an antiandrogen or puberty suppression with a GnRH agonist to provide time for appropriate counseling and to ensure the young person is involved in the decision making. Careful assessment and support from a multidisciplinary team and experienced psychologist are important, and long-term follow-up is important for hormone replacement and support.

Steroid 5α-Reductase Type 2 Deficiency

Steroid 5α-reductase type 2 deficiency in 46,XY individuals is also characterized by normally differentiated testes and male internal ducts, but external genitalia may be more ambiguous at birth than in 17βHSD deficiency. Classic features of this enzyme deficiency are summarized in Table 24.15.

The description of a genetic variant in *SRD5A2,* the gene that encodes steroid 5α-reductase type 2, in the Dominican Republic and Mexico and analysis of the biochemical and molecular features underline the importance of DHT in the development of the male phenotype.[338–340] At birth, there is typically a bifid scrotum, a urogenital sinus, a blind vaginal pouch, and a clitoris-like hypospadiac phallus. Testes differentiate normally and are located in the inguinal canal or in the labioscrotal folds. No müllerian structures are present. The wolffian ducts are stabilized so that the epididymides, vasa deferentia, and seminal vesicles are well differentiated; the ejaculatory ducts usually terminate in the blind vaginal pouch. The prostate is hypoplastic. Up to a third of cases may present with isolated hypospadias.[341]

At puberty, there is a striking degree of virilization: The voice deepens, muscle mass increases, the phallus lengthens to 4 to 8 cm, the bifid scrotum becomes rugated and pigmented, and the testes enlarge and descend into the labioscrotal folds. Postpubertal affected individuals do not have acne, temporal hair recession, or enlargement of the prostate. They rarely develop gynecomastia, in contrast to individuals with 17βHSD3 deficiency or AIS. There is normal libido with penile erections. Histologic examination of the testes shows Leydig cell hyperplasia and decreased spermatogenesis. Infertility is caused by a composite of failure to transform spermatogonia into spermatocytes, the adverse effect of a cryptorchid testis, and the specific role of DHT in regulating semen volume and viscosity.[342] Nevertheless, some individuals with 5α-reductase deficiency have a normal sperm count. One man in the Dominican cohort fathered a child after intrauterine insemination, and two affected brothers in a Swedish family were spontaneously fertile after hypospadias repair performed in childhood.[343,344] Gender changes occur frequently in 5α-reductase deficiency, particularly in individuals who do not undergo gonadectomy. Rates of social gender change in three cohorts ranged from 12% to 50% and seemed related to the age at diagnosis, with social gender

TABLE 24.15 Clinical Features of 5α-Reductase Type 2 Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in *SRD5A2* gene
Genitalia	Usually ambiguous with small, hypospadiac phallus; blind vaginal pouch
Wolffian duct derivatives	Normal
Müllerian duct derivatives	Absent
Gonads	Normal testes
Physiologic features	Decreased facial and body hair, no temporal hair recession, prostate not palpable
Hormone profile	Decreased ratio of 5α/5β C21 and C19 steroids in urine; increased T/DHT ratio before and after hCG stimulation; modest increase in plasma LH; decreased conversion of T to DHT in vitro

DHT, Dihydrotestosterone; *hCG,* human chorionic gonadotropin; *LH,* luteinizing hormone; *SRD5A2,* steroid-5α-reductase type 2; *T,* testosterone.

change being less common in the cohort where individuals were diagnosed at a younger (prepubertal) age.[345] Male sex designation is now increasingly chosen when the diagnosis is made in infancy.[345,346] An alternative approach similar to that sometimes used for 17β-hydroxysteroid dehydrogenase deficiency would be to rear the child as female with the gonads kept intact pending further informed discussions before puberty. Females (46,XX) homozygous for 5α-reductase deficiency undergo normal puberty and have normal fertility.[347]

The biochemical profile in 5α-reductase deficiency typically shows an elevated testosterone-to-DHT ratio basally or after hCG stimulation (see Table 24.15). Various ratios have been suggested as diagnostic, but none is unequivocal. A ratio exceeding 10:1 (when testosterone and DHT are expressed in the same units) had a sensitivity and specificity of 78% and 72%, respectively, in a cohort of 90 patients investigated for this enzyme deficiency.[348] Serum LH and FSH levels may be normal or elevated after puberty. The most reliable biochemical test (undertaken after 3 months of age) is analysis of a urinary steroid profile by gas chromatography and mass spectrometry to demonstrate a diminished ratio of urinary 5α/5β-reduced C19 and C21 steroids.[349,350] The diagnosis can still be confirmed biochemically after gonadectomy because of persistent effects on 5α/5β-reduced C21 steroids.[351] Early genetic testing is also useful to make the diagnosis or to confirm it when suspected from the biochemical profile.

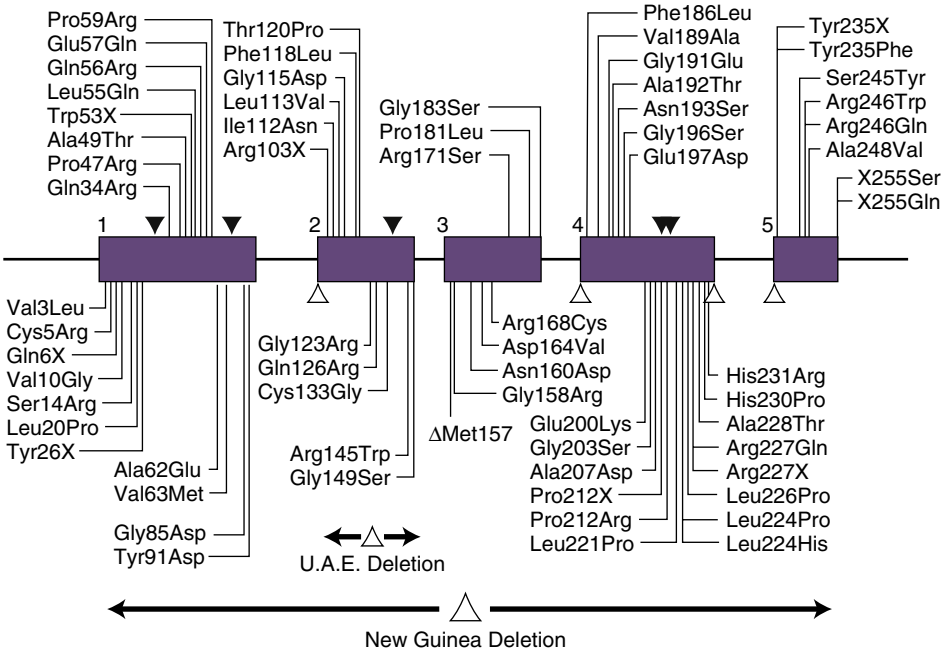
Early diagnosis of 5α-reductase type 2 deficiency is important because of its bearing on sex designation. The natural history of this condition, with a tendency for change to a male gender role with virilization at puberty, indicates that male sex designation is now a frequent option even when the external genitalia are relatively severely underandrogenized at birth.[352] The enzyme deficiency can masquerade as PAIS in newborns.[353] DHT, which may be applied topically increases penile length and facilitates repair of the hypospadias, but commercial availability may be limited.[354]

Two microsomal 5α-reductase enzymes catalyze the NADPH-dependent conversion of testosterone to DHT. 5α-reductase type 2 is a 254–amino acid protein encoded by the *SRD5A2* gene on chromosome 2p23. The type 2 isozyme is expressed predominantly in the primordia of the prostate and external genitalia but not in the wolffian ducts until after their differentiation into the male internal genital ducts.[355] The type 1 isoenzyme is expressed in skin, including human genital skin fibroblasts. The action of this isoenzyme may contribute to the virilization that occurs in 5α-reductase–deficient patients at puberty.[356]

5α-reductase type 2 deficiency is transmitted as an autosomal recessive trait. 5α-reductase type 2 deficiency is genetically heterogeneous, and the more than 60 mutations detected in the *SRD5A2* gene are distributed among all five exons (Fig. 24.30). Most are missense mutations; a complete gene deletion is found in the New Guinea population. There is a predominance of mutations in exon 4, mostly localized between codons 197 and 230, where the effect is complete inactivity of the mutant enzyme. Consanguinity is common, but a significant number of cases are compound heterozygotes. Male heterozygotes are not affected.

Disorders of Androgen Action

Androgen insensitivity syndrome (AIS) is the paradigm of a clinical disorder resulting from hormone resistance.[136] A detailed description



• **Fig. 24.30** Diagram of the 5α-reductase type 2 gene *(SRD5A2)* shows the mutations that result in 5α-reductase deficiency. The numbered *solid boxes* depict the exons. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; X indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift and splice site mutations are shown by *solid triangles* and *open triangles*, respectively. Large deletions found in affected United Arab Emirates (U.A.E.) and New Guinea populations are shown. (Adapted from Grumbach MM, Hughes IA, Conte FA. Disorders of sex differentiation. In: Larsen PR, Kronenberg HM, Melmed S, et al, eds. *Williams Textbook of Endocrinology,* 10th ed. Philadelphia, PA: Saunders; 2003, with additional data provided courtesy of Dr. Julianne Imperato-McGinley, Department of Medicine, Weill Medical College of Cornell University, Ithaca, NY.)

of the role of androgens in sex development and the molecular actions of the androgen receptor are provided earlier in this chapter.

Complete Androgen Insensitivity Syndrome

CAIS is an X-linked condition that typically presents in an adolescent female who has breast development and a pubertal growth spurt but who has not had menarche (Table 24.16). Pubic and axillary hair is absent or scant, and the uterus is absent as a result of normal AMH action, although there may be müllerian remnants. The wolffian ducts are stabilized in many patients, with a well-developed vas deferens and epididymis observed when gonadectomy is performed.[328] Estimates of the prevalence of CAIS range from 1 case in 20,400 to 1 in 99,000 individuals with a 46,XY karyotype.[357] The main differential diagnosis in an adolescent with a 46,XY karyotype is complete gonadal dysgenesis (Swyer syndrome), which is distinguished from CAIS by (1) absence of gonadal sex steroid production, resulting in poor breast development, and (2) absence of AMH production, resulting in retention of müllerian structures in Swyer syndrome.[358] CAIS may present in early infancy with bilateral inguinal or labial swellings that on evaluation are found to be partially descended testes. 17βHSD3 deficiency (or rarely 5α-reductase deficiency or SF1 deficiency) may also present this way. Bilateral inguinal hernias are rare in girls, of whom 1% to 2% are estimated to have CAIS.[359] Girls with this type of hernia should undergo evaluation for the presence of a Y chromosome by fluorescence in situ hybridization (FISH) or a full karyotype. If the hernial sac contains gonads, a biopsy can be performed together with cytogenetic studies.[360] Presently, with fetal chromosomal analysis being commonplace, a mismatch between chromosomal sex and the external genital phenotype at birth can be the presenting feature of CAIS.

Partial Androgen Insensitivity Syndrome

PAIS is characterized by incomplete androgenization resulting from a partial biologic response to androgens (Table 24.17). The phenotype for PAIS is highly variable and may include penoscrotal hypospadias, micropenis, and bifid scrotum. The testes may be undescended. The most severe form of PAIS manifests as isolated clitoromegaly. The milder end of the spectrum includes isolated hypospadias; PAIS does not present as isolated micropenis. As with other forms of AIS, müllerian structures are absent. Gynecomastia is common at puberty. The differential diagnosis for a PAIS-like phenotype is lengthy and includes partial gonadal dysgenesis (e.g., due to an *SF1*/*NR5A1* mutation or 45,X/46,XY mosaicism) and partial defects in androgen biosynthesis (e.g., due to LH receptor, 17βHSD, or 5α-reductase deficiencies).

Minimal or Mild Androgen Insensitivity Syndrome

This category of AIS is generally associated with typical male genitalia but can present with gynecomastia at puberty and infertility in adulthood.[361] Cancer of the breast is rare in males, but the risk is increased in MAIS as well as in those with PAIS raised male. In contrast, breast cancer has not been reported in women with CAIS. A mild form of androgen insensitivity is also found in spinal and bulbar muscular atrophy (Kennedy syndrome), a condition caused by hyperexpansion of the N-terminal polyglutamine repeat region of the androgen receptor, which can be associated with gynecomastia and reduced fertility.[362]

Hormone Profiles in Androgen Insensitivity Syndromes

In pubertal and adult individuals with CAIS, serum testosterone is within or above the adult male range with a moderately but inappropriately increased concentration of LH due to loss of negative feedback from androgens (though negative feedback from estrogens remains intact).[363] Serum estradiol is usually within and sometimes above the adult male reference range due to aromatization of androgens.[363] The concentration of sex hormone–binding globulin (SHBG), which is suppressed by

TABLE 24.16 Clinical Features of Complete Androgen Insensitivity Syndrome

Karyotype	46,XY
Inheritance	X-linked recessive; mutations in *AR* gene
Genitalia	Female with blind vaginal pouch
Wolffian duct derivatives	Often present, depending on mutation type
Müllerian duct derivatives	Absent or vestigial
Gonads	Testes
Physiologic findings	Scant or absent pubic and axillary hair; breast development at puberty; primary amenorrhea
Hormone and metabolic profile	Increased LH and testosterone levels; normal or increased estradiol (for male reference range); FSH levels often normal or slightly increased; resistance to androgenic and metabolic effects of testosterone

AR, Androgen receptor; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

TABLE 24.17 Clinical Features of Partial Androgen Insensitivity Syndrome

Karyotype	46,XY
Inheritance	X-linked recessive; mutations in *AR* gene
External genitalia	Ambiguous with blind vaginal pouch → isolated hypospadias → male with infertility (mild AIS)
Wolffian duct derivatives	Often normal
Müllerian duct derivatives	Absent
Gonads	Testes (usually undescended)
Physiologic features	Decreased to normal axillary and pubic hair, beard growth, and body hair; gynecomastia common at puberty
Hormone and metabolic profile	Increased LH and testosterone concentrations; normal or increased estradiol (for men); FSH levels may be normal or slightly increased Partial resistance to androgenic and metabolic effects of testosterone

AIS, Androgen insensitivity syndrome; *AR*, androgen receptor; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

androgens and enhanced by estrogens, is similar to that found in 46,XX females. Serum AMH concentration is typically in or above the normal male range in CAIS, a finding that distinguishes CAIS from gonadal dysgenesis, in which AMH levels are low.[364]

During the first few months of life, male infants have an active reproductive endocrine system with robust production of LH and testosterone; this period is known as *minipuberty*. For reasons that are unclear, this early reproductive endocrine activity is absent in most infants with CAIS (but not in PAIS),[365] and this may be a distinguishing feature of CAIS.

Molecular Pathogenesis of Androgen Insensitivity Syndromes

Information about mutations that affect the AR is recorded on an International Mutation Database at McGill University[366] (Fig. 24.31). More than 400 germline mutations are recorded for AIS; the database also records somatic mutations associated with prostate cancer. There is no specific hot spot for mutations, but certain locations, such as exons 5 and 7 within the LBD, are affected more frequently. Approximately 20% of mutations are located in the DBD. The most common functional AR defect results from disruption of the hydrophobic ligand-binding pocket, which is necessary for repositioning of helix 12 to form the AF2 coregulator interaction surface.

The phenotype of individuals with AIS can vary according to different substitutions at the same codon. For example, phenylalanine at codon 754 in helix 5 has a side chain that points away from the ligand-binding pocket. When substituted for a valine, the mutant AR is transcriptionally inactive and causes CAIS.[367] In contrast, serine and leucine substitutions result in a PAIS phenotype, explained by some residual transcriptional activity as measured in vitro. Linking the DBD to the LBD is a flexible hinge region defined by residues 628 to 669. This region stabilizes receptor interaction with selective androgen response elements and signals nuclear localization. Deletion of the hinge region by site-directed mutagenesis results in enhanced gene transcription, suggesting that it has a role in repression.[368]

There can be considerable heterogeneity in the phenotypic expression of a particular mutation, sometimes even within families. A mutation at codon 703 in exon 4 of the LBD, which changes a serine to a glycine, is reported in four individuals listed in the McGill database. One patient had typical female genitalia consistent with CAIS. The other three all had ambiguous genitalia consistent with PAIS, but the degree of androgenization of

(From the McGill Androgen Receptor Gene Mutation Database. Available at http://www.androgendb.mcgill.ca.)

the external genitalia was sufficiently variable that two were raised male and the third was raised female.[369] About 30% of mutations in AIS are de novo. Such mutations arise from a single mutational event in a parental germ cell (the mother in the case of AIS) or as germ cell mosaicism in the maternal gonad. When the mutation arises at the postzygotic stage, the index case is a somatic mosaic. Perhaps one-third of de novo mutations arise at the postzygotic stage, giving rise to expression of mutant and wild-type AR in different target tissues. This may explain some of the phenotypic variability in PAIS.[370]

Implicating a variant in *AR* as the cause of AIS generally requires proof of pathogenicity when it is novel and particularly with a PAIS phenotype. A commonly used assay assesses transcriptional activity using a promoter-luciferase system after transient transfection of the variant *AR* in an androgen receptor–negative cell line (such as Cos-1, Hela, CV1, or the PC3 prostate cancer cell line). Fig. 24.32 illustrates the application of such an assay for analysis of three different amino acid substitutions at codon 582 in the DBD.[136] A range of phenotypes from CAIS to severe and mild PAIS is found, depending on the nature of the substitution. Furthermore, the data demonstrate that high doses of androgens can overcome the resistance of the mutant AR. This has particular relevance for patients with PAIS who are raised male and may require large doses of androgens to induce puberty or to stimulate spermatogenesis. In addition to functional studies in vitro, structure-guided modeling of the androgen receptor can be used to predict the likely consequences of an *AR* mutation (see Fig. 24.16C). However, the N-terminal domain has a disordered flexible structure that has yet to be analyzed by crystallography. Nonsense mutations have long been identified in the NTD, but improved sequencing techniques have now identified a number of missense mutations generally associated with milder forms of AIS. It is possible that the structural flexibility of the NTD enables the AR to tolerate amino acid substitutions with little functional consequence. Analysis of such mutations provides a means to better define the structure-function relationship of the N-terminal domain.[371] The discovery of novel mutations is more common now that full sequencing of the *AR* gene is more straightforward.[372]

Androgen Insensitivity Syndromes Without an Androgen Receptor Mutation

An *AR* gene mutation is identified in about 95% of individuals when the clinical and biochemical phenotypes are consistent with CAIS.[373] There may also be mutations outside the *AR* coding region, such as the mutation in the 5′ untranslated region that was recently reported in two unrelated individuals with CAIS, which generates an upstream open reading frame and results in reduced AR protein levels.[374] In addition, in some individuals with a phenotype consistent with AIS, no *AR* mutation is identified, but assessment of DHT-dependent transcriptional induction of an

AR target gene (i.e., apolipoprotein D) in cultured genital skin fibroblasts shows a pattern consistent with functional androgen insensitivity.[375]

In contrast, the likelihood of finding a pathogenic *AR* variant in those with a PAIS phenotype is much lower, even when other causes of a similar phenotype have been excluded.[369] The genital phenotype in patients without an AR mutation, as based on a validated external masculinization score (EMS), is no different than that in infants with PAIS with a proven AR mutation, but gynecomastia is much less common.[376–378] Boys with an AR mutation are more likely to have poorer outcome than those without a mutation.[378] Birth weight for gestational age is significantly lower in mutation-negative patients compared with infants with PAIS who have an *AR* gene mutation.[270,379] It has been suggested that this form of 46,XY DSD with fetal growth restriction is a discrete category that as yet remains unexplained. The term PAIS is best reserved for individuals with *AR* mutations. Individuals with 17βHSD3, 5α-reductase deficiency, and especially SF1 mutations might also have been mislabeled as PAIS in the past. Although there is evidence that the AR can interact with more than 200 unique coregulator proteins, no mutations have been identified when screening these proteins in AIS, in contrast to findings in prostate cancer.[380]

Management of Androgen Insensitivity Syndromes

Sex designation and gender of rearing are uniformly female in CAIS. Inguinal hernias need repair when presenting in infancy. There is an option then to perform gonadectomy at this early stage, but most patients, families, and providers now favor late gonadectomy, as this approach enables spontaneous puberty to occur, allows the patient to be involved in the decision-making process, and does not substantially increase the risk for malignancy (discussed later in chapter). If gonadectomy is performed before puberty, hormone induction of puberty is similar to that used for girls with other causes of hypogonadism, typically starting around 10 to 11 years of age; the precise timing should consider the patient's wishes, family history of pubertal timing, growth and the degree of skeletal maturation as assessed by bone age X-ray, and whether gonadotropins are starting to rise. In the

absence of a uterus, hormone replacement can be continuous, unopposed estrogen, with no need for a progestin. Some adults with CAIS report improved well-being when androgen replacement is also given; the mechanism of this androgenic effect is not understood. One double-blind crossover trial found increased sexual desire with testosterone compared with estradiol treatment but otherwise found no difference in mental-health outcomes.[381] Bone mineral density of the lumbar spine in women with CAIS with intact gonads is lower than in typical 46,XX women, indicative of the direct effect of androgens on bone mineralization,[382] and women who have undergone gonadectomy have lower bone mineral density than those with intact gonads. Optimal estrogen therapy is essential as well as adequate calcium, vitamin D, and physical exercise. A small increase in fractures has been reported in AIS, although this study did not show any difference in underlying osteoporosis.[383]

There is an increased risk of gonadal germ cell tumors in 46,XY DSD, including AIS. Germ cell maturation is delayed in the abnormal microenvironment. Some of the immature germ cells may subsequently mature, and while many may undergo apoptosis, some may retain fetal characteristics and become premalignant/malignant. Within the testicular environment, the premalignant lesion is termed *germ-cell neoplasia in situ* (GCNIS) (previously called *carcinoma in situ* [CIS] or *intratubular germ cell neoplasia unclassified* [ITGNU]). GCNIS may progress to invasive germ cell tumors, most commonly a seminoma. Recently, the stage between maturational delay and GCNIS has been termed *pre-GCNIS*.[384] GCNIS cells express immunohistochemical markers such as placenta-like alkaline phosphatase (PLAP), c-KIT (the receptor for the stem cell factor SCF), POU5F1 (a transcription factor also called OCT3/4), and NANOG. However, in individuals with DSD, germ cells frequently show delayed maturation and prolonged expression of these markers. Therefore additional histologic criteria have been developed to distinguish maturational delay from GCNIS (see "Tumor Risk and DSDs" later in the chapter). In addition, SCF (or KIT ligand [KITLG]) has been proposed as a marker specific for germ cell neoplasia that is not expressed in germ cells with maturational delay.[384] Nearly all GCNIS eventually progress to invasive germ cell cancer in individuals without DSD, but it is hypothesized that this progression requires androgenic activity and may therefore be much more uncommon in AIS.[384,385] In CAIS the risk of developing GCNIS or a germ cell tumor before puberty is low (in the order of 0.8–2%).[386,387] Hence there is a general preference to delay gonadectomy until young adulthood to enable spontaneous puberty to occur. The risk of pre-GCNIS, GNIS, or malignancy is estimated to be 10% to 14% in adolescent and adult individuals with CAIS.[385,387] Some adults with CAIS elect to retain the gonads, though monitoring can be difficult, especially in case of abdominal gonads (see "Tumor Risk and DSDs").

Surgery to bring abdominal gonads to a more superficial location is a potential option; a biopsy can be taken at the time of surgery to assess the risk of germ cell cancer.[214] GCNIS and seminoma usually do not secrete tumor markers such as βhCG and α-fetoprotein (AFP), and GCNIS cannot be detected using ultrasound or MRI.[388] Noninvasive monitoring may potentially become available with the development of techniques to measure embryonic microRNAs in serum, but this method is also currently unable to detect GCNIS.[389] Common findings in CAIS gonads on MRI include Sertoli cell adenomas and epididymal cysts.[388]

Surgery in CAIS is generally confined to gonadectomy. For vaginal hypoplasia, self-dilatation is the first-line approach.[390,391] This technique is effective in lengthening the vagina for most CAIS women but requires time; thus it should be started when a girl is thinking about sexual relations and when there is clear focus and motivation. A specialist nurse or gynecologist with experience of vaginal dilatation is important to provide support and guidance, and several useful written materials are becoming available (e.g., www.dsdteens.org). In situations in which self-dilatation is not appropriate or possible, alternative forms of vaginoplasty, such as the laparoscopic Vecchietti procedure, may be offered.[390]

The early management of PAIS centers on sex designation and the subsequent plan and timing for surgery. There has been an increasing trend in recent decades to choose a male gender of rearing.[392] A recent prospective study of boys with PAIS showed the value of the EMS at birth as a predictor of pubertal development.[393] Those with an EMS of 5 or more started puberty spontaneously. Further studies on this cohort of 27 boys with PAIS involved functional analysis of the mutant ARs using reporter gene assays. In contrast to the EMS as a predictor, the results were not a reliable indicator of whether androgens would be required to induce puberty. However, such assays may have a place in guiding the magnitude of high-dose androgens sometimes required in adulthood in men with PAIS. Several surgical procedures may be required to correct hypospadias and relocate the testes in a scrotal sac. Gynecomastia is an almost universal finding as boys with PAIS reach puberty. This raises the possibility of prevention by the use of antiestrogens and aromatase inhibitors and thereby avoids the need for surgical reduction mammoplasty, but long-term safety has not been established. The risk of germ cell tumor of the testis had previously been reported to be high in PAIS, but more recent reports suggest a lower risk, comparable to that in CAIS.[378,394] When scrotal in position, testes should be monitored by regular self-examination and periodic imaging by ultrasound. It has been suggested that bilateral testicular biopsies should be undertaken at the time of orchidopexy and after puberty to determine the presence of GCNIS.[395] In view of the risk of malignant progression, gonadectomy is advised if GCNIS is discovered, although an alternative may be irradiation of bilateral in situ lesions.

When an infant with PAIS is designated a female sex, gonadectomy will be required before puberty if the adolescent wishes to prevent virilization. If gonadectomy is performed, estrogen replacement is needed to induce puberty and for hormone replacement thereafter. Whether and when to perform genitoplasty is a subject of controversy and is discussed in "Surgery and DSDs." In MAIS, clinical presentation occurs either in adolescence because of gynecomastia or in adulthood because of male factor infertility. Reduction mammoplasty is required for the gynecomastia. There is one report of successful fertility after testicular sperm extraction in a man with MAIS.[396,538]

Other Conditions Affecting 46,XY Sex Development

Persistent Müllerian Duct Syndrome

AMH is a glycoprotein homodimer that is secreted by the Sertoli cells of the developing testes from approximately 7 wpc. It acts through the AMH type 2 receptor between 8 and 12 wpc to cause regression of the müllerian duct (see "Development of Reproductive Systems").[124]

AMH is encoded by a 2.75-kb gene containing 5 exons in the region of chromosome 19p13.3. The AMHR2 is a serine/threonine kinase with a single transmembrane domain that is encoded by an 11-exon gene on 12q13. Exons 1 to 3 code for the signal sequence and the extracellular domain of the AMHR2, exon 4 codes for the transmembrane domain, and exons 5 through 11 code for the intracellular serine/threonine domain.

Persistent müllerian duct syndrome is a condition in which 46,XY males have well-developed testes and normal male external genitalia but also have müllerian duct derivatives. The diagnosis is often not made until a fallopian tube and uterus are incidentally encountered in patients undergoing inguinal hernia repair, orchiopexy, or abdominal surgery. In the more prevalent form, a boy presents with bilaterally undescended testes, and the uterus, tubes, and testes are in the pelvis. In other situations, a hernia contains a partially descended or scrotal testis, and the ipsilateral fallopian tube and uterus are in the hernia, which is known as *hernia uteri inguinale*. In some instances, the contralateral testis and tube also are present in the hernial sac, known as *transverse testicular ectopia*.

Approximately one-half of all genetically proven cases of PMDS result from defects in AMH, and half are caused by mutations in its receptor (Fig. 24.33).[397–399] *AMH* gene mutations are most commonly found in Mediterranean and North African countries,[400] and most familial mutations are homozygous. In contrast, mutations in the gene encoding AMHR2 are more commonly found in Northern Europe and the Middle East. Europeans are often compound heterozygous for mutations involving a 27-bp deletion in exon 10.[401,402] Measurement of serum AMH levels can provide a useful means for guiding genetic analysis; patients with PMDS caused by mutations of the *AMH* gene typically have low or undetectable levels of serum AMH (except for the p.Gln496His mutation thought to affect receptor binding), whereas AMH concentrations are normal for age or elevated in patients with mutations of *AMHR2*. Approximately 12% of patients with PMDS have an idiopathic form, with no mutation in *AMH* or *AMHR2*; they often have associated malformations.[399]

The main aim of management of PMDS is to prevent testicular cancer and preserve fertility in males, which can be difficult because of the anatomic findings. An increased prevalence of testicular degeneration has been described, which probably results from torsion of the testes and/or their anatomic location. Anatomic abnormalities of the epididymis and the vas deferens are common. Infertility may result from late orchiopexy or from mechanical problems associated with entrapment of the vas deferens in the müllerian derivatives. Treatment consists of early orchidopexy, which often requires removal of mullerian structures, although it should not be attempted to remove these in toto as this will likely damage the genital ducts or blood supply. Men with high pelvic testes rarely have successful orchidopexy, and many of these individuals are androgen deficient. Increasing rates of testicular malignancy have been reported in adult men with this condition, which further complicates long-term management of gonads that cannot be orchidopexed.[399] Fertility is rare, but successful TESE-ICSI has been reported in isolated cases.[399]

Hypospadias

Hypospadias is incomplete fusion of the penile urethra due to an arrest in development of the urethral spongiosum and ventral prepuce.[403] The normal embryologic resolution of penile curvature may also be interrupted, resulting in chordee. It is a common congenital anomaly with an estimated birth prevalence of 3 to 4 cases per 1000 live births. Although it has been suggested that the rate of hypospadias has been increasing, this is not borne out in contemporaneous studies.[404] The cause is unknown in most cases, but it is assumed that there is an interplay of genetic and environmental factors.[405–407] Mutations in candidate genes such as *MAMLD1, NR5A1,* and the *AR* are found in a minority of cases.[408] There is a familial clustering of cases in hypospadias, with a 7% incidence of one or more additional affected family members.[409] Four chromosomal regions have been identified in familial hypospadias by fine-mapping analysis of genes involved in steroid metabolism.[410] A genome-wide association study involving a total of 2978 cases and 7298 controls of European ancestry identified 18 genetic loci associated with hypospadias at genome-wide significance.[407] None of these loci lay near known 46,XY DSD genes, so distinct pathways may underlie the susceptibility to hypospadias.

Hypospadias is associated with increased maternal age, multiple births, maternal exposure to diethylstilbestrol in utero, paternal subfertility, maternal vegetarian diet, maternal smoking, assisted reproductive techniques, paternal exposure to pesticides, and fetal growth restriction.[411] The association with low birth weight is remarkably consistent across all studies of idiopathic hypospadias.[412]

Hypospadias may be the only phenotype in mild forms of 46,XY DSD, but it is not entirely clear when an evaluation for DSD is needed in a child with isolated hypospadias. Recommendations have been made to conduct such an evaluation if the hypospadias is severe (midshaft or more proximal) or if there are additional genital findings (e.g., unilateral or bilateral cryptorchidism, micropenis, anomalies of the scrotum), but the prevalence of DSD conditions with each of these presentations has yet to be reported.

Management is generally surgical. The urethral meatus is relocated to the glans, and the penis is straightened by correcting any chordee to give a forward-directed urinary stream and the ability to have sexual intercourse. Numerous techniques are described; repairs may require more than one stage, usually starting at 6 to 18 months of age or deferred until 4 years or later. Delaying surgery allows the child to be involved in decisions regarding surgery, but older age at surgery has been reported to be a risk factor for complications.[413] A course of testosterone is often given to induce penile growth prior to surgery, particularly if micropenis is present. The severity of the hypospadias may not be apparent until release of the chordee. Complications include fistula formation, meatal stenosis, urethral stricture, and residual chordee. Follow-up studies in adulthood indicate a less satisfactory cosmetic appearance compared to control subjects, shorter penile length, more dysfunction with voiding, and a lower urinary flow rate.[414] These problems were more evident in severe forms of hypospadias.

Anorchia and Cryptorchidism

The term *testicular regression syndrome* (also called *vanishing testis syndrome*) is used to describe the phenotype of bilateral anorchia in a male infant with otherwise typical-appearing genitalia. The phenotype suggests the presence of testes in early gestation functioning appropriately to differentiate male external genitalia, induce müllerian duct regression, and stabilize wolffian duct development. Bilateral anorchia with a normally differentiated but small phallus (micropenis) is a variant of the syndrome and may represent a form of testicular dysgenesis. The cause of testicular regression syndrome is unknown, but an interruption of the testis blood supply by a torsion or vascular occlusion event in utero has been proposed. Familial cases suggest that there may be a genetic cause in some cases. Surgical exploration and histologic findings typically show nubbins of fibrous tissue devoid of any testicular tissue attached to a blind-ending vas deferens.

Diagnosis is based on a combination of biochemical tests, imaging studies, and/or surgical exploration. An undetectable serum AMH level coupled with elevated serum levels of gonadotropins (particularly FSH) is highly predictive of the absence of

testes.[415] If such findings are present, there may be no need for surgical exploration. Androgen replacement is required to induce puberty at around 11 to 12 years of age. Testicular prostheses can be inserted if and when the young person desires. It is unclear whether the testicular nubbins pose a risk for gonadal tumors, but most studies suggest that the risk is low; whether nubbins should be removed surgically remains a subject of debate.

Testes that have not descended at birth (i.e., cryptorchidism) present the most common congenital abnormality in boys, affecting 2% to 9% of term infants.[140,416] Because testicular descent occurs late in gestation, undescended testes are a common finding in premature baby boys. There is epidemiologic evidence of an increasing prevalence to 6% in populations studied in the United Kingdom.[417] Longitudinal studies demonstrate the expected spontaneous descent of the testis by early infancy but an unexpected reascent of the testis to a cryptorchid position in later childhood. It is now recognized that there are just as many boys with acquired cryptorchidism as there are with congenital cryptorchidism.[418] There is a strong association with low birth weight, disorders of the pituitary-gonadal axis, and a number of syndromes, but in the majority of situations the cause of maldescent is unknown. Unilateral cryptorchidism does not require an evaluation to identify an underlying cause, but bilateral cryptorchidism could be a sign of hypogonadotropic hypogonadotropism, which could in turn be a sign of combined pituitary hormone deficiency that would require prompt diagnosis and treatment to avoid neurocognitive deficits due to untreated central hypothyroidism and hypoglycemia due to ACTH and growth hormone deficiency. In addition, bilateral nonpalpable gonads can rarely be the presenting feature of 46,XX congenital adrenal hyperplasia. Unilateral and bilateral cryptorchidism in the context of other signs of underandrogenization, such as hypospadias, also warrants a DSD evaluation. Mutations in *INSL3* and the gene for its receptor, *RXFP2*—factors involved in the transabdominal phase of testis descent—were reported in a few boys with cryptorchidism.[419] Cord blood levels of INSL3 but not testosterone are decreased in idiopathic cryptorchidism, particularly in infants whose testes descended by 3 months of age.[420]

Congenital and acquired forms of cryptorchidism differ in their management. Orchidopexy is the recommended treatment in the former after 6 months but preferably no later than 12 to 18 months of age according to recent guidelines.[421,422] There is no consensus on the role of hormonal treatment with GnRH or hCG due to poor-quality evidence and lack of long-term data.[422] It is not routinely recommended because complete testicular descent is often not achieved. Both positive and negative potential effects of hormonal treatment on germ cells and testicular volume have been reported. The European Urology Association/European Society for Paediatric Urology guidelines recommend offering hormonal treatment to boys with bilateral undescended testes to possibly improve further fertility potential, whereas the Canadian Urological Association–Pediatric Urologist of Canada guideline considers such treatment experimental.[422,423] hCG has been shown to induce descent to a lower level in the majority of testes, so as neoadjuvant therapy it may improve testis position before surgery to increase the chances of successful orchidopexy.[424] Some also recommend orchidopexy for acquired cryptorchidism, but an alternative approach is to wait until puberty because in more than 50% of cases the testes descend spontaneously at this time.[425] There is substantial evidence to indicate that the relative risk of germ cell tumor development in adulthood associated with cryptorchidism is more than halved if orchidopexy is undertaken before puberty.[426] Early orchidopexy is also beneficial for testis development and spermatogenesis, although the evidence that this is translated into improved fertility is lacking.[427]

Anatomic Defects of the Pelvis and Penis

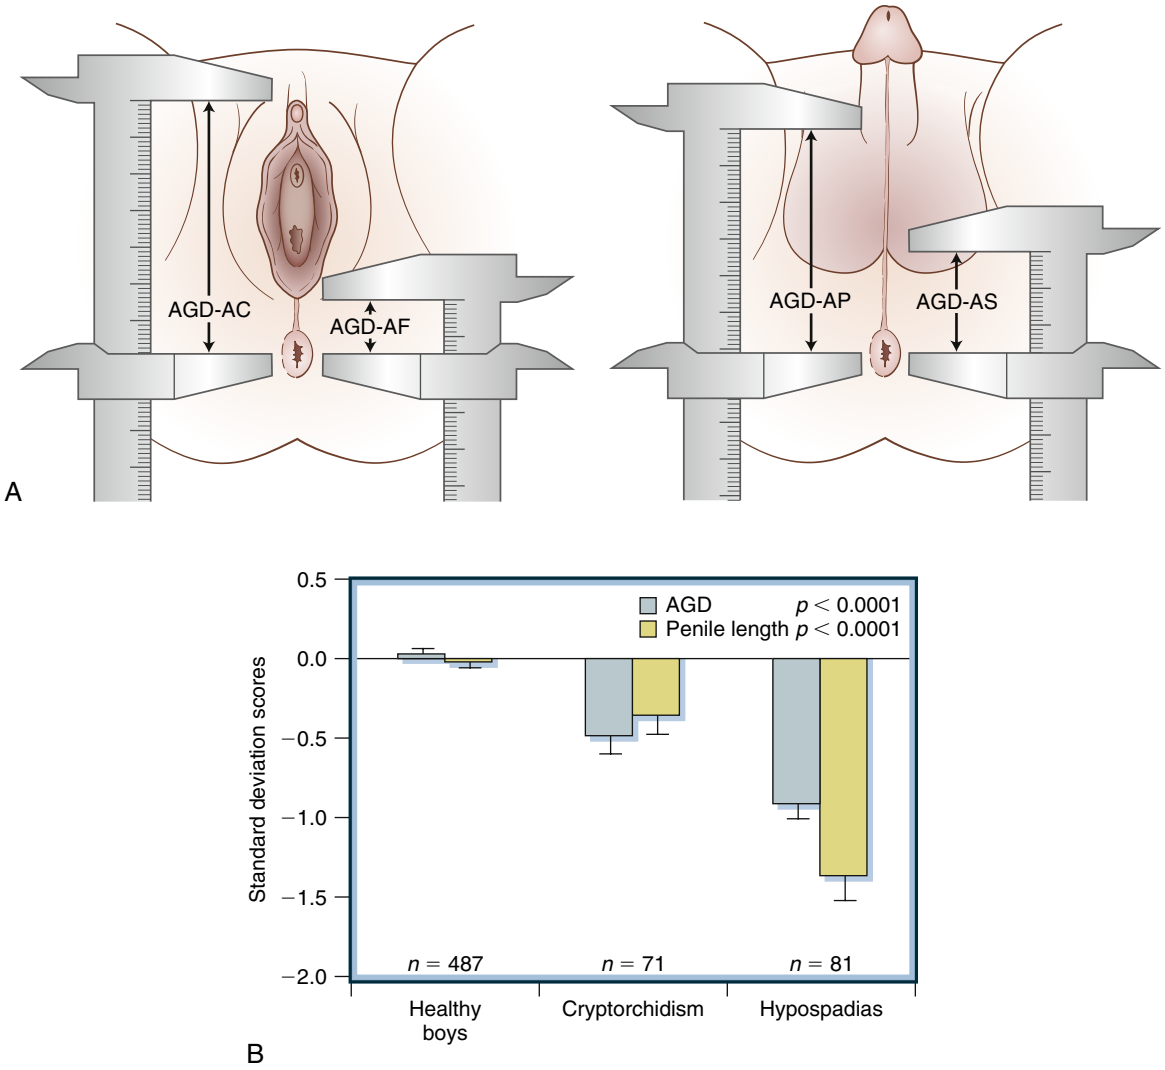
Cloacal exstrophy is an important developmental condition that can affect genital development as part of a complex anatomic anomaly involving the bladder, usually with associated gastrointestinal, anorectal, and skeletal features. *Penile agenesis* is a very rare isolated defect in penile development. In both these conditions, there is usually typical androgen synthesis by the testes, and androgen responsiveness in the brain, so a male gender identity is most likely.

Endocrine Disruptors

The proposed increase in male reproductive tract disorders (testis cancer, abnormal spermatogenesis, cryptorchidism, and hypospadias) led to the concept that testicular dysgenesis syndrome (TDS) of fetal origin might be triggered by lifestyle factors and exposure to endocrine-disrupting chemicals (EDCs) operating during the fetal and perinatal periods.[428,429] The US Environmental Protection Agency has defined an EDC as an exogenous agent that interferes with synthesis, secretion, transport, metabolism, binding action, or elimination of natural blood-borne hormones that are present in the body and are responsible for homeostasis, reproduction, and developmental processes.[430] The types of compounds generically include detergents, pesticides, and cosmetics with postulated modes of action comprising estrogenic and antiandrogenic effects. Such a broad definition and the ubiquity of thousands of compounds in the environment, which may have endocrine-disrupting effects, pose an enormous challenge for scientific studies to prove that adverse health effects occur in humans, and, if so, what measures can be taken for prevention. Analgesics commonly used during pregnancy, such as paracetamol/acetaminophen and ibuprofen, have also been suggested as potential endocrine disruptors interfering with testicular and ovarian development.[431–434]

Classic toxicological methods used in animals are not apposite for human studies, but application of a phenotypic marker long used by toxicologists testing EDCs in animals has been validated in humans for epidemiologic studies.[435] Anogenital distance (AGD) is significantly reduced in isolated hypospadias and cryptorchidism in comparison with normative data (Fig. 24.34).[436] As an exemplar of the application of this marker in epidemiologic studies in reproductive development, prenatal exposure to phthalates widely used as plasticizers in many products was associated with reduced AGD in males at birth.[437,438] Xenografts of human fetal testis tissue in animals is a recent developed methodology which usefully informs on chemical effects relevant to human reproductive development.[439] Another approach is the study of occupational exposure where there is evidence of increased risk of hypospadias and cryptorchidism in offspring of parents working with pesticides, industrial chemicals, cosmetics, and several other potentially toxic substances.[440,441]

The relevance of these epidemiologic findings to the assessment of an individual child with DSD remains uncertain. There is no consensus yet about low-dose effects on health from the combination of a myriad of chemicals to which humans are exposed over the lifespan or the optimal toxicological methodology to measure exposure.[442,443] An expert panel has identified compelling evidence for male infertility attributable to phthalate exposure and estimated the financial burden that accrues to the European Union from the consequences of needing additional assisted reproductive technology procedures.[444] A similar analysis can be undertaken to



• **Fig. 24.34** Measurement of anogenital distance (AGD). (A) Different landmarks used for measurement in female and male infants. The distance from the posterior fourchette (AF) and from the clitoris (AC) to the midpoint of the anus in females and from the cephalad insertion of the penis (AP) and from the junction of the scrotal and perineal (AS) skin to the midpoint of the anus in males are commonly used methods to determine AGD in epidemiologic studies. (B) Measurements of penile length and AGD in boys with cryptorchidism and hypospadias compared with normal male infants. (Redrawn from Thankamony A, Lek N, Carroll D, et al. Anogenital distance and penile length in infants with hypospadias or cryptorchidism; comparison with normative data. *Environ Health Perspect*. 2014;122:207–211, used with permission of Environmental Health Perspectives.)

estimate the additional cases of cryptorchidism requiring orchidopexy. Adopting the precautionary principle to reduce exposure to chemicals to as low as is reasonably practicable is a sensible approach in the face of so much uncertainty about the adverse effects of EDCs on human health. This applies particularly to pregnant women who may need to take an analgesic periodically.

46,XX Disorders of Sex Development

46,XX DSDs can be divided into disorders of ovarian development, disorders of steroid hormone synthesis leading to androgen excess, and other conditions affecting sex development (see Table 24.3).

Disorders of Ovarian Development

Disorders of ovarian development (i.e., ovarian dysgenesis or resistance) usually manifest as absent puberty due to the absence of estrogen production. Other disorders of gonadal development can result in a 46,XX individual with an ovary containing testicular tissue (i.e., 46,XX ovotesticular DSD) or a testis capable of producing enough testosterone for a male phenotype and/or sufficient AMH to regress the uterus (i.e., 46,XX testicular DSD).

Ovarian Dysgenesis

Ovarian dysgenesis most often occurs as a result of sex chromosome aneuploidy (e.g., Turner syndrome; 45,X and variants) with progressive follicular apoptosis. Mutations in many genes can result in POI, but each accounts for only a small proportion, and often no cause of POI is identified. Two recent reviews provide an excellent overview of the various groups of genes that are involved.[445,446] Some of these genes are important for formation of the indifferent gonad; these include *NR5A1* and *WT1*, which have been discussed earlier. *FOXL2* plays a role in early ovarian

determination, and mutations are associated with POI, usually but not always, as part of the blepharophimosis, ptosis, epicanthus inversus syndrome. Other genes are involved in meiosis and DNA repair, such as cohesins (e.g., *STAG3*), and various helicases (e.g., *MCM8* and *HFM1*). Mutations in these genes disrupt meiotic progression of oocytes and result in oocyte degeneration. They form an important group of genes to consider in women with POI, as mutations in these genes are associated with an increased risk of various cancers. A group of genes involved in mitochondrial functions cause sensorineural deafness in combination with POI, also known as Perrault syndrome and other neurosensory syndromes (e.g., *POLG*). Other syndromic causes include premature aging syndromes (e.g., *LMNA*) and skeletal syndromes (e.g., *BMPR1B*). Mutations in genes involved in the formation and maturation of the primordial follicles, such as *SOHLH1*, *SOHLH2*, *NUP107*, *FIGLA,* and *NOBOX*, as well as those involved in the next hormone-dependent step, maturation and growth from primary to ovulatory follicles, such as *ESR1*, *FSHR*, *LHCGR,* and *BMP15*, cause nonsyndromic POI. One of the most common monogenic causes is a premutation of *FMR1*, found in approximately 2% to 6% of women with sporadic POI. *SOX8* mutations have recently been identified in 5% of a cohort of females with POI.[249]

46,XX Ovotesticular and 46,XX Testicular Disorders of Sex Development

In rare situations, the developing ovary may contain testicular tissue (i.e., 46,XX ovotesticular DSD) or may even develop as a functioning testis (i.e., 46,XX testicular DSD). In 46,XX ovotesticular DSD, the patient usually presents with ambiguous genitalia at birth and progressive virilization at puberty if the testicular component is not removed. In contrast, 46,XX testicular DSD is usually associated with a male phenotype at birth and absence of müllerian structures. However, infertility occurs in both situations as crucial spermatogenesis genes on the Y chromosome are absent, and testicular androgen production may not be sufficient to support full pubertal development or may decrease with age, so careful monitoring is needed. In some circumstances ovotesticular DSD and testicular DSD may represent a spectrum of the same molecular condition.

The presentation, endocrinology, and management of 46,XX ovotesticular DSD is similar to those of ovotesticular DSD due to 46,XX/46,XY chimerism, as described earlier (see "Sex Chromosome Disorders of Sex Development"). However, 46,XX males cannot achieve male fertility. As discussed, a 46,XX karyotype is the most frequent finding in ovotesticular DSD, especially in patients from sub-Saharan Africa.[219,220] Familial cases have been described, and it is likely that a genetic basis exists in some situations. Indeed, mutations affecting a specific residue (p.Arg92Trp or p.Arg92Gln) of NR5A1 (SF1) have recently been identified in a number of individuals with ovotesticular/testicular DSD from diverse ancestral backgrounds (see "Gonadal Sex") (see Fig. 24.20).[71,72] These specific changes initiate a testis development pathway, possibly through loss of repressor activity, and account for up to 10% of ovotesticular DSD. Disruption of another nuclear receptor, NR2F2 (COUP-TFII), has also been reported in ovotesticular/testicular DSD and cardiac defects, sometimes with additional features (e.g., diaphragmatic hernia, BPES).[122] Homozygous mutations of the ovarian-testis repressor gene *RSPO1* (encoding R-spondin 1) can cause ovotesticular/testicular DSD with eye and skin abnormalities and hearing impairment.[222,447]

In contrast, patients with 46,XX testicular DSD often present first with male factor infertility, although sometimes hypospadias is present. In some cases, a family history is found. Because different family members can have different phenotypes, it is possible that 46,XX testicular DSD represents the most severe end of the spectrum of ovarian transdifferentiation phenotypes. Up to 80% of 46,XX males harbor translocations of Y-chromosomal material containing *SRY*, the testis-determining factor. This finding helped considerably in mapping the *SRY* gene in the first instance (see "The Y Chromosome"), and in some situations, residual ovarian tissue (ovotestis) develops. Individuals with *SRY* translocations can be diagnosed by FISH analysis using a probe directed to that gene (see Fig. 24.3). A number of *SRY*-negative cases have been reported. Sometimes, these arise from the same mutations in NR5A1 or NR2F2 that can cause 46,XX ovotesticular DSD. Duplication of the genetic locus containing *SOX9* or deletions or rearrangements in distant regulatory regions that result in *SOX9* overexpression,[107–109] and similar alterations in the X chromosome resulting in overexpression of *SOX3,* have also been described.[448] In addition, it has been hypothesized that overexpression of *SOX10* may be the cause of 46,XX ovotesticular/testicular DSD in two individuals with an increased copy number of the 22q13 area.[449] Loss-of-function mutations in *RSPO1* have been reported in individuals with 46,XX testicular DSD as well as in ovotesticular DSD. Severe disruption of *WNT4* can result in 46,XX ovotesticular/testicular DSD as part of the SERKAL syndrome, which also encompasses renal, adrenal, and lung dysgenesis.[450]

Disorders of Androgen Excess

The steroid biosynthetic disorders causing androgen excess and 46,XX DSD are summarized in Table 24.6. Although CYP21 deficiency is by far the most common cause of this condition, alternative diagnoses should be considered because approaches to counseling and management may vary.

3β-Hydroxysteroid Dehydrogenase Type 2 Deficiency

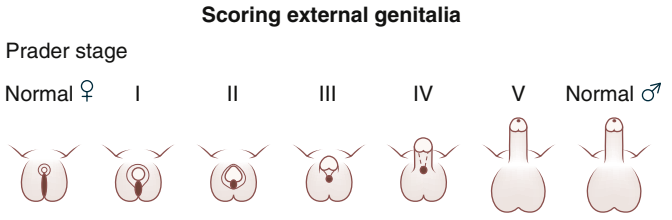
3βHSD/$\Delta^{4,5}$-isomerase catalyzes the conversion of Δ^5 steroids to Δ^4 steroids and is required for the generation of mineralocorticoids, glucocorticoids, and more potent androgens (e.g., testosterone, DHT) by the adrenal glands and gonads (see Fig. 24.11). The actions of 3βHSD and the consequences of deficiency of the type 2 enzyme (3βHSD2) were described earlier because, in 46,XY individuals, this deficiency results in adrenal insufficiency with variable defects in androgenization.

Defects in 3βHSD2 can also cause a genital phenotype in 46,XX females. Severe, recessively inherited defects in enzyme function can cause mild clitoral enlargement at birth in girls with glucocorticoid deficiency with or without salt loss. This mild androgenization occurs not as a direct androgenic effect of the excess DHEA but as a result of conversion of DHEA and other Δ^5-3β-hydroxy-C19-steroids to testosterone by 3βHSD1 in the placenta and in the peripheral tissues of the fetus. This conversion, coupled with the limited capacity of the placenta to aromatize androgens to estrogens early in gestation, can increase circulating levels of androgens in the female fetus and cause modest clitoromegaly in a minority of patients. Other girls have normal genitalia but show adrenal features. Milder, nonclassic forms of 3βHSD2 deficiency can cause premature pubarche in girls. Breast development can occur at puberty in affected females, presumably by peripheral conversion of Δ^5C19 steroids to Δ^4C19 steroids by 3βHSD1 expressed principally in the liver and peripheral tissues and by the subsequent aromatization of androgens to estrogens.

The diagnosis of 3βHSD2 deficiency can be challenging in nonclassic forms of this condition.[299] The levels of Δ^5 steroids (e.g., 17-hydroxypregnenolone, DHEA, and its sulfate, DHEAS) usually are increased, and the ratio of Δ^5 steroids to Δ^4 steroids (e.g., the ratio of 17-hydroxypregnenolone to cortisol) is markedly increased, especially after stimulation with intravenous ACTH. The urinary steroid profile can also be informative because 17-ketosteroids and especially DHEAS and 16-hydroxy-DHEAS are elevated. Although adrenal production of 17-OHP is reduced due to the enzymatic block, plasma concentrations of 17-OHP can actually be increased as a result of peripheral conversion of $\Delta^5$17-hydroxypregnenolone to 17-OHP by the 3βHSD type 1 enzyme. This finding may lead to confusion with other forms of CAH such as CYP21A2 deficiency or POR deficiency. Mild forms of 3βHSD2 deficiency may manifest in a fashion similar to that of virilizing adrenal tumors. Suppression of the increased plasma and urinary levels of C19 and C21 3β-hydroxysteroids by glucocorticoids distinguishes 3βHSD deficiency in such cases. Treatment for 3βHSD deficiency is glucocorticoid, mineralocorticoid, and salt supplementation, as appropriate, and estrogen replacement to induce puberty, if needed.[300]

21-Hydroxylase Deficiency

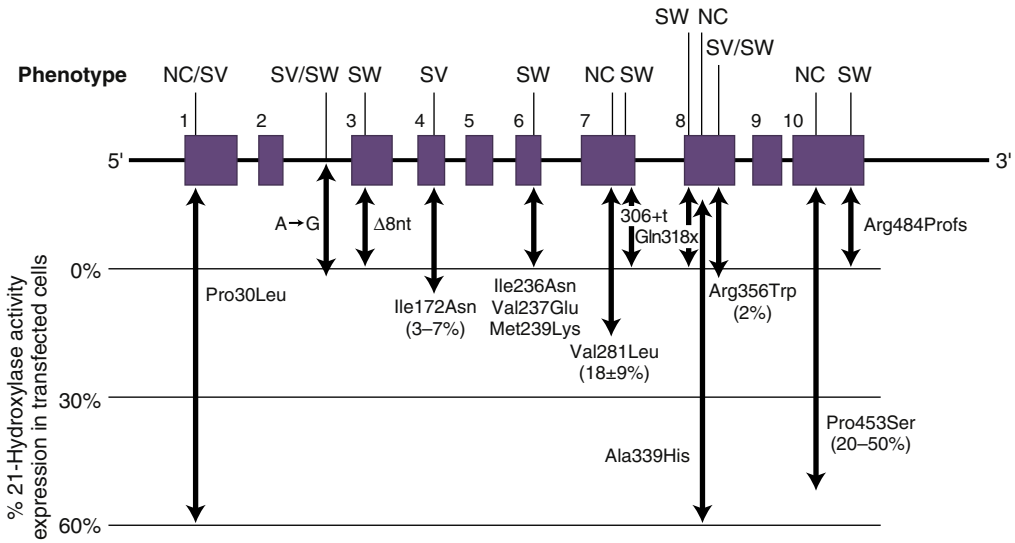
CYP21A2 deficiency (see Fig. 24.11) is one of the most common causes of ambiguous genitalia of the newborn. It is a disorder of adrenal steroidogenesis that affects around 1 in 15,000 children, with most 46,XX patients presenting at birth due to virilization of the genitalia (see Chapter 15).[451,452]



• **Fig. 24.35** Prader classification of the degree of androgenization in a 46,XX individual with congenital adrenal hyperplasia.

A 46,XX fetus with CYP21A2 deficiency can become androgenized to various degrees, as illustrated by the Prader classification (Fig. 24.35). High fetal concentrations of 17-OHP, androstenedione, and testosterone are the hallmark of CAH due to CYP21A2 deficiency. More than 75% of patients with classic CAH, characterized by cortisol deficiency, are also salt losers because of their inability to synthesize sufficient mineralocorticoids. This is sometimes referred to as *salt-wasting* 21-hydroxylase deficiency. Other children do not develop such significant salt loss and are termed *simple virilizing*. A third form is *nonclassic* 21-hydroxylase deficiency, which is characterized by mild subclinical mineralocorticoid and glucocortiocoid deficiency but varying degrees of excess androgen production, and usually presents with premature pubarche, irregular menses, or hirsutism but may also be asymptomatic. Salt loss is usually caused by mutations/deletions of the *CYP21A2* gene on chromosome 6p21.3 that result in a completely inactive enzyme. The concordance between genotype and phenotype for the single-gene disorder is reasonably strong but not invariable (Fig. 24.36). In patients who are compound heterozygotes, the phenotype is usually determined by the milder allele. More than 90% of cases result from *CYP21A2* deletion or one of nine mutations derived from recombination with the nonfunctional pseudogene *CYP21P* (see Fig. 24.36). About 5% of *CYP21A2* mutations arise spontaneously.[453] Worldwide, around 100 non–pseudogene-derived mutations are reported for the *CYP21A2* allele.

The diagnosis of CYP21A2 deficiency in a newborn with ambiguous genitalia is readily confirmed by markedly elevated serum 17-OHP concentrations (>300 nmol/L) after the first 48 hours. Sick and/or preterm infants can have moderately increased steroid levels, so ACTH stimulation may be needed to resolve any



• **Fig. 24.36** Diagram of the *CYP21* gene and locations of the mutations that cause more than 90% of cases of 21-hydroxylase deficiency. The *numbered boxes* depict the exons. The three-letter abbreviations for amino acids are used; *X* indicates a nonsense (stop) mutation. An adenine (A) to guanine (G) transition in intron 2 causes a common splice site mutation. Other mutations include an 8-nucleotide deletion (Δ8nt) in exon 3, a thymidine insertion at codon 306 (306+t), and a guanine (G) to cytosine (C) transition at codon 484. The activities of the mutant enzymes, expressed as a percentage of the wild type, are indicated on the vertical axis and in parentheses for some missense mutations. Historic codon numbering is shown. Current classification of codon numbering is usually n + 1 (e.g., Pro30Leu is Pro31Leu, Ile 172Asn is Ile173Asn). *NC,* nonclassic form; *SV,* simple virilizing; *SW,* salt wasting.

diagnostic confusion. The affected male usually has no alerting clinical signs at birth and, if a salt loser, does not decompensate with hyponatremia, hyperkalemia, and weight loss until 1 to 2 weeks after birth.[452] Newborn screening programs to measure blood spot 17-OHP concentrations soon after birth have been introduced in some countries.[454] Elevated 17-OHP can also be seen in conditions such as 3βHSD deficiency, 11β-hydroxylase deficiency, and P450 oxidoreductase deficiency, although the levels are usually not as high as in 21-hydroxylase deficiency.

Treatment of 21-Hydroxylase Deficiency

Prompt diagnosis and treatment of 21-hydroxylase deficiency are required to replace adrenal steroids and to suppress androgen production. Details of adrenal treatment are discussed in Chapter 15, and the approach to diagnosis and initial management are provided later (see "Investigation and Management of Disorders of Sex Development"). 21-hydroxylase deficiency is a potentially life-threatening condition, and the atypical genitalia give an important sign that this diagnosis should be considered.

Of relevance to DSD is the potential to prevent ambiguous genitalia of the newborn through prenatal treatment with dexamethasone, although this treatment is considered experimental.[455,456] Androgenization can be prevented if dexamethasone is administered to the mother early enough in gestation, indicating an intact fetal pituitary-adrenal axis that is responsive to negative-feedback regulation. Treatment is effective if dexamethasone is started by 6 to 7 weeks of gestation but has side effects in treated mothers and fetuses. Traditionally, karyotype analysis and *CYP21* genotype analysis have not been available until weeks 9 to 11, when chorionic villus biopsy can be performed. This means that seven unaffected or male fetuses would need to be treated with dexamethasone during this initial period for every one affected female fetus who might benefit. However, recent advances in the detection of circulating free fetal DNA in the maternal serum have increased the sensitivity and specificity of determining fetal chromosomal sex much earlier in pregnancy.[457] Furthermore, using parental haplotype analysis by targeted massively parallel sequencing of the *CYP21* locus, it has been possible to determine the genotype of the fetus earlier in pregnancy so that fewer unaffected females would be treated.[458] With this approach CAH can be diagnosed using a maternal blood sample drawn at 6 weeks of gestation, although this awaits validation in larger studies.[459] These are all potentially promising advances to prevent exposure of unaffected babies to dexamethasone, if parents do decide to have dexamethasone treatment in pregnancy in a center that offers it.

Several concerns have been raised about the potential effects of dexamethasone on the developing fetus. Although cognitive and motor development based on questionnaires appeared not to be adversely affected by exposure to dexamethasone, direct examination of children who had been exposed to dexamethasone from gestational age 6 to 7 weeks did show adverse effects on verbal working memory compared with control subjects.[460–463] All of these studies were observational, and a meta-analysis emphasized the paucity of good-quality, long-term follow-up data to inform a risk-benefit analysis.[464] Cognitive function may be more affected in girls than in boys.[465] Limited long-term data in older children, adolescents, and adults have suggested that any changes may not persist.[466,467] However, this aspect should be considered when counseling families about prenatal treatment. Clinical practice guidelines have suggested that prenatal therapy should only be undertaken using protocols approved by institutional review boards and at centers capable of collecting long-term outcome data as part of multicenter studies.[468,469]

P450 Oxidoreductase Deficiency

POR is a membrane-bound flavoprotein that plays a central role in electron transfer from NADPH to all microsomal P450 enzymes, including CYP17, CYP21, and CYP19 (aromatase) (see Fig. 24.28). Defects in POR can cause apparent combined CYP17 and CYP21 deficiency, with or without Antley-Bixler syndrome, a form of craniosynostosis. These conditions were described earlier (see "Disorders of Androgen Synthesis").[320,322] POR deficiency can be associated with ambiguous genitalia in both 46,XX and 46,XY infants. The androgenization of 46,XX fetuses may result from a defect in aromatase activity or occur through a proposed backdoor pathway of DHT production that does not involve androstenedione or testosterone as intermediates.[134] Children with this condition usually have cortisol deficiency, but mineralocorticoid function is relatively preserved. Careful monitoring of puberty is needed as this can be delayed or disrupted.[320]

11β-Hydroxylase Deficiency

11β-hydroxylase (CYP11B1) deficiency can cause profound androgenization in an affected 46,XX fetus and accounts for approximately 5% of patients with CAH.[470,471] 11β-hydroxylase deficiency typically presents with ambiguous genitalia in the 46,XX newborn, although in some situations the androgenization may be so marked that the baby is thought to be a boy with a small penis and undescended testes.[472] Subsequently in childhood there can be hyperandrogenism and precocious puberty, with accelerated growth and skeletal maturation. Hypertension occurs in two-thirds of cases as prolonged accumulation of 11-deoxycorticosterone, which has some mineralocorticoid activity, leads to salt and fluid retention, and plasma renin is suppressed. Milder changes in 11β-hydroxylase cause a nonclassic form of the condition, similar to nonclassic 21-hydroxylase deficiency, which presents mostly with hyperandrogenism.[473] The biochemical diagnosis can be made by urine steroid profile and through a pattern of reduced cortisol and elevated intermediates such as 11-deoxycorticosterone.

11β-hydroxylase is encoded by the *CYP11B1* gene, which is located on chromosome 8q21-22 in tandem with *CYP11B2*, which encodes aldosterone synthase, the enzyme catalyzing the conversion of deoxycorticosterone to corticosterone and then to aldosterone. Some *CYP11B1* mutations that cause 11β-hydroxylase deficiency are shown in Fig. 24.37. Most changes are missense mutations. Arg448 appears to be a relative hot spot for mutations, with Arg448His possibly a founder mutation in the Moroccan Jewish population. Treatment of 11β-hydroxylase deficiency includes glucocorticoid replacement to reduce ACTH drive and in some situations antihypertensive treatment.

Familial Glucocorticoid Resistance

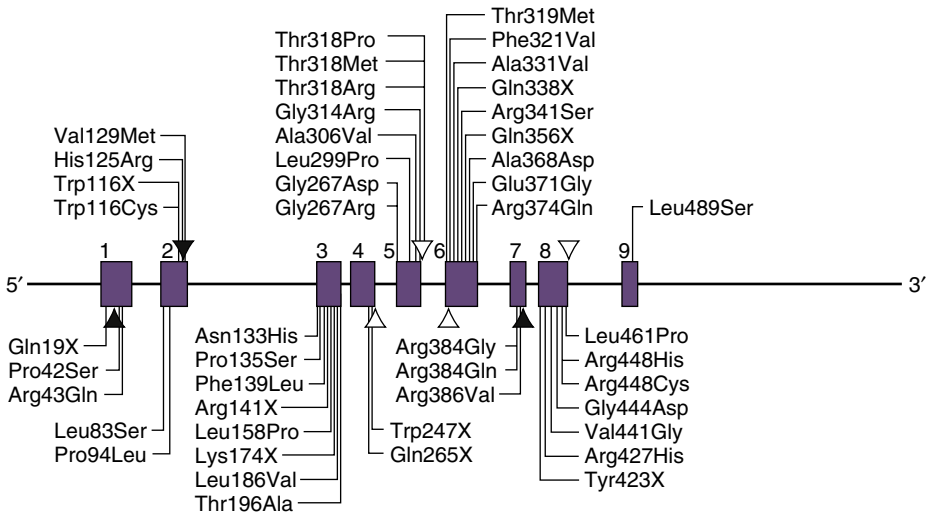
Glucocorticoid resistance is a rare disorder that is usually caused by sporadic heterozygous mutations in the glucocorticoid receptor α-isoform (GRα), encoded by the *NR3C1* gene.[474] Partial end-organ insensitivity to glucocorticoid action coupled with impaired feedback mechanisms results in excess ACTH secretion and elevated circulating cortisol levels without the clinical features of Cushing syndrome. In many cases, elevated levels of mineralocorticoids cause hypertension and hypokalemia, and elevated levels of adrenal androgens cause hirsutism and acne. Although classic glucocorticoid resistance is not associated with atypical genitalia,

one homozygous *NR3C1* mutation (Val571Ala) was reported in a Brazilian girl who had a large clitoris, posterior labioscrotal fusion, and a urogenital sinus at birth.[475] This mutation caused marked reduction in GRα function without complete loss of receptor activity. She also harbored a heterozygous mutation in *CYP21*, which may have influenced the phenotype.

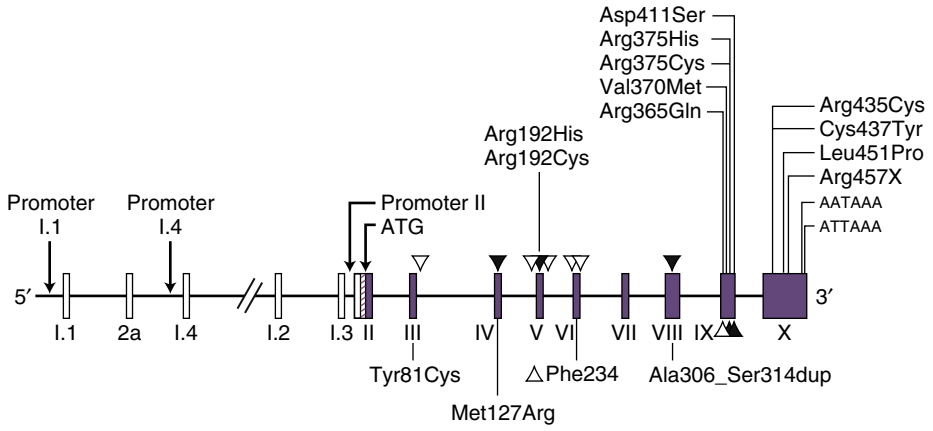
Aromatase Deficiency

Aromatase (CYP19A1), a cytochrome P450 enzyme, is the only enzyme known to catalyze the conversion of androgens (C19 steroids) to estrogens (C18 steroids) in vertebrate species.[476] Aromatase is expressed in many tissues, including the placenta, ovary, brain, bone, vascular endothelium, breast, and adipose tissue, where it is regulated by a number of tissue-specific promoters to convert testosterone to estradiol and androstenedione to estrone (Fig. 24.38). Aromatase plays a crucial role in the local production of estrogens and in the synthesis of circulating estrogens from the ovary at the time of puberty.

Aromatase deficiency due to recessively inherited mutations in *CYP19* has been described in approximately 40 girls with 46,XX DSD (see Fig. 24.38). The clinical and biochemical features of this condition underscore the key role aromatase plays in the



• **Fig. 24.37** Diagram of the *CYP11B1* gene and locations of selected mutations causing 11β-hydroxylase deficiency. The *numbered solid boxes* depict the exons. The three-letter abbreviations for amino acids are used; X indicates a nonsense (stop) mutation. A deletion of cytosine (C) at codon 32 and the addition of two nucleotides at codon 394 cause frameshift mutations; insertions and deletions resulting in a frameshift and splice site mutations are shown by *solid triangles* and *open triangles*, respectively.



• **Fig. 24.38** Diagram of the *CYP19* gene and selected mutations causing aromatase deficiency. The *numbered solid boxes* represent translated exons. The septum in the open box in exon II represents the 3′ acceptor splice junction for the untranslated exons. Multiple alternative promoters and the untranslated exons *(open boxes)* are indicated. The three-letter abbreviations for amino acids are used to indicate the positions of missense mutations; X indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift and splice site mutations are shown by *solid triangles* and *open triangles*, respectively. In addition to the mutations causing classic aromatase deficiency, a homozygous Arg435Cys mutation and deletion of a phenylalanine residue at position 234 are both associated with a partial aromatase insufficiency phenotype. (Modified from Morishima A, Grumbach MM, Simpson ER, et al. Aromatase deficiency in male and female siblings caused by a novel mutation and the physiological role of estrogens. *J Clin Endocrinol Metab*. 1995;80:3689–3698, used with permission of The Endocrine Society, Copyright 1995.)

fetoplacental unit, and this condition is sometimes referred to as *placental aromatase deficiency*. Aromatase plays a critical role in protecting the fetus and mother from excessive androgen exposure during gestation. In the absence of aromatase, estrogen cannot be synthesized by the placenta, and large quantities of placental testosterone and androstenedione are transferred to the fetal and maternal circulation, resulting in androgenization of the female fetus and virilization of the mother during pregnancy.[477]

Females (46,XX) with aromatase insufficiency are born with clitoromegaly, various degrees of posterior fusion, scrotalization of the labioscrotal folds, and in some infants a urogenital sinus with a single perineal orifice.[478–480] There is often a striking history of maternal virilization after the second trimester of pregnancy (e.g., acne, hair growth, voice changes) coupled with elevated maternal androgen levels, which usually resolve after the infant is born, but maternal virilization does not always occur.[481,482] As expected for a steroidogenic defect, affected girls (46,XX) have normal müllerian structures because AMH is not produced. The histologic picture of the ovaries in infancy is normal, but under increased FSH stimulation in the absence of ovarian aromatase, multiple enlarged follicular cysts develop. At puberty, affected females have hypergonadotropic hypogonadism, typically fail to develop female secondary sex characteristics, and exhibit progressive virilization. Plasma androstenedione and testosterone levels are elevated, and estrone and estradiol levels are low or not measurable. The hypergonadotropism and the multiple ovarian cysts respond to estrogen replacement therapy, but in some cases, temporary treatment with an antiandrogen is necessary.

In addition to a role in the reproductive axis, aromatase deficiency has implications for bone development, metabolism, and immune function, as determined by the long-term follow-up of the small numbers of women (46,XX) and men (46,XY) with aromatase deficiency and by studies of aromatase-knockout mice. Males present only after puberty and have tall stature, delayed bone maturation and delayed epiphyseal fusion, and osteopenia, demonstrating that estrogens are essential for normal skeletal maturation and proportions and for the prevention of osteoporosis in males and females.[483] Hyperinsulinemia and abnormal plasma lipids have also been reported in aromatase deficiency, which may in part reflect estrogen insufficiency and/or testosterone overproduction but may also reflect specific actions of aromatase itself. The finding of apparently normal psychosexual development in the three aromatase-deficient adolescent or adult patients and in a man with an estrogen receptor defect suggests that estrogen does not play a critical role in sex differentiation of the human brain, as has been reported in nonprimate mammals.

CYP19A1 mutations cause aromatase deficiency in males and females and are inherited in a recessive fashion (see Fig. 24.38). Functional assays of aromatase activity have shown severe loss of enzyme function (~0.3%) in nearly all cases associated with classic aromatase deficiency; in one case, approximately 1% activity was found for an Arg435Cys change in a compound heterozygous state together with a null Cys437Tyr mutation.[480] Partial aromatase deficiency has also been described; a homozygous Arg435Cys change has been reported in a girl who presented with androgenized genitalia at birth and showed some limited breast development during puberty, and deletion of a single phenylalanine residue (Phe234del) causing partial loss of aromatase activity was described in an androgenized 46,XX individual who achieved significant breast development (to Tanner stage 4) during puberty.[484]

Thus a spectrum of phenotypes may be seen with aromatase insufficiency in humans. This important diagnosis should be considered in all androgenized 46,XX infants when more common forms of CAH (e.g., CYP21 deficiency) and ovotesticular DSD have been excluded. A history of maternal virilization in pregnancy should always be sought but may not always be present, and increased levels of Δ^4 androstenedione, testosterone, and DHT and low levels of plasma estriol, urinary estriol, and amniotic fluid estrone, estradiol, and estriol may be detected. The diagnosis can be difficult to make during childhood years, when the HPG axis is relatively quiescent, and genetic analysis may be needed.

Maternal Androgen Excess

Maternal sources of androgens that may virilize a female fetus may be endogenous from adrenal and ovarian tumors or exogenous from maternal exposure to androgenic compounds. Danazol, a synthetic derivative of ethisterone with androgenic, antiestrogenic, and antiprogestogenic activities, is used in diverse conditions such as endometriosis, benign fibrocystic breast disease, and hereditary angioedema and in women with unexplained subfertility. It crosses the placenta and is contraindicated in pregnancy in view of reports that a female fetus may become androgenized.[485] Ovarian causes of virilization include primary malignancy and benign lesions such as luteoma and hyperreactio luteinalis. Recurrence in subsequent pregnancies and maternal virilization can occur with luteomas.[486] A case of a similar pattern of recurrent hyperandrogenization without evidence of placental aromatase deficiency has been reported.[487]

Other Conditions Affecting 46,XX Sex Development

Several syndromic associations can cause developmental genital abnormalities in 46,XX females. Complex pelvic anomalies such as cloacal exstrophy can affect both sexes and require major reconstructive surgery for bladder and bowel function and for the lower genital system.

Abnormalities in uterine development can result in bicornate uterus (i.e., Fryns syndrome), uterine hemiagenesis or hypoplasia, or uterine agenesis. These conditions can be part of Mayer-Rokitansky-Küster-Hauser syndrome, which may be associated with vaginal and/or ovarian agenesis as well as with renal, cardiac, and cervical spinal abnormalities, as in MURCS (müllerian, renal, and cervical spine syndrome).[488,489] The cause of these conditions is unknown for most women, although some familial cases have been described, and a mutation in *WNT4* was reported in a patient with absent müllerian structures (uterus and upper vagina), unilateral renal agenesis, and mild hyperandrogenemia.[120] Uterine abnormalities have also been associated with maturity-onset diabetes of the young type 5 (MODY5, *HNF1B*) and with vaginal abnormalities in patients with hand-foot-genital syndrome *(HOXA13)* and McKusick-Kaufman syndrome (*MKKS*, formerly called *BBS6*). Because a prominent clitoris can be associated with conditions such as Fraser syndrome (not to be confused with Frasier syndrome) or neurofibromatosis, careful evaluation is necessary before a hyperandrogenic cause is diagnosed.

Other common conditions that may be mistaken for a more serious underlying disorder include apparent clitoromegaly seen in premature or formerly premature babies or when little labial adipose tissue is present. Assessment by a surgeon or physician with experience in recognizing normal variability in clitoral size is important. Sometimes this form of isolated clitoromegaly can persist into childhood.[490] Labial adhesions are a common finding in female infants. They often resolve spontaneously, although estrogen cream can be used to accelerate the process. Transient

menstrual bleeding during the first week of life can be seen frequently in female infants with the withdrawal of large amounts of estrogens and progesterones after birth. This can be alarming for parents but rapidly resolves, and no treatment is needed.

Investigation and Management of Disorders of Sex Development

DSDs can present at many ages and to a wide range of different health professionals. Some of the most common presentations are shown in Table 24.18, and the range of conditions discussed in our center over a 2-year period is shown in Table 24.19. The potential diagnosis of DSD has major implications for the child and the family. Most people will never have heard of DSD or have thought that they may be faced with, for example, a situation in which they cannot be told immediately whether their newborn is a boy or a girl. Talking about such issues can be difficult, and sensitive and positive support and education from all health professionals is essential to provide parents with knowledge and confidence.[491]

Specialist multidisciplinary (or interdisciplinary) team (MDT) involvement with families, young people, and adults with DSD is important.[1–3,348,492] The pediatric (or adult) endocrinologist plays a central role in the team with support from psychologists, urologists, and other health professionals (Fig. 24.39).[3,492,493] The structure and available expertise vary depending on the center. Specialist MDTs are usually based only at large centers, so effective communication between the team and those health professionals managing the initial presentation is crucial. Sometimes regional or national networks (e.g., the Scottish Genital Anomalies Network) are needed to provide support where the population is scattered geographically or to link experts in different centers together, with meetings held by teleconference rather than in person.[494] It is important to keep the primary care physician informed. It is also useful for families to have a clearly defined point of contact if they need to ask further questions.

Although there is often uncertainty at the start, a general diagnosis can usually be reached following a series of careful assessments and basic investigations. Reaching a more specific diagnosis can be important in some situations and may take longer and involve more detailed investigations or genetic tests (discussed later). Every person is different, and many DSD-related conditions can have a spectrum of presentations, so it is also important to take an individualized approach to the child and the family.

The following is a discussion of the investigation and management of DSDs at different ages. Several overarching themes are subsequently highlighted. More extensive details for specific conditions are discussed earlier in the chapter.

TABLE 24.18 Common Presentations of DSDs at Different Ages

Presentation	Feature	Examples
Prenatal	Karyotype-phenotype discordance	Complete androgen insensitivity, 46,XY complete gonadal dysgenesis, 46,XX testicular DSD with SRY translocation
Neonatal	Atypical genitalia	21-hydroxylase deficiency (46,XX), 45,X/46,XY mosaicism, partial AIS, 5α-reductase deficiency, SF1/*NR5A1* (46,XY)
	Salt-losing crisis	21-hydroxylase deficiency, 3βHSD deficiency (46,XX) StAR, CYP11A1, 3βHSD deficiency, SF1/*NR5A1* (46,XY)
Childhood	Inguinal hernia	Complete AIS
	Androgenization	21-hydroxylase deficiency, 11β-hydroxylase deficiency
	Associated features	Wilms tumor
Puberty	Androgenization	17βHSD deficiency, 5α-reductase deficiency (rarely SF1/*NR5A1*, partial AIS, ovotestes)
	Absent puberty	Complete gonadal dysgenesis (Swyer syndrome), 17α-hydroxylase deficiency
Postpuberty	Amenorrhea	Complete AIS
Adult	Tumors	Minimal AIS, SF1/*NR5A1*, etc.

AIS, Androgen insensitivity syndrome; *CYP*, cytochrome P450 enzyme; *DSDs*, disorders/differences of sex development; *HSD*, hydroxysteroid dehydrogenase; *SF1*, steroidogenic factor 1; *StAR*, steroidogenic acute regulatory (protein).

Prenatal Diagnosis

Prenatal diagnosis of DSD is increasingly common as fetal ultrasonography improves and as more people have karyotype analysis or cell free fetal DNA for various reasons in pregnancy.[495] Although some prospective parents choose not to know the sex of their baby, many couples ask whether they are having a boy or a girl, and issues can arise when the genital appearance is unclear on the scan or when the appearance of the genitals is discordant with the known karyotype. These situations can generate great anxiety, and early contact with the DSD MDT is helpful to support the parent(s). Sometimes prenatal genetic testing such as a microarray is considered, especially when multiple congenital anomalies are suspected on ultrasound. However, prenatal genetic testing can occasionally produce inaccurate results that are not confirmed on karyotyping of the baby (e.g., in cases of twin fetal demise). Also, genital appearance at birth can differ from that seen on prenatal scans. Support to deal with the uncertainty and explanations of what will happen if their baby does have atypical genitalia are important, and discussion of specific diagnoses is best deferred until after birth. Nonetheless, prenatal suspicion of DSD can have benefits as it gives parents time to learn about possible conditions and to think how they will deal with the situation as long as support is provided in a sensitive manner.

The Newborn With Atypical Genitalia

The most established presentation of DSD occurs when a newborn baby has atypical (or ambiguous) genitalia, and it is not possible to say immediately whether the baby is a boy or a girl. Sometimes atypical genital features are first discovered on the first full newborn examination rather than immediately at birth. Further investigations such as a karyotype are usually needed, and specialist review may be required. It is estimated that around 1 in 4500 babies cannot have a sex designated immediately at birth, although the exact incidence is not known. Some presentations

TABLE 24.19 The Range of Diagnoses of DSD Seen in a Single Center Over 2 Years

Sex Chromosome DSD (n = 13)	46,XY DSD (n = 65)	46,XX DSD (n = 23)
A: 47,XXY (Klinefelter syndrome and variants) (2)	A: Disorders of gonadal (testis) development	A: Disorders of gonadal (ovary) development
B: 45,X (Turner syndrome and variants) (2) (both Y fragment)	Complete gonadal dysgenesis (7)	Ovotesticular DSD (1)
C: 45,X/46,XY mosaicism (mixed gonadal dysgenesis and variants) (8)	Partial gonadal dysgenesis (8)	Testicular DSD (1)
D: 46,XX/46,XY (chimerism/mosaicism) (1)	Steroidogenic factor 1 (2)	
	B: Disorders in androgen synthesis or action	B: Androgen excess
	Disorders of androgen biosynthesis	Fetal
	StAR (1)	21-hydroxylase (10)
	17βHSD3 (2)	11β-hydroxylase (2)
	5α-reductase 2 (6)	Fetoplacental
	Disorders of androgen action	Maternal
	CAIS (6)	
	PAIS (5)	
	C: Other	C: Other
	Syndromic associations of male genital development (11) (e.g., chromosomal variants, skeletal, lung, skin, gastrointestinal, Cornelia de Lange, CHARGE)	Syndromic associations (e.g., cloacal anomalies) (1)
		Müllerian agenesis (1)
	Cloacal anomalies (1)	Clitoromegaly, possible clitoromegaly or clitoral variants (6)
	IUGR/preterm/hypospadias (4)	Ovarian cysts (1)
	Persistent müllerian duct syndrome (3)	
	Vanishing testis syndrome (2)	
	Isolated severe hypospadias (4)	
	Micropenis (1)	
	Bilateral undescended testes (2)	

CAIS, Complete androgen insensitivity syndrome; *CHARGE,* coloboma, heart defect, atresia choanae, retarded growth and development, genital hypoplasia, ear anomalies (deafness); *DSDs,* disorders of sex development; *IUGR,* intrauterine growth restriction; *PAIS,* partial androgen insensitivity syndrome; *StAR,* steroidogenic acute regulatory (protein).

• **Fig. 24.39** Overview of the multidisciplinary team (MDT). (From Brain CE, Creighton SM, Mushtaq I, et al. Holistic management of DSD. *Best Pract Res Clin Endocrinol Metab*. 2010;24:335–354.)

may be mistaken for a DSD condition, such as labial swelling after a breech delivery, undescended testes, or mild hypospadias, which can affect up to 1 in 300 male infants. Examples of genital features that should trigger consideration of a DSD condition are outlined in Table 24.20. In particular, any child with nonpalpable testes needs careful review because this child could—rarely, but importantly—be a 46,XX baby with severe, life-threatening CAH.

History and Examination

A careful history is important but must be done sensitively and rarely points to an immediate diagnosis. Key points to consider include aspects of the pregnancy such as growth restriction and preeclampsia, maternal acne or hair growth in pregnancy (which would suggest aromatase or POR deficiency), and any prenatal tests or scans performed. Theoretically, medications and drugs may have an effect on the fetus (e.g., 5α-reductase inhibitors), and assisted reproduction or the need for fertility treatment might indicate an underlying and variably penetrant genetic cause. A careful family history should include any history of adrenal conditions, known CAH or infant death, other known DSD, hypospadias, or infertility (with attention to X-linked patterns that could suggest androgen insensitivity syndrome), but such issues may not be known or widely discussed. Consanguinity is associated with an increased risk of autosomal recessive conditions such as many of the steroidogenic enzyme deficiencies. It is important to understand the parents' thoughts and beliefs and not to generate additional anxiety by insensitive questions.

A careful physical examination is needed but should be done sensitively and only after the parents have had some time to be with their baby. Key features to note are the length of the phallus, consistency of the corpora and glans, extent of chordee; scrotal transposition (extension of the scrotal folds above the phallus), features of the foreskin (hooded, excess skin), position of the urethral opening; presence or absence of a separate vaginal opening, rugosity (wrinkling of the scrotal skin, also called scrotalization) and degree of midline fusion of the labioscrotal folds, and size and position of any palpable gonads (likely to be testes). Genital appearances can sometimes be misleading because of chordee (bending and tethering of the phallus) and/or a large suprapubic fat pad, so palpation as well as inspection is important. Various scales such as the external masculinization score, the Prader scale, and the Quigley scale can be used to summarize findings and are particularly useful for research purposes, but it is also important to note and document individual features (Fig. 24.40).[376]

TABLE 24.20 Problems in Newborns That Merit Investigation for DSDs

Ambiguous (atypical) genitalia
Apparent female genitalia
Enlarged clitoris
Posterior labial fusion
Inguinal/labial mass
Apparent male genitalia
Nonpalpable testes
Isolated penoscrotal hypospadias
Severe hypospadias, undescended testes, micropenis
Family history of DSD, such as complete AIS
Discordance between genital appearance and prenatal karyotype

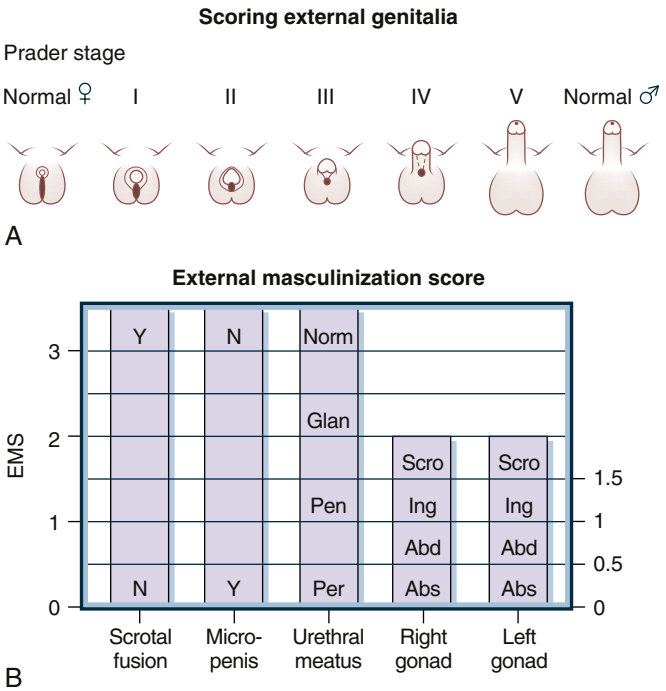
AIS, Androgen insensitivity syndrome; *DSDs*, disorders of sex development.

Asymmetry of the genitalia can suggest mixed gonadal dysgenesis associated with 45,X/46,XY mosaicism and can also be seen in partial gonadal dysgenesis or ovotesticular DSD. Other findings such as low birthweight; position of the anus; skeletal, cardiac, or other congenital anomalies; and dysmorphic features are important to note. Hyperpigmentation is a rare but important sign of primary adrenal insufficiency due to elevated ACTH, but increased labioscrotal pigmentation can often be seen in babies of Asian or African ancestry.

The Initial Approach to the Baby With Atypical Genitalia

A useful mnemonic for the initial approach is BASIC: *b*onding, *a*drenal insufficiency, *s*ex designation, *i*maging, and *c*ytogenetics. Each of these is introduced briefly here and discussed more extensively elsewhere.

Bonding between the parents and baby can be disrupted by the shock of the situation or if the newborn is taken away to an intensive care nursery without good reason. Allowing parents time to focus on their new baby is important, and putting the genital issue aside at times is key. At the same time, the impact of the situation should not be trivialized; striking the right balance requires an individualized approach involving frequent feedback from parents. Nursing staff can play a crucial role in helping families initially by engaging with them and acknowledging the stress that uncertainty can bring while also addressing routine newborn issues such as establishing feeding, changing diapers, and sleeping.



• **Fig. 24.40** (A) Prader staging for scoring the degree of androgenization of the external genitalia in a female infant with congenital adrenal hyperplasia. (B) The external masculinization score (EMS) is used to assess the degree of underandrogenization in an individual with 46,XY DSD. The score is based on the presence or absence of a micropenis and bifid scrotum, the location of the urethral meatus (normal, glandular, penile, perineal), and the position of the testes (scrotal, inguinal, abdominal/absent). (B, from Ahmed SF, Khwaja O, Hughes JA. The role of a clinical score in the assessment of ambiguous genitalia. *BJU Int*. 2000;85:120–124.)

Staff members themselves may feel uncomfortable and may also need support and guidance.

Adrenal insufficiency is associated with some causes of DSD and is potentially life threatening if not promptly recognized and treated. The common scenario is a 46,XX baby with 21-hydroxylase deficiency, which occurs in about 15% to 20% of babies with atypical genitalia, more in some studies. Adrenal insufficiency can also occur in 46,XY babies (e.g., StAR, CYP11A, HSD3B2, CYP17A1, NR5A1) but is rare. Monitoring for hypoglycemia, hyponatremia, and hyperkalemia is necessary, but the electrolyte changes usually take several days to manifest. During this time the infant can be kept with its mother if otherwise well. Micropenis and/or undescended testes may be caused by gonadotropin deficiency, which can be associated with deficiency of other pituitary hormones, including ACTH.

Sex designation should be undertaken as soon as possible but should not be rushed. Parents sometimes have strong preconceptions about their baby, especially if they have been told prenatally to expect a boy or a girl, and/or may want a child of a specific sex to fit their desired family structure. If wrong decisions are made, it can be very traumatic to reverse them, so keeping an open mind from the start and avoiding premature recommendations is critical.[496] In the interim, it is advisable to use neutral terms such as "phallus" rather than "penis" or "clitoris," and to refer to the child as "your baby," "your child," or "little one" rather than "he" or "she."

Imaging is useful but can be operator dependent, and results can sometimes be deceptive. Pelvic ultrasound or MRI can show internal structures, but structures are not always clearly visualized, a utricular remnant (commonly found in boys with hypospadias) can be confused with a uterus, and lymph nodes can be confused with testes.[228,497] Parents and providers need to know the limitations of these tests.

Cytogenetics, or a rapid assessment of sex chromosome complement, is essential. This testing has been done traditionally by fluorescence in situ hybridization for X-chromosome and Y-chromosome markers (see Fig. 24.3), but in some centers is now being performed by quantitative fluorescent polymerase chain reaction (qfPCR) on DNA. The relevant laboratories should be informed of the urgency of the test, and samples should be transported quickly. An attempt to look for mosaicism should be made by determining the genotype in a sufficient number of cells, but FISH on a second tissue (such as a buccal smear) may be necessary to detect mosaicism. Rapid karyotyping can help with the next stages of management and investigation, and a result is usually available within 2 working days.

Support for the Parents

Providing parents with adequate support in the first days while awaiting results is essential.[491] It can be useful to stress that many other parents are in a similar position each year, that specialists who have knowledge and experience are available, and that the situation will become clearer in the next days. Expressions of anxiety by the staff may exacerbate anxiety in the parents. On the other hand, excessive nonchalance may be viewed as trivializing a serious situation. Parents need to be provided with information about the tests performed and a realistic expectation of when results will be available. They should be encouraged to ask questions and to rediscuss information that is not clear or difficult to understand. Sometimes recording conversations can be helpful so that families have an opportunity to listen to information again.

Being repeatedly asked by family and friends if they have a boy or a girl can be highly stressful for parents. There is no single strategy that suits all parents, but many seek the safe haven of the hospital and will try to delay announcing the birth until the situation is clearer. It is reasonable to ask friends for some private time and to say that they will be in touch soon with more information. It often helps parents to confide in one or two close friends or family members; sometimes parents can be under pressure with work, and siblings may have questions or need care. Several resources have been developed to help support parents during this time.[498] It is important to emphasize to parents that they need to look after themselves, too.

Sex Designation

Most people wish to raise their child as either a boy or a girl. Sufficient information should be gathered so that parents can be informed and educated to make the best decisions for their child. This should be done as quickly as practical but without rushing decisions. The karyotype per se does not determine gender identity, but it is a useful starting point for focusing investigations and reaching a diagnosis (see Table 24.3 for classification of DSDs). A broad diagnosis is often sufficient for designating sex, and a more specific diagnosis can be reached later. Within the context of the karyotype and diagnosis, useful points to consider are the child's future gender identity, functional anatomic aspects such as likely urologic and sexual function, potential endocrine function (whether consistent or inconsistent with designated sex), fertility options, and the risk of gonadal tumors. Many of these questions are difficult to answer, and in some situations more investigations may be undertaken to inform the parents, but often the choice is relatively straightforward based on findings from physical examination, imaging studies, and karyotype. Current recommendations are for 46,XX individuals with congenital adrenal hyperplasia to be raised as girls, though some have suggested that those with highly androgenized genitalia may be raised as boys.[499] A female sex designation is appropriate for 46,XY individuals with complete androgen insensitivity syndrome or complete gonadal dysgenesis (Swyer syndrome), who have female-appearing external genitalia and are highly likely to identify as women in adulthood; a female sex designation is probably also appropriate for those with minimal androgenization (e.g., isolated clitoromegaly). Particularly challenging situations arise in babies with limited phallic development and a 46,XY karyotype who have intact testosterone responsiveness (such as 17β-hydroxysteroid dehydrogenase deficiency, 5α-reductase deficiency, and partial testicular dysgenesis) or with mixed internal and external phenotypes (e.g., 45,X/46,XY or various forms of ovotesticular DSD). In the past there was a greater focus on the genitalia and a tendency to raise children with a very small phallus as female. More recently, there has been a trend to raise more 46,XY children as male and to look at other aspects of the child such as likely gender identity, possible fertility, and endocrine function.[392] Sometimes, cultural influences can be important for the parents.[500] In most countries there is a time limit to register the birth of a baby (e.g., 42 days in England and Wales), but this can usually be deferred or done without defining sex (e.g., in Germany).

Investigations for DSDs

Once the initial analysis of sex chromosomes is available, several investigations can be undertaken to reach a more specific diagnosis or to obtain a more detailed assessment of urogenital anatomy and future function.[2,492] It is difficult to develop rigid guidelines for investigations because local availability and affordability of tests around the world vary greatly.[501] Details of some of the commonly used tests for DSD are shown in Table 24.21, and potential investigations based on karyotype are shown in Fig. 24.41. It is important to consider what the likelihood of a specific diagnosis might be. An overview of diagnoses discussed in our setting is shown in Table 24.19, but in areas of the world with greater consanguinity, the relative prevalence of recessive conditions such as CAH is greater. There may also be hotspots of specific diagnoses due to founder effects (e.g., 5α-reductase in the Dominican Republic), so knowledge of the local prevalence of certain conditions is important. Genetic testing is more widely available and may sometimes avoid the need for invasive tests or prolonged endocrine stimulation, but it has certain drawbacks, which are discussed later.[335]

Chromosomal DSD

In our experience, approximately 10% to 15% of newborn referrals have a chromosomal DSD (usually 45,X/46,XY), and an individualized approach is needed.[3,207] This includes assessment of anatomy and gonadal function and, if indicated, screening for Turner syndrome–associated features (e.g., renal and cardiac conditions) (see Fig. 24.41). Sometimes an early examination under

TABLE 24.21 Potential Investigations for DSDs

Approach	Test	Uses
Genetics	FISH[a] (X-specific and Y-specific probes)	Rapid analysis of sex chromosome complement on cells
	qfPCR[a]	Rapid analysis of sex chromosome signal in DNA
	Karyotype[a]	Analysis of sex chromosomes and autosomes in cells with ability to look for mosaicism by screening multiple cells, as well as detection of major deletions, duplications, and balanced translocations
	Array CGH or SNP microarray[a]	Analysis of chromosome signal across the genome, with ability to detect smaller copy number variants but not balanced translocations, using DNA
	Multiple ligation probe-dependent amplification	Analysis of the loss or gain of specific exons or whole genes on a predefined panel of probes, such as for DSD genes, using DNA
	Single-gene analysis	Sanger sequencing and analysis of individual genes that are highly likely to be the cause of DSD based on incidence and clinical and biochemical features (e.g., *CYP21A2*)
	Targeted panel sequencing	Analysis of large numbers of known DSD-causing genes using high throughput sequencing of DNA
	Whole-exome sequencing	Analysis of all the coding exons in the DNA, which may show changes in known, putative, or novel DSD-associated genes, using high-throughput sequencing
Endocrine	Routine serum biochemistry[a]; urinalysis[a]	May reveal a salt-losing crisis or associated renal disorder (e.g., WT1)
	17-hydroxyprogesterone,[a] 11-deoxycortisol, 17-hydroxypregnenolone	May help to diagnose CAH or reveal a specific block in an adrenal pathway relevant to DSD
	Renin, ACTH	May show a salt-losing state or primary adrenal insufficiency
	Testosterone,[a] androstenedione, DHT; in the basal state or following hCG stimulation	Indicates the degree of androgen production and ratios of androgens and may help to diagnose a block in androgen production consistent with a specific diagnosis (e.g., 17βHSD or 5α-reductase deficiencies); can also reveal androgen production in ovotesticular DSD
	Gonadotropins	May indicate an underlying block in steroidogenesis or androgen insensitivity (LH), or impaired Sertoli cell function (FSH), or gonadal dysgenesis (FSH and LH)
	AMH, inhibin B	Can be useful markers of testicular integrity: AMH is detectable throughout childhood and is reduced in testicular dysgenesis or absent in case of streak gonads or anorchia; AMH may be high in AIS or reduced androgen production due to steroidogenic defects; AMH may help to reveal the presence of testicular tissue in 46,XX (ovo)testicular DSD
	Urinary steroids by GC/MS	Can be used to diagnose specific steroidogenic defects in the newborn period (e.g., 21-hydroxylase deficiency, 11β-hydroxylase deficiency, 3β-hydroxysteroid dehydrogenase deficiency, P450 oxidoreductase deficiency, 17α-hydroxylase deficiency); can reveal 5α-reductase deficiency only after 3–6 months of life
	Dynamic tests: ACTH stimulation	Used to assess the adrenal gland stress response (quantitative) and can be coupled with measurement of steroid metabolites or poststimulation urine steroid analysis to study ratios of metabolites (diagnostic)
	hCG stimulation	Used in short (e.g., 3 day) or prolonged (e.g., 3 week) formats to assess androgen production (quantitative) and androgen biosynthesis pathways (diagnostic); can also be used to assess the presence of testicular tissue (e.g., anorchia, ovotestis), although AMH is now more often used initially
	FSH stimulation test	Rarely used to investigate the presence of ovarian tissue by measuring inhibin A and estradiol response

TABLE 24.21 Potential Investigations for DSDs—cont'd

Approach	Test	Uses
Imaging	Abdominopelvic and renal ultrasound[a]	Can reveal the size, position, and structure of gonads (especially testes), the presence of müllerian structures, and associated changes (such as renal size or anomalies)
	MRI	Sometimes used to assess internal structures, especially in adolescence
	Cystourethroscopy, sinogram	Can reveal the structure of the bladder, vagina, and common channel
Surgical	Laparoscopy	Can reveal internal structures by direct visualization, such as gonads and müllerian structures
	Gonadal biopsies	Can be used to determine the nature of gonads, especially if dysgenetic testes or ovotestes are suspected

[a]Indicates first-line investigations for which results are available within days. For images of G-banded karyotypes and FISH analysis, see Fig. 23.3.

anesthesia and laparoscopy is performed to assess anatomy and to determine gonadal characteristics and histologic features.

46,XX DSD

The majority of babies with a 46,XX DSD have 21-hydroxylase deficiency, although other rarer forms of CAH, ovotesticular DSD, and clitoromegaly associated with prematurity are seen. Children have variable genital appearances; sometimes the baby may have a clitoris that is naturally large (Table 24.22) or appears slightly more prominent or with excess clitoral skin. However, any 46,XX baby with atypical genitalia must be assumed to be at risk of adrenal insufficiency until proved otherwise. Serial electrolytes should be monitored and tests to confirm or refute the diagnosis

Consensus statement on management of intersex disorders. *Arch Dis Child*. 2006;91:554–562, used with permission.

should be undertaken according to local protocol and assay availability (such as 17-OHP, basal and stimulated cortisol, ACTH, plasma renin activity, and urine steroid profiling). Results can be inaccurate before 3 days of age using conventional assays due to interfering substances, although liquid chromatography/tandem mass spectrometry (LC/MS-MS) assays may be more useful if available.[502,503] Steroid replacement treatment can be started once the diagnosis is clear and any additional samples obtained. Of note, 17-OHP can be mildly elevated in other forms of CAH (e.g., 11β-hydroxylase deficiency, 3βHSD, POR), and investigation of steroid intermediates (e.g., 11-deoxycortisol, 11-deoxycorticosterone, 17-hydroxypregnenolone) and urine steroid profiling can be useful in these situations.[350] If all adrenal investigations are negative, rare diagnoses such as 46,XX ovotesticular DSD and aromatase deficiency should be considered and AMH measured to investigate for testicular tissue.[492] The presence of ovarian tissue can be difficult to assess in early infancy without laparoscopy or even biopsy. Occasionally, follicles can be seen on imaging, or there can be a rise in estradiol and inhibin A following recombinant FSH stimulation, but such tests are rarely performed.[175]

46,XY DSD

The most common newborn karyotype in our experience is 46,XY, which occurs in approximately 60% of babies with atypical genitalia. These children can have a range of conditions, including variable forms of partial testicular dysgenesis, disorders of androgen synthesis and action, or other diagnoses such as proximal hypospadias of unknown cause or a DSD-associated syndrome. In some situations, the diagnosis might influence decision making. For example, some clinicians would advocate raising a baby with 5α-reductase deficiency as a boy and giving dihydrotestosterone cream, whereas a child with androgen resistance causing a more severe form of PAIS might be raised as a girl. Basic investigations in the 46,XY baby can include karyotype or array analysis looking for established chromosomal alterations (e.g., 9q deletion, 10p deletion, Xp21 duplication) and basal assessment of testis integrity (e.g., AMH/MIS, androgens).[2,125] Additional diagnostic tests to assess androgen synthesis include basal androgens (DHEA, androstenedione, testosterone, DHT) and short-term and long-term hCG-stimulated androgens.[504] Basal androgens may be low initially and can be reassessed during minipuberty, around age 6 to 8 weeks. The ratios of intermediates after hCG stimulation can be useful in diagnosing specific blocks, such as 17β-hydroxysteroid dehydrogenase deficiency (testosterone to androstenedione ratio often <0.8) and 5α-reductase deficiency (testosterone to dihydrotestosterone ratio often >10–20).[349] However, these assays may not be accurate in the first few days of life unless performed by LC/MS-MS, and diagnosing these conditions by androgen ratios or urine steroid profiling can be difficult in the first few

months of life, possibly because of other pathways or isoenzymes influencing the results.[350] Adrenal disorders do occur but are rare. Most children with complete blocks in steroid production (e.g., StAR, CYP11A1) do not present with atypical genitalia but rather present as a phenotypic girl with a salt-losing crisis, and the 46,XY karyotype is only found afterward. Atypical genitalia at birth can be a sign of *partial* defects in high steroidogenic enzymes (e.g., partial StAR, CYP11A1) or *partial* 17α-hydroxylase insufficiency (CYP17A1), as well as classic presentations of 3β-hydroxysteroid dehydrogenase deficiency (3βHSD2) or P450 oxidoreductase deficiency (POR). It is currently unclear whether detailed investigations of adrenal function are justified in all boys with 46,XY DSD, but an adrenal diagnosis should at least be considered.

Genetic Testing and DSDs

Genetic testing plays an increasingly important role in the diagnostic process.[505] It is important for reaching a specific diagnosis (for both the individual and other affected family members), as well as counseling about the risk of recurrence in future children, defining the need to look for associated features, and in some situations providing guidance on issues such as potential gender identity, endocrine function and fertility, and tumor risk.[334] Reaching a specific genetic diagnosis can provide a sense of resolution and reduce uncertainty but may generate anxiety if no cause is found or if incidental genetic information is uncovered. Parents may experience guilt or blame for transmitting a mutation to their child. Individuals and families should have a clear understanding about what genetic tests are being performed and what the potential benefits and disadvantages might be. Genetic testing can be expensive and may not be available or affordable locally, especially as a clinical service.[334]

Approaches to genetic testing are changing rapidly with new technologies for the analysis of chromosomes as well as individual genes. In some centers, sex chromosome FISH is being replaced by qfPCR, and microarray or array-based comparative genomic hybridization (CGH) approaches are being used to replace or supplement traditional karyotype analysis. These technologies can detect much smaller copy number variations than traditional G-banded karyotypes but do not detect balanced translocations and, as with traditional karyotyping, may miss low levels of mosaicism. Multiplex ligation-dependent probe amplification (MLPA) is a method of looking for specific copy number changes (deletions or duplications) in known DSD genes (e.g., duplication of *NR0B1*, or loss of exons of other genes) that are too small to be detected on arrays.

Analysis of single genes is also changing with the development of next-generation sequencing approaches. Traditionally, candidate genes for a condition were amplified one by one by PCR and analyzed by Sanger sequencing. This direct sequencing approach is still the method of choice when there is a clear candidate gene from biochemical analysis (e.g., *HSD17B3, SRD5A2*), especially when the presence of a pseudogene can make sequencing difficult (e.g., *CYP21A2*).[334] However, this approach is relatively time consuming and expensive, particularly if there are several candidate genes. Newer approaches involve using NGS to sequence panels of genes relevant to DSD or sequencing all of the exome or even whole genomes.[176,506] These methods can provide high throughput analysis but are still expensive, generate large amounts of data (including so-called bystander or incidental data for other genes, which may or may not be desired), and are still mostly only available as research tools, although increasingly these approaches are used in clinical testing. Positive findings can be validated by focused clinic testing, which can then provide useful information for the family and clinician. Interpretation of identified variants in DSD genes can be challenging and may require detailed information on anatomy and endocrine function in the affected individual, genetic analysis in family members (to look at segregation of the variant with the phenotype), or (in vitro) functional studies of the variant.

Given the advances in genetics and increasing recognition that DSD can be a feature of many well-defined syndromes, a clinical geneticist can be a very valuable member of the MDT, especially when a child needs to be examined for additional syndromic features or when the family needs to be counseled about genetic testing and the significance of any results.

Presentation During Childhood

DSD can occasionally present during the childhood years. Sometimes a parent may notice genital differences for the first time in childhood or feel inguinal masses that turn out to be testes. A small proportion of inguinal hernias in girls are found to contain testes, most often in patients with CAIS. Sometimes associated features present for the first time in childhood; for example, a small proportion of boys with penoscrotal hypospadias develop an abdominal mass due to a Wilms tumor and are found to have Denys-Drash syndrome (due to mutations in *WT1*).

Presentation During Adolescence

Another common time for DSD to present is during adolescence in one of three well-recognized ways: (1) a girl who experiences spontaneous virilization at puberty, (2) a girl with absence of pubertal development, and (3) a girl who has primary amenorrhea after having normal breast development.[2] Although the situation is not as urgent as in the newborn who may be at risk of salt-wasting CAH, it is equally if not more important to handle the situation with sensitivity, as the young person is aware of the issues as well as the parents and must be involved in decision making and consent.

The conditions that are typically associated with virilization at puberty are 5α-reductase deficiency type 2 and 17β-hydroxysteroid dehydroxygenase deficiency type 3. Alternative diagnoses include cases in which previous clitoromegaly may have been overlooked in partial testicular dysgenesis (e.g., mutations in *SF1*/*NR5A1*),[507] partial androgen insensitivity syndrome, or testicular/ovotesticular DSD. Usually the diagnosis is relatively straightforward based on serum concentrations and ratios of androgens, urine steroid profiling, and genetic testing.[2] It is best to avoid further stimulation with hCG tests if virilization is undesired, and some have proposed that puberty can be blocked for a period with a GnRH analog, or if not available, antiandrogens to provide time to obtain a genetic diagnosis, educate and counsel the young person and the family, and give them time make a decision. An MDT approach is invaluable, and the input of an experienced psychologist or expert in gender medicine is key. A proportion of young people with 5α-reductase deficiency will choose to transition from female to male, and this has also been reported for some individuals with 17-HSD deficiency.[151,152] Many girls with these conditions continue to identify as females and often want to have their gonads removed; appropriate counseling about risks,

benefits, and fertility options is essential. If gonads are dysfunctional or removed, puberty will need to be induced with estrogens. Gathering and sharing the information and providing psychological support over a period of time can help ensure that the young person makes the best choices for the future.

Another presentation in adolescence is a girl who does not have any pubertal development. This situation may represent many diagnoses in a 46,XX girl, including constitutional pubertal delay, hypogonadotropic hypogonadism, and congenital or acquired (e.g., autoimmune) primary ovarian insufficiency. Absence of pubertal development may also be the presenting feature of sex chromosomal DSD (Turner syndrome) or a 46,XY DSD (complete gonadal dysgenesis or 17α-hydroxylase/17,20-lyase deficiency). In complete testicular dysgenesis (Swyer syndrome), both Leydig cell production of testosterone and Sertoli cell production of AMH are impaired. As a result, müllerian structures are typically present. The immature uterus may be difficult to see, even on MRI scan, but may become more easily visualized following estrogen treatment (the "clandestine" uterus).[508] Dysgenetic gonads, which may appear streak-like (i.e., flat and scar-like), have a high tumor risk even in prepubertal children and should therefore be removed. True streak gonads (i.e., gonads that consist of fibrous tissue and lack germ cells and support cells) are not at risk of germ cell cancers (GCC) by definition, but this can only be confirmed at histologic examination. The underlying cause of complete gonadal dysgenesis may be a range of genetic conditions (see Table 24.6), but a cause is often not found. Puberty can be induced with estrogens. In contrast, 46,XY girls with 17α-hydroxylase/17,20-lyase deficiency have intact Sertoli cell function and AMH production, and as a result they do not have a uterus. The block in adrenal steroidogenesis can be associated with hypertension and hypokalemia, which can cause arrhythmias, so this is a rare but important diagnosis to make. Estrogen treatment is needed. The gonads are typically undescended but not dysgenetic, and the risk for GCC in pubertal children is likely to be low, but there may be an increased risk of germ cell tumors in late adolescence and adulthood. Two large studies of gonadal tumors in XY DSD individuals, which included 42 females with 17α-hydroxylase/17,20-lyase deficiency, reported one dysgerminoma, two Sertoli cell tumors, and one Leydig cell tumor.[509,510] A decision about gonadectomy should be made after discussing these risks.

The third common presentation is with primary amenorrhea in a girl who has experienced breast development. Acquired hypogonadotropic hypogonadism should be considered, and primary ovarian insufficiency may also be associated with some breast development but absent menarche. Hormone measurements, a karyotype, and pelvic ultrasound are often useful initial investigations.[2] If a uterus is visualized, obstruction of the outflow tract is likely, such as imperforate hymen; this is usually accompanied by cyclic abdominal pain. In the absence of a uterus, the diagnosis is most likely a form of uterine agenesis, such as MRKH syndrome if the karyotype is 46,XX and complete androgen insensitivity syndrome (CAIS) if the karyotype is 46,XY. Girls with CAIS often have reduced pubic and axillary hair. Detailed discussion about the management of these conditions is provided earlier in this chapter (see "Complete Androgen Insensitivity Syndrome").

Presentation During Adulthood

Occasionally, DSD may first present in adulthood. Examples include mild variants in DSD genes associated with male factor infertility or ovarian insufficiency (e.g., *NR5A1*), conditions such as persistent müllerian duct syndrome when a uterine-like structure is found incidentally in a man, or when a person with a more typical form of DSD presents to health professionals later in life, sometimes after migration from a medically underserved area or from one country to another.

Information Sharing, Transitioning, and Adult Services

Information sharing (disclosure) is an important part of educating people about their condition and giving them insight into the future. In the past, there was more secrecy around DSD, but most research supports sharing information in an age-appropriate manner over time.[511] Sometimes parents need considerable help in how to deal with questions and concerns, and psychological support is important to allow them to feel confident in discussing these issues with their child.[491,512,513] Education is an ongoing process and must account for ongoing changes with the child's cognitive development.[511,514] Different families may prefer different strategies, but being prepared for an open dialogue when opportunities arise usually works well. Sometimes a psychologist or pediatric endocrinologist can provide information at key stages and support the family in reinforcing information or answering questions as they come up. It is important to discuss what terminology the child and parents prefer; most people prefer the use of the specific diagnosis rather than the general term DSD.[515]

During childhood, growth and development are monitored. In adolescence, hormone replacement therapy may be indicated in cases of gonadal dysfunction, or as discussed, in some situations puberty may be blocked to delay the progression of virilization.

Transitioning the care of young people from pediatric to adult services is another important aspect of the care of DSD management.[516,517] Often the pediatric endocrinologist will induce puberty before transfer to an adult endocrinologist, but it may be useful to involve the adult provider at an earlier stage so that the young person can build trust with the doctor. In childhood and later, any genital examinations should be performed only when necessary and ideally by someone with experience who will be involved in long-term care. Photography should be avoided unless absolutely necessary and then only with consent.

As more young people transition into adult services, the need for specialist adult centers for DSDs is becoming apparent. Standardized follow-up has been proposed to detect and treat health problems associated with DSD in adulthood.[514] The team still largely includes an endocrinologist, psychologist, urologist, and gynecologist, and radiologists can be important team members, especially when discussing young people with retained gonads or complex anatomy. Multidisciplinary clinics in which all team members are available are useful for coordinating care and reducing the number of hospital visits and time away from work. The key issues in long-term management of DSDs include hormone replacement, bone health, sexual activity, relationship issues, genital/urinary issues, psychological well-being, fertility/family building, and other factors that contribute to overall quality of life.[518–520] Some data are now emerging on outcomes in adulthood for general medical issues and quality of life (see later).

Support Groups and Information

Support groups can also have a very important role in providing additional information for children, adolescents, and adults with

DSD and for bringing members of the community together.[521] There are well-established support groups in several countries for general aspects of DSD as well as for specific conditions such as CAH and AIS (for a recent overview, see Lee and colleagues[522]). Increasingly accessible information about DSD is becoming available through the internet, such as the biology of DSDs,[523] support for families (e.g., dsdfamilies.org),[498,524] and information for young people about DSDs (e.g., dsdteens.org).[525] It is useful to guide young people and families in how to search for information, as general search terms such as *sex* can result in many inappropriate hits. Patients and families should also be counseled that there is great variability within and between DSD conditions, and thus some information may not be applicable.

Tumor Risk and DSDs

The gonads of individuals with DSD with Y chromosomal material containing the GBY region are at risk of malignant change, but the incidence varies widely, depending on the underlying diagnosis (Table 24.23). Precise risk assessment per diagnosis is hampered by the lack of a molecularly confirmed diagnosis in various studies, report bias, inconsistent criteria to define precursor lesions, and the practice of early gonadectomy that has limited information on the natural history. In general, forms of DSD with impaired or arrested gonadal development have a high risk of germ cell cancers, whereas forms with normal testis development but reduced androgen synthesis or action have a lower risk, especially in childhood.[384] Scrotal testes are thought to be at lower risk of GCC development than undescended testes.[384] True streak gonads (i.e., gonads that consist of fibrous tissue and lack germ cells) are by definition not at risk of GCC, but this can only be concluded at histologic examination. Streak-like gonads (i.e., gonads that appear scar-like and lack endocrine function) may in fact contain germ cells, and these dysgenetic gonads are at risk of GCC.

Various subtypes of GCC exist: seminomatous cancers, on the one hand, classified as seminoma in the testis, dysgerminoma in the ovary and dysgenetic gonad, and germinoma when located extragonadally; nonseminomatous cancers, on the other hand, including teratoma, yolk sac tumor, choriocarcinoma, and embryonal carcinoma.[384] The development of GCC is preceded by abnormal germ cell development.

In poorly differentiated gonads, germ cells may be present without the formation of follicles or seminiferous tubules; this is known as *undifferentiated gonadal tissue*. These germ cells may develop into a gonadoblastoma, which is the precursor lesion of a dysgerminoma.[384] If the gonad is more testicularized, the germ cells are present in seminiferous tubules, although these may remain immature due to reduced synthesis or action of androgens. Delayed germ cell maturation is often seen in DSD and is characterized by luminal gonocytes that show prolonged expression of markers such as POU5F1 (also known as OCT3/4) that are normally only expressed during early life. Once these germ cells have migrated to the basal membrane but continue to express POU5F1, coexpress TSPY in a heterogeneous pattern, and show focal KITLG expression, they are classified as pre-GCNIS.[384] If germ cells show cytonuclear atypia with homogeneous TSPY expression and diffuse KITLG expression, then GCNIS is diagnosed.[384] GCNIS is the precursor lesion of GCC in an undervirilized testis. GCNIS was previously known as *carcinoma in situ, testicular intraepithelial neoplasia,* or *intratubular germ cell neoplasia, unclassified*.

In the general population, GCNIS is thought to progress to invasive GCC in the majority of cases, but this progression seems rare in CAIS, suggesting that androgens influence this progression.[384,385]

The risk of GCC can be estimated using information from clinical assessment, endocrine and genetic evaluation, and imaging. Gonadal biopsy is the gold standard, although it is important

TABLE 24.23 Risk of Germ Cell Malignancy According to Diagnosis

Risk Group	Disorder	Malignancy Risk (%)	Recommended Action	No. Studies	No. Patients
High	GD[a] (+Y)[b] intraabdominal	15–35	Gonadectomy[d]	12	350
	Partial AIS[c] nonscrotal	50	Gonadectomy[d]	2	24
	Frasier syndrome	60	Gonadectomy[d]	1	15
	Denys-Drash syndrome (+Y)	40	Gonadectomy[d]	1	5
Intermediate	Turner syndrome (+Y)	12	Gonadectomy[d]	11	43
	17βHSD	28	Watchful waiting	2	7
	GD (+Y)[b] scrotal	Unknown	Biopsy[e] and irradiation?	0	0
	Partial AIS scrotal gonad	Unknown	Biopsy[e] and irradiation?	0	0
Low	Complete AIS[f]	2	Biopsy[e] and ?	2	55
	Ovotesticular DSD	3	Testis tissue removal?	3	426
	Turner syndrome (–Y)	1	None	11	557
No (?)	5α-reductase	0	Unresolved	1	3
	Leydig cell hypoplasia	0	Unresolved	1	2

[a]GD including disorders not further specified, 46XY, 45X/46XY, mixed, partial, and complete.

[b]GBY region positive, including the *TSPY* gene.

[c]More recent reports suggest a lower risk, comparable to that in CAIS.[378,394]

[d]At time of diagnosis.

[e]At puberty, allowing investigation of at least 30 seminiferous tubules, preferentially diagnosis based on OCT3/4 immunohistochemistry.

[f]This risk estimate concerns postpubertal individuals; the risk is lower before puberty.[387]

AIS, Androgen insensitivity syndrome; *DSDs,* disorders of sex development; *GD,* gonadal dysgenesis; *17βHSD,* 17β-hydroxysteroid dehydrogenase.

Reproduced with permission from Hughes IA, Houk C, Ahmed SF, et al. Consensus statement on management of intersex disorders. *Arch Dis Child.* 2006;91:554–562.

that appropriate immunohistochemical markers are used and that the pathologist has a high level of expertise, and one should be aware that a biopsy may not be representative of the entire gonad. Genetic predisposition to GCC development is thought to play a role; SNPs in candidate genes for disease development have been investigated as predictors of GCC risk but were found to have insufficient discriminatory value to use in clinical practice.[394]

The highest risk for early gonadoblastoma occurs with Frasier syndrome (caused by mutations in *WT1*), for which the risk may be as high as 60%.[212]

In individuals with gonadal dysgenesis due to a 45,X/46,XY karyotype, the prevalence of gonadoblastoma has been estimated to be 15% to 40%.[212]

The risk of GCC is lower in AIS[385] (see "Disorders of Androgen Action"). Fewer data are available on the risk in conditions affecting steroidogenesis, but the risk seems relatively low but not negligible.[212] Other tumors such as Sertoli cell adenomas are common in CAIS.

When counseling patients and their family about surveillance and/or treatment, the MDT should take into account the risk of gonadal GCC based on diagnosis, age of the individual, location of the gonad and results of gonadal biopsy if available, options for relocating the gonad, options for reliable surveillance, endocrine potential of the gonad and whether this endocrine function is desired by the individual, fertility potential of the gonad, risk of surgery, and side effects of hormone replacement therapy.[214,384,526]

Because of the high risk for early tumor development, prophylactic gonadectomy in infancy or early childhood is typically recommended for dysgenetic gonads and streak-like gonads that are undescended and cannot be placed in a lower position where they can be monitored. Serial monitoring with physical examination, and for older individuals self-examination, and imaging (e.g., ultrasound) may be more appropriate for gonads that are descended or can be placed in an extraabdominal, preferably scrotal position, and that exhibit more robust endocrine function. In conditions such as CAIS with a lower risk of germ cell tumors and where GCC generally do not occur before puberty, gonadectomy is deferred until after puberty; after appropriate counseling, some individuals may prefer to leave the gonads in situ in adulthood, although monitoring of abdominal gonads is difficult. GCNIS cannot be detected directly on ultrasound, although microlithiasis, especially when associated with inhomogeneous testis parenchyma, may be suggestive.[385] Abdominal gonads may not be visualized on ultrasound, and while MRI has been suggested as an alternative, this cannot reliably detect GCNIS either.[385] An alternative may be to move abdominal gonads to a more superficial location[214] (see "Complete Androgen Insensitivity Syndrome"). Standard circulating tumor markers (e.g., α-fetoprotein, βhCG, lactate dehydrogenase) are of limited use in detecting GCNIS or seminomas. Novel serum biomarkers such as microRNAs (e.g., miR371-3 and miR302/367) may be useful to detect malignant lesions but currently cannot detect premalignant lesions.[385]

Surgery and DSDs

Surgical approaches to DSD were once regarded as standard management, but there is much greater consideration now about the need for surgery and its timing.[527,528]

Surgery can potentially be performed on the gonads, the urogenital tract, and the genitals. The indication, timing, and choice of any potential procedure should be made on an individual basis and can be influenced by the underlying diagnosis. The MDT should inform the patient and family of all treatment options and their potential benefits and risks and should take into account medical, psychological, social, and cultural aspects so that a well-informed shared decision can be made.[529]

Some procedures are functionally important (e.g., to prevent hematocolpos or to mitigate high tumor risk), whereas others such as clitoral reduction surgery might be viewed as cosmetic. Some people believe that early surgery can be beneficial because the tissues are easier to operate on and heal better and that parents can make decisions for their child, acting in the child's best interest, whereas others feel that surgery should be deferred until a time when a young person can be part of the decision-making and consent process.[528–531] The psychological implications of these decisions can be great. Some parents experience great distress because of the appearance of their child's genitals.[532] Performing early surgery to make the appearance of the genitalia more typical may make some parents feel more comfortable, but the child may later regret the parents' decisions, especially if there is impaired sexual function or sensation or if further surgeries are required. On the other hand, bringing up a child with very atypical genitalia protects the child's rights to bodily integrity but needs strong positive parenting and support, and it is not well understood how well young people cope in these situations as they mature.

For a child born with atypical genitalia and raised female, the parents should be guided through a balanced discussion about all options. The most common scenario where clitoral reduction surgery is considered is in 46,XX girls with CAH. In a baby with CAH there is often considerable reduction in the size of the enlarged clitoris once androgen exposure is reduced by adrenal suppression, and the clitoris may also become less prominent as the child grows, so a period of observation is appropriate before decisions about surgery are made.[530] Psychological support in dealing with worries such as diaper changing should be provided, and in many situations surgery may not be considered. Outcome studies involving assessment of genital sensitivity and sexual function in women with CAH show impairment related to previous feminizing genital surgery.[531,533] Although surgical procedures have changed, with greater emphasis on nerve sparing, these data have had a bearing on decisions taken during infancy and childhood for the surgical management of conditions such as CAH, and long-term outcome data are awaited for newer approaches. In centers that offer surgical options, it is generally accepted that clitoroplasty should be reserved only for the most severe degree of clitoromegaly, and in many situations vaginal surgery is deferred until after puberty. In adulthood, vaginal lengthening in conditions such as CAIS and the MRKH syndrome can often be achieved by dilator treatment alone.[390] If a surgical vaginoplasty is performed, the Vecchietti procedure is often preferred.

Subjects with DSD raised male usually undergo surgery to correct hypospadias and orchidopexy for testis maldescent. Hypospadias repair can be scheduled between 6 and 18 months of age or deferred until approximately 4 years of age or later. More than one procedure is often required, and complications such as stenosis, fistula, or need for redo surgery are relatively frequent. The surgeon should provide complete information on these procedures to the parents and ensure that their expectations are realistic.[534] Many boys with severe hypospadias undergo surgery in early life, as performing these approaches in adolescence may be more difficult and associated with a higher rate of complications, but there is a lack of data for optimal timing and outcomes.[535] Open discussions with the parents and later with the child are needed, and boys may need more support in childhood and adolescence than is usually currently offered.

The topic of gonadectomy before puberty in 46,XY individuals raised female to prevent virilization and in others with DSD to avoid gonadal tumors has previously been mentioned. The irreversible nature of such a procedure has created uncertainty among professionals, particularly when the procedure is performed before the affected child can be engaged in discussions and in situations where there could be a potential for future fertility or endocrine function. Temporary suppression of puberty using GnRH analogues may be used to delay a decision on gonadectomy.[528] Gonadectomy is another issue that requires the collective discussion of the multidisciplinary team and may include input from an ethicist. The practice of cryopreserving excised gonads with unrealistic expectations for preservation of reproductive potential should be viewed cautiously, especially because current knowledge is based primarily on the gonadal effects of cancer therapies.[536] If tissue is preserved, there needs to be a clear dialogue about likely outcomes and options. However, germ cell number and viability may decline with time, so there could be a limited window of opportunity.[536] Furthermore, reproductive technologies are changing rapidly, there are highly publicized stem cell approaches such as germ cell reprogramming reported in animals, and successful birth following cryopreservation of (normal) prepubertal testis has been achieved in monkeys.[537] Whether these technologies will eventually provide useful clinical approaches remains to be seen.

Fertility/Family Building

Many forms of DSD are associated with reduced fertility or infertility. Successful use of assisted reproductive techniques has been reported in some cases, such as TESE and/or ICSI in men with PAIS or 5α-reductase deficiency,[396,538,539] and a few pregnancies using donor oocytes have been reported in women with 46,XY DSD who have a uterus.[540,541] Uterus transplantation has recently been shown to make pregnancy possible for women who do not have a uterus, resulting in live birth in a woman with MRKH syndrome.[542] Alternative options to build families include the use of donor sperm, adoption, or foster care. It is important to provide individuals with information on the possibilities in their specific situation; a recent study found that provision of such information is suboptimal.[543]

DSD in Resource-Limited Countries

Many of our approaches to DSD are being developed within the context of large medical centers and experienced MDTs with ready access to biochemical assays such as AMH, imaging, and state-of-the-art genetic tests. In reality, many children and adults with DSD live in countries with less access to resources or with different social and cultural pressures.[501] Each clinician needs to work with the tests and treatments that are available and affordable to optimize their ability to assess, diagnose, and treat individuals with DSD. Knowledge of the local prevalence of certain forms of DSD and genetic hotspots can be very important, as well as relevant social, cultural, and religious factors that might influence the way a child and the family view DSD. Limited education about DSD is available to clinicians in some countries, but tools such as the European Society for Paediatric Endocrinology (ESPE) e-learning may be valuable.[544] The Paediatric Training Centres in Africa (PETCA) established in 2008 to provide specialist training in endocrinology and diabetes for qualified pediatricians is beginning to pay dividends with more than 100 additional qualified specialists distributed among 13 sub-Saharan African countries.[545]

Outcome Studies

There is such a wide range of conditions included under the umbrella of DSD that it is difficult to obtain an overarching assessment of the health and quality of life in adulthood for individuals who have lived with DSD from childhood. Standardizing longitudinal assessment in individuals with DSD across centers should facilitate future outcome studies.[514]

Most data regarding sexual function and quality of life come from women with CAH who had various genitoplasty procedures during their childhood.[546,547] The debate continues regarding the timing of any surgery for girls with CAH and whether one-stage or two-stage surgery is the preferred option.[548] Adult endocrinologists are now undertaking detailed studies of the comorbid conditions associated with CAH and its medical treatment (see also Chapter 15). The UK Congenital Adrenal Hyperplasia Adult Study Executive (CaHASE) studies on cohorts of more than 200 adults show poorer health status relating to increased obesity, hypertension, insulin resistance, osteoporosis, impaired fertility, and reduced quality of life.[549–551] Despite improvements in growth achievement in recent years, shorter adult height was one of the adverse outcomes, particularly in relation to hypertension. Similar findings were found in outcome studies of a Swedish population of adults with CAH.[552] The Swedish CAH population also had lower educational achievement and reduced income, had increased disability allowance and sick leave, were less likely to be married, and had fewer children compared to control subjects.[553] The medical comorbid conditions may result from long-standing inadequate control of CAH by replacement glucocorticoids, estimated to be the case in more than a third of adults. Studies of modified-release hydrocortisone preparations that mimic more closely the cortisol circadian rhythm are showing promising results, with a reduction in the total hydrocortisone daily dose required for adequate adrenal androgen suppression.[554]

There are fewer outcome studies available for adults with conditions within the category of 46,XY DSD, but data are beginning to emerge. A nationwide study of females with 46,XY DSD in Denmark showed that morbidity is not increased when diagnoses directly related to the DSD itself were excluded.[383] A Swedish study reported a higher rate of psychiatric morbidity in women with CAIS and CGD compared to controls but similar to that in women with primary ovarian insufficiency.[555]

Quality-of-life studies have recently been reported in populations of German, Italian, and Brazilian individuals with 46,XX DSD and 46,XY DSD and of either male or female social gender, so study cohorts are quite heterogeneous.[556–558] In general, quality of life was satisfactory, there was no evidence of gender dysphoria, and psychosocial adjustment was better in younger people when compared with an older generation of DSD individuals. Among the 46,XY DSD group in the Brazilian population, those with a male social gender had a better quality of life than those with a female social gender (e.g., the group with CAIS). There were more difficulties overall in partnerships and sexual relationships. Another study from Germany, which included individuals with both 46,XX and 46,XY DSD, showed evidence of dissatisfaction with health care services available, especially in the group with 46,XY DSD.[559] In a study that focused on comparing women with either CAIS or MRKH syndrome, there was greater lack of sexual confidence and sexual satisfaction in women with CAIS, whereas those with MRKH syndrome, while apprehensive in sexual situations, reported being satisfied with their sex life.[560] Danish women with 46,XY DSD had lower rates of cohabitation

and motherhood compared to female controls, but education and income were similar to or higher than in controls.[383] In contrast, Danish men with 46,XX DSD had poorer education and reduced income in some age groups.[561]

As discussed, a recent study of more than 400 46,XY subjects subdivided according to clinical diagnoses of PAIS, disorders of gonadal development (partial gonadal dysgenesis), and disorders of androgen synthesis (such as 5α-reductase deficiency) has shown an increasing trend for babies with atypical genitalia to be raised as boys.[392] Therefore outcome studies are needed for these groups of individuals. A recent review of 46,XY DSD provided mainly anecdotal data on issues such as gender identity and sex redesignation, whether males were satisfied with the appearance of their genitalia, and the prevalence of sexual dysfunction.[562] Overall, males were satisfied with their gender, and rarely did male-to-female gender redesignation occur in adulthood. Most males had some concern about the appearance of the genitalia, and many were dissatisfied with sexual function. Another small Dutch study reported poor outcome in terms of penile size and sexual function, although their overall body image and psychosexual functioning was no different from control subjects.[563]

There is a paucity of information about outcome in specific causes of 46,XY DSD, such as PAIS.[565,566] Often this label is applied without confirmation that the phenotype is due to a mutation in the *AR* gene; as a result, other diagnoses may have been included inadvertently. A French multicenter study reported on 15 adults with PAIS who had been monitored since birth.[567] The EMS (see Fig. 24.40) was very low and penile length was markedly reduced in adulthood irrespective of additional androgen treatment. All boys developed gynecomastia in adolescence, and sexual function was severely impaired. An international study of 29 males with PAIS who were at least 16 years old and a more recent study of 27 males with PAIS studied prospectively also confirmed universal development of gynecomastia.[378,393] Micropenis was common at initial presentation but less so when assessed after puberty. Onset of puberty was often spontaneous, although androgen treatment may be required subsequently.

There has been considerable progress in many aspects of DSD since the previous edition of this chapter. What is clearly needed now are outcome studies in larger cohorts of individuals with DSD, particularly within the 46,XY DSD category. A major step toward that goal is the establishment of international registries for DSD studies (I-DSD) and allied activities such as evaluation of long-term care and outcomes in DSD (DSD-Life), interactive networks for activities in DSD (DSDnet), European Reference Networks for rare conditions such as DSD, and a DSD Translational Research Network (DSD-TRN).[568] Such networking should provide the means to gather more data on the individual rare causes of DSDs across the lifespan that can then be translated into improved management and outcome.

Acknowledgments

We recognize the major contribution made to this chapter by the late Melvin Grumbach MD and his close colleague, Felix Conte MD. John C. Achermann holds a Wellcome Trust Senior Research Fellowship in Clinical Science (209328/Z/17/Z). Ieuan A. Hughes is supported by the NIHR Cambridge Biomedical Research Centre for his work on disorders of sex development. Yee-Ming Chan is supported by the US National Institutes of Health and the Eunice K. Shriver National Institute of Child Health and Human Development (R01 HD089521).

Normal and Aberrant Growth in Children

DAVID W. COOKE, SARA A. DIVALL, AND SALLY RADOVICK

CHAPTER OUTLINE

KEY POINTS

- Height is an important vital sign to obtain during childhood because deviations from the normal linear growth pattern may indicate an underlying disorder.
- An intact hypothalamic (growth hormone–releasing hormone [GHRH])/pituitary (growth hormone [GH])/insulin-like growth factor 1 (IGF1) axis, adequate nutrition, and absence of significant systemic disease are requirements for normal linear growth.
- A comprehensive past medical, family, and social history with assessment of an accurate growth velocity is required for the initial investigation of abnormal growth. Laboratory and radiologic investigations include an evaluation for occult systemic disease and exclusion of hormonal abnormalities.
- Successful treatment of the underlying disorder or correction of hormone deficiency(ies) improves linear growth.
- Treatment of short stature with growth-promoting agents may improve linear growth in select patients with intact GHRH/GH/IGF1 axis function.

Normal Growth

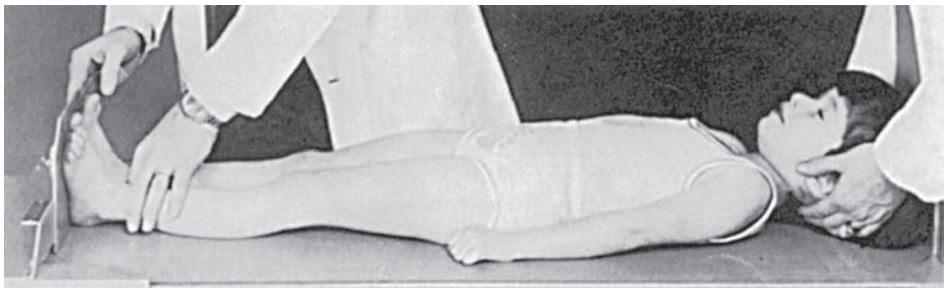
Overview

Growth is a fundamental, intrinsic aspect of childhood health. It is also a complex yet tightly regulated process. An individual's final height and the path taken to reach that end point are significantly determined by that person's genetic composition. But growth and final height can also be affected by external factors, including the quality and quantity of nutrition, and by psychosocial factors. This process is regulated by multiple hormones and growth factors interacting with an array of membrane receptors that activate seemingly redundant intracellular signaling cascades. Yet, as complex as this process is, 1 standard deviation (SD) of adult height represents about only 4% of the mean adult height.

Whether linear growth occurs as a continuous process or with periodic bursts of growth and arrest[1–4] has been hard to characterize definitively. There do appear to be seasonal variations of growth, with slower growth in autumn and winter and greater growth in spring and early summer.[5,6] Some normal children have a broad growth channel, with many showing diverse but characteristic growth tracks.[7] Nonetheless, even though the process of growth is multifactorial and complex, children usually grow in a remarkably predictable manner. Deviation from such a normal pattern of growth can be the first manifestation of a wide variety of disease processes, including endocrine and nonendocrine disorders and involving virtually any organ system of the body. Therefore frequent and accurate assessment of growth is of primary importance in the care of children.

Measurement

Assessment of growth requires accurate and reproducible determinations of height. Supine length is routinely measured in children younger than 2 years of age, and erect height is assessed in older children. It can be useful to measure both length and height in children between 2 and 3 years of age to allow comparisons with prior length measurements and to begin to record height measurement for ongoing comparisons. The inherent inaccuracies involved in measuring length in infants are often obscured by the rapid skeletal growth during this period. For measurement of supine length (Fig. 25.1), it is best to use a firm box with an inflexible board, against which the head lies, and a movable footboard, on which the feet are placed perpendicular to the plane of the supine length of the infant. Optimally, the child should be



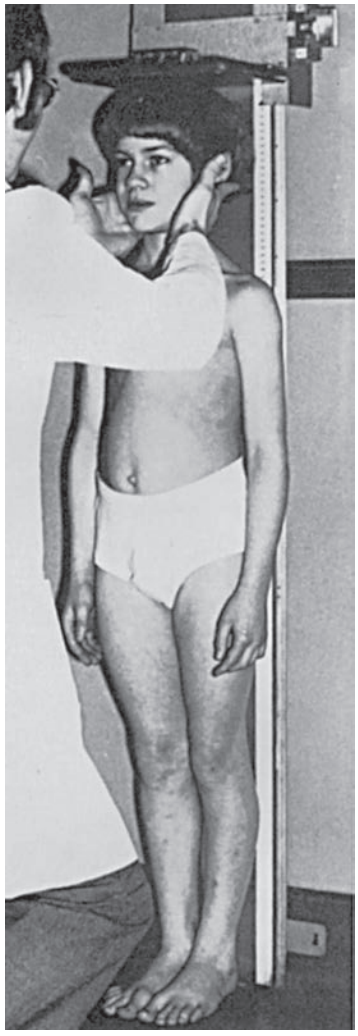
• **Fig. 25.1** Technique for measuring recumbent length. (A device suitable for measurement of length of infants can be purchased from Raven Equipment Limited, Essex, UK.) (Photograph courtesy Noel Cameron.)

relaxed, the legs should be fully extended, and the head should be positioned in the Frankfurt plane, with the line connecting the outer canthus of the eyes and the external auditory meatus perpendicular to the long axis of the trunk.

When children are old enough (and physically capable) to stand erect, it is best to use a wall-mounted Harpenden stadiometer similar to that designed by Tanner and Whitehouse for the British Harpenden growth study. The traditional measuring device of a flexible arm mounted to a weight balance is notoriously unreliable and does not provide accurate serial measurements.

As with length measurements in infants, positioning of the child in the stadiometer is critical (Fig. 25.2). The child should be fully erect, with the head in the Frankfurt plane; the back of the head, thoracic spine, buttocks, and heels should touch the vertical axis of the stadiometer, and the heels should be together. Every effort should be made to correct discrepancies related to lordosis or scoliosis. Ideally, serial measurements should be made at the same time of day, because standing height may undergo diurnal variation.

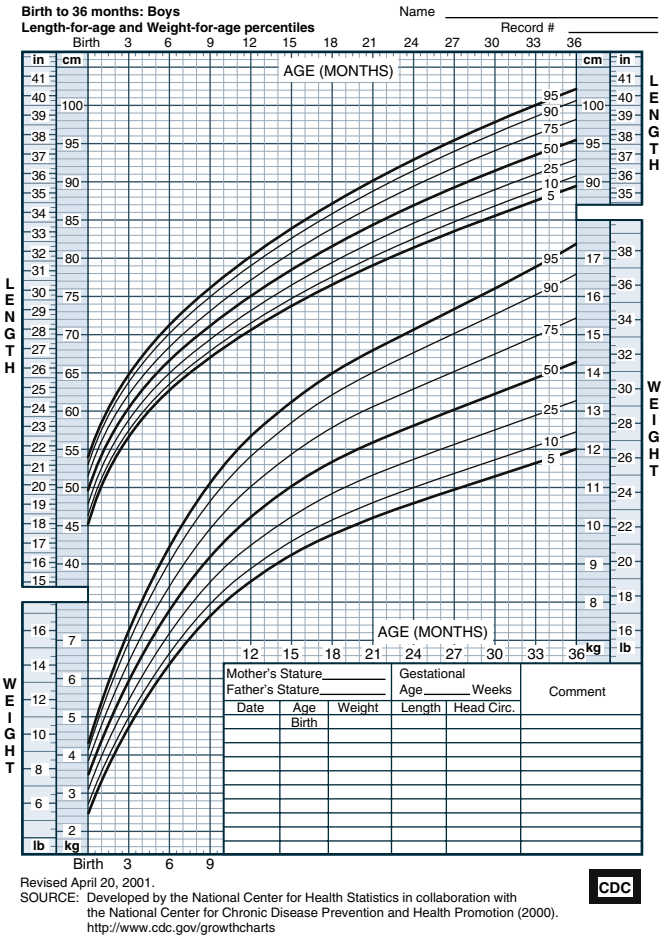
Height determinations should be performed by a trained individual rather than an inexperienced member of the staff. We recommend that lengths and heights be measured in triplicate, that variation should be no more than 0.3 cm, and that the mean height should be recorded. For determination of height velocity when several measurements are being made within a short period, the same individual should perform the determinations to eliminate interobserver variability. Even when every effort is made to obtain accurate height measurements, a minimum interval of 6 months is necessary for meaningful height velocity computation. Nine to 12 months of data are preferable so that errors of measurement are minimized and the seasonal variation in height velocity is assimilated into the data.



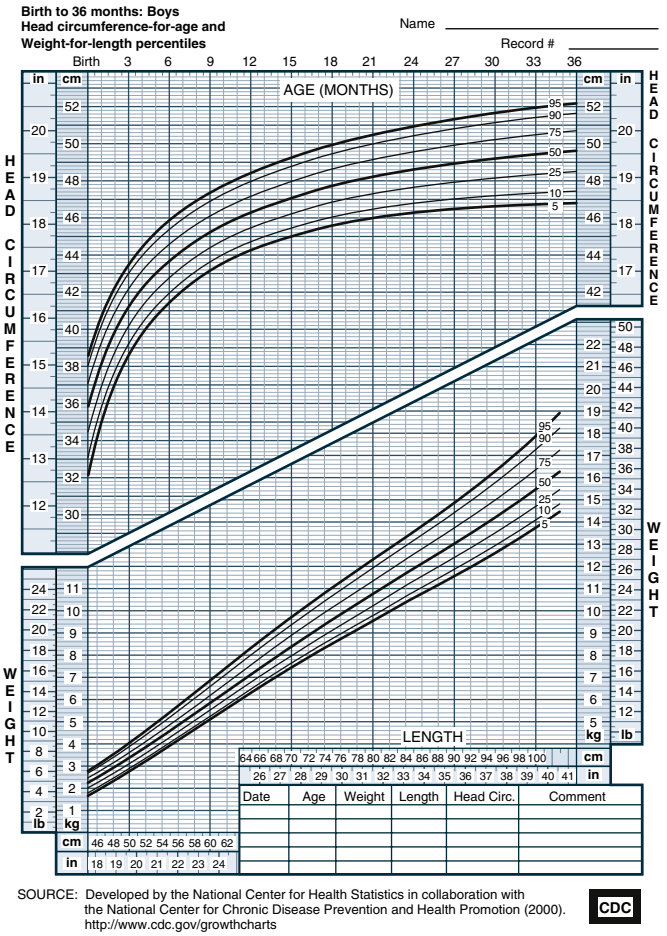
• **Fig. 25.2** Technique for measuring erect height using the Harpenden stadiometer with direct digital display of height. (Devices of this type are available from Holtain Ltd., Wales, UK, and Seritex Inc., Carlstadt, NJ.)

Growth Charts

Evaluation of a child's height must be done in the context of normal standards. Most American pediatric endocrine clinics use the cross-sectional data provided by the National Center for Health Statistics (NCHS), which were originally introduced in 1977. Revised and updated growth charts have been available on the Centers for Disease Control and Prevention (CDC) website (www.cdc.gov/growthcharts) since 2000 (Figs. 25.3 through 25.8).[8] The data for these charts encompass measurements obtained in the United States between 1963 and 1995, and they include a broader representation of the US population for all measures than was available in earlier charts. Growth charts based on the World Health Organization (WHO) data gathered from 1997 throughout 2003 should be used to monitor the growth of children under 2 years of age. While the data on length are very similar between the CDC and WHO curves, the CDC curves describe higher weight gain that, among other things, reflects the lower prevalence of breastfed infants in the CDC data and is not felt to represent optimal growth.[9]



• **Fig. 25.3** Length-for-age and weight-for-age percentiles for boys (birth to 36 months). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion, 2000. http://www.cdc.gov/growthcharts.)



• **Fig. 25.4** Head circumference-for-age and weight-for-length percentiles for boys (birth to 36 months). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion, 2000. http://www.cdc.gov/growthcharts.)

These charts allow comparison of individual children with the 3rd, 10th, 25th, 50th, 75th, 90th, and 97th percentiles of normal American children. There are, however, two limitations of these charts when applied to the individual child. First, they do not satisfactorily define children below the 3rd or above the 97th percentiles—the very children in whom it is most critical to define the degree to which they deviate from the normal growth centiles. However, the NCHS data tables (also available on the CDC website) can be used to compute standard deviation scores (SDS). For example, a short child below the 3rd percentile can be described more precisely as being, for example, approximately 4.2 SDS below the mean for age. A height SDS for age is calculated as follows: The SDS equals the child's height, minus the mean height for normal children of the child's age and gender, divided by the SD of the height for normal children of this age and gender. Second, cross-sectional data are of greater value during infancy and childhood than in adolescence, because differences in the timing of pubertal onset can considerably influence normal growth rates. To address this issue, Tanner and Davies[10] developed longitudinal growth charts in an effort to construct the curve shapes with centile widths obtained from a large cross-sectional survey, thus accounting for variability in the timing of puberty. Such charts are of particular value in assessing growth during adolescence and puberty and for plotting sequential growth data for any individual child.

The data from cross-sectional and longitudinal growth studies have been used to develop *height velocity* standards (Figs. 25.9 and 25.10). It is important to emphasize that carefully documented height velocity data are invaluable in assessing a child with abnormalities of growth. There is considerable variability in normal height velocity of children at different ages; however, between the age of 2 years and the onset of puberty, children grow with remarkable fidelity relative to the normal growth curves. Any crossing of percentile curves on the height chart during this age period should be considered abnormal and warrants further evaluation.

Syndrome-specific growth curves have been developed for a number of clinical conditions associated with growth failure, such as Turner syndrome (TS),[11] achondroplasia,[12] and Down syndrome.[13,14] Such growth profiles are invaluable for tracking the growth of children with these clinical conditions. Deviation of growth from the appropriate disease-related growth curve suggests the possibility of a second underlying cause, such as acquired autoimmune hypothyroidism in children with Down syndrome or TS.

Body Proportions

Many abnormal growth states, including both short stature and excessive stature, are characterized by *disproportionate* growth. The

following determinations should be made as part of the evaluation of short stature:

1. Occipitofrontal head circumference
2. Lower body segment: distance from top of pubic symphysis to the floor
3. Upper body segment: the difference between total height and lower body segment (it can also be measured as the sitting height, subtracting the height of the chair or stool)
4. Arm span

Published standards exist for these body proportion measurements, which must be evaluated relative to the patient's age.[15] The ratio of upper segment to lower segment ranges from 1.7 in the neonate to slightly less than 1.0 in the adult (Fig. 25.11).

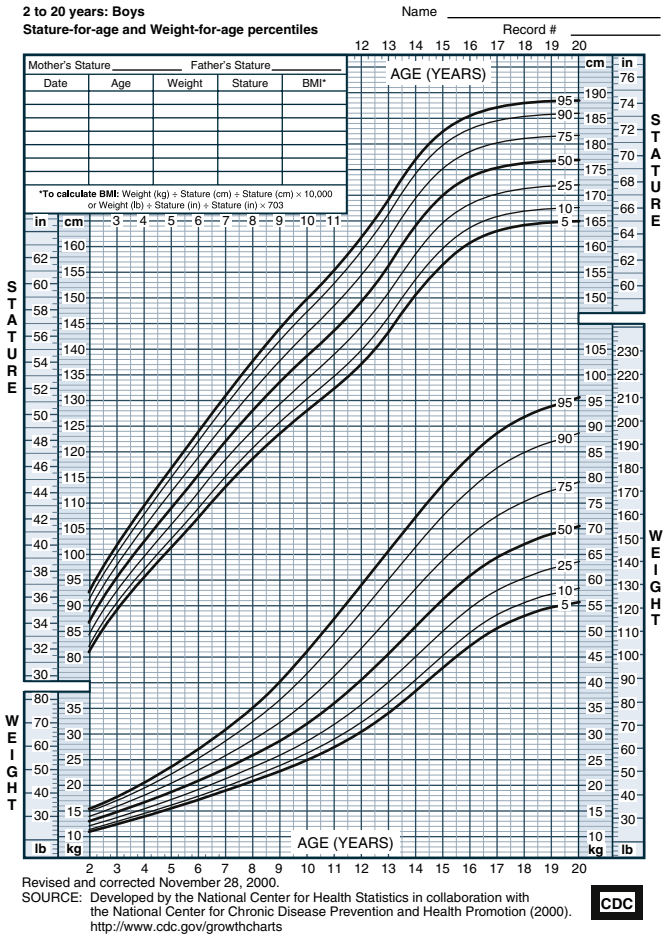
Parental Target Height

Genetic factors are important determinants of growth and height potential. Therefore it is useful to assess a patient's stature relative to that of siblings and parents. Tanner and associates developed a growth chart that factored parents' heights into the evaluation of the heights of children ages 2 to 9 years.[16] One can also calculate a child's expected final height based on the parents' heights by calculating the midparental height. This is the average of the parents' heights, after accounting for the average difference in height between adult men and women (13 cm). In other words, a boy's midparental height equals the average of his parents' heights plus 6.5 cm, and a girl's midparental height equals the average of her parents' heights minus 6.5 cm.

Because of regression to the mean,[17,18] children of short parents are likely to be less short than their parents, and children of tall parents are likely to be less tall than their parents. Therefore a child's genetic *target height range* centers on the point that represents 80% of the difference between the child's midparental height and the mean adult height for the child's gender.[17] For example, if a boy's father is 168 cm tall and his mother is 153 cm tall, his midparental height is 167 cm, which is 10 cm below the mean height of adult men (177 cm). Therefore the boy's target height range centers on 169 cm, which is 8 cm below the mean adult height for men. In more than 95% of children, the adult height falls within 10 cm of the point thus calculated.[16,17] In children with extremely short stature (≥3 SD), the father's height may more strongly correlate with the patient's height, and the mother's height may more greatly influence birth length.[19]

Skeletal Maturation

The growth potential in the tubular bones can be assessed by evaluation of the progression of ossification within the epiphyses. The



• **Fig. 25.7** Stature-for-age and weight-for-age percentiles for boys (2 to 20 years). (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion, 2000. http://www.cdc.gov/growthcharts.)

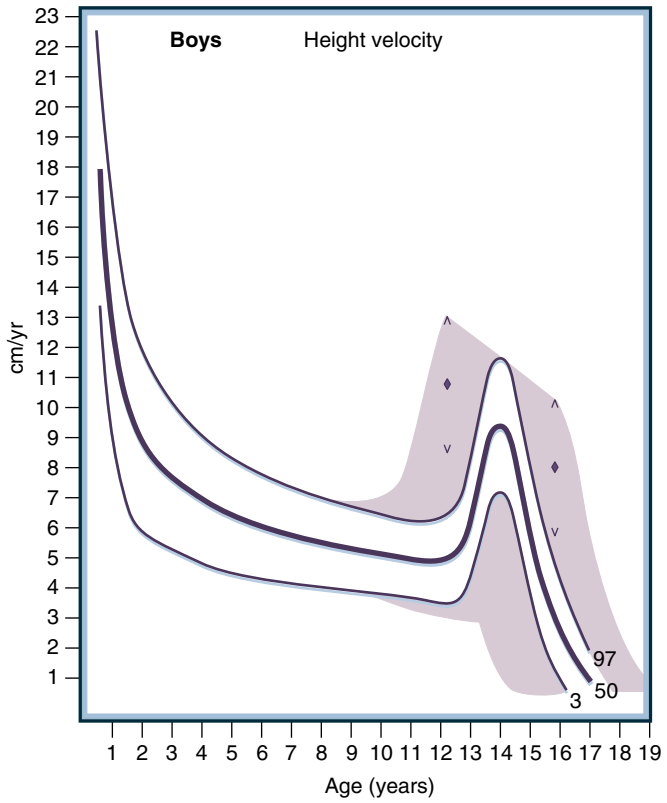
ossification centers of the skeleton appear and progress in a predictable sequence in normal children, and this skeletal maturation can be compared with normal age-related standards. This forms the basis of the *bone age* or *skeletal age*, a quantitative determination of net somatic maturation that serves as a mirror of the tempo of growth and maturation. The bone age also reflects the degree of growth plate senescence and is therefore a useful adjunct in estimating growth opportunity (i.e., the ultimate adult height), as discussed later in this chapter.

Not all of the factors that determine the normal pattern of skeletal maturation have been identified, but genetic factors and multiple hormones, including thyroxine, growth hormone (GH), and gonadal steroids, are involved.[20] Ultimately, growth cessation occurs after exhaustion of the proliferative capacity of the growth plate chondrocyte.[21] Estrogen plays an important role in this process: Animal studies have indicated that estrogen accelerates growth plate senescence,[22] and studies in patients with mutations of the gene for the estrogen receptor[23] or for the aromatase enzyme[24,25] demonstrated that estrogen is primarily responsible for epiphyseal fusion.[26]

Phases of Normal Growth

Growth occurs at differing rates during intrauterine life, early and middle childhood, and adolescence and then ceases after fusion of long bone and vertebral epiphyseal growth plates. Karlberg and associates resolved the normal linear growth curve into three additive, partially superimposable phases[27,28]: an "infancy" phase, starting in midgestation and then rapidly decelerating until about 3 to 4 years of age; a "childhood" phase, of slowly decelerating growth through early adolescence; and a sigmoid-shaped "puberty" phase that comprises the adolescent growth spurt. Prenatal growth averages 1.2 to 1.5 cm per week but varies dramatically (Fig. 25.12); the midgestational length growth velocity of 2.5 cm per week falls to almost 0.5 cm per week immediately before birth. Growth velocity (see Figs. 25.9 and 25.10) averages about 15 cm per year during the first 2 years of life; it then slows to approximately 6 cm per year during middle childhood. During this time, a normal child's height, plotted on a growth curve, typically remains within a given growth channel; that is, it does not cross percentile lines on the growth curve.

Prepubertal growth is similar between boys and girls. The height difference between men and women, an average of 13 cm, is accounted for by two factors. First, boys grow for an average of 2 years longer than girls, because girls have an earlier onset of puberty and, consequently, earlier cessation of growth. Therefore prepubertal growth is greater for boys; they are 8 to 10 cm taller when their puberty starts, compared with girls' heights when their puberty starts.[17] Second, boys achieve a greater maximal pubertal growth velocity than girls, giving them 3 to 5 cm greater pubertal growth. The time of onset of puberty varies in normal children,



• **Fig. 25.9** Height velocity chart for boys constructed from longitudinal observations of British children. The 97th, 50th, and 3rd percentile curves define the general pattern of growth during puberty. Shaded areas indicate velocities in those children with peak velocities occurring up to 2 standard deviations before or after the average age depicted by the percentile lines. (*Up arrows*, *diamonds*, and *down arrows* mark, respectively, the 97th, 50th, and 3rd percentiles of peak velocity when the peak occurs at these early or late limits.) resulting in a normal variation in the timing of the pubertal growth spurt. However, in most normal children, the final height is not influenced by the chronologic age at onset of the pubertal growth spurt because the additional time for prepubertal growth that occurs when puberty is late is balanced by the fact that pubertal growth is smaller the later it occurs (see Figs. 25.9 and 25.10). After puberty, chondrocyte proliferation in the growth plate slows and senescence occurs due to depletion of stem-like cells in the resting zone of the growth plate.[29,30]

There are two variants of normal growth whose characteristic patterns are such that children exhibiting these growth variants are often evaluated for a growth disorder. These two variants are crossing linear percentiles of infancy and constitutional delay of growth and development (CDGD). In many cases, it is difficult to differentiate children with these normal growth variants from children with a growth disorder.

Crossing Linear Percentiles of Infancy

As in postnatal growth, genetic and environmental factors are important determinants of fetal growth and of the size of an infant (weight and length) at birth. However, there are significant differences between the factors affecting birth size and those affecting childhood growth and adult stature. There is much less correlation between length at birth and ultimate adult height than between length at birth and height in the later years of childhood.[31]

Parental stature affects birth length, as it does adult stature; this is an indicator of the genetic influence on growth. Although maternal and paternal stature contribute equally to childhood growth and adult stature, the effect of maternal stature may predominate over that of paternal stature on length at birth.[32,33] However, some studies have found equal effects of maternal and paternal stature on birth size.[34] Maternal nutrition and health have significant effects on fetal growth. Maternal weight has a positive effect, and smoking during pregnancy has a negative effect. Maternal diabetes has a strong positive effect on fetal growth. It is possible for the prenatal determinants of growth to result, for example, in a child who will ultimately grow to below-average stature but is above average size at birth. For this reason, it is common for infants' lengths to cross percentiles on the growth curve. Indeed, it is more common for the growth of an infant to cross percentiles than to follow a single percentile from birth into childhood: Approximately one-third of infants have lengths that cross percentiles moving upward on the growth curves, and approximately one-third have lengths that cross percentiles moving downward.[33,35] Most normal infants crossing percentiles do so in the first 6 to 12 months, although some normal infants cross percentiles after 1 year of age.

Infants who are small at birth can be divided into (1) those who are small only because of prematurity and are therefore of a size appropriate for gestational age (AGA) and (2) those who are small for gestational age (SGA). SGA is usually defined as a birth weight or length (or both) below the 3rd percentile (or, sometimes, below the 10th percentile) for gestational age.[36] Some infants born SGA represent the small percentage of individuals whose genetic potential leads to small size at birth, and they can be expected to remain small throughout childhood and adulthood. However, many infants are SGA due to intrauterine growth retardation (IUGR) and have a genetic potential that would not be expected to result in small adult stature. Most infants who are born small, either AGA or SGA, have catch-up growth and achieve lengths greater than the 3rd percentile within the first 2 years of life. However, up to 10% of SGA infants do not show such catch-up growth.[37,38] The pathologic aspects of IUGR and of SGA in infants who do not have catch-up growth are discussed later.

Constitutional Delay of Growth and Development

CDGD is a normal variant of growth.[39] It describes the growth pattern of children who will experience a later than average timing of puberty. Their birth size is normal, and their final height is within their genetic potential. However, during most of their childhood, they grow at a height percentile below that expected based on their genetic potential. Typically, these children have a low growth velocity during the first years of life, crossing downward on the length percentile growth curves, so that by 2 years of age their heights are at or slightly below the 5th percentile. After age 3 years, their growth rate is typically normal, so that their height growth usually remains parallel to the 5th percentile until adolescence, although the height SDS may gradually drift slightly lower during the middle childhood years in some cases.[39,40] Their height diverges even further from that of average children during the early teen years due to the declining prepubertal growth velocity of these children compared with the accelerating growth rate of children with an average timing of the onset of puberty.

Ultimately, children with CDGD have a late growth spurt, consistent with their late puberty, and this brings their height into the normal adult range. Final height is often in the lower part of the parental target height range, and few patients exceed the parental target height,[41–43] although this finding is probably at least in part the result of a selection bias of the children examined for such studies. However, there is evidence that a delayed growth spurt may adversely affect growth of the spine, resulting in a decrease in the final ratio of the upper to the lower segment and perhaps contributing to a limited final height.[44] Studies have also reported that prepubertal boys with CDGD have decreased bone mineral density (BMD),[45] although by young adulthood the majority of the BMD deficit is lost.[46,47]

Secular Changes in Height

There are surprisingly few data concerning the stature of modern humans before the measurement of military recruits became customary in the 18th century. Skeletal remains from the last ice age appear to indicate that adult stature 10,000 to 20,000 years ago was not substantially different from that of contemporary adults, although this record is obviously fragmentary.[48] It has been suggested that a reduction in stature was observed with the introduction of agriculture approximately 5000 years ago, with growth attenuation resulting from the combined effects of nutrient deficiency, population growth, and spread of infectious diseases.

Military recruits in the 18th and 19th centuries were clearly shorter than those of today, although it must be recognized that soldiers were commonly recruited from the lower socioeconomic classes, and poor health and nutrition would have contributed to both poor growth and late maturity.[49] Whereas men in the 20th century averaged 5 to 10 cm greater in height than those in the 18th century for whom we have records, much of this height gain has occurred over the past 100 years and probably reflects the dramatic improvement in overall nutrition and health seen in the Western world. This upward trend in height appears to have stopped in many developed countries in the early 21st century.[50]

Therefore secular changes in height appear to reflect fundamental alterations in the standard of living rather than major genomic differences among populations; future economic advances in developing countries can be predicted to lead to improvement in adult stature and a reduction in international differences in growth.

Endocrine Regulation of Growth

The Hypothalamic-Pituitary Axis: Embryogenesis and Anatomy

The pituitary gland is central to the regulation of mammalian growth. The pituitary gland develops from oral ectoderm in response to inductive signals from the neuroepithelium of the ventral diencephalon and intrinsic signaling gradients determining expression patterns of pituitary-specific transcription factors in the developing anterior pituitary gland.[51] The primordium of the anterior pituitary, Rathke pouch, forms as an upward invagination of a single-cell-thick layer of ectoderm that contacts the neuroectoderm of the primordium of the ventral hypothalamus at embryonic day 8.5 (E8.5) in the mouse embryo[52] and can be identified by the third week of pregnancy in humans. The neurohypophysis (posterior pituitary) originates in the neural ectoderm of the floor of the forebrain, which also develops into the third ventricle. During anterior pituitary development, overlapping but regionally specific and temporally distinct patterns of homeobox transcription factor expression lead to the sequential appearance of the terminally differentiated cell types from E12.5 to birth.[52]

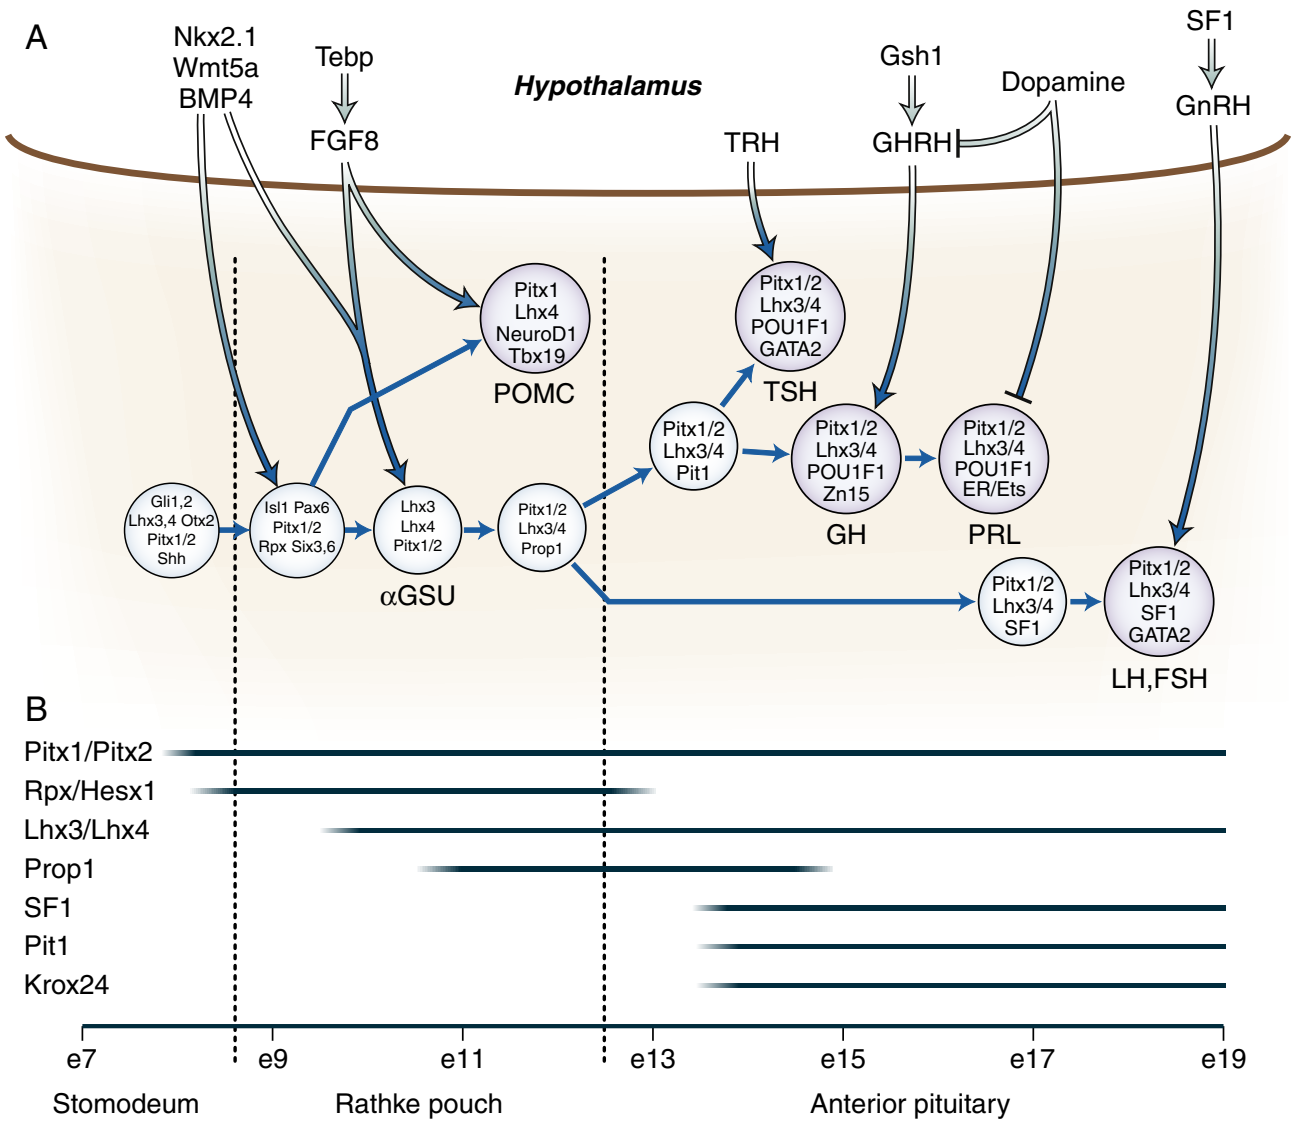
The initiation of anterior pituitary gland development depends on the competency of the oral ectoderm to respond to inducing factors from the neural epithelium of the ventral diencephalon.[53] The bone morphogenetic protein 4 (BMP4) signal from the ventral diencephalon is the critical dorsal neuroepithelial signal required for organ commitment of the anterior pituitary gland. Wnt5a and fibroblast growth factor 8 (FGF8) are also expressed in the diencephalon in distinct overlapping patterns with BMP4. Subsequently, a BMP2 signal arises from the boundary of a region of oral ectoderm in which Sonic hedgehog (SHH) expression, initially expressed uniformly in the oral ectoderm, is selectively excluded from the developing Rathke pouch. Also expressed are Gli1 and 2, Lhx3, and Pitx1 and 2, which are important in progenitor pituitary cell type development. The ventral-dorsal BMP2 signal and the dorsal-ventral FGF8 signal appear to create opposing activity gradients that are suggested to dictate overlapping patterns of specific transcription factors underlying cell lineage specification. The various extensions of these transcription factors in their fields are theorized to combinatorially determine the specific cell types. The FGF8 gradient determines the dorsal cell phenotypes,[53,54] and dorsally expressed transcription factors include Hesx1, Nkx-3.1, Six3, Pax6,[55] and prophet of Pit1 (PROP1).[56] The attenuation of Hesx1 is required for the expression of PROP1. Temporally specific attenuation of the BMP2 signal is required for terminal differentiation of the ventral cell types, and ventrally expressed transcription factors include islet-1 (Isl1), Brn4, P-Frk, and GATA2.[53,56,57] Pit1 (encoded by the gene *POU1F1*) is expressed upon the attenuation of PROP1 expression and required for somatotroph, lactotroph, and thyrotroph development,[58,59] whereas the orphan nuclear receptor steroidogenic factor 1 (SF1) is selectively expressed in the gonadotrophs.[60,61]

The ventral-dorsal gradient induces GATA2 in a corresponding gradient in presumptive gonadotrophs and thyrotrophs, and high levels of GATA2 in the most ventral aspect of the developing anterior pituitary directly or indirectly restrict expression of *POU1F1* out of the presumptive gonadotrophs. In the absence of Pit1, GATA2 expression appears sufficient to induce the entire set of transcription factors that are typical of the gonadotroph cell type, including SF1, P-Frk, and Isl1. Conversely, the absence of GATA2 dorsally is critical for differentiation of Pit1-positive cells to somatotroph/lactotroph fates. It is hypothesized that the level of GATA2 expression in the thyrotrophs is below the threshold required to inhibit activation of the *POU1F1* gene early enhancer, permitting the emergence of a Pit1+, GATA2+ cell that results in the thyrotroph fate.[57] Pax6 has a role in the sharp boundary of attenuation of the ventral signals that dictate thyrotroph and gonadotroph cell lineages. In the absence of Pax6, the ventral lineages, particularly thyrotrophs, become dorsally extended at the expense of somatotroph and lactotroph cell types,[55] and Pax6 mutant mice are GH and PRL deficient.[62]

The earliest marker of the anterior pituitary is expression of the glycoprotein α-subunit (αGSU), which appears at E11.5 in the mouse. These αGSU-positive cells also express the transcription factor Isl1 and mark a population of differentiating thyrotrophs that disappears after birth.[54,58,63,64] αGSU is expressed in mature thyrotrophs and gonadotrophs. At E12.5, corticotrophs start to differentiate and produce pro-opiomelanocortin (POMC).[54,64] Intensified cell proliferation within Rathke pouch results in formation of a visible nascent anterior pituitary lobe on E12.5.[52] Definitive thyrotrophs are observed at 14.5 days postconception (dpc), characterized by the expression of *Tshb* at E14.5 and followed by the expression of GH and prolactin (PRL) in somatotrophs and lactotrophs, respectively, at E15.5. The gonadotrophs are the last cell type to develop, at E16.5, marked by expression of luteinizing hormone (LH) and later by follicle-stimulating hormone (FSH). Eventually the mature gland is populated by at least five highly differentiated cell types: Ventrally to dorsally, they are the gonadotrophs, thyrotrophs, somatotrophs, lactotrophs, and corticotrophs.[53] Ultimately, some of these same transcription factors are also involved in the cell-specific expression and regulation of the gene products of these pituitary cell types, with corticotrophs producing adrenocorticotropin hormone (ACTH), thyrotrophs producing thyrotropin (thyroid-stimulating hormone [TSH]), gonadotrophs producing gonadotropins (LH and FSH), somatotrophs producing GH, and lactotrophs producing PRL. The developmental factors that play an in vivo role in pituitary gland development and differentiation are shown in Fig. 25.13.

In humans, GH-producing cells can be found in the anterior pituitary gland by 9 weeks of gestation,[65] and vascular connections between the anterior lobe of the pituitary and the hypothalamus develop at about the same time,[66] although hormone production can occur in the pituitary in the absence of connections with the hypothalamus. Somatotrophs can be demonstrated in the pituitary in anencephalic newborns.[67]

In the newborn, the pituitary weighs about 100 mg. In the adult, the mean weight is about 600 mg, with a range of 400 to 900 mg; the pituitary is slightly heavier in women than in men and increases during pregnancy.[68] The mean adult pituitary size is 13 × 9 × 6 mm.[69] The anterior pituitary normally constitutes 80% of the weight of the pituitary. The pituitary resides in the sella turcica, immediately above and partially surrounded by the sphenoid bone. The volume of the sella turcica is a good index of pituitary size and may be reduced in the child with pituitary hypoplasia. The optic chiasm is located superior to the pituitary gland, so suprasellar growth of a pituitary tumor may initially manifest with visual complaints or evidence of decreases in peripheral vision. Furthermore, development of the neurohypophysis and the pituitary are intimately related, leading to potential anatomic associations of central nervous system (CNS) abnormalities with pituitary hypoplasia. For example, septo-optic dysplasia is associated with several



• **Fig. 25.13** Development of pituitary cell lineages. (A) Schematic representation of pituitary cell precursors shows the expression of prevalent transcription factors at each stage of development. Terminally differentiated cells are shown as larger and shaded circles together with the hormones produced (lineage-specific transcription factors are highlighted in bold in these cells). The interaction with transcription factors and signaling molecules in the hypothalamus is also depicted. Transcription factors are represented in lowercase (except for SF1 and GATA2), whereas signaling molecules appear in uppercase. CNS anatomic abnormalities and pituitary hormone deficiencies. For this reason, children with congenital blindness or nystagmus should be monitored for hypopituitarism.

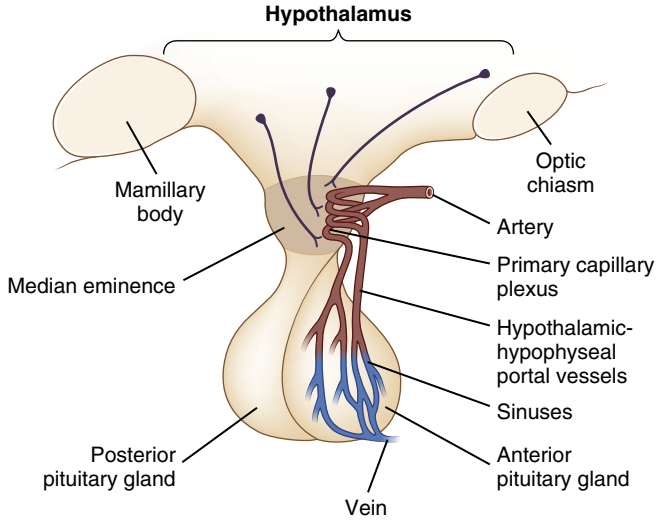
The anterior pituitary receives controlling signals from the hypothalamus through the portal circulatory system (Fig. 25.14).[66] The hypothalamus integrates signals from other brain regions and the environment, resulting in the release of factors that control pituitary hormone synthesis and secretion. Hypothalamic neurons that synthesize peptides terminate in the infundibulum, enter the primary plexus of the hypophyseal portal circulation, and are transported via the hypophyseal portal veins to the capillaries of the anterior pituitary. This portal system in the pituitary stalk provides a means of communication between the neurons of the hypothalamus and the anterior pituitary.

Growth Hormone–Releasing Hormone

Growth hormone–releasing hormone (GHRH) is a 44–amino acid peptide hormone[70,71] secreted by neurons located in the arcuate nucleus (ARC) of the hypothalamus.[72] GHRH is the main hypophysiotropic neuropeptide responsible for the generation and maintenance of pulsatile GH secretion.[73,74] Regulation of GH production by GHRH is mediated largely at the level of transcription and is enhanced by increases in intracellular cyclic adenosine monophosphate (cAMP) levels. Evidence includes administration of GHRH antagonists resulting in an impairment of GH pulsatility, ablation of the ARC nucleus resulting in loss of GH secretion,[74,75] and administration of synthetic GHRH increasing GH secretion.[75] GHRH binds to GHRH receptors (GHRH-R) in somatotropes to activate multiple intracellular signaling pathways to stimulate somatotroph cell proliferation, differentiation, and growth[76,77] as well as to stimulate the secretion and synthesis of GH (Fig. 25.15).[78,79] The GHRH receptor is a member of the G protein–coupled receptor (GPCR) family BIII.[80] GH signaling pathways engaged by GHRH-R activation include adenylate cyclase (AC), increasing cAMP production, which in turn leads to an increase in protein kinase A (PKA) activity,[81–83] intracellular and extracellular Ca^{2+}, NOS/NO/GC/cGMP, and PKC/PLC pathways.[81,84] In a dwarf transgenic mouse model with diminished GHRH production, pituitary somatotroph proliferation is markedly decreased.[85,86] Transgenic mice that overexpress GHRH grow at a faster rate than control mice.[87]



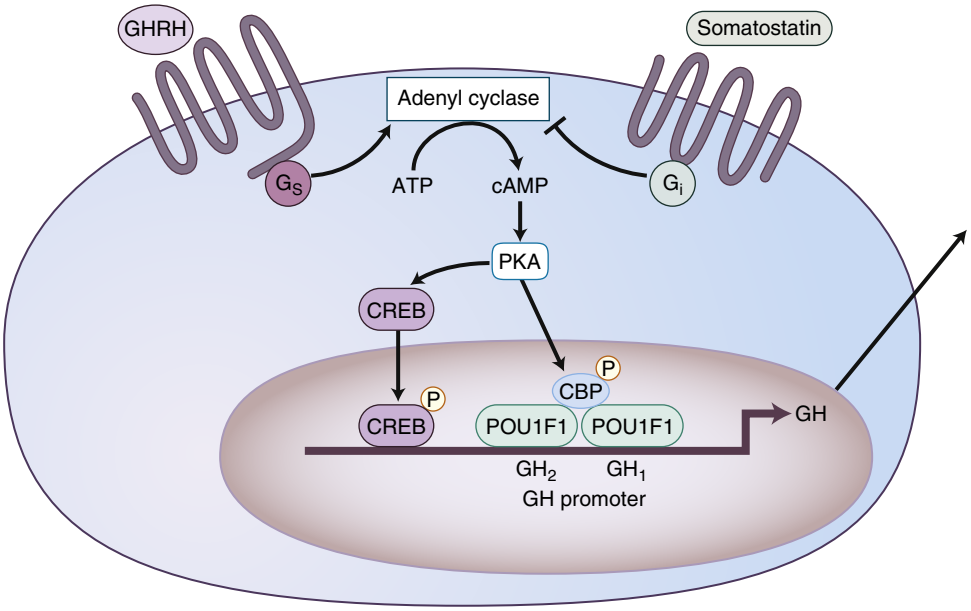
• **Fig. 25.14** The main components of the hypothalamic-pituitary portal system. (From Guyton AC, Hall JC. *Human Physiology and Mechanisms of Disease,* 6th ed. Philadelphia: WB Saunders; 1997:600, used with permission.)

Somatostatin (SST)

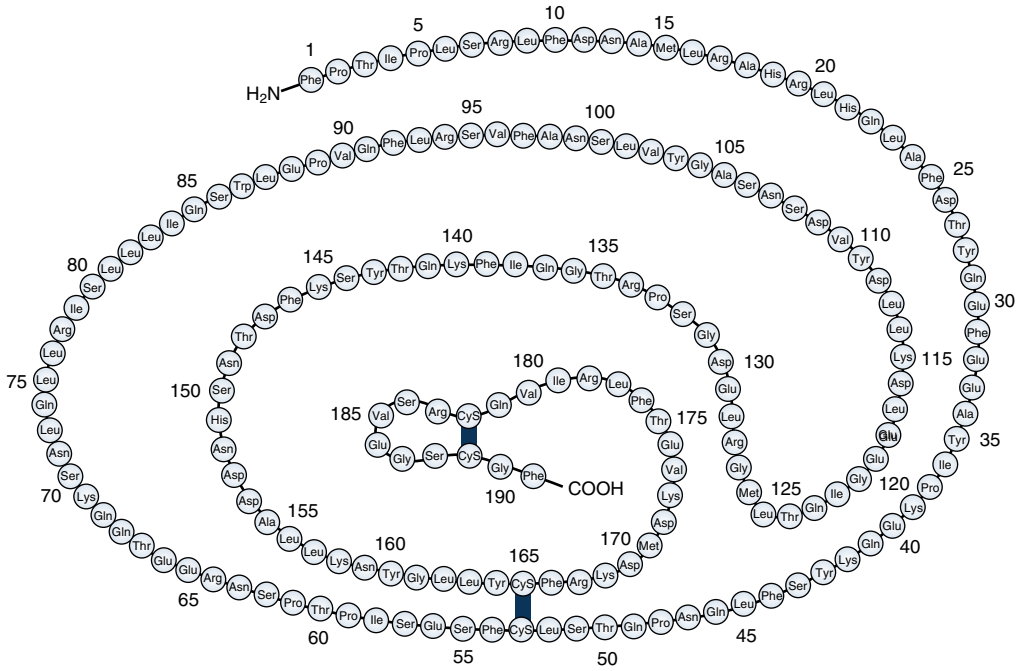
SST or somatotropin-release inhibitory factor (SRIF) is derived from a 116 precursor that produces two different cyclic forms, somatostatin-14 and somatostatin-28, by alternative post-translational processing. Somatostatin binds to at least five receptor subtypes (SST1–5 receptors), which are GPCRs with seven transmembrane domains. Subtypes 2 and 5 are the predominant types found in the pituitary.[88–90] SST binding results in the recruitment of several downstream signaling pathways, including AC, protein phosphatases, cyclic guanosine monophosphate (cGMP)–dependent protein kinases, and calcium in addition to other ion channels.[91–93] SST inhibits GH release and antagonizes the stimulatory effects from GHRH or ghrelin.[73]

Growth Hormone

Human GH is produced as a single-chain, 191–amino acid, 22-kDa protein containing two intramolecular disulfide bonds (Fig. 25.16). GH shares sequence homology with PRL, chorionic somatomammotropin (CS, placental lactogen), and a 22-kDa GH variant (GH-V) that is secreted only by the placenta and



• **Fig. 25.15** Schematic diagram summarizing the main signaling pathways in the somatotroph involved in the response to GHRH and somatostatin. GHRH binding to its receptor increases intracellular cAMP. Activation of the PKA pathway results in binding of POU1F1 to specific promoter sequences on the GH gene to increase transcription. Somatostatin binding to its receptor decreases intracellular cAMP.



• **Fig. 25.16** Covalent structure of human growth hormone. (From Chawla RK, Parks JS, Rudman D. Structural variants of human growth hormone: biochemical, genetic and clinical aspects. *Annu Rev Med*. 1983;34:519–547.)

differs from pituitary GH by 13 amino acids. The genes encoding these proteins most likely evolved from a common ancestral gene, despite being located on different chromosomes (chromosome 6 for PRL and chromosome 17 for GH).[94] The genes for GH, PRL, and placental lactogen share a common structural organization, with four introns separating five exons. The GH subfamily contains five members, with genes located on a 78-kilobase (kb) section of chromosome 17; the 5′ to 3′ order of the genes is GH, a CS pseudogene, CS-A, GH-V, and CS-B. Normally, about 75% of GH produced by the pituitary is of the mature, 22-kDa form. Alternative splicing of the second codon results in deletion of amino acids 32 through 46, yielding a 20-kDa form that normally accounts for 5% to 10% of pituitary GH.[94] The remainder of pituitary GH includes desamidated and *N*-acetylated forms and various GH oligomers.

Growth Hormone Pulsatility

The pulsatile pattern characteristic of GH secretion reflects the interplay of the two hypothalamic regulatory peptides, GHRH and somatostatin, with modulation by other putative GH-releasing factors.[95,96] Somatostatin appears to have its major effect on the timing and amplitude of pulsatile GH secretion and lesser effects on the regulation of GH synthesis. The pulsatile secretion of GH in vivo is believed to result from a simultaneous reduction in hypothalamic somatostatin release and increased GHRH release.[97] Conversely, a trough of GH secretion occurs when somatostatin is released in the face of diminished GHRH activity. The coordinated secretion of GH pulses in response to GH secretagogues results from a continuum of GH cells geographically connected by adherens junctions as revealed by three-dimensional reconstructive microscopy.[98]

Regulation of the reciprocal secretion of GHRH and somatostatin is imperfectly understood. The hypothalamus integrates signals for stress, sleep, hemorrhage, fasting, hypoglycemia, and exercise through the secretion of multiple neurotransmitters and neuropeptides to regulate the release of these hypothalamic factors and ultimately to influence GH secretion. This physiologic phenomenon forms the basis for a number of GH-stimulatory tests used in the evaluation of GH secretory capacity or reserve. GH secretion is also influenced by a variety of nonpeptide hormones, including androgens,[99] estrogens,[100] thyroxine,[101] and glucocorticoids.[102,103] The mechanisms by which these hormones regulate GH secretion may involve actions at the hypothalamus and the pituitary. For example, hypothyroidism and glucocorticoid excess may each blunt spontaneous and provocative GH secretion. Gonadal steroids appear to be responsible for the rise in GH secretion that characterizes puberty.

Ghrelin

Synthetic hexapeptides capable of stimulating GH secretion are termed *GH secretagogues*.[80] These peptides stimulate GH release and enhance the GH response to GHRH, although they work at receptors distinct from those for GHRH, at hypothalamic and pituitary sites. Kojima and colleagues[104] identified a natural ligand called *ghrelin*, a 28–amino acid protein with the serine 3 residue *n*-octanoylated. It is produced mainly by the oxyntic cells of the stomach (and throughout the gastrointestinal tract[105]) and in the hypothalamus, heart, lung, and adipose tissue.[106,107] Ghrelin has a potent, dose-related, GH-releasing effect[108] and potentiates the GHRH-dependent secretion of GH. At the hypothalamic level, it increases GHRH secretion and inhibits somatostatin neurons.[81,109–111] GH release results from the binding of ghrelin to the growth hormone secretagogue 1a receptor (GHSR1a) on somatotrophs in the pituitary[108] and on GHRH-containing neurons in the hypothalamus.[112] The coupling of ghrelin to the GHSR1a receptor results in activation of multiple signaling cascades, including phospholipase C (PLC), protein kinase C (PKC), PKA,[113] intracellular and extracellular Ca^{2+}, or mitogen-activated

protein kinases.[110,114,115] Many studies have demonstrated that ghrelin has a wide range of effects, including on immune function, cognition, other anterior pituitary hormones (including gonadal axis regulation), bone metabolism, gastrointestinal motility, cell proliferation, and the cardiovascular system.[111,116–123]

However, it is difficult to separate the direct effects of ghrelin from those related to GH secretion. Although ghrelin has documented physiologic effects in vivo, GHSR1a knockout mice have a phenotype similar to that of wild-type animals, suggesting that ghrelin does not have a role in growth. However, compensatory mechanisms may provide an explanation for these findings.[124,125]

More recently, studies have documented a positive correlation between ghrelin and anthropometric parameters in the first months of life, a finding that strengthens the hypothesis that ghrelin exerts an influence on growth.[126] Two reports of mutations in GHSR1a in familial short stature provide evidence to the contrary.[127,128] Further studies indicate that the aging process may be associated with decreased expression of GHSRs in the hypothalamus[129] and with systemic concentration of ghrelin.[130] In addition to direct effects on linear growth, ghrelin has been shown to increase energy stores by stimulating appetite and affecting peripheral glucose and lipid metabolism.[131–133] These data suggest that ghrelin is an important stimulus for nutrient allocation for growth and metabolism and a central component of the GH regulatory system. Orally active ghrelin analogues have been considered as therapeutic agents in the treatment of GH deficiency (GHD), because they may provide a more physiologic approach to increasing the pulsatile release of endogenous GH compared with a single daily dose of recombinant human GH. However, there has been no definite evidence of the therapeutic efficacy of ghrelin analogues in the treatment of GHD states.

Pituitary Adenylate Cyclase–Activating Polypeptide

Pituitary adenylate cyclase–activating polypeptide (PACAP) is a hypothalamic peptide that has been shown to be effective in releasing GH from cultured pituitary cells. It belongs to a superfamily of hormones that includes glucagon, secretin, glucagon-like peptide 1 (GLP1), GLP2, GHRH, vasoactive intestinal polypeptide (VIP), peptide histidine methionine (PHM), and glucose-dependent insulinotropic polypeptide (GIP). Studies on the role of PACAP on GH release have been contradictory, some reporting a stimulatory action while others showing no effect on GH release.[73] PACAP increased both cAMP production and GH release in human somatotrope tumor cell lines[134] involving activation of voltage-operated/gated Ca^{2+} channels and signaling through the AC/PKA pathway.[73,135] However, studies in humans did not reveal an induction of GH release after intravenous PACAP administration.[136]

PACAP binds to several G protein–coupled receptors with differential affinity for PACAP or VIP. PACAP type 1 receptors (PAC1R) are more specific for PACAP, while VPAC1 and VPAC2 receptors bind VIP and PACAP isoforms with similar affinity. Further complexity is added by at least five alternative splice products of PAC1R alternative splicing, which have differential affinity for PACAP isoforms and induce different signaling pathways.[137,138] PACAP receptors (PAC1R) are found throughout the brain and in peripheral tissues.[137,138] Gene knockout of the specific PACAP receptor (PAC1R) resulted in a 60% mortality rate in the PAC1R null mice in the first 4 weeks after birth, providing insight into the importance of PACAP, even though other superfamily members may compensate some of its functions.[139] The surviving knockout mice showed reduced glucose-stimulated insulin release and glucose intolerance. This observation suggests that PACAP is important in carbohydrate metabolism, potentially through GH.

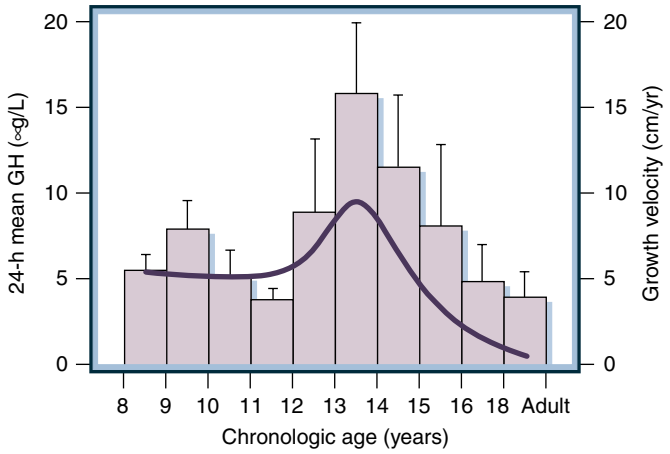
The synthesis and secretion of GH are also regulated by the insulin-like growth factor (IGF) peptides. Receptors specific for IGF1 and IGF2 have been identified in the hypothalamus and pituitary.[140] Inhibition of GH secretion by IGF1 or IGF2, or both, has been demonstrated,[141,142] and spontaneous GH secretion is diminished in humans treated with synthetic IGF1.[143]

Growth Hormone Secretion in Humans

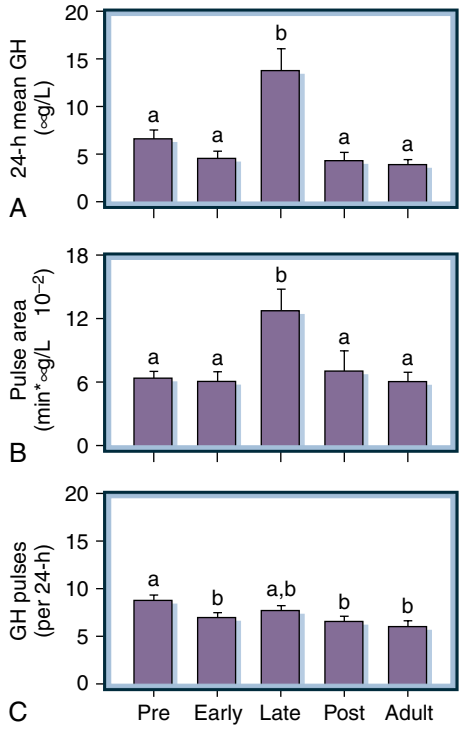
The episodic release of GH from the pituitary somatotrophs results in intermittent increases in serum levels of GH separated by periods of low or undetectable levels, during which time GH secretion is minimal.[97,144] The pulsatile nature of GH secretion has been demonstrated by frequent serum sampling coupled with the use of sensitive immunofluorometric or chemiluminescent assays of GH.[144] GHRH is primarily responsible for the generation and maintenance of pulsatile/episodic GH secretion.[73,74] Under normal circumstances, serum GH levels are less than 0.04 mg/L between secretory bursts. It is impractical to assess GH secretion by random serum sampling. Extensive sampling studies at different ages in normal persons and in many abnormal conditions have defined GH pulses, basal secretion, and diurnal variability. Computer programs have been developed to indicate whether changes in GH levels in various life periods and under diverse clinical circumstances occur because of a change of secretory mass or pulse frequency, altered clearance, or a combination of these processes.[144,145] Deconvolution techniques allow accurate estimates of the quantity of GH secreted per burst, GH clearance kinetics, and pulse amplitudes and frequencies, as well as an overall calculation of endogenous GH production. Approximate entropy, a model-free measure, is applied to quantify the degree of orderliness of GH release patterns.[146] The impact of the specific nature of pulsatile GH secretion on its biologic actions is under study.[144,145] For example, it appears that better statural growth is associated with large swings of GH output of relatively uniform magnitude in an irregular sequence (high approximate entropy).[147,148]

GH-secreting cells have been identified by 9 to 12 weeks of gestation, and immunoreactive pituitary GH is present by 7 to 9 weeks of gestation.[149] Fetal pituicytes secrete GH in vitro by 5 weeks, before the hypothalamic-portal vascular system is differentiated. PitT1 mRNA and Pit1 protein are expressed by at least 6 weeks of gestation; their abundant presence early in gestation suggests an important role in cytodifferentiation and cell proliferation.[150] GH can be identified in fetal serum by the end of the first trimester, with peak levels of approximately 150 mg/L in midgestation.[149] Serum levels fall throughout the latter part of pregnancy and are lower in full-term than in premature infants, perhaps reflecting feedback by the higher serum levels of IGF peptides that characterize the later stages of gestation.[151]

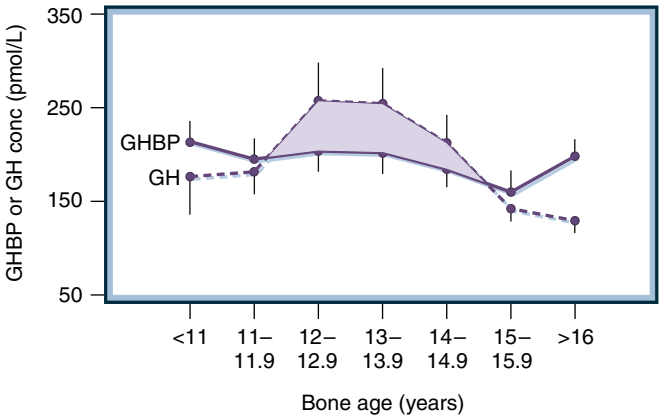
Mean levels of GH decrease from values of 25 to 35 mg/L in the neonatal period to approximately 5 to 7 mg/L through childhood and early puberty.[152] Twenty-four-hour GH secretion peaks during adolescence, undoubtedly contributing to the high serum levels of IGF1 that are characteristic of puberty. The increase in GH production during middle to late puberty is caused by enhanced pulse amplitude and increased mass of GH per secretory burst, rather than by a change in pulse frequency (Figs. 25.17 and 25.18).[145,146,152] Greater irregularity in GH secretion corresponds to greater linear growth.[153] In the face of stable levels of the growth hormone–binding protein (GHBP),[154] the enhanced pubertal GH production appears to be associated with higher



• **Fig. 25.17** Relation between 24-hour mean growth hormone (GH) levels and age in boys and men. The bars represent the 24-hour mean and standard error (+SE) values of GH *(left axis)* obtained from 60 24-hour GH profiles of healthy boys and men subdivided according to chronologic age. An idealized growth velocity curve reproduced from the 50th percentile values for whole-year height velocity of North American boys[16] is superimposed. (From Martha PM Jr, Rogol AD, Veldhuis JD, et al. Alterations in the pulsatile properties of circulating growth hormone concentrations during puberty in boys. *J Clin Endocrinol Metab.* 1989;69:563–570.)



• **Fig. 25.18** (A) The 24-hour and standard error (+SE) levels of growth hormone (GH) for groups of normal boys at varied stages of pubertal maturation. (B) The mean (+SE) area under the GH concentration-vs.-time curve for individual GH pulses, as identified by the cluster pulse detection algorithm. (C) The number of GH pulses (+SE), as detected by the cluster algorithm, in the 24-hour GH concentration profiles for boys in each of the pubertal study groups. Notice that the mean 24-hour GH concentration changes are largely mediated by changes in the amount of GH secreted per pulse, rather than the frequency of pulses. In each panel, bars bearing the same letter are statistically indistinguishable. (From Martha PM Jr, Rogol AD, Veldhuis JD, et al. Alterations in the pulsatile properties of circulating growth hormone concentrations during puberty in boys. *J Clin Endocrinol Metab.* 1989;69:563–570.)



• **Fig. 25.19** Levels of growth hormone (GH) and growth hormone–binding protein (GHBP) measured in normal pubertal boys throughout adolescence. The GHBP levels do not significantly change during puberty, but there is a significant increment of GH production and therefore of GH levels during this same time. These data suggest that there may be greater amounts of "free GH" during this period, leading to greater production of insulin-like growth factor 1. (Based on data from Martha PM Jr, Rogol AD, Blizzard RM, et al. Growth hormone-binding protein activity is inversely related to 24-hour growth hormone release in normal boys. *J Clin Endocrinol Metab*. 1991;73:175–181; Martha PM Jr, Rogol AD, Veldhuis JD, et al. Alterations in the pulsatile properties of circulating growth hormone concentrations during puberty in boys. *J Clin Endocrinol Metab.* 1989;69:563–570.)

levels of "free" GH (Fig. 25.19), potentially facilitating the delivery of IGF1 to target tissues. This enhanced activity of the GH-IGF axis contributes to the insulin resistance that occurs during puberty.[155] Production of GH and IGF begins to decline by late adolescence and continues to fall throughout adult life. Normal young adult men experience 6 to 10 GH secretory bursts per 24 hours, a value similar to that observed in younger children and adolescents.[144,152] On the other hand, 24-hour GH production rates for normal men range from 0.25 to 0.52 mg/m^2 surface area,[103] about 20% to 30% of pubertal levels; this is largely due to decreased GH pulse amplitude with age.[152] Indeed, puberty may be considered, with some justification, a period of "physiologic acromegaly," whereas aging, with its decrease in GH secretion, has been termed the *somatopause*.[100,156]

Physiologic states that affect GH secretion, in addition to maturation and aging, include sleep,[157] nutritional status,[95,158] fasting, exercise,[159] stress,[159] and gonadal steroids. Maximal GH secretion occurs during the night, especially at the onset of the first slow-wave sleep period (stages III and IV). Rapid eye movement (REM) sleep, on the other hand, is associated with low GH secretion.[157] A circadian rhythm of somatostatin secretion, upon which is superimposed episodic bursts of GHRH release, may help explain the nocturnal augmentation of GH production.[160]

When testosterone was administered to boys with delayed puberty, spontaneous GH release was enhanced, but such a change was not duplicated by administration of nonaromatizable androgens, emphasizing the possible unique importance of estrogen in GH secretion.[161] The effects of testosterone on serum IGF1 levels may in part be independent of GH because individuals with mutations of the GH receptor (GHR) still experience a modest rise in serum IGF1 during puberty.[162] With a combination of deconvolution analysis, approximate entropy, and cosine regression analysis, Veldhuis and associates[146,161] carefully evaluated intensive GH sampling data derived from measurements in sensitive GH assays

in prepubertal and pubertal children of both genders. In addition to the amplified secretory burst mass caused by jointly increased GH pulse amplitude and duration, they found that sex steroids selectively affect facets of GH neurosecretory control: Estrogen increases the basal GH secretion rate and the irregularity of GH release patterns, whereas testosterone stimulates greater GH secretory burst mass and greater IGF1 concentrations.

Obesity is characterized by lowered GH production, reflected by a diminished number of GH secretory bursts and shorter half-life duration.[163,164] Obesity in childhood and adolescence is characterized by decreased GH production with normal IGF and increased GHBP levels and often by increased linear growth.[164] The hyperinsulinism associated with obesity causes lowered levels of IGF-binding protein 1 (IGFBP1) and, perhaps, higher levels of "free" IGF1.[165] Endogenous GH secretion and levels achieved during provocative tests in obese subjects[166] approximated the diagnostic range of GHD. Fasting increased both the number and the amplitude of GH secretory bursts, presumably reflecting decreased somatostatin secretion and enhanced GHRH release, while lowering GHBP concentrations. Rapid changes in levels of IGFBPs in response to altered nutrition and changes in insulin levels may modify the effect of IGF1 on its negative feedback and effector sites.[158,164] Body mass also influences GH production in normal prepubertal and pubertal children and adults.[167–169]

Peripheral Modulators of Growth Hormone

Glucocorticoids

Conflicting studies have shown that glucocorticoids (GCs) are able to either stimulate or inhibit GH secretion, depending on specific conditions.[170–178] During a short-term (1-hour) incubation, GCs inhibited GHRH-stimulated GH secretions due to an increase in SST secretion.[172,179–181] After a 3-hour treatment with dexamethasone in normal human subjects, GH release was stimulated, followed by an inhibition after 12 hours.[173,174] After 4 days of treatment with prednisone, GHRH- stimulated GH secretion was blunted.[175] Signaling is thought to involve the activation of cAMP/PKA or PKC signaling pathways and intracellular free calcium mobilization.[182]

Thyroid Hormones

Several studies have shown that an increase in thyroid hormone (TH) levels in humans inhibits GH release due to either an increase in SST tone or a direct effect to decrease GHRH release.[183,184] THs have also been shown to inhibit human growth hormone (hGH) gene expression and secretion of GH in somatotroph cell cultures.[185] T_3 treatment also decreased hGH RNA levels without an effect on GH protein in transgenic (171hGH/CS-TG) mice overexpressing the human GH gene.[186]

Insulin and IGF1

IGF1 and IGFBP3 have been shown to positively affect spontaneous 24-hour GH secretion in human volunteers.[187] IGF1 has a negative feedback role to the hypothalamus and pituitary to regulate GH secretion. Low doses of recombinant IGF1 infusion resulted in a blunted response to the fasting-stimulated GH secretion,[188] and its administration at physiologic doses decreased the GH response to GHRH without altering spontaneous GH levels.[189] Further, free and not total IGF1 levels may be the primary mediator of GH secretion[190]; however, a single dose of recombinant IGF1 does not affect basal or pulsatile GH release.[191]

Similarly, insulin reduces GH response to GHRH,[192] and the elevated insulin associated with obesity is thought to decrease GH levels.[193] IGF1 and insulin have a direct effect on the somatotropes to decrease GH mRNA levels and GH secretion.[194] Somatotrophs are suppressed by IGF1-mediated signalings through the PI3K, mTORC1, and MEK pathways and insulin by the PI3K signaling pathway.[176,195,196] Deletion of the IGF1 receptor from somatotrophs in a genetically engineered mouse line resulted in mice of normal weight and length with only slightly elevated GH messenger RNA (mRNA) and serum GH levels.[197]

Free Fatty Acids

Free fatty acids (FFAs) inhibit GHRH-stimulated GH secretion by suppressing GHRH and/or stimulating SST secretion, or a direct effect on somatotropes.[198–205]

Adipokines

The adipokines (leptin, adiponectin, and resistin) are members of the cytokine family of proteins, which are released from adipose tissues. Although studies have reported an effect of leptin or adiponectin on somatotrophs, the precise relevance is unknown. Adiponectin has been associated with GH pulse secretion; however, whether this is a direct or indirect effect is unknown.[206] Adiponectin has also been shown to decrease GHRH-stimulated, but not ghrelin-stimulated, GH release. Leptin and resistin both increase GH secretions. The adipokines all utilize the AC/PKA signaling pathway; leptin also signals through intracellular/extracellular calcium and PLC/PKC, adiponectin through intracellular/extracellular calcium, and resistin through the mTOR pathway.[207]

Estrogens

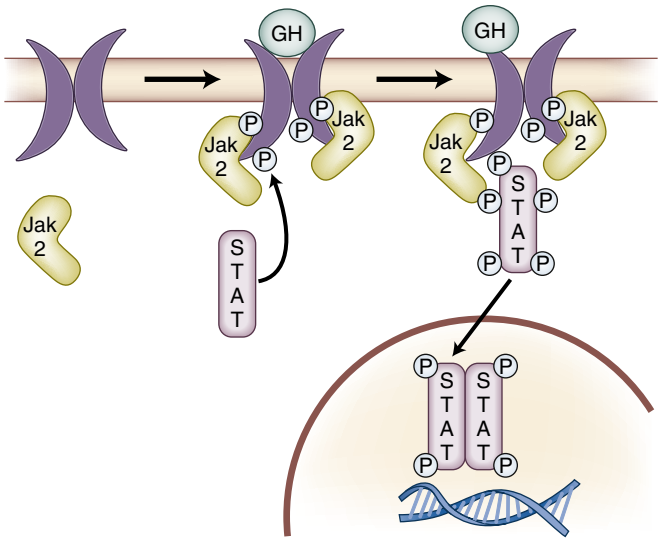
Estrogen receptors are expressed in somatotropes, and treatment with estradiol decreased IGF1 and elevated basal GH concentrations in men.[208] In postmenopausal women, estrogen treatment increased GH secretions and decreased IGF1 levels. These effects may be mediated directly or indirectly by negative feedback effects of IGF1.[209] In rodents, deletion of the estrogen receptor alpha resulted in a decrease in GH mRNA expression and secretion.[210] Both estrogen receptor α and β stimulate pituitary GH gene expression.

The Growth Hormone Receptor and Growth Hormone–Binding Protein

The gene for the human GHR is located on chromosome 5p13.1-p12, where it spans more than 87 kb.[211] The GHR gene *(GHR)* contains 10 exons: Exon 1 contains the 5′ untranslated region; exons 2 through 10 encode the three domains of the GHR—the extracellular ligand-binding domain, a single transmembrane domain, and a cytoplasmic domain for signal transduction.[212] The highest level of *GHR* expression is in the liver, followed by muscle, fat, kidney, and heart. The receptor is 638 amino acids long, with a predicted molecular weight of 70 kDa before glycosylation.

Two isoforms of the *GHR* have been found in humans—a full-length form and a form that has a deletion of exon 3 *(GHRd3)* with a loss of a 22–amino acid segment of the extracellular domain of the receptor.[213] The *GHRd3* allele is present in approximately 33% of the general population.[213] Several studies have investigated the clinical significance of the *GHRd3* allele on growth and GH responsiveness in specific disease states.

GH must be bound to a homodimer complex of GHR to activate its intracellular signaling pathways (Fig. 25.20). Whether dimerization of the GHR subunits occurs before or after GH binding is a matter of debate. It was initially thought that dimerization would occur only after GH binding; GH would bind to the first subunit, after which the GH-GHR complex would diffuse within



• **Fig. 25.20** A model depicting intracellular signaling intermediates induced by binding of growth hormone (GH) with the GH receptor (GHR). *Jak,* Janus kinase; *P,* phosphorylation; *STAT,* signal transducer and activator of transcription. (From Le Roith DC, Bondy S, Yakar J-L, et al. The somatomedin hypothesis. *Endocrine Rev.* 2001;22:53–74.)

the membrane until contacted by a second subunit, leading to receptor activation.[214] However, it was shown in live cells that the subunits of the GHR are constitutively dimerized in an inactive (i.e., unbound) state.[215] The GH binding sites on the extracellular domains of the two subunits are placed asymmetrically. Therefore once GH binds to both subunits, it induces rotation of the two subunits of the dimer that is transmitted via the transmembrane domain to the intracellular domain, allowing downstream kinase activation by transphosphorylation.

After binding to its receptor, GH stimulates phosphorylation of Janus kinase 2 (JAK2), a tyrosine kinase associated with the GHR (see Fig. 25.20). On recruitment or activation, the JAK2 molecule causes phosphorylation of critical tyrosines on the intracellular portion of the GHR, a sort of transphosphorylation. The phosphorylated tyrosines on the GHR provide docking sites for critical intermediary STAT (signal transducers and activators of transcription) proteins.[214] STAT proteins dock, via their Src homology 2 (SH2) domain to phosphotyrosines on ligand-activated receptors, such as the GHR. After docking, phosphorylation occurs on single tyrosines at the carboxy-terminus (C-terminal) of the protein. Then STATs dissociate from the GHR, dimerize, translocate to the nucleus, and bind to DNA through their DNA-binding domain to regulate gene transcription. There are seven known mammalian STATs; of these, STAT5B appears to be most critically involved in mediating the growth-promoting actions of the GHR.[216]

GHR signaling also leads to activation of extracellular-regulated kinase 1 (ERK1) and ERK2 to increase transcription.[217] How GHR activation promotes ERK1/2 activation is a matter of debate. A JAK2-independent but Src-dependent phosphorylation has been modeled,[167] as has a JAK2-dependent but Src-independent mechanism.[218] Experiments were conducted in different cell lines, so it is possible that the mechanisms of ERK1/2 activation by GHR are different in different cells. It is unclear what role these pathways play in the GH stimulation of growth.

GHBP prolongs the half-life of GH, presumably by impairing glomerular filtration, and modulates its binding to the GHR. It binds GH with high specificity and affinity but with low capacity; only about 45% of circulating GH is bound.[154] GHBP is derived from proteolytic cleavage of the extracellular domain of the receptor.[219] GHBP levels reflect GHR levels and activity; that is, low levels are associated with states of GH insensitivity.[154] Levels of GHBP are low early in life, rise through childhood, and plateau during the pubertal years and adulthood.[220] Impaired nutrition, diabetes mellitus, hypothyroidism, chronic liver disease, and inherited abnormalities of the GHR are associated with low levels of GHBP, whereas obesity, refeeding, early pregnancy, and estrogen treatment are associated with elevated levels of GHBP.[154] In general, GHBP levels reflect GHR levels and activity. Patients with GH insensitivity due to defects of the extracellular domain of the GHR have low GHBP levels, and GHBP levels can therefore be useful in identifying these individuals. Patients with GH insensitivity due to nonreceptor abnormalities, defects of the intracellular domain of the GHR, or inability of the receptor to dimerize may have normal levels of GHBP.[162]

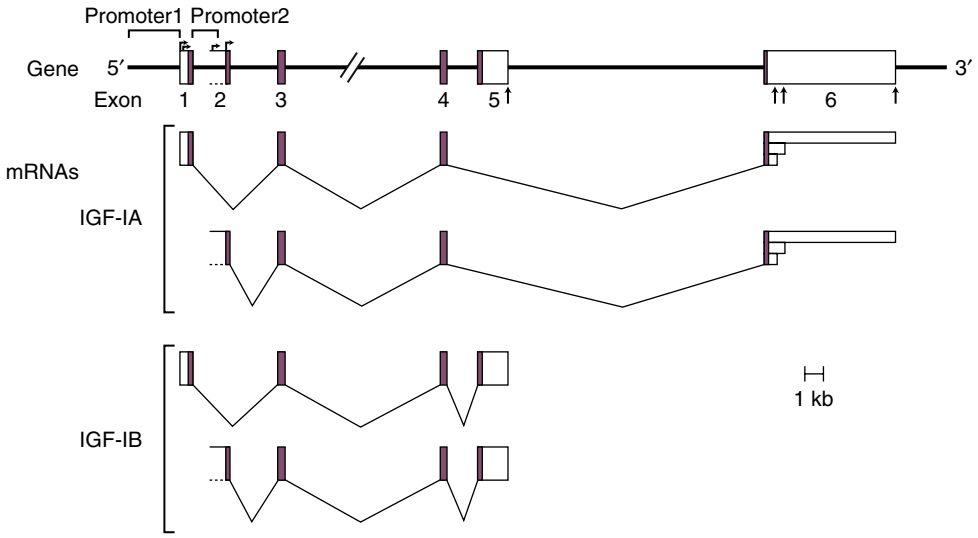
GHR signaling affects the transcription of many genes immediately (<3 hours after stimulation) and other genes over a longer period of stimulation. After acute GH stimulation in GH-deficient rats, hepatic genes immediately induced by GH included signal transducers (STAT3, gp130, p38), DNA repair proteins, receptor proteases, and metabolic regulators such as Igf1, Igfbp3, and Mct1.[221] GHR signaling is involved in regulation of expression of genes involved in carbohydrate, fat, and steroid metabolism.[222]

The study of mice that lack *Ghr* or downstream components of GHR signaling has shed light on the role of GH in normal physiology. *Ghr*$^{-/-}$ mice exhibit normal size at birth but have attenuated postnatal growth, with body weight about half of normal and length about two-thirds of normal.[223] *Ghr*$^{-/-}$ mice also exhibit delayed pubertal maturation, longer life span, and increased insulin sensitivity compared with a control group. Mice with *Ghr* deleted only in the liver have low IGF1 levels and high GH levels. These mice exhibit normal growth but have significantly lower bone density than controls. They also exhibit liver steatosis with insulin resistance and elevated serum free fatty acid levels,[224] showing the metabolic function of excessive GHR signaling independent of serum IGF1 signaling.

Deletion of *Jak2* in mice is embryonically lethal,[225] as is deletion of *Stat3*. Deletion of *Stat1* or *Stat5a* does not affect body size. However, deletion of *Stat5b* leads to decreased size in male but not female mice. The *Stat5a/b*$^{-/-}$ mouse is smaller than the *Stat5b*$^{-/-}$ mouse.[226] The combined *Igf1* and *Ghr*$^{-/-}$ mouse had a more severe attenuation of postnatal growth than mice with knockout of either gene alone, indicating that GH and IGF1 promote growth by both common and independent functions.[227] The liver-specific IGF1 knockout mouse with extremely low serum IGF1 levels has normal linear growth, suggesting IGF-independent actions of GH or paracrine production and effects of IGF1, or both.[228]

Historically, the anabolic actions of GH were thought to be mediated entirely by the IGF peptides (the so-called somatomedin hypothesis).[164] Although a majority of GH actions are mediated by IGFs, the opposite effects of GH and IGFs on metabolism and in knockout mouse models suggest that there are IGF-independent actions of GH. Indeed, the "diabetogenic" actions of GH are contradictory to the glucose-lowering effects of IGFs. In vitro studies suggest potential IGF-independent action of GH in the following tissues:

1. Epiphysis—stimulation of epiphyseal growth
2. Bone—stimulation of osteoclast differentiation and activity, stimulation of osteoblast activity, and increase in bone mass through endochondral bone formation



• **Fig. 25.21** Structure and expression of the human insulin-like growth factor 1 (IGF1) gene. The structure of the different human IGF1 messenger RNAs (mRNAs) is displayed below the map of the gene. Sites of pre-mRNA processing are indicated by the *thin lines*. Sites of differential polyadenylation are marked at the 3′ end of the gene by *vertical arrows* and in the mRNAs by *horizontal boxes* of varying length. (From Rotwein P. Structure, evolution, expression and regulation of insulin-like growth factors I and II. *Growth Factors.* 1991;5:3–18.)

3. Adipose tissue—acute insulin-like effects, followed by increased lipolysis, inhibition of lipoprotein lipase, stimulation of hormone-sensitive lipase, decreased glucose transport, and decreased lipogenesis
4. Muscle—increased amino acid transport, increased nitrogen retention, increased lean tissue, and increased energy expenditure

Insulin-Like Growth Factors

Historic Background. The IGFs (somatomedins) are a family of peptides that are, in part, GH dependent and mediate many of the anabolic and mitogenic actions of GH. They were originally identified in 1957 by their ability to stimulate [^{35}S]-sulfate incorporation into rat cartilage and were called *sulfation factors*.[164] In 1972, that term was replaced with *somatomedin*,[169] and purification of somatomedin from human serum yielded a basic peptide (somatomedin C) and a neutral peptide (somatomedin A).[229] In 1978, Rinderknecht and Humbel[230,231] isolated two active somatomedins from human plasma and, after demonstrating a striking structural resemblance to proinsulin, renamed them *insulin-like growth factors* (IGFs).

IGF Genes and Protein Structure. There are two IGFs circulating in humans, IGF1 and IGF2. IGF1 is a basic peptide of 70 amino acids, and IGF2 is a peptide of 67 amino acids. The two peptides share 45 of 73 possible amino acid positions and have 50% amino acid homology to insulin.[164,230,231] Like insulin, both IGFs have A and B chains connected by disulfide bonds. The connecting C-peptide region is 12 amino acids for IGF1 and 8 amino acids for IGF2, bearing no homology for the C-peptide region of proinsulin. The structural similarity to insulin explains the ability of both IGFs to bind to the insulin receptor and the ability of insulin to bind to the type I IGF receptor (encoded by *IGF1R*). On the other hand, structural differences probably explain the failure of insulin to bind with high affinity to the IGFBPs.

Insulin-Like Growth Factor 1

Gene Regulation. The human IGF1 gene *(IGF1)* is located on the long arm of chromosome 12 and contains at least six exons (Fig. 25.21). Exons 1 and 2 encode alternative signal peptides, each containing several transcription start sites; that is, the multiple existing *IGF1* transcripts consist of either exon 1 or exon 2. Two different promoters regulated in a tissue-specific manner[232] control the use of exon 1 or 2. Exons 3 and 4 encode the remaining signal peptide, the remainder of the mature IGF1 molecule, and part of the trailer peptide (E peptide). Exons 5 and 6 encode alternatively used segments of the trailer peptide and 3′ untranslated sequences with multiple different polyadenylation sites. As a result, multiple mRNA species exist, allowing for tissue-specific, developmental, and hormonal regulation of *IGF1* gene expression.

GH is the primary regulator of *Igf1* transcription, resulting in a 20-fold rise in *Igf1* mRNA. There may be tissue-to-tissue variability in the extent of GH-induced expression of *Igf1* mRNA.[233,234] Estrogen also regulates *IGF1* transcription, as its administration to a *Ghr*$^{-/-}$ mouse can stimulate hepatic *Igf1* synthesis and growth.[223] The sex steroid effects on *IGF1* transcription play a role in the pubertal rise of IGF1 levels in humans[235] (see later discussion).

The mechanisms involved in regulation of IGF gene expression include the existence of multiple promoters, heterogeneous transcription initiation within each of the promoters, alternative splicing of various exons, differential RNA polyadenylation, and variable mRNA stability. The transcription factor STAT5B is the most critical mediator of GH-induced activation of *IGF1* transcription, as detailed earlier. Two adjacent STAT5B binding sites are present in the second intron of the rat *Igf1* gene, within a region that undergoes acute changes in chromatin structure upon GH treatment.[216]

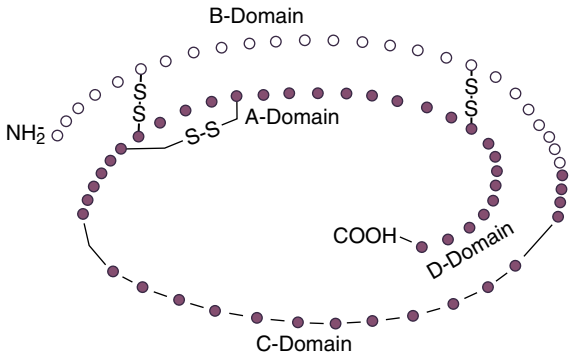
Once translated, IGF1 pre-propeptides require processing to form the mature IGF1 peptide (Fig. 25.22). Proteases from the subtilisin-related proprotein convertase family (SPC) cleave pro-IGF1.[236]

Serum Levels. In human fetal serum, IGF1 levels are relatively low and positively correlated with gestational age.[237] There is a reported correlation between fetal cord serum IGF1 levels and birth weight,[238] but this relationship is controversial.[239] IGF1 levels in newborn serum are typically 30% to 50% of adult levels and rise

during childhood. During puberty, IGF1 levels rise to two to three times the adult range. Levels during adolescence correlate better with Tanner stage or bone age than with chronologic age.[240] The pubertal rise in gonadal steroids may stimulate IGF1 production indirectly by contributing to a rise in GH secretion and directly by augmenting liver synthesis and secretion of IGF1. Girls with gonadal dysgenesis show no adolescent increase in serum IGF1, providing evidence of the association of the pubertal rise in IGF1 with the production of gonadal steroids.[241] As further evidence, patients with GH insensitivity due to GHR mutations exhibit a modest rise in IGF1 during puberty despite a decline in GH levels. After 20 to 30 years of age, serum IGF1 levels gradually and progressively fall, and this decline is implicated in the negative nitrogen balance, decrease in muscle mass, and osteoporosis of aging.[242]

Insulin-Like Growth Factor 2

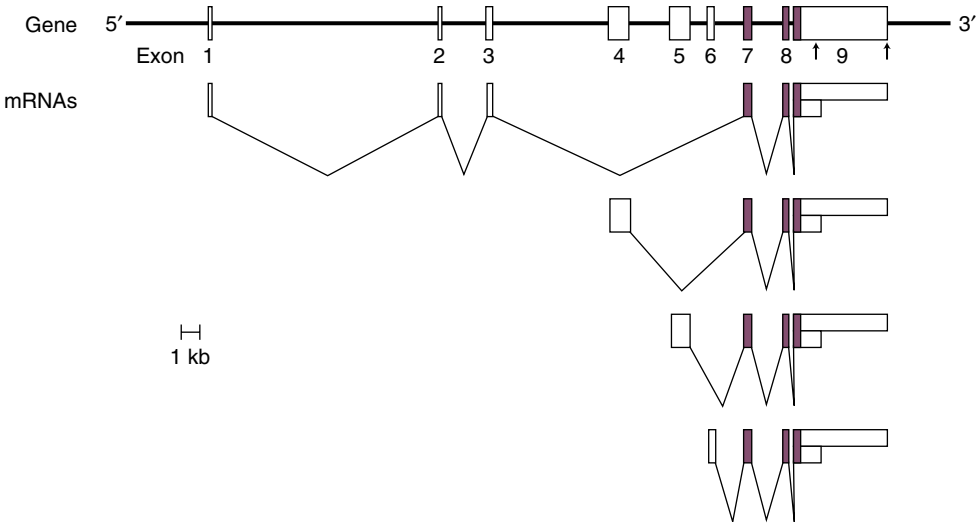
Gene Regulation. The gene for IGF2 *(IGF2)* is located on the short arm of chromosome 11, adjacent to the insulin gene, and contains 9 exons (Fig. 25.23). Exons 1 through 6 encode 5′ untranslated RNA, exon 7 encodes the signal peptide and most of the mature protein, and exon 8 encodes the C-terminal portion of the protein. As with *IGF1*, multiple mRNA species exist to allow for developmental and hormonal regulation of expression. *IGF2* mRNA expression is high in fetal life and has been detected as early as the blastocyst stage in mice.[243] Fetal tissues generally have high *IGF2* mRNA levels that decline postnatally.



• **Fig. 25.22** Structure of the insulin-like growth factor 1 (IGF1) peptide. See discussion in text. (From Yakar S, Wu Y, Setser J, et al. The role of circulating IGF-1. *Endocrine.* 2002;19:239–248.)

IGF2 is imprinted—that is, only one allele is active, depending on parental origin. In the case of *IGF2*, only the paternally expressed allele is active. Most imprinted genes occur in clusters with reciprocally imprinted genes, and *IGF2* is no exception. The noncoding gene *H19* is downstream from *IGF2* and is oppositely imprinted, meaning that only the maternal allele is expressed and the paternal allele is inactive. The promoters of *IGF2* and *H19* share a set of enhancers that act on either gene. On the paternal allele, the *H19* promoter region is methylated and thus inactivated (so-called epigenetic regulation of expression).[244] The *IGF2* promoter does not contain regions that can be methylated. Instead, upstream from the *H19* and *IGF2* promoter region is a so-called differentially methylated region (DMR). When it is methylated, binding of CCCTC binding factor (CTCF) is prevented, allowing enhancers to act on the *IGF2* promoter to activate transcription.[245] On the maternal chromosome, the DMR is not methylated, allowing CTCF to bind and preventing transcription (Fig. 25.24).[246]

The fact that *IGF2* is monoallelically expressed emphasizes the importance of gene dosage to normal physiology and development. Loss of imprinting of *IGF2* can lead to constitutively expressed *IGF2* mRNA and excessive IGF2. *IGF2* mRNA is expressed constitutively in a number of mesenchymal and embryonic tumors, including Wilms tumor,[247] rhabdomyosarcoma, neuroblastoma, pheochromocytoma, hepatoblastoma, leiomyoma, leiomyosarcoma, liposarcoma, and colon carcinoma.[248] Loss of imprinting of *IGF2* resulting in biallelic gene expression occurs in Beckwith-Wiedemann syndrome (BWS), which is characterized by fetal and neonatal overgrowth and an increased risk of childhood



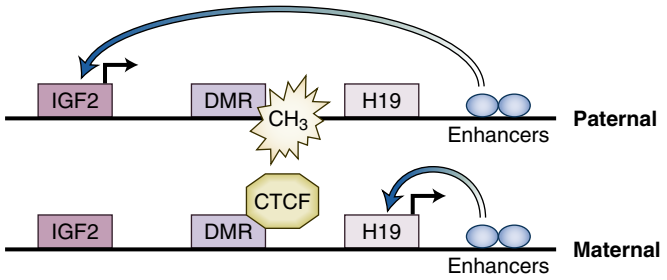
• **Fig. 25.23** Structure and expression of the human insulin-like growth factor 2 (IGF2) gene. The structure of different human IGF2 messenger RNAs (mRNAs) is displayed below the map of the gene. The patterns of mRNA processing are indicated by the *thin lines*. Sites of differential polyadenylation are marked at the 3′ end of the gene by *vertical arrows* and in the mRNAs by *horizontal boxes* of varying length. (From Rotwein P. Structure, evolution, expression and regulation of insulin-like growth factors 1 and 2. *Growth Factors.* 1991;5:3–18.)

cancers. Loss of imprinting in BWS results from mutations that affect imprinting in the region of chromosome 11 that contains *IGF2*,[249] methylation defects that cause hypermethylation of the region or duplication of the expressed paternal allele, resulting in increased *IGF2* expression, or paternal uniparental disomy (i.e., inheritance of only the expressing paternal allele).

Serum Levels. Human newborn levels of IGF2 are typically 50% of adult levels. By 1 year of age, adult levels are attained, and there is little if any subsequent decline, even up to the seventh or eighth decade.[250]

Insulin-Like Growth Factor Receptors

There are two types of IGF receptors, type I and type II (Fig. 25.25). Structural characterization of these receptors has provided documentation of the differences between these two forms.[251] The type I IGF receptor is closely related to the insulin receptor; both are heterotetramers comprising two membrane-spanning



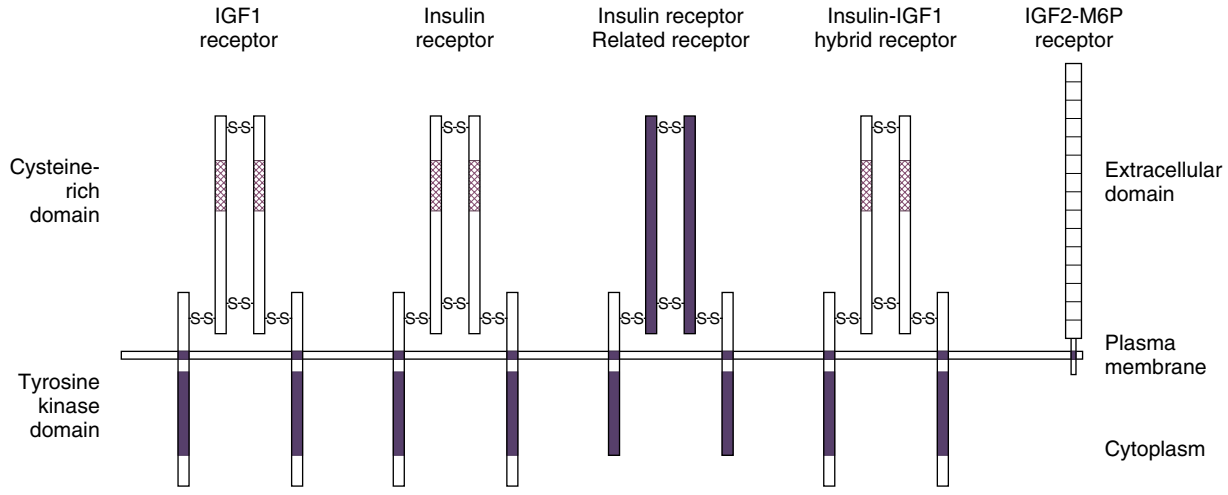
• **Fig. 25.24** Schematic of the imprinted region of the insulin-like growth factor 2 *(IGF2)-H19* locus. *CTCF,* CCCTC binding factor; *CH3,* methylation; *DMR,* differentially methylated region. (Adapted from Chao W, D'Amore P. IGF2: epigenetic regulation and role in development and disease. *Cytokine Growth Factor Rev.* 2008;19:111–120.)

α-subunits and two intracellular β-subunits. The α-subunits contain the binding sites for IGF1 and are linked by disulfide bonds. The β-subunits contain a transmembrane domain, an adenosine triphosphate (ATP)–binding site, and a tyrosine kinase domain, which constitute the presumed signal transduction mechanism for the receptor.

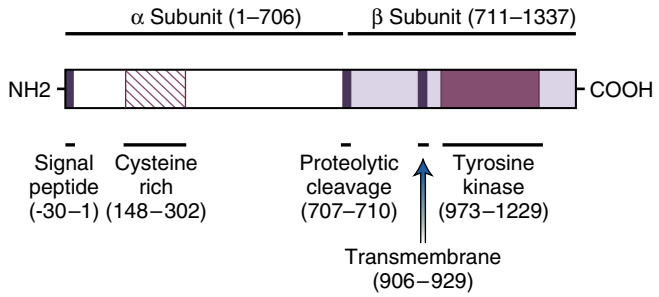
Although the type I IGF receptor has been commonly termed the *IGF1 receptor*, this receptor binds both IGF1 and IGF2 with high affinity, and both IGF peptides can activate tyrosine kinase by binding to the type I receptor. The affinity of the type I IGF receptor for insulin is usually 100-fold less, explaining the relatively weak mitogenic effect of insulin.

The mature IGF receptor peptide has 1337 amino acids with a predicted molecular mass of 151,869 kDa (Fig. 25.26). The translated αβ heterodimer is cleaved at an Arg-Lys-Arg-Arg sequence at positions 707 through 710. The released α-subunit and β-subunit, linked by disulfide bonds, then form the mature $(\alpha\beta)_2$ receptor, in which two α chains are joined by secondary disulfide bonds. The α-subunits are extracellular and contain a cysteine-rich domain that is critical for IGF binding. The β-subunit has a short extracellular domain, a hydrophobic transmembrane domain, and the intracellular tyrosine kinase domain with the ATP-binding site.

The gene for the type I IGF receptor *(IGF1R)* spans more than 100 kb of genomic DNA, with 21 exons; the genomic organization resembles that of the insulin receptor gene.[252] Exons 1 through 3 encode for the 5′ untranslated region and the cysteine-rich domain of the α-subunit that is involved in ligand binding. The remainder of the α-subunit is encoded by exons 4 through 10. The peptide cleavage site involved in generation of the α-subunit and β-subunit is encoded by exon 11, and the tyrosine kinase domain of the β-subunit is encoded by exons 16 through 20. It is in the latter region that *IGF1R* and the insulin receptor gene share the greatest sequence homology, ranging from 80% to 95%.



• **Fig. 25.25** Structure of the insulin-like growth factor (IGF) receptors. The insulin receptor and the IGF type 2 receptor are both heterotetrameric complexes composed of extracellular α-subunits that bind the ligands and β-subunits that anchor the receptor in the membrane and contain tyrosine kinase activity in their cytoplasmic domains. The tyrosine kinase domain of the insulin receptor–related receptor (IRR) is homologous to the tyrosine kinase domains of the insulin and IGF1 receptors. The carboxyl-terminal domain is deleted in the IRR. Hybrids consist of a hemireceptor from both insulin and IGF1 receptors. The IGF type 2/mannose-6-phosphate (M6P) receptor is not structurally related to the IGF1 and insulin receptors or to the IRR, having a short cytoplasmic tail and no tyrosine kinase activity. (From LeRoith D, Werner H, Geitner-Johnson D, et al. Molecular and cellular aspects of the insulin-like growth factor I receptor. *Endocr Rev.* 1995;16:143–163.)



• **Fig. 25.26** Structure of the human insulin-like growth factor type I receptor precursor. Molecular cloning of human IGF1 receptor complementary DNAs isolated from a placental library revealed the presence of an open reading frame of 4101 nucleotides. The 1367–amino acid polypeptide contains, at its NH_2-terminus, a 30–amino acid hydrophobic signal peptide that is responsible for the transfer of the nascent protein chain into the endoplasmic reticulum. After digestion by endopeptidases at a proteolytic cleavage site (Arg-Lys-Arg-Arg) located at residues 707 through 710, α-subunit and β-subunit are released and linked by disulfide bonds to yield the configuration of the mature heterotetrameric receptor. Also shown are the cysteine-rich domain of the α-subunit and the transmembrane and tyrosine kinase domains of the β-subunit. (From LeRoith D, Werner H, Beitner-Johnson D, et al. Molecular and cellular aspects of the insulin-like growth factor I receptor. *Endocr Rev.* 1995;16:143–163.)

IGF1R mRNA has been identified in virtually every tissue except liver.[253] The mRNA is most abundant in embryonic tissues and appears to decrease with age. *IGF1R* becomes widely expressed after implantation, consistent with the observation that this receptor is essential for normal fetal growth.

As with other growth factor receptor tyrosine kinases, binding of ligand (IGF1 or IGF2) induces receptor autophosphorylation of critical tyrosine residues in the type I IGF receptor.[221] Specifically, ligand binding to the α-subunits leads to activation of the tyrosine kinase domain of the β-subunits. Autophosphorylation appears to occur by transphosphorylation of sites on the opposite β-subunit.[254] A tyrosine proximal to the tyrosine kinase domain, Tyr 950, is part of a motif that, when deleted, reduces receptor autophosphorylation, affects receptor internalization, and inhibits postreceptor signaling; the adapter proteins Shc and insulin receptor substrate 1 (IRS1) bind to this domain.

Autophosphorylation and activation of the cytoplasmic region of the IGF type I receptor promotes recruitment or activation of several docking proteins, each of which activate distinct signaling pathways, with some overlap (Fig. 25.27). Proteins that dock onto the activated IGF type I receptor include members of the IRS family, Shc, p85 subunit of PI3 kinase, tyrosine phosphatase PTP1D, and mGRB10. Of these docking proteins, the pathways involving IRS and Shc are best characterized.

IRS1 is a 185-kDa protein that, when phosphorylated, contains specific phosphotyrosine motifs that can associate with proteins containing Src homology 2 domains such as the p85 subunit of PI3 kinase, growth factor receptor–bound protein 2 (Grb2), Syp (a phosphotyrosine phosphatase), and Nck (an oncogenic protein). Activation of Shc and Grb2 results in activation of the Ras, Raf, MAP kinase kinase, and S6 kinase pathways.[255] Binding of the p85 subunit of PI3 kinase leads to activation of the p110 subunit of PI3 kinase. This process then activates downstream phospholipid signal transduction pathways that include Akt. Activation of Akt leads to regulation of diverse cellular processes, including apoptosis, glucose transport and metabolism, protein synthesis, mitosis, and differentiation.[255] Phosphorylated Shc is a docking site for the SH2 domain of Grb2. Grb2 then binds SOS, a guanine nucleotide exchange factor that converts inactive Ras guanosine diphosphate (GDP) into guanosine triphosphate (GTP). GTP-bound Ras then recruits Raf, and Raf subsequently activates MAP kinase and mitogen and extracellular signal-related kinases (MEK) 1 and 2. Activation of these proteins ultimately regulates gene transcription. Given that insulin and IGF peptides activate similar signaling pathways through their own specific receptors, it is unclear how the cell distinguishes among these overlapping ligands. Whether the consequences merely reflect the relative levels of receptors and whether divergent downstream pathways exist for insulin and IGF action remain questions for future investigation.

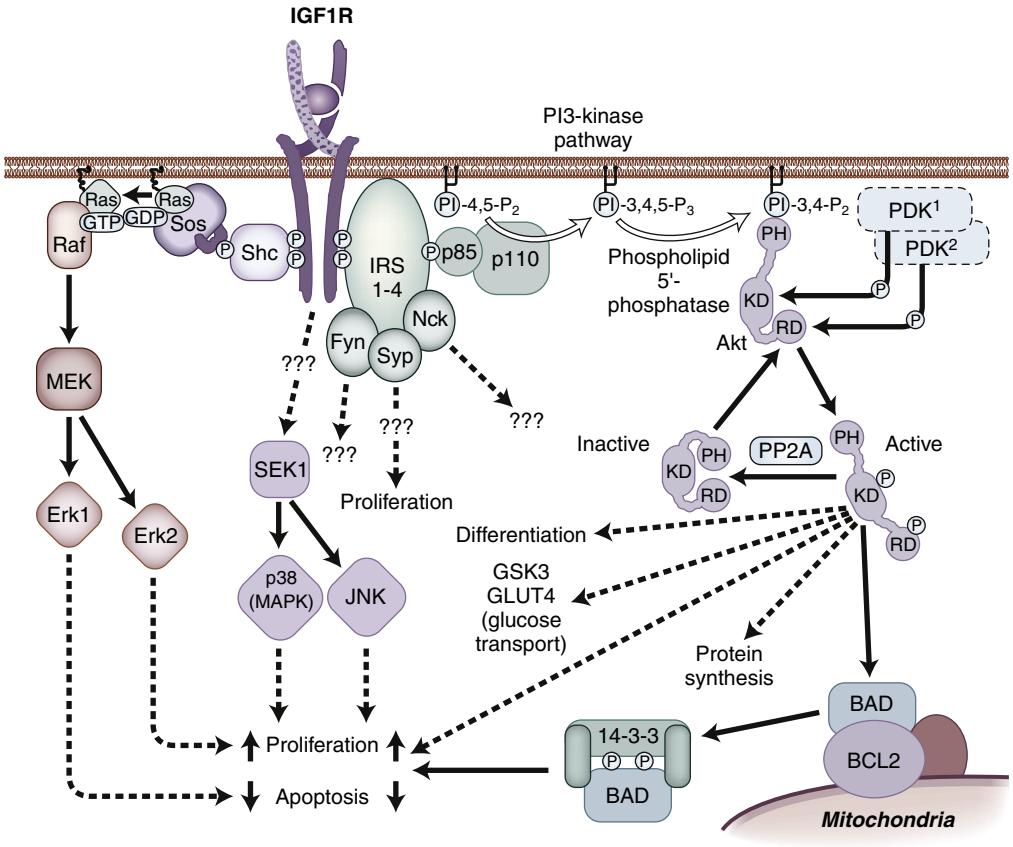
The α-subunit and β-subunit of the IGF receptor can form heterodimer with the α-subunit and β-subunit of the insulin receptor, forming hybrid receptors (see Fig. 25.25). Hybrid receptors have been found in significant amounts in most tissues. The hybrid receptor can bind either insulin of IGF1, but IGF1 may bind with higher affinity. No matter the ligand bound, autophosphorylation of the β-subunit of the insulin or IGF1 receptor occurs.[256] The physiologic significance of these hybrid receptors is unknown as studies thus far have been performed in vitro.

The type II IGF receptor bears no structural homology with either the insulin receptor or type I IGF receptors (see Fig. 25.25). The receptor does not contain an intrinsic tyrosine kinase domain or any other recognized signal transduction mechanism. The type II IGF receptor is identical to the cation-independent mannose-6-phosphate (M6P) receptor, a protein involved in the intracellular lysosomal targeting of acid hydrolases and other mannosylated proteins.[257] This common receptor is often referred to as the IGF2/M6P receptor. The gene for the IGF2/M6P receptor *(IGF2R)* is located on the long arm of chromosome 6. Exons 1 through 46 encode the extracellular region of the receptor, which contains 15 repeat sequences of 147 residues each. Exons 47 and 48 encode the 23-residue transmembrane domain and a small cytoplasmic domain consisting of only 164 residues.[258] Unlike *IGF2*, gene expression is biallelic in humans. Like *IGF2*, *IGF2R* expression is highest early in fetal development and declines postnatally.[258]

The IGF2/M6P receptor has an apparent molecular weight of 220,000 under nonreducing conditions and 250,000 after reduction, indicating that it is a monomeric protein.[259] The 15 repeat sequences contain cysteines to form intramolecular disulfide bonds necessary for receptor folding.[258] Repeat 11 binds IGF2, whereas repeats 3, 5, and 9 bind M6P. Because of receptor folding, it appears that the IGF2 binding site is on the opposite face to the M6P binding site.[260]

The IGF2/M6P receptor binds a variety of M6P-containing proteins, including lysosomal enzymes, transforming growth factor-β (TGFβ),[261] and leukemia inhibitory factor (LIF).[262] The IGF2/M6P receptor binds only IGF2 with high affinity, IGF1 binds to this receptor with lower affinity, and insulin does not bind at all.[263] The receptor participates in lysosomal enzyme trafficking between the trans-Golgi network and the extracellular space, regulates extracellular IGF2 and LIF levels, and plays a role in TGFβ activation (reviewed by El-Shewy and colleagues[264]). Mice null for the type II IGF receptor have macrosomia and fetal death, implicating a role in IGF2 degradation.[265]

The mitogenic and metabolic actions of IGF2 is mediated through the type I IGF receptor, because monoclonal antibodies directed against the IGF1 binding site on the type I IGF receptor inhibit the ability of both IGF1 and IGF2 to stimulate thymidine incorporation and cell replication.[266] Polyclonal antibodies that block IGF2 binding to the IGF2/M6P receptor do not block IGF2 actions.[267,268]



• **Fig. 25.27** Schematic representation of intracellular signaling pathways of the insulin-like growth factor type 1 (IGF1) receptor. On binding of IGF1, the IGF receptor undergoes autophosphorylation at multiple tyrosine residues. The intrinsic kinase activity of the receptor also phosphorylates insulin receptor substrate 1 (IRS1) at multiple tyrosine residues. Various SH domain–containing proteins, including phosphatidylinositol 3 (PI3) kinase, Syp, Fyn, and Nck associate with specific phosphotyrosine-containing motifs within IRS1. These docking proteins recruit diverse other intracellular substrates, which then activate a cascade of protein kinases, including Raf1, and one or more related kinases, including mitogen-activated protein kinase (MAPK), mitogen and extracellular signal-related kinase (MEK), and others. These protein kinases, in turn, activate various other elements, including nuclear transcription factors. Alterations in expression of various IGF1-responsive genes result in longer-term effects of IGF1, including growth and differentiation. This model of signal transduction cascades also shows a potential mechanism for inhibition of apoptosis. *BAD,* BCL2-associated agonist of cell death; *Erk,* extracellular signal-regulated kinase; *GDP,* guanosine diphosphate; *GLUT4,* glucose transporter 4; *GTP,* guanosine triphosphate; *JNK,* c-Jun N-terminal kinase; *KD,* catalytic kinase domain of Akt; *MEK,* mitogen-activated protein kinase; *P,* phosphorylation; *PH,* pleckstrin homology domain of Akt; *PP2A,* protein phosphatase 2A; *RD,* regulatory C-terminal tail of Akt; *SEK1,* serum-inducible and glucocorticoid-inducible protein kinase 1. Function-Targeted Disruption of IGF and IGF Receptor Genes

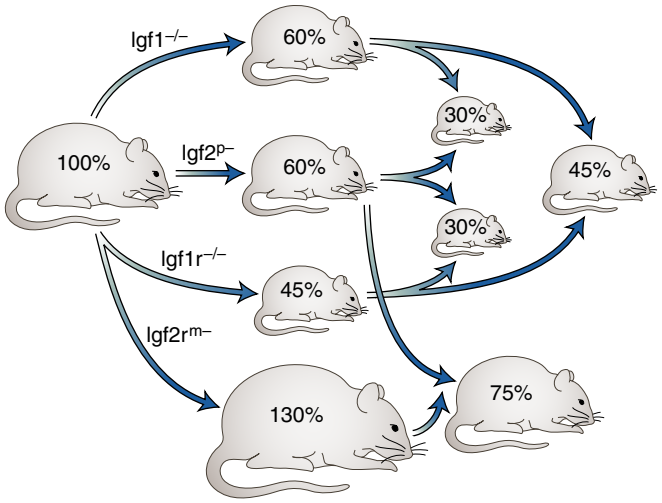
The in vivo role of the IGF axis in prenatal and postnatal growth was firmly established by a series of studies involving IGF and IGF receptor gene null mutations.[269] Unlike *Gh* or *Ghr* null mice that are near-normal size at birth, mice with deletions of *Igf1* or *Igf2* have birth weights approximately 60% of normal.[269] Fetal size is proportionately reduced, but mice with deletion of *Igf1* have a higher neonatal death rate than mice with *Igf2* deletion. Postnatally, mice with deletion of *Igf1* that survive the neonatal period continue to have growth failure, with weights 30% of normal by 2 months of age. When both *Igf1* and *Igf2* were disrupted, weight at birth was only 30% of normal and all animals died shortly after birth, apparently from respiratory insufficiency secondary to muscular hypoplasia (Fig. 25.28).

Mice lacking *Igf1* and the *Ghr* are only 17% of normal size.[227] Therefore both IGF1 and IGF2 are important in fetal growth, but GHR signaling may have IGF-independent actions on growth as well. The postnatal growth of *Igf1*$^{-/-}$ mice was poorer than that observed in mice with *Ghr* or *Ghrh* receptor mutations, indicating that both GH-dependent and GH-independent effects of IGF1 are necessary for normal growth.

Specific ablation of hepatic IGF1 production through the Cre/LoxP recombination system confirmed that the liver is the principal source of circulating IGF1, but the resulting 80% reduction in serum IGF1 levels had no effect on postnatal growth,[228,270] suggesting that postnatal growth is relatively independent of hepatic IGF1 production. Presumably, production of IGF1 from local chondrocytes or other tissues maintains adequate endocrine sources of IGF1 to account for growth preservation. Only modest decrement of postnatal growth is seen in mice null for *Igfals* (the gene encoding ALS).[271]



• **Fig. 25.28** Effects of the disruption of one or more genes of the insulin-like growth factor (Igf) system on fetal growth in mice, expressed as percentage of normal body weight. *Igf1*$^{-/-}$, Igf1 gene null mice; *Igf2*$^{p-}$, Igf2 paternal allele null mice; *Igf1r*$^{-/-}$, Igf1r gene null mice; *Igf2r*$^{m-}$, Igf2r maternal allele null mice. Mice with two source arrows are the combined genotype of the source arrow mice. (From Gicquel C, LeBouc Y. Hormonal regulation of fetal growth. *Horm Res.* 2006;65:28–33.)

By crossing the liver-derived IGF1 gene–deleted mice with ALS gene–deleted mice, 85% to 90% reduction in serum IGF1 occurred, with early postnatal growth retardation.[272] These findings suggest that postnatal growth is dependent on both hepatic and tissue IGF1, although definite conclusions are problematic in the face of elevated GH production and perturbations of the IGFBP system observed in these studies.

Deletion of *Igf1r* resulted in birth weights 45% of normal with 100% neonatal lethality.[273] Concurrent deletion of *Igf1* and *Igf1r* resulted in no further reduction in birth size compared with deletion of *Igf1r* alone; this is consistent with the hypothesis that all IGF1 actions are mediated via the IGF type I receptor.

Deletion of *Igf2r* in mice causes an increase in birth weight but death in late gestation or at birth.[265] Because this receptor normally degrades IGF2, increased growth reflects excess IGF2 acting through the IGF type I receptor, with variable accumulation of IGF2 in tissues. Deletion of *Igf2r* plus *Igf2* results in a birth weight 60% of normal, similar to the size of mice with knockout of *Igf2* alone, with no effect on neonatal survival.[274] Simultaneous knockout of the genes for *Igf2* and *Igf1r* causes further reduction of birth size to 30% of normal, suggesting that some of the fetal anabolic actions of IGF2 are mediated by another mechanism such as via placental growth or interactions with the insulin receptor. Indeed, specific deletion of *Igf2* in the placenta causes small placenta and growth retardation.[275]

These studies allow the following conclusions: (1) IGF1 is important for both fetal and postnatal growth; (2) IGF2 is a major fetal growth factor but has little role in postnatal growth; (3) the IGF type I receptor mediates anabolic actions of both IGF1 and IGF2; (4) the IGF type II receptor is bifunctional, serving to target lysosomal enzymes and to enhance IGF2 turnover; (5) IGF2 deletion results in impaired placental growth; and (6) IGF1 is the major mediator of GH effects on postnatal growth, although GH and GHR may have small IGF1-independent effects.

Insulin-Like Growth Factor–Binding Proteins

In contrast to insulin, the IGFs circulate in plasma complexed to a family of binding proteins that extend the serum half-life of the IGF peptides, transport the IGFs to target cells, and modulate the interactions of the IGFs with surface membrane receptors.[276] In addition, the IGFBPs have effects on cells independent of IGFs. The presence and various actions of the IGFBPs provide layers of regulation to the GH-IGF axis, greatly increasing its complexity (Fig. 25.29). In the following paragraphs, the structure of the IGFBP family is described first, followed by the role of IGFBPs in IGF physiology and the characteristics of individual IGFBPs.

Structure of IGFBPs

The six IGFBPs share structural homology in the N-terminal and C-terminal domains but have highly variable midsections, which probably accounts for the more specialized properties of the individual IGFBPs, such as cell dissociation, IGF-binding enhancement, and IGF-independent actions. In each of the conserved N-terminal and C-terminal domains, there are a high number of cysteine-rich residues with a conserved spatial order, implying that the disulfide bond–dependent secondary structure of the IGFBPs is also conserved.[277] Reduction of the disulfide proteins results in loss of IGF binding, further demonstrating the importance of the cysteine-rich region.

The N-terminal domain contains residues that have been shown to be essential for IGF binding to IGFBPs 1, 3, and 4.[278] The exact sequences in the C-terminal domain that are responsible for binding may differ among the IGFBPs. The highly variable midregion segment of the IGFBPs is the site of post-translational modifications such as glycosylation and phosphorylation and of proteolysis. Both the primary structure of IGFBPs and their post-translational modifications are responsible for the differential targeting to tissues: Glycosylation can affect cell interactions, phosphorylation can affect IGF1 binding affinity and susceptibility to proteases, and proteolysis can affect IGF/IGF receptor–dependent and IGF/IGF receptor–independent actions.[279]

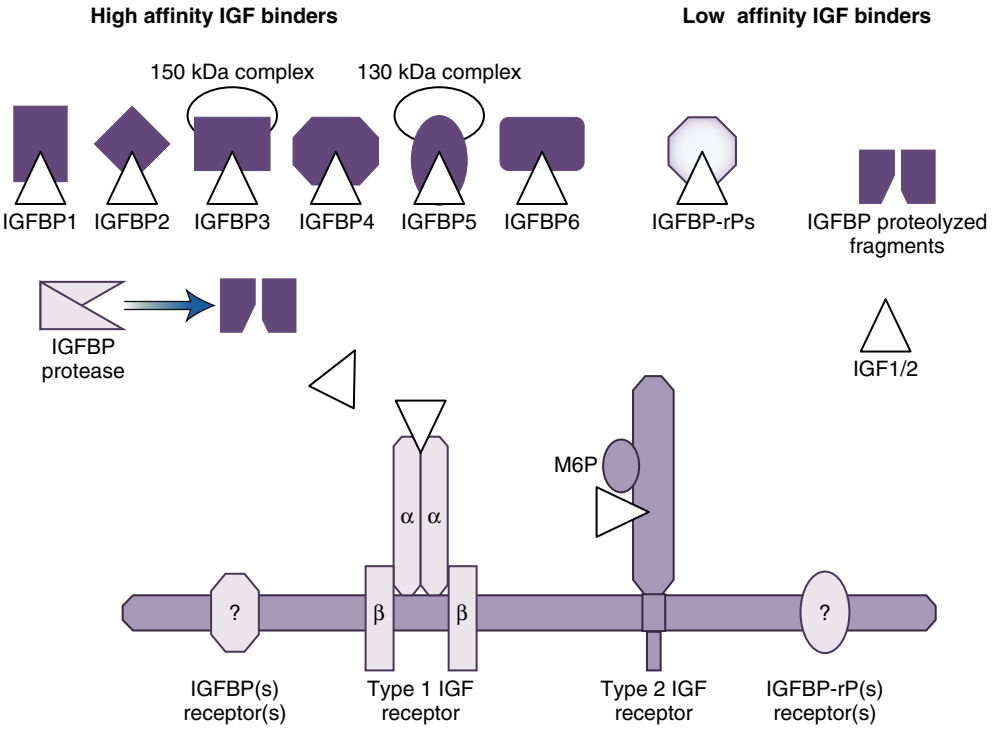
The three-dimensional structure of IGFBPs 1, 2, 4, and 5 details IGF-binding sites in the N-terminal and C-terminal domains. Crystallography indicates that the structure of the N-terminal domain is critical for IGF binding, whereas the C-terminal domain is important for inhibiting interactions between IGF1 and its receptor.[280,281]

Analysis of IGFBPs is complicated by the presence of IGFBP proteases that degrade IGFBP (Fig. 25.30).[282] Proteolysis of IGFBPs complicates their assay and must be taken into consideration when measuring the various IGFBPs in biologic fluids. Multiple IGFBP proteases exist, including calcium-dependent serine proteases, kallikreins, cathepsin, and matrix metalloproteases.[283,284] Proteolysis of IGFBPs releases IGFs to interact with cell surface receptors, thereby enhancing the mitogenic and anabolic effects of IGF peptides.

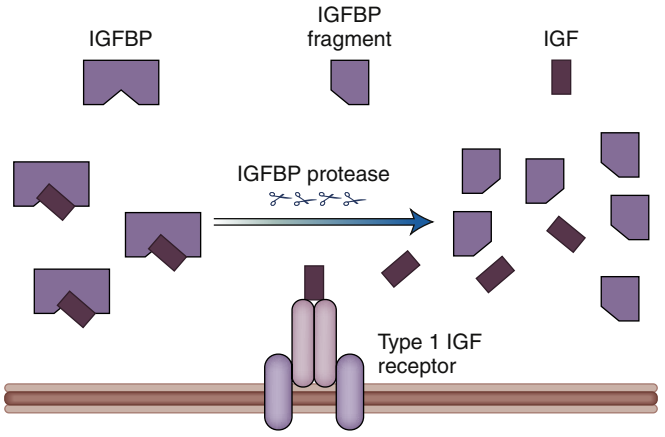
Role of IGFBPs in IGF Physiology

IGFBPs as Carrier Proteins

The IGFBPs complex almost all of the circulating IGF1 and IGF2 secondary to their high affinity for the IGFs (10^{-10} to 10^{-11} mol/L).[285] In adults, 75% to 80% of IGFs are carried in a ternary complex consisting of one molecule of IGF plus one molecule of IGFBP3 plus one molecule of the protein ALS.[286] This ternary complex is too large to leave the vascular compartment and thus extends the half-life of IGF peptides from approximately



• **Fig. 25.29** Schematic representation of the insulin-like growth factor (IGF) system, including IGF ligands (IGF receptors 1 and 2), binding proteins (both high-affinity and low-affinity binders), IGF-binding protein (IGFBP) proteases, type 1 and type 2 IGF receptors, and potential receptors for other IGFBPs and IGFBP-related proteins (IGFBP-rPs). *M6P,* mannose-6-phosphate. (From Hwa V, Oh Y, Rosenfeld RG. The insulin-like growth factor–binding protein [IGFBP] superfamily. *Endocr Rev.* 1999;20:761–787, copyright © Endocrine Society.)



• **Fig. 25.30** Schematic representation of the effect of insulin-like growth factor (IGF)–binding protein (IGFBP) proteases on IGF action. In this model, proteolysis of IGFBPs results in a reduction in their affinity for IGF ligands, leading to enhanced binding of IGF peptides by IGF receptors. (From Cohen P, Rosenfeld RG. The IGF axis. In Rosenbloom AL, ed. *Human Growth Hormone: Basic and Scientific Aspects.* Boca Raton, FL: CRC Press; 1995:43–58.)

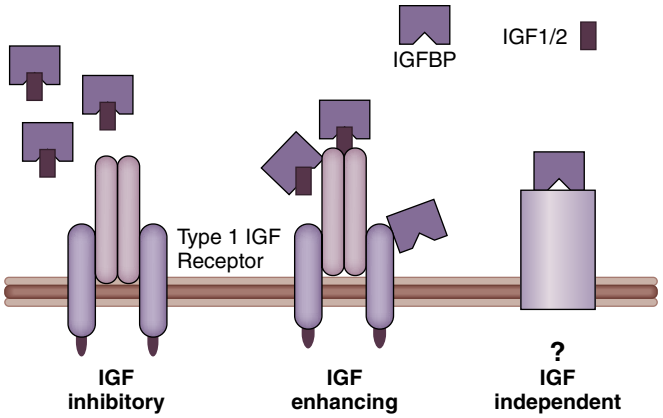
10 minutes for IGF alone to 12 to 15 hours for IGF in the ternary complex.[287] Binding of IGF to IGFBP3 in a binary complex extends the half-life of IGF to 1 to 2 hours as diffusion out of the vascular compartment may occur.[288]

Both IGFBP3 and ALS are GH dependent, providing an additional mechanism for GH regulation of the IGF axis. GH administration to GH-deficient patients shifts IGF to the ternary complex.[289] However, after IGF1 treatment alone, there is no increase in IGFBP3 levels, and ALS levels may decrease; thus IGF does not shift to the ternary complex.[290] In serum of patients with GHD or GH insensitivity, little IGF is present in the 150-kDa ternary complex; the IGF present is in the IGF-IGFBP3 binary complex or is bound by other IGFBPs such as IGFBPs 1, 2, 4, or 5.[291]

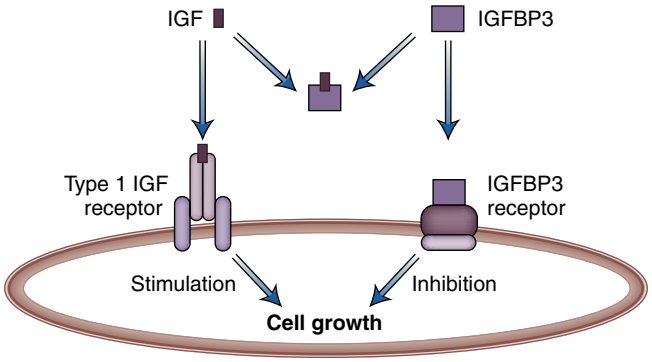
IGFBPs as Modulators of IGF Action

IGFBPs also regulate biologic actions by modulating the availability of IGFs (Fig. 25.31). The binding affinity of IGFs for IGFBPs is higher than for IGF receptors, and dissociation of IGFs from IGFBPs is required for IGFs to interact with IGF receptors.[285] Additionally, the concentration of IGFBPs is in excess, compared with IGFs, in many bodily fluids.[292] Dissociation of IGFs from IGFBPs is achieved by mass action, proteolysis, or other unknown mechanisms. Inhibition of IGF1 action by the presence of IGFBP4 occurs in vitro and in vivo.[293] IGFBPs 1, 3, and 5 have potentiating effects on IGF action, perhaps by facilitating the delivery of IGF to target receptors, as is for IGFBP3.[294]

The enhancing effects of IGFBP5 involve binding of IGFBP5 to extracellular matrix proteins, which reduces the affinity of IGFBP5 for IGF. Possibly, IGFBP5 binding to the extracellular matrix brings IGF close to the cell surface in a low-affinity complex, from which it can be released slowly to bind neighboring IGF receptors.[295] To complicate matters, it appears that the same IGFBP can potentiate or inhibit IGF action in vitro, depending on cell culture conditions, cell type, IGFBP dose, and post-translational modifications such as phosphorylation state.[296]



• **Fig. 25.31** Theoretic mechanisms of cellular actions of insulin-like growth factor (IGF)–binding proteins (IGFBPs). See text for details.



• **Fig. 25.32** Schematic diagram of insulin-like growth factor (IGF)–dependent and IGF-independent actions of IGF-binding protein 3 *(IGFBP3),* the latter being mediated through a putative membrane-associated IGFBP3 receptor.

It has also been proposed that IGFBP-IGF complexes can be stored in tissues to act in a paracrine manner. This has been demonstrated for IGFBP5 and bone matrix. IGFBP5 is produced by osteoblasts, and the IGFBP5-IGF complex can bind hydroxyapatite, possibly participating in bone turnover.[295]

IGFBP proteases, which degrade IGFBPs, are postulated to play a role in altering IGF availability by lowering affinities of IGFBPs for their ligand, thereby increasing the availability of IGFs to cell membrane receptors. The best characterized protease is pregnancy-associated plasma protein-A2 (PAPP-A2). *Papp-a2* knockout mice of postnatal growth restriction[297] and mutation of *PAPP-A2* causes growth retardation with high IGF1 levels in humans,[298] thus indicating the importance of these proteases for tissue IGF1 availability.

IGF-Independent Actions of IGFBPs

IGFBPs also have IGF-independent actions, such as growth inhibition of certain cell types, growth stimulation of tissues, direct induction of apoptosis, and modulation of the effects of other non-IGF growth factors. The mechanisms of IGF-independent actions are slowly being unraveled and include binding to IGFBP-specific cell surface receptors, binding to other cell surface receptors, and interaction with nuclear receptors (Fig. 25.32).

IGF-independent actions have been characterized for IGFBPs 1, 2, 3, and 5. IGFBP1 is implicated in cell motility and adhesion; IGFBP2 has mitogenic actions independent of IGF1 binding. In vitro, IGFBP3 administration or overexpression inhibits DNA synthesis and cell proliferation in conditions in which IGF1 or the IGF type I receptor is neutralized, suggesting IGF-independent inhibition by IGFBP3.[285] IGFBP5 has IGF-independent effects on osteoblasts.[279]

The IGFBPs also have IGF-independent effects via binding to IGFBP-specific membrane receptors for IGFBP3, IGFBP5, or other receptors such as the TGFβ receptor type V.[279] The downstream signaling pathways activated by the IGFBP-specific receptors are unknown, as are the possible interactions with IGF receptor signaling.

Characteristics of IGFBPs 1 Through 6

IGFBP1 was the first of the IGFBPs to be purified and to have its cDNA cloned. The gene is located on the short arm of chromosome 7, comprises four exons,[299] and is strongly expressed in decidua, liver, and kidney. It is the major IGFBP in fetal serum in early gestation, reaching levels as high as 3000 μg/L by the second trimester. Levels of IGFBP1 in newborn serum are inversely correlated with birth weight, suggesting an inhibitory role on fetal IGF action.

IGFBP1 may be involved in reproductive function, including endometrial cycling, oocyte maturation, and fetal growth.[300] It also appears to have an important metabolic role in that its gene expression is enhanced in catabolic states[250] while insulin suppresses IGFBP1 expression. Serum IGFBP1 levels correlate with insulin sensitivity. Low levels are associated with lower insulin sensitivity. Fasting levels predict risk of diabetes development in longitudinal cohorts.[301] IGFBP1 null mice have normal glucose homeostasis, but IGFBP1 transgenic mice are protected against insulin resistance when challenged with a high-fat diet. The cellular target(s) of IGFBP1 that mediate these effects are not known, as IGFBP1 can have IGF1-independent effects.

The *IGFBP2* gene is located on the long arm of chromosome 2 and is highly expressed in fetal tissues, particularly in the CNS.[302] It is the second most abundant IGFBP in the serum, behind IGFBP3. Unlike IGFBP1, its expression does not change with feeding. IGFBP2 transgenic mice have diminished postnatal weight gain and slightly reduced fasting insulin levels with protection against age-related insulin resistance.[301]

The *IGFBP3* gene is located on chromosome 7. IGFBP3 is composed of the conserved N-terminal and C-terminal domains and the variable midsection. The midsection is the site of N-linked glycosylation, which is not present in IGFBP1 or IGFBP2 and is the site of phosphorylation. This midsection is the site responsible for interaction with cell surfaces.[303]

IGFBP3 is the predominant IGFBP in adult serum, where it carries approximately 75% of the total IGF, primarily as part of the 150-kDa ternary complex consisting of IGF1, IGFBP3, and ALS. IGFBP3 and IGFBP5 are the only IGFBPs to form this complex. It is believed that formation of this ternary complex limits IGF access to target cells, while at the same time prolonging serum half-lives of both the IGF peptide and its binding protein.[304] Serum levels of IGFBP3 and ALS are reduced in patients with GHD or GH insensitivity, conditions in which assays for serum IGFBP3 have important diagnostic value. IGFBP3 is increased in states of GH excess and acromegaly.

IGFBP3 action is GH dependent, either directly or through regulation by IGF. IGF1 treatment of patients with GH insensitivity does not greatly alter serum IGFBP3 levels,[143] and GH treatment of GH-deficient patients does not increase serum levels. Whether these observations mean that GH has a direct effect on

IGFBP3 or reflects GH regulation of ALS and ternary complex formation is unclear, although it appears likely that both factors are contributory.

IGFBP3 associates with cell membrane proteins in a specific, cation-dependent manner and with high affinity.[279] Whether the cell membrane proteins constitute genuine IGFBP3 receptors remains to be determined, although they may mediate IGF-independent actions of IGFBP3.

IGFBP3 expression can be induced by cell cycle regulators and growth-inhibitory factors such as TNFα, TNFβ, retinoic acid, vitamin D, antiestrogens, and antiandrogens.[305] Like many genes, *IGFBP3* expression is affected by methylation and histone modification. Abnormal methylation or histone modification of the *IGFBP3* gene is present in many different types of human cancers (reviewed by Jogie-Brahim and colleagues[305]).

The *IGFBP4* gene is located on chromosome 17 and contains four exons. It is widely expressed in embryonic tissues, fibroblasts, osteoblastic cells, prostatic cells, ovarian cells, and liver. The circulating form is derived mostly from the liver. IGFBP4 inhibits IGF action in most tissues.[306] The inhibitory effect of IGFBP4 is reduced upon proteolysis by PAPP-A, as proteolysis of IGFBP4 results in an increase of free IGF1. Circulating IGF1 or IGF2 activates IGFBP4 proteolysis by inducing a conformational change allowing PAPP-A to access the cleavage site.[306]

The *IGFBP5* gene is located on chromosome 5 and contains four exons. IGFBP5 binds extracellular matrix proteins such as types III and IV collagen, laminin, and fibronectin, and it does so in response to binding of IGF1.[307] The affinity of IGFBP5 is reduced about sevenfold when the binding protein is associated with extracellular matrix, providing a potential mechanism for release of IGFs to cell surface receptors. Association of IGFBP5 with extracellular matrix protects it from proteolysis.[308] Unlike proteolysis of IGFBP4, which is enhanced by the addition of IGFs, degradation of IGFBP5 is inhibited by the binding of IGF peptides.[309]

The *IGFBP6* gene is located on chromosome 12 and contains four exons. Although IGFBP6 binds both IGF1 and IGF2, it has a significantly greater affinity for IGF2.[310] IGFBP6 is found in high levels in cerebrospinal fluid, as is IGFBP2, which also binds IGF2 with high affinity. IGFBP6 may have a role in regulating ovarian activity, perhaps by functioning as an antigonadotropin.[311]

Mice null for the individual IGFBPs exhibit modest, if any, alterations in growth. Modest decreases in organ size have been noted in IGFBP2 null mice,[312] whereas growth in IGFBP4 null mice is 85% to 90% of normal. Increases in other IGFBP levels were noted in these mice. Triple knockout mice null for IGFBPs 3, 4, and 5 exhibit lengths 80% of normal with IGF1 levels 45% of wild type.[313] Transgenic mice overexpressing the IGFBPs 1, 2, 3, and 4[314] exhibit growth retardation to varying degrees, demonstrating the role of the IGFBPs in sequestering IGF1 or inhibiting its actions. Mice overexpressing IGFBP1 and IGFBP3 exhibit impaired glucose tolerance and decreased fertility, further implicating a role for IGF1 or a separate role for these IGFBPs in glucose metabolism and reproduction.

Gonadal Steroids

Androgens and estrogens affect growth predominantly through two mechanisms: regulation of the GH-IGF1 axis and maturation of the epiphyseal growth plates. The adolescent rise in serum gonadal steroid levels is an important part of the pubertal growth spurt. In addition, it is the stimulation of epiphyseal fusion by the pubertal rise of gonadal steroid production that results in the ultimate cessation of linear growth. The details of the roles of androgens and estrogens in enhancing GH secretion and directly stimulating IGF1 production were discussed earlier.

Both androgens and estrogens increase skeletal maturation and accelerate growth plate senescence. However, most of these effects are due to the action of estrogen, with androgens acting indirectly after their conversion to estrogens by aromatase in extraglandular tissues, including locally within the growth plate. The primacy of the role of estrogen comes from animal studies[22] as well as reports of human subjects with mutations. A mutation of the estrogen receptor in a man was associated with tall stature and open epiphyses,[23] and similar findings were reported in patients with mutations of the gene encoding the aromatase enzyme.[315] In addition, variants of the estrogen receptor have been associated with height in males[316] and in females,[317] and increased aromatase expression results in short adult stature in males.[318,319]

Whereas most of the effects of androgen on growth are mediated through actions that occur after their aromatization to estrogen, there is evidence of androgen-specific effects. Notably, dihydrotestosterone, a nonaromatizable androgen, can accelerate linear growth in boys. This effect of androgen does not appear to be mediated by either GH or circulating IGF1, but it may be mediated by an increase in local IGF1 production.[320]

Gonadal steroids, along with GH and IGF1, contribute to the attainment of peak bone mass in adults. Again, this sex hormone effect is largely mediated by estrogen action.[321–323]

Thyroid Hormone

Thyroid hormone is of relatively little importance in the growth of the fetus, but it has significant effects on postnatal growth and bone maturation. Patients with hypothyroidism have decreased spontaneous GH secretion and blunted responses to GH provocative tests. Thyroid hormone also has a direct effect on chondrocytes and osteoblasts, which both express thyroid hormone receptors. Thyroid hormone regulates chondrocyte proliferation and stimulates terminal differentiation, mineralization, and angiogenesis.[324,325] In particular, thyroid hormone is essential for hypertrophic chondrocyte differentiation.[326] Postnatally, hypothyroidism can cause growth failure and delayed skeletal maturation, whereas hyperthyroidism can accelerate linear growth and skeletal maturation.

Glucocorticoids

Glucocorticoids have both stimulatory and inhibitory effects on GH secretion, with the absolute effect depending on the timing and the glucocorticoid concentration. Glucocorticoid deficiency, as in Addison disease, leads to a decrease in GH secretion due to decreased expression of GHRH and GH secretagogue receptors.[170] Acute exposure to supraphysiologic levels of glucocorticoids decreases GH secretion within 1 hour followed by a subsequent transient increase in GH secretion.[170,327] Ongoing glucocorticoid excess then causes ongoing suppression of GH secretion. This decrease in GH secretion is due to an increase in somatostatin tone.[170] Glucocorticoids can also impair growth through direct actions at the growth plate by inhibiting local IGF1 production through suppression of chondrocyte GHR expression, impairment of chondrocyte IGF1 receptor expression,[170,328] alterations in IGFBP levels, and impairment of intracellular signaling.[329] Finally, glucocorticoids may stimulate apoptosis of growth plate chondrocytes.[320]

Additional indirect effects of excess glucocorticoids on growth can result from glucocorticoid inhibition of calcium absorption

and reabsorption, with the development of secondary hyperparathyroidism.[325] In pubertal children, glucocorticoid excess can induce sex hormone deficiency, causing a loss of the normal growth stimulatory effect of these hormones.[325]

Pathologic Basis of Growth Retardation

A classification of growth retardation is presented in Table 25.1. Growth disorders can also be subdivided into (1) disorders of the hypothalamic-pituitary axis resulting in deficiency of GH, (2) disorders resulting in deficiency or resistance to the action of IGF1, (3) growth disorders that primarily affect the growth plate or are caused by chronic disease, and (4) idiopathic short stature (ISS), which is considered separately but may have a pathogenic basis in the GH-IGF1 axis or at the growth plate. A schematic diagram of known defects in the GH-IGF1 axis is shown in Fig. 25.33, and the known involved genes are listed in Table 25.2.

Disorders of the GH-IGF1 Axis

Growth Hormone Deficiency

Although it is not always possible to establish definitively whether hypothalamic or pituitary dysfunction is responsible for the hormone deficiency, these compartments are differentiated to facilitate discussion of the pathology. Table 25.3 indicates possible causes for deficiency in the GH-IGF axis. The term *idiopathic* is often used to designate lack of understanding of the basis for the GHD. Developmental or functional abnormalities of the hypothalamus account for most idiopathic cases of hypopituitarism, and recent molecular studies have begun to elucidate the molecular bases of these disorders. It is anticipated that most cases of idiopathic hypopituitarism will be defined at the genetic level in the future.

The Hypothalamus

Congenital Disorders

The primary hypothalamic neuropeptide responsible for synthesis and release of GH is GHRH. Somatostatin plays an antagonistic role in GH release. Synthesis of these two hypothalamic proteins is controlled by a series of neurochemicals, and the balance between them is responsible for the tight neuroendocrine control of GH biosynthesis. Mutations of some of the genes encoding hypothalamic peptides explain some cases of GHD due to hypothalamic dysfunction.

As noted earlier, patients with early-diagnosed congenital GHD frequently have an abnormal pituitary stalk, ectopia of the posterior pituitary, and hypoplasia of the anterior pituitary (Fig. 25.34). Anencephaly results in a pituitary gland that is small or abnormally formed and is frequently ectopic. Despite the loss of hypothalamic regulation, somatotrophs differentiate and proliferate, although in diminished overall mass.[67] During intrauterine life, serum GH and IGF1 levels are 30% to 50% of the normal range,[151] and pituitary GH content at birth is about 15% to 20% of normal,[149,151] with similarly low neonatal plasma GH levels.[330]

In most patients, so-called idiopathic hypopituitarism or GHD is presumed to be due to abnormalities of synthesis or secretion of hypothalamic hypophysiotropic factors.[331,332] In a number of reports, idiopathic GHD is associated with magnetic resonance imaging (MRI) findings of an ectopic neurohypophysis, pituitary stalk dysgenesis, and hypoplasia or aplasia of the anterior pituitary. Overall, those patients with the most striking abnormalities of the hypothalamic-pituitary region, largely those with combined pituitary hormone deficiency (CPHD), had the smallest anterior pituitary glands.[333] Patients with more severe deficiencies of GH have greater frequency of significant morphologic abnormalities.[334]

TABLE 25.2 Genetic Defects of the GH-IGF Axis Resulting in Somatotroph Dysfunction and GH Deficiency

Factor	Gene Function	Affected Cell Types	Clinical Phenotype	Mode of Inheritance
Mutations in Factors Resulting in Growth Hormone and Associated Hormone Deficiencies				
Hesx1	• Paired-like homeobox gene • Early marker for pituitary primordium and Rathke pouch • Requires Lhx3 for maintenance and PROP1 for repression	Somatotrophs, thyrotrophs, gonadotrophs (posterior pituitary may also be affected)	• Isolated GH deficiency or multiple hormone deficiency (including diabetes insipidus) • Puberty may be delayed • Associated with septo-optic dysplasia • Abnormal MRI findings: pituitary hypoplasia, ectopic posterior pituitary, midline forebrain abnormalities	AD, AR
Lhx3 (Lim3, P-LIM)	• Member of LIM-homeodomain family of gene regulatory proteins • Required for survival and proliferation of Rathke pouch • Activates αGSU promoter • Acts with Pit1 to activate TSHβ gene promoter	Somatotrophs, lactotrophs, thyrotrophs, gonadotrophs, possibly corticotrophs	• Patients may present with rigid cervical spine causing limited neck rotation • Hypoplastic anterior/intermediate pituitary lobe	AR
Lhx4	• A LIM protein with close resemblance to Lhx3 • Important for proliferation and differentiation of cell lineages • May have overlapping function with PROP1 and POU1F1	Somatotrophs, lactotrophs, thyrotrophs, gonadotrophs, corticotrophs	• Combined pituitary hormone deficiencies with predominant GH deficiency • Severe anterior pituitary hypoplasia, ectopic neurohypophysis	AD
SIX6	• Member of the *SIX/sine oculis* family of homeobox genes • Expressed early in hypothalamus, later in Rathke pouch, neural retina, and optic chiasma	Somatotrophs, gonadotrophs	• Bilateral anophthalmia • Pituitary hypoplasia • Associated with deletion at chromosome 14q22-23	Unknown
FGF8, FGFR1, PROKR2	• Ventral diencephalon	Somatotrophs, gonadotrophs	• Septo-optic dysplasia	AD

PITX2 (RIEG1)	• Bicoid-related homeobox gene expressed early in Rathke pouch
	• Important in maintaining expression of *Hesx1* and *PROP1*
		Somatotrophs, lactotrophs, thyrotrophs, reduced expression of gonadotrophs	• Associated with Rieger syndrome:
			  • Anterior-chamber eye anomalies
			  • Dental hypoplasia
			  • Protuberant umbilicus
			  • Mental retardation
			  • Pituitary dysfunction
				AD

PROP1 (Prophet of Pit1)	• Paired-like homeodomain transcription factor required for *PIT1* expression • Coexpressed with *Hesx1*	Somatotrophs, lactotrophs, thyrotrophs, gonadotrophs, corticotrophs (delayed)	• Combined pituitary deficiencies (GH, TSH, PRL, and late-onset ACTH reported) • Gonadotropin insufficiency or normal puberty with later onset of deficiency • Several mutations noted in nonconsanguineous families	AR
POU1F1 (PIT1)	• Member of the POU transcription factor family • Important for activation of *GH1*, *PRL*, and *TSHβ* genes	Somatotrophs, lactotrophs, thyrotrophs	• Combined pituitary deficiencies (GH, TSH, PRL, and late-onset ACTH reported); TSH secretion may initially be normal • Pituitary hypoplasia	AD, AR
Otx2	• Bicoid-type homeodomain gene required for forebrain and eye development • Antagonizes *FGF8* and *SHH* expression • May have importance in activation of *Hesx1*	Somatotrophs, thyrotrophs, corticotrophs, and probably gonadotrophs	• Severe ocular malformation including anophthalmia • Combined pituitary hormone deficiencies with LH/FSH deficiency • Anterior pituitary hypoplasia with ectopic posterior pituitary	Unknown

TABLE 25.2 Genetic Defects of the GH-IGF Axis Resulting in Somatotroph Dysfunction and GH Deficiency—cont'd

Factor	Gene Function	Affected Cell Types	Clinical Phenotype	Mode of Inheritance
SOX2	• Member of SOXB1 subfamily as *SOX1* and *SOX3* expressed early in development	Somatotrophs, gonadotrophs (and, in animal models, thyrotrophs)	• Hypogonadotropic hypogonadism • Anterior pituitary hypoplasia • Bilateral anophthalmia/microphthalmia • Midbrain defects, including corpus callosum and hippocampus • Sensorineural defects • Esophageal atresia and learning difficulty	De novo
SOX3	• Member of SOX (SRY-related HMG box) • Developmental factor expressed in developing infundibulum and hypothalamus	Somatotrophs, additional anterior pituitary cell types	• Duplications of Xq26-27 in affected males (female carriers unaffected) • Variable mental retardation • Hypopituitarism with abnormal MRI • Anterior pituitary hypoplasia • Infundibular hypoplasia • Ectopic/undescended posterior pituitary • Abnormal corpus callosum • Murine studies suggest SOX3 dosage critical for normal pituitary development	X linked
Isolated Growth Hormone Deficiency				
GLI2	• Member of the *GLI* gene family; transcription factors that mediate SHH signaling	Somatotrophs	• Heterozygous loss-of-function mutations in patients with holoprosencephaly • Penetrance variable • Pituitary dysfunction accompanied by variable craniofacial abnormalities	Unknown
GHRHr	• Encodes GHRH receptor	Somatotrophs	• Short stature • Anterior pituitary hypoplasia	AR
GH1	• Encodes GH peptide • Several mutations shown to affect GH secretion or function	Somatotrophs	• Short stature • Abnormal facies • Presentation includes bioinactive GH	AR, AD, or X linked

ACTH, Adrenocorticotropic hormone; *AD,* autosomal dominant; *AR,* autosomal recessive; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GHRH,* growth hormone–releasing hormone; *αGSU,* glycoprotein α-subunit; *HMG,* high mobility group; *IGF,* insulin-like growth factor; *LH,* luteinizing hormone; *MRI,* magnetic resonance imaging; *PRL,* prolactin; *SHH,* Sonic hedgehog; *TSH,* thyroid-stimulating hormone (thyrotropin).

Although the increased incidence of breech presentation and birth trauma with neonatal asphyxia in congenital idiopathic hypopituitarism has led some to suggest an etiologic role for these occurrences,[335] the syndrome of pituitary stalk dysgenesis with congenital hypopituitarism is probably the result of abnormal development, and the perinatal difficulties are likely the consequence rather than the cause of the abnormalities. Findings of a similar MRI appearance in patients with septo-optic dysplasia,[149,336] in association with type I Arnold-Chiari syndrome and syringomyelia,[149,333] and possibly in holoprosencephaly,[149] and the occurrence of micropenis with congenital hypopituitarism[149,337,338] all support the concept that congenital hypopituitarism is a genetic or developmental malformation, not a birth injury. Further indirect evidence in studies[339] of isolated, complete anterior pituitary aplasia indicates that hypothalamic hypopituitarism and breech delivery are consequences of congenital midline brain defects, although perinatal residua of breech delivery may exacerbate ischemic damage to the hypothalamic-pituitary unit.

The MRI findings described for early-diagnosed patients with hypopituitarism are also found in children diagnosed at a later age. Most of these children have hypothalamic dysfunction as the cause of diminished pituitary hormone secretion. In the older group, as in the infants, structural, acquired hypothalamic, stalk, or pituitary abnormalities must be considered.

Holoprosencephaly. Holoprosencephaly, which is caused by abnormal midline development of the embryonic forebrain, usually results in hypothalamic insufficiency and has been associated with mutations in developmental proteins.[340–344] These mutations are associated with diminished signaling by SHH, a critical factor in forebrain development.[343] Hedgehog ligands bind to and activate the transmembrane receptor Patched (PTCH), which results in release of the coreceptor Smoothened (SMO), activating GLI transcription factors. SHH and FGF8 play a role in the induction of BMP2 and LHX, which are important for proliferation in the developing pituitary gland and are influenced by loss-of-function mutations of the *GL12* gene.[342,343]

Facial dysmorphism of holoprosencephaly ranges from cyclopia to hypertelorism and is accompanied by absence of the nasal septum, midline clefts of the palate or lip, and sometimes a single central incisor. GHD may be accompanied by other pituitary hormone insufficiencies.[345] The incidence of GHD is increased in cases of simple clefts of the lip or palate (or both),[346] and children with cleft palates who grow abnormally require further evaluation.

TABLE 25.3 GH-IGF1 Deficiency Syndromes

Congenital Growth Hormone Deficiency

GH deficiency resulting from hypothalamic dysfunction
Holoprosencephaly and septo-optic dysplasia
GH deficiency resulting from pituitary dysfunction
GH deficiency resulting from mutations of the GHRH receptor and GH
GH deficiency resulting from CPHD
Bioinactive GH

Acquired Growth Hormone Deficiency

GH deficiency resulting from CNS tumors, trauma, or inflammation
Circulating antibodies to GH that inhibit GH action

Congenital IGF1 Deficiency

Abnormalities of the GHR
STAT5 mutations
ALS mutations
IGF1 mutations
IGF1 receptor mutations

Acquired IGF1 Deficiency

Circulating antibodies to the GHR
Chronic disease states

ALS, Acid-labile subunit; *CHPD,* combined pituitary hormone deficiencies; *CNS,* central nervous system; *GH,* growth hormone; *GHR,* growth hormone receptor; *GHRH,* growth hormone–releasing hormone; *IGF1,* insulin-like growth factor 1.

Septo-Optic Dysplasia. In its complete form, the rare syndrome of *septo-optic dysplasia* (SOD) combines hypoplasia or absence of the optic chiasm or optic nerves (or both), agenesis or hypoplasia of the septum pellucidum or corpus callosum (or both), and hypothalamic insufficiency.[336,347,348] The extent of the anatomic and functional abnormalities can vary but usually are in parallel to each other.[347,348] GHD can occur by itself or in combination with deficiencies of TSH, ACTH, or gonadotropins. About 50% to 70% of children with severe anatomic defects have hypopituitarism or, at least, identifiable abnormalities of the GH-IGF axis,[349] and the diagnosis should be considered in any child who has growth failure associated with pendular or rotatory nystagmus or impaired vision and a small optic nerve disc. In some patients, a hypoplastic or interrupted pituitary stalk and ectopic posterior pituitary placement have been identified by MRI.[149,336,347] An increasing number of mutations in developmental transcription factors, including HESX1, SOX2, SOX3, and OTX2, are implicated in the pathogenesis of septo-optic dysplasia. Recently, mutations in genes known to be associated with hypogonadotropic hypogonadism, prokineticin receptor 2 (PROKR2), FGF8, and FGF receptor 1 (FGFR1) have been found to be associated with other pituitary hormone deficiencies along with septo-optic dysplasia.[350]

The varying conditions of environment and genetics likely contribute to the variable phenotype.[351,352] There is an increased incidence in offspring of young mothers, in first-born children, in areas of high unemployment, and in babies exposed to intrauterine medications, smoking, alcohol, or diabetes.[353]

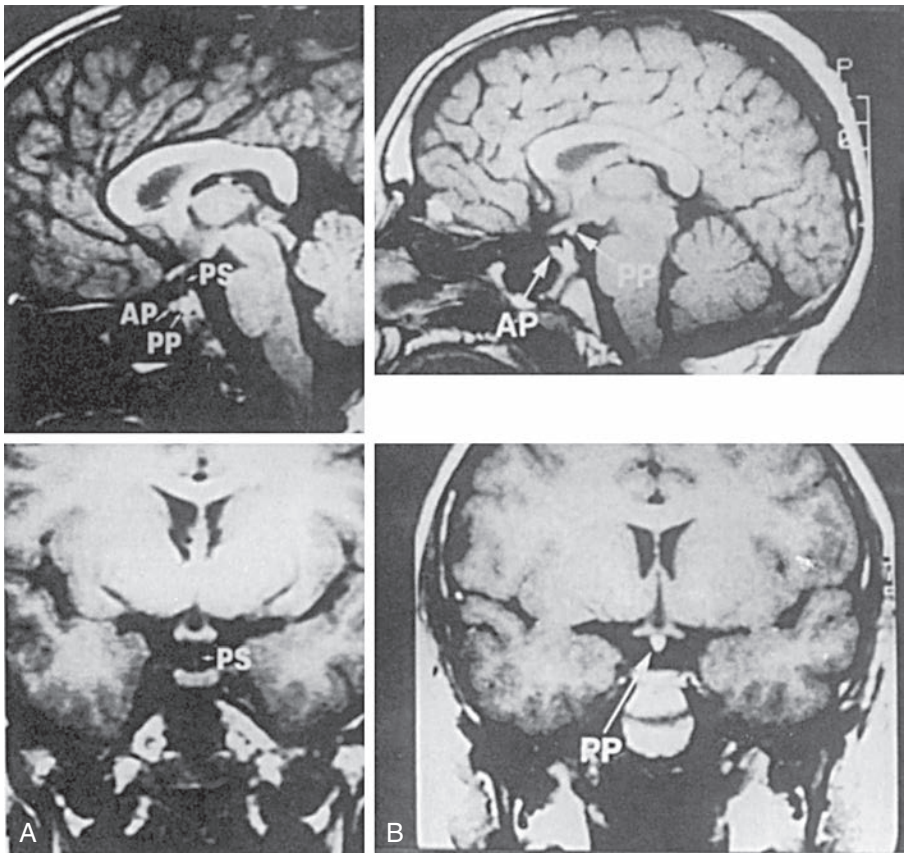
HESX1. The first homozygous missense mutation (N53C) has been detected within the homeobox domain of HESX1 in two siblings born to consanguineous parents with SOD.[354–361] Mutations of *HESX1*, a paired-like homeodomain gene that is expressed early in pituitary and forebrain development, are associated with familial forms of septo-optic dysplasia.[351,354,362,363] *HESX1*, also referred to as *RPX* (Rathke pouch homeobox), is a member of the paired-like class of homeobox genes and is essential for normal forebrain and pituitary formation.[364] It is one of the earliest known specific markers for the pituitary primordium and encodes for a developmental repressor with localization to the Rathke pouch.[357] TLE1 (the mammalian ortholog of the *Drosophila* protein Groucho) and the nuclear corepressor NCOR1 bind to HESX1 to exert repression.[365,366] *HESX1* downregulation is required for cell determination mediated by PROP1 to occur.[367] The LIM homeodomain proteins LHX1 and LHX3 are required for activation of the HESX1 promoter.[368]

Hesx1 null mutant mice display abnormalities in the forebrain, eyes, and other anterior structures such as the pituitary.[354] Mouse embryos heterozygous for both *Hesx1* and *Six3* null mutations have a mild phenotype, suggesting that these developmental factors control a switch in progenitor proliferation between repression by HESX1 and activation of PROP1.[369] These defects have similarity with human phenotypes such as septo-optic dysplasia and CPHD. Patients with septo-optic dysplasia may present with a wide spectrum of phenotypes associated with congenital hypopituitarism. Several homozygous and heterozygous mutations have been identified in *HESX1* (Online Mendelian Inheritance in Man [OMIM] no. 601802) in patients with hypopituitarism with variable phenotypes.[354,356,357,359,363,370–373]

Two siblings (born to consanguineous parents) with a severe septo-optic dysplasia phenotype, including anterior pituitary hypoplasia, an ectopic posterior lobe, agenesis of the corpus callosum, absent septum pellucidum, and optic nerve hypoplasia, were found to have a homozygous mutation at a highly conserved arginine residue of the homeodomain (p.R160C) that resulted in loss of DNA binding of the mutant protein. Another homozygous mutation, a threonine/isoleucine substitution at residue 26 (p.I26T), was identified in a child with GH and gonadotropin deficiency that later evolved to deficiencies of ACTH and TSH. She had no forebrain abnormalities and normal optic nerves, but on MRI had hypoplasia of the anterior pituitary and an undescended posterior pituitary. This mutation lies in a highly conserved engrailed homology domain (eh-1) that is required for transcriptional repression. Loss of repressor function was found to be caused by impaired interaction with the TLE1 corepressor. To determine the mechanisms by which these mutations cause the disorder, mice homozygous for these mutations were generated.[374] Mice homozygous for the p.R160C mutation displayed pituitary and forebrain defects similar to those in the *Hesx1* null embryos, indicating the critical role of HESX1 interactions with DNA in transcriptional repression during development. Mice homozygous for the p.I26T allele displayed pituitary defects and ocular abnormalities suggestive of a hypomorph allele, indicating the important role of TLE interaction in pituitary and ocular development.

Heterozygous mutations of *HESX1* have been identified in patients with hypopituitarism and septo-optic dysplasia and are usually associated with less affected phenotypes. Approximately 850 patients were studied for mutations in *HESX1,* including more than 300 patients with septo-optic dysplasia; 410 with isolated pituitary dysfunction, optic nerve hypoplasia, or midline neurologic abnormalities; and 126 with familial inheritance. The incidence of coding region mutations in *HESX1* within this population was about 1%, suggesting that mutations in *HESX1* are a rare cause of hypopituitarism and septo-optic dysplasia.[370]

Most of the HESX1 screenings performed in large CPHD cohorts failed to detect mutations. The only mutations



• **Fig. 25.34** Magnetic resonance imaging of infundibular dysgenesis. (A) T1-weighted sagittal and coronal images of the hypothalamic-pituitary area in a normal 8-year-old girl. The anterior (AP) and posterior pituitary (PP) lobes and the pituitary stalk (PS) are marked. (B) T1-weighted sagittal and coronal images of the hypothalamic-pituitary area of a 17-year-old boy with isolated growth hormone deficiency. The anterior pituitary lobe (AP) is hypoplastic, the posterior pituitary (PP) is ectopic, and the pituitary stalk is absent. (From Root AW, Martinez CR. Magnetic resonance imaging in patients with hypopituitarism. *Trends Endocrinol Metab.* 1992;3:283–287.)

identified were detected in sporadic subjects with an estimated global frequency of 0.45%.[375]

OTX2. Mutations in other genes have been associated with CNS anatomic abnormalities and hypopituitarism. *OTX2* is a homeobox gene that is expressed earliest in the neuroectoderm[376] cells of the forebrain and midbrain and encodes a transcription factor belonging to the orthodenticle family. This factor also plays a role in ocular development. Murine models harboring mutant *Otx2* genes demonstrate abnormal primitive streak organization and a headless phenotype.[376] OTX2 has a role in regulating early expression of HESX1 and is expressed in the pituitary to regulate POU1F1 (Pit1). Dateki and colleagues[377] identified a frameshift OTX2 mutation in a patient with bilateral anophthalmia and partial isolated GHD (IGHD) with minimal transactivation activity. A heterozygous OTX2 mutation was described in two unrelated patients with hypopituitarism; although initial studies demonstrated normal binding to HESX1 binding sites, the mutant *OTX2* gene was demonstrated to have decreased activation of the HESX1 promoter, suggesting a dominant negative effect leading to CPHD.[378] This relationship between the transcription factors OTX2 and HESX1 emphasizes the complexities of pituitary development and suggests that genetic causes may be multifactorial. Further studies have revealed two frameshift mutations, a nonsense mutation in two unrelated patients and a heterozygous microdeletion in a fifth patient.[377–385]

SOX3. A syndrome of X-linked hypopituitarism and mental retardation involving duplications of Xq26-27 encompassing *SOX3* (OMIM 313430) has been described in several pedigrees. SOX3 is a member of the SOX (SRY-related high mobility group box) family of transcription factors expressed in neuroepithelial progenitor and stem cells beginning in the earliest stages of embryogenesis involved in different developmental processes, such as gastrulation, neural induction, specification, and the differentiation of many cell types. Both the overexpression and underexpression of SOX3 can cause different phenotypes, ranging from IGHD to CPHD with ectopic neurohypophysis, anomalies of the corpus callosum with or without intellectual disability.[386–388] Microduplications and deletions of genomic regions containing SOX3 as well as expansion of a polyadenine tract (in one case, a deletion) have been reported.[389,393,394] The affected males have anterior pituitary and infundibular hypoplasia with an undescended posterior pituitary and abnormalities of the corpus callosum. Other abnormalities may include anophthalmia or microopthalmia, esoplageal atresia, and sensorineural hearing loss.[395,398,399] The GHD may also be associated with deficiencies of ACTH, TSH, or gonadotropins. Because *Sox3* is not expressed in Rathke pouch in the mouse, the anterior pituitary developmental defects are probably secondary to disruption of infundibular development.[351,386–389] Female carriers appear to be clinically unaffected, and no mutations have been found in patients with sex reversal, gonadal dysgenesis, or

infertility.[388–394] Synonymous changes have been found in children who inherited the variant from a clinically unaffected parent.[395,396] A patient was reported with isolated hypogonadotropic hypogonadism and a normal anterior pituitary suggesting that SOX2 may be involved in development and control of the hypothalamic neuronal reproductive axis. Indeed, SOX2 expression has been colocalized with LHX3 and HESX1.[374,395]

SOX2. Heterozygous mutations within *SOX2* in males have been associated with anophthalmia or microphthalmia and anterior pituitary hypoplasia. The resulting hormonal abnormalities include GH and gonadotropin deficiency. Some patients also present with genital abnormalities.[395] A wide variety of additional abnormalities may be present, including hypoplasia of the corpus callosum, hypothalamic hamartoma, hippocampal malformation, esophageal atresia, sensorineural hearing loss, and learning difficulties.[395–399] In addition to de novo heterozygous mutations, nonsynonymous changes have been identified in individuals who inherited the variant from a clinically unaffected parent.[395,396] A perplexing case of a patient with isolated hypogonadotropic hypogonadism but without anterior pituitary hypoplasia suggests that *SOX2* may be independently involved in hypothalamic neuronal development. The expression of *SOX2* has been found to overlap with that of *LHX3* and *HESX1* within Rathke pouch.[374,395,400]

GLI2. Heterozygous frameshift or nonsense GLI2 mutations have been reported in patients with holoprosencephaly. In addition, nonsynonymous GLI2 variants in patients with congenital hypopituitarism with CPHD and an ectopic posterior pituitary lobe without holoprosencephaly were found. Several patients with pituitary abnormalities, polydactyly, and abnormal facial features, also without holoprosencephaly, were reported to have truncating mutations. The pattern of inheritance of these mutations has been dominant with incomplete penetrance and variable expression.[401–403]

PROKR2. Patients with septo-optic dysplasia with CPHD have been found to have mutations in PROKR2, a known cause of isolated idiopathic hypogonadotropic hypogonadism and anosmia. Recently, a novel heterozygous substitution (c.742C>T;p.R248W) was identified in PROKR2 in a patient with panhypopituitarism and pituitary dysplasia.[350,404–406]

Acquired Disorders

Inflammation of the Brain or Hypothalamus. Bacterial, viral, or fungal infections may result in hypothalamic/pituitary insufficiency, and the hypothalamus or pituitary (or both) may also be involved in sarcoidosis.[407]

Tumors of the Brain or Hypothalamus. Brain tumors are a major cause of hypothalamic insufficiency,[408] especially midline brain tumors such as germinomas, meningiomas, gliomas, ependymomas, and gliomas of the optic nerve.[409] Although short stature and GHD are most often associated with suprasellar lesions in neurofibromatosis, they may also exist without such lesions. Whether growth impairment antedates the pathologic findings is not yet clear.[408] Metastases from extracranial carcinomas are rare in children, but hypothalamic insufficiency can result from local extension of craniopharyngeal carcinoma or Hodgkin disease of the nasopharynx. The laboratory diagnosis of GHD in children with brain tumors can be difficult because levels of IGF1 type I and IGFBP3 are poor predictors, especially in pubertal patients.[410] Craniopharyngiomas and histiocytosis can cause hypothalamic dysfunction (see later discussion).

Trauma of the Brain or Hypothalamus. Head trauma, resulting from boxing and various injuries, can cause IGHD or multiple anterior pituitary deficiencies. Some series of patients with GHD have indicated an increased incidence of birth trauma, such as breech deliveries, extensive use of forceps, prolonged labor, or abrupt delivery. Although GHD can be a consequence of a difficult delivery or hypoxemic perinatal period, it is more commonly associated with developmental deficiencies (discussed previously) or head trauma later in life. In a series of 22 head-injured adolescents and adults, almost 40% had some degree of hypopituitarism.[411–413]

Psychosocial Dwarfism. An extreme form of failure to thrive is termed *psychosocial dwarfism* or *emotional deprivation dwarfism.*[414–417] Most cases of failure to thrive can be traced back to a poor home environment and inadequate parenting, with improved weight gain and growth upon removal of the infant from the dysfunctional home. Some children have been reported, however, to show dramatic behavioral manifestations beyond those in the typical failure-to-thrive infant, namely, bizarre eating and drinking habits such as drinking from toilets, social withdrawal, and primitive speech.[414] Hyperphagia and abnormalities of GH production may be associated.[415] GH secretion is low in response to pharmacologic stimuli but returns to normal upon removal from the home. Concomitantly, eating and behavioral habits returned to normal, and a period of catch-up growth ensued. Careful assessment of endogenous GH secretion showed reversal of the GH insufficiency within 3 weeks, including enhancement of GH pulse amplitude and a variable increase of pulse frequency.[415] The reversibility of GH secretory defects and the later growth increment in the context of the clinical findings described previously confirm the diagnosis of psychosocial dwarfism.[415]

The neuroendocrinologic mechanisms involved in psychosocial dwarfism remain to be elucidated. GH secretion is abnormal, and ACTH and TSH levels may also be low, although some patients have high plasma cortisol levels. Even when GH secretion is reduced, treatment with GH is not usually of benefit until the psychosocial situation is improved. Management of the environmental causes of the growth failure is imperative and often associated with substantial growth. In our experience, although psychosocial dysfunction is a common cause of failure to thrive in infancy, the constellation of bizarre behaviors described in psychosocial dwarfism is rare.

The fact that GH production is impaired in adults with varied psychiatric disorders and the growth aberrations of functional GHD with psychosocial dwarfism together suggest that children with emotional problems may have impaired GH secretion and growth.[416] Indeed, depression in children, as adults, can lower GH production,[417] and in girls, anxiety disorders predict a modest height loss in adults.[416]

The Anterior Pituitary

As discussed earlier, many of the disease processes that impair hypothalamic regulation of GH secretion also impair pituitary function. Another group of abnormalities specifically affect pituitary somatotroph development and function.

Congenital Disorders. As many as 3% to 30% of patients with GHD have an affected parent, sibling, or child.[418] Inborn errors of the genes for nuclear transcription factors affecting hypothalamic-pituitary development, the GHRH receptor, or the GH gene can cause GHD and IGF deficiency.

Combined Pituitary Hormone Deficiency. During pituitary development, a series of transcription factors are expressed in a specific timeframe and in a spatial context. The result of cell differentiation and proliferation is a mature anterior pituitary gland with five distinct cell types.[352]

PITX2. *PITX2* (also known as *RIEG*) is a member of the bicoid-like homeobox transcription factor family that is closely related to the mammalian OTX genes expressed in the rostral brain during development; it is required at many stages of pituitary development.[352] Studies have shown that activation of the WNT signaling pathway or constitutive activation of β-catenin can induce *PITX2* expression. Further, protein inhibitors of activated STAT (PIAS) modulate PITX2 expression.[419] *PITX2* is expressed in thyrotrophs, gonadotrophs, somatotrophs, and lactotrophs but not in corticotrophs.[420]

PITX2 acts to activate the promoters of pituitary hormone target genes.[421,422] Homozygous loss of *PITX2* results in early embryonic lethality with pituitary development severely affected.[423–426] This is thought to be related to the control of cell cycle regulatory genes by PITX2.[427,428] Furthermore, the lack of *PITX2* also results in excessive cell death during early pituitary development, suggesting a role in cell survival.[429] A mouse line expressing a hypomorphic allele of *Pitx2* provided evidence that the extent of pituitary hypoplasia and cellular differentiation is proportional to the reduced dosage of *Pitx.*[426,430] In this model, the gonadotroph lineage was primarily affected and the numbers of differentiated somatotrophs and thyrotrophs were reduced, but the corticotroph population was unaffected.[430]

In a *Pitx2* overexpression model, the gonadotroph population was expanded, probably because of the role of *Pitx2* in the expression of gonadotroph-specific transcription factors GATA2, EGR1, and NR5A1 (SF1).[429] Mutations of *PITX2* have been described in patients diagnosed with Rieger syndrome, an autosomal dominant condition with variable manifestations, including anomalies of the anterior chamber of the eye, dental hypoplasia, a protuberant umbilicus, mental retardation, and pituitary abnormalities. PHX2 has been further associated with a role in left-right signaling, odontogenesis, cardiac development, and atrial fibrillation.[431–433] Mutations of *PITX2*, located within the homeodomain responsible for DNA binding, have been described, and several of these mutations show loss of DNA binding capacity.[434] A heterozygous mutation that changes the lysine at position 50 to glutamic acid in the homeodomain has been found to impart a dominant negative effect leading to a pronounced phenotype.[435]

SOX2. Heterozygous mutations in SOX2 (sex-determining region Y box 2) have been associated with eye abnormalities (i.e., anophthalmia, microphthalmia, and coloboma) and hypopituitarism characterized by anterior pituitary hypoplasia associated with GH and gonadotropin deficiency. Numerous nonsense, frameshift, and missense mutations, as well as chromosome deletions of SOX2, resulting in expression of SOX2 proteins with impaired function, have been identified.[352]

LHX3. LHX3 is a member of the LIM-type homeodomain protein family of transcription factors that feature two LIM domains in their amino terminus (N-terminal) and a centrally located homeodomain required for interaction with specific DNA elements on target genes. During development, expression of *LHX3*, which persists in the adult pituitary, is seen in the anterior and intermediate lobes of the pituitary, spinal cord, and medulla.[436] Murine models with targeted disruption of *Lhx3*, reporter transgenic mice, and mutants of LHX3[437] show depletion of thyrotrophs, gonadotrophs, and somatotrophs, suggesting that *Lhx3* is important for cell specification and proliferation.[438] Three LHX3 isoforms have been identified in humans: LHX3a, LHX3b, and M2LHX3.[439] Of these, LHX3a displays the greatest ability to activate the promoters of pituitary genes. LHX3 interacts with components of the inhibitor of histone acetyltransferase (INHAT) to modulate chromatin structure.[440] Patients with reported mutations in *LHX3* have deficits of GH, PRL, TSH, and gonadotropins, as well as abnormal pituitary morphology along with a rigid cervical spine that limits head rotation.[441–443] Other associated symptoms can include hearing loss and ACTH deficiency.

LHX3 mutations are a rare cause of reported hypopituitarism, and one study reported that the incidence of a homozygous *LHX3* mutation in patients studied with CPHD was 2.2%.[444] LHX3 mutations showed very low mutation frequency in genetic screening (0.3% in sporadic and 11.1% in familial cases). The two most northern counties of Sweden have an unexpectedly high prevalence of mutations, with carrier frequency estimated at 1 in 50, in apparently unrelated individuals, likely explained by a common ancestor dating back to the 17th century. Several other novel *LHX3* mutations in patients with CPHD demonstrating autosomal recessive inheritance have been reported and characterized.[441,442,444–448]

LHX4. LHX4 is another LIM homeodomain protein with homology to LHX3, and it is also expressed in the developing brain, including the cortex, pituitary, and spinal cord.[449] It contains two LIM domains in its N-terminus and a DNA-binding homeodomain.

Despite similarities in protein structure, the role of LHX4 in development is distinct from that of LHX3, as demonstrated by single and combined gene-deletion targeting in mice. Murine models with targeted deletion of *Lhx4* form a definitive Rathke pouch that arrests and results in a hypoplastic pituitary. In contrast to *Lhx3* gene knockout mice, *Lhx4*$^{-/-}$ mice contain all five differentiated cell types.[450,451] *Lhx3* expression is impaired in the *Lhx4* mutants, suggesting that *Lhx4* is required for cell survival, expansion of the pouch, and differentiation of pituitary-specific cell lineages. Since proper expression of Lhx4 is also crucial for the normal development of other organs such as lungs, *Lhx4*$^{-/-}$ mice die shortly after birth due to pulmonary failure, whereas heterozygous appear to be normal.

Several reports have described CPHD patients with evidence of a hypoplastic pituitary who harbored *LHX4* mutations.[436,452,453] These heterozygous mutations have been shown to result in proteins that are unable to bind DNA and activate pituitary gene expression.[454] Further studies have demonstrated a functional relationship between POU1F1 and LHX4 in the regulation of POU1F1 expression in specific pituitary cell types.[455] Also, several studies have suggested that LHX4 and PROP1 have overlapping functions in pituitary development.[450] Finally, in addition to pituitary hormone deficiencies, *LHX4* mutations have been implicated in structural abnormalities; patients with an *LHX4* mutation have been reported with abnormal MRI findings, including a hypoplastic anterior pituitary, ectopic posterior lobe, poorly developed sella turcica, and Chiari malformation.[456] In the nine cases described in the literature to date, large interfamilial and intrafamilial variabilities are present.[454,457–459] Recently a novel recessive mutation has been reported (pT126M), which is associated with a lethal form of congenital hypopituitarism. However, functional assay failed to show any difference between the mutant and the wild-type LHX4, making it difficult to implicate the mutation with pathogenicity.[460]

SIX6. *SIX6* is a member of the SIX/sine oculis family of homeobox genes that is expressed in retina, optic nerve, hypothalamus, and pituitary.[461] Murine expression studies of the TCF/LEF family of transcription factors during pituitary development demonstrated that *Six6* plays a role in proliferation of cells during early formation of Rathke pouch.[462] *SIX6* has also been shown

to interact with the Groucho family of transcriptional repressors.[463,464] Mice lacking *SIX6* demonstrate infertility.[465] *SIX6* has been mapped to chromosome 14q22-23, and patients with deletions of this chromosomal region display bilateral anophthalmia and pituitary anomalies.[466,467] Patients with anophthalmia/microphthalmia were shown to have several frequent polymorphisms of *Six6* and one potential causative missense mutation.[461] One case report implicated *SIX6* haploinsufficiency as being responsible for ocular and pituitary maldevelopment. Despite its importance in early development, further studies are required to determine whether *SIX6* mutations are present in patients with pituitary hormone deficiency.

ISL1. ISL1 is a member of the LIM homeodomain family of transcription factors, which are characterized by two tandemly repeated cysteine/histidine-rich LIM domains that are involved in protein-protein interactions. ISL1 has been shown to be a transcriptional regulator of LHX3.[468] Its expression is restricted to cells that will express the pituitary of glycoprotein hormone α-subunit (αGSU) gene.[469,470] Homozygous loss of *Isl1* in mice results in developmental arrest with no pouch formation.[471] To date, no human mutations in *ISL1* have been identified.

PROP1. Mutations in *PROP1*, a paired-like homeodomain transcription factor with expression restricted to the anterior pituitary during development, have also been found to result in CPHD.[472] Mutation of this gene is responsible for a form of murine pituitary-dependent dwarfism known as the Ames mouse.[473] The pituitary gland appears to be enlarged in mice bearing mutations in *Prop1*, although the mechanism is unclear.[473–476] In the end, a decrease in proliferation and apoptosis results in pituitary hypoplasia, similar to that seen in humans.[402,450,474–478] The switch from repression of target gene expression by HESX1 to activation by PROP1 is important for development of the POU1F1 (GH, PRL, and TSH) and gonadotroph lineages.[366,476,479] PROP1 and β-catenin have been shown to form a complex that represses *Hesx1* while activating *Pou1f1* expression.[480] PROP1 bends to a palindrome TAAT sequence as a dimer to actuate target gene expression.[481,482] The gonadotropin deficiency in the Ames dwarf remains unexplained, although treatment with thyroxine (T_4) or GH (or both) restored fertility in some male mice and restored sexual maturation, but not fertility, in female mice.[483,484]

Mutations of *PROP1* in humans result in GH, PRL, and TSH deficiencies, although failure in all cell lineages, including gonadotrophs and corticotrophs, has been reported.[485–487] The characterization of *PROP1* mutations is complex, because the phenotypes are variable and dynamic and hormone deficiencies may develop over time even in patients with similar genetic backgrounds.[485,488,489] Gonadotropin abnormalities are particularly diverse in that approximately 30% of patients have spontaneous pubertal development, including menarche, before ultimately developing hypogonadotropic hypogonadism.[485,490] Apparently normal growth without GH has also been found in a child with PROP1 deficiency.[491,492] The ACTH deficiency may develop in the fourth or fifth decade of life.[493] Striking variability has been described in pituitary size, with very large glands, possibly arising from the intermediate lobe,[494] producing a hyperintense T1-weighted signal occasionally demonstrated by MRI.[486,495,496] These glands may undergo involution, leaving a large empty sella in patients with complete anterior hypopituitarism, including ACTH deficiency.[497–499]

Many *PROP1* (chromosome 5q35, OMIM 601538) abnormalities have been identified, including missense, frameshift, and splicing mutations. A GA repeat in exon 2 (295-CGA-GAG-AGT-303) has been reported to be a "hot spot" in *PROP1;* any combination of a GA or AG deletion in this repeat region results in a frameshift in the coding sequence and premature termination at codon 109.[490,500] Similar abnormalities result from homozygous lesions at other sites on exon 2 and affect codons 73, 88, and 149.[490,500] Compound heterozygosity for two mutations was detected in 36% of children from four families; two different common deletions both led to a stop codon at position 109.[501] These mutations are predicted to result in loss of the DNA-binding and C-terminal transactivating domains of *PROP1*. Some missense mutations have been shown to retain partial activity.[486,487,502] Two mutations in the transactivating domain, not the DNA binding domain (W194 X Prop1, S156 insTProp1), were shown to differentially affect DNA binding and transactivation.[503]

To date, PROP1 mutations represent the most commonly known genetic cause of CPHD both in sporadic (6.7%) and familial cases (48.5%) with a global mutation frequency of 11% considering all the patients. A screen of 73 subjects (36 families) diagnosed with CPHD by Deladoey and associates identified 35 patients with *PROP1* gene defects, including three different missense mutations, two frameshift mutations, and one splice site mutation. In 12 of 36 unrelated families, defects were located in the region nt296 through nt302, suggesting a possible hot spot for *PROP1* mutations in CPHD.[490] Although *PROP1* mutations appear to be rare in sporadic cases, their prevalence is 29.5% in familial cases of CHPD, as reported by Turton and colleagues.[391,504] The mutation rate varies considerably among the different geographic areas: While Western European, US, Australian, and Japanese cohorts presented a mutation prevalence lower than 1%, the Eastern European and Russian cohorts showed a much higher frequency, reaching 64.8% in the Lithuanian population. Two variants, namely c.301_302delAG and c.150delA, are the most common mutations found in PROP1 and represent more than 90% of the mutated alleles in the Eastern European cohorts. Recently Dusatkova et al.[505] genotyped 21 SNPs flanking a 9.6-Mb region around PROP1 and demonstrated an ancestral origin for both variants that are carried on haplotypes spanning 0.2e0.3 Mb, showing that the most frequent PROP1 variants are not mutation hot spots as previously assumed but founder variants.[375,488,501,506–511]

There does not appear to be a strong correlation between phenotype and genotype.[490] Nyström and associates reported compound heterozygous mutations in the *PROP1* gene in twins with hypopituitarism and late ACTH deficiency.[512]

POU1F1. The *POU1F1* gene (chromosome 3p11, OMIM 173110) encodes Pit1, a member of a large family of transcription factors referred to as POU-domain proteins that is responsible for pituitary-specific transcription of genes for GH, PRL, TSH, and the GHRH receptor.[59,513–515] Pit1, a 290–amino acid protein, contains two domains, the POU-specific domain and POU-homeo domain; both are necessary for DNA binding and activation of GH and PRL genes and for regulation of the PRL, TSHβ, and POU1F1 genes.[516] Its expression is restricted to the anterior pituitary to control differentiation, proliferation, and survival of somatotrophs, lactotrophs, and thyrotrophs.[418,515–517] Pit1 regulates target genes by binding to response elements and recruiting coactivator proteins, such as cAMP response element–binding protein (CREB)–binding protein (CBP).[518] Gene expression microarray assays combined with chromatin immunoprecipitation (CHIP) were used to detect targets of POUIFI.[519]

Two mouse models were first reported to have GH, PRL, and TSH deficiencies associated with mutations or rearrangements of

the *Pit1* gene; these were the Snell (dw/dwS) and the Jackson (dw/dwJ) dwarf mice.[520,521] Many different mutations of the *POU1F1* gene have been found internationally in families with GHD and PRL deficiency and variable defects in TSH expression.[522–525] These mutations are transmitted as autosomal recessive or dominant traits and cause variable peptide hormone deficiencies with or without anterior pituitary hypoplasia.[522–528]

The most common mutation, present in about the 30% of the patients that carry a POU1F1 mutation, is an R271W substitution that affects the POU homeodomain, encoding a mutant protein that binds normally to DNA and acts as a dominant inhibitor of transcription.[528–531] Vertical transmission of the R271W mutation was shown, emphasizing the importance of diagnostic and therapeutic management during pregnancy.[532] Evidence from a patient with the R271W mutation suggests that Pit1 may have a role in cell survival.[531] Indeed, the mutation was used to target cell proliferation tumoral model systems. A patient diagnosed with GHD, along with dysregulation of PRL and TSH, was reported to have a lysine-to–glutamic acid mutation at codon 216 (K216E).[516] This mutant Pit1 binds to DNA and appears not to inhibit basal activation of GH and PRL genes; however, the mutant is unable to support retinoic acid induction of *POU1F1* gene expression. Another report suggested that CBP (p300) recruitment and Pit1 dimerization are necessary for target gene activation and that disruption of this process may account for the pathogenesis of CPHD.[533] All of the reported mutations involve sites affecting *POU1F1* DNA-binding, dimerization, or target gene transactivation.[524,525,528,534–542]

Phenotypic variability occurs among patients with apparently similar genotypes. It does not appear that ACTH or gonadotropin deficiencies occur, as is frequently the case with *PROP1* defects,[504] but adrenarche has been reported to be absent or delayed in patients with a POU1F1 mutation.[543] Circulating antibodies against Pit1 have been identified to be responsible for hypopituitarism similar to that caused by mutations.[544] Of the sporadic cases of CPHD, 1.6% are found to have POU1F1 mutations with no significant differences among populations. A higher frequency of POU1F1 mutations (21.6%) has been detected in familial cases.[375]

ARNT2

Six members of a consanguineous family with CPHD and microcephalia were found to have a homozygous frameshift mutation (c1373_1374dupTC) in aryl-hydrocarbon receptor nuclear translocator 2 (ARNT2).[545]

GRP161

Recently a homozygous mutation in GRP161, encoding the orphan G protein–coupled receptor 161, was identified in a family with CPHD and pituitary stalk interruption.[546]

Isolated Growth Hormone Deficiency. The incidence of IGHD is estimated to be 1 in every 3480 to 10,000 live births.[86,547–549] In most children with IGHD, no cause can be identified, and this group is often referred to as having idiopathic GHD. However, there is increasing recognition that genetic defects underlie some cases of GHD. It has been estimated that mutations in the GH and growth hormone receptor genes can be detected in up to 34% of familial cases of IGHD. Patients with GHD may develop deficiencies of additional anterior pituitary hormones.[550] Four forms of IGHD have been reported (see Table 25.2).[551] The classification system is based on clinical characteristics, inheritance patterns, and GH secretion but not necessarily on disease causation. IGHD was most recently reviewed by Alatzoglou and associates.[552]

The gene encoding GH *(GH1)* is located on chromosome 17q23 in a cluster of five highly homologous genes that includes two chorionic somatomammotropin genes CHS1 and CHS2, the placentally expressed growth hormone gene GH2, and a pseudogene, CSHP1. *GH1* and *GH2* differ in mRNA splicing pattern: *GH1* generates 20-kDa and 22-kDa proteins (of approximately equal bioactivity), whereas *GH2* yields a protein that differs from *GH1* by 13 amino acid residues.

The 22-kDa isoform includes the five exons with the complete biologic activity of GH. A cryptic in-frame splice site within exon 3 gives rise to alternative spliced transcripts lacking the first 45 bp of exon 3 and produces a 20-kDa peptide missing aa 32-46.[94] The 17.5-kDa form results from the complete skipping of exon 3 lacking aa 32-71 representing 1% to 5% of the total GH1 transcripts. Two isoforms lacking exons 3 and 4 encoding a 11.3-kDa and exons 2 through 4 encoding a 7.4-kDa peptide have been detected.[553–559]

IGHD Type I. IGHD type IA results primarily from large deletions, with rare frameshift and nonsense mutations of the *GH1* gene that prevents synthesis or secretion of the hormone.[552,560] IGHD IA is inherited as an autosomal recessive trait, and affected individuals have profound congenital GHD, including hypoglycemia in infancy and severe dwarfism by 6 months of age.[561] It has been reported that about 10% to 15% of subjects with a height below 4.5 SDS and severe IGHD carry GH1 gene deletions; however, geographic and patient selection criteria are present between studies. Frameshift and nonsense GH1 mutations have also been found in subjects with the IGHD IA phenotype.[561]

Because GH is not produced even in fetal life, patients are immunologically intolerant of GH and typically develop anti-GH antibodies when treated with either pituitary-derived or recombinant DNA–derived GH. When antibodies prevent patients from responding to GH, IGHD IA can be viewed as a form of GH insensitivity, and such patients are candidates for IGF1 therapy.[554,561–563]

The less severe form of autosomal recessive GHD, termed IGHD type IB, may also result from mutations or rearrangements of the *GH1* gene that causes production of an aberrant GH molecule that retains some function or at least generates immune tolerance. The phenotypic variability is greater than in IGHD IA.[551,552] These patients usually respond to exogenous GH therapy without antibody production. The very low frequency (1.7%) of *GH1* gene mutations in familial type IB IGHD suggests the importance of studying the *GH1* gene promoter region in patients with unexplained GHD.[564]

Mutations in *GHRHR* are also classified as IGHD type IB. Mutation of the gene for *Ghrhr* in its ligand-binding domain has been identified in the *little* mouse *(lit/lit)*[565] and results in dwarfism and decreased numbers of somatotrophs.[515,556,566] In this model, the fetal somatotroph mass is normal, and hypoplasia of the somatotrophs is evident only postnatally.[515,517,556,566] Such data suggest that GHRH is not an essential factor for fetal differentiation of the somatotrophs and that GHRH-independent cells persist or that mutation does not cause total loss of GHRH function.[567–569]

Wajnrajch and colleagues reported the first human cases of a mutation in the *GHRHR* gene in two cousins in a consanguineous Indian Muslim family with IGF deficiency and profound growth failure.[570] The gene defect, a nonsense mutation that introduced a stop codon at position 72 (E72X), resulted in a markedly truncated GHRHR protein that lacked the membrane-spanning regions and the G protein–binding site. The affected children had

undetectable GH release during standard provocative tests and after exogenous GHRH administration but responded to GH treatment. The same mutation was also identified in a reportedly unrelated Tamoulean kindred in Sri Lanka,[571] in a consanguineous kindred in Pakistan ("dwarfism of Sindh"),[572,573] and in 17 patients from one Muslim and four Hindu families in Western India.[574] The largest kindred in which a mutation of *GHRHR* was identified was a Brazilian family with a homozygous donor splice mutation (G to A at position +1) of exon 1.[86] This mutation disrupts the highly conserved consensus GT of the 50-donor splice site, generating a truncated GHRHR.[575,576]

A *GHRHR* missense mutation in exon 11 (R357C) was described in two consanguineous Israeli Arab families.[577] Patients in all of the groups had early growth failure with short stature (–4.5 to –8.6 SD), a high-pitched voice, and increased abdominal fat accumulation.[572,576] As expected, all of the patients demonstrated severely reduced or undetectable serum concentrations of GH in response to provocative GH stimulation, as well as very low serum concentrations of IGF1, IGFBP3, and ALS.[576] The adults manifest an unfavorable cardiovascular risk profile, which includes increased levels of low-density lipoprotein cholesterol and total cholesterol, elevated C-reactive protein, elevated blood pressure, and abdominal obesity. However, a perplexing study found no evidence of premature atherosclerosis or premature myocardial ischemia in these patients with *GHRHR* mutations.[578] The patients respond well to exogenous GH without antibody formation. Heterozygotes may have minimal height deficits and may show moderate biochemical deficiencies of the GH-IGF axis.[572] Despite extensive study, the geographic separation and ethnic differences among these patient groups do not suggest recent (>200 years) contact among the families from the Indian subcontinent. At present, the likely explanation for all four families is that of a "founder effect" or one-time mutation in each group followed by propagation within a geographically isolated gene pool.[86] In an analysis of 30 families with IGHD type IB, Salvatori and colleagues[579] found new missense mutations in transmembrane and intracellular domains of the *GHRHR* in three families (10%), with two affected members in each. Transfection experiments indicated normal cellular expression of these mutant receptors. Mutations in GHRH were recently reviewed by Corazzini and Salvatori.[580]

A recent dominant mutation with incomplete penetrance was reported due to a missense substitution (Val10Gly) in the signal peptide in three unrelated patients, resulting in a defect in receptor processing and translocation to the cell surface.

Most of the reported GHRHR mutations occur within consanguineous families, and of those a minority of the affected are compound heterozygotes. In a group of 65 children with IGHD IB, the GHRH receptor gene *(GHRHR)* was normal in domains coding for the extracellular region,[581] but mutations in transmembrane and intracellular gene domains were found in 10% of families with IGHD IB.[86,556,577,579,582–587]

IGHD Type II. IGHD type II is inherited as an autosomal dominant trait. The most common cause appears to be mutations that inactivate the 5′ splice donor site of intron 3 of the *GH1* gene, which contains multiple *cis*-acting splicing enhancers in the exon and intron required to activate canonic splice sites for intron 2 and 3 and silencing of the cryptic sites. The skipping of exon 3 results in a 17.5-kDa GH isoform mutant that has been shown to function in a dominant-negative manner to suppress intracellular accumulation and secretion of wild-type GH.[565,588,589] In patients with missense mutations in exon 4 or 5, clinical presentation is quite variable, with some evidence for reversibility of the impairment of intracellular GH storage and secretion by GH treatment.[590] Mullis and coworkers[591] studied 57 subjects from 19 families and found that patients with IGHD type II not only have a variable phenotype in terms of onset, severity, and progression of GHD but also may demonstrate later onset of ACTH or TSH deficiencies and pituitary hypoplasia. An extensive assessment of *GH1* gene mutations in short children with and without GHD revealed a substantial number of heterozygous mutations.[591] Recent studies characterizing the mechanism of the GH secretory defects and the increased expression of the 17.5-kDa isoform may lead to novel molecular therapies.[592]

IGHD Type III. IGHD type III, transmitted as an X-linked trait with associated hypogammaglobulinemia (XLA),[593] has not yet been related to a mutation of the *GH1* gene. A large Australian kindred demonstrated GHD with a variable spectrum of pituitary hormonal deficiencies that may have been caused by duplication of the Xq25.Xq28 region.[594]

A splicing mutation within the Bruton tyrosine kinase *(BTK)* gene in patients with XLA and IGHD has been reported. Mutations in *BTK,* a cytoplasmic tyrosine kinase expressed in B lymphocyte and myeloid cells, have also been identified in several patients with XLA but without IGHD.

SOX3. Mutations in SOX3, a member of the SOX (SRY-related high mobility group box) family of transcription factors on Xq27.1, have been found in families with IGHD with ectopic neurohypophysis, anomalies of the corpus callosum, and intellectual disability.[388] Several patients with GH deficiency and complex phenotypes with duplications in the proximal Xq chromosome have been reported.[595,596] A complete description of SOX3 can be found in the section on septo-optic dysplasia earlier in the chapter.

Bioinactive GH. Serum GH exists in multiple molecular forms, reflecting the consequences of alternative post-transcriptional or post-translational processing of the mRNA or protein, respectively. Some of these forms are presumed to have defects in the amino acid sequences required for the binding of GH to its receptor, and different molecular forms of GH may have varying potencies for stimulating skeletal growth, although this remains to be rigorously proved. Short stature with normal GH immunoreactivity but reduced biopotency has been suggested,[597,598] but the molecular abnormalities have been characterized in relatively few patients, and many cases of suspected bioinactive GH have not been rigorously proved.[599,600]

In one child with extreme short stature (–6.1 SDS), a mutant GH caused by a single missense heterozygous mutation (cysteine to arginine, codon 77 of *GH1*) bound with greater affinity than normal to GHBP and the GHR and inhibited the action of normal GH. The child grew more (6 vs. 3.9 cm/year) during a period of exogenous GH in moderate dosage. The father was found to have the same genetic abnormality but did not express the mutant hormone. In a second patient[600] with marked short stature (–3.6 SDS), a heterozygous alanine-to-glycine substitution in exon 4 of GH led to a substitution of glycine for arginine. This mutation was located in site 2 of GH molecular binding with its receptor and apparently led to failure of appropriate molecular rotation of the dimerized receptor and subsequent diminished tyrosine phosphorylation and the GH-mediated intracellular cascade of events. Bioactivity determined in a mouse B-cell lymphoma line was about 33% of immunoreactivity.[601] Exogenous GH substantially increased growth velocity (from 4.5 to 11 cm/year).

An Ile179Met substitution found in a short child was characterized by normal STAT5 activation but a 50% decrement in ERK activation.[217] This novel finding demonstrated the complexity of

the functional interaction of GH with its receptor, but because STAT5B is clearly the major (if not the sole) GH-dependent mediator of *IGF1* gene transcription, the role of this mutation is not clear. Six GH heterozygous variants with evidence of impairment of JAK/STAT activation were found by screening short children, suggesting that further studies are needed to determine the mechanism of interaction of GH with its receptor.[602] Because these variants occur in heterozygotes, the genotype-phenotype correlations are unclear. In one of the more convincing cases of bioinactive GH reported to date, Besson and associates[603] found a homozygous missense mutation (G705C) in a short child (–3.6 SDS) that resulted in the absence of two disulfide bridges. Both GHR binding and JAK2/STAT5 signaling activity were markedly reduced.

Some patients demonstrate a decrease in bioactivity (when measured by sensitive in vitro assays) but not in immunoreactivity. The absence of mutations suggests that abnormal post-translational modifications of GH or other peripheral mechanisms may be responsible.[604,605]

Acquired Disorders

Craniopharyngiomas and Other Tumors. Many tumors that impair hypothalamic function also affect pituitary secretion of GH. In addition, *craniopharyngiomas* are a major cause of pituitary insufficiency. These tumors arise from remnants of Rathke pouch, the diverticulum of the roof of the embryonic oral cavity that normally gives rise to the anterior pituitary. The diagnosis and treatment of craniopharyngioma have been recently reviewed. This tumor is a congenital malformation present at birth and gradually grows over the ensuing years. The tumor arises from rests of squamous cells at the junction of the adenohypophysis and neurohypophysis and forms a cyst as it enlarges; the cyst contains degenerated cells and may calcify but does not undergo malignant degeneration. The cyst fluid ranges from the consistency of machine oil to a shimmering, cholesterol-laden liquid, and the calcifications may be microscopic or gross. About 75% of craniopharyngiomas arise in the suprasellar region; the remainder resemble pituitary adenomas. Mutations in β-catenin have been found in patients with adamantinomatous craniopharyngiomas.[606]

Craniopharyngiomas can cause manifestations at any age from infancy to adulthood but usually manifest in middle childhood. The most common presentation results from increased intracranial pressure and includes headaches, vomiting, and oculomotor abnormalities. Visual field defects result from compression of the optic chiasm, and papilledema or optic atrophy may be present. Visual and olfactory hallucinations have been reported, as have seizures and dementia. Most children with craniopharyngiomas have evidence of growth failure at the time of presentation, and they are often found retrospectively to have had reduced growth since infancy.[607] GH and the gonadotropins are the most commonly affected pituitary hormones in children and adults, but deficiency of TSH and ACTH may also occur, and diabetes insipidus is present in 25% to 50% of patients.[607] Between 50% and 80% of patients have abnormalities of at least one anterior pituitary hormone at diagnosis.

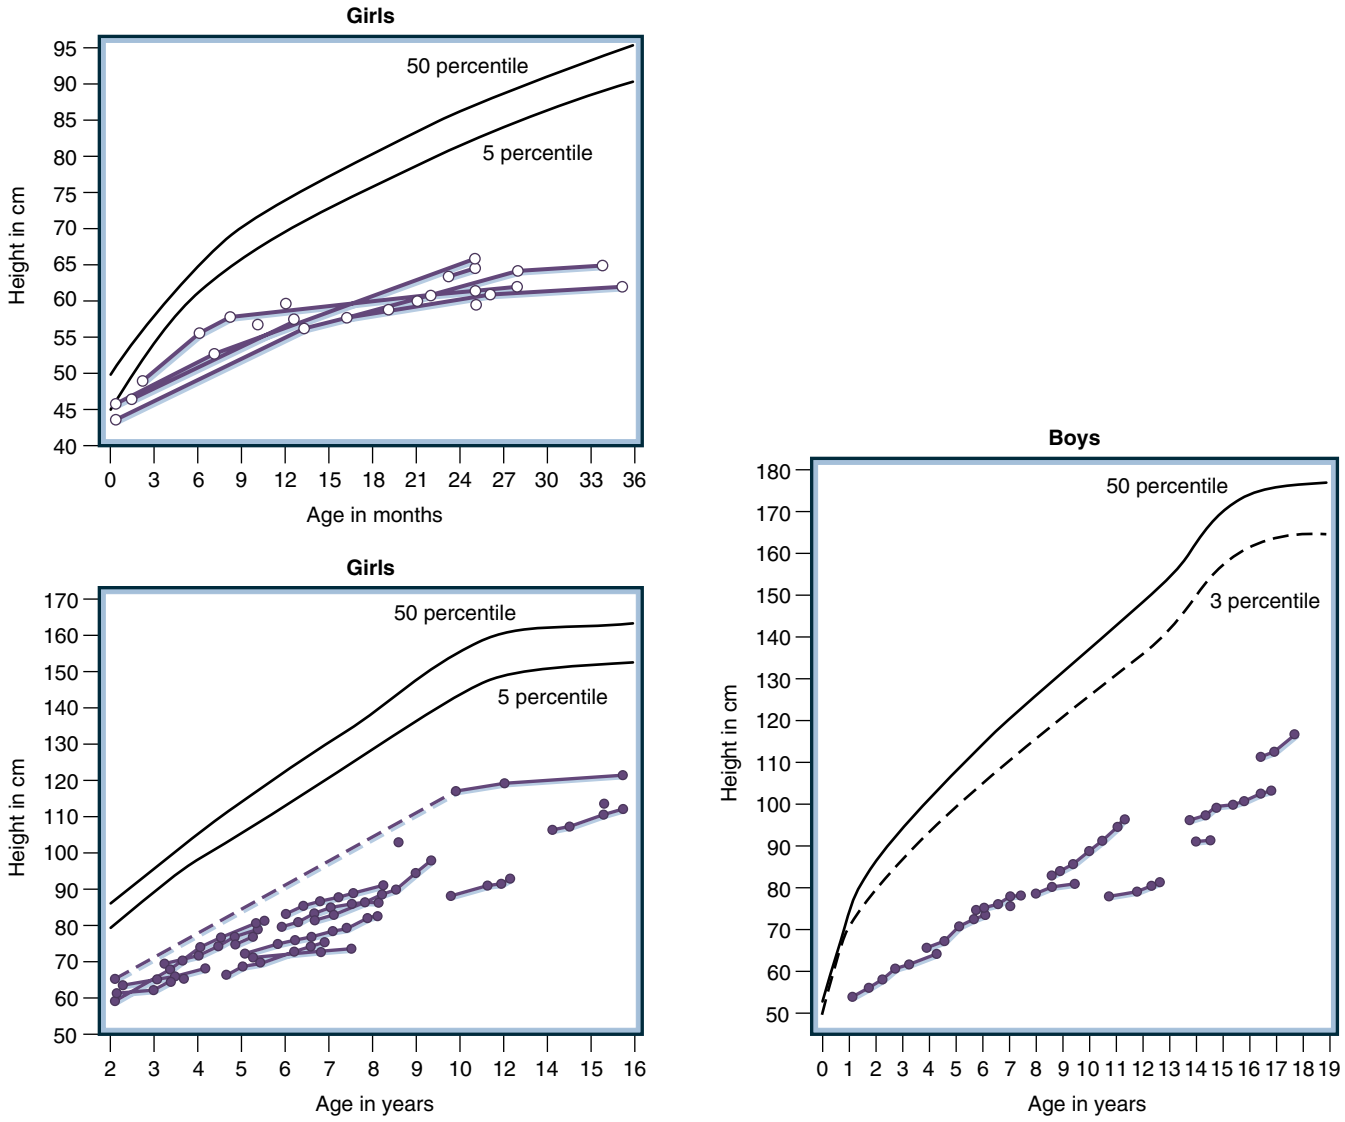
Cystic and solid components can be identified by MRI, and anatomic relationships can be delineated to help plan a rational operative approach. Operative intervention via craniotomy or transsphenoidal resection may result in partial or almost complete removal of the lesion. Postoperative irradiation is commonly used, especially if tumor resection was incomplete. In some patients, particularly those who become obese, a syndrome of normal linear growth without GH may occur. The metabolic syndrome, with evidence of insulin insensitivity and increased body mass index (BMI), is common and is a predictor of potential major long-term morbidity.[607–609] The long-term childhood and adolescent consequences of craniopharyngioma are substantial, with many quality-of-life issues exacerbating the hypopituitarism. Patients with a history of hypothalamic obesity associated with craniopharyngiomas undergoing brain surgery were favored to have sustained weight loss.

Pituitary adenomas (see Chapter 9) are infrequent during childhood and adolescence, accounting for fewer than 5% of patients undergoing surgery at large centers. Almost two-thirds of tumors immunochemically stain for PRL, and a small number stain for GH. GH-secreting pituitary adenomas are exceedingly unusual in youth. There is a variable experience as to the invasive nature of pituitary adenomas, but the prevailing opinion is that they are less aggressive in children than in adults. In 56 patients at the Mayo Clinic with non–ACTH-secreting adenomas removed transsphenoidally, macroadenomas were about one-third more frequent than microadenomas, with cases in girls outnumbering those in boys 3.3 to 1. The patients with macroadenoma had an approximately 50% incidence of hypopituitarism, compared with zero incidence in those patients with microadenomas; long-term cure rates were between 55% and 65% for both tumor sizes. Familial isolated pituitary adenoma (FIPA) accounts for about 2% of pituitary adenomas and is associated with aryl hydrocarbon receptor interacting protein (AIP) gene mutations. Gigantism is a feature of some patients with somatotropinomas.[610]

Histiocytosis X. The localized or generalized proliferation of mononuclear macrophages (histiocytes) characterizes Langerhans cell histiocytosis, a diverse disorder that occurs in patients of all ages, with a peak incidence at ages 1 to 4 years. Endocrinologists are more familiar with the term *histiocytosis X,* which includes three related disorders: solitary bony disease (eosinophilic granuloma), Hand-Schüller-Christian disease (chronic disease with diabetes insipidus, exophthalmos, and multiple calvarial lesions), and disseminated histiocytosis X (Letterer-Siwe disease, with widespread visceral involvement). These syndromes are characterized by an infiltration and accumulation of Langerhans cells in the involved areas, such as skull, hypothalamic-pituitary stalk, CNS, and viscera. Although these disorders, especially Hand-Schüller-Christian disease, are classically associated with diabetes insipidus, approximately 50% to 75% of patients in selected series have growth failure and GHD at the time of presentation. The degree of pituitary stalk thickness has been shown to correlate with long-term risk outcomes.[611] In contrast, a French national registry (n = 589) found GHD in 61 subjects, with overall endocrine dysfunction in 148. In the latter group, an evolving neurodegenerative syndrome (identified in 10% of patients with 15-year follow-up) seemed to be associated with pituitary involvement.[612] Only 1% of unselected children with Langerhans cell histiocytosis living in Canada during a 15-year period had GHD.[613]

Growth Hormone Insensitivity

Mutations in GHR Signaling Proteins and ALS. GH insensitivity, also known as *primary IGF1 deficiency,* encompasses a variety of genetic conditions characterized by growth failure, high serum GH levels, and very low serum IGF1 levels.[614] These findings, first described in siblings in 1966 by Laron and colleagues,[615] are also known as *Laron syndrome*. Most individuals with a diagnosis of classic GH insensitivity are from pedigrees of Mediterranean or Middle Eastern descent. Members of a well-described pedigree



• **Fig. 25.35** Height measurements for Ecuadorian children with insulin-like growth factor (IGF) deficiency resulting from growth hormone (GH) insensitivity. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J. Growth hormone [GH] resistance due to primary GH receptor deficiency. *Endocr Rev.* 1994;15:369–390.)

from Ecuador were from a consanguineous population with Mediterranean origins.[616]

The phenotypic characteristics of classic GH insensitivity include growth failure evident at birth[615] with postnatal subnormal growth velocities and stature –4 to –10 SD below the mean (Fig. 25.35).[614] Patients also have subnormal head circumference, protruding forehead, abnormal upper-body to lower-body ratio, short extremities, and sparse hair (Table 25.4). There is delayed motor development, indicating the importance of IGF1 in cerebral development. The genitalia are small and puberty is delayed, but fertility is normal. Metabolically, the most striking feature of IGF1 deficiency is hypoglycemia with later development of obesity, relative hyperinsulinemia, and insulin resistance.[617] Individuals do not respond to exogenous GH, as determined by growth velocity, hypoglycemia incidence, or serum IGF1 or IGFBP1 levels.[618] GHBP activity is usually undetectable in sera of these patients,[619,620] but measurable levels correspond to higher final heights.

Liver biopsy performed on two affected patients demonstrated that microsomal cells did not bind recombinant GH, suggesting a defect in the GHR.[621] Both deletions and homozygous point mutations (missense, nonsense, and abnormal splicing) in the GHR have been described in persons with GH insensitivity.[622–624] Described gene deletions involve exons 3, 5, and 6.[625] Deletion of exons 5 and 6 results in a frameshift and a premature translational stop signal with consequent encoding of a receptor lacking most of the extracellular GH-binding domain.

More than 70 mutations of the *GHR* gene resulting in GH insensitivity have been reported to date.[626] Most of the mutations are in the extracellular (GH-binding) domain of the receptor and result in impaired ability of GH to bind to the receptor; this also leads to a deficiency of circulating GHBP, which is derived from the extracellular domain of the receptor. One reported mutation of the extracellular domain does not affect GH binding to the receptor but prevents dimerization of the receptor.[627] Homozygous mutations have also been reported in the transmembrane domain.[628,629] These mutations result in GH insensitivity with normal GH binding but lack of receptor transduction. Because the extracellular domain is intact and the mutant receptor protein

TABLE 25.4 Clinical Features of Growth Hormone Insensitivity

Parameter	Clinical Finding
Growth and Development	
Birth weight	Near-normal
Birth length	May be slightly decreased
Postnatal growth	Severe growth failure
Bone age	Delayed, but may be advanced relative to height age
Genitalia	Micropenis in childhood; normal for body size in adults
Puberty	Delayed 3 to 7 years
Sexual function and fertility	Normal
Craniofacies	
Hair	Sparse before age 7 years
Forehead	Prominent; frontal bossing
Skull	Normal head circumference; craniofacial disproportion due to small facies
Facies	Small
Nasal bridge	Hypoplastic
Orbits	Shallow
Dentition	Delayed eruption
Sclerae	Blue
Voice	High pitched
Musculoskeletal/Metabolic/Miscellaneous	
Blood glucose	Hypoglycemia in infants and children; fasting symptoms in some adults
Walking and motor milestones	Delayed
Hips	Dysplasia; avascular necrosis of femoral head
Elbow	Limited extensibility
Skin	Thin, prematurely aged
Bone mineral density	Osteopenia

apparently becomes detached from the cell receptor surface, GHBP levels are normal to elevated.

Mutations affecting the intracellular domain of the GHR also occur; these directly involve the intracellular domain leading to dominantly inherited GH insensitivity.[630–636] In the heterozygous mutations reported, truncation of the GHR results in absence of the intracellular domain. In vitro, this truncated GHR molecule behaves in a dominant negative manner, presumably by retaining an ability to dimerize with the normal GHR and thereby inhibiting GH-induced tyrosine phosphorylation of STAT5. Mutations resulting in C-terminal deletions of the intracellular domain of the GHR exhibit normal GH binding and JAK2 phosphorylation but impaired phosphorylation of STAT5B.[637,638]

That a dominant negative effect has been described for some mutations raises the question of whether heterozygosity for defects of the extracellular domain can also result in short stature. Heterozygosity for defects of *GHR* has been reported to cause some degree of relative GH insensitivity, with modest growth improvement occurring only with high doses of GH.[639–642] In addition, a truncated *GHR* splice variant has been described that functions as a dominant negative inhibitor of the full-length receptor and results in large amounts of GHBP, further downregulating GHR function.[643]

The most extensively studied polymorphism in the *GHR* gene is the deletion of exon 3 *(GHRd3)*, which is present in up to 50% of Caucasians. It has been proposed that GHRs without exon 3 bind GH with comparable affinity[644,645] but may transduce the signal with a different intensity in vitro.[644,645] Upon GH treatment, children with GHD, TS, or SGA with one or two copies of the *GHRd3* variant grow faster than those without the variant after correction for GH dosing. However, different studies reported different findings on whether GH-deficient children with the *GHRd3* variant experience faster growth.[646–648] Different GH dosing among studies and differences among the populations studied could account for the varying results.

Some patients with the phenotype of GH insensitivity but without mutations of the *GHR* gene may have mutations in downstream GHR signaling molecules. Homozygous mutations in the *Stat5B* gene cause GH insensitivity either by decreasing the phosphorylation of tyrosine[649] with resultant inability to dock with phosphotyrosines on GH-activated receptors, or to stably bind DNA,[650] or by causing an insertion in exon 10 leading to early protein termination.[651] A mutation in the SH2 domain of *Stat5b* has also been described, leading to an inability to induce gene transcription.[652] Patients with mutations in *Stat5b* have immune dysfunction and recurrent pulmonary infections, as Stat5B is involved in downstream signaling for multiple cytokines. Heterozygous STAT5b variants in the DNA-binding domain or the coiled-coil domain can lead to disruption of GHR signaling.[653] The mutated protein acts in a dominant negative manner because it can dimerize with wild-type STAT5b but cannot bind DNA to induce transcription. Affected patients had short stature, but immune dysfunction is not as pronounced as in persons with homozygous mutations in STAT5b.

Markedly reduced serum concentrations of IGF1 and IGFBP3 are present in persons with mutation in the ALS gene.[654] IGF1 and IGFBP3 are low as in patients with classic GH insensitivity, but the height deficit is less severe, with reported patients with heights between –3.6 and –0.3 SDS.[655] Affected male patients have delayed puberty and varying degrees of bone mineral density. Insulin insensitivity is present. Found mutations in the IGFALS gene are homozygous or compound heterozygous, all in exon 2. Since ALS levels are undetectable in affected patients, it is believed that the mutation prevents the protein from being expressed, secreted, or stable in serum.[655] Whether the relatively normal growth of these patients reflects the greater importance of locally produced IGF1 or altered kinetics of serum IGF1 in the face of reduced concentrations of binding proteins remains uncertain. The mechanism underlying the observed insulin resistance is also unknown but is postulated to be due to GH excess.[655]

Abnormalities of IGF1 and IGF1 Receptor Signaling. Woods and colleagues[656] described a 15-year-old boy with deletion of exons 4 and 5 of the *IGF1* gene that resulted in a truncated IGF1 molecule. The boy exhibited severe prenatal and postnatal (approximately –7 SDS) growth retardation unresponsive to GH in addition to sensorineural deafness, mental retardation, and microcephaly. He had normal IGFBP3 and GHBP levels,

undetectable IGF1 levels, and hyperinsulinism. On treatment with IGF1, the child experienced growth and improved metabolic parameters.[657] In a kindred of members with height SDS –4.0 and low but detectable IGF1, heterozygous mutation in the *IGF1* gene caused splicing of exon 4 and resultant protein truncation.[658] A child with height of –2.7 SDS and an IGF1 level in the low normal range was found to have a 260-kb heterozygous deletion of chromosome 12, which includes the *IGF1* gene.[659]

Inactivating Mutation of the IGF1 Gene. An adult with the same phenotype as the boy with the *IGF1* deletion but with markedly elevated serum IGF1 levels[660] had a homozygous point mutation in the *IGF1* gene. This mutation resulted in an IGF1 molecule with markedly reduced affinity for the IGF1 receptor that poorly stimulated autophosphorylation of the IGF1 receptor and activation of AKT or ERK.[661] Family members heterozygous for this mutation have significantly lower birth weight, final height, and head circumference, suggesting an effect of heterozygosity for this mutation on IGF1 function.

Primary Defects of IGF Transport and Clearance. Siblings from two families with high IGF1 and IGF2 levels, normal to high IGFBP3 levels, normal ALS levels, and height SDS scores between –2.2 and 1.06 were found to have mutation in the pregnancy-associated plasma protein A2 *(PPAP-A2)* gene.[298] The described mutations generate truncated proteins that cannot cleave IGFBP3 or IGFBP5. Because PAPP-A2 cleavage of IGFBP3 releases IGF1 from the ternary complex, free IGF1 levels in the affected persons were low. Serum from affected patients could not stimulate IGF1 receptor in vitro, further providing evidence of the loss of function induced by the mutation. That the IGF1 levels were elevated suggests that GH signaling was amplified. This amplification of GH signaling may account for the mild degree of height deficit seen in these patients compared to those with GH receptor defects. Treatment of the children with this mutation with rIGF1 resulted in increased growth rate after 1 year.[662] rIGF1 treatment's effect on adult height is unknown.

Primary Defects of IGF1 Receptor Production or Responsiveness. Patients with IUGR and postnatal growth failure, microcephaly, and mental retardation with normal to elevated serum IGF1 levels have been reported to have mutations in the IGF1 receptor gene leading to reduced binding of IGF1 to its receptor.[663,664] Fang and associates published a report of a patient with a missense mutation in *IGF1R* and height –5.9 SDS, elevated IGF1 levels, and resultant decreased activation of downstream signaling pathways.[665]

In leprechaunism, a syndrome of growth failure and insulin receptor dysfunction, there is variable IGF1 insensitivity.[666,667] The profound abnormality of the insulin receptor suggests that heterodimeric insulin and IGF1 receptor combinations might lead to failed activation of the IGF1 signaling cascade. The IGF1 receptor gene resides on 15q, so persons with deletions of the distal long arm of chromosome 15 or ring chromosome 15 have heterozygosity of the IGF1 receptor.[667,668] These patients may have IUGR and postnatal growth failure, but lack of a biologic response to IGF1 has not been conclusively demonstrated.[668] Therefore whether the growth failure is caused by altered levels of IGF1 receptor or is a result of the loss of other genes located on 15q remains to be determined.

Disorders Outside the Growth Hormone–IGF Axis

Many systemic disorders, if severe enough, can cause growth failure in children. Those that primarily alter hormones that directly regulate growth (e.g., thyroid hormone, glucocorticoids) can be understood based on the known actions of those hormones. Even in those disorders in which the pathology is not primarily within the endocrine system, there is often an underlying hormonal abnormality contributing to the growth failure. In some cases, the underlying disorder produces a secondary hormone deficiency. Those disorders in which a hormone deficiency cannot be identified may be thought of as demonstrating hormone resistance, because these children have growth failure in the presence of normal GH production.

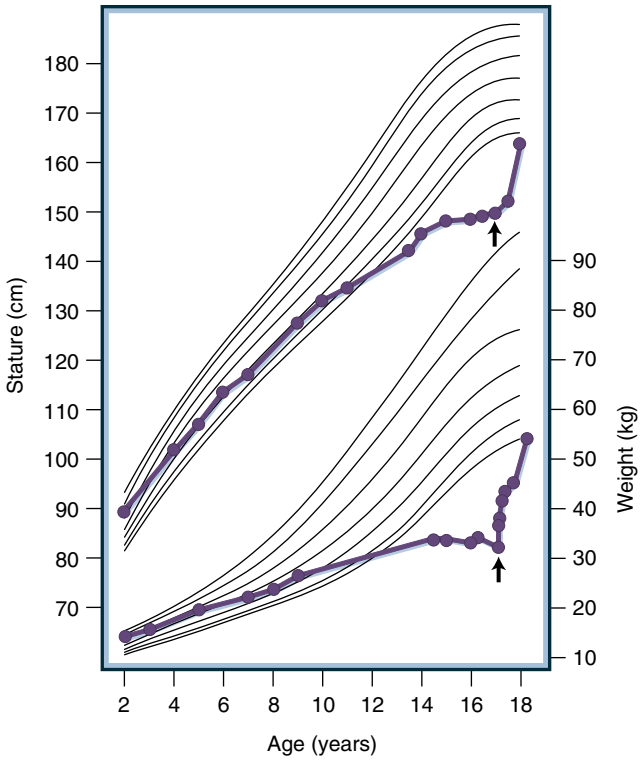
Malnutrition

Given the worldwide presence of undernutrition, inadequate intake of energy (calories), protein, or both is the most common cause of growth failure. *Marasmus* refers to an overall deficiency of calories, including protein malnutrition. Subcutaneous fat is minimal, and protein wasting is marked. *Kwashiorkor* refers specifically to inadequate protein intake, although it may also be characterized by some caloric undernutrition. Frequently, the two conditions overlap. Decreased weight growth usually precedes the failure of linear growth by a very short time in the neonatal period and by several years at older ages. Stunting of growth due to caloric or protein malnutrition in early life often has lifelong consequences, including diminished skeletal growth.[669]

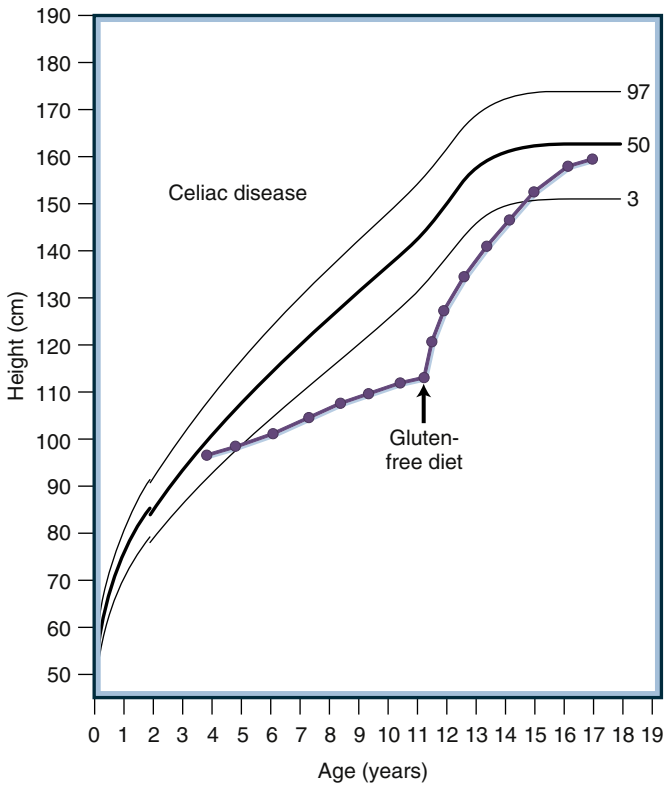
Both acute and chronic malnutrition affect the GH-IGF1 system. The impaired growth seen in malnutrition is usually associated with elevated basal or stimulated serum GH levels,[670,671] although in some cases of generalized malnutrition (marasmus), the GH levels are normal or low.[672] In both conditions, serum IGF1 levels are reduced.[671,673] The increase in GH levels is caused by a decrease in negative feedback by IGF1 and a decrease in somatostatin tone.[674] Malnutrition also results in increased ghrelin levels,[675,676] which could also contribute to an increase in GH secretion, although the role of ghrelin in regulating GH secretion remains unclear.[677] With serum IGF1 levels reduced despite normal or elevated GH levels, malnutrition is a form of GH insensitivity.[671] One cause of this insensitivity is a decrease in GHR expression, which is reflected in decreased serum GHBP levels.[670,678] In addition, fasting increases expression of FGF21, which may cause GH insensitivity by inhibiting STAT5.[679] This GH insensitivity may be an adaptive response, diverting scarce energy resources from growth toward use for acute metabolic needs. The low IGF1 minimizes stimulation of anabolism, whereas the direct actions of the elevated GH levels (e.g., lipolysis, insulin antagonism) may increase the availability of energy substrates.[671,680,681] These adaptive mechanisms are accompanied by changes in serum IGFBPs that further limit IGF action during periods of malnutrition.[670,682]

Inadequate calorie or protein intake complicates many chronic diseases that are characterized by growth failure. Anorexia is a common feature of renal failure and inflammatory bowel disease, and it also occurs with cyanotic heart disease, congestive heart failure, CNS disease, and other illnesses. Some of these conditions may be further characterized by deficiencies of specific dietary components, such as zinc, iron, and vitamins necessary for normal growth and development.

Undernutrition may also be voluntary, as occurs with dieting and food fads (Fig. 25.36).[682] Caloric restriction is especially common in girls during adolescence, in whom it may be associated with anxiety concerning obesity, and in gymnasts and ballet dancers. Anorexia nervosa and bulimia are extremes of "voluntary" caloric deprivation that are commonly associated with impaired growth before epiphyseal fusion, which may result in diminished



• **Fig. 25.36** Curves of weight and height for a child who had growth failure resulting from prolonged self-imposed caloric restriction due to a fear of becoming obese. Notice that crossing of percentiles on the weight curve preceded that on the height curve, and that, after caloric intake was normalized *(arrow)*, gain in weight occurred before improvement in linear growth. At the end of the prolonged period of caloric restriction, weight age (10.2 years) was less than height age (12 years). (From Pugliese MT, Lifshitz F, Grad G, et al. Fear of obesity: a cause of short stature and delayed puberty. *N Engl J Med.* 1983;309:513–518. Reprinted by permission of the *New England Journal of Medicine*.)



• **Fig. 25.37** Catch-up growth in a girl with gluten-induced enteropathy (celiac disease). After 8 years of growth impairment, the patient was placed on a gluten-free diet and demonstrated substantial catch-up growth, returning to the previous growth percentiles. (Courtesy J.M. Tanner.)

final adult height.[683,684] Adolescent bone mineral accretion is impaired, and significant osteopenia may persist into adulthood.[685] Later in adolescence, malnutrition may cause delayed puberty or menarche (or both), as well as a variety of metabolic alterations. In anorexia nervosa, hormonal profiles are similar to those in protein-energy malnutrition,[683,684,686] with high basal levels of GH. However, in contrast to chronic critical illness, in which there is an increase in nonpulsatile secretion but a decrease in pulsatile GH secretion, in anorexia both nonpulsatile and pulsatile secretion of GH are increased.[674] The GH secretion stimulated by insulin-induced hypoglycemia, dopaminergic agents, or acute administration of dexamethasone is impaired in patients with anorexia nervosa, whereas clonidine and arginine elicit normal GH responses. Finally, a paradoxical increase in GH release to intravenous glucose infusion has been described.[674] As in malnutrition in general, low levels of IGF1 and IGFBP3 are found in anorexia nervosa, indicating GH resistance. Similarly, GHBP levels are decreased,[674] indicating a decrease in GHR expression as a contributing factor to the GH resistance. The hormones of the GH-IGF1 axis return to normal levels with refeeding.[670,683,687]

A rare cause of failure to thrive in infants and young children is the diencephalic syndrome.[688] This syndrome is characterized by a marked impairment of weight gain, or even weight loss, but with normal linear growth (at least initially). It is caused by hypothalamic tumors. Similar to the findings in other causes of low weight for length or height, increased GH levels have been found in patients with diencephalic syndrome. As in patients with anorexia nervosa, GH levels paradoxically increase in response to a glucose load. However, in contrast to the increased GH secretion seen in malnutrition or anorexia nervosa, IGF1 levels are normal rather than decreased.[688] Therefore diencephalic syndrome does not demonstrate GH resistance in the same way as these other disorders.

Chronic or Systemic Diseases

Malabsorption and Gastrointestinal Diseases

Intestinal disorders that impair absorption of calories or protein cause growth failure, for many of the same reasons as malnutrition per se.[680,689,690] Growth retardation may predate other manifestations of malabsorption or chronic inflammatory bowel disease. Celiac disease (gluten-induced enteropathy) and regional enteritis (Crohn disease) should be considered in the differential diagnosis of unexplained growth failure. Serum levels of IGF1 may be reduced,[680,691] reflecting malnutrition, and it is critical to discriminate between these conditions and disorders related to GHD. Documentation of malabsorption requires demonstration of fecal wasting of calories, especially fecal fat, along with other measures of gut dysfunction such as the D-xylose or breath hydrogen studies.

In celiac disease, an immune-mediated disorder in which the intestinal mucosa is damaged by dietary gluten (Fig. 25.37), impaired linear growth may be the first manifestation of disease.[680] The degree of growth impairment may be similar in patients with or without gastrointestinal symptoms.[680] The incidence of childhood celiac disease in the United States is about 0.9%,[692] but its

prevalence is approximately 5% in children being evaluated for short stature.[693] Celiac disease also has an increased incidence in individuals with TS, insulin-dependent (type 1) diabetes mellitus (IDDM), Down syndrome, or Williams syndrome.[693] The onset and progression of puberty may be delayed, and menarche may be late.[694] Measurement of an immunoglobulin A (IgA) tissue transglutaminase antibody (tTG-IgA)[695] is the currently recommended screening test. This test has a sensitivity of up to 99%, with much higher specificity than IgA gliadin antibodies (AGA-IgA). However, tTG-IgA has significantly lower sensitivity in children younger than 18 months of age,[696] in whom it may be preferable to also measure AGA-IgA. When measuring IgA antibodies, it is necessary to measure total IgA levels to exclude IgA deficiency, particularly because IgA deficiency has an increased incidence in patients with celiac disease.[697] (In subjects with IgA deficiency, tTG-IgG may be used.[697]) Nonetheless, the diagnosis of celiac disease ultimately requires demonstration of the characteristic mucosal flattening in small bowel biopsy.[692] Gluten withdrawal is a highly effective treatment for celiac disease and results in rapid catch-up growth and decreased clinical symptoms during the first 6 to 12 months of treatment.[680,694] Low IGF1 and IGFBP3 levels return to normal during this period.[691,698] Most children who receive appropriate dietary management ultimately achieve a normal final height.[699,700]

Growth failure in Crohn disease, which correlates with disease severity,[701] is probably due to a combination of malnutrition from malabsorption, anorexia, nutrient loss, chronic inflammation,[690,701] inadequacy of trace minerals in the diet, and use of glucocorticoids. IGF1 levels are low, especially with impaired growth.[680,690] In an animal model, approximately one-half of the decrease in IGF1 levels was accounted for by undernutrition, with the other half attributable to the effects of inflammation.[702] One-third to two-thirds or more of children with Crohn disease have impaired growth at diagnosis. In some patients, the growth failure precedes clinical symptoms of bowel disease by a few years, with a significant number showing linear growth failure before any weight loss.[680,690,701,703,704] Adequate nutritional supplementation and surgical resection of the diseased intestine can lead to improved growth, but surgery is not always an option.[705–707] Osteopenia is common.[708,709] An elevated erythrocyte sedimentation rate, anemia, and low serum albumin are useful clues, but diagnosis of Crohn disease ultimately requires colonoscopy and biopsy, along with gastrointestinal imaging studies. Permanent impairment of linear growth and deficits of final height may occur in 30% of patients.[710] Approximately 20% of patients at adult height are more than 8 cm below the midparental target height.[711] Small, mostly uncontrolled trials of GH treatment in children with Crohn disease have had conflicting results: Some have shown improved growth velocity,[712,713] but others have not.[714] Some have shown improved body composition and BMD.[713] None of the reports, however, has extended beyond 2 years of treatment to determine whether there is a long-term benefit.

Chronic Liver Disease

Chronic liver disease in childhood can cause impaired linear growth. Decreased food intake, fat and fat-soluble vitamin malabsorption, and trace element deficiencies contribute to growth failure.[715–718] In addition, these children show evidence of GH resistance, having decreased levels of IGF1 and IGFBP3 and increased GH secretion.[719–722] IGF2 levels are also decreased, and IGFBP1 levels are increased.[719–721] Although the low IGF1 levels might be due to the impaired synthetic capacity of the liver, there is decreased expression of the GHR in cirrhotic liver, just as in malnutrition.[723] However, despite provision of adequate calories, insensitivity to the action of GH persists,[718,720] suggesting that the GH resistance of liver failure is not due solely to malnutrition. Liver transplantation prolongs life expectancy, and linear growth is variably improved in the early post-transplantation years.[717,721,724,725] Exogenous glucocorticoid administration presumably plays a major role in the continued growth retardation[717,725]; GH and IGF1 production are normal, but the amount of "free IGF" may be decreased because IGFBP3 levels are relatively high.[721,724] Post-transplantation growth is inversely correlated with age and directly correlated with the degree of growth impairment at transplantation.[716,717,724] Exogenous GH treatment enhances growth rates and increases median height SDS by 0.3 to 0.6 unit after 1 year of treatment,[472,726,727] with continued increases in height SDS for up to 5 years during treatment.[472]

Cardiovascular Disease

Congenital heart disease with cyanosis or chronic congestive heart failure can cause growth failure.[728–730] Although some children with congenital heart disease will have growth failure related to an underlying genetic disorder, the disease itself can cause growth failure. The growth failure in children with CHD is often due to malnutrition, which can have a number of causes in children with CHD. Frequently this is due to inadequate calorie intake due to feeding difficulties associated with the heart disease.[728,729,731] In addition, chronic congestive heart failure is associated with malabsorption that includes protein-losing enteropathy, intestinal lymphangiectasia, and steatorrhea. Greater cardiac and respiratory work requirement and the relatively higher ratio of metabolically active, energy-utilizing brain and heart tissue to the growth-retarded body mass (cardiac cachexia) cause an increased basal metabolic rate in these children.[732,733] Thus food intake that appears adequate for the child's weight is often inadequate for normal growth. Finally, in children with cyanotic CHD, the hypoxemia impairs cellular metabolism and growth. Decreased levels of IGF1 and IGFBP3[733–735] and normal levels of GH and hepatic GHRs in chronically hypoxemic newborn sheep[735] suggest GH insensitivity distal to the GHR.

In the past, up to 30% of children with congenital heart disease had heights and weights that fell below the 3rd percentile for age.[730] In the developing world, up to 90% of children with CHD continue to suffer growth failure.[729] In contrast, in the developed world the impact of CHD on the growth of children has been nearly eliminated owing to the ability to make an early diagnosis, as well as on improvements in supportive care and the early surgical correction of these lesions. The nutritional management of these infants before surgical correction includes the use of calorie-dense feedings because of the need to restrict fluids, calcium supplementation because of the use of diuretics that can cause calcium loss in the urine, and iron to maintain an enhanced rate of erythropoiesis. Early surgical correction restores normal growth, frequently after a phase of catch-up growth with normalization of energy expenditure.[728,730,732,736]

Renal Disease

All conditions that impair renal function can impair growth.[737–740] Uremia and renal tubular acidosis can cause growth failure before other clinical manifestations become evident. The growth impairment results from multiple mechanisms, including inadequate formation of 1,25-dihydroxycholecalciferol (1,25-dihydroxyvitamin D_3, calcitriol) with resultant osteopenia, decreased caloric

intake, loss of electrolytes necessary for normal growth, metabolic acidosis, protein wasting, insulin resistance, chronic anemia, compromised cardiac function, and impairment of GH and IGF production and action. In nephropathic cystinosis, acquired hypothyroidism contributes to the inadequate growth.[741] Between 60% and 75% of patients with chronic renal failure treated before the GH therapeutic era had final adult heights more than 2 SD below the mean.[742]

The effects of renal failure on the GH-IGF1 axis are complex, and there is evidence for both GH and IGF1 resistance. Children and adolescents have normal or elevated circulating levels of GH, depending on the degree of renal failure.[737,738,743–745] The increased GH levels result from both an increase in GH secretory bursts and a decrease in renal GH clearance.[746] Serum IGF1 and IGF2 levels are usually normal in patients with renal failure.[737,745,747,748] Early reports of decreased serum IGF levels in uremia were an artifact caused by inadequate separation of IGF from IGFBPs before assay.[749] However, the normal IGF1 levels in the face of elevated GH levels denotes GH resistance, which is also indicated by the finding of decreased hepatic IGF1 production.[750] The mechanism for GH resistance includes decreased GHR gene expression in the liver and in the growth plate.[747,751] There is also evidence that the uremic state causes a postreceptor defect in GH signal transduction by diminishing phosphorylation and nuclear translocation of GH-activated STAT proteins.[746,752] Although a defect in IGF1 receptor signaling has been demonstrated in renal failure,[751] the more important mechanism for decreased IGF1 action in renal failure is alterations in the serum level of IGFBPs that decrease the bioavailability of IGF1. IGFBPs 1, 2, 4, and 6 are increased.[737,738,751,753–756] In addition, low-molecular-weight IGFBP3 fragments, which have decreased affinity for IGF1, accumulate as a result of reduced renal clearance.[751] In nephrotic syndrome, an additional contribution to growth failure may come from reduced serum levels of IGF1 and IGFBP3 resulting from urinary loss of IGF-IGFBP complexes.[739] Finally, glucocorticoid therapy that may be used for treatment of the renal disease can exacerbate growth retardation by diminishing GH release and blunting IGF1 action at growth plates.[755,757,758]

After successful renal transplantation, growth may completely return to normal.[759,760] Based on data from the large cohort of patients in the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS), children who underwent transplantation before 6 years of age showed catch-up growth for the subsequent 1 to 2 years, followed by a plateauing of their growth rate.[759] In contrast, children older than 6 at the time of transplant have not shown catch-up growth; their final height is determined by their height at the time of transplantation.[759] In spite of this, final height in children requiring renal transplant has improved dramatically in the past 25 years so that the final heights of children in the NAPRTCS registry that were transplanted in the years 2002 to 2010 had a final height of –0.94 SDS, compared with final heights averaging –1.93 SDS in those transplanted between 1987 and 1991. This improvement appears to be driven almost completely by the improved height at the time of transplantation: –1.5 SDS in 2009 versus –2.5 SDS in 1987.[759] The importance of height at the time of transplantation in determining final adult height, despite the complex post-transplantation health issues, confirms the value of improving growth velocity and absolute height before transplantation. Additional factors that impact growth after transplantation include the function of the allograft and the use of glucocorticoids in the immunosuppressive regimen. Immunosuppressive regimens with alternate-day glucocorticoid treatment, rather than daily treatment,[760,759] utilizing a glucocorticoid withdrawal approach[759,761] and regimens that avoid glucocorticoids have all been associated with improved post-transplant growth rates.[759] There are conflicting data on whether sirolimus impairs growth in comparison to tacrolimus.[759] Growth-retarded post-transplantation children receiving daily or alternate-day glucocorticoid treatment have decreased GH secretion, normal levels of IGF1 and IGFBP1, and elevated levels of IGFBP3. They differ from patients with end-stage renal disease in that IGFBP1 levels are not strikingly elevated, perhaps because of altered glucose tolerance and hyperinsulinism due to chronic glucocorticoid therapy.[755]

Hematologic Disorders

Chronic anemias, such as sickle cell disease, are characterized by growth failure.[762] In general, the decrease in height and weight is greater in adolescent years than earlier because the onset of the adolescent growth spurt is delayed and menarche is late.[762–764] However, the adolescent growth and final adult height in patients with sickle cell disease may be normal.[764] The causes of growth retardation probably include suboptimal nutrition and hypogonadism.[765] Impaired oxygen delivery to tissues, increased work of the cardiovascular system, and energy demands of increased hematopoiesis are likely contributors to impaired nutrition. Long-term chronic transfusion therapy as part of stroke prevention treatment is associated with enhanced growth.[766] The GH-IGF1 system probably does not have a primary role in the growth impairment of sickle cell anemia, although abnormalities in the GH-IGF1 system have been described.[763]

In thalassemia, in addition to the consequences of chronic anemia, endocrine deficiencies can result from chronic transfusions and accompanying hemosiderosis.[767] Despite vigorous efforts to maintain hemoglobin levels near normal and to avoid iron overload, growth failure is still a common feature of thalassemia, especially in male adolescents.[768] The patients tend to show body disproportion, with truncal shortening but normal leg length. It is likely that anemia, impaired IGF1 synthesis, hypothyroidism, gonadal failure, and hypogonadotropic hypogonadism all contribute to growth failure in this disorder. GH insensitivity in some cases is suggested by generally adequate GH production with low IGF1 levels.[769,770] Several groups have reported data on treatment of thalassemia patients in whom GH production seemed diminished. In most patients, GH treatment increased growth, at least initially.[769,771] In a longer term study (average duration, 59 months) starting with young patients (7.2 years of age), an increased growth velocity was maintained throughout the treatment period[772]; when treatment was initiated at an older age (13.6 years), final height was not improved.[773] A small number of adults with thalassemia are found to have continued GHD, so GH treatment for cardiac and bone health reasons may be important in this disease.[774]

About half of the patients in the International Fanconi Anemia Registry have short stature. GHD was demonstrated by provocative testing (22 of 48 patients) or with assessment of endogenous secretion (13 of 13) in a group with a mean height of –2.23 SDS.[775] In pure red blood cell aplasia,[776] approximately 30% of patients demonstrated growth retardation. The frequency increased with age (42% in individuals >16 years) and with treatment programs such as chronic transfusions or glucocorticoids.

Inborn Errors of Metabolism

Inborn errors of metabolism are often accompanied by growth failure that may be pronounced. Glycogen storage disease, the mucopolysaccharidoses, glycoproteinoses, and mucolipidoses

are characterized by poor growth. Many inborn metabolic disorders are also associated with significant skeletal dysplasia. In a small number of patients with organic acidoses, such as methylmalonic and propionic acidurias, IGF1 levels are low and GH levels are normal, suggesting a possible state of GH insensitivity related to nutritional status.[777] Preliminary data suggest that exogenous GH treatment may improve the metabolic status of such children.[777,778]

Pulmonary Disease

Growth can be retarded in children with asthma, including those who have not received glucocorticoid therapy. The lowered growth in asthmatic children does not appear to be associated with abnormalities of the GH-IGF1 axis.[779] Impaired nutrition and increased energy requirements, along with chronic stress, especially with nocturnal asthma and enhanced endogenous glucocorticoid production, cause poor linear growth. However, despite this growth impairment, there is at most only a small difference in final height achieved by those with asthma, with the majority of the growth failure due to a delay in puberty.[780] Systemic glucocorticoid therapy, which is rarely required, can be expected to impair growth. Intermittent glucocorticoid therapy is usually not associated with impaired final height. Alternate-day or aerosolized glucocorticoid therapy often ameliorates growth retardation and can be associated with an accelerated catch-up phase.[781,782] The large Childhood Asthma Management Program investigated the effect of inhaled corticosteroids (ICS) on the growth of children with asthma. Although growth rate declined with the initiation of ICS, it subsequently normalized, and the final height in children treated with ICS for 4 to 6 years was only 1.2 cm below that in control subjects.[783] ICS can, however, suppress the hypothalamic-pituitary axis, and investigation for this is appropriate in children who have a more marked suppression of growth with ICS treatment.[780]

Bronchopulmonary dysplasia (BPD), a sequela of neonatal respiratory distress syndrome and prematurity, has an incidence as high as 35% in infants with very low birth weight (<1500 g).[784] The use of dexamethasone in the treatment of BPD in neonates causes a transient cessation of growth[785] and has engendered long-term concern for neurodevelopment and somatic growth.[786] Growth in surviving infants is poor through early childhood,[787–789] but the defect usually disappears by 8 years of age.[790–792] Long-term hypoxemia, poor nutrition, chronic pulmonary infections, and reactive airway disease are responsible for the poor early growth.

In patients with cystic fibrosis (CF), chronic pulmonary infection with bronchiectasis, pancreatic insufficiency with exocrine and endocrine inadequacy, malabsorption, and malnutrition all contribute to decreased growth and late sexual maturation. Over 20% of individuals with CF under 25 years of age will have heights or weights below the 10th percentile.[793] With newborn screening for CF, the failure to thrive that was a common presenting feature is now less likely to be seen, although these infants still demonstrate some growth failure.[794] Infants who are not identified by newborn screening often show marked growth failure before diagnosis followed by catch-up growth after diagnosis. The linear growth rate during childhood is generally normal before puberty,[795] followed by delayed puberty, including a delayed and attenuated pubertal growth spurt. Adult height in individuals with CF is slightly decreased compared with population norms by approximately –0.2 to –0.7 SD.[795–797] The GH-IGF1 axis in CF patients shows evidence for some degree of acquired GH insensitivity with lowered mean IGF1 and elevated GH levels.[798] The degree of growth retardation is related most closely to the severity and variability of the pulmonary disease rather than to pancreatic dysfunction.[799,800] While the degree of steatorrhea does not correlate well with growth impairment, improved nutrition programs do enhance the overall clinical picture.[801,802] Endocrine abnormalities, such as failure of both alpha and beta islet cells with decreased glucagon and insulin production, do not seem to influence prepubertal growth patterns in children with CF. Alterations of vitamin D metabolism, while potentially affecting skeletal mineralization, do not diminish growth.[803]

There is the potential for the anabolic effects of GH treatment to improve the health in patients with CF. A number of short-term trials of up to 12 months with GH treatment have been reported.[793,804,805] These studies have demonstrated that GH treatment of CF patients increases height, weight, and lean body mass. In addition, some measures of lung function are slightly improved, notably forced vital capacity, although this improvement did not always exceed that expected based on the improved growth.[805] Although some studies have demonstrated a decreased rate of hospitalization in GH-treated patients, there has not been clear evidence of a decrease in pulmonary exacerbations.[805,804] These studies, as well as reports of uncontrolled treatments of up to 4 years, have not raised serious safety concerns of GH treatment in CF patients. Specifically, there has not been an increase in glucose intolerance or diabetes mellitus, although in some studies fasting glucose levels were increased.[804–806] Although the current data demonstrate the possibility that GH treatment will benefit patients with CF, there are not yet sufficient data to indicate that GH treatment improves long-term health outcomes in these patients.

Chronic Inflammation and Infection

Poor growth is a characteristic feature of chronic inflammatory disease and recurrent serious infection. The impaired growth associated with such disorders as Crohn disease, CF, and asthma, in which inflammatory processes may be significant, has already been discussed. Inflammatory states are associated with increased levels of numerous cytokines. Interleukin 6 (IL6), specifically, has been implicated in this growth impairment. De Benedetti and colleagues,[807] studying juvenile rheumatoid arthritis in humans and in a transgenic murine model expressing excessive IL6, demonstrated an IL6-mediated decrease in IGF1 production. IL6 has been demonstrated to activate SOCS3; this provides a pathway for inflammation to inhibit IGF1 production because SOCS3 is a negative regulator of the JAK2/STAT5 GH signal transduction pathway.[702,808,809] IL6 may also cause a decrease in serum IGF1 levels by increasing its clearance through a decrease in IGFBP3 levels.[702] In addition, cytokines can affect the endocrine system at many other levels,[810,811] impairing mineral and nutrient metabolism and the growth and remodeling of bone.[812]

Exposure to human immunodeficiency virus (HIV) in children and adolescents occurs through perinatal transmission, blood transfusions, drug usage, and sexual contact. Growth failure is a cardinal feature of childhood acquired immunodeficiency syndrome (AIDS).[813–817] However, HIV-infected infants and children show growth failure even before demonstrating severe immune dysfunction.[818,819] Weight, length, and head circumference are all affected, although weight-for-height may be normal.[815,817,820] Before the era of highly active antiretroviral therapy (HAART), height growth velocity was associated with survival, independent of either $CD4^+$ T-cell lymphocyte count or viral load, with HAART therapy normalizing growth in most studies.[820] Studies of

the GH-IGF1 axis in HIV-infected children have shown evidence of decreased GH secretion, GH resistance, and IGF1 resistance; both normal and low levels of GH and IGF1 are seen.[818] Lipodystrophy associated with HAART therapy occurs in children, although less commonly than in adults, and decreased GH secretion has been demonstrated in HIV-associated lipodystrophy,[818] potentially contributing to impaired growth. HIV-infected children frequently have delayed puberty, which could contribute to their linear growth failure. In a short-term treatment trial with standard doses of GH, height and weight growth increased and protein catabolism diminished, without any adverse effect on viral burden.[821]

Endocrine Disorders

Hypothyroidism

Untreated severe congenital hypothyroidism results in profound growth failure. With proper treatment, however, children with congenital hypothyroidism reach a height appropriate for their genetic potential.[822]

Acquired hypothyroidism during childhood may also result in growth failure that can range from subtle to profound, depending on the severity and duration of the hypothyroidism. Growth failure may be the most prominent manifestation of hypothyroidism in children.[823] The poor growth is more apparent in height than in weight gain, so these children tend to be overweight for height. Rivkees and coworkers[823] reported a mean 4.2-year delay between the slowing of growth and the diagnosis of hypothyroidism; at diagnosis, girls were 4.04 SD below and boys 3.15 SD below the mean height for their age. Skeletal maturation is delayed in those children in whom the hypothyroidism was sufficient to retard growth, with the bone age at diagnosis corresponding to the age at onset of the hypothyroidism.[823] Body proportion is immature, with an increased upper-body to lower-body segment ratio. Although chronic hypothyroidism is usually associated with delayed puberty, precocious puberty and premature menarche can occur in hypothyroid children (see Chapter 26).

In those children with severe growth failure, treatment with thyroid hormone results in rapid catch-up growth. This growth is typically accompanied by marked skeletal maturation. In cases of prolonged severe hypothyroidism, the advancement of skeletal maturation with treatment can exceed the growth acceleration, resulting in a compromised adult height.[823] The deficit in adult stature correlates with the duration of hypothyroidism before initiation of treatment. Catch-up growth may be particularly compromised if therapy is initiated near puberty.[824]

As expected, hyperthyroidism has effects on growth opposite to those of hypothyroidism: It results in accelerated growth and epiphyseal maturation. Children with hyperthyroidism present with an increased height and advanced bone age. In neonates, hyperthyroidism can result in craniosynostosis. However, despite the advanced bone age at diagnosis, the final height of children treated for hyperthyroidism remains normal in relation to genetic potential.[825]

Diabetes Mellitus

Although weight loss may occur immediately before the onset of clinically apparent IDDM, children with new-onset diabetes are frequently taller than their peer group, possibly because GH and insulin levels are increased during the preclinical evolution of the disease.[826–828] Most children with IDDM, even those with marginal control,[829] grow quite normally, especially in prepubertal years, although growth velocity may decrease during puberty.[830] However, growth failure can occur in diabetic children with long-standing poor glycemic control.[831,832] The Mauriac syndrome[833] describes children with poorly regulated IDDM, severe growth failure, and hepatosplenomegaly due to excess hepatic glycogen deposition. This type of growth retardation has become increasingly rare with modern diabetes care.

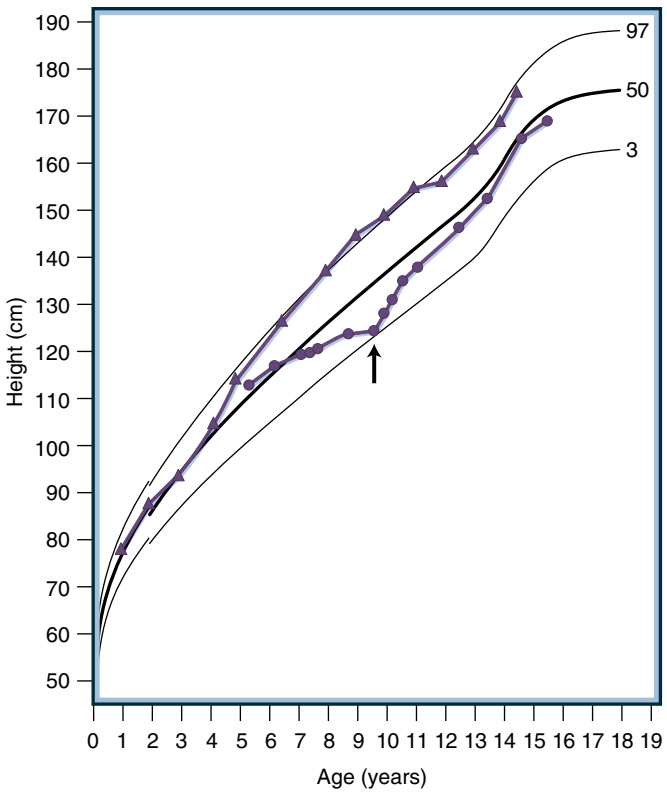
Many pathophysiologic processes, including malnutrition, chronic intermittent acidosis, increased glucocorticoid production, hypothyroidism, impaired calcium balance, and end-organ unresponsiveness to either GH or IGF, may contribute to growth failure in IDDM.[826,834–836] IGF1 and IGFBP3 levels are diminished in the face of enhanced GH production,[837–841] reflecting acquired GH insensitivity. GHBP levels are decreased,[834,840] supporting the concept of impaired GHR number or function. Furthermore, IGFBP1 is normally suppressed by insulin, and hypoinsulinemia results in elevated serum IGFBP1 levels that may inhibit IGF action.[612,840,842–844] In contrast to the situation in adolescents and adults, IGFBP1 levels are not elevated in well-growing prepubertal children.[844] On the contrary, increased IGFBP3 proteolysis may enhance the bioactivity of the available IGF1.[613,841] Most children with IDDM attain normal cellular nutrition and growth factor action despite intermittent hypoinsulinemia and derangements of peripheral indices of the GH-IGF1 system.

Even though glycemic control is inversely correlated with IGF1 level,[835,837,840,845] the correlation between glycemic control and growth is weak. After conflicting reports as to the influence of glycemic regulation on growth,[826,827,846,847] a longitudinal study[847] of 46 children whose diabetes began before age 10 indicated that initial heights at diagnosis were normal and that the final height SDS was minimally reduced from that at onset. In boys, despite a delay of about 2.5 years in onset of puberty, total pubertal height gain was normal. In girls with diabetes, however, total pubertal height gain was diminished and the age at menarche was delayed; the effects of altered insulin and IGF1 levels on ovarian function have not been assessed in such patients. Chronic metabolic control did not correlate with the pubertal height gain or with the normal final height. Nevertheless, good glycemic control may improve growth at certain maturational periods such as puberty.[826,839,848]

Cushing Syndrome: Glucocorticoid Excess

Glucocorticoid excess impairs skeletal growth, interferes with normal bone metabolism by inhibiting osteoblastic activity, and enhances bone resorption.[849–851] These effects are related to the duration of steroid excess,[852] regardless of whether the Cushing syndrome is due to ACTH hypersecretion, adrenal tumor, or glucocorticoid administration.

Even modest doses of oral glucocorticoids can inhibit growth; these doses may be as low as 3 to 5 mg/m^2 per day of prednisone or 12 to 15 mg/m^2 per day of hydrocortisone (i.e., only slightly above what is considered physiologic replacement).[853] The "toxic" effects of glucocorticoids on the epiphysis may persist to some degree after correction of chronic glucocorticoid excess, and patients frequently do not attain their target height.[854,855] The longer the duration and the greater the intensity of glucocorticoid excess, the less likely it is that catch up growth will be completed. Alternate-day glucocorticoid treatment decreases but does not eliminate the risk of growth suppression.[782,856,857] Inhaled glucocorticoids given for the treatment of asthma have an even lower risk of growth suppression, but even at modest doses (e.g., 400 μg/day of beclomethasone,[858] 200 μg/day of fluticasone,[858] or 400



• **Fig. 25.38** Growth curves of two boys with obesity. The boy depicted by the *circles* had cortisol excess related to Cushing disease. He had onset of rapid weight gain associated with a decrease in linear growth velocity at age 7. The diagnosis was made, and an adrenalectomy *(arrow)* was performed at age 9.5 years, with an almost immediate increase in growth rate and striking catch-up growth. The boy whose growth is depicted by *triangles* had exogenous obesity. At age 9.5 years, his weight was approximately the same as that of the patient with Cushing disease, but his height was at the 97th percentile, reflecting the enhancement of linear growth in individuals with exogenous obesity.

μg/day of budesonide[783]), they can cause at least temporary slowing of growth. However, inhaled corticosteroids do not appear to significantly impair final height.[783]

GH therapy can overcome some of the growth-inhibiting effects of excess glucocorticoids. The GH-induced increase in growth rate is inversely related to the glucocorticoid dose,[859] with one small study finding no benefit of GH treatment for prednisone doses greater than 0.35 mg/kg per day.[860] GH or IGF1 administration can diminish many of the catabolic effects of excess glucocorticoids.[850,861,862]

Adrenal tumors secreting large amounts of glucocorticoids can produce excess androgens, which may mask the growth-inhibitory effects of glucocorticoids. In addition, Cushing syndrome in children may not cause all the clinical signs and symptoms associated with the disorder in adults and may manifest with growth arrest. However, Cushing syndrome is an unlikely diagnosis in children with obesity because exogenous obesity is associated with normal or even accelerated skeletal growth, and growth deceleration is usually evident by the time other signs of Cushing syndrome appear (Fig. 25.38). In a series of 10 children and adolescents treated for Cushing disease with surgery and cranial irradiation, post-therapy GHD was common and mean final height was –1.36 SDS.[863]

Pseudohypoparathyroidism: Albright Hereditary Osteodystrophy

Albright hereditary osteodystrophy (AHO) is caused by mutations in the stimulatory GTP-binding protein, $G\alpha_s$. It exists both with and without multihormone resistance—termed *pseudohypoparathyroidism type 1A* (PHP1A) and *pseudo-pseudohypoparathyroidism* (pseudo-PHP). This condition is discussed in detail in Chapter 29 but is included here because short adult height is a common feature.[864] AHO is characterized by obesity (more marked in PHP1A than in pseudo-PHP[865]), short metacarpals, subcutaneous ossifications, round facies, and cognitive impairments. Patients with AHO, whether they have PHP1A or pseudo-PHP, typically have short adult stature. Many patients with PHP1A demonstrate GHD due to resistance to GHRH.[866,867] Interestingly, patients with PHP1B, which is caused by a methylation defect in the *GNAS* gene that encodes $G\alpha_s$, have PTH and TSH resistance like PHP1A patients, but have neither the AHO phenotype nor GHRH resistance.[868] Although AHO patients have evidence of GHD, their growth pattern suggests that there is another contributor to growth failure as they have modest growth failure in early and middle childhood, with early epiphyseal fusion contributing to their short final height.[866,869] Consistent with this likely multifactorial cause for short stature, preliminary data in patients with PHP1A found an increase in growth rate with GH treatment, but without an increase in final height, as the few children reaching final height appeared to have an absence of a pubertal growth spurt.[870]

Rickets

In the past, hypovitaminosis D was a major cause of short stature and was often associated with other causes of growth failure, such as malnutrition, prematurity, malabsorption, hepatic disease, or chronic renal failure (see Chapter 29). In isolated nutritional vitamin D deficiency, breastfed infants typically have poor exposure to sunlight and are not nutritionally supplemented with vitamin D. Characteristic skeletal manifestations of rickets include frontal bossing, craniotabes, rachitic rosary, and bowing of the legs. With vitamin D supplementation, whether due to prescribed supplementation or a broadened diet, amelioration of the early decrease of linear growth velocity typically occurs. The association of vitamin D receptor gene polymorphism with birth length, growth rate, adult stature, and BMD[871–874] emphasizes the importance of vitamin D in normal growth.

Hypophosphatemic Rickets

Hypophosphatemic rickets is typically an X-linked dominant disorder caused by decreased renal tubular reabsorption of phosphate related to mutations in the phosphate-regulating endopeptidase gene, *PHEX*, located on chromosome Xp22.1. Other hypophosphatemic syndromes include autosomal-dominant hypophosphatemic rickets, hereditary hypophosphatemic rickets with hypercalciuria, and tumor-induced osteomalacia (see Chapter 29).[875] In all of these conditions, there are increased levels of FGF23, a major phosphaturic agent.[876] The features are usually more severe in boys and include short stature,[776,877] prominent bowing of the legs, and sometimes rachitic signs.[878]

The metabolic and skeletal abnormalities cannot be overcome by vitamin D therapy alone. Treatment requires oral phosphate replacement, but such therapy may result in poor calcium absorption from the intestine. The addition of calcitriol to oral phosphate increases intestinal phosphate absorption and prevents hypocalcemia and secondary hyperparathyroidism. Such combined therapy

TABLE 25.5 Classification of Osteochondrodysplasias

I. Defects of the tubular (and flat) bones and axial skeleton
  A. Achondroplasia group
  B. Achondrogenesis
  C. Spondylodysplastic group (perinatally lethal)
  D. Metatropic dysplasia group
  E. Short rib dysplasia group (with or without polydactyly)
  F. Atelosteogenesis/diastrophic dysplasia group
  G. Kniest-Stickler dysplasia group
  H. Spondyloepiphyseal dysplasia congenita group
  I. Other spondyloepiphyseal/metaphyseal dysplasias
  J. Dysostosis multiplex group
  K. Spondylometaphyseal dysplasias
  L. Epiphyseal dysplasias
  M. Chondrodysplasia punctata (stippled epiphyses) group
  N. Metaphyseal dysplasias
  O. Brachyrachia (short spine dysplasia)
  P. Mesomelic dysplasias
  Q. Acromesomelic dysplasias
  R. Dysplasias with significant (but not exclusive) membranous bone involvement
  S. Bent bone dysplasia group
  T. Multiple dislocations with dysplasias
  U. Osteodysplastic primordial dwarfism group
  V. Dysplasias with increased bone density
  W. Dysplasias with defective mineralization
  X. Dysplasias with increased bone density
II. Disorganized development of cartilaginous and fibrous components of the skeleton
III. Idiopathic osteolysis

improves the rickets but may not correct growth.[875,879,880] Early initiation of this therapy in early infancy may lead to achievement of greater childhood and adult height.[877] There is no clear association between endogenous GH secretion, IGF1, or phosphate levels and height in this disorder.[881–883] Nevertheless, GH therapy in eight trials, including 83 patients, resulted in an enhancement of skeletal growth and improvement in BMD.[884–886] In 14 of those patients, treatment for 4 to 5 years resulted in a height gain of up to 1.2 SDS. However, a Cochrane review did not find conclusive evidence that GH treatment improved growth in patients with hypophosphatemic rickets.[887] One report cautioned that GH treatment appeared to exaggerate disproportionate truncal growth.[888]

Treatment with the FGF23 monoclonal antibody burosumab increased serum phosphate and improved linear growth rates after 64 weeks of treatment.[889] This therapy may supplant current therapies with phosphate supplementation and calcitriol.

Osteochondrodysplasias

The osteochondrodysplasias encompass a heterogeneous group of disorders characterized by intrinsic abnormalities of cartilage and bone.[890] These disorders include abnormalities in the size or shape of bones in the limbs, spine, or skull, often with abnormalities seen on radiographic evaluation. More than 100 osteochondrodysplasias have been identified based on physical characteristics and radiographic characteristics (Table 25.5).

Diagnosis of osteochondrodysplasias can be difficult, with clinical and radiologic evaluation central to the diagnosis. The family history is critical, although many cases are caused by de novo mutations, and this is generally the case in autosomal-dominant achondrodysplasia and hypochondrodysplasia. Measurement of body proportions should include arm span, sitting height, upper and lower body segments, and head circumference. Radiologic evaluation should be used to determine whether involvement is of the long bones, skull, or vertebrae and whether abnormalities are primarily at the epiphyses, metaphyses, or diaphyses. The osteochondrodysplasias most commonly encountered in endocrine practice are discussed in the following paragraphs.

Achondrodysplasia is the most common of the osteochondrodysplasias, with a frequency of 1 in 26,000 individuals. Characteristic abnormalities of the skeleton include megalocephaly, low nasal bridge, lumbar lordosis, short trident hand, and rhizomelia (shortness of the proximal legs and arms) with skin redundancy. Radiologic findings include small, cuboid-shaped vertebral bodies with short pedicles and progressive narrowing of the lumbar interpedicular distance. The small foramen magnum may lead to hydrocephalus, and spinal cord and root compression may result from kyphosis, stenosis of the spinal canal, or disk lesions.[891] Diminished growth velocity is present from infancy, although short stature may not be evident until after 2 years of age. Mean adult heights in males and females are 130 and 120 cm, respectively. GH secretion is comparable to that in normal subjects.

Achondrodysplasia is caused by mutations in the transmembrane domain of the FGF receptor 3 gene *(FGFR3)*.[892] It is transmitted in an autosomal dominant manner, but 80% to 90% of cases are caused by de novo mutations. Most of the cases are the result of activating mutations at nucleotide 1138 of the *FGFR3* gene, which creates new recognition sites for restriction enzymes, thus easing the molecular diagnosis. The mutation rate reported at this site is very high, and *FGFR3* has been labeled the most mutable gene in the genome. As a result of the upregulation of receptor activity, there is abnormal chondrogenesis and osteogenesis during endochondral ossification, leading to the typical phenotypic findings. The homogeneity of the mutation in achondroplasia probably explains the minimal heterogeneity in the phenotype. Infants homozygous for the mutation have severe disease, typically dying in infancy from respiratory insufficiency due to a small thorax.

Hypochondroplasia is also autosomal dominant, and 70% of affected individuals are heterozygous for mutations in the *FGFR3* gene, frequently at amino acid position 1620.[893] The facial features of achondroplasia are absent, and both short stature and rhizomelia are less pronounced. Adult heights are typically in the range of 120 to 150 cm. Poor growth may not be evident until after 2 years of age, but stature then deviates progressively from normal. Occasionally, the disproportionate short stature is not apparent until adulthood. Outward bowing of the legs may be accompanied by genu varum. On radiologic evaluation, lumbar interpedicular distances are diminished between L1 and L5, and there may be flaring of the pelvis and narrow sciatic notches. The diagnosis can be difficult to make, with mild variants of the syndrome difficult to distinguish from normal.

The short stature homeobox-containing (SHOX) gene is located in the pseudoautosomal region of distal Xp and Yp. Mutations or deletion of *SHOX* is associated with syndromes of poor growth and skeletal dysplasia, including Léri-Weill dyschondrosteosis (LWD), TS, and Langer mesomelic dysplasia (LMD).[894] Findings include short stature, Madelung deformity, increased carrying angle, tibial bowing, scoliosis, and high arched palate. The auxologic finding of relatively short limbs suggests a defect in *SHOX*, because the SHOX protein may affect cellular proliferation and apoptosis of chondrocytes at the growth plate.[895] Indeed, the skeletal manifestations have been associated with areas in which there is intrauterine expression of *SHOX*.[895] LWD is caused by homozygous gene

defects, whereas TS and LMD are caused by haploinsufficiency. The profound findings in LWD, compared with TS, may reflect the impact of pubertal estrogen exposure in LWD.[894]

Endochondral growth is regulated by multiple endocrine, paracrine, and autocrine factors, and many inborn errors have been identified. In the syndrome of acromesomelic dysplasia, growth is remarkably impaired, leading to adult heights that may be more than 5 SD below the mean. A homozygous mutation in the homodimeric transmembrane natriuretic peptide receptor B (NPR-B) that impairs binding of the ligand C-type natriuretic peptide has been found in some affected individuals.[896] Obligatory heterozygotes are significantly shorter than normal but have normal skeletal anatomy.[897] Therefore heterozygous mutations of NPR-B demonstrate that a subset of children with unexplained short stature may in fact have mild forms of osteochondrodysplasias.

Chromosomal Abnormalities

Abnormalities of autosomes or sex chromosomes can cause growth retardation without evidence of skeletal dysplasia, frequently with somatic abnormalities and developmental delay. In many cases, the precise cause of growth failure is not clear because the genetic defects do not affect known components of the GH-IGF1 system. Chromosomal lesions may directly influence normal tissue growth and development or indirectly modulate local responsiveness to IGF or other growth factors at the growth plate.

Down Syndrome

Trisomy 21, or Down syndrome, is probably the most common chromosomal disorder associated with growth retardation, affecting approximately 1 in 600 neonates. On average, newborns with Down syndrome have birth weights 500 g below normal and are 2 to 3 cm shorter than normal. Growth failure continues postnatally and is typically associated with delayed skeletal maturation and a delayed and incomplete pubertal growth spurt. Adult heights range from 135 to 170 cm in men and 127 to 158 cm in women.[14] The cause of growth failure in Down syndrome is unknown, and attempts to find underlying hormonal explanations for growth retardation have been unsuccessful. Growth retardation may be due to GH deficiency associated with hypothalamic dysfunction. A morphometric study of patients with Down syndrome revealed fewer neurons in the arcuate and ventromedial nuclei, which are areas responsible for GHRH neurosecretory function.[898] Fourteen children with Down syndrome (aged 10 months to 5 years, height SD scores [SDS] varying between −1.3 and −4.9) were studied and found to have a lack of response to levodopa and clonidine provocative testing, while responding to GH-releasing hormone (GHRH), indicating a likely hypothalamic deficiency.[899] Marginal levels of GH secretion and low-normal serum levels of IGF1 have been reported in patients with Down syndrome. Exogenous GH has been tried in some patients with Down syndrome and has produced increases in growth velocity, but the long-term effects on final adult height have not been studied. In addition, no improvements in gross motor or mental development were noted.[900,901] Hashimoto thyroiditis is common in individuals with Down syndrome and should be sought and treated promptly. Because of the concern for development of leukemia, which is more common in individuals with Down syndrome, GH use is generally not recommended.

Turner Syndrome

In girls with TS, short stature is the single most common feature, occurring more frequently than delayed puberty, cubitus valgus, or webbing of the neck.[902–904] Short stature occurs in 95% to 100% of girls with a 45,X karyotype.[905–908] Mean adult heights in the United States and Europe range from 142 to 146.8 cm, with important genetic and ethnic influences on growth of girls in different regions. Parental height correlates well with final adult height,[908,909] and a cross-cultural study in 15 countries demonstrated a very strong correlation between final height in TS and in the normal population, with an approximate 20-cm deficit.[905] Several distinct phases of growth have been identified in girls with TS[910,911]:

1. Mild IUGR with a mean birth weight of 2800 g and a mean birth length of 48.3 cm
2. Slow growth recognized during early infancy and reaching −3 SDS by 3 years of age[912]
3. Delayed onset of the "childhood" phase of growth[27,28,913] and progressive decline in height velocity from age 3 years until approximately 14 years, resulting in further deviation from normal height percentiles
4. A prolonged adolescent growth phase, characterized by a partial return toward normal height, followed by delayed epiphyseal fusion

These girls have many features of skeletal dysplasia, such as Madelung deformity and are haploinsufficient for the *SHOX* gene, which is located in the pseudoautosomal region of the short arm of the X chromosome.[914] When heights of girls with TS are compared with those of girls with LWD, which involves a *SHOX* deletion, it appears that the *SHOX* defect may account for about two-thirds of the height deficit in TS.[915] Girls with TS have normal GH and IGF levels during childhood; reports of low levels of GH or IGF, or both, in adolescents are likely due to low serum levels of gonadal steroids.[916] Multiple studies have shown that GH therapy is capable of accelerating short-term growth and increasing final adult height.[907,917,918] GH treatment in TS is discussed in detail later in the chapter.

Noonan Syndrome

Individuals with Noonan syndrome have postnatal growth failure, right-sided cardiac abnormalities (most often pulmonary valve abnormalities), webbing of the neck, low posterior hairline, ptosis, cubitus valgus, and malformed ears. Microphallus and cryptorchidism are common, and puberty may be delayed or incomplete. Cognitive delay of variable degrees is present in about 25% to 50% of patients. Although this disorder shares phenotypic features with TS, the two are clearly distinct.[919,920] In Noonan syndrome, the sex chromosomes are normal, and transmission is autosomal dominant, although about 50% of cases are sporadic. Noonan syndrome is caused by heterozygous activating mutations in the genes of proteins in the RAS-MAPK pathway, including *PTPN11, SOS1, RAF1, KRAS,* and *NRAS,* with approximately half of patients having mutations in *PTPN11*.[921,922] Through much of childhood, mean growth in length and weight is below the third percentile.[923–925] GH secretory abnormalities do not account for the short stature, although endogenous GH production may be slightly reduced.[925,926] The protein product of the *PTPN11* gene is the nonreceptor type 2 tyrosine phosphatase (SHP2). SHP2 dephosphorylates JAK2, suggesting that the growth failure of Noonan syndrome might be due to growth hormone resistance from the enhanced action of SHP2.[927–929] However, SHP2 is a positive regulator of the RAS-MAPK pathway, and the development of Noonan syndrome from activating mutations in other proteins in this pathway suggests that alterations in RAS-MAPK signaling are responsible for the phenotype. GH therapy has been used in the treatment of patients with Noonan syndrome who have short stature, as discussed in detail later.

Prader-Willi Syndrome

Prader-Willi syndrome (PWS), a neurogenetic developmental disorder, was initially described by Prader, Willi, and Labhart in 1956. This syndrome is characterized by obesity, hypotonia, hyperphagia, delayed motor skill development, short stature, mental retardation, hypothalamic dysfunction, and hypogonadism.[930]

PWS has an incidence of 1 in every 12,000 births, making it the most common syndrome causing obesity. PWS is caused by the absence of expression of genes on the paternally inherited chromosome 15 (q11–13). In about 70% to 75% of cases, PWS is due to deletion of the paternal allele; in 25% of cases, it is due to the presence of maternal uniparental disomy (UPD). Other rarer causes of PWS are due to translocations, molecular defects, or imprinting errors.[931,932] Although several genes and gene products of the PWS locus have been identified, the specific gene(s) responsible for its pathogenesis are not completely understood.[933,934]

In PWS, growth failure may be evident at birth but is more pronounced postnatally.[935] The hypothalamic dysfunction in PWS is associated with endocrinopathies that include short stature, hyperphagia and obesity with abnormal body composition, deficient growth hormone (GH) secretion, central hypothyroidism, and hypogonadism.[936–938]

Interestingly, a recent study showed that GH secretion in the patients with UPD was significantly lower than those with deletions.[939] Although infants with PWS typically have hypotonic and poor weight gain, the percentage of body fat is increased before the onset of hyperphagia and obesity.[940] This syndrome is discussed at length in a later section of this chapter.

Other Syndromes

Other syndromes associated with moderate to profound growth failure include Bloom syndrome, de Lange syndrome, leprechaunism, Ellis–van Creveld syndrome, Aarskog syndrome, Rubinstein-Taybi syndrome, mulibrey nanism, Dubowitz syndrome, progeria, Cockayne syndrome, and Johanson-Blizzard syndrome.[941]

Small for Gestational Age

Historically, infants born SGA have composed a heterogeneous group with birth weight or length below the 3rd, 5th, or 10th percentile for gestational age, depending on the study.[36] As the growth and metabolic consequences of being born SGA have been observed and characterized, studies have more consistently used the definition of SGA as birth weight or length (or both) at least 2 SD below the mean for gestational age (usually at or below the 2.3 percentile for a population). The term *IUGR* has been used interchangeably with SGA to describe these infants. However, it has been proposed that, because IUGR implies a known underlying pathologic process, that term should be reserved for infants whose abnormal prenatal growth has been confirmed by intrauterine growth assessments and whose growth restriction can be attributed to a specific cause.[942] The reason for abnormal fetal growth is unclear in up to 40% of cases[943]; known underlying reasons are listed in Table 25.6. Accurate assessment of an infant as SGA depends on accurate gestational dating and weight and length measurements, which can be difficult in both developed and developing countries.[944] However, recent technology has allowed ultrasound measurements of fetal size in utero to become increasingly more precise.[945]

Most SGA infants exhibit catch-up growth (as defined by a growth velocity greater than the median for chronologic age and gender) by 2 years of age. Catch-up growth occurs during the first 6 months of life in approximately 80% of infants born SGA.[37] Approximately 10% to 15% of infants born SGA exhibit slow, attenuated growth with persistent height deficits in childhood and adolescence. The remaining 5% to 10% exhibit a slower catch-up growth pattern, reaching heights 2 SD below the mean between 3 and 5 years of age. These estimations vary by study; in a population of severely affected infants with SGA who required care in a neonatal intensive care unit, 27% had not achieved catch-up growth by 6 years of age.[946]

Low-birth-weight premature babies who are appropriate for gestational age invariably experience catch-up growth in the first 2 years of life. Final adult height of all children born SGA is –0.8 to –0.9 SDS, a mean deficit of 3.6 to 4 cm when adjusted for family stature.[947] It has been estimated that the 10% to 15% of SGA children with short stature account for as much as 20% of all short children. In the United States, 2.3% of the population fitting the definition of SGA represents roughly an incidence of 1 in 43 neonates. Therefore SGA children have a fivefold to sevenfold greater possibility of short stature than AGA children.[36]

Normal fetal growth depends on a complex interplay of maternal and fetal genetic and external environmental influences. Abnormal intrauterine growth can result from pathologic processes in the fetus, the placenta, or the mother. Growth in length occurs early in fetal life, whereas weight gain occurs later in fetal life[948]; first-trimester growth failure has been closely associated with low birth weight and low-birth-weight percentile.[949] Because there is a differential effect on weight and length depending on the fetal period when the pathologic processes occur, IUGR has been subclassified into symmetric and asymmetric types. The

TABLE 25.6 Factors Associated With Small for Gestational Age (SGA) Births

I. Intrinsic Fetal Factors

A. Chromosomal disorders
   1. Mutations in genes encoding IGF1, IGF2, IGF1R, INS, KCNJ11, ABCC8, chromosome 6ICR, INSR (Donohue syndrome [leprechaun], Rabson-Mendenhall syndrome), PTF1A, IPF1, BLM (Bloom syndrome), FANC A-M (Fanconi syndrome), ACAN
B. Syndromes
   1. Russell-Silver syndrome
   2. Seckel syndrome
   3. Progeria
   4. Cockayne syndrome
   5. Rubinstein-Taybi syndrome

II. Placental Abnormalities

A. Abnormal implantation of the placenta
B. Placental vascular insufficiency; infarction
C. Vascular malformations

III. Maternal Disorders

A. Malnutrition
B. Constraints on uterine growth
C. Vascular disorders
   1. Hypertension
   2. Toxemia
   3. Severe diabetes mellitus
D. Uterine malformations
E. Drug ingestion
   1. Tobacco
   2. Alcohol
   3. Narcotics

symmetric type of IUGR results from an insult early in the pregnancy, often due to fetal genetic factors or syndromes, congenital infections, or toxic effects; asymmetric IUGR results from an insult occurring late in gestation, often due to fetoplacental insufficiency. Historically, it was thought that infants with symmetric IUGR do not experience catch-up growth, whereas those with asymmetric IUGR who have normal head circumference and length yet low birth weight usually experience catch-up growth postnatally.[948] However, studies have suggested that infants with asymmetric IUGR have worse perinatal outcomes than those with symmetric IUGR[950,951] and that both types of growth restrictions can arise in the second trimester of pregnancy.[952,953] Therefore the subclassification of IUGR, like the term *IUGR* itself, is controversial. A recent study found that 16% of dysmorphic children born SGA with postnatal growth retardation had pathologic genomic copy number variants.[954] In a recent study, 14% of children born SGA with advanced skeletal maturation had an ACAN gene mutation.[955]

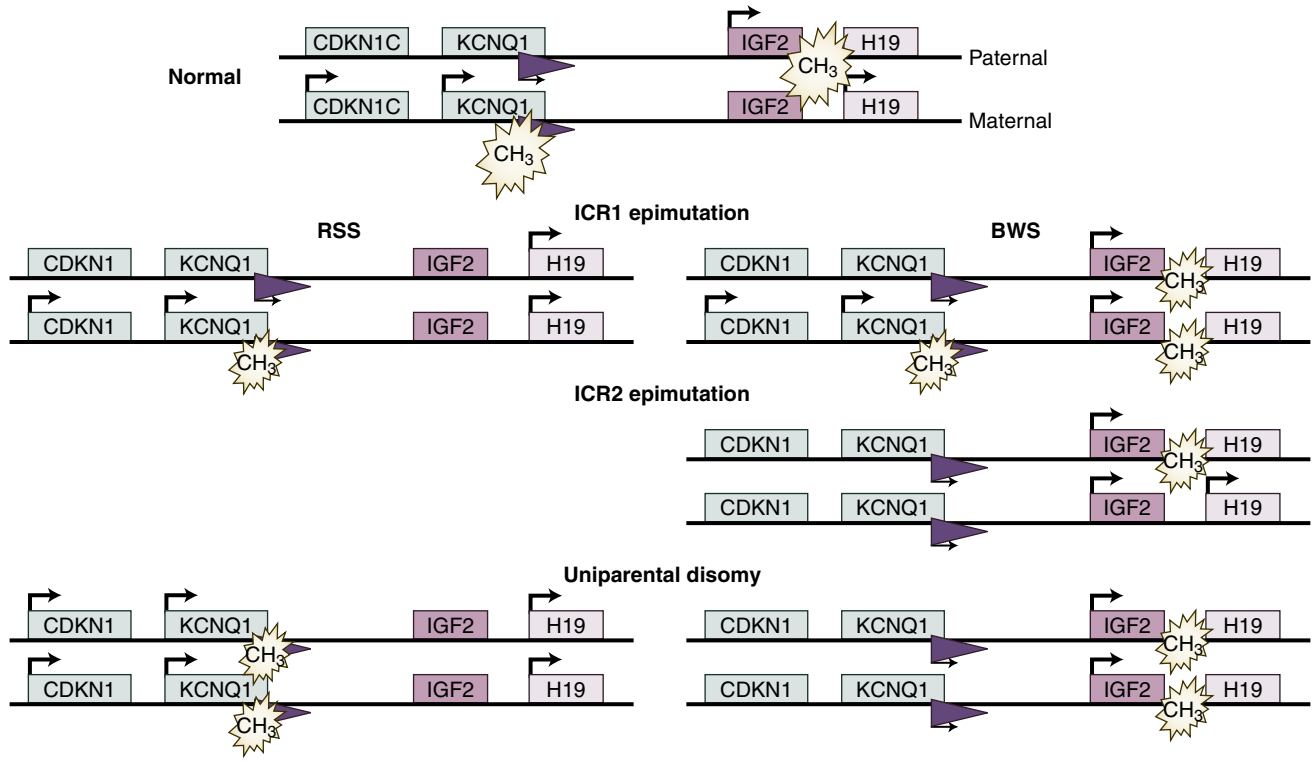
Endocrine-related causes account for a small fraction of the many contributors to fetal growth abnormalities, but hormonal disorders associated with fetal and neonatal growth restriction shed light on the endocrine mechanisms of growth in the fetus. Although GH plays a major role in postnatal growth, it has less of a role in fetal growth; infants with neonatal GHD are typically −0.5 to −1.5 SD below the mean in length and are heavy for this length.[338,956] An adequate nutrient supply is the main determinant of fetal growth, but growth factors such as insulin, IGF1, and IGF2 also play a role. IGF1 and IGF2 are the major hormonal regulators of fetal growth and can compensate for each other.[265,273,957–960] The growth-promoting effects of the IGFs are mediated by the type I or IGF1 receptor.[273] During fetal life, the IGF system operates largely independently of GH. Genetically modified mouse models have shown that approximately 70% of body size is due to IGF, half of which are mediated by GH-induced changes in IGF concentration and half due to direct IGF effects.[227] The direct effect of GH on body size is relatively minor. Neonates who are SGA exhibit hormonal patterns consistent with insensitivity to GH and IGF1 and insulin action. In neonates with IUGR, GH levels are elevated[961] and IGF1 and IGFBP3 levels are low.[151,961–964] IGFBP1 and IGFBP2 levels have been reported to be higher than in AGA infants,[291] a pattern seen in individuals with insulin resistance. Similar patterns are found in the first week of life after severe fetal malnutrition.[965] Exogenous GH treatment has little or no effect on growth, body composition, or energy expenditure[966,967] in the neonatal period. In most infants with SGA, normalization of GH, IGF1, and IGFBP3 levels occurs by 3 months of age, with normal response to GH stimulation testing in childhood.[968] In measurement of spontaneous GH secretion, high pulse frequency with attenuated pulse amplitude and elevated trough values of GH have been noted in SGA children.[969–971] Serum IGF1 levels in children with short stature born SGA are slightly but significantly lower than in children with catch-up growth.[968,969,971]

Defects of insulin secretion or action are associated with impaired fetal growth.[948] Congenital defects of insulin secretion such as glucokinase deficiency[972] or pancreatic agenesis[973] are associated with severe IUGR. Leprechaunism is caused by defects in the insulin receptor and is associated with severe insulin resistance and IUGR.[27] The initial case of a deletion of the IGF1 gene had profound intrauterine growth failure.[974,656] Polymorphisms of the *IGF1* gene have also been reported to be associated with IUGR.[974–976]

SGA children who have striking weight gain during the first several years of life can develop endocrine disorders later in childhood, including premature adrenarche, insulin resistance, polycystic ovary syndrome, and an attenuated growth spurt.[977] This subset of SGA children have increased risks of hypertension, maturity-onset diabetes, and cardiovascular disease later in life.[978–980] This is consistent with the Barker hypothesis, which states that fetal metabolic responses to a nutritionally hostile intrauterine environment may lead to inappropriate extrauterine consequences.[979,981] These problems do not appear to occur in SGA babies without catch-up growth, although insulin resistance has been described.[982] Whether being SGA is causally related to these disorders or is a symptom of an underlying inborn metabolic disorder is not yet known.

Russell-Silver syndrome (RSS) was independently described by Russell[983] and by Silver.[984] Findings include IUGR with postnatal growth failure, congenital hemihypertrophy, and small, triangular facies.[985] Other nonspecific findings include clinodactyly, delayed closure of the fontanel, delayed bone age, and precocious puberty.[986–988] Adults are short, with final heights approximately −4 SD below the mean.[985] The incidence is between 1 in 50,000 and 1 in 100,000 live births. Endogenous GH secretion in prepubertal RSS children is similar to that in other short IUGR children and less than in AGA short children.[969,989] Maternal uniparental disomy of chromosome 7 is present in 7% to 10% of cases.[985,990] Although there are a number of imprinted genes or factors involved in growth and development on chromosome 7, numerous studies have not detected any pathologic mutations in the candidate genes. A gene on chromosome 7p, *GRB10,* is involved in regulation of insulin and IGF1 receptor signaling and is mainly expressed from the maternal allele; loss of the maternal allele results in fetal and placental overgrowth.[990,991] Mutations that could cause overexpression of *GRB10* have not been found in patients with RSS.

A small number of patients with RSS have duplication of the maternal allele of the 11p15 region[992]; duplication of the paternal allele in this region is associated with BWS and overexpression of IGF2. The 11p15 region contains two imprinting control regions (ICR), ICR1 and ICR2 (Fig. 25.39). ICR1 comprises the *IGF2* and *H19* genes. The noncoding gene *H19* is downstream from *IGF2* and is oppositely imprinted, meaning that only the maternal allele is expressed and that the paternal allele is inactive. The promoters of the *IGF2* and *H19* genes share a set of enhancers that act on either gene. On the paternal allele, the *H19* promoter region is methylated and therefore inactivated.[244] Upstream from the *H19* and *IGF2* promoter region is a paternally methylated region that prevents binding of CTCF, allowing enhancers to act on the *IGF2* promoter to activate transcription.[245] On the maternal chromosome, this region is not methylated, allowing CTCF to bind and preventing transcription.[246] In this ICR1 region, mutations causing hypomethylation of the *H19* promoter region have been described in approximately 40% of patients with RSS.[993] Oppositely, hypermethylation of the ICR1 region has been associated with BWS. Disruption of ICR2 has been described in BWS (described later) but not in RSS. Reduced *IGF2* expression has been demonstrated in fibroblasts of patients with RSS in vitro,[993] but serum levels of IGF2 in patients with RSS are normal.[994] Mice with a null mutation of IGF2 have prenatal growth retardation but normal postnatal growth; how reduced expression of IGF2 contributes to postnatal growth failure in RSS has yet to be elucidated. A number of other rare genetic defects have also been associated with RSS, such that a known molecular abnormality may be identified in 60% of these individuals.[995]



• **Fig. 25.39** Schematic representation of the 11p15 region and the epigenetic mutations associated with Russell-Silver syndrome and Beckwith-Wiedemann syndrome. *Red and pink boxes* represent genes of imprinting control region 1 (1CR1), and *green boxes* represent genes of 1CR2. The *arrow* represents the presence of gene transcription. *Dark triangles* represent antisense transcripts that can repress transcription of *ICR2* genes. When methylated (represented by CH_3), the transcripts cannot be formed, allowing transcription of *ICR2* genes and reciprocal suppression of transcription of downstream genes (i.e., *IGF2*). (Adapted from Eggerman T. Silver-Russell and Beckwith-Wiedemann syndromes: opposite [epi]mutations in 11p15 result in opposite clinical pictures. *Horm Res.* 2009;71:S30–S35.)

Maternal and Placental Factors

Maternal factors and placental insufficiency can impair fetal growth and likely account for most cases of asymmetric IUGR. Maternal nutrition is an important contributor to fetal growth and to growth during the first year of life.[996] Fetal growth retardation may result from use of alcohol,[997] cocaine,[998] marijuana,[998] or tobacco[999] during pregnancy. The mechanisms for drug-induced fetal growth retardation are unclear but may include uterine vasoconstriction and vascular insufficiency, placental abruption, or premature rupture of membranes. The maternal hormonal milieu is affected by placental steroids and peptides. Maternal IGF1 affects placental function and may facilitate transport of nutrients to the fetus. Maternal IGF1 levels have been found to correlate with fetal growth.[1000,1001] Increased levels of free IGF1 are found during normal human pregnancy.[1002]

The placenta has multiple functions, including the transport of nutrients, oxygen, and waste and the production of hormones. It consumes oxygen and glucose brought by the uterine circulation. Placental GH affects maternal IGF production, which in turn affects placental function. A woman with GHD due to *PIT1* mutation exhibited normal levels of placental GH and IGF1, demonstrating the independent production of GH and IGF1 by the placenta.[1003] Human placental lactogen (hPL) is a major regulator of glucose, amino acid, and lipid metabolism in the mother, aiding in the mobilization of nutrients for transport to the fetus. Damage to the placenta resulting from vascular disease, infection, or intrinsic abnormalities of the syncytiotrophoblasts can impair these important functions. At times, examination of the placenta may yield causal information about fetal growth retardation.

An X-linked homeobox gene, *ESX1,* detected only in extraembryonic tissues and human testes, is a chromosomally imprinted regulator of placental morphogenesis.[1004–1006] Heterozygous and homozygous mutant mice are born 20% smaller than normal and have large edematous placentas.[1004] Vasculature is abnormal at the maternal-fetal interface, presumably causing the growth retardation.

Pathologic Basis of Excess Growth

Although by definition there are as many children with heights greater than 2 SD above the mean as those with heights less than 2 SD below the mean, tall stature as a chief complaint is encountered much less often in endocrine practice. Nevertheless, it is critical to identify those situations in which tall stature or an accelerated growth rate provides clues of an underlying disorder (Table 25.7).

Statural Overgrowth in the Fetus

Maternal diabetes mellitus is the most common cause of large-for-gestational-age (LGA) infants. LGA is defined as length or weight greater than the 90th percentile for gestational age. Even in the absence of clinical symptoms or family history, the birth of an excessively large infant should lead to evaluation for maternal or gestational diabetes. Two syndromes, Sotos syndrome and BWS, can also cause LGA infants.

TABLE 25.7 Differential Diagnosis of Statural Overgrowth

Fetal Overgrowth

Maternal diabetes mellitus
Cerebral gigantism (Sotos syndrome)
Weaver syndrome
Beckwith-Wiedemann syndrome
Other insulin-like growth factor 2 (IGF2) excess syndromes

Postnatal Overgrowth Leading to Childhood Tall Stature

Familial (constitutional) tall stature
Cerebral gigantism
Beckwith-Wiedemann syndrome
Exogenous obesity
Excess growth hormone (GH) secretion (pituitary adenoma with gigantism)
McCune-Albright syndrome or multiple endocrine neoplasia (MEN) associated with excess GH secretion
Precocious puberty
Marfan syndrome
Klinefelter syndrome (XXY karyotype)
Weaver syndrome
Fragile X syndrome
Homocystinuria
XYY karyotype
Hyperthyroidism

Postnatal Overgrowth Leading to Adult Tall Stature

Familial (constitutional) tall stature
Androgen or estrogen deficiency/estrogen resistance (in males)
Testicular feminization
Excess GH secretion
Marfan syndrome
Klinefelter syndrome (XXY karyotype)
XYY karyotype

Sotos Syndrome

Children with cerebral gigantism (Sotos syndrome) are typically above the 90th percentile for length and weight at birth.[1007–1009] Clinical features also include a prominent forehead; dolichocephaly; macrocephaly; high arched palate; hypertelorism with unusually slanting eyes; prominent ears, jaw, and chin; large hands and feet with thickened subcutaneous tissue; cognitive delay; and motor incoordination. Children continue to grow rapidly during early childhood, but puberty is usually early, with premature epiphyseal fusion. Therefore most children with Sotos syndrome have a final height within the normal range.[1009] GH secretion and serum IGF levels are normal, and no specific cause of the overgrowth has been identified. About 80% of patients have a loss-of-function mutation in the *NSD1* gene whose product is a nucleus-localized basic transcription factor.[1010]

Beckwith-Wiedemann Syndrome

BWS is the most common (1 of every 13,700 live births) of the overgrowth disorders, the group of disorders associated with excessive somatic and specific organ growth. It is characterized by fetal macrosomia with omphalocele[1011] and other clinical features secondary to organomegaly, such as macroglossia, renal medullary hyperplasia, and neonatal hypoglycemia due to islet cell hyperplasia.[1012] Excessive childhood growth ultimately leads to earlier puberty and early epiphyseal fusion with resultant normal adult height.[1013]

Various lines of evidence have shown that BWS is associated with loss of imprinting of the genes on chromosome 11p15.5, home of the *IGF2* gene (see Fig. 25.39). Under normal conditions, the paternally derived *IGF2* gene is expressed and the maternally transmitted gene is not active, as described in detail earlier in this chapter. BWS has been associated with uniparental disomy or duplication of the paternal 11p15 region and resultant overexpression of the *IGF2* gene.[1014] The ICR1 region of 11p15 contains the *IGF2* and *H19* genes; the noncoding gene *H19* is located downstream from *IGF2* and is oppositely imprinted. The promoters of the *IGF2* and *H19* genes share a set of enhancers that act on either gene. On the paternal allele, the *H19* promoter region is methylated and therefore inactivated.[244] Upstream from the *H19* and *IGF2* promoter region is a paternally methylated region that prevents binding of CTCF, allowing enhancers to act on the *IGF2* promoter to activate transcription.[245] On the maternal chromosome, this region is not methylated, allowing CTCF to bind and preventing transcription.[246] Hypermethylation of the *H19* promoter region with resultant loss of imprinting and biallelic expression of IGF2 has been associated with fewer than 10% of the cases of BWS.[1015,1016] Point mutations in the ICR1 region have been identified in patients with BWS. These mutations alter binding of OCT (octamer) transcription factors to the region leading to hypermethylation of the promoter.[1017] Hypomethylation of this region is associated with RSS, a syndrome associated with prenatal and postnatal growth failure (see earlier discussion).

ICR2, located 5′ of *ICR1*, contains the genes for cyclin-dependent kinase inhibitor 1C *(CDKN1C)* and potassium channel KQT family member 1 *(KCNQ1)*, among others that are methylated on the maternal allele. Associated with these two genes is an antisense transcript with paternal expression that may suppress transcription; it has been postulated that this cluster of genes is in "expression competition" with the *IGF2/H19* cluster.[1018] Up to 25% of familial cases of BWS are associated with mutations in the *CDKN1C* or *KCNQ1* gene,[1019] but there is debate about whether loss of imprinting of the *IGF2* gene convincingly occurs with most of the mutations. Four children with somatic overgrowth but not the diagnostic features of BWS had *IGF2* gene overexpression.[1020] Additionally, mutations in *GPC3,* a glypican gene that codes for an IGF2 neutralizing membrane receptor, cause the related Simpson-Golabi-Behmel overgrowth syndrome.[1021,1022]

Postnatal Statural Overgrowth

As in the case of the child with growth attenuation, crossing of height percentiles between infancy and the onset of puberty is an indication for further evaluation because it can indicate serious underlying pathology. As with short stature, children with tall stature must be evaluated in the context of familial growth and pubertal patterns.

Tall Stature

GH secretion and levels of IFG1 and IGFBP3 in familial tall stature are often in the upper-normal range.[1023] Tauber and colleagues[1024] divided 65 children with familial tall stature into a subset with high GH secretion rates and frequent secretory bursts and another subset with lower GH secretion and fewer episodic spikes. IGF1 levels were higher among those producing more GH and normal in the low-GH group. The authors postulated that both enhanced secretion of GH and greater efficiency of GH-mediated IGF1 production might be potential causes of familial tall stature.

Tall stature is also a characteristic of certain syndromes. Marfan syndrome, an autosomal dominant disorder of collagen

metabolism, is characterized by hyperextensible joints, dislocation of the lens, kyphoscoliosis, dissecting aortic aneurysm, and long, thin bones that result in arachnodactyly and moderately tall stature. It is caused by mutations in the fibrillin-1 gene *(FBN1)*. The abnormal FBN1 monomers from the mutated gene disrupt the normal aggregation of FBN1, impairing microfibril formation. Homocystinuria is an autosomal recessive disorder that phenotypically resembles Marfan syndrome, but patients also have cognitive disabilities. Tall stature has also been found in patients with familial ACTH resistance due to a defective ACTH receptor.[1025]

Dosage effects of the *SHOX* gene may result in tall stature.[1026] In females with three copies of the *SHOX* gene and gonadal dysgenesis, adult stature was +2 to +2.9 SDS.[1027] In women with the 47,XXX karyotype, mean final heights are 5 to 10 cm taller than population means, and men with the 47,XXY karyotype (Klinefelter syndrome) are about 3.5 cm taller than population means.[31,1028] Males with an XYY karyotype may also have moderately tall stature. In addition to SHOX effects, the variable degree of estrogen production in these syndromes may also influence skeletal maturation and final height.[26]

Failure to enter puberty and complete sexual maturation may result in sustained growth during adult life with ultimate tall stature and a characteristic eunuchoid habitus. The description of tall stature with open epiphyses resulting from mutation of the estrogen receptor or from aromatase deficiency[23,24] underscores the fundamental role of estrogen in promoting epiphyseal fusion and termination of normal skeletal growth.

Obesity

Obesity is frequently associated with rapid skeletal growth and early onset of puberty.[1029] Rapid early postnatal weight gain has been associated with taller stature at 8 years of age than that predicted from the midparental target height.[1030] Others have shown that early postnatal growth is associated with altered tempo of development, but sudden weight gain in middle childhood has little effect on height trajectory.[1031] Patients with obesity tend to have diminished overall GH production but normal to high GHBP, and IGF1 levels appear to be capable of maintaining adequate or enhanced linear growth velocity. Bone age is usually modestly accelerated, so that both puberty and epiphyseal fusion occur early and adult height is normal. This association between obesity and rapid growth is so characteristic that a child with obesity and short stature should always be evaluated for underlying pathology, such as hypothyroidism, GHD, Cushing syndrome, or PWS.

Tumors

Pituitary gigantism is a rare condition, analogous to acromegaly in the adult (see Chapter 9).[1032–1034] GH-secreting tumors of the pituitary are typically eosinophilic or chromophobic adenomas. Their cause is uncertain, although many result from somatic mutations that generate constitutively activated G proteins with reduced GTPase activity (see Chapter 9).[1035] The resulting increase in intracellular cAMP in the pituitary leads to increased GH secretion. Somatotropic tumors with excess GH secretion may occur in McCune-Albright syndrome, which is caused by mutations resulting in constitutive activation of G proteins.[1036,1037] GH-secreting tumors have also been reported in multiple endocrine neoplasia (MEN) and in association with neurofibromatosis and tuberous sclerosis.[1038]

GH excess that occurs before epiphyseal fusion results in rapid growth and attainment of adult heights above expected adult potential. When GH hypersecretion is accompanied by gonadotropin deficiency, accelerated linear growth may persist for decades, as was the case for the Alton giant, who reached a height of 280 cm by the time of his death in his 20s.[1039] Manifestations typical of acromegaly may also appear, such as soft tissue swelling; enlargement of the nose, ears, and jaw with coarsening of facial features; pronounced increases in hand and foot size; diaphoresis; galactorrhea; and menstrual irregularity.

Evaluation and Treatment of Growth Abnormalities

Clinical Evaluation of Growth Retardation

The most important parameter in assessing children with growth failure is careful clinical evaluation, including accurate serial assessment of height and height velocity. Consideration of a growth disorder is raised when a child's length or height falls below the normal range (<3rd percentile), the growth velocity is subnormal (indicated by length or height measurements that cross percentiles on the growth curve or by an annual growth velocity less than the 3rd percentile for age), or the child's height is below the range expected based on the parents' heights. To grow along the 3rd percentile for height, a child must maintain a height velocity at the 25th percentile for age.[1040] Therefore a height velocity consistently below the 25th percentile in a short child suggests abnormal growth. However, because of the greater error intrinsic to assessment of growth velocity compared with height velocity,[1041] a single height velocity measurement above the 25th percentile for age, even based on annual height data, cannot fully exclude a growth abnormality in a short child.[1041]

GH is relatively less important as a growth factor prenatally compared with its role postnatally. However, GH is not without impact on prenatal growth, so that although many of these children have lengths and weights within the normal range, the average size of infants with congenital GH deficiency is decreased, with a mean birth length of –1.3 SDS and a mean birth weight of –1.0 SDS.[1042] Growth velocity over the first year averages near –2 SD, so that over half of these infants have a length more than 2 SD below the mean at 1 year of age.[1042]

Table 25.8 provides an algorithm for evaluation of the child with growth failure. Although one-third of healthy infants will cross downward on the length percentile growth curve (discussed previously), this is normal only in relatively large infants born to small parents or in those infants who are following a growth pattern of CDGD (see later discussion). In other situations, the infant who is crossing downward on the length percentile curve should be investigated in the same way as other children with subnormal growth velocities.

History and Physical Examination

The many illness-related causes of diminished growth were discussed in earlier sections of this chapter. A growth pattern in which weight gain is impaired before linear growth or in which there is greater impairment of weight gain than of length/height gain suggests an impairment of nutrition, such as inadequate intake, malabsorption, or increased energy requirements. Nonhormonal causes of growth failure should be investigated based on data obtained from a careful history and physical examination. In addition, careful evaluation of the growth curve in the context of the family history may suggest a normal variant growth pattern,

TABLE 25.8 Clinical and Biochemical Evaluation of Growth Failure: Evaluating the GH-IGF1 Axis

Step 1: Defining the Risk of Disorders of the GH-IGF1 Axis

Auxologic abnormalities
- Severe short stature (height SDS <–3 SD)
- Severe growth deceleration
  - Height <–2 SD and height velocity <–1.0 SD over 2 years
  - Height <–1.5 SD and height velocity <–1.5 SD over 2 years

Risk factors
- History of a brain tumor, cranial irradiation, or other documented organic or congenital hypothalamic-pituitary abnormality
- Incidental finding of hypothalamic-pituitary abnormality on MRI
- If any of the above exists, proceed with step 2; if not, follow clinically and return to step 1 in 6 months

Step 2: Screening for Disorders of the GH-IGF1 Axis and Other Diseases

A. Order a laboratory panel, including a bone age, free T_4, TSH, chromosomes (in females), and nonendocrine tests; if indicated, refer back to primary care physician or treat diagnosed conditions as appropriate.
B. Order an IGF1 and IGFBP3 level.
   - If IGF1/IGFBP3 are both above the –1 SD, follow clinically and return to step 1 in 6 months.
   - If IGF1/IGFBP3 are both below –2 SD, proceed to step 4. If MRI is abnormal, GH provocative testing is optional.
   - Otherwise, proceed to step 3. If this is a patient with delayed adolescence, consider sex steroid treatment prior to step 3.

Step 3: Testing GH Secretion

This step can be bypassed if a clear GHD risk factor and severe IGF deficiency are identified.

Perform two of the following GH stimulation tests (if appropriate, estrogen prime) (see Table 25.11):
- Clonidine
- Arginine
- Insulin
- Glucagon
- L-Dopa
- Propranolol

If all GH levels are <7 μg/L, go to step 4.

If peak GH >15 μg/L, obtain GHBP; if GHBP <–2 SD, consider an IGF-generation test and, if abnormal, IGF treatment.

If peak GH >15 μg/L and GHBP is normal, follow clinically and return to step 1 in 6 months.

If peak GH is between 7 and 15 μg/L, return to step 1 in 6 months.

Step 4: Evaluating the Pituitary

Perform MRI, with particular emphasis on hypothalamic-pituitary anatomy.

Test HPA, if not already done (CRH stimulation or ITT), and teach cortisol supplementation as needed (must do this if MRI is abnormal).

Consider molecular evaluation of GH, GHR, or GHRHR and other potential genetic defects (see Fig. 25.2).

Step 5: Treating for Growth Promotion

Initiate GH treatment at appropriate dose levels.

If GHIS is suspected, consider IGF therapy, if available.

Regularly evaluate growth parameters, IGF1, and IGFBP3, as well as compliance and safety (see Table 25.14).

GH secretion should be retested, according to adult GH assessment protocols, at the end of growth.

CRH, Corticotropin-releasing hormone; *GH,* growth hormone; *GHD,* growth hormone deficiency; *GHIS,* growth hormone insensitivity; *GHR,* growth hormone receptor; *GHRHR,* growth hormone–releasing hormone receptor; *HPA,* hypothalamic-pituitary axis; *IGF1,* insulin-like growth factor 1; *IGFBP3,* IGF-binding protein 3; *ITT,* insulin tolerance test; *MRI,* magnetic resonance imaging; *SD,* standard deviation; *SDS,* standard deviation score; T_4, thyroxine; *TSH,* thyroid-stimulating hormone (thyrotropin).

TABLE 25.9 Key History and Physical Examination Findings That Suggest the Diagnosis of Growth Hormone Deficiency[a]

Findings That Suggest the Diagnosis of GHD

In the Neonate

Hypoglycemia
Prolonged jaundice
Hepatitis
Microphallus
Traumatic delivery

In a Child With Short Stature or Growth Failure

Cranial irradiation
Head trauma or central nervous system infection
Consanguinity or an affected family member
Craniofacial midline abnormalities

Findings That Support Immediate Investigation for GHD

In a Child With Short Stature

Signs indicative of an intracranial lesion
Neonatal symptoms and signs of GHD
Auxologic findings
- Severe short stature (<–3 SD)
- Height <–2 SD and height velocity over 1 year of <–1 SD
- A decrease in height SD of >0.5 over 1 year in children >2 years of age
- A height velocity <–2 SD over 1 year
- A height velocity >1.5 SD below the mean sustained velocity over 2 years

Signs of multiple pituitary hormone deficiency (MPHD)

[a]The Growth Hormone Research Society 2000 Criteria.

GHD, Growth hormone deficiency; *SD,* standard deviation.

From Growth Hormone Research Society. Consensus guidelines for the diagnosis and treatment of growth hormone (GH) deficiency in childhood and adolescence: summary statement of the GH research society. *J Clin Endocrinol Metab.* 2000;85:3990–3993.

such as crossing linear percentiles of infancy, familial short stature, or CDGD. In such cases, careful observation may be all that is required. One-third of all infants have growth parameters that cross percentiles downward on the growth curve, and 3% of all children have a length or height below the 3rd percentile. Most of these children have no disease or growth disorder and will demonstrate this by having a normal growth velocity on continued observation.

The physical examination should look for evidence of an underlying organ-specific or systemic disease. It should also evaluate for clues specific to growth disorders, such as findings suggestive of genetic disorders (e.g., Noonan syndrome, RSS, or TS). In addition, body proportions should be measured because skeletal disproportion suggests a skeletal dysplasia.

Findings on the history and examination may point to an increased likelihood of the presence of GHD (Table 25.9). Micropenis in a male newborn should always lead to an evaluation of the GH-IGF1 axis. Nystagmus, indicating neonatal blindness, suggests hypopituitarism due to its association with optic nerve hypoplasia in the syndrome of septo-optic dysplasia. A history of other midline defects, such as cleft lip and cleft palate,[1043] or a single central incisor increases concern for hypopituitarism. Unexplained neonatal hypoglycemia, hepatitis, or prolonged jaundice should prompt an evaluation of pituitary function. Older children with GHD have less impaired weight gain than height gain, resulting in

an increased weight for height; they are often described as having a "cherubic" appearance. Increased weight for height with growth failure is also characteristic of hypothyroidism. If the weight gain is dramatic, Cushing syndrome should be considered. (However, linear growth acceleration with excess weight gain is not consistent with Cushing syndrome.) Finally, GHD should be suspected in children with known or suspected CNS pathology (e.g., tumors, prior radiation therapy to the CNS, malformations, infection, trauma) or with documented deficiency of TSH, ACTH, antidiuretic hormone, or gonadotropin.

Laboratory Testing

If the history and physical examination do not suggest a specific disorder causing growth failure, and the growth pattern and family history do not provide sufficient reassurance that the growth is following a normal variant growth pattern, it is necessary to perform laboratory testing. In many cases, the testing does not identify an abnormality, and the child either is ultimately found to have a normal variant growth pattern or falls into the classification of ISS. The laboratory tests can be divided into those screening for disorders outside the GH-IGF1 axis and those evaluating that axis.

Screening Tests

Because a number of illnesses can cause growth failure either before or in the absence of other signs or symptoms, it is necessary to screen for these disorders in children with abnormal growth. A complete blood count looks for evidence of anemia, chronic infection, and inflammation. A complete blood chemistry panel provides evidence for silent renal disease (including renal tubular acidosis), liver disease, and disorders of calcium and phosphorus. The erythrocyte sedimentation rate is measured to look for evidence of disorders involving chronic inflammation, such as presymptomatic juvenile idiopathic arthritis and inflammatory bowel disease. A urinalysis is obtained to look for renal disease and chronic urinary tract infection. Tissue transglutaminase IgA (and total serum IgA) is measured to screen for celiac disease. In girls in whom no other explanation for short stature is found, a karyotype should be obtained to exclude TS. This is done even in the absence of other physical features of TS, because growth failure may be the only evident feature, particularly in cases of significant mosaicism.

Hypothyroidism should be screened for in children with growth failure. Because of the importance of thyroid hormone on brain development in infants, this possibility should be considered early in the evaluation of an infant with growth failure to correct identified hypothyroidism quickly. In addition, hypothyroidism results in lower serum IGF1 levels and decreases GH levels during provocative testing.[1044–1046] Therefore it is necessary to ensure that thyroid function is normal before evaluating for GHD. TSH is measured because it is the most sensitive indicator of primary hypothyroidism. However, because central hypothyroidism must also be considered as a cause for growth failure in children, the thyroxine level should also be measured.

Bone Age

After the neonatal period, a bone age determination can be useful in the evaluation of children with growth disorders. A radiograph of the left hand and wrist is commonly used for comparison with the published standards of Greulich and Pyle.[1047] An alternative method for assessing bone age from radiographs of the left hand involves a scoring system for developmentally identified stages of each of 20 individual bones,[1048] a technique that has been adapted for computerized assessment.[1049,1050] The left hand is used because radiographs of the entire skeleton would be tedious and expensive and would involve additional radiation exposure. However, the hand does not contribute to height, and accurate evaluation of growth potential may require radiographs of the legs and spine.

Although the bone age result does not identify a specific diagnosis in a child with a growth disorder, it can be used to classify the child's growth in relation to groups of diagnoses. Growth disorders caused by an underlying illness or hormone disorder (e.g., renal disease, malnutrition, glucocorticoid excess) are associated with a delayed bone age—that is, a bone age that is younger than the patient's chronologic age. Similarly, hypothyroidism and GHD are associated with a delayed bone age. If short stature is intrinsic to the condition, however, bone age is not delayed and is within the range of normal for the chronologic age. This is true for genetic disorders such as TS, Noonan syndrome, and RSS, and also for familial short stature. In CDGD, the bone age is delayed, consistent with the future delay in puberty and late epiphyseal fusion. Given the lack of precise diagnostic laboratory tests for GHD, a lack of bone age delay argues against this diagnosis. On the other hand, the fact that patients with CDGD have a delayed bone age does not help in the sometimes difficult discrimination between this condition and GHD.

A number of important caveats concerning bone age must be considered. Experience in the determination of bone age is essential to minimize intraobserver variance, and clinical studies involving bone age benefit from having a single reader perform all interpretations. The normal rate of skeletal maturation differs between boys and girls and among different ethnic groups. The standards of Greulich and Pyle are separable by sex but were developed in American white children between 1931 and 1942. Both those and the Tanner and Whitehouse standards are based on normal children[1051] and may not be applicable to children with skeletal dysplasias, endocrine abnormalities, or other forms of growth retardation or acceleration.

Prediction of Adult Height

The extent of skeletal maturation observed in an individual can be used to predict the ultimate height potential. Such predictions are based on the observation that the more delayed the bone age (relative to the chronologic age), the longer the time before epiphyseal fusion prevents further growth. The most commonly used method for height prediction, based on Greulich and Pyle's *Radiographic Atlas of Skeletal Development,*[1047] was developed by Bayley and Pinneau[1052] and relies on bone age, height, and a semiquantitative allowance for chronologic age (Table 25.10). The system of Tanner and colleagues[1048] uses measurements of height, bone age, chronologic age, and, during puberty, height and bone age increments during the previous year, as well as menarchal status. Roche, Wainer, and Thissen[1053] used the combination of height, bone age, chronologic age, midparental height, and weight (RWT method). Attempts have been made to calculate final height predictions without requiring the determination of skeletal age[1054] by using multiple regression analyses with available data such as height, weight, birth measurements, and midparental stature. These systems are, by nature, empiric and are not absolute predictors. Indeed, the 90% confidence intervals for the predictions are approximately ±6 cm at younger ages. The more advanced the bone age, the greater the accuracy of the

[a]The column headed "Retarded" is used when bone age is >1 year below chronologic age; the column headed "Advanced" is used when bone age is >1 year greater than chronologic age.

Table derived from Post EM, Richman RA. A condensed table for predicting adult stature. *J Pediatr*. 1981;989:440–442 based on the data of Bayley and Pinneau.[1052] Predicted final height is calculated by dividing the current height by the fraction of adult height achieved determined from the table.

adult height prediction because a more advanced bone age places a patient closer to his or her final height.

All methods of predicting adult height are based on data from normal children, and none has been documented to be accurate in children with growth abnormalities. For this kind of precision, it would be necessary to develop disease-specific atlases of skeletal maturation (e.g., for achondroplasia or TS). In addition, height predictions will clearly be inaccurate in predicting the final height in the case of a growth-impairing process that is not adequately treated. In addition, height predictions must be used with care in assessing height outcomes during treatment. For example, in patients with precocious puberty treated with GnRH agonists, height prediction is known to overpredict the actual final height.[1055] Thus height predictions should only be considered a reasonable estimate.

Tests of the GH-IGF1 Axis

In children with growth retardation in whom other causes have been excluded, the possibility of GHD should be considered. However, these tests can have poor specificity, so clinical assessment must always play an important part in the evaluation of abnormalities in the GH-IGF1 axis. For example, a child growing consistently just below the 3rd percentile for height, with a growth rate that is accordingly above the 25th percentile for age, is very unlikely to be GH deficient. Abnormal test results in this situation would most likely represent false-positive results.

Testing of the GH-IGF1 axis begins with "static" testing of GH function, measuring IGF1. It may also be helpful to measure IGFBP3. In some cases—if the clinical presentation is highly suggestive of GHD (see Table 25.9)[1056] and the IGF1 level (and the IGFBP3 level, if obtained) also indicates a high likelihood of GHD—it is appropriate to proceed directly to the dynamic tests of GH secretion. In most cases, however, unless there is an abnormality identified on the screening tests, it is appropriate to monitor the child's growth for a period of 6 to 12 months to accurately assess the child's growth rate. Then, based on the complete clinical picture, including the growth rate and the IGF1 level, the decision is made to proceed with dynamic testing of GH secretion or to continue monitoring the child's growth.

There is no test that definitively diagnoses GHD. Because there is no gold standard, it is impossible to precisely define the sensitivity or specificity of any test for GHD. Some information on specificity can be obtained by comparing the results with those obtained in normal children, although, for the more complicated tests, these data can be difficult to obtain in children. Sensitivity relies on comparing positive results from one test with those of another—for example, comparing low IGF1 concentrations to failed results on provocative GH tests. Poor sensitivity of IGF1 as an indicator of GHD has been based on results from children with normal IGF1 concentrations who have abnormal results on provocative GH tests.[1057] However, because of the known limited specificity of these provocative tests (discussed later), one cannot determine whether the discrepant results are due to the poor sensitivity of the IGF1 test or the poor specificity of the provocative GH test. Again, it is critical to interpret all results together and in the context of the clinical data.

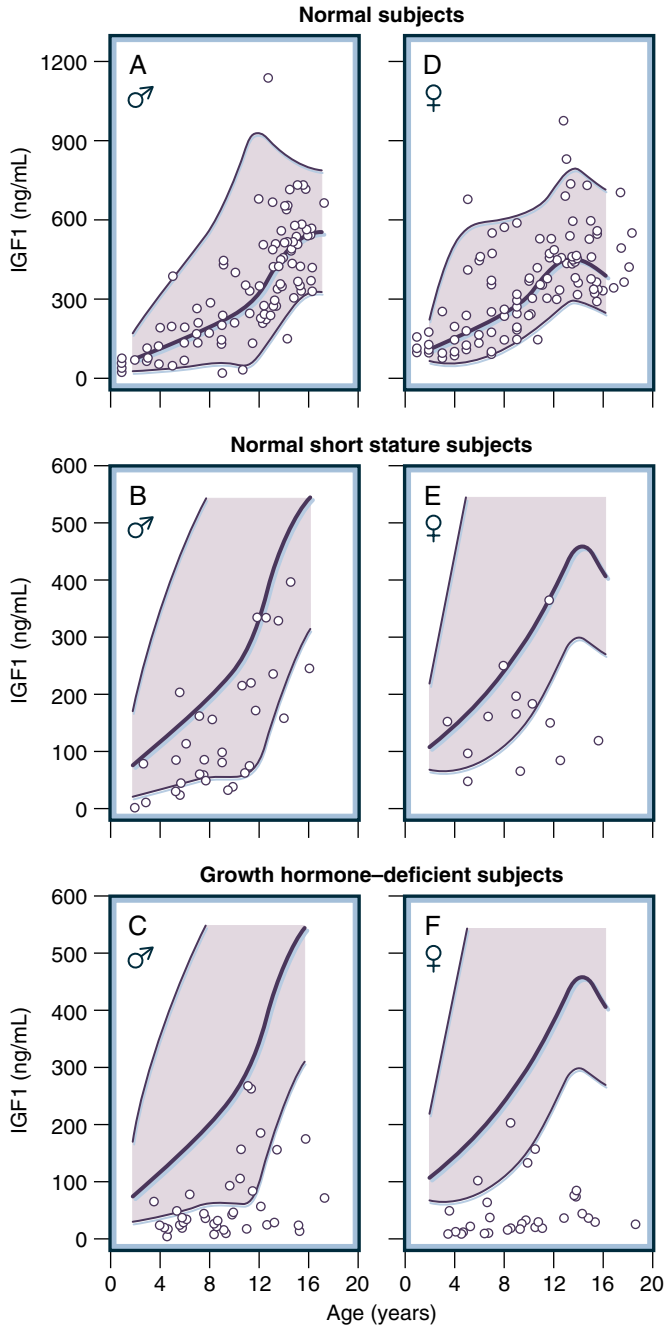
Insulin-Like Growth Factor 1

GHD is associated with low serum concentrations of IGF1 (Fig. 25.40). Unlike GH levels, which rise and fall with its pulsatile secretion, the IGF1 level in blood has minimal diurnal variation. The GH dependency of the IGFs was established in the initial

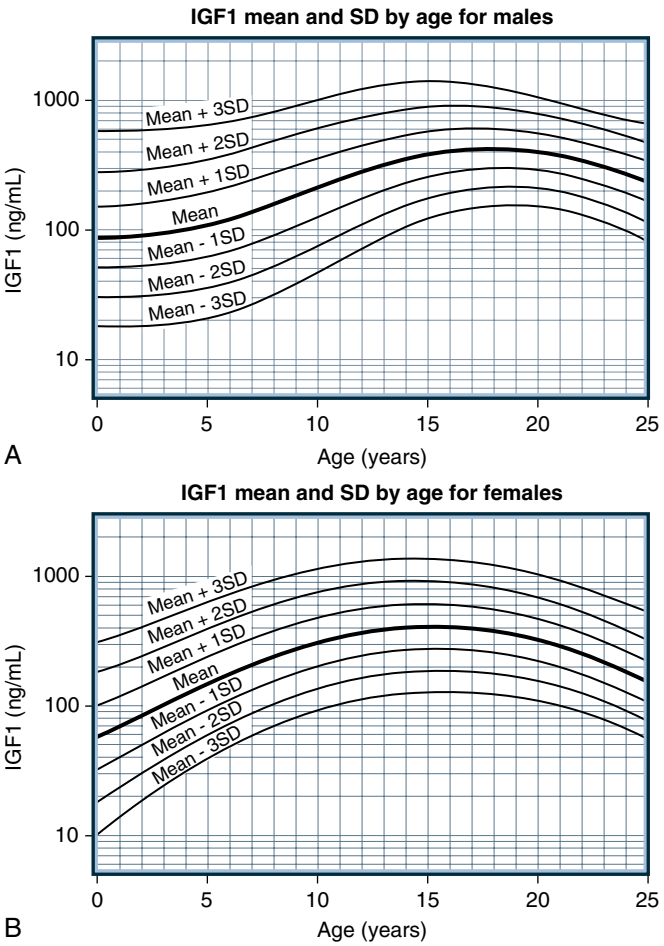
report from Salmon and Daughaday[164] and was further clarified with the development of sensitive and specific immunoassays that distinguish between IGF1 and IGF2.[1058] IGF1 levels are more GH dependent than IGF2 levels and are more likely to reflect subtle differences in GH secretory patterns. However, serum IGF1 levels are also influenced by age,[240,1059,1060] degree of sexual maturation, and nutritional status. Therefore IGF1 levels must be compared with age-specific ranges (Fig. 25.41) and with ranges defined by stage of sexual maturation. Some clinicians evaluate IGF1 results against the reference range based on bone age (rather than the chronologic age). This may improve the specificity of this test for GHD, although there are no data to address the validity of this approach.

IGF1 levels in normal children younger than 5 or 6 years of age are low. This leads to poor sensitivity of IGF1 levels for identifying GHD in young children. As few as 40% to 50% of young, short children with evidence of GHD on provocative tests have IGF1 levels below the lower level of the reference range.[1061,1062] IGF1 levels increase with age, resulting in better separation of IGF1 levels in GH-deficient children from those in normal children and a higher sensitivity of IGF1 levels for GHD. However, although sensitivities of 85% to 100% have been reported in some studies,[1062,1063] in others it has averaged approximately 70%.[1044,1063–1066] Again, however, the lack of a gold standard means that some of the false-negative findings obtained by measurement of IGF1 levels might rather represent false positives on provocative GH testing.

IGF1 levels also suffer from a lack of specificity in diagnosing GHD. In general, IGF1 levels have higher specificity in younger children, with declining specificity in older children. Juul and Skakkebaek[1066] found that IGF1 levels had a specificity for GHD of 98% in children younger than 10 years of age but a specificity



• **Fig. 25.40** Serum levels of insulin-like growth factor 1 (IGF1) in normal patients and in patients with growth disorders. *Circles* represent IGF1 levels in normal subjects (A and D), normal short stature subjects (B and E), and growth hormone–deficient subjects (C and F). The *lines* represent the 5th, 50th, 95th percentiles for log-normalized IGF1 levels in normal subjects. (From Rosenfeld RG, Wilson DM, Lee PD, et al. Insulin-like growth factors I and II in the evaluation of growth retardation. *J Pediatr.* 1986;109: 428–433.)



• **Fig. 25.41** Normal serum levels of insulin-like growth factor 1 (IGF1) for males (A) and females (B). *SD,* standard deviation. (Data courtesy Diagnostic Systems Laboratories, Inc., Webster, TX.)

of only 67% in those older than 10 years. Similarly, Cianfarani and colleagues[1061] found a specificity of 100% in children younger than 9 years of age that dropped to 76% in older children. Thus the overall specificity of a low IGF1 measurement may only be approximately 70%.[1044,1063,1064]

In addition to the specific challenges of accurately quantitating IGF1 levels in serum (see later discussion), the nutritional dependence of IGF1 levels significantly affects the accuracy of this test in evaluating for GHD. Even a few days of decreased caloric intake can lower IGF1 levels.[1044,1067] This probably contributes to the finding that IGF1 levels can vary by as much as 38% from day to day in a given patient.[1067,1068]

Early quantitation of IGFs used bioassays based on [^{35}S]-sulfate incorporation (hence "sulfation factor" as an early synonym for IGF/somatomedin C); on stimulation of the synthesis of DNA, RNA, or protein; or on glucose uptake.[1069,1070] Development of specific antibodies permitted the development of accurate and specific measurement of IGF1 and IGF2.[1058,1064,1071,1072] However, the presence of IGFBPs results in a significant technical challenge for the accurate quantitation of IGF1 (and IGF2) in serum.[620,1044,1069] Interference is a particular problem in conditions with a relatively high IGFBP/IGF peptide ratio and at the extremes of the assay (i.e., GHD, acromegaly). In uremia, IGFBPs artifactually lower IGF1 levels and increase IGF2 levels in assays that do not eliminate this interference.[749]

The most effective way to deal with IGFBPs is to separate them from IGF peptides by chromatography under acidic conditions.[1073] This labor-intensive procedure has occasionally been replaced by an acid ethanol extraction procedure.[1074] Although the latter method may be reasonably effective for most serum samples, it is problematic in conditions of high IGFBP/IGF peptide ratios, such as conditioned media from cell lines and sera from newborns or from subjects with GHD or uremia. A number of alternative approaches to addressing the interference from the IGFBs have been developed, including the use of tracers that do not bind to IGFBPs[1075] and "sandwich" assay methods.[1076] Automated IGF1 immunometric (IRMA) or immunochemiluminometric (ICMA) assays typically add an excess of IGF2 to the assay to displace the IGFBPs and use highly specific IGF1 antibodies.[1044,1069,1077] Although current IGF1 assays significantly minimize the interference from IGBPs, it is important that each assay develop reference ranges that match the clinical samples to be tested because ethnic variations and nutritional and environmental factors can affect "normal" serum IGF1 concentrations. However, even with assay-specific reference ranges, the variability in IGF1 assays can result in a lack of concordance across assays when levels are near the upper or lower edge of the reference range, potentially misclassifying the results as "normal" or "abormal."[1078]

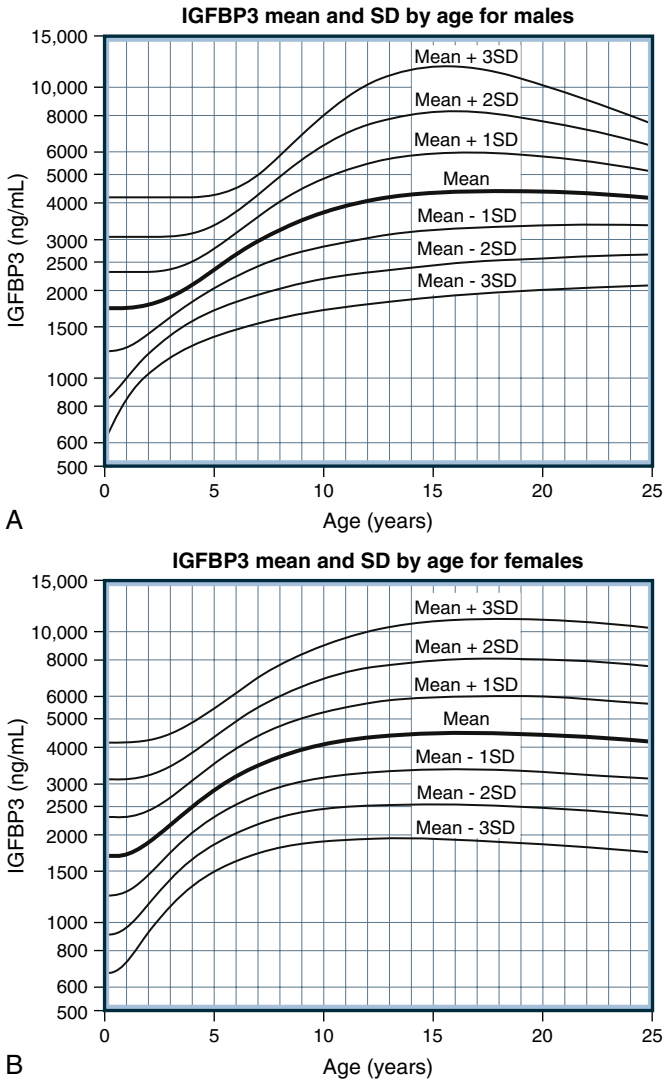
A number of assays have been developed that purport to measure "free" or "free dissociable" IGF1 as a means of assessing concentrations of IGF1 peptides that circulate unbound to IGFBPs.[1079] Both the accuracy and the physiologic relevance of these determinations remain open to debate.[240,1044,1079]

Insulin-Like Growth Factor–Binding Protein 3

Measurement of the serum level of IGBP3, the major serum carrier of IGF peptides, is a potential additional tool for evaluating GH function.[754,1080,1081] The advantages of assaying IGFBP3 concentration include the following:

1. IGFBP3 levels are GH dependent.
2. IGFBP3 levels are constant throughout the day.
3. The immunoassay of IGFBP3 is technically simple and does not require separation of the binding protein from IGF peptides.
4. Normal serum levels of IGFBP3 are high, typically in the range of 1 to 5 mg/L, so that assay sensitivity is not an issue. (The molar concentration of IGFBP3 approximates the sum of the molar concentration of IGF1 and IGF2.)
5. Serum IGFBP3 levels vary with age to a lesser degree than is the case for IGF1 (Fig. 25.42). Even in infants, serum IGFBP3 levels are sufficiently high to allow discrimination of low values from the normal range.
6. Serum IGFBP3 levels are less dependent on nutrition than serum IGF1, reflecting the "stabilizing" effect of IGF2 levels.

Like IGF1 levels, determination of the sensitivity and specificity of IGBP3 levels for identifying GHD suffers from the lack of a gold standard. With that limitation in mind, Blum and colleagues[754] initially found that low IGFBP3 levels had both high sensitivity (97%) and high specificity (95%) for GHD. Most subsequent studies confirmed the high specificity, with values generally greater than 80% to 90%.[1044,1061,1063,1065,1066] However, most



• **Fig. 25.42** Normal serum levels of insulin-like growth factor–binding protein 3 (IGFBP3) for males (A) and females (B). (Data courtesy Diagnostic Systems Laboratories, Inc., Webster, TX.)

studies have found that many children diagnosed with GHD on the basis of provocative GH testing actually have normal IGFBP levels, and the sensitivity of this test is less than 60%. In a study by Cianfarani and colleagues,[1061] only 7% (2/28) of children younger than 14 years of age with GHD had an IGFBP3 level more than 1 SD below the mean. Low IGFBP3 levels may be an indicator of more severe GHD. For example, in one study the sensitivity of the IGFBP3 assay was 93% if the peak GH was less than 5 μg/L on provocative testing, but when the peak GH was 5 to 10 μg/L, the sensitivity was only 43%.[1082]

Insulin-Like Growth Factor 2

IGF2 levels are higher than those of IGF1. Levels increase rapidly after birth, but thereafter IGF2 levels are less age dependent than those of IGF1. However, although GHD is associated with low IGF2 levels, IGF2 is much less GH dependent than IGF1 (Fig. 25.43). In two studies, IGF2 levels were more than 2 SD below the mean in only 21% and 31% of children defined as GH deficient based on provocative GH testing.[1061,1083]

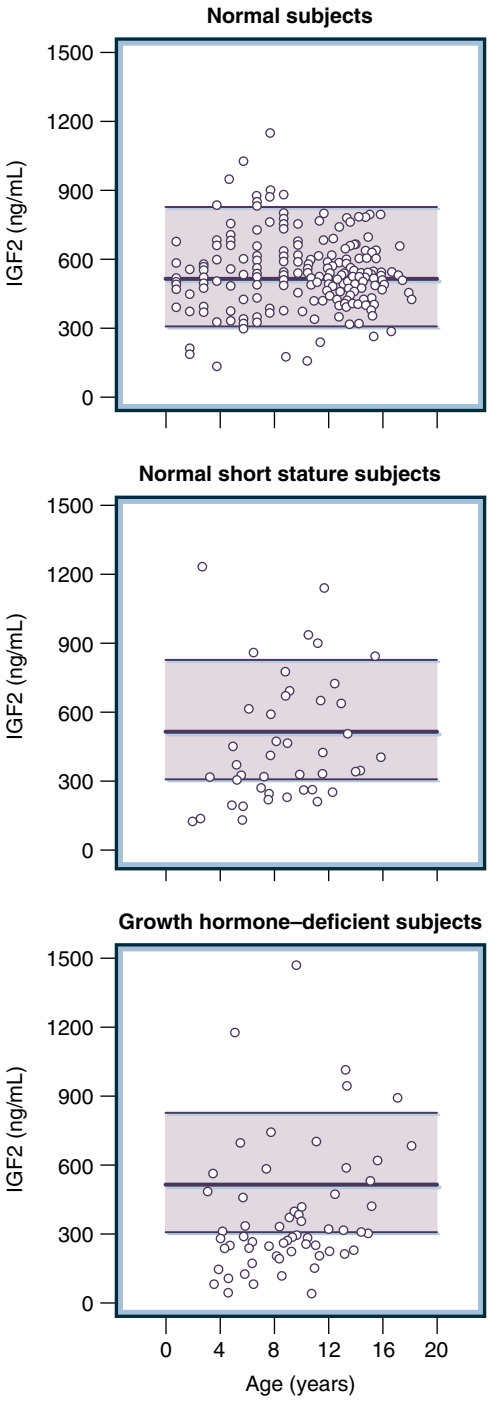
Rosenfeld and colleagues[1064] found low IGF2 levels in 52% of GH-deficient children and in 35% of normal short children. However, only 4% of GH-deficient children and 11% of normal short children had normal plasma levels of both IGF1 and IGF2, showing a similar sensitivity and specificity to combined IGF1/IGFBP3 testing.

Growth Hormone

Assessment of pituitary GH production is difficult because GH secretion is pulsatile, with the most consistent surges occurring at times of slow-wave electroencephalographic rhythms during stage 3 and stage 4 of sleep. Spontaneous GH secretion varies with gender, age, pubertal stage, and nutritional status, all of which must be factored into the evaluation of GH production.

Between normal pulses of GH secretion, serum GH levels are low (often <0.1 μg/L), below the limits of sensitivity of most conventional assays (typically <0.2 μg/L). Accordingly, measurement of random serum GH concentrations is almost useless in diagnosing GHD but may be useful in the diagnosis of GH insensitivity and GH excess. Measurement of GH "secretory reserve" relies on the use of physiologic or pharmacologic stimuli, and such provocative tests have formed the basis for diagnosis of GHD for more than 40 years.[1084,1085]

Assay Limitations. One of the biggest confounders in the evaluation of GH secretion is the variability of measured GH levels across different assays. Many studies have demonstrated as much as threefold variability in the measurement of serum GH levels among established laboratories.[1086,1087] A more recent study found an interassay coefficient of variation of 24.3% among nine assays for values within the range of 5 to 10 μg/L and a maximal difference for a given sample as high as 11.4 μg/L.[1088] This variability is explained, in part, by the presence of several molecular forms of GH in serum. Circulating GH consists of monomers of the two secreted GH isoforms (with ~43% existing as the monomeric 22-kDa isoform and 8% as the monomeric 20-kDa isoform), along with dimers and higher-order oligomers of the two isoforms, acetylated forms of GH, desamidated GH, and peptide fragments of GH.[1044] Therefore much of the variability in results is due to the use of different monoclonal or polyclonal antibodies, including variability in recognition of the different circulating forms of GH by these antibodies. Additionally, variations in the choice of standards, labeling techniques, and assay buffers



• **Fig. 25.43** Serum insulin-like growth factor 2 (IGF2) levels in normal patients and in patients with growth disorders. (From Rosenfeld RG, Wilson DM, Lee PD, et al. Insulin-like growth factors I and II in the evaluation of growth retardation. *J Pediatr.* 1986;109:428–433.)

(matrix) are also contributory.[1044] Consequently, a child who is determined to have GHD by one assay may be considered normal by another.[1088]

Provocative Tests. Because random GH levels cannot be used to diagnose GHD, evaluation of GH secretion requires that samples be obtained after an expected stimulation of GH secretion. Physiologic stimuli include fasting, sleep, and exercise, and pharmacologic stimuli include levodopa, clonidine, glucagon,

TABLE 25.11 Tests to Provoke Growth Hormone Secretion

Stimulus	Dosage	Times Samples Are Taken (min)	Comments
Sleep	Obtain sample from indwelling catheter	60–90 min after onset of sleep	
Exercise	Step climbing; exercise cycle for 10 minutes	0, 10, 20	Observe child closely when on the steps
Levodopa	<15 kg: 125 mg 10–30 kg: 250 mg >30 kg: 500 mg	0, 60, 90	Nausea, rarely emesis
Clonidine	0.15 mg/m^2	0, 30, 60, 90	Tiredness, postural hypotension
Arginine HCl (IV)	0.5 g/kg (max 30 g) 10% arginine HCl in 0.9% NaCl over 30 min	0, 15, 30, 45, 60	
Insulin (IV)[a]	0.05–0.1 unit/kg	0, 15, 30, 60, 75, 90, 120	Hypoglycemia, requires close supervision
Glucagon (IM)	0.03 mg/kg (max 1 mg)	0, 30, 60, 90, 120, 150, 180	Nausea, occasional emesis
GHRH (IV)[b]	1 μg/kg	0, 15, 30, 45, 60, 90, 120	Flushing, metallic taste

Patients must be euthyroid at the time of testing. Tests should be performed after an overnight fast. For prepubertal children, pretreating with sex hormones increases the specificity of the tests (see text).

[a]Insulin-induced hypoglycemia is a potential risk of this procedure, which is designed to lower the blood glucose by at least 50%. Documentation of appropriate lowering of blood glucose is recommended. If GHD is suspected, the lower dosage of insulin is usually administered, especially in infants. A solution of 10% dextrose in water ($D_{10}W$) and glucagon should be available.

[b]The cutoff used for tests involving GHRH is higher than that for other tests. (Maghnie M, Cavigioli F, Tinelli C, et al. GHRH plus arginine in the diagnosis of acquired GH deficiency of childhood-onset. *J Clin Endocrinol Metab*. 2002;87:2740–2744; Pandian R, Nakamoto JM. Rational use of the laboratory for childhood and adult growth hormone deficiency. *Clin Lab Med*. 2004;24:141–174.)

propranolol, arginine, and insulin. Standard provocative GH tests are summarized in Table 25.11. GH levels are measured on multiple specimens obtained after the stimulus. Failure to increase serum GH above a defined cutoff level is believed to indicate GHD.

Although provocative GH testing has been the foundation for the diagnosis of GHD since GH assays first became available, they have a number of weaknesses when used to identify GHD.[1084,1089,1090] Most important, there is no clear cutoff level that discriminates a normal response from a deficient response; second, these provocative tests have poor specificity.

Determination of the "Subnormal" Response to Provocative Tests. GH secretion has a continuous distribution; there is not a bimodal distribution of either spontaneous GH secretion or peak GH levels after provocative tests that would clearly separate normal from deficient secretion. The initial levels of GH during provocative testing that were used to define GHD were based on the study of patients with profound classic findings or organic destruction of the adenohypophysis.[1091] In addition, partly because of the limited supply of GH, one goal was to identify the most severely affected children.

Initially, a cutoff level of 2.5 μg/L was used; this was later increased to 5 μg/L and subsequently to 7 μg/L. After the development of recombinant DNA-derived GH eliminated the limits on GH supply, many pediatric endocrinologists considered a peak GH level lower than 10 μg/L to be indicative of GHD. The higher cutoff level can be partially justified by the desire to identify children with GHD that is less complete (i.e., partial GHD). Nonetheless, there have been few data validating the higher cutoff values.[1090,1092]

Further confounding the determination of an evidence-based cutoff level is the variability in GH levels measured across different assays (discussed earlier). Many new GH assays give results that are 33% to 50% lower than earlier assays, but there has not been a systematic reassessment of the "new normal" GH cutoff levels, nor has there been a critical evaluation by many endocrinologists of which assay their center might be using.[1093,1094] The same cutoff level has been applied without regard to the stimulus used. While insulin and arginine result in similar GH peaks, clonidine[1095] and GHRH[1096–1098] stimulate significantly higher levels of GH, thereby indicating a need for a higher cutoff value for such tests.

Specificity of Provocative Tests for Growth Hormone Deficiency. The data that are available suggest a low specificity for the provocative tests, with a substantial number of normal children having peak GH levels lower than 7 to 10 μg/L.[1089] Ghigo and colleagues[1097] studied 472 healthy, normal children, including 296 with normal stature and 177 with normal short stature. Excluding tests that used GHRH (which has generally not been used in the evaluation of GH function in children), they found that between 10% and 25% of their subjects had peak GH levels lower than 7 μg/L and 23% to 49% had peak levels lower than 10 μg/L. Similar results were found in other studies,[1099–1102] with the 5th percentile for peak GH response to most provovactive stimuli being less than 5 μg/L in normally growing children.[1103] Because of this poor specificity, failure on two provocative tests should be obtained before GHD is diagnosed on the basis of provocative testing. This approach significantly improves the specificity of provocative testing, although it remains imperfect. In the study of Ghigo and colleagues,[1097] two tests were performed on

78 children, and 10% had peak GH levels lower than 10 μg/L on both tests (2.6% had peak GH levels <7 μg/L on both tests).

The specificity of provocative GH tests can be increased by using a lower cutoff point to define a normal response. However, this is undesirable if it excludes individuals with less severe degrees of GHD. Because of the continuous nature of GH secretion across individuals and the lack of a gold standard test for GHD, the conflict between specificity and sensitivity cannot be completely resolved. However, two reports have examined multiple clinical and laboratory characteristics of short children who were divided into three groups based on their results on GH stimulation testing: a group whose results were low (<5 or <7 μg/L), fulfilling criteria for GHD; a group whose results were greater than 10 μg/L and therefore were believed not to have GHD; and a group whose results were intermediate between these high and low cutoff points. In both of these studies, the group with the lowest peak GH levels differed significantly from both the intermediate-level and the high-level GH groups on numerous measures.[1104,1105] However, the intermediate group was indistinguishable from the group without GHD, rather than having characteristics intermediate between the other two groups, as might be expected if they had a less severe degree of GHD. As noted earlier, 5 μg/L is the 5th percentile for GH levels on provocative testing of normally growing children; this same level of 5 μg/L identifies those children who will have the highest first-year growth response to GH treatment.[1103] Finally, a recent study using clonidine as the stimulus identified 3 μg/L (on an immunochemiluminescent assay) as the optimal cutoff to identify GHD in children and adolescents,[1106] while another identified cutoffs of 5.1 to 6.8 μg/L depending on the stimulus, with sensitivities of 88% to 93% and specificities of 92% to 97%.[1107]

Sex Hormone Priming. Serum GH levels rise during puberty, with GH secretion stimulated by the rise in estrogen produced from the ovary or from aromatization of testosterone.[152,1108] This same process results in higher peak GH levels during provocative testing in pubertal children (compared with prepubertal children)[1100,1109] and in children who have received treatment with estrogen or testosterone.[1057,1100,1109–1111] In a study by Marin and colleagues,[1100] 61% of normal prepubertal children and 44% of normal children in early puberty (Tanner stage II) had GH levels lower than 7 μg/L on provocative testing; based on these results (but not on their heights), they would have met criteria for a diagnosis of GHD. However, after 2 days of treatment with estrogen, 95% of these children had a peak GH level higher than 7 μg/L. Therefore the specificity of GH provocative tests can be improved by pretreating ("priming") the pediatric patients with exogenous gonadal steroids.[1112,1113] In a placebo-controlled comparison, the specificity of GH provocative tests (using 9 μg/L as a cutoff point on a polyclonal GH assay) increased from 80% to 98% after estrogen priming.[1057] In a study of 50 growth-retarded boys who had subnormal results on provocative GH tests without testosterone priming but normal results after priming, final height (without intervention) was greater than the midparental height, consistent with normal GH function in these children.[1114] The most recent guidelines from the Pediatric Endocrine Society recommends sex hormone priming in prepubertal boys older than 11 years and in prepubertal girls older than 10 years.[1103]

Another factor to consider when evaluating provocative GH testing is the impact of body weight on GH secretion. In both adults[144,1115–1117] and children,[1118,1119] obese individuals have decreased spontaneous and stimulated GH levels, compared with nonobese individuals. Even within the normal range, the BMI SDS is inversely associated with peak GH level on provocative tests in children.[1120] Therefore particular care must be taken when interpreting GH stimulation test results in obese individuals.

Although there are limitations to the information gained from provocative GH tests, they continue to be helpful in evaluating a child for GHD. The tests should be performed after an overnight fast, and the patient needs to be euthyroid at the time of testing. Testing should not be performed if the patient is taking supraphysiologic doses of glucocorticoid (i.e., >15 mg/m^2 per day of hydrocortisone or the equivalent of a synthetic glucocorticoid) because these drugs can suppress the GH response. The tests are generally safe, although appropriate precautions must be taken. Specifically, tests involving insulin administration carry the risk of hypoglycemia and seizures and should be performed only by experienced medical personnel and under appropriate patient supervision. Deaths have been reported from insulin-induced hypoglycemia and from its overly vigorous correction with parenteral glucose.[1121] The specificity of the tests can be increased by pretreating the child with estrogen or testosterone (e.g., 1–2 mg of micronized estradiol[1057] or 50–100 μg/day of ethinyl estradiol for 3 consecutive days before testing, or 100 mg of depot testosterone 3–7 days before testing) and by carefully selecting the lower limit for a normal response.

Tests of Spontaneous Growth Hormone Secretion. Another diagnostic approach to evaluate GH secretion involves measurement of spontaneous GH secretion. This can be done either by multiple sampling (every 5–30 minutes) over a period of 12 to 24 hours or by continuous blood withdrawal over 12 to 24 hours.[103,1122–1124] The former method allows one to evaluate and characterize GH pulsatility, whereas the latter only permits determination of the mean GH concentration. Both methods are subject to many of the same limitations as provocative GH testing. The problems of expense and discomfort are obvious, and, although it was thought that this approach might be more reproducible than provocative GH tests, variability remains a problem.[1095,1125,1126] The ability of such tests to discriminate between children with GHD and those with normal short stature is very limited because of significant overlap of each of the parameters measured between normal children and children with GHD. Rose and coworkers[1127] reported that measurement of spontaneous GH secretion identified only 57% of children with GHD as defined by provocative testing. Similarly, Lanes[1128] reported that one-fourth of normally growing children have low overnight GH levels, and a longitudinal study of normal boys through puberty demonstrated a wide intersubject variance, including many "low" 24-hour GH production rates in children with fully normal growth.[152,1129] Therefore measurement of spontaneous GH secretion does not appear to offer advantages over alternative means of evaluating GH function.

Summary. Despite the many problems associated with GH measurement methods, there continues to be value in determining GH secretory capacity in the diagnostic evaluation of a child with growth failure. Documentation of GH levels as being decreased, normal, or increased helps in discriminating among GHD, non–GH/IGF1-related growth failure (including ISS), and GH insensitivity. Results supporting the presence of GHD alert the clinician to the possibility of other pituitary deficiencies. The presence of pituitary dysfunction mandates clinical and radiologic evaluation for evidence of congenital or acquired structural defects of the hypothalamus or pituitary, including the possibility of intracranial tumors. Finally, documentation

of GHD, either alone or combined with other pituitary deficiencies, may warrant evaluation for molecular defects of GH production.

Growth Hormone–Binding Protein

Mutation of the GHR impairs GH signaling, resulting in GH insensitivity. The most severe mutations cause profound growth failure (Laron dwarfism). The extracellular portion of the GHR is cleaved from the remaining portion and circulates in the blood as GHBP, which can be measured in serum. Low levels, particularly undetectable levels, may be diagnostic of GH insensitivity due to GHR mutations.

GHBP levels are not low in all forms of GH insensitivity. The levels may be normal, or even increased, with mutations in the GHR that do not alter the GHBP portion of the protein (i.e., mutations in the transmembrane or intracellular domains) or with defects that are downstream of the GHR.

IGF1 and IGFBP Generation Tests

IGF1 and IGFBP3 generation tests are designed to evaluate for the presence of GH insensitivity.[1130] When patients with GH insensitivity are treated with GH for several days, the levels of IGF1 and IGFBP do not increase as they would in normal individuals.[1131,1132] Criteria for a response indicating GH insensitivity have included a rise in IGF1 of less than two times the intraassay variation (~10%)[617] or a failure to increase IGF1 by at least 15 μg/L.[750] Given the different protocols and cutoffs used to adequate define IGF1 generation, the recent Pediatric Endocrine Society guidelines suggest caution when using this diagnostic test and to combine it with other diagnostic tests, including genetic testing.[1103]

Interpretation of Tests

Neonate

GH levels in the neonate are much higher than levels seen after this period. Levels are highest in cord blood and within the first days of life.[1133] Cornblath and colleagues reported in 1965 an average GH concentration in cord blood of 66 μg/L; this fell over the first week to an average of 16 to 20 μg/L in infants 7 to 55 days of age.[1133] However, even under the assay conditions used, the range of levels reported included measurements as low as 1 μg/L. Subsequent studies confirmed the high GH levels in neonates, with many documenting cord blood levels in the range of 20 to 40 μg/L, although other studies using similar assays found levels of 13 to 18 μg/L.[1134] Other studies also confirmed that GH levels fall during the first week of life so that low basal values are seen by 1 to 2 months of age.[1134,1135] GH levels in preterm infants have generally been found to be even higher than those in full-term infants.[1133]

The neonatal period is one period during which random measurement of GH levels may be useful. However, low values can be found in healthy neonates.[1135] Therefore, although a high value can exclude GHD, a single low value is not diagnostic of GHD—except, perhaps, for the first few days of life in infants with a high probability of GHD.[1103] An IGFBP3 measurement is of value for the diagnosis of neonatal GHD and should be measured in infants with suspected GHD; IGF1 levels are rarely helpful.[1136]

Growth Hormone Deficiency

Both clinical and laboratory evaluation must be utilized when considering the diagnosis of GHD in a child being evaluated because of short stature or growth failure.[1056] As discussed earlier, there is no definitive test for the diagnosis for GHD. In addition, the laboratory tests for GHD have poor specificity and should be performed only in children who have a clinical presentation consistent with GHD. Short children who have well-documented normal height velocities usually do not require evaluation of GH function. Therefore the evaluation starts with identifying those children who may have GHD based on risk factors or growth parameters (see Tables 25.8 and 25.9).

In a child with a history and growth pattern that indicate a risk for GHD and in whom other causes for growth failure (including hypothyroidism) have been excluded, testing for GHD begins with measurement of the IGF1 level and proceeds to GH provocation tests in selected patients (see Table 25.8). In some cases, particularly in younger children, it may also be helpful to measure the IGFBP3 level. If IGHD is suspected, two GH provocation tests (given sequentially or on separate days) are required. A patient is diagnosed with classic GHD when the IGF1 (or IGFBP3) level is below the normal range (i.e., >2 SD below the mean for age and pubertal status) and peak GH levels on two provocative tests are below the cutoff value that supports a diagnosis of GHD. The diagnosis is more firmly established if the child is pretreated with estrogen or testosterone before the provocative GH tests. In some patients, provocative testing of GH levels is not required to make the diagnosis. This includes children with growth failure and a pituitary hormone deficiency other than growth hormone in the setting of a known risk of hypopituitarism, such as anatomic abnormalities of the pituitary (such as ectopic posterior pituitary and pituitary hypoplasia with an abnormal stalk), tumor, or irradiation.[1103] Similarly, a diagnosis of GHD due to congenital hypopituitarism can be diagnosed if random GH levels are below 5 ng/dL in the first week of life in an infant with hypoglycemia and either one other pituitary hormone deficiency or classic imaging findings (ectopic posterior pituitary and pituitary hypoplasia with abnormal stalk).[1103] In patients who have had cranial irradiation or malformations of the hypothalamic-pituitary unit, GHD may evolve over years, and its diagnosis may require serial testing.

Some patients with auxology suggestive of GHD may have IGF1 or IGFBP3 levels below the normal range on repeated tests but GH responses in provocation tests above the cutoff level. Such children do not have classic GHD but may have an abnormality of the GH-IGF1 axis. The child with a history of cranial irradiation, decreased height velocity, and reduced serum levels of IGF1 and IGFBP3 may have GHD (or GH insensitivity) even in the face of normal provocative tests.[1137] Other children may have GHD that is not supported by the results of nonphysiologic provocative tests (perhaps a milder degree of GHD than in those who fail the provocative tests), or they may have GH insensitivity (discussed later). Systemic disorders affecting the synthesis or action of IGF1 must again be considered and excluded.

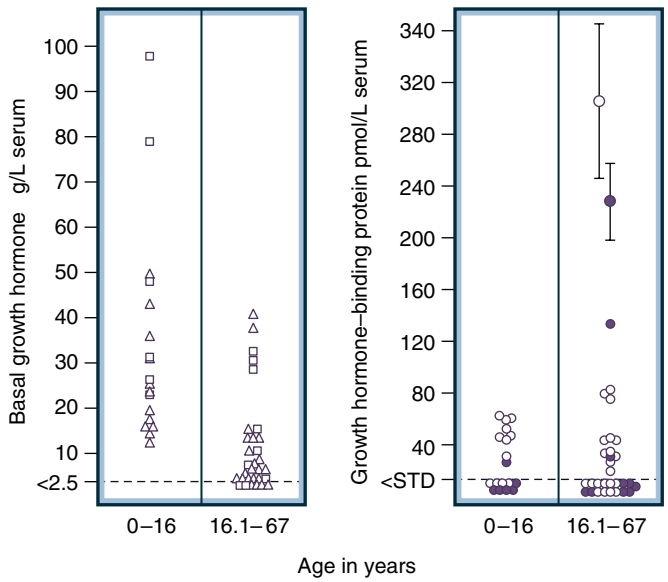
A difficult clinical situation to resolve is that of the short child with a persistently subnormal growth velocity whose IGF1 and IGFBP3 levels are normal. One can reasonably exclude consideration of GHD if the IGF1 level is higher than 1 SD below the normal mean. However, because up to 30% of children with GHD identified by GH stimulation testing have had IGF1 levels that were not low,[1044,1063–1066] it is appropriate to consider provocative GH testing in those children with persistent growth failure who have an IGF1 level between –1 SD and –2 SD for age and puberty status, with abnormal results on two tests indicating a diagnosis of GHD. In this situation in particular, it would be appropriate to pretreat the child with testosterone or estrogen to maximize the specificity of the provocative tests.

A cranial MRI scan with particular attention to the hypothalamic-pituitary region should be carried out in any child who is diagnosed as having GHD. In addition, documentation of abnormal pituitary GH secretion should prompt evaluation for other pituitary hormone deficiencies. Based on the clinical scenario, one may also consider molecular evaluation of GH, GHR, GHRHR, and other potential genetic defects.

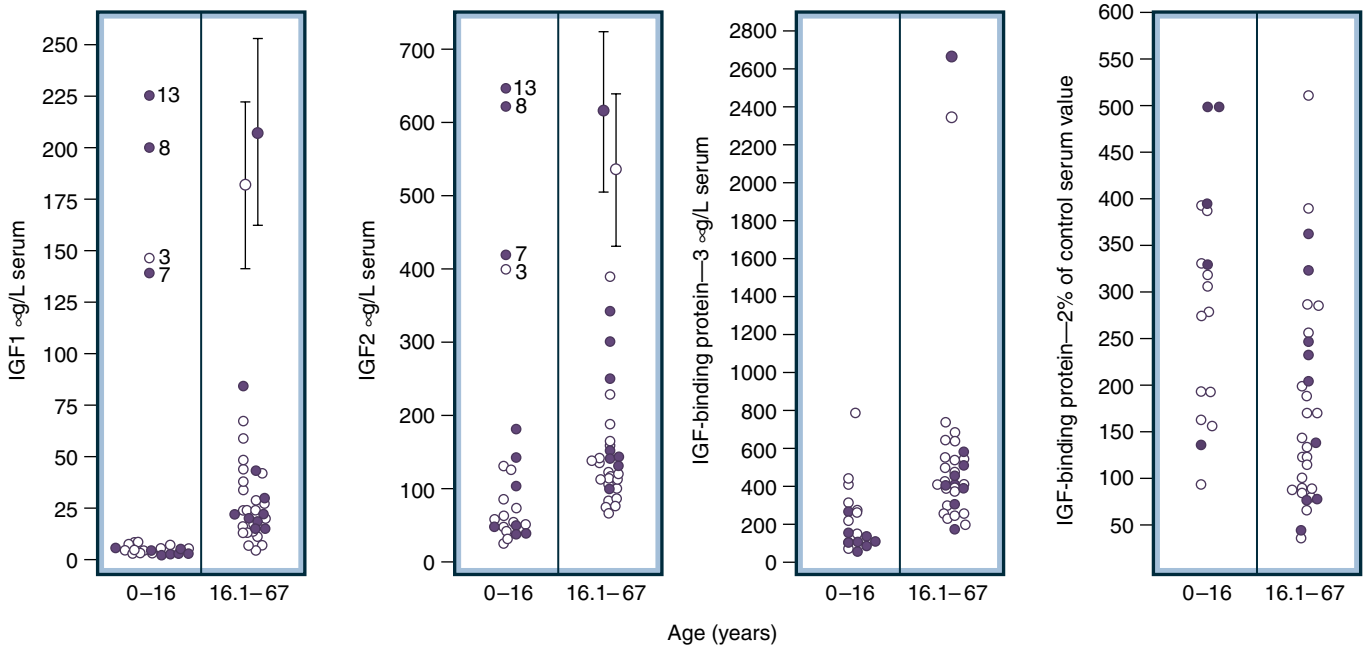
Growth Hormone Insensitivity

GH insensitivity is characterized by low serum IGF1 concentrations in the presence of normal (or increased) production of GH (Figs. 25.44 and 25.45). As discussed earlier, GH insensitivity can be caused by defects of the GHR (Laron syndrome), the GH signaling cascade, IGFBPs, IGF1, or the IGF1 receptor. GH insensitivity should be considered in a patient with growth failure who has a low IGF1 level but evidence of increased GH secretion based on increased basal or stimulated GH levels (e.g., basal GH levels >5 μg/L or stimulated levels >15 μg/L). This pattern is also seen with malnutrition, a form of physiologic GH insensitivity. If GH insensitivity is suspected, GHBP and ALS can be measured: Low values support the diagnosis of GH insensitivity due to mutations in the genes for the GHR or ALS, respectively. Growth attenuation with elevated IGF1 levels and IGFBP3 levels may indicate disruption in IGF1 bioavailability, as is seen in persons with mutation in the PAPP-A2 gene.[298]

The Pediatric Endocrine Society Guidelines suggest basing the diagnosis of primary IGF1 deficiency/GH insensitivity syndrome on a combination of factors, including testing of serum IGF1 and GHBP, exclusion of secondary IGF1 deficiency due to malnutrition, liver disease, of GH deficiency, and possibly IGF1 generation test.[1103] The IGF1 generation test has limitations and must be interpreted cautiously as there is limited normative data or standardization of such tests. Given the growing cadre of genes known to be involved in the GH-IGF1 growth cascade, genetic testing may play a vital role in diagnosis in the near future. However, there are currently few clinical laboratories offering mutation analysis of the genes involved in the GH-IGF1 growth cascade.



• **Fig. 25.44** GH assays were performed by radioimmunoassay *(squares)* and by immunoradiometric assay *(triangles)*. For GHBP levels, *open circles* represent females, and *closed circles* represent males. Standard error of the mean (±SD) for GHBP levels in adult Ecuadorian control subjects are shown. *STD,* Assay standard. (From Rosenfeld RG, Rosenbloom AL, Guevara-Acquirre J. Growth hormone [GH] resistance due to primary GH receptor deficiency. *Endocr Rev.* 1994;15:369–390.)



• **Fig. 25.45** Serum levels of insulin-like growth factors (IGF) and IGF-binding proteins in patients from Ecuador with growth hormone receptor deficiency. *Open circles* represent females, *closed circles* represent males. Control values for Ecuadorian adults are shown as mean ±SD for males and females, except for IGFBP3, for which large circles represent pooled male *(closed circle)* and female *(open circle)* control sera. Numbers adjacent to circles represent normal Ecuadorian children 3, 7, 8, and 13 years of age. (From Rosenfeld RG, Rosenbloom AL, Guevara-Acquirre J. Growth hormone [GH] resistance due to primary GH receptor deficiency. *Endocr Rev.* 1994;15:369–390.)

Additional considerations related to GH insensitivity include the following:

1. The presence of IUGR (in addition to severe postnatal growth attenuation) and developmental delay suggests *IGF1* gene deletions, bioinactive IGF1, or IGF type I receptor abnormalities.
2. Low GHBP suggests a defect in the extracellular domain of the GHR, but normal (or increased) GHBP may be seen in some patients with defects of the GHR or the GH signaling cascade.
3. An elevated IGF1 level (in a child with growth attenuation) may suggest a defect in the IGF type I receptor or defects in PAPP-A2.
4. IGFBP3 and ALS concentrations may be increased in patients with molecular defects of IGF1.
5. STAT5B defects should be suspected in a child with evidence of GH insensitivity who has evidence of immune deficiency; an elevated PRL level has also been reported in the presence of STAT5B mutation.[1138]

Constitutional Delay of Growth and Development

The term *constitutional delay of growth and development* describes children who have a normal variant of maturational tempo characterized by short stature with relatively normal growth rates during childhood, delayed puberty with a late and attenuated pubertal growth spurt, and attainment of a normal adult height that is also within the target height range based on parental heights (Table 25.12).[39,1139] In childhood, such patients have heights that are lower than expected based on parental heights. CDGD aggregates in families.[1140] The diagnosis of CDGD may be suspected in a child with short stature if one or both parents have a history of a late timing of puberty. Bone age is usually delayed, so the predicted final height is in the normal range and is within the child's target height range, although the correlation between predicted and final height is imperfect and must be viewed with caution.[44,1141,1142] The predicted final height, especially when the skeletal age is extremely delayed, is greater than that usually achieved but is difficult to reliably anticipate.[44,1142,1143] Although the findings described can lead to a presumptive diagnosis of CDGD, the diagnosis can only be made retrospectively, once the child demonstrates a late timing for puberty and completes his or her growth in the normal range and at a height consistent with the parents' heights.

Because of the estrogen stimulation associated GH secretion that occurs during puberty, children with CDGD can be expected to have decreased GH secretion and lower IGF1 levels compared with their pubertal, age-matched peers. However, IGF1 levels should be normal for pubertal stage, and GH levels on provocative tests should be normal after pretreatment with gonadal steroids.[1112,1143–1145] Overnight GH secretion is usually normal in these children when control groups are carefully matched.[1146]

It is often difficult to differentiate CDGD from GHD. Both groups of patients have height SDS below their target height SDS range, and both have delayed bone ages. As the child with CDGD enters the usual age for puberty, his or her growth rate can be too low to exclude GHD on that basis. (The growth rate normally declines throughout childhood until it increases at the time of the pubertal growth spurt; a child with CDGD and a delayed pubertal growth spurt may have an additional 2 or more years of declining growth velocity, which can result in growth velocities <4 cm/year.) If there is a clear family history of CDGD, the likelihood is high that the child also has CDGD, and careful continued observation may be all that is needed. An increase in growth velocity after treatment with a short course of sex hormone can be taken as evidence against the presence of GHD.[1147] In some cases, however, a laboratory investigation to exclude GHD is necessary. In such children, levels of IGF1 and IGFBP3 that are low for pubertal stage or skeletal age and a poor GH response to provocative testing after priming with gonadal steroids would raise concern for GHD and would mandate the appropriate investigation for underlying disease (e.g., intracranial tumor).

TABLE 25.12 Criteria for Presumptive Diagnosis of Constitutional Delay of Growth and Development

1. No history of systemic illness
2. Normal nutrition
3. Normal physical examination, including body proportions
4. Normal thyroid and growth hormone levels
5. Normal complete blood count, sedimentation rate, electrolytes, blood urea nitrogen
6. Height ≤3rd percentile but with annual growth rate >5th percentile for age
7. Delayed puberty: in males, failure to achieve Tanner G2 stage by age 13.8 years or P2 by 15.6 years; in females, failure to achieve Tanner B2 stage by age 13.3 years
8. Delayed bone age
9. Normal predicted adult height: in males, >163 cm (64 inches); in females, >150 cm (59 inches)

Genetic (Familial) Short Stature

The control of growth in childhood and the final height attained are polygenic in nature. Familial height affects the growth of an individual, and evaluation of a specific growth pattern must be placed in the context of familial growth and stature. As discussed at the beginning of this chapter, calculations can be made to determine whether a child's growth pattern is appropriate based on his or her parents' heights. As a general rule, a child who is growing at a rate that is inconsistent with that of siblings or parents warrants further evaluation.

Genetic short stature (GSS), also called familial short stature, is a normal growth pattern that describes the growth of healthy individuals who fall at the lower extreme of the distribution of height (i.e., below the 3rd percentile). Their height is appropriate for their genetic potential based on the parents' heights; that is, their height SDS is within the target height SDS range. Particularly when the midparental height is significantly above or below the mean, it is important to include adjustment for regression toward the mean when calculating this target height range.

Although the differentiation may not be complete, children with GSS are generally distinguished from children with CDGD: Those with GSS will have a final height that is below the 3rd percentile, whereas children with CDGD will achieve a final height in the normal range. The midparental height of children with GSS is lower than that of children with CDGD; often, height in both parents is below the 10th percentile. Growth in children with GSS is at or below the 3rd percentile, but the velocity is usually normal. The onset and progression of puberty are normal, so the skeletal age is concordant with chronologic age. Final heights in these individuals are in the target height range for the family.[43] By definition, the GH-IGF1 system is normal (as are all other systems).

Many diseases characterized by growth retardation are genetically transmitted, including GH insensitivity due to mutations

of the *GHR* gene; *GH* gene deletions; mutations of the *PROP1, POUF1,* or *SHOX* genes; pseudohypoparathyroidism; and some forms of hypothyroidism. Inherited nonendocrine diseases characterized by short stature include osteochondrodysplasias and dysmorphic syndromes associated with IUGR (both described earlier), inborn errors of metabolism, renal disease, and thalassemia. Identifying a patient's short stature as inherited does not, by itself, relieve the clinician of responsibility for determining the underlying cause of growth failure. Moreover, a parent's short stature may be the result of an uncharacterized genetic difference that has been transmitted to the child and is causing the child's short stature. Because height is normally distributed in the population, it can be arbitrary whether one characterizes such genetic differences as mutations or as allelic variants. However, the further the parents' and the child's heights are from the mean, the more reasonable it is to consider such genetic alterations as abnormal.

Idiopathic Short Stature

ISS is defined as "a condition in which the height of the individual is more than 2 SD below the corresponding mean height for a given age, sex and population group, and in whom no identifiable disorder is present."[1138] This definition includes children with CDGD, those with GSS, and short children who will not have delayed puberty and whose height is not consistent with parental heights. Therefore this definition includes both normal, healthy children (those with GSS and CDGD) and children who are presumed to have an unidentified disorder impairing their growth. It is not always a simple matter to distinguish among these possibilities: CDGD can be definitively diagnosed only at the completion of growth, and GSS does not exclude inherited disorders of growth.

Children with ISS may have undiagnosed disorders outside the GH-IGF1 axis (e.g., an uncharacterized chondrodystrophy) or they may have subtler disorders of the hypothalamic-pituitary-IGF axis than those identified by the currently available diagnostics tests.[640,1148] Because of the lack of a gold standard for the diagnosis of GHD, the distinction between isolated partial GHD and ISS is somewhat arbitrary, relying heavily on the results of the nonphysiologic provocative stimulation tests. The activity of different GH promoter haplotypes can differ as much as sixfold.[602,1149] Some children with ISS may have GH neurosecretory dysfunction that cannot be detected with current diagnostic tests.[1122,1123] Similarly, although the severe GH insensitivity of Laron syndrome can be identified by laboratory testing, partial GH insensitivity may be an unrecognized cause of ISS.[1150]

Heterozygous mutations in the GHR have been found in significant numbers of children with ISS.[639,642,1140] In heterozygotes, protein from the mutant allele may disrupt the normal dimerization and rotation that is needed for normal GHR activation, leading to diminished GH action and growth impairment.[215] In addition, GHBP expression may be decreased in patients with ISS, 20% of whom have serum levels of GHBP below the normal range.[1150–1152] Other potential causes for partial GH insensitivity in ISS include heterozygous mutations in other components of the growth system, a relatively greater preponderance of blockers of the GH-signaling cascade (e.g., enhanced intracellular phosphatase activity, production of such signaling factors as SOC2 and CIS), gene-mediated alterations in patterns of GH or IGF production, or other possibilities yet to be discovered.[1153]

Treatment of Growth Failure

When growth failure is the result of a chronic underlying disease, such as renal failure, CF, or malabsorption, therapy must first be directed at treatment of the underlying condition. Although growth acceleration may occur in such children with GH or IGF1 therapy, complete catch-up requires correction of the primary medical problem. If treatment of the underlying condition involves glucocorticoids, growth failure may be profound and is unlikely to be correctable until steroids are reduced or discontinued.

Correction of growth failure associated with chronic hypothyroidism requires appropriate thyroid replacement. As discussed earlier, thyroid therapy causes dramatic catch-up growth but also markedly accelerates skeletal maturation, potentially limiting adult height.

Treatment of Constitutional Delay

CDGD is a normal growth variant with delayed pubertal maturation and a normal adult height. Most subjects can be managed by careful evaluation to rule out other causes of abnormal growth or delayed puberty combined with appropriate explanation and counseling. A family history of CDGD is frequently a source of reassurance. The skeletal age and Bayley-Pinneau table are often helpful in explaining the potential for normal growth to the patient and parents. The predicted final height is usually greater than that achieved, especially when the skeletal age is extremely delayed, but this is difficult to reliably anticipate.[44,1141,1154]

On occasion, the stigmata of short stature and delayed maturation are psychologically disabling for a preadolescent or teenage patient. Some adolescents with delayed puberty have poor self-image and limited social involvement.[1155] In such patients and in some in whom pubertal delay is predicted based on the overall clinical picture, there may be a role for judicious short-term treatment with androgen.

Androgen (Oxandrolone and Testosterone)

Two aspects of CDGD in boys are addressed by androgen treatment: short stature, especially in boys 10 to 14 years of age, and delayed puberty after age 14. In the younger group, in whom CDGD is the presumed cause of short stature, the orally administered synthetic androgen oxandrolone has been used extensively to accelerate growth so that height increases into (or closer to) the normal range sooner than it would without treatment.[1156] In several controlled studies,[1139,1157–1161] oxandrolone therapy for 3 months to 4 years increased linear growth velocity by 3 to 5 cm/year without adverse effects and without decreasing either actual[1161–1163] or predicted[1158,1162,1164] final height. (This treatment does not increase the final height of these boys.) The growth-promoting effects of oxandrolone appear to be related to its androgenic and anabolic effects rather than to augmentation of the GH-IGF1 axis.[1165,1166] The lack of a measurable effect on the GH-IGF1 axis probably reflects the fact that oxandrolone cannot be aromatized to estrogen. Currently recommended treatment is 0.05 to 0.1 mg/kg orally per day.

Oxandrolone is a relatively weak androgen, and its use stimulates only minimal pubertal masculinization. In older boys in whom the delayed pubertal maturation is highly stressful and anxiety provoking, testosterone enanthate has been administered intramuscularly with success.[1156,1157,1167] Criteria for treatment in such adolescents should include (1) a minimum age of

14 years, (2) height below the 3rd percentile, (3) prepubertal or early Tanner G2 stage with an early-morning serum testosterone level of less than 3.5 nmol/L (<1 ng/mL), and (4) a poor self-image that does not respond to reassurance alone. Therapy consists of intramuscular testosterone enanthate, 50 to 100 mg every 3 to 4 weeks, for a total of four to six injections.[1155,1165,1167,1168] Patients typically show early secondary sex characteristics by the fourth injection and grow an average of 10 cm in the ensuing year. Testosterone enhances growth velocity by direct actions, increases GH production, and may have a direct effect on IGF1 secretion.[970,1108,1165,1169–1171] Brief testosterone regimens do not cause overly rapid skeletal maturation, compromise adult height, or suppress pubertal maturation.[1172] It is important to emphasize to the patient that he is normal, that therapy is short term and is designed to provide some pubertal development earlier than he would on his own, and that treatment will not increase his final adult height. In such situations, the combination of short-term androgen therapy, reassurance, and counseling can help boys with CDGD to cope with a difficult adolescence.

The availability of several new forms of testosterone, which are approved for adults with hypogonadism, provides adolescents with an opportunity for a choice among different androgen replacement therapies. Testosterone gel is painless and easy to apply and has proved popular since its release.[1173] However, there are concerns about environmental contamination, including reports of precocious puberty in children caused by topical testosterone use by an adult in the household.[1174–1176] If topical testosterone is prescribed, careful instruction must be given to avoid such inadvertent exposure of others. Testosterone patches also avoid the need for injections, but they are often poorly tolerated because of local skin reactions. The most recent testosterone products include a solution applied in the axilla and a nasal gel. Another disadvantage of these topical testosterone preparations and the transdermal patches is the need for daily application. The dosing of these alternative forms of therapy in children and adolescents has not been established, and care must be taken to avoid treating with too high a dose, which risks compromising final height.

Patients must be reevaluated to ensure that they enter "true" puberty. One year after testosterone treatment, boys should have testicular enlargement and a serum testosterone level in the pubertal range. If this is not the case, a diagnosis of hypothalamic-pituitary insufficiency or hypogonadotropic hypogonadism should be considered. Although the diagnosis of constitutional growth delay remains most likely in such patients, some eventually prove to be gonadotropin deficient, especially if they are still prepubertal late in adolescence.

Referrals for CDGD are more common in boys than girls. When CDGD is a problem in girls, short-term estrogen therapy may be used, but the acceleration of skeletal maturation is a greater hazard at doses that enhance growth velocity and sexual maturation.

Growth Hormone

The final height of a child with CDGD will be in the normal range and appropriate for the child's genetic potential. No treatment is needed for these children to achieve a normal height. However, as discussed earlier, the diagnosis of CDGD cannot be confirmed until a late puberty and normal height are achieved. Therefore it can be difficult in some cases to distinguish these children from children with ISS or GHD. In such cases, there may be uncertainty about whether the final height will be in the normal range, and treatment to try to increase final height may be considered. If laboratory studies support a diagnosis of GHD, then GH treatment would be appropriate. If there is no evidence of GHD, the consideration regarding treatment with GH would be the same as that regarding the use of GH to treat ISS (discussed later).

The Food and Drug Administration (FDA) indication for GH treatment includes in its definition of ISS the criterion that the child has "growth rate[s] unlikely to permit attainment of normal adult height." A child with CDGD, who is expected to achieve a normal adult height, would not fit within this definition. Nonetheless, partly because of the uncertainty of the diagnosis and the inability to perfectly predict final height, the database on outcomes of children treated with GH for ISS includes within it data on the treatment of children with CDGD. ISS GH treatment trials may include children with significant bone age delay,[1177,1178] at least some of whom have CDGD. For this reason, the outcome data for GH treatment of ISS (see later) can be taken as an indication of the expected outcome of GH treatment of CDGD. Moreover, because estimated final height gain with GH treatment of ISS is proportional to the bone age delay at the time of initiation of treatment,[1179] height gain with GH treatment of CDGD may be greater than that for treatment of ISS. However, a retrospective study specifically reporting the outcome of GH treatment in CDGD found no difference in adult height between those treated with GH and those receiving either no treatment or testosterone treatment.[1180]

Aromatase Inhibitor

In view of the important role of estrogen in the process of skeletal maturation, aromatase inhibitors could be used in conjunction with androgen therapy to prevent an acceleration of bone age and further enhance final adult height.[1181,1182] The one report of combined use of an aromatase inhibitor (letrozole) and testosterone did not provide a clear answer as to whether the addition of an aromatase inhibitor increased final height in boys with CDGD. Whereas the near-final height in the boys treated with letrozole plus testosterone was higher than that of boys treated with testosterone alone, the letrazole-treated boys were a year older at the time of these height measurements and had higher pretreatment and midparental heights.[1182] In addition, the boys treated with testosterone alone achieved a near-final height within the normal range (consistent with the diagnosis of CDGD). Given the lack of long-term safety data on the use of aromatase inhibitors in pubertal boys, there are insufficient data to suggest a role for aromatase inhibitors in CDGD.

Treatment of Growth Hormone Deficiency

Nomenclature and Potency Estimation

The nomenclature for the various biosynthetic GH preparations reflects the source and the chemical composition of the product. *Somatropin* refers to GH of the same amino acid sequence as that in naturally occurring human GH. Somatropin from human pituitary glands is abbreviated *GH* or *pit-GH;* somatropin of recombinant origin is termed *recombinant GH* or *rGH. Somatrem* refers to the methionine derivative of recombinant GH and is abbreviated *met-rGH.* Although the latter is a more antigenic preparation, that propensity is not clinically relevant; despite the presence of anti-GH antibodies, growth responses to met-rGH were similar to those in patients treated with rGH.[1183,1184] This derivative of GH is no longer available for use. In this discussion, we refer to the biosynthetic preparations as GH.

The biopotency of commercially available biosynthetic GH preparations, expressed as international units per milligram of the second WHO recombinant GH reference reagent for somatropin 98/574, is 3 IU/mg.[1185] It was necessary to standardize the early GH preparations by bioassay because of variable production techniques (e.g., extraction, column purification). The most common bioassays have been the hypophysectomized rat weight-gain assay, the tibial width assay, and the more sensitive Nb2 rat lymphoma proliferation assay.[1186–1188] With the availability of purified and essentially equivalent recombinant GH products, the requirement for bioassays has become an FDA requisite to substantiate biologic activity rather than to assess potential differences among preparations. The bioassays are likely to be replaced by in vitro binding assays using GHRs or GHBP derived from molecular techniques.

Historical Perspective

Because untreated patients with GHD have profound short stature (averaging almost –5 SDS[1189,1190]), the clinical urgency to use GH therapy as soon as it became available is understandable.[1092] The action of GH is highly species specific, and humans do not respond to animal-derived GH (except that from other primates).[1191] Human cadaver pituitary glands were for many years the only practical source of primate GH for treatment of GHD, and more than 27,000 children with GHD worldwide were treated with pit-GH.[1192] The limited supplies of pit-GH, the low doses used, and interrupted treatment regimens resulted in incomplete growth increments; usually, therapy was discontinued in boys who reached a height of 5 feet 5 inches and in girls who reached 5 feet. Nonetheless, this treatment did increase linear growth and in many patients enhanced final adult height. The dose-response relationship and the relation of age to GH response were recognized during this period.[1193]

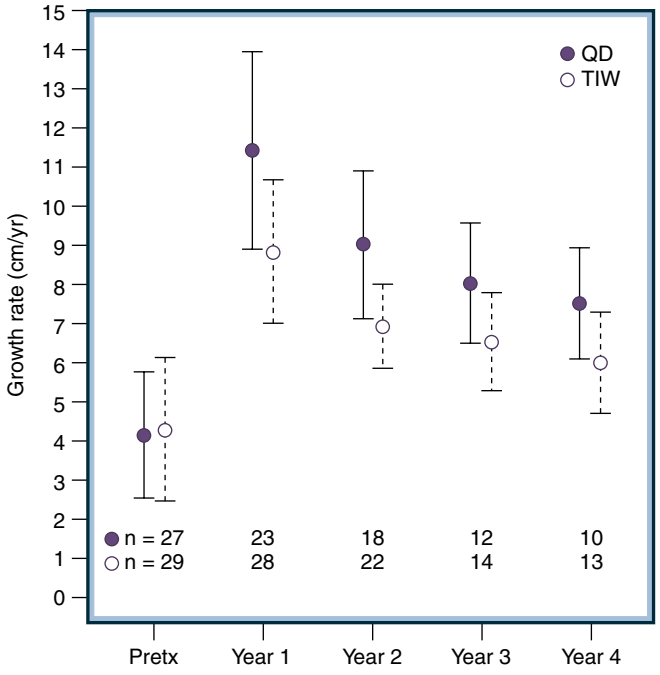
Distribution of pit-GH was halted in the United States and most of Europe in 1985 because of concern about a causal relationship with Creutzfeldt-Jakob disease (CJD), a rare and fatal spongiform encephalopathy that had been previously reported to be capable of iatrogenic transmission through human tissue. In North America and Europe, this disorder has an incidence of approximately 1 case per 1 million in the general population, and it is exceedingly rare before the age of 50 years. To date, more than 200 young adults who had received human cadaver pituitary products have been diagnosed with CJD, with the sad likelihood that all affected patients will die of the disease.[1194–1196] The onset of CJD has occurred 5 to 42 years after treatment, with a mean incubation of 17 years.[1196] No cases of CJD have been identified in Americans who began treatment after new methods of purifying the hormone came into use in the United States in 1977.

By the time the risks of pituitary-derived GH were discovered, biosynthetic GH was being tested for safety and efficacy.[1183,1197,1198] The original recombinant GH mimicked pit-GH in regard to both anabolic and metabolic actions and was scrupulously scrutinized for monoisomerism, antigenic bacterial products, and toxins of any sort. GH has universally replaced pit-GH as the accepted treatment for children with GHD.

Treatment Regimens

The recommended therapeutic starting dose of GH in children with GHD is 0.16 to 0.24 mg/kg body weight per week, administered in seven daily doses.[1103,1199] Alternative regimens include a 6-day/week and a 3-day/week schedule, with the same weekly dosage, but they are not as successful. In general, the growth response to GH is a function of the log-dose given, so increasing dosages further enhance growth velocities,[1192,1193,1200] but daily dosing may be the most important treatment parameter.[1201] Subcutaneous and intramuscular administration has equivalent growth-promoting activity[1202]; the former is now used exclusively. At this time, all of the commercially available GH preparations yield comparable growth outcomes.

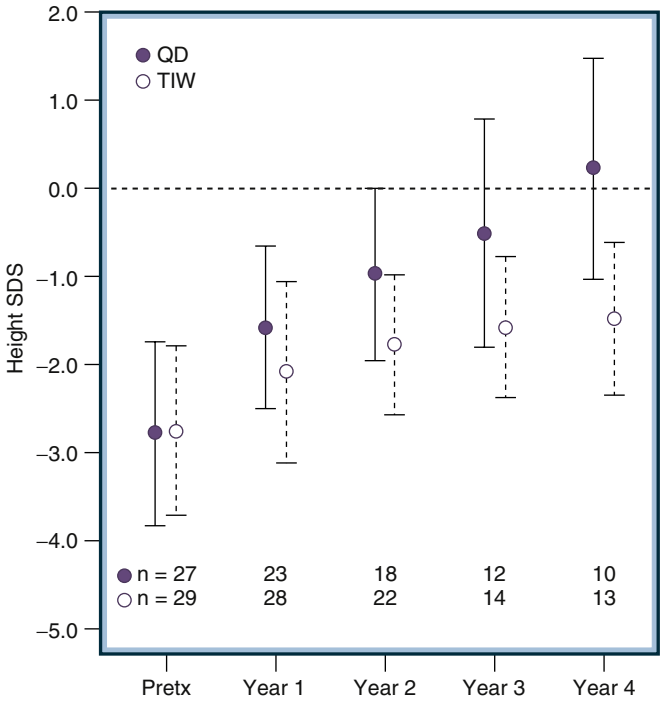
Growth responses to exogenous GH vary, depending on the frequency of administration, dosage, age (greater absolute gain in a younger child, although not necessarily greater growth velocity SDS), weight, GHR type and amount (as assessed by serum GHBP levels), and, perhaps, seasonality.[646,1203–1206] Nevertheless, the general regimen of daily GH at the recommended doses typically accelerates growth in a GH-deficient child from a pretreatment rate of 3 to 4 cm/year to 10 to 12 cm/year in year 1 of therapy to 7 to 9 cm/year in years 2 and 3. Progressive waning of GH efficacy occurs and is poorly understood. The importance of dosage frequency is illustrated (Figs. 25.46 and 25.47) by data from a carefully done assessment of growth responses in prepubertal naïve GH-deficient children randomly assigned to receive thrice-weekly or daily GH at the same total weekly dose (0.30 mg/kg per week).[1201] The mean total height gain during this period was 9.7 cm greater in the patients treated daily (38.4 vs. 28.7 cm, $p < 0.0002$), with similar increments in skeletal maturation and no acceleration of the onset of puberty. Mean height SDS at the end of 4 years was +0.2 or at the midpoint of normal for



• **Fig. 25.46** Annual growth velocity (mean ± standard deviation) for prepubertal patients with growth hormone (GH) deficiency before and during 4 years of GH treatment, contrasting results from daily *(QD)* versus thrice-weekly (TIW) injections. The mean annual growth velocity in the QD group was significantly greater than that in the TIW group during each year, although significance diminished from year 1 to year 4. (From MacGillivray MH, Baptista J, Johanson A. Outcome of a four-year randomized study of daily versus three times weekly somatropin treatment in prepubertal naive growth hormone deficient children. *J Clin Endocrinol Metab.* 1996;81:1806–1809. Reproduced by permission of M.H. MacGillivray.)

age. Studies using varying dosing of GH based on gender, growth responsivity, and growth factor concentrations have suggested the need for greater sophistication and individualization of the current treatment regimens.[1207,1208]

Sophisticated mathematical models[1200,1209] have examined many laboratory and auxologic parameters that influence response to GH therapy. Because age at onset of treatment is inversely correlated with growth responses, and because the smaller, lighter child requires less GH (with marked economic benefit), it is important to assess growth data in children treated early. In short-term studies of 134 patients[1210–1212] treated before age 3 years, marked early catch-up growth occurred, with a mean height gain of about 3 SDS by 4 years of therapy, allowing most children to reach their normal height range by middle childhood. Mean height in one study[1210] reached –0.4 SDS after 8 years of treatment. Near-adult height in 13 patients treated before 5 years of age[1213] did not differ significantly from the midparental target height (–0.9 vs. –0.7 SDS). In a group of 25 children treated before 12 months of age,[1214] adult height also matched the target height despite low dosage and less frequent administration. In an analysis of postmarketing data for development of a growth prediction model, a greater height gain per GH amount occurred in the very young children, but a seemingly lowered sensitivity to endogenous GH in early infancy adds complexity to interpretation of these data.[1215]



• **Fig. 25.47** Height standard deviation score (SDS) for prepubertal patients with growth hormone (GH) deficiency before and during 4 years of GH treatment, contrasting results (mean ± standard deviation) with daily (QD) versus thrice-weekly (TIW) injections. The mean SDS in the QD group was significantly greater throughout the treatment period. Younger patients had the greatest increase in height SDS, and the effect of age was more marked in the QD group. (From MacGillivray MH, Baptista J, Johanson A. Outcome of a four-year randomized study of daily versus three times weekly somatropin treatment in prepubertal naive growth hormone deficient children. *J Clin Endocrinol Metab.* 1996;81:1806–1809. Reproduced by permission of M.H. MacGillivray.)

Adult Height Outcomes

Treatment of growth-deficient children with pit-GH significantly increased their final heights, although the majority had final heights below –2 SD.[1216] This was likely due to the lower doses used, as well to treatment interruptions and the shorter duration compared to current treatment.

Patients treated with biosynthetic GH[1092,1213,1216–1225] have improved final adult height SDS, with average final height in more than 1400 patients approximating –1.3 SD. Data from the two largest databases,[1217,1219,1224–1226] representing the North American and European experiences as reported by pediatric endocrinologists, are shown in Table 25.13.

Despite the use of GH therapy, long-term studies still show that most patients fail to reach their genetic target heights. Evaluation of adult heights in 121 patients with childhood GHD treated in the Genentech GH research trials indicated a mean adult height in both male and female patients of –0.7 SDS, with 106 patients being within 2 SDS for normal adult Americans.[1222] Even in these closely monitored patients, however, a difference of –0.4 to –0.6 SDS from midparental target height still occurred. The achievement of the genetic target is possible, however: A Swedish subgroup (in the Kabi International Growth Study [KIGS] database) of consistently treated patients reached a median final height SDS of –0.32, which was equivalent to the midparental target height.[1226] A more recent study of the Swedish subgroup actually found a final height SDS greater than midparental target height by +0.2 (see Table 25.13).[1217]

Factors that have been found to correlate with enhanced adult height in GH-treated, GH-deficient children include baseline height, younger age at onset of treatment, longer treatment duration (especially during prepubertal years), and a greater growth velocity during the first year of treatment (Figs. 25.48 and 25.49).[1225] Increased height velocity and subsequent superior adult height outcome, although with considerable overlap, were demonstrated in children with GHD who carried one or both *GHRd3* alleles (i.e., with an exon 3 deletion),[646,1227,1228] although no difference in outcome was seen with GH treatment for ISS based on the GHRd3 allele polymorphism.[1229] Data from the National Cooperative Growth Study (NCGS) and KIGS showed that the height gained during puberty in patients with GHD was generally comparable to that in healthy children with delayed bone age.[1224,1230] As might be expected based on that observation, final height correlates with height at the onset of puberty in GHD patients.[1205,1221,1231–1233] Therefore every effort should be made to enhance growth before puberty, and delays in diagnosis and initiation of therapy probably contribute to the compromised adult heights still reported in many studies.

GH treatment of children who develop GHD as a result of cranial irradiation represents a special case when evaluating final height outcomes. In these children, who have received cranial irradiation for the treatment of malignancy, GH treatment is not initiated until there is no evidence of active tumor; this results in a delay between the diagnosis of GHD and the initiation of treatment. Final height is negatively correlated with the length of that lag time.[1234] In addition, those who have received spinal irradiation in addition to cranial irradiation have a lower final height due to impairment of spinal growth after irradiation.[1234,1235]

In an effort to increase final height in GHD patients, the use of high-dose GH during puberty has been studied, based on the rationale that GH secretion normally rises twofold to fourfold during the pubertal growth spurt, with dramatic concomitant

• **Fig. 25.49** Relationship between prepubertal change in height standard deviation score (SDS) and total change in height SDS between start of growth hormone (GH) treatment and near-final height in children with idiopathic isolated GH deficiency. *KIGS,* Kabi International Growth Study database. (Modified with permission from Reiter EO, Price DA, Wilton P, et al. Effect of growth hormone [GH] treatment on the final height of 1258 patients with idiopathic GH deficiency: analysis of a large international database. *J Clin Endocrinol Metab.* 2006;91:2047–2054.)

increases in serum IGF1 levels, and the pubertal growth spurt normally accounts for approximately 17% of adult male height and 12% of adult female height. Earlier studies by Stanhope and associates[1236,1237] indicated that little difference in height gain could be observed when adolescent patients were treated with 30 versus 15 IU/m^2 per week of GH (~0.04 vs. 0.02 mg/kg per day). Mauras and colleagues[1238] evaluated higher pubertal GH doses (0.1 vs. 0.043 mg/kg per day) and found that the higher dosage resulted in a 4.6-cm increase in near-final height. Mean height SDS achieved in the group receiving 0.043 mg/kg per day of GH (as in the earlier report[1222]) was –0.7 ± 0.9, but in the group receiving 0.1 mg/kg per day, it was 0.0 ± 1.2. The higher GH dosage did not result in more rapid acceleration of skeletal maturation.

Another approach that has been taken to attempt to increase final height in GH-treated patients has been to adjust the dose of GH to reach a target IGF1 level rather than treating with a fixed, weight-based dose.[1239,1240] A study reported by Cohen and colleagues found that targeting a high IGF1 level (reaching a mean IGF1 SDS of approximately +1.5) resulted in an increase in growth rate compared with the two comparator groups, which had mean IGF1 SDS of approximately +1.[1239] It required a GH dose approximately three times higher to reach this IGF1 level (0.11 mg/kg per day vs. 0.041 and 0.033 mg/kg per day for the comparator groups).[1239] In the study reported by Marchisotti and colleagues,[1240] the difference in IGF1 levels between groups (+0.8 SDS vs. –0.3 SDS) was even greater than that in the report by Cohen and colleagues,[1239] but the Marchisotti study did not find a difference in growth rate between the two groups. The difference in GH dose was much smaller, however (0.038 vs. 0.30 mg/kg per day). Therefore, as would be expected, a higher GH dose results in a higher growth rate, but it is not yet known whether targeting a specific IGF1 level results in an increased final height; nor is it known whether these higher doses have adverse effects not seen with the more usual doses currently used. An interesting finding was the wide range of doses required to reach a given IGF1 level: The high-IGF1 targeted group required GH doses ranging from less than 0.025 mg/kg per day to greater than 0.25 mg/kg per day, whereas the low-IGF1 targeted group required doses ranging from less than 0.025 to 0.15 mg/kg per day.[1239]

The impact of treatments to alter sex hormone levels (e.g., GnRH agonists, aromatase inhibitors) with the aim of improving final height in GHD and other conditions is discussed later.

Benefits of GH Treatment Other Than Improved Growth

GH has effects beyond its impact on growth in childhood. Many non–growth-related benefits are discussed in the section on GH treatment in adulthood. There have been some data to suggest non–growth-related health benefits of GH treatment in childhood. A small study found treatment of GHD in childhood improved impaired cardiac function and structure identified in these subjects and improved body composition as seen with treatment of adult GHD.[1241]

Combined Pituitary Hormone Deficiencies

If GHD is part of a combined pituitary deficiency syndrome, it is necessary to address each endocrine deficiency, both for general medical reasons and to ensure maximal effect of GH therapy. TSH deficiency is often "unmasked" during the initial phase of therapy, and thyroid function should be assessed before the onset of therapy during the first 3 months of GH treatment[1242] and at least on an annual basis thereafter. The pituitary-adrenal axis can be evaluated during the insulin stimulation test in the workup for GHD or separately if GHD is identified with the use of a different provocative test. If ACTH secretion is impaired, patients may be placed on the lowest safe maintenance dose of glucocorticoids, certainly no more than 10 mg/m^2 per day of hydrocortisone and less if possible. Higher doses impair the growth response to GH therapy but should be given during times of stress. It is critical to monitor the long-term evolution of glucocorticoid deficiency, especially in those with *PROP1* mutations (discussed earlier). However, Lange and colleagues studied 24 adults with a prior history of idiopathic isolated childhood GHD and identified adrenal insufficiency in 10 of them, half of whom did not have evidence of ongoing GHD[1243]; this suggests a need to consider monitoring for impaired ACTH secretion even in those patients with presumed IGHD.

Gonadotropin deficiency may be evident in the infant with microphallus. This can be treated with three or four monthly injections of 25 mg of testosterone enanthate in the first months of life.[1244] Management at puberty can be more complicated, in that the physical and psychologic benefits of promoting sexual maturation must be balanced against the effects of epiphyseal fusion. When GH therapy is initiated in childhood and growth is normal before adolescence, it is appropriate to promote pubertal development with gonadal steroid replacement.

TABLE 25.14 Monitoring Growth Hormone Therapy

- Close follow-up with a pediatric endocrinologist every 3–6 months
- Determination of growth response (change in height SDS)
- Evaluation of compliance
- Screening for potential adverse effects
- Interval measurements of serum IGF1 and IGFBP3
  - Annual assessment of thyroid function
  - Consideration of dose adjustment based on IGF values, growth response, and comparison with growth prediction models
  - Periodic reevaluation of adrenal and thyroid function

IGBP, Insulin-like growth factor–binding protein; *IGF*, insulin-like growth factor; SDS, standard deviation score.

Monitoring Growth Hormone Therapy

Patients treated with GH should be seen every 3 to 6 months to monitor their response to treatment (Table 25.14). An increase in linear growth velocity should be seen within the first 6 months. Height SDS should increase at least 0.25 SDS in the first year.[1199] Treatment models have been developed that predict the expected growth rate in response to GH treatment.[1200,1209,1245–1247] A model[1200] explaining 61% of growth response variability in the first year of therapy includes inverse relationships with maximum GH response during provocative testing, age, and height SDS minus midparental height SDS and positive correlation with body weight SDS, GH dose, and birthweight SDS.[1248,1249] The single most important predictive factor for growth in years 2 through 4 is the first-year height velocity. These models can be used to quantify whether the individual patient is responding appropriately to GH treatment. If a patient's initial growth response is lower than predicted, the clinician should consider whether the diagnosis of GHD was correct, whether additional growth disorders (e.g., hypothyroidism) are present, and whether there is lack of compliance with the treatment.[1246]

It is appropriate to monitor the IGF1 levels after initiation of GH treatment and perhaps yearly thereafter.[1199,1250] A failure of IGF1 levels to increase into the normal range with treatment, together with an inadequate growth response, suggests compliance failure or the presence of GH insensitivity. Because of the association of elevated IGF1 levels with certain cancers (see later discussion), a reduction in GH dose should be considered for patients with serum IGF1 levels substantially above the normal range after the first 2 years of therapy.[1199] Whether the IGF1 level should be used to guide GH dosing awaits additional studies (see earlier discussion).

CPHD may evolve over several years, so children who are initially diagnosed with IGHD may develop CPHD. Thyroxine levels should be assessed after GH treatment has been initiated, and

annually thereafter, to identify the development of central hypothyroidism during treatment. Periodic reevaluation for ACTH deficiency should be performed. It is not necessary to routinely monitor fasting insulin and glucose levels, but if impaired glucose control is suspected, a fasting glucose level and glycosylated hemoglobin (HbA_{1c}) should be measured.

The growth response to GH typically attenuates after several years but should continue to be equal to or greater than the normal height velocity for age throughout treatment. Use of statistical growth treatment models can prove valuable in judging therapeutic efficacy.[1251–1253] A suboptimal response to GH can result from several causes: (1) poor compliance, (2) improper preparation of GH for administration or incorrect injection techniques, (3) subclinical hypothyroidism, (4) coexisting systemic disease, (5) excessive glucocorticoid therapy, (6) prior irradiation of the spine, (7) epiphyseal fusion, (8) anti-GH antibodies, or (9) incorrect diagnosis of GHD as the explanation for growth retardation (particularly in a patient with idiopathic IGHD and normal findings on MRI). Although 10% to 20% of recipients of recombinant GH develop anti-GH antibodies, growth failure is rarely caused by such antibodies, except in the case of individuals who have GHD as a result of GH gene deletion.[1254–1256]

Treatment During the Transition to Adulthood and in Adulthood

A growing challenge in the management of patients with GHD has been the issues surrounding their care after the growth process has ceased.[1257] This period, from the middle to late teenage years until the mid-20s, is a normal physiologic phase during which peak bone and muscle mass is achieved and the independence and self-sufficiency characteristics of adulthood are attained. It is also a time during which care of pediatric patients is transferred to endocrinologists who treat adults.

Clinical consequences of GHD in adults and the potential benefits of GH therapy in such patients have already been described.[1258,1259] Signs and symptoms of adult GHD include reduced lean body mass and musculature, increased body fat, reduced BMD, reduced exercise performance, and increased plasma cholesterol. Adults with GHD have a significantly increased risk of death from cardiovascular causes, a finding potentially linked to increased visceral adiposity and other cardiovascular risk factors.[1260] Adults with GHD have been found to have "impaired psychological well-being and quality of life."[1261] Several placebo-controlled studies have demonstrated that GH therapy for adult GHD results in marked alterations in body composition, fat distribution, bone density, and sense of well-being.[1259]

Given the metabolic derangements associated with untreated GHD, documentation of persistent GHD and continuation of GH treatment in late adolescence in the patient who shows persistent GHD is important. Among nearly 500 patients with IGHD, 207 (44%) had normal GH levels on provocative retesting.[1262,1263] In contrast, approximately 96% of patients with CPHD, with or without structural abnormalities of the hypothalamic-pituitary area, had sustained GHD.[1262,1263] The PES Guidelines on GH treatment recommend that persons with more than two pituitary hormone deficiencies be diagnosed with persistent GH deficiency.[1103] Persons with two or less pituitary hormone deficiencies, idiopathic GHD, idiopathic GHD with a small pituitary or isolated ectopic posterior pituitary, or persons postradiation require diagnostic evaluation for persistent GHD.

Many patients do not wish to continue the daily GH regimen, but the data support consideration for sustained treatment. After 1 to 2 years off GH therapy, IGF1 and IGFBP3 levels decrease substantially below baseline levels.[1258,1264,1265] Resumption of GH normalizes these levels, although there is a strong suggestion of a gender-based difference in GH requirements, with females needing higher GH doses.[1258,1264,1265] Loss of energy and strength may occur, and some quality-of-life data suggest age-specific psychologic issues in patients with untreated severe GHD during the transition to adulthood.[1266] Quality-of-life data with rigorous study designs are lacking in GH-treated childhood GHD.[1267] In untreated patients, total body fat and abdominal fat increase significantly and lean body mass is lost, compared with control subjects, comparable GH-treated patients, and patients who have reinstituted therapy.[1159,1268,1269]

Because bone mass accrual is not completed until the third decade, late adolescence is an important time for GH sufficiency, to prevent later osteopenia.[708,1257] There have been numerous GH treatment studies carried out in the transition age group to assess the impact on bone mineralization.[1265,1268,1270,1271] Differences in age at onset of retreatment, duration of therapy, GH dosage, and gender distribution have led to variations in results. In general, however, the data affirm the concept that reinstitution of treatment for 2 years in the transition period prevents deterioration in bone mineral density as experienced by untreated young adults with persistent GHD.

These studies support the continuation of GH treatment in late adolescence, albeit at lower doses than in childhood, to prevent the development of adverse cardiovascular risk, diminished bone mineralization, and a deterioration in quality of life. Whether the diversity of treatment and response data relates to the efficacy of the childhood GH therapeutic process is not clear, but the period of time off GH and the degree of persistent GHD would seem likely predictors of clinical status at the time of reinitiation of GH treatment.

After the adolescent with GHD has completed skeletal growth, the persistence of GHD is evaluated.[1103] Completion of skeletal growth is defined as growth rate less than 2 to 2.5 cm per year and bone age of 14 in females or 17 in males. GH at childhood doses should be discontinued, and if evaluation for persistent GHD is needed, GH therapy should be halted for 1 to 3 months, followed by a thorough reevaluation. A recommended algorithm for this evaluation is shown in Fig. 25.50.[1272]

As in childhood GHD, laboratory testing is imperfectly precise for diagnosis of ongoing GHD. Some patients have results that neither indicate nor eliminate ongoing GHD but are intermediate, suggesting either probable or partial GHD. If ongoing GHD is considered to be present or probable, assessment of body composition, BMD, and fasting lipid levels should be determined. The decision to reinitiate GH treatment is then based on a discussion with the patient and family regarding the risks and benefits in light of the laboratory test results and the risk for metabolic consequences (see Fig. 25.50).[1272] In addition, caution should be exercised in considering whether to continue GH therapy when there is a known risk of diabetes or malignancy. This is also an opportunity for a thorough clinical reassessment and a determination of the need for replacement of other hormones. The transition to adult GH replacement should be arranged as a close collaboration between endocrinologists who treat pediatric patients and those who treat adult patients and should include discussion with the patient and family.

Growth Hormone Treatment of Other Forms of Short Stature

Prader-Willi Syndrome

Growth failure due to PWS is an approved indication for hGH therapy in the United States and disordered body composition is an additional indication in Europe. In addition to promoting growth, hGH therapy improves body composition and physical strength, and increases energy expenditure.[1273–1276]

Guidelines for the clinical management of PWS were published after an international multidisciplinary expert meeting in 2013.[1277] Short stature due to GH insufficiency is almost always present in children with PWS. In a large cohort of 1135 children with PWS starting GH treatment, median height SDS was –2.2 (range, –4.1 to –0.3) at a median age of 6.4 years (range, 1.3 to 12.9 years).[1278] Growth standards for infants with PWS have been pubished.[1279]

Serum levels of IGF1 are reduced in most children with PWS.[938,1280–1282] Studies have shown that spontaneous GH secretion is reduced, and 70% of children with PWS have GH peaks of less than 10 μg/L during pharmacologic stimulation tests.[1273] Most experts agree that prior GH testing is not required before GH treatment is initiated. Numerous clinical trials have documented the efficacy of GH therapy to increase growth and improve body composition, energy expenditure, and strength and agility,[1283–1287] as well as increase growth and enhance gain of motor skills in infants and toddlers with PWS.[1288,1289]

In randomized, controlled studies there were significant increases in height and growth velocity and a significant decrease in percent body fat, as well as increased percentage of fat-free mass, improved muscle strength and agility, and increased fat oxidation during the first year of GH treatment.[1281,1290] Stabilization of these parameters occurs after the second year of therapy. Lean body mass increased significantly during the first 2 years in children with PWS who received GH treatment, compared with no treatment.[1220,1284] GH therapy for 2 additional years resulted in continued beneficial effects on body composition. When the dose of GH was reduced to 0.3 mg/m^2 per day, these improvements were not maintained.[1284] Beneficial effects continued after 8 years of GH treatment.[1287]

BMD improves in children with PWS treated with GH. In two German cohorts, the mean spontaneous adult heights were reported in one study as 162 cm in boys and 150 cm in girls[1291] and the other as 159 cm in boys and 149 cm in girls.[1292] In the KIGS database, 33 patients (21 boys and 12 girls) reached adult height, and two-thirds of them were above –2 SDS; the median adult height was –1 SDS after a mean duration of 8.4 years.[1293] Another study with 21 adults (13 males, 8 females) revealed a mean adult height of 0.3 SDS after a mean duration of 7.9 years of GH treatment.[1293] In this cohort, the strength and agility that were evident during the initial 2 years continued into adulthood. The patients also reported a higher quality of life and reduced depression.[1294] In 55 children monitored during 4 years of continuous GH treatment (1 mg/m^2 per day), body composition was significantly improved, mean height normalized, head circumference increased, and BMI significantly decreased. GH treatment had no adverse effects on bone maturation, blood pressure, glucose homeostasis, and serum lipids.[1295] Improved body composition and metabolic status were demonstrated in adults treated with GH in childhood and adolescence.[1296]

Before GH therapy is begun, screening for hypothyroidism is indicated because of the association with primary and central hypothyroidism.[1297,1298] Continued screening is also recommended. Treatment with GH beginning as early as 2 years of age is recommended, but there may be additional benefits to starting therapy between 6 and 12 months of age. Several studies have found improvements in motor development, muscle tone, head circumference, and, possibly, cognition and behavior.[1288,1299–1301]

A recent review documents the benefits of GH therapy, including an increase in female height, improved body composition, and increased exercise tolerance.[1302] Cognitive function was improved in children with treated GH.[1303]

Since October 2002, several reports of unexpected deaths in infants and children with PWS have been published.[1304–1306] Between 1985 and 2006, the NCGS monitored the safety and efficacy of recombinant human GH in 54,996 children. Two deaths were reported in patients with PWS.[1307] Although death from presumed obesity-induced hypoventilation or apneic events in PWS without GH treatment is well described, the occurrence of such deaths during GH administration raises the question of whether GH exacerbates this condition.[1308,1309] Tonsillar hypertrophy and fluid retention associated with GH therapy are potential risk factors. Most of the deaths, with or without GH treatment, were related to obesity or to a complicated course of a relatively mild respiratory tract infection, sleep apnea, adenoid or tonsillar hypertrophy (or both), hypoventilation, and aspiration. The obesity-hypoventilation syndrome is the more likely etiologic factor, suggesting that ventilatory and pulmonary function should be assessed with polysomnographic studies before and during GH treatment.[1308,1310]

In a review that included 64 children (42 boys and 22 girls, 28 receiving GH treatment), the highest death risk occurred during the first 9 months of GH treatment.[1306] Therefore it is recommended that GH treatment be started at a low dose (e.g., 0.25–0.30 mg/m^2 per day or 0.009–0.012 mg/kg per day) and increased during the first weeks and months to reach the standard replacement dosage of approximately 1 mg/m^2 per day or 0.24 mg/kg per week. Patients should be monitored for sleep apnea and IGF1 levels. The GH dose should be decreased if there is evidence of high IGF1 levels, especially if associated with edema, worsening or new onset of snoring, headache, or acromegalic clinical features. A longitudinal observational study evaluated 75 children with PWS and showed an increase in the apnea-hypoxia index (AHI) after GH treatment.[1311]

Five prospective studies have evaluated the effects of GH treatment on breathing disorders in PWS.[1285,1312–1314] Carbon dioxide responsiveness, resting ventilation, and airway occlusion pressure improved during 6 to 9 months of GH treatment,[1314] and the inspiratory and expiratory muscle strength improved during 12 months of GH treatment, compared with control subjects.[1312] In a double-blind, placebo-controlled, crossover study, AHI was found to decrease in 12 children with PWS, compared with control subjects, after 6 months of GH therapy although the difference was not statistically significant.[1285] Another study found a decrease in AHI in most of the adults and children studied after 6 weeks of GH therapy.[1315] A subset of patients had an increased AHI with more obstructive events, but most of these latter patients had upper respiratory tract infections and adenoid/tonsil hypertrophy, and two of them had high IGF1 levels. In another study in 35 prepubertal children with PWS, the AHI did not significantly change during 6 months of GH therapy.[1316] However, four of these children had an increase in the number of episodes

of obstructive apnea during an upper respiratory illness; these episodes were not present after recovery. Therefore it is recommended that obesity-related sleep and breathing problems be evaluated before and vigilantly monitored after GH treatment begins. Polysomnography and ear, nose, and throat evaluations should be performed as necessary. A longitudinal review of polysomnography data suggests that children younger than 2 years of age are most vulnerable to sleep-related disordered breathing (SRDB) after initiation of GH therapy.[1317]

A recent study[1318] showed that 60% of PWS patients had central adrenal insufficiency. This may explain the high rate of sudden death, especially during infection-related stress. The authors concluded that patients with PWS should be treated with hydrocortisone during stress until adrenal insufficiency can be ruled out.[1318,1319]

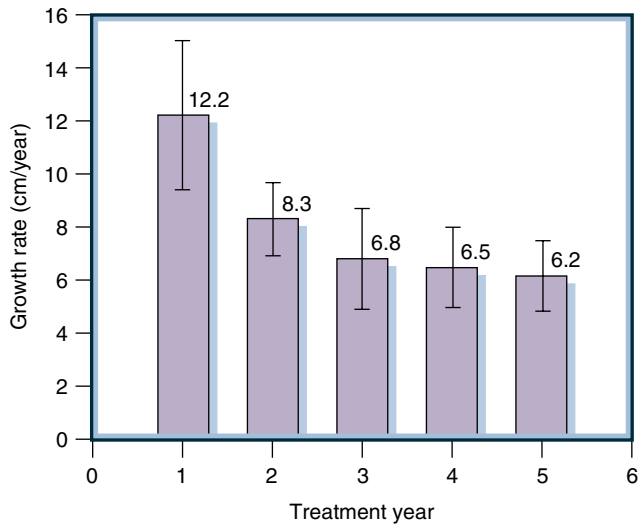
Between 30% and 70% of children with PWS have scoliosis.[1320–1325] Weight control is a vital part of its prevention and management. Therefore, before GH treatment is initiated, spinal radiographs and, if appropriate, orthopedic assessment are recommended. Reports of scoliosis worsening during GH treatment reflect the natural history of this condition rather than a side effect of treatment in most cases, and discontinuation of GH is not indicated.

In view of the childhood findings of low lean body mass and high fat content, osteopenia, and some degree of glucose intolerance ameliorated by GH, the issue of long-term therapy through adulthood must be considered and studied.[1326–1328] After growth is complete, attainment of a normal peak bone mass, continued improvement of muscle mass and strength, reduction of body fat, prevention of cardiovascular morbidity, and improvement in well-being and quality of life are potential benefits of continued GH therapy.[1329] Adult GHD and low IGF1 levels have been reported in patients with PWS.[1282,1330] Short-term GH treatment in GH-naïve adults with PWS has been reported to modestly improve body composition, cognition, motor performance, and social status.[1330] Further long-term studies are needed on adolescents with PWS transitioning to adult therapies.

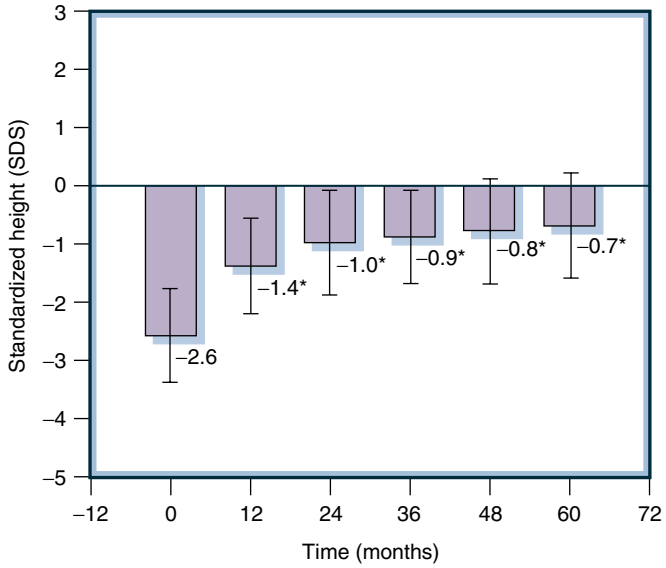
Chronic Renal Disease

Chronic renal disease (CRD) is regarded as an indication for the commencement of GH administration. Short stature is more severe in children with congenital renal disorders than in children with acquired renal diseases.[738,1331,1332] Even after renal transplantation, final height is below the lower limit of normal in about 50% of children.[1333] GH treatment is able to increase height velocity and height SDS[748,1334,1335] and significantly improves final height[1336–1338] in patients with CRD (Figs. 25.51 and 25.52). The therapy should be implemented if short stature persists for longer than 6 months and in subjects with marked deceleration of growth velocity, and it should be continued until transplantation is performed.[1339] Typical growth patterns for the year after GH initiation have been devised. A growth velocity less than –1 SDS for age (in a child without dialysis or transplant) is inadequate and indicates presence of confounding factors that require investigation.[1340]

GH accelerates growth in children with CRD, at least over 5 years of therapy.[1341–1344] Using a GH dosage of 0.05 mg/kg per day, Fine and colleagues[1334] reported a mean first-year growth rate of 10.7 cm in GH recipients and 6.5 cm in the placebo group; in the second year, GH-treated patients had a mean growth rate of 7.8 cm/year compared with 5.5 cm/year in placebo recipients,



• **Fig. 25.51** Annual growth velocity (mean ± standard deviation) in 20 growth-retarded prepubertal patients with chronic renal insufficiency who were treated with growth hormone. (From Fine RN, Kohaut E, Brown D, et al. Long-term treatment of growth retarded children with chronic renal insufficiency with recombinant human growth hormone. *Kidney Int.* 1996;49:781–785. Reproduced with permission of R.N. Fine.)



• **Fig. 25.52** Height standard deviation score (SDS) in 20 growth-retarded prepubertal patients with chronic renal insufficiency (mean ± standard deviation). Note that the basal height is outside the normal range (at –2.6 SDS), enters the normal range within 1 year of treatment initiation, and is not different from the mean by the fifth year of growth hormone therapy. (From Fine RN, Kohaut E, Brown D, et al. Long-term treatment of growth retarded children with chronic renal insufficiency with recombinant human growth hormone. *Kidney Int.* 1996;49:781–785. Reproduced with permission of R.N. Fine.)

resulting in an improvement of height SDS from –2.9 to –1.5. Twenty patients who were treated for 5 years reached a normal height SDS of –0.7, with a mean height increase of 40 cm.[1344] The youngest patients (<2.5 years of age) had the most impressive growth response to GH therapy (14.1 cm/year). Doses recommended in children with CRD are higher than in GHD patients (i.e., about 0.35 mg/kg per week) because growth patterns in these

patients are dose dependent. Deleterious effects on renal function and progression of osteodystrophy were not observed.[1345] This treatment regimen does not adversely affect renal graft function after transplantation, nor is there significant "catch-down" growth after the transplantation.[1346] The final height in 38 German children treated with GH for an average of 5.3 years was –1.6 ± 1.2 SDS, an increment of 1.4 SDS over the pretreatment baseline. The final height of an untreated control group was –2.1 ± 1.2, or 0.6 SDS below baseline.[1337]

More recently, adult heights of 178 French patients treated with GH were reported. Mean adult height was 162.2 cm in men and 152.9 cm in women, and 46% were more than –2 SDS for height. Adult height SDS was correlated with height SDS and spontaneous height velocity before treatment and with the effect of treatment. These adult heights were significantly better when compared with historic cohorts of patients not treated with GH.[1347]

In 2009, a review of longitudinal data from 7189 patients enrolled in the chronic renal insufficiency registry of the North American Pediatric Renal Trials and Collaborative Studies revealed that 827 patients (11.5%) had received GH. A total of 787 children with CRD who were previously naïve to GH treatment and received recombinant human GH for 1 to 4 years (median, 1.5 years) were paired with 787 control patients and monitored for 4 years. The GH-treated group had a significantly greater height velocity SDS than the control group at 2.5 years. Among 220 pairs evaluated at 2 years, the height SDS of the GH-treated group was 0.56 SDS higher than that of the control group (p <0.05). Treatment with GH had no significant impact on BMI or estimated glomerular filtration rate (GFR).[1348]

The magnitude of response to GH treatment depends on the GH dosage. A dose of 0.35 mg/kg per week appears to be optimal for short patients with CRD; half of this dose was less effective, and doubling did not significantly improve the response in double-blind studies.[1342] Long-term GH treatment has also been shown to be safe and effective for extremely short (–4.0 SDS) children with nephropathic cystinosis and should be considered if nutrition and cysteamine treatment do not prevent growth failure.[1332] Because children are often short at the time of renal transplantation, have hormone findings of relative GH insensitivity, and receive chronic prednisone therapy, GH is sometimes administered in the post-transplantation period. Data after 1 and 2 years of treatment of such children and adolescents[1349] indicated a large increment of growth velocity at year 1 and a smaller benefit at year 2. As with GH treatment of CRD, the pharmacologic regimen overcomes the relative GH insensitivity. Individual patients show a wide variation in response, and predictors include age, GFR, need for dialysis treatment, target height, and pretreatment growth rate.[1350]

A mathematic model for prediction of the individual response to GH in prepubertal children with CRD was developed from the KIGS.[11] Thirty-seven percent of the variation in the first-year growth response was explained by this model, with the greatest first-year response in younger children who had no weight reduction, no hereditary renal disorder, and high residual renal function. There was a small GH dose effect during the first treatment year.[11] Such models, using clinical variables, may allow individualized GH treatment decisions in children with CRD.

Considerable assessment must yet be undertaken to demonstrate whether there is increased growth over a longer term, that renal function does not deteriorate during therapy, and that the risk of rejection is not enhanced. GH treatment does not appear to cause an accelerated decline of allograft function[1351–1353] or changes in histopathologic findings.[1354] Use of nonsteroid-based immunosuppressive regimens may obviate the need for post-transplantation GH treatment.

A short-term study in chronic, well-nourished dialysis patients showed that combined administration of moderate doses of GH with recombinant human IGF1 (rhIGF1) had a complementary effect on protein metabolism.[1355] This approach is theoretically reasonable; however, the safety profile of this intervention is unknown.

Juvenile Idiopathic Arthritis

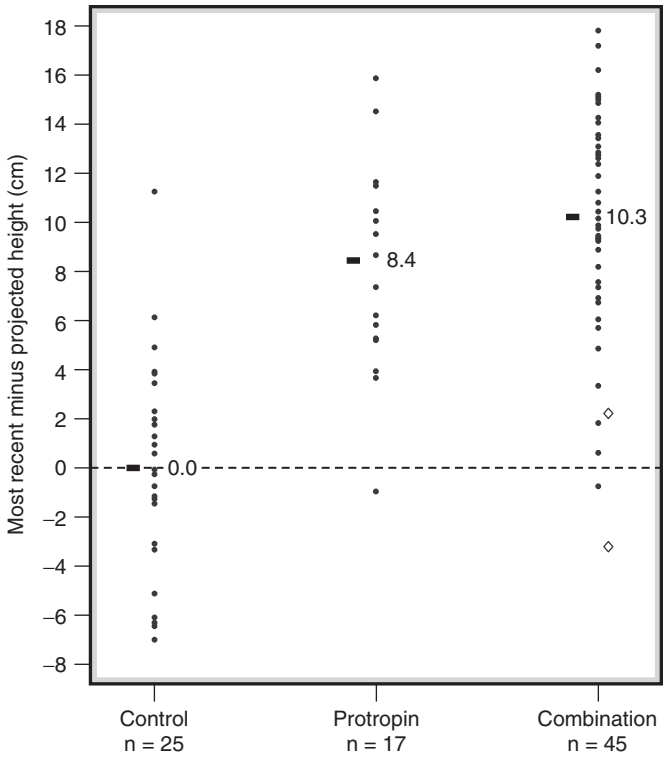
Juvenile idiopathic arthritis (JIA) is often complicated by growth deficiency. The decrease in linear growth usually correlates with the severity of the disease, although catch-up growth may not occur during remissions. The final height is less than –2 SDS in 11% of patients with polyarticular JIA and in 40% of those with systemic JIA.[1356] Serum GH levels are normal or low, usually with low plasma IGF1 levels.[1357] The pathogenesis of short stature is thought to be GH insensitivity associated with both the inflammatory process and glucocorticoid treatment.[1358] Several trials have been conducted to determine whether GH replacement therapy is effective in patients with JIA.[1359–1361] In trials of GH replacement, using GH dosages ranging from 0.1 to 0.46 mg/kg per week increased serum levels of IGF1 and linear growth velocity. However, the trials all had significant interindividual variability.[1362] GH therapy for up to 3 years was notable for a decrease in the loss of growth velocity associated with the active phase of JIA.[1363]

In a randomized, controlled trial of GH therapy (0.33 mg/kg per week for 4 years) in 31 children with JIA, a height increase of 1 SDS was found, compared with a decrease of 0.7 SDS in the untreated control group.[1361] The GH-treated patients had a significantly greater final height compared with untreated control patients (–1.6 ± 0.25 SDS vs. –3.4 ± 2.0 SDS; p <0.001).[1364] As expected, the severity of inflammation negatively affected the efficacy of GH therapy.[1361,1364] In a randomized trial of normal-height children with JIA treated with high-dose GH therapy (0.46 mg/kg per week) starting within 12 to 15 months after initiation of glucocorticoid therapy, the 3-year follow-up showed that the heights of GH-treated children remained normal (–1.1 SDS at baseline and –0.3 SDS after 3 years) while linear growth of the control patients declined from –1.0 SDS to –2.1 SDS.[1359] In the randomized, controlled trials published to date, patients were followed for up to 7 years, and no substantial differences were found in disease activity variables, including worsening of preexisting bone deformities, between GH-treated and control patients.[1358,1360,1361,1363]

In a longitudinal study of patients treated for a mean of greater than 5 years, GH increased and normalized final height and improved bone and muscle mass.[1365] Because chronic inflammation, glucocorticoid treatment, and GH therapy are all associated with decreased sensitivity to insulin, children with JIA are at risk for impaired glucose homeostasis.[328,1362,1366] Therefore monitoring of glucose tolerance using blood glucose, fasting insulin, and HbA_{1c} assays at intervals of 6 to 12 months is recommended. More intensive monitoring with oral glucose tolerance tests at baseline and then once yearly during treatment may be indicated.

Turner Syndrome

Patients with TS have a final height averaging 143 cm in the United States,[11,907] about 20 cm lower than the mean final height of normal women.[905] The goals of growth-promoting therapies are to attain



• **Fig. 25.53** Adult heights of patients with Turner syndrome treated with growth hormone (GH) or with a combination of GH plus oxandrolone and of historic control subjects, relative to each subject's projected adult height (indicated by the *dotted zero line*). The mean increments in relative adult height are indicated. The *diamonds* in the combination group indicate two subjects with poor compliance who terminated treatment early. (From Rosenfeld RG, Attie KM, Frane J, et al. Growth hormone therapy of Turner syndrome: beneficial effect on adult height. *J Pediatr.* 1998;132:319–324.)

a normal height for age as early as possible, to progress through puberty at a normal age, and to attain a normal adult height. A delay in diagnosis of TS is often the greatest obstacle for girls with TS to obtain a normal height. A 7-year delay in diagnosis was reported in one study in patients who averaged 2.9 SD below the mean in height and were below the 5th percentile for height for an average of 5.3 years.[1367] Growth should be assessed frequently after the diagnosis is made and plotted using TS-specific growth charts to monitor for associated growth issues and effectiveness of therapy.[11,912,1368]

Before the availability of recombinant GH, there were conflicting data concerning its efficacy in this disorder, but the ability of GH to accelerate growth has now been demonstrated in multiple reports. Growth responses are not affected by the karyotype. In 1983, a randomized, controlled North American study of treatment with GH (at a dose of 0.375 mg/kg per week) with or without added oxandrolone was initiated, with a mean age at onset of treatment of approximately 9 years.[1369] Analysis of all 62 girls enrolled in the study at near-final height showed a mean stature of 152.1 cm in the group treated with GH plus oxandrolone (a gain of 10.3 cm compared with the height predictions derived from Lyon and colleagues),[11] whereas girls receiving GH alone averaged 150.4 cm (a gain of 8.4 cm) (Fig. 25.53).[907] In another arm of this study, addition of estrogen to the GH regimen before age 15 years lowered the final height gain from 8.4 cm to 5.1 cm.[1370] In a reassessment of North American data in the NCGS, early initiation of GH treatment was shown to allow estrogen administration at a physiologic age without loss of adult height.[1371,1372]

Several other studies[917,1373] using higher doses of GH showed even greater gains in adult height outcomes. In a multicenter trial, Sas and coworkers used a maximum GH dose of approximately 0.63 mg/kg per week for 4.8 estrogen-free GH treatment years beginning at a mean age of 8.1 years, resulting in a gain of 16 cm over the modified Lyon and colleagues' projection.[11,917] In the same study, the group receiving a GH dose similar to that in the American studies achieved a height gain of 12.5 cm by age 16 with 4.8 estrogen-free GH treatment years starting at 7.9 years. In these girls, induction of puberty at a normal (not delayed) age was associated with these excellent height outcomes.[1374] Carel and colleagues,[1373] using 0.7 mg/kg per week in a group that received 5.1 estrogen-free GH treatment years beginning at 10.2 years, gained 10.6 cm over the projections of Lyon and colleagues.[11] The group receiving a conventional dose (0.3 mg/kg per week) gained only 5.2 cm with 3.0 estrogen-free GH treatment years starting at 11 years. Because girls with TS usually have a normal GH secretory pattern, provocative GH testing should be performed only in those whose growth is clearly abnormal relative to that expected for patients with TS, as determined by plotting lengths and heights on TS-specific growth curves.[11,910,914,1375]

Although it was well established that GH therapy was effective in increasing final adult height, the magnitude of the gain in height varied in the earlier studies, depending on study design and treatment parameters. In 2005, in the first randomized, controlled trial to follow GH-treated subjects with TS to final height, the Canadian Growth Hormone Advisory Committee corroborated the increases in adult stature reported by studies with historic control subjects.[907,1374,1376,1377] In the Canadian study, girls with TS (age 7–13 years) who were randomized to receive GH (0.3 mg/kg per week; maximum weekly dose, 15 mg) achieved a final adult stature 7.2 cm taller than that seen in the control group after an average of 5.7 years. Factors predictive of taller adult stature include a relatively tall height at initiation of therapy, tall parental heights, young age at initiation of therapy, a long duration of therapy, and a high GH dose.[917,1372,1378,1379]

Although the optimal age for initiation of GH treatment has not been established, preliminary data from the Toddler Turner Study, in which 88 girls between the ages of 9 months and 4 years were randomized to receive GH or no GH therapy, showed that GH therapy is effective beginning as early as 9 months, with a safety profile similar to that in older children with TS.[1380] Treatment with GH should be considered as soon as growth failure is evident. GH therapy in the United States is typically initiated at the FDA-approved dose of 0.375 mg/kg per week. The dose can be changed in response to the patient's growth response and IGF1 levels. Growth prediction models may be helpful in determining the potential effects of changes in dosing.[1378]

Studies have shown that higher doses produce a relatively small gain in final height, although there is no apparent increase in short-term adverse events.[1381] In a study by the Dutch Working Group, the mean gain in final height with 4 IU/m^2 per day (0.045 mg/kg per day), 6 IU/m^2 per day, and 8 IU/m^2 per day averaged 11.9 ± 3.6, 15.7 ± 3.5, and 16.9 ± 5.2 cm, respectively.[1374] However, when GH was given at the higher doses, IGF1 levels were often above the normal range, which theoretically could lead to long-term adverse effects.[1382]

In girls naïve to GH who are older than 9 years of age and in those with extreme short stature, consideration can be given to using higher doses of GH and adding a nonaromatizable anabolic steroid, such as oxandrolone.[907] The maximum suggested dose of oxandrolone is 0.05 mg/kg per day, because higher doses

have been associated with virilization and accelerated skeletal maturation. Liver enzymes should be monitored. Therapy may be continued until a satisfactory height has been attained (bone age >14 years) or until the yearly growth velocity falls to less than 2 cm/year. The children should be monitored at intervals of 3 to 6 months.[1383]

The substantial variations in GH-induced growth increments in these studies were presumably related to GH dose, duration of estrogen-free GH treatment years, and age at initiation of GH and estrogen administration, as well as the population and parental adult heights. Additionally, the *GHRd3* polymorphism has been reported to be associated with increased responsivity to GH in girls with TS.[1384] Transdermal or depot estrogen administration, as opposed to oral estrogen, may also contribute positively to growth outcomes.[1385,1386] In these higher-dose treatment studies, hyperinsulinism with presumed insulin resistance was evident but reversible.[1373,1387] Other data suggest that impaired insulin secretion may ultimately be the significant issue in patients with TS,[1388,1389] although long-term GH therapy has been well tolerated.

None of these studies were placebo-controlled to adult height, and some studies have yielded much poorer height outcomes,[918] so some uncertainty existed until the randomized, controlled, multicentered Canadian study, in which the mean height gain ascribed to GH treatment was 7.3 cm at 1 year after cessation of the treatment protocol. Estrogen was initiated at 13 years of age.[1376] Another temporally matched control study from Italy showed a gain of 8.1 cm.[1377] These studies corroborated and supported the information that had accumulated from historic data on natural growth in TS juxtaposed to the available GH treatment results. Such data, in aggregate, provides convincing support that GH can both accelerate growth velocity and increase adult height.

Recommendations include seeking the diagnosis vigorously at any age in every girl with otherwise unexplained short stature and initiating therapy at that young age (i.e., at diagnosis or in early childhood). One must bear in mind that growth velocity in girls with untreated TS can be slowed as early as ages 1 to 3 years old.[911,913] Treatment with the FDA-approved GH dosage of 0.375 mg/kg per week should be initiated, and compliance should be monitored with auxologic and IGF1 measurements; continued normal thyroid status should be assured. In overweight girls, the use of body weight for calculating dosage may result in the delivery of excess GH. Adult height was compared in two Dutch trials that used BSA-based dosing and five Swedish trials that used body weight (BW)–based dosing,[1390] finding that adult height was greater in girls treated with BSA-based dosage versus those using a BW-based dosing. A dose 0.375 mg GH/kg per week is approximately equivalent to 1.38 mg GH/m^2 per day.

Oxandrolone may be added to the regimen in the late-diagnosed girl. Initiation of estrogen therapy at 12 years of age, rather than at age 14 years and above, has recently been shown to improve adult height.[1374,1386]

A 2011 randomized, placebo-controlled study (double placebo, estrogen alone, GH alone, or GH and estrogen) that followed girls ages 5 to 12.5 to adult height showed that very low-dose ethinyl estradiol given prior to age 12 years, along with growth hormone treatment, had the greatest impact on increasing adult height.

The diminished areal bone density in TS is enhanced by GH, but estrogen therapy is needed to normalize volumetric density (i.e., not simply size).[1391] Absence of an adverse impact of GH on aortic diameters is reassuring, given the predisposition of such patients for dissecting aneurysms.[543] Use of statistical prediction models for long-term growth in TS may permit a more quantitative assessment of individual therapeutic efficacy.[1378]

Despite evidence for aggressive GH treatment of girls with TS to achieve adequate adult heights and relatively high quality-of-life assessments in adulthood,[1392,1393] health-related issues continue to imperil outcomes. Carel and colleagues[1394] reviewed health outcomes of 568 adult French women (in their mid-20s) with GH-treated TS who had a mean height of 150.9 cm (having gained about 9 cm over prediction) and found that neither height nor height gain was associated with quality-of-life scores. Rather, issues regarding cardiologic and otologic health concerns and delay of pubertal initiation beyond 15 years were of greater concern. In contrast, a long-term follow-up assessment of 49 women from the Netherlands who had reached a mean adult height of 160.7 cm (a gain of >15 cm), suggested that the high quality-of-life scores were related to height gain and adequate estrogenization.[1395]

The NCGS recently published data on the efficacy and safety of GH therapy in 5220 children with TS treated during the past 20 years. A total of 442 adverse events were reported for these patients, including 117 that were considered serious. Seven deaths occurred, including five from aortic dissection or rupture. The incidences of intracranial hypertension, slipped capital femoral epiphysis, scoliosis, and pancreatitis were increased compared with other patients in the registry who did not have TS. Ten new-onset malignancies occurred, including six in patients without known risk factors. The number of patients who developed IDDM also appeared to be increased. It is believed that these adverse events are likely to be unrelated to treatment with GH. The incidence of aortic dissection or rupture reflects the higher baseline risk in TS.[1396]

Two echocardiography studies reported normal left ventricular morphology and function in girls with GH-treated TS,[1397,1398] and two MRI studies found no deleterious effect of GH treatment on aortic diameter.[532,1383,1399,1400] Because GH treatment can alter craniofacial proportions, all girls with TS treated with GH should receive periodic orthodontic follow-up.[1401] These studies were not controlled, but their findings emphasize the broad range of health concerns in women with TS and affirm the need for multidisciplinary follow-up care.

Recommendations:

1. Early diagnosis and initiation of treatment.
2. GH therapy offered to all girls with TS with a subnormal predicted adult height.
3. Provocative testing of GH secretory status is not required since GH secretion is not impaired.
4. GH treatment at higher dosing than used for GH-deficient patients and the GH dose should be titrated to increase growth velocity. A GH dose of up to 67 mcg/kg per day has been approved by the USFDA, although this dose is higher than usually prescribed.
5. Initiate GH therapy at an earlier age, once decreasing height percentiles on the normal growth curve are noted (the current average age is around 9 years), since a longer time on therapy will result in improved adult height.
6. Therapy should be continued until an appropriate adult height is attained or the growth rate falls below 2 to 2.5 cm per year.
7. Early treatment with ultralow-dose estrogen may improve growth. Pubertal estradiol should begin at approximately 12 years of age. Oxandrolone at a dose of approximately 0.03 mg/kg per week may be considered in girls older than 8 years.

Small for Gestational Age

Studies using GH in short children born SGA have been hampered by the heterogeneity of this group of patients, whose poor

growth may reflect maternal factors, chromosomal disorders, dysmorphic syndromes (e.g., RSS, Dubowitz syndrome), toxins, and idiopathic factors.[1402] A 2001 consensus statement recommended that SGA be defined as a birth weight or length at least 2 SD below the mean.[1403] Almost 90% of infants born SGA undergo catch-up growth within the first 2 years of life, and those who do not would then be eligible for GH treatment.[37,38,947,989,1402,1404,1405] Based on these proportions, and because the prevalence of "short SGA" is 2 to 3 per 1000 children, between 1 in 300 and 1 in 500 children are eligible for GH treatment, as approved in the United States in 2001 and in Europe in 2003. It appears that GH mediates the postnatal catch-up growth.[1406] Children born SGA appear to grow at a low-normal growth velocity during childhood,[1407] but puberty tends to occur at a somewhat earlier age and to progress rapidly, resulting in decreased pubertal height gain and an adult height about 1 SD (~7 cm) below the mean[38,987,989,1408–1411] and about 4 cm below the midparental target height.[947]

The impaired postnatal growth observed in children born SGA is probably due to many factors, including generalized cellular hypoplasia,[1412] altered diurnal GH secretion patterns,[237,969,971,1407,1413] and, potentially, abnormalities in the GH-IGF axis resulting from GH sensitivity as determined by the presence or absence of exon 3 of the GHR.[1414–1416] Deletions and mutations of the *IGF1* gene have been reported in patients with profound IUGR, microcephaly, deafness, and postnatal growth failure.[974,660,1417] SGA patients have also been reported to have *IGF1* gene polymorphisms or missense mutations resulting in low serum IGF1 concentrations.[975,976,989,1416,1418,1419] Reduced levels of IGF2 expression, associated with hypomethylation of the telomeric domain of chromosome 11p15, were found in a cohort of SGA patients who had RSS.[993] Mutations in the type I IGF receptor gene (one compound heterozygous, one nonsense) were found in two patients with IUGR and poor postnatal growth (one with elevated IGF1).[663]

The low levels of IGF1 and IGFBP3 in many infants with IUGR, apparently related to fetal malnutrition, do not seem to predict the degree of subsequent growth impairment,[968] although continuing low levels are associated with poor catch-up growth.[1420] Short children born SGA make up a substantial portion of growth-retarded patients seen in pediatric endocrine practices.[947,989,1421] Because these children may have heights in the range seen in IGF deficiency syndrome, therapeutic attempts are appropriate, assuming that the insulin resistance noted in these thin, small children[982] does not become a clinical issue. Encouraging growth responses have been obtained with GH treatment.

The FDA approval of GH for the long-term treatment of growth failure in children born SGA who fail to manifest catch-up growth by age 2 was based on data obtained from four randomized, controlled, open-label, clinical trials that enrolled 209 patients between the ages of 2 and 8 years. Height velocity was determined after 1 year without treatment, and then patients were randomized to receive either GH treatment (34 or 69 mg/kg per day [0.24 or 0.48 mg/kg per week]) or no treatment for 2 years, after which a crossover design occurred. Children who received the higher GH dose had an increase of about 0.5 SDS in height after 2 years, compared with the children who received the lower dose, although both treated groups had significant increases in height velocity compared with untreated children (prescribing information for Genotropin somatropin of recombinant DNA origin for injection, Pfizer, Inc., New York, 2006). In Europe, the criteria for treatment differ from those in the United States: height SDS below –2.5, height velocity SDS below 0 during the previous year, and age greater than 4 years.

The data documenting efficacy in regard to adult height continues to be limited despite European regulatory authorities' requiring this evidence before approval. A meta-analysis of final height data for 56 children born SGA was performed at the request of European authorities and demonstrated a mean height increase of 1.9 SDS for subjects treated with GH at 34 mg/kg per day versus 2.2 SDS for 69 mg/kg per day. A meta-analysis of three randomized studies of 28 patients reported that GH treatment for 7 to 10 years, initiated at doses of 34 to 69 mg/kg per day, can be expected to increase adult height by about 1.0 to 1.4 SDS.[1422] A larger, randomized, controlled study of 91 GH-treated and 33 untreated French adolescents (mean age, 12 years) reported a lower intergroup difference of 0.6 SDS in adult height after 2.7 years of treatment.[1423]

The many studies documenting efficacy of GH therapy in thousands of children with SGA are far too numerous to report in detail here and have been reviewed elsewhere.[1422,1424,1425] Although results vary, it appears that GH treatment can be expected to result in a 1-cm increment in height gain each year. The factors that can increase the gain in height include a greater height deficit relative to the midparental height, a higher GH dose, initiation of therapy at an earlier age, longer treatment duration, and the proposed presence of the *GHRd3* allele.[1384,1403,1424,1426] The addition of a GnRH analogue was shown to improve adult height in a select group of children born SGA.[1427] In a prediction model derived from KIGS SGA data, Ranke and coworkers[1426] found that age and GH dose were strong predictors of initial growth but that growth achieved during the first year was a powerful predictor of later growth. Although from these studies it appears that relatively high doses may be required for the growth response (the FDA-approved dose is 70 μg/kg per day), initial GH dosing at 35 to 50 μg/kg per day is reasonable since the response in individual patients is highly variable. The dose may be increased if the growth rate is insufficient.

Routine measurement of serum IGF1 has been recommended for patients receiving GH as a safety marker; the rationale being that elevated levels of IGF1 may result in an increased risk of side effects and potential for future malignancy.[1199,1428,1429] However, there is no documented evidence of such a link, and some children with SGA may have evidence of IGF1 resistance, requiring higher serum IGF1 levels to optimize growth.[1430] Further, using IGF1 levels to inform GH dosing has been shown to be less efficacious than standard dosing.[1431] This is likely due to the wide range of "normal" IGF1 levels in children and that serum IGF1 levels are relatively poor indicators of IGF1 sensitivity.

Children born SGA, especially those who have rapid postnatal weight gain, have reduced insulin-mediated glucose uptake and are more likely to have insulin resistance.[982,1432–1437] However, there have been no solid data documenting an increased risk of non-IDDM.[1436] There have been reports of several children in GH registration studies who had mild, transient hyperglycemia (prescribing information for Genotropin somatropin of recombinant DNA origin for injection, Pfizer, Inc., New York, 2006). Insulin resistance during GH treatment in children born SGA has been reported[1381,1438,1439] and typically resolves after discontinuation of GH.[1440] In a large database of children treated with GH, no differences in glucose regulation were found in 1900 children born SGA compared with children with ISS.[1441] With 6000 patient-years of exposure, no cases of diabetes mellitus have been reported during GH treatment.[1441–1444]

The European product labeling for GH treatment of children born SGA reads, "The management of these patients should follow accepted clinical practice and include safety monitoring of fasting

insulin and blood glucose before treatment and annually during treatment."[1425] Since GH treatment of children who are SGA reduces insulin sensitivity but only rarely causes glucose intolerance, and insulin resistance returns to normal following cessation of GH therapy, there is currently no indication to routinely monitor metabolic parameters.[1445,1446] In addition to insulin resistance alone, children born SGA have an increased risk of metabolic syndrome.[1443,1447–1449] The current literature provides no information on whether GH treatment in childhood increases risks for adult metabolic disease. Long-term follow-up studies are needed to determine the metabolic risk associated with GH treatment.

Osteochondrodysplasias

GH therapy has been studied in several skeletal dysplasias. The largest published study in achondroplasia involved 40 children; during the first year of treatment, the height velocity increased from 3.8 to 6.6 cm per year, and in the second year it decreased to approximately 5 cm per year.[1450] A modest improvement was seen in the ratio of lower limb length to height. Although GH was well tolerated, atlantoaxial dislocation during GH therapy was reported in one patient. In another study, normal growth velocity was achieved for up to 6 years in 35 subjects, with a significant increment in height SDS for at least 4 years[1450,1451]; in that study, vertebral growth was disproportionately greater than limb growth.

Bridges and Brook[1452] reported on the effects of GH therapy in 27 patients with hypochondroplasia; response was maximal during the first year of treatment, but substantial benefit was seen through 4 years of treatment in pubertal subjects.

Experience with GH treatment is limited in other skeletal disorders, such as dyschondrosteosis, hereditary multiple exostoses, osteogenesis imperfecta, and Ellis–van Creveld syndrome.

SHOX Haploinsufficiency and Léri-Weill Syndrome. Patients with mutations or deletions of the *SHOX* gene have variable degrees of short stature with or without mesomelic skeletal dysplasia. If untreated, short patients with SHOX deficiency remain short in adulthood. The *SHOX* gene is located in the pseudoautosomal region 1 (PAR1) on the distal end of the X and Y chromosomes at Xp22.3 and Yp11.3.[1453] Because genes in PAR1 do not undergo X inactivation, normal individuals express two copies of the *SHOX* gene. This gene encodes a homeodomain transcription factor that is expressed during early fetal life in the growth plate and functions in the regulation of chondrocyte differentiation and proliferation.[895,1454] SHOX haploinsufficiency (or deficiency) is the primary cause of short stature in patients with LWD (see earlier discussion).[941,1455] *SHOX* mutations and deletions are also found in patients with short stature without clinical evidence of dyschondrosteosis.[1456]

Clinical manifestations of SHOX deficiency include bowing of the forearms and lower legs, cubitus valgus, Madelung deformity or partial dislocation of the ulna at the wrist and elbow, short fourth and fifth metacarpals, and a high-arched palate along with characteristic radiologic signs.[894,941,1455] In a randomized 2-year study of 52 prepubertal subjects with a *SHOX* gene defect, the first-year height velocity in the GH-treated group was significantly greater than in the untreated control group (mean ± standard error of the mean [SE], 8.7 ± 0.3 vs. 5.2 ± 0.2 cm/year; $p < 0.001$) and was similar to the first-year height velocity to GH-treated subjects with TS (8.9 ± 0.4 cm/year; $p < 0.592$). GH-treated subjects with SHOX deficiency also had significantly greater second-year height velocity (7.3 ± 0.2 vs. 5.4 ± 0.2 cm/year; $p < 0.001$), second-year height SDS (–2.1 ± 0.2 vs. –3.0 ± 0.2; $p < 0.001$), and second-year height gain (16.4 ± 0.4 vs. 10.5 ± 0.4 cm; $p < 0.001$) compared with untreated subjects.[1457] Data on 28 persons with SHOX deficiency who received GH for a mean of 4.5 years through to adult height indicate that adjusted final height was –2.1 SDS, similar to girls with TS enrolled in the study. Calculated height SDS gain was 1.3, again similar to girls with TS.[1458]

Turner Syndrome and Langer Mesomelic Dysplasia. Homozygous mutation of the *SHOX* gene results in the Langer type of mesomelic dwarfism (i.e., LMD). A child with LMD and TS was found to have a *SHOX* gene abnormality resulting from a downstream allele deletion in her normal X chromosome. Although there have been numerous studies documenting growth improvement with GH therapy in patients with TS[907,1373,1396] and in those with heterozygous *SHOX* gene deletions,[1455] only one case of growth response to GH therapy in the rare condition of LMD with TS has been found. Growth rates of 3.46, 3.87, 2.3, and 0.7 cm per year were observed in the first, second, third, and fourth years of GH therapy, respectively, and there was no clinical deterioration of the skeletal deformities in this patient. Because there was a failure to achieve growth improvement with GH therapy, the authors concluded that GH therapy was not beneficial in patients with the severe short stature caused by combined TS and LMD resulting from homozygous *SHOX* deficiency.[1459]

Noonan Syndrome

Since 1994, when a gene for Noonan syndrome was mapped to chromosome 12 (12q24.1) and a mutation in the protein tyrosine phosphatase nonreceptor type 11 *(PTPN11)* was identified and characterized in familial cases, at least three other gene mutations have been identified.[922,923,1460–1463] While contributing to the broad heterogeneity of NS, these mutations have not completely localized the cause of the short stature. However, several genotype-phenotype correlations are relevant to patient management. Patients with *PTPN11* mutations often have normal or elevated GH levels and low serum IGF1 concentrations.[928] The *PTPN11* genetically modified mouse model had a GH-stimulated increase in ERK activation, and growth was stimulated by inhibition of ERK1/2.[1464] Several studies have reported effects of GH on near-adult height in patients with Noonan syndrome,[1465–1469] but all involved small numbers of patients with varied enrollment ages, treatment durations, GH doses, and responses. The largest study of the response to GH in children with Noonan syndrome came from the NCGS, a postmarketing observational study of recombinant human GH treatment in children with various disorders. A total of 370 patients with Noonan syndrome (mean enrollment age, 11.6 years) received GH (mean dosage, 0.33 mg/kg per week) for a mean of 5.6 years. In the 65 patients with data to derive near-adult height, the mean gain above the projected height was 10.9 ± 4.9 cm in boys and 9.2 ± 4.0 cm in girls. Duration of prepubertal recombinant human GH therapy and height SDS at puberty were important contributors to the near-adult height. No new adverse events were observed. The authors suggested that greater growth optimization would be possible with earlier initiation of therapy.[1470] This height increase was similar to the change observed in patients with TS but significantly less in those with idiopathic GHD in the same study.

Most experience with GH treatment of short stature in Noonan syndrome has been limited to small, uncontrolled studies in which few patients reached final height.[920,1471,1472] The clinical diagnosis of a dysmorphic syndrome potentially makes the treatment groups heterogeneous, although identification of a mutant *PTNN11* gene[1473] helps with characterization. Overall, treatment results for 3 to 4 years are similar to those attained in patients with TS; mean

growth velocities improve by 2 to 4 cm per year (over baseline rates of ~4 cm/year) during the first 4 years of therapy, with patients gaining from about –3.5 to –1.7 SDS of stature without inordinate advancement of bone age.[919,920,929,1472] Those children with identifiable *PTPN11* mutations are reported to have a poorer response to GH treatment in terms of growth and IGF production, suggesting impaired efficiency of phosphorylation-dependent GH signaling pathways.[927–929] Although the initial anecdotal experience suggested progression of ventricular hypertrophic cardiomyopathy, this was not confirmed in larger, carefully monitored studies.[920,1474,1475] However, it has been suggested that children with Noonan syndrome receiving GH be monitored for hypertrophic cardiomyopathy and hematologic abnormalities.[921] Although neoplasia is a theoretic concern, there are no studies associating GH therapy with malignancy. A recent report of brain tumor growth after several years of GH therapy[1476] suggests caution when treating with GH.

Idiopathic Short Stature (Subtle Errors Throughout the Growth Axis)

Although children with ISS, by definition, are without an identifiable cause of growth retardation, the term clearly encompasses a heterogeneous group that may include children with constitutional growth delay, genetic short stature, or subtle defects of the GH-IGF axis. Even though they are often grouped in one category, children with ISS have been shown to have a broad range of provocative GH responses, ranging from normal to elevated, and a wide range of serum IGF concentrations, from normal to IGF deficient. This group may also include children with unidentified syndromes or unidentified chronic illnesses or endocrine disorders. Children with ISS may experience stressful behavioral circumstances, but studies suggest that the relationship of psychosocial problems to the short stature is variable.[1477–1479] Nonetheless, hormonal intervention to enhance growth, with the aim of diminishing such difficulties, has been used.

Although the specific etiologies are often unknown, GH treatment has been used widely. Important questions have been raised about the financial, ethical, and psychosocial impact of GH therapy in "normal" short children.[1474,1480,1481] Given the cost of GH, the financial implications of treating such children are considerable. The point is well taken that 5% of the population will always be below the 5th percentile, whether we treat with GH or not, and that focusing on short stature could potentially handicap an otherwise normal child psychologically and socially. No convincing data have been presented to show that GH treatment of short children definitively improves psychologic, social, or educational function.[1481–1483] A possible exception is the improved intellectual function in SGA children treated with GH.[1484] Furthermore, final adult height in the subset of children with CDGD (probably a common inclusion, although not ISS as defined in the FDA approval) may be adequate without any treatment.[41–43]

Finally, the known and unknown treatment risks of GH therapy in otherwise apparently normal children, even if exceedingly small, are a legitimate concern.[1485] The failure to report levels of IGF1, IGFBP3, and GHBP in many studies and differing interpretations of endogenous GH secretion studies (e.g., assay variance, control group size), as well as the heterogeneity of the patient groups, confounds assessment of response data. Nevertheless, it is clear that many children who do not meet conventional criteria for the diagnosis of GHD and who fall under the heading of ISS have as great a degree of growth retardation as children with bona fide GHD and might be considered suitable candidates for growth-promoting therapy.

Members of the Growth Hormone Research Society, the Lawson Wilkins Pediatric Endocrine Society, and the European Society for Pediatric Endocrinology meeting in 2007 published a manuscript detailing their agreement on the evidence-based evaluation and management of ISS in children. They agreed that the primary goal of therapy should be the attainment of normal adult height. They also agreed that the expectation from patients and their families that taller stature is associated with positive changes in quality of life should be discouraged.[1480] Physicians should inform families about the available therapeutic options and provide a realistic expectation for height gain with therapy, including the fact that there may be variability in the outcome, and the psychologic counseling options should be discussed. In addition, the patient and family should be aware that therapy may be discontinued if the growth response is poor or if the child no longer provides assent. The physician is responsible for continued monitoring of efficacy and safety and should provide flexibility in treatment options.

The studies that ultimately led to approval of GH treatment in the United States included the long-term, randomized, double-blind, placebo-controlled trial at the National Institutes of Health by Leschek and associates[1178] and the randomized dosing trial of the European Idiopathic Short Stature Study Group.[1486] In the former trial, which used a less optimal regimen of 0.22 mg/kg per week given thrice weekly in subjects with a mean starting height of almost –3 SDS, the treated children had mean final height gain of 3.7 cm over the control group.[1178] In the latter randomized study, GH doses of 0.24 and 0.37 mg/kg per week, given as a regimen of six doses per week in children with a mean starting height of –3.0 to –3.4 SDS, the improvement in the higher-dose group exceeded that in the lower-dose group by 3.6 cm, with subjects achieving a final height of –1.12 SDS.[1486] When the data from the two trials were combined, there was a cumulative gain of 7.3 cm in the group treated with 0.37 mg/kg per week, compared with placebo.

In a meta-analysis looking at an aggregate group of 1089 children, there were four controlled trials that presented adult height data showing treatment benefits ranging from 0.54 to 0.84 SDS, corresponding to a mean effect on growth of 5 to 6 cm.[1487]

Concerns had been raised that GH treatment might accelerate pubertal onset and progression in children with ISS, resulting in failure to improve height SDS for bone age and offsetting the positive responses observed during the early years of GH treatment. In the European ISS study,[1488] there was no evidence of accelerated pubertal or skeletal maturation in the group receiving the higher dose, in contrast to data reported by Kamp and colleagues[1489] with a 30% greater GH dose. This hypothetical effect of advancing maturation has not been substantiated by additional studies.[1490–1493] Taken together, these data show that GH treatment of prepubertal children with ISS increases growth velocity and final height.

The auxologic criteria for GH therapy in the United States are based on FDA approval of GH treatment for children shorter than –2.25 SDS (1.2 percentile). Some believe that children should be treated if their height is below –2.0 SDS and more than 2.0 SDS below their midparental target height or if their predicted height is below –2.0 SDS (or both). Although there is no consensus on the age for initiating treatment, most studies of GH therapy in children with ISS have involved children from 5 years to early puberty. There are no accepted biochemical criteria for initiating GH treatment in ISS. The bone age is used to predict adult height, although in a longitudinal study of ISS subjects, bone age delay had an effect on the precision of the prediction. In children with

a bone age delay of about 2 years, the average adult height was almost equal to the predicted height; in children with no bone age delay, the adult height was greater than the initial predicted height; and if the bone age was delayed by more than 2 years, the adult height was significantly below the predicted adult height.[1494] The psychologic benefits of GH therapy in children with ISS are unproved,[1495] but medical and psychologic interventions should be considered for the child who seems to suffer from his or her short stature.

The clinical trials of the treatment of ISS with GH in the literature often did not contain long-term control groups, hence the results show variable growth responses.[1485,1496] Most short children treated with GH experience growth acceleration that is usually sustained over the first several years of therapy, with attenuation of the treatment response over time. In general, a slower pretreatment growth velocity and a higher weight-to-height ratio—factors suggestive of GHD and, to a lesser degree, bone age retardation—are associated with better early growth responses. Three thousand children were classified as having ISS in the KIGS database, with 153 having reached final height.[1491] GH treatment (0.2–0.25 mg/kg per week) resulted in achievement of target height in patients with familial short stature, although they continued to have short stature as adults (–1.7 SDS in males and –2.2 SDS in females), with a mean gain during therapy of 0.6 to 0.9 SDS. In children who did not have familial short stature, the mean final height was greater for males (–1.4 SDS), although not for females (–2.3 SDS), with average gains of 1.3 and 0.9 SDS, respectively. These attained heights were quite different from the midparental target heights, which were near 0 SDS. Hintz and colleagues[1177] assessed adult height in 80 North American children with ISS who were treated for up to 10 years at a GH dose of 0.3 mg/kg per week. At the conclusion of the study, the mean height SDS was –1.4 SDS with a gain of 1.3 SDS, results quite similar to those from the KIGS database. Although the Hintz study was not placebo controlled, the data were compared with predicted and actual final heights in two groups of untreated short children followed for similar periods. Compared to untreated children, treated boys achieved a mean of 9.2 cm and girls 5.7 cm stature above predicted heights.

Several additional studies have documented the increase in final height with GH therapy in children with ISS, although the responses have been highly variable and dose dependent. The mean increase in adult height in children with ISS is 3.5 to 7.5 cm (with an average duration of therapy of 4–7 years) when compared with historic control subjects,[1177,1497] with patients' pretreatment predicted adult heights, or with nontreatment or placebo control groups.[1178,1487] Multiple factors affect the growth response to GH, and the best response is seen in children who are younger or heavier, those receiving higher GH doses, and those who are shortest relative to their target height. Adult height outcome is influenced negatively by age at initiation of therapy and positively by midparental height, initial height, delayed bone age, and the magnitude of the first-year response to GH.[1498,1494] A 2-year study suggested that an increase in IGF1 correlates with height gain.[1178] Recently, a review of the literature on ISS was published, concluding that GH therapy increases height in some children; however, the cost-benefit ratio and long-term safety are concerning.[1499]

Studies using monotherapy with GnRH agonists have shown only a small and variable effect on final adult height, so GnRH agonist therapy is not recommended. Furthermore, GnRH agonists have been shown to have short-term adverse effects on BMD.[1500] However, combination therapy with a GnRH agonist and GH has potential value in increasing final height, but only with treatment lasting at least 3 years.[1501,1502] However, in a randomized study, children treated with a combination of GnRH agonist and GH and control subjects had no difference in adult height.[1502] A recent meta-analysis of eight selected studies showed a significant difference in adult height and predicted adult height comparing GnRHa and GnRHa/GH groups, but there was no significant difference in final height SDS and initial height SDS between the groups. The results suggest adding GH to GnRHa therapy may increase adult height in girls with early puberty. The study was limited by the small number of studies, its focus on early puberty in girls, and was not stratified to assess associations between patient age and predicted adult height at initiation of therapy and adult height.[1503]

Monitoring of GH treatment should include height, weight, pubertal development, and adverse effects (scoliosis, tonsillar hypertrophy, papilledema, and slipped capital femoral epiphysis) two to three times per year. After 1 year of therapy, the height velocity SDS and the change in height SDS should be calculated. The bone age may be obtained to reassess height prediction and if one is considering intervention to delay puberty. IGF1 levels may be helpful in guiding GH dose adjustment. Because elevated blood glucose levels in patients with GH-treated ISS have not been reported, routine monitoring of glucose metabolism is not advised.

The FDA-approved dose for GH in ISS is 0.3 to 0.37 mg/kg per week.[1504] The dose may be increased if the growth response is inadequate and compliance was assured. However, there are no data regarding the long-term safety of GH doses higher than 0.5 mg/kg per week in children with ISS. IGF1 levels may be helpful in assessing compliance and GH sensitivity. IGF1 levels that are elevated (>2.5 SDS) should prompt consideration of GH dose reduction. IGF-based dose adjustments in children with ISS increased short-term growth when higher IGF targets were selected, but long-term studies with respect to efficacy, safety, and cost effectiveness have not been done.[1489] If the growth rate continues to be inadequate, GH treatment should be stopped and alternative therapies considered. The duration of treatment is controversial, with consideration given for stopping treatment when near-adult height is achieved (height velocity <2 cm/year or bone age >16 years in boys or >14 years in girls) if height is in the normal adult range (above –2 SDS). Stopping therapy may be influenced by satisfaction of the patient and family with the resulting height, an ongoing cost-benefit analysis, or desire of the child to stop for other reasons (e.g., dissatisfaction with daily injections).

The possible side effects in GH-treated children with ISS are similar to those previously reported in children receiving GH therapy for other indications, with no long-term adverse effects documented.[1505,1506] Posttreatment surveillance with a focus on cancer prevalence and metabolic side effects is advisable.

The average cost of GH treatment of children with ISS is $10,000 to $20,000 per centimeter of growth improvement.[1497] The benefits are less clear,[1497] because it is unknown whether a gain in height improves quality of life. Therefore recommendations for treatment that increases adult height should be balanced against the high cost of these therapies.

Miscellaneous Causes of Growth Failure

In addition to the clinical conditions described earlier, GH has been used in the treatment of short stature associated with a variety of other conditions involving postnatal growth failure. In general, such trials have been uncontrolled and have not included sufficient numbers of subjects for efficacy to be evaluated. Examination of such treatments should be continued in the large international databases.

Down Syndrome. The encouraging results of GH trials in TS led to studies of GH therapy in children with Down syndrome. In several preliminary studies, GH accelerated growth in such patients, although ethical issues were raised concerning the appropriateness of such therapy.[901,1507–1509] In the uncontrolled NCGS experience, 23 children experienced a 1.3-SDS height gain over the first 4 years of GH therapy.[1471] No convincing data exist that GH improves neurologic or intellectual function in such patients. The increased risks of diabetes mellitus and leukemia in children with Down syndrome could be augmented by GH therapy.[1510] A review of GH therapy given to 15 children with Down syndrome reported an increase in mean height but no effect on mental development. They do not recommend GH therapy and call for further controlled studies.[900]

Normal Aging and Other Catabolic States. Detailed consideration of the potential use of GH in normal aging is beyond the scope of this chapter. The rationale for such therapy is based on the concept of the *somatopause,* a term that highlights the progressive decline in GH secretion after 30 years of age, as reflected in decreasing IGF1 levels. Aging can be viewed as a catabolic state, with the potential that GH therapy might reverse or retard the loss of muscle mass and strength and the decrease in bone density that occur with aging. There is no evidence that GH supplementation during aging improves muscle strength or quality of life.[1511]

Growth failure, often with impaired final adult height, is a characteristic clinical finding in endogenous or exogenous Cushing syndrome. Excess glucocorticoids cause a catabolic state characterized by increased proteolysis, decreased protein synthesis, lowered osteoblastic and increased osteolytic activity, and insulin resistance.[1254] GH treatment blunts some of these catabolic actions but increases the insulin resistance.[1255] Mauras and Beaufrere[862] showed that IGF1 therapy similarly induces an anabolic response, despite excess glucocorticoids, but does not cause insulin resistance. GH treatment after transplantation[1351–1353] and in other glucocorticoid-treated children[851] causes some height increments but does not produce as good a response as in individuals not taking glucocorticoids. GH does enhance bone formation and increases osteoblastic activity in such children.[1512] The marked increase in IGF1 levels during GH treatment may be sufficient to overcome the local insensitivity to IGF action.[300,756,757,1513]

GH therapy is also being investigated in catabolic states such as burns, tumor cachexia, major abdominal surgery, AIDS, sepsis, metabolic acidosis, and situations requiring total parenteral alimentation. GH should not be used in critically ill patients, because a randomized, controlled trial demonstrated increased morbidity and mortality rates with GH treatment of such patients.[1514] The FDA-approved indications for the use of GH for purposes other than stimulation of growth are (1) GHD in adults, (2) AIDS-associated wasting or cachexia, and (3) short-bowel syndrome requiring total parenteral nutrition.

Adverse Effects of Growth Hormone

Pituitary-derived human GH had an enviable safety record for a quarter of a century but proved to be an agent for transmission of the fatal spongiform encephalopathy, CJD.[1194–1196] Although pit-GH was removed from use in the United States in 1985, and later throughout the world, more than 200 patients with GH-derived CJD have been identified.[1194–1196] Although recombinant DNA–derived GH does not carry this risk, the experience with pit-GH serves as a grim reminder of the potential toxicity that can reside in products used for physiologic replacement.

Extensive experience with recombinant GH over nearly 30 years has been encouraging.[1092,1307,1430,1515–1517] Concerns have been raised about a number of potential complications, which clearly require continued follow-up and assessment. This evaluation has been facilitated by the extensive databases that have been established by GH manufacturers, for example, Genentech (NCGS)[1307] and Pharmacia (KIGS).[1442,1518] An important limitation of these registries, however, is that although they have provided valuable information about the risks of disease during GH use, they were not designed to provide data on adverse effects after discontinuation of GH use.

Development of Leukemia and Other Malignancies

A report in 1998 of five cases of leukemia that developed in GH-treated Japanese children raised concern that GH therapy could increase the risk of leukemia.[1519] One difficulty in assessing the role of GH treatment in this disorder is that many GH-deficient children have conditions that predispose to the development of leukemia, such as prior malignancy, a history of irradiation, or concurrent syndromes that themselves are associated with the development of leukemia (e.g., Bloom syndrome, Down syndrome, Fanconi anemia). After the initial concerns about the role of GH treatment in the development of leukemia, long-term data have shown that GH treatment does not increase the incidence of leukemia in children who are not already at an increased risk of leukemia,[1307,1520–1522] does not increase the risk of leukemia as a subsequent neoplasm in cancer survivors,[1523] and does not increase the rate of leukemia relapse.[1442,1520,1524] Although it is not possible to determine if GH treatment increases the incidence of leukemia in children at increased risk for reasons other than prior malignancy, the incidence of leukemia in these at-risk children does not appear to be out of line with the expected rate.[1521] Nonetheless, care should be used in prescribing GH therapy for children with a past history of leukemia or lymphoma or other disorders conveying an increased risk of leukemia.

With respect to malignancies other than leukemia, data from more than 88,000 GH-treated patients with more than 275,000 patient-years at risk did not reveal an increased risk for nonleukemic extracranial neoplasms.[1307,1452,1516] However, an increased risk of post-transplant lymphoproliferative disease (odds ratio 1.88; 95% confidence interval [CI] 1.00–3.55, $p = 0.05$) was found in children treated with GH before transplant for growth failure related to their end-stage renal disease.[1525] And a statistically nonsignificant increase in malignancies was found in GH-treated girls with TS (standardized incidence ratio compared with the age-matched general population of 2.1; 95% CI, 0.76–4.49).[1396]

Recurrence of Central Nervous System Tumors

Because many recipients of GH have acquired GHD due to CNS tumors or their treatment, the possibility of tumor recurrence with therapy is of obvious importance. Estimates of CNS tumor recurrence rates in non–GH-treated children and adolescents are difficult to obtain, bearing in mind the vast array of treatment programs used in the past four decades. In a total of 1083 patients compiled from 11 reports who were not treated with GH, 209 (19.3%) had recurrences.[1251,1524,1526–1534] Such data in a heterogeneous group, including patients with craniopharyngiomas, gliomas, ependymomas, medulloblastomas, and germ cell tumors, provide a background for assessing recurrence rates in GH-treated youth. Reports from nine centers, encompassing 390 patients, indicated recurrence in 64 patients (16.4%) at the time of publication,[1524,1526,1534–1539] which is not much different from the

recurrence rate observed in a much larger number of untreated patients. In a particularly well-done comparative study at three pediatric neuro-oncology centers comprising 1071 brain tumor patients, 180 patients were treated with GH for a mean of 6.4 years, and 31 of them were monitored for more than 10 years; the relative risk of recurrence or death was similar with and without GH treatment.[1538] In a study of 361 cancer survivors (including 172 brain tumor patients), disease recurrence of all cancers in GH-treated children did not differ from recurrence in those children not treated with GH.[1523] A single center study of 110 previously irradiated brain tumor patients found no difference in recurrence in GH-treated patients compared to matched control subjects after approximately 15 years of follow-up.[1540] Finally, extensive analysis of 4410 patients with a history of brain tumor or craniopharyngioma before GH therapy in the NCGS and KIGS databases[1442,1516,1541] showed a similar lack of increased tumor recurrence. In the NCGS series, recurrence rates of the most common CNS neoplasms, craniopharyngioma (6.4%), primary neuroectodermal tumors (medulloblastoma and ependymoma, 7.2%), and low-grade glioma (18.1%) were lower than or similar to those reported in non–GH-treated children.[1252,1524,1542]

Development of Subsequent Neoplasms

Children who have survived cancer are at an increased risk of developing a second neoplasm because of either an underlying genetic predisposition or the consequences of the treatment for the primary malignancy, including radiation therapy and treatment with alkylating agents. Because of the mitogenic and antiapoptotic effects of GH and IGF1, there is concern that GH treatment could increase the rate of subsequent neoplasms. This has been monitored through both the large NCGS and KIGS GH treatment databases, as well as through the Childhood Cancer Survivor Study (CCSS) group. The CCSS studies followed 361 GH-treated cancer survivors, and the initial report found an overall increased risk of 3.21 (95% CI, 1.88–5.46) for second neoplasms.[1523] Although the majority of these second neoplasms were meningiomas, there were three children who developed osteogenic sarcoma out of 122 leukemia/lymphoma survivors who had been treated with GH. A similar increased risk for second neoplasms, also largely meningiomas, was found in a study of 60 GH-treated adult patients.[1543] In 2500 GH-treated cancer survivors in the NCGS database, there was also an increased incidence in secondary malignances, predominantly CNS tumors (glioblastoma/glioma, astrocytoma, meningioma) and osteogenic sarcoma.[1307] However, the most recent follow-up of the CCSS found that the rate of meningioma in those children not treated with GH had risen over time to equal that of survivors treated with GH. Therefore the CCSS data found that the rate of subsequent CNS neoplasms was not increased by GH treatment,[1544] with an adjusted rate of 1.0 for any CNS secondary neoplasm, 0.8 for meningiomas, and 1.9 (95% CI, 0.7–4.8; $p = 0.21$) for gliomas. The equalization of the rate ratio for meningiomas with longer follow-up raised the possibility that GH treatment may accelerate the manifestation of these tumors, rather than increase the absolute rate. Another possible explanation, however, is that the GH-treated patients had more intense surveillance because of their GH treatment and were therefore identified at an earlier stage.

Pseudotumor Cerebri

Pseudotumor cerebri (idiopathic intracranial hypertension) has been reported in GH-treated patients.[1307,1442,1516,1545] The disorder may develop within months after treatment starts or as long as 5 years into the course; it appears to be more frequent in patients with renal failure than in those with GHD.[1307,1516] The mechanism for the effect is unclear but may reflect changes in fluid dynamics within the CNS. Pseudotumor has also been described after thyroid hormone replacement in patients with hypothyroidism. In any case, clinicians should be alert to complaints of headache, nausea, dizziness, ataxia, or visual changes. Significant fluid retention with edema or hypertension is rare.[1546] Because of the possible association of pseudopapilledema with GHD, perhaps representing a variant of optic nerve hypoplasia,[1547] careful ophthalmologic evaluation should be undertaken in patients with suspected GH therapy–associated pseudotumor cerebri to avoid overdiagnosis and invasive treatments.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis is associated with both hypothyroidism and GHD. Whether GH therapy plays a role in this disorder has been difficult to determine, in part because the incidence of slipped capital femoral epiphysis varies with age, gender, race, and geographic locale. The reported incidence is between 2 and 142 cases per 100,000 population; the data in the KIGS and NCGS studies are in this range.[1307,1442,1516] Accordingly, although slipped capital femoral epiphysis cannot be attributed to GH therapy per se, complaints of hip and knee pain or limp should be evaluated carefully. The occurrence of such pain in a GH-treated child with an exceedingly rapid growth rate should lead to consideration of this diagnosis.

Scoliosis

Both progression of preexisting scoliosis and new-onset scoliosis have been described in children treated with GH.[1307] The numbers are extremely small, with only 238 reported cases among 54,996 patients in the NCGS database. There is specific concern for GH effects on scoliosis in TS and PWS patients, in whom the underlying rate of scoliosis is increased. Although the rate of scoliosis in GH-treated TS patients was higher than in other GH-treated patients, it remained rare, being reported in only 0.69% of patients.[1396] PWS by itself has a rate of scoliosis of 30% to 80%, and GH treatment does not appear to increase the rate or severity of scoliosis in PWS patients.[1325,1548]

Diabetes Mellitus

The association of GH treatment with insulin resistance is well documented.[1549] In addition, candidates for GH therapy include some who are known to have increased risk of type 2 diabetes mellitus (T2DM), including patients with TS, PWS, or those born IUGR. Data from the NCGS database estimated the incidence of T2DM in GH-treated patients as approximately 14 cases per 100,000 patient-years,[1307,1442] and data from KIGS and from GeNeSIS (Genetic and Neuroendocrinology of Short Stature International Study; another large pharmaceutical company–sponsored postmarketing surveillance database) found the incidence of T2DM in GH-treated children to be approximately 30 cases per 100,000 patient-years.[1550,1551] The incidence found in the KIGS and GeNeSIS studies was 6 to 6.5 times higher than the expected incidence.[1550,1551] Many of these children did have risk factors for T2DM, although not all of them were obese.[44,45,1516] In some, but not all, of the subjects who developed T2DM, there was resolution of the diabetes on discontinuation of GH treatment,[1520,1550,1551] likely highlighting the underlying risk of diabetes in these individuals and supporting a causative role of GH treatment in the development of diabetes. Therefore the reduction

of insulin sensitivity induced by GH is a concern that demands close assessment, particularly in high-risk patients such as those with PWS or TS or a history of IUGR. Reassuringly, however, the prevalence of diabetes in young adults who had previously been treated with GH in childhood was not increased in a large population-based study.[1552]

Miscellaneous Side Effects[1307,1442,1516]

Other potential side effects of GH therapy include prepubertal gynecomastia,[1553] pancreatitis,[1554] growth of nevi[1555,1556] (although typically without evidence of malignant degeneration[1520]), behavioral changes, worsening of neurofibromatosis, hypertrophy of tonsils and adenoids, and sleep apnea. GH treatment increases the conversion of cortisol to cortisone, which may trigger a need for glucocorticoid replacement therapy in those with subclinical central adrenal insufficiency.[1430] GH treatment also increases the conversion of thyroxine to triiodothyronine, which could either increase levothyroxine dose requirements in those treated for central hypothyroidism or unmask preexisting but undiagnosed central hypothyroidism.[1430] A report[1557] of reduced testicular volume and elevated gonadotropin levels in four young adult men previously treated with GH for ISS was not confirmed by a double-blind, placebo-controlled study,[1558] nor by the international databases.[1559] This list of side effects is only partial. It is best for the clinician to remember that GH and the peptide growth factors it regulates are potent mitogens with diverse metabolic and anabolic actions. All patients receiving GH treatment, even as replacement therapy, must be carefully monitored for side effects.

For the most part, the side effects of GH are minimal and rare. When they do occur, a careful history and physical examination are adequate to identify their presence. Management of these side effects may include transient reduction of dosage or temporary discontinuation of GH.[1056] In the absence of other risk factors, there is no evidence that the risk of leukemia, brain tumor recurrence, or slipped capital femoral epiphysis is increased in recipients of long-term GH treatment. Any patient receiving GH who has a second major medical condition (e.g., being a tumor survivor) should be followed up in conjunction with an appropriate specialist such as an oncologist or neurosurgeon. Whereas GH has been shown to increase the mortality rate of critically ill patients in intensive care units,[1514] there is no evidence that GH replacement therapy needs to be discontinued during intercurrent illness in children with GHD.

Recent in vitro studies have found that growth hormone could play a role in the progression of certain cancer types through the induction of an epithelial to mesenchymal transition.[1560] This effect would potentially increase the risk of cancer metastasis; therefore it strongly argues against GH treatment in patients with active malignancies.

While the impact of GH treatment on long-term mortality is complex (see upcoming discussion), there is no evidence that GH treatment in childhood increases the acute mortality risk.[1561]

The Question of Long-Term Cancer Risk

Several epidemiologic studies have suggested an association between high serum IGF1 levels and an increased incidence of malignancies.[1562–1564] Such studies have found an association of higher IGF1 levels with breast, prostate, and colon cancer.[1564–1566] In contrast, higher IGFBP3 levels have been associated with a decreased risk of prostate and breast cancer, although other studies found no association of IGFB3 levels and cancer[1564] or found a positive association.[1564,1566] Because GH increases production of both IGF1 and IGFBP3, the studies that found the highest association with cancer with high IGF1 and low IGFBP3 levels do not suggest a simple relationship between GH and cancer risk.

Epidemiologic studies assessing the risk of malignancy in patients with acromegaly found differing results, with some,[1566–1569] but not others,[1570,1571] identifying significant associations between acromegaly and colon cancer risk. The small size and uncontrolled retrospective nature of these studies and the multiple possible sources of bias make these reports difficult to interpret. The largest study to date, reviewing more than 1000 patients, indicated no overall increased cancer incidence in acromegaly.[1572] Although colon cancer risk was also not increased in that study, the mortality rate was higher, suggesting an effect of GH or IGF on established tumors.[1573] A prospective analysis of colon cancer and colonic polyps in acromegalics did not observe an association between these two diseases when using either autopsy series or prospective colonoscopy screening series for the control population.[1574] Acromegaly is associated with a marked increase in the incidence of benign hyperplasia in several organs, including colonic polyps.[1575] Such findings suggest that the GH-IGF1 axis may lead to symptomatic benign proliferative disease, which could be associated with symptoms, such as rectal bleeding, that would lead to a potential detection (or ascertainment) bias.

Children receiving GH do not appear to have a greater risk of de novo or recurrent tumors.[1092,1307,1442,1516,1576] A cohort of 1848 patients treated with GH in the United Kingdom was assessed after as long as 40 years and found to have increased rates of colorectal cancer and Hodgkin disease, but the tumor-associated deaths were so few that a single patient death would markedly alter the risk ratios.[1577,1578] No increased incidence of cancer was found in GH recipients among adults who were treated for GHD.[1579,1580] A large European study found no overall increase in cancer risk in adults who were treated with growth hormone as children and who did not have an apparent underlying cancer risk.[1576] However, that study did find an increased incidence of bone and bladder cancer, along with possible evidence of an increase in Hodgkin lymphoma risk in these adults. In addition, although not found in all studies,[1581] there have been some data suggesting an increased risk of cancer mortality after childhood GH treatment.[1576,1581,1582] One of these studies found an increased mortality rate from bone tumors,[1581] while a large European study found an increased cancer mortality risk associated with the daily GH dose in patients treated with GH after previous cancer.[1576] These reports represent imperfect, uncontrolled studies. The overall data do not indicate a clear association of GH therapy with the future development of neoplasms in the absence of other risk factors, but there remains some uncertainty over the risk of specific cancers and perhaps over cancer mortality risk.

The use of IGF1 and IGFBP3 in the monitoring of GH recipients, both adult and pediatric, has been recommended and endorsed by international bodies such as the Growth Hormone Research Society,[1055] the Drug and Therapeutics Committees of the Lawson Wilkins Pediatric Endocrine Society, and the European Society of Pediatric Endocrinology.[1577,1578] Until the issue of cancer risk in GH therapy is fully resolved, the prudent approach appears to be regular monitoring of both IGF1 and IGFBP3 and alteration of the GH dose to ensure that the theoretic risk profile induced by GH therapy is favorable. This can be done by avoiding the unlikely situation of a GH-treated patient with an IGF1 level at the upper end of the normal range and an IGFBP3 level at the lower end of the normal range.

Long-Term Mortality with GH Treatment

The effect of GH deficiency and GH treatment on overall mortality is complex. Subjects with untreated congenital GH deficiency from mutations in *PROP1* appear to have increased lifespan.[1564] In contrast, individuals with GH deficiency from *GH1* gene deletion have a decreased lifespan, with increased cardiovascular and infectious disease mortality rates,[1564] yet subjects with GH deficiency from *GHRH* mutations have no change in mortality rate compared with the local population.[1564,1583] The background mortality rates of the gene deletion and *GHRH* mutation ethnic populations were quite different, which may account for some of the mortality discrepancy. Untreated Laron patients have been found to have a marked decrease in cancer mortality rate.[1564] Mortality data on GH-treated Laron patients are not available. Mortality risk is increased in adults with untreated GH deficiency (due to increased mortality rate from cardiovascular disease) but also in adults with GH excess (due to an increase in cardiovascular, cerebrovascular, and respiratory deaths).[1564] In 2012, investigators reported on the all-cause mortality rate of French children treated with GH for isolated GH deficiency. GH treatment in this cohort was initiated between 1985 and 1996, with a mean age at follow-up of 28 years. They found an increase in all-cause mortality rate when compared to the French general population, with a standardized mortality ratio of 1.33 (95% CI 1.08–1.64).[1581] The diseases contributing to this increase in mortality rate were diseases of the circulatory system and subarachnoid or intracerebral hemorrhage. In response to this report, investigators looked at all-cause mortality rate in GH-treated children in Sweden, Belgium, and the Netherlands.[1582] These patients started treatment between 1985 and 1997 and had a mean age of 27 to 29 years at follow-up. In this cohort, no subjects died from cancer or cardiovascular disease. Another report also found no increase in mortality in 3847 adults in Sweden treated with GH in childhood for IGHD, ISS, or SGA.[1584] Thus the data do not give a clear answer to the long-term effects of GH treatment on longevity, including whether the impact would differ based on the indication for GH treatment.

IGF1 Treatment

In 2005, the FDA approved the use of rhIGF1 for "long term treatment of growth failure in children with severe primary IGF1 deficiency and in children with GH gene deletions who have developed neutralizing antibodies to GH. Severe primary IGF1 deficiency is defined by height SD score less than –3.0 and a basal IGF1 SD score less than –3.0 and normal or elevated GH. Severe primary IGF1 deficiency includes patients with mutations in the GHR, post-GHR receptor signaling pathway, and IGF1 gene defects" (Increlex [rhIGF1] prescribing information, 2009, Tercica, Inc.). Clinical trials to study the safety and efficacy of rhIGF1 therapy have been conducted mostly in individuals with proven mutations in the *GHR*; fewer than 10% of enrollees have had GH insensitivity due to GH antibodies. Because of the rarity of *GHR* mutations, the clinical trials have been small.

A number of short-term growth-related studies with subcutaneous IGF1 treatment at varied doses have been reported. Despite slight differences in IGF1 dosage and inclusion criteria, the short-term effects of IGF1 on growth in GH insensitivity were consistent: Growth increased from pretreatment rates of 3 to 5 cm per year to 8 to 11 cm per year on average. In five children with GHR deficiency, single daily doses of 150 μg/kg for 3 to 10 months resulted in growth acceleration to rates of 8.8 to 13.6 cm per year.[1585] Wilton[1253] reported collaborative data on the treatment of 30 patients, ages 3 to 23 years, with GH insensitivity due to GHR deficiency or IGHD type IA with anti-GH antibodies; the dose of IGF1 varied from 40 to 120 μg/kg twice daily. With the exception of the two oldest individuals, growth rates increased in Wilton's subjects by at least 2 cm per year. A mean increment of more than 4 cm per year in growth velocity was found in 11 prepubertal children treated with 80 μg/kg twice daily.[1585] This study also demonstrated a significant inverse relationship between growth response to exogenous IGF1 and severity of the GH insensitivity phenotype.

Longer-term studies of IGF1 treatment of GH insensitivity demonstrated a progressive waning effect of IGF1 on growth velocity.[1586] Data from 17 patients in a European collaborative trial who were treated for at least 4 years showed an increase in mean height SDS from –6.5 to –4.9, with two adolescents reaching the 3rd percentile. Children who received rhIGF1 for 2 years or less had a higher growth velocity than those children who received rhIGF1 for longer periods. In the longest treatment study of 58 children with GH receptor mutations, GH antibodies, or biochemical evidence of GH insensitivity without documented mutation,[1587] outcomes were similar to those in the European study, with an initial burst of growth (from 3.1 to 8.0 cm/year) followed by slowing to just above baseline (4.8 cm/year) by the fourth year of therapy. Height SDS improved from –6.5 to –5.2 after 5 to 6 years of therapy. Data on 21 of these patients at or near adult height with average treatment duration of 10 years ranged from –8.0 to –6.2 SDS, lower for those persons with GH antibodies as the underlying cause for their GH resistance.[1588]

These limited data indicate that rhIGF1 is effective in increasing statural growth, but the growth response is neither as robust nor as sustained as the growth response to GH among children with GHD. The suboptimal growth response to rhIGF1 compared with recombinant human GH has been attributed to (1) inability of rhIGF1 to increase IGFBP3 and ALS levels, leading to decreased delivery of IGF1 to target tissues; (2) lack of GH-induced proliferation of prechondrocytes in the growth plate; (3) absence of GH-induced local IGF1 at the growth plate; and (4) difficulty in using higher doses of IGF1 because of the risk of hypoglycemia.

IGF1 treatment administered to individuals with *IGF1* gene deletion[656] and post-GHR signaling defects with growth patterns was similar to those of children with GH insensitivity due to GHR deficiency. First-year results from an open-label trial of 124 children with low serum IGF1 and height SDS below –2 without biochemical evidence of GH insensitivity indicate that growth velocity increased for the year of therapy (from 5 to 7 cm/year).[1256]

The most common adverse effect of rhIGF1 is hypoglycemia. In some studies, it occurred in almost half of the patients with GH insensitivity treated with rhIGF1,[1587] usually within the first month of therapy. Importantly, individuals with GHR defects, the highest proportion of enrollees in these treatment studies, have baseline hypoglycemia. In a 6-month, placebo-controlled trial, 67% of children receiving placebo experienced hypoglycemia, compared with 85% of children receiving rhIGF1—a difference that was not statistically significant.[1589] In a study of 23 patients with GH insensitivity, hypoglycemia was noted before the start of treatment; after 3 months, 2.6% of glucose values in those receiving placebo were less than 50 mg/dL, compared with 5.5% of glucose values in those receiving rhIGF1.[1587] The hypoglycemia was not to be avoidable with adequate food intake. In children with low IGF1 but without GH insensitivity, 20% of subjects who received the higher IGF1 dose experienced symptoms attributed to hypoglycemia; documentation of hypoglycemia was only noted in one subject.[1256]

Patients with GH insensitivity treated with rhIGF1 have also experienced lymphoid tissue hypertrophy, encompassing tonsillar/adenoidal growth and associated snoring and sleep apnea, and thymic and splenic enlargement.[1587] The hypertrophy occurred in 22% of patients, with 10% of patients requiring tonsillectomy/adenoidectomy. Coarsening of the face was observed in patients of pubertal age.[1587] Studies have reported an increase in BMI with treatment and a twofold to threefold increase in body fat as assessed by dual-energy x-ray absorptiometry (DEXA).[1590] The study to adult height did not note this significant increase in body fat.[1588] Intracranial hypertension with associated papilledema has also been observed in as many as 5% of treated patients. In the study by Midyett and coworkers, 2 of 100 patients receiving IGF1 had documented intracranial hypertension.[1256] Anti-IGF1 antibodies develop in about half of treated patients during the first year, but they have no effect on the response.[1587] As with recombinant human GH treatment, an increased cancer risk with rhIGF1 treatment is an unknown but legitimate concern, considering the role of IGF1 in neoplasias and the increased cancer risk associated with hypersomatotropism.[1591]

Approval of rhIGF1 by the FDA and the European Agency for the Evaluation of Medical Products has ignited debate about expansion of the diagnosis of severe IGF1 deficiency and consequent expanded use of rhIGF1 beyond those patients with neutralizing GH antibodies or documented mutations in the *GHR*, GHR signaling pathways, or the IGF1 gene. Some advocate that individuals with ISS, low serum IGF1, or poor response to a GH trial may have unidentified subtle alterations in GHR signaling and could benefit from treatment with rhIGF1.[1592] Others express reservations about expanding the diagnosis of IGF1 deficiency and rhIGF1 use, postulating that the response of children with ISS to rhIGF1 may be minimal considering the lower long-term growth response of children with GHR defects treated with IGF1 compared with GH-deficient children treated with GH. Another theoretic concern regards negative feedback of rhIGF1 on GH secretion, which leads to diminished IGF1-independent effects of GH on growth.[1593]

Other Treatments to Promote Growth

GnRH Agonists

Increasing Adult Height of Children with Idiopathic Short Stature. The effect of GnRH agonist therapy on adult height has been studied in girls with ISS and normal puberty (8–10 years of age); there was a mean gain of 0 to 4.2 cm, compared with predicted height.[1485,1594–1605] In boys with rapidly progressing puberty, GnRH agonist therapy increased adult height compared with predicted height,[1606,1607] with mean gains of 4.4 to 10 cm in those receiving the combination therapy, compared with 0.5 to 6.1 cm in untreated control subjects.[1487,1608]

In these studies, the effects of GH cannot be separated definitively from those of the GnRH agonist. In two randomized studies of adopted girls with normal puberty, treatment with a GnRH agonist plus GH was compared with GnRH agonist alone, and a 3-cm height gain was demonstrated with the combination therapy.[1609,1610]

Disadvantages of the use of GnRH agonists in children with ISS include absence of pubertal growth acceleration, delayed puberty with potential psychosocial disadvantage, and decreased BMD. Long-term follow-up studies are lacking. A panel of experts concluded that GnRH agonist therapy alone in children with ISS and normally timed puberty is minimally effective in increasing adult height, may compromise BMD, and cannot be suggested for routine use.[1611] Combined GnRH agonist and GH therapy leads to a significant height gain but may have adverse effects. Routine use of GnRH agonists in children with ISS being treated with GH cannot be suggested (level of evidence, C-III).

Increasing Adult Height of Children Born SGA. Short children born SGA usually have a normal pubertal timing, although some have rapidly progressing puberty and may be treated with GH.[1445] Data on the additional effect of treatment with GnRH agonists are limited. Routine use of the combination of a GnRH agonist and GH in children born SGA cannot be suggested.

Increasing Adult Height of Children with Growth Hormone Deficiency. Some children with GHD are short at the start of puberty and are at risk for short adult stature. Retrospective studies evaluating the addition of GnRH agonists to GH therapy involved a limited number of subjects and provided controversial results.[1612,1613] Three prospective studies that reported near-adult or adult heights showed a height gain of –1 SDS.[1614–1616] Routine use of combined therapy with a GnRH agonist and GH in GH-deficient children with low predicted adult height at onset of puberty cannot be suggested (level of evidence, C-III).

Aromatase Inhibitors

Men with estrogen deficiency due to aromatase gene defects or estrogen resistance due to inactive estrogen receptors experience growth into the third decade, demonstrating the role of estrogen in growth plate fusion.[23,315] The aromatase enzyme catalyzes aromatization of testosterone and androstenedione to estradiol and estrone, respectively. Various studies have been conducted to explore the efficacy of the aromatase inhibitor class of drugs delaying growth plate fusion and increasing height in disorders associated with short stature in boys. Studies to date have been small, and many have used adjuvant treatments, including GH, GnRH agonist, or testosterone, so the singular effect of the aromatase inhibitor has been unclear. Additionally, most studies to date have been short term and have measured changes in predicted adult height, with only one study investigating the effect on final adult height.

Aromatase inhibitors were first tried in disorders of sex steroid excess and precocious puberty, with only modest, if any, effects on predicted adult height. Treatment of boys with familial male-limited precocious puberty with testolactone, a first-generation aromatase inhibitor, resulted in an improvement in predicted adult height only after 5 to 6 years of treatment.[1617] The improvement in predicted adult height after 6 years was robust, however, at 12.9 cm compared with untreated control subjects. In contrast, first-generation and second-generation aromatase inhibitors have not significantly affected predicted adult height in patients with McCune-Albright syndrome.[1618–1620] Final height data are not available.

Aromatase inhibitors have also been used in boys with CDGD. Available studies had a small number of subjects enrolled, and boys with CDGD who received the second-generation aromatase inhibitor letrozole, in combination with testosterone, for 12 months experienced an increase in predicted adult height of 5.1 cm compared with control subjects treated with testosterone alone.[1181] When followed to adult height, those boys who received letrozole in addition to testosterone achieved a final adult height 5.7 cm higher than that of boys receiving testosterone alone.[1182] In GH-deficient boys treated with GH, the addition of anastrozole for 3 years increased predicted adult height by 6.7 cm, compared with an increase of 1 cm in boys treated with GH alone.[1498] The results of these preliminary small trials indicate that aromatase

inhibitors may be able to increase adult height, but larger, longer trials are needed to determine the optimal conditions and duration of treatment to significantly increase adult height. In addition, longer follow-up will be needed to demonstrate the safety of such treatments in peripubertal and pubertal boys.

Given the observation of decreased BMD in males with defects in estrogen synthesis or action, the effects of short-term aromatase inhibitor therapy on BMD were investigated in these treatment studies. None of the studies found a difference in BMD as assessed by DEXA scans in patients who received aromatase inhibitor or placebo for up to 3 years.[1498,1621] However, mild vertebral abnormalities were noted in boys who received the aromatase inhibitor compared with placebo[1622]; it is unknown whether the deformities are due to treatment effects and whether they resolve upon longer duration letrozole therapy. In light of these effects, aromatase inhibitors must be used with caution. Clearly, longitudinal follow-up is needed to better characterize the safety and efficacy of aromatase inhibitors to promote growth.

Oxandrolone

Oxandrolone, an anabolic steroid, has been used to increase growth velocity in a number of disorders. Because it cannot be aromatized to estrogen, it should not accelerate skeletal maturation. In general, studies evaluating the effect of oxandrolone on growth have found that it increases growth velocity but is not associated with an increase in final height.

Clinical Trials of Efficacy. Numerous studies have investigated oxandrolone therapy in boys with CDGD. The studies have found that oxandrolone increases growth velocity in these boys.[1139,1158] The typical response is an increase in growth velocity from approximately 4 to 4.5 cm per year up to 8 to 9 cm per year. Although treatment does not decrease final height, as might occur with accelerated skeletal maturation from excessive sex hormone exposure, neither does it increase final height.[1158] Therefore oxandrolone can be used to accelerate the growth of boys with CDGD to allow them to increase their height sooner than they would naturally, but it does not increase their final adult height. There have been no trials comparing efficacy of oxandrolone versus testosterone treatment in boys with CDGD.

Oxandrolone has been studied in girls with TS, both as a single agent and as combined therapy with GH. As in boys with CDGD, oxandrolone increases the growth rate in girls with TS.[1623,1624] Although some studies found no effect on final height with oxandrolone treatment alone,[1625] others found a mean increase in final height of up to 5.2 cm with oxandrolone treatment.[1624] Results of three controlled trials testing the effects of combination therapy with GH versus GH alone on adult height were reviewed.[1626] The studies had different average age at treatment start and used different GH and oxandrolone doses.[1627–1629] In general, the studies reported a positive effect of oxandrolone when added to standard GH therapy, with the effect on adult height varying between 2.3 and 4.6 cm.

Side Effects. No significant side effects have been reported in boys treated with oxandrolone for CDGD. Although oxandrolone has significantly fewer androgenic effects than testosterone, mild virilization has been reported in girls taking oxandrolone, including clitoromegaly. This is less of a concern at lower doses.[1626] There are also reports of a delay in breast development that improves upon higher estrogen dosing. Hepatic dysfunction has been reported with oxandrolone treatment, manifested by alterations in HDL cholesterol, and thus monitoring of lipids is suggested.[1626]

Diagnosis and Treatment of Excess Growth and Tall Stature

Diagnosis

The normal distribution of height predicts that 2.5% of the population will be taller than 2 SD above the mean. The most common cause of tall stature is familial, and the diagnostic evaluation centers on distinguishing tall or constitutional stature from rare pathologic causes of tall stature. As with short stature, children with tall stature must be evaluated relative to familial growth patterns and parental target heights. When a family history of tall stature is available and the growth rate and physical examination findings are normal, support and reassurance are frequently all that is needed without further testing. A careful assessment of pubertal status and bone age facilitates prediction of adult height and discussions with the patient and family. If the history suggests an underlying disorder or growth rate is accelerated, additional testing should be done to investigate the GH-IGF1 axis, chromosomal disorders, puberty, or other rare causes.

In GH excess, serum IGF1 levels are elevated, although high IGF1 levels may be a normal manifestation of puberty. Basal serum GH levels may be normal to increased, but serum GH is not suppressed by administration of glucose (1.75 g/kg body weight up to a maximum of 100 g). Although abnormalities of the sella turcica can be evident on lateral skull films, the demonstration of increased GH-IGF secretion should lead to radiologic evaluation of the hypothalamus and pituitary by MRI or computed tomography.

Treatment

Definitive treatment of GH-secreting tumors requires surgical ablation, either transsphenoidally or with a more aggressive surgical approach if large. As described in Chapter 9, somatostatin analogues, dopamine agonists, and GH-receptor antagonists are important components of treatment programs for GH excess.

In the past, most patients treated for familial tall stature were females. The number of patients treated in the United States has fallen markedly over the past four decades as tall stature in girls has become increasingly acceptable socially and psychologically. Treatment regimens were generally with estrogen prior to pubertal onset to induce early epiphyseal maturation[1630] and considered girls with predicted heights greater than 183 cm (6 feet 0 inches). Treatment regimens varied considerably, and there are no randomized trials testing treatment effectiveness. Controversy surrounds the treatment of girls with tall stature, especially in light of long-term studies that raised the possibility of effects on fertility.[1631] One-fifth of pediatric endocrinologists reported use of estrogens for treatment of tall stature in 1999,[1632] a percentage that is likely diminishing. In males, androgens have been used to accelerate skeletal maturation via aromatization to estrogen, but virilization is rapid.

Physiology and Disorders of Puberty

DENNIS M. STYNE

CHAPTER OUTLINE

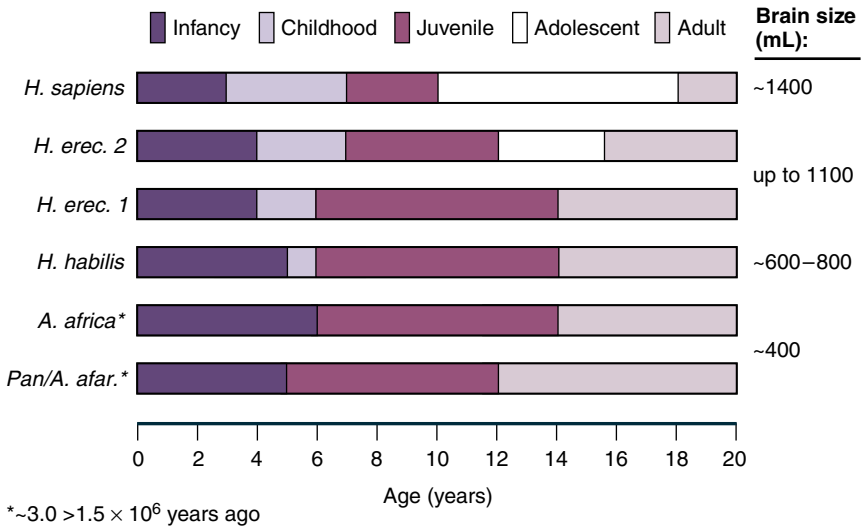
KEY POINTS

- Puberty is not a de novo event but rather a phase in the continuum of development of gonadal function and the ontogeny of the hypothalamic-pituitary-gonadal system from the fetus to full sexual maturation and fertility.
- During puberty, secondary sexual characteristics appear, and the pubertal growth spurt occurs, resulting in the striking sex dimorphism of mature individuals; fertility is achieved, and profound psychologic effects ensue.
- Gonadarche, or the awakening of gonadal sex steroid secretion, and adrenarche, or the awakening of adrenal androgen secretion, are separate processes that must be evaluated individually, as the customary chronologic relationship between the events may vary considerably among individuals.
- The age of onset of thelarche, or breast development, has decreased over the past several decades according to international data; the obesity epidemic may be one of the factors responsible for this secular trend toward earlier female development, although other factors are suspected.
- The discovery of new genes involved in regulation of the hypothalamic control of pubertal development greatly expands our understanding of the cause of delayed and precocious puberty, but the complex mechanisms that initiate normal pubertal development at a given age remain largely unknown.
- Evaluation of puberty in children and adolescents should include the use of highly specific and sensitive assays with pediatric standards; sex steroids should be measured with high-performance liquid chromatography tandem mass spectroscopy (HPLC-MS/MS) methods, unless painstaking extraction and manual immunoassays are invoked.
- The remarkable success in treatment of childhood neoplasia has led to secondary effects on pubertal development, either advancing or delaying the age of onset of puberty and often impairing subsequent fertility.

Puberty is not a de novo event but rather a phase in the continuum of development of gonadal function and the ontogeny of the hypothalamic-pituitary-gonadal system from the fetus to full sexual maturation and fertility. During puberty, secondary sexual characteristics appear, and the pubertal growth spurt occurs; this results in the striking sex dimorphism of mature individuals, and fertility is achieved.[1] These changes result from stimulation of the gonads by pituitary gonadotropins and a subsequent increase in gonadal steroid output. The term *puberty* is characteristically used to refer to the physical and endocrine changes of this period, while *adolescent* usually refers to the profound psychologic changes encountered during this time.

Puberty and Evolution

Human beings evolved into the most reproductively successful of mammals, and many anthropologists attributed this success to the prolonged pattern of human growth and development and to the delay in attaining full sexual maturity.[2] The human scheme of growth involves a childhood stage and a pubertal stage that includes a pubertal growth spurt (Fig. 26.1). Not even our closest biologic relative, the chimpanzee, which matures twice as rapidly as the human, unequivocally exhibits these two stages, and chimpanzees lack the unique human pubertal growth spurt.[3] Learning and practice of adult behaviors related to sex and childrearing, particularly provisioning children (not just infants) with food, which

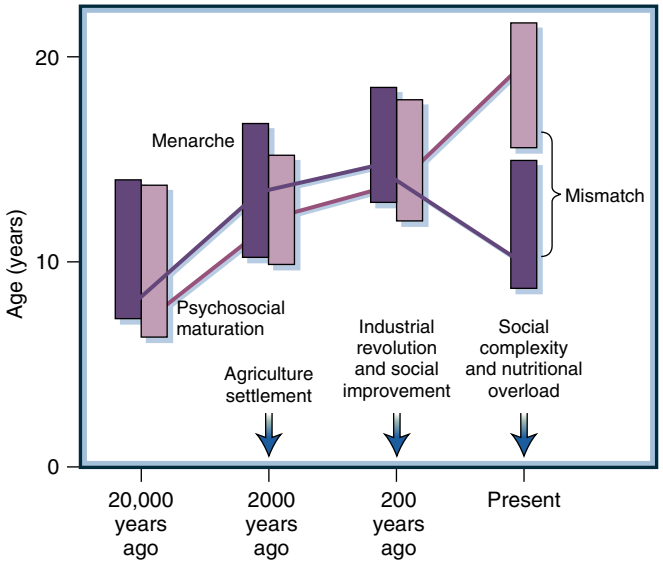


• **Fig. 26.1** Evolution of the human pattern of postnatal growth and development during the first 20 years of life. Specimens include A. afar, *Australopithecus afarensis*, a "bipedal chimpanzee"; A. africa, *Australopithecus africanus*; H. habilis, *Homo habilis*, the toolmaker; H. erec. 1, early *Homo erectus*; H. erec. 2, late *Homo erectus*; *H. sapiens*, *Homo sapiens*. The early hominid australopithecine specimens from South Africa date to about 3 to 1.5 million years ago. *H. afarensis*, although a hominid (family of all human species), retained many anatomic features of nonhominid species, such as an adult brain size of about 400 mL compared with *H. habilis* (650–800 mL), early *H. erectus* (850–900 mL), late *H. erectus* (up to 1100 mL), and modern *H. sapiens* (about 1400 mL). Infancy is the period when the mother's breast milk is the sole or most important source of nutrition, and in preindustrialized societies, it ends at about 36 months. Childhood is the period after weaning, when the child depends on others for food and protection; this period ends when the growth of the brain in weight is almost complete, at about age 7 years. The juvenile stage is defined as prepubertal individuals who are no longer dependent on their parents for survival. The adolescent stage, which begins with the onset of puberty, ends when adult height is attained (Moggi-Cecchi; Conroy and Kuykendall). The pattern in *A. afarensis* is no different from that of the chimpanzee *(Pan troglodytes)*. Notice the first appearance of the childhood stage in *H. habilis* (arising about 2 million years ago) and the first appearance of the adolescent stage in *H. erectus* 2 (about 500,000 years ago); *H. sapiens* arose about 120,000 to 150,000 years ago. (Modified from Bogin B. Growth and development: recent evolutionary and biocultural research. In: Boaz NT, Wolfe LD, eds. *Biological Anthropology: The State of the Science.* Bend, OR: International Institute for Human Evolutionary Research; 1995:49–70. Additional data from Moggi-Cecchi J. Questions of growth. *Nature.* 2001;414:595–597; Conroy GC, Kuykendall K. Paleopediatrics: or when did human infants really become human? *Am J Phys Anthropol.* 1995;98:121–131.)

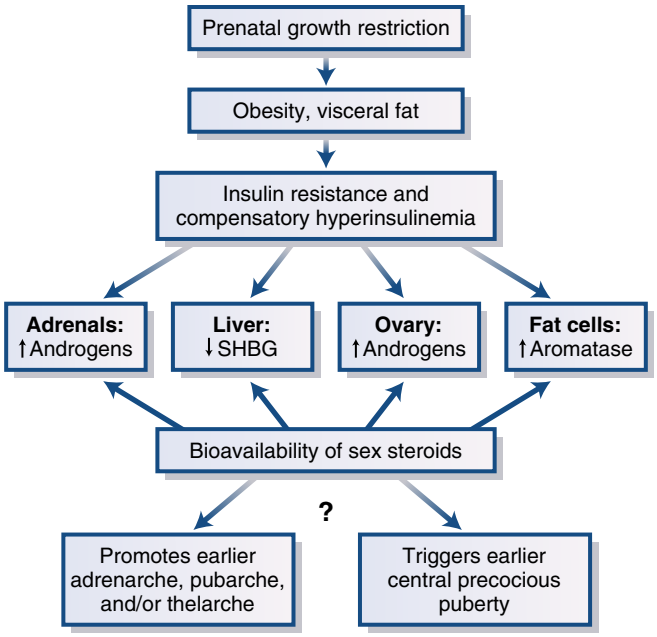
is unique to human beings, is considered a critical part of human success: "the building of a better, healthier body and the developing of greater biological, behavioral, and cultural resilience prior to sexual maturity that leads to greater adult health, fitness, and longevity."[2] Toolmaking preceded the evolutionary development of adolescence, suggesting that the evolution and value of human childhood and adolescence and this unique pattern of growth and development have had significant roles in the reproductive success of humans.

In the developed world, reproductive maturity occurs years earlier than psychosocial maturation, causing a mismatch between biologic stages and psychosocial expectations and roles (Fig. 26.2).[4] In past eras, such as the Neolithic, Greek, or Roman periods, there was not such a mismatch because menarche occurred at an age close to that of reproductive maturity.

With increased population, the advent of agriculture, and the growth of cities and later urban centers, menarche occurred later, and the complexity of life led to a delay in the attainment of an adult role in society. In Roman Britain, 2000 years ago, pubertal growth as an indication of puberty occurred at ages similar to those of today, but puberty progressed at a slower pace apparently leading to a later attainment of reproductive maturity.[5]



• **Fig. 26.2** The relationship between the likely range of ages of menarche *(purple)* and achievement of psychosocial maturity *(pink)* from 20,000 years ago to the current day. The mismatch in timing between these two processes is a novel phenomenon. (From Gluckman PD, Hanson MA. Evolution, development, and timing of puberty. *Trends Endocrinol Metab.* 2006;17:7–12.)



• **Fig. 26.3** Proposed endocrine pathways linking childhood obesity and insulin resistance to early pubertal onset and maturation. Childhood obesity and the predisposition to visceral adiposity after intrauterine growth restraint lead to insulin resistance and peripheral hyperinsulinemia. Insulin acts on various organs, including the adrenals, liver, ovary, and fat cells, to increase sex steroid bioavailability. Elevated circulating and tissue sex steroid levels in obese prepubertal children can have only mild local effects or activate early hypothalamic-pituitary puberty and early reproductive maturation. *SHBG,* sex hormone–binding globulin. (From Ahmed ML, Ong KK, Dunger DB. Childhood obesity and the timing of puberty. *Trends Endocrinol Metab.* 2009;20:237–242.)

In modern times, the age of menarche has decreased, but the age of social adulthood still occurs later, causing a discrepancy that probably has not occurred previously in human history. The study of human evolution adds to the understanding of many modern medical conditions as well as puberty, and the discipline of evolutionary biology is now recommended as a required premedical course by the American Association of Medical Colleges.[6,7]

Fetal Origins of Adult Disease

There are long-lasting effects of abnormalities in fetal and neonatal growth. As seen in longitudinal studies, low birth weight followed by rapid weight gain in infancy (i.e., catch-up growth) leads to tall childhood stature and early pubertal development. Poor prenatal nutrition and small-for-gestational-age (SGA) status tend to advance the age of puberty in girls and the age of adrenarche[8–10]; a secondary effect of increased postnatal nutrition, often leading to overweight or obesity, also lowers the age of puberty. Fig. 26.3 describes the relationship between excessive adipose tissue and early puberty. A prospective study demonstrated that a lower expected birth weight ratio (i.e., ratio of observed infant's birth weight to median birth weight appropriate for maternal age, weight, height, parity, infant sex, and gestational age) and a higher body mass index (BMI) at 8 years led to an earlier age of menarche.[11] Girls who are longer and lighter at birth and subsequently have greater BMI values at 8 years tend to have earlier menarche.[12] Rapid weight gain in the second to ninth months but not thereafter correlated with a greater BMI at 10 years and with earlier menarche in a longitudinal study.[13] On the other hand, higher birth weight is related to a later age of menarche, judging from data across several countries.[14] Large-for-gestational-age (LGA) infants tend to have an earlier age of takeoff of the pubertal growth spurt.[15] Many international studies find a relationship between low birth weight or catch-up growth and chronic diseases in adulthood; this phenomenon, the Barker hypothesis, is found in a wide range of populations.[16]

Birth weight and rate of postnatal growth—not prematurity alone—are inversely related to cardiovascular mortality risk and prevalence of insulin resistance syndrome (i.e., metabolic syndrome or syndrome X), which consists of hypertension, impaired glucose tolerance, and elevated triglyceride levels, among a growing list of other findings. This outcome is attributed to fetal and neonatal metabolic programming, in which early adjustments to enhance survival in difficult intrauterine circumstances set the stage for later disorders. Insulin resistance, which may be the basis for most of these complications or may be just one feature of the syndrome, may spare nutrients from use in muscle, leaving them available for the brain. This mechanism can minimize central nervous system (CNS) damage in the fetus during periods of malnutrition.

Determinants of the Age of Puberty and Menarche

Although historic records show that puberty occurs at an earlier age today, most evidence derives from reports of the age of menarche (Table 26.1).[17,18] Age of menarche is removed by several years from the first sign of secondary development in girls, and modern studies demonstrate correlation coefficients of only 0.37 between age of menarche and age of onset of puberty, suggesting both unique and similar factors exerting effects on these ages.[19] Changes in health and socioeconomic status in regions where data were collected during different decades lead to complexity in the interpretation of modern national data.

Age of menarche is determined in various ways. Recalled age of menarche is considered to be accurate within 1 year (in 90% of cases) up to 30 years after the event.[20] Contemporaneous recordings are performed with the probit method of asking for a response of "yes" or "no" to the question, "Are you menstruating?" However, the results are subject to social pressures of the culture and socioeconomic group considered.[21]

Physical examination with palpation of gonads or breasts by trained observers is the most accurate method of assessment of pubertal development. Detection of the onset of stage 2 breast development in an overweight girl on physical examination may be difficult even for a trained observer (although stage 3 usually is obvious). Visual observation of the stage of development in person (not by photographs) is one step removed from physical examination and palpation; errors in the evaluation of breast tissue in obese girls or the stage of testicular enlargement in boys may occur. Visual observation by multiple observers was used in the Third National Health and Nutrition Examination Survey (NHANES III) (and in the National Health Examination Survey [NHES] that occurred more than 20 years earlier), and visual observation is subject to interobserver variation. In a study by Pediatric Research in the Office Setting (PROS), a network fostered by the American Academy of Pediatrics, specially trained pediatricians, nurse practitioners, or physician assistants in 225 offices used palpation for 30% of the study population and visual inspection for all members of a convenience sample of 17,070 girls across the United States.[22]

TABLE 26.1 Comparison of Menarcheal Ages Reported by Various Studies

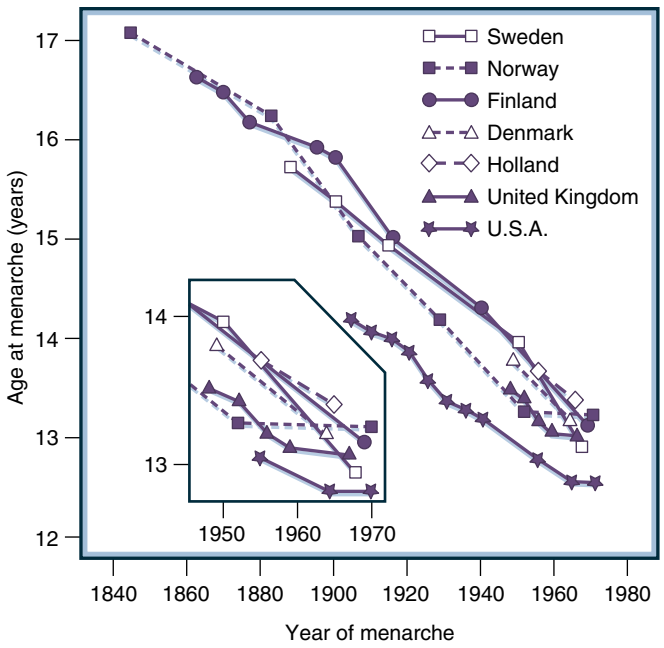
From Styne DM. Puberty, obesity and ethnicity. *Trends Endocrinol Metab.* 2004;15:472–478.

The availability of only limited numbers of trained personnel for examination or subjects' refusal of embarrassing examinations sometimes leads to the use of proxy measures. Photographs or drawings of pubertal development allow self-reporting or parental reporting of pubertal progress, but correlations range widely from 0.48 to 0.91 compared with physicians' examinations or visual observation of subjects.[23] The answers to self-assessment may be influenced by subjects' wishes to conform with their understanding of normal development and may be less accurate in some ethnic groups than others, similar to reported menarcheal age. Obese girls may overestimate breast developmental stage, and boys may overestimate pubic hair development. Individuals with learning disabilities, chronic diseases (e.g., cystic fibrosis, Crohn disease), or psychologic conditions (e.g., anorexia nervosa) may have less accurate pubertal staging.[24] Self-report is related to testosterone values for boys and girls and is said to be accurate enough if precision is not needed.[25] With all of its difficulties, physical examination remains the best method to accurately evaluate pubertal development, although self or parent report can likely determine prepuberty from puberty.[26,27]

The Secular Trend in Puberty and Menarche

Review of classic writings gives us insight into the changes in age of puberty and menarche through the epochs, although much of the data are inferred.[28,29]

During Paleolithic and Neolithic eras, menarche was estimated to occur between 7 and 13 years of age, equal to or earlier than



• **Fig. 26.4** The changes in age at menarche between 1840 and 1978 illustrate the advance in the age at menarche in Western Europe and the United States since 1840 and slowing of this trend since about 1965. (Modified from Tanner M, Eveleth PB. Variability between populations in growth and development at puberty. In: Berenberg SR, ed. *Puberty, Biologic and Psychosocial Components*. Leiden, The Netherlands: H.E. Stenfert Kroese; 1975:256–273.)

the present average. It was postulated that early menarche allows reproduction in the face of an early death. Writings during Greek, Roman, and Indian history suggest an age of menarche of 12 to 14 years and age of ejaculation in boys to be similar. Records from medieval Europe suggest a menarche at age 12 to 15 years. Up to the 20th century menarche age appeared to increase to 14 to 16 years.

The Developed World

The average age of menarche in industrialized European countries has decreased by 2 to 3 months per decade over the past 150 years; in the United States, the decrease has been approximately 2 to 3 months per decade during the past century[17,30] (Fig. 26.4). However, this secular trend slowed in developed countries such as the United States, Australia, and Western Europe between approximately 1940 and 1970, presumably due to improved socioeconomic status, better health, and the benefits of urbanization. There is a relatively small range of ages of menarche in the well-off developed world, where lower socioeconomic classes do not have an increased burden of disease or malnutrition. Chronic diseases previously increased the age of menarche, and delay in menarche is still associated with serious conditions (e.g., celiac disease, asthma) that are not adequately treated. The standard deviation of the mean age of menarche also decreased, suggesting a diminished number of those maturing very late, as might be found among disadvantaged people.[31] Teasing out the various factors involved in subtler secular trends will require further long-term study and newer methodologic approaches in areas where nutrition and health are optimal or close to it.[32] Remarkably, a reverse secular trend is reported in certain areas of Europe, leading to a later age of menarche. This has been attributed to a resurgence of physical and psychologic stress, as was seen in previous eras (e.g., World War II).[32]

There are cross-sectional and longitudinal data from the late 20th century demonstrating a resurgence of a secular trend in the United States, including ethnic influences.[33,34] The median age of menarche in the United States was 12.8 years according to the 1973 US National Center for Health Statistics National Health Education Study, and data from NHANES III (1988–1994) indicate the median age at that time was 12.43 years, 0.37 year earlier than in 1973.[35] During a 20-year period in the Bogalusa Heart Study, the median menarcheal age decreased by approximately 9.5 months among African-American girls compared with 2 months among white girls,[36] leading to a 4-month difference. Between the ages of 5 and 9 years, African-American girls in the Bogalusa study had taller stature and greater weight, factors that were predictive of menarche before age 11 years. African-American girls have advanced secondary sexual development compared with white American girls of the same age during the first three stages of puberty, and they have an advanced bone age; this may be related to the higher prevalence of obesity among African-American girls and to an ethnic-specific genetic influence.[37–39]

Obesity is defined as a BMI (calculated as weight in kilograms divided by height in meters squared) equal to or above the 95th percentile for age, and overweight is defined by the Centers for Disease Control and Prevention (CDC) as a BMI equal to or greater than the 85th percentile for age. Many studies have reported on the effect of the epidemic of childhood obesity and overweight on age of menarche.[40,41] Most cross-sectional and longitudinal studies found an inverse relationship between menarcheal age or other stages of puberty and BMI or other reflections of adiposity.[42,43] If the population in the 1970s had had the same range of BMI values as was found in the 1990s, the projected age of menarche would have been the same in the 1970s as it was in the 1990s.[44] Girls had a greater prevalence of overweight or obesity between the ages of 8 and 10 years if they were in puberty or had advanced breast development.[45] A study of the age at onset of puberty in US boys of various ethnic groups indicated an earlier age of onset between 6 months and 2 years depending upon indicator and ethnic group.[46] Except for a delay in pubertal development with BMI less than 15% there was no effect of overweight or obesity in these boys as was found in girls in other studies.

Longitudinal studies are limited in the United States but of great importance in the evaluation of a secular trend. The longitudinal National Heart, Lung, and Blood Institute (NHLBI) Growth and Health Study followed 1266 white and 1313 African-American girls from 9 or 10 years of age for 10 or more years. A recent report of a sample of 1239 girls from the study noted that 10.4% of white, 23.4% of black non-Hispanic, and 14.9% of Hispanic girls had attained breast stage 2 at 7 years; 18.3%, 42.9%, and 30.9%, respectively, attained breast stage 2 at 8 years, younger than data from 10 to 30 years ago. In a sample of 1155 girls, the mean age of menarche among whites was 12.7 years, and among African Americans it was 12.1 years; a direct relationship was found between weight and BMI and the age of menarche.[38] Of these girls, 51.6% started puberty with only one manifestation. Those who experienced breast development first (i.e., thelarche pattern), rather than the appearance of pubic hair (i.e., adrenarche pattern), had an earlier menarche (12.6 vs 13.1 years); this was associated with a greater BMI and body weight, which was not true for those girls manifesting the adrenarche pattern.[47] These findings support the analysis of NHANES III, in which girls with earlier breast development had greater BMI values at the time of menarche than those with adrenarche occurring first.[48]

African-American girls in the National Longitudinal Study of Adolescent Health (Add Health) were 1.55 times more likely than white girls to have menarche before 11 years[49] of age, and Mexican Americans were 1.76 times more likely to do so than whites. Asians were 1.65 more likely than whites to mature later than 14 years. Those undergoing early menarche were twice as likely to be overweight, and African-American girls had a 2.57-fold greater risk for overweight if they had menarche before they were 11 years old. Among early menarcheal African Americans, 57.5% had a BMI greater than the 85th percentile, and 32.5% had a BMI greater than the 95th percentile. A longitudinal study of 180 girls indicated earlier pubertal development in these cases: between the ages of 5 and 9 years with a higher percentage of body fat at 5 years; those with a higher percentage of body fat, higher BMI percentile, or larger waist circumference at 7 years; those with larger increases in the percentage of body fat from 5 to 9 years; and those with larger increases in waist circumference from 7 to 9 years.[50]

During the past 40 years, menarcheal age in the white subjects in the Fels Longitudinal Study has remained stable even as BMI has increased, with no relationship shown between the two. Subjects with early menarche had a tendency to increase BMI after menarche,[51] suggesting that increased weight appears to be a consequence rather than determinant of the age at menarche and that secular changes in BMI and in mean age at menarche may be independent phenomena. There was a rise in BMI, waist circumference, hip circumference, and serum levels of luteinizing hormone (LH), androstenedione, testosterone, and dehydroepiandrosterone sulfate (DHEAS) during the years immediately after menarche in a shorter longitudinal study.[52]

International data support the effects of BMI on puberty, but earlier onset of pubertal growth and a tall stature in childhood do not lead to a taller adult height.[53] Children studied longitudinally in Denmark showed earlier breast development (estimated mean age of 9.86 years compared to 10.88 years) and menarche (13.42 years compared to 13.13 years) in 2006 compared to 1991, which could not be explained by BMI or even by a difference in gonadotropin values suggesting other factors were operative.[54]

The Developing World

The interaction of socioeconomic conditions, nutrition, energy expenditure, states of health, and puberty is of particular importance in areas of the world where nutrition is suboptimal; where the most rapid improvement is found, such as in Oaxaca, Greenland, or South Korea, the age of menarche decreases more rapidly. Where standards of living do not change, the age of menarche is more stable. In South America and Africa, some rural children fare better and have earlier puberty and taller stature than urban children, demonstrating a trend of adverse health and nutritional conditions in crowded urban centers. Malnourished individuals have later age of menarche across the world.[55]

As a whole, these reports indicate that populations existing in the most difficult conditions who experience improvement in socioeconomic status demonstrate a greater decrease in the age of menarche. Once a minimum nutritional status or state of health is reached, the effects of socioeconomic status on the age of menarche are minimized or eliminated, but increased BMI can lower the age of menarche further. However, there are other factors, apparently environmental factors, that are postulated to affect the age of thelarche, which may not have as much effect on the age of menarche.

Factors Affecting the Age of Puberty and Menarche

The composition of diet and the number of calories in the diet may relate to menarche.[56] The prospective, longitudinal Harvard Longitudinal Studies of Child Health and Development found that girls had earlier menarche if they were taller and consumed more animal protein and less vegetable protein as early as 3 to 5 years old and that they had earlier peak growth velocity if they had higher dietary fat intake at 1 to 2 years old and higher animal protein intake at 6 to 8 years. Peak height velocity (PHV) increased, controlling for body size, if more calories and animal protein were consumed 2 years before peak growth. The correlation between higher animal protein intake and lower age of menarche is confirmed in Germany and Britain.[57,58] A positive relationship between high fiber intake and age of menarche held true in a comparison of 46 countries,[59] and a longitudinal study demonstrated a later onset of puberty and PHV in girls with higher isoflavone intakes, suggesting a lower risk for breast cancer with a high fiber prepubertal diet.[60] On the other hand, lifelong vegetarian dietary intake does not affect the age of menarche,[61] and a low-fat diet in otherwise healthy, prepubertal children 8 to 10 years old with elevated low-density lipoprotein (LDL) cholesterol produced no difference in age of menarche or pubertal progression.[62] Phytoestrogen (flavonol but not lignan) intake delays breast development, particularly in girls with lower BMI values.[63,64]

Another influence of the age of menarche is the maternal environment. Macrosomia due to maternal diabetes or obesity is associated with increased BMI in childhood, which itself is related to earlier puberty and menarche. Increased or decreased weight gain in pregnancy likewise decreases the age of menarche according to data from the Nurses' Health Study II.[65] Heavy maternal smoking of cigarettes but not of marijuana leads to earlier male puberty but not female puberty in offspring.[66] Maternal tea drinking but not coffee drinking was associated with a later age of menarche and puberty in their daughters. Daughters of mothers who were more physically active during pregnancy had a modest delay in menarche.[67]

Stress and Puberty

Life history theories aiming to explain influences on the age of puberty address energetics, stress suppression, psychosocial acceleration, paternal investment, and child development, each of which may have various effects on the timing and progression of pubertal development.[68] This approach acknowledges the fact that evolution optimizes allocation of limited resources to maximize fitness and allow reproductive success.[69]

Stress is variably reported to increase or decrease the age of menarche. The absence of a father or lower parental education increases the likelihood of early menarche; however, there is evidence that the exposure to paternal psychopathology that precedes the absence of the father might be causative in such situations.[70] War increases the age of voice breaking in boys (e.g., in Bach's choir during the War of Austrian Succession in 1727–1749), and the age of menarche increased during World War II and during more recent hostilities in the former Yugoslavia.[71] Sexual abuse is associated with earlier onset of puberty and earlier menarche compared with a control population in a large US national study, although it is difficult to eliminate the effect of family dysfunction in this situation as well.[72] Child abuse of various types is associated with delayed puberty and menarche in a large British study, and sexual abuse in this cohort led to both early and late menarche.[73]

Genetic Effects on Puberty and Menarche

There remains a difference in age at attainment of stages of puberty in different countries even with stability in socioeconomic factors; for example, Japanese boys undergo changes in testicular size about 1 year earlier than Swiss boys do.[74] When socioeconomic and environmental factors lead to good nutrition, general health, and infant care, 60% to 80% of the determination of the age at onset of puberty in normal children appears to be due to genetic causes.[31]

The important role played by genetic factors in the onset of puberty is illustrated by the similar age of menarche in members of an ethnic population and in parent-child and sibling or twin pairs.[75,76] The correlation between mother and daughter patterns should theoretically be equal to sister-sister age at menarche if only genetic factors are operative, but because sister-sister correlations are higher than mother-daughter correlations, environmental influences must provide an additional influence beyond genetic factors; the secular trend and nutritional factors may be invoked.

Concordance of ages of pubertal developmental stages and menarche is closer between monozygotic than dizygotic twins, supporting the influence of genetic factors. Monozygotic twins reared together have more similar ages of menarche than those reared apart, and dizygotic twins reared together are less similar than either of the monozygotic groups, pointing to environmental influences on genetic factors. Some twin research suggests that additive genetic factors account for 96% of the variance in the age of puberty in girls and 88% of the variance in boys (although other sources from the United States, Australia, Great Britain, Finland, and Norway have found genetic effects accounting for between 50% and 80% of the variance), with the remainder resulting from shared and nonshared environmental influences.[77,78]

A large study of 180 twins, 132 monozygotic and 48 dizygotic, showed a high level of hereditability of DHEAS sulfate levels and pubertal development with a higher estimate in monozygotic twins.[79]

Genome-wide association study (GWAS) techniques approach the greatly complex question of the genetic control of puberty and growth. Alleles near 6q21 (T) at rs7759938 *(LIN28B)* correlated with earlier puberty and shorter prepubertal childhood height, as well as age of menarche.[80,81] A meta-analysis of GWAS data for 17,510 women demonstrated the strongest signal related to age of menarche $\times 10^{-9}$, where the nearest genes include *TMEM38B, FKTN, FSD1L, TAL2*, and *ZNF462*, and the next strongest signal near the *LIN28B* gene (rs7759938; $p = 7.0 \times 10^{-9}$), which also influences adult height and cancer risk.[82] Studies of thousands of European individuals linked locus upstream of myocardin-like 2 *(MKL2)* ($p = 8.9 \times 10^{-9}$) with earlier puberty with reduced pubertal growth ($p = 4.6 \times 10^{-5}$) and short adult stature ($p = 7.5 \times 10^{-6}$) in both males and females.[83] Variants near *MAPK3, PXMP3*, and *VGLL3* linked taller prepubertal stature with earlier menarche, and a variant near *ADCY3-POMC* was associated with increased BMI, reduced pubertal growth, and earlier puberty.[83]

Gonadotropin-releasing hormone type I (GnRH-I) and its receptor (GnRHR) genes are only modestly related to the age of menarche.[84] The *LEP1875* and XbaI and PvuII polymorphisms of the estrogen receptor α (ERα) gene *(ESR1)* and maternal age at birth (i.e., >30 or <30 years) were associated with age of menarche.[85,86] High-activity *CYP17* alleles involved in estrogen formation and high-activity *CYP1A2* and *CYP1B1* alleles, whose gene products metabolize estradiol, are not associated with pubertal stage,[87] whereas the high-activity *CYP3A4** 1B/1B girls had an earlier age of onset of normal puberty alleles. The variant rs10235235 of *CYP3* is associated with a reduction in breast cancer risk for women who had their menarche age at 15 years or older but not for those with menarche younger than 11 years.[88] Girls with longer (>8) TAAAA repeats in their sex hormone–binding globulin gene *(SHBG)* have a later age of menarche than those with fewer repeats.[89] A GWAS study showed the common genetic variants contribute to early puberty in girls more than late puberty, and they contribute in boys to delayed puberty more than early puberty. It suggested that this may be an explanation why precocious puberty is more likely to be idiopathic than organic in girls and delayed puberty more likely to be constitutional in boys.[90] This study also found that early puberty regardless of BMI was associated with higher risks of breast, ovarian, and endometrial cancers in women.

Cancer and Age of Puberty

There is divergent data on puberty and prostatic cancer. The preceding study showed increased risk of prostate cancer in men with early puberty, which was confirmed in a study of 2927 cases of prostatic cancer that found that older onset of puberty led to a lower risk of prostate cancer, especially aggressive types, and another study of 757 men.[91] Conflicting results occurred in a study of 1088 cases of prostate cancer, which demonstrated an increased risk of 6% for each year of recalled delayed puberty with an odds ratio (OR) of 1.35 if puberty commenced after 15 years.[92]

There are genetic effects upon the age of onset of testicular growth in boys as well. Danish and Chilean boys had a later onset of puberty when they had genetic alteration in follicle-stimulating hormone (FSH) beta production (FSHβ c.-211G>T), which was further enhanced with a genetic variation in FSH receptor sensitivity (FSHR c.-29G>A).[93] There was a 1.5% to 1.7% variance explained by the genetic modifications in contrast to the effect of BMI, which explained 7.2% variance in Chilean boys and 17.2% variance in Denmark boys.

Other Factors

Seasonality of menarche was observed in a US cohort of 3000 college students; those born after 1970 had an earlier age of menarche and a more pronounced frequency peak in July. Factors hypothesized to contribute to seasonality of menarche include stress and the photoperiod.[94] In Peru, puberty begins at a later age, and pubertal development lasts longer at high altitudes than at low altitudes even when nutritional status is similar. There is a north-to-south decrease in the age of menarche in Europe[25] that may result from environmental factors or genetic influences.[31]

The Comorbid Conditions of Early Puberty

Many international studies show that earlier age at menarche is associated with a greater risk of development of breast cancer by a factor of 1.050 (95% confidence interval [CI] 1.044-1.057; $p < 0.0001$) for every year younger at menarche.[95] The risk of premenopausal breast cancer decreases 9% per year of delay in menarche, and the risk for postmenopausal breast cancer decreases 4%.[96] This trend in which a longer period of reproductive function increases the risk for breast cancer is more due to early menarche than to later menopause and has been found in other studies as well. In disease-discordant monozygotic twins, the one with cancer recalled puberty to be earlier; in disease-concordant

twins, the one with earlier menarche had the earlier diagnosis of breast cancer.[97] Women with breast cancer were taller and leaner in childhood and had increased height velocity at age 4 to 7 years and age 11 to 15 years; higher BMI increased this risk. These variables were particularly significant in women with early menarche (at age <12.5 years).[98] Remarkably, another study of 117,415 women found that increased birth weight, height at 8 years of age, peak growth at an early age, taller stature at 14 years of age, and low BMI at 14 years of age were independent risk factors for breast cancer, but there was no effect on age of menarche.[99] However, increased body weight at 8 years appeared to decrease the risk of breast cancer in another study of 90, in 50% of women.[100]

There is indirect evidence relating earlier menarche to increasing likelihood of hepatocellular carcinoma. On the other hand, later age of menarche (>14 years) is associated with an increased risk of glioma or non-Hodgkin lymphoma.[101,102]

Evidence from the Fels Longitudinal Study of white females revealed that girls with self-reported menarcheal age of less than 11.9 years (classified as early menarche; 23% of the sample) had adverse cardiovascular risk factors such as elevated blood pressure and glucose intolerance unrelated to body composition.[103] There was increased carotid artery intima media thickness in women with an age of menarche less than 11 years compared to those with the age of menarche over 11 years in 461 women in the Bogalusa Heart Study.[104]

National Trends in Pubertal Development

Limits of Normal Pubertal Development

The NHES enrolled subjects who were 12 years old; although it is useful for defining the upper limits of normal pubertal development, the survey is uninformative about the lower limits of the age at onset of puberty.[37,105] A longitudinal study (Tables 26.2 and 26.3) that enrolled 9.5-year-old white boys and girls added much to the determination of the mean age at attainment of stages of puberty[106]; however, it started too late to include normal children entering puberty at an earlier age. Two studies used data from NHANES III. One found onset of stage 2 breast development for African Americans, Mexican Americans, and whites to occur at 9.5, 9.8, and 10.3 years, respectively, and pubic hair stage 2 to occur at 9.5, 10.3, and 10.5 years, respectively, using a sample of 1623 girls.[107] The other study reported that the ages for onset of stage 2 breast development were 9.5 years for African Americans, 9.8 years for Mexican Americans, and 10.4 years for white Americans, whereas the onset of stage 2 pubic hair occurred at 10.4 years for white Americans, 9.4 years for African Americans, and 10.6 years for Mexican Americans in a sample of 2145 girls.[108]

Because the PROS started at 3 years of age but ended at 12 years of age, it excluded a proportion of normal girls who enter puberty at a later age, although the probit statistical method can estimate events even when only a portion of the population has achieved the event.[22] This study was criticized because the subjects from the convenience sample were not matched for the many factors considered in a national study such as NHANES. The standard deviation of the longitudinal study described earlier was low, 1.0 year or less in most cases, whereas the cross-sectional study PROS had a larger standard deviation of approximately 2 years. Any study of puberty will demonstrate a limit in the spread of the upper end of the age at onset of puberty curve, because rarely do individuals with the most severe constitutional delay of puberty (CDP) spontaneously enter puberty after 18 years of age. There may be a skewing of the normal age at onset of puberty to an earlier spread of ages.

A study of the age of pubertal stages in children in NHANES revealed that in those with normal BMI values, pubertal signs occurred before 8 years of age in fewer than 5% of the non-Hispanic white female population, although thelarche occurred before age 8 in 12% to 19% of normal-BMI, non-Hispanic black and Mexican-American girls; the 5th percentile for menarche was 0.8 year earlier for non-Hispanic black than non-Hispanic white subjects.[43] Although the appearance of pubic hair occurred in up to 3% of 8-year-old girls with normal BMI values in all ethnicities, it did occur significantly earlier in the minority groups. Girls with the higher BMI values had a significantly higher prevalence of thelarche between the ages of 8 and 9.6 years and pubarche from the ages of 8 to 10.2 years, compared with girls with normal BMI values. Menarche was significantly more likely to occur in younger girls with elevated BMI values. In boys with normal BMI values, pubic hair appeared in fewer than 2% before 10 years. The study authors concluded that pubertal development in girls with normal BMI values before 8 years of age is premature. These data support other analyses of NHANES III, in which the heaviest girls tended to have thelarche before pubarche and the heaviest boys had pubarche before gonadarche.[48]

The latest and largest multiracial and ethnic study of the age at onset of puberty in a convenience sample of 4131 American boys between the ages of 6 and 16 years found the mean ages for onset of Tanner 2 genital development for non-Hispanic white boys was 10.14, African-American boys was 9.14, and Hispanic boys was 10.04 years; and for stage 2 pubic hair, the ages were 11.47, 10.25, and 11.43 years, respectively. Mean ages for achieving testicular volumes of greater than 3 mL were 9.95 for white, 9.71 for African-American, and 9.63 for Hispanic boys; and for greater than 4 mL ages were 11.46, 11.75, and 11.29, respectively.[46]

Weight affects the onset of puberty in boys but not in a linear manner. Overweight boys have earlier puberty than normal weight boys, while obese boys start puberty later.[109]

Spanish investigators demonstrated that the earlier normal girls entered puberty, the longer the duration of puberty before menarche. In one of these studies, girls who started puberty at 9, 10, 11, 12, and 13 years of age experienced menarche 2.77, 2.27, 1.78, 1.44, and 0.65 years later, respectively, demonstrating a normalizing trend that keeps the age of menarche relatively stable in the group as a whole.[110] These data may suggest that earlier onset of the first stages of puberty may not exert major effects on the age of menarche. This contrasts with a suggestion of a decrease in the time required to transit puberty from start to end in Dutch and Swedish boys and girls.[31]

In sum, the data show that African-American girls develop before white girls, regardless of socioeconomic issues. There is evidence that rising BMI values in childhood are associated with earlier pubertal maturation, which may explain some of the increasing age differences between these ethnic groups. Environmental disruptors may also play a role. Although there is evidence for earlier menarche, a secular trend toward earlier puberty in girls in the absence of increased BMI cannot be supported from these data because of the different ages studied and lack of comparable studies over past decades.[34,111]

The United States is lacking a comprehensive, large, longitudinal study that would start early enough to include the youngest normal pubertal subjects and last long enough to include the oldest and that would be based on direct physical examination

rather than observation. Such a study must be balanced in terms of ethnic groups, and the planners must use the predicted increase of certain ethnic populations in the United States to avoid the unfortunate position we now have as we look back and try to draw conclusions about secular trends without sufficient data from various ethnic groups.[34]

From all of the longitudinal and some of the cross-sectional data, we may consider the mean age at onset of puberty in boys to be 11 years, with the normal limits being 9 to 14 years.[106] It is possible that some normal boys, especially African-American boys, will enter puberty or adrenarche between 8 and 9 years of age. The influence of BMI must be taken into account. Obese boys characteristically enter puberty early, especially when there is an *MCR4* mutation, but obesity is also associated with delayed puberty.

Guidelines for the normal variation in pubertal development for girls in the United States are controversial. In the cross-sectional, convenience sample study, 3% of white girls had stage 2 breast development in their sixth year and 5% by the seventh year, whereas 6.4% of African Americans had stage 2 breast development by the sixth year and 15.4% by the seventh year. African-American girls have an earlier onset of pubertal development by about 1 year, even though their average age at menarche in the cross-sectional study was only 8.5 months different (12.2 years for African Americans and 12.9 for whites). We may combine these findings and set the normal range for age at puberty in white girls at 7 to 13 years and in African-American girls at 6 to 13 years. However, some girls in this early range may have a loss-of-function *MKRN3* mutation, possibly in a familial pattern; testing is available only in research laboratories at present but may be available for clinical diagnosis in the future.

These guidelines help the decision of which children with early onset of puberty are candidates for expensive diagnostic tests and for consideration of long-term therapy, because many of those children who appeared to have mild sexual precocity in years past may now be considered to represent a normal variation. We emphasize that family history, the rapidity of development of secondary sex characteristics, the rate of growth, and the presence or absence of CNS or other types of diseases must enter into the decision to evaluate a child. We recommended these ideas in previous editions of this textbook, and the Drug and Therapeutics and Executive Committees of the Lawson Wilkins Pediatric Endocrine Society supported such a revision of the lower limit of the normal age at onset of puberty to age 7 for white girls and age 6 for African-American girls, with no changes in the current guidelines for evaluating boys, which target those with signs of puberty developing before 9 years of age.[112]

Several studies indicate the likelihood of missing serious endocrine disorders if the new guidelines are followed.[113–115] With all of these studies, it may be inferred that if the examining physician looks for signs and symptoms of disease rather than just relying on the age criteria, less than 10% of true precocious puberty will be missed; of those cases, some (probably many) will be so mild as to not need intervention and may represent variations of normal. A multinational study from Europe suggested that valid indications for magnetic resonance imaging (MRI) of the CNS in the diagnosis of precocious puberty are puberty onset in girls before 6 years of age, in agreement with our recommendations, and an estradiol value higher than the 45th percentile (in the laboratory performing the diagnostic tests) for girls with central precocious puberty (CPP), a new criterion.[116]

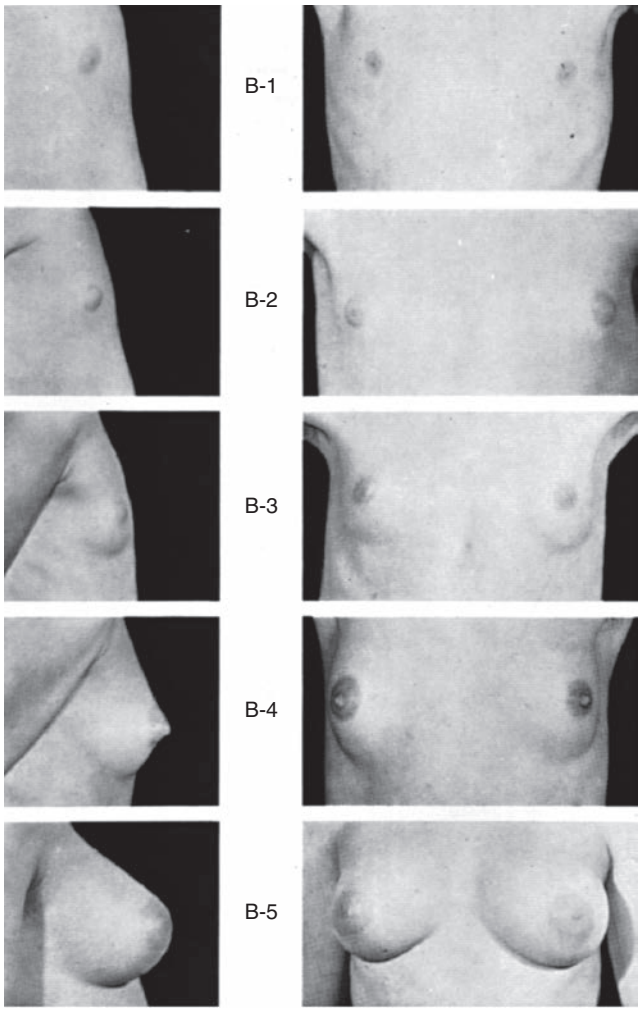
As noted, there are variations of pubertal development that do not demonstrate pubertal elevations of LH values. For instance, early breast development with bone age advancement and increased growth without elevation of LH may be described as "thelarche variant"[117] or "early normal variant puberty."[118] These classifications are not clearly explained in the literature. Obese girls may have local production of estrogen leading to thelarche without elevation of LH, but some studies, particularly from Denmark, demonstrate thelarche without elevation of LH in girls who do not have elevated BMI values.

Secondary Sexual Characteristics and Physical Changes of Puberty

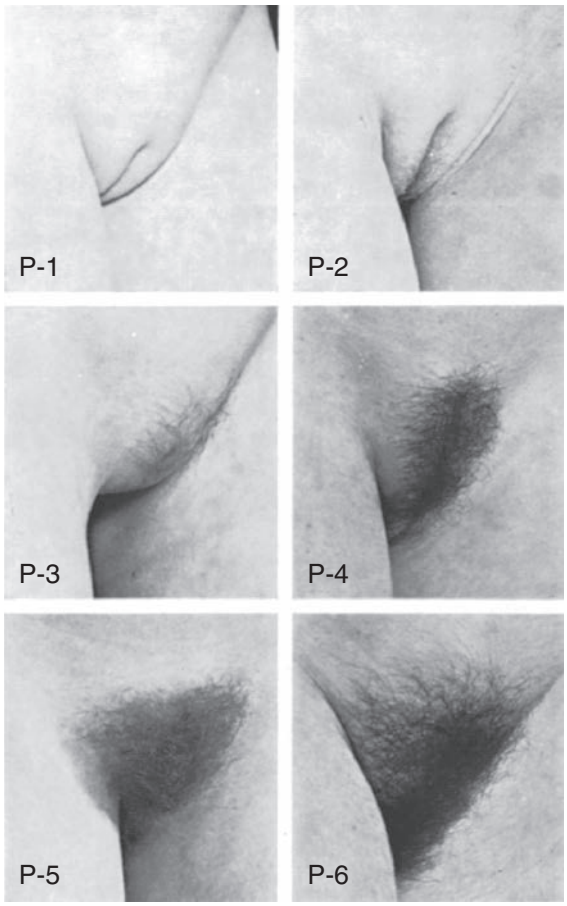
Female Development

Two distinct phenomena occur in the female. The development of the breast and its modified apocrine glands is primarily under the control of estrogens secreted by the ovaries (Fig. 26.5); the growth of pubic and axillary hair (Fig. 26.6) is mainly under the influence of androgens secreted by the adrenal cortex and the ovary. Breast cancer develops in rodents exposed to environmental toxins (e.g., endocrine disruptors) that alter normal mammary development, and this same relationship is postulated to occur in girls exposed to endocrine-disrupting chemicals, especially if development occurs early.[119] Aromatase is present in adipose tissue, and estrogen produced in excess adipose tissue may stimulate breast development at an earlier age in obese girls. Peripubertal obese girls also demonstrated elevated values of androgens, especially just before the onset of puberty and in the early stages of puberty, and there is also decreased LH secretion compared to nonobese girls.[120,121]

The five stages of breast development described by Tanner are the most widely used staging mechanism (see Fig. 26.5). Initial breast development may be unilateral for several months, causing unfounded concern by girls or parents. Needless surgical biopsies



• **Fig. 26.5** Stages of breast development according to Marshall and Tanner (1969). Stage 1: preadolescent; elevation of papilla only. Stage 2: breast bud stage; elevation of breast and papilla as a small mound, with enlargement of the areolar diameter. Stage 3: further enlargement of the breast and areola, with no separation of their contours. Stage 4: projection of the areola and papilla to form a secondary mound above the level of the breast. Stage 5: mature stage; projection of the papilla only, resulting from recession of the areola to the general contour of the breast. (Photographs from Van Wieringen JD, Wafelbakker F, Verbrugge HP, et al. *Growth Diagrams 1965 Netherlands: Second National Survey on 0-24 Year Olds.* Netherlands Institute for Preventative Medicine TNO. Groningen, The Netherlands: Wolters-Noordhoff; 1971. Additional data from Marshall WA, Tanner JM. Variations in pattern of pubertal changes in girls. *Arch Dis Child.* 1969;44:291–303.)



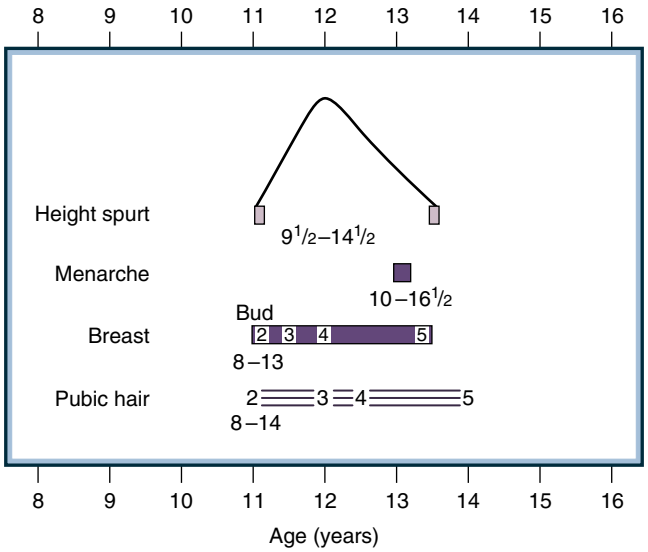
• **Fig. 26.6** Stages of female pubic hair development according to Marshall and Tanner (1969). Stage 1: preadolescent; the vellus over the pubes is not further developed than that over the anterior abdominal wall; there is no pubic hair. Stage 2: sparse growth of long, slightly pigmented, downy hair that is straight or only slightly curled, appearing chiefly along the labia. This stage is difficult to see on photographs. Stage 3: hair is considerably darker, coarser, and curlier. The hair spreads sparsely over the junction of the pubic region. Stage 4: hair is adult in type, but the area covered by it is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. Stage 5: hair is adult in quantity and type, distributed as an inverse triangle of the classic feminine pattern. The spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle. (Photographs from Van Wieringen JD, Wafelbakker F, Verbrugge HP, et al. *Growth Diagrams 1965 Netherlands: Second National Survey on 0-24 Year Olds.* Netherlands Institute for Preventative Medicine TNO. Groningen, The Netherlands: Wolters-Noordhoff; 1971. Additional data from Marshall WA, Tanner JM. Variations in pattern of pubertal changes in girls. *Arch Dis Child.* 1969;44:291–303.)

are carried out for this normal variation, and an ultrasound examination may preempt unfounded concerns about breast cancer. If concern arises about breast cancer during puberty (a rare event), ultrasound evaluation is suggested because of the dense nature of the tissue at this stage. Inherited or sporadic agenesis of the breast allows no glandular or fat enlargement, regardless of the level of estrogen stimulation. Virginal breast hypertrophy, an extreme and rapid increase in breast size at the onset of puberty, is rare but is attributed in part to increased sensitivity to estrogen action or to increased local estrogen synthesis and growth factors.

Changes in the diameter of the papilla of the nipple are sequential and are linked to stages of pubertal development.[122] Nipple papilla diameter (3–4 mm) does not increase much during pubic hair stage 1 to 3 or breast stage 1 to 3 but does increase after breast stage 3, providing an objective method of differentiating stage 4 from[123] stage 5 (final diameter, ~9 mm).

The stage of breast development usually progresses along with the stage of pubic hair development in normal girls, but because different endocrine organs control these two processes, discordance can occur. Therefore breast and pubic hair developmental stages should be classified separately for greatest accuracy (Fig. 26.7; also see Table 26.2).

A dulling and thickening of the vaginal mucosa from the prepubertal reddish, glistening appearance occurs as the lining cells cornify, changing the mucosa to a pink appearance, and the secretion of clear or whitish discharge increases in the



• **Fig. 26.7** The sequence of events at puberty in females. Diagram of the sequence of events at puberty in males. An average is represented in relation to the scale of ages; the range of ages within which some of the changes occur is indicated by the numbers below. The ages are from British girls 40 years in the past, so the sequence of changes, rather than the ages, is the important factor. (From Marshall WA, Tanner JM. Variations in pattern of pubertal changes in girls. *Arch Dis Child.* 1969;44:291–303.)

months before menarche as a result of estrogen action. Girls may notice light-colored discharge on their underwear at this stage. The vaginal pH decreases as menarche approaches due to the increase in lactic acid produced by lactobacilli in the vaginal flora. The length of the vagina increases from about 8 cm at onset of puberty to 11 cm at menarche. Thickening, protrusion, and rugation of the labia majora and minora occur. Fat is deposited in the area of the mons pubis, and the appearance of the labia majora becomes wrinkled. Occasionally, the labia minora may enlarge on one or both sides enough to suggest a tumor; childhood asymmetric labium majus enlargement is a disorder of prepuberty or early puberty.[124] The clitoris enlarges slightly, and the urethral opening becomes more prominent. Photographic atlases of normal female prepubertal genitalia are available and include standards for the variation in appearance of the hymenal opening; this information is invaluable in the evaluation of a victim of suspected child abuse.

Ovarian Development

The peak cohort of germ cells in the fetal ovary is attained at 16 to 20 weeks of gestation. Primordial follicles start to appear at 20 weeks of fetal life, and primary follicles soon follow; they constitute the lifelong store of follicles for the individual, which decreases with development and aging.[125] Follicle-stimulating hormone receptors have not been detected in midtrimester human fetal ovaries; fetal pituitary FSH is not required for proliferation of oogonia, oocyte differentiation, or formation of primordial follicles.[126] During fetal life and childhood, follicular growth to the large antral stage occurs, but before menarche all developing follicles are destined to undergo atresia (Fig. 26.8). Large preovulatory follicles are rarely present before puberty.

The ultrasound appearance of the prepubertal ovary changes with pulsatile gonadotropin secretion, and a multicystic appearance occurs with more than six follicles of at least 4 mm in diameter; this appearance differs from that found in the polycystic ovary syndrome (PCOS). During prepuberty, the ovarian volume is 0.2 to 1.6 mL on ultrasound scans, and after the onset of puberty the volume increases to 2.8 to 15 mL. Tall girls have greater ovarian volume than average-size girls.

The uterus grows until the age of 16 years under the influence of estradiol, progesterone, growth hormone (GH),[127] and insulin-like growth factor 1 (IGF1). Ultrasound studies (Fig. 26.9) show that the corpus of the uterus increases during pubertal progression, from an initial tubular shape to a bulbous structure; the length of the uterus increases from 2 to 3 cm to 5 to 8 cm, and the volume increases from 0.4 to 1.6 mL to 3 to 15 mL.[128] Decreased uterine size is found in patients with Turner syndrome, childhood exposure to radiotherapy, and abnormalities in *HOX* and *WNT* gene expression; maternal cigarette smoking can decrease uterine size at adolescence. Smaller uterine size is associated with an increased risk of miscarriage and failed implantation.

Uterine ultrasonography measurements are proposed to aid the clinician in differentiating premature thelarche from precocious puberty. The addition of color Doppler studies may improve accuracy of the diagnosis of precocious puberty and can differentiate the condition from premature thelarche. A Doppler study showed the lowest impedance of the uterine artery to be in girls with established CPP.[129]

Endometriosis is considered to be an estrogen-dependent process, although it has been reported in premenarcheal girls. It was suggested that this cause for chronic abdominal pain is more common than previously considered. One proposed explanation for early-onset endometriosis is that the condition results from müllerian rests.[130]

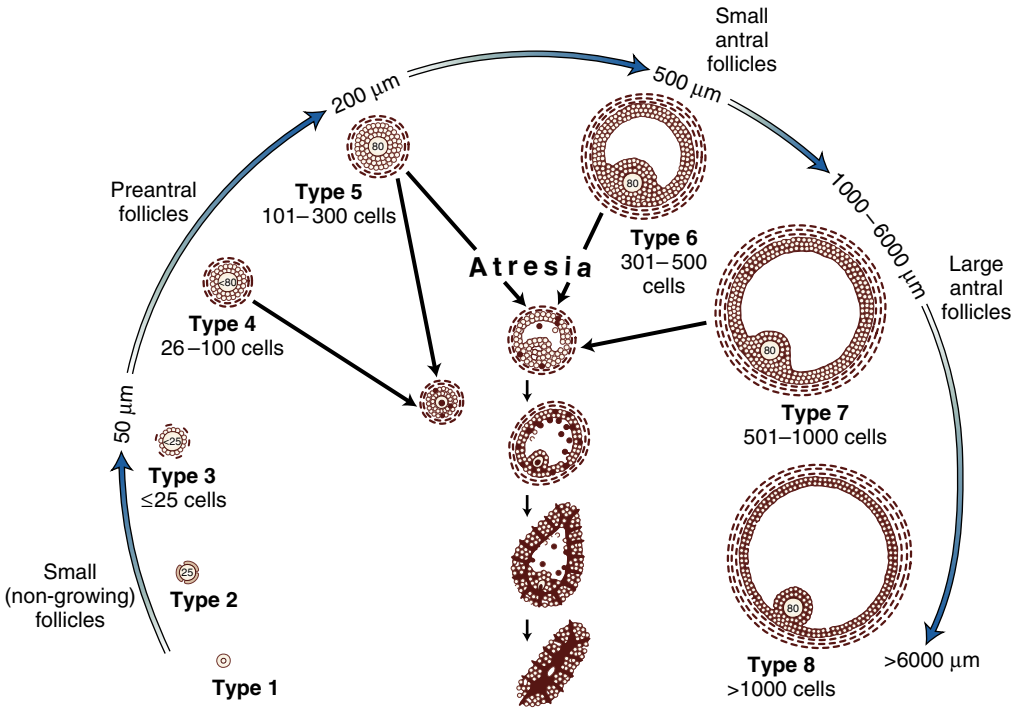
Menarche and Teenage Pregnancy

Menarche usually occurs in the 6 months preceding or following the epiphyseal fusion of the second and first distal phalanges and the appearance of the sesamoid bone; this corresponds to Tanner stage 4 in most cases. The 95th percentile for menarche is 14.5 years, although many textbooks define primary amenorrhea as absence of menses at 16 years. Reconsideration of the age at onset of female puberty may lead to a reconsideration of the definition of primary amenorrhea. Anovulatory cycles are common in the first years after menarche. There is a reported prevalence of 55% anovulation in the first 2 years after menarche that decreases to 20% anovulatory cycles by the fifth year; others have observed a lower number of ovulatory events shortly after menarche and 5 years after the event. With the high prevalence of PCOS, it is unclear how often delayed regularity is an early sign of PCOS or normal variation.

Male Development

The growth and maturation of the penis usually correlate closely with pubic hair development, because both features are under androgen control. However, the stages of pubic hair development and genital development should be determined independently, because discordant stages provide clues to potential disease states of the adrenal gland or testes (Figs. 26.10 and 26.11; also see Table 26.3).

Growth of the testes is usually the first sign of puberty in the male, and it begins approximately 6 months after the average chronologic age of initiation of breast development in girls (see Fig. 26.4). Pubertal testicular enlargement is indicated when the longitudinal measurement of a testis is greater than 2.5 cm (excluding the epididymis) or the volume is greater than 3 mL.



• **Fig. 26.8** Schematic representation of the growth of ovarian follicles during infancy and childhood. Type 1 (primordial follicle) and type 2 (primary follicle) are composed of a small oocyte and a few to a ring of flat granulosa cells. In the diplotene (nesting) stage of prophase, primary follicles are the predominant form of oocyte and constitute the reservoir of cells from which follicular growth occurs. Types 3 to 5 (preantral follicles) are follicles that have entered the growth phase; the oocyte is enlarging and is surrounded by a zona pellucida, and granulosa cells increase in number and differentiate. The growth of the oocyte is complete by the end of the preantral stage, and the increased follicular size is caused by follicular growth and fluid accumulation. Types 6 to 8 represent antral follicles (graafian follicles) and contain a fully grown oocyte, a large number of granulosa cells, a fluid-filled cavity, and a well-developed theca external to the basement membrane. Large preovulatory follicles are absent (10,000–15,000 µm). Follicular growth and atresia take place throughout childhood. All follicles that enter the growth phase become atretic, and this can occur at any stage in their development but mainly involves large antral follicles. (From Peters H, Byskov AG, Grinsted J. Follicular growth in fetal and prepubertal ovaries of humans and other primates. *Clin Endocrinol Metab.* 1978;7:469–485.)

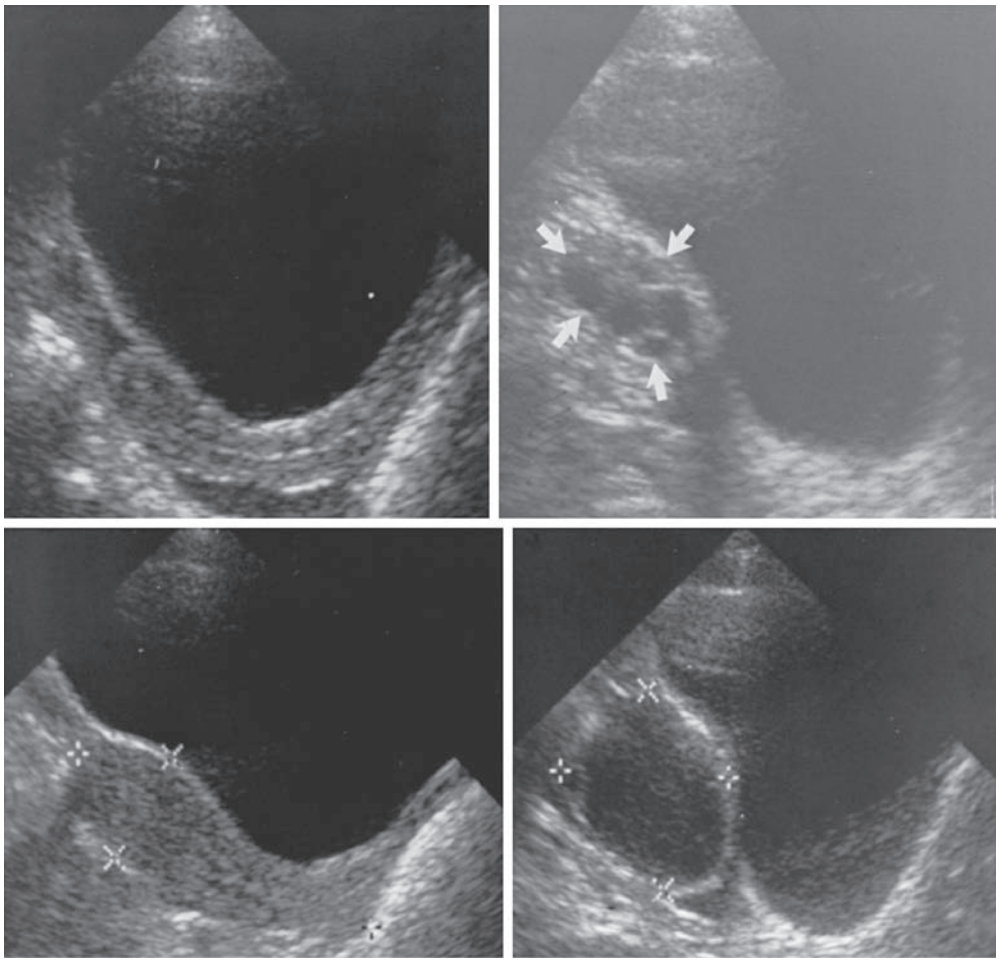
The testicular volume index ([length × width of right testis] + [length × width of left testis]/2) and testicular volume, measured by comparing the testes with ellipsoids of known volume (orchidometer), correlate with the stages of puberty.[131,132] A longitudinal study supported the utility of adding a stage 2a when testicular volume is 3 mL; further pubertal progression occurred within 6 months in 82% of boys who had reached this 3-mL phase[133] (Table 26.4). The most significant changes in serum testosterone and calculated free testosterone occur at the transitions of testicular volume between 1 and 2 mL, 2 and 3 mL, 6 and 8 mL, and 10 and 15 mL, suggesting the denotation of stages pre-1 (testis, 1 mL), pre-2 (testis, 2 mL), early (testis, 3–6 mL), middle (testis, 8–12 mL), late-1 (testis, 15–25 mL, the boy has not reached final height), and late-2 (testis, 15–25 mL, the boy has reached final height).[134] The right testis is normally larger than the left testis, and the left testis is located lower in the scrotum than the right testis.

The phallus should be measured while stretched and in the flaccid state because there is much variation among individuals in the length of the unstretched penis. The length of the erectile tissue (excluding the foreskin) increases from an average of 6.2 cm in the prepubertal state to 12.4 ± 2.7 cm in the white adult. Ethnic differences have been identified; the mean value in African-American men is 14.6 cm, and in Asians it is 10.6 cm.[135]

As in girls, the areolar diameter increases in boys during puberty, with a distinct separation between the sexes occurring in stage 4, when female areolar diameter increases much more than in the male. In gynecomastia, the areolar diameter increases to above-normal values.

Male Testicular Development in Puberty

The testes are active during the prepubertal period albeit at a lower level than during pubertal development.[136] During pubertal development, the testes increase in size, principally because of the growth of the seminiferous tubules associated with the onset of spermatogenetic activity and mitosis of Sertoli cells, and testosterone production increases (Fig. 26.12 and Table 26.5). The Sertoli cells are the major cell type in the seminiferous cords in prepuberty and early puberty, but in the adult, germ cells predominate. During progression through puberty, the Sertoli cells cease to undergo mitosis, differentiate into adult-type Sertoli cells, and form occlusive junctions with the development of the blood-testes barrier. Although Leydig cells are found in early gestation and during the neonatal period of testosterone secretion, the interstitial tissue is composed principally of undifferentiated mesenchyme-type cells during childhood. With pubertal development and rising serum LH levels, adult-type Leydig cells appear (Table 26.6). It is suggested that three phases of Leydig



• **Fig. 26.9** High-resolution pelvic ultrasonography. *Top left*, Prepubertal uterus. *Top right*, Prepubertal ovary demonstrating four small follicular cysts *(arrows)*. *Bottom left*, Pubertal postmenarchal uterus. *Bottom right*, Ovarian cyst in a girl with true precocious puberty.

cell maturation correspond with ages of increased testosterone production: 14 to 18 weeks of fetal life, 2 to 3 months after birth, and puberty through adulthood.[137] The seminal vesicle enlarges through childhood to puberty to hold 3.4 to 4.5 mL, or 70% of the seminal fluid. The mean blood flow in the testes increases to adult values (measured by Doppler sonography) in boys, with a testicular volume greater than 4 mL.

Testicular size is generally measured at the longest diameter excluding the epididymis or volume as determined by comparing the testis to a Prader orchidometer. New smoothed curves of testicular volume versus age are available as based on physical examination and ultrasonography in 769 healthy Dutch boys.[138]

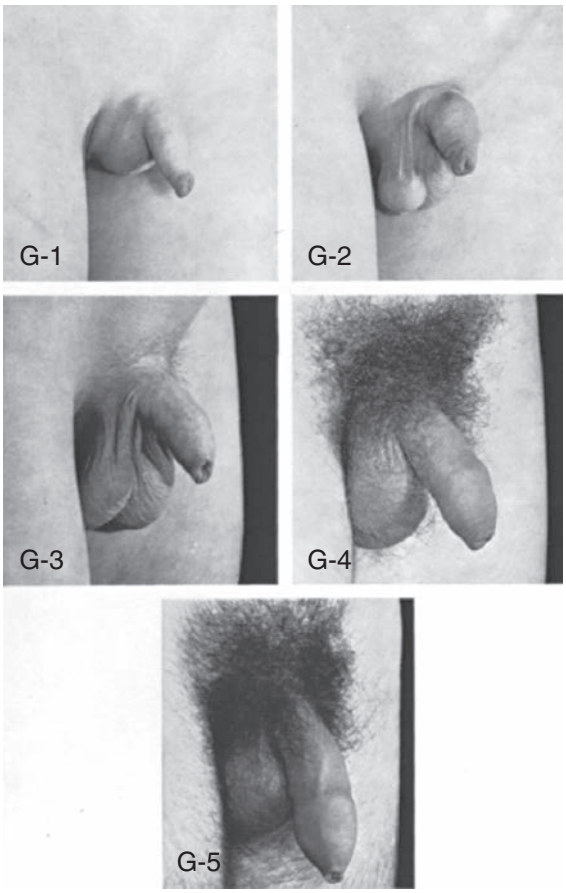
Spermatogenesis

The first histologic evidence of spermatogenesis appears between ages 11 and 15 years (Fig. 26.13; also see Figs. 26.6 and 26.9). Spermaturia may be the first sign of pubertal development, but the presence of sperm in urine is intermittent and therefore not a reliable indicator in all boys. Spermaturia is more prevalent in early puberty than in late puberty, suggesting that there may be a continuous flow of sperm through the urethra in early puberty but that ejaculation is necessary for sperm to appear in the urine in late puberty. Spermaturia in the first-morning urine specimen occurs at a mean chronologic age of 13.3 years and at a mean pubic hair stage 2 to 3 in one study (or 16 years in another study), but may be found in normal boys with bilateral testicular volumes of only 3 mL and no signs of puberty.[139] Normospermia (i.e., normal sperm concentration, morphologic appearance, and motility) is not present until a bone age of 17 years. The first conscious ejaculation occurs at a mean chronologic age of 13.5 years in normal boys and at a mean bone age of 13.5 years in boys with delayed puberty.[140] The age of the first ejaculation, spermarche, decreased in China between 1995 and 2010, and a higher BMI led to an earlier age of spermarche; this pattern mirrors to a degree the secular trend of menarche in girls.[141,142]

The potential for fertility is reached before an adult phenotype is attained, before adult plasma testosterone concentrations are reached, and before PHV occurs.

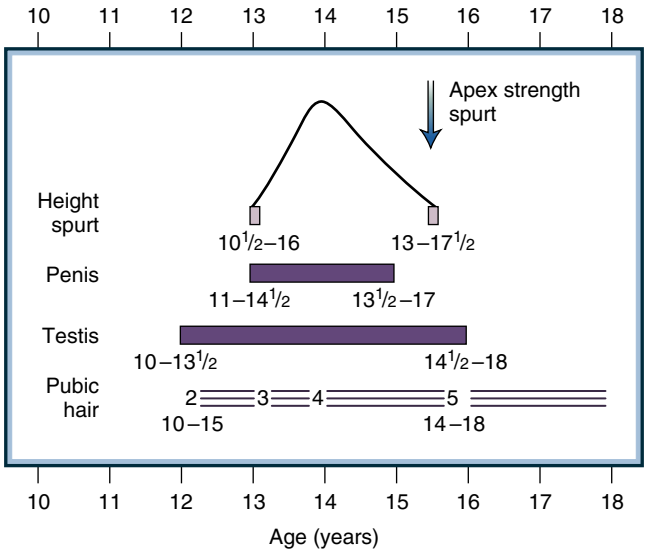
Other Physical and Biochemical Changes of Puberty

The gender difference in voice develops during puberty. In the peripubertal period, the length of the vocal cords in boys and girls is about 12 to 15 mm, of which the membranous portion is 7 to 8 mm.[143] In adult men, the vocal cords attain a length of 18 to 23 mm (membranous portion, 12–16 mm), whereas in women, the cords enlarge only slightly (13–18 mm). During puberty, the male larynx, cricothyroid cartilage, and laryngeal muscles enlarge,



• **Fig. 26.10** Stages of male genital development and pubic hair development according to Marshall and Tanner (1969). Genital development: stage 1: preadolescent. Testes, scrotum, and penis are about the same size and proportion as in early childhood. Stage 2: the scrotum and testes have enlarged; the scrotal skin shows a change in texture and some reddening. Stage 3: growth of the penis has occurred, at first mainly in length but with some increase in breadth; there is further growth of the testes and scrotum. Stage 4: the penis is further enlarged in length and breadth, along with development of the glans. The testes and scrotum are further enlarged. The scrotal skin has further darkened. Stage 5: genitalia are adult in size and shape. No further enlargement takes place after stage 5 is reached. Pubic hair development: stage 1: preadolescent; the vellus over the pubic region is not further developed than that over the abdominal wall; there is no pubic hair. Stage 2: sparse growth of long, slightly pigmented, downy hair that is straight or slightly curled, appearing chiefly at the base of the penis. Stage 3: hair is considerably darker, coarser, and curlier and spreads sparsely over the junction of the pubes. Stage 4: hair is adult in type, but the area it covers is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. Stage 5: hair is adult in quantity and type, distributed as an inverse triangle. The spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle. Most men will have further spread of the pubic hair. (Photographs from Van Wieringen JD, Wafelbakker F, Verbrugge HP, et al. *Growth Diagrams 1965 Netherlands: Second National Survey on 0-24 Year Olds.* Netherlands Institute for Preventative Medicine TNO. Groningen, The Netherlands: Wolters-Noordhoff; 1971. Additional data from Marshall WA, Tanner JM. Variations in pattern of pubertal changes in girls. *Arch Dis Child.* 1969;44:291–303.)

leading to the appearance of an Adam's apple. The largest changes in singing and speaking frequencies occur between Tanner genital stages 3 and 4; breaking of the voice occurs at approximately 13 years, and the adult voice is achieved by about 15 years. Higher



• **Fig. 26.11** Diagram of the sequence of events at puberty in males. An average is represented in relation to the scale of ages, and the range of ages within which some of the changes occur is indicated by the numbers below. The ages are from British boys 40 years in the past, so the sequence of changes, rather than the ages, is the important factor. (From Marshall WA, Tanner JM. Variations in the pattern of pubertal changes in boys. *Arch Dis Child.* 1970;45:13–23.)

BMI is associated with earlier voice breaking. Voice breaking is suggested to be a noninvasive method to monitor pubertal development in boys.[144]

Facial hair in boys is first apparent on the corners of the upper lip and the upper cheeks; it then spreads to the midline of the lower lip and finally to the sides and the lower border of the chin. The first stage of facial hair development usually occurs during pubic hair stage 3 (average age of 14.9 years in the United States), and the last stage occurs after pubic hair stage 5 and genital stage 5.

Axillary hair appears at approximately 14 years in boys. Ninety-three percent of African-American girls have axillary hair by age 12, in contrast to 68% of white girls.[22] Axillary sweat glands begin to function as the hair appears. The appearance of circumanal hair slightly precedes that of axillary hair in boys.

Comedones, acne, and seborrhea of the scalp appear as a result of the increased secretion of gonadal and adrenal sex steroids.[145] Early-onset acne correlates with the development of severe acne later in puberty. Acne vulgaris, the most prevalent skin disorder in adolescence, appears at a mean age of 12.2 ± a standard deviation (SD) of 1.4 years (range, 9–15 years) in boys and progresses with advancement through puberty. However, acne vulgaris can be the first notable sign of puberty in a girl, preceding pubic hair and breast development.[145] Analysis of the Nurses' Health Study II indicates that intake of milk and skim milk is related to the development of acne, an association suggested to reflect the hormone content of milk.[146] At late prepuberty, comedones are present in many boys, and 100% of boys have comedones by genital stage 5.

Facial morphologic appearance changes with pubertal development, leading to the mature appearance. The mandible and nose enlarge more in boys, but they and the maxilla, brow, frontal sinuses, and middle and posterior fossae enlarge in both sexes, mainly during the pubertal growth spurt. Children with isosexual precocity (ISP) have the facial appearance of older children, and

TABLE 26.4 Correlation of Testicular Volume (TV) With Stage of Pubertal Development

Parameter	PUBERTAL STAGE 1	2	3	4	5
TV Index[a]					
Burr et al and August et al	1.8	4.5	8.2	10.5	—
Volume (cm^3)					
Zachmann et al[b]	2.5	3.4	9.1	11.8	14

Testicular volume during adolescence. Cross-sectional and longitudinal studies. *Helv Paediatr Acta*. 1974;29:61–72.

individuals with delayed puberty have faces of younger children. There is a greater change in various measurements of the face compared with measurements of the skull, with the jaw showing the most increase.[147]

The size of the thyroid gland evaluated by ultrasonography normally increases roughly 40% to 50% with growth in height, weight, surface area, and fat-free mass during puberty but not with BMI.[148] This may lead an examiner to wrongly conclude there is a thyroid disorder due to the physiologic change. Lymphoid tissue growth reaches a maximum at about age 12 and thereafter decreases with pubertal progression.

A host of other physiologic and biochemical measurements change with the onset of puberty and must be interpreted in terms of the stage of pubertal development. Age-related standards should be used in all laboratories but often are not, and the interpreting clinician must turn to a textbook of pediatrics or *The Harriet Lane Handbook*. For example, hemoglobin levels increase at puberty in boys; the effect appears to be mediated by androgen, as treatment of boys with CDP with testosterone and letrozole (to block aromatization to estrogen) resulted in increased hemoglobin levels, even in the absence of a rise in IGF1.[149]

Adolescent Growth

Pubertal Growth Spurt

The pubertal growth spurt may be divided for purposes of comparison into three stages: the time of prespurt minimal growth velocity in peripuberty just before the spurt (takeoff velocity); the time of most rapid growth, or PHV; and the stage of decreased velocity and cessation of growth at epiphyseal fusion. The greatest postnatal growth occurs in infancy; growth decreases to the nadir known as the *minimal prespurt velocity,* the slowest period of growth in childhood, immediately before the pubertal growth spurt.

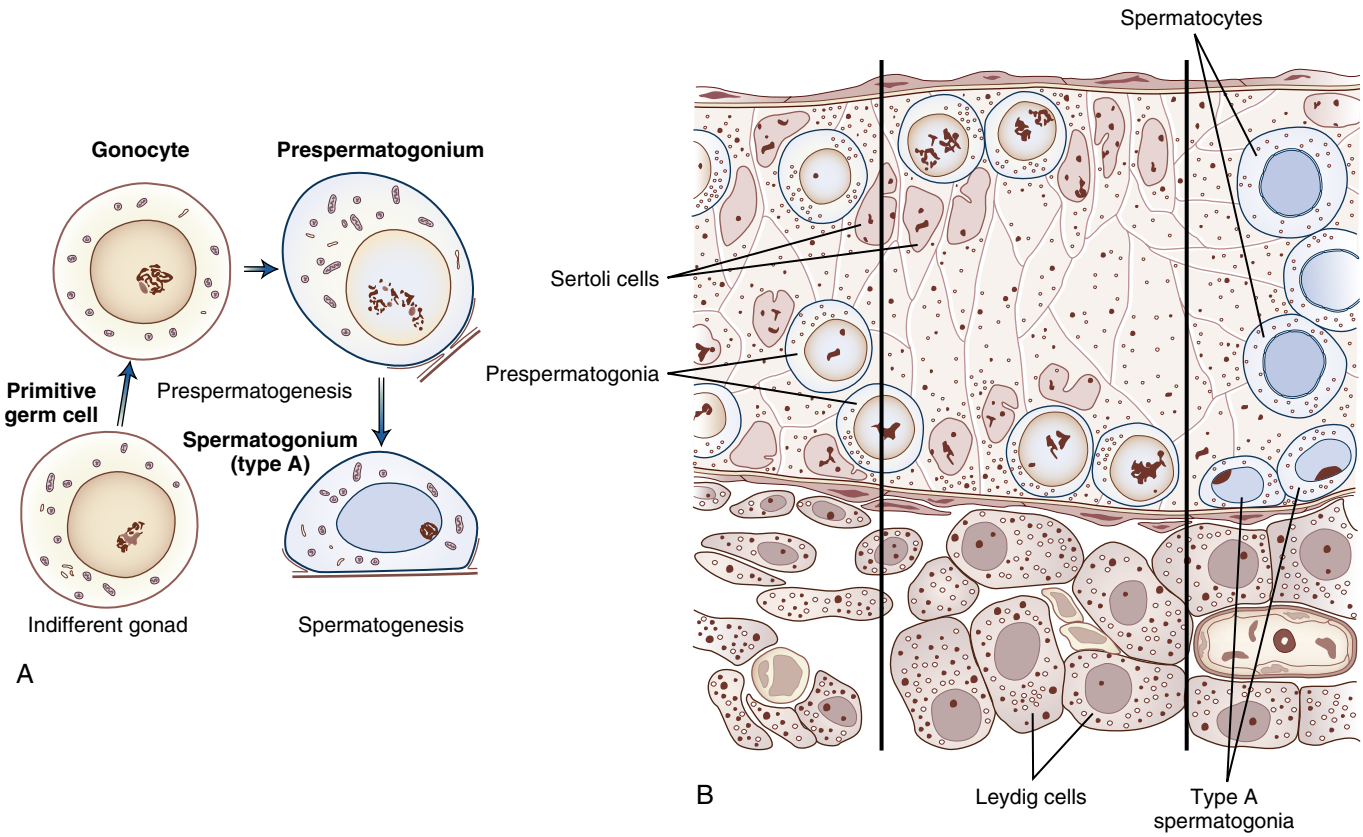
During puberty, boys and girls experience a growth velocity greater than at any postnatal age since infancy (but paling in comparison to fetal growth, when one fertilized cell grows to 7 pounds in 9 months). Boys reach PHV approximately 2 years later than girls and are taller at takeoff (Fig. 26.14); PHV occurs during stage 3 to 4 of puberty in most boys (see Fig. 26.11) and is completed by stage 5 in more than 95% of boys. Boys achieve a PHV of 9.5 cm per year at a mean of about 13.5 years, with a greater PHV in those who mature earlier than in those who mature later.[150] The pubertal growth spurt in girls (PHV in girls is ~8.3 cm/year at a mean chronologic age of 11.5 years) occurs between stages 2 and 3 (see Fig. 26.7). Boys grew a mean of 28 cm, and girls grew 25 cm between takeoff and cessation of growth in a study in the United Kingdom.[151] Although the 8 to 11 cm of increased height gained during the pubertal growth spurt in boys has been held mainly responsible for the difference in adult height between the sexes,[150] twin studies of bone morphologic appearance indicate that the difference in adult height results more from the later onset of pubertal growth in boys than a difference in growth rate between the genders. The difference in bone widths between boys and girls is in large part established before puberty.[152]

A mathematical model that attempts to define the various stages of the pubertal growth curve based on longitudinal data separates the infancy, childhood, and pubertal phases of growth and allows evaluation of growth despite variation in the age at onset of puberty. A slowly decelerating childhood component is the base, with a sigmoidal pubertal component added during secondary sexual development (see Fig. 26.14C). The infancy-childhood-puberty (ICP) model detected the onset of the pubertal growth spurt, predicted the actual magnitude of the pubertal growth spurt, and predicted adult height using only the age at onset of puberty and a measurement of height.[153] Tanner and Davies constructed growth curves for American children using data from the National Center for Health Statistics, and data calculated from theoretical growth curves can be adjusted for time of PHV.[154]

Daily, meticulous observations of girls during puberty over 120 to 150 days show stasis periods in each girl (three to seven events lasting between 7 and 22 consecutive days); steep changes in each girl (one to four episodes, with the sum of these steep changes calculated as a percentage of total growth during the study period ranging from 15.3–42.9%); and continuous growth the remainder of time, with no rhythms or cycles found.[155] Clinicians observe an integrated growth rate during puberty, rather than these various complex patterns occurring during shorter periods of observation.

In a large Swedish registry, faster linear growth during infancy and childhood was associated with earlier PHV during adolescence but less height gain between 8 and 18 years, although greater height and BMI at birth were associated with later PHV in adolescence and more height gain between the ages of 8 and 18 years.[156]

Because girls reach PHV about 1.3 years before menarche, there is limited growth potential after menarche; most girls grow only about 2.5 cm taller after menarche, although there is a variation from 1 to 7 cm. The ages at menarche, takeoff, and PHV are not good predictors of adult height because the duration of



• **Fig. 26.12** (A) The diagram shows the developmental stages of testicular germ cells based on electron microscopic findings in the rabbit. Notice the differences between prespermatogonium and spermatogonium. (B) The diagram shows maturation of testicular cell types in the rabbit from prepubertal appearance *(left)* to onset of spermatogenesis *(right)*. Interstitial cells undergo changes in shape, size, and arrangement in the process of Leydig cell differentiation. (From Gondos B. Testicular development. TABLE 26.5 Mean Values of Various Body Measurements and Serum Hormone Levels by Pubertal Stage in Boys (Ohio)[a]

Variable	PS1	PS2a	PS2b	PS3	PS4	PS5
Age (yr)	11.44 (NS)	12.18	12.79	13.74	14.63	15.19
Height (cm)	144.2	149.8	154.6	162.3	169.9	173.3
Weight (kg)	38.18	41.65	47.27	54.67	61.11	66.88
Body mass index (kg/m^2)	18.1	18.4	19.5	20.6	21.0	22.2
Testosterone (nmol/L [ng/dL])						
Blacks	0.8 (23)	3.0 (86)	4.9 (141)	11.5 (331)	13.4 (338)	15.5 (449)
Whites	0.6 (16)	2.9 (83)	4.6 (132)	9.7 (281)	13.3 (383)	14.6 (422)
Free testosterone (pmol/L [ng/dL])	11 (0.33)	60 (1.74)	114 (3.28)	294 (8.49)	413 (11.9)	504 (14.5)
DHEAS (μmol/L [μg/dL])	2.71 (99.7)	3.31 (121.8)	4.04 (148.7)	4.75 (175.0)	5.08 (187.0)	5.89 (217.0)
TeBG (nmol/L)	34.6 (NS)	33.3 (NS)	28.4	21.5	14.4	10.7

[a]Subjects were 515 boys from Ohio, including 237 blacks and 278 whites, aged 10 to 15 years at intake, who were monitored every 6 months for 3 years. All values were significant by Duncan post hoc analysis at $p < 0.01$ except those marked *NS*. Pubertal stages were defined as follows: *PS1,* absence of pubic hair, testicular volume <3 mL; *PS2a,* absence of pubic hair, testicular volume ≥3 mL; *PS2b,* Tanner stage 2 pubic hair; *PS3* to *PS5,* Tanner pubic hair stages 3 to 5.

DHEAS, Dehydroepiandrosterone sulfate; *NS,* not significant; *TeBG,* testosterone-binding globulin.

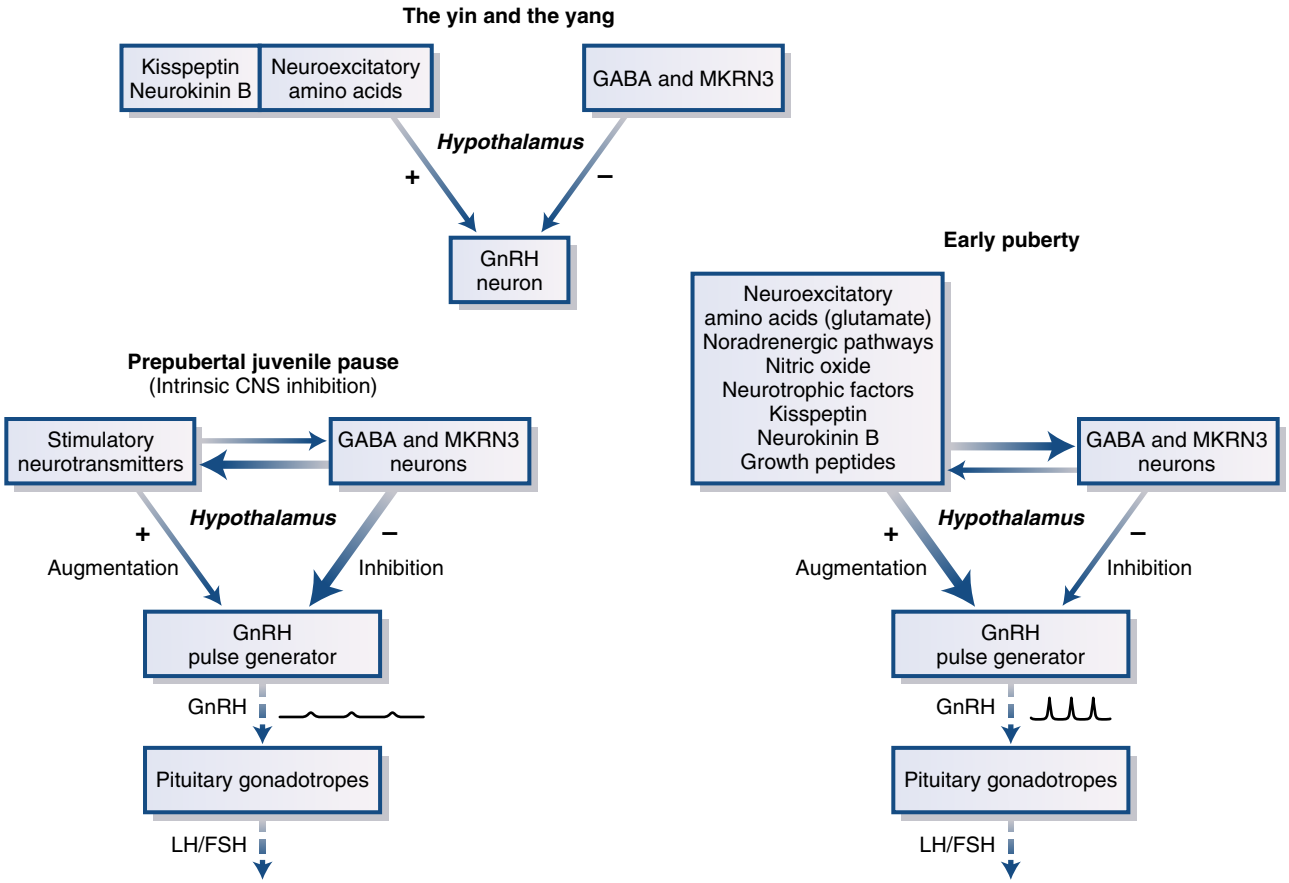
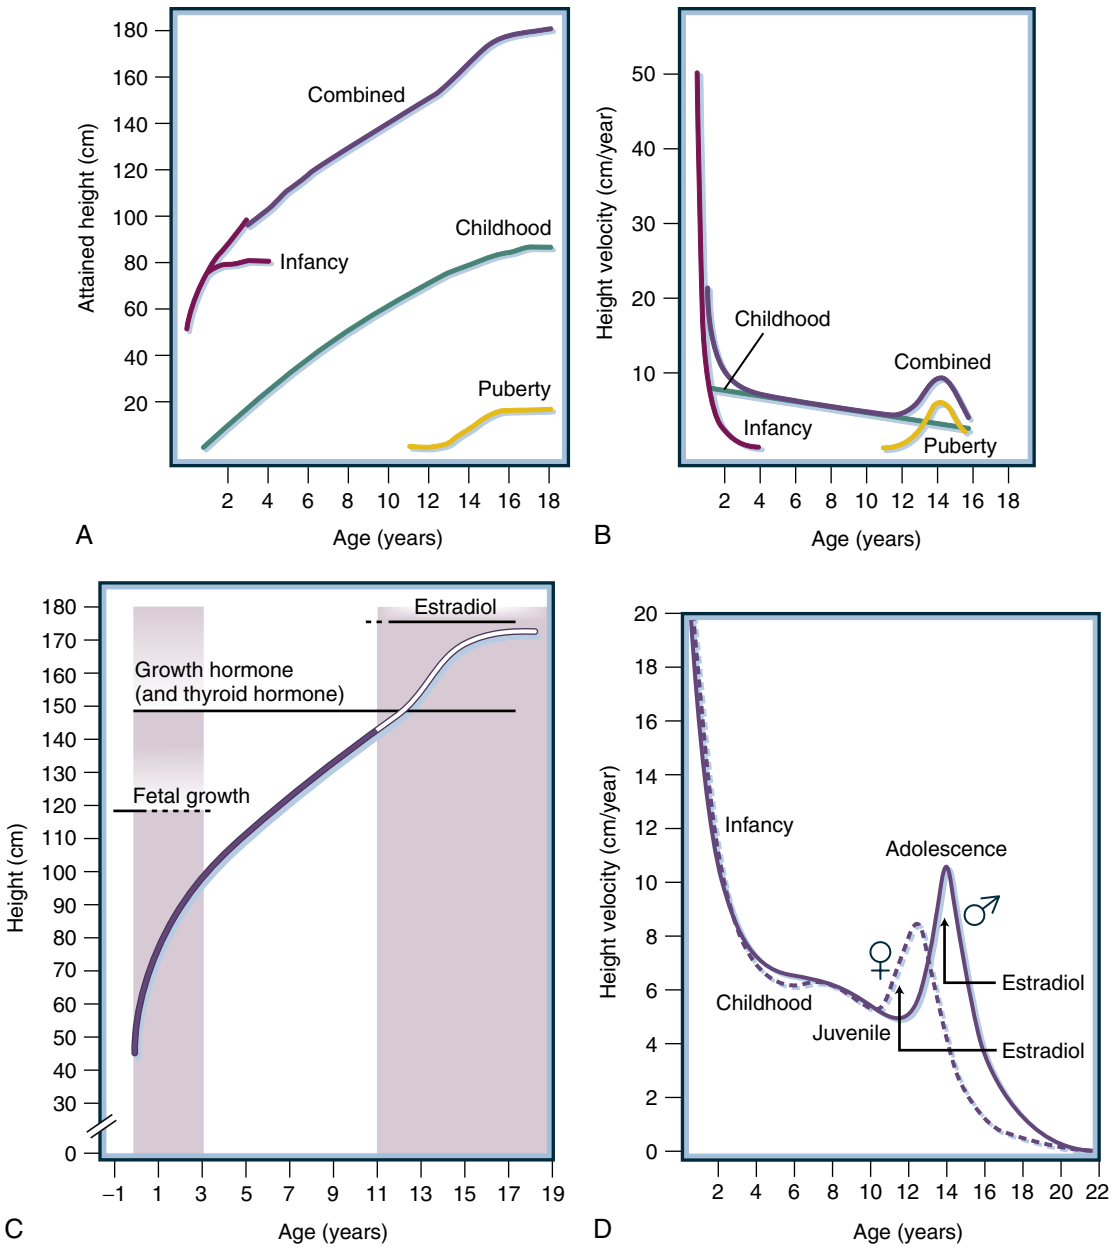
TABLE 26.6 Cellular Activity in Human Testis at Various Stages of Development

Stage	Germ Cells	Sertoli Cells	Leydig Cells
Prepubertal	Prespermatogenic cells are present	Predominant cells in seminiferous cords	Scattered, partially differentiated cells are present
Pubertal	Initiation of spermatogenesis	Increased complexity, formation of occlusive junctions	Fully differentiated cells appear
Adult	Active spermatogenesis, predominant cells	Individual cells associated with groups of germ cells	Groups of fully differentiated cells are present

From Gondos B, Kogan S. Testicular development during puberty. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:387–398.



• **Fig. 26.13** The yin and yang of the neuroendocrinology of the prepubertal juvenile pause and its intrinsic central inhibition of the gonadotropin-releasing hormone (GnRH) pulse generator and the reversal of this inhibition and termination of the juvenile pause, which leads to the onset of puberty. The GABAergic neuronal network and its neurotransmitter γ-aminobutyric acid (GABA) constitute the most ubiquitous inhibitory transmitter in the hypothalamus and the brain. During the prepubertal juvenile pause, this neurotransmitter system appears to play the major neural role in inhibiting the GnRH pulse generator. Suppression of GABA inhibition during this period promptly results in reactivation of the suppressed GnRH pulse generator in the rhesus monkey. With the approach of puberty, GABA inhibition of the GnRH pulse generator wanes, and its reactivation gradually occurs. This reactivation likely is augmented by stimulatory neurotransmitters (e.g., kisspeptin, excitatory amino acids), some of which depend on increased gonadal steroids for their activation, and by neurotrophic factors and growth peptides. A critical component of the reawakening of the GnRH neuronal network is the increase, independent of sex steroids, in KISS1 messenger ribonucleic acid (mRNA) expression in kisspeptinergic neurons in the medial basal hypothalamus and the secretion of kisspeptins, the cognate ligands for the kisspeptin receptor (KISS1R, formerly GPR54) on the surface of the GnRH neuron (Shahab et al). As a consequence, the amplitude and, to a lesser extent, the frequency of GnRH pulses increase, which leads to increased pulsatile secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) and the activation of the ovary and testis. As shown experimentally in monkeys, the GnRH pulse generator can function in the absence of hypothalamic stimulatory factors. The nature of and factor(s) responsible for this transition from central inhibition and the postulated dominance of GABA in the release of inhibition and reactivation of the GnRH pulse generator are unknown. (Additional data from Shahab M, Mastronardi C, Seminara SB, et al. Increased hypothalamic GPR54 signaling: a potential mechanism for initiation of puberty in primates. *Proc Natl Acad Sci U S A*. 2005;102:2129–2134.)



• **Fig. 26.14** The infancy-childhood-puberty (ICP) model of Karlberg for mean attained height (A) and height velocity (B) for boys. The mean value for each component (infancy, childhood, and puberty) and their sums (combined growth [A] and combined velocity [B]) are plotted. The growth curve for an individual represents the additive effect of the three biologic phases of the growth process (ICP). Karlberg has provided mathematical functions for each component of his model. *Infancy:* This component starts before birth and falls off by age 3 to 4 years. It can be described by the exponential function $y = a + b[1 - \exp(-ct)]$. Average total gain in height for Swedish boys is 79 cm (44% of final height) and for girls is 76.8 cm (46.2%). *Childhood:* This phase begins at the end of the first year of life and continues to mature height. A second-degree polynomial function describes this component: $y = a + bt + ct^2$. Average total gain in height for boys is 85.2 cm (47.4%) and for girls is 78.4 cm (47.3%). *Puberty:* The model for the pubertal growth spurt is a logistic function: $y = a/[1 + \exp(-b(t - t_v))]$. Average total gain in height for boys is 15.4 cm (8.6%) and for girls is 10.9 cm (6.5%); y designates attained height at time t in years from birth; a, b, and c are constants; t_v is the age at peak height velocity. (C) A schematic male growth chart shows the features of the ICP pattern overlaid and illustrates the predominant endocrine mechanisms controlling each phase of growth. The first *shaded area* emphasizes the decreasing velocity of infantile growth as the individual leaves the rapid growth phase of fetal life. The *open area* is the childhood phase, which continues and magnifies the decreased velocity of growth into a plateau of rather constant growth during childhood. These two phases depend largely on the effects of growth hormone (GH) and thyroid hormone, with no or little effect derived from gonadal steroids. In the next period of the pubertal growth spurt, gonadal steroids exert their direct and indirect effects. Gonadal steroids exert direct effects on the bone by stimulating the generation of insulin-like growth factor 1 (IGF1) and other growth factors locally, and they exert indirect effects by stimulating increased GH secretion, which exerts its own effects on bone and stimulates the production of IGF1. In the female, the major gonadal steroid involved in the pubertal growth spurt is estradiol, whereas in the male, testosterone and estradiol (arising mainly from the aromatization of testosterone) are the major gonadal steroids. (D) The adolescent growth spurt in girls and boys (growth velocity curves). Notice the later onset of the pubertal growth spurt in boys and the approximately 2-year difference in peak height velocity and the greater magnitude of peak height velocity compared with girls. The timing of the effects of estradiol is indicated. Progressive epiphyseal fusion terminates the growth spurt and leads to final or adult height. (A and B, modified from Karlberg J. On the construction of the infancy-childhood-puberty growth standard. *Acta Paediatr Scand Suppl.* 1989;356:26–37; C and D, from Grumbach MM. Estrogen, bone, growth, and sex: a sea change in conventional wisdom. *J Pediatr Endocrinol Metab.* 2000;13:S1439–S1455.)

pubertal growth is the more important determinant. Later onset of puberty and consequent increase in height at takeoff of the pubertal growth spurt can be balanced by a decrease in actual height achieved during PHV and result in no net change in adult height. However, early onset of puberty can diminish ultimate adult stature, prolonged delay of puberty can increase stature, and an older age at menarche leads to taller adult height in women. The age at PHV and the age at initiation of puberty correlate well with the rate of passage through the stages of pubertal development in normal children. Physical examination of a boy can reveal that he is likely to have significant growth left if he is in early puberty, whereas limited growth is likely in boys who are in late puberty.

Stature and the upper-to-lower (U/L) segment ratio, defined as the length from the top of the pubic ramus to the top of the head divided by the distance from the top of the pubic ramus to the sole of the foot, change markedly during the peripubertal and early pubertal periods because of the elongation of the extremities.[157] At birth, the U/L ratio is about 1.7; at 1 year, it is 1.4; at 10 years, it is 1.0 in a normal healthy individual. The legs begin to grow before the trunk, although late in puberty, during the growth spurt, growth of the legs is similar to growth of the upper torso.[158]

The mean U/L segment ratio of white adults is 0.92, and that of African-American adults is 0.85. There are no differences in U/L segment ratio between the sexes. In general, hypogonadal patients have delayed epiphyseal fusion and lack a pubertal growth spurt; therefore their extremities grow for a prolonged period, leading to a decreased U/L segment ratio and an increased span for height, a condition known as *eunuchoid proportions*. Eunuchoid proportions are found in subjects with defects in estrogen synthesis and estrogen receptor deficiency, but normal proportions occur in patients with complete androgen insensitivity syndrome, demonstrating the primary role of estrogen in mitigating or establishing these proportions.[159–161] The distal parts of the extremities, the hands and feet, grow before the proximal parts; a rapid increase in shoe size is a harbinger of the pubertal growth spurt. Boys with Klinefelter syndrome have long legs but not long arms, a physical feature that can assist diagnosis before the onset of puberty. The shoulders become wider in boys, and the hips enlarge more in girls. The female pelvic inlet widens, mainly because of growth of the os acetabuli. The size of the head approaches the adult size by age 10 years, and the brain reaches 95% of adult size by the onset of puberty.

Bone Age

Skeletal maturation is assessed by comparing radiographs of the hand, the knee, or the elbow with standards of maturation in a normal population.[162,163] Ossification centers appear in early life, the bones mature in shape and size and develop articulation of surfaces; ultimately, the epiphyses or growth plates fuse with their shafts in the process of epiphyseal fusion. Bone age, an index of physiologic maturation, does not have a well-defined relationship in normal children to the onset of puberty because it appears to be more variable than chronologic age.[164] In addition, the bone age evaluator must have experience with the method or an erroneous reading may occur; smaller hospitals/radiology offices will not likely have such experience. However, bone age is still used for predicting the age of menarche, and in boys, the onset of normal, premature, and delayed puberty in a general sense.

A difference between bone age and chronologic age must exceed 2 SDs to be of biologic significance. Standard deviations may range from a few months in infancy to 1 year in later adolescence; a 2-year variation of bone age from chronologic age is within normal limits in teenage years. As commonly estimated, bone age is imprecise and is a qualitative rather than a quantitative measure.[165] The development of techniques for scanning radiographs coupled with computer analysis is now approved in Europe and may improve accuracy of assessment.[166]

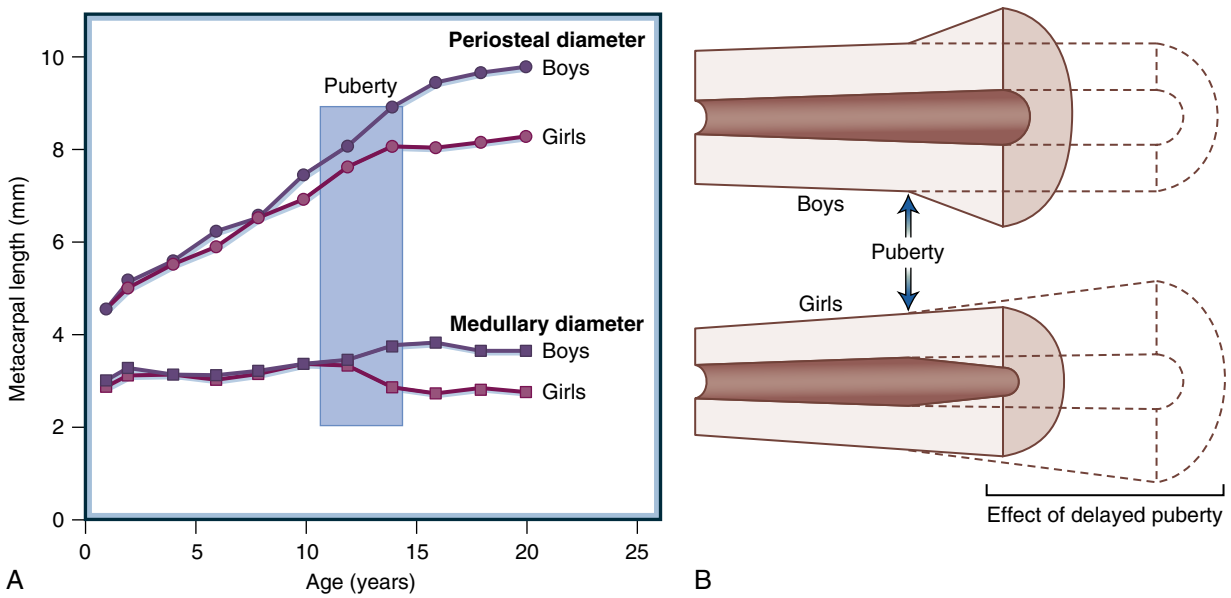
African-American children have reportedly had slightly more advanced bone ages than white children of the same chronologic age,[167] but recent evidence suggests that Asian and Hispanic children have more advanced bone ages than African Americans or Caucasians at the same chronologic age.[168]

Bone age, height, and chronologic age can be used for prediction of adult height from the Bayley-Pinneau tables[169] or by the use of the Roche-Wainer-Thissen,[170] Khamis-Roche[171] (for healthy whites only), or Tanner-Whitehouse techniques TW2[158] and TW3.[172] Skeletal maturation is more advanced in girls than in boys of the same chronologic age because the early pubertal bone ages of 11 years in girls and 13 years in boys are equivalent stages of bone maturation by the hand-wrist method. There are reportedly considerable variations in height prediction between the methods, so the subjective manner of prediction must be borne in mind.[173]

Skeletal Density

Prevailing views locate the determinants of adult bone density in large part in genetic tendencies and the appropriate acquisition of bone mineral in childhood during growth. Osteoporosis and osteopenia are important conditions of the adult that are held to have antecedents in youth, and increasing interest focuses on bone health in children and adolescents, including the effects of age of menarche, nutrition, exercise, and genetics on normal skeletal development.[174,175] A relationship of bone density exists between generations if the effects of age and puberty are eliminated, as 60% to 80% of variance in peak bone mass is attributed to genetic factors.[176] Clinical studies and animal models lead to the conclusion that distant-past patterns of bone growth are less important than recent conditions and that childhood bone growth does not exert a strong effect on adult bone density.[177] Thus even with poor diet in childhood and adolescence, improvement in bone density may be possible later in life.

Areal bone mineral density (BMD) represents a two-dimensional image and is a function of the size of bone; this is the measurement most often available clinically with commercial dual-energy x-ray absorptiometry (DXA) devices. Smaller bones attenuate the radiation beam less than larger bones, and this factor must be considered in the interpretation when measuring bone density using commercial DXA devices. BMD of the total body, lumbar spine, and femoral neck measured by DXA increases at a mean annualized rate of 0.047 g/cm^2 for boys and 0.039 g/cm^2 for girls (Fig. 26.15A). Longitudinal studies of total-body DXA assessments indicate that boys accumulate 407 g per year and girls 322 g per year of mineral (i.e., 359 mg/day for boys and 284 mg/day for girls); 26% of adult calcium is laid down during the adolescent years of peak calcium accretion—14 years (mean) for boys and 12.5 years for girls.[178] BMD approaches a maximum accretion in girls by the age of 16 years, and in boys by about 17 years, with the difference in timing related to the disparity in PHV; the rate then decreases, reaching a plateau in the third decade of life.[179]



• **Fig. 26.15** (A) Periosteal diameter of the metacarpal bones does not differ before puberty in boys and girls. During puberty, the periosteal diameter expands in boys and ceases to expand in girls, whereas medullary diameter remains fairly constant in boys throughout growth but contracts in girls. (B) In boys, delayed puberty may reduce periosteal apposition, leaving a smaller bone with a thinner cortex but normal medullary diameter *(top)*. In girls, delayed puberty may result in reduced endocortical apposition, leaving a normal or larger bone (if periosteal apposition continues in the absence of the inhibitory effect of estrogen) with a thinner cortex and larger medullary diameter *(bottom)*. (From Seeman E. Pathogenesis of bone fragility in women and men. *Lancet.* 2002;359:1841–1850.)

Quantitative computed tomography (CT) is at present a research technique but provides important information about the material aspects of bone.[180] Although quantitative CT demonstrates an increase in the cortical bone density of the lumbar spine with age, less increase in cancellous bone density with age occurs until the later stages of puberty.

Increased BMD correlates well with height, weight (a main determinant of bone density in adolescent and postpubertal females), age, pubertal development, and BMI but has less relationship with serum IGF1 levels. Increased bone density in a longitudinal study of 227 girls was associated with an earlier onset of puberty.[181]

Some consider that the concept of age at peak bone density attainment is too simplistic and prefer to consider the strength of the bone and its geometry.[182]

Volumetric bone density (bone mineral apparent density [BMAD]) represents the amount of bone within the periosteal envelope and is of more physiologic importance, because it does not rely on the size of the bone that is changing during growth, particularly pubertal growth (see Fig. 26.15A). Volumetric bone density grows in a region-specific pattern, and conditions in childhood and adolescence that affect the accrual of bone mineral have different effects based on the length of time the affected bone has left to achieve its maximum bone mineral content (BMC); deficits may occur in limb dimensions (prepuberty), spine dimensions (early puberty), or volumetric bone density by interference with mineral accrual (late puberty).[183]

Calculations for BMAD are made as follows:

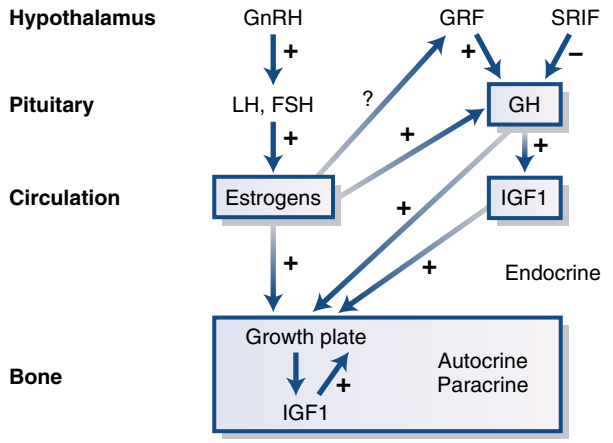
$$\text{BMAD} = \text{BMC} \div \text{the area of the region under consideration}$$

The patterns of areal or volumetric bone density differ during development.[184]

DXA device manufacturers do not always provide standards for children and adolescents. Children are often referred for evaluation of osteoporosis because their DXA results are compared with young adult values, although they have not come close to reaching maximal bone density characteristic of young adults. Bone reaches its adult size and PHV occurs before maximal BMC is reached[185]; these factors may result in a period of increased fragility and susceptibility to trauma characteristic of adolescence. Lean body mass (LBM) is related to skeletal density (stronger in boys than girls) and fat mass and skeletal density (stronger in girls than in boys).[186] Standards are available to interpret BMC in terms of LBM, which appears to be better related to normal bone growth than to chronologic age; muscle stress is an important factor in the development of bone.[187] Normative data for pediatric DXA studies are available from various centers.[179,187,188]

Quantitative ultrasound standards are available for children and adolescents.[189] Because they do not require radiation exposure, they may achieve wider use in childhood.

Seeman presented what he considers to be two fallacies in the interpretation of densitometry.[184] The first is the concept that volumetric BMD increases during growth. It does not. Growth builds a bigger, not denser, skeleton. Second is the idea that peak volumetric BMD is higher in men than in women. It is not. Bone size is greater and is underestimated in patients with larger bones than controls. The misconceptions occur because the result of areal bone density is the BMC per unit projected bone area of bone in the coronal plane, or an areal BMC (g/cm^2). Too often, the "areal" element is deleted, and "content" is replaced by density, so that BMC per unit projected area is



• **Fig. 26.16** Interactions of the major growth-promoting hormones during puberty. Plus (+) indicates stimulatory action; minus (–) indicates inhibitory action. Circulating insulin-like growth factor 1 (IGF1) arises mainly from liver, but other tissues also contribute (i.e., endocrine action). Growth hormone (GH) and gonadal steroids have a direct stimulatory effect on the generation of IGF1 (i.e., paracrine action) locally in bone and cartilage cells. For simplification, the feedback loops for IGF1 and gonadal steroids on the hypothalamic pituitary unit are omitted. *FSH,* follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *GRF,* growth hormone–releasing factor; *LH,* luteinizing hormone; *SRIF,* somatotropin release–inhibiting factor.

called BMD, even though volumetric bone density is the desired measurement. Although BMC may normally be higher in boys than in girls and rises with development, volumetric bone density of the long bones is identical in boys and girls. In contrast to the long bones, volumetric bone density increases at the spine in both sexes.[179,183,184]

The increase in BMD during the prepubertal and pubertal years reflects the increase in the size of the long bones. Legs grow more rapidly than the trunk in prepubertal girls, but during puberty there is more truncal growth. Boys develop greater bone size due to increased periosteal apposition (increasing bone strength) and endosteal resorption compared with girls; girls add bone on the endocortical surface, which may serve as a reservoir for calcium for later lactation and pregnancy.[190]

Birth weight, weight gain during infancy, and weight gain during the years 9 through 12 influence bone mass achieved at 21 years.[191] The BMD at the beginning of puberty predicted the peak bone mass at sexual maturity and appeared to predict the likelihood of osteoporosis as an adult in longitudinal studies, suggesting a method of identification of those most in need of intervention[192] (Fig. 26.16). The mechanostat concept posits that developmental changes in bone strength result from the increasing loads imposed by larger muscle forces, which stimulate bone mineral acquisition. In a longitudinal study, a rise in LBM occurred before peak BMC, and fat mass later exerted more influence.[193] Increased physical activity is generally beneficial for bone health, but excessive running, gymnastics, and cheerleading are progressively more likely to lead to stress fractures,[194] and excessive exercise can lead to the female athletic triad (discussed later). Femoral head strength increases markedly during puberty, and the femoral neck increases in density more with impact load sports such as running (compared with active load sports such as swimming); only 3 to 12 minutes of daily exercise increases femoral bone density in early pubertal children,[195] with greater increases occurring during puberty.

Prepubertal girls engaged in gymnastics have increased bone density in the limbs that are more often used, and this occurs in a dose-response manner.[196] A longitudinal study of gymnasts and their mothers found that these effects do not mainly result from genetic influences. Female adolescent athletes have increased bone density, although the effects last only as long as the activity continues.

Calcium intake during puberty has been documented to affect bone density later in life in most studies,[176] but the effect of increased ingestion of calcium may last only as long as the calcium is administered. Pubertal girls are estimated to get well below the recommended intake levels, and even recommended levels may be too low for optimal mineralization. Two cups of milk or equivalent is shown to provide adequate calcium intake for children 8 to 16 years of age.[197] Children who avoid dairy products and are without calcium supplementation have an increased prevalence of fractures in the prepubertal period, even with minor trauma.[198] Early pubertal girls cannot increase gastrointestinal calcium absorption enough to compensate for a poor diet, as older individuals may. African-American children retain more calcium than white children do, and the bone structure is thicker in African-American children; the difference in vertebral bone density between ethnic groups appears to develop by late puberty. Randomized, placebo-controlled clinical trials between 1985 and 2005 that enrolled normal children for at least 3 months revealed a small effect of calcium supplementation in the upper limb, but the increase in BMD was not thought to influence the likelihood of a fracture later in life.[199] However, the lack of effects applies only to normal children, and studies of subjects with disorders of puberty that affect bone development may reveal other findings. Remarkably, calcium intake is directly related to the rate of bone age advancement to a degree.[200] Increased sodium intake at the expense of calcium intake adversely affects bone accretion. Adequate zinc intake is another factor related to BMD in puberty.

Vitamin D status is a concern, because 32% of girls with low calcium intake were also vitamin D deficient and had elevated serum concentrations of parathyroid hormone (PTH) and thyroid hormone receptor–associated protein 5b (TRAP5b), as well as significantly lower cortical volumetric BMD of the distal radius and tibia shaft, and another 46% had low-normal concentrations of vitamin D.[201] Deficient calcium and vitamin D can lead to secondary hyperparathyroidism in adolescence.

Girls with heterozygote ERα genotype (Pp) and high levels of physical activity had significantly higher bone mass, higher BMD, and thicker cortex at loaded bone sites (compared with the distal radius, which is not a weight-bearing bone) than their counterparts[202] with low physical activity. These results suggest that high physical activity benefits those with heterozygous ER genotypes, and the less favorable Pp genotype may be compensated by increasing the amount of leisure-time physical activity at early puberty.

Studies of male athletes are less common than those of girls, but athletic boys age 16 to 19 years can still gain more bone mass in the spine and femora than nonathletic control subjects.[203] Abnormalities of puberty impair bone accretion in both sexes and are mainly consequences of estrogen deficiency due to decreased secretion or peripheral aromatization of androgens (see Fig. 26.15B). A 1.9-year increase in mean age at menarche in young women was associated with lower radial areal BMD T-scores; lower trabecular number, thickness, and spacing; and cortical thickness without a reduction in cross-sectional area, a finding compatible with less endocortical accrual and a possible explanation of

how late menarche is a risk factor for forearm osteoporosis.[204] Urinary adrenal hormone metabolites are related to the achievement of increased proximal radial diaphyseal bone strength; the level of urinary androstenediol at about 8 years of age is an early predictor of diaphyseal bone strength in late puberty (about 16 years of age).[205] Peripheral conversion of adrenarchal dehydroepiandrosterone (DHEA) by 17β-hydroxysteroid dehydrogenase (17βHSD) to androstenediol may be associated with radial bone accretion during growth.

Testosterone administration to normal prepubertal boys increases calcium retention and bone growth and also increases bone density in adolescents with CDP, testosterone-deficient Klinefelter syndrome, or male hypogonadotropic hypogonadism. Bone density is increased in females with excess androgens, whereas girls with anorexia nervosa, hypothalamic amenorrhea, or ovarian failure have decreased bone density.

Serum levels of inorganic phosphate, alkaline phosphatase, serum osteocalcin (Gla-protein level), collagen type I cross-linked N-terminal telopeptides (NTX),[206] and procollagen type I C-terminal propeptide (PICP); the cross-linked C-terminal telopeptide of type I collagen (ICTP), procollagen type III N-terminal propeptide (P3NP), and tartrate-resistant acid phosphatase isoform 5b; and urinary pyridinoline, deoxypyridinoline, and galactosyl-hydroxy-lysine excretion reflect the increased osteoblastic activity and growth rate during childhood and pubertal growth in both sexes, with values reaching a peak at midpuberty and decreasing thereafter.[207]

Body Composition

Just as endocrine changes bring about remarkable changes in secondary sexual development and growth, body composition is dramatically affected. GH and gonadal steroids play major roles in this process.[208] LBM, skeletal mass, and body fat are equal in prepubertal boys and girls, but by maturity, men have 1.5 times the LBM and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat (25%) as men (13%), producing a gynecoid (woman-like) or android (man-like) appearance.[209] LBM increases by the age of 6 years in girls and 9.5 years in boys. Boys acquire fat-free mass more quickly and for a longer period than girls during puberty; stability is attained by 15 to 16 years in girls and 2 to 3 years later in boys.[150] Fat mass increases in girls at an average rate of 1.14 kg per year, but the fat mass does not change in boys during the pubertal years, leading to the greater fat value in girls than boys with age.[150]

The generalized distribution of fat in males (central fat, apple shaped, android), which is different from that in females (lower body fat predominance, pear shaped, gynecoid), develops largely during puberty as males become more android than they were in prepuberty, although girls start and remain gynecoid. There are ethnic differences in the pattern of change, and Asians have the most significant changes.[210]

A strength spurt occurs during puberty after the pubertal growth spurt. Muscle mass is 54% of body weight in adolescent boys and 42% of body weight in adolescent girls, with the difference partly due to the presence of more muscle cells and larger muscle cells in men. There is little gender difference before 8 years of age, but by 14 years, boys usually have developed greater lean leg mass and greater power than girls.[211]

Obesity, Puberty, and the Metabolic Syndrome

Between NHANES II and NHANES III, a period of roughly 20 years, there was more than a tripling of the prevalence of children and adolescents equal to or above the 95th percentile in weight (denoted by the CDC as overweight), to a prevalence of 17.1%, and a 50% increase in those equal to or above the 85th percentile (denoted as obese).[212]

Weight is not an adequate reflection of body fat. The BMI is now invoked in describing the shape of the body in age-adjusted terms and is used as a better, if imperfect, reflection of body fat in childhood and adolescence.[40] BMI changes with age, and there is no specific number indicating normal or abnormal BMI at all stages of development, as there is for adults. Reference charts of BMI compared with age and gender between the 3rd and 97th percentiles are available online for interpretation of BMI values.[213] There are racial differences in the correlation of BMI with the amount of body fat, which decreases its accuracy.

Increased visceral fat (i.e., intra-abdominal adipose tissue [IAAT]) in obese teenagers is associated with hypertriglyceridemia, decreased high-density lipoprotein (HDL) cholesterol, and small, dense, cholesterol-laden very low-density lipoprotein (VLDL) particles. Subcutaneous fat is associated with large, lipid-laden VLDL particles, which are removed directly from the circulation and pose less risk. The subcutaneous adipose tissue that leads to visibly different body forms is only an imperfect reflection of this internal distribution of fat cells, because increased IAAT may cause metabolic derangements without increasing total-body fat. Studies support the role of increased intra-abdominal visceral fat in children as a cause of insulin resistance and dyslipidemia, with small adipocytes demonstrating limited storage ability, leading to increased ectopic fat deposition in myocytes and hepatocytes.[214,215] Waist-to-hip ratios may not reflect IAAT in children and adolescents, because subcutaneous abdominal fat may be low despite increased visceral fat.[214] Although there is interest in waist circumference in children as a reflection of IAAT and standards are available, there is question if the waist circumference adds to the determination of IAAT more than BMI alone.[216]

DXA is used to determine the percentage of body fat, water, and bone mineral with great accuracy but cannot differentiate visceral from subcutaneous adipose tissue. CT was used until the validation of MRI to determine intra-abdominal and subcutaneous fat distribution without the use of radiation. Excessive body fat during childhood and adolescence has significant medical effects early and later in life. Obesity, glucose intolerance, and hypertension in childhood are strongly associated with increased rates of premature death among Native Americans, but childhood hypercholesterolemia is not.[217]

Serum Lipids in Normal Puberty and in Obesity and the Metabolic Syndrome

In normal puberty, testosterone increases serum levels of LDL cholesterol and decreases HDL cholesterol concentrations, accounting for the adverse LDL to HDL ratio in men compared with women.[218] Postheparin hepatic lipase activity is increased by exogenous androgens (and decreased by estrogens), accounting for the decrease in HDL after androgen treatment or after a rise in endogenous androgen secretion. Standards for lipid levels in childhood differ from adult values.[219]

The epidemic of obesity has led to the advent of the metabolic syndrome in youth. Diagnosis of metabolic syndrome varies among studies, and a generally accepted definition is needed.[220] Elevated cholesterol levels in children and adolescents track to adult values in longitudinal studies. Although familial hypercholesterolemia leads to carotid intimal plaques by puberty, random autopsies demonstrate macroscopic or microscopic evidence

of arteriosclerosis in normal youth without familial hypercholesterolemia, and the tendency is increased by obesity. By 15 to 19 years, 2% of autopsied males had advanced (American Heart Association grade 4 or 5) atherosclerotic coronary artery lesions associated with increased serum cholesterol, obesity, and hypertension.[221]

Insulin and Insulin Resistance

Insulin resistance is a hallmark of obesity and is thought to be the cause of or an associated factor in the metabolic syndrome associated with cardiac disease.[222] Euglycemic clamp techniques are the gold standard for measurement of insulin resistance. Fasting insulin concentrations offer little insight into insulin resistance in an individual, and equations such as the homeostatic model assessment (HOMA) that are based on fasting insulin levels offer little more; however, fasting insulin values are used in epidemiologic studies and offer more useful information.[223] The fasting insulin concentration increases twofold to threefold with PHV, insulin secretion after a glucose load increases over prepubertal levels, and insulin-mediated glucose disposal in peripheral tissues decreases in the hyperinsulinemic euglycemic clamp or the minimal model frequently sampled intravenous glucose tolerance test (IVGTT), showing increased insulin resistance during normal puberty. Insulin sensitivity is inversely related to pubertal stage and BMI.

The response of insulin to an oral glucose tolerance test is greater in African-American subjects than in white subjects at all stages of pubertal development; this ethnic difference in insulin resistance is suggested as a cause for the increased incidence of type 2 diabetes among African-American adults compared with white adults and appears to offer a similar explanation of the ethnic disparity in youth, with white teenagers having greater insulin sensitivity than African-American or Hispanic youth.[224,225] Insulin resistance occurs early in the course of Turner syndrome and thalassemia major, but even in Turner syndrome, in which there is an underlying increase in insulin resistance, there seems to be low or no risk of these conditions developing with GH treatment.

With the increased prevalence of type 2 diabetes (non–insulin-dependent diabetes mellitus [NIDDM]), proposed screening criteria are being evaluated. Currently, children with a BMI higher than the 85th percentile should be screened if they (1) have a family history of type 2 diabetes, (2) have signs of insulin resistance (e.g., acanthosis nigricans, functional ovarian hyperandrogenism, hypertension, dyslipidemia), or (3) belong to one of several specific ethnic groups (e.g., African American, Native American, Hispanic American, Asian American). If a fasting plasma glucose level is higher than 126 mg/dL or a 2-hour postprandial value is higher than 200 mg/dL, or if there are symptoms such as weight loss, polyuria, or polydipsia and a casual plasma glucose level higher than 200 mg/dL, the diagnosis of diabetes is likely, and determination of the type of diabetes (type 1 or 2) is appropriate.

Patients with type 1 diabetes (insulin-dependent diabetes mellitus [IDDM]) usually require an increase in the dose of insulin for euglycemic control at puberty. The cause of insulin resistance has been attributed in part to increased fat oxidation at puberty, which correlates with rising serum IGF1 levels and may be linked to increased GH secretion. However, there is no evidence that GH treatment alone increases the likelihood of development of type 2 diabetes or impaired glucose tolerance. Weight gain increases in children with type 1 diabetes during puberty, leading to a higher incidence of obesity in children with IDDM than would be expected from family patterns. Some adolescents with IDDM, predominantly girls, reduce their insulin use to lose weight, with dire consequences. Retinopathy due to IDDM characteristically appears in the teenage years or later, but duration and control of diabetes in the prepubertal years are contributing factors. The American Diabetes Association recommends screening for microalbuminuria, an indicator of the development of diabetic nephropathy during puberty.

A normal individual adapts to the changes in the physiologic rise in pubertal insulin resistance, but an individual at genetic risk for type 2 diabetes, with the accompanying defect in pancreatic beta-cell function,[226] may not adapt to the insulin resistance and, with the additional insulin resistance characteristic of obesity, may develop clinical type 2 diabetes during the pubertal years or earlier. Type 2 diabetes in children or adolescents should not be confused with the various forms of monogenetic diabetes (previously called maturity-onset diabetes of the young [MODY]), which are inherited as autosomal dominant traits.[227]

Although PCOS is common, several rare syndromes of severe insulin resistance combine hyperglycemia and virilization.[228] The Kahn type A syndrome features include a lean, muscular adolescent female phenotype with acanthosis nigricans, hirsutism, oligomenorrhea or amenorrhea, and ovarian hyperthecosis and stromal hyperplasia associated with abnormalities of the insulin receptor gene. Hyperandrogenism, insulin resistance, acanthosis nigricans (HAIR-AN) syndrome, and PCOS are less severe than Kahn type A and usually manifest in adolescent females. Persons with Rabson-Mendenhall syndrome have severe insulin resistance (possibly leading to diabetic ketoacidosis), dysmorphic facies, acanthosis nigricans, thickened nails, hirsutism, dental dysplasia, abdominal distention, and phallic or clitoral enlargement. The Rabson-Mendenhall syndrome, similar to the Donahue (leprechaunism) syndrome, which shares some of these features, is caused by homozygous or compound heterozygote defects in the insulin receptor gene. Kahn type B syndrome is caused by inhibitory or stimulatory antibodies to the insulin receptor and sometimes occurs with acanthosis nigricans and ovarian hyperandrogenism. This syndrome can occur with ataxia-telangiectasia syndrome or in otherwise normal adolescents. Individuals with the Berardinelli-Seip syndrome combine lipodystrophy and severe insulin resistance and complete or partial absence of subcutaneous fat with increased growth and skeletal maturation, muscle hypertrophy, acanthosis nigricans, hypertrichosis, organomegaly, and mild hypertrophy of the external genitalia.

Most of these NIDDM syndromes can be treated with oral hypoglycemic agents initially; progression of the disorder may require the use of insulin. Several girls with these syndromes of insulin resistance have been described to have low serum gonadotropin values during puberty without response to GnRH but with enlarged ovaries, suggesting a direct role for insulin in stimulating the growth of the ovary. The hypoleptinemic state found in various degrees of lipodystrophy does not appear to affect pubertal progression, but administration of leptin has led to resumption of menstrual periods in some females and adjustment of testosterone production toward normal levels in males.[229]

Blood Pressure

Blood pressure is related to the age, gender, and height of the child using appropriate standards.[230] Blood pressure increases with pubertal maturation, related to increased stature and synchronized with the pubertal growth spurt, suggesting some

relationship in the control of the two processes.[231] Hypertension is becoming common in puberty as a comorbid condition of obesity. Increased blood pressure at puberty depends on BMI and height, factors that are interrelated. Blood pressure in childhood and adolescence is predictive of adult blood pressure (tracking). Blood pressure rises in African-American children at lower BMIs than in white children, making the problem worse in the African-American population. In sexual precocity, blood pressure rises above prepubertal levels to values commensurate with body size and BMI.

Central Nervous System Anatomy, Function, Psychology, and Electroencephalographic Rhythm in Puberty

Brain anatomy and function change substantially during late childhood and adolescence (Fig. 26.17). Puberty is the time of appearance of the ability to solve complex problems in a mature manner. An increase in cortical metabolic rate in infancy is followed by a late childhood decline to adult levels; this decline ceases by the end of the second decade. The prefrontal association cortex, an area of the brain that is concerned with forward planning and regulatory control of emotional behavior, continues to develop until the age of 20 to 25 years.[232] Stress at various stages of development, even in early childhood, may cause psychologic manifestations during puberty.

Behavior or psychopathology that becomes evident at this time has its basis in these changes and exposures dating from early life and the prenatal period, all interacting against a genetic background. The anatomic changes revealed by functional MRI studies of the prefrontal cortex, an area that is involved with emotional regulation and planning, occur during a time of physical maturation and are likely to relate to many of the characteristic behavior changes of puberty. The volume of white matter increases linearly between 4 and 22 years of age owing to an increase in myelination during development.[233] A reduction in cortical synaptic density and neuronal density, analogous to programmed cell death, occurs between 2 and 16 years of age, and this pruning of synapses appears to be linked to improved memory. This change in gray matter follows an inverted U-shaped curve of increase from the age of 6 years. Longitudinal studies using dynamic mapping of human cortical development demonstrate that higher order association cortices (e.g., those involved in executive function, attention, and motor coordination) mature after lower-order somatosensory, motor, and visual cortices mature, and those areas that are phylogenetically older mature before newer ones.[234,235] Intrauterine excess of androgens leads to enlargement of the amygdala, and girls reach greater mass of gray matter 2 years before boys during puberty, demonstrating aspects of the effects of sex steroids on brain growth and remodeling in human beings. Gray matter volume, at least in girls, appears to be related to a pubertal increase in estradiol[236] levels. Increased LH levels are related to areas of increased white matter density, including the cingulum, middle temporal gyrus, and splenium of the corpus callosum; there is a genetic overlay to this relationship. Brain plasticity decreases during puberty. Examples include the inability to learn to speak a foreign language without an accent after puberty and recovery of a child from the effects of a CNS injury that in an older teenager or an adult might have led to aphasia. Loss of plasticity may be maladaptive to our rapidly changing world and extended life span compared with prehistoric times.[237] Plasticity allowed developmental learning before puberty, but lack of plasticity and a standard response to conditions in the adult allowed success in that static environment of the past.

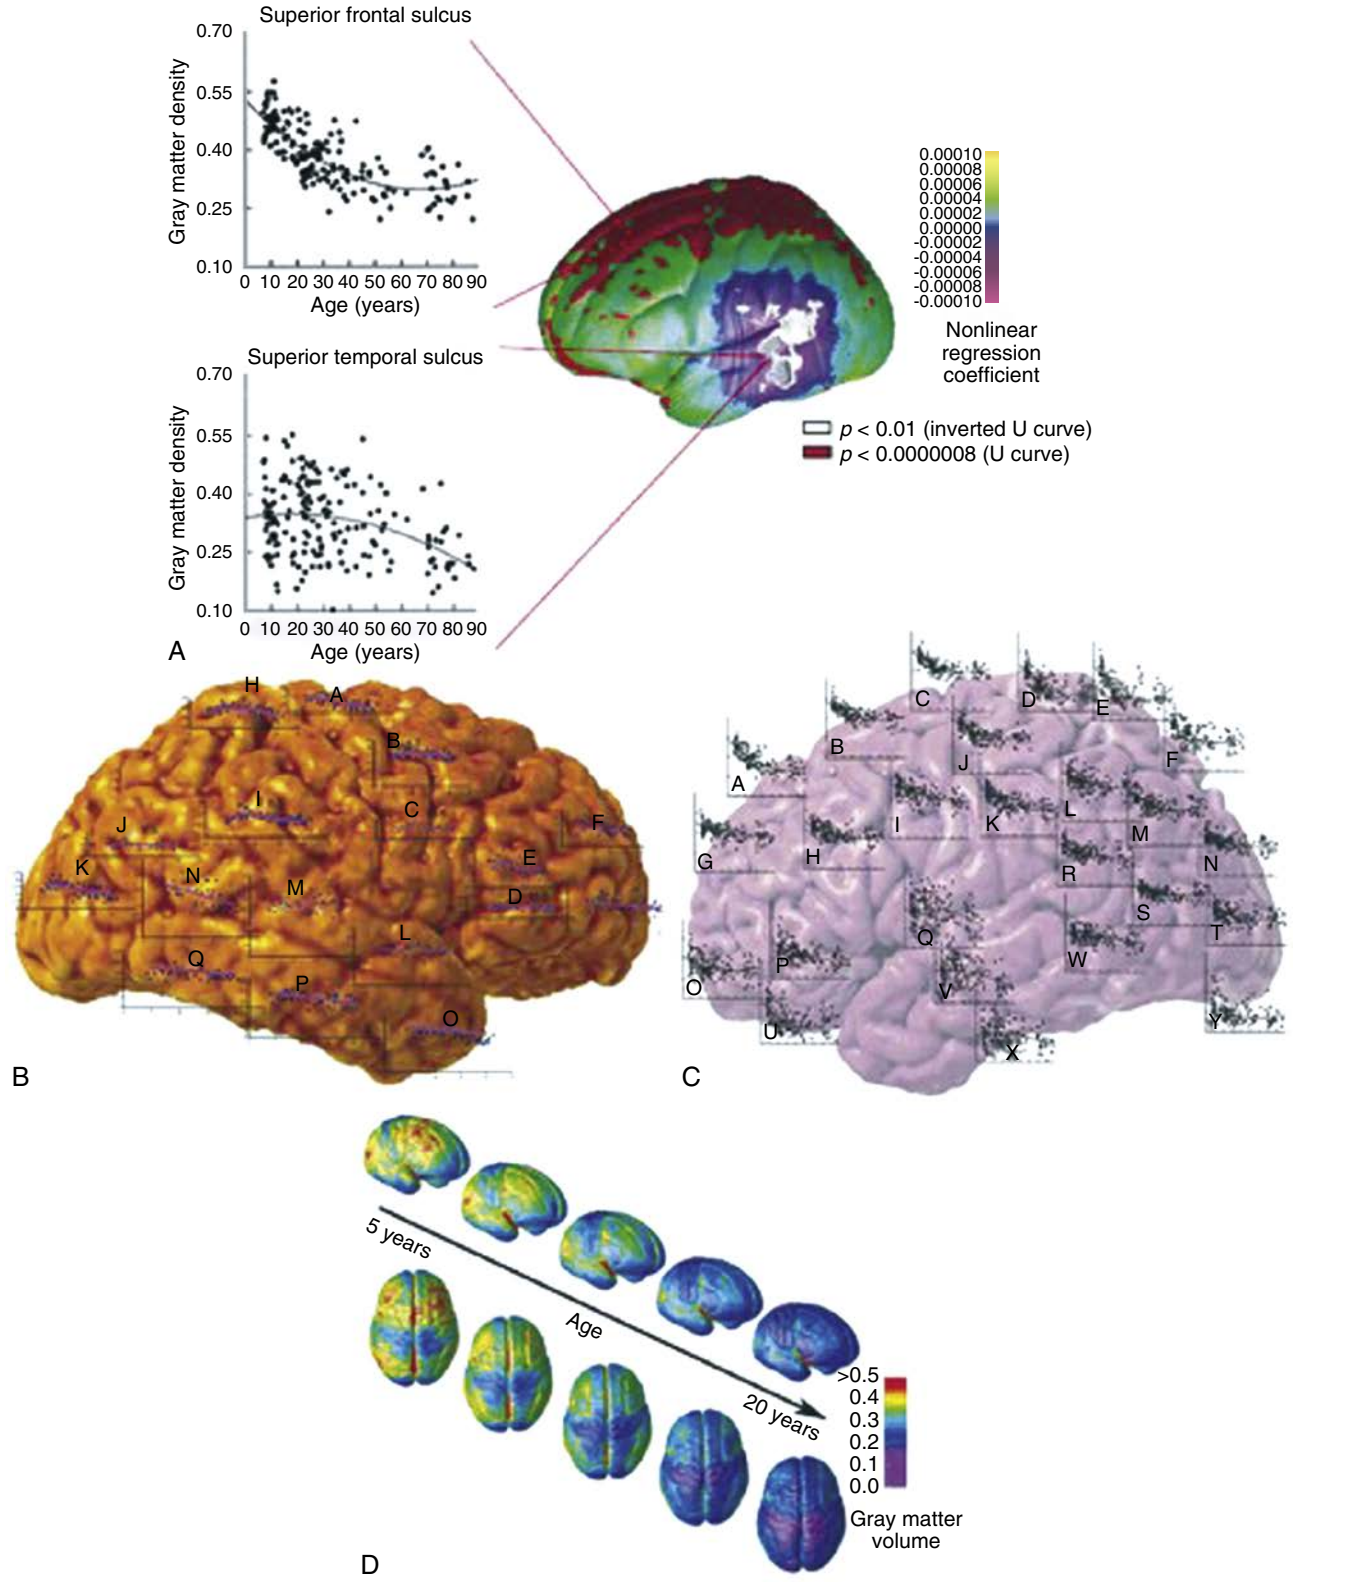
Mania, depression, obsessive-compulsive disorders, and schizophrenia are more common after puberty. They are postulated to be related to alterations of the normal changes in brain architecture and function that occur during puberty.

Sleep Patterns in Puberty

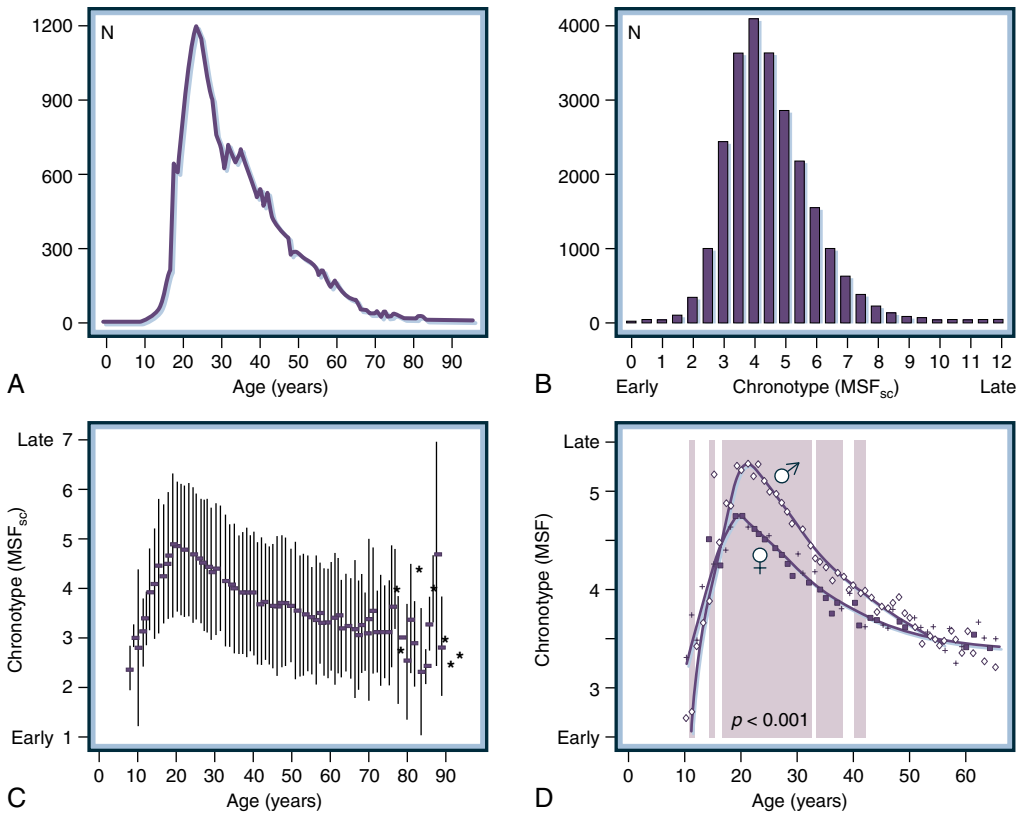
Increased sleep is characteristic of the period of growth and development across species. Because sleep is a time of vulnerability, threats leading to stress are antithetical to normal sleep, and a feeling of safety is thought to be necessary to allow sleep to proceed normally as the adolescent is preparing for independence and increased self-care in a possibly hostile world. Rising complexity of brain function during puberty is reflected in increases in the amplitude and frequency of delta waves (0–3-Hz electroencephalographic waves) found during deep sleep, which appears more related to age than to pubertal development or growth.[238] The function of deep sleep (i.e., slow-wave or non–rapid eye movement sleep) is thought to be restorative to learning and other activities of the waking state, and the most restorative portion is high-amplitude delta-wave sleep. During adolescence, the time spent in deep (stage 4) sleep declines by 40% to 50%, and increased (19.7%) stage 2 sleep occurs with pubertal development. The decline of slow-wave sleep during adolescence may reflect developmental changes of the brain.

When an individual is allowed to "run free," the period is entrained (synchronized) close to the earth's 24-hour light-dark cycle. Because human beings had little to do after dark, evolution favored an early bedtime, but within this schedule, developmental changes occur. One-year-old infants sleep an average of 11 hours per day, and by age 18, if circumstances permit, the mean is 8 hours. Older people have earlier waking times and rate themselves as more morning-like than adolescents or young adults; because children are also morning-like, there is an inverted U-shaped curve of preferred times of awakening across the span of development.[239] This change to evening from morning alertness during puberty appears to be related to biologic factors, in contrast to social factors; in the past, social factors were thought to be more important.

Without the pressure of work or school, adolescents would stay up longer and awaken hours later than a normal weekday schedule would dictate, a schedule far different from the one they followed at a younger age. Adolescents with early school starts awaken earlier than those with later school starts, but they do not change the time they go to sleep, leading to great variation in the amount of sleep attained. Data from the Add Health study showed decreased self-reported sleep duration during self-reported pubertal development, with girls reporting more problems with sleep (e.g., insomnia, insufficient sleep, awakening tired) as puberty progressed but with no such relationship seen in boys.[240] There is an increase in daytime sleepiness during adolescence, particularly during midpuberty up to stage 3 to 4, even if total sleep time is held constant during longitudinal multiple-year studies.[241] With voluntary sleep deprivation (e.g., with late-night homework habits), sleepiness can reach levels seen in narcolepsy and sleep apnea. Adolescents adapt more poorly to changes in sleep patterns than other age groups;



• **Fig. 26.17** Mapping brain change over time. Brain changes in development can be identified by fitting time-dependent statistical models to data collected from subjects cross sectionally (i.e., across a group of subjects at a particular time) or longitudinally (i.e., following individual subjects as they aged), or both. Measurements such as cortical thickness are then plotted onto the cortex using a color code. Trajectory of gray matter loss over the human life span is based on a cohort of 176 subjects between 7 and 78 years of age.[13] (A) represents a region in which the gray matter density decreases rapidly during adolescence (i.e., superior frontal sulcus in which the decrease in gray matter is described by a quadratic equation represented by an inverted U-shaped curve), or follows a more steadily declining time course during the life span (i.e., superior temporal sulcus in which the decrease in gray matter is described by a quadratic equation represented by a U-shaped curve). (B, C) plots superimposed on the brain show how gray matter density decreases for particular regions with age, with the regions denoted by different letters. Brain maturation and change in gray matter density is mapped by year of age in (D) with fractional change in gray matter shown by color coding (C, D). (From Sowell ER, Peterson BS, Thompson PM, et al. Mapping cortical change across the human life span. *Nat Neurosci.* 2003;6:309–315; Toga AW, Thompson PM, Sowell ER. Mapping brain maturation. *Trends Neurosci.* 2006;29:146–159.)



• **Fig. 26.18** Assessment of chronotype (time of awakening in the absence of external cues) using the MCTQ database (N ≈ 25,000). Age distribution within the database (A). Distribution of chronotypes (B). Age-dependent changes (C) in average chronotype (± SD [standard deviation]) are highly systematic (except for the age groups of 19, 21, 22, and 23, all other age-dependent averages ± SD are significantly different from that of age group 20; t-test, $p < 0.001$). Age-dependent changes of the chronotype (D) are different for males and females (*filled circles and black line*: females; *open circles* and *gray line*: males). Gray areas indicate significant male-female differences (t-test, $p < 0.001$). (From Roenneberg T, Kuehnle T, Pramstaller PP, et al. A marker for the end of adolescence. *Curr Biol.* 2004;14:R1038–R1039.)

this is manifested in the difference in hours awake between the school week and the weekend. Adolescents are able to shift to a later schedule more easily than to an earlier schedule. When self-selected bedtimes are late during summer but have to be changed to allow for school attendance, the adjustment is particularly lengthy and difficult.

After study of 27,000 individuals, it was proposed that the point of inflection from evening alertness during adolescence (after a morning-like pattern in childhood) to morning alertness in adulthood might be used as a marker of the end of adolescence, a sign that developmental remodeling of brain pathways is completed.[242] The age of this inflection point is about 20.9 years in males and 19.5 years in females, who have an earlier change in this and other aspects of puberty than males (Fig. 26.18).

Characteristics of Adolescence

Most of this chapter deals with the biochemical and physical changes of the period we denote as puberty, but there are also profound psychosocial changes during this period, usually denoted as adolescence. Although the attainment of an adult role in society occurs within a few years after achievement of reproductive maturity in non-Western societies, the more technologically advanced the society, the more protracted the time allowed for adolescent psychosocial development. The prolonged period of adolescence in current society, ranging from 11 to 20 years in the United States, arose recently in human history, beginning no more than 100 years ago in Western society.

As expressed by Remschmidt, the most important psychologic and psychosocial changes in adolescence are the emergence of abstract thinking, the growing ability to absorb the perspectives or viewpoints of others, an increased capacity for introspection, the development of personal and sexual identity, the establishment of a system of values, increasing autonomy from family and personal independence, greater importance of peer relationships of sometimes subcultural quality, and the emergence of skills and coping strategies to overcome problems and crises.[243]

Adolescence may be divided into three periods (early, middle, and late) by chronologic age. However, these periods may be reached at different maturational ages, because rates of physiologic maturation differ among individuals in these age groups.[244]

Early adolescence (age 11–15 years) encompasses most of the physical changes of puberty and in American society includes a profound social change from the sheltered, single-classroom environment of elementary school to the multiple-classroom and multiple-teacher experience of middle school or junior high school. The individual develops a maturing, but not mature, capacity for abstract thought and decision-making processes in contrast to the concrete reasoning of childhood.

Middle adolescence (ages 15–17 years) is the period of the high school years, a calmer period than early adolescence. The school experience is not a striking change, and many of the most

prominent biologic and physical changes of puberty have been accomplished. There is acceptance of some increased autonomy (e.g., driver's permit and license are allowed), but the individual still lives at home. The individual emotionally moves away from the family and is less influenced by his or her peer group than are early adolescents; friendships assume an increasingly important role.

Late adolescence starts at the senior year of high school and is the age of acceptance of adult roles in work, family, and community. If the individual attends college, this stage is prolonged.

Behavior and Normal Puberty

Almost 100 years ago, G. Stanley Hall, without using what would be considered contemporary research techniques, characterized the maturing child as experiencing *Sturm und Drang* (i.e., storm and stress), which is normally restrained by cultural influences.[245] Contrary to this view, most recent empiric studies describe adolescent development as a continuous, adaptive phase of emotional growth characterized more by stability than disorder and more by harmonious relationships between generations than conflict. Although mood changes are normally more rapid (occurring over hours or days) and more clearly marked in teenagers than in adults, these shifts must be differentiated from long-standing mood and behavior changes associated with serious psychopathology.

Turmoil, or truly tumultuous behavior, in adolescence is not a normal phase but may reflect psychopathology that requires diagnosis and treatment. It is often misdiagnosed as a temporary problem of adjustment reactions of adolescence. When the conditions extend from adolescence to the adult stage, they are more severe. A 4-year longitudinal study of normal first-year US high school students showed that 25% experienced continuous growth, characterized by smooth, well-adjusted functioning despite stressful situations; 34% experienced surgent growth, demonstrating good adaptation in general and short periods of difficulty and distress after some stressful situations. Twenty-one percent were judged to be in turmoil, characterized by mood swings, anxiety, and depression; these teenagers mainly came from homes characterized by conflict, familial mental illness, and socioeconomic distress.[246] Many with adolescent turmoil had not "grown out of it" when studied 5 years later and eventually were diagnosed with unipolar and bipolar depressive disorders. It may be concluded that 80% to 90% of adolescents do well psychologically during puberty and are happy individuals, but 10% to 20% have significant difficulties.

Mood and Self-Image in Puberty

Young girls at the beginning of puberty frequently exhibit a negative self-image but a positive body image; positive peer relationships and superior adjustment improvement are observed with continued breast development. Mood in adolescence is not closely related to stage of puberty, but a significant curvilinear trend is seen for depressive affect (i.e., an increase followed by a decrease), for impulse control (a decrease followed by an increase), according to the level of serum estradiol. These data suggest that hormonal changes may be more important than physical changes as determinants of certain mood and behavior patterns during adolescence.

Behavior in Variations of the Normal Age at Onset of Puberty

Within the normal limits of pubertal development, early-maturing girls and late-maturing boys have the greatest prevalence of adjustment reactions in puberty and thereafter. Boys and girls who mature earlier are at increased risk for abuse.[247]

Early-developing boys are perceived to be more mature, attractive, and smart and are given more leadership roles; late-developing boys are more insecure, more susceptible to lower levels of self-esteem and body image, and more vulnerable to peer pressure, especially in working-class and minority groups. Most of these difficulties of late maturation focus on the decreased height of the individual rather than the lack of sexual development. Social maturation lags even after androgen treatment in patients with severe CDP. Delayed social maturation may put boys at risk for missing educational opportunities.

In contrast, early-maturing girls tend to experience more difficulty, especially in the junior high school setting, where they may attract the attention of older, more mature boys and have a higher prevalence of internalizing symptoms and disorders. They are more often the target of bullying but also more often the perpetrator of bullying than average-maturing girls.[248]

Early puberty may lead to negative body image in girls, compared with boys, in whom the effect is positive. Early maturation may increase a propensity to violent behavior, which is fostered by living in a disadvantaged neighborhood. Early pubertal maturation in girls may be related to a small intelligence quotient (IQ) advantage over late-maturing girls. Late-maturing girls are often more comfortable, remaining with the support of their families longer, and they are less often brought to medical attention than late-maturing boys. Early-maturing and late-maturing girls have a tendency to engage in health-risking behaviors involving strategies to lose weight, strategies to increase muscle, disordered eating, use of food supplements and steroids, and exercise dependence—tendencies not found in boys at the same developmental stages.

Risk-Taking Behavior

Adolescents who function at lower levels of cognitive complexity or concrete thinking and have an early onset of puberty demonstrate an increase in risk-taking behavior. The age at onset of cigarette smoking and alcohol use is proportional to the age at onset of puberty in girls: early-maturing girls partake earlier, and boys may follow the same pattern.

Sexuality During Puberty

The social pressures are more mixed in their messages to girls, both encouraging sexuality and restricting it in a way more disparate than that encountered by boys. The earlier onset of puberty today compared with previous centuries has had a profound effect on societal norms of sexual behavior.[4] For example, early onset of puberty is associated with earlier onset of sexual intercourse.[249]

The percentage of adolescents who have had sex rises from less than 2% by 12 years of age, 16% by age 15, 33% by 16, 48% by 17, 61% by 18, and 71% by 19-year-olds for either sex. Teenagers are waiting longer to have sex than they did in the recent past. Factors such as the onset of puberty, weak self-concept, having tried smoking or drinking, and not being overweight were significantly associated with early sexual activity in girls. For boys, older age, a poor relationship with parents, low household income, and having tried smoking were factors significantly associated with sexual activity. Add Health revealed that adolescents at the upper and lower ends of the intelligence distribution were less likely to have sex.

Fertility is reached well before adult phenotype is acquired in boys and girls. The number of pregnancies for US teenagers 15

to 19 years old decreased almost 50% since 1991 and 22% since 2009; it was 31.3 per 1000 women in 2011.[250] However, there is an ethnic-specific difference as the rate for Hispanic was 49.6 per 1000, non-Hispanic black was 47.3, American Indian/Alaska Native (AIAN) was 36.1, non-Hispanic white was 21.7, and American Pacific Islanders (API) was 10.2. The decline is attributed to pregnancy prevention messages, and there is evidence of increased use of contraception.

Sexuality appears to be correlated with testosterone production in boys in some studies, but in others it appears to be modified by the social effects of pubertal maturation. Religious activity may decrease the likelihood of sexual activity.

A randomized, double-blind, placebo-controlled, crossover clinical trial of boys and girls with delayed puberty addressing the effects of administration of oral conjugated estrogen to girls and testosterone enanthate to boys at three dose levels that were intended to simulate early, middle, and late pubertal levels demonstrated modest or no effects on sexual behavior. Boys had increased nocturnal emission and touching behaviors at the middle and high doses but no other effects. Girls demonstrated a significant increase in necking related to the administration of estrogen only at the late pubertal dose and no other effects.

Hormonal and Metabolic Changes in Puberty

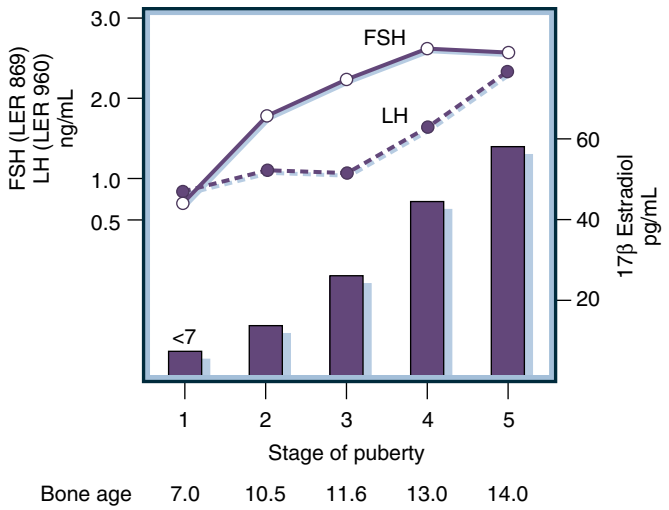
Increased amplitude and alterations of the patterns of GnRH secretion at puberty initiate and regulate the sequential increases in secretion of pituitary gonadotropins and gonadal steroids that culminate in fertility.

Gonadotropins

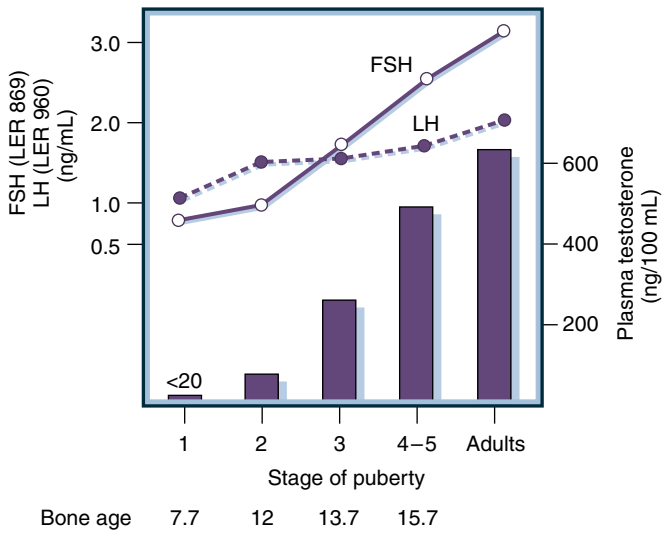
Because of the pulsatile secretion of GnRH, gonadotropin secretion is also episodic. The newer immunometric supersensitive assays allow accurate measurement in small pediatric samples. The results are lower than previously reported by the older assays.

During the first 2 years after birth, plasma levels of LH and FSH rise intermittently to adult values (the "mini puberty of infancy") and occasionally higher but then remain low until puberty. In healthy Danish girls below 3 years of age LH increases up to 9.2 IU/L after GnRH test with lower values after 3 years.[251] Ultrasensitive assays and third-generation assays for LH and FSH confirm earlier evidence of pulsatile secretion of the gonadotropins in prepuberty and indicate that the basal immunoreactive levels of LH are much lower than previously reported.[252,253] The serum FSH level is higher than the LH level in prepubertal boys and girls.[254] There is a more striking rise in serum LH amplitude by at least 1 year before the onset of puberty (i.e., the peripubertal period immediately preceding the appearance of signs of sexual maturation) that reaches an early plateau, whereas FSH rises more consistently through male puberty rather than before, with increased pulse amplitude. An increased amplitude of LH and FSH secretion occurs at night in prepubertal boys and girls by 5 years of age; the amplitude and frequency of such peaks increase, and daytime secretion increases with the progression of pubertal development.

In girls, FSH levels rise during the early stages of puberty, and LH levels tend to rise in the later stages; from beginning to late puberty, the LH concentration rises more than 100-fold (Figs. 26.19 and 26.20). Disorderly patterns of secretion of LH, but not FSH, were noted just before the onset of puberty; this was followed by, first, increased orderliness in early puberty and,



• **Fig. 26.19** Mean plasma estradiol, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) concentrations in prepubertal and pubertal females by pubertal stage of maturation (1, prepubertal; 5, menstruating adolescents) and the mean bone age for each stage. Single daytime values of gonadotropins have limited usefulness because of pulsatility of gonadotropin release and the increased amplitude of LH pulses during sleep throughout puberty. The gonadal steroid values, however, are useful in determining the stage of pubertal development. To convert FSH values (LER-869) to international units per liter, multiply by 8.4. To convert LH values (LER-960) to international units per liter, multiply by 3.8. To convert estradiol values to picomoles per liter, multiply by 3.671. (From Grumbach MM. Onset of puberty. In: Berenberg SR, ed. *Puberty, Biologic and Social Components*. Leiden, The Netherlands: H.E. Stenfert Kroese; 1975:1–21. Reprinted by permission of Kluwer Academic Publishers.)



• **Fig. 26.20** Mean plasma testosterone (after solvent extraction and chromatography) and gonadotropin levels in normal boys by stage of maturation (1, prepubertal) and mean bone age for each stage (see Fig. 26.19). To convert testosterone values to nanomoles per liter, multiply by 0.03467. (From Grumbach MM. Onset of puberty. In: Berenberg SR, ed. *Puberty, Biologic and Social Components*. Leiden, The Netherlands: H.E. Stenfert Kroese; 1975:1–21. Reprinted by permission of Kluwer Academic Publishers.)

then, increased disorderliness again in later puberty. This suggests that a more integrated feedback system operates in early puberty and is then followed by less stability.[255]

Doses of exogenous GnRH that are relatively ineffective in stimulating gonadotropin or gonadal steroid secretion before puberty become effective with the onset of puberty; an amplification occurs in the hypothalamic-pituitary-gonadal axis with progression of puberty.[256] Although the GnRH or GnRH agonist test usually requires multiple sampling after the administration of GnRH, a single determination at 60 or 24 minutes now suffices with the new, sensitive assays.[257–260] The basal values of serum LH and FSH measured in modern supersensitive assays are reported to predict the onset of pubertal development as well as GnRH testing does; a value of serum LH greater than 4 mIU/mL measured by immunochemiluminometric assay (ICMA) is consistent with the onset of puberty. Moreover, the use of these ultrasensitive assays to determine concentrations of LH and FSH in urine reveals a pattern of a 5-fold rise in urinary FSH in boys and girls, with a 50-fold rise in urinary LH in boys and a 100-fold rise in girls during puberty.[261]

In addition to the well-defined quantitative changes that occur in the pattern of FSH and LH in the pituitary gland, serum, and urine during development, qualitative changes occur. The pattern of glycosylation of the α-subunit and β-subunit of the gonadotropins is influenced by maturation, GnRH secretion, and the effects of gonadal steroids on the pituitary gonadotrophs. Variation in glycosylation that affects the size and charge of the hormone is the principal cause of the heterogeneity of FSH and LH and the large number of isoforms that varies according to the more acidic or more basic charge.[262] This pleomorphism has an important effect on biologic half-life and biologic activity and provides an additional mechanism of regulating the biologic activity of the gonadotropins. Discrepancies between serum bioactivity and immunoactivity of LH during pubertal development have been reported by some but not all researchers. However, a change in the isoforms of FSH released during puberty may favor the secretion of increased bioactive FSH, which may favor reproductive development.[262]

Gonadal Steroids

Only recently has it been appreciated that many actions on linear skeletal growth, skeletal maturation, and accretion of bone mass thought to be due to testosterone in the male are mainly attributable to its peripheral aromatization to estrogen (Table 26.7).

Testosterone

The Leydig cells of the testes produce testosterone and, in lesser amounts, androstenedione, α5-androstenediol, dihydrotestosterone, and estradiol, although a small amount of testosterone is derived from extraglandular conversion of androstenedione secreted by the testes and the adrenal. In the female, extraglandular conversion of ovarian and adrenal androstenedione accounts for almost all of the circulating testosterone.

Previous methods of determination of low levels of sex steroids have been demonstrated to be inaccurate.[263,264] This insensitivity is mainly due to the presence of interfering substances and relative insensitivity of antibodies used in assays. Now, larger national laboratories are beginning to use HPLC-MS/MS, which allows the accurate measurement of extremely low values present in pediatric samples.[265] These newer techniques may lead to revision of some of the results (described here) obtained by older methods. Measurement of testosterone and estradiol by HPLC-MS/MS in laboratories with pediatric standards is the preferred method to measure gonadal steroids to investigate disorders of puberty.

Prepubertal boys and girls have plasma testosterone concentrations of less than 0.3 nmol/L except during the first 3 to 5 months of infancy in the male, when pubertal levels are found. Nighttime elevations of serum testosterone levels are detectable in the male by 5 years of age, before the onset of physical signs of puberty, and increase during early puberty after the appearance of sleep-entrained secretion of LH and increased pituitary sensitivity to GnRH. The 60-minute lag between the peak of LH and the increase in testosterone is presumably due to synthesis and secretion of the steroid. In the daytime, increases in testosterone levels are detectable after the testis volume is greater than 4 mL, with a consistent increase throughout puberty. The steepest increment in testosterone concentration occurs between pubertal stages 2 and 3 in males (see Fig. 26.20 and Table 26.5). The ratio of testosterone to epitestosterone in the urine, which is used to evaluate doping of athletes, may be elevated normally during puberty.

TABLE 26.7 Early Clinical Clues to the Effect of Estrogen on Growth and Skeletal Maturation in the Male

Complete androgen insensitivity (resistance) syndrome (Zachmann M, Prader A, Sobel EH, et al. Pubertal growth in patients with androgen insensitivity: indirect evidence for the importance of estrogen in pubertal growth of girls. *J Pediatr.* 1986;108:694–697.)
Short-term estradiol administration increased rate of ulnar growth in prepubertal boys (Caruso-Nicoletti M, Cassorla FG, Skerda MC, et al. Short term, low dose estradiol accelerates ulnar growth in boys. *J Clin Endocrinol Metab.* 1985;61:896–898.)
Aromatase inhibitor decreased rapid growth and skeletal maturation in testotoxicosis, whereas antiandrogen had no effect on skeletal maturation (Laue L, Jones J, Barnes K, et al. Treatment of familial male precocious puberty with spironolactone and deslorelin. *J Clin Endocrinol Metab.* 1993;76:151–155.)
Aromatase excess syndrome in boys associated with increased rate of growth and skeletal maturation, elevated plasma estrogen concentrations, but prepubertal testosterone values (Stratakis CA, Vottero A, Brodie A, et al. The aromatase excess syndrome is associated with feminization of both sexes and autosomal dominant transmission of aberrant P450 aromatase gene transcription. *J Clin Endocrinol Metab.* 1998;83:1349–1357.)
Estrogen-secreting tumors: adrenal and testicular neoplasms (especially Peutz-Jeghers syndrome) (Bulun SE, Rosenthal IM, Brodie AM, et al. Use of tissue-specific promoters in the regulation of aromatase cytochrome P450 gene expression in human testicular and ovarian sex cord tumors, as well as in normal fetal and adult gonads. *J Clin Endocrinol Metab.* 1993;77:1616–1621.)

From Grumbach MM. Estrogen, bone, growth, and sex: a sea change in conventional wisdom *J Pediatr Endocrinol Metab.* 2000;13:S1439–S1455.

Free testosterone measurements may be determined by dialysis or by calculation using testosterone values and available protein binding sites; low accuracy of the testosterone assay can make free testosterone measurements inaccurate.[265] Nonetheless, if the total testosterone concentration on which the free testosterone level is based is measured by a highly specific assay, free or bioavailable testosterone determinations are helpful in evaluation of PCOS or nonclassic congenital adrenal hyperplasia (CAH) in girls.

A sensitive mammalian cell recombinant bioassay for androgen bioactivity strongly correlates with serum immunoreactive testosterone concentration and demonstrates a rise with pubertal development in concert with progression of pubic hair and penile development in patients with CDP.[266] In contrast to this specific bioassay, a novel, highly sensitive transcriptional androgen receptor (AR)–mediated bioassay system demonstrated higher circulating values of bioactive androgen in menopausal women and may be directed toward children in the future.[267]

The values of sex steroids measured in saliva are much lower than in the serum, but trauma (even tooth brushing) that leads to blood in the specimen can influence the results, and the accuracy of the basic assay is critical (see earlier discussion).[265] The steroid level in saliva is not a direct representation of free steroid in the serum, as is often claimed. Testosterone in saliva is said in some reports to correlate well with serum levels of testosterone in normal subjects and in patients with chronic disease (e.g., cystic fibrosis). Salivary progesterone is said to rise with the progression of puberty. Salivary DHEA is higher after the onset of puberty than before. Salivary steroid measurements, if accurate, can increase the ability of investigators to address the relationship between development and behavior in a noninvasive manner, but it may take the use of LC/MS-MS in salivary assays to achieve such accuracy.

Estrogens

In the female, estradiol is secreted principally (90%) by the ovary; a small fraction of circulating estradiol arises from the extraglandular conversion of testosterone and androstenedione. In the male, approximately 75% of estradiol is derived from extraglandular aromatization of testosterone and (indirectly) androstenedione, and 25% is from testicular secretion.

In the fetus and at term, estrogen is high due to conversion of fetal and maternal adrenal C19-steroids to estrogen by the placenta, but they drop precipitously during the first few days of life. Plasma estradiol levels are so low in prepuberty that detection by standard immunoassays is difficult, but a rise through puberty and a diurnal rhythm is seen with a sensitive radioimmunoassay (Table 26.8; see Fig. 26.19). Estrone levels rise early and reach a plateau by midpuberty. A highly sensitive bioassay demonstrated higher estradiol concentrations in girls than in boys before puberty, with a rise through puberty until the pubertal growth spurt and a decrease thereafter. Today, estrogen measurements by high-performance liquid chromatography (HPLC) tandem mass spectroscopy is preferred. There is a significant correlation between peak growth velocity and the rise in estradiol concentration; the rise is earlier in girls than in boys, but bioactive estradiol levels are equivalent at peak growth velocity.[160,268] The higher estrogen levels in girls may be an important factor in the more advanced levels of skeletal maturation in girls compared with boys and may play a part in their earlier onset of sexual maturation. A human cell bioassay measuring total estrogenic bioactivity (rather than estradiol alone) in children has an extremely sensitive detection limit of less than 1 pg/mL.[269]

The daily peak of estradiol in early pubertal girls occurs about 6 to 9 hours after the peak of serum LH detected during the night, apparently related to time required for synthesis. In all stages of puberty, boys have higher concentrations of estrone than estradiol, and levels of both estrogens are lower than those measured in girls at comparable stages.

Protein Products of the Gonads

Inhibin, Activin, and Follistatin

Inhibin, a heterodimeric glycoprotein product of the Sertoli cell of the testes and the ovarian granulosa cell (as well as the placenta and other tissues), exerts negative feedback action on the secretion of FSH from the pituitary. Inhibin is composed of an α-subunit and one of two β-subunits, β_A or β_B, which, respectively, form inhibin A or inhibin B, dimers with apparently identical function. Inhibin is a member of the transforming growth factor-β (TGFβ) superfamily that includes antimüllerian hormone (AMH) and the dimers of two inhibin subunits, activin A and activin B, which stimulate the release of FSH from pituitary cells.[270] Synthesis and secretion of gonadal inhibin are induced by FSH. Inhibin plays a role in the feedback regulation of FSH secretion during puberty in males and females.

Like inhibin, follistatin inhibits, whereas activin stimulates, FSHβ-subunit expression and therefore affects FSH biosynthesis and secretion. Inhibin may also be an inhibitor of LH release in the follicular phase.[271] These hormones are synthesized in a variety of tissues in addition to the gonads and have diverse activities apart from those on the reproductive apparatus.

Two distinct binding proteins for inhibin and activin are present in the circulation, the gonads, and other tissues: α_2-macroglobulin, a high-capacity, low-affinity binding protein; and follistatin, a glycosylated, single-peptide chain that functions as a high-affinity binding protein and as a regulator of activin bioactivity (e.g., in the pituitary gland, a site of synthesis of activin and follistatin).

During pregnancy, the placenta secretes inhibin A, and the fetal membranes secrete inhibin A and inhibin B, but for at least the first 20 weeks of gestation, only inhibin A is detected in maternal serum. In umbilical cord serum from term female newborn infants, no inhibin dimer was detected, whereas cord serum from male newborns contained inhibin B, the only inhibin detected in adult males.[272] In the human fetal testis, α-subunit and β_B-subunit (but not β_A-subunit) were present in Sertoli and Leydig cells at 16 weeks of gestation; by 24 weeks of gestation, immunoexpression of both subunits was greater in the Sertoli cells. Postnatally the expression of both subunits was decreased by 4 months of age. Inhibin subunits were not detected in the fetal ovary, nor was immunoreactive follistatin present in fetal or neonatal gonads.[273]

In large, cross-sectional studies using highly specific inhibin B and inhibin A immunoassays that correlate with the bioactivity of inhibin and distinguish inhibin B from inhibin A, the mean concentration of serum inhibin B in males increased between prepuberty (a stage when it is higher than the undetectable levels in castrated men)[274] and the first stage of puberty; when the strong

correlation with chronologic age was taken into account, a correlation with LH and testosterone values remained. From genital stage 2 of puberty on, inhibin B levels were relatively constant, despite a rise in the mean concentration of serum FSH between stages 2 and 3, after which the FSH value was relatively unchanged. The rise in inhibin B is mirrored by a drop in AMH in early puberty, apparently reflecting Sertoli cell maturation.[275] By genital stage 3, a negative partial correlation between inhibin B and FSH was found that persisted as puberty advanced, and by genital stage 4, there was a clear negative correlation of inhibin with serum FSH. Dimeric inhibin B rises twice during development, reflecting the two periods of Sertoli cell proliferation in infancy and in early puberty, whereas an inverse relationship between inhibin and FSH is seen at midpuberty and thereafter, indicating the development of negative feedback inhibition. In the early stages of puberty, inhibin B values are closely related to LH and testosterone levels, but in stage 3, when inhibin B values peak, this relationship is lost, and inhibin B values become more closely related to FSH levels.[276]

Serum levels of inhibin A and B increase early in puberty in girls, although there are individual increases in the prepubertal period directly related to FSH levels, demonstrating sporadic follicular development in the infant and child due to FSH stimulation. Inhibin B is predominant in the follicular phase, as is inhibin A during the luteal phase. Inhibin A and inhibin B peak in midpuberty, and inhibin B is thereafter decreased. During the early stages of puberty, inhibin B values are related to estradiol and FSH values, but these relationships diminish with the progression of puberty.[277] Although there is no significant change in activin during female puberty, follistatin decreases from a midpuberty peak to later values that fall below prepubertal values.

Serum values of FSH-regulating proteins follow circadian patterns, with higher values of LH and FSH overnight, just after a nadir of inhibin B. Follistatin concentrations were found to reach their greatest value in early morning, and activin A concentrations declined coincident with the nighttime increase in FSH levels in pubertal girls.[278] Diurnal variation of inhibin B in boys in the peripubertal or early pubertal period demonstrates a fall in inhibin during the night as LH and, subsequently, testosterone rise, showing the negative feedback effect of testosterone on inhibin B secretion.[279] Recombinant FSH treatment, which raises testosterone secretion, suppresses inhibin B, demonstrating the ability of testosterone to negatively influence inhibin B secretion.[280] Administration of a GnRH agonist led to an increase in the FSH level by 30 minutes as well as an increase in the inhibin B level in girls older than 5 years of age by 8 hours and in boys by 20 hours.[281] The baseline inhibin B concentration was greater in boys than in girls, baseline activin A concentrations were greater in girls, and activin did not change with GnRH administration. Testosterone administration to boys in Tanner stage 2 led to decreased FSH and LH, increased activin, and decreased inhibin B levels but caused no change in follistatin. Estradiol administered to girls in Tanner stage 1 or 2 led to decreased LH and

FSH and increased activin A levels but no change in inhibin B or follistatin concentrations, whereas administration of estradiol to girls with Tuner syndrome led to decreased serum levels of FSH, although the effectively nondetectable levels of activin and inhibin did not change.[282]

A low concentration of inhibin B in men and pubertal boys is an indicator of impaired seminiferous tubule function.[283] Early pubertal boys with testicular defects have higher FSH concentrations and low inhibin levels. Inhibin B is the form most closely related to testicular function, and it is absent in orchidectomized men. Inhibin B is related to Sertoli cell function in prepuberty, but a developmental change occurs during puberty so that later in life, inhibin B concentration is related to spermatogenesis. Prepubertal boys with the Sertoli cell–only syndrome had normal inhibin B levels, whereas postpubertal affected boys and men with Sertoli cell–only syndrome and early-stage spermatogenic arrest had undetectable or low levels of inhibin B, and those with late-stage spermatogenic arrest or obstructive azoospermia had normal or near-normal levels of serum inhibin B.[274] In prepuberty, the α and the β_B inhibin subunits are expressed in Sertoli cells, but during puberty and in men, fully differentiated Sertoli cells express only the α-subunit; the β-subunit is expressed in germ cells. Inhibin B in the adult appears to be a product of germ and Sertoli cells. In prepubertal boys, basal plasma inhibin B concentrations have a high correlation with the incremental testosterone response to administration of human chorionic gonadotropin (hCG), and they provide a useful assessment of the presence of testes and their function.[284]

Antimüllerian Hormone

AMH (also called müllerian inhibiting substance [MIS] or factor [MIF]), a 14-kDa homodimeric glycoprotein that is structurally related to the subunit of inhibin and TGFβ, is produced by the Sertoli cells of the fetal testis after 7 weeks and the prepubertal testis and causes the regression of the müllerian ducts in boys during early fetal development and later in gestation by granulosa cells of the fetal ovary. AMH production is first stimulated by SOX9, SF1, GATA4, and WT1 before FSH rise but later is stimulated by FSH.[285] Immunoassayable concentrations of AMH values rise from birth to relatively high levels during the first year of life in males, decrease by age 10 years, and decrease further during puberty.[286] Newborn females have low or nondetectable serum levels of AMH, which rise only slightly thereafter; serum AMH concentrations are virtually nondetectable in most girls just before puberty. Serum levels of AMH and of estradiol after GnRH analogue stimulation are increased in low-birth-weight and high-birth-weight female infants, suggesting altered follicular development.[287] Increased poststimulation FSH levels and low adiponectin concentrations are observed only in high-birth-weight infants, indicating that altered ovarian function occurs by a different mechanism than that found in low-birth-weight infants.

Serum levels of AMH and inhibin B are inversely related to androgen concentrations in pubertal boys,[275] and values in boys with CPP are appropriate for pubertal stage rather than chronologic age.[286] Elevated serum AMH concentrations occur in androgen resistance. Treatment with recombinant FSH and hCG in hypogonadotropic hypogonadism increases testosterone and decreases the elevated levels of serum AMH (due to immature Sertoli cells) and inhibin B, further demonstrating this relationship.[280] AMH is slightly higher in boys with delayed puberty than in pubertal age-matched control subjects and lower in those with testicular dysgenesis associated with impaired virilization than in normal boys. Boys with isolated cryptorchidism have normal values of AMH, and AMH and inhibin B are absent in anorchia, allowing a differential diagnosis during the first month after birth.[288] Dysgenetic testes secrete only low serum AMH levels; the testosterone response to hCG indicates the presence of testicular tissue.[289]

AMH is elevated in girls with PCOS and in girls with oligomenorrhea without classic AMH. This finding suggests that oligomenorrheic adolescents may have increased antral follicle number, similar to that observed in girls with PCOS.[290] AMH is a useful gonadal tumor marker because values are elevated in males with primitive Sertoli-like tumors and in girls and women with granulosa cell tumors.

Adrenal Androgens

A progressive increase in plasma levels of Δ^5-steroids, DHEA, and DHEAS in boys and girls begins before age 8 (skeletal age of 6–8 years) and continues through early adulthood (Table 26.9). The increase in the secretion of adrenal androgen and its precursors is known as *adrenarche,* and the appearance of pubic hair caused by adrenarche is known as *pubarche*. Plasma DHEA levels have a diurnal rhythm similar to that of cortisol, but plasma levels of DHEAS show less variation and are a useful biochemical marker of adrenarche.

TABLE 26.9 Mean Serum Concentrations (mmol/L [ng/mL]) of DHEAS During Childhood

	6-8 yr	8-10 yr	10-12 yr	12-14 yr	14-16 yr	16-20 yr
By Chronologic Age						
Boys	0.5 (188)	1.6 (586)	3.4 (1260)	3.6 (1330)	7.2 (2640)	7.2 (2640)
Girls	0.8 (306)	3.2 (1170)	3.1 (1130)	4.6 (1690)	6.9 (2540)	6.3 (2320)
By Bone Age						
Boys	0.98 (360)	1.6 (574)	3.4 (1250)	5.8 (2150)	10.9 (4030)	
Girls	0.73 (276)	3.1 (1130)	4.33 (1560)	7.1 (2610)	3.9 (1450)	

DHEAS, Dehydroepiandrosterone sulfate.

Modified from Reiter EO, Fuldauer VG, Root AW. Secretion of the adrenal androgen, dehydroepiandrosterone sulfate, during normal infancy, childhood, and adolescence, in sick infants, and in children with endocrinologic abnormalities. *J Pediatr*. 1977;90:766–770.

DHEA is the predominant precursor to more potent androgens in females, but DHEAS cannot be converted. DHEAS is produced from DHEA by the action of the sulfotransferase enzyme SULT2A1, mainly in the adrenal glands and the liver. The sulfate donor phosphoadenosine phosphosulfate (PAPS) is required by SULT2A1, and in human beings, PAPS is synthesized by the two isoforms of PAPS synthase, PAPSS1 and PAPSS2.[291]

Testosterone-Binding Globulin

Between 97% and 99% of circulating testosterone and estradiol is reversibly bound to testosterone-binding globulin (TeBG) (or sex steroid–binding globulin [SHBG]); prepubertal levels of TeBG are approximately equal in boys and girls, but a decrease in TeBG level occurs with advancing prepubertal age and the concomitant increase in the plasma gonadal steroid levels.[292] At puberty, there is a small decrease in TeBG levels in girls; as a consequence of testosterone, there is a greater decrease in boys, although the drop observed in normal boys is attenuated by treatment with tamoxifen, even with advancing pubertal development. The rise in adrenal androgen levels at adrenarche may explain the early drop in TeBG levels, which allows more circulating free hormone at a given concentration of testosterone. Although the plasma concentration of testosterone is 20 times greater in men than in women, the concentration of free testosterone is 40 times greater. Boys with hypogonadotropic hypogonadism and patients with the androgen resistance syndrome show the same characteristic fall in TeBG levels at puberty, but values are intermediate between those of normal adult males and females.

Prolactin

Prolactin levels rise in girls during puberty. Prepubertal mean (± standard error) plasma prolactin concentrations are less than 10 μg/L in boys and 3 to 12 μg/L in girls. Late pubertal girls and adult women have higher concentrations of prolactin (3–20 μg/L and 3–20 μg/L, respectively), whereas the mean concentration in adult men is 2 to 18 μg/L.[293] This sex difference is probably a consequence of the higher estradiol levels during puberty in girls and in women.

Insulin-Like 3 Protein

During puberty, serum levels of insulin-like 3 (INSL3), a protein produced by the Leydig cells, rise in normal boys under LH stimulation and in those in whom increased secretion is induced by letrozole treatment.[294,295] Values do not increase in Klinefelter syndrome, in which the initial rise levels off during midpuberty.[295] INSL3 is said to be as sensitive as testosterone as an indication of Leydig cell function.[296]

Prostate-Specific Antigen

Prostate-specific antigen (PSA) is detectable in male and female cord blood and in the serum of infants, but PSA concentrations decrease to undetectable levels during childhood. PSA concentrations rise to the measurable range with the onset of puberty in the male and correlate with the progression of pubertal stage, the size of the testes, serum LH and testosterone concentrations, and, presumably, the size of the prostate.[297,298] PSA values are increased to the pubertal range in boys with idiopathic CPP, and they decrease with GnRH agonist treatment.

Hormonal Control of the Pubertal Growth Spurt

Postnatal growth follows a specific pattern: An extremely high growth rate just after birth is followed by a deceleration that continues until 3 years of age; next, there is a slower phase of deceleration until puberty. The subsequent pubertal growth spurt, the second greatest period of postnatal growth, is followed by maturation of the spine and long bones until adult height is reached.[151] Many factors influence the growth plate.[299] The adolescent growth spurt in normal girls and boys depends on estradiol and GH levels, among other factors.

Hormonal control of the pubertal growth spurt is complex (see Figs. 26.15 and 26.16). GH is involved in increasing growth at puberty through stimulation of IGF1 production. Gonadal steroids have two effects on pubertal growth: (1) induction of an increase in GH secretion, with a consequent increase in IGF1 production, thereby indirectly stimulating pubertal growth; (2) a direct effect on cartilage and bone through stimulation of local production of IGF1 and other local factors.[160,300]

Gonadal Steroids[159,160]

In the developing human skeleton, gonadal steroids have growth-promoting and maturational effects on chondrocytes, osteoblasts, and other bone constituents.[159,160] This action, which eventually leads to epiphyseal fusion and the cessation of longitudinal growth in boys and girls, is mediated mainly by estrogen that is directly secreted (in girls) or arises from the conversion of testosterone and androstenedione to estrogen in peripheral tissues by aromatase (see Table 26.8). Detection of estrogen resistance resulting from a null mutation in the gene encoding the estrogen receptor and from derangements in the *CYP19A1* gene, leading to severe cytochrome P450 aromatase deficiency, has highlighted the cardinal role of estradiol (but not testosterone) in both boys and girls in the pubertal growth spurt, completion of epiphyseal maturation, and normal skeletal proportions and mineralization. Individuals with a mutation in the ERα gene *(ESR1)* or the *CYP19A1* gene encoding aromatase continue to grow, lack a pubertal growth spurt, and have open epiphyses and osteopenia.[301–303] Estrogen treatment of men with aromatase deficiency leads to epiphyseal closure, cessation of growth, and a striking increase in bone mass.[304–306] Patients with aromatase excess, who produce excess estrogen, have advanced skeletal maturation and rapid growth and ultimately reach short adult stature.[307]

Although estradiol secreted by the ovary has long been recognized as the major sex steroid responsible for the pubertal growth spurt, skeletal maturation, and bone mineral accrual in females, until the detection of the rare human genetic defects in estrogen synthesis or action, conventional wisdom dictated that testosterone mediated these maturational changes during puberty in males. Now it is known that estrogen (not androgen) is the critical sex hormone in males and females in the pubertal growth spurt, skeletal maturation, accrual of peak bone mass, and maintenance of bone mass in the adult. Estrogen stimulates chondrogenesis in the epiphyseal growth plate, increasing pubertal linear growth.[270] At puberty, estrogen promotes skeletal maturation and the gradual progressive closure of the epiphyseal growth plate.[159] The use of a supersensitive assay for plasma estradiol in prepubertal and pubertal boys revealed a high positive correlation between estradiol concentrations and peak growth velocity (but not serum GH level), which was greatest about 3 years after the onset of puberty,[268]

further implicating estrogen in the pubertal growth spurt and skeletal maturation of boys and girls.

There are estrogen receptors, both ERα and ERβ, in the growth plate chondrocytes.[299] Histologic studies of the bone and cartilage of rodents treated with corticosteroids or estrogen and clinical evaluations of children with precocious puberty support the theory that senescence of the growth plate occurs because of estrogen exposure in precocious puberty, causing decreased growth during treatment with GnRH agonists.[308]

The high rate of bone turnover in early puberty followed by a decrease in periosteal apposition and endosteal resorption within cortical bone and decreased bone remodeling within cortical and cancellous bone mediated by apoptosis of chondrocytes in the growth plate and osteoclasts within cortical and cancellous bone is mediated in part by estrogen. This leads to a reduction in bone turnover markers at menarche, reflecting the closure of the epiphyseal growth plates.[309]

Girls with Turner syndrome without estrogen exposure retain elevated markers of bone turnover. Prepubertal girls with Turner syndrome tend to lose bone, but that ceases when estrogen therapy begins.[310] During puberty and into the third decade, estrogen has an anabolic effect on the osteoblast and an apoptotic effect on the osteoclast, increasing bone mineral acquisition in the axial and appendicular skeletons. Evolutionary theory suggests that positive effects of estrogen on bone density, added to mechanical loading, allow women to carry increased weight for pregnancy and lactation; this process is unnecessary after reproduction, and osteoporosis becomes more common at menopause.[311]

Testosterone may also have a direct action on bone in the human male, because ARs are found in human tibial growth plates in osteoblasts and chondrocytes, osteocytes, mononuclear cells, and endothelial cells of blood vessels in the bone marrow.[312] Androgens that cannot be aromatized to estrogen still cause an increase in growth rate, presumably due to interaction with these receptors. The greater increase in periosteal bone deposition, the resultant thickening of cortical bone and greater bone strength, and the greater bone dimensions in boys probably result from direct effects of testosterone. Androgens may protect men against osteoporosis by maintenance of cancellous bone mass and expansion of cortical bone.

A pubertal growth spurt leading to adult height close to that of genotypic men occurs in individuals with the complete form of androgen resistance, demonstrating the critical role of estrogen rather than androgen in the adolescent growth spurt in boys. A modest decrease in BMD Z-scores occurs in the spine but not in the hip based on age-specific female standard values, but the reductions are greater when male standards are used. Affected women have an increased prevalence of fractures, even with estrogen replacement. This suggests that lack of a direct effect of testosterone on the skeleton, especially the spine, has a part in the defects in bone mineralization observed in women with complete androgen insensitivity[313] (see Table 26.8).

Growth Hormone and Growth Factors

GH secretion approximately doubles during puberty in boys and girls in the basal state or after stimulation but decreases after pubertal development. Remarkably, peak values after hexarelin, a 6–amino acid GH-releasing peptide (or GH secretagogue) stimulates as much GH secretion in prepuberty as in puberty. The greater elevation in girls starts at an earlier age and pubertal stage than in boys due to the earlier onset of puberty in girls. GH secretion increases coincident with the onset of breast development (Tanner stage 2) and is maximal at Tanner stage 3 to 4 breast development; in boys, GH rises later and peaks at stage 4 genital development. GH secretion and IGF1 levels decrease after late puberty in both sexes. Adolescents of normal height have an inverse relationship between weight and GH levels. Increased GH pulse amplitude and content of GH secreted per pulse (but not frequency, metabolic clearance rate, or intersecretory burst interval and half-life of GH) in the basal state are mainly responsible for the augmented GH levels.[314]

The increase in estradiol at puberty, which in boys results from testicular secretion and extraglandular synthesis from testosterone and androstenedione and in girls from secretion by the ovaries, is the principal mediator of the increase in pulse amplitude and amount of GH secreted per pulse. Administration of exogenous androgens in delayed puberty raises GH secretion. Transdermal application of testosterone increases spontaneous GH secretion overnight independent of growth hormone–releasing hormone (GHRH), because infusion of GnRH antagonist does not affect this phenomenon.[315] The effect of testosterone is mediated mainly through its conversion to estradiol, because treatment of late pubertal boys with tamoxifen, an estrogen receptor blocker, causes smaller GH secretory peaks and fewer GH secretory episodes. Exogenous estrogen increases the peak GH reached after insulin-induced hypoglycemia, exercise, and arginine, a priming effect that is used in clinical practice, because estrogen administered before a provocative test in prepubertal subjects increases the GH response. Androgens that cannot be aromatized to estrogen (e.g., oxandrolone, dihydrotestosterone) have less effect on GH secretion; however, androgen blockade with flutamide increases GH secretion. Dihydrotestosterone, which is not aromatized to estrogen, does not increase GH secretion or the plasma concentration of IGF1 and may decrease the integrated GH secretion, but it still stimulates increased growth rate, suggesting a possible direct effect of androgen on pubertal growth independent of GH or estradiol.[300] Increased GH secretion also occurs in sexual precocity. GH secretion decreases with the fall in gonadal steroid levels after treatment of CPP with potent GnRH agonists.[316]

GH deficiency or GH resistance causes an attenuated pubertal growth spurt, indicating the importance of GH and IGF1 in this process. Severe primary or secondary hypogonadism leads to a minimal or absent growth spurt, demonstrating the primary role of gonadal steroids in pubertal growth. Hypopituitary patients deficient in GH and gonadotropins do not have an adolescent growth spurt when GH alone is replaced; gonadal steroids must also be given, substantiating the interaction of GH and gonadal steroids in the pubertal growth spurt. In normal puberty, neither the magnitude of the increase in GH secretion nor the concentration of plasma IGF1 correlates with the PHV of the pubertal growth spurt. Although a threshold level of GH secretion is necessary, the extent of the growth spurt correlates with gonadal sex steroid secretion. Individuals with both CPP and GH deficiency (usually as a consequence of cranial irradiation for a brain tumor) have a growth spurt clinically indistinguishable from that of CPP and normal GH secretion.[300] After treatment with a GnRH agonist for sexual precocity, growth velocity in patients with GH deficiency and CPP is decreased and pubertal progression is suppressed, illustrating the direct effect of gonadal steroids, principally estradiol, on the pubertal growth spurt.

Urinary GH excretion reflects serum levels and changes occurring with pubertal development. A peak is reached at pubertal stage 3 to 4. The level is higher in boys than in girls.

Growth Hormone–Binding Protein

Growth hormone–binding protein (GHBP) has the same amino acid sequence as the extracellular component of the GH receptor (GHR), and serum concentrations are directly related to the number of GHRs. In normal children, the plasma GHBP level is inversely related to 24-hour GH secretion. The serum GHBP level rises early in childhood and also through puberty in some cross-sectional studies, but not in others. Because plasma GHBP does not change appreciably with the onset of puberty, at the time of the pubertal growth spurt there is a relative increase in unbound (free) GH in relation to GH bound to GHBP. GHBP is related to adiposity, and it may be this factor that accounts for the increased levels of GHBP in girls compared with boys, the rise in GHBP in girls with precocious puberty, and the negative influence of testosterone on GHBP levels.[317]

Insulin-Like Growth Factor Type 1

Concentrations of IGF1 rise during puberty to levels higher than those of prepuberty or adulthood; they remain elevated past the time of PHV, with a peak attained 1 or 2 years after the pubertal growth spurt (later in boys than in girls) and then fall to normal adult levels.[316,318] The pattern of the GH-dependent serum levels of IGF-binding protein 3 (IGFBP3) in pubertal development is similar to that of serum[319] IGF1. However, serum IGFBP3 concentrations correlate with BMI even though IGF1 does not. Measurement of free IGF1 shows the same pattern of change with development as does that of total IGF1, a slow rise in serum free IGF1 in prepuberty followed by a steeper rise during puberty. A decrease of free IGF1 is associated with age in the later stages of puberty.[319,320] The increase in the serum ratio of IGF1 to IGFBP3 at the time of the pubertal growth spurt appears to result from production, because proteolysis of IGFBP3 does not change in puberty in normal children. The testosterone level in boys and the estradiol level in girls correlate with the rise in IGF1 concentration, but gonadal steroids are not the direct cause of the increase in circulating IGF1 levels; rather, GH secretion approximately doubles during puberty owing to the effect of estrogen causing augmented release of GH.

Plasma IGF1 concentrations are high for chronologic age in sexual precocity and low in delayed puberty. Estrogen mediates the pubertal increase in IGF1 concentration through increased secretion of GH, with an additional effect through the gonadal steroid–induced local generation of IGF1 in cartilage and bone. Treatment with GnRH agonist in a 16-year-old boy with a homozygous mutation in the WSXWS-like motif of the human GHR causing Laron syndrome led to a further decrease in the already low serum levels of IGF1 and IGFBP3, which did not reverse with dihydrotestosterone treatment, suggesting a direct effect of estradiol on IGF1 production.[299,321] Children with CPP treated with a GnRH agonist showed suppression of the untreated elevated serum GH concentrations and a decrease in plasma IGF1 concentrations, although not to prepubertal values, supporting the concept that GH is the major (but not the only) factor that raises circulating IGF1 levels in puberty.[316]

A confounding factor is the relative roles of hepatic-generated circulating IGF1 (i.e., endocrine role) and of locally produced IGF1 (i.e., paracrine/autocrine role) in linear growth. For example, mice with a totally deleted hepatic IGF1 gene have strikingly reduced circulating levels of IGF1 but normal postnatal body and bone growth.[322]

GH stimulates local IGF1 production in resting zone chondrocytes, located at the epiphyseal end of the growth plate in the area known as the reserve zone or stem cell zone, through GHRs in the chondrocytes. This IGF1 production stimulates, through autocrine and paracrine effects, the clonal expansion of proliferating chondrocytes derived from the resting chondrocyte or germ cells. GH and IGF1 can reduce the stem cell cycle time, proliferating cell cycle time and duration of the hypertrophic phase, a phase that leads to apoptosis, leaving the cells serving as a scaffold for the mineralization and production of new bone.

Other Hormones

There are glucocorticoid receptors in human growth plates, mostly in hypertrophic chondrocytes. However, children with chronic adrenal insufficiency who receive appropriate replacement therapy have a normal pubertal growth spurt despite deficient adrenal androgen secretion, indicating a minimal impact of these adrenal androgens on normal growth at puberty.[290]

Hypothyroid subjects lack a pubertal growth spurt even when the disorder is accompanied by sexual precocity.[323] Thyroid hormone has a permissive role in the pubertal growth spurt but is a requisite for normal growth. Hypothyroidism decreases GH secretion and affects growth indirectly. However, thyroid hormone also interacts with the thyroid hormone receptors α1 and β, whose proteins are found in early proliferating chondrocytes of the human growth plate and in the messenger ribonucleic acid (mRNA) found in other developing stages of chondrocytes and osteoblasts. Thyroid hormones also interact with the local effects of IGF1 and GH at the growth plate.[299] A longitudinal cohort study of 323 children demonstrated that higher prepubertal free T_4 (FT_4) and total T_4 (TT_4) are associated with earlier pubarche.[324]

Central Nervous System and Puberty

Two independent but associated processes (controlled by different mechanisms but closely linked temporally) are involved in the increased secretion of sex steroids in the peripubertal and pubertal periods. In the first process, adrenarche, the increase in adrenal androgen secretion[301,325] precedes by approximately 2 years the second process, gonadarche, which is a consequence of the pubertal reactivation of the hypothalamic-pituitary gonadotropin-gonadal apparatus.[290,325,326]

The onset of puberty is a consequence of maturational changes, including the development of secondary sexual characteristics, the adolescent growth spurt, the attainment of fertility, and psychosocial changes, all emanating from the disinhibition or reaugmentation of the hypothalamic GnRH pulse generator and gonadotropin secretion, causing an increase in gonadal steroid secretion[256,327] (Table 26.10). The events characterizing the development of gonadal function can be viewed as a continuum extending from sexual differentiation and the ontogenesis of the hypothalamic-pituitary gonadotropin-gonadal system during fetal life and early infancy,[126,254,326,327] through a juvenile pause (in which the system is suppressed to a low level of activity,[326] discussed later), to the attainment of full sexual maturation and fertility during puberty, leading to the ability to procreate (Fig. 26.21). In this light, puberty does not represent the initiation or first occurrence of pulsatile secretion of GnRH or pituitary gonadotropins but the reactivation or disinhibition of GnRH neurosecretory neurons in the medial basal hypothalamus and the endogenous, apparently self-sustaining oscillatory secretion of GnRH after the period of quiescent activity during childhood. An increase in the pulsatile

TABLE 26.10 Hypothesis of the Control of the Onset of Human Puberty

1. *Central dogma:* The CNS exercises the only major restraint on the onset of puberty. The neuroendocrine control of puberty is mediated by the hypothalamic GnRH-secreting neurosecretory neurons in the medial basal hypothalamus, which act as an endogenous pulse generator (oscillator).
2. The development of reproductive function is a continuum extending from sexual differentiation and the ontogeny of the hypothalamic-pituitary-gonadal system in the fetus to the attainment of full sexual maturation and fertility.
3. In the prepubertal child the GnRH pulse generator, operative in the fetus and infant, functions at a low level of activity (the juvenile pause) because of steroid-independent and steroid-dependent inhibitory mechanisms.
4. Puberty represents the *reactivation* (disinhibition) of the CNS suppressed GnRH pulse generator characteristic of late infancy and childhood, leading to increased amplitude and frequency of GnRH pulsatile discharges, to increased stimulation of the pituitary gonadotropes, and finally to gonadal maturation. Hormonally, puberty is initiated by the recrudescence of augmented pulsatile GnRH and gonadotropin secretion, mainly at night.

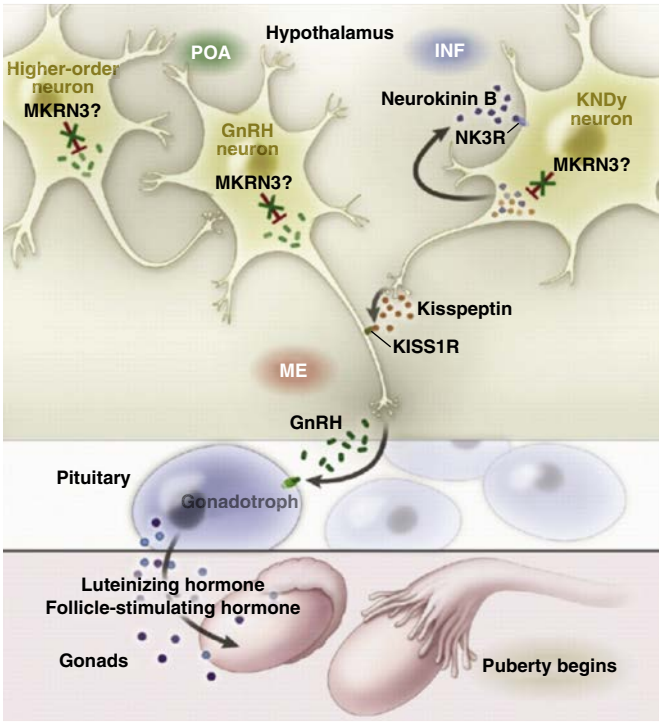
CNS, Central nervous system; *GnRH,* gonadotropin-releasing hormone.

From Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins, 1990:1–68. © 1990, the Williams & Wilkins Co., Baltimore.

release of GnRH heralds the onset of puberty in primates and other mammals.[126,327,328] The CNS, and not the hypothalamic GnRH pulse generator, pituitary gland, gonads, or gonadal steroid target tissues, restrains activation of the hypothalamic-pituitary-gonadal system during the prepubertal years.

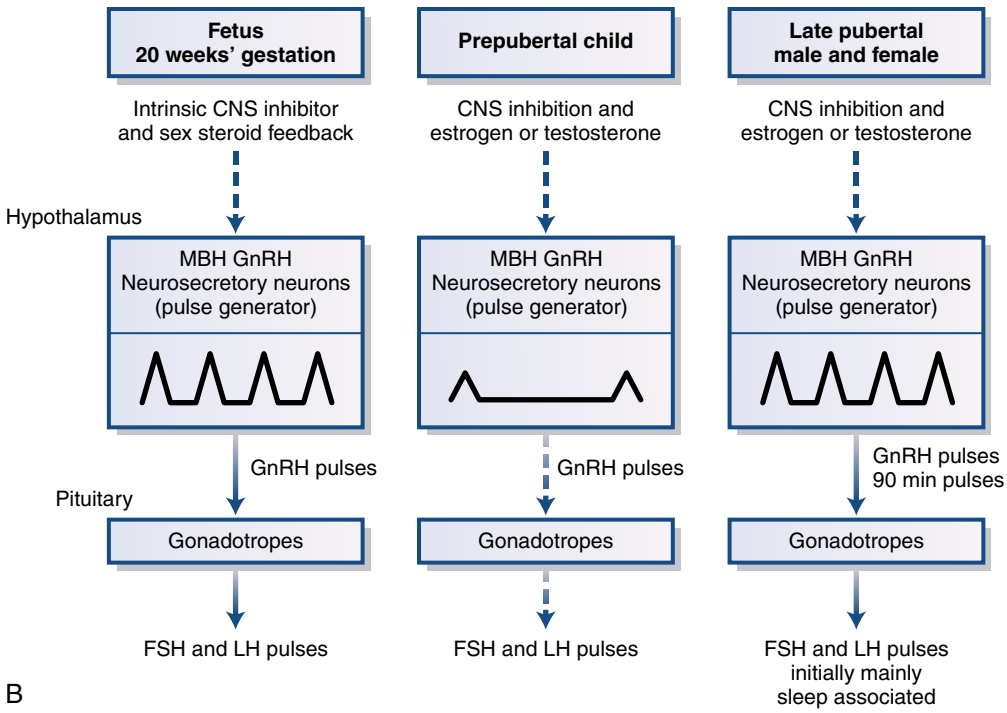
Certain CNS lesions involving the hypothalamus and nearby structures can advance or delay the onset of human puberty.[256,326] CPP, including cyclic ovulation in girls and spermatogenesis in boys, can result from a variety of CNS disorders. Several regulatory systems control puberty (Fig. 26.22):

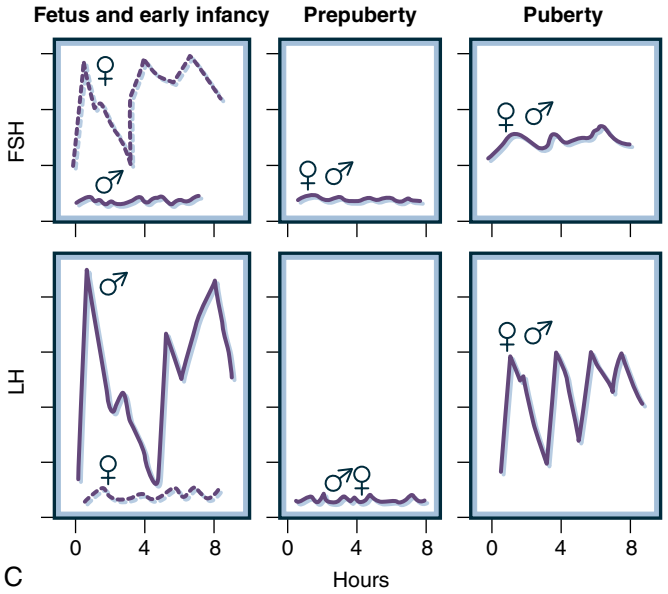
1. In primates, the neural component controlling gonadotropin secretion resides in the medial basal hypothalamus, including the arcuate region. There are about 1500 to 2000 transducer GnRH neurosecretory neurons, which are not segregated into a specific nucleus but are functionally interconnected. These GnRH neurons comprise the GnRH pulse generator, which drives and controls the pituitary gonadal components, stimulates the release of LH and FSH, and translates neural signals into a periodic, oscillatory chemical signal, GnRH, in a coordinated manner. These pulses appear to be generated by a propagated depolarization, the firing of action potentials in individual cells, and the resulting influx of calcium through L-type calcium channels.[329]
2. In response to the GnRH rhythmic signal, the pituitary gonadotrophs, which contain the seven-transmembrane domain G_s-coupled LH/hCG receptors (LHCGRs),[330] release LH and FSH in a pulsatile manner. Each LH and FSH pulse is induced by a pulse of GnRH.



A

• **Fig. 26.21** Timing of puberty. A pivotal event in the onset of puberty in mammals is the resumption of pulsatile release of gonadotropin-releasing hormone (GnRH) from neurons of the hypothalamus. Known influences on the timing of the onset of puberty in mammals include the photoperiod, leptin levels, and the increased expression of neurokinin. (A) Kisspeptin, and their receptors (NK3R and KISS1R, respectively). Abreu and associates[427] implicate MKRN3, a protein that is believed to mediate ubiquitination, in puberty onset. In contrast with kisspeptin and neurokinin B, which stimulate the commencement of puberty, MKRN3 seems to inhibit puberty: Abreu and associates[427] show that mutations in MKRN3 predicted to cause loss of function of the protein cause central precocious puberty. *INF,* infundibular nucleus; *KNDy,* kisspeptin–neurokinin B–dynorphin; *MBH,* medial basal hypothalamus; *ME,* median eminence; *POA,* preoptic area.

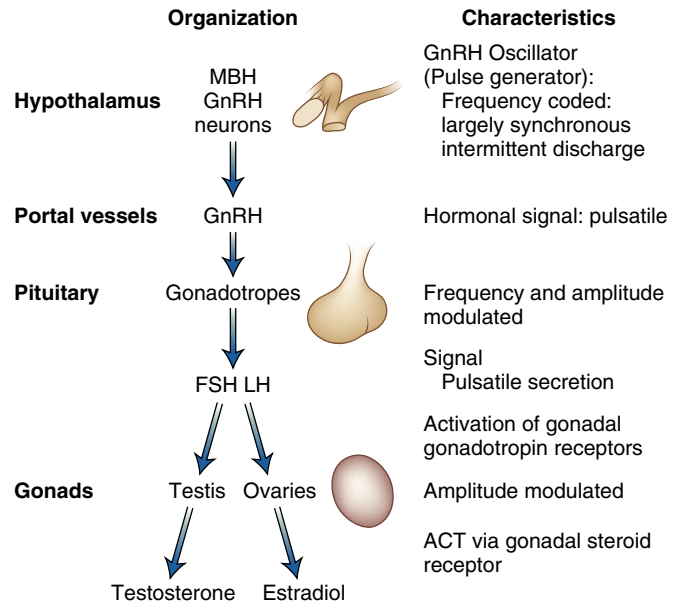




• **Fig. 26.21, cont'd** (B) Postulated ontogeny of the dual mechanism for the inhibition of puberty. *Dashed arrows* indicate inhibition. Notice the action of both components during the juvenile pause (i.e., prepuberty) (see Fig. 26.45 for the relative roles of these two mechanisms during development). (C) Change in the pattern of pulsatile follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion in the fetus and early infancy, prepuberty, and puberty (data from Waldhauser et al). Notice the pulsatile secretion in the fetus and infant and the striking difference in the amplitude of FSH and LH pulses between male and female infants. After infancy, the amplitude and frequency of gonadotropin pulses decrease greatly for almost a decade (i.e., juvenile pause) until the onset of puberty. (A, from Hughes IA. Releasing the brake on puberty. *N Engl J Med.* 2013;368:2513–2515; B and C, modified from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:1–68. Additional data from Waldhauser F, Weissenbacher G, Frisch H, et al. Pulsatile secretion of gonadotropins in early infancy. *Eur J Pediatr*. 1981;137:71–74.)

3. The gonads, which are modulated primarily by the amplitude of the gonadotropin pulse, transmit the episodic gonadotropin signal into pulsatile secretion of gonadal steroids.[331]

This control mechanism is common to all mammalian species. At the last two levels—the pituitary gland and the gonad—the target cells contain receptors for the peptide hormones that mediate the cellular response to the signal.[330,331] Diverse adaptive mechanisms and strategies have evolved among species and between the sexes that influence the biology and timing of puberty. Photoperiodicity and seasonal breeding, biologic clocks, and pheromones are integral parts of the pubertal process in some species but not humans. The most enlightening studies on the neuroendocrinology of human puberty have emerged from studies of humans and nonhuman primates.[328,332]



• **Fig. 26.22** Organization and characteristics of the hypothalamic-pituitary gonadotroph-gonadal system. The medial basal hypothalamus (MBH) contains the transducer gonadotropin-releasing hormone (GnRH) neurosecretory neurons. These neurons translate neural signals into a periodic, oscillatory chemical signal, GnRH. This MBH complex functions as a GnRH pulse generator (oscillator), which is frequency coded and releases GnRH from its axon terminals at the median eminence as a largely synchronous, intermittent discharge into the primary capillary plexus of the hypothalamic-hypophyseal portal circulation. The GnRH pulse generator is influenced by biogenic amine neurotransmitters, peptidergic neuromodulators, neuroexcitatory amino acids, and neural pathways. During the follicular phase in women and men, a GnRH pulse (estimated indirectly by monitoring luteinizing hormone [LH] pulses in peripheral blood) occurs approximately every 90 to 120 minutes throughout the day. Changes in the frequency and probably in the amplitude of the GnRH secretory episodes modulate the pattern of LH and follicle-stimulating hormone (FSH). The major site of action of testosterone and progesterone is on the GnRH pulse generator, because these two classes of steroids decrease LH pulse frequency, but a pituitary site of action has also been described. Estrogens have major direct inhibitory and stimulatory effects on the GnRH-primed pituitary gonadotroph; the inhibitory or negative feedback action is associated with a decrease in the frequency and the amplitude of pituitary LH secretion. Evidence supports the negative and positive feedback action of estrogen on the GnRH pulse generator. Inhibin has a direct inhibitory effect on the pituitary gland and the secretion of FSH. The secretion of gonadal steroids by the gonads is controlled mainly by the amplitude of the gonadotropin signal. (Modified from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:1–68.)

Pattern of Gonadotropin Secretion

Tonic Secretion

Tonic, or basal, secretion is regulated by a negative, or inhibitory, feedback mechanism in which changes in the concentration of circulating gonadal steroids and inhibin result in reciprocal changes in the secretion of pituitary gonadotropins. This is the pattern of secretion in the male and one of the control mechanisms in the female. Clinical studies reveal that testosterone and estradiol in the male have independent effects on LH secretion. Inhibition of LH by testosterone requires aromatization for its pituitary but not its hypothalamic effects, and estradiol-induced negative feedback on LH occurs at the level of the hypothalamus.[333]

In the female, cyclic secretion involves a positive, or stimulatory, feedback mechanism in which an increase in circulating estrogens, to a critical level and of sufficient duration, initiates the synchronous release of LH and FSH (i.e., preovulatory LH surge) that is characteristic of the normal adult woman before menopause.

Pulsatile Secretion

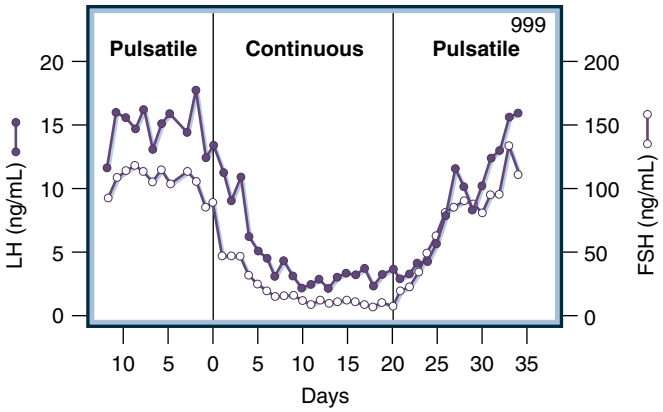
The GnRH Pulse Generator

GnRH. Generation of the GnRH pulse is an intrinsic property of the GnRH neurosecretory neuronal network, and other factors modulate the fundamental autorhythmicity of the GnRH neuron, including the downstream effects of cyclic adenosine monophosphate (cAMP)–gated cation channels on the regulation of pulsatility by cAMP.[334] The immortalized GnRH neurosecretory neuronal cell line and cultured monkey GnRH-I neurons exhibit spontaneous pulsatile release of GnRH at a frequency similar to that observed in vivo. Patch-clamped primary GnRH neurons show disordered patterns of release that are sensitive to increased extracellular potassium; firing activity can be stimulated by exposure to estrogen in a manner that appears to function through the estrogen receptor.[335]

The secretion of FSH and LH is always pulsatile or episodic, regardless of developmental stage, due to the pulsatility of the GnRH pulse generator. The pulsatile secretion of immunoreactive FSH in normal adults is less prominent than that of LH; this is attributed in part to the longer half-life of FSH compared with LH, to differences in the factors that modulate the action of GnRH on FSH and LH release by the gonadotrophs (especially gonadal steroids, inhibin, and possibly activin and follistatin), and to intrinsic differences in the secretory pattern of the two gonadotropins. For example, a change in the frequency of GnRH pulses can modify the ratio of FSH to LH released; midfollicular-phase concentrations of estradiol and adult male concentrations of plasma testosterone have a greater inhibitory effect on the response of FSH to pulsatile injections of GnRH, compared with that of LH.

Intermittent or pulsatile administration (e.g., GnRH, 1 μg/minute for 6 minute/hour) induces pulsatile release of LH and FSH in adult monkeys in which hypothalamic lesions have obliterated the arcuate nucleus region and eliminated endogenous GnRH secretion.[336] Continuous infusion of GnRH inhibits gonadotropin secretion because of desensitization of GnRH receptors on the gonadotroph. Pulsatile GnRH administration reestablished gonadotropin secretion in animals in which gonadotropin secretion was suppressed by the continuous infusion of GnRH (Fig. 26.23). The GnRH signal to the pituitary gonadotrophs of the adult is frequency coded.

The GnRH neurosecretory neurons of the hypothalamic GnRH pulse generator that arise in the olfactory placode exhibit spontaneous autorhythmicity and function intrinsically as a neuronal oscillator for entrainment of the repetitive release of GnRH. The autorhythmicity in the GnRH neurosecretory neurons involves cAMP and cyclic nucleotide-gated cation channels associated with oscillatory increases in intracellular calcium ions (Ca^{2+}), a hallmark of neurosecretion and gap junctional communication.[337] Moreover, the immortalized GnRH neuronal cell line contains neuronal nitric oxide (NO) synthase, and NO generated by GnRH neurons may act as an intercellular or intracellular



• **Fig. 26.23** The Knobil paradigm. Effect of pulsatile administration of gonadotropin-releasing hormone (GnRH) in contrast to continuous infusion of GnRH in adult oophorectomized rhesus monkeys in which gonadotropin secretion has been abolished by lesions that ablated the medial basal hypothalamic GnRH pulse generator. Notice the high concentrations of plasma luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in monkeys given one GnRH pulse per hour, the suppression of gonadotropin secretion by continuous infusion of GnRH even though the total dose of GnRH was the same, and the restoration of FSH and LH secretion when the pulsatile mode of GnRH administration was reinitiated. (From Belchetz PE, Plant TM, Nakai Y, et al. Hypophysial responses to continuous and intermittent delivery of hypothalamic gonadotropin releasing hormone. *Science.* 1978;202:631–633.)

messenger.[338] GnRH acting as an autocrine factor may play a role in the synchronization mechanism. GnRH is synthesized in these neurons and released episodically from axon terminals at the median eminence into the primary plexus of the hypothalamic-hypophyseal portal circulation; it is then transported by the portal vessels to the anterior pituitary gland to produce the pulsatile LH and FSH secretion. Remarkably, GnRH neurons exhibit characteristics of both axons and dendrites and are known as *dendrons*.[339] Ionotropic γ-aminobutyric acid (GABA) and glutamate receptors on the dendrons can be stimulated to depolarize the cells to produce action potentials.

Gonadotropin-Inhibitory Hormone. Gonadotropin-inhibitory hormone (GnIH), a peptide first described in quail but now homologues of GnIH known in most animals, is a member of the RFamide family that has an RFamide (Arg-Phe-NH2) motif at the C-terminus.[340] The family is called *RFamide–related peptides* (RFRPs); kisspeptin is one of the neurotransmitters belonging to this family. The human homologue is known as *RFRP3* and is coded for by the *NPVF* gene. The mammalian receptor for RFP3 is GPR147, a seven-transmembrane domain G protein–coupled receptor.[341] RFP3 and its receptor are found in the human dorsomedial hypothalamus with axons terminating both on the GnRH neuron and the median eminence, suggesting a role on the hypothalamus and the pituitary in human beings. Surprisingly, the first survey of isolated hypogonadotropic hypogonadism (IHH) and CPP in a well-characterized cohort of patients noted a 3-nucleotide in-frame deletion in the *NPVF* gene (p.I71K72), associated with a reduced risk for the occurrence of CPP.[342] Further study is needed to determine if RFP3 may play a role in the treatment of disorders of puberty.

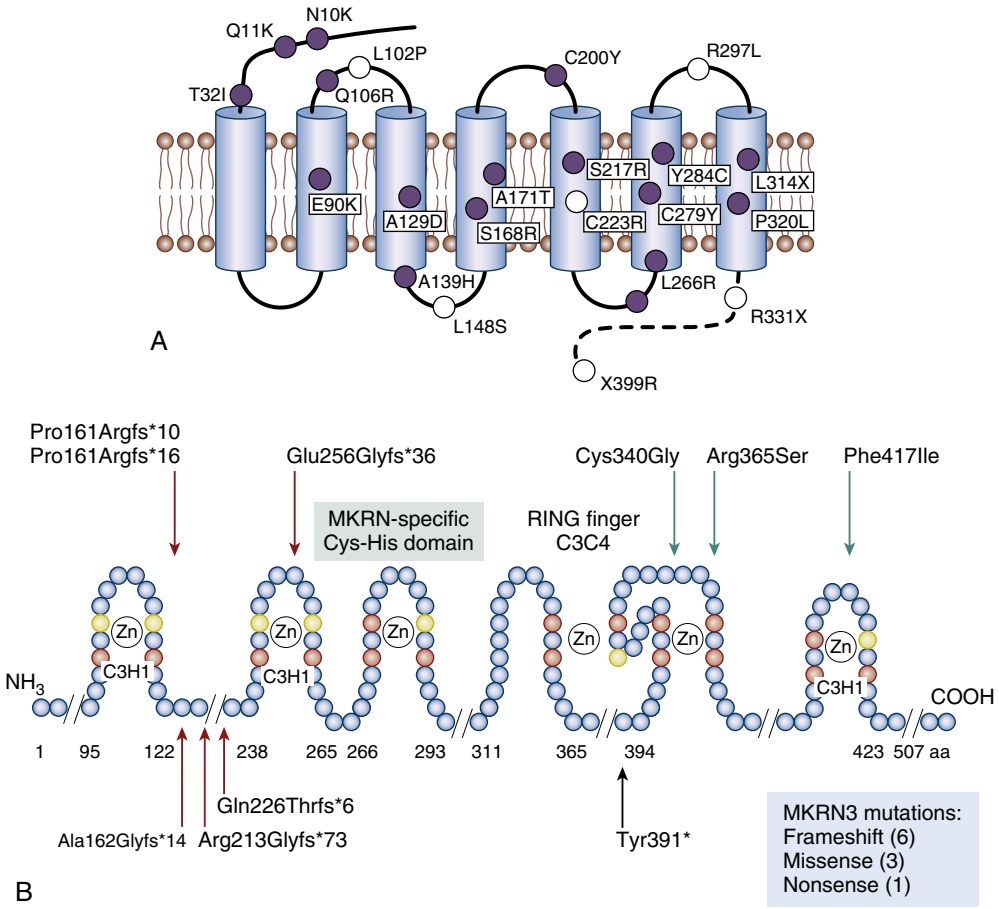
Kisspeptins and KISS1R. Kisspeptins and their receptors (KISS1R or GRP54) in the CNS hypothalamic-pituitary-gonadal axis play a major role in reproduction (Figs. 26.24 and 26.25; see Fig. 26.21).[343,344] *KISS1* is a human metastasis suppressor gene at gene map locus 19p13.3, and *KISS1* mRNA is found in placenta, testes, pancreas, liver, small intestine, and the brain, mainly in the hypothalamus and basal ganglion.[345,346] *KISS1* mRNA is present in the primate in the medial arcuate nucleus only, but in the mouse it occurs in the arcuate, periventricular, and anteroventral periventricular (AVPV) nuclei, regions important in reproductive function.[347,348] While Kiss neurons do not affect the migration of GnRh neurons from the olfactory placode, under the influence of steroids they connect to the GnRH neurons once they reach the hypothalamus. The product of the *KISS1* gene is a 145–amino acid peptide, but the cleaved and secreted product is a 54–amino acid protein known as *metastin* or *kisspeptin,* which binds to an endogenous receptor.

The KISS1 receptor, KISS1R (formerly called GPR54), is a G protein–coupled receptor found in the brain, mainly in the hypothalamus and basal ganglia, and in the placenta, from which it was first isolated and sequenced. KISS1R is coexpressed within GnRH neurons in the rat, in the medial and lateral sections of the arcuate nucleus and the ventral aspect of the ventromedial hypothalamus in mice, and in primates.[347,349] Although the expression of KISS1R mRNA does not increase with development in the mouse, kisspeptin mRNA increases dramatically in the AVPV nucleus, and the number of receptors responsive to kisspeptin increase with development.[350] Activation of GnRH neurons by kisspeptin at puberty in the mouse reflects a dual process involving an increase in kisspeptin input from the AVPV and a post-transcriptional change in KISS1R signaling within the GnRH neuron. Increases in kisspeptin lead to increased GnRH release by means of an interneuron, rather than acting directly on the GnRH-secreting neurons.[351] It is released in a pulsatile manner as is GNRH.

Mice transfected with mutant KISS1R genes exhibited hypogonadotropic hypogonadism, although they had normal content of GnRH in their hypothalamus and were responsive to GnRH or gonadotropin administration, suggesting normal function of the gonadotroph GnRH receptors and the gonadal LH and FSH receptors despite the mutation.[352] The intact mouse also releases significant LH boluses after kisspeptin administration, an effect that is abolished in the $KISS1R^{-/-}$ mouse, which lacks the receptor.[349]

Underfed prepubertal mice have decreased hypothalamic KISS1, but kisspeptin administration leads to increases in KISS1R mRNA, which in turn leads to increased in vivo LH secretion and in vitro GnRH secretion.[353] Chronic kisspeptin administration to these underfed mice restores vaginal opening and enhances gonadotropin and estrogen responses.

Administration of kisspeptin into the rostral preoptic area (RPOA), medial preoptic area (MPOA), paraventricular nuclei (PVN), and arcuate nuclei of the hypothalamus of male adult rats increased plasma LH and testosterone substantially,[354] and intracerebral kisspeptin administration stimulated the release of FSH, albeit at a far higher dose than needed to stimulate LH release.[355,356] Because the release of FSH is abolished with blockade of GnRH, GnRH modulates the central actions of kisspeptin in the rodent. In the rat, the mRNA for kisspeptin and its receptor increases at puberty, and administration of intracerebral injection of kisspeptin in prepubertal female rats caused large peaks of LH and advanced vaginal opening as a sign of pubertal development and premature ovulation.[357,358] The ovulation elicited by peripheral kisspeptin in the prepubertal female rat is abolished by blockade of GnRH.[359]

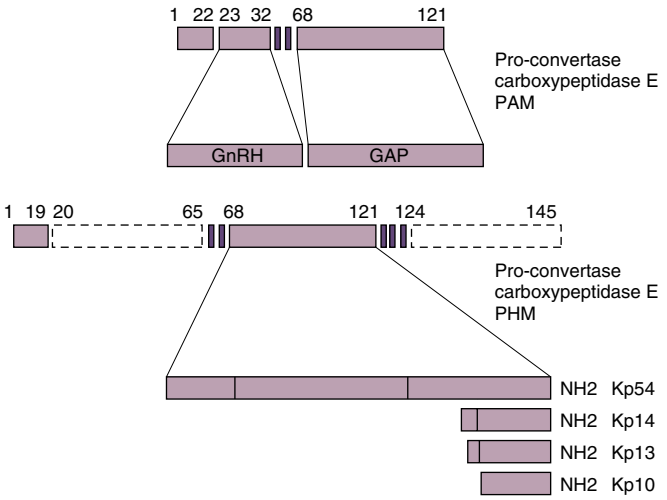


• **Fig. 26.24** (A) Inactivating mutations of the gonadotropin-releasing hormone receptor GnRHR *(closed circles)* and the kisspeptin receptor (KISS1R, formerly GPR54) *(open circles)* were identified in patients with isolated hypogonadotropic hypogonadism. The *dashed line* indicates the intracellular domain of KISS1R. The seven-transmembrane G protein–coupled receptor model is used for illustration of both receptors. (B) Schematic illustration of mutations found in the *MKRN3* gene causing precocious puberty. The amino acid positions in the protein are noted by the numbers and frameshift mutations are indicated by *red arrows*, a nonsense mutation is indicated by a *black arrow*, and the three missense mutations are indicated by *green arrows*. (A, from de Roux N. GnRH receptor and GPR54 inactivation in isolated gonadotropic deficiency. *Best Pract Res Clin Endocrinol Metab.* 2006;20:515–528; B, from Macedo DB, Brito VN, Latronico AC. New causes of central precocious puberty: the role of the genetic factors. *Neuroendocrinology.* 2014;100:1–8.)

KISS1 and KISS1R mRNA expression is found in the posterior two-thirds of the arcuate nucleus of the monkey.[360] Kisspeptin-containing axons make only infrequent contacts with GnRH neurons in the medial basal hypothalamus, whereas in the median eminence, kisspeptin and GnRH axons were found extensively, and intimate association with GnRH contacts on kisspeptin perikarya and dendrites was observed. Nonsynaptic pathways of communication in the median eminence may offer a possible mechanism of kisspeptin regulation of GnRH release and provide an anatomic basis for reciprocal control of kisspeptin neuronal activity by GnRH.[361] Although KISS1 increases with puberty in intact male and female monkeys, KISS1R mRNA levels increase in intact females but not in agonadal male monkeys. Administration of KISS1 through intracerebral catheters to GnRH-primed juvenile female rhesus monkeys stimulates GnRH release, but this release is abolished by infusion of GnRH antagonist. These findings have led to the postulation that KISS1 signaling through KISS1R of primate hypothalamus may be activated at the end of the juvenile pause and may contribute to the pubertal resurgence of pulsatile GnRH release at puberty.[347]

Short-term administration of kisspeptin raises gonadotropin secretion in men and nonhuman primates (Fig. 26.26A). Just as continuous infusion of GnRH suppresses GnRH release, continuous infusion of kisspeptin decreased the response of gonadotrophs in the agonadal male monkey to boluses of kisspeptin. However, the release of FSH and LH after a bolus of *N*-methyl-D-aspartate (NMDA) or GnRH was maintained demonstrated that the desensitization of the KISS1Rs was selective for kisspeptin administration[362] (see Fig. 26.26B). This is in contrast to the finding that continuous infusion of kisspeptin in men and a woman with *TAC3* mutations and hypogonadotropic hypogonadism experienced renewed pulsatile release of gonadotropins, and the men had increased secretion of inhibin B.[363] Treatment with kisspeptin for a variety of disorders of puberty and reproduction appears promising, but the pattern of optimal administration is not yet clear.

Administration of testosterone to castrated young male monkeys led to decreased kisspeptin mRNA in the mediobasal hypothalamus but not in the preoptic area. There was no change in KISS1R expression. This suggests that feedback inhibition of



• **Fig. 26.25** Post-translational maturation of gonadotropin-releasing hormone (GnRH) (*top*) and kisspeptins (Kp). Doublets of basic residues and glycine are indicated by *shaded vertical bars*. gonadotropin secretion by testosterone is mediated by kisspeptin upstream of the GnRH network.[364]

KISS1R mRNA is expressed in the pituitary gland, and there is evidence that kisspeptin can act directly on the gonadotroph to prompt LH secretion.[355] In sheep, kisspeptin colocalizes to a high proportion of GnRH receptor cells in the preoptic area as well as various neuronal fibers within the external neurosecretory zone of the median eminence. This raises the possibility that both kisspeptin and GnRH are secreted into the pituitary portal system to affect the pituitary gland.[365] There are also single-labeling KISSP1R cells in the preoptic area, and the number rises with ovariectomy.

In addition to neurons that specifically secrete kisspepetin, other infundibular nucleus neurons in the human being that coexpress kisspeptin and neurokinin B as well as B-dynorphin (an opioid inhibitor) are known as *kisspeptin-neurokinin* (KNDy) neurons.[366] KNDy cells have receptors for neurokinin B and B-dynorphin axons and connect with their own KNDy cell and other KNDy cells as well as GnRH neurons. It appears that the stimulatory role of neurokinin B and the inhibitory action of dynorphin autosynaptically coordinate the pulsatile release of kisspeptin, which in turn stimulates the pulsatile release of GnRH.[366] There are no steroid receptors on GnRH neurons, but there are steroid receptors on kisspeptin and KNDy neurons, which appear to modulate both the feedback inhibition and positive feedback effects of estrogen on gonadotropin secretion.

Spontaneous mutations in the KISS1/KISS1R axis in human beings are rare but instructive in elucidating the role of KISS1 in pubertal development; hypogonadotropic hypogonadism and CPP occur with different mutations of KISS1R (see later). Plasma concentrations of kisspeptin are higher in children than adults, and preliminary studies indicate that a rise occurs at puberty in boys and girls.[367] These cases, augmented with studies of various animal species, demonstrate that kisspeptin acting through the KISS1R is an afferent influence that stimulates GnRH secretion.

With the demonstrated importance of KISS/KISSR in human reproduction, it is interesting to note that in mice alterative pathways operate. Thus elimination of KISS signaling by knockout of *KISS* (5% remained) and of *KISSR* genes (90% remained) did not eliminate puberty or fertility in developing female mice, although acute ablation of the axis in adult mice did eliminate fertility.[368] Alternative studies demonstrated that retention of 5% of the KISS/KISSR axis in male mice allowed fertility but conversely demonstrated decreased fertility in female mice.[368] The discrepancy in the female mouse results may be due to variations in techniques used in the studies but is not yet resolved. However, it does appear clear that there are far more KISS or KISSR neurons than are needed for fertility and that redundancy is invoked to ensure the vital role of reproduction can occur.

Ontogeny

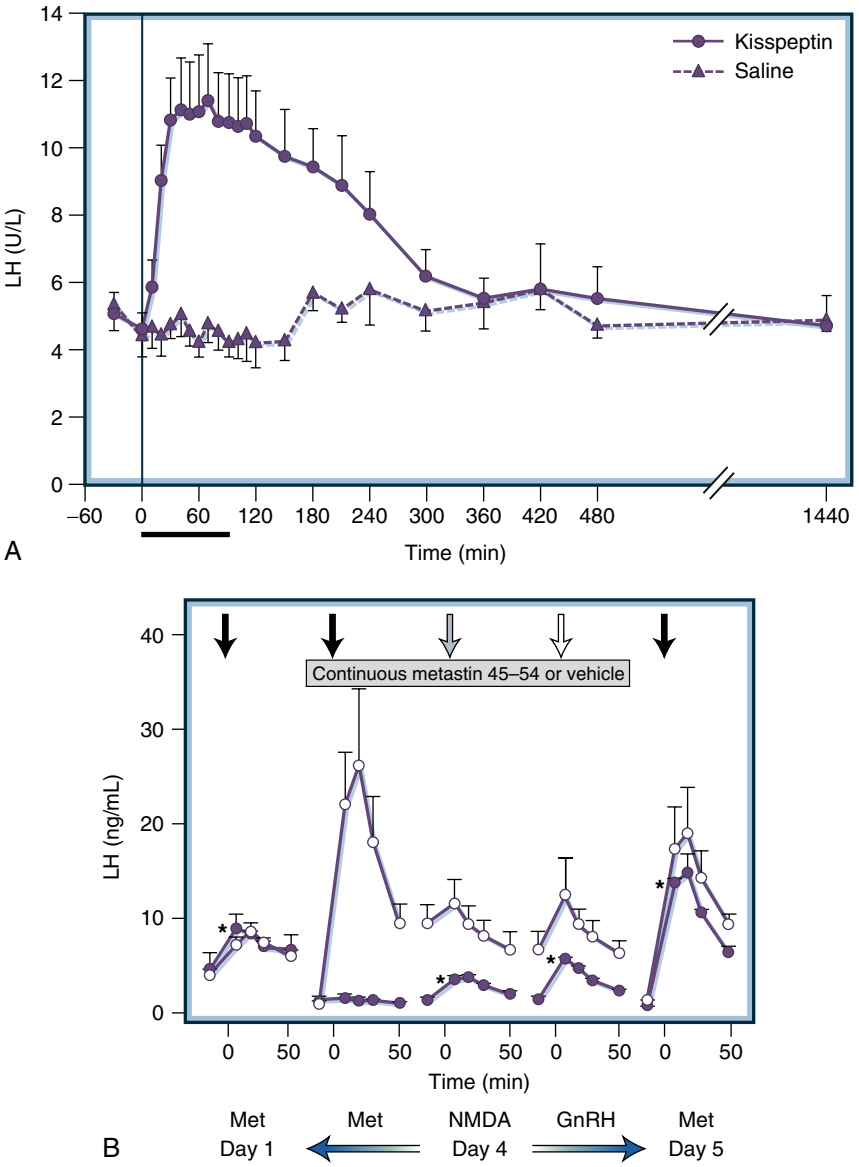
In all vertebrates examined, GnRH neurons arise in the embryo from the epithelium of the olfactory placode and migrate in a rostrocaudal direction by an ordered spatiotemporal course along the pathway of the nervus terminalis-vomeronasal complex to the forebrain.[369] The terminalis-vomeronasal complex also originates in the olfactory placode and forms a connection between the nasal septum and the forebrain. This contrasts to the pattern of growth hormone–releasing factor (GRF), thyrotropin-releasing factor (TRF), or corticotropin-releasing factor (CRF) neurosecretory neurons, which originate from ventricular zones within the embryonic forebrain.[370]

The GnRH green fluorescent protein model demonstrates an increase in dendritic and somal spines in adult mice compared with juveniles, suggesting an increase in direct excitatory inputs to GnRH neurons and increased glutamatergic stimulation of GnRH neurons across the time of puberty.[371] Embryonic GnRH neurons of the olfactory placode and the hypothalamus coexpress mRNAs for GnRH and the type 1 GnRH receptor. These neurons demonstrate spontaneous electrical pulsatile activity, which can be stimulated by GnRH agonist and abolished by GnRH antagonist in the same pattern as GnRH pulses, all in a calcium-dependent manner (i.e., the intracellular calcium responses are stimulated by the agonist and inhibited by the antagonist).[353]

Human Fetus

GnRH immunoreactivity was observed in the epithelium of the medial aspect of the olfactory placode of the normal human fetus by 42 days of gestation but not at 28 to 32 days[369] (Table 26.11). No GnRH neurosecretory neurons were found in the brain, including the hypothalamus, of a 19-week gestational male human fetus with Kallmann syndrome,[372] and the olfactory bulbs were absent. However, dense clusters of GnRH cells and fibers were present in the nose, including the nasal septum and cribriform plate, and within the dural layers of the meninges under the forebrain. The GnRH neurosecretory neurons migrate from the olfactory placode, where they arise outside of the central nervous system from neural crest and ectodermal progenitors, to the hypothalamus in normal humans and other mammals.[373] As they reach the hypothalamus they detach from the olfactory axons that guided them there and some end at the median eminence where they can release their products into the hypothalamic pituitary portal system.

Numerous genes are involved in the migration of the gonadotropin-releasing hormone neurons. They include fibroblast growth factor 8 (FGF8), chromodomain helicase DNA-binding protein 7 (CHD7), and sex-determining region Y-box 10 (SOX10). Other



• **Fig. 26.26** (A) Effects of kisspeptin-54 (4 pmol/kg/min) or saline infusion in male volunteers (n = 6) on mean plasma. Each volunteer received both kisspeptin-54 and saline infusions and acted as their own controls. (B) Effect of single sequential boluses of human metastin 45-54 (Met-Kisspeptin 10) *(black arrow)*, *N*-methyl-D-aspartate (NMDA) *(gray arrow)*, and gonadotropin-releasing hormone (GnRH) *(white arrow)* on plasma luteinizing hormone (LH) concentrations (mean ± SEM [standard error of the mean]) during the last 3 hours of the 98-hour intravenous infusion *(shaded box)* of human metastin 45-54 at a dose of 100 μg/hour *(closed circles)* or vehicle compared with the LH response to the same bolus of human metastin 45-54 1 hour before (day 1) and 21 hours after (day 5) the termination of continuous human metastin 45-54 or vehicle infusion. Kisspeptin-54 stimulates the hypothalamic-pituitary gonadal axis in human males. *J Clin Endocrinol Metab.* 2005;90:6609–6615; B, from Seminara SB, Dipietro MJ, Ramaswamy S, et al. Continuous human metastin 45-54 infusion desensitizes G protein–coupled receptor 54-induced gonadotropin-releasing hormone release monitored indirectly in the juvenile male rhesus monkey *(Macaca mulatta)*: a finding with therapeutic implications. *Endocrinology.* 2006;147:2122–2126.)

genes influencing the migration are the Kallmann protein (now called anosmin-1 with gene *ANOS1*) as well as prokineticin-2 and prokineticin receptor 2 (PROK2 and PROKR2), WD repeat domain 11 (WDR11), semaphorin-3A (SEMA3A), FEZ family zinc finger 1 (FEZF1), NELF,[374] *DAX1* (or *NR0B1*), *LEP*, *LEPR*, *KISS1*, *KISS1R*, *TAC3*, *TACR3*, and *GNRH1*.

The number of the GnRH neurons and the GnRH mRNA levels in nonhuman primates and mice do not appear to change during pubertal development. The ability of the GnRH neuron to respond to electrical or neurochemical (e.g., glutamatergic, kisspeptinergic) stimuli does not change with pubertal development.[375]

TABLE 26.11 Early Development of the Human Fetal Pituitary and Hypothalamus

Gestational Age (wk)	Hypothalamus	Pituitary	Portal Circulation
3	Forebrain appears		
4		Rathke pouch in contact with stomodeum	
5	Diencephalon differentiated	Rathke pouch separated from stomodeum and in contact with infundibulum; pituitary in culture can secrete corticotropin, prolactin, GH, FSH	
6	Premammillary preoptic nucleus; GnRH detected	Intermediate-lobe primordia; cell cords penetrate mesenchyme around Rathke pouch	
7	Arcuate, supraoptic nucleus	Sphenoidal plate forms	
8	Median eminence differentiated: TRH detected	Basophils appear	Capillaries in mesenchyme
9	Paraventricular nucleus; dorsal medial nucleus	Pars tuberalis formed: β-endorphin detected[a]	
10	Serotonin and norepinephrine detected[a]	Acidophils appear	
11	Mammillary nucleus; primary (hypothalamic) portal plexus present; β-endorphin and opioidergic neurons detected[a]	Secondary (pituitary) portal plexus present; catecholamines detected by IF	Functional hypothalamic hypophyseal portal system
12	Dopamine present		
13	Corticotropin-releasing hormone detected[a]	α-Melanocyte-stimulating hormone detected	
14	Fully differentiated hypothalamus	Adult form of hypophysis developed	

[a]Hormone is detected at this gestational age but may be present earlier.

FSH, Follicle-stimulating hormone; *GH,* growth hormone; *GnRH,* gonadotropin-releasing hormone; *IF,* immunofluorescence; *TRH,* thyrotropin-releasing hormone.

Modified from Gluckman P, Grumbach MM, Kaplan SL. The human fetal hypothalamus and pituitary gland. In: Tulchinsky D, Ryan KJ, eds. *Maternal-Fetal Endocrinology.* Philadelphia: WB Saunders, 1980:196–232.

The pituitary gland develops from cells originating in Rathke pouch and ultimately contains five different cell types. Development of the pituitary gland is influenced by multiple genes, including *HESX1, LHX3, LHX4, POU1F1, PROP1, SIX6, OTX2, PITX1, PITX1, PTX2, GLI2, GLI1,* and *SOX3*.[376]

Gonadotropin cells are affected by *TBX19* (or *TPIT*), *GATA2*, and *SF1* (or *NR5A1*). Luteinizing hormone can be detected in human fetal pituitary glands from gestational week 12; follicle-stimulating hormone can be detected by week 14.[254]

GnRH has been detected in human embryonic brain extracts by 4.5 weeks and in the fetal hypothalamus by 6 weeks (see Table 26.11); the fetal pituitary gonadotrophs are responsive to GnRH. The hypothalamic-hypophyseal portal system is functional by 11.5 weeks of gestation, and by 16 weeks, axon fibers that contain GnRH are present in the median eminence and terminate in contact with capillaries of the portal system.[126,254,326,327] The available data are consistent with the development of a human fetal hypothalamic GnRH pulse generator by at least the end of the first trimester.[127,327]

The adreno-gonadal primordium gives rise to the testes, which can be detected by 7 weeks of gestation. Sertoli cells under the influence of FSH after the first few weeks of gestation proliferate and produce antimüllerian hormone as well as inhibin B, which rises by midgestation. Leydig cells differentiate 1 week later than Sertoli cells and initially secrete testosterone under the influence of chorionic gonadotropin during the first third of gestation. By the second third of gestation, LH is the major driving force toward Leydig cells producing testosterone. Both human chorionic gonadotropin and LH utilize the LH-CG receptor, which when stimulated causes Leydig cell proliferation, testosterone secretion, and secretion of INSL3.

The human fetal gonad is affected by placental gonadotropins and by fetal pituitary FSH and LH.[327] The placental gonadotropin hCG may play an important role in the secretion of testosterone by the Leydig cells of the fetal testes during masculinization of the wolffian ducts and the external genitalia at 8 to 13 weeks of gestation. However, it is uncertain whether functional hCG/LH and FSH receptors are present in the fetal testis by 12 weeks of gestation and whether the early fetal testis responds to hCG. Fetal Leydig cells are a unique population of Leydig cells limited to the fetus and infant, which regress to be followed by the differentiation of adult-type Leydig cells in the peripubertal period.[377] Fetal testosterone and hCG levels, but not LH levels, were decreased in fetuses studied after elective second-trimester abortions between 11 and 19 weeks of gestation, with no significant change in testicular responsiveness. The proportion of nonfunctional LH-CGR transcripts in fetal testes was 2.3-fold lower than in adults, so available ligand may exert a greater effect. Fetal hCG was reduced, and the ratio of inactive to active LH-CGR isoforms was lowered by maternal smoking. Second-trimester fetal testosterone levels appear to decrease due to decreasing maternal hCG because Leydig cell LH/hCG responsiveness remains constant. Even with the decrease of fetal hCG caused by maternal cigarette smoking, because the ratio of inactive to active LHCGR isoforms is reduced, testosterone remains normal due to fetal gonadotropin stimulation.

Compared with the adult type, fetal Leydig cells form tightly opposed clusters joined by gap junctions and lack Reinke crystals; they are resistant to hCG/LH-induced desensitization (hCG/LH produce upregulation of LH-CGRs), and they contain little aromatase activity and few estradiol receptors.

In contrast to the fetal testis, FSH receptors in the fetal ovary appear only late in the second trimester, well after completion of male phenotypic differentiation, demonstrating a sex difference in the stage of gestation at which fetal pituitary gonadotropins have an important effect on the development of the fetal gonad. In the anencephalic fetus (which is deficient in hypothalamic GHRH, resulting in deficiency of pituitary gonadotropins), the testes appear hypoplastic by early in the third trimester; however, the ovaries in this disorder are normal until at least 32 weeks of gestation.[126,327] Androgen receptor mRNA expression is lower, and AMH mRNA expression is higher in fetal testicular Sertoli cells than in adult testes. This may explain the failure of testicular testosterone to support spermatogenesis and to suppress AMH at that stage; patients with androgen insensitivity syndrome also have an increase in circulating testosterone and AMH and have combined gonadotropin stimulation that is consistent with a failure of testosterone to repress AMH in the absence of AR signaling.[378] AR was expressed in peritubular and Leydig cells.

The human fetal pituitary gland contains FSH and LH by 10 weeks, secretion begins by 11 to 12 weeks, and the gonadotropin content increases until approximately 25 to 29 weeks of gestation.[126,254,327] Fetal serum LH and FSH concentrations rise to peak levels by midgestation and then decrease to low values in umbilical venous blood at term. The serum concentrations of FSH and LH and of bioactive FSH at 17 to 24 weeks of gestation are strikingly higher in female than in male fetuses, and in both sexes, they decrease remarkably between 25 and 40 weeks of gestation. Mean FSH and LH concentrations are elevated at the beginning of the third trimester and decrease with advancing gestational age to undetectable values in term fetuses. Mean FSH values are higher in female fetuses between 26 and 36 weeks, whereas the mean LH level is higher in males. In the ovine fetus, LH and FSH are secreted in a pulsatile manner in response to the episodic secretion of fetal hypothalamic GnRH; human fetal pituitary gonadotropins are probably released in the same mode. The mean FSH and LH content of fetal pituitary glands is greater in female than in male fetuses at midgestation. This difference has been ascribed to the higher concentration of plasma testosterone between 11 and 24 weeks in the male fetus (the only major difference in gonadal steroids between the male and female fetus) and to fetal testicular inhibin.[126,327] The decrease in serum FSH and LH concentrations during late gestation and near term is attributed to maturation of the negative feedback mechanism, the development of gonadal steroid receptors in the hypothalamic-pituitary unit,[254] and the effect of inhibin.[126,327]

In vitro studies indicate that the human fetal pituitary gland is responsive to GnRH as early as 10 weeks of gestation; the GnRH-stimulated release of LH is greater in second-trimester fetal pituitary cells cultured from females than in those cultured from males and is augmented by estradiol in both sexes.[354] In vivo studies during middle and late gestation demonstrate the stimulating action of exogenous GnRH on fetal FSH and LH release by 16 weeks, with a striking sex difference in the FSH response and a fall in responsiveness to GnRH in late gestation. Anencephalic infants and some infants with neonatal hypothalamic hypopituitarism have an absent or diminished gonadotropin response to GnRH,[126,254,327] in contrast to the brisk increase demonstrated in the normal infant.

A pattern of increasing synthesis and secretion of FSH and LH leading to peak serum concentrations at castrate levels—probably the result of relatively autonomous, unrestrained activity of the fetal hypothalamic GnRH pulse generator and subsequent stimulation of the fetal gonadotrophs by GnRH—is followed by a decline after midgestation that persists to term, probably due to maturation of the negative feedback mechanism and increasing sensitivity of the GnRH pulse generator to the inhibitory effects of the high concentration of sex steroids (estrogens and progesterone from the placenta and, in the male, testosterone from the fetal testes) in the fetal circulation; in the male fetus, there is also a contributory effect on the decrease in FSH by testicular inhibin in late gestation. The increasing CNS control of gonadotropin secretion seems to require the maturation of gonadal steroid receptors (intracellular or on the cell surface, or both) in the fetal hypothalamus and in the pituitary gonadotrophs.[254]

Sheep Fetus

In fetal sheep, the hypothalamus secretes GnRH in a pulsatile manner.[326] By 0.6 gestation, the secretion of fetal LH and FSH is pulsatile, mediated by the hypothalamic GnRH pulse generator.[326] A sex difference in gonadotropin secretion occurs in ovine and human fetuses, and orchiectomy (but not oophorectomy) in the ovine fetus leads to increased pulsatile secretion of LH and, to a lesser degree, of FSH.[379] Opioidergic neurons have a tonic suppressive effect on the pulsatile release of GnRH in the ovine fetus,[380] and the excitatory amino acid analogue NMDA evokes an LH pulse mediated by GnRH.[381] The excitatory amino acids, glutamate and aspartate, can stimulate the GnRH pulse generator directly or indirectly. Glutamate is present in abundance in the hypothalamus and is released from glutamatergic neurons by exocytosis in an adenosine triphosphate–dependent and calcium-dependent process. FSH stimulates inhibin synthesis by the ovine fetal testis and ovary, and administration of an inhibin-rich extract inhibits fetal FSH but not LH secretion, evidence of the functional capacity of the FSH-fetal gonadal inhibin feedback system.[382] These observations provide support for the central role of this process in the regulation of the CNS in the hypothalamic GnRH-pituitary gonadotropin unit.

Human Neonate and Infant[291,326]

In both sexes, the concentration of plasma FSH and LH is low in cord blood as a consequence of the inhibitory effect of the high levels of placental-derived estrogens, but within a few minutes after birth, the concentration of LH increases abruptly in peripheral blood (about 10-fold) in the male neonate, but not in the female; this is followed by an increase in serum testosterone concentration during the first 3 hours that persists for 12 hours or longer.[326,383] After the fall in circulating levels of steroids of placental origin (especially estrogens) during the first few days after birth, the serum concentrations of FSH and LH increase and exhibit a pulsatile pattern with wide perturbations during the first few months of life. FSH pulse amplitude is much greater in the female infant and is associated with a larger FSH response to GnRH throughout childhood; LH pulses are of greater magnitude in the male. This striking sex difference also is present in agonadal male and female infants and in infant rhesus monkeys.[326,384,385] This sex difference

may in part be related to the effect of testosterone in the male fetus on the development and function of the hypothalamic-pituitary apparatus.[126,327]

The high gonadotropin concentrations are associated with a proliferation of Sertoli cells and gonocytes (and their transformation into spermatogonia) and with a transient second wave of differentiation of fetal-type Leydig cells and increased serum testosterone levels in male infants during the first few postnatal months and increased estradiol levels intermittently during the first year of life and part of the second year in females.[377] The mean FSH concentration is higher in females than in males during the first few years of life. By approximately 6 months of age for boys and 2 to 3 years for girls, the concentration of plasma gonadotropins decreases to the low levels that are present until the onset of puberty (earlier in boys than girls) in the juvenile pause.

The neonatal-to-midinfancy surge in pulsatile gonadotropin secretion, sex hormones, and inhibin—the postnatal surge or minipuberty of infancy—is attributable to an increase in GnRH pulse amplitude and is associated in the male infant with the following[327]:

1. Increase in testicular volume (by direct measurement) due to increased seminiferous tubule length (about a sixfold increase in year 1)
2. Rapid expansion of the Sertoli cell population (which makes up 85–95% of seminiferous tubular cell mass)
3. High concentration of circulating inhibin B (low in hypogonadotropic hypogonadism)
4. Sertoli cell number, including postnatal proliferation, as a determinant of spermatogenic function

The increase in circulating testosterone in the normal male infant may lead to facial comedones and even to acneiform lesions, and the increase in gonadotropins may lead to a transient increase in testicular size, but there may be subtler changes. A detailed study of 18,570 infants in Finland (51% were boys) demonstrated more rapid growth in boys and girls during minipuberty with the increase in the rate of growth in boys compared to girls being similar to that noted during pubertal growth.[386]

The minipuberty of infancy offers an excellent time to evaluate children who have features that have been described as red flags of congenital hypogonadotropic hypogonadism.[387] Missing an opportunity to measure testosterone in a sensitive pediatric assay at this age may delay diagnosis of hypogonadism until well past the pubertal period. An LH and testosterone surge is absent in this period in those with the complete androgen insensitivity syndrome.

The postnatal surge apparently is not essential for masculine-typical psychosexual development. The brain in patients with congenital hypogonadotropic hypogonadism, including Kallmann syndrome, is masculinized by testosterone therapy at puberty despite the lack of an infantile surge in gonadotropins and testosterone.

The transient postnatal to midinfancy function of the GnRH pulse generator in the male infant may be related to future spermatogenic function and fertility.[388,389] Sertoli cells and germ cells proliferate for about 100 days after birth (indicating mitotic activity and the transformation of gonocytes into adult dark [Ad] spermatogonia, the stem cells for spermatogenesis), with a subsequent decrease, mainly by apoptosis, after about 6 months of age, coincident with the waning of gonadotropins and testosterone.

Neural Control

Maturation of the CNS is the outcome or consequence of the totality of environmental and genetic factors that retard or accelerate the onset of puberty. It is a provocative but unproven hypothesis that a metabolic signal related to body composition is an important factor in the maturation or activation of the hypothalamic GnRH pulse generator and not a result of the early hormonal and body composition changes in human puberty. In either event, clinical and experimental data support the contention that the factors influencing the timing of puberty are expressed finally through CNS regulation of the onset of puberty.[256,326] In humans, the pineal gland and melatonin do not appear to have a major effect on this control system.[326,390]

Timing and Onset of Puberty

Genetic Neural Control

Because many levels control the onset of pubertal development, a systems biology approach holds promise in characterizing the complex components of this neural and neuroendocrine network. It appears that normal and some types of abnormal puberty are under polygenic control. Although the increased pulsatile release of GnRH is most frequently considered, this change is caused by a balance in the inhibitory and excitatory factors through coordinated changes in transsynaptic and glial-neuronal communication, increased stimulatory factors (most prominently glutamate and kisspeptin), and decreased inhibitory tone, mostly through GABAergic neurons (i.e., those secreting γ-aminobutyric acid), opioidergic neurons, and MKRN3 expression all controlled by gene expression. Glial cells affect GnRH secretion through growth factor–dependent cell-cell signaling coordinated by numerous unrelated genes. A second level of genes is postulated to control cell-cell interaction. The third highest level of control occurs through transcriptional regulation of the subordinate genes by other higher level genes that maintain the function and integration of the network.

The activation of GnRH release at puberty involves many different cellular phenotypes and intracellular and cell-cell signaling molecules, which is controlled by a highly coordinated and interactive regulatory system involving hundreds of gene products; a systems biology approach is proposed to explain how these networks are organized in a hierarchical fashion.[391] This theory states that there are transcriptional regulators that direct expression of downstream subordinate genes to allow stability and to coordinate the cellular networks involved in controlling the onset of puberty. Epigenetic mechanisms sensitive to external inputs such as nutrition or endocrine disruptors are posited to integrate the response of these gene networks.[392] Endocrine disrupting chemicals discussed elsewhere in this chapter appear to exert their effect through epigenetic mechanisms.

Although the action of multiple genes (i.e., quantitative or polygenic inheritance) on the time of onset of puberty (e.g., on stature) has long been recognized, little is known about the gene loci involved in this complex quantitative trait or the effect of gene interactions on this paradigm of complex traits.[393] Genetic factors are estimated to account for 50% to 80% of the variation in the onset of normal puberty. These complex traits have been analyzed by linkage analyses (in which quantitative trait loci have been shown to relate to the age of menarche) and by large-scale haplotype-based association studies. Pedigree analyses have revealed relative risks for delay of puberty in kindreds with histories of CDP compared with those without such a history; for

example, for first-degree relatives, the risk of a 2-SD delay in the onset of puberty is 4.8. There are clear genetic influences on the time of onset of puberty in monogenetic disorders, such as *KAL1, KISS, KISS1R (GRP54)*, *MKRN3,* and mutations and other influences, that can prevent or advance pubertal development (see earlier discussion of genomic effects on the onset of puberty and later discussion of specific genomic conditions).

Nutrition and Metabolic Control

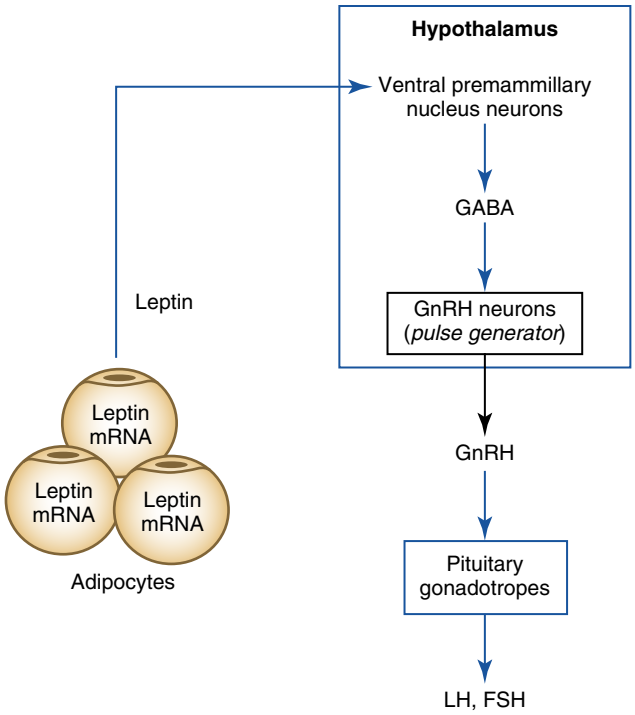
The genetic effects on the time of onset of puberty and its course are influenced by environmental factors (e.g., socioeconomic factors, nutrition, general health, geography) operating through the CNS. It has long been postulated that some alteration of body metabolism linked to energy metabolism may affect the CNS restraints on pubertal onset and progression, because of the earlier age of menarche in moderately obese girls, delayed menarche in states of malnutrition and chronic disease and with early rigorous athletic or ballet training, and changes in gonadotropin secretion and amenorrhea in girls with anorexia nervosa, voluntary weight loss, and strenuous physical conditioning.

An invariant mean weight (48 kg) for initiation of the pubertal spurt in weight, the maximal rate of weight gain, and menarche in healthy girls regardless of chronologic age was proposed in the 1970s, but the concept generated controversy and criticism, in part because the empiric estimations and the equations used to determine fat mass were challenged and because no direct measurements supported the theory.[394] A more recent, 5-year longitudinal study of 469 girls revealed that there was a similar percentage of body fat associated with the onset of puberty, although there was a spread of chronologic ages at onset.[395] Body composition in the 2 years before puberty had a modest impact on the age of pubertal growth, but higher fat mass led to more rapid progress through pubertal stages.[396]

The relationships of adipose tissue mass, fat metabolism, and energy balance to reproduction were illuminated by the discovery of the genes encoding leptin, an adipocyte satiety factor,[397,398] and its receptor.[399] Considerable interest has focused on the potential role of leptin in the control of the onset of puberty—from a proposal that it was an essential, if not a key, factor in triggering the onset of puberty to one in which it had a more subsidiary role. Leptin is a well-established afferent satiety factor in humans; it acts on the hypothalamus, including nuclei controlling appetite, to suppress appetite. Leptin reflects body fat and therefore energy stores and has an important role in the control of body weight and the regulation of metabolism.

Ob/ob mice (which lack leptin) and db/db mice (which lack leptin receptors) are obese and exhibit hypogonadotropic hypogonadism, providing evidence for an important role of leptin in reproduction. Administration of recombinant leptin to hypogonadal ob/ob mice and to rats experiencing pubertal delay associated with food restriction in the rat partially reverses the hypogonadism. However, leptin administration to normal prepubertal rats did not advance the time of onset of puberty. A critical threshold level of leptin was necessary for puberty to begin and advance, but leptin alone (as in administration to normal rodents) was insufficient to promote puberty; it was but one among several permissive factors.[400]

The site of action of leptin in its effect on the hypothalamic GnRH-pituitary gonadotropin apparatus was clarified by experiments in the mouse.[401] Even though leptin receptors (LepR) were reported to be expressed in immortalized mouse GnRH (GT1) cells, leptin receptors are not expressed on GnRH neurons in vivo.[402] Mice with selective deletion of the long form (signaling) of the leptin receptor underwent normal puberty and fertility. Kiss1 neurons express the leptin receptor (Ob-Rb isoform), and the suggestion was advanced that the effect of leptin on puberty onset and fertility was mediated through the Kiss1/Kiss1n complex. Mice with selective deletion of the leptin receptor from Kiss1 neurons underwent normal puberty and fertility, strongly suggesting that the action of leptin on the hypothalamic GnRH-pituitary gonadotropin system is not mediated through Kiss1 neurons.[403,404] The leptin receptor is expressed at a high level in ventral premammillary neurons, which express the excitatory neurotransmitter glutamate, which stimulates either GnRH neurons or GnRH terminals in the median eminence or both sites. These observations dissociate the action of leptin on reproductive function and on nutrition (Fig. 26.27).



• **Fig. 26.27** The leptin receptor is expressed in ventral premammillary neurons (PMV). Leptin secreted by adipocytes evokes release of the excitatory neurotransmitter glutamate from the PMV leading to activation of gonadotropin-releasing hormone (GnRH) neurons. Leptin functions as a permissive factor, not a trigger, in the onset of human puberty. In rodents, leptin advances the onset of puberty and plays a key role in initiating puberty and infertility. The hypothalamic pathway that regulates energy expenditure and food intake by leptin is independent of the effect of leptin on reproduction. *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *mRNA,* messenger ribonucleic acid.

Leptin levels in the male rhesus monkey were similar during the advancement of prepuberty to puberty. In peripubertal rhesus monkeys age 3 to 5 years and fasted for 2 days, the administration of leptin prevented the decrease in plasma gonadotropins detected in the untreated animals. Continuous infusion of leptin into the lateral ventricle of agonadal male monkeys failed to evoke an increase in GnRH on gonadotropin secretion.[332]

Is leptin the peripheral, somatic trigger for the onset of puberty to the CNS, or does it have a permissive role, signaling the hypothalamus and the GnRH pulse generator that a critical energy store has been attained? A longitudinal study of serum leptin levels in prepubertal and pubertal boys and girls showed leptin

to increase gradually during the prepubertal years, with similar levels in the two sexes.[405] During puberty, leptin continued to rise in girls, whereas in boys, the leptin mean levels peaked at Tanner stage 2 and decreased to prepubertal concentrations by genital stage 5.[406] This decrease is attributed to the effect of testosterone on leptin secretion.[407] Adipose tissue mass, percentage of body fat, and age correlated with leptin levels, among other variables,[405,408] but there was no correlation between 24-hour serum estradiol and leptin concentrations in nonobese and obese prepubertal and early pubertal girls. Serum leptin levels rose after administration of pulsatile GnRH administration for 36 hours to children with delayed puberty but not after a single dose of buserelin, a GnRH agonist, suggesting that, rather than puberty being triggered by leptin, pubertal increase in GnRH pulsatility increases leptin.[409]

Leptin circulates in both a free form and a high-molecular-weight, bound form. Leptin-binding activity in serum is highest in childhood and decreases to relatively low levels during puberty. Free leptin is postulated to have more relevance to reproductive development than total leptin measured in the circulation; the soluble leptin receptor appears to be higher in males than in females and is inversely related to leptin levels later in development in females.[410] A study of a 132 monozygotic female twin pairs and 48 dizygotic female twin pairs demonstrated a rise in leptin throughout puberty and a decrease in the soluble leptin receptor between stages 1 and 2, leading to a rise in the free leptin index between stages 1 and 2; there was greater heritability for the soluble leptin receptor than leptin,[411] and there was also high heritability of free IGF1 values. There is no known relationship between leptin and leptin receptor gene polymorphism and CDP; however, the presence of a short allele of leptin was associated with heavier weight, whereas those who were thin, had significant bone age delay, and had increased frequency of parental pubertal delay were less likely to have this leptin short allele.[412]

As in the ob/ob mouse, human beings with a homozygous mutation in the leptin gene[413] or the leptin receptor[414] have morbid obesity and a striking delay in puberty because of hypogonadotropic hypogonadism. In a pedigree affected by a stop codon mutation in the gene encoding leptin, a 23-year-old man failed to attain puberty because of hypogonadotropic hypogonadism, and two affected women were prepubertal and amenorrheic, one until 29 years of age, after which she began to have irregular, scanty periods, and the other until age 36 years, at which time she began to menstruate monthly. A 9-year-old girl with a bone age of 13 years who was affected with congenital leptin deficiency lost weight and had an early pubertal pattern of LH release in response to the administration of GnRH after treatment with recombinant leptin.[415] A 4-year-old affected relative of this 9-year-old girl benefited from the metabolic improvement that occurred with leptin administration but did not undergo early pubertal development, indicating the permissive nature of leptin on puberty.

Boys with CDP have lower mean levels of leptin than expected and can enter puberty without an increase in circulating leptin. Two women with congenital lipoatrophic diabetes (Berardinelli-Seip syndrome), which is associated with absence of subcutaneous and visceral adipose tissue, did not have a delay in menarche despite severe hypoleptinemia, and one of the women had three unaffected children.[416] Severe leptin deficiency causes hypogonadotropic hypogonadism, suggesting that a critical level of leptin and a leptin signal are required to achieve puberty, but a rise in leptin is not required to trigger puberty. In summary, leptin is a permissive factor (tonic mediator) and not a trigger (phasic mediator) in the onset of human puberty (Table 26.12).

TABLE 26.12 Leptin and Puberty: A Permissive Factor, Not a Trigger for the Onset of Puberty

Pro-Trigger Evidence

Congenital leptin deficiency or congenital leptin resistance related to mutations is associated with delayed puberty and gonadotropin deficiency, evidence that the virtual absence of leptin or the leptin signal leads to severe hypogonadotropic hypogonadism.

In congenital leptin deficiency, administration of leptin led to a reduction in weight and an early pubertal pattern of luteinizing hormone release in an affected prepubertal girl.

Pro-Permissive Evidence

A sharp rise in circulating leptin does not occur at the onset of puberty.

In prepubertal and early pubertal girls, the rise in serum leptin did not correlate with the increase in serum estradiol.

In constitutional delay in growth and adolescence, an increase in prepubertal leptin levels is not essential for the onset of puberty.

In congenital lipoatrophic diabetes, despite the absence of subcutaneous and visceral adipose tissue and, as a consequence, severe hypoleptinemia, puberty can occur at the usual age and fertility is reported.

Supportive experimental data exist in rodents, sheep, and nonhuman primates.

From Grumbach MM. The neuroendocrinology of human puberty revisited. *Horm Res.* 2002;57:S2–S14.

In a longitudinal study of boys leading up to an increase in morning salivary testosterone concentrations, they had a relatively constant ratio of basal metabolic rate (BMR) to LBM but an increase in the ratio of BMR to total daily energy expenditure. A subtle energy-dependent process is in play, possibly related to an increase in brain BMR as a secondary phenomenon at the initiation of puberty or indicating that a central rise in BMR is a signal for the onset of puberty.

Ghrelin is the natural ligand for the GH secretagogue receptor but also serves as an orexigenic signal that is increased after food deprivation; ghrelin is usually negatively correlated with BMI. Ghrelin administration delays pubertal development in rats because of gonadal and central effects, suggesting a link between malnutrition and the decrease in reproductive development or function.[417]

Adiponectin is an adipocytokine produced in fat cells that has antidiabetic, antiatherogenic, and anti-inflammatory effects. Adiponectin decreases in the face of excess fat mass in obesity and is suppressed by rising testosterone and DHEAS levels. The concentration of adiponectin falls during pubertal development in males but remains rather stable in females with advancing Tanner stage.[418]

Resistin is an adipocytokine belonging to the resistin-like molecular family of cysteine-rich molecules (RELMs). Values increase with pubertal development in boys, and this appears to be true in girls as well, although the evidence is weaker. Because resistin serum levels were elevated in mouse models of obesity, it was considered to be a potential link between insulin resistance and obesity, but serum resistin levels appear to relate more to pubertal development than to insulin resistance.[419]

Mechanisms of Control

Diverse strategies and adaptive mechanisms have evolved to control puberty in different species.[332,385] In rodents, exteroceptive factors and cues, including light, olfaction, and pheromones, have an important influence by way of the CNS on gonadotropin secretion. In seasonal-breeding species such as sheep, the length of the light-dark cycle is critical, and the pattern of gonadotropin secretion is different. In contrast, male and female primates exhibit an estrogen-provoked LH surge.

In humans and nonhuman primates, after the initial development and function in the fetus, the infantile surge of increased LH and FSH secretion occurs; this is followed by a decade of suppression (but not absence) of activity of the hypothalamic GnRH pulse generator and the resulting quiescence of the pituitary gonadotropin-gonadal axis, known as the prepubertal period or juvenile pause (Table 26.13).[126,326,332,385] Then there is gradual disinhibition and reactivation, mainly at night during late childhood,[326,332,385,420] and, finally, the increased amplitude of the GnRH pulses, reflected in the progressively increased and changing pattern of circulating LH pulses that occurs with the approach of and during puberty. Two interacting mechanisms have been proposed to explain the juvenile pause[326,420] (Fig. 26.28).

Gonadal Steroid–Dependent Negative Feedback Mechanism

There are three lines of evidence for an operative negative feedback mechanism in prepubertal[256,326] children[258,327]:

1. The pituitary of the prepubertal child secretes small amounts of FSH and LH, showing a low level of activity of the hypothalamic-pituitary-gonadal complex.
2. In agonadal infants and prepubertal children (e.g., in Turner syndrome), secretion of FSH and, to a lesser degree, LH is increased, suggesting that even low levels of hormones secreted by the normal prepubertal gonad inhibit gonadotropin secretion by a sensitive, functional, tonic, negative feedback mechanism[256,326,420] (Fig. 26.29).
3. The low level of gonadotropin secretion in childhood is shut off by administration of small amounts of gonadal steroids, showing that the hypothalamic-pituitary gonadotropin unit is highly sensitive (approximately 6–15 times more sensitive than in the adult) to the feedback effect of gonadal steroids.[258,327]

Gonadal Steroid–Independent (Intrinsic) Central Nervous System Inhibitory Mechanism

The diphasic pattern of basal and GnRH-induced FSH and LH secretion from infancy to adulthood is similar in normal individuals and in agonadal patients, but in the latter, gonadotropin concentrations are higher, except during the middle childhood nadir.[392,393,420] The high plasma concentrations of FSH and LH in agonadal children between infancy and about 4 years of age and the increased gonadotropin reserve reflect the absence of gonadal steroid inhibition (see Fig. 26.29) of the hypothalamic-pituitary unit by the low plasma levels of gonadal steroids.[326,327] However, the striking fall in gonadotropin secretion between the ages of 4 and 11 years suggests the presence of a CNS inhibitory mechanism that restrains the hypothalamic GnRH pulse generator, independent of gonadal steroid secretion. The resulting fall in gonadotropin secretion in agonadal children does not result from gonadal steroid feedback (because functional gonads are lacking) nor from increased secretion of adrenal steroids (because concentrations are low, and glucocorticoid suppression of the adrenal does not augment the concentration of circulating gonadotropins).[326,329,327] A CNS steroid-independent inhibitory mechanism for suppression of the hypothalamic GnRH pulse generator seems to be the dominant factor in restraint of puberty between[326,421] the ages of 4 and 11 years,[327,394] and a gradual loss of this intrinsic CNS inhibitory mechanism leads to disinhibition or reactivation of the GnRH pulse generator at puberty.

• **Fig. 26.29** Interaction of the negative feedback mechanism and the putative intrinsic central nervous system (CNS) inhibitory mechanism in restraining puberty as extrapolated from the pattern of change in the concentrations of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in agonadal infants, children, and adolescents. *Triangles* designate patients with the 45,X karyotype. *Circles* indicate Turner syndrome patients with X chromosome mosaicism or structural abnormalities of the X chromosome, or both. Notice the values for the 2-day-old and 3-day-old infants. The *solid line* represents a regression line of best fit. The *hatched area* indicates the mean plasma values for normal females. To convert FSH values to international units per liter, multiply by 8.4. For about the first 3 years of life, the sensitive gonadal steroid negative feedback mechanism has a dominant role in restraining gonadotropin secretion, as exemplified by the high gonadotropin concentrations in this age group in the absence of gonads (and gonadal steroid feedback). A major role of the intrinsic CNS inhibitory mechanism in this age group is unlikely in light of the rise in gonadotropins to castrate levels in the absence of functional gonads. From 4 to 6 years of age, the postulated intrinsic CNS inhibitory mechanism is dominant, as indicated by the fall in FSH and LH concentrations in the absence of gonads. Even in this age group, the augmented gonadotropin response evoked by gonadotropin-releasing hormone (GnRH) and the slightly higher mean basal gonadotropin concentrations in agonadal individuals support a role, although a subsidiary one, for gonadal steroid negative feedback in the suppression of gonadotropin secretion during this period of the juvenile pause. The investigators suggested that the intrinsic CNS inhibitory mechanism suppresses the functional GnRH pulse generator. After about 10 years of age, the CNS inhibition gradually wanes, resulting in disinhibition of the GnRH pulse generator. The gonadal steroid negative feedback mechanism with an adult-type set-point and inhibin plays a dominant role in regulating the GnRH pulse generator and pituitary gonadotropin system. For conversion to SI units, see Fig. 26.19. (Modified from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. A diphasic pattern of gonadotropin secretion in patients with the syndrome of gonadal dysgenesis. *J Clin Endocrinol Metab.* 1975;40:670–674. Copyright by The Endocrine Society.)

Interaction of the Negative Feedback Mechanism and the Intrinsic Central Nervous System Inhibitory Mechanism

The negative feedback mechanism and the intrinsic CNS inhibitory mechanism appear to interact in restraining puberty (see Fig. 26.29). During the first 2 to 3 years of life, the gonadal-steroid negative feedback mechanism seems to be dominant, but beginning at about 3 years of age, the intrinsic CNS inhibitory mechanism becomes dominant and remains so during the rest of the juvenile pause, as evidenced by the fall in FSH and LH levels between the ages of 3 and 10 years despite the lack of functional gonads. The negative feedback mechanism remains operative during the juvenile pause; agonadal patients in this age group have higher mean plasma FSH levels than normal prepubertal children and a greater FSH and LH response to the acute administration of GnRH.[392,393,420] As puberty approaches, the CNS inhibitory mechanism gradually wanes, initially during nighttime sleep, and the hypothalamic GnRH pulse generator becomes less sensitive to gonadal steroid negative feedback (see Fig. 26.29).[326,327] After the onset of puberty, gonadal-steroid negative feedback becomes the dominant mechanism in restraining gonadotropin secretion (along with inhibin), as reflected in the increased gonadotropin concentrations that are characteristic of the adolescent with severe primary hypogonadism.[332] The postulated ontogeny of this dual mechanism of restraint of puberty is illustrated in Fig. 26.29.

Potential Components of the Intrinsic Central Nervous System Inhibitory Mechanism

The intrinsic CNS inhibitory mechanism has long remained elusive.[385] In the rhesus monkey, despite the damping of the GnRH pulse generator during the juvenile pause, the content of hypothalamic GnRH and GnRH mRNA during this phase is similar to that in the infant or the adult monkey. Low-amplitude LH and FSH pulses are detectable by sensitive and specific immunoradiometric assays in the juvenile pause, demonstrating a low level of activity of the GnRH pulse generator.[329,385] The end of the juvenile pause is marked by an increase in LH pulse amplitude that is most evident during the early hours of sleep.

Children with CPP associated with posterior hypothalamic neoplasms (usually a pilocytic astrocytoma), irradiation of the CNS, midline CNS developmental abnormalities such as septo-optic dysplasia with deficiency of one or more pituitary hormones, or other CNS lesions provide indirect evidence for an inhibitory neural component located in or projecting through the posterior hypothalamus. These lesions compromise the neural pathway, which inhibits the hypothalamic GnRH pulse generator and results in its disinhibition and activation leading to CPP.[326] For example, a suprasellar arachnoid cyst can cause CPP by compressing and distorting the hypothalamus,[326] but the puberty is reversed with regression of the hormonal and physical features of puberty after decompression of the cyst due to reversal of the disinhibition of the CNS inhibitory mechanism of the posterior pituitary (Fig. 26.30). Precocious sexual maturation can be induced in the juvenile female rhesus monkey by posterior hypothalamic lesions; such lesions advance the age at onset of a pubertal increase in LH secretion and the time of the first positive feedback effects of estrogen.[385]

The GnRH-secreting hypothalamic hamartoma, a heterotypic mass of nervous tissue that contains GnRH neurosecretory neurons attached to the tuber cinereum or the floor of the third ventricle, can cause CPP.[422,423] The GnRH neurons within the hamartoma with their axon fibers projecting to the median eminence secrete GnRH in pulsatile fashion. We consider the hypothalamic hamartoma to be an ectopic GnRH pulse generator that functions independently of the CNS inhibitory mechanism, which normally restrains the hypothalamic GnRH pulse generator (Fig. 26.31).[326,423] An analogy can be drawn between the GnRH-secreting hypothalamic hamartoma and the rescue of fertility in GnRH-deficient hypogonadal (hyp/hyg) mice by transplantation of fetal or neonatal hypothalamic tissue into the third ventricle. Some rare, large hypothalamic hamartomas that cause CPP contain TGFα, an astroglia-derived growth factor, with few or no GnRH neurosecretory neurons, raising the possibility that the secretion of TGFα may interact directly or indirectly to stimulate GnRH release.

The recent discovery of families with precocious puberty associated with loss of function mutations in the *MKRN3* gene has led to important insights into the CNS "brake" that intrinsically restrains puberty.[424,425] *MKRN3* decreases in mice at the same time that KISS and neurokinin B rise to promote puberty.

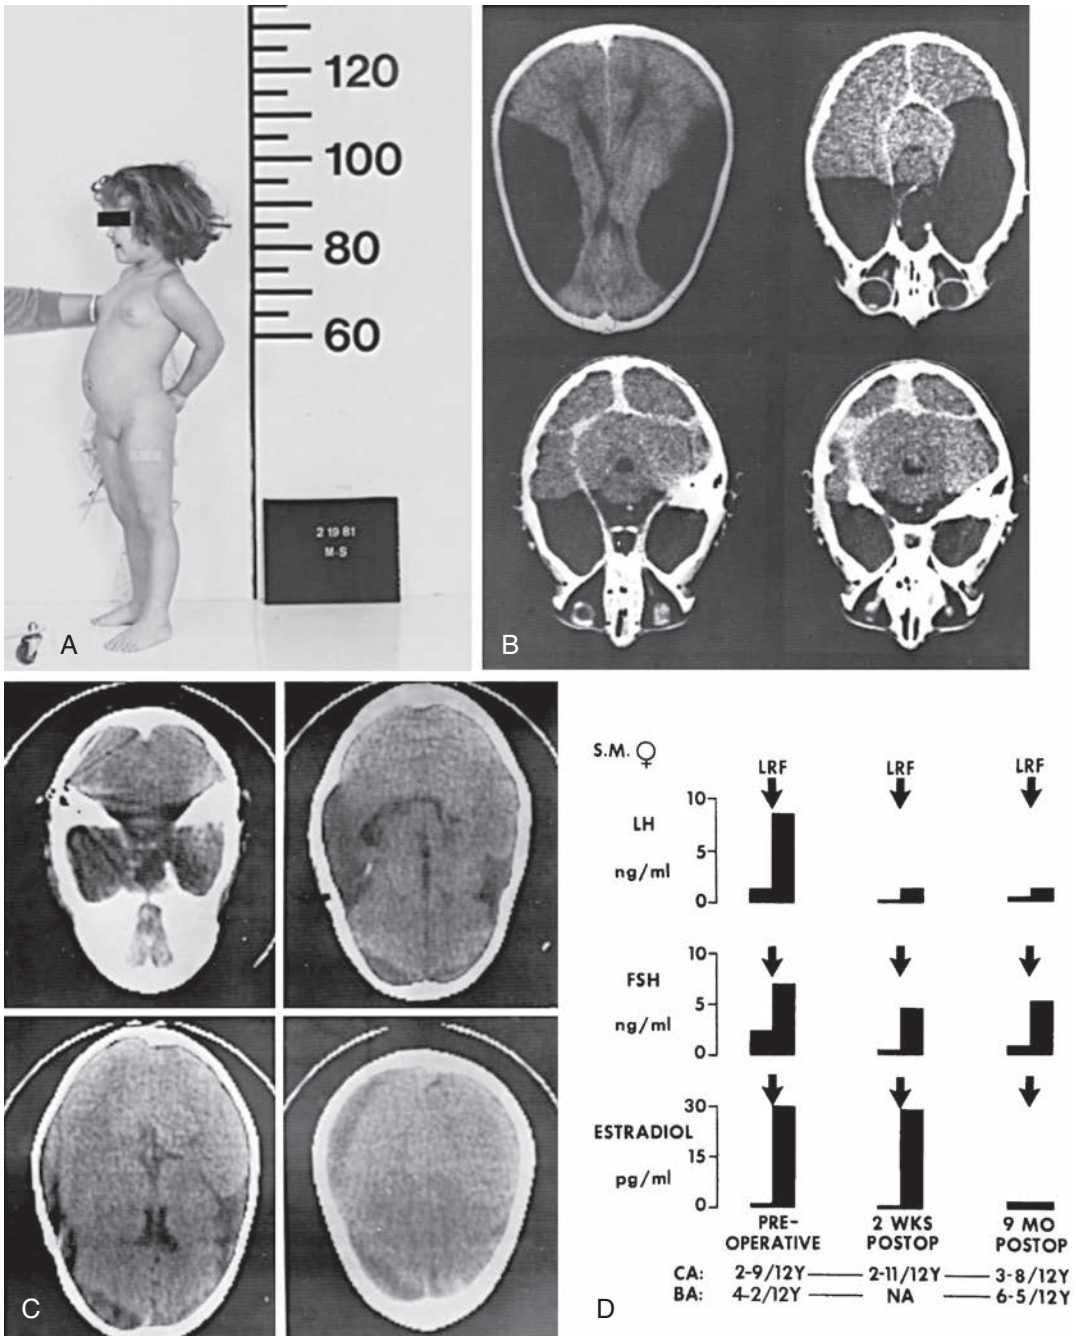
MKRN3 is imprinted as the maternal allele is methylated and suppressed in normal individuals and only the paternal gene functions; with the mutation in the paternal *MKRN3* there is no longer function. *MKRN3* encodes makorin ring finger protein 3, which is involved with ubiquitination and cell signaling, and is expressed in the arcuate nucleus, a location where other genes involved with puberty are found. MKRN3 concentrations in blood decrease in both boys and girls prior to the onset of puberty.[426,427,984]

At present, more than 10 different loss-of-function mutations of *MKRN3* have been described in CPP, including eight frameshift defects, three missense mutations, one nonsense mutation, and a most recent heterozygous deletion in the MKRN3 promoter region[428,429] (see Fig. 26.24B).

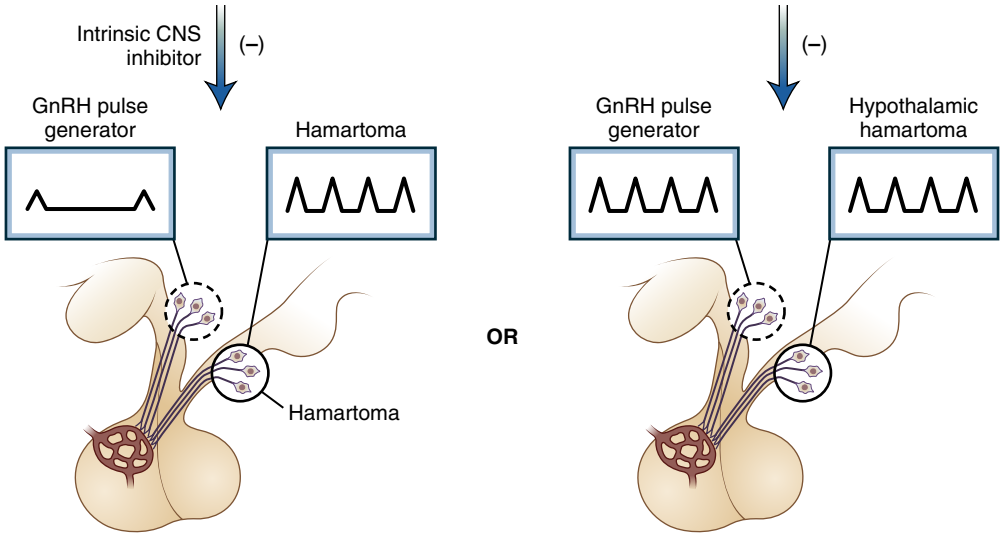
The following affect the hypothalamic GnRH pulse generator: noradrenergic, dopaminergic, serotoninergic, and opioidergic pathways; inhibitory neurotransmitters (e.g., GABA); excitatory amino acids (e.g., glutamic acid, aspartic acid); nitrergic transmitters; other brain peptides, including neurotrophic and growth factors; and corticotropin-releasing hormone (CRH) (see Table 26.13). Melatonin is not a critical restraining factor in primates, nor are endogenous opioid peptides.[326,330,384]

The GnRH pulse generator is inhibited by GABA (the most important inhibitory neurotransmitter in the primate brain) and GABAergic neurons during prepuberty, but exogenous administration of GABA in prepuberty is ineffective because of the high local endogenous GABA levels[328,329] (Fig. 26.32). Both GAD65 and GAD67 forms of glutamic acid decarboxylase (GAD), the enzyme that catalyzes the conversion of glutamate to GABA, are present in the mediobasal hypothalamus, the site of the GnRH pulse generator. Antisense oligodeoxynucleotides for GAD67 and GAD65 mRNAs infused into the stalk median eminence of prepubertal monkeys induced a striking increase in GnRH release, whereas nonsense D-oligos did not. These studies provided additional support for GABA arising from interneurons as the intrinsic CNS inhibitor during the juvenile pause of prepuberty.

GABA acting through $GABA_A$ and $GABA_B$ receptors affects GnRH secretion in the perifused mouse GT1 GnRH-releasing neuronal cell line. Stimulation of $GABA_B$ receptors also inhibits kisspeptin secretion in the adult mouse.[430] Conversely, chronic, repetitive administration of bicuculline, a GABA inhibitor, into the base of the third ventricle of a prepubertal monkey caused premature menarche and the onset of the first ovulation.[328] Although GABA is inhibitory in the juvenile and adult brain, it is excitatory early in brain development through the postnatal period.[431]



• **Fig. 26.30** (A) True precocious puberty in a 2.75-year-old girl is caused by a large, bilateral, congenital suprasellar arachnoid cyst. Signs of sexual precocity were observed during the preceding year. The head circumference was +5 SD above the mean value for age, and frontal bossing was present. Breasts were Tanner stage 3. The serum estradiol level was 26 pg/mL, the estrone level was 38 pg/mL, and the dehydroepiandrosterone sulfate (DHEAS) level was less than 3 μg/dL. The serum luteinizing hormone (LH) concentration rose from 1.4 to 8.7 ng/mL (LER-960) after intravenous administration of gonadotropin-releasing hormone (GnRH), which constitutes a pubertal response. Bone age was 3.5 years. Pelvic ultrasonography showed pubertal-size uterus and ovaries. To convert estrone values to picomoles per liter, multiply by 3.699. To convert DHEAS values to micromoles per liter, multiply by 0.02714. For other conversions, see Fig. 26.19. (B) Cranial computed tomography (CT) scans show a low-density fluid collection in the middle cranial fossa, thinning of the cortex, and striking compression of the lateral and third ventricles. (C) Cranial CT scans 8 months later, after decompression of the arachnoid cyst and creation of a communication between the cyst and the basal cerebrospinal fluid cisterns and a cystoperitoneal shunt. Notice the striking decrease in size of the fluid collections and expansion of the cerebral cortex. (D) Basal and peak LH and follicle-stimulating hormone (FSH) concentrations after GnRH administration in SM and serum estradiol values before surgical decompression and 2 weeks and 9 months after surgical decompression of the arachnoid cyst. Notice the prepubertal LH response to GnRH and fall in serum estradiol level by 9 months after surgery. The bone age had increased by 3 years over an 11-month period, but the velocity returned to normal. The patient remained prepubertal during follow-up. *LRF,* luteinizing hormone-releasing factor; *SD,* standard deviation. (From Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:1–68.)



• **Fig. 26.31** Hypothalamic hamartoma as an ectopic gonadotropin-releasing hormone (GnRH) pulse generator that escapes the intrinsic central nervous system (CNS) inhibitory mechanism and results in true precocious puberty. Two possible mechanisms are proposed. *Left,* The GnRH neurosecretory neurons in the hamartoma are functioning as a GnRH pulse generator without activation of the suppressed, normally located GnRH pulse generator. *Right*, The hamartoma acts as an ectopic GnRH pulse generator but communicates with and activates (possibly through axonic connections or by GnRH itself) the normally located hypothalamic GnRH pulse generator, which then functions synchronously with the hamartoma.

The switch from dominance of the gonadal steroid-dependent negative feedback mechanism in infancy and early childhood to dominance of the intrinsic CNS inhibitory mechanism may be associated with the developmental switch of GABAergic synaptic transmission from excitatory to inhibitory.

The onset of puberty in the rhesus monkey is characterized by a decrease in GABAergic (and possibly neuropeptide Y [NPY]) inhibition of the hypothalamic GnRH pulse generator and increased release of glutamate,[329] the major excitatory amino acid neurotransmitter in the hypothalamus.[328] The sensitivity to the stimulatory glutamatergic input into the GnRH pulse generator increases strikingly after the onset of puberty, but it is the reduction in GABAergic inhibition that is the critical factor in disinhibition of the GnRH pulse generator.[329]

A persistent question has been how a single central signal can activate GnRH neurons to cause LH release and bring about ovulation by simultaneous suppression of GABA and stimulation of glutamate release, both of which converge in the AVPV nucleus. Most neurons in the AVPV of female rats express both vesicular glutamate transporter 2 (VGLUT2), a marker of hypothalamic glutamatergic neurons, and GAD and vesicular GABA transporter (VGAT), markers of GABAergic neurons. These dual-phenotype neurons are twice as prevalent in females than in males and are the main targets of the E2 binding site in the region.[432] Moreover, dual-phenotype synaptic terminals contact GnRH neurons, and at the time of the surge, VGAT-containing vesicles decrease and VGLUT2-containing vesicles increase in these terminals. Dual-phenotype GABA/glutamate neurons may act as central transducers of hormonal and neural signals to GnRH neurons to simultaneously decrease GABA and increase glutamate release.

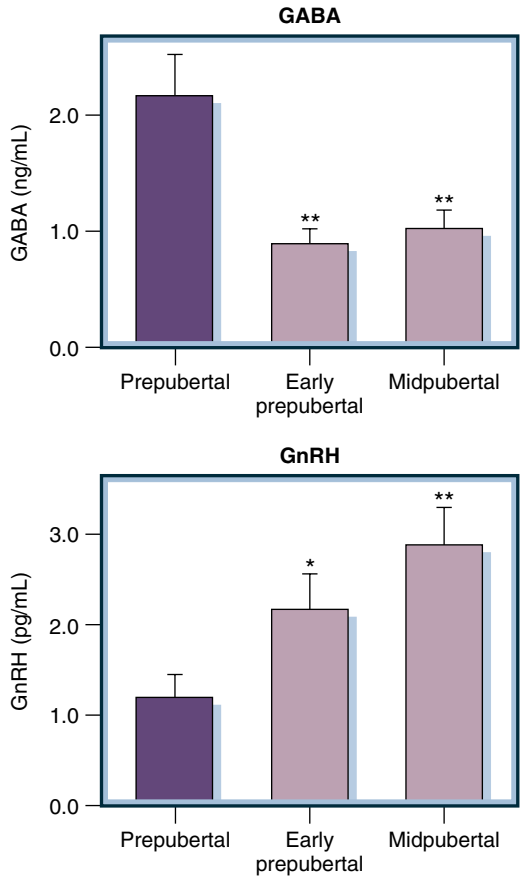
NELL2, a protein containing epidermal growth factor (EGF)–like repeats, is selectively expressed in the glutamatergic neurons containing VGLUT1 and in those expressing VGLUT2 in the postnatal rodent brain. NELL2 mRNA abundance increases selectively in the medial basal hypothalamus of the female rat, reaching a peak at the end of the juvenile period, and declines at the time of puberty with less change observed in the preoptic area. Intraventricular administration of antisense oligodeoxynucleotides to NELL2 reduced GnRH release from the medial basal hypothalamus and delayed the initiation of female puberty. Therefore NELL2 plays an important role in glutamate-dependent processes of neuroendocrine regulation in puberty.[433]

Excitatory NMDA stimulates LH release in neonatal and adult rats, fetal sheep, and prepubertal and adult rhesus monkeys, and its receptors are widely distributed throughout the CNS, including the hypothalamus. NMDA evoked GnRH secretion from rat hypothalamic explants from a GnRH neuronal cell line and acutely stimulated the GnRH pulse generator in the ovine fetus but did not have a direct effect on pituitary gonadotrophs.[332,381,385,434]

Immortalized GnRH neurons contain inotropic NMDA receptors that mediate the release of GnRH by NMDA.[404] The prepubertal male rhesus monkey may be forced to enter puberty by repetitive intravenous administration of NMDA; in the prepubertal and pubertal female rhesus monkey, NMDA administered centrally and peripherally induced the release of GnRH.[435]

NPY has been suggested as a component of the central restraint mechanism in the male rhesus monkey. A small study of girls demonstrated higher NPY concentrations in those with CDP than in those with normal onset of puberty, supporting this relationship.[332,436]

These observations provide additional evidence that the hypothalamic GnRH neurosecretory neuron is not a limiting factor in puberty, as is the GnRH pulse generator; the anterior pituitary gland, gonads, and gonadal steroid end organs are functionally intact in the fetus and prepubertally and can be fully activated by the appropriate stimulus. CNS restraint of puberty lies therefore above the level of the autorhythmic GnRH neurosecretory neurons in the hypothalamus. Fig. 26.13 contrasts the direct and indirect effects of the GABA inhibitory and excitatory amino acid stimulatory neurotransmitters (as represented by NMDA and



• **Fig. 26.32** The striking developmental changes in γ-aminobutyric acid (GABA) and gonadotropin-releasing hormone (GnRH) release between the prepubertal and the pubertal rhesus monkey as measured in 10-minute perfusate samples from the stalk of the median eminence. Multiple samples were obtained from each animal. Mean ± SEM (standard error of the mean); $^{**}p < 0.01$; $^{*}p < 0.05$ vs prepubertal monkeys. (From Mitsushima D, Hei DL, Terasawa E. γ-Aminobutyric acid is an inhibitory neurotransmitter restricting the release of luteinizing hormone-releasing hormone before the onset of puberty. *Proc Natl Acad Sci U S A.* 1994;91:395–399.)

other glutamate receptors) on GnRH release. In the primate, the GABA hypothalamic neural network seems to be the major component of the intrinsic CNS inhibitory mechanism during the juvenile pause.

Sleep-Associated Luteinizing Hormone Release and Onset of Puberty

In sensitive radioimmunoassays, a diurnal rhythm of serum LH, FSH, and testosterone is already demonstrable in short but otherwise normal girls age 5 to 6 years, demonstrating that preparation for the changes of puberty starts long before the physical features and classic endocrine markers of puberty appear.[252,326] Although adult men and women during most phases of the menstrual cycle have little difference in the amplitude or frequency of LH pulses over a 24-hour period, sleep-associated pulsatile release of LH is prominent in early and midpuberty; only in late puberty are prominent LH-secretory episodes detected during the day, but they are still less than during sleep until the adult pattern is achieved. Augmented LH release during sleep leads to a rise in the plasma concentration of testosterone at night in boys, in children with CPP, in glucocorticoid-treated children with CAH who have an advanced bone age and early onset of true puberty, and in agonadal patients during the pubertal age period, suggesting that it does not depend on gonadal function. There is significantly increased excretion of urinary LH in prepubertal children at night compared with the day.

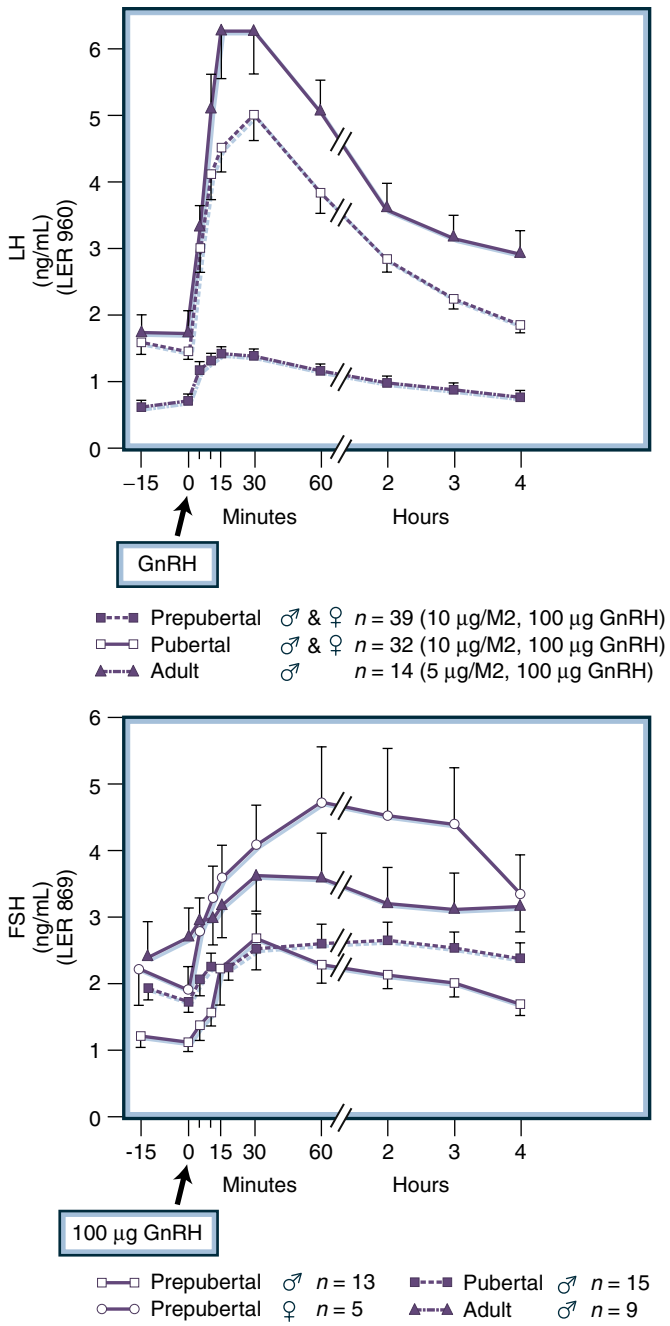
Sleep-enhanced LH secretion can be viewed as a maturational phenomenon related to changes in the CNS and in the hypothalamic restraint of GnRH release. Episodic release of gonadotropins is suppressed by anti-GnRH antibodies and by the administration of gonadal steroids or certain catecholaminergic agonists and antagonists and is augmented by the opioid antagonist naloxone. Naloxone does not alter the testosterone-mediated suppression of LH, nor does it alter the testosterone effect on LH pulsatility in boys in early to middle puberty. We have suggested that an increase in endogenous GnRH secretion at puberty has a priming effect on the gonadotroph and leads to increased sensitivity of the pituitary to endogenous or exogenous GnRH.[256] In monkeys, a striking increase in pulse amplitude and a lesser increase in pulse frequency occurs between prepuberty and puberty.[328,332] Sleep-associated LH release in the peripubertal period correlates with increased sensitivity of the pituitary gonadotrophs to administration of GnRH in the peripubertal period and in puberty and is an indication that the hypothalamic GnRH pulse generator initially is less inhibited during sleep, even in prepubertal children.

Pituitary and Gonadal Sensitivity to Tropic Stimuli

Endogenous GnRH secretion is estimated indirectly and qualitatively by determining the pulsatile pattern of LH and by the gonadotropin response to exogenous GnRH at different stages[425] and in disorders of the hypothalamic-pituitary-gonadal system. The release of LH after administration of GnRH is minimal in prepubertal children beyond infancy, increases during the peripubertal period and puberty (Fig. 26.33), and is still greater in adults (depending on the phase of the menstrual cycle in women).[256] These results support the concept that the prepubertal state is characterized by functional GnRH deficiency. FSH release after the administration of GnRH is comparable in prepubertal, pubertal, and adult males, indicating similar pituitary sensitivity to GnRH, but females release more FSH than males at all stages of sexual maturation. There is a striking reversal of the FSH/LH ratio after administration of GnRH to males or females between prepuberty and puberty (see Fig. 26.33).

These observations suggest a striking change in pituitary sensitivity to GnRH in prepubertal and pubertal individuals and indicate a sex difference in the dynamic reserve of pituitary FSH because the pituitary gonadotrophs of prepubertal females are more sensitive to GnRH than those of prepubertal males, even though the concentration of circulating gonadal steroids is very low in both sexes at that stage of maturation.[256] Prepubertal girls have a larger readily releasable pool of pituitary FSH than prepubertal or pubertal males, possibly related in part to the higher concentration of inhibin B in prepubertal boys (see Fig. 26.33). These may be factors in the higher frequency of idiopathic CPP in girls and in the occurrence of premature thelarche.[437] The available data are consistent with the hypothesis that less GnRH is required for FSH than for LH release.

This change in responsiveness of the gonadotrophs is apparently mediated by increased pulsatile secretion of GnRH[256,326]; the increased LH response to synthetic GnRH is one of the earliest hormonal markers of puberty onset. Studies of the effects of acute and chronic administration of synthetic GnRH in hypergonadotropic hypogonadism, hypogonadotropic hypogonadism, constitutionally delayed growth and adolescence, and idiopathic



• **Fig. 26.33** Changes in plasma luteinizing hormone (LH) *(top)* and follicle-stimulating hormone (FSH) *(bottom)* levels in prepubertal, pubertal, and adult individuals. Notice the limited LH response in prepubertal children compared with that of pubertal and adult subjects. The FSH response to gonadotropin-releasing hormone (GnRH) is similar in prepubertal, pubertal, and adult males. In females, the FSH response is significantly greater than that of prepubertal, pubertal, or adult males. For conversion to SI units, see Fig. 26.19. (Modified from Grumbach MM, Roth JC, Kaplan SL, et al. Hypothalamic pituitary regulation of puberty in man: evidence and concepts derived from clinical research. In: Grumbach MM, Grave GD, Mayer FE, eds. *Control of the Onset of Puberty.* New York, NY: John Wiley & Sons; 1974:115–166.)

precocious puberty indicate that the degree of previous exposure of gonadotrophs to endogenous GnRH appears to affect both the magnitude and the quality of LH responses—a self-priming phenomenon.[256] With the approach of puberty, the derepression of the hypothalamic GnRH pulse generator and the increased pulsatile secretion of GnRH augment pituitary sensitivity to GnRH and enlarge the reserve of LH. Reduction in the frequency of exogenous GnRH pulses (from one per hour to one every 3 hours) in adult rhesus monkeys with ablative hypothalamic lesions that eliminated endogenous GnRH secretion increased the FSH/LH ratio, suggesting that GnRH pulse frequency is one factor affecting relative secretion of FSH and LH. Inhibin and endogenous gonadal steroids may also affect this ratio through action on the hypothalamus or the pituitary or both.

Pulsatile administration of GnRH to prepubertal monkeys promptly initiates puberty (and ovulatory menstrual cycles in females) and restores complete gonadal function in adult monkeys with hypothalamic lesions.[332,438] Similar studies in humans yielded comparable results for prepubertal children, patients with anorexia nervosa, and adults with hypothalamic-hypogonadotropic hypogonadism.[439] These results provide further support for reactivation of the hypothalamic GnRH pulse generator as the first hormonal change in the onset of puberty.

Responsiveness of the gonads to gonadotropins increases during puberty. For example, the augmented testosterone secretion in response to administration of hCG at puberty in boys is probably a consequence of the priming effect of the increase in endogenous secretion of LH (in the presence of FSH) on the Leydig cells.

Maturation of Positive Feedback Mechanism

Estrogen exerts suppressive effects from late fetal life to peripuberty, when the positive action of endogenous (or exogenous) estradiol on gonadotropin release is not demonstrated.[256,326] A positive feedback effect, which is required for ovulation, is a late maturational event in puberty and probably does not occur before midpuberty in normal girls. The positive feedback effect requires an increased concentration of plasma estradiol for a sufficient length of time during the latter part of the follicular phase in later pubertal and adult women.[336]

Among the requirements for the positive feedback action of estradiol on gonadotropin release at puberty are ovarian follicles that are primed by FSH to secrete sufficient estradiol to reach and maintain a critical level in the circulation, a pituitary gland that is sensitized to GnRH and contains a large enough pool of releasable LH to support an LH surge, and sufficient GnRH stores for the GnRH neurosecretory neurons to respond with an acute increase in GnRH release in addition to the usual adult pattern of pulsatile GnRH secretion (this last requirement is controversial in humans but not in lower animals).[256]

Estrogen exerts effects at the anterior pituitary and the hypothalamus.[440] In the rhesus monkey, positive and negative feedback can occur in adult ovariectomized females in whom the medial basal hypothalamus is surgically disconnected from the remainder of the CNS.[332] In monkeys with hypothalamic lesions, unvarying, intermittent GnRH administration leads to sufficient estradiol release from the ovary to induce an ovulatory LH surge in the absence of an increase in the dose of the GnRH pulses.[336,438] Estradiol has a positive feedback effect directly on the pituitary gland in normal women, and prolonged administration of estradiol is accompanied by an augmented LH response to GnRH administration. The fact that the major positive feedback action on the pituitary gland is demonstrable in the absence of an increase in pulsatile GnRH secretion suggests that the failure to elicit positive feedback action with administration of estradiol to prepubertal girls may be related to the inadequate GnRH pulses or insufficient LH reserve or both.

Gonadotropin cyclicity and estradiol-induced positive feedback can be demonstrated by midpuberty and before menarche but may be insufficient to induce an ovulatory LH surge even when there is an adequate pituitary store of readily releasable LH and FSH.[1,256] The ovary does not secrete estradiol at a high level or long enough to induce an ovulatory LH surge. We visualize the process leading to ovulation as a gradual one in which the ovary (i.e., the zeitgeber for ovulation[336]) and the hypothalamic-pituitary-gonadal complex become progressively more integrated and synchronous until an ovary primed for ovulation secretes sufficient estradiol to induce an ovulatory LH surge.

As many as 55% to 90% of cycles are anovulatory during the first 2 years after menarche, but the proportion decreases to less than 20% of cycles by 5 years after menarche.[441] The mechanism of ovulation seems unstable and immature, and it does not appear to have attained the fine tuning and synchronization that are requisite for maintenance of regular ovulatory cycles. However, the prevalence of PCOS adds to the irregularity of menses and anovulation in puberty.

Overview of Current Concept

Puberty is not an immutable process; it can be arrested or reversed. Environmental factors and certain disorders that affect the onset or progression of puberty mediate their effects by direct or indirect suppression of the hypothalamic GnRH pulse generator and its periodic oscillatory signal, GnRH. Table 26.14 lists some of these factors.

Adrenal Androgens and Adrenarche

Speculation has focused on the mechanism of adrenarche (the adrenal component of pubertal maturation), the fact that adrenarche occurs earlier than gonadarche (the maturation of the hypothalamic-pituitary-gonadal system), and the interaction between adrenal and gonadal hormones at puberty.[290,325,442]

Nature and Regulation of Adrenal Androgens

The major adrenal androgen precursors secreted by the adrenal cortex are DHEA, DHEAS, and androstenedione, which can undergo extraglandular metabolism to produce physiologically active testosterone and estradiol[159]; however, adrenal androgens do not directly activate the AR. DHEA and especially DHEAS (which binds avidly to serum proteins, particularly albumin) are useful biochemical markers of adrenal androgen secretion and the onset of adrenarche. Androstenedione is the major androgen secreted by the ovary during and after puberty, and it is more readily converted to potent androgens than DHEA or DHEAS.

Cross-sectional and longitudinal studies have demonstrated a progressive increase in the plasma concentration of DHEA and DHEAS in boys and girls starting by 3 years of age and becomes more noticeable approximately 2 years before the increase in gonadotropin and gonadal steroid secretion that continues through puberty (13–15 years),[290,325,443,444] reaches a peak at age 20 to 30 years, and then gradually decreases (Fig. 26.34).[442] The increase is not associated with increased sensitivity of the pituitary gonadotrophs to GnRH[430] or with sleep-associated LH secretion and occurs at an age when the hypothalamic-pituitary-gonadal complex is functioning at a low level.[290,437] The importance of adrenarche is a matter of long-term debate. DHEA is a neurosteroid with parallel patterns of increase along with cortical maturation from approximately age 6 years to the middle 20s, suggesting that adrenarche affects brain development. DHEAS may increase activity of the amygdala and hippocampus and promote synaptogenesis within the cortex, with effects on fearfulness,

TABLE 26.14 Postulated Ontogeny of the Hypothalamic-Pituitary-Gonadal Circuit

Fetus

- Medial basal hypothalamic GnRH neurosecretory neurons (pulse generator) operative by 80 days of gestation
- Pulsatile secretion of FSH and LH by 80 days of gestation
- Initially unrestrained secretion of GnRH (100–150 days of gestation)
- Maturation of negative gonadal steroid feedback mechanism by 150 days of gestation—sex difference
- Low level of GnRH secretion at term

Early Infancy

- Hypothalamic GnRH pulse generator highly functional after 12 days of age
- Prominent FSH and LH episodic discharges until approximately age 6 mo in males and 18 mo in females, with transient increases in plasma levels of testosterone in males and estradiol in females

Late Infancy and Childhood

- Intrinsic CNS inhibition of hypothalamic GnRH pulse generator operative; predominant mechanism in childhood; maximal sensitivity by approximately 4 years of age
- Negative feedback control of FSH and LH secretion highly sensitive to gonadal steroids (low set-point)
- GnRH pulse generator inhibited; low amplitude and frequency of GnRH discharges
- Low secretion of FSH, LH, and gonadal steroids

Late Prepubertal Period

- Decreasing effectiveness of intrinsic CNS inhibitory influences and decreasing sensitivity of hypothalamic-pituitary unit to gonadal steroids (increased set-point)
- Increased amplitude and frequency of GnRH pulses, initially most prominent with sleep (nocturnal)
- Increased sensitivity of gonadotrophs to GnRH
- Increased secretion of FSH and LH
- Increased responsiveness of gonad to FSH and LH
- Increased secretion of gonadal hormones

Puberty

- Further decrease in CNS restraint of hypothalamic GnRH pulse generator and in the sensitivity of negative feedback mechanism to gonadal steroids
- Prominent sleep-associated increase in episodic secretion of GnRH gradually changes to adult pattern of pulses about every 90 min
- Pulsatile secretion of LH follows pattern of GnRH pulses
- Progressive development of secondary sexual characteristics
- Spermatogenesis in males
- Middle to late puberty—operative positive feedback mechanism and capacity to exhibit an estrogen-induced LH surge
- Ovulation in females

(A) The close correlation between the development of the zona reticularis and the increase in the plasma DHEAS level. (B) The age at which focal islands of reticular tissue or a continuous reticular zone was found in a series of patients with sudden death who had not had an antecedent illness. (C) The increase in adrenal volume at the time of puberty. For conversion to SI units, see Fig. 26.19. (From Grumbach MM, Richards HE, Conte FA, et al. Clinical disorders of adrenal function and puberty: assessment of the role of the adrenal cortex and abnormal puberty in man and evidence for an ACTH-like pituitary adrenal androgen stimulating hormone. In: James VHT, Serio M, Giusti G, et al, eds. *The Endocrine Function of the Human Adrenal Cortex.* New York, NY: Academic Press; 1978:583–612.)

anxiety, and memory that increase social interaction with unfamiliar individuals and shape cognitive development.[445]

Associated with the increase in adrenal secretion of DHEA and DHEAS (and independent of a change in the secretion of cortisol or aldosterone) is the appearance and growth of the zona reticularis (i.e., the principal source of DHEA and DHEAS) that occurs coincidently with adrenarche (Fig. 26.35).

In contrast to the zona glomerulosa and fasciculata, four main features distinguish the zona reticularis:

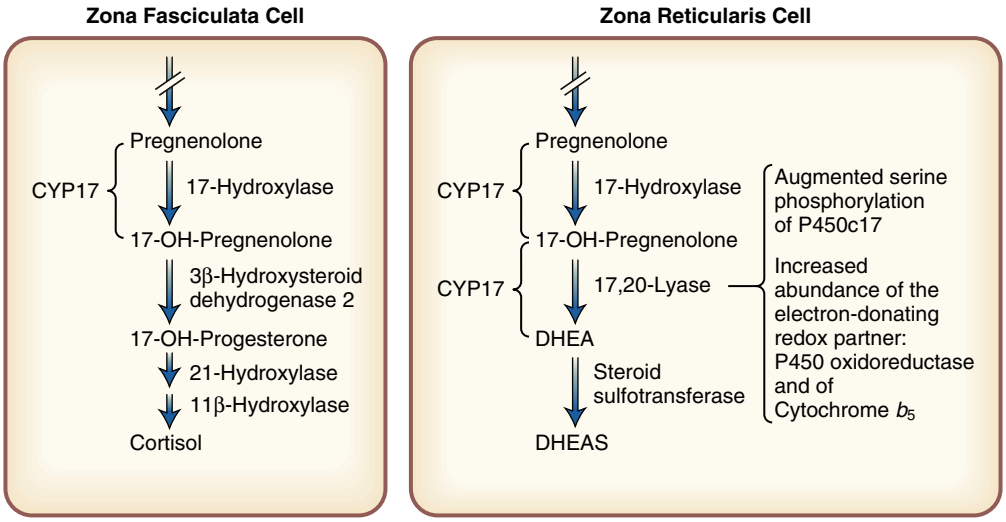
1. There is a low level of expression of 3βHSD/$\Delta^{4,5}$-isomerase type 2 and CYP21 mRNAs and enzyme activities.
2. Abundant DHEA (hydroxysteroid) sulfotransferase activity is found.
3. There is a relative increase in 17,20-lyase vs 17α-hydroxylase activity of CYP17, the enzyme that catalyzes both activities. These characteristics are shared by the fetal zone of the fetal adrenal cortex.
4. There is expression of major histocompatibility complex (MHC) class II (HLA-DR) antigens, which are not expressed in the fetal zone of the fetal adrenal cortex.

In contrast to the zona fasciculata, the zona reticularis has an increased ratio of 17,20-lyase to 17α-hydroxylase. An Arg347Ala mutation in human CYP17 resulted in strikingly decreased 17,20-lyase activity but retention of 17α-hydroxylase activity. Two XY phenotypic females with hypergonadotropic hypogonadism and normal mineralocorticoid and glucocorticoid function had isolated 17,20-lyase deficiency due to homozygous mutations at the Arg347 or the Arg358 residue in CYP17.

In contrast to these observations of loss of 17,20-lyase activity with retention of 17α-hydroxylase activity, the ratio of human 17,20-lyase to 17α-hydroxylase activities was increased by increased phosphorylation of serine and threonine residues on the CYP17 enzyme and by the increased abundance of redox partners such as cytochrome P450 oxidoreductase and by cytochrome b_5, which preferentially promotes 17,20-lyase activity by allosterically affecting the interaction between CYP17 and P450 oxidoreductase.[446] These studies provided a provisional hypothesis of the mechanisms that appear to be involved in the relatively increased 17,20-lyase activity of the zona reticularis, although not its regulation (see Fig. 26.35).

Regulation of adrenal androgen secretion in the zona reticularis is postulated to be based on a dual-control mechanism. First, corticotropin (adrenocorticotropic hormone [ACTH]) is obligatory, as evidenced by the findings in cases of ACTH deficiency or resistance. Second, the mechanism requires the action of an unidentified adrenal androgen-stimulating factor, possibly pituitary in origin or from a nonadrenal source or an intra-adrenal event.[301] This concept is illustrated in Fig. 26.36.[443]

CRH has been advanced as an adrenal androgen secretagogue that has stimulatory action on the zona reticularis. The intravenous infusion of human CRH into dexamethasone-suppressed young men increased DHEA, DHEAS, and androstenedione secretion within 3 hours. Similar results were obtained in adolescent girls with hyperandrogenism and a history of premature adrenarche. CRH directly stimulates DHEAS secretion and the expression of CYP17 by the fetal adrenal cortical cells.[447] Leptin in vitro vigorously stimulates 17,20-lyase activity and transiently stimulates 17α-hydroxylase activity of the microsomal enzyme CYP17, implying a role in adrenarche,[448] but no clinical evidence suggests a pivotal role of leptin in adrenarche. Therefore a distinct hormone or factor that in addition to ACTH stimulates the zona reticularis and adrenal androgen secretion has not been isolated, and the mechanism regulating adrenarche remains unknown.[325]



• **Fig. 26.35** Adrenarche and the zona reticularis. The rise in circulating dehydroepiandrosterone sulfate (DHEAS) levels is the biochemical hallmark of adrenarche. The diagram compares and contrasts the major steroidogenic pathway in the zona fasciculata with that in the zona reticularis. In contrast to the zona fasciculata, the expression of 3β-hydroxysteroid, $\Delta^{4,5}$ isomerase type 2 messenger ribonucleic acid (mRNA), and its activity (the enzyme that irreversibly traps Δ^5 precursors into Δ^4 steroids) is very low in the zona reticularis, whereas the expression of and activity of steroid sulfotransferase is high. A single gene, *CYP17* (now designated *CYP17A1*), encodes a single enzyme that has 17α-hydroxylase and 17,20-lyase activity, but the ratio of 17,20-lyase to 17α-hydroxylase activity is relatively high in the zona reticularis compared with that in the zona fasciculata. Some of the factors that seem to amplify the increased 17,20-lyase activity of *CYP17* are the augmented serine phosphorylation of the enzyme and the apparent increased abundance of the electron-donating redox partner, including P450 reductase and of cytochrome b_5.

A distinct adrenal androgen-stimulating factor, whether of pituitary, intra-adrenal, or other origin, may explain the following observations[301]:

1. The spurt in adrenal growth and the differentiation and growth of the zona reticularis at adrenarche occur independently of an increase in ACTH or cortisol secretion but correlate with the increase in plasma levels of DHEAS (see Fig. 26.35).
2. Cortisol and adrenal androgen secretions vary independently with age, during normal and premature adrenarche, and in Cushing disease, starvation, malnutrition, anorexia nervosa, and chronic disease.
3. Unlike cortisol secretion, the secretion of DHEA and DHEAS in response to ACTH administration varies with age.
4. Dissociation of adrenarche and gonadarche occurs in a variety of disorders of sexual maturation (see Fig. 26.36), including premature adrenarche (i.e., onset of pubic or axillary hair before 8 years of age), chronic adrenal insufficiency, CPP (when the onset is before age 6 years), primary hypogonadism, isolated gonadotropin deficiency, and anorexia nervosa.[442]

A longitudinal study of 42 children demonstrated that an increase in BMI (but not the value itself at any age) was related to the rise in urinary excretion of DHEAS, suggesting that a change in nutritional status is one physiologic regulator of adrenarche.[444,449]

The increase in DHEA before and at adrenarche might suggest a similarity to the actions of the fetal adrenal zone; indeed the histologic finding and biochemistry are similar in both the fetal adrenal zone and the zona reticularis. However, the fetal adrenal zone undergoes involution at birth; in addition biomarkers such as enzyme AKR1C3 (17β-hydroxysteroid dehydrogenase type 5 [17βHSD5]) are higher in the zona reticularis than the fetal adrenal zone.[325]

Adrenal Androgens and Puberty

The earlier onset of adrenarche than gonadarche and the contribution of adrenal androgens to the growth of pubic and axillary hair have led some to suggest that adrenal androgens in normal children are an important factor in the onset of puberty and the maturation of the hypothalamic-pituitary-gonadal complex.

Although CPP may occur when the prepubertal child has previously been exposed to excessive levels of androgens from an endogenous or exogenous source (e.g., after the initiation of glucocorticoid therapy in congenital virilizing adrenal hyperplasia or after removal of a sex steroid–secreting adrenal or gonadal neoplasm[290,450]), there is little evidence that adrenal androgens play an important qualitative or rate-limiting role in the onset of puberty in normal children.[290] Most patients with premature adrenarche, who secrete excessive amounts of adrenal androgens for their age, enter puberty and experience menarche within the normal age range.[290] Moreover, prepubertal children who have congenital or acquired chronic adrenal insufficiency (i.e., Addison disease) and consequently have deficient or absent adrenal androgen secretion usually have a normal onset and normal progression through puberty when given appropriate glucocorticoid and mineralocorticoid replacement therapy.[290] Studies of children with chronic adrenal insufficiency, isolated gonadotropin deficiency, hypergonadotropic hypogonadism, or androgen resistance suggest that adrenal androgens in girls and boys are not essential for the adolescent growth spurt, whereas gonadal steroids secreted by the testis and ovary are essential and act in concert with GH.[290] The transient increase in height velocity (about 1.5 cm/year in both sexes) that occurs in middle childhood (6–7 years) and lasts about 2 years terminates while the serum DHEAS level continues

to increase. This increase in height velocity is related to the cyclic pattern of prepubertal growth and to genetic regulation of growth rather than to an increase in adrenal androgen or GH secretion.[451]

Disorders of Puberty

Delayed Puberty and Sexual Infantilism

The upper limits of the normal age of onset of puberty are 2 SD above the mean and are 14 years for boys (although some sources say 13.5 years) and 13 years for girls (Table 26.15). Functionally, delayed puberty can be divided into disorders that affect the operation of the GnRH pulse generator, the pituitary gland, or the gonad.

Idiopathic or Constitutional Delay in Growth and Puberty

Otherwise healthy girls who spontaneously enter puberty after the age of 13 years and boys who begin after 14 years may have constitutional delay in growth and adolescence (CDP), the most common diagnosis for delayed puberty. Affected individuals usually are short (2 SD below the mean value of height for age) at evaluation and have been shorter than their classmates for years, although growth velocity and height are usually appropriate for bone age (Fig. 26.37 and Table 26.16). Family history in as many as 77% of cases reveals a mother who had delayed menarche or a father (or sibling) who entered puberty late (i.e., age 14–18 years), and the pattern in some cases suggested dominant inheritance with incomplete penetrance.[452–454]

Recent GWAS studies demonstrate a low prevalence of genes found in CHH in CDP[455,456]; remarkably, genes usually in CHH were found in 17% of controls. However, there was only 2% oligogenicity in controls compared to 15% oligogenicity in CHH subjects, demonstrating the importance of this genetic phenomenon (oligogenicity is discussed later). Recently mutations in immunoglobulin superfamily member 10 (IGSF10) were found in males with CDP.[457] This gene is important in the earliest stage of GnRH neuron migration from the nasal mesenchyme to the border with the telencephalon in mice; mutations in this gene appear to inhibit the normal migration of the neurons. While the IGSF10 gene is not solely responsible for IHH, it appears to play a role in partial HH found in hypothalamic amenorrhea. Finding mutations in CDP may demonstrate a relationship with IHH.

Constitutional delay in development is physiologic immaturity with a slow tempo of maturation; full sexual maturity will be reached, but the process takes longer than usual but almost always occurs by 18 years. Because of delay in reactivation of the GnRH pulse generator, there is functional deficiency of GnRH for chronologic age but not for the stage of physiologic development. Adrenarche and gonadarche occur later in individuals with constitutional (idiopathic) delay in growth and adolescence,[452] whereas adrenarche reportedly occurs at a normal age in patients with isolated gonadotropin deficiency.[442] Bone age is delayed at presentation, but after a bone age of approximately 12 to 14 years for boys or 11 to 13 years for girls is achieved, sexual maturation begins (although bone age is variable and not a reliable indicator). Patients achieve sexual maturation by 18 years of age.

Most of these patients with CDP are thin, but 25% are above the 85th percentile in BMI for age, and the bone age in these heavier boys is less delayed than in classic thin patients with congenital disorders of glycosylation (CDG) (i.e., they tend to achieve taller adult stature[452]). Prepubertal boys who meet the criteria for diagnosis with delayed bone age have greater increased total energy expenditure (TEE) per kilogram fat-free mass (FFM) and increased nutritional needs possibly due to an alteration in mitochondrial metabolism or increased nonexercise activity thermogenesis (NEAT); increased nutrition increased energy intake but TEE rose as well, continuing the need for high energy intake.[458,459] There is no impairment of olfaction, as in Kallmann syndrome, and undescended testes occur in the rate found in the general population. Plasma gonadal steroid levels are low in sensitive pediatric assays at the time of presentation, but as bone age advances, the serum gonadotropin concentration and the amplitude of LH

IDIOPATHIC (CONSTITUTIONAL) DELAY IN GROWTH AND PUBERTY (DELAYED ACTIVATION OF HYPOTHALAMIC LRF PULSE GENERATOR)

HYPOGONADOTROPIC HYPOGONADISM: SEXUAL INFANTILISM RELATED TO GONADOTROPIN DEFICIENCY

CNS Disorders

Tumors

Craniopharyngiomas
Germinomas
Other germ cell tumors
Hypothalamic and optic gliomas
Astrocytomas
Pituitary tumors (including MEN1, prolactinoma)

Other Causes

Langerhans histiocytosis
Postinfectious lesions of the CNS
Vascular abnormalities of the CNS
Radiation therapy
Congenital malformations especially associated
  with craniofacial anomalies
Head trauma
Lymphocytic hypophysitis

Isolated Gonadotropin Deficiency

Kallmann syndrome
  With hyposmia or anosmia
  Without anosmia
LHRH receptor mutation
Congenital adrenal hypoplasia (*DAX1* mutation)
Isolated LH deficiency
Isolated FSH deficiency
Prohormone convertase 1 deficiency (PCI)

Idiopathic and Genetic Forms of Multiple Pituitary Hormone Deficiencies Including PROP1 Mutation

Miscellaneous Disorders

Prader-Willi syndrome
Laurence-Moon and Bardet-Biedl syndromes
Functional gonadotropin deficiency
  Chronic systemic disease and malnutrition
  Sickle cell disease
  Cystic fibrosis
  Acquired immunodeficiency syndrome (AIDS)
  Chronic gastroenteric disease
  Chronic renal disease
  Malnutrition
  Anorexia nervosa
  Bulimia
  Psychogenic amenorrhea
  Impaired puberty and delayed menarche in female athletes and ballet dancers (exercise amenorrhea)
  Hypothyroidism
  Diabetes mellitus
  Cushing disease
  Hyperprolactinemia
  Marijuana use
  Gaucher disease

HYPERGONADOTROPIC HYPOGONADISM

Males

The syndrome of seminiferous tubular dysgenesis and its variants (Klinefelter syndrome)
Other forms of primary testicular failure
  Chemotherapy
  Radiation therapy
  Testicular steroid biosynthetic defects
  Sertoli-only syndrome
  LH receptor mutation
  Anorchia and cryptorchidism
Trauma/surgery

Females

The syndrome of gonadal dysgenesis (Turner syndrome) and its variants
XX and XY gonadal dysgenesis
  Familial and sporadic XX gonadal dysgenesis and its variants
  Familial and sporadic XY gonadal dysgenesis and its variants
Aromatase deficiency
Other forms of primary ovarian failure
  Premature menopause
  Radiation therapy
  Chemotherapy
  Autoimmune oophoritis
  Galactosemia
  Glycoprotein syndrome type 1
  Resistant ovary
  FSH receptor mutation
  LH/hCG resistance
  Polycystic ovarian disease
  Trauma/surgery
  Noonan or pseudo-Turner syndrome
  Ovarian steroid biosynthetic defects

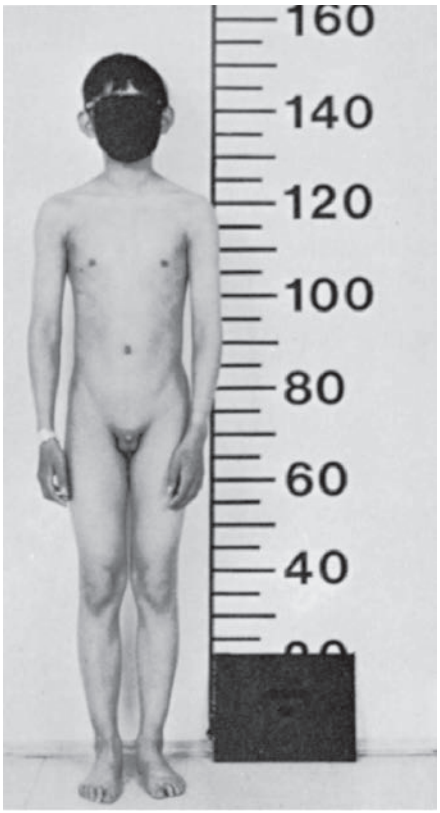
pulses increase (initially at night); the basal serum gonadotropin concentrations measured by third-generation assays and the LH response to GnRH or GnRH agonists reflect maturation of the hypothalamic-pituitary system.

The first signs of secondary sexual development occur within 1 year after LH rises to pubertal levels in response to administration of intravenous synthetic GnRH or subcutaneous GnRH agonist or within 1 year after gonadotropin and testosterone or estradiol concentrations begin to increase spontaneously above prepubertal values.[256,326] An 8 AM serum testosterone value of 0.7 nmol/L (20 ng/dL) heralds the development of phenotypic puberty in boys within 12 to 15 months.[460]

CDP is more common in boys and may be the opposite of idiopathic CPP, a condition that is many times more common in girls. Familial short stature is a physiologic variant of growth in which the velocity of development and bone age are normal but stature is decreased, in contrast to CDP, which is a disorder of tempo that secondarily impairs growth. The combination of CDP and familial short stature leads to conspicuous shortness during adolescence, especially when other children increase their growth velocity,



• **Fig. 26.37** A boy age 16 years and 2 months has constitutional delay in growth and puberty. His height is 149.5 cm (4 SD [standard deviation] below the mean value for age); upper-to-lower body ratio is 1.1 (retarded for age); phallus is 6.0 × 1.6 cm; testes are 2.5 × 1.4 cm; and the scrotum showed early thinning. At a chronologic age of 15 years and 4 months, the bone age was 11 years and the sella turcica was normal. The plasma concentration of luteinizing hormone (LH) was 0.7 ng/mL (LER-960); the concentration of follicle-stimulating hormone (FSH) was 0.5 ng/mL (LER-869). On gonadotropin-releasing hormone (GnRH) testing, the plasma concentration of LH increased to 2.2 ng/mL (an increment of 1.5 ng/mL), and the testosterone level rose from 52 to 77 ng/dL. The testes subsequently spontaneously enlarged, and the patient progressed through puberty. For conversion to SI units, see Figs. 26.19 and 26.20. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*. 2nd ed. Philadelphia, PA: WB Saunders; 1986:313–384.)

and referrals occur more often with this combination than with either condition alone. Because no single test reliably distinguishes between CDP and IHH, watchful waiting is usually in order.

The growth rate before the actual onset of puberty in constitutional delay is often suboptimal for chronologic age, but growth velocity usually increases to normal levels after puberty begins.[461] Affected boys seem to be more distressed by short stature than by delay in sexual development.

GH release in the basal state and in response to GH secretagogues, including the administration of GHRH, is low for age and may be decreased further in children with CDP, but the amplitude of GH secretion and the GH response to GHRH is greater after administration of exogenous (aromatizable) androgens or estrogens. Therefore CDP may constitute a temporary state of functional GH insufficiency for chronologic age but not for bone age. Patients with CDP are sometimes mistakenly diagnosed with growth hormone deficiency. IGF1 interacts with gonadotropins in the ovary and testis, and the relatively low secretion of GH (and presumably intragonadal IGF1) in CDP may impair the gonadal response to gonadotropins.

TABLE 26.16 Constitutional Delay in Growth and Adolescence

A variation of normal
Males more often seek assistance
Family history of delayed menarche or delayed secondary sexual characteristics
Height is often below the 5th percentile, but growth rate is normal for skeletal age
Onset of adrenarche is delayed
The combination of genetic short stature and constitutional delay leads to more profound short stature
Final height is less than predicted

Patients with constitutional delay in adolescence and growth often do not reach their predicted height. When the genetic tendency for growth is greater, subjects with CDP reach taller adult stature, but the patients most likely to be referred are those who combine genetic short stature with CDP. Girls with CDP have a mean deficit in adult height of 2.4 cm below the mean predicted height, although the range of adult height varies about 10 cm above or below predictions. The magnitude of the catch-up in linear growth during puberty in boys is a major determinant of adult height. Heavier individuals with CDP reach greater height than those who are thinner.[452] Adult height is lower if affected individuals show decreased height standard deviation scores (SDS) in earlier life.[462,463]

Because 15% to 20% of adult height is gained during puberty, many approaches aim to increase stature in otherwise normal, short children. Delaying the onset or progression with puberty by the use of GnRH agonists was suggested by some, but a decrease in bone density 1 year after cessation led to warnings that routine administration of this treatment carries substantial risk.[464] The additional psychologic risk of delaying puberty in otherwise normal children must also be considered, and this treatment is neither established nor recommended.[465]

The US Food and Drug Administration (FDA) approved GH treatment for children who are predicted to reach an adult height less than the 1st percentile (160 cm), which includes some children with CDP (but it is not specifically approved for CDP itself), and some studies reported an increase in adult height with this treatment. Because endogenous GH level rises during pubertal development, the FDA approved GH therapy in larger doses for subjects with GH deficiency during puberty. However, there are only moderate effects of increased GH doses during puberty on adult height. Male gender has a positive effect and age at onset of puberty has a negative effect on this increased dose on adult height.[466]

The cost of GH for treatment of non–GH-deficient short stature is exceptionally high: $14,000 per cm or $35,000 per inch gained.[467] Payers are reluctant in many cases to cover the cost of the GH therapy for those without confirmed GH deficiency. There are few controlled studies of adult height, but some available results demonstrate an increase in adult height of several centimeters; more studies are strongly recommended to better determine the efficacy of this treatment in short, normal children with CDP.[468]

The combination of GnRH agonist therapy with GH treatment in attempts to increase adult height in children who were

normal except for genetic short stature and in SGA children led to inconclusive results or to increased predicted or near-final height, which does not necessarily translate into increased adult height. This approach to treatment remains experimental. Review of a large database from a postmarketing survey did not support the efficacy of this approach,[469] and there was no good follow-up evaluation of adult height. This combination therapy cannot be supported by substantial evidence.[470]

When the critical role of estradiol in skeletal maturation was appreciated, treatment with a potent aromatase inhibitor to increase adult height by inhibiting skeletal maturation[159,160,303] aroused interest. A double-blind, randomized, placebo-controlled study enrolled boys with CDP who were treated with 6 months of monthly testosterone or testosterone plus an added 12-month trial of daily oral letrozole (a potent fourth-generation aromatase inhibitor). The results revealed a mean increase in predicted adult height of 5.1 cm in the letrozole plus testosterone group; a subsequent study supported these promising effects on increasing the time of pubertal growth height without affecting the development of male secondary sex characteristics, but there are few data on actual adult height.[471] The boys in the group treated with testosterone and letrozole developed increased bioactive testosterone, analyzed by a cellular assay, compared with control boys.[266] Serum testosterone measured by HPLC-MS/MS can reach levels of more than 1000 ng/dL. However, markers of bone turnover decrease, and vertebral abnormalities may develop with the use of these agents in idiopathic short stature.[472] A 1-year study of the aromatase inhibitor anastrozole plus GH, compared with GH treatment alone, in boys demonstrated no ill effects on body composition, plasma lipids, bone metabolism, or the tempo of puberty (although estrogen decreased, as expected, with the use of anastrozole), and the predicted height was increased.[473] This treatment has not been supported by long-term studies observing patients up to adult height. Concerns about possible effects on bone density and morphology must be addressed, probably until the patients are at least 20 to 25 years old, as well as a decrease in serum HDL cholesterol levels and increase of erythrocytosis before this off-label therapy can routinely be recommended.[474,475]

Hypogonadotropic Hypogonadism: Sexual Infantilism Related to Gonadotropin Deficiency

Insufficient pulsatile secretion of GnRH and the resulting FSH and LH deficiency lead to delayed sexual maturation, which may be permanent. The phenotype in hypogonadotropic hypogonadism can vary from severe sexual infantilism to apparent CDP. Both conditions may be found in the same family, or hypogonadotropic hypogonadism may first appear to be CDP (e.g., a homozygous R262Q mutation in GNRHR presented with constitutional delay but later was associated with oligospermia).[476] There may be an absolute or relative quantitative deficiency of pulsatile GnRH, or the deficiency may be qualitative, especially in females; it may involve abnormalities in amplitude or frequency of GnRH pulses or in both components (Fig. 26.38). The many forms of this condition occur in about 1 in 4000 males and three to five times less in females.

Patients with IHH usually are of normal height in early or middle adolescent years, whereas patients with CDP usually have a normal growth rate for bone age but are short for chronologic age. In contrast to CDP patients, those with hypogonadotropic hypogonadism usually do not respond to GnRH stimulation, nor do they have a pulsatile LH profile commensurate with bone age. Although serum concentrations of plasma FSH and LH and urinary gonadotropins are low, the differences are relative rather than absolute and are not diagnostic for an individual.

Hypogonadotropic hypogonadism can involve puberty and reproduction alone or can be a manifestation of a life-threatening condition such as a brain tumor. Hypogonadotropic hypogonadism may result from a genetic or developmental defect present at birth but remain undetected until the age of expected puberty, or it may be caused by a tumor, inflammatory process, vascular lesion, irradiation, or trauma to the hypothalamus. Similarly, hypogonadotropic hypogonadism may arise from lesions or defects that involve the pituitary gland directly. When GH is affected as well as gonadotropins, impaired growth is manifested by decreased growth velocity, especially during the expected pubertal growth spurt, and short stature.

Isolated Hypogonadal Hypogonadism

A defect involving the GnRH pulse generator or gonadotrophs without an anatomic lesion causes selective deficiency of gonadotropins, producing IHH (Tables 26.17 and 26.18).[477] Puberty fails to begin by 14 years in boys and 13 years in girls, or pubertal maturation is incomplete or transient. In boys, micropenis (the penis is normally formed but stretched length is less than 2 cm in length, which is 2.5 SD below the mean length in average newborn males) or undescended testes or both findings are evidence of a fetal testosterone deficiency caused by gonadotropin deficiency. Prepubertal concentration of gonadal sex steroid values (testosterone in boys; estradiol in girls) and low serum gonadotropin levels or values within the normal range (i.e., normal in the basal state but not in the stimulated state) are characteristic. Concentrations of gonadal sex steroids and gonadotropins are low, pulsatile LH secretion is often virtually absent, and the LH response to GnRH or GnRH agonist administration is deficient in the severe form. The testes are small (1–2 mL), and serum inhibin B, an estimate of seminiferous tubule function, is lower than in CDP in initial studies.[478]

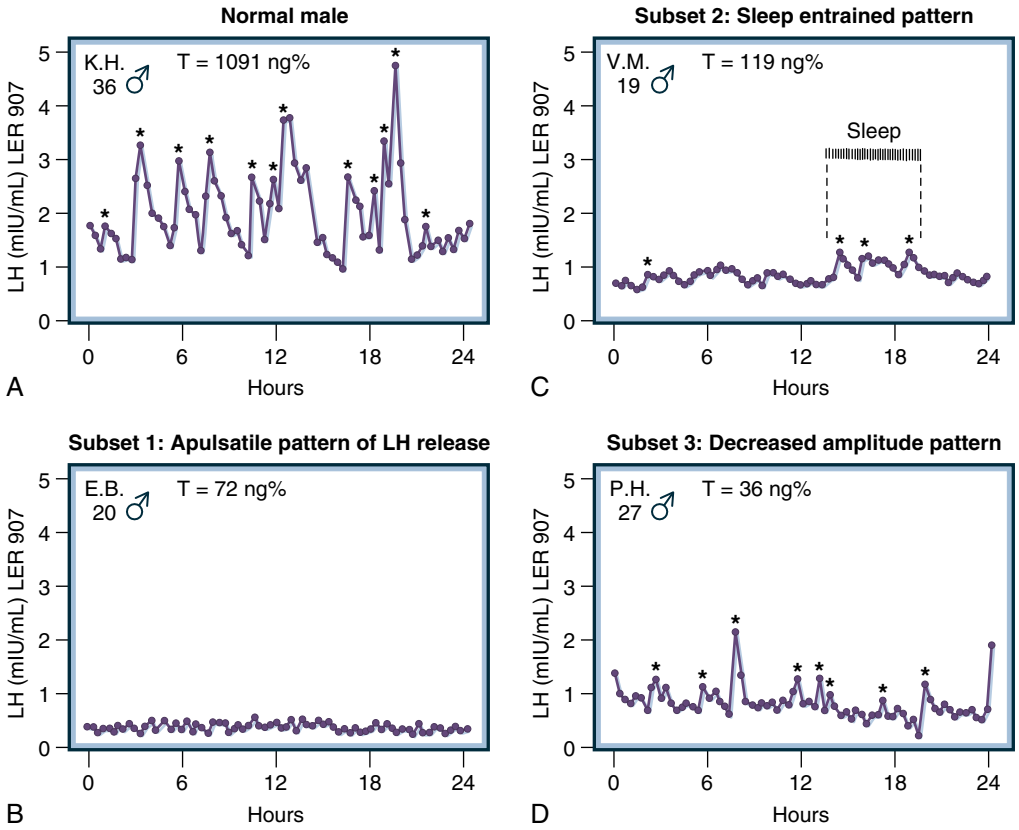
IHH may occur in families (about 20–30% of patients), or it may occur sporadically. There are a growing list of gene defects that cause hypogonadotropic hypogonadism.[479] Some patterns of inheritance are rare and follow the classic mendelian schema; others are oligogenetic, whereby multiple defects of common genes synergize to bring about a condition no single one of them could cause alone.[454,480]

Oligogenicity is more common in IHH than CDP, and IHH genes are more common in IHH than CDP, suggesting a different genetic architecture in IHH compared to CDP.[456]

In contrast to CNS tumors (in which patients usually have GH deficiency and growth failure) and to CDP (in which patients are short for chronologic age), height is appropriate for age in patients with IHH (Fig. 26.39). Because the levels of estradiol are too low to cause epiphyseal fusion at the normal age, increased arm span for height and a decreased ratio of upper to lower body segments (i.e., eunuchoid body proportions) are present. If the condition is left untreated, growth continues, and adult height is tall.[481–483]

Remarkably, about 22% of affected patients with IHH and severe delay of puberty spontaneously increase their testicular size and enter full puberty.[484] Five men who experienced reversal once again became hypogonadal. Thus long-term follow-up is essential.

Kallmann Syndrome. Anosmia or hyposmia resulting from agenesis or hypoplasia of the olfactory lobes or sulci is associated



• **Fig. 26.38** Various patterns of pulsatile luteinizing hormone (LH) secretion that can occur in isolated hypogonadotropic hypogonadism (B–D) are compared with LH secretion in a normal man (A). (A) Discrete LH pulses occur about every 2 hours in a normal 36-year-old man. (B) Typical apulsatile LH pattern is associated with a low testosterone (T) concentration usually found in isolated hypogonadotropic hypogonadism. (C) Pattern of developmental arrest with low-amplitude nocturnal LH pulses is apparent only during sleep. (D) Low-amplitude LH pulse pattern occurs during sleep and wake periods. To convert LH values to international units per liter, multiply by 1.0. (From Spratt DI, Crowley WF. Hypogonadotropic hypogonadism: GnRH therapy. In: Krieger DT, Bardin CW, eds. *Current Therapy in Endocrinology and Metabolism, 1985-1986*. Toronto, Canada: BC Decker; 1985:155–159.)

TABLE 26.17 Isolated Gonadotropin Deficiency

Males more commonly affected
Familial (more common in females) or sporadic (more common in males)
Height normal for age; tall adult height if untreated
Eunuchoid skeletal proportions
Delayed bone age
Small, often cryptorchid testes: diameter <2.5 cm prepubertal size; phallus may be small
Normal adrenarche
Examine for anosmia or hyposmia (Kallmann syndrome)
Look for associated malformations (facial, central nervous system, skeletal, renal)

with GnRH deficiency in Kallmann syndrome, the most common form of IHH[485] (see Table 26.18). The condition was first observed in 1856 during the autopsy of a 40-year-old man with micropenis, small cryptorchid testes, and absence of the olfactory bulbs, but Kallmann described a familial pattern in 1944 (Fig. 26.40). The prevalence is 1 of every 10,000 males and 1 of every 40,000 females. Although the loss of olfaction usually correlates with the degree of GnRH deficiency, even in complete anosmia (found in the classic KAL1 form), the GnRH deficiency may be partial (see "Isolated Luteinizing Hormone Deficiency").[486] Because affected individuals often do not notice impaired olfaction, testing with graded dilutions of pure scents is necessary to determine partial anosmia. Patients with Kallmann syndrome have diminished or absence of nocturnal pulses of gonadotropins found in normal prepubertal boys, although daytime values are equal. Undescended testes are common in this and all types of hypogonadotropic hypogonadism in boys.[483] The magnitude of the GnRH deficiency correlates with the size of the testes. Micropenis occurs in about one-half of males with Kallmann syndrome because of absence of the elevated pituitary gonadotropins characteristic of the normal midgestation fetus (Fig. 26.41).

Associated defects that are inconsistently present include cleft lip, cleft palate, imperfect facial fusion, seizure disorders, short metacarpals, pes cavus, neurosensory hearing loss (rarely found in the X-linked form), cerebellar ataxia and nystagmus, ocular motor abnormalities, unilateral or rarely bilateral renal aplasia or dysplasia, and mirror movements of the upper extremities (i.e., bimanual synkinesia), limited to the X-linked form (see Table 26.18).

KAL1. In classic, X-linked KAL1, fetal GnRH neurosecretory neurons do not migrate from the olfactory placode to the medial basal hypothalamus, where they normally constitute the

TABLE 26.18 Features of Kallmann Syndrome

Clinical

GnRH deficiency: absent or arrested puberty
Anosmia or hyposmia
In infancy: microphallus; cryptorchidism
Normal stature and growth in childhood
Normal adrenarche
Eunuchoid proportions
Associated midline defects (e.g., cleft lip, cleft palate, midline cranial anomalies)
MRI: aplasia or hypoplasia of olfactory bulbs and/or sulci

Prevalence

Approximately 1 in 7500 males, 1 in 50,000 females; 10% prevalence of Klinefelter syndrome

Inheritance

Sporadic and familial cases; genetic heterogeneity
X linked
- X-linked recessive (Kallmann et al)
- X chromosome deletion: Xp22.3 (Meitinger et al)

Autosomal
- Dominant (sex limitation) (Santen and Paulsen; Merriam et al)
- Recessive (White et al)

Anatomy

Developmental field defect
Aplasia or hypoplasia of olfactory bulb and sulcus
Arrested migration of GnRH neurosecretory neurons from olfactory placode to medial basal hypothalamus

GnRH, Gonadotropin-releasing hormone; *MRI,* magnetic resonance imaging.

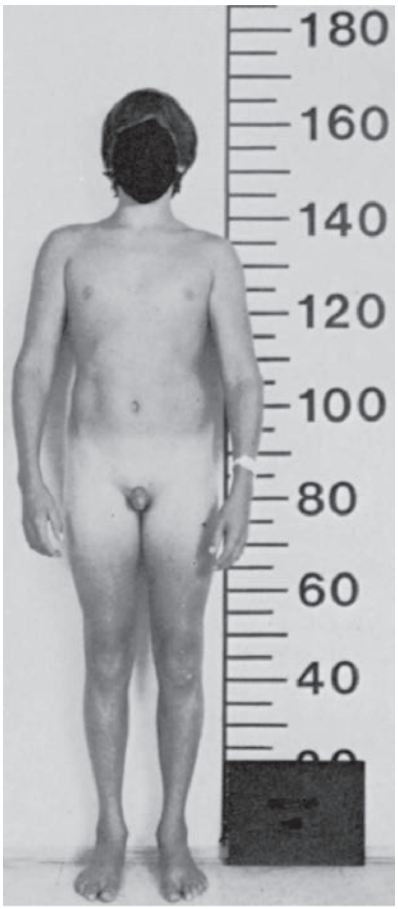
• **Fig. 26.39** A girl aged 18 years and 8 months has isolated gonadotropin deficiency (i.e., sexual infantilism and primary amenorrhea). Her height is 173 cm (+1 SD [standard deviation]), weight was 66.5 kg (+1 SD), and the skeletal age was 13 years. Adrenarche with pubic hair development occurred at age 13.5 years. At the time of the photograph, pubic hair was in stage 3, and there was slight breast and nipple development resulting from a previous short course of estrogen therapy. Immature labia minora and majora were observed, and no estrogen effect was seen on the vaginal mucosa. Olfactory testing results were normal. The plasma luteinizing hormone (LH) (LER-960) level after gonadotropin-releasing hormone (GnRH) administration rose from 0.5 to 1.8 ng/mL (a prepubertal response). Serum estradiol was undetectable. The dehydroepiandrosterone sulfate (DHEAS) level was 92 μg/dL (appropriate for pubic hair stage 2). Notice the discrepancy between adrenarche and gonadarche. For conversion to SI units, see Figs. 26.19 and 26.30. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*. 2nd ed. Philadelphia, PA: WB Saunders; 1986:313–384.)

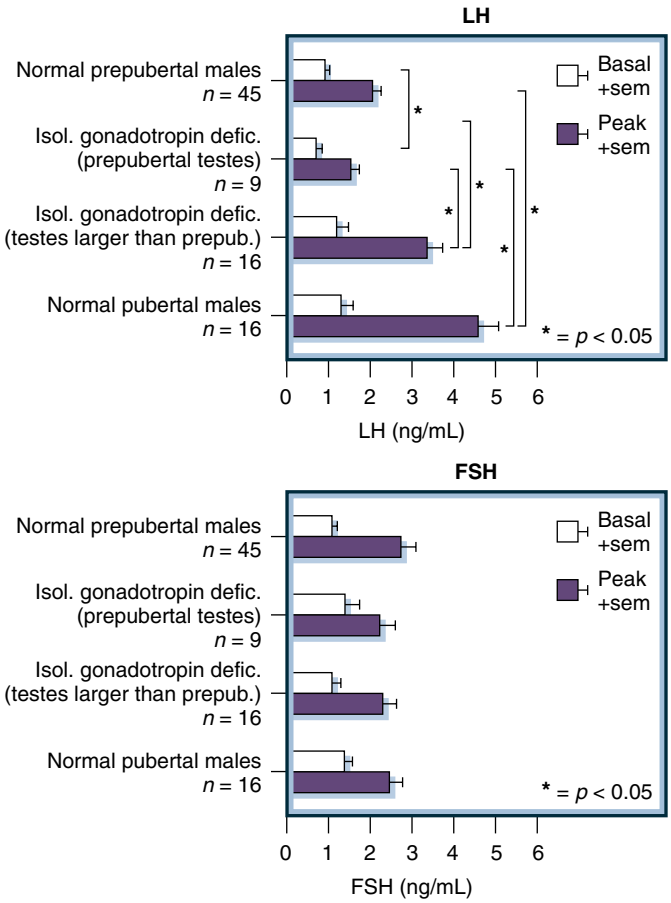
GnRH pulse generator, but instead end in a tangle around the cribriform plate and in the dural layers adjacent to the meninges beneath the forebrain.[372] Abnormal or absent olfactory bulbs or folds are seen on MRI scans with other changes in brain morphometry resulting.[487] Coronal and axial cranial MRI scans of the olfactory bulbs and sulci, unilaterally or bilaterally, reflect this defect in about 90% of cases and can point to the diagnosis, especially in affected infants and prepubertal-age children (Fig. 26.42).

An increasing number of genes are implicated in Kallmann syndrome, starting from the classic *ANOSM1* (previously *KAL1*) gene in the X-linked form first described, but only 30% of patients can be shown to have an identifiable gene defect. Further digenetic and oligogenetic inheritance is now recognized and may explain the genetic heterogeneity of the syndrome and the variation in phenotype encountered within a family—that is, 10% to 20% of IHH are explained with oligogenetic inheritance. Recently, mutations in genes "synexpressed" with fibroblast growth factor 8 were found in IHH and Kallmann syndrome (*FGF17, IL17RD, DUSP6, SPRY4*, and *FLRT3*), supporting this oligogenetic nature of the condition.[488]

A variety of deletions and mutations of the *ANOSM1* gene have been described, including large and small (exon) deletions, point mutations, and a variety of nonsense mutations leading to frameshift and premature stop codons. The ANOSM1 mutations are more prevalent in Japanese than in white patients, and they can be associated with normal olfactory function.[489] The defect in some rare patients with no ANOSM1 mutation but X-linked inheritance may be located in the promoter region of the *ANOSM1* gene. Kallmann syndrome associated with X-linked ichthyosis caused by steroid sulfatase deficiency, mental retardation, and chondrodysplasia punctata occurs in a contiguous gene syndrome. Only 14% of familial cases and 11% of sporadic cases involve mutations in the *ANOSM1* gene on the X chromosome,



• **Fig. 26.40** A boy aged 15 years and 10 months had isolated gonadotropin deficiency and anosmia (Kallmann syndrome). He had undescended testes, but after administration of 10,000 U of human chorionic gonadotropin (hCG), the testes descended and were palpable in the scrotum. His height was 163.9 cm (+1.5 SD [standard deviation]); the upper-to-lower body ratio was 0.86, which is eunuchoid. The phallus measured 6.3 × 1.8 cm, and the testes were 1.2 × 0.8 cm. The concentration of plasma luteinizing hormone (LH) was less than 0.3 ng/mL; the follicle-stimulating hormone (FSH) level was 1.2 ng/mL; and the testosterone level was 16 ng/dL. After 100 μg of gonadotropin-releasing hormone (GnRH), the plasma LH level (LER-960) was 0.7 ng/mL, and the FSH level (LER-869) was 2.4 ng/mL. For conversion to SI units, see Figs. 26.19 and 26.20. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*. 2nd ed. Philadelphia, PA: WB Saunders; 1986:313–384.)

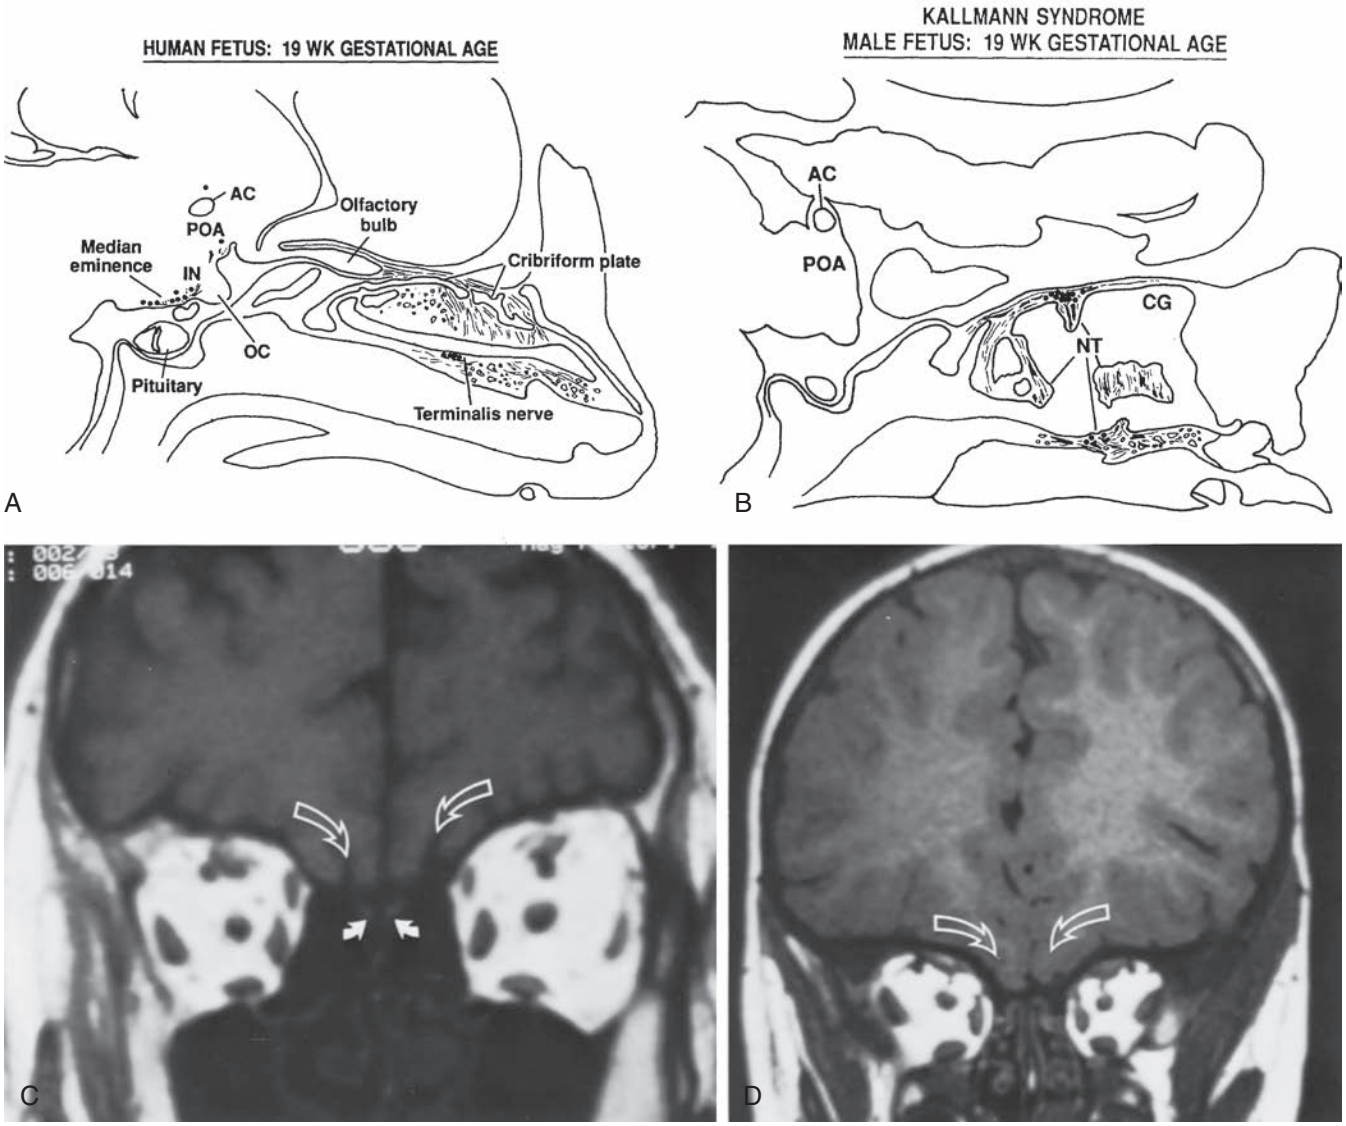


• **Fig. 26.41** Serum luteinizing hormone (LH) and follicle-stimulating hormone (FSH) responses to the administration of gonadotropin-releasing hormone (GnRH) in 25 males with an isolated gonadotropin deficiency with or without anosmia were segregated according to whether the volume of the testes was prepubertal or greater than 2.5 cm^3. Testicular volume in those with testes larger than 2.5 cm^3 was as large as 4 cm^3. Basal and GnRH-stimulated gonadotropin levels after the intravenous injection of 100 μg GnRH (peak value) are shown (p <0.05). For conversion to SI units, see Fig. 26.16. *sem,* standard error of the mean. (From Van Dop C, Burstein S, Conte FA, et al. Isolated gonadotropin deficiency in boys: clinical characteristics and growth. *J Pediatr.* 1987;111:684–692.)

but these patients are more likely to have complete absence of gonadotropin secretory pulses and absence of migration of GnRH neurons to the hypothalamus.[490] Hypogonadotropic hypogonadism is rarely caused by a mutation in the *ANOSM1* gene in females.

KAL2. The autosomal dominant form is known as Kallmann syndrome type 2 (KAL2), and the associated gene is fibroblast growth factor receptor 1 (*FGFR1*, previously *KAL2*) with a gene map locus of 8p11.2-p11.1 and its ligand FGF8. Mutations result in autosomal dominant Kallmann syndrome, autosomal dominant normosmic hypogonadotropic hypogonadism, or delayed puberty. Evaluation of FGF8 in patients with idiopathic hypogonadotropic hypogonadism revealed inactivating mutations of FGF17, IL17RD, DUSP6, SPR-Y4, and FL-RT3.[488] A Kallmann syndrome patient had a premature termination of FGFR1 resulting in a soluble receptor with dominant negative effect, which produced a truncated FGFR1 without the transmembrane and intracellular domains.[491] Intracerebral administration of anti-FGFR1 antibodies causes weight loss in rodents; FGF21, which is secreted by the liver under the stimulatory effects of beta-klotho (KLB), an obligate coreceptor mediating FEF21 signaling, is also involved in nutritional metabolism. While there is to date no report of mutation FGF21 causing hypogonadism, mutations in KLB impair FGF21 signaling leading to GnRH deficiency of various degrees of severity.[492] Since KLB and FGF21 genes are expressed on GnRH neurons, they may provide a means in which GnRH neurons can detect nutritional status and determine whether it is appropriate to allow reproduction to progress or cease.[493]

KAL2 is associated with developmental delay, choanal atresia, short stature, congenital heart defects, and sensorineural hearing loss, and its presentations are more varied than those of KAL1.



• **Fig. 26.42** Comparison of the brain and nasal cavities of a normal 19-week-old male fetus (A) and those of a male fetus of similar age with Kallmann syndrome caused by an X chromosome deletion at Xp22.3 (B). In the normal fetal brain, the gonadotropin-releasing hormone (GnRH) neurosecretory neurons *(black dots)* are located in the hypothalamic area, including the medial basal hypothalamus, the anterior hypothalamic area, and of interest regarding hypothalamic hamartoma as an ectopic GnRH pulse generator, the premammillary and retromammillary areas. A small cluster of GnRH neurons exists among the fibers of the terminalis nerve on the floor of the nasal septum. In the male fetus with Kallmann syndrome, no GnRH neurons were detected in the hypothalamic region, including the basal hypothalamus, median eminence, and preoptic area. The GnRH cells fail to migrate to and enter the brain from their origin in the nose; these cells end in a tangle beneath the forebrain on the dorsal surface of the cribriform plate and in the nasal cavity. *AC,* anterior commissure; *CG,* crista galli; *IN,* infundibular nucleus; *NT,* terminalis nerve; *OC,* optic chiasm; *POA,* preoptic area. (C and D) show magnetic resonance imaging scans of brain (coronal section, TI-weighted image). (C) Normal olfactory sulci *(open arrows)* and bulbs *(solid arrows)* in a 15-year-old boy. (D) Absent olfactory sulci *(open arrows)* and bulbs in a 17-year-old, anosmic, sexually infantile boy with Kallmann syndrome.

The loss-of-function mutation of the *FGFR1* gene interferes with migration of the olfactory cells to the olfactory bulb. Anosmin-1, a neuronal protein, may act through *FGFR1* to bring about FGF signaling. ANOSM1 partially escapes inactivation in females, and it is postulated that enough ANOSM1 may be produced in affected females, despite *FGFR1* haploinsufficiency, to maintain adequate FGF signaling and allow olfactory function and GnRH neuron migration. One kindred of Kallmann syndrome contained four women with *FGFR1* mutations that were transmitted to affected male offspring, although the mothers had normal reproduction and olfaction.[494]

Although gain-of-function mutations of the *FGFR1* gene are associated with craniosynostosis, a loss-of-function mutation is not associated with lack of fusion of the cranial sutures. One kindred with an *FGFR1* mutation (Arg622X) in the tyrosine kinase domain, in which some of the manifestations were temporary, is

reported; the mother of the proband had delayed puberty, and the maternal grandmother had anosmia, whereas the proband with KAL2 exhibited normal LH levels, testosterone production, and spermatogenesis after prior testosterone therapy.[495]

Studies of mice revealed that the early emergence of GnRH neurons from the embryonic olfactory placode requires FGF8 signaling as a ligand mediated through *FGFR1*.[496] About 30% of FGF8/FGFR1 loss-of-function mutations are associated with cleft palate, whereas *FGFR1* mutations may rarely lead to cartilage abnormalities in the ears, nose, or digits.[496] An unusual kindred with a proband demonstrating severe ear anomalies, mandibular hypoplasia, thoracic dystrophia, and other usual findings was associated with an Arg622 mutation in the *FGFR1* gene, and investigation for hypogonadism is indicated when such facial abnormalities occur.[497] Prevalence of *FGFR1* mutations in the Japanese population is equal to the prevalence among whites. Although renal aplasia is characteristic of ANOSM1 mutations, and cleft palate and dental agenesis are characteristic of *FGFR1* mutations in KAL2, these findings can occur in Kallmann patients without ANOSM1 or *FGFR1* mutations.[489]

KAL3. Apparent autosomal recessive inheritance characterizes other kindreds with Kallmann syndrome type 3 (KAL3), for which the affected gene is *PROKR2*. Unilateral renal agenesis, hypotelorism, cleft lip and palate, and a midline cranial fusion defect occur. Fibrous dysplasia, sleep disorder, severe obesity, synkinesia, and epilepsy are described in patients with *PROK2* or *PROKR2* mutations, and 3% of IHH patients were affected in one study. Knockout mice lacking the *PROK2* gene (formerly called *KAL4*), which encodes prokineticin 2, an 81–amino acid peptide that signals through the G protein–coupled product of the *PROKR2* gene (formerly called *KAL3*), had defective development of the olfactory bulbs and failed migration of GnRH neurons.[498] This model led to demonstration of loss-of-function mutations in *PROKR2* or *PROK2* in 9% of patients with Kallmann syndrome,[499] who were mostly heterozygous, although homozygous and compound heterozygous mutations were also described. Some families appear to have autosomal dominant inheritance.

Other Forms of Kallmann Syndrome. The human equivalent of the mouse nasal embryonic GnRH factor gene *(Nelf)* is *NELF*; a mutation of this gene is found in patients with IHH and in Kallmann syndrome.[500]

A mutation in the binding domain of the membrane coreceptor neuropilin-1 *(SEMA3A)* gene is found in Kallmann syndrome in an autosomal dominant pattern.[501] This mutation was found in some patients who already had mutations in other Kallmann syndrome genes, further suggesting the oligogenic nature of the disorder. Semaphorin 3E (SEMA3E) is a protein involved with axonal growth, and missense mutations were found in two brothers with Kallmann syndrome.[502]

About 30% of Kallmann syndrome patients have hearing impairment, and of those about 38% have heterogeneous mutations of the *SOX10* gene.[503] Deafness may also be found in the CHARGE syndrome (discussed later), but in the absence of other CHARGE findings a search for a mutation in *SOX10* is indicated.

Mutations in heparin sulfate 6-*O*-sulfotransferase 1 *(HS6ST1)* are found in patients and families with IHH and Kallmann syndrome.[504,505] This abnormality is found in complex inheritance patterns as patients may also have mutations in *FGF1* and *NELF*. Thus *HS6ST1* mutations may not be sufficient to cause disease but may add to it.

Recently, Kallmann syndrome has been linked to mutations in *HESX1* (found in septo-optic dysplasia, discussed later)[506] and *FEZF1*.[507]

Congenital hypogonadotrophic hypogonadism can be associated with many other clinical features not involving the reproductive system. The CHARGE syndrome is characterized by coloboma or microphthalmia, coloanal stenosis or atresia, middle and inner ear defects, various cranial nerve defects (including anosmia or hyposmia [including absent olfactory bulbs]), and IHH. In autosomal dominant familial cases, causative mutations were found in *CHD7*, which encodes a chromatin-remodeling factor, which in a small percentage of cases were found in patients with Kallmann syndrome and in some patients with IHH due to apparent loss-of-function mutations. Hypogonadotropic hypogonadism may be more frequent if there is deafness and hypoplasia of the semicircular canals.[508]

Patients with demyelinating sensorimotor polyneuropathy, developmental delay, and severe hypoglycemia initially, with later nonautoimmune insulin-dependent diabetes mellitus, had mutations in DMXL2, which codes for rabconnectin-3α.[509]

Kallmann syndrome has been reported in patients with heterozygous mutations in the WDR11 gene, which is involved in the development of olfactory neurons.[502,510]

The protein CCDC141 is expressed in GnRH neurons and in the back in activating mutations led to normal osmotic hypogonadotropic hypogonadism.[511] Mutations in FEZF1 were found in two families with Kallmann syndrome.[507] This gene promotes the expression of a protease, which allows the olfactory receptor neurons to enter the brain along with GnRH neurons.

Mutations in SMC-HD1 led to the absence of the nose in 41 individuals, most of whom had hypogonadism along with anosmia.[512]

The Gordon Holmes syndrome presents with congenital hypogonadotropic hypogonadism, normosmia, and cerebellar atrophy/ataxia; this syndrome is associated with mutations in the *OTUD4, RNF216,* and *PNPLA6* genes.[513]

The various forms of Kallmann syndrome result from heterogeneous mutations in which the phenotype can vary. For example, a 20-year-old man with the complete picture of Kallmann syndrome had an identical twin brother (proved by genetic fingerprinting) with anosmia but a normal adult phenotype and normal plasma testosterone and gonadotropin concentrations.

Other postulated defects that may interfere with GnRH neuron migration are mutations in the genes for neural cell adhesion molecules (NCAM) and related proteins, such as tenascin, laminin, and phosphacan. Various glycoconjugates may also be involved.

Other Forms of Isolated Hypogonadotropic Hypogonadism. Only about 15% of normosmic hypogonadotropic patients have a definable genetic defect. The combination of human genetic studies and mouse models has led to the discovery of many genes involved in gonadotropin regulation.[514] Inheritance of hypogonadotropic hypogonadism (Table 26.19) with none of the other features of Kallmann syndrome may be found in autosomal dominant (gene map locus 19p13.3, 9q34.3), autosomal recessive (8p21-p11.2), or X-linked recessive (Xp21)[515,516] disorders. Males with cerebellar ataxia and deficient gonadotropin production are reported in kindreds with X-linked inheritance (possibly a variant form of Kallmann syndrome), and hypogonadotropic hypogonadism may be associated with the multiple lentigines and basal cell nevus syndromes.

Gonadotropin-Releasing Hormone Gene Mutations. The GnRH gene *(GNRH1)* would seem a likely candidate for the cause of hypogonadotropic hypogonadism, but although mutations of the GnRH

TABLE 26.19 Molecular Basis for Developmental Disorders Associated With Hypogonadotropic Hypogonadism

Gene	Phenotype	Complex Phenotype
	ISOLATED HYPOGONADOTROPIC HYPOGONADISM	
Kallmann Syndrome or Normosmic IHH (With the Same Mutant Gene)		
KAL1 (Xp22.3)	X-linked Kallmann syndrome	Anosmia/hyposmia, renal agenesis, dyskinesia
FGFR1 (KAL2) (8p11.2)	Autosomal dominant Kallmann syndrome (± recessive)	Anosmia/hyposmia, cleft lip/palate
FGF8 (ligand for FGFR1) (10q25)		
NELF (9p34.3)	Autosomal dominant (?) Kallmann syndrome	
PROK2 (3p21.1)	Autosomal recessive Kallmann syndrome	
PROKR2[a] (20p12.3)		
CHD7 (8p12.1)	Autosomal dominant (some)	CHARGE syndrome includes hyposmia
Normosmic Isolated Hypogonadotropic Hypogonadism		
GNRH1 (8p21-11.2)	Autosomal recessive	
GNRHR[a] (4q13.2-3)	Autosomal recessive (± dominant)	
GPR54[a] (19p13.3)	Autosomal recessive	
SNRPN		Prader-Willi syndrome
Lack of function of paternal 15q11-q13 region or maternal uniparental disomy		Obesity
LEP (7q31.3)	Autosomal recessive	Obesity
LEPR (1p31)	Autosomal recessive	Obesity
NR0B1 (DAX1) (X21.3-21.2)	X-linked recessive	Adrenal hypoplasia
TAC3 (12q13-12)	Autosomal recessive	
TACR3 (4q25)	Autosomal recessive	
Multiple Pituitary Hormone Deficiencies		
PROP1 (POU1F1)	Autosomal recessive GH, PRL, TSH, and LH/FSH (less commonly, later-onset ACTH deficiency)	
HESX1 (RPX)	Autosomal recessive; and heterozygous mutations	Septo-optic dysplasia
	Multiple pituitary deficiencies, including diabetes insipidus, but LH/FSH uncommon	
LHX3	Autosomal recessive GH, PRL, TSH, FSH/LH	Rigid cervical spine
PHF6	X linked; GH, TSH, ACTH, LH/FSH	Börjeson-Forssman-Lehmann syndrome: mental retardation; facies

[a]A G protein–coupled receptor.

See text for details.

receptor gene *(GNRHR)* were identified years ago, mutations in the *GNRH1* gene were not demonstrated until 2009. An autosomal recessive form had been described in the mouse (hyg/hyg), in which there is a deletion of part of the GNRH gene. There appears to be normal migration of GnRH neurons to the medial basal hypothalamus based on information from the mouse model.[517]

GNRH1 mutation is a very rare condition with a prevalence of under 1% in isolated populations and probably far lower in the general population. A homozygous *GNRH1* frameshift mutation in human beings, characterized by the insertion of an adenine at nucleotide position 18 (c.18-19insA) in the sequence encoding the N-terminal region of the signal peptide–containing protein

precursor of GnRH (prepro-GnRH), was found in a teenage brother and sister who had normosmic IHH.[518] When expressed in vitro, the mutant peptide did not demonstrate immunoreactive GnRH. Only 1 of 310 patients with severe, congenital, normosmic IHH (with micropenis, bilateral cryptorchidism, and absent puberty) had a homozygous frameshift mutation that is predicted to disrupt the three C-terminal amino acids of the GnRH decapeptide and to produce a premature stop codon.[517] Of four patients with normosmic IHH, one had a nonsynonymous missense mutation in the eighth amino acid of the GnRH decapeptide; one had a nonsense mutation that causes premature termination within the GnRH-associated peptide (GAP), which lies C-terminal to the GnRH decapeptide within the GnRH precursor; and two had sequence variants that cause nonsynonymous amino acid substitutions in the signal peptide and GnRH-associated peptide.

Gonadotropin-Releasing Hormone Receptor Mutations. Mutations of the gene encoding the type 1 GnRH receptor (*GNRHR*, gene map locus 4q21.2) that affect the G protein–coupled, seven-transmembrane segments lead to various degrees of familial and sporadic hypogonadotropic hypogonadism with normosmia. A *GNRHR* mutation is found in about 40% to 50% of cases of familial, autosomal recessive, normosmic IHH and in about 17% of sporadic cases of normosmic IHH.

Mutations in hypergonadal hypogonadism with amino acid substitutions in the extracellular N-terminal domain (Thr32Ile), the second extracellular loop (Cys200Tyr), the third intracellular loop (Leu266Arg), and the sixth transmembrane helix (Cys279Tyr) were found to affect specific GnRH binding.[519,520] Except for Thr32Ile, there was no significant inositol phosphate accumulation after GnRH stimulation, demonstrating loss of function even if binding was accomplished. However, an increased dose of GnRH allowed stimulation of the gonadotropin subunit and GnRHR promoters and the ability to partially activate extracellular signal-regulated kinase 1 and stimulate cAMP response element (CRE)–luciferase activity. A higher dose of GnRH caused the Cys200Tyr mutant to stimulate gonadotropin subunit and GnRHR promoter activity because this mutant reduces cell surface receptor expression.

Another human GnRH receptor *(GNRHR)* gene mutation of a highly conserved sequence located in the second-transmembrane helix impairs *GNRHR* effector coupling due to loss of surface expression of the receptor and leads to a severe manifestation of IHH.[521]

Certain GnRH receptor defects may be rescued by membrane-permeant pharmacologic agents that can act as a folding template (chaperones) that rescue the structural defects caused by the mutations and allow function to occur (i.e., ligand binding and restoration of receptor coupling to effector).[522] This approach may allow a therapeutic approach to conditions caused by this and other mutations in receptors that result in protein misfolding.

The clinical presentation of patients with mutations in the GnRH receptor is heterogeneous, and impairment of signal transmission is highly variable (e.g., severe features of IHH, sexual infantilism, long-delayed puberty with reversal in adulthood, relatively mild hypogonadism and infertility), even within the same pedigree and especially in patients with compound heterozygous mutations. For example, two women with a normal pubertal history with hypothalamic amenorrhea had mutations in the *GNRHR* gene[523] while the other had mutations in the *FGFR1, PROKR2,* and *ANOSM1* genes. When the mutation is homozygous, the phenotype is related to the number of mutations. However, when it is monoallelic, there is no relationship, which indicates that other genes interact with the single allelic mutation in *GNRH1*.[524] Biallelic mutations in *GNRHR* were found in two girls (compound heterozygous c.317A>G p.[Gln106Arg] and c.924_926delCTT p.[Phe309-Del] and homozygous c.785G>A p.[Arg262Gln]) with incomplete pubertal development or secondary amenorrhea, and twin boys with incomplete pubertal development had compound heterozygous for GNRHR mutations c.317A>G p.(Gln106Arg) and c.785G>A p.(Arg262Gln).[525] With the increasing number of mutations of the GnRH receptor found in partial and reversible normosmic IHH, this gene is suggested to be the first to evaluate in such cases.[526] In all types of congenital gonadotropin deficiencies, male patients are likely to manifest micropenis (penile length <2 cm at birth and in infancy) due to lack of fetal gonadotropin stimulation of fetal testes during the last half of gestation. Boys with congenital GH deficiency have micropenis even if gonadotropin function is normal. Because testosterone therapy is effective in increasing penile size (see later discussion), sex reversal is not indicated in these cases of microphallus.[527]

KISS1/KISS1R Axis Mutations. The KISS1/KISS1R axis plays a role in the increased amplitude of GnRH signaling in puberty. KISS1/KISS1R axis mutations are rare but instructive. Of 30 normosmic subjects with hypogonadotropic hypogonadism who were evaluated, one person had two missense mutations in KISS1R (Cys223Arg in the fifth transmembrane helix and Arg297Leu in the third extracellular loop); the former had no activity, and the latter manifested as mildly decreased signaling ability.[528] Homozygous deletions of 155 nucleotides in the *KISS1R* gene encompassing the splicing acceptor site of the intron 4–exon 5 junction and part of exon 5 were found in all affected family members with IHH,[529] but unaffected family members had no deletion or only one mutant allele. Another kindred had a Leu48Ser mutation in the second intracellular loop (IL2) of KISS1R, and another had two separate mutations in the gene,[352] Arg331Xaa and Xaa399Arg. The latter patient had decreased secretion of GnRH and decreased response to GnRH administration. A line of mice transfected with the affected gene exhibited hypogonadotropic hypogonadism with decreased GnRH in the hypothalamus but were responsive to GnRH or gonadotropin administration. Agonist stimulation may stabilize the switch II region of Gα to promote the opening of Gα switch II to facilitate exchange of guanosine diphosphate (GDP) and guanosine triphosphate (GTP).[530] The Leu148Ser mutation does not affect the expression, ligand-binding properties, or protein interaction network of KISS1R, but diverse KISS1R functional responses are markedly inhibited.

X-Linked Congenital Adrenal Hypoplasia and Hypogonadotropic Hypogonadism. A rare deletion or mutation in the dosage-sensitive sex reversal-A (DSS) adrenal hypoplasia congenita gene on the X chromosome gene 1 (*NR0B1*, formerly called *DAX1*; gene map locus Xp21.3-p21.2) leads to an X-linked recessive disorder of adrenocortical organogenesis.[531] The gene encodes an orphan receptor, a member of the nuclear receptor superfamily, that is a putative transcriptional repressor mapping to the Xp21 locus. A double dose of *NR0B1* is associated with a female phenotype or ambiguous genitalia in 46,XY males. The NR0B1 protein has a novel domain in the N-terminus that contains two putative unique zinc finger motifs, and the C-terminus contains a conserved ligand-binding domain that binds DNA, localizes in the nucleus, and contains a transcriptional silencing domain that antagonizes the steroidogenic factor 1 (SF1, also called NR5A1) transactivation function. NR0B1 has an SF1 response element in the 5′-promoter region that is another orphan member of the nuclear hormone receptor superfamily. Both NR0B1 and SF1 are expressed in the adrenals, gonads,

pituitary, and hypothalamus, raising the possibility of an important interaction between these two genes and their products.

Rare abnormalities of NR0B1 are characterized by severe glucocorticoid, mineralocorticoid, and, at puberty, androgen deficiency. The abnormal structure of the adrenal cortex resembles that of the fetal zone because it consists of disorganized, vacuolated, cytomegalic cells with a normal mature cortex. The severe primary adrenal insufficiency with hyponatremia, hyperkalemia, acidosis, and hypoglycemia is characterized by failure to thrive, vomiting, poor feeding, dehydration, circulatory collapse, and increased pigmentation and is lethal if not treated early in life in affected boys.

Adrenoleukodystrophy may manifest with adrenal failure long before neurologic symptoms develop, and some cases of X-linked Addison disease may represent this diagnosis. This condition is in the differential diagnosis of adrenal hypoplasia. Plasma renin activity is high; plasma cortisol and aldosterone levels are low. Symptomatic adrenal insufficiency may first manifest in later childhood. In male infants, signs of salt wasting are usually the most prominent feature, but cortisol deficiency is detectable, and adrenal insufficiency includes deficient secretion of the zona reticularis steroids, DHEA and DHEAS. An early sign of elevated ACTH is increased skin pigmentation. The testes are undescended in fewer than one-half of patients; micropenis is rare, but urogenital abnormalities and hearing loss occasionally are present. Boys who do not present with clinical evidence of adrenal insufficiency in infancy often have a more insidious onset during childhood or adulthood.

In a pedigree in which two affected boys had a hemizygous *NR0B1* nonsense mutation and neonatal onset of adrenal insufficiency, a maternal aunt who was homozygous for the mutation had sexual infantilism and primary amenorrhea, but even after decades of follow-up, she maintained normal adrenal function. A maternal grandfather who carried the same mutation was asymptomatic.[532] This pedigree highlights the limitations and complexities of genotype and phenotype correlations. Most commonly, due to hypogonadotropic hypogonadism, signs of sexual maturation at the age of puberty (e.g., pubic and axillary hair, testicular enlargement) are lacking, and the concentrations of serum FSH, LH, and testosterone are low. Delayed puberty is a manifestation in some female carriers of a *NR0B1* mutation.

Intragenic mutations in *NR0B1* (i.e., frameshift mutations, nonsense mutations, and missense mutations) indicate that the hypogonadotropic hypogonadism is an intrinsic characteristic of the disorder, a manifestation of the single-gene mutation and not a result of involvement of a contiguous gene. The *NR0B1* gene is expressed in the adrenal cortex, in testes (and weakly in the ovary), and in the hypothalamus and pituitary. There is evidence of GnRH deficiency and an abnormality in the gonadotrophs, yielding a mixed picture of hypothalamic and intrinsic gonadotroph defects with absent or erratic pulsatile secretion of LH. Even if basal immunoreactive LH and FSH levels are normal, gonadotropins seem to lack bioactivity. In some affected boys, the GnRH pulse generator and pituitary gonadotropin apparatus is intact and functional in infancy and early childhood, and the GnRH-gonadotroph defects do not manifest until later in childhood or during the peripubertal period. Azoospermia unresponsive to gonadotropin treatment was detected in a few affected men.[508,515,533,534]

A deletion of the adrenal hypoplasia congenita locus (at Xp21) can include the glycerol kinase *(GK)* and Duchenne muscular dystrophy *(DMD)* genes if it extends centromerically or produce developmental delay if there is extension toward the telomere, leading to contiguous gene syndromes.

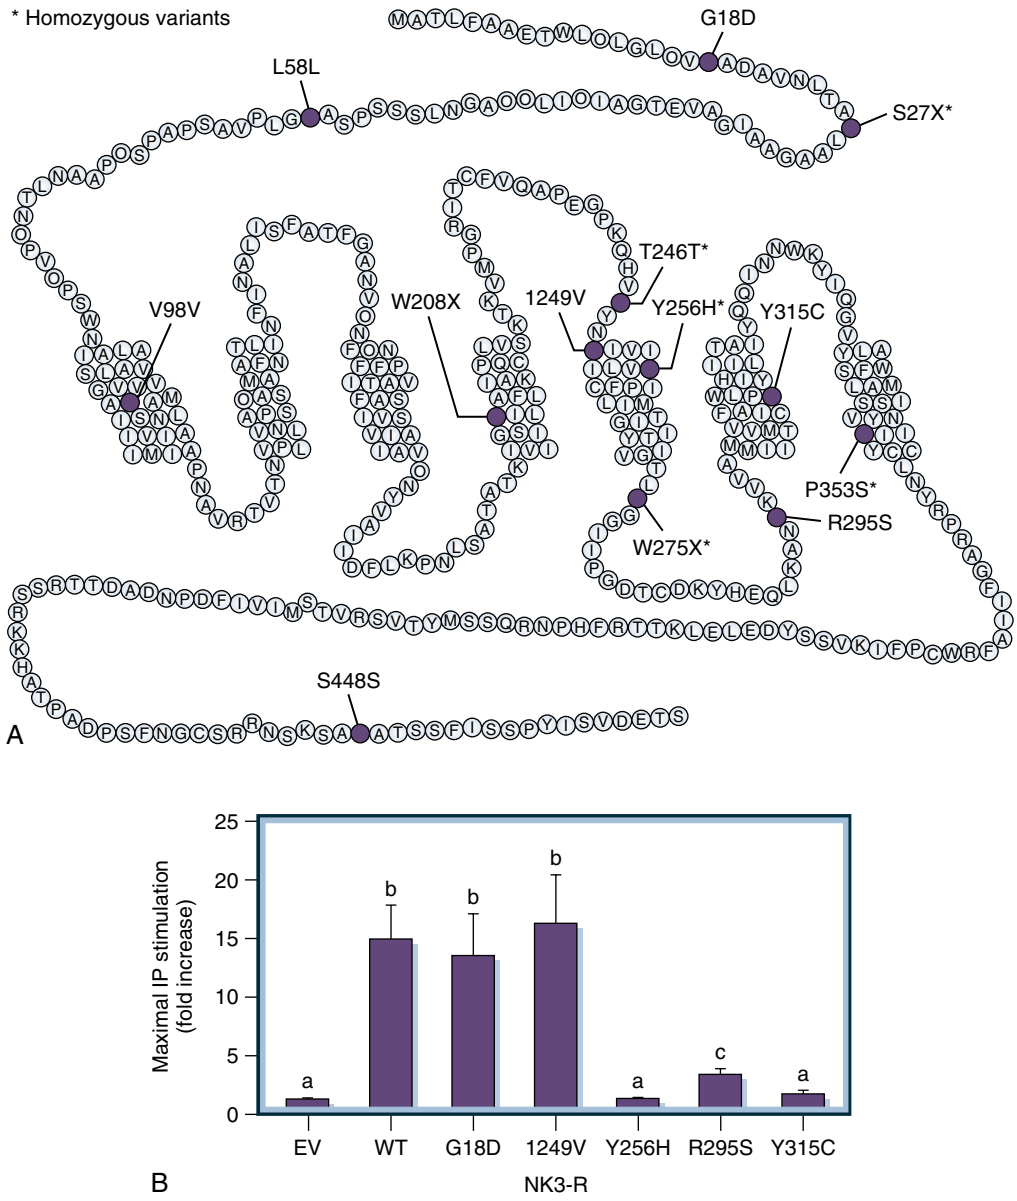
Other mutations of the X chromosome may be associated with IHH. Two brothers were reported who had hypogonadotropic hypogonadism, obesity, and short stature associated with a maternally inherited pericentric inversion (X) (p11.4q11.2). Because the breakpoint is not related to other genes associated with pubertal disorders, it is not clear whether this is a functional relationship or a coincidence.[535]

The *TAC3* gene codes for tachykinin-3, which is cleaved to neurokinin B, a member of the tachykinin superfamily of 127 neuropeptides that includes substance P and neurokinin A. Its cognate G protein–coupled receptor 126 is neuromedin-K receptor 3 (NK3R), which is encoded by TACR3. There are neurons in the arcuate nucleus of the hypothalamus that coexpress kisspeptins and NKB, the kisspeptin/NKB/Dyn (KNDy) neurons that also express dynorphin A (endogenous opioid peptide) and NK3R.[536] Loss-of-function mutations occur in this system in familial, congenital hypogonadotropic hypogonadism; administration of pulsatile GnRH caused resumption of gonadotropin secretion[537–539] (Fig. 26.43). A survey of 345 patients with normosmic hypogonadotropic hypogonadism found 13 rare, distinct nucleotide sequence coding variants (three nonsense, six nonsynonymous, and four synonymous mutations [one predicted to affect splicing]) in *TACR3* and one homozygous single-base-pair deletion, resulting in complete loss of neurokinin B. Of the 16 males for whom phenotype information was available, 15 had microphallus, and none of the females had spontaneous thelarche. When subjects were assessed after discontinuation of therapy, six of seven males and four of five females demonstrated evidence for reversibility of their hypogonadotropism.[540] Continuous infusion of kisspeptin to two patients with loss-of-function mutations in neurokinin B (TAC3) or its receptor (TAC3R) led to pulsatile gonadotropin secretion, indicating that pulsatile administration of kisspeptin is not necessary to institute pulsatile GnRH secretion.[363]

Mutations in the prohormone convertase 1 gene (*PCSK1*, also called *PC1*) lead to extreme childhood obesity, hypocortisolemia, defects in conversion of proinsulin to insulin leading to hypoglycemia, diabetes insipidus, and isolated partial hypogonadotropic hypogonadism, allowing spontaneous pubertal development but primary amenorrhea. The hypogonadal hypogonadism probably resulted from impaired processing of GnRH or neuropeptides involved in its secretion. Findings in another subject extended to gastrointestinal disturbance, small intestinal malabsorption related to monosaccharide and fats, and elevation in progastrin and proglucagon levels, showing that prohormone processing in enteroendocrine cells was abnormal.[541]

Isolated Luteinizing Hormone Deficiency. Isolated LH deficiency (fertile eunuch syndrome) is associated with deficient testosterone production (which responds to hCG administration) and decreased virilization in the presence of mature testicular size and variable spermatogenesis; the disorder may be idiopathic or may result from a hypothalamic pituitary neoplasm. A homozygous Gln106Arg mutation in the first extracellular loop of the GnRH receptor at gene map locus 4q21.2 was associated with normal testicular volume (17 mL) but with apulsatile, low gonadotropin values and low testosterone[542] values in one subject. After hCG stimulation, he developed adequate spermatogenesis to father a child, and after cessation of hCG treatment, he demonstrated adult testosterone values and pulsatile gonadotropin secretion, an example of reversibility of the syndrome.

Isolated Follicle-Stimulating Hormone Deficiency. Homozygous or compound heterozygous mutations in the FSH β-subunit



• **Fig. 26.43** (A) Schematic of mutations in the NK3-R, which is encoded by *TAC3*. (B) Effects of mutations in *TACR3* on neurokinin B (NKB)–mediated activation of signal transduction. COS7 cells transfected with wild-type (WT) G18D, I249V, Y256H, R295S, and Y315C NK3R or empty vector (EV) were treated with NKB (10-7 M) for 1 hour. A significant increase in inositol phosphate (IP) accumulation occurred in cells transfected with WT, G18D, or I249V NK3R. In contrast, there was a marked reduction in NKB-stimulated IP production in cells transfected with Y256H, R295S, or Y315C NK3-R, or with EV. *a*, *b*, and *c* denote significantly different fold increases in IP accumulation. (From Gianetti E, Tusset C, Noel SD, et al. *TAC3/TACR3* mutations reveal preferential activation of gonadotropin-releasing hormone release by neurokinin B in neonatal life followed by reversal in adulthood. *J Clin Endocrinol Metab.* 2010;95:2857–2867.)

have been reported in three females and two males with delayed puberty or poorly developed secondary sex characteristics and with primary amenorrhea but normal adrenarche in the women.[543] The LH concentration was elevated, the serum level of estradiol was low, and immunoactive FSH was absent. Two of the three women had a homozygous nonsense mutation (Val61X) in the FSH β-subunit gene at gene map locus 11p13, and the other was a compound heterozygote (Cys51Gly/Val61X). The women had antral follicles but no progression, demonstrating that FSH action may not be necessary for development to the antral stage. The two men had azoospermia; small, soft testes; and absence of serum FSH. One had normal puberty and normal LH and testosterone values, with a missense mutation (Cys82Arg), and the other had slightly delayed puberty, low testosterone and inhibin B levels, high LH levels, and a nonsense mutation (Val61X). The low testosterone may indicate a necessity for FSH to promote testosterone production.

Follicle-Stimulating Hormone Receptor Mutations. Hypergonadotropic hypogonadism is noted with rare mutations in FSH receptors.[544] Women may have several mutations, but only five men are described as homozygous for the Finnish p.Ala189Val *FSHR* gene mutation. Although the affected women had amenorrhea, some of the men were fertile and all progressed through puberty with normal or slightly small testes. The defect in the

FSH receptor appears to be less severe than the absence of the ligand. Variations in FSHR are associated with age of thelarche in healthy Danish girls, while variance in LIN28B is related to age of menarche and thelarche; this demonstrates a differential impact of specific gene loci on age of thelarche and menarche.[545]

Developmental Defect of the Midline

Septo-optic or optic dysplasia is caused by abnormal development of the prosencephalon, leading to small, dysplastic, pale optic discs with a double outline and pendular (evenly moving side to side) nystagmus; blindness may occur. The prevalence is 1.9 and 2.5 per 100,000 births.[546] A midline hypothalamic defect may cause GH deficiency, diabetes insipidus, and ACTH, TSH, and gonadotropin deficiency. Short stature and delayed puberty may result, although CPP is an alternative.[546] The septum pellucidum is often absent in association with optic hypoplasia or dysplasia, which is readily demonstrable by imaging techniques.[547] In the University of California at San Francisco (UCSF) series, the syndrome was associated with decreased maternal age; recent series found maternal age of 20 to 24 years to carry the highest risk.[545] The pituitary may be hypoplastic because of the lack of hypothalamic stimulatory factors, and the neurohypophysis may have an ectopic location identified by the location of the posterior pituitary hot spot on MRI.

Abnormalities of the corpus callosum and cerebellum are common on MRI. Four groups are described: those with normal MRI results, those with abnormalities of the septum pellucidum and with a normal hypothalamic pituitary area, those with abnormalities of the hypothalamic pituitary area and a normal septum pellucidum, and those with abnormalities in both areas.[548] No endocrine abnormalities were described in the first group, but the others had progressively more endocrine abnormalities, with precocious puberty most common in the second group. Early diagnosis is important because of the risk of sudden death associated with adrenal insufficiency.

The condition is usually sporadic, but inherited cases involving transcription factors HESX1, SOX2, SOX3, and OTX2 are reported.[549]

The solitary median maxillary incisor syndrome is associated with the eponymous midline defect and with a prominent midpalatal ridge (torus palatinus) and hypopituitarism. The defect in this autosomal dominant condition is in the sonic hedgehog gene *(SHH)* at gene map locus 7q3.[550]

Other congenital midline defects ranging from complete dysraphism and holoprosencephaly to cleft palate or lip are associated with hypothalamic-pituitary dysfunction. Delayed puberty is rarely described in duplication of the hypophysis. Myelomeningocele (myelodysplasia) is associated with endocrine abnormalities, including hypothalamic hypothyroidism, hyperprolactinemia, and elevated gonadotropin concentrations, and with CPP.

Long-term follow-up of hypogonadotropic hypogonadism or partial pubertal development revealed that even with defined genetic defects, restoration of normal gonadal function, including pulsatile LH secretion and spermatogenesis in adulthood, may occur in over 20% of cases.[551,552] A recent series of 308 patients demonstrated that 22% underwent reversal.[484] One had undetectable olfactory bulbs demonstrating that this anatomic finding does not necessarily lead to long-term infertility. There was a higher prevalence of neurokinin B signaling (10%) of the subjects undergoing reversal, but none had mutations in KAL1. Five men undergoing reversal reverted back to hypogonadotropic hypogonadism. Long-term follow-up is necessary, even for patients with established anatomic and genetic defects.

• **Fig. 26.44** A 20-year-old man with idiopathic hypopituitary dwarfism and deficiencies of gonadotropins, thyrotropin, corticotropin, and growth hormone had a history of arrested hydrocephalus. His height was 129 cm (–8 SD [standard deviation]), the phallus was 2 cm long, and the testes measured 1.5 × 1 cm. He had received thyroid hormone and glucocorticoid replacement. The basal luteinizing hormone (LH) level was less than 0.2 ng/mL (LER-960), follicle-stimulating hormone (FSH) level was 0.5 ng/mL (LER-869), and testosterone level was less than 0.1 ng/mL. In response to 100 μg of gonadotropin-releasing hormone (GnRH), the plasma LH concentration increased slightly to 0.6 ng/mL, and there was no increase in the plasma testosterone level. The excretion of urinary 17-ketosteroids was 1.1 mg/24 hours. The bone age was 10 years, and the volume of the sella turcica was small on skull radiographs. For conversion to SI units, see Figs. 26.19 and 26.20. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*. 2nd ed. Philadelphia, PA: WB Saunders; 1986:313–384.)

Idiopathic Hypopituitary Dwarfism

In addition to *HESX1* mutations, autosomal recessive mutations in homeobox genes encoding transcription factors involved in the early aspects of pituitary development lead to hypogonadotropic hypogonadism and other pituitary hormone deficiencies.[553,554] *PROP1* mutations at gene map locus 5q cause GH and TSH deficiency and produce delayed puberty or late onset of secondary hypogonadism in adulthood and rarely cause ACTH deficiency (Fig. 26.44).[555] In one study of 73 patients with idiopathic multiple pituitary hormone deficiencies, 35 had a mutation in *PROP1*. Homozygous Arg73Cys mutation of *PROP1* allowed spontaneous puberty in 2 of 10 affected family members. ACTH deficiency may develop later than other deficiencies and is more rarely a feature of *PROP1* deficiency.

Homozygous mutations occur in the *LHX3* gene at gene map locus 9q34.3. It encodes a member of the LIM class of

homeodomain proteins, which are associated with multiple pituitary hormone deficiencies, including LH and FSH, and often with severe restriction of head rotation.[556] *LH4* and *GLI2* mutations may cause isolated GH deficiency or combined pituitary hormone deficiencies, including gonadotropin deficiency.[557,558]

The familial forms of multiple pituitary hormone deficiencies with autosomal recessive or X-linked inheritance are less common. The degree of hormone deficit and the age at onset of pituitary hormone deficiencies may vary within a single kindred having the same genetic defect.

The X-linked form of hypopituitarism can be associated with duplication of the *SOX3* gene.[559] Deficiency of SOX2, a transcription factor involved in early hypothalamic-pituitary embryonic development, leads to anterior pituitary hypoplasia. Patients with *SOX2* mutations have major eye abnormalities, including anophthalmia, microphthalmia, and coloboma. They also have hypogonadotropic hypogonadism as the most common pituitary defect, in contrast to most other types of pituitary hypoplasias, demonstrating GH deficiency most frequently.[560]

There is an association between breech delivery (especially for male infants), perinatal distress, and idiopathic hypopituitarism.[126] Malformations of the pituitary stalk demonstrable by MRI are common in these patients. Other types of birth traumas or complications may lead to hypopituitarism as well.

Common to many patients with congenital hypopituitary dwarfism is early onset of growth failure; late onset of diminished growth is an ominous finding, suggesting the presence of a CNS tumor.

Isolated GH deficiency allows spontaneous pubertal development when the bone age reaches the pubertal stage of 11 to 13 years, usually after the corresponding chronologic age is reached. Associated gonadotropin deficiency does not allow spontaneous puberty, even when the bone age advances to the pubertal stage during GH therapy.

Miscellaneous Conditions

Prader-Willi Syndrome. Prader-Willi syndrome is an autosomal dominant disorder that combines a tendency for intrauterine growth retardation, delayed onset and poor fetal activity, infantile central hypotonia, and lethargy, followed by early-onset childhood hyperphagia, pathologic obesity, and carbohydrate intolerance (leading to type 2 diabetes in 25% of patients at a mean age of 20 years). Features include short stature, small hands and feet, mild to moderate mental retardation, and emotional instability, including perseveration, obsessions, and compulsions. Almond-shaped eyes, a triangular mouth, and narrow bifrontal diameter combined with delayed puberty and hypogonadotropic hypogonadism caused by combined hypothalamic and gonadal dysfunction are characteristic.[561] Despite the late or absent puberty, there is a tendency to early adrenarche (14%) or even precocious puberty rarely (3.6%).

Affected boys usually have a micropenis and cryptorchidism (100% in a large series[562]), and an underdeveloped scrotum (69%) is common. In a study of 37 adults with Prader-Willi syndrome, none achieved full genital development, and primary testicular defects were suggested.[563] Serum AMH levels were near the lower limits of normal, inhibin B levels were consistently low or undetectable, and in the adults, FSH levels were high, although LH levels were normal. Two adults had undetectable levels of LH and FSH, but in contrast to the others, they had high AMH levels. Female subjects exhibit underdevelopment of the labia majora, labia minora, or clitoris (76%). Amenorrhea occurs in about one-half of cases (53%), and irregular menses or spotting is common in others. Weight reduction may lead to menarche in some females, because severe obesity may play a role in the impaired puberty in some patients. Dietary therapy during years 2 through 10 can provide effective treatment of obesity but may decrease growth, although contemporaneous GH therapy may overcome slow growth.[564]

The role of relative GH deficiency in this disorder is uncertain and controversial. The FDA approved Prader-Willi syndrome as an indication for recombinant human GH treatment without a requirement for assessing GH secretion. Genetic testing is used to confirm the clinical diagnosis of the syndrome. GH treatment (in a dose of 0.24 mg/kg/week subcutaneously given six to seven times per week) was shown in long-term, randomized, controlled trials to decrease body fat; increase fat utilization, LBM, linear growth, and energy expenditure; and possibly improve physical strength and motor development.[565] Children with Prader-Willi syndrome are at risk for sudden death due to gastrointestinal, respiratory, or cardiac complications.[566] However, the report of sudden deaths due to respiratory complications during GH treatment led to a recommendation for evaluation for sleep apnea or respiratory difficulties before instituting GH therapy. More recent data cast doubt on the beneficial effects of GH on body composition and BMI, but higher parental educational status was correlated with better clinical outcome.[986]

This distinct genetic disorder, with a frequency of about 1 case in 15,000 to 30,000 individuals, is rarely familial (i.e., the recurrence risk depends on the type of the genetic defect). It is caused by abnormalities involving the long arm of chromosome 15 in the q11-q13 region. Approximately 70% of Prader-Willi cases are caused by a paternal deletion of 15q11-q13 (commonly 3–5 megabase pairs long); 20% to 25% of cases involve maternal uniparental disomy (isodisomy or heterodisomy) in which both chromosomes 15 are derived from the mother, possibly by nondisjunction during maternal meiosis, representing a striking example of genomic imprinting.[561] In 2% to 5% of cases, an imprinting center defect has been detected. Lack of a functional paternal 15q11-q13 region, caused by any of a variety of genetic mechanisms, can result in the syndrome. One imprinted gene, that for small nuclear ribonucleoprotein-associated polypeptide SmN *(SNRPN)*, which is implicated in splicing pre-mRNA, is expressed in the brain, including the hypothalamus, and has been advanced as one explanation of some characteristics of the syndrome.

Elevated serum concentrations of the GH secretagogue and orexigenic gastrointestinal hormone ghrelin are found in the basal state in Prader-Willi syndrome.[567] Increased levels are identified after meals, when values should be suppressed, and are a possible cause of the insatiable appetite. Administration of the somatostatin analogue octreotide leads to a decrease in basal ghrelin values and some decrease in values after meals, but no change in appetite was demonstrated as yet.

Laurence-Moon and Bardet-Biedl Syndromes. The Laurence-Moon syndrome and the Bardet-Biedl syndrome were previously separated as rare autosomal recessive traits, with retinitis pigmentosum and hypogonadism of various types. Currently the conditions are considered as one, and the present term is *Bardet-Biedl syndrome*. The estimated incidence is 1 in 160,000 in northern European populations and 1 in 13,500 in some Arab populations.[568] The findings are developmental delay, spastic paraplegia, postaxial polydactyly, onset of obesity (usually in early infancy), and renal dysplasia. Hypgonadism is characteristic, and males are

infertile as are most females. The genetically and phenotypically heterogenous Bardet-Biedl syndrome is linked to 16 genes, which account for 80% of cases. The basic defect is a ciliopathy. The Biemond syndrome II has similar features, with iris coloboma, hypogenitalism, obesity, polydactyly, and developmental delay, but it is a distinct entity.

Functional Gonadotropin Deficiencies and Other Chronic Conditions. The effects of malnutrition, which can lead to functional hypogonadotropic hypogonadism, should be separated from the primary effects of chronic systemic disease, some of which have direct effects on the function of the hypothalamic-pituitary unit or the gonads. Weight loss from any cause to less than 80% of ideal weight for height can lead to gonadotropin deficiency and low serum leptin levels; weight regain usually restores hypothalamic-pituitary gonadal function over a variable period, although the weight needed to restart menstrual periods varies among individuals and is related to the weight at which menstruation first ceased.[569]

If adequate nutrition and body weight are maintained in patients with regional enteritis or chronic pulmonary disease, gonadotropin secretion is usually adequate. Cystic fibrosis is also associated with delay in puberty and the age of PHV, in large part through malnutrition; improved management and newborn screening have increased PHV and advanced the age of PHV, but neither has reached normal values.[454,570,571] The age of menarche in girls with cystic fibrosis is related to maternal age, as expected, but is delayed by approximately 1 year compared with menarche in the mother, an effect that is mainly related to nutritional status.[570,987] However, even with normal pubertal progression, boys with cystic fibrosis almost universally have oligospermia caused by obstruction of the spermatic ducts, which is unrelated to nutritional status. The greater prevalence of reproductive difficulties in male patients with cystic fibrosis compared with female patients may reflect the greater prevalence of the cystic fibrosis transmembrane regulator (CFTR) in male reproductive tissues (e.g., epididymis, vas deferens), and more viscid luminal contents, which ultimately damage the testes and can lead to absence of the epididymides and the vasa deferentia. Normal ovaries do not express CFTR, and endometrial tissue expresses it only after puberty, with variable levels found in cervical epithelium and the fallopian tubes. Even though the *CFTR* gene and its protein are expressed in the human hypothalamus, mutations in the corresponding gene did not appear to affect LH and FSH secretion in an immortalized mouse hypothalamic GnRH-secreting cell line.

Boys and girls with sickle cell disease have delayed pubertal development by about 2 years and delayed menarche of about 6 months even with modern treatment techniques.[572] This may be due to nutritional status. Boys with sickle cell anemia often exhibit impaired Leydig cell function caused by ischemia of the testes or gonadotropin deficiency or both.

Thalassemia carries the risk of hemochromatosis due to transfusional iron deposition in the pituitary and hypothalamus; as a consequence, 60% to 80% patients may have hypogonadotropic hypogonadism and impairment of growth.[573] The gonads can be stimulated by exogenous gonadotropins, and satisfactory sexual development, including fertility, can be promoted by the use of hCG and human FSH in many patients without gonadal damage, although pituitary and gonadal damage may be severe in children with poorly controlled disease. Primary hypothyroidism is prevalent in this condition, but it is only part of the problem of sexual maturation. Desferrioxamine therapy may cause skeletal dysplasia and compromise pubertal growth, and growth failure due to GH deficiency may also affect pubertal growth.[574] Decreased BMD in thalassemia makes early recognition and treatment of the problem all the more important.

Cytotoxic effects of the alkylating agents used to prepare patients for bone marrow transplantation in this condition add to the problem. Treatment after the onset of puberty is safer for gonadal function in boys but not necessarily in girls. Girls with early bone marrow transplantation and apparently normal pubertal development have elevated serum FSH levels and menstrual abnormalities ranging up to amenorrhea,[575] suggesting that gonadal impairment is universal in girls with thalassemia major after bone marrow transplantation.

Puberty is significantly delayed in children with prenatally acquired human immunodeficiency virus (HIV) infection compared to those exposed but not affected.[988] Modern treatment regimens are predicted to decrease this delay.

Chronic gastrointestinal disease (e.g., Crohn disease) is often accompanied by delayed puberty, and therapy to restore nutrition, if successful, enables puberty to progress. The pubertal growth spurt is compromised by active inflammatory bowel disease, especially if glucocorticoid therapy is necessary. Celiac disease decreases the growth rate in childhood and adolescence, but with appropriate dietary restrictions, adult height appears to be normal.

Chronic renal disease is associated with delayed pubertal development and decreased pulsatile gonadotropin secretion due to a decrease in the mass of bioactive and immunoactive LH secreted rather than an alteration of the frequency. Successful renal transplantation usually restores gonadotropin secretion and improves growth. Immunoreactive gonadotropin concentrations may be elevated, presumably because of impaired renal clearance, but the response to GnRH is blunted in severe renal impairment. TeBG is elevated in chronic renal failure, and the level of free testosterone is low. Survivors of renal transplantation who are undergoing immune suppression and alternate-day steroid treatment often have delayed onset of puberty and decreased pulsatility of GH and gonadotropins at night.

Patients with nephrotic syndrome have poor pubertal growth, poor secondary sexual development, and deficient gonadotropin secretion in a pattern resembling CDP. Glomerulonephritis treated with alternate-day glucocorticoid therapy leads to a late, diminished, but prolonged pubertal growth spurt that can result in a normal final height.

Children with early onset of leukemia and early long-term remission experience puberty at an appropriate age or with only a slight delay, whereas patients with initial symptoms of leukemia in late childhood may have considerable delay of pubertal development. Radiation treatment to the CNS may cause hypogonadotropic hypogonadism or GH deficiency or both, and irradiation of the abdomen or pelvis and certain types of chemotherapies, especially if administered during puberty, may impair gonadal function and cause primary hypogonadism, although ovarian function may return even in the face of elevated serum gonadotropin levels.[568] Total-body irradiation for bone marrow transplantation exerts the most significant effects, such as severe GH deficiency in 50%, hypothyroidism in 56%, and hypogonadism in 83% of males, and 100% of women had ovarian failure; insulin resistance was found in 83% and dyslipidemia in 61%.[576] Children with leukemia treated with CNS irradiation had a diminished pubertal growth spurt and diminished final height. Long-term follow-up studies

demonstrate the rising incidence of the metabolic syndrome survivors and high lifetime risk for cardiovascular disease in childhood cancer.[577]

Other Endocrine Conditions and Puberty. Hypothyroidism may delay the onset of puberty or menarche (except in extreme cases in which puberty starts early); treatment with levothyroxine reverses this pattern, but there is likely to be a permanent loss of height if the diagnosis is delayed.

Diabetes mellitus type 1 is associated with delayed menarche.[578] Remarkably, this may occur no matter the degree of glycemic control. Prepubertal children are most vulnerable to poor glycemic control, and pubertal subjects exhibit normal growth unless severe hyperglycemia occurs. The degree of control necessary to avoid these complications cannot be exactly quantified, but adolescents with even moderately poor control frequently manifest some degree of growth impairment and delayed puberty or irregular menses. Mauriac syndrome is characterized by poorly controlled diabetes, hepatomegaly with fatty infiltration of the liver, and delayed puberty that is likely related to poor nutritional status.[579]

Cushing disease can be associated with delayed onset or arrest of gonadarche, although excessive virilization is an alternative finding.

Anorexia Nervosa and Variants.[580,581,990]

Anorexia Nervosa. Anorexia nervosa,[582] a common cause of gonadotropin deficiency in adolescence, is a functional disorder. Prevalence is increased among girls (it is the third most common chronic disease of adolescent girls), but it is rarer in boys. This condition has the highest mortality rate of all psychiatric disorders[583]; weighted mortality rates (i.e., deaths per 1000 person-years) were 5.1 for anorexia nervosa, and 1.7 standardized mortality ratios were 5.86 for anorexia nervosa. It is characterized by a distorted body image, obsessive fear of obesity, and food avoidance that can cause severe self-induced weight loss (to less than 85% of normal weight for age and height or a BMI <17.5 kg/m^2 after cessation of growth), primary or secondary amenorrhea in affected females, widespread endocrine disorders, and even death. Specific diagnostic details are provided in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) criteria of the American Psychiatric Association[581]:

A. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. Significantly low weight is defined as a weight that is less than minimally normal or, for children and adolescents, less than that minimally expected.
B. Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.
C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

There are subtypes:

Restricting type and binge-eating/purging type

The onset of amenorrhea may precede the onset of severe weight loss. Other common features include onset in middle adolescence, hyperactivity, defective thermoregulation with hypothermia and sensitivity to cold, constipation, bradycardia and hypotension, decreased BMR, dry skin, fine or downy hypertrichosis, peripheral edema, and parotid enlargement. The pathogenesis is multifactorial and includes a genetic factor and a well-characterized psychologic component. Before the diagnosis of anorexia nervosa is made, organic disease must be excluded; for example, a girl with macroprolactinoma may present with signs consistent with anorexia nervosa. The prevalence of anorexia nervosa is increased among individuals with Turner syndrome.

Anorexia nervosa has considerable endocrine ramifications.[584] The concentrations of plasma FSH, LH, leptin, and estradiol and the excretion of urinary gonadotropins are characteristically low. There may be a reversion to a circadian rhythm of LH secretion and to the sleep-associated increase in episodic LH secretion or LH response to GnRH characteristic of early puberty, or the amplitude of the pulsatile episodes may be diminished, as in the pattern of prepubertal children, if onset occurs during puberty. Pulsatile administration of intravenous GnRH at intervals of 90 to 120 minutes can produce LH pulses that are indistinguishable from the normal pubertal pattern, demonstrating functional GnRH deficiency. Serum leptin levels are low, consistent with the strikingly decreased mass of adipose tissue, and increase with regain of weight. Other hormonal changes include increased mean concentrations of plasma GH and plasma cortisol; low levels of plasma IGF1, DHEAS, and triiodothyronine (T_3) with normal levels of thyroxine (T_4) (unless the low thyroxine syndrome is present) and TSH; a decreased rise in serum prolactin after administration of thyrotropin-releasing hormone (TRH) or insulin-induced hypoglycemia; and a diminished capacity to concentrate urine. This condition must be considered in the differential diagnosis of growth failure in younger subjects.

Lower heart rates are characteristic and a dangerous sign of severe disease and not to be confused with an athletic bradycardia in view of the excessive exercise the patient engages in. A lower systolic blood pressure, lower body temperature, anemia, and leukopenia are found in persons with anorexia nervosa. The ratio of bone age to chronologic age is significantly lower in girls with anorexia nervosa and correlates positively with duration of illness and markers of nutritional status. All measures of BMD are lower, and the most significant predictors of bone density are LBM, BMI, and age at menarche. Treatment of decreased bone density in these individuals is accomplished with improved nutrition, and a degree of catch-up in bone density occurs, although reversion to normal may not occur.

Normal endocrine and metabolic function may follow weight gain, but amenorrhea may persist for months, suggesting persistent hypothalamic dysfunction. In view of the associated mortality rate, parenteral alimentation may be indicated in resistant patients with severe weight loss, especially in those with infection or an electrolyte imbalance. However, refeeding syndrome with attendant hypophosphatemia may result if not handled appropriately. Treatment of this disorder requires skillful management, understanding, patience, and psychiatric consultation in a team approach. Unfortunately, an evidence-based approach to optimal treatment is not plentiful, and the difficulty in obtaining therapy in uninsured individuals remains.[585]

Functional hypothalamic amenorrhea is defined as the absence of menses, low or normal gonadotropin levels, and normal gonadotropin response to GnRH stimulation but lack of or an inadequate midcycle LH surge and a decrease in normal pulsatile secretion (amplitude or frequency, or both) of gonadotropins and hypoestrogenemia without organic abnormality.[523] This condition

can occur in women with normal weight but decreased percentage of body fat. These patients have higher than average cortisol values; decreased levels of free T_4, free T_3, and total T_4 with normal TSH levels; and decreased leptin concentrations that are probably caused by subtle dysfunction of eating patterns and altered energy expenditure. The consequences range from severe estrogen deficiency to anovulation to a short luteal phase. Reduced bone density is a concern. Genes involved in the cause of hypogonadotropic hypogonadism such as *GNRHR*, *KAL1*, and *PROKR2* are found in heterozygous patterns in women with functional hypothalamic amenorrhea, suggesting a genetic susceptibility to the condition that is brought out by various types of stresses[523]; thus functional amenorrhea may not be simply functional.[586,587]

Bulimia Nervosa. Bulimia nervosa is now separated from the diagnosis of anorexia nervosa[582]; DSM-IV diagnostic criteria are as follows:

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what most individuals would eat in a similar period of time under similar circumstances.
   2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
B. Recurrent inappropriate compensatory behaviors to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.
C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.
D. Self-evaluation is unduly influenced by body shape and weight.
E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Bulimia occurs in about 1.5% of young women. A hand lesion from the induced vomiting (i.e., Russell sign) and an abnormal level of serum electrolytes are useful clinical markers. Abuse of laxatives, diet pills, and diuretics is frequent. Although weight loss is not frequent, amenorrhea is common. Bulimia is especially prevalent in female high school and college students. A history of childhood sexual abuse is more common than in unaffected adolescents. Cessation of growth can occur in infants and young children with psychosocial dwarfism. Stressful social situations can also inhibit growth and physical pubertal development at adolescence.

Exercise, Hypo-ovarianism, and Amenorrhea: The Female Athlete Triad. In 1992, the American College of Sports Medicine defined the female athletic triad as primary or secondary amenorrhea, disordered eating, and osteoporosis.[582] Although there are substantial endocrine effects of excessive athletic training in girls, elite prepubertal and pubertal female athletes suffer relatively few physical injuries. Because there is no demonstrable effect on pubertal development from moderate exercise in subelite female runners, moderate exercise should not be discouraged during adolescence. However, extensive training (10–12 hours/week) may be excessive for prepubertal girls.

Bulimia, anorexia nervosa, or anorexia athletica is most often found in girls engaged in sports that emphasize weight.[587] Teenage ballet dancers are lighter, have less body fat, and have a high incidence of delayed puberty and of primary and secondary amenorrhea than less physically active girls. Factors other than decreased body weight can impair pubertal progression and delay menarche through inhibition of the hypothalamic GnRH pulse generator in healthy ballet dancers and female athletes such as swimmers who are not underweight.

Athletes who began strenuous training before menarche have a delay in menarcheal age.[588] However, genetic influences overlie changes due to weight or activity because there is a positive correlation between the delayed menarche found in athletic girls and the age of menarche of their mothers. Although some studies of artistic and rhythmic gymnasts found delayed menarche when compared with their mothers and sisters, with a more significant delay in artistic gymnasts,[589–591] a recent survey of the literature by a committee of the Scientific Commission of the International Gymnastics Federation found the following: "(1) Adult height or near adult height of female and male artistic gymnasts is not compromised by intensive gymnastics training. (2) Gymnastics training does not appear to attenuate growth of upper (sitting height) or lower (legs) body segment lengths. (3) Gymnastics training does not appear to attenuate pubertal growth and maturation, neither rate of growth nor the timing and tempo of the growth spurt. (4) Available data are inadequate to address the issue of intensive gymnastics training and alterations within the endocrine system."[592] The implication is that these athletes may be shorter and delayed in puberty due to self-selection. There are studies with findings at odds with these conclusions.

Higher bone density is reported in the femurs of gymnasts compared with those of ballet dancers and control subjects, but lower radial bone density in the gymnasts and ballet dancers reflects the effect of the application of force on bone remodeling; a positive relationship between serum leptin and tibial bone density is found.[593] The bone density of female long-distance runners is greater in those with regular menses than in those with menstrual irregularities. Osteopenia in later life may result from amenorrhea in ballet dancers, even with estrogen replacement, and nutrition therapy is considered important to improve outcome.[594]

Thinness and strenuous physical activity appear to act synergistically, but strenuous exercise training by itself may inhibit the GnRH pulse generator, mediated in part by endogenous opioidergic pathways involving β-endorphin. When the strenuous physical activity is interrupted (e.g., by injury), puberty advances, and menarche often occurs within a few months in those with amenorrhea, in some cases before a significant change in body composition or weight. Even though gonadarche is retarded, adrenarche is not delayed.

Female athletes of normal weight who have less fat and more muscle than nonathletic girls (e.g., ice skaters, swimmers) are also at risk for delayed puberty and for primary and secondary amenorrhea. However, the mechanism apparently is different from the hypothalamic amenorrhea in runners and ballet dancers. In swimmers, menstrual cycles frequently are irregular and anovulatory rather than absent, and the plasma concentrations of DHEAS and LH were higher than normal, but plasma estrogen levels were normal.

Prospective study of gymnasts contrasted with swimmers demonstrated decreased growth velocity, stunting in leg length growth, and in some studies decreased height prediction in the gymnasts.[595]

Prolactin levels may be elevated in women athletes and may contribute to the delayed menarche found in this group. Osteopenia can result from the associated chronic hypoestrogenism.[588]

Scoliosis in girls usually develops during the pubertal growth spurt and more often occurs in girls with a more rapid pubertal growth spurt. Ballet dancers have a higher incidence of scoliosis

than the general population and often have delayed puberty and delayed menarche. These girls have decreased leptin levels, but soluble leptin receptor and adiponectin levels were increased throughout puberty; these changes were related to changes in LBM rather than BMI. Idiopathic scoliosis in the general population is associated with a statistically earlier age of menarche and an early adolescent growth spurt. The strongest association with scoliosis is taller stature at the time of the pubertal growth spurt. Adult height in familial constellations of scoliosis does not vary from the family norm.

Although men are less affected than women, men may also be affected by rigorous physical training. They may have decreased LH response to GnRH and decreased spontaneous LH pulse frequency and amplitude; the serum testosterone level is normal or low with extreme activity levels.

Other Causes of Delayed Puberty

Marijuana use has been associated with gynecomastia and is a putative cause of pubertal delay. Untreated Gaucher disease causes delay in pubertal development, but early treatment with enzyme replacement allows puberty to begin on time.[596] Girls with familial dysautonomia have delayed menarche and often have a severe premenstrual syndrome. The condition is ultimately compatible with pregnancy. Chronic infections may delay the onset of puberty.

Central Nervous System Tumors

Extrasellar masses may interfere with GnRH synthesis, secretion, or stimulation of pituitary gonadotrophs. Most patients with hypothalamic-pituitary tumors causing gonadotropin deficiency have one or more additional pituitary hormone deficiencies (or an increased serum prolactin level with prolactinomas). Those with GH deficiency due to a neoplasm have late onset of growth failure compared with those who have idiopathic and familial hypopituitarism, in which growth failure starts early in life. The presence of anterior and posterior pituitary deficiencies in infancy suggests a midline developmental defect, but the development of this combination after infancy ominously suggests an expanding CNS lesion.

Craniopharyngioma. Craniopharyngioma is a rare embryonic malformation of nonglial origin in childhood (0.5–2 new cases per 1 million population annually, or 1.2–4% of pediatric intracranial tumors), a common CNS neoplasm.[597] It is, however, the most common brain tumor associated with hypothalamic-pituitary dysfunction and sexual infantilism and accounts for 80% to 90% of neoplasms found in the pituitary and up to 15% of all intracranial tumors in childhood.[598] Symptoms usually arise before the age of 20 years with a peak incidence between the ages of 6 and 14 years with about 30% to 50% occurring in the pediatric age range. Harvey Cushing introduced the term *craniopharyngioma* and considered them "the most formidable of intracranial tumors."[599]

Various theories of the embryologic origin of this nonglial intracranial tumor are current: One theory favors development from ectodermal remnants of Rathke pouch and another development from residual embryonic epithelium of the anterior pituitary gland and of the anterior infundibulum. Craniopharyngiomas may reside within or above the sella turcica, or more rarely, they may be found in the nasopharynx or the third ventricle.

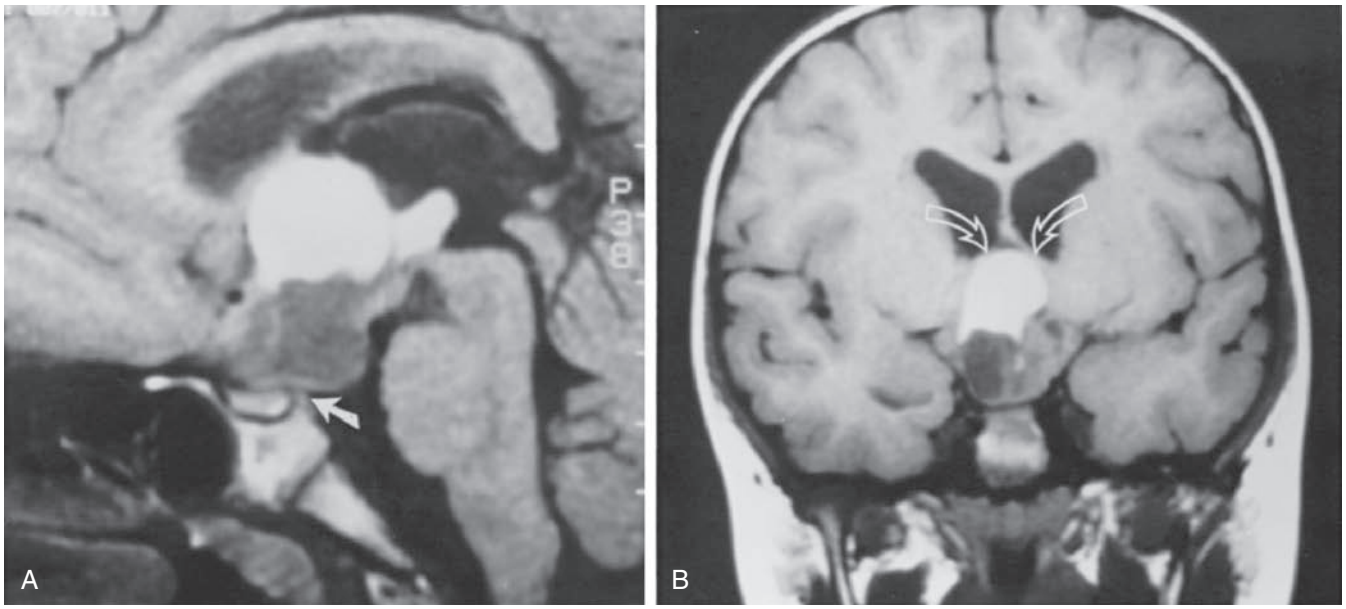
Craniopharyngioma appears to be a monoclonal tumor, and about 50% have cytogenetic abnormalities such as gains in 1q, 12q, and 17q. About 70% of cases of craniopharyngioma in childhood are the adamantinomatous type with cyst formation. These types have dysregulation of the Wnt signaling pathway and a mutation in the β-catenin gene *(CTNNB1)* in contrast to the papillary type of craniopharyngioma that has *BRAF* mutations and is more often found in adult patients.[600,601]

CNS signs of craniopharyngiomas develop as the tumor encroaches on surrounding structures. Symptoms of craniopharyngioma include headache, visual disturbances, short stature, diabetes insipidus, vomiting, and weakness of one or more limbs. Visual defects (including bilateral temporal field deficits), optic atrophy or papilledema, and signs of GH deficiency, delayed puberty, and hypothyroidism are features of craniopharyngiomas. Although most patients are below the mean in height and height velocity at diagnosis, a long, indolent course is possible. Deficiencies of gonadotropins, GH, thyrotropin (TSH, thyroid-stimulating hormone), ACTH, and arginine vasopressin are common. The serum concentration of prolactin is normal or increased. Delayed bone age is common and may point to the onset of tumor growth.

About 70% of patients with a craniopharyngioma have suprasellar or intrasellar calcification (found in fewer than 1% of normal individuals) and an abnormal sella turcica, which are sometimes found on radiographs taken for other indications, including orthodontia. CT (but not MRI) reveals fine calcifications that are not apparent on lateral skull radiographs. MRI scans before and after gadolinium are the diagnostic procedures of choice for suspected craniopharyngioma and can determine whether the tumor is cystic or solid and indicate the presence of hydrocephalus; if necessary a CT scan can be used to search for calcifications, and CT or MRI with contrast can determine whether the tumor is cystic or solid and indicate the presence of hydrocephalus (Fig. 26.45).

Smaller craniopharyngiomas, usually intrasellar, can be treated by transsphenoidal microsurgery, but larger or suprasellar masses usually require craniotomy, and the approach must be individualized. The reported postsurgical 5-year overall survival rate is 88% to 94%, and the reported 10-year overall survival rate is 70% to 92% with a 20-year survival rate of 76%. The combination of limited tumor removal and radiation therapy leads to a satisfactory neurologic prognosis, better cognitive outcome, and better endocrine outcome compared with attempts at complete surgical extirpation. Frequent and early tumor relapse after apparently complete resection and tumor progression after incomplete resection suggest the wisdom of radiation therapy after surgery. Alternative approaches include proton beam therapy; in mainly cystic craniopharyngioma cases, instillation of radioisotopes or sclerosing substances such as bleomycin or interferon-α are being investigated.[602] Nonetheless, the preferred manner of treatment to retain the best quality of life is not yet established, but longitudinal studies such as the randomized multinational trial KRANIOPHARYNGEOM 2007 may answer this question.[602]

Postoperative hyperphagia and obesity (BMI >5 SD above normal) can be striking and correlate with the magnitude of hypothalamic damage on cranial MRI. Injury to the hypothalamic ventromedial nuclei (associated with increased parasympathetic activity and hyperinsulinemia) or to the PVN may cause these findings, and insulin suppression may be helpful. Short-term follow-up studies demonstrate the efficacy of bariatric surgery in the management of obesity in affected patients.[601] Hypothalamic



• **Fig. 26.45** Craniopharyngioma in a short 5-year-old girl with a history of frontal headaches, impaired vision, and poor growth. (A) Midline, sagittal, T1-weighted image shows a hyperintense region superiorly and an inferior hypointense region. The combination of hyperintense and hypointense areas in a non–contrast-enhanced examination is the most characteristic finding for craniopharyngioma. Notice the erosion of dorsum sellae *(solid arrow)* and posterior pituitary bright spot. (B) Coronal, T1-weighted image shows tumor extending upward to the inferior frontal horns, narrowing the foramen of Monro, and causing mild hydrocephalus. The *open arrows* indicate the upper border of the hyperintense area of the tumor.

sparing surgery decreases the risk of postoperative hyperphagia and obesity.[602] Aberrant sleep patterns and even narcolepsy and daytime somnolence may follow surgical treatment of craniopharyngiomas, with melatonin improving sleep patterns in some.[603] Although the endocrine complications are more manageable, the combination of antidiuretic hormone insufficiency (i.e., diabetes insipidus) and impaired sense of thirst remains a complex management problem.

A Rathke cleft cyst is often discovered as an incidental finding on MRI, but it can produce symptoms and signs indistinguishable from those of a craniopharyngioma, such as precocious or delayed puberty.[604] Surgical drainage and excision of the cyst wall are customary approaches.

Other Extrasellar Tumors

Germinomas. Germinomas (i.e., pinealomas, ectopic pinealomas, atypical teratomas, or dysgerminomas) and other germ cell tumors of the CNS are the most common extrasellar tumors that arise in the suprasellar hypothalamic region and in the pineal region that commonly cause sexual infantilism. Germinomas constitute 66% of all intracranial germ cell tumors (GCTs), which make up 3% to 11% of pediatric brain tumors. About 84% are found in the pineal and the neurohypophyseal regions. Peak incidences occur in the second decade and during infancy. They are found more often in males.[605] Polydipsia and polyuria are the most common symptoms, followed by visual difficulties and abnormalities of growth and puberty or movement disorders. Diagnosis may be delayed for months to years because the findings are attributed to psychiatric disorders. Deficiencies of vasopressin and GH are most common, but other anterior pituitary hormone deficiencies (including gonadotropin deficiency) and elevated serum prolactin levels are also frequent. Determination of the concentration of hCG in spinal fluid and in serum and assessment of α-fetoprotein levels provide useful tumor markers in children and adolescents with germ cell tumors. Germ cell tumors in boys cause isosexual GnRH-independent sexual precocity (GISP) by secretion of hCG (see "Sexual Precocity"). Tumors secreting hCG cause precocious puberty in boys, and there has been one case report of an affected girl.

Subependymal spread of germ cell tumors along the lining of the third ventricle is common, and seeding may involve the lower spinal cord and corda equina. MRI with contrast enhancement is useful in the detection of isolated enlargement of the pituitary stalk, an early finding that requires periodic MRI monitoring, especially in patients with diabetes insipidus.[481] The size of the pituitary gland increases by 100% between year 1 and year 15, but the pineal gland does not normally change in size after the first year of life; any later enlargement indicates a mass lesion. Pineal cysts are a rare cause of CPP.

Irradiation is the preferred treatment for pure germ cell tumors such as germinomas; surgery is rarely indicated, except for biopsy to establish a tissue diagnosis.[481] However, attempts to decrease the long-term morbidity of radiation therapy lead to consideration of chemotherapy. Chemotherapy alone is inadequate, but the combination of chemotherapy and radiation therapy can be successful,[485,606] and both treatment methods are recommended for a mixed germ cell tumor. Because testicular germ cell tumors are occasionally found years after successful therapy for CNS germ cell tumors, long-term surveillance is indicated.[557,607]

Hypothalamic and optic gliomas or astrocytomas, occurring as part of neurofibromatosis (von Recklinghausen disease) or arising independently, can also cause sexual infantilism. Gliomas and meningiomas are the most common CNS tumors to develop in childhood cancer survivors treated with CNS radiation, often the young adult or even late teenage years.[608]

Pituitary Adenomas. Only 2% to 6% of all surgically treated pituitary tumors occur in childhood and adolescence, with about 1 in 1 million children affected.[598] Most functional pituitary adenomas are ACTH secreting, with prolactinomas or GH secreting or nonfunctioning adenomas occurring less commonly. Most pituitary tumors are monoclonal lesions caused by mutations of *GNAS*. Adolescent onset of pituitary team tumors may be the first manifestation of multiple endocrine neoplasia type I or familial isolated pituitary adenoma (FIPA).[609] With higher sensitive imaging techniques the presence of a pituitary incidentaloma, a previously unsuspected pituitary lesion that is discovered on an imaging study performed for an unrelated reason, may be discovered.[610] Evaluation of secretory activity of such a lesion, consideration of mass effects, and follow-up to monitor a change in size are important, but some lesions detected will not be related to the pubertal abnormality.

Incidence of prolactinoma is low in childhood but one in five present in the age group 15 to 24 years.[611] A survey of 44 cases reported that 61% of prolactinomas were macroadenomas (more often in boys; hypopituitarism and growth failure were common) and 39% were microadenomas (more often in girls; delayed puberty was common).[612] Only 2 of these 29 patients had delayed onset of puberty, although primary amenorrhea was the presenting symptom in 13 of 20 pubertal females. Presenting symptoms included oligomenorrhea and galactorrhea in the girls and headache in the boys. Galactorrhea may be demonstrable only by manual manipulation of the nipples (blood samples for prolactin should be obtained before examination or many hours later, because manipulation of the nipples raises prolactin levels).

Dopaminergic therapy is often successful in decreasing prolactin values. The dopamine agonist bromocriptine may decrease serum prolactin concentrations and decrease tumor size, which is a useful approach before surgery of large macroprolactinomas is undertaken and when resection of the adenoma is incomplete. Transsphenoidal resection of microprolactinomas in children and adolescents is an effective treatment. Pubertal progression and normal menstrual function in girls usually follow reduction of serum prolactin levels. Pituitary apoplexy followed cabergoline treatment of a macroprolactinoma in a 16-year-old girl[613]; this complication has been seen in adults treated with bromocriptine, and tricuspid regurgitation may be a cumulative effect.[614] High serum levels of macroprolactin, a complex of immunoglobulin G and monomeric prolactin with little biologic activity in vivo, cross-react in commercial prolactin assays, leading to a finding of pseudohyperprolactinemia; high prolactin values should be rechecked with subfractionation after polyethylene glycol precipitation.[615]

Other Central Nervous System Disorders Leading to Delayed Puberty

Langerhans Cell Histiocytosis. Langerhans cell histiocytosis (i.e., Hand-Schüller-Christian disease or histiocytosis X) is a clonal proliferative disorder of Langerhans histiocytes or their precursors. It is characterized by the infiltration of lipid-laden histiocytic cells or foam cells in skin, viscera, and bone.[616] The cause is not clear because there are features of a neoplasm and features of a reactive immunologic disorder. Diabetes insipidus, caused by infiltration of the hypothalamus or the pituitary stalk, is the most common endocrine manifestation, with GH deficiency and delayed puberty possible. The lung, liver, and spleen, cystlike areas in flat and long bones, and the dorsolumbar spine may be involved. "Floating teeth" within rarefied bone of the mandible, absent or loose teeth, and exophthalmos due to infiltration of the orbit are seen. Mastoid or temporal bone involvement may lead to chronic otitis media. Treatment with glucocorticoids, antineoplastic agents, and radiation therapy is promising in terms of survival, but more than 50% of patients have late sequelae or disease progression. The natural waxing and waning course of this rare disease makes evaluation of therapy difficult and highlights the importance of national treatment protocols.[616]

Postinfectious Inflammatory Lesions of the Central Nervous System, Vascular Abnormalities, and Head Trauma. Tuberculous or sarcoid granulomas of the CNS are associated with delayed puberty. Hydrocephalus may cause delayed puberty that can be reversed with decompression, as may pressure from a subarachnoid cyst.

Irradiation of the Central Nervous System. Irradiation of the CNS for treatment of tumors, leukemia, or neoplasms of the head and face may result in the gradual onset of hypothalamic-pituitary failure.[617] Although GH deficiency is the most common hormone disorder resulting from irradiation, gonadotropin deficiency, hypothyroidism, and decreased bone density also occur.[618,619] Exposure of the hypothalamic pituitary axis to 30 Gy carries a recurrence rate of about 6 for premature ovarian failure in women and requirement for testosterone treatment in men.[620]

Self-reported fertility was reported to be lower in women who received CNS radiotherapy for acute lymphoblastic leukemia at about the time of menarche,[621] although the average age of women in this long-term study was in the early 20s, and longer follow-up of fertility may change the results. Irradiation of the CNS in early life predisposes the patient to later onset of secondary CNS tumors sometimes in just a few years after treatment of the first tumor.[608]

Fröhlich Syndrome. Fröhlich syndrome or adiposodysgenesis is a constellation of endocrine abnormalities, combining findings of obesity and hypogonadism due to a hypothalamic-pituitary disorder. Remarkably, the original description involved a patient with tuberculosis involving the hypothalamic-pituitary axis.

Hypergonadotropic Hypogonadism: Sexual Infantilism Caused by Primary Gonadal Disorders

The most common forms of primary gonadal failure are associated with sex chromosome abnormalities and characteristic physical findings.[590,622] Testicular or ovarian dysfunction as an isolated finding is less commonly a cause of pubertal hypergonadotropic hypogonadism.

Boys
